Seizures may occur following contrast administration. Although this can occur in subjects with no predisposition, it is of greater likelihood in patients with brain metastases because they have an altered blood–brain barrier. Treatment includes turning the patient’s head to the side to protect the airway, monitoring of vital signs, oxygen, and consideration of administration of diazepam 5 mg intravenous (repeated if needed) or midazolam 0.5 to 1 mg intravenous.

DELAYED REACTIONS

Delayed reactions are defined as adverse events following intravenous contrast injection with onset more than 1 hour but less than 1 week after exposure; in most instances, symptoms appear within 3 days. The incidence of delayed reactions is greater than commonly recognized, since they are often not brought to the attention of the radiologist because of the late onset (and may not be considered associated with contrast administration by the patient). Investigations have reported the incidence between 1% and 9%. These do not have association with anaphylactoid reactions and in general are not life threatening. They have been reported following both high and low osmolar iodinated contrast administration, but not following gadolinium contrast agents.

Cutaneous reactions are most common, with an exanthem variable in size and distribution, macular or maculopapular, sometimes similar to angioneurotic edema. Patients usually have pruritis, but hives are uncommon. If a limited cutaneous reaction is observed, treatment with topical steroids may be effective.

Other common symptoms reported include fever, chills, dizziness, arthralgias and musculoskeletal pain, diarrhea, vomiting, headache, and rarely hypotension. Most cases are mild to moderate and many are self-limited.

The only significant association is that delayed reactions are clearly more common in patients treated with interleukin II for malignancy; these cases have similar symptoms but may be more severe.

The etiology of delayed reactions remains unclear. Treatment is largely supportive. Antipyretics, anti-inflammatory agents and antihistamines for pruritis may be used as needed. For more severe cases, systemic steroids have been recommended. There is a relatively high rate of recurrence, as much as 25%. Pretreatment may be used, although there is no published literature documenting effectiveness or comparing different regimens. Recommendations are to follow the same protocol for patients with prior moderate acute reaction, using steroids and antihistamines.

Additional types of adverse events after contrast administration may be called “very late reactions,” defined as those occurring more than 1 week after exposure. NSF following intravenous gadolinium contrast would fall in this category. Others are thyrotoxicosis and acute parotitis following intravenous iodinated contrast administration. Risk factors for thyrotoxicosis include untreated Grave disease and multinodular goiter with thyroid autonomy especially if in an iodine deficient area. Patients with normal thyroid function are *not* at risk. Prophylaxis is not recommended, rather iodinated contrast should be. If iodinated contrast absolutely must be given to a patient at risk, they should be monitored by an endocrinologist.

Following intravenous iodinated contrast administration, radioiodine diagnostic tests or therapy should be avoided for 2 months owing to decreased uptake by the gland. Thus patients with thyroid cancer should be screened with this specific concern.

CONTRAST-INDUCED NEPHROTOXICITY

INCIDENCE

Despite advances, especially lower osmolality iodinated contrast, impairment of renal function due to exposure to contrast remains a serious issue. Radiologists must be knowledgeable about methods to minimize this potential serious adverse event (Table 55-2). Although there is a considerable body of literature, much remains unclear and much of the literature is conflicting. Uncertainty about contrast-induced nephrotoxicity (CIN) arises from the variability in its definition. Most until recently defined CIN based on a rise in serum creatinine, but some used an absolute rise (e.g., 0.5 or 1, or even 2 mg/dL), others a percentage (25% or 50%); some specified the time of serum creatinine determination, others did not, and the timing of the testing could affect results. More recently, alterations

 Consider administration N-acetylcysteine 600 mg po bid
 Monitor serum creatinine

in estimated glomerular filtration rate (eGFR) have been used. Normal serum creatinine level may be maintained until GFR is reduced to half of normal. However, formulas for calculating eGFR are known to have varying accuracy with differing levels of renal function, tending to be less accurate with either normal or very reduced GFR. Very few studies have had true control groups, such as a matched group of hospitalized patients who did not get iodinated contrast. Some studies report on intravenous administration, others intra-arterial, often coronary angiography, and whether results from one route can be applied to another remains controversial. Thus, even the exact incidence of CIN remains surprisingly unclear. Most episodes are self-limited, with serum creatinine beginning to rise within 24 hours of exposure to contrast, peaking at approximately 96 hours (4 days), and returning to baseline within 7 to 10 days. The course may be more severe, especially with greater degrees of preexisting renal disease, or concurrent insults whether cardiovascular or other nephrotoxic drugs. Some patients may require short-term dialysis, and a small number require chronic dialysis.

PATHOGENESIS

Prevention and intervention are also limited by a lack of full understanding of the pathogenic mechanism. Most

current theories are based on some evidence of renal hemodynamic changes due to vasoconstriction resulting from contrast and due to direct toxicity to tubule cells. There may be agent-specific chemotoxicity, and osmotic mechanisms may play a role. Oxygen free radicals may also have some role. Cofactors such as state of hydration can potentiate this scenario, for example, by increasing the time contrast resides in the tubules or by enhancing perfusion changes. The role of contrast viscosity is unclear but may be significant.

Because many of the demonstrated physiologic effects of contrast are to some degree proportional to the osmolality, it was expected these effects would be reduced with development of LOCM, and this to some degree has been proven correct. There may be some differences between agents with similar osmolality (although this is not proven). The osmolality of LOCM, which is typically 600 to 700 mOsm/kg, is much less than that of HOCM (greater than 1500 mOsm/kg) but still higher than that of blood (280 mOsm/kg). Whether the near isosmolar agents result in significantly lower rate of permanent renal impairment than low osmolar agents for all routes of administration remains unclear. The lowest osmolality agents, nonionic dimmers, also have the highest viscosity.

PREVENTION

Renal insufficiency is variably defined but may be considered present when eGFR is less than 60 mL/min/1.73 m², serum creatinine greater than 1.5 mg/dL or 133 mmol/L. Renal failure may be defined as eGFR less than 30 mL/min/1.73 m². Studies have revealed fairly consistent risk factors for CIN. The patients at greatest risk have diabetes and preexisting renal insufficiency. Renal insufficiency without diabetes is an independent risk factor, as is diabetes alone but somewhat less. Dehydration, cardiovascular disease especially recent myocardial infarction or shock, use of nephrotoxic drugs, especially aminoglycosides, diuretics, NSAIDs, ACE inhibitors, prostaglandins; myeloma (or other proteinemic states), hyperuricemia, hypertension, prior nephrectomy, and advanced age are additional risk factors.

Other factors that increase likelihood and severity of CIN include dose of contrast (both for single study and cumulative dose for multiple examinations over 24 hours), osmolality, and potentially, route of administration (intra-arterial especially directly into renal artery, versus intravenous, with virtually no nephrotoxicity expected from nonvascular administration such as HSG). A large meta-analysis provided strong evidence that LOCM (ratio 3 agents) are less nephrotoxic than HOCM (ratio 1.5 agents), and subsequent studies have confirmed

this finding. It holds true for patients with preexisting renal disease and diabetes. Evidence is much more mixed whether ratio 6 agents, near isosmolar, produce significantly less renal impairment than LOCM.

A reasonable practice is to screen all patients for risk factors for CIN before administering contrast (Table 55-2). Although blood testing is not mandated by any society, it may be justified as interviewing patients has limits; many are poorly informed about their own condition. Point-of-service blood test devices are also available. If serum creatinine is measured, it is recommended to calculate eGFR, which provides more reliable information about degrees of renal insufficiency. For any patient with a risk factor, LOCM should be used, and dose should be limited to that necessary for diagnostic quality images. A consensus on strict cutoff values does not exist. For patients with GFR greater than 60 mL/min/1.73 m², there is essentially no risk of CIN; with GFR less than 30 mL/min/1.73 m², risk is quite high; with GFR between 30 and 60 mL/min/1.73m², the risk is moderate.

INTERVENTION

When giving contrast to a patient with high risk of CIN, preventative intervention is advisable (Table 55-2). However, the only intervention well supported by extensive studies to be effective is hydration. Diuretics including furosemide and mannitol have been shown to be harmful. Normal saline has been shown to be more effective than one-half normal saline and intravenous hydration superior to oral. Limited, unconfirmed studies, suggest hydration with sodium bicarbonate may be more effective than normal saline, but either can be justified. The most effective hydration protocols, however, require intravenous administration for several hours preceding and following the procedure, limiting its implementation in an outpatient setting. Administration of 1 mL/kg/h of normal saline for 4 hours before and 6 hours following contrast has been recommended; alternatively, Merten et al. used infusion of isotonic sodium bicarbonate 3 mL/kg/h for 1 hour prior and 6 hours postprocedure.

Many other interventions have been tried, but none has been consistently shown to be useful. These include atrial natriuretic peptide, prostaglandin E, fenoldopam, dopamine, adenosine inhibitors, endothelin, and calcium channel blockers. Acetylcysteine has yielded conflicting results, although not shown in any study to be harmful, and is relatively inexpensive, so is recommended by some (600 mg orally twice daily the day before and day of the examination).

Patients already on chronic dialysis for end-stage renal disease may safely be given intravascular iodinated contrast. However, LOCM or IOCM should be used. Contrast

TABLE 55-3 Medications Containing Metformin

Rosiglitazone/metformin	Avandamet

is poorly protein bound that is cleared readily by dialysis, which does not have to be scheduled to immediately follow contrast administration, unless very high doses are used. Although dialysis clears contrast, evidence that it prevents CIN is not solid. Patients on intermittent or occasional dialysis should have an alternate study.

METFORMIN

Patients given intravenous contrast are at potential risk for a serious adverse event if they are taking an oral antihyperglycemic agent containing metformin. This is a biguanide oral medication for non–insulin-dependent diabetes. It decreases hepatic glucose production and enhances peripheral glucose uptake. It has the advantage of rarely causing hypoglycemia. The active drug, metformin, is included in several medications with different trade names (Table 55-3).

Metformin accumulates unmetabolized in the urine by glomerular filtration with 90% excreted within 24 hours after administration, if renal function is normal. However, in the setting of renal dysfunction, there is potential for accumulation of metformin at levels that can lead to lactic acidosis. This could occur if the patient has preexisting renal failure. Of most concern is a patient who may suffer acute renal dysfunction because of contrast-associated nephropathy. Thus, the greatest concern is a patient with risk factors for CIN (mainly diabetes and preexisting mild-to-moderate renal insufficiency). Metformin itself is not nephrotoxic. There is no direct drug interaction between iodinated contrast and metformin.

The symptoms of lactic acidosis (blood pH less than 7.25) are vomiting, somnolence, nausea, epigastric pain, anorexia, hyperpnea, lethargy, diarrhea, and thirst. Morbidity rate is as high as 50% (usually with comorbidities such as cardiac disease). Although it is life threatening, its actual incidence is low.

The key factor in management is avoidance. Patients must be consistently screened for metformin. Patients with normal renal function and no comorbidities are not at risk (with no cases of lactic acidosis reported). Patients with significant renal failure should not be given contrast and are not good candidates for metformin,

which is excreted by the kidney. Patients with normal renal function but other comorbidities including diabetes, liver dysfunction, and cardiac disease should have metformin discontinued at the time (just prior to) of the contrast administration and resumed after a delay of 48 hours. Patients with mild renal insufficiency, especially if diabetic, should have metformin administration stopped at the time of or before the administration of contrast and held for 48 hours. Ensuring good hydration and limiting the dose of contrast may be helpful. It is judicious to re-measure the serum creatinine to assure it has not changed before resuming metformin in these cases.

GADOLINIUM CONTRAST

In general, gadolinium-based contrast agents are very well tolerated. This may in part be due to the lower overall volumes usually used compared with dosing for CT. Some of the gadolinium agents are hyperosmolar, some less osmolar. Idiosyncratic reactions similar to those occurring with iodinated contrast have been reported, but at much lower rates, overall approximately 2.4% and with severe reactions much less than 1%. Mechanism has not been determined; however, it is not likely to be due to the gadolinium itself. Since reactions are uncommon, little literature exists. Most treatments respond to similar treatment for the same symptoms occurring after an iodinated contrast reaction. If a repeat study is needed, and a patient has had a prior moderate reaction to a gadolinium-based agent, pretreatment with a similar regimen as for iodinated contrast can be used. It would also be wise to use a different agent. There has not been a significant increase in reaction rates to gadolinium contrast in patients with prior reaction to iodinated contrast. However, patients with prior reaction to gadolinium are believed to be at significant risk of repeat reactions.

NEPHROGENIC SYSTEMIC FIBROSIS

Contrast agents for use in MRI were developed and released in the 1980s, with gadopentetate dimeglumine (Gd-DTPA) being the first and it was found useful for improving diagnostic capability. It was early recognized that gadolinium agents were well tolerated and not nephrotoxic. Although excretion was prolonged in patients with renal insufficiency, they did not seem to impair renal function even in those with preexisting renal disease. Thus, gadolinium agents became used as an alternate for iodinated contrast in patients with increased CIN risk.

Despite many years of use, it was not until 2000 and thereafter that a previously unrecognized illness was reported. Because of the predominance of cutaneous manifestations, this was initially labeled nephrogenic fibrosing dermopathy (NFD), but was renamed nephrogenic systemic fibrosis (NSF) when the multisystem aspect of

FIG. 55-1 Typical woody plaque-like lesions along anterior surface of lower extremity in patient with NSF. Extremities are most commonly affected, trunk less so with sparing of the face and upper chest.

the disease was recognized. The earliest recognized case was identified in 1997.

NSF is a fibrosing illness involving predominantly skin and subcutaneous tissues but also lungs, esophagus, heart, and skeletal muscles (Fig. 55-1). The typical patient is middle aged with renal failure, most on either peritoneal or hemodialysis. Cases have been reported about equally in men and women, and no racial or ethnic predilection is known. No case has been reported under age 7 years. A few years after the initial identification of this disease, it was recognized that nearly all patients had prior exposure to an intravenous gadolinium contrast agent.

Numerous investigations have been published and several registries organized to develop information. Although criteria for diagnosis has varied (not all pathologically proven), incidence is reported between 1% and 7% in patients with renal disease. No case has to date been reported in a patient exposed to any of the gadolinium contrast agents with normal renal function.

The typical course includes onset of symptoms within a few days and up to 3 months from time of exposure; swelling of distal parts of extremities with skin induration, sometimes extension to thighs, antebrachium, and lower abdomen, with pain, muscle restlessness, and loss of skin flexibility. The disease may progress to development of contractures and cachexia and may involve internal organs including heart, liver,

lungs, and diaphragm, possibly resulting in death. No curative treatments have yet been reported.

Initially it was recognized that NSF patients invariably had renal disease. It eventually became clear that there was a strong association with exposure to intravenous gadolinium contrast. Almost all cases have had exposure to gadolinium, although some have not. In some cases, this may be due to inaccurate records. In some cases, patients did not have MRI but were exposed to gadolinium when used as an alternate intravascular contrast agent for radiographic studies such as angiography in patients with renal failure (a practice no longer acceptable). The great majority (at least 90%) have been exposed to the linear chelate agent gadodiamide (Table 55-4). Other agents have also been associated although some only in patients who also received gadodiamide.

Most NSF patients have had severe renal disease, many requiring dialysis. This seems to be the highest risk group and may be even more so if gadolinium is given some time before dialysis commences. Cases have been reported with lower levels of renal disease but the risk seems considerably higher with GFR less than 15 mL/min/1.73 m², less so with GFR between 15 and 30 mL/min/1.73 m² and rather low, probably less than 1% between 30 and 60 mL/min/1.73 m². No documented cases have been reported with GFR greater than 60 mL/min/1.73 m² even with gadodiamide. Since many, in fact the majority, of renal failure patients exposed to gadolinium do not contract NSF, other factors must be involved. However, none of the cofactors have been proven consistently. Although many studies seem to show greater risk from higher doses (and a stronger correlation with MRA often done with double or triple dosing) or high cumulative dose, numerous cases have been reported after a single routine dose. Additional proposed factors include liver failure especially acute; metabolic acidosis; increased iron, calcium, or phosphate levels; abnormal iron metabolism; high-dose erythropoietin therapy; immuno-

suppression; vasculopathy, acute proinflammatory event; and infection. It is difficult to discern which associated factors derive merely from the accepted indications for MRI/MRA at the time versus true etiologic factors, and none are established as independent risk factors.

The exact pathologic mechanism of the disease is unclear, although there are prevailing theories with some supportive evidence. Partly based on demonstration of deposition of gadolinium ion in skin in NSF patients, a prevailing theory rests on dissociation of the gadolinium ion from the chelate. This is called transmetallation, wherein another heavy metal ion replaces the gadolinium allowing it to associate with other anions such as phosphate. Because of the known heavy metal toxicity of gadolinium, all contrast agents use a chelate to reduce the toxicity. Some are linear, some macrocyclic, some ionic, some nonionic (Table 55-4). One factor of concern is the stability of the binding of the gadolinium ion by the chelate; it has been shown that gadodiamide has greater likelihood for transmetallation than some other agents (although at very low levels, and transmetallation occurs to some degree with all agents). Some theories report altered iron metabolism and metabolic acidosis may enhance transmetallation. Free gadolinium can bind with anions and become deposited. Stimulated by some mechanism, an inflammatory process with activated fibroblasts develops and produces progressive fibrosis.

Because no effective treatment has been reported, the necessary approach is to avoid this potentially devastating illness by avoiding unnecessary exposure to patients at risk. This primarily consists of screening patients for renal disease, with concern also for liver failure, especially acute. This may be done by history, but laboratory testing with serum creatinine determination and calculation of eGFR is best particularly for high-risk groups, or in a practice where the linear agent gadodiamide may be used. American College of Radiology recommends eGFR should be performed within 6 weeks of exposure. In

general, using the lowest reasonable contrast dose, having an accepted indication for the study, and confirming no equivalent alternative examinations exist are recommended especially with risk groups.

In patients with end-stage renal disease on dialysis, primary consideration should be for CT with iodinated contrast as CIN is not an issue. If for some reason MRI with gadolinium must be given, the lowest possible dose and immediate dialysis may be done, but there is no good evidence that dialysis prevents NSF in this circumstance, and several cases have been reported of NSF developing despite immediate dialysis. Investigation has shown that 9 total hours of dialysis in three separate sessions is needed to effectively remove all gadolinium.

If eGFR is less than 15 mL/min/1.73 m², contrast of any type probably should be avoided if at all possible. With eGFR 15 to 30 mL/min/1.73 m² gadolinium contrast of type not commonly associated with NSF (gadobenate dimeglumine, gadobutrol, gadoterate meglumine, gadoteridol) may be safer than iodinated contrast although risk may not be zero. With eGFR over 30 mL/min/1.73 m², risk is very low, and no cases have been reported with eGFR over 60 mL/min/1.73 m² with any agent. Patients in acute severe renal failure, especially if associated with acute hepatic failure, probably should receive no contrast.

EXTRAVASATION OF CONTRAST

Extravasation of contrast into soft tissues adjacent to the injection site can result in significant adverse outcome. Although some facts are clear, much remains controversial, particularly regarding treatment. The incidence of extravasation has been varyingly reported between 1/100 and 1/1000 patients. It can occur with either hand or power injection, although it is more likely with the latter. It does not appear to be clearly related to injection flow rate (perhaps because most injectors will monitor pressure and alter flow rate). Defined risk factors include use of power injector, poor injection sites (poor venous access, small veins such as in hand, wrist, foot, and ankle), large volume of injection, obesity, and inability of the patient to communicate. Lines in place for more than 24 hours and veins subject to multiple venipunctures may also be at risk. Factors such as arterial insufficiency, poor lymphatic or venous drainage, and higher osmolality contrast agent may increase the degree of injury, although they probably do not increase risk of the event.

Symptoms and signs include swelling, tightness, stinging, or burning pain although some patients express little discomfort. Edema, erythema, and tenderness are common. The extravasated contrast stimulates a local inflammatory response, worse with higher osmolality

contrast and larger amounts. While most extravasations produce a limited effect with no permanent injury, skin ulceration and tissue necrosis can occur. A compartment syndrome may be produced, independent of extravasation volume. Because the clinical course is uncertain, close follow-up for several hours is recommended.

There is no clear consensus on treatment, largely because attempts at investigation and comparison of different treatments have produced variable and conflicting results. Conservative management is adequate in most instances. Elevation of the affected limb is recommended (although there is no study proving this). Both warm and cold compresses have been advocated, with cold having improved pain relief, but warm compresses would be expected to speed resorption of contrast. Most now recommend ice packs, as symptomatic relief seems more effective. Aspiration of the contrast and local injection of steroids or hyaluronidase are not supported. Outpatients may be sent home with instructions but should be advised to self-monitor and return for medical attention if symptoms worsen or if skin ulceration or paresthesias develop. Surgical consultation is recommended if the patient develops increasing swelling or pain for more than 2 hours after the event, and if there is poor capillary refill, change in sensation, or skin ulceration.

In the event of an extravasation, documentation in the medical record (either in the radiology report or incident report) should include site of extravasation, type of contrast agent and estimated volume extravasated, physical findings, treatment, and advice to the patient.

CONTRAST IN PREGNANCY AND LACTATION

Studies have shown both intravenous iodinated and gadolinium contrast agents administered to the mother will cross the placenta and are excreted in fetal urine, subsequently swallowed by the fetus. It is possible that a small amount is absorbed across the fetal GI tract. While there has been no documented evidence of harm to the fetus from either agent, convincing evidence of safety has also not been established. Thus for administration of contrast to a pregnant woman, special consideration should be given to the clinical indication for the study, whether exposure to contrast is justified, that the information derived will affect care during the period of the pregnancy and thus cannot be delayed until after delivery, and that there are no reasonable alternatives. Documented informed consent by the patient is recommended.

Investigation has shown that both intravenous iodinated contrast and gadolinium contrast agents are secreted in small quantities in breast milk. Less than 1% of iodinated contrast appears in milk; since the infant will absorb less than 1% of this from the GI tract, the baby is

exposed to less than 0.01% of the dose to the mother and less than 1% the recommended dose for a newborn examination. The risks are considered to be minimal. Less than 0.04% of gadolinium contrast administered to the mother is secreted in breast milk; again since only 1% is absorbed, the baby is exposed to 0.0004% of the dose given to the mother. There is no evidence this miniscule oral ingestion is harmful to the baby.

Thus, if contrast must be administered to a breast-feeding woman, she should be reassured there is no evidence of risk to the baby from the tiny amounts of contrast in the milk. If the mother is apprehensive about this, she may abstain from breast-feeding for 24 hours, discarding expressed milk during that period, and then resume as by 24 hours all the contrast will have been cleared assuming if she has normal renal function.

CONTRAST FOR HYSTEROSALPINGOGRAPHY

For many years HSG has been a valuable test primarily for investigating infertile women. Although indications are fewer with advances in sonography, hysterosonography, MRI, and laparoscopy, HSG is still performed. A variety of contrast agents have been used. An oil-based agent, Lipiodol, was developed in the 1920s. Another oil-based agent Ethiodol (an ethyl alcohol ester of poppy seed oil with 37% iodine) was introduced in the 1950s. While the oil-based agents were quite effective and relatively well tolerated, there were two major concerns: absorption from the peritoneal cavity was very slow (although, because of this, delayed images could be done to assess performed for adhesions); and intravasation could lead to oil embolism to the lungs (Table 55-5). However, in a study of 593 patients having oil contrast HSG, 6.9% of all patients had intravasation, most with tubal blockage, but only 1% had oil emboli and none developed significant symptoms.

Water-soluble agents, initially ionic, were developed. Methylglucamine iothalamate and methylglucamine diatrizoate were both used. Sinografin a combination of diatrizoate meglumine and iodipamide meglumine was preferred by some due to higher viscosity. The water-

soluble agents have improved mucosal detail of the tubes. However, although well tolerated at the time of the examination, investigations have shown patients have greater delayed pain (perhaps due to peritoneal irritation) with water-soluble HOCM than with oil-based agents. At present, because of availability and cost factors, LOCM is commonly used. While the viscosity and density may not be optimal, they are effective for determination of tubal patency and uterine morphology, which are the two items of greatest interest.

Although HSG is not intravascular procedure, because of possibility of intravasation, there is concern if a patient has had prior contrast reactions. As in all such situations, one must consider the risk benefit ratio. Using LOCM and premedication are recommended. In circumstances of extremely severe prior reaction, use of gadolinium may be considered (Table 55-5).

Controversy existed for years regarding fertility rate following HSG. Some argued the procedure itself improved fertility. A number of practitioners believed oil-based agents would have greater effect on enhancing fertility (due to higher viscosity). Conflicting results were reported in the literature, although some showed advantage for oil-based agents, methodology was criticized. The most recent research, which included low osmolar contrast compared with oil-based, demonstrates no significant difference in conception or live birth rates.

CONTRAST ISSUES FOR THE FUTURE

While much progress has been made in reducing the negative impact of diagnostic contrast agents, issues remain for the future. The use of LOCM and screening has reduced the incidence of serious contrast reactions to the point where they are unexpected and personnel may not be emotionally prepared to deal with them. Maintaining infrastructure and training are necessary. Careful applications of policies described above should limit the incidence and severity of nephrotoxicity. Proper screening and procedures has virtually eliminated lactic acidosis associated with metformin. With proper screening and policies, incidence of NSF has dropped dramatically.

Further research is needed to determine for certain whether isoosmolar contrast or some new agent may truly reduce nephrotoxicity. Additional study may prove usefulness of some other intervention besides hydration. If an agent or treatment could be developed to prevent NSF, perhaps from better understanding of etiologic processes, patients with severe renal failure might be able to benefit from gadolinium-enhance MR procedures.

It will behoove practicing radiologists to continue with life-long learning to keep aware of new developments that may lead to safer use of contrast.

TABLE 55-5 Adverse Events with Hysterosalpingography

Contrast-related	Idiosyncratic contrast reaction
	Intravasation (with potential pulmonary oil embolism)
	Abdominal pain (peritoneal irritation)
	Granuloma formation (peritoneal irritation)
Procedure-related	Pain from uterine distension
	Infection
	Hemorrhage
	Uterine perforation

- C. History of asthma
- D. History of cardiovascular event

ANSWER: A. Although all are considered risk factors, prior adverse event carries the greatest risk for another such event.

2. A patient is undergoing a contrast-enhanced CT and becomes agitated. Upon questioning, you notice a distinct change in his/her voice. After administration of oxygen, what is the next best step?
 - A. Diphenhydramine IM, 50 mg
 - B. Diphenhydramine IV, 50 mg
 - C. Epinephrine (1:1000), 0.1 to 0.3 mL SC
 - D. Metaproterenol inhaler, 2 to 3 puffs

ANSWER: C. Voice changes suggest laryngeal edema, and after administration of oxygen by mask, subcutaneous or intramuscular epinephrine (1:100) is indicated.

3. What is the most appropriate next step in a patient (in need of a contrast-enhanced, cross-sectional imaging examination) with a prior history of a significant life-threatening contrast reaction requiring intravenous epinephrine and intubation?
 - A. Any type of contrast-enhanced examination is contraindicated in this patient.
 - B. Gadolinium-enhanced MRI
 - C. Gadolinium-enhanced MRI after premedication
 - D. Noncontrast CT

ANSWER: B. A patient with a history of a severe reaction should probably not undergo another study with iodinated contrast. Instead, MRI can be considered and is likely more informational than non-contrast study. There are no studies to support premedication before gadolinium administration in a patient with iodinated contrast allergy.

4. What is the minimum time needed after pretreatment with steroids in a patient with history of moderate contrast reaction before intravenous contrast can be safely administered?
 - A. 2 hours
 - B. 8 hours
 - C. 10 hours
 - D. 12 hours

ANSWER: D. At least 12 hours are needed to prevent reaction.

5. What is the concentration of epinephrine that is administered intravenously?
 - A. 1 mg/1 mL
 - B. 1:1000
 - C. 1:10 000
 - D. 1:100 000

QUESTIONS AND ANSWERS

1. Which of the following is the most significant risk for iodinated contrast reaction?
 - A. History of prior iodinated contrast reaction
 - B. History of shellfish allergy

ANSWER: C. 1:10000 is concentration used for intravenous administration. $1 \text{ mg}/10 \text{ mL} = 1:10000$ concentration, which is the dose for intravenous administration. Concentration of 1:1000 is used subcutaneously.

6. What is the time frame of occurrence for a contrast reaction to be considered delayed?
- 1 day to 1 week
 - 1 hour to 1 week
 - 1 day to 2 weeks
 - 1 hour to 2 weeks

ANSWER: B. Delayed reactions occur after 1 hour and within 1 week, most within 3 days of administration.

7. What is the only proven intervention for contrast-induced nephrotoxicity?
- Intravenous hydration
 - Intravenous hydration with diuretic
 - Oral hydration
 - Intravenous hydration with acetylcysteine

ANSWER: A. Hydration is the only proven preventative measure for CIN, and intravenous hydration is a more effective route than oral.

8. A patient is undergoing contrast-enhanced CT and is currently taking metformin. What is the recommendation for discontinuing the drug?
- 48 hours before and after the examination
 - 48 hours before the examination
 - 48 hours after the examination
 - No action needs to be taken since the patient has no other comorbidities.

ANSWER: C. There is no need to discontinue metformin before contrast, only for 48 hours after contrast in patients with comorbidities. Presumably most (not all) patients taking metformin are diabetic, although it has other limited applications.

9. What is the eGFR below which a Gadolinium-enhanced MRI should not be performed?
- $20 \text{ mL}/\text{min}/1.73 \text{ m}^2$
 - $30 \text{ mL}/\text{min}/1.73 \text{ m}^2$
 - $40 \text{ mL}/\text{min}/1.73 \text{ m}^2$
 - $50 \text{ mL}/\text{min}/1.73 \text{ m}^2$

ANSWER: B. Unless the benefits significantly outweigh the risks of NSF, gadolinium should not be administered in the setting of acute or significant chronic renal disease (eGFR less than $30 \text{ mL}/\text{min}/1.73 \text{ m}^2$).

10. What is the recommendation for a breast-feeding mother who is to undergo contrast-enhanced CT?

- There is no evidence of risk to the baby, so no measures need to be employed.
- Because of a small risk to the baby from contrast excreted in breast milk, breast milk should be discarded for 24 hours after the examination.
- A non-contrast examination should be performed.
- A contrast MRI should be performed.

ANSWER: A. There is no study demonstrating a risk to the baby from contrast secreted in breast milk. Therefore, there are no additional actions to be taken, assuming that the study is truly indicated. If she chooses (because of anxiety), a mother can discard her milk for 24 hours, at which time all contrast should be cleared.

56 KIDNEYS

*Michelle M. McNamara and
Mark E. Lockhart*

ANATOMY

NORMAL ANATOMY

The kidneys and renal pedicle are located in the perirenal space which is bounded by the anterior and posterior renal (Gerota) fascia. The renal pedicle consists of the renal artery, renal vein, collecting system, and lymphatics. The kidneys are approximately 10 to 12 cm long (spanning three to four lumbar vertebral bodies), and approximately 5 to 7 cm wide. Left and right kidney length should not vary more than 2 cm. The right kidney is 1 to 2 cm lower than the left kidney and slightly more lateral. The collecting system consists of minor (usually 10–14 in number) and major calyces and the renal pelvis. Intravenous pyelograms overestimate true renal length secondary to magnification and renal engorgement from osmotic diuresis. Ultrasound may underestimate true renal length because of technical difficulties in imaging the entire kidney.

VARIANT ANATOMY

Persistent fetal lobulation can be identified in approximately 5% of adult patients. The kidneys have a scalloped appearance. The number of lobes depends on the overall calyceal number and represents a vestige of lobar development of the kidney, which is visible at birth. With cellular multiplication, lobar anatomy is usually

obscured by age 4 to 5 years. Persistent lobulation is of no clinical significance but may be mistaken for another entity such as tumor. With persistent fetal lobulation, renal parenchymal thickness should be normal (approximately 10 mm), and the renal indentations should be smooth and regular. An important finding in identifying persistent fetal lobulation is that the calyces are centered between indentations. This differs from indentations caused by reflux nephropathy in which indentations in the renal parenchyma overlie the calyces. The indentations, which may result from papillary necrosis, also overlie the necrotic renal papilla and its subtending calyx. Lobulation can also be mimicked by multiple renal infarcts when interlobar vessels are involved, most commonly seen in patients with small vessel disease such as chronic diabetes. In this circumstance, indentations in the renal parenchyma occur between calyces, but overall renal parenchyma thickness is diminished by atrophy.

ABNORMAL NUMBER OF KIDNEYS

Renal agenesis results from failure of the ureteric bud to reach the metanephric blastema secondary to either failure of formation or premature degeneration of the ureteric bud. Induction of the functional nephron does not occur. The resulting Mullerian duct anomalies are considered part of the Mayer-Rokitansky-Kuster-Hauser syndrome in females. In 70% of women with unilateral renal agenesis, associated genital anomalies are present; these include absence or atresia of the uterus or vagina, a unicornuate uterus with absence or atresia of the vagina and ovary, or duplication anomalies of the genital tract. In 20% of male individuals with renal agenesis, there is absence of the ipsilateral epididymis and vas deferens, or presence of an ipsilateral seminal vesicle cyst. Absence of the ipsilateral adrenal gland is associated with renal agenesis in 10% of patients. Compensatory hypertrophy of the contralateral kidney is usually evident. Renal agenesis can be diagnosed by ultrasound, CT, or radionuclide renography. Findings may be seen on conventional radiographs of the abdomen. With absence of one kidney, bowel (usually colon) will occupy the empty renal fossa. The colonic flexure on the affected side will be displaced medially. This is better appreciated in the case of left renal agenesis.

SUPERNUMERARY KIDNEYS

In this rare anomaly, more than two discrete kidneys are present on one side. It is likely a result of formation of two ureteral buds on one side. A supernumerary kidney is more often seen on the left side, caudal to the normal

kidney, and is often hypoplastic. The supernumerary kidney may be drained by a bifid ureter, which also drains the second kidney on the ipsilateral side. Alternatively, a separate ureter may drain the supernumerary kidney.

ABNORMAL POSITION

Malrotation and nonrotation of the kidneys is commonly seen. This is a result of failure to rotate about the vertical renal axis. Nonrotation results in an anterior position of the ureteropelvic junction, with some calyces located medial to the renal pelvis. Overrotation of the kidney is rare and results in the ureteropelvic junction oriented posteriorly. Pelvic kidney is a common renal ectopia without fusion.

ABNORMAL FUSION

Horseshoe kidney is a common renal anomaly and occurs more frequently in males. An isthmus forms between the two developing masses of renal tissue. This connection may consist of a fibrotic band or a functioning renal parenchyma. Normal renal ascent is arrested when the horseshoe kidney becomes caught under the origin of the inferior mesenteric artery. There is an increased incidence of renal vascular and urinary tract anomalies associated with horseshoe kidney. Complications of horseshoe kidney include obstruction, stone formation, urinary tract infections, and increased risk for certain malignancies, include transitional cell carcinoma (TCC), Wilms tumor, and rarely renal carcinoid. The horseshoe kidney is susceptible to injury during blunt abdominal trauma.

Crossed fused ectopia is a rare congenital renal anomaly in which one kidney crosses the midline and fuses to the opposite kidney. The ureters insert in their normal positions, with the ureter from the crossed kidney crossing the midline. The left kidney more commonly crosses the midline to lie on the right retroperitoneum.

ABNORMAL VESSELS

Vascular anomalies of the kidney most often include duplicate renal arteries and supernumerary renal veins. Anomalies of renal vasculature are much more common with ectopic kidneys. A crossing vessel near the ureter is commonly seen in patients with ureteropelvic junction obstruction. However, most anomalous renal vessels are of no clinical significance, although recognition, of these vessels may be important for surgical planning in certain cases.

TABLE 56-1 Renal Cell Cancer Staging, TNM

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 7 cm or less in diameter and limited to the kidney
T2	Tumor more than 7 cm in greatest dimension limited to the kidney
T3	Tumor extends into major veins or invades the adrenal gland or perinephric tissues, but not beyond Gerota's fascia
T4	Tumor invades beyond Gerota's fascia
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in a single regional lymph node
N2	Metastasis in more than one regional lymph node
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

RENAL MASSES

Renal cell carcinoma (RCC) is the most common primary renal malignancy. It arises from renal tubular epithelium and usually develops in renal cortex. It is bilateral in 2% of cases. RCC is usually solid, although a small percentage is predominately cystic. Calcification occurs in approximately 25% to 30% of tumors overall, and intratumoral fat is very rarely seen. Direct tumor invasion into the renal vein or IVC may affect tumor staging (Table 56-1). Risk factors include family history, male gender, tobacco use, chronic dialysis, and advancing age. There is an increased incidence of bilateral renal tumors in Von Hippel-Lindau disease.

Lymphoma rarely primarily involves the kidneys. The kidney is commonly involved by hematogenous lymphoma metastases or by direct invasion of retroperitoneal adenopathy, usually non-Hodgkin lymphoma. Patterns of renal involvement include diffuse enlargement of the kidney, multiple bilateral solid renal masses, solitary bulky tumor, tumor invasion into the renal sinus, and perirenal tumor surrounding the kidneys. On CT, lymphoma is seen as a homogeneous poorly enhancing mass; extensive adenopathy supports the diagnosis.

Metastatic disease involving the kidneys often appears as multiple bilateral small irregular renal masses. Solitary hypervascular masses may be indistinguishable from RCC. Most renal metastases are detected late in the course of malignancy, and common primary tumors include lung, breast, and colon cancer as well as melanoma. Unlike RCC, which is typically exophytic, most metastases do not disrupt the cortical margins, but those from colon cancer may.

TCC is a uroepithelial tumor, which may arise anywhere within the collecting system. Tumors are often multifocal. TCC often has an infiltrative appearance and may diffusely invade along the collecting system

urothelium. Calcifications in upper tract TCC are rare, less than 5%, and vascular invasion is not generally present.

Oncocytoma is a rare benign solid tumor, which rarely demonstrates hemorrhage or necrosis. The mass may disrupt the cortical margins, similar to RCC. Large tumors may demonstrate a stellate central scar that is suggestive of the diagnosis but can be seen in malignant renal tumors. Therefore, oncocytomas are not distinguishable from RCC by standard imaging methods.

Angiomyolipoma (AML) is a rare benign tumor composed of variable amounts of fat, smooth muscle, and abnormal vessels. Tumors larger than 4 cm are susceptible to spontaneous hemorrhage. Most are solitary unilateral tumors incidentally discovered. Approximately 10% of AMLs are seen in patients with tuberous sclerosis; 80% of patients with tuberous sclerosis have AMLs, typically multiple bilateral lesions. However, less than half of patients with AML have tuberous sclerosis. CT demonstration of gross fat density within a solid renal tumor without calcification is considered diagnostic of AML.

Multilocular cystic nephroma is a rare benign thick-walled neoplasm comprising a cluster of noncommunicating cysts of varying size separated by thin connective tissue septations. It is seen most commonly in male children younger than 4 years and middle-aged women in the fourth to sixth and decade of life.

CYSTIC DISEASE

Autosomal recessive polycystic kidney disease is detectable in utero and usually presents in the neonate. The condition is characterized by involvement of the kidneys and occasionally the liver. There is a spectrum of disease from infantile polycystic disease with severe renal disease at birth to juvenile polycystic disease with relatively mild renal disease and development of hepatic fibrosis and liver failure in childhood.

Autosomal dominant polycystic kidney disease can be detected in neonates and children, but usually becomes clinically apparent between the third and fifth decades of life, with hypertension and renal failure. The renal parenchyma is progressively replaced by multiple noncommunicating cysts of varying size and complexity. The renal volume increases with the number and size of the cysts. Cysts may be seen in other organs, often the liver (60%), pancreas (10%), and rarely spleen. Extrarenal cysts are seldom clinically significant. There is an association with intracranial aneurysms (3%–20%) as well as mitral valve prolapse, bicuspid aortic valve, and aortic aneurysms/dissections.

Medullary sponge kidney is dysplastic dilatation of the collecting tubules in the papilla. This results in

urinary stasis causing stone formation and sometimes infection. There is no genetic predisposition. The kidneys remain of normal size. The condition may be bilateral and symmetric or may be focal and asymmetric. Excretory urography demonstrates striations or sacular contrast collections in the papilla. Stones in the papilla result in increased density seen on CT and increased medullary echogenicity seen on ultrasound.

Multicystic dysplastic kidney is usually diagnosed in utero or at birth. It appears as a mass of noncommunicating cysts of varying sizes. The kidney progressively atrophies; by adulthood there is only a small focus of often calcified tissue remaining.

ACQUIRED CYSTIC DISEASE

Hemodialysis and end-stage renal disease may result in the development of multiple cysts in the native kidneys, also called acquired cystic kidney disease. The atrophic kidneys demonstrate predominately cortical cysts generally no greater than 2 cm in size. There is significantly increased risk of RCC in these patients.

SIMPLE CYST

The most common renal mass in the adult is the cyst. They may be solitary or multiple and arise anywhere within the kidney. Cysts tend to increase in size and number over years. They are usually asymptomatic but if large can cause mass effect leading to hypertension or obstruction of the collecting system. If imaging criteria for simple cyst are met on CT or ultrasound, no further evaluation is needed. Bosniak classification of cystic renal lesions is used to assess risk of neoplasm in renal lesions and to address risk of neoplasm in a complex-appearing renal cyst (Table 56-2).

INFECTION/INFLAMMATION

Pyelonephritis usually results from an ascending urinary tract infection caused by gram-negative organisms. Often, there are no imaging abnormalities. Edema and swelling associated with acute infection may cause wedge-shaped defects in the enhancing parenchyma, referred to as a striated nephrogram (Table 56-3). Abscess may form as a complication of acute pyelonephritis.

Emphysematous pyelonephritis is a rapidly progressing and life-threatening form of acute pyelonephritis with gas in the renal parenchyma. Risk factors include diabetes, obstruction, or immune system compromise. Mixed flora infection with gram-negative organisms is most common.

TABLE 56-2 Bosniak Classification

Bosniak I	Simple renal cyst, uniformly water density, no enhancement, imperceptible or barely perceptible margin	Benign No intervention
Bosniak II	Thin septations, nonenhancing high density or thin peripheral calcification and smaller than 3 cm	Benign No intervention
Bosniak IIF	Lesions which would otherwise be considered Bosniak II but are larger than 3 cm, including high attenuation lesions. Lesions with multiple thin septae, mildly thick or nodular septae or wall, or perceived enhancing thin septa. No measureable enhancement.	Probably benign Follow-up to prove stability
Bosniak III	Thick irregular calcifications, thick or enhancing septations, areas of nodularity, thick wall or multilocular appearance	Indeterminate. Biopsy, ablation/excision, or follow-up
Bosniak IV	Irregular solid nodules, irregular shaggy walls and solid enhancing areas	Malignant Ablation or excision

Chronic pyelonephritis is a chronic interstitial nephritis caused by infection. When associated with vesicoureteral reflux it is referred to as reflux nephropathy. In adults, chronic pyelonephritis is most commonly associated with conditions resulting in urinary stasis, such as stones with chronic obstruction, neurogenic bladder, and ileal conduit. Imaging demonstrates focal scarring overlying dilated calyces, often with normal calyces intervening.

Xanthogranulomatous pyelonephritis is more frequently seen middle-aged females in the setting of recurrent urinary tract infections. Infection-based stones are common, and the stones may be fragmented during the swelling of the kidney. Imaging demonstrates renal enlargement with a hypo- or nonfunctioning inflammatory mass, which may mimic malignancy, often with perinephric inflammatory change. These lesions are irreversible and surgical intervention may be required.

Renal tuberculosis may occur as a late complication of primary pulmonary tuberculosis, up to 10 to 15 years later. In cases of renal tuberculosis, 30% show chest radiograph evidence of prior tuberculosis, and 10% show findings of active tuberculosis. Patients may present with asymptomatic hematuria or sterile pyuria. Imaging suggests the diagnosis with findings of parenchymal

TABLE 56-3 Etiologies of Striated Nephrogram

COMMON	UNCOMMON	RARE
Pyelonephritis	ADPKD	Radiation nephritis
Acute ureteral obstruction	Acute renal vein thrombosis	
	Renal contusion	

destruction and cavity formation with eventual fibrosis causing strictures of the collecting system and ureter. Granuloma formation may result in parenchymal masses, and calcification is frequent.

Nephrolithiasis refers to the presence of calculi in the intrarenal collecting system. Nearly all stones appear high attenuation on noncontrast CT, with attenuations ranging from approximately 150 to 1000 HU, depending on composition. The uncommon exception is crystalline stones previously associated with the use of protease inhibitors in the treatment of HIV infection. High attenuation of stones on CT facilitates differentiation of calculi from other collecting system lesions such as tumors, hematoma, fungus balls, or sloughed papilla, which generally are less than 50 HU.

Types of stones:

Calcium. Approximately 80% of renal calculi contain sufficient calcium oxalate or calcium phosphate to be apparent on radiographs.

Struvite (magnesium ammonium phosphate) stones are formed in the presence of alkaline urine and infection. They make up approximately 15% of renal calculi and are also somewhat radiopaque on radiographs.

Urate/xanthine stones account for approximately the remaining 3% to 4% of renal stones. These are typically radiolucent on radiographs.

Nephrocalcinosis (Table 56-4) is the pathologic deposition of calcium in the renal parenchyma. It is usually bilateral and secondary to systemic disorders. Medullary nephrocalcinosis is the more common form and is usually related to hypocalcemia or hypercalciuria. Imaging demonstrates dense or echogenic renal pyramids. Cortical nephrocalcinosis is rare (less than 5%).

Delayed/persistent nephrogram has a broad differential diagnosis (Table 56-5). Contrast enhanced imaging shows retention of contrast in the kidneys. If the finding is bilateral and symmetric this reflects medical disease. Asymmetric or unilateral involvement is usually secondary to an underlying disorder requiring surgical intervention.

TABLE 56-4 Differential Diagnosis for Nephrocalcinosis

MEDULLARY	CORTICAL
Hyperparathyroidism	Acute cortical necrosis (severe ischemia)
Medullary sponge kidney	Chronic glomerulonephritis
Renal tubular acidosis Type 1	Primary hyperoxaluria
Milk alkali syndrome	
Hypervitaminosis D	
Hypocalcemia/ hypercalciuric states	
Primary hyperoxaluria	

TABLE 56-5 Etiologies for Delayed Nephrogram

Intrarenal (70%)
Acute tubular necrosis: drugs, including IV contrast, ischemia
Acute glomerulonephritis
Interstitial nephritis: drug reaction, especially antibiotics
Papillary necrosis: sickle cell, DM, analgesics
Prerenal (15%)
Hypovolemia/hypotension
Low cardiac output
Renal artery stenosis
Renal vein thrombosis
Postrenal (15%)
Obstructive uropathy

PARENCHYMAL DISEASE

Bilateral small kidneys (less than 9 cm) imply renal injury secondary to a systemic disease process (Table 56-6).

Unilateral small kidney implies global injury to the renal parenchyma (Table 56-7). The contralateral kidney can sometimes show compensatory hypertrophy.

Bilateral large kidneys (greater than 13 cm) imply systemic disease that adds to the renal size by deposition of protein, cells, or fluid (Table 56-8).

Unilateral large kidney may result from infiltrating neoplasm, duplicated collecting system and compensatory hypertrophy as well as a number of acute processes. A small contralateral kidney suggests compensatory hypertrophy as the etiology. Acute processes include acute renal vein thrombosis, acute arterial infarction, obstructive uropathy, and acute pyelonephritis.

RENAL VASCULAR DISEASE

The two most common causes of renal artery stenotic disease are atherosclerosis and fibromuscular disease (FMD). Patients with atherosclerotic renal disease are usually older than 60 years and may clinically present with hypertension, renal failure or both. FMD is the most common cause of renovascular hypertension in patients younger than 40 years. Atherosclerotic disease typically affects the renal artery ostia, and often requires stenting with dilatation. With FMD, the mid and distal portions of the vessel are most frequently affected and FMD typically responds well to dilatation alone. There are three

TABLE 56-6 Differential Diagnosis for Bilateral Small Kidneys

Uremic medullary disease
Chronic glomerulonephritis

TABLE 56-7 Differential Diagnosis for Unilateral Small Kidney

Renal artery stenosis
Postobstructive uropathy
Postinflammatory atrophy
Global renal infarction
Radiation nephritis
Congenital hypoplasia (less than 5 lobes)

types of FMD, intimal (7%–8%), medial (85%), and periarterial (7%–8%). Medial fibroplasia demonstrates the classic “string of beads” appearance.

RENAL TRANSPLANT

A normal transplant kidney appears well defined and elliptical with preserved corticomedullary differentiation. Ultrasound echogenicity should be similar to liver echogenicity.

Renal transplant complications: peritransplant collections include hematoma, abscess, urinoma, and lymphocele. Hematoma may be seen in the immediate postoperative period. Acute hematoma is hyperechoic by ultrasound, and there may be an associated decrease in hematocrit. Abscess, appearing as a complex fluid collection and associated with fever, may develop within weeks. Urinoma tends to occur within the first month and appears as a bland collection on ultrasound. In the absence of active leak, it will not demonstrate activity on a nuclear medicine study. Lymphocele is seen in up to 20% of transplants and tends to occur at 1 to 4 months after transplantation surgery. These collections often contain thin septations and are of no consequence unless they result in obstruction or pain.

Reversal of diastolic flow in the renal vein implies compromise of drainage by the transplant renal vein or high resistance in intrarenal vessels. Differential considerations include severe rejection (most common), acute tubular necrosis, renal vein thrombosis, intimal flap, and extrinsic compromise secondary to peritransplant collection. Although only 10% of cases, renal vein thrombosis must be considered due to poor outcomes if left untreated.

TABLE 56-8 Differential Diagnosis for Bilateral Large Kidneys

Proliferative disorders	Parenchymal edema
Acute glomerulonephritis	Acute tubular necrosis
Lupus nephritis	Acute cortical necrosis
Diabetic glomerulosclerosis	Acute bilateral
	Pyelonephritis
Cell infiltration	Protein deposition
Lymphoma	Multiple myeloma
Leukemia	Amyloidosis
	Urate deposition
	Urate nephropathy

Arterial stenosis is suggested by an elevated peak systolic velocity and elevated renal artery to iliac artery ratio with tardus parvus waveforms in segmental renal arteries. This is the most common vascular complication of renal transplant.

Rejection is characterized by elevated resistive indices greater than 0.7–0.8 by Doppler ultrasound and demonstrates decreased perfusion on nuclear medicine study. Hyperacute rejection occurs within the first 24 hours. Accelerated acute rejection occurs between 1 and 5 days and acute rejection between 1 and 5 weeks (usually within 3 months) after transplant placement. Chronic rejection is seen months to years posttransplant. Chronic rejection diagnosed by scintigraphy can often not be differentiated from cyclosporin toxicity, renal artery stenosis, or ureteral stenosis.

Acute tubular necrosis is the most common form of acute reversible renal failure in transplant patients. It is usually seen within 24 hours of transplant and rarely occurs beyond 1 month posttransplant. Nuclear medicine study will demonstrate normal flow with reduced excretion. Causes include renal ischemia and nephrotoxicity.

Cyclosporin toxicity is uncommon within the first month after transplant. Renal scintigraphy shows decreased perfusion and function with decreased excretion, but biopsy is often required for definitive diagnosis.

Hydronephrosis may be associated with urinoma or other peritransplant collection, stone formation, or stricture.

QUESTIONS AND ANSWERS

- What is the most common primary renal malignancy?
 - Transitional cell carcinoma
 - Renal cell carcinoma

- C. Metastasis
- D. Lymphoma

ANSWER: B. Renal cell carcinoma accounts for approximately 3% of adult malignancies and 90% to 95% of neoplasms arising from the kidney. It arises from the proximal renal tubular epithelium and is most often cortical location.

Transitional cell carcinoma accounts for approximately 90% of renal pelvic tumors and is the second most common primary malignancy of the kidney. The vast majority of urothelial tumors arise in the bladder. Urothelial tumors of the renal pelvis and ureter are rare, comprising approximately 5% to 6% of all urothelial tumors and 5% to 9% of renal cancers.

Primary lymphoma of the kidneys is rare. The incidence of renal lymphoma in patients with known lymphoma may be as high as 50%. Renal involvement is more often seen with non-Hodgkin than Hodgkin lymphoma.

Renal metastases are most often found in patients with known malignancies, usually in association with metastatic disease.

2. Which of the following has an increased incidence of bilateral renal cell carcinoma?
 - A. Von Hippel-Lindau disease
 - B. Tuberous sclerosis
 - C. Klippel-Trenaunay Syndrome
 - D. Sturge-Weber Syndrome

ANSWER: A. Von Hippel-Lindau syndrome is an autosomal dominant, inherited, phakomatosis, characterized by a predisposition to bilateral and multicentric retinal angiomas, central nervous system hemangioblastoma; renal cell carcinoma; pheochromocytoma; islet cell tumor of the pancreas; endolymphatic sac tumor; and renal, pancreatic, and epididymal cysts. Tuberous sclerosis is an autosomal dominant disorder characterized by hamartoma/benign tumor formation in the skin, brain/nervous system, and kidneys, including angiomyolipoma. Clinical triad of epilepsy, low intelligence, and adenoma sebaceum is seen. Klippel-Trenaunay syndrome is a congenital vascular disorder of unknown cause, characterized by a triad of symptoms: port-wine stain covering one or more limbs, congenital vascular anomalies, and hypertrophy or atrophy of the limb.

Sturge-Weber syndrome is a congenital, nonfamilial disorder of unknown incidence and cause. It is characterized by a congenital facial birthmark and neurologic abnormalities.

3. Which of the following is commonly associated with renal angiomyolipoma?

- A. Von Hippel-Lindau disease
- B. Tuberous sclerosis
- C. Klippel-Trenaunay Syndrome
- D. Sturge-Weber Syndrome

ANSWER: B. See explanation for question 2.

4. Most patients with renal angiomyolipoma have tuberous sclerosis.
 - A. True
 - B. False

ANSWER: B. Eighty percent of patients with tuberous sclerosis have angiomyolipomas, typically multiple bilateral lesions. Less than half of patients with AML have tuberous sclerosis.

5. A 2.5-cm renal cyst with thin peripheral calcification and no solid enhancing component is seen. What is its Bosniak Classification?
 - A. I
 - B. II
 - C. IIF
 - D. III

ANSWER: B. A Bosniak II lesion demonstrates thin septations and/or thin peripheral calcification and are smaller than 3 cm. Hyperdense cysts are included in this category.

Bosniak IIF are lesions that would otherwise be considered Bosniak II but are larger than 3 cm, including high attenuation lesions. Also included in this category are lesions that are slightly more complex, demonstrating multiple septations, and/or mild septal or wall thickening/nodularity without measurable contrast enhancement.

6. What is the most common type of renal calculus?
 - A. Calcium
 - B. Struvite
 - C. Xanthine
 - D. Crystalline

ANSWER: A. Calcium rich calculi constitute approximately 80% of urinary tract stones. Struvite stones make up approximately 15%, and xanthine approximately 3% to 4%. Crystalline stones are rare.

7. What type of renal calculus may not be visualized on CT?
 - A. Calcium
 - B. Struvite
 - C. Xanthine
 - D. Crystalline

ANSWER: D. Crystalline stones are a result of treatment with a protease inhibitor. They are nonopaque on CT imaging. They are suspected in the appropriate clinical setting with imaging findings of

obstructive uropathy without stone or other obstructing lesion visualized.

8. Renal scintigraphy demonstrates normal flow with reduced excretion in a transplanted kidney on post-transplant day 1. What is the most likely diagnosis?
- Arterial stenosis
 - Rejection
 - Acute tubular necrosis
 - Cyclosporin toxicity

ANSWER: C. Acute tubular necrosis and cyclosporine toxicity typically demonstrate normal flow with reduced excretion. Decreased perfusion may be seen with cyclosporine toxicity. ATN typically develops within 24 to 48 hours posttransplant and is rare after 1 month. Cyclosporine toxicity is not typically seen within the first month following transplant and is associated with elevated cyclosporine levels. Rejection typically demonstrates decreased flow and reduced excretion. A major point of distinction between acute tubular necrosis and rejection is that perfusion is preserved in ATN. Transplant renal artery stenosis is best assessed sonographically and may appear similar to chronic rejection on radionuclide imaging.

9. A peritransplant collection is identified 6 months after renal transplant. What is the most likely diagnosis?
- Lymphocele
 - Hematoma
 - Urinoma
 - Abscess

ANSWER: A. Lymphoceles are the most common peritransplant fluid collection. They develop as a result of leakage from disrupted lymphatic channels. They generally require approximately 1 to 2 months before they become large enough to produce symptoms. They are usually asymptomatic but may cause obstruction secondary to mass effect.

Hematoma is typically seen as a small peritransplant collection immediately after surgery. Differential diagnosis is seroma. These often appear mildly complex and maybe echogenic if they are acute.

Urinoma is a relatively rare complication following transplant. Urine leaks generally occur within the first 2 weeks postoperative. On ultrasound, a urinoma appears as a well-defined anechoic fluid collection that rapidly increases in size. Septations are uncommon.

10. A patient has developed an intimal flap in the transplant vein in the immediate postoperative period. What is the expected sonographic finding?
- Tardus parvus waveform
 - Reversal of diastolic flow

- Triphasic waveform
- Square wave

ANSWER: B. Reversal of diastolic flow may be caused by a variety of factors. Less than 24 hours from transplant, renal vein thrombosis, vascular kinking, and perigraft hematomas are more common. In the longer term, reversal of diastolic flow is associated with chronic rejection. Tardus parvus waveform is variably seen with arterial stenosis. A triphasic waveform is a normal high resistance arterial waveform. A square wave is a kind of waveform commonly used to represent digital information.

57 URETERS

Heather L. Haddad and Mark E. Lockhart

NORMAL ANATOMY

The ureters range in length 25 to 30 cm and are retroperitoneal in location. They course from the renal pelvis caudally, anterior to the psoas muscle. Ureters cross over the distal common iliac or proximal external iliac vessels and continue caudally along the lateral pelvic walls. At the level of the inferior greater sciatic foramen, they course medially and run obliquely through the bladder wall to empty at the lateral angles of the bladder trigone.

The ureters consist of three layers:

- The outer fibrous layer, the adventitia, is continuous with the renal capsule and adventitia of the urinary bladder.
- The muscularis consists of outer circular and inner longitudinal muscular layers.
- Transitional epithelium forms the mucosal layer beneath which lies the submucosal connective tissue of the lamina propria.

DEVELOPMENTAL ABNORMALITIES

Vesicoureteral reflux is retrograde flow of urine from the bladder into the ureters. It results due to a primary maturation abnormality of the ureterovesicular junction (UVJ) or due to submucosal segment of the ureter that is too short as it travels through the bladder wall; disrupting the ureteral valve mechanism. Reflux is categorized by a grading system of the International Reflux Committee (Table 57-1).

TABLE 57-1 Grades of Vesicoureteral Reflux

Grade I	Reflux into the distal ureter
Grade II	Reflux reaches the level of the kidney without dilation of the collecting system
Grade III	Reflux to the kidney with mild dilation of the collecting system
Grade IV	Moderate dilation of the ureter, pelvis, and calyces. Obliteration of sharp forniceal angles
Grade V	Marked tortuosity of the ureter with massive dilation of the ureters, pelvis, and calyces loss of papillary impressions on calyces

Megaureter is a ureteral diameter greater than or equal to 7 mm in a child or 10 mm in an adult. Primary megaureter develops when there is a short, aperistaltic segment of ureter near the UVJ, with the most severe dilatation just proximal to this segment. The ureter is usually most dilated just above the more normal caliber aperistaltic segment. Primary megaureter can be distinguished from ureteral obstruction as the intraparenchymal collecting system typically remains normal in caliber with primary megaureter and dilates with ureteral obstruction. Reflux is uncommonly (20%) associated with primary megaureter. The condition is more prevalent in males with a left-sided predominance.

An ectopic ureter, secondary to an abnormal ureteral bud migration, usually inserts caudal to the normal ureteral insertion at the trigone. Approximately 70% to 80% are associated with complete ureteral duplication, each ipsilateral ureter inserting separately into the bladder.

WEIGERT-MEYER RULE

In a duplicated renal collecting system, the upper pole moiety ureter inserts inferior and medial to the ureter draining the lower pole moiety. The upper pole is associated with an ureterocele and obstruction. The lower pole ureter inserts at or near the normal location and is associated with reflux secondary to a short intravesicular ureteral segment.

Ectopic ureter is more common in females and can result in incontinence when the ureter inserts distal to the external sphincter in the vestibule, uterus, or vagina. Ectopic ureter is not associated with incontinence in males as the ureter inserts proximal to the external sphincter.

An ureterocele is cystic dilation of the intravesicular ureteral segment secondary to obstruction at the ureteral orifice. The outer wall consists of bladder epithelium and the inner wall consists of ureteral epithelium. Intravenous urography demonstrates the “cobra head” sign: contrasted urine within the ureterocele surrounded by the thin, radiolucent wall of the epithelium, protruding

TABLE 57-2 Medial Deviation of the Ureter

Iliac lymphadenopathy
Iliac artery aneurysm
Pelvic lipomatosis
Lateral retroperitoneal mass

into the contrast-filled bladder. Approximately 75% of ureteroceles are associated with the upper pole moiety of a duplicated collecting system.

Retrocaval ureter occurs secondary to anomalous development of the infrarenal inferior vena cava (IVC), when the IVC forms from a persistent right posterior cardinal vein instead of the right supracardinal vein. The proximal right ureter passes posterior to the IVC, abruptly deviating medially (Table 57-2). Compression of the ureter can cause varying degrees of obstruction. Intravenous urography demonstrates a reverse “J” or fishhook appearance of the ureter.

Congenital narrowing at the ureteropelvic junction (UPJ) causes varying degrees of hydronephrosis depending on the severity of the narrowing. Approximately 20% to 30% of UPJ obstructions are bilateral. The majority are intrinsic to the ureter, while some are associated with extrinsic compression by a crossing vessel. Imaging reveals hydronephrosis without accompanying ureterectasis. UPJ obstruction is the most common cause of antenatal hydronephrosis.

NONNEOPLASTIC CONDITIONS

The vast majority of ureteral calculi result from the migration of renal calculi into the ureter (Table 57-2). The calculi are prone to lodge within the ureter at locations of anatomic narrowing including the UPJ, the UVJ, and the pelvic brim. Ureteral calculi can be confused with phleboliths. Ureteral calculi generally demonstrate uniform opacity and a soft tissue rim of the surrounding ureter on CT where as phleboliths are often multiple, do not exhibit a soft tissue rim sign, and have central lucency because of recanalization of the thrombosed vein. Calcification within the ureteral wall can occur secondary to infection with tuberculosis or schistosomiasis but is uncommonly seen in the United States.

Ureteritis cystica reveals multiple tiny (2–3 mm) subepithelial fluid-filled cysts in the wall of the ureter (Table 57-3). Development of the condition can be associated with urinary calculi, chronic inflammation, or urinary tract infection (UTI). Intravenous urography demonstrates multiple tiny smooth ureteral filling defects.

TABLE 57-3 Ureteral Filling Defects

Malakoplakia
Leukoplakia

Ureteral pseudodiverticulosis consists of multiple, tiny pseudodiverticula. This is typically bilateral, more common in the proximal and mid ureter. Development of pseudodiverticuli can be associated with urinary calculi, obstruction, and infection. There is a possible association with transitional cell carcinoma (TCC).

Malacoplakia is an inflammatory condition that occurs in the setting of chronic UTIs. Plaque-like or nodular intramural lesions develop as a result of defective macrophage digestion of bacteria, which are incompletely phagocytized and form intracellular inclusion bodies termed Michaelis-Gutmann bodies. These are identifiable with histologic evaluation. The bladder is more commonly affected than the ureters. This condition is not considered premalignant and usually regresses with antibiotic treatment.

Leukoplakia is squamous metaplasia of the urothelium secondary to chronic irritation from chronic UTI or urolithiasis. The bladder is affected more commonly than the ureters. Imaging findings in the ureter include mural filling defects. Leukoplakia is considered premalignant; there is an association with the development of squamous cell carcinoma.

URETERAL NEOPLASMS

TCC accounts for approximately 90% of renal collecting system neoplasms. Approximately 75% of ureteral TCC occur in the distal one-third of the ureter. Risk factors include tobacco, dyes used in manufacturing such as aniline, chemicals used in rubber, gas, printing and plastic industries, and drugs including chronic phenacetin abuse and cyclophosphamide. It has been theorized that bathing of the collecting system with a renally excreted carcinogen leads to the development of synchronous and metachronous lesions. The majority of metachronous bladder lesions develop within 18 to 24 months. The most common clinical symptoms include

hematuria, urinary frequency, dysuria, and pain. Diagnosis can be made with retrograde pyelography, CT urography, and intravenous urography. Retrograde pyeloureterography demonstrates the “goblet or champagne glass sign.” Slow growth of the TCC leads to expansion of the ureter above and below the tumor giving the dilated ureter the appearance of cupping the tumor. TCC metastasizes via lymphatics to regional lymph nodes. Hematogenous metastasis occurs to the liver, lungs, and bones.

Squamous cell carcinoma occurs much less frequently than TCC, and predisposing factors include calculi, chronic infection, and schistosomiasis infection. It infiltrates and spreads superficially.

A fibroepithelial polyp is a benign tumor of the ureter, which consists of a stalk of loose fibrous and vascular tissue covered by urothelium. These polyps are usually located in the proximal ureter and produce a smooth, oblong, mobile filling defect on urography.

SECONDARY INVOLVEMENT OF THE URETER

Retroperitoneal fibrosis is a process of progressive fibrosis, often idiopathic in etiology. Known causes include inflammatory aortic aneurysm, retroperitoneal metastasis, hematoma, abscess, and medications such as hydralazine and ergot alkaloids. Encasement of the ureters can lead to urinary obstruction. On CT, retroperitoneal fibrosis appears as a confluent mass centered at the L4 level. Classically, the ureters are medially deviated centered at the L3-L5 level (Table 57-2).

Retroperitoneal adenopathy can displace or encase the ureters. The upper ureters are displaced laterally and anteriorly by retroperitoneal adenopathy and the distal ureters are displaced medially by iliac adenopathy (Tables 57-2 and 57-4). Direct extension of metastatic disease can cause irregular strictures of the ureter. Primary sites of malignancy include cervix, prostate, bladder, uterus, and sarcomas.

Hematogenous metastasis to the ureters occurs most commonly from breast, gastrointestinal, prostate, cervix, and renal primaries. Metastasis may infiltrate the peri-ureteral soft tissues, demonstrate transmural involvement

TABLE 57-4 Lateral Deviation of Ureter

Aortic aneurysm
Retroperitoneal mass/hematoma
Central pelvic mass
Psoas hypertrophy (proximal ureter)

of the ureteral wall, or may manifest as submucosal nodules. The majority of patients are asymptomatic; however, presenting symptoms may include hematuria or urinary obstruction.

Genitourinary tuberculosis occurs as a result of hematogenous seeding. Ureteral involvement includes wall thickening, abnormal peristalsis, and strictures resulting in proximal dilation. Urothelial calcifications may occur.

QUESTIONS AND ANSWERS

- At which location would a ureteral calculus be *least* likely to impact?
 - UPJ
 - L4 level
 - Pelvic brim
 - UVJ

ANSWER: B. A ureteral calculus is most likely to impact at one of the three points of ureteral narrowing, the UPJ, the pelvic brim, and the UVJ.

- The Weigert-Meyer rule states that in a duplicated collecting system:
 - Lower pole moiety ureter inserts inferior and medial.
 - Lower pole moiety ureter inserts inferior and lateral.
 - Upper pole moiety ureter inserts inferior and medial.
 - Upper pole moiety ureter inserts inferior and lateral.

ANSWER: C. The upper pole moiety inserts inferior and medial to the lower pole moiety. The upper

pole moiety tends to obstruct, and the lower pole moiety tends to reflux.

- Which direction is the ureter displaced by retroperitoneal fibrosis?
 - Medially
 - Laterally
 - Anteriorly
 - Posteriorly

ANSWER: A. Retroperitoneal fibrosis and retrocaval ureter typically displace the ureter medially, while adenopathy and aortic aneurysm displace laterally.

- What most commonly causes abrupt medial deviation of the proximal right ureter?
 - Lymphoma
 - Retroperitoneal hematoma
 - Retrocaval ureter
 - Retroperitoneal fibrosis

ANSWER: C. Retrocaval ureter occurs secondary to anomalous development of the infrarenal IVC. The proximal right ureter passes posterior to the IVC, abruptly deviating medially. Compression of the ureter can cause varying degrees of obstruction. Intravenous urography demonstrates a reverse “J” or fishhook appearance.

- What is the classic radiographic sign describing ureteral transitional cell carcinoma?
 - Cobra head sign
 - Soft tissue rim sign
 - Fishhook sign
 - Goblet sign

ANSWER: D. Slow growth of the TCC leads to expansion of the ureter above and below the tumor giving the dilated ureter the appearance of cupping the tumor. Cobra head sign describes the appearance of an ureterocele. The soft tissue rim sign helps distinguish a ureteral calculus from a phlebolith as a ureteral calculus will have a rim of ureteral tissue surrounding it.

- What is the most likely diagnosis with radiographic findings of multiple tiny smooth filling defects in the ureter of a patient with chronic UTI?
 - Ureteritis cystica
 - Malacoplakia
 - Leukoplakia
 - Ureteral pseudodiverticulosis

ANSWER: A. Ureteritis cystica reveals multiple tiny (2–3 mm) subepithelial fluid-filled cysts in the wall of the ureter. Development of the condition can

be associated with stone disease, chronic inflammation, or UTI. Malacoplakia is also associated with chronic UTI, but the findings include plaque-like or nodular lesions in the bladder more commonly than ureter.

7. A smooth, mobile filling defect in the proximal ureter is most likely
 - A. Transitional cell carcinoma
 - B. Squamous cell carcinoma
 - C. Fibroepithelial polyp
 - D. Calculus

ANSWER: C. Benign fibroepithelial polyp is usually located in the proximal ureter and produces a smooth, oblong, mobile filling defect on urography.

8. Concerning malacoplakia, which of the following is true?
 - A. More common in ureters than the bladder
 - B. Histology reveals gamma-Gandy bodies.
 - C. Premalignant
 - D. Regresses with antibiotic treatment

ANSWER: D. Malacoplakia is not considered premalignant and usually regresses with antibiotic treatment. It occurs more commonly in the bladder. Bacteria are incompletely phagocytized and form intracellular inclusion bodies termed Michaelis-Gutmann bodies, which are visible upon histologic evaluation.

9. Which of the following concerning ectopic ureter is true?
 - A. Upper pole moiety ureter obstructs.
 - B. More common in males
 - C. Leads to incontinence in males
 - D. Lower pole moiety ureter typically has a ureterocele.

ANSWER: A. In a duplicated collecting system, the upper pole is associated with an ureterocele and obstruction. The lower pole ureter inserts at or near the normal location and is associated reflux.

10. Where does transitional cell carcinoma of the ureter most commonly occur?
 - A. Ureteropelvic junction
 - B. Proximal third
 - C. Middle third
 - D. Distal third

ANSWER: D. Transitional cell carcinoma accounts for approximately 90% of renal collecting system neoplasms. Approximately 75% of ureteral TCCs occur in the distal third of the ureter.

58 URINARY BLADDER

Heather L. Haddad and Mark E. Lockhart

NORMAL ANATOMY

The urinary bladder is located in the extraperitoneal space and is composed of four layers. The inner, luminal layer is lined by transitional urothelium. The majority of bladder neoplasms arise from this urothelial layer. The lamina propria lies deep to the epithelium. The third layer is the muscularis propria, which consists of bundles of smooth detrusor muscle. The outer adventitial layer is formed by connective tissues. The dome of the bladder is covered by peritoneum.

DEVELOPMENTAL ANOMALIES OF THE URINARY BLADDER

Bladder diverticula usually occur in males and are caused by congenital muscular anomalies of the bladder wall. A periureteric diverticulum, also known as a Hutch diverticulum, is often associated with vesicoureteral reflux. Diverticula can also be seen in patients with Ehlers-Danlos syndrome or secondary to chronic bladder obstruction, such as prostatic hypertrophy.

Bladder duplication results from a rare disturbance in the embryogenesis of the hindgut. The most common form is sagittal duplication in which two bladders lay side-by-side and are separated by a fold of peritoneum. Each bladder is drained by its own urethra.

Prune belly syndrome consists of a triad of three major findings including undescended testes, abnormal urinary tract, and renal dysmorphism. These individuals have a wrinkled and lax abdominal wall due to absence of the rectus muscles. The urinary bladder is enlarged and elongated without trabeculation and is seen in association with tortuous dilated ureters and a dilated prostatic urethra.

With cloacal malformation, the urinary, genital, and gastrointestinal tracts drain through a common perineal opening due to persistence of an early embryologic state. This condition occurs only in females.

BLADDER NEOPLASMS

Rhabdomyosarcoma is the most common bladder neoplasm in children younger than 10 years (Table 58-1). It arises from primitive fetal muscle cells demonstrating various stages of maturation. Genitourinary sites include

TABLE 58-1 Bladder Neoplasms

MALIGNANT		BENIGN	
Rhabdomyosarcoma	Most common bladder neoplasm in children	Leiomyoma	Most common mesenchymal tumor
Transitional cell carcinoma	Most common overall Risk factors: environmental agents, drugs, and tobacco	Neurofibroma	NF I or isolated
Squamous cell carcinoma	Risk factors: chronic inflammation, schistosomiasis, and tobacco	Paraganglioma	Extra-adrenal pheochromocytoma (NF, VHL, Sturge-Weber, TS, MEN)
Adenocarcinoma	Risk factors: chronic inflammation, urachal, remnant, exstrophy	Hemangioma	
Small cell	Neuroendocrine (can have carcinoid variant)	Inflammatory pseudotumor (pseudosarcomatous fibromyxoid tumor)	Non-neoplastic
Leiomyosarcoma		Nephrogenic adenoma	Metaplastic

bladder, prostate, testes, paratesticular tissues, penis, perineum, vagina, and uterus. These tumors often have an infiltrative growth pattern and the exact site of origin can be difficult to determine. In males, tumors are grouped into paratesticular rhabdomyosarcomas and bladder-prostate rhabdomyosarcomas. Symptoms include hematuria, bladder outlet obstruction, abdominal distention, dysuria, and urinary tract infections. Metastases are most commonly to lungs, cortical bone, and lymph nodes. Ultrasound, CT, and MRI show a heterogeneous mass, which may invade adjacent structures. On MRI, rhabdomyosarcoma demonstrates low T1 signal and high T2 signal with heterogeneous enhancement. Botryoid variant produces a polypoid mass, which resembles a cluster of grapes.

Greater than 90% of bladder carcinomas are transitional cell carcinoma (TCC). Risks factors include tobacco, manufacturing dyes such as aniline, cyclophosphamide, and long-term phenacetin use. Synchronous and metachronous upper urinary tract and bladder TCCs are common. Development of TCC occurs as a result of renally excreted carcinogenic substances bathing the urothelial surfaces. Approximately 90% to 95% of the TCCs occur in the urinary bladder. A propensity for bladder TCC development is hypothesized to result secondary to the longer exposure time of the bladder mucosa to urine and the larger surface area of the bladder as compared with the upper tracts.

TCC, now termed urothelial carcinoma, can be papillary, sessile, or nodular and occurs most frequently in the bladder base. Superficial papillary neoplasms are most common. Approximately 20% of tumors are invasive at presentation, extending into the detrusor muscle layer. There is a male predilection, and patients often present with gross hematuria. On imaging, TCC can appear as focal wall thickening or a papillary/nodular mass. At the time of diagnosis, up to one-third of bladder TCCs are multifocal. On ultrasound, lesions appear hypoechoic. On MRI, lesions are isointense to bladder muscle on T1-weighted images and mildly hyperintense

to muscle on T2-weighted images. On both CT and MRI, tumors demonstrate early enhancement following intravenous contrast administration. MRI is the best modality for determining extent of invasion into the bladder wall and perivesicular fat. Tumors metastasize to pelvic lymph nodes, lung, liver, and abdomen.

Development of squamous cell carcinoma (SCC) in the bladder is associated with chronic inflammation from etiologies such as chronic UTI, bladder calculi, and chronic indwelling catheters. Tobacco use is also a risk factor. In countries with schistosomiasis, the majority of SCCs result from chronic bilharzial infection. Most patients present with gross hematuria. SCC can vary in appearance occurring as wall thickening or a mass. There is a predilection for the bladder trigone and the lateral walls. Often, the disease is advanced at presentation, and muscle wall invasion is common. On CT and MRI, SCC enhances following contrast administration. On delayed CT images, the tumor can be seen as a low attenuation filling defect against the contrasted urine. On T2-weighted images, the lesion is slightly higher in signal than the bladder wall. SCC invades locally and metastasizes to regional lymph nodes, bone, lung, and bowel.

Adenocarcinoma accounts for less than 2% of bladder neoplasms and may be primary or metastatic. Risk factors include persistent urachus, bladder exstrophy, and intestinal metaplasia from chronic mucosal irritation in cystitis glandularis. Of primary adenocarcinomas, only one-third are urachal in origin. Nonurachal primary adenocarcinomas are most common in the bladder base. Ninety percent of urachal carcinomas are located at the dome of the bladder in the midline. Both urachal and nonurachal adenocarcinomas are generally mixed solid and cystic with the cystic component composed of mucin. Calcifications are common, as is bladder wall invasion and extravesical spread.

Small cell/neuroendocrine tumors are rare bladder neoplasms believed to originate from dedifferentiated neuroendocrine cells. Patients often present with hematuria.

Tumors most commonly involve the lateral bladder walls and are usually large with a nodular or polypoid configuration. Tumors exhibit local invasion, peritoneal metastasis, and lymph node metastasis. The carcinoid variant of neuroendocrine tumors is rare. These tumors are small and round, located at the bladder neck or trigone.

Leiomyoma is a mass that originates in the submucosa and is the most common mesenchymal bladder tumor. Tumors may be small and incidentally discovered, or may grow large causing symptoms of obstruction, urinary frequency, hematuria, and pressure. The most common location of these lesions is the trigone. On MR imaging, leiomyomas have intermediate T1 signal and low signal on T2-weighted images. Tumors can be solid and homogeneous, or demonstrate degenerative changes with cystic components and heterogeneous signal. Leiomyoma and leiomyosarcomas can be difficult to distinguish radiographically. Leiomyosarcomas are generally poorly circumscribed with regions of necrosis.

Neurofibroma is a rare bladder neoplasm, which can occur in association with neurofibromatosis type 1 or as an isolated lesion. Neurofibroma arises from the nerve plexus of the bladder. They can be localized, diffuse, or plexiform in configuration. These tumors can grow to involve surrounding pelvic structures. On MRI, neurofibromas are low in signal on T1; they demonstrate a characteristic target appearance on T2 with a low signal center surrounded by high signal myxoid stroma.

A paraganglioma is an extra-adrenal pheochromocytoma. Bladder paragangliomas account for 0.1% of bladder tumors. Most tumors occur sporadically but can be seen in association with neurofibromatosis, Von Hippel-Lindau, Sturge-Weber, tuberous sclerosis, and MEN. Catecholamines can be released during micturition causing symptoms including headache, sweating, anxiety, hypertension, and syncope. Lesions are submucosal in location and demonstrate marked enhancement on contrasted CT and MRI. When present, peripheral ring calcification suggests the diagnosis.

Hemangiomas are detected in both childhood and adulthood. Patients usually present with gross hematuria. CT and MRI reveal a hypervascular mass.

INFLAMMATORY AND NON-NEOPLASTIC CONDITIONS

Inflammatory pseudotumor, also termed pseudosarcomatous fibromyxoid tumor, is a non-neoplastic lesion composed of myofibroblastic spindle cells and inflammatory cells with myxoid components. The lesion may develop in response to infection, inflammation, or malignancy; however, the pathogenesis not fully delineated.

Patients often present with hematuria. At imaging, the tumors appear as an exophytic or polypoid mass, sometimes demonstrating ulceration. These lesions can act aggressively, invading through the bladder to involve adjacent structures. Inflammatory pseudotumors are often heterogeneous on T2-weighted MRI with central hyperintense necrosis surrounded by a hypointense periphery. Contrast-enhanced CT and MRI images reveal enhancement of the non-necrotic periphery.

Nephrogenic adenoma is a reactive, metaplastic process in the urothelium, which results from chronic irritation by calculi, infection, or surgery. Patients present with hematuria or irritative voiding symptoms. Imaging findings are nonspecific, demonstrating a polypoid mass, sessile mass, or wall thickening.

Malacoplakia is a rare, chronic granulomatous condition predominantly found in women. The pathogenesis is thought to involve impaired host defenses and defective phagocytosis. Macrophages ingest but do not completely destroy bacteria, which become mineralized and result in calcified intracellular inclusions—Michaelis-Gutmann bodies. Malacoplakia is highly associated with *Escherichia coli* infection and is commonly seen in diabetic patients and immunocompromised individuals. Patients present with hematuria and urinary tract infection symptoms. Malacoplakia varies in appearance from plaque-like wall thickening to a polypoid vascular mass.

Cystitis cystica and cystitis glandularis are rare chronic reactive inflammatory disorders. Chronic irritation caused by infection, calculi, or outlet obstruction induces metaplasia of the urothelium. The abnormal urothelium grows into the lamina propria and differentiates into cystic deposits (cystitis cystica) or glandular deposits (cystitis glandularis). Usually there is a combination of the two elements that causes a nodular mass in the lamina propria. CT and MR imaging reveal a hypervascular, polypoid mass. Imaging characteristics can overlap with urothelial carcinoma; however unlike carcinoma, cystitis should not involve the muscular layer of the bladder. Cystitis glandularis can occur in association with pelvic lipomatosis.

Emphysematous cystitis can occur secondary to infection with *E. coli*, *Aerobacter aeogenes*, and *Candida*. Imaging demonstrates foci of gas within the bladder wall. It is generally a non-life-threatening condition treated by antibiotics.

Eosinophilic cystitis, where eosinophils infiltrate into the bladder wall, is a rare chronic inflammatory condition of the bladder. Inflammation can eventually lead to fibrosis and muscle necrosis resulting in a small, contracted bladder. Patients most commonly present with hematuria and frequency. At imaging, a single mass is seen more often than multiple masses. On MR, the mass

is hyperintense to muscle on T1-weighted images, isointense on T2-weighted images, and enhances following contrast administration.

Tuberculosis of the bladder is rare in the United States. The upper urinary tracts are usually primarily involved with secondary involvement of the bladder. In the acute phase, the mucosa is irregular with thickening and trabeculation of the bladder wall. There can be ureteral thickening with stricture or a patulous ureterovesical junction with reflux. In the chronic phase, the bladder is thick walled and contracted with small volume because of fibrosis. Bladder wall or upper tract urothelial calcifications can be seen with healing.

Schistosomiasis, infection with *Schistosoma haematobium*, is rare in the United States but is more commonly seen in North Africa. Eggs are deposited in the vessels supplying the bladder wall. The presence of the eggs incites a chronic inflammatory response, predisposing to the development of SCC. The granulomatous reaction initially causes nodular wall thickening and eventually leads to a contracted, fibrotic bladder containing curvilinear calcifications representing calcified eggs. Associated ureteral findings include calcification, stricture, dilation, and vesicoureteral reflux.

Chemotherapy and radiotherapy can cause hemorrhagic cystitis by denuding the urothelium. The bladder wall appears irregularly thickened, and intraluminal blood clot may be present. Chronic radiation changes are a result of ischemic changes from obliterative endarteritis and interstitial fibrosis. Patients experience frequency and urgency because of the contracted bladder.

Fistulous connections between the bladder and bowel can result as complications from Crohn disease, diverticulitis, colon carcinoma, and pelvic radiation. Patients present with complaints of UTI symptoms, fecaluria, and pneumaturia. On imaging, thickening of the bladder wall with intraluminal gas or orally administered contrast in the bladder are indicative of a fistulous communication. Vesicovaginal fistulas can result from gynecologic malignancy, gynecologic surgery, and pelvic radiation. Delayed contrast CT or cystogram may demonstrate contrast in the vagina.

Neurogenic bladder can result from spinal trauma, meningomyelocele, central nervous system tumor, diabetes, polio, and multiple sclerosis. Neurogenic bladder has two forms, spastic with a small contracted bladder and atonic with a large dilated bladder. Neurogenic bladder leads to urinary stasis, chronic infection, stone formation and vesicoureteral reflux.

Acquired bladder diverticula are usually associated with bladder outlet obstruction such as neurogenic bladder and prostatic hypertrophy. They are most commonly located near the UVJ. Diverticula can lead to stasis with development of TCC or SCC, calculi, and infection.

TABLE 58-2 Conditions Associated with Development of Bladder Calculi

Chronic outlet obstruction
Neurogenic bladder
Bladder diverticula
Bladder infection (<i>Proteus mirabilis</i>)
Migration of upper tract calculus
Foreign body nidus

Bladder calculi can develop secondary to stasis associated with chronic outlet obstruction, neurogenic bladder, and bladder diverticula or secondary to infection with organisms such as *Proteus mirabilis* (Table 58-2). A renal calculus, which has migrated into the urinary bladder or a foreign body within the bladder, can act as a nidus for calculus growth. Patients can present with microhematuria and suprapubic pain. Chronic bladder irritation caused by the presence of the calculus may predispose to the development of TCC or SCC. Calculi will appear echogenic on ultrasound with posterior acoustic shadowing, radiopaque on CT, and as an intraluminal signal abnormality with variable signal intensity on MRI.

Bladder rupture is classified as intraperitoneal or extraperitoneal in location. Extraperitoneal bladder rupture occurs due to puncture of the bladder by a bone fragment from a pelvic fracture. On conventional or CT cystogram, contrast extravasates into the extraperitoneal space including the perivesical space, the anterior abdominal wall, the groin/thigh, and retroperitoneum. The extravasated contrast is amorphous in shape or occasionally flame shaped and does not outline bowel loops. Intraperitoneal bladder rupture occurs when blunt force causes a rise in intravesicle pressure with rupture of the bladder dome. In contradistinction to intraperitoneal rupture, conventional or CT cystogram findings of intraperitoneal bladder rupture demonstrate extravasated contrast surrounding intraperitoneal bowel loops and layering in the paracolic gutters. A combined injury demonstrates features of both intraperitoneal and extraperitoneal rupture. Pelvic hematoma can cause extrinsic compression of the bladder (Table 58-3).

TABLE 58-3 Extrinsic Bladder Compression

QUESTIONS AND ANSWERS

1. A patient with history of multiple subcutaneous nodules presents with a bladder mass. This mass demonstrates low signal central core surrounded by high signal rim. What is the most likely diagnosis?
 - A. Paraganglioma
 - B. Neurofibroma
 - C. Leiomyoma
 - D. Adenocarcinoma

ANSWER: B. Bladder neurofibromas can be a manifestation of neurofibromatosis type 1 and may demonstrate a characteristic target sign on T2 with a low signal center surrounded by high signal myxoid stroma.

2. Where is contrast leakage identified on CT cystogram in a patient with intraperitoneal bladder rupture?
 - A. Retroperitoneum
 - B. Suprapubic space
 - C. Perivesical fat
 - D. Surrounding small bowel loops

ANSWER: D. Small bowel loops are intraperitoneal in location; therefore, contrast outlining small bowel indicates intraperitoneal bladder rupture.

3. What histologic type of mass develops in an urachal remnant?
 - A. Squamous cell carcinoma
 - B. Adenocarcinoma

- C. Transitional cell carcinoma
- D. Small cell carcinoma

ANSWER: B. A persistent urachus is a risk factor for developing adenocarcinoma. Most urachal carcinomas are located at the dome of the bladder in the midline.

4. What is the most common type of bladder carcinoma?
 - A. Squamous cell carcinoma
 - B. Adenocarcinoma
 - C. Urothelial carcinoma
 - D. Small cell carcinoma

ANSWER: C. The urinary bladder is lined by transitional epithelium. Greater than 90% of bladder carcinomas are transitional cell (urothelial) carcinoma.

5. Where is a Hutch diverticulum located?
 - A. Bladder neck
 - B. Bladder dome
 - C. Anterolateral bladder wall
 - D. Near ureterovesical junction

ANSWER: D. A periureteric diverticulum is also known as a Hutch diverticulum and is often associated with vesicoureteral reflux.

6. A patient experiences syncope during micturition and is found to have an enhancing bladder mass. What is the most likely diagnosis?
 - A. Paraganglioma
 - B. Neurofibroma
 - C. Neuroendocrine tumor
 - D. Nephrogenic adenoma

ANSWER: A. A paraganglioma is an extra-adrenal pheochromocytoma. Catecholamines can be released during micturition causing symptoms including headache, sweating, anxiety, hypertension, and syncope.

7. A diabetic patient with chronic *E. coli* infection demonstrates multiple nodular bladder masses. Pathology reveals Michaelis-Gutmann bodies. What is the most likely diagnosis?
 - A. Nephrogenic adenoma
 - B. Malakoplakia
 - C. Pseudotumor
 - D. Cystitis cystica

ANSWER: B. Malakoplakia is a rare, chronic granulomatous condition predominantly found in women. Macrophages ingest but do not completely destroy bacteria, which become mineralized and result in calcified intracellular inclusions, Michaelis-Gutmann

bodies. Malacoplakia is highly associated with *E. coli* infection and is commonly seen in diabetic patients and immunocompromised individuals.

8. A paraplegic patient with a long-term suprapubic catheter presents with a bladder mass. What is the most likely diagnosis?
 - A. Adenocarcinoma
 - B. Rhabdomyosarcoma
 - C. Transitional cell carcinoma
 - D. Squamous cell carcinoma

ANSWER: D. Chronic irritation such as that due to an indwelling catheter is a risk factor for developing squamous cell carcinoma.

9. Concerning rhabdomyosarcoma, which of the following is true?
 - A. Most common bladder neoplasm in young adults
 - B. Noninfiltrative growth pattern
 - C. Botryoid variant produces a grape-like mass.
 - D. Occurs only in females

ANSWER: C. Rhabdomyosarcoma is the most common bladder neoplasm in children younger than 10 years. These tumors often have an infiltrative growth pattern, and the exact site of origin can be difficult to determine. Botryoid variant produces a polypoid mass that resembles a cluster of grapes.

10. What is the best modality for determining depth of urothelial carcinoma invasion into the bladder musculature?
 - A. MRI
 - B. CT
 - C. Ultrasound
 - D. Cystogram

ANSWER: A. The ability of MRI to display soft tissue differentiation allows for visualization of the bladder wall layers and determination of tumor depth.

59 ADRENAL GLANDS

Mark E. Lockhart and Mark D. Little

NORMAL ANATOMY

The adrenal glands play an important role in endocrine function and are a frequent site of disease. The paired glands in the retroperitoneum are located along the superior-medial aspect of both kidneys, invested in perinephric

fat and bound by Gerota fascia. Positioned adjacent to the diaphragmatic crus, the glands normally have a “V” or “Y” shape configuration composed of two limbs, medial and lateral, which communicate through the apex or body. Each limb is approximately 3 to 6 mm thick, and the entire width of the gland should not be greater than 1 cm.

The adrenal glands have a complicated vascular supply. Each gland is supplied by superior, middle, and inferior adrenal arteries. The superior adrenal artery originates from the inferior phrenic, the middle from the aorta, and the inferior from a branch of the ipsilateral renal artery. Each gland is drained by a single vein. Because of the position of the inferior vena cava on the right, the right adrenal vein drains directly into the cava, while the left vein drains into the left renal vein.

Each adrenal gland has a cortex and medulla. The cortex is derived from the mesoderm and has three distinct layers, organized superficial to deep: zona glomerulosa, zona fasciculata, and zona reticularis. Each cortical zone has a distinct endocrine function, which becomes important when evaluating hyperfunctioning adrenal lesions. The zona glomerulosa produces aldosterone. The zona fasciculata produces cortisol. Androgens are derived from the zona reticularis. Production of each of these hormones is regulated by adrenocorticotrophic hormone (ACTH), produced by the anterior pituitary gland. The medulla originates from neural crest cell migration and produces catecholamines such as epinephrine and norepinephrine.

PATHOLOGY

The central imaging question to be answered when confronted with an incidental adrenal mass is whether or not this represents a benign or malignant lesion. In addition, adrenal masses can be divided into functioning or non-functioning lesions (Table 59-1), based on whether or not the lesion hypersecretes hormones. The majority of adrenal tumors encountered in clinical practice will be adenomas, usually incidental, nonfunctional, and benign. Unilateral versus bilateral adrenal lesion(s) determines differential diagnosis (Table 59-2). CT is usually the initial imaging modality of choice when evaluating the adrenal glands owing to its superior spatial resolution and defined diagnostic criteria. In such instances when CT is equivocal, MRI with opposed phase imaging may be used.

CONN SYNDROME (PRIMARY ALDOSTERONISM)

Hypersecretion of aldosterone is characterized clinically by mild hypertension and hypokalemia. Approximately 80% of patients demonstrate a functioning adrenal

TABLE 59-1 Functional Adrenal Lesions

Cushing disease	Increased cortisol, glucocorticoids	Ectopic ACTH production from pituitary adenoma
Cushing syndrome	Increased cortisol, glucocorticoids	Adenoma, hyperplasia, carcinoma, paraneoplastic
Conn syndrome (adenoma)	Increased aldosterone	Adenoma, hyperplasia
Adrenogenital syndrome (adenoma)	Increased sex hormones	Hyperplasia (enzymatic deficiency), adenoma, carcinoma
Pheochromocytoma	Increased catecholamines	Unilateral, bilateral, syndromic (MEN IIa, MEN IIb, familial)
Cortical carcinoma	50% functional	

adenoma on thin slice CT. These lesions are usually small (less than 2 cm in diameter), eccentrically located within the adrenal gland and appear uniformly low in attenuation, secondary to lipid laden cells of the zona fasciculata. When an adenoma is demonstrated in these patients, they are often treated with unilateral adrenalectomy.

The other 20% of patients demonstrate adrenal gland hyperplasia, usually bilateral. On imaging, the adrenal glands may appear enlarged, thickened (greater than 1 cm), and mildly nodular. However, up to one-third of patients with adrenal hyperplasia have normal-appearing glands. In such instances, adrenal vein sampling for elevated levels of aldosterone may be performed. Patients with primary aldosteronism from hyperplasia are often treated pharmacologically. In rare cases, primary aldosteronism can be caused by adrenal carcinoma.

CUSHING SYNDROME

Cushing syndrome is characterized by increased serum glucocorticoids, particularly cortisol. Clinically, patients present with obesity, hypertension, muscle wasting, bruising, and abdominal striae. In addition, abnormal glucose metabolism results in diabetes mellitus in a minority of patients.

Hypersecretion of glucocorticoids can be divided as either ACTH-dependent or independent forms. When the increase in secretion is dependent on ACTH (approximately 80% of patients), the condition is termed Cushing disease and is usually secondary to a hyperfunctioning ACTH-producing pituitary adenoma. Consequently, initial workup for patients with hypercortisolism usually involves pituitary brain MRI, plasma or

urinary cortisol levels, and a dexamethasone suppression test. In Cushing disease, dexamethasone should suppress glucocorticoid production by negative feedback inhibition of pituitary gland ACTH production. Adrenal morphology in Cushing disease is variable. The adrenals may appear normal, diffusely enlarged, micronodular, or macronodular.

Cushing syndrome is distinguished by increased cortisol production secondary to an adrenal adenoma. These adenomas are similarly low in attenuation, but are usually larger than the adenomas seen in Conn syndrome, measuring approximately 2 to 4 cm in size. Interestingly, when a functional cortisol producing adenoma is present, the remaining adrenal tissue should appear hypoplastic/atrophic owing to inhibition of ACTH production.

In rare instances (less than 5%), increased cortisol production may be secondary to ectopic ACTH production, primarily from lung, ovary, or pancreatic islet cell neoplasms. In addition, approximately 50% of adrenal cortical carcinomas, a rare tumor, secrete cortisol as well.

ADRENOGENITAL SYNDROME

Adrenogenital syndrome is rare and presents clinically as the excess secretion of sex hormones resulting in precocious puberty, feminization, or virilization. The syndrome can either be congenital or acquired. Congenital adrenal hyperplasia is usually secondary to an enzymatic deficiency in steroid synthesis. Less commonly, an acquired adrenal adenoma or carcinoma may be the cause.

PHEOCHROMOCYTOMA

Pheochromocytomas are paraganglionic neuroendocrine tumors usually arising from the adrenal medulla. These tumors are typically unilateral and may secrete catecholamines, such as epinephrine, dopamine, and norepinephrine. Patients present clinically with episodic palpitations, tachycardia, flushing, and severe hypertension. Pheochromocytomas are extremely rare, responsible for less than 1% of hypertensive patients. Approximately, 10% of pheochromocytomas are non-

TABLE 59-2 Adrenal Masses

UNILATERAL	BILATERAL

Cyst	Hemorrhage
Myelolipoma	Infection (granulomatous, histoplasmosis, TB)
Metastasis	Metastasis
Pheochromocytoma	Pheochromocytoma (rare)
Cortical carcinoma	

functional and are therefore usually larger in size when discovered incidentally.

In suspected patients, initial evaluation includes measurements for elevated serum catecholamines and increased 24 hours urine metanephrines and vanillylmandelic acid. The majority of pheochromocytomas originate in the adrenal gland. However, as paragangliomas these tumors can arise anywhere along the sympathetic chain. The most common extra-adrenal location being the organ of Zuckerkandl, located between the origin of the inferior mesenteric artery and the aortic bifurcation. As a general rule, approximately 10% of pheochromocytomas are extra-adrenal, 10% are malignant, and 10% are bilateral. When bilateral, consideration should be made of a syndrome. Specifically, pheochromocytomas are associated with MEN IIA (pheochromocytoma, medullary thyroid carcinoma, parathyroid adenoma) and MEN IIB (pheochromocytoma, medullary thyroid carcinoma, mucosal ganglioneuromas). Additionally, these tumors may be associated with neurofibromatosis type I, von Hippel-Lindau, and familial pheochromocytomas.

Pheochromocytomas are vascular tumors and therefore demonstrate significant heterogeneous enhancement. These lesions may also demonstrate a characteristic “lightbulb bright” T2 hyperintense signal on MRI imaging, due to internal necrosis or cystic change. If no tumor is localized in suspected patients by cross-sectional imaging, further radiopharmaceutical evaluation with I-131 or I-123 MIBG or, less commonly, In-111 octreotide may be performed. Surveillance for recurrence and metastases may also be similarly performed with MIBG avid tumors. If biopsy or surgery is contemplated, alpha-adrenergic blockade is usually required to prevent inciting a hypertensive crisis. Surgery is usually curative for solitary pheochromocytomas.

ADENOMA

As discussed earlier, the majority of incidental adrenal masses are benign nonfunctioning adenomas. In fact, adenomas are very common, seen in approximately 2% to 8% of the population, and increase in frequency with age, hypertension, or diabetes mellitus. However, in certain clinical settings, the importance of differentiating benign and malignant adrenal masses is important for patient management. Specifically, when an incidental adrenal mass is discovered during imaging workup for an unrelated condition, or when the adrenal mass is the only possible evidence of metastasis in a patient with a known primary neoplasm, accurate characterization of the adrenal mass may have profound impact on patient outcome. Typically, the CT imaging characteristics of an adenoma are a small, well-circumscribed homogeneous low density adrenal

mass. These lesions are often round or oval, bilateral or multifocal, and may be central or eccentrically located within the gland. Accurate CT characterization of these lesions takes advantage of the increased lipid content of these lesions. On nonenhanced CT, a lipid rich adrenal adenoma will demonstrate an attenuation of less than 10 HU with 98% specificity. Adenomas enhance homogeneously, similar to some metastases, but also demonstrate increased washout. Therefore, 15 minutes delayed CT images may be performed to help characterize indeterminate adrenal lesions. Two strategies are employed to help diagnose indeterminate adrenal lesions as lipid poor adenomas.

Relative washout criterion for adenoma

$$\frac{(\text{enhanced} - \text{delayed})}{\text{enhanced}} \times 100 \\ = \text{greater than } 40\%$$

Absolute washout criterion for adenoma

$$\frac{(\text{enhanced} - \text{delayed})}{(\text{enhanced} - \text{unenhanced})} \\ = \text{greater than } 60\%$$

If CT evaluation is still equivocal, the lipid content of adenomas can be exploited for MRI evaluation as well. Using opposed phase MRI compared to in-phase sequence, intravoxel lipid signal will be suppressed compared to nonlipid tissue, resulting in near 90% specificity for the diagnosis of adenomas. Finally, if an indeterminate adrenal mass cannot be confidently characterized as an adenoma by imaging, percutaneous retroperitoneal biopsy or PET-CT may be indicated.

MYELOLIPOMA

Myelolipomas are unique but rare, benign tumors most commonly involving the adrenal gland. They are made up of fat and bone marrow elements and usually present incidentally. Typically, these tumors can be confidently diagnosed by CT or MRI characteristics without the need for biopsy. On CT, myelolipomas characteristically demonstrate macroscopic fat with associated small soft tissue components. Calcification is unusual. Similarly, the macroscopic fat on MRI demonstrates high T1 and T2 signal that is suppressed by fat saturation. Large lesions can occasionally present with flank pain from mass effect or internal hemorrhage or necrosis. As a result, differentiation from a liposarcoma may be difficult and biopsy is indicated. Myelolipomas are often treated conservatively unless symptoms develop.

ADRENAL CYSTS

Cysts of the adrenal gland are rare and can be characterized as epithelial, endothelial, parasitic, or posttraumatic.

True epithelial cysts are uncommon and most cystic lesions of the adrenal gland are endothelial or posttraumatic pseudocysts. These lesions can appear simple or complex, demonstrating thick walls, multiple septations, or increased attenuation due to internal hemorrhage or protein, making differentiation from malignancy difficult. These lesions occasionally calcify; however, they should not enhance. On unenhanced CT, simple cysts can occasionally be confused with adenomas due to their similar attenuation characteristics.

HEMORRHAGE (Table 59-3)

The most common cause of adrenal hemorrhage is blunt trauma, occurring more commonly on the right side. Occasionally, unilateral hemorrhage can result from adrenal vein thrombosis following catheterization or as the presentation of a hemorrhagic metastasis. When bilateral, hemorrhage is usually the result of anticoagulation, blood dyscrasia, or sepsis. An important cause of childhood bilateral adrenal hemorrhage is meningococcal sepsis resulting in Waterhouse-Friderichsen syndrome and associated adrenal insufficiency. However, adrenal insufficiency from hemorrhage is rare, necessitating destruction of approximately 90% to 98% of adrenal tissue.

On unenhanced CT, adrenal hemorrhage is usually characterized by an adrenal mass with adjacent periaxial fat stranding and increased attenuation between 50 and 90 HU. However, on enhanced CT, it may be difficult to differentiate hemorrhage from neoplasm. In contrast to tumor, hemorrhage decreases in size and attenuation on follow-up imaging. Additionally, MRI may be useful in certain instances when CT is equivocal. Subacute adrenal hemorrhage typically demonstrates areas of increased T1/T2 signal consistent with methemoglobin. In cases of chronic hemorrhage, the adrenal mass may demonstrate a T1/T2 hypointense ring consistent with hemosiderin deposition. Late sequelae of adrenal hemorrhage can result in calcification or cyst formation.

TABLE 59-3 Adrenal Hemorrhage

UNILATERAL	BILATERAL
Trauma/Surgery	Anticoagulation
Adrenal vein thrombosis	Sepsis
Metastasis	Blood dyscrasia
	Hypotension
	Hypoxemia
	Birth trauma

INFECTION

Adrenal infection is most often caused by histoplasmosis, tuberculosis, or other granulomatous infections. Involvement of the adrenal glands is usually bilateral and asymmetric with imaging characteristics that are nonspecific. Typically, the adrenal glands are acutely enlarged, but they may also demonstrate hemorrhage, cystic change, or calcification. Rarely, infection, such as tuberculosis or meningococcemia, can result in chronic adrenal insufficiency—Addison disease. Clinically, these patients present with fatigue, hypoglycemia, orthostatic hypotension, nausea, and emesis. Interestingly, these patients also demonstrate hyperpigmentation. When the adrenal glands are destroyed, decreased cortisol results in unregulated increased ACTH production. Melanocyte stimulating hormone shares the same precursor molecule as ACTH and therefore is also increased, resulting in the characteristic “bronzed appearance” of the skin. Addison disease can also be caused by autoimmune destruction, bilateral metastases, or hemorrhage.

MALIGNANT NEOPLASMS

METASTASES

The adrenal glands are a common location for metastasis, occurring in approximately 27% of patients with a known malignancy. The most common responsible tumors are melanoma, breast, and lung, particularly small cell carcinoma. Adrenal metastases are typically large, (greater than 3 cm), more ill defined, and may be solitary or bilateral at presentation. Calcification is rare. With increased size, metastases usually demonstrate more heterogeneous enhancement due to the areas of hemorrhage or necrosis, therefore making imaging characterization easier. However, when small, these lesions can often be difficult to differentiate from benign tumors. Small metastases often appear homogeneous on enhanced CT, but demonstrate decreased relative or absolute washout characteristics on delayed images. Similarly, an adrenal metastasis will not demonstrate loss of signal on opposed phase MRI images due to lack of intracellular lipid seen in adenomas. Finally, for indeterminate adrenal masses in cancer patients where there is no other evidence of metastatic disease, percutaneous CT-guided biopsy may be indicated. Collision tumors occur when an adrenal metastasis occurs with a preexisting adenoma.

Metastatic involvement of the adrenal glands can also be a manifestation of lymphoma. Primary adrenal lymphoma is rare, with secondary involvement of retroperitoneal lymphoma, usually non-Hodgkin type, being more common. The imaging characteristics are

often nonspecific. However, the diagnosis can usually be inferred due to the presence of coexistent retroperitoneal adenopathy. Involvement of the adrenal glands is usually bilateral and may be masslike or present as diffuse adeniform enlargement. Typically, lymphoma enhances relatively poorly. On MRI, lymphoma demonstrates hypointense T1 and hyperintense T2 signal.

ADRENOCORTICAL CARCINOMA

Carcinoma of the adrenal glands is extremely rare and occurs in 2/1 000 000 patients. Approximately 50% of these tumors are functional, most often producing cortisol, and may present with Cushing type symptoms. As a result, functional adrenocortical carcinomas usually present earlier and are smaller in size. In general, however these tumors are large when discovered, often greater than 10 cm, and have a dismal prognosis because of the high rate of liver, lung, and lymph node metastases seen at the time of presentation. On CT, these lesions are well defined but heterogeneously enhancing, large adrenal masses with central areas of necrosis. Approximately 30% of these tumors calcify. If surgical excision is considered, attention should be given to possible vascular invasion of the renal vein or cava.

OTHER RARE LESIONS

HEMANGIOMA

Adrenal hemangioma is a benign tumor, which is usually discovered incidentally. It commonly presents as large, unilateral, hypervascular lesion with persistent peripheral nodular enhancement on delayed CT images. It is often calcified, either from prior hemorrhage or phleboliths, and may have a central fibrous scar. On MRI, this lesion typically shows low T1 and high T2 signal. Occasionally, internal high T1 signal may be seen due to the presence of methemoglobin from prior hemorrhage. Hemangiomas, and especially malignant hemangiosarcomas, are rare.

GANGLIONEUROMA

Similarly, ganglioneuromas is a rare, benign tumor that occasionally originates from the adrenal medulla. However, this lesion may arise anywhere along the sympathetic chain and are most often extra-adrenal. It is non-functional, presents incidentally, and therefore typically large (greater than 20 cm) at presentation. Their imaging characteristics are nonspecific.

NEUROBLASTOMA

Neuroblastomas are primary tumors of neural crest cell origin and rarely seen in adults. These tumors may originate anywhere along the sympathetic chain and may have imaging characteristics similar to pediatric cases. Typically, neuroblastomas appear as large, ill defined, inhomogeneous, soft tissue masses with stippled calcification and necrosis. However, adult neuroblastoma is less often calcified and is usually widely metastatic at presentation. As a result, it can be confused with other malignancies and biopsy is usually required.

QUESTIONS AND ANSWERS

1. A 40-year-old man presents with obesity, mild hypertension, and abdominal striae. What is the most likely diagnosis?
 - A. Pheochromocytoma
 - B. Adrenal carcinoma
 - C. Adrenal adenoma
 - D. Pituitary adenoma

ANSWER: D. The case describes Cushing type symptoms secondary to increased glucocorticoid secretion. The more common ACTH-dependent form, Cushing disease, is secondary to a pituitary adenoma.

2. A 62-year-old man with a history of lung cancer and a homogeneous left adrenal mass with attenuation of -40 HU on CT. What is the most likely diagnosis?

A. Pheochromocytoma
B. Myelolipoma
C. Metastasis
D. Adenoma

ANSWER: B. Negative attenuation suggests macroscopic fat, consistent with a myelolipoma.

3. A 70-year-old woman with history of metastatic breast cancer and a homogenous left adrenal mass with attenuation of 8 HU on CT. What is the most likely diagnosis?

A. Metastasis
B. Adenoma
C. Myelolipoma
D. Angiomyolipoma

ANSWER: B. Lipid rich lesions with attenuation less than 10 HU are 98% specific for adenomas.

4. A 35-year-old man presents with mild hypertension, metabolic alkalosis, and hypokalemia. What is the most likely cause?

A. Adrenal adenoma
B. Adrenal hyperplasia
C. Pheochromocytoma
D. Pituitary adenoma

ANSWER: A. The case describes the typical symptoms of Conn syndrome, which is secondary to an adrenal adenoma in 80% of patients.

5. A 41-year-old man with Conn disease has a small adrenal lesion on MRI. When compared with in-phase images, what will out-of-phase images of the lesion most likely demonstrate?

A. Increase in signal
B. No change in signal
C. Decrease in signal
D. Enhancement

ANSWER: C. Eighty percent of patients with Conn syndrome present with an adrenal adenoma. Typically, adrenal adenomas drop signal on out of phase MRI imaging.

6. A 64-year-old man has lung cancer. A right adrenal lesion has pre- and postcontrast attenuation of 20 and 60 HU, respectively. Delayed images at 15 minutes demonstrated an attenuation of 40 HU. What is the most likely diagnosis?

A. Metastasis
B. Adenoma

C. Pheochromocytoma
D. Myelolipoma

ANSWER: A. The calculated absolute washout of 50% ((enhanced – delayed)/(enhanced – unenhanced)) is less than the expected 60% seen in adenomas. Therefore, metastasis should be suspected.

7. A 32-year-old woman is in a motor vehicle collision and presents with a right adrenal lesion with unenhanced attenuation of 17 HU. What is the most likely diagnosis?

A. Metastasis
B. Hematoma
C. Lipid poor adenoma
D. Myelolipoma

ANSWER: C. Incidental adrenal lesion detected in a patient without a history of cancer is most likely adenomas. The attenuation is less than the 50 to 90 HU expected of hemorrhage.

8. A 49-year-old woman with breast cancer demonstrates increased 24 hours urine metanephrines and vanillylmandelic acid. On MRI, a T2 hyperintense lesion will most likely be discovered within:

A. Organ of Zuckerkandl
B. Pararenal space
C. Morrison pouch
D. Gerota fascia

ANSWER: D. The case describes the typical findings of a pheochromocytoma, which are most likely found in the adrenal gland. The adrenal gland is contained by Gerota fascia.

9. A 35-year-old man with a history of left renal cell carcinoma, severe hypertension, and new enhancing right adrenal mass. What is the most likely diagnosis?

A. Neurofibromatosis
B. Multiple endocrine neoplasia (MEN)
C. Familial pheochromocytoma
D. Von Hippel-Lindau

ANSWER: D. Pheochromocytoma is associated with multiple syndromes. Von Hippel-Lindau has a high incidence of renal cell carcinoma.

10. A 56-year-old woman with melanoma is involved in a motorcycle accident. Initial routine enhanced CT demonstrates a right adrenal mass with attenuation of 70 HU. Follow-up thoracic MRI 1 month later demonstrates decreased size of the lesion. What is the most likely diagnosis?

A. Metastasis
B. Adenoma

- C. Hematoma
- D. Angiomyolipoma

ANSWER: C. In the setting of trauma, adrenal lesions with attenuation between 50 and 90 HU should suggest adrenal hemorrhage/hematoma. Decreased size on follow-up imaging makes this the most likely diagnosis.

60 MALE REPRODUCTIVE SYSTEM

*Therese M. Weber and
Heather L. Haddad*

NORMAL MALE ANATOMY

PROSTATE

The normal prostate gland weighs up to 10 g with an upside-down pear appearance. The base is cephalad and the apex is caudal. Three separate zones within the prostate have been described. The peripheral zone contains true prostatic tissue and represents the bulk of the prostate gland. Approximately 70% of prostate cancers involve the peripheral zone. The central gland contains the central and transitional zones, which can undergo hypertrophy.

VAS DEFERENS

The vas deferens are paired structures that arise from the tail of the epididymis, course along the spermatic cord, and enter the pelvis through the internal spermatic ring. In the pelvis, the vas deferens follows the lateral pelvic wall and crosses superficial to the external iliac vessels and ureter. The vas deferens becomes convoluted and dilated as it crosses the ureter, the ampulla of the vas deferens. As the ampulla courses to the midline it joins the excretory duct of the seminal vesicle. The distal ampulla and excretory duct join to form the ejaculatory duct. The ejaculatory duct passes through the prostate posteriorly to empty into the verumontanum.

SEMINAL VESICLES

The seminal vesicle is a blind-ending tube, which is coiled and convoluted, with an appearance of multiple

diverticula. The lower end of the seminal vesicle is funneled to form the excretory duct, which joins with the distal end of the ampulla of the vas deferens to form the ejaculatory duct. The distal posterior surface of the seminal vesicle is closely adjacent to the base of the prostate.

URETHRA

ANTERIOR URETHRA

The anterior urethra extends from the external meatus to the inferior edge of the urogenital diaphragm and consists of the penile and bulbous portions (Fig. 60-1). The penile urethra extends from the external meatus to the penoscrotal junction inferiorly, and to the suspensory ligament superiorly. The penile urethra has a slightly dilated segment proximal to the external meatus, which represents the fossa navicularis, approximately 1 to 1.5 cm in length. The bulbous urethra extends from the penoscrotal junction to the inferior fascia of the urogenital diaphragm. The diameter of the anterior urethra is greatest in the proximal half of the bulbous urethra, which represents the bulbous urethral sump, approximately 2 to 3 cm in length. The bulbous urethral sump is the most inferior part of the urethra.

The anterior urethra is lined by stratified columnar epithelium except at the external meatus, where it changes to stratified squamous epithelium, which covers

FIG. 60-1 Male urethra.

SOURCE: Courtesy of Anthony F. Zagar, UAB, Department of Radiology, Birmingham, Alabama.

the glans penis. Small, mucus-secreting submucosal glands, glands of Littre, are found along the length of the anterior urethra, and are more numerous in the bulbous sump and in the superior aspect of the penile urethra. Two ducts from the glands of Cowper, which lie on either side of the membranous urethra within the urogenital diaphragm, empty into the bulbous urethral sump. Cowper glands secrete mucus during sexual stimulation.

A small musculotendinous sling of the bulbocavernosus muscle, known as the musculus compressor nuda, extends from the anterior and lateral surfaces of the proximal bulbous urethra. This structure may indent the proximal bulbous urethra on dynamic retrograde urethrography or, rarely, on voiding urethrography, and should not be mistaken for a stricture.

POSTERIOR URETHRA

The anterior and posterior urethra are separated by the urogenital diaphragm. The posterior urethra extends from the bladder neck to the inferior aspect of the urogenital diaphragm and consists of the prostatic and membranous portions. The prostatic urethra passes through the prostate gland and continues as the membranous urethra.

The prostatic urethral mucosa is continuous with the bladder mucosa and composed of transitional epithelium, but changes to stratified columnar epithelium at the membranous urethra.

The verumontanum contains three distinct orifices. The most proximal central orifice is the prostatic utricle, a vestigial remnant of the müllerian duct. Below the prostatic utricle on either side of midline, two additional openings are the ejaculatory ducts, formed at the junction of the ampulla of the vas deferens and the short duct of the seminal vesicles. The verumontanum tapers inferiorly to continue as the urethral crest, which continues to the membranous urethra. The verumontanum and urethral crest form a smooth muscle organ, which lengthens the posterior urethra during voiding, and shortens the urethra at the end of voiding. This muscular organ is likely involved in contracting the posterior urethra during emission and ejaculation, directing the emission through the membranous urethra into the bulbous urethra for ejaculation by contraction of the bulbocavernosus muscle.

URETHRAL SPHINCTERS

Two separate smooth muscle sphincters in the posterior urethra function as muscles maintaining passive continence. The internal urethral sphincter lies in the trigourethral area at the bladder neck and is the primary

muscle of passive continence. A second smooth muscle sphincter, the intrinsic sphincter lies below the verumontanum in the distal one-third of the prostatic urethra, surrounding the membranous urethra. If the internal sphincter at the bladder neck is ablated in prostatectomy or as a result of trigourethral injury in pelvic fracture, the intrinsic sphincter becomes the primary smooth muscle of passive continence.

The external sphincter, which surrounds the membranous urethra peripheral to the intrinsic sphincter, is a striated voluntary muscle involved in active continence or interruption of micturition.

PENIS

The penis contains two separate bodies of cavernous tissue. The urethra passes through the corpus spongiosum. The corpora cavernosa are symmetric, parallel cavernous bodies, which become separated proximally at the root of the penis, with each firmly attached to the rami of the pubic arch.

PATHOLOGY

BENIGN PROSTATIC HYPERTROPHY

Benign prostatic hypertrophy (BPH) is due to hyperplasia of the periurethral glands in the transitional zone. After 50 years of age, 50% of men have some degree of BPH. Excretory urography images may show bladder-base elevation, indenting of the bladder base, and “J-ing” or “hooking” of the distal ureters. As the prostate enlarges, evidence of bladder outlet obstruction may increase with large postvoid residual, bladder trabeculation, or bladder diverticula. On CT or ultrasound examination of the bladder, prostate enlargement indenting the bladder base should not be confused for a bladder mass. With long-standing, severe bladder outlet obstruction, the upper urinary tract will become dilated in a bilaterally symmetric fashion with ureteral dilatation to the level of the ureterovesical junction (UVJ). Asymmetric or unilateral ureteral obstruction should raise the question of prostate cancer extension into the distal ureter. Bladder stones may result from long-standing outlet obstruction by BPH.

PROSTATE CANCER

Prostate cancer is now the most common cancer in men other than skin cancer. The majority of prostate neoplasms are adenocarcinomas arising from the peripheral zone of

the prostate. Other rare prostate tumors include squamous cell carcinoma (SCC), endometrioid carcinoma arising from the prostatic utricle, carcinosarcoma, melanoma, rhabdomyosarcoma, leiomyosarcoma, and fibrosarcoma. Small cell carcinoma of the prostate is extremely rare and usually occurs in association with adenocarcinoma.

PROSTATE CANCER SCREENING

Prostate-specific antigen (PSA) is a serine protease normally secreted only into the ductal system of the prostate. PSA can leak from the acini into the stroma of the gland and enter the circulation through lymphatics and capillaries if there is derangement of the prostate architecture. Elevated PSA levels can be found in association with prostatitis, prostatic infarct, acute urinary retention, BPH, and interventional procedures involving the prostate or bladder. Serum PSA level has an upper limit of normal of 4.0 ng/mL. PSA velocity (the rate of PSA increases over time) may be a more useful indicator of malignancy. An increase of 20% or more in serum PSA per year is far more suggestive of prostate cancer than of BPH.

The digital rectal examination (DRE) is another screening tool, which detects only approximately 40% of prostate cancers less than 1.5 cm in diameter. A large number of prostate cancers will be clinically advanced at the time they are detected by DRE. There is, however, a significant benefit in combining DRE with PSA. If both DRE and PSA are positive, 60% of those patients will have prostate cancer. If both DRE and PSA are normal, only 2% will have cancer.

Although prostate cancer screening remains a controversial subject, both the American Cancer Society and the American Urological Association recommend annual DRE and PSA beginning at 50 years of age. In high-risk men, such as those with a strong family history of prostate cancer or African American men, screening is recommended earlier, at 40 years of age.

HISTOLOGY

The Gleason system is commonly used for grading prostate cancer. Correlation between tumor grade and degree of spread is usually good. The tumor is studied histologically with identification of predominant and secondary tumor patterns. Each of these is assigned a score of 1 through 5. A better differentiated tumor will have a lower tumor grade. The higher the grade, the less differentiation is present. These numbers are added for the final score, between 2 and 10. Tumors with a Gleason score of 2 to 4 rarely have metastatic lymphadenopathy, while tumors with Gleason scores of 8 to 10 do.

TABLE 60-1 Comparison of Staging Systems for Prostate Cancer

WHITMORE-JEWETT	TNM	DESCRIPTION
	T0	No evidence of tumor
A	T1	Nonpalpable tumor
B	T2	Palpable tumor continued to the prostate
C	T3	Extracapsular tumor extension
	T4a	Invasion of bladder neck, external sphincter, or rectum
	T4b	Invasion of levator muscles or fixation to pelvic sidewall
D1	N	Regional (pelvic) node involvement
D2	M	Distant metastases

PROSTATE CANCER STAGING

Staging can be done with the Whitmore-Jewett staging method or the TNM staging method (Table 60-1). The Whitmore-Jewett staging method is commonly used in North America. Stage A carcinoma has no clinical manifestations and is not palpable on DRE. Stage A carcinoma is usually found incidentally in pathology specimens or autopsy specimens. Stage B carcinoma is a clinically palpable, firm nodule in the peripheral zone without evidence of capsular or distant extension. Stage C carcinoma extends beyond the capsule. Differentiation of stage B and C tumors with DRE may be difficult. At least 50% of patients with Stage C carcinoma have metastatic pelvic lymphadenopathy. Stage D carcinoma patients may present with urinary symptoms, palpable extension of tumor beyond the prostate, bone metastases, and hydronephrosis due to ureteral obstruction by carcinoma at the UVJ.

PROSTATE CANCER DISSEMINATION

Spread of prostate cancer occurs by three methods: direct extension, lymphatic spread, and hematogenous spread. Prostate cancer typically originates in the peripheral zone closer to the prostatic capsule than to the urethra. Capsular extension allows the tumor to spread to perineural lymphatics and to the periprostatic venous plexus of Santorini, allowing distant metastases to the viscera and axial skeleton. Tumor spreads locally to the seminal vesicles, urethra, bladder neck, bladder base, and interureteric ridge, which will cause asymmetric or unilateral ureteral obstruction. Less commonly tumor may spread posteriorly and superiorly to grow into the rectosigmoid colon.

Lymphatic spread starts within prostate lymphatics with spread to the pelvic lymph nodes. Nodal groups

most commonly involved include the obturator, external iliac, and internal iliac nodes. The common iliac, para-aortic, mediastinal, and supraclavicular lymph nodes may be involved in advanced disease.

Hematogenous spread is to the axial skeleton or viscera. In patients dying with prostate cancer, 85% will have bony metastases in the axial skeleton, most frequently the lumbar spine, proximal femur, bony pelvis, thoracic spine, ribs, sternum, skull, and proximal humerus, in decreasing frequency. The intervertebral venous plexus of Batson, which directly communicates with the periprostatic venous plexus of Santorini, provides the route of early hematogenous spread to the spine and pelvis. The majority (greater than 90%) of prostatic metastatic lesions to bone are blastic.

In order to more accurately predict the pathologic stage of the cancer, especially whether or not tumor has extended beyond the prostatic capsule, nomograms have been developed, known as the Partin Tables. The Partin Tables combine clinical stage (determined by DRE), serum PSA levels, and the Gleason grade in the biopsy specimen.

TRANSRECTAL ULTRASOUND

Once prostate cancer is suspected based on DRE, PSA, or both, transrectal ultrasound (TRUS) is usually performed for further evaluation and to guide biopsy. Prostate cancer is most frequently seen on TRUS as a hypoechoic lesion; however, this is nonspecific and other entities, such as prostatitis, infarct, abscess, etc., can also appear as a focal hypoechoic lesion. Antibiotics are recommended before the biopsy to reduce the incidence of infection.

RADIONUCLIDE BONE SCINTIGRAPHY

Recent studies indicate that it is extremely rare to find bony metastases in patients with PSA of 10 ng/mL or less. Therefore, bone scans should be reserved for those patients with PSA levels greater than 10 ng/mL at the time of diagnosis, or for patients with localized bone pain suggesting osseous metastases. Most metastatic bone lesions will occur in the thoracolumbar spine, pelvis, and ribs, with the majority being blastic (90%).

Prostate cancer can be so diffusely metastatic that all bones are involved, and no focal areas of uptake are identified. The key finding will be absence of visualization of the kidneys. In patients with diffuse osseous metastases, the radionuclide is completely absorbed by the bones, leaving little for the kidneys to excrete. This pattern is known as a “super bone scan.” The differential diagnosis of diffuse bone uptake includes myelosclerosis, urticaria pigmentosa, and fluorine poisoning, in addition to diffuse blastic metastases.

MAGNETIC RESONANCE IMAGING

On T2-weighted images the central gland is medium to low-signal intensity and frequently heterogeneous, while the normal peripheral zone shows high signal intensity. Prostate cancer is typically seen on MRI as an area of lower signal intensity in the otherwise high-signal peripheral zone. MRI is not useful for early detection of prostate cancer but can be useful for staging prostate cancer after this diagnosis has been made. A 1.5T magnet is used with an endorectal coil in a pelvic phased-array coil or images can be obtained using a 3T magnet without or with an endorectal coil. Gross extension of tumor beyond the prostate into an adjacent structure is usually readily seen with MRI. More subtle extension of tumor beyond the prostate gland may be more difficult to determine. A smooth or irregular bulge in the contour of the gland in the region of the tumor or asymmetry of the fat plane surrounding the neurovascular bundle should increase suspicion. Smooth capsular bulge is predictive of tumor extension in approximately 25% of cases, while an irregular bulge is predictive of tumor extension in 75% of cases. The normal seminal vesicles will show high-signal intensity on T2-weighted images, while tumor involvement of the seminal vesicles appears as areas of lower signal. An exception will be patients who have received radiation or hormonal therapy, which may show lower than normal signal intensity in the seminal vesicles. Accuracy of MRI in detecting seminal vesicles involvement in patients with prostate cancer is reported as greater than 90%. The major limitation in widespread use of MRI in staging has been the lack of consistent prediction of tumor extent because of microscopic involvement. Magnetic resonance spectroscopy of the prostate is a potentially useful adjunctive study that may be helpful in evaluating patients with elevated serum PSA level with previous negative biopsy specimens.

SEMINAL VESICLE STONES

Seminal vesicle stones, which are uncommon, are related to stone disease elsewhere in the urinary tract or ectopic insertion of a ureter into the ipsilateral seminal vesicle. Stones should not be confused with seminal vesicle wall calcification, which can be seen in diabetic men. Small stones may result in pain and hematospermia if they become impacted in the duct from the seminal vesicle or the ejaculatory duct.

SEMINAL VESICLE CYSTS

Seminal vesicle cysts are also uncommon. There is an association with ipsilateral renal agenesis in at least

two-thirds of patients with a congenital seminal vesicle cyst. In rare cases, cystic dilatation of a seminal vesicle may be related to a small dysplastic kidney with its ureter ectopically inserting into the ipsilateral seminal vesicle. When a seminal vesicle cyst is identified, imaging of the kidneys is usually indicated. Acquired seminal vesicle cysts may be related to obstruction or inflammation. Congenital or acquired cysts may become quite large and indent the bladder posteriorly. Hemorrhage into the lumen of a cyst may be differentiated with MRI, which will show high signal intensity on both T1- and T2-weighted images. Seminal vesiculitis in conjunction with prostatitis is common, although imaging findings are nonspecific. The most common cause of neoplastic involvement of the seminal vesicles is direct invasion by prostate cancer.

ACQUIRED URETHRAL STRICTURES IN MEN

Urethral strictures may be the result of infectious or inflammatory etiology, iatrogenic, or traumatic (Table 60-2).

Approximately 40% of all urethral strictures in the United States are caused by gonorrhea. The proximal bulbar urethra is the site of stricture in 70% of patients with gonococcal urethritis because of the high concentration of periurethral glands in this area and the dependent position of this portion of the male urethra. Infectious strictures may be multiple and of various lengths. Serial strictures are common. At urography, the Littre glands may be opacified when strictures are present because of inflammatory dilation of duct ostia. An important clue to the urodynamic significance of a stricture may be backfilling of ducts or glands that empty into the urethra proximal to a stricture. Pseudodiverticulum formation results from a gonococcal periurethral abscess that eventually ruptures into the urethra leaving a cavity. Occasionally, a large periurethral abscess will extend to and penetrate the perineum, re-

sulting in an urethrocutaneous fistula, which may be multiple. Urine may pass through these perineal fistulae, resulting in the “watering can perineum,” which is more typical of tuberculosis or schistosomiasis rather than of gonorrhea.

Urethral surgery, instrumentation, or catheterization may result in stricture formation. These strictures occur most often in parts of the urethra that are anatomically fixed and narrow (i.e., the membranous urethra and the penoscrotal junction of the anterior urethra). The majority of instrument-related urethral strictures occur in the bulbomembranous region, with less than 20% occurring at the penoscrotal junction. An iatrogenic stricture can be focal and short, multifocal or long.

Urethral injury is a common complication of pelvic trauma. The most common injury involves the posterior urethra. Traumatic stricture will occur more commonly after complete transection of the urethra; a partial laceration will more likely heal without significant narrowing. The majority of patients with injuries to the posterior urethra who develop strictures will require repeated dilatations or urethroplasty regardless of initial treatment. Traumatic strictures are usually solitary, less than 2 cm in length, and flanked by segments of urethra that are normal in caliber. Traumatic strictures form more rapidly than inflammatory strictures.

Straddle injury occurs most commonly when a male patient falls astride a hard object such as a bicycle crossbar, or a steel or wooden beam. Straddle injuries involve the bulbous urethra. Coexisting pelvic fractures are less common with a straddle injury. This injury results from compression of the anterior urethra against the pubis. The typical straddle injury will result in a focal stricture in the proximal third of the bulbous urethra on follow-up examination.

The two most commonly used systems of classification or urethral injuries are the American Association for the Surgery of Trauma (AAST) and the one originally proposed by Colapinto and McCollum and revised by Goldman et al. The unified classification system proposed by Goldman et al. uses the anatomic location of injury, whether is it nearer to the urogenital diaphragm or the external sphincter, and includes a category for bladder injuries that involve or simulate posterior urethral injury (Table 60-3). Accurate classification of urethral injuries plays an important role in effective treatment planning. If a complete urethral transection is observed on initial retrograde urethrogram, the length of the defect must be accurately demonstrated for effective urethroplasty planning. The length of the defect can be effectively demonstrated by performing simultaneous antegrade and retrograde studies.

Stricture formation rarely is the sole manifestation of a urethral carcinoma; however, when stricture formation

TABLE 60-2 Urethral Stricture

ETIOLOGY	LOCATION	APPEARANCE
Nongonococcal urethritis, gonococcus, or rarely tuberculosis	Bulbar urethra strictures	Multiple and serial
Iatrogenic (surgery, instrumentation, catheterization)	Membranous urethra or penoscrotal junction	
Traumatic; occurs after complete rupture	Goldman type II—V injuries	Solitary, short stricture

TABLE 60-3 Goldman System for Classification of Urethral Injuries at Urethrography

INJURY TYPE	INJURY DESCRIPTION	URETHROGRAPHIC APPEARANCE
I	Stretching or elongation of the otherwise intact posterior urethra	Intact but stretched urethra
II	Urethral disruption above the urogenital diaphragm while the membranous segment remains intact	Contrast agent extravasation above the urogenital diaphragm only
III	Disruption of the membranous urethra, extending below the urogenital diaphragm and involving the anterior urethra	Contrast agent extravasation below the urogenital diaphragm, possibly extending to the pelvis or perineum; intact bladder neck
IV	Bladder neck injury extending into the proximal urethra	Extraperitoneal contrast agent extravasation; bladder neck disruption
IVa	Bladder base injury simulating a type IV injury	Periurethral contrast agent extravasation; bladder base disruption
V	Isolated anterior urethral injury	Contrast agent extravasation below the urogenital diaphragm, confined to the anterior urethra

Reprinted with permission from Goldman SM, Sandler CM, Corriere JN, Jr., et al. Blunt urethral trauma: a unified, anatomical mechanical classification. *J Urol*. 1997;157:85-89. Copyright © Elsevier.

occurs in an elderly patient with no previous medical history of urethral surgery, instrumentation, or infection, carcinoma should be suspected. Radiology evaluation should assess the location, length, severity, and multiplicity of these strictures.

Penetrating injuries to the male urethra from gunshot or knife wounds are uncommon. Penetrating injuries more commonly affect the anterior, rather than the posterior urethra. These injuries usually require immediate surgical exploration and antibiotic therapy.

URETHRAL TUMORS

BENIGN TUMORS

Benign urethral neoplasms include the fibrous polyp (also known as congenital urethral polyp or fibroepithelial polyp), transitional cell, and squamous cell papillomas.

MALIGNANT TUMORS

Carcinoma of the urethra is the only epithelial malignancy of the urinary tract that occurs more frequently in women, with the peak age range of 40 to 60 years. Carcinoma of the male urethra occurs predominantly in men older than 50 years. SCC, the most common type, occurs in 75% of these patients, followed by transitional cell carcinoma (TCC). Adenocarcinoma is the most common malignancy in a urethral diverticulum due to the origin of diverticula, as they arise secondary to infection in paraurethral Bartholin's glands. The tumor type involving the male urethra varies by location of in-

volvement. TCC involves the prostatic urethra. Adenocarcinoma involves the glands of Littre and Cowper's glands. SCC involves the anterior urethra and is associated with prior urethral stricture in up to 75% of cases. Lymphogenous spread occurs before hematogenous dissemination.

Risk factors associated with carcinoma of the male urethra include a medical history of chronic urethral inflammation or sexually transmitted disease and urethral stricture. The majority of carcinomas of the male urethra, almost 80%, are SCCs. Two-thirds arise in the bulbar or membranous urethra. The majority of the remaining carcinomas are found in the anterior urethra, especially the fossa navicularis. Approximately 15% of male urethral carcinomas will be TCC, arising in the posterior urethra in most patients. There is an association between TCC of the prostatic urethra and previous transurethral resection of bladder carcinoma. Initial spread of tumor is again predominantly lymphogenous. Bulbar and posterior urethral carcinomas spread to the internal iliac or obturator nodes, prior to spread to more proximal nodal groups. Carcinoma of the penile urethra spreads to the deep inguinal and external iliac lymph nodes. The diagnosis of urethral carcinoma is made with urethroscopy or urethrography. The diagnosis should be suspected on urethrography when the margin of a stricture is irregular or poorly defined.

METASTASES TO THE URETHRA

Bladder and colorectal carcinomas can involve the urethra through extensive local spread. Prostate, cervical, and vaginal cancers also may invade the urethra.

PENILE CANCER

Primary penile cancer is rare, representing only 0.4% of all malignancies in the male population in the United States. The majority of penile cancers (95%) are SCCs, and usually occur in the sixth and seventh decades of life. The most predisposing factor is the presence of a foreskin, which results in the accumulation of smegma. Penile cancers, therefore, are most commonly located on the glans penis and are usually solitary, ill defined, and infiltrative in nature. The primary factors involving survival are the depth of invasion of the primary tumor and the extent of involvement of the draining inguinal lymph nodes. MRI is the most sensitive method for evaluation of these characteristics. Penile cancer is typically low signal intensity relative to the corpora on both T1- and T2-weighted images. Tumors will enhance following gadolinium administration, although with less enhancement than seen in the corpora cavernosa. T2-weighted and gadolinium enhanced T1-weighted sequences are the most useful sequences for determining the extent of tumor into the tunica albuginea, corpora, or the urethra.

Metastatic tumors to the penis will most commonly arise from a primary tumor in the genitourinary system. The typical MRI appearance will be multiple discrete masses in the corpora cavernosa and corpus spongiosum, which are low signal intensity relative to the normal corporal tissue on both T1- and T2-weighted images.

POSTOPERATIVE URETHRAL CHANGES

URETHROPLASTY

Urethroplasty performed for treatment of anterior urethral strictures, especially two-stage procedures, may result in saccular dilatation of the urethra, more frequently near the proximal and distal ends of the repair. When these sacculations become large, they may resemble urethral diverticula. Large sacculations may collect urine during voiding, resulting in postvoid dribbling. Retrograde urethrography will differentiate these urethroplasty sacculations from acquired diverticula.

PROSTATECTOMY

Possible complications from radical prostatectomy include lymphocele formation after pelvic lymph node dissection and vesicourethral anastomotic leak. During radical prosta-

tectomy the entire prostate including the prostatic urethra and seminal vesicles are removed. The lower urinary tract continuity is reestablished by anastomosing the bladder neck to a stump of the membranous urethra extending from the urogenital diaphragm. This surgical intervention results in a funnel-shaped bladder base that extends below the top of the pubic symphysis. This finding is essentially pathognomonic of a radical prostatectomy.

QUESTIONS AND ANSWERS

1. Concerning seminal vesicle cysts, which of the following is true?
 - A. Imaging will differentiate congenital from acquired seminal vesicle cysts.
 - B. Most frequently an association with trauma.
 - C. Association with ipsilateral renal agenesis.
 - D. Association with multicystic dysplastic kidney.

ANSWER: C. There is an association with ipsilateral renal agenesis in at least two-thirds of patients with a congenital seminal vesicle cyst. In rare cases, cystic dilatation of a seminal vesicle may be related to a small dysplastic kidney with its ureter ectopically inserting into the ipsilateral seminal vesicle.
2. From what structure does the vas deferens arise?
 - A. Verumontanum
 - B. Seminal vesicles

- C. Ampulla of the vas deferens
- D. Tail of the epididymis

ANSWER: D. The vas deferens arises from the tail of the epididymis and after entering the pelvis, become the ampulla of the vas deferens. The ampulla courses toward the midline of the pelvis and joins the excretory duct of the seminal vesicle to form the ejaculatory duct, and eventually empties into the verumontanum.

3. A man with a straddle injury has difficulty urinating. What is the most likely location of stricture?
 - A. Bulbous urethra
 - B. Membranous urethra
 - C. Penile urethra
 - D. Posterior urethra

ANSWER: A. Straddle injury occurs most commonly when a male patient falls astride a hard object such as a bicycle crossbar, or a steel or wooden bean. Straddle injuries involve the bulbous urethra.

4. Patient presents with PSA of 8, what do you do?
 - A. Nothing
 - B. Endorectal coil MRI
 - C. Nuclear medicine bone scan
 - D. Ultrasound guided biopsy

ANSWER: D. Normal PSA is <4 ng/mL. Abnormal PSA, alone, does not confirm prostate cancer. TRUS of the prostate with ultrasound-guided biopsy is the most likely of the group to differentiate BPH from prostate cancer. Bone scans should be reserved for those patients with PSA levels greater than 10 ng/mL at the time of diagnosis, or for patients with localized bone pain suggesting osseous metastases. Endorectal coil MRI is most helpful for staging prostate cancer after the diagnosis has been made with biopsy.

5. What percent of prostate cancers involve the peripheral zone?
 - A. 33%
 - B. 62%
 - C. 70%
 - D. 82%

ANSWER: C. The bulk of the prostate is the peripheral zone and is involved in 70% of prostate cancers.

6. At what age does the American Cancer Society and the American Urological Association recommend annual DRE and PSA screening in an African American man?
 - A. 35 years
 - B. 40 years

- C. 45 years
- D. 50 years

ANSWER: B. In high-risk men, such as those with a strong family history of prostate cancer or African American men, screening is recommended to begin at 40 years of age.

7. Using the Gleason system of grading a prostate cancer, which of the following statements is true?
 - A. Stage A carcinoma is usually found incidentally in pathology specimens or autopsy specimens.
 - B. Better differentiated tumor will have a higher grade.
 - C. Gleason scores of 8 to 10 frequently have metastatic pelvic lymphadenopathy.
 - D. Highest Gleason score is the result of the histology of an aggressive tumor divided by the estimated volume of the prostate gland.

ANSWER: C. The tumor is studied with identification of the predominant and secondary histological patterns of tumor, with each assigned a score of 1 through 5, for a total maximum score of 10. A better-differentiated tumor will have a lower tumor grade.

8. What venous plexus directly communicates with the plexus of Batson?
 - A. Vesuvius
 - B. Galen
 - C. Santorini
 - D. Virchow

ANSWER: C. The vertebral plexus of Batson directly communicates with the periprostatic venous plexus of Santorini and provides the route of early hematogenous spread to the spine and pelvis.

9. The glands of Littre are found in what part of the urethra?
 - A. Anterior urethra
 - B. Posterior urethra
 - C. Prostatic urethra
 - D. Semimembranous urethra

ANSWER: A. These are small, mucus secreting glands that are found along the length of the anterior urethra and are more numerous in the bulbous sump and in the superior aspect of the penile urethra.

10. What is the location in the urinary tract where uroepithelial malignancy is more common in women than men?
 - A. Renal pelvis
 - B. Proximal ureter

- C. Distal ureter
- D. Urethra

ANSWER: D. Carcinoma of the urethra is the only epithelial malignancy of the urinary tract that occurs more frequently in women, with the peak age range of 40 to 60 years.

61 FEMALE REPRODUCTIVE SYSTEM

*Heather L. Haddad and
Therese M. Weber*

URETHRA

NORMAL ANATOMY

The female urethra measures approximately 4 cm in length. It originates at the internal urethral meatus at the bladder neck, courses obliquely in an anteroinferior direction from the internal meatus, and extends through the urogenital diaphragm to the external urethral meatus. The proximal third of the urethra is lined by transitional epithelium and the distal two-thirds are lined by stratified squamous epithelium. Multiple periurethral glands of Skene secrete mucus, which drains into the distal urethra via periurethral ducts.

The urethra can be evaluated with imaging modalities such as ultrasound, MRI, voiding cystourethrogram (VCUG), and double-balloon catheter urethrogram; however, the superior soft-tissue contrast, noninvasiveness, and lack of ionizing radiation of MRI make it a superior imaging modality. On T2-weighted MR images, the urethra demonstrates a target-like appearance with an outer hypointense rim corresponding to striated muscle, a middle hyperintense ring corresponding to smooth muscle, and an inner hypointense ring corresponding to the mucosa and submucosa.

URETHRAL AND PERIURETHRAL ABNORMALITIES

Urethral diverticula commonly occur in the midurethra along the posterolateral wall. These diverticula are postulated to develop secondary to inflammation or infection of the periurethral Skene glands. The inflammation or infection leads to ductal obstruction with subsequent rupture into the urethra. Symptoms include postvoid dribbling, pain, and dyspareunia. MR imaging demon-

strates hyperintense fluid signal on T2 images manifesting as a posterolateral outpouching or a horseshoe configuration surrounding the urethra. MRI can detect diverticular septations, calculi, neoplasms, and inflammation. If visualized, the location of a diverticular neck should be described to aid in surgical resection planning. Differential diagnosis for a periurethral cystic lesion includes diverticulum, submucosal cyst, and Skene gland abscess.

Complications of urethral diverticula include infection, calculus formation, and neoplasm. Calculi can develop because of urinary stasis within the diverticulum and superimposed infection. Adenocarcinoma is the most common neoplasm to occur within a diverticulum, but squamous cell and transitional cell carcinomas (TCC) also occur.

Leiomyoma is a benign smooth muscle tumor, which arises from the smooth muscle layer of the urethra. Urethral leiomyoma is extremely rare.

URETHRAL MALIGNANCIES

Urethral malignancies are very rare and are much more common in women than in men. Approximately 60% to 70% of urethral carcinomas are squamous cell carcinomas (SCCs). These tumors usually involve the distal one-third of the urethra, the anterior urethra. Lesions can be infiltrating or lobular. Approximately 20% of urethral malignancies are TCC that most commonly involve the proximal urethra. Urethral TCC often appear lobulated in configuration. Human papillomavirus infection is associated with development of SCC and TCC. Adenocarcinoma represents only 10% of urethral carcinomas, but accounts for over one-half of the malignancies developing in urethral diverticula. Urethral carcinomas demonstrate heterogeneous enhancement on contrast-enhanced MRI.

Secondary involvement of the urethra can occur secondary to extension of malignancy from adjacent organs including the vagina, cervix, and bladder.

URETHROVAGINAL FISTULAS

Urethrovaginal fistulas can develop following pelvic surgery, vaginal delivery, urethral inflammation, or radiation therapy. Urethral fistulas can also communicate with the rectum and perineum.

TRAUMA

Urethral trauma is very rare in females because of the short length and mobility of the urethra.

TABLE 61-1 Periurethral/Vaginal Cysts

	ORIGIN	SITE
Periureteral diverticulum	Paraurethral gland	Posterolateral wall midurethra
Skene cyst	Paraurethral gland	Distal urethra
Müllerian cyst	Müllerian (paramesonephric) ducts	Anterolateral vagina above lower margin of pubic symphysis
Gartner cyst	Wolffian (mesonephric) ducts	Anterolateral vagina above lower margin of pubic symphysis
Bartholin cyst	Bartholin gland	Introitus medial to labia minora at/or below pubic symphysis

PERIURETHRAL CYSTS

Periurethral cysts do not communicate with the urethra (Table 61-1). Most periurethral cysts originate from vaginal structures. Presenting symptoms include infection, mass effect, hemorrhage, and rupture.

Müllerian and Gartner duct cysts are embryologic cysts, which are often discussed in conjunction as they arise in the same location and are treated similarly. Müllerian cysts arise from the embryologic remnants of the Müllerian (paramesonephric) ducts and are lined by mucinous epithelium. Gartner cysts arise from remnants of the Wolffian (mesonephric) duct and are lined by non-mucinous epithelium. Both types of cysts are located in the anterolateral wall of the vagina posterior to the urethra. They are typically located above the inferior border of the pubic symphysis. Uncomplicated cysts are hyperintense fluid signal on T2-weighted images. Symptomatic cysts are surgically excised.

Bartholin glands are derived from the urogenital sinus. They are located at the posterolateral introitus medial to the labia minora and are usually found at or below the level of the pubic symphysis. Ductal obstruction leads to the formation of a retention cyst, without or with superimposed infection. Uncomplicated cysts are hyperintense on T2-weighted images while infected cysts may appear heterogeneous with pericystic enhancement following contrast administration.

Periurethral collagen injections are performed to treat stress urinary incontinence. On ultrasound, the collagen appears as echogenic foci. On T1-weighted MR imaging, it appears as hyperintense foci.

UTERUS

NORMAL ANATOMY

The uterus consists of the uterine corpus and cervix, which on T2-weighted images demonstrate multiple zones of different signal intensity. The uterine zonal anatomy from outer to inner is myometrium, junctional zone (lower signal intensity rim separating the myometrium and endometrium), and endometrium (inner, higher signal intensity). The uterus will enhance rapidly

and intensely following intravenous gadolinium administration.

PATHOLOGY

BENIGN UTERINE PROCESSES

Leiomyomas

Leiomyomas are smooth muscle tumors that commonly occur in the uterus. MRI is accurate in demonstrating the number, location, and their enhancement pattern. Leiomyomas tend to appear as low signal intensity, distinct uterine masses on all MR imaging sequences. Exceptions include leiomyomas with hemorrhagic, cystic, hyaline, or myxoid degeneration. Areas of hemorrhagic degeneration will appear as high signal intensity on T1-weighted images. Areas of cystic, hyaline, or myxoid degeneration will show increased signal intensity on T2-weighted images. Calcifications will appear as signal voids. Leiomyoma location may be submucosal, intramural, subserosal, or cervical. Subserosal leiomyomas may be pedunculated and mimic ovarian masses, or may undergo torsion. Lipoleiomyomas are very rare and contain fat. Sarcomatous transformation is rare but difficult to confirm with imaging unless the tumor becomes invasive. Leiomyomas can show variable enhancement patterns. Well-vascularized enhancing leiomyomas are more likely to respond to uterine artery embolization. Successful embolization therapy should result in smaller uterine size, smaller leiomyoma size, and reduced or absent enhancement on follow-up imaging.

ADENOMYOSIS

Adenomyosis is a process where ectopic endometrial glands extend into the myometrium. Characteristic features on MRI include thickening of the junctional zone (more than 12 mm) on T2-weighted images; it may be focal or diffuse. The border between the junctional zone and the myometrium is frequently indistinct. Many centers use 12 mm as the threshold for diagnosing adenomyosis with MRI; however, not all cases of adenomyosis will show that degree of junctional zone thickening, and additional features should be evaluated.

Differentiation of leiomyomas and adenomyosis can be difficult. Adenomyosis tends to show ill-defined borders with minimal mass effect, as compared to leiomyomas, which tend to have a more distinct border with greater mass effect on the endometrium, or give a bumpy contour to the uterine border when they occur in a serosal location. With adenomyosis, small high-signal-intensity foci may be seen within the junctional zone or myometrium on T2-weighted images.

MALIGNANT UTERINE PROCESSES

Endometrial Carcinoma

Endometrial carcinoma is the most common gynecologic malignancy and is seen predominantly in postmenopausal women. Endometrial carcinoma, most commonly adenocarcinoma, arises from the endometrium. The International Federation of Gynecology and Obstetrics (FIGO) staging system is summarized in Table 61-2. The depth of myometrial invasion is extremely important. When tumor is confined to the uterus, stage I disease, primary therapy will be total abdominal hysterectomy and bilateral salpingo-oophorectomy. Characteristics of endometrial carcinoma on MRI include widening of the endometrium (more than 5 mm in postmenopausal women). Disruption of the junctional zone implies deep myometrial invasion. Lymphatic spread initially involves the pelvic lymph nodes, followed by paraaortic lymph nodes. The presence of deep myometrial invasion markedly increases the likelihood of nodal metastases. Contrast-enhanced MRI provides more accurate information regarding tumor volume and depth of tumor invasion. There is variable enhancement of endometrial carcinomas, with some tumors showing increased enhancement relative to normal endometrium and myometrium, and others showing less enhancement relative to normal myometrium. The most frequent site of hematogenous metastasis is the lung. Endometrial polyps, endometrial hyperplasia, and uterine sarcoma may mimic endometrial carcinoma.

Cervical Carcinoma

Cervical carcinoma is the third most common gynecologic malignancy and tends to be seen in younger

women, as compared to ovarian and endometrial carcinomas. Cervical carcinoma is most commonly a SCC. The FIGO staging system for cervical carcinoma is summarized in Table 61-3. There is an association with human papillomavirus infection. Tumor begins in the cervix with spread predominantly by local invasion of surrounding structures. Most commonly involved lymph node groups are obturator, iliac, and paraaortic nodes. MR imaging is now widely accepted as optimal for evaluation of important prognostic factors that will impact treatment strategy. Cervical carcinoma tends to show increased signal intensity relative to the cervical stroma on T2-weighted images. Typically, cervical carcinoma will show mass-like expansion of the cervix, with disruption of the normal cervical zonal anatomy on T2-weighted images. Dynamic gadolinium-enhanced images are very helpful in demonstrating extent of tumor with typical early enhancement of cervical carcinoma relative to surrounding structures. MRI can be helpful in demonstrating parametrial and sidewall invasion. An intact dark cervical stroma surrounding relatively high-signal tumor on T2-weighted images demonstrates absence of parametrial invasion. Conversely, disruption of the cervical stroma that is due to tumor extension demonstrates parametrial invasion. Radiation-induced changes in the pelvis may be difficult to distinguish from recurrent cervical carcinoma. Increased signal intensity on T2-weighted images may be present in areas of radiation fibrosis for up to 1 year following radiation therapy. Signs of recurrent cervical tumor include an identifiable mass, asymmetric tissue in the pelvis, lymphadenopathy, and ureteral obstruction. Atypical manifestations of recurrent cervical carcinoma include solid organs of the abdomen, the peritoneum, mesentery, omentum, gastrointestinal tract, pulmonary, pleural or pericardial metastases, and osseous metastases.

OVARIAN TUMORS

Ovarian tumors are categorized into four groups according to their cell type of origin: epithelial, germ cell, sex cord-stromal tumors, and metastatic (Table 61-4). Ovarian neoplasms are further classified as benign, low malignant potential, or malignant. Staging of ovarian carcinomas is based on the FIGO staging system (Table 61-5). In stage I, disease is limited to one or both ovaries. In stage II, there is extra ovarian spread confined to the pelvis. Stage III disease includes peritoneal implants involving the abdomen and/or retroperitoneal lymph node metastasis. Stage IV disease involves distant metastasis, such as hepatic or intrathoracic lesions. Intraperitoneal dissemination

TABLE 61-2 Endometrial Carcinoma FIGO Staging

I	Tumor confined to uterine corpus
Ia	Tumor limited to the endometrium
Ib	<50% invasion of the myometrium
Ic	≥50% invasion of the myometrium
II	Cervical invasion
III	Tumor beyond the uterus, but within the true pelvis
IV	Tumor outside the true pelvis

TABLE 61-3 Correlation Between FIGO Staging, MR Imaging Staging, and Treatment of Cervical Carcinoma

FIGO	STAGING	MR IMAGING STAGING	TREATMENT
0	Carcinoma in situ	Not visible	
I	Confined to cervix		
	IA Microscopic		
	IA-1 Stromal invasion <3 mm	No tumor visible	Surgery
	IA-2 >3 mm, <5-mm invasion, <7-mm width	Small enhancing tumor may be seen	Surgery
	IB Clinically visible (>5 mm)	Tumor visible, intact stromal ring surrounding tumor	Surgery
	IB-1 <4 cm		Surgery
	IB-2 >4 cm		Radiation therapy
II	Extends beyond uterus but not to pelvic wall or lower one-third of vagina		
	IIA Vaginal extension, no parametrial invasion	Disruption of low-signal-intensity vaginal wall (upper two-thirds)	Surgery (if <4 cm), radiation therapy (if >4 cm)
	IIB Parametrial invasion	Complete disruption of stromal ring with tumor extending into the parametrium	Radiation therapy
III	Extension to lower one-third of vagina or pelvic wall invasion with hydronephrosis		
	IIIA Extension to lower one-third of vagina	Invasion of lower one-third of vagina	Radiation therapy
	IIIB Pelvic wall invasion with hydronephrosis	Extension to pelvic muscles or dilated ureter	Radiation therapy
IV	Located outside true pelvis		
	IVA Bladder or rectal mucosa	Loss of low signal intensity in bladder or rectal wall	Radiation therapy
	IVB Distant metastasis		Radiation therapy

is the most common mode of extrapelvic metastasis followed by lymphatic and hematogenous dissemination. Approximately 90% of ovarian carcinomas occur sporadically and the remaining 10% are hereditary.

EPITHELIAL TUMORS

Epithelial tumors are the most commonly occurring group of ovarian tumors, accounting for 60% to 70% of all ovarian neoplasms and more than 85% of malignant neoplasms. Epithelial neoplasms rarely occur before puberty and are most prevalent in older women. Imaging features can suggest benignity or malignancy (Table 61-6). In general, benign lesions are predominantly cystic in nature, while malignant lesions contain solid components and papillary projections.

Serous neoplasms include benign serous cystadenomas and malignant serous cystadenocarcinomas. They are the most common epithelial neoplasms, both benign

TABLE 61-5 Ovarian Cancer Staging

Stage I	Tumor limited to one or both ovaries $\pm$ malignant ascites
Stage II	Tumor involves one or both ovaries with pelvic extension to other structures $\pm$ malignant ascites
Stage III	Tumor involves one or both ovaries peritoneal implants outside the pelvis or retroperitoneal or inguinal lymph node metastasis
Stage IV	Hematogenous metastasis to solid organs (e.g., liver or malignant pleural effusion)

TABLE 61-6 Benign Versus Malignant Epithelial Tumors

	BENIGN	MALIGNANT
Wall thickness	Thin	Thick, >3 mm, irregular
Septa	None or thin septations	Thick septations, >3 mm septal nodularity
Internal structure	Lacking	Papillary projections, solid components

and malignant. Serous cystadenocarcinoma accounts for over half of all ovarian malignancies. Benign serous lesions are usually unilocular cystic lesions but can contain a small amount of tissue. Malignant lesions contain a larger component of papillary soft tissue and may be multilocular. Up to a quarter of benign lesions and up to half of malignant lesions are bilateral. Calcification of peritoneal metastasis has been reported in up to one-third of cases.

Mucinous neoplasms include benign mucinous cystadenomas and malignant cystadenocarcinomas. Mucinous cystadenomas are the second most common benign epithelial neoplasm after serous cystadenomas. These tumors are often very large and multilocular. The locules may demonstrate slightly varying densities at imaging, which is due to differences in viscosity of the protein content. This finding is in contrast to serous tumors, which are generally simple fluid attenuation. Mucinous cystadenocarcinomas are much less likely than serous carcinomas to be bilateral. Rupture of a mucinous adenocarcinoma produces pseudomyxoma peritonei.

Endometrioid cancer accounts for approximately 10% to 15% of ovarian cancers. Endometrioid carcinomas are almost always malignant. Bilateral ovarian involvement can be present in 25% to 50% of cases. These lesions are complex cystic and solid masses at imaging. Synchronous endometrial carcinoma or endometrial hyperplasia occurs in up to a third of cases.

Clear cell carcinoma represents approximately 5% of ovarian carcinomas. These lesions are always malignant. Imaging appearance is similar to serous neoplasms displaying a large cyst with solid protrusions. Both endometrioid and clear cell carcinomas can arise from endometriosis.

Brenner tumors represent approximately 2% to 3% of ovarian tumors. These lesions are rarely malignant. Histologically, the tumors are composed of transitional cells and fibrous stroma. At imaging, lesions are small predominately solid masses or multiloculated cystic and solid masses. Amorphous calcifications can be present within the solid component. The fibrous stroma is low in signal on T2-weighted MR imaging. Brenner tumors can occur in association with mucinous cystic tumors.

GERM CELL TUMORS

Germ cell tumors are the second most common group of ovarian tumors after epithelial tumors. These lesions account for 20% to 30% of all ovarian tumors. Malignant germ cell tumors can produce elevated levels of alpha-fetoprotein and human chorionic gonadotropin.

A mature teratoma is named as the most common benign ovarian tumor in some series. Approximately 15% to 20% are bilateral. It is the only benign neoplasm in the germ cell tumor group. Malignant transformation is rare. These lesions are derived from all three germ cell layers: mesoderm, endoderm, and ectoderm. The ectodermal components usually predominate. Teratomas are lined by squamous epithelium and filled with sebaceous material. Hair, muscle, bone, and teeth can also be present within teratomas. A soft-tissue protuberance called a Rokitansky nodule or a dermoid plug can be seen projecting into the cyst. If present, bone or teeth are usually located with the soft-tissue protuberance. At ultrasound imaging, the classic finding is the echogenic dermoid plug with posterior acoustic shadowing termed the “tip of the iceberg” sign. At CT, fat attenuation and teeth can be seen. On MR imaging, the fatty sebaceous material follows fat signal. Teratoma which is primarily composed of thyroid tissue is termed struma ovarii.

Less than 1% of all teratomas are immature teratomas. They contain immature tissue from all three germ cell layers. These lesions are malignant and occur in the first two decades. In contrast to mature teratomas, an immature teratoma contains small scattered foci of fat, prominent solid components, and scattered calcifications.

Dysgerminoma is a rare ovarian neoplasm occurring in children and young women. Imaging reveals a multilobulated solid mass with prominent fibrovascular septa. Speckled calcifications and areas of necrosis and hemorrhage can be present. Approximately 5% of dysgerminomas will produce human chorionic gonadotropin. Seminoma is the testicular counterpart of dysgerminoma.

Endodermal sinus tumor is a rare ovarian tumor, which usually occurs in the second decade of life. This lesion is also known as a yolk sac tumor. Imaging reveals a large complex mass with cystic and solid components. Elevated serum alpha-fetoprotein levels are detectable.

SEX CORD-STROMAL TUMORS

Sex cord-stromal tumors derive from coelomic epithelium or mesenchymal cells of the embryologic gonads. These tumors account for approximately 8% to 10% of ovarian neoplasms and occur in all age groups.

Granulosa cell tumor is the most common malignant sex cord-stromal tumor. These lesions predominately occur in perimenopausal and postmenopausal women. At imaging, the lesions vary widely in appearance from cystic to solid masses. Granulosa cell tumor is the most common ovarian neoplasm to produce estrogen. Estrogenic effects on the endometrium can result in endometrial hyperplasia and uterine hemorrhage. Endometrial carcinoma can occur in up to 25% of women with granulosa cell tumors.

Fibrothecomas contain varying quantities of thecoma and fibroma. Thecoma is lipid rich and exhibits estrogenic activity while fibroma contains fibroblasts and collagen and exhibits no hormonal activity. Ovarian fibroma is the most common sex cord tumor. These lesions occur in both premenopausal and postmenopausal women. The imaging appearance is a solid mass which may contain dense calcifications. The collagenous component appears low in signal on both T1- and T2-weighted MR imaging. Meigs syndrome is a triad of fibroma, ascites, and pleural effusions.

Rare sex cord-stromal tumors occurring in young women include sclerosing stromal tumor and Sertoli-Leydig cell tumor. Imaging of a sclerosing stromal tumor reveals a cystic and solid mass demonstrating early peripheral enhancement with centripetal progression. Sertoli-Leydig cell tumors appear as enhancing solid masses with intratumoral cysts. Approximately 30% of tumors are hormonally active producing virilizing changes.

METASTATIC OVARIAN TUMORS

Approximately 5% of all ovarian tumors are metastases. Colon and stomach carcinomas are the most common primary neoplasms to metastasize to the ovaries. Breast, lung, and contralateral ovarian neoplasms also metastasize to the ovary. Krukenberg tumors are ovarian metastases from gastrointestinal tract carcinomas, classically the stomach, which are composed of mucin-secreting signet-ring cells.

MISCELLANEOUS OVARIAN LESIONS

Endometriosis is the presence of endometrial tissue outside of the uterus. The ovary is the most commonly affected site. Chronic cyclic hemorrhage results in a cyst containing hemorrhagic material surrounded by a thick fibrous wall. These cysts are high signal intensity on T1-weighted MR images and can be either high or low in signal on T2-weighted images. The low T2 signal occurs because of T2 shortening associated with the high iron concentration related to chronic hemorrhage and is termed “shading.” Fluid-fluid and fluid-debris levels may be seen. The imaging appearance of some endometriotic cysts,

high T1 and T2 signal, can overlap with that of hemorrhagic functional cysts; however, hemorrhagic functional cysts are usually solitary and regress within 2 months.

Tuboovarian abscess usually manifests as a complication of pelvic inflammatory disease (PID)—infection of the upper genital tract caused by ascending infection from the lower genital tract. The most common infectious sources are chlamydia and gonorrhea. Patients present with fever and pelvic pain. The diagnosis is often made on ultrasound, which reveals a multilocular thick-walled fluid collection. Contrast CT and MRI images demonstrate enhancement of the thickened walls.

Polycystic ovarian syndrome is an endocrine disorder. Women with the syndrome have abnormal production and metabolism of androgen, abnormal metabolism of estrogen, and peripheral insulin resistance. Obesity compounds these abnormalities. Secondary effects include hirsutism, obesity, anovulation with oligomenorrhea or amenorrhea, and reduced fertility. Ultrasound or MR imaging may reveal enlarged ovaries with numerous subcentimeter follicles located peripherally in the cortex. The ovaries may demonstrate increased echogenicity on ultrasound.

HYSTEROSALPINGOGRAMS

Hysterosalpingograms (HSG) are used primarily as a component of routine infertility evaluation. Other indications for HSG include evaluation for repeated abortions, abnormal uterine bleeding, assessing for successful tubal occlusion in tubal ligation, locating an intrauterine device, and postsurgical evaluation. HSG is performed during the follicular phase of the menstrual cycle. The cervix is cannulated with an “acorn” tip cannula or a balloon catheter. Oil- or water-soluble contrast is injected into the uterus and fallopian tubes under fluoroscopic visualization. With oil-based agents, there is increased risk of oil embolization to the lungs via venous intravasation. In animal models, slow resorption of the oil-based contrast from the peritoneal cavity may lead to inflammatory or granulomatous reactions. Water-based contrast provides better uterine and ampullary mucosal detail; however, it also has a higher incidence of pain and bleeding following the procedure (Tables 61-7 and 61-8).

TABLE 61-7 HSG Risks

Pain
Bleeding
Vascular intravasation
Contrast reaction
Uterotubal perforation
Postprocedure infection
Radiation to fetus

TABLE 61-8 HSG Contraindications

Active infection (PID)
Recent uterine or tubal surgery
Active uterine bleeding
Pregnancy

There is a purported therapeutic effect of HSG leading to increased rates of pregnancy. This therapeutic effect may be due to lavage of the fallopian tubes, stimulation of cilia, release of peritubal adhesions, alteration of cervical mucus, concomitant therapy, or bacteriostatic effect. There is debate in the literature whether the choice of contrast material leads to significant differences in live birth rates.

UTERUS

NORMAL ANATOMY

The normal uterus is triangular in shape with the fundus forming the base. The fundus is usually straight in contour but may also demonstrate a mildly concave or convex contour.

UTERINE ABNORMALITIES

Uterine filling defects and irregularities can be caused by a number of etiologies (Table 61-9). Smooth uterine filling defects include air bubbles, polyps, leiomyomas, and adenomyomas. Air bubbles are injected through the tubing and cause transient filling defects. Leiomyomas can be intramural, submucosal, or subserosal in location. The majority is intramural in location. Submucosal and large intramural tumors can distort, enlarge, and fill portions of the uterine cavity. Uterine fibroids can also obstruct the cornua or intramural portions of the fallopian tube.

Adenomyosis appears as single or multiple cavities in the uterine wall. Adenomyosis is usually seen in the upper body and fundus, while lower uterine segment cavities are often dilated glands near the cervical isthmus. Synechiae are intrauterine adhesions, which result from trauma such as dilation and curettage. They manifest as focal or diffuse filling defects, which are irregular and angulated in shape. Asherman syndrome is extensive intrauterine adhesive disease associated with infertility.

Diethylstilbestrol (DES) is synthetic estrogen, which was used in the 1940s to 1960s to prevent pregnancy. In female fetuses, exposure to DES interferes with development of mesenchymal layers of the genital tract. Associated anomalies include a hypoplastic uterus with a small, irregular cavity in a T-shape configuration, narrowed endocervical canal with irregular contour, and

TABLE 61-9 Uterine Filling Defects and Irregularity

Retained products of conception	Mucus

short irregular fallopian tubes. Females exposed to DES in utero have twofold risk of abortion and ninefold risk of ectopic pregnancy. There is also an association with the development of clear cell carcinoma of the vagina.

A caesarian section performed utilizing a lower uterine segment incision can produce an irregular defect, which may reveal unilateral or bilateral outpouchings at HSG.

FALLOPIAN TUBES

NORMAL ANATOMY

The fallopian tubes arise at the uterine cornua and are 10 to 12 cm in length. They are divided into four segments—the interstitial segment which travels through the myometrium, the isthmus, the ampulla, and the fimbria. Patent fallopian tubes show free spill of contrast into the peritoneum. Cornual spasm or tubal mucoid plug can mimic tubal occlusion (Table 61-10).

PID is caused by an ascending infection from the lower genital tract and is the most common cause of tubal obstruction leading to infertility. PID causes salpingitis, inflammation of the tubes. Resolving salpingitis is associated with mucosal scarring and peritubal adhesions. The ampullary portion of the tube is the most common site of obstruction. Scarring of the fimbria can lead to ampullary dilation with serous or purulent fluid, termed hydrosalpinx and pyosalpinx respectively. On HSG, hydrosalpinx appears as contrast filling a dilated distal tube. Peritubal adhesions can lead to contrast loculations seen at HSG.

Salpingitis isthmica nodosa (SIN) is glandular mucosal proliferation with tubal irregularity and multiple

Tuberculosis
Endometriosis

diverticula. It usually occurs in the isthmic portion of the tube. SIN is suspected to be postinflammatory in etiology and is associated with PID, infertility, and ectopic pregnancy.

Tubal ligation is performed with clips, bands, rings, ligatures, division, resection, and microinserts. HSG can show bulbous termination of the isthmic portion.

CONGENITAL UTERINE MALFORMATION

The uterus and fallopian tubes develop from paired Müllerian ducts. There is a spectrum of failure of ductal elongation and fusion (Fig. 61-1). Agenesis can occur involving any segment of the duct. The most common

FIG. 61-1 Classification of congenital uterine abnormalities.

TABLE 61-11 Bicornuate Versus Septate Uterus

	CONGENITAL MALFORMATION	INTERCORNUAL ANGLE	INTERCORNUAL DISTANCE	EXTERNAL FUNDAL CONTOUR
Bicornuate uterus	Partial nonfusion of Müllerian ducts	Obtuse >105 degrees	>4 cm	Cleft between horns
Septate uterus	Partial or complete failure of septal resorption	Acute <75 degrees	<4 cm	Normal

form of agenesis is Mayer-Rokitansky-Kuster-Hauser syndrome, which is agenesis of the uterus, cervix, and upper portion of the vagina. The development of the urinary and genital systems is related embryologically. Congenital urinary anomalies can be seen in association with uterine anomalies including unilateral renal agenesis, renal ectopia, cystic renal dysplasia, and duplicated collecting system.

A unicornuate uterus results because of the failure of one of the Müllerian ducts to elongate. The endometrial cavity of a unicornuate uterus is fusiform in shape on HSG. The incompletely developed Müllerian duct may exist as a rudimentary horn or may be absent. The rudimentary horn can have no endometrial cavity, or it can have an endometrial cavity, which may or may not communicate with the unicornuate uterine cavity. Unicornuate uterus carries an increased risk of abortion and premature labor.

Uterus didelphys occurs because of complete failure of the ducts to fuse. There are two separate uterine cavities and cervixes. HSG demonstrates two separate fusiform uterine horns flexed in opposite directions. There may be vaginal duplication or vaginal septum. Uterus didelphys carries an increased risk of spontaneous abortion.

Bicornuate uterus results because of partial nonfusion of the ducts. There is a spectrum of degree of abnormal fusion. In a partial bicornuate uterus, there are two divergent horns, which are fused caudally with communication of the two endometrial cavities. In a complete bicornuate uterus, the myometrial cleft between the horns extends to the internal cervical os, termed bicornuate unicollis. In a bicornuate bicollis uterus, the myometrial cleft extends to the external cervical os. Arcuate uterus is a mild form of bicornuate uterus in which HSG reveals mild concavity of the fundal uterine contour. Gestations are normal term with arcuate uterus.

Septate uterus results due to partial or complete failure of the septum dividing the Müllerian ducts to resorb. This is the most common developmental abnormality. With complete failure of septal resorption, the septum extends from the fundus to the lower uterine segment. With partial failure of septal resorption, the fundal portion of the septum remains. On HSG, contrast fills two

separate uterine horns. There is a high incidence of spontaneous abortion and premature labor because of vascular deficiency of the septum.

On HSG, bicornuate uterus and septate uterus can have overlapping appearances with two separate horns (Table 61-11). The intercornual angle, the intercornual distance, and the external fundal contour can be used to distinguish between the two entities. The bicornuate uterus has an obtuse intercornual angle more than 105 degrees while the septate uterus has an acute intercornual angle less than 75 degrees. The bicornuate intercornual distance is more than 4 cm while the septate intercornual distance is less than 4 cm. The external fundal contour of a bicornuate uterus demonstrates an indentation between the horns, while the external fundal contour of a septate uterus is normal. The multiplanar capability of MRI makes it an excellent modality in assessing the external fundal contour (Table 61-1).

QUESTIONS AND ANSWERS

- Which of the following is the most common location of a periurethral diverticulum in a female with respect to the urethra?
 - Anterior
 - Posterior
 - Anterolateral
 - Posterolateral

ANSWER: D. Periurethral diverticula most commonly occur along the posterolateral wall of the midurethra.

- A cyst is identified in the anterolateral wall of the vagina. Which of the following is the most likely diagnosis?
 - Bartholin cyst
 - Gartner cyst
 - Periurethral cyst
 - Skene cyst

ANSWER: B. Gartner cyst arises from remnants of the Wolffian (mesonephric) duct and is lined by non-mucinous epithelium. Gartner cysts are located in the anterolateral wall of the vagina posterior to the urethra.

- HSG reveals a distorted and enlarged uterine cavity with a smooth filling defect. Which of the following is the most likely diagnosis?
 - Polyp
 - Synechia
 - Leiomyomas
 - DES exposure

ANSWER: C. Leiomyomas can distort and enlarge the endometrial cavity. Submucosal fibroids produce smooth filling defects on HSG.

- HSG reveals two fusiform uterine horns, which are fused caudally with communication of the endometrial cavities. The horns are flexed in opposite directions with an obtuse intercornual angle. Which of the following is the most likely diagnosis?
 - Bicornuate uterus
 - Septate uterus

- Uterus didelphys
- Unicornuate uterus

ANSWER: A. Bicornuate uterus results because of a defect in Müllerian ductal fusion. Classically, the uterine cavity is fused caudally with two divergent horns, which are fusiform in shape. There is an obtuse intercornual angle and a dip in the external fundal contour.

- Which of the following is the most common malignant ovarian neoplasm?
 - Teratoma
 - Mucinous cystadenocarcinoma
 - Serous cystadenocarcinoma
 - Dysgerminoma

ANSWER: C. Serous cystadenocarcinoma accounts for more than one-half of all malignant ovarian neoplasms.

- Which of the following is the most common primary female urethral malignancy?
 - Adenocarcinoma
 - Transitional carcinoma
 - Squamous cell carcinoma
 - Sarcoma

ANSWER: C. Approximately 60% to 70% of urethral carcinomas are squamous cell carcinomas. Approximately 20% of urethral malignancies are TCC, with adenocarcinomas representing only 10% of urethral carcinomas.

- Where do most periurethral cysts originate?
 - Periurethral glands of Skene
 - Cowper glands
 - Glands of Littre
 - Vaginal structures

ANSWER: D. Most periurethral cysts originate from the vaginal structures and do not communicate with the urethra. These cysts have their origin from the Müllerian and Gartner ducts and the Bartholin glands.

- The most common ovarian tumors have their origin from which of the following cell type?
 - Epithelial tumors
 - Germ cell tumors
 - Sex cord-stromal tumors
 - Metastatic tumors

ANSWER: A. Epithelial tumors are the most common lesions, accounting for 60% to 70% of all ovarian neoplasms and more than 85% of malignant neoplasms.

9. Up to what percent of serous cystadenocarcinomas will be bilateral?
- A. 15%
 - B. 22%
 - C. 50%
 - D. 75%

ANSWER: C. Up to 25% of serous cystadenomas and 50% of serous cystadenocarcinomas will be bilateral.

10. Which of the following can be used to distinguish a bicornuate uterus from a septate uterus?

- A. Bicornuate uterus will have an intercornual angle of more than 105 degrees.
- B. The external fundal contour of a septate uterus demonstrates an indentation.
- C. The septate uterus intercornual distance is more than 4 cm.
- D. The external fundal contour of a septate uterus demonstrates a pleated fold.

ANSWER: A. A bicornuate uterus will have an intercornual angle of more than 105 degrees, demonstrate a contour with an indentation, and have an intercornual distance of more than 4 cm.

ULTRASOUND

62 ULTRASOUND PHYSICS

Kenneth Hoyt and Franklin N. Tessler

BASIC PROPERTIES OF SOUND

DEFINITION OF SOUND AND SOURCES

Sound is a form of mechanical energy that possesses the capacity to do work. In response to a transmitted pressure wave, molecules and particles within a medium (e.g., tissue) physically vibrate against each other, causing the energy to propagate. Sound is produced by a vibrating source. In medical ultrasound, the source is a piezoelectric transducer that converts high-frequency electrical energy to sound and vice versa. When placed in contact with tissue, the transducer acts like a piston, producing short bursts or pulses of mechanical energy that propagate through the tissue in a beam-like fashion.

LONGITUDINAL VERSUS TRANSVERSE WAVES

Ultrasound can be classified by the direction of wave propagation in relation to particle vibration. Longitudinal waves, which are used in medical ultrasound, propagate along the axis of particle vibration. However, wave propagation perpendicular to particle vibration can also occur in solid tissue. Termed transverse waves, they propagate over considerably shorter distances than longitudinal waves since they are not transmitted as effectively. In general, only longitudinal waves are considered important in medical ultrasound.

COMPRESSION AND RAREFACTION

A propagating ultrasound wave causes local disturbances in tissue as the particles move back-and-forth.

This mechanical energy is conducted to neighboring particles and allows the wave to propagate further. Compared to unperturbed tissue, *zones of compression* describe regions of slightly higher particle density, while *zones of rarefaction* define regions of slightly lower particle density.

WAVE MOTION

A propagating ultrasound wave may be visualized as a sinusoidal signal that varies in amplitude over time. The *frequency* of the wave is the number of oscillations (cycles) that it undergoes per second (Fig. 62-1). The unit for frequency is hertz (Hz), where 1 Hz equals 1 cycle/s. In medical ultrasound, wave frequency is typically between 2 and 20 MHz, although higher frequencies are used for special applications.

The *period* of a wave is the reciprocal of its frequency, and denotes the time required for the wave to oscillate one full cycle (Fig. 62-2). The physical distance a wave travels over one full cycle is termed the *wavelength*.

Propagation speed is a measure of how quickly ultrasound travels in a given tissue and is influenced by both tissue density and stiffness. An increase in tissue stiffness or a decrease in tissue density results in a corresponding increase in the speed of sound through that tissue (Fig. 62-3). In medical ultrasound imaging, the speed of sound in the human body is assumed to be 1540 m/s.

Typically, ultrasound propagates at a given frequency that is defined as the fundamental (transmit) frequency. However, as the wave propagates, its shape gradually changes, resulting in energy redistribution and generation of waves at multiples of the fundamental frequency. Termed harmonics, these waves contain useful information that can be isolated and exploited to improve visualization of tissues or ultrasound contrast agents.

FIG. 62-1 Amplitude versus time plots describing a low- (left) and high- (right) frequency sinusoidal signal. Note the low-frequency signal has a longer period.

ACOUSTIC PRESSURE AND INTENSITY

The strength or *amplitude* of an ultrasound wave is typically measured by its pressure. Zones of *compression* have a higher pressure than undisturbed tissue, whereas zones of *rarefaction* have a lower pressure. In fact, it is this cyclic oscillation between states of high and low pressure that compel the particles to vibrate back-and-forth and allow ultrasound wave propagation. The plots illustrated in Figs. 62-1 and 62-2 describe signal amplitude, but pressure could be used interchangeably.

An alternative measure of ultrasound strength is *acoustic intensity*. At any point along the path of a propagating ultrasound wave, the intensity is proportional to the square of the pressure. Signal intensity is typically denoted in *decibel*, which denotes the logarithmic ratio of two intensities (or amplitudes). For example, a 40-dB difference between two sounds is equivalent to a 10 000-fold intensity change.

INTERACTION OF ULTRASOUND BEAMS WITH TISSUE

SOURCES OF ATTENUATION

As ultrasound propagates through tissue, there is a loss of energy termed *attenuation*. This progressive reduction in signal amplitude is attributed to two sources. The first results from reflection and scattering of ultrasound as it passes through the tissues and the second is due to absorption, the conversion of wave energy to heat energy. Absorption is the dominant source of ultrasound attenuation in soft tissues.

FREQUENCY DEPENDENCE OF ATTENUATION

Ultrasound attenuation in tissue is highly dependent on signal frequency. Specifically, higher-frequency ultrasound waves are attenuated more than lower-frequency waves in

FIG. 62-2 Sinusoidal signals describing the physical concept of period (left) and wavelength (right).

FIG. 62-3 An ultrasound wave orthogonally incident on a boundary between two tissues characterized by different acoustical impedances. As shown, ultrasound incident at the interface (a) is separated into lower amplitude reflected (b) and transmitted (c) waves.

any given tissue. This means that tissue penetration is compromised at higher frequencies, limiting the amount of useful information that can be extracted at depth. However, since spatial resolution improves with ultrasound frequency, there is a fundamental trade-off between tissue penetration and spatial resolution that must be taken into account during every ultrasound examination.

ACOUSTICAL IMPEDANCE

Ultrasound imaging is based on the detection and display of reflected ultrasound waves called echoes, which are produced at tissue interfaces. In ultrasound imaging, these interfaces represent boundaries between tissue that differs in a property called *acoustical impedance*, which is defined as the product of a tissue's density and the speed of sound within that tissue. Spatial variations in acoustical impedance proportionally influence the amplitude of echoes that are detected to generate the ultrasound image.

If an area of tissue produces echoes of greater amplitude than the surrounding tissue, then this region is referred to as *hyperechoic* or *echogenic*. Alternatively, a tissue region that generates echoes lower in amplitude than the surrounding tissue is termed *hypoechoic*. Lastly, a region of tissue is referred to as *anechoic* if ultrasound passes through with no discernible backscatter. All three terms are used to characterize ultrasound findings.

REFLECTION AND TRANSMISSION

Ultrasound striking a smooth tissue boundary produces a *reflection*. The amount of reflection at an interface is dependent on the acoustical impedance of the two

FIG. 62-4 An ultrasound wave obliquely incident on a boundary between two tissues characterized by different acoustical impedances (or ultrasound propagation speeds). As shown, ultrasound incident on the interface at an angle θ_I (a) is separated into lower amplitude reflected (b) and transmitted (c) waves with angles to the normal θ_R and θ_T , respectively. The transmission angle is governed by the difference in propagation speeds between tissues 1 and 2.

tissues on either side of the boundary, as well as on the angle of incidence of the ultrasound wave. Specifically, ultrasound that strikes a boundary at 90 degrees results in a fraction of the wave being reflected back toward the source, termed specular reflection. The reflected wave (called backscatter) has a lower amplitude. The remainder of the wave is transmitted across the interface (Fig. 62-3).

Ultrasound striking a boundary obliquely also results in wave reflection and transmission. However, the lower-amplitude reflected wave is redirected back away from the source at an angle equal to the incident angle (Fig. 62-4). If the tissue interface is not orthogonal to the ultrasound beam, the reflected wave will not reach the imaging transducer and the echoes will go undetected. Most soft-tissue interfaces encountered in the human body possess relatively small differences in acoustical impedance, which leads to a majority of the incident waves being transmitted into the deeper tissues.

SCATTERING

Scattering is the weak reflection of ultrasound by structures with dimensions smaller than the wavelength of the incident wave (i.e., micrometer scale), and is encountered at rough surfaces or in heterogeneous organs such as the liver. Such reflectors produce reflections in multiple directions, with intensity directly proportional to the frequency and scatterer size. Since specular reflection is highly angle-dependent, images of tissue interfaces or organ boundaries are generally attributed to

the mechanism of scattering, which is less dependent on the incident angle. Furthermore, it is the simultaneous detection and interference of echoes from many neighboring scattering sites that produces the characteristic image texture, called speckle that is associated with solid organs.

REFRACTION

When ultrasound traverses a tissue boundary, the wave may change direction, indicating that the incident angle is different than the transmission angle (Fig. 62-4). This change in direction is termed *refraction* and is attributed to the difference in the speed of sound in the two tissues and on the obliqueness of the incident wave.

ULTRASOUND IMAGING PRINCIPLES

PULSED ULTRASOUND

In medical ultrasound, short bursts of acoustical energy are produced by a transducer and pass through the tissues in a beam-like pattern. As the ultrasound pulses propagate, echoes are generated that travel back to the tissue surface. This backscatter is continuously detected by the transducer and is recorded as a function of time. Assuming an average speed of sound in tissue of 1540 m/s, the time elapsed between transmission and echo detection is used to calculate the depth of the structure that produced the echo. This pulse-echo principle is the foundation for the vast majority of ultrasound imaging.

AMPLITUDE MODE

Mapping the reflected echo amplitude along the beam path as a function of depth is termed amplitude-modulated (or A-mode) imaging. This produces a single scan line or line of sight for a given imaging angle. Beyond some ophthalmic applications, this modality is now rarely used clinically.

MOTION MODE

Motion-modulated (or M-mode) imaging is similar to A-mode ultrasound described in the previous paragraph. An M-mode display maps echo amplitudes to a color scale over time. Today, the M-mode display is most often used in cardiac applications and to document cardiac motion in small embryos.

BRIGHTNESS MODE AND REAL-TIME IMAGING

Sequential acquisition of multiple scan lines produces a two-dimensional cross-sectional image. This is termed brightness-modulated (or B-mode) imaging, since the echo amplitude is mapped to a brightness scale (Fig. 62-5). Typically, the background (absence of echoes) is black and successively lighter shades of gray represent higher echo amplitudes (originating from stronger ultrasound reflectors). Hence, these images are commonly referred to as grayscale images. Transmission of a single pulse and detection of echoes is sufficient to produce a scan line. However, several transmissions may be required if multiple focal points are used, since each focus requires a separate pulse-echo sequence.

Generation of multiple images in rapid succession results in an illusion of motion that is referred to as real-time ultrasound. The time required to collect echoes from the deepest lying reflectors at a given imaging depth determines the delay before the next scan line can be acquired. Because image acquisition depends on the depth and number of scan lines, a deep or wide imaging field of view limits the achievable frame rate. Typical frame rates for pulsed ultrasound imaging are in the order of tens of frames per second and are suitable for real-time visualization of tissue structures and organs. High frame rates are needed to image fast-moving structures such as the fetal heart.

THREE-DIMENSIONAL IMAGING

In three-dimensional ultrasound imaging, the ultrasound system collects echoes from a volume of tissue. The resultant data may be analyzed to produce two-dimensional images in any arbitrary plane or shaded, volumetric images.

FIG. 62-5 A pulse-echo sequence allows acquisition of one scan line of ultrasound data. The subsequent acquisition of scan lines produces a two-dimensional cross-sectional B-mode (grayscale) ultrasound image for a fixed tissue depth. The number of scan lines used in image formation determines the image width.

RESOLUTION

One measure of ultrasound image quality is the spatial resolution, which is defined as the ability to resolve closely spaced objects as distinct structures. *Axial resolution* describes the ability to distinguish objects along the ultrasound beam path and is determined by the transmit pulse length. In ultrasound, the pulse length is a product of the wavelength and number of transmit cycles (typically two or three). Since wavelength is the inverse of frequency, shorter pulses improve axial resolution through increases in ultrasound frequency. But, as noted, increasing the ultrasound frequency also increases attenuation, minimizing penetration depth. Therefore, the selection of ultrasound frequency for any application is always a compromise between spatial resolution and depth.

Lateral resolution is defined as the ability to distinguish objects located at right angles to the ultrasound beam, parallel to the transducer surface. Lateral resolution is primarily influenced by the ultrasound beam width. For unfocused transducers, the lateral resolution is highest in the Fresnel zone closest to the transducer, and decreases as the beam diverges in the far field, or Fraunhofer zone. However, most modern transducers are focused either mechanically or electronically to produce beams that are optimized for a specific depth.

Finally, *elevational resolution* refers to the spatial resolution perpendicular to the imaging plane. Decreasing the elevational resolution results in a greater effective slice thickness, which produces echoes from structures adjacent to the imaging plane. It is especially important in three-dimensional imaging applications.

PULSED DOPPLER

In medical ultrasound imaging, the Doppler effect refers to the change in frequency of a sound beam as it interacts with moving structures, typically red blood cells. The Doppler frequency (f_D) and the received ultrasound frequency (f_0) are related to the velocity (v) of the moving scatterers by the following equation:

$$v = \frac{f_D c}{2f_0 \cos \theta}$$

where c and θ denote the speed of sound and angle between the ultrasound beam and moving scatterers, respectively. A positive Doppler shift indicates that scatterers are moving toward the ultrasound beam while a negative Doppler shift denotes motion away. Note that there is no Doppler shift at an angle of 90 degrees.

Doppler imaging is typically performed at an angle of 60 degrees or less to minimize the effects of errors in setting the Doppler angle.

Blood velocity measurements using ultrasound are made using the pulsed Doppler technique, which detects Doppler shifts within a small area of interest called the sample volume. The operator adjusts the sample volume to match the size and depth of the vessel being examined. In pulsed Doppler, a series of ultrasound pulses are transmitted at a given rate (termed pulse repetition frequency, PRF) and echoes are acquired periodically. (An older Doppler technique uses continuous insonation along a line of sight, but it is rarely used in radiology.)

The sample volume typically encompasses a range of blood flow velocities at any given instant; therefore, the pulsed Doppler signal encodes a corresponding range of Doppler shift frequencies. Contributions from much slower-moving tissue structures such as blood vessel walls are removed from the Doppler signal using wall filters, which allow higher-frequency signals to pass.

The Doppler spectrum is computed using a mathematical technique known as the fast Fourier transform. The resultant Doppler spectral tracing is presented as a moving graph, where the vertical axis represents the magnitude of the Doppler shift frequency (or velocity), corrected for the Doppler angle, and the horizontal axis denotes time. The Doppler spectrum is usually displayed along with a grayscale or color Doppler ultrasound image, which lets the operator adjust the Doppler angle to match the flow axis. Since the Doppler shift frequency is within the human audible frequency range, it is also typically played through speakers on the ultrasound system.

COLOR DOPPLER

Color Doppler imaging uses color coding to denote flow velocity and direction within a region of interest. Similar to B-mode ultrasound, a sequence of pulsed beams generates signals from a given region. Velocity information is derived in the same manner as in pulsed Doppler, but a large number of volumes are sampled along each beam. Depending on the size of the imaging field of view, the number of sample volumes can easily reach thousands. Therefore, pulse-echo acquisitions from a given location are limited to 4 to 24 echo sequences (termed the ensemble length or packet size). The rate at which this occurs is determined by the PRF. Since echoes from deeper-lying structures must be received before another pulse-echo sequence can be initiated, color flow imaging at depth requires a longer delay between pulses, which means a lower PRF.

FIG. 62-6 Illustration of color flow and power Doppler signal mapping. The spectra of two different Doppler signals are depicted. For a given Doppler signal and sample volume, color flow Doppler estimates and maps the mean Doppler frequency shift and power Doppler measures and maps the signal amplitude.

Because the ensemble length used for color flow Doppler is considerably shorter than that used for pulsed Doppler, an alternative mathematical technique called autocorrelation is employed to give an estimate of the Doppler shift frequency after wall filtering. The blood velocity estimates derived using this technique are cruder than those used in pulsed Doppler imaging. However, color Doppler is still very helpful to depict flow within a relatively large area, as opposed to the small sample volume used in pulsed Doppler.

In color flow imaging, the sign and mean value of velocity estimates are mapped to a color scale at each location within the region of interest. Typically, red and blue denote flow toward or away from the transducer, respectively (Fig. 62-6). The color flow image is overlaid on a B-mode image for anatomical mapping. Owing to the amount of processing needed, the frame rate is usually less than that for grayscale imaging alone. However, the frame rate can be improved by reducing the size of the color region of interest.

POWER DOPPLER

As mentioned in the previous section, color flow Doppler estimates the mean Doppler frequency shift using a sequence of pulse-echo acquisitions and maps these measurements to an image. An alternative but

similar imaging technique, known as power Doppler, estimates and maps the total strength (power) of the Doppler signal within each sample volume (Fig. 62-6). For blood flow applications, the power Doppler value corresponds to the number of red blood cells in a given sample volume. Power Doppler imaging offers more sensitive detection of blood flow, allowing improved depiction of slow flow and small vessels, but at the expense of eliminating directional information.

CONTRAST IMAGING

Ultrasound contrast agents are composed of gas-filled micrometer-sized spheres, typically known as microbubbles. The use of low-diffusivity gas and thin stabilizing shell permits a circulatory lifetime in the order of tens of minutes. Because of a large acoustical impedance difference between the microbubbles and the surrounding blood, they are excellent ultrasound scatterers and improve the sensitivity to blood flow.

Ultrasound contrast agents undergo an oscillatory movement, or resonate, in response to an ultrasound field, a process called stable cavitation. Under sufficiently high ultrasound pressures, this can lead to non-linear scattering and generation of echoes with frequency components at harmonic multiples of the transmit frequency. These harmonic signals can be selectively isolated from the backscatter signals using various signal processing and pulsing techniques to improve image contrast. At present, contrast agents are only approved for echocardiographic applications in the United States, although they are widely employed elsewhere.

ULTRASOUND INSTRUMENTATION

TRANSDUCER ARRAYS

An ultrasound transducer converts electrical signals to acoustical energy and vice versa. In any medical ultrasound system, the transducer transmits the acoustic pulses that propagate through tissue and receives the echoes that are generated. The received echoes are then converted to electrical signals for processing. To allow the sound pulses to pass from the transducer into the patient, a coupling gel is placed between the transducer and the skin.

The active elements in a typical ultrasound transducer are small piezoelectric elements. When excited with a very short high-frequency electrical signal, a piezoelectric element mechanically vibrates and generates an ultrasound pulse. The dominant frequency of this

ultrasound pulse is the same as the electrical signal used for excitation. However, there are also additional frequencies that are above and below this nominal frequency. This spread or range of frequencies is termed the bandwidth of the ultrasound pulse. The transducer bandwidth defines the range of frequencies that can be transmitted and received. Higher-bandwidth transducers (often called broadband) are suitable for a wider range of clinical settings.

The piezoelectric elements that make up a transducer can be arranged in a variety of configurations to suit various applications. The most common types are linear, curved, and phased arrays. Linear and curved arrays are composed of 120 to 250 elements. Small subgroups of elements are activated sequentially to produce pulses and receive echoes along a series of scan lines to make up the image. The number of transducer elements activated and the timing sequence determines the transmit focal depth. Linear arrays produce a series of beams that are parallel to each other, resulting in a rectangular image. Curved arrays have a convex shape, so the beams diverge at depth, producing a sector format image that is wider at the bottom. Phased arrays are typically made of 120 or more elements and are much smaller than linear and curved arrays. They function by firing all the elements to form an ultrasound beam. Through proper timing of individual element excitation, the ultrasound beam can be steered through a field of view to produce a sector image.

As noted above, modern ultrasound transducers are also designed to focus at particular depths. Electronic focusing, which is achieved by applying electronic delays when the ultrasound pulses are transmitted and received, is the most flexible. This allows the operator to adjust the focal zone to match the depth of the area of interest.

BASIC FUNCTIONAL LAYOUT OF AN ULTRASOUND SYSTEM

Modern ultrasound systems are highly complex. However, their basic functional layout includes transducer probes, a central processing unit (CPU), system controls, display, keyboard, print network, and storage (Fig. 62-7).

The CPU directs the overall operation of the ultrasound system and is usually a collection of microprocessors. Under direction from the CPU, the transducer receives a high-voltage signal and acquires echoes that are amplified and transferred back to the CPU for processing and display. External controls allow the operator to optimize the image for a particular examination. The operator typically adjusts the system using a

FIG. 62-7 Block diagram illustrating the basic functional layout of a typical ultrasound imaging system.

keyboard and a series of switches and dials. The resultant images are viewed on a monitor and printed or saved digitally for subsequent review.

IMAGING PARAMETERS AND CONTROLS

In ultrasound imaging, the received echoes are typically very weak and must be amplified. An adjustable master gain control allows amplification of all the echoes. However, since the ultrasound beam is attenuated as it passes through tissue, echoes from deeper structures are weaker. To compensate for this, depth-dependent amplification, known as time gain compensation, is used. In older equipment, the time gain compensation controls were set by the operator. However, many newer machines set the time gain compensation automatically.

The received echoes span a very wide range of values (up to 120 dB), which is called the dynamic range. However, since ultrasound system can only display a much smaller range (usually approximately 40 dB), the echo data are compressed logarithmically before it is displayed. In most ultrasound systems, dynamic range mapping is under the operator's control. Lower values are typically used to improve grayscale contrast between vessels and adjacent structures, while higher settings are used for soft-tissue imaging.

Other common user-adjustable parameters include pre- and postprocessing, grayscale mapping, smoothing, and frame averaging. The last control, which averages successive frames to produce a more pleasing image, also has the effect of blurring small moving structures such as the embryonic heart. This emphasizes the importance of optimizing the machine controls for each clinical application.

Various controls also exist for Doppler imaging. In pulsed Doppler, the sample volume size and position are defined by the user. The sample volume size determines the transmitted pulse length and its depth along the beam axis establishes the PRF. Although the sample volumes are fixed in color flow and power Doppler imaging, the depth is adjustable and establishes an upper limit on the achievable frame rate. The frame rate is also limited by the Doppler packet size (ensemble length). A larger packet size improves flow velocity estimates but lowers the frame rate.

In all Doppler imaging modes, wall filters remove low-frequency clutter below a certain cutoff frequency from the Doppler signal. This cutoff frequency is adjustable by the user. In color flow and pulsed Doppler, the zero point of the Doppler display, called the baseline, is also adjustable. When the baseline is centered, there is equal room above and below it to display flow toward or away from the transducer. However, if flow in a vessel is unidirectional, the baseline may be adjusted accordingly.

ULTRASOUND ARTIFACTS

PROPAGATION

Ultrasound reverberations occur when echoes shuttle back-and-forth between two highly reflective structures. For example, strong echoes (such as those originating at the wall of a cyst) may reflect off the transducer surface and be redirected into the body, only to return to the transducer after an additional delay. This produces spurious echoes deep to the interface. In some situations, multiple reflections occur within or adjacent to small structures such as gas bubbles. This produces a train of equally spaced echoes that are called ringdown or comet-tail artifacts. Multiple reflections also may occur if a structure lies between the transducer and a highly reflective interface such as the diaphragm, producing a mirror image artifact.

Refraction occurs when an ultrasound beam strikes a tissue boundary obliquely, changing the beam's direction. This is attributed to a difference in the speed of sound in the two tissues. Echoes produced from a refracted ultrasound beam are misregistered by the ultrasound system, resulting in image distortion and a loss of resolution. As noted previously, ultrasound systems assume that the speed of sound in tissue is a constant 1540 m/s. However, the actual speed varies from tissue to tissue (Table 62-1), and even within a particular type of tissue. Any deviation from the assumed speed of sound leads to misregistration, as well.

TABLE 62-1 Propagation Speed of Ultrasound in Various Biological Tissues

TISSUE TYPE	SPEED OF SOUND (m/s)
Air	330
Fat	1450
Water	1480
Soft tissue (average)	1540
Liver	1550
Kidney	1560
Blood	1570
Muscle	1580
Tendon	1750
Bone	4080

Side lobe artifacts result from the interactions of off-axis components of the sound beam with tissues. Although these components are weak, they produce low-level echoes that may simulate debris in cystic structures. Similarly, slice thickness or beam width artifacts occur when the ultrasound beam interacts with structures just outside the desired imaging plane. This can produce spurious echoes at the margins of vessels and other fluid-containing structures.

ATTENUATION

When an ultrasound beam encounters structures that absorb or reflect it strongly, the pulses that are transmitted to the deeper tissues are weakened. In some cases, deeper echoes are minimal or absent, leading to artifacts known as *acoustic shadows*, which are analogous to shadows in beams of light. Acoustic shadowing is most often associated with interfaces where there is a large difference in acoustical impedance, such as bone, calcium, metal, or gas. Conversely, when the beam passes through a structure that transmits sound more readily than the tissues on either side of it, deeper structures appear more echogenic. This artifact, termed *acoustic enhancement* or increased-through transmission, is helpful to distinguish fluid from solid structures.

PULSED DOPPLER

Sampling theory requires that PRF for a pulsed Doppler system be at least twice the Doppler shift frequency to be detected. This limit is known as the Nyquist sampling rate. Because the PRF is restricted by the time required to collect echoes from each pulse before the next one is sent, this limits the maximum Doppler frequency shift (velocity) that can be accurately detected. When the PRF is not high enough, the

system cannot determine the true Doppler shift. Known as aliasing, this artifact is easily recognized by appearance of the spectral tracing “wrapping around” from the top to bottom of the pulsed Doppler display window, suggesting a reversal of blood flow. This artifact may be eliminated by increasing the system PRF, adjusting the baseline, reducing the Doppler frequency, or increasing the Doppler angle.

COLOR DOPPLER

The Nyquist limit also applies to color Doppler imaging. If the color Doppler PRF is not sufficiently high, aliasing occurs, and high-frequency signals appear incorrectly as reversed flow. Aliasing artifacts can generally be removed in color Doppler by increasing the PRF.

Color Doppler not only detects motion from blood flow but also from slow-moving adjacent structures such as vessel walls. These signals, called clutter, are removed by wall filters, which suppress low-frequency signals below a cutoff frequency. Although wall filters are effective in removing low-frequency noise, care must be taken so that signals from slowly moving blood are not eliminated.

Twinkling artifact is unique to color flow imaging. It results from interaction of the sound beam with the irregular surface of stones and other calcifications, and appears as alternating bands of color deep to the stone. In some cases, it is helpful to distinguish stones from other small reflective structures.

BIOLOGICAL EFFECTS OF ULTRASOUND

THERMAL

Ultrasound is a form of mechanical energy that is absorbed by tissue and converted to heat as it propagates. The temperature rise is tissue-dependent and is more pronounced in highly attenuating tissues such as bone. Heat is also produced at the transducer surface. Factors that determine the amount of heating include the tissue’s ability to conduct heat, tissue perfusion, and the ultrasound intensity and exposure time. The thermal index has been adopted as a standard to minimize any thermal bioeffects associated with ultrasound exposure. Displayed on the scanner monitor for reference, the thermal index value represents the ratio between the current ultrasound power and the intensity that will result in a maximum temperature rise of 1°C.

MECHANICAL

The propagation of ultrasound through tissue imparts a low-level radiation force that perturbs the tissue along the beam path. This absorption-based mechanical effect can induce fluid movements termed streaming and may also stress cells and tissue interfaces. However, radiation forces associated with diagnostic ultrasound exposures are generally considered unlikely to promote any adverse bioeffects.

CAVITATIONAL

Cavitation describes the ultrasound-induced formation and behavior of gas bubbles at high negative peak pressures. Stable cavitation denotes an oscillatory movement of gas bubbles in response to ultrasound and its cyclic pressure variations. If the oscillations become too large, gas bubbles may implode. Termed inertial cavitation, this can lead to extremely high localized temperatures and significant tissue destruction. Therefore, the mechanical index was adopted as a standard to quantify the likelihood of cavitation-related bioeffects. Commercially available ultrasound scanners are limited to a maximum mechanical index value of 1.9 for most diagnostic purposes.

ALARA PRINCIPLE

An acronym for “as low as reasonably achievable,” ALARA is an important concept in ultrasound imaging, as well as in other medical imaging modalities. The ALARA principle is based on the assumption that any amount of exposure to ultrasound energy can increase (even minutely) the risk of adverse bioeffects. The guiding principle of ALARA is to keep the patient exposed to ultrasound energy as low as possible for a given diagnostic result. In general, Doppler ultrasound deposits more energy in the tissues than grayscale imaging—therefore, its use in very early pregnancy should be restricted. However, it is generally agreed that ultrasound exposure in typical clinical applications, including early obstetric imaging, is very safe.

QUESTIONS AND ANSWERS

- Concerning ultrasound, which of the following is *true*?
 - Transverse waves propagate over longer distances.
 - Bone conducts sound more slowly than soft tissue.
 - It is a form of mechanical energy.
 - Period is the distance a wave travels during one full cycle.

ANSWER: C. Like all sound, ultrasound is a form of mechanical energy that is transmitted through a solid, liquid, or gaseous medium.

- Concerning the frequency of ultrasound, which of the following is *true*?
 - Higher-frequency ultrasound penetrates more readily than lower-frequency sound.
 - Frequency is directly related to spatial resolution.
 - Modern transducers produce a narrower range of frequencies.
 - Most ultrasound transducers operate at 15–20 MHz.

ANSWER: B. As the frequency goes up, the spatial resolution increases at the expense of penetration.

- Concerning ultrasound imaging modes, which of the following is *true*?
 - A-mode produces images along a single line of sight.
 - M-mode produces images along multiple lines of sight.
 - Increasing the image depth results in a higher frame rate.
 - In B-mode scanning, the returning echo frequency is mapped to a gray scale.

ANSWER: A. A-mode ultrasound detects echoes from structures along a single line of sight.

- Which of the following statements about spectral Doppler ultrasound is *true*?
 - Doppler angle should not be less than 60 degrees.
 - Lower the PRF, the higher the Nyquist limit.
 - Wall filters remove high-frequency components from the Doppler signal.
 - In medical applications, frequency shifts are usually in the audible range.

ANSWER: D. Doppler shifts are typically in kilohertz, and so fall well within the range of human hearing. Experienced ultrasound operators can grossly estimate a stenosis based on the pitch of the audible shift.

- Which of the following statements about color Doppler imaging is *true*?
 - Less accurate than spectral Doppler
 - Depicts flow over a smaller region of interest than spectral Doppler
 - Frame rates are higher than for grayscale imaging.
 - No directional information

ANSWER: A. Color Doppler imaging provides a less accurate measure of flow velocity than spectral Doppler, but depicts blood flow over a much larger area.

- Concerning ultrasound transducers, which of the following is *true*?
 - Phased arrays are larger than linear arrays.
 - Convert one form of energy to another
 - Coupling agent is used for patient comfort.
 - Most transducers have a single element.

ANSWER: B. Ultrasound transducers convert electrical signals to sound at transmit and do the opposite at receive.

- Which of the following statements about ultrasound artifacts is *true*?
 - Aliasing occurs with spectral Doppler, but not color Doppler imaging.
 - Twinkling artifact is only seen with grayscale imaging.
 - The assumption of a constant ultrasound transmission speed in tissues is responsible for some artifacts.
 - Comet-tail artifacts appear between the transducer and the interface that produced them.

ANSWER: C. Pulse-echo imaging is based on the assumption that the speed of ultrasound in tissue is a constant 1540 m/s. However, this assumption is incorrect for some types of tissue, resulting in misregistration artifacts.

8. Which of the following will reduce aliasing when flow is toward the transducer?
- A. Increasing the PRF
 - B. Increasing the Doppler frequency
 - C. Reducing the Doppler angle
 - D. Moving the baseline up

ANSWER: A. Increasing the PRF raises the Nyquist limit, and hence makes it possible to detect higher-velocity flow without aliasing. All the other choices have the opposite effect.

9. Concerning bioeffects, which of the following is *true*?
- A. Gas bubble implosion is a thermal effect.
 - B. Thermal index uses the intensity needed to cause a temperature rise of 0.5°C as a reference point.
 - C. Stable cavitation is related to cyclic pressure variation in the ultrasound beam.
 - D. Doppler imaging results in less energy deposition than grayscale imaging.

ANSWER: C. Stable cavitation refers to oscillation of tiny gas bubbles in tissue in response to pressure variations in the ultrasound beam.

10. Concerning the interaction of ultrasound with solid organs, which of the following is *true*?
- A. Interfaces with large differences in acoustical impedance cause weak reflections.
 - B. Specular reflections predominate.
 - C. Speckle in solid organs results from scattering and interference.
 - D. Low-frequency sound is absorbed at a higher rate than high-frequency ultrasound.

ANSWER: C. In solid organs like the liver, scattering and interference predominate to produce a typical echotexture that is called speckle.

sonogram. It is divided into right and left lobes, which are separated by an oblique plane that intersects the middle hepatic vein and the gallbladder fossa. The right lobe, in turn, is divided into anterior and posterior segments, which are demarcated by a roughly horizontal plane that follows the course of the right hepatic vein. The intersegmental fissure divides the medial and lateral segments of the left lobe. Finally, the fissure for the ligamentum venosum bounds the caudate lobe anteriorly. All of the structures that demarcate the hepatic lobes and segments are usually well visualized on ultrasound, and knowledge of typical anatomy and common variations is essential for localization of focal liver lesions.

Sonographically, the hepatic parenchyma is of medium-level echogenicity that is slightly higher than that of the adjacent right renal cortex. Superiorly, the liver is bounded by the diaphragm, which appears as a curvilinear bright reflector. Liver size varies greatly, but the craniocaudal span of the right lobe is typically less than 15 to 16 cm in adults. The liver is traversed by portal and hepatic veins, which are usually readily visible as anechoic structures. The hepatic arteries are generally not as prominent on grayscale ultrasound, although they are easily depicted on color Doppler imaging. The inferior vena cava (IVC) is also easily seen as it courses craniocaudally along the posterior aspect of the liver.

CIRRHOSIS AND STEATOSIS

The liver usually appears normal in early cirrhosis. As cirrhosis advances, the liver becomes increasingly coarse and nodular, although these changes may be subtle. The gross morphologic changes in cirrhotic livers that are manifest on CT and MRI, including contour nodularity and enlargement of the caudate lobe, are also visible sonographically. Surface nodularity is most easily appreciated by scanning the anterior liver margin with a high-frequency linear array transducer. Visualization of the hepatic contour is also facilitated in the presence of ascites.

Deposition of fat in the liver produces an appearance that often results in a coarse echotexture. This is usually accompanied by an increase in backscatter, which causes the liver to appear much more echogenic than the cortex of the right kidney. Fatty deposition also attenuates the sound beam, so specular reflectors such as the diaphragm and the walls of the portal veins appear less prominent. Unfortunately, these are subjective findings, and it is easy to over- or undercall steatosis sonographically. As well, because echogenicity is a relative term, it is important to be aware that steatosis may significantly alter the appearance of focal liver lesions.

63 ABDOMINAL ULTRASOUND

Franklin N. Tessler

LIVER

NORMAL ANATOMY AND ULTRASOUND APPEARANCE

The liver is the largest organ in the abdomen and is usually the anchor point for any nonfocused abdominal

INFECTION

Acute viral hepatitis may cause the portal triads to appear more echogenic than their surroundings, resulting in the so-called starry sky pattern, but the liver is often normal appearing. *Bacterial infection* may cause one or more abscesses, which often appear solid early in their course, progressing to a cystic appearance as they liquefy. *Amebic abscesses* have a similar appearance, and may be differentiated on the basis of serologic testing and the patient's clinical history. *Hepatic candidiasis*, which is most commonly encountered in immunocompromised patients, typically appears as multiple, hypoechoic foci. However, in some cases, the sonographic finding of hypoechoic lesions with a central echogenic focus may be a helpful clue to the diagnosis. Finally, *echinococcal infection* may affect the liver, resulting in cysts that vary from simple to complex.

FOCAL FATTY CHANGE AND SPARING

In addition to the diffuse pattern noted earlier in this chapter, fat may be deposited in a focal or multifocal pattern that simulates solitary or multiple echogenic masses. Unlike true space-occupying lesions, however, focal fat tends not to distort normal structures such as vessels. In problematic cases, CT or MRI can be helpful to confirm the diagnosis. Conversely, fatty livers may harbor spared areas that contain less fat than the adjacent liver parenchyma and hence appear less echogenic. Often, these appear in characteristic locations, notably in the medial segment adjacent to the portal vein and adjacent to the gallbladder. While focal sparing may simulate neoplasm, it generally has an elongated or geographic appearance. And, like focal fatty change, focal sparing tends not to distort vessels.

CYSTS

Hepatic cysts are common incidental findings on liver sonograms. Most are benign epithelial cysts that have little or no clinical significance unless they become large or infected, a rare occurrence. Although benign cysts may appear complex, the greater the number of septations or mural nodules, the higher the suspicion for biliary cystadenoma or cystadenocarcinoma, which may be further assessed with multiphasic CT or MRI. Multiple cysts are also commonly seen in patients with the adult form of polycystic kidney disease.

BENIGN HEPATIC NEOPLASMS

Cavernous hemangiomas are the most common benign liver neoplasms. They are encountered frequently as incidental findings in clinical practice. The typical lesion is small, well defined, and uniformly echogenic, without a hypoechoic halo. Often, they exhibit slightly increased through transmission because they contain multiple vascular spaces. In the setting of steatosis, however, they may appear less echogenic than the adjacent reflective liver parenchyma. In young asymptomatic patients without known or suspected malignancy, they may be safely ignored. If there is any doubt as to the diagnosis, further imaging with multiphasic CT or MRI may be warranted for confirmation. (In some centers, contrast-enhanced ultrasound is a viable alternative for sonographic evaluation of hemangiomas and other focal liver lesions).

Focal nodular hyperplasia is a benign tumor that is most often encountered in young women. The ultrasound appearance is usually nonspecific, although at times ultrasound may demonstrate a characteristic central scar. Similarly, the sonographic findings in *hepatic adenoma*, a benign neoplasm that is associated with oral contraceptive use in women, are not specific. In both instances, other imaging modalities or percutaneous biopsy are often needed to make the diagnosis.

MALIGNANT HEPATIC NEOPLASMS

Hepatocellular carcinoma (HCC) is the most common form of primary liver malignancy. It is most commonly encountered in patients with cirrhosis, particularly the alcoholic variety. The ultrasound findings range from solitary, fairly well-defined masses to subtle, diffuse infiltration, which may be echogenic, hypoechoic, or mixed. Invasion of the portal and hepatic veins is an important distinguishing feature, especially if arterial flow is demonstrated within malignant tumor thrombus using color and spectral Doppler ultrasound.

A variety of other primary malignant tumors may arise in the liver; however, their ultrasound appearance is nonspecific. Much more common are *metastatic liver lesions*, which have extremely variable ultrasound appearances that range from focal masses to subtle, diffuse alterations of liver architecture. Colorectal and other gastrointestinal cancer metastases tend to be echogenic, as do metastases from carcinoid tumors and renal cell cancers. Calcifications may be seen in tumors with a mucinous component. Lymphomatous liver involvement tends to be hypoechoic, but there is considerable overlap, and percutaneous biopsy under ultrasound or CT guidance may be required to establish a diagnosis before initiating therapy.

PORTAL HYPERTENSION

Increased portal venous pressure may be caused by intrahepatic pathology (typically cirrhosis) or extrahepatic conditions, such as portal vein or splenic vein thrombosis. As the portal venous pressure rises, flow in the main portal vein as depicted by color or spectral Doppler sonography slows and eventually reverses. There is an intermediate stage in which the portal vein is patent, but the flow rate is below the Doppler detection threshold. In these instances, grayscale sonography may demonstrate to-and-fro motion within the portal vein, avoiding the misdiagnosis of portal vein thrombosis. This pitfall highlights the role of grayscale imaging in diagnosing nonocclusive thrombosis anywhere in the portal or hepatic venous system, as small thrombi may be obscured on color flow, particularly if the gain and scale settings are incorrect.

Over time, thrombosis of the portal vein may lead to *cavernous transformation*, which refers to the development of periportal collateral vessels. These collaterals may become quite large, mimicking the portal vein itself. In some patients, collaterals that develop around the gallbladder may be a clue to the diagnosis.

With increasing portal venous pressure, flow is preferentially directed through portosystemic collaterals, which may be seen sonographically. These include the coronary vein, perigastric and perisplenic varices, and the paraumbilical veins, which course from the left portal vein to run along the falciform ligament toward the umbilicus. Indirect signs of portal hypertension include ascites and splenomegaly, which are easily depicted sonographically.

THERAPY OF PORTAL HYPERTENSION

Historically, surgical shunts played an important part in the treatment of portal hypertension. Their role has diminished over time, but operative shunts are still sometimes performed or otherwise encountered in clinical practice. These shunts, which are surgically created anastomoses between the portal and systemic circulations, include mesocaval (portal vein to superior mesenteric vein), portocaval (portal vein to inferior vena cava), and splenorenal (splenic vein to left renal vein) shunts. With meticulous technique, it is often possible to demonstrate shunt patency.

In recent years, transjugular intrahepatic portosystemic shunts (TIPS) have assumed a greater role in the treatment of patients with portal hypertension. These shunts are placed via the transjugular route, and consist of one or more metallic stents that course from the portal vein to the right or middle hepatic vein. Because TIPS are prone to complications that lead to shunt failure, ultrasound surveillance is vital for management of these patients.

Doppler assessment of TIPS includes color flow and spectral Doppler interrogation of the shunt itself, as well as the entire portal venous system and the hepatic veins. Peak flow velocities should be measured in the main portal vein beyond the shunt orifice, at the portal vein terminus, at midshunt, and in the hepatic vein terminus of the shunt. Flow velocities typically rise toward the outflow end of the shunt. Flow in the main portal vein should be antegrade (into the liver), while flow within intrahepatic portal vein branches usually is retrograde.

Shunt thrombosis is usually easily demonstrated, but criteria for the diagnosis of stenosis remain controversial. Because stenosis decreases flow, shunt velocity has received the widest attention. A flow rate of 90 cm/s has been recommended as a normal lower limit, but this is not universally accepted. Changes from baseline also may be a clue to developing stenosis. It is therefore helpful to obtain baseline flow measurements within 1 week after shunt placement, although acoustic shadowing may impair visibility in the first few days.

BUDD-CHIARI SYNDROME

Budd-Chiari syndrome refers to the effects of obstruction to hepatic venous outflow at any level, whether caused by intrinsic (e.g., thrombi, webs) or extrinsic causes (e.g., masses obstructing the cavoatrial junction). Sonographically, flow in the hepatic veins may be dampened, reversed, or absent. As well, grayscale ultrasound may demonstrate enlargement of the caudate lobe and signs of associated portal venous hypertension, such as ascites and splenomegaly. Similarly, bone marrow transplant and other patients with *hepatic venoocclusive disease* may show diminished portal venous flow, although sonography is insensitive for detection of this condition.

Patients with right heart dysfunction may have large hepatic veins with increased pulsatility. Increased pulsatility is also sometimes demonstrated in the portal vein in these patients, although this is often a normal finding in young individuals. Conversely, hepatic vein flow may be dampened or monophasic in patients with cirrhosis.

PORTAL VENOUS GAS

Gas in the portal venous system almost always results from extrahepatic pathology. Gas in the portal vein was formerly thought to be a premorbid condition associated with gastrointestinal tract necrosis, but it also may occur in patients with benign intestinal pneumatosis. On ultrasound, portal vein gas appears as bright echoes that move in the direction of blood flow. They may be distinguished from red cell clumps, which are a clinically

insignificant finding, by the presence of sharp spikes in the portal vein spectral Doppler tracing.

HEPATIC TRANSPLANTATION

Ultrasound plays a central role in the evaluation of patients after whole and partial liver transplants. Because the hepatic artery assumes the primary role in supplying blood to the liver following transplantation, verification of arterial patency is the most important part of the sonogram. Hepatic arterial thrombosis is an early complication that has a high mortality rate. Signs of hepatic arterial thrombosis include absent flow in the hepatic artery and its intrahepatic branches, although intrahepatic flow may be demonstrated in the presence of collaterals, especially in children.

Hepatic arterial stenosis may be an early or late complication. An attempt should be made to image the anastomosis between the donor and recipient hepatic arteries directly. A perianastomotic velocity rise (more than 200 cm/s) and turbulence are considered suspicious, especially in the setting of declining hepatic function. Often, however, the anastomosis cannot be visualized because of overlying bowel gas and dressings. Indirect signs of stenosis include a decrease in the resistive index within intrahepatic arterial branches to less than 0.5. Decreased echogenicity within the liver parenchyma and along the bile ducts is worrisome for necrosis.

In addition to the hepatic arterial system, the postoperative scan should evaluate the portal vein and IVC to look for velocity gradients or luminal narrowing at their respective anastomoses. Surveillance for hematomas, bilomas, seromas, and abscesses is also essential. Finally, although rejection is an important clinical concern, ultrasound plays little role in its diagnosis.

GALLBLADDER

NORMAL, CHOLELITHIASIS, AND SLUDGE

The gallbladder typically lies in the right upper quadrant, extending obliquely from the interlobar fissure, although its position varies considerably. Anatomic variants include prehepatic and intrahepatic locations; occasionally, the gallbladder may extend through the foramen of Winslow into the lesser sac. Variations in size and configuration are even more frequent, and folds or kinks are seen commonly. The normal gallbladder usually measures no more than 4 to 5 cm in transverse diameter. Bile is anechoic or nearly so, accounting for the echolucent appearance of the normal gallbladder on grayscale ultrasound. An echogenic wall that measures

up to 3 mm in thickness bounds the gallbladder. Because the gallbladder contracts after a meal, biliary sonography is best performed after a fast. Contraction makes it more difficult to visualize calculi and other pathology, and may lead to artifactual wall thickening.

Sonography is a mainstay in the noninvasive diagnosis of *cholelithiasis*. Gallstones typically appear as dependent echogenic structures that exhibit acoustic shadowing, although the latter sign may not be present if the scanning frequency is too low or the focal zone is not set correctly. Most gallstones consist primarily of cholesterol, with a minority consisting of calcium bilirubinate. Minute calculi, also called “biliary sand,” may not exhibit shadowing unless they are clumped. Turning the patient to move the stones toward the fundus facilitates this. Even if the gallbladder appears normal with the patient in the supine position, rotating the patient into the left lateral decubitus or prone-oblique position may cause stones hidden in the neck to move into the body or fundus, where they are more readily identified.

As the number of calculi increases, the residual lumen becomes less apparent, and it may be very difficult to distinguish the stone-filled gallbladder from adjacent structures. The so-called wall-echo-shadow sign is often helpful to distinguish a contracted gallbladder filled with stones from bowel. This sign comprises two echogenic lines (the gallbladder wall and the anterior margin of the calculi) separated by a thin hypoechoic layer. Care must be taken not to confuse this sign with mural calcification (porcelain gallbladder) or gallbladder wall air (emphysematous cholecystitis), neither of which possesses the trilayered appearance.

The term *gallbladder sludge* refers to viscous material that consists of minute bile crystals. Sludge is a common incidental finding in hospitalized patients and usually is not clinically significant. Sonographically, sludge appears as a dependent layer of medium-level echogenicity that slowly changes position as the patient moves. Occasionally, however, sludge may form aggregates (so-called tumefactive sludge or sludge balls) that have a mass-like appearance. As with layering sludge, these aggregates move or alter their configuration as the patient's position changes.

CHOLECYSTITIS

Acute cholecystitis is usually caused by obstruction of the gallbladder neck by stones, which leads to progressive inflammation of the gallbladder wall. If left untreated, the changes may progress to frank gangrene. Patients with acute cholecystitis typically present with right upper quadrant pain, fever, nausea, and vomiting, but these symptoms may be encountered in various

TABLE 63-1 Etiology of Sonographic Gallbladder Wall Thickening

Acute cholecystitis
Chronic cholecystitis
Gallbladder carcinoma
Adenomyomatosis
Hepatic, cardiac, or renal dysfunction
Hypoproteinemia
Sepsis
Portal hypertension

other conditions, including acute pyelonephritis and pancreatitis.

The most sensitive sonographic findings in patients with acute cholecystitis are gallstones and tenderness over the gallbladder, the sonographic Murphy sign. In eliciting this sign, it is important to have the patient indicate if they experience pain as the transducer is moved over the right upper quadrant, rather than simply asking if pressing on their abdomen causes discomfort. As well, the sonographic Murphy sign may be diminished or absent if the patient has received analgesic medication shortly before the sonogram. Other less specific signs of acute cholecystitis include pericholecystic fluid and gallbladder wall thickening. The latter is particularly nonspecific, as it is associated with a broad range of conditions (Table 63-1).

Gangrenous cholecystitis, which may lead to gallbladder perforation and sepsis, is a particularly dire complication of acute inflammation. As inflammation and necrosis progress, the gallbladder mucosa detaches and is visualized as linear intraluminal echoes that parallel the wall. Microperforations are usually not perceptible, but frank perforation may be seen as a discontinuity of the gallbladder wall, with or without a focal fluid collection. Interestingly, patients with perforation may report a sudden improvement in their pain as the increased luminal pressure is relieved.

Emphysematous cholecystitis is another form of acute inflammation that is associated with high morbidity and mortality. It is often associated with diabetes, and its hallmark is the presence of infection with gas-forming organisms in the gallbladder wall. Gas may be visible sonographically as high-level echoes associated with ringdown artifacts, which appear as diminishing echo trains deep to the gas.

As its name implies, *acalculous cholecystitis* is characterized by inflammation in the absence of gallbladder calculi. It is most often encountered in hospitalized patients with serious illnesses that may limit evaluation for the sonographic Murphy sign, which is the most specific finding in the intensive care unit patient population. Other signs, including gallbladder distension and wall

thickening, are nonspecific. Therefore, percutaneous cholecystostomy is sometimes recommended in septic patients with at least one of these sonographic signs and no other evident etiology.

ADENOMYOMATOSIS AND CHOLESTEROLOSIS

Adenomyomatosis and cholesterolosis comprise the so-called hyperplastic cholecystoses. *Adenomyomatosis* is a benign condition of uncertain etiology that is characterized by focal or diffuse mural hyperplasia and the formation of intramural diverticula that are termed Rokitsansky-Aschoff sinuses. The sinuses often contain minute calculi that produce comet-tail artifacts which are V-shaped echoes that are similar to the ringdown artifacts associated with gas bubbles. The segmental form of adenomyomatosis causes constriction of the gallbladder contour. The focal form of adenomyomatosis, which results in a mass-like appearance at the gallbladder fundus, may be difficult to distinguish sonographically from gallbladder carcinoma.

Cholesterolosis is characterized by multiple fatty deposits within the lamina propria of the gallbladder wall that result in a gross appearance termed strawberry gallbladder. Sonographically, cholesterolosis appears as multiple echogenic foci with comet-tail artifacts within the gallbladder wall. Unlike adenomyomatosis, however, there is no wall thickening.

POLYPS AND GALLBLADDER CARCINOMA

Polyps are frequently discovered incidentally at gallbladder sonography. They usually can be readily distinguished from stones by their nondependent, fixed position and lack of acoustic shadowing, although some calculi that are adherent to the gallbladder wall may have a similar appearance. Approximately 90% of gallbladder polyps are cholesterol polyps that are of no clinical significance. The remaining 10% are adenomas, which may have some malignant potential. Although it is difficult to distinguish small cholesterol polyps from adenomatous polyps, lesions that measure less than 10 mm do not require follow-up or surgery unless they enlarge over time.

Gallbladder carcinoma is most often seen in elderly women. It is associated with cholelithiasis, chronic gallbladder infection, and porcelain gallbladder. Signs and symptoms are nonspecific. At ultrasound, gallbladder cancer presents as a hypoechoic mass that occupies part or all of the lumen, or as focal or diffuse wall thickening that mimics chronic cholecystitis. Invasion of the contiguous liver is a frequent associated finding. The focal

form of gallbladder carcinoma may be impossible to distinguish sonographically from metastases to the gallbladder.

BILE DUCTS

NORMAL APPEARANCE

Normal intrahepatic bile ducts appear as tubular structures that measure 1 to 2 mm in diameter and accompany portal vein branches. Ducts from the right and left lobes converge at the porta hepatis to form the right and left hepatic ducts, which unite to form the common hepatic duct. It joins the cystic duct at a variable distance from its origin to form the common bile duct, which courses caudally and obliquely through or behind the pancreatic head to enter the duodenum. The cystic duct is not usually visualized as a separate structure, but the common hepatic and common bile ducts are readily identified in almost every patient owing to their fixed relationship to the portal vein and the hepatic artery.

Much has been written about the diameter of the common duct. However, as a rule of thumb, it should not measure more than 6 mm in patients younger than 60 years. There is some evidence to suggest that the duct dilates with advancing age, and an upper limit of 8 to 9 mm may be appropriate for patients older than 80 years. Whether the common duct enlarges following cholecystectomy is more controversial, although some studies suggest that this does occur.

BILIARY DILATION AND OBSTRUCTION

The hallmark of biliary obstruction from any cause is dilation of the segments that lie proximal to the obstructing process. For example, a mass that fortuitously obstructs the right hepatic duct will only result in right-sided dilation, but a stone in the distal common duct will cause intrahepatic and extrahepatic enlargement. Early intrahepatic dilation may be difficult to distinguish from normal, and dilated intrahepatic arterial branches may mimic dilated bile ducts if color Doppler sonography is not used. With progressive dilation, intrahepatic bile ducts become increasingly conspicuous as tortuous tubular structures that follow the portal veins, an appearance that has been termed the “too many tubes” sign. The dilated ducts also frequently exhibit posterior acoustic enhancement.

Dilation of the extrahepatic duct is more sensitive for obstruction below the hepatic duct confluence. As already noted, the diagnosis depends on distinguishing a

normal from a dilated common duct, which can be challenging in elderly patients or in individuals who are post cholecystectomy. In equivocal cases, correlation with laboratory indices of biliary obstruction may be helpful.

If the common duct is dilated, an effort should be made to identify the obstructing process. Cholelithiasis may be diagnosed sonographically in as many as 80% to 90% of patients with common duct stones. The appearance of common duct calculi is similar to that of stones in the gallbladder. Placing the patient in the Trendelenburg position, which causes distal stones to move proximally, may enhance visualization.

Neoplastic causes of biliary obstruction, including distal cholangiocarcinomas and pancreatic carcinomas, appear as hypoechoic masses, although conventional ultrasound usually does not play a major role in establishing the diagnosis. (On the other hand, endoscopic sonography is often extremely helpful in this regard.) Common duct strictures and ampullary carcinomas are usually not visible sonographically.

OTHER BILE DUCT CONDITIONS

Caroli disease is a rare condition that has an autosomal recessive inheritance and is associated with infantile polycystic kidney disease and congenital hepatic fibrosis. Patients are prone to developing recurrent bacterial infections, abscesses, and intrahepatic biliary stones, and also have an increased risk of cholangiocarcinomas. Ultrasound usually reveals multiple fusiform or saccular dilations of intrahepatic bile ducts that are bridged by fibrovascular bundles.

Pneumobilia, which refers to the presence of gas within the bile ducts, is most often encountered in patients with biliary stents, following sphincterotomy, or after surgical biliary-enteric anastomoses. Regardless of the etiology, pneumobilia appears as linear bands of high echogenicity that follow the ductal system and are associated with acoustic shadowing and ringdown artifacts. In patients with biliary stents, the stent may be appreciated as a tubular echogenic structure within the duct lumen.

AIDS cholangiopathy refers to the syndrome of biliary infection and obstruction in patients with AIDS, usually secondary to cryptosporidium, cytomegalovirus, or mycobacterium avium-intracellulare. Ultrasound findings include wall thickening that involves the gallbladder and bile ducts as well as ductal dilation. In some patients, the edematous papilla of Vater appears as an echogenic focus at the distal common bile duct.

SPLEEN

NORMAL APPEARANCE

The spleen is visualized in the left upper quadrant using a coronal approach. It is slightly more echogenic than the liver, although direct comparison of the echogenicity of the two organs is generally not possible unless the left lobe extends far to the left, as occasionally occurs as a normal variant or in the setting of hepatomegaly. In such cases, the relatively hypoechoic liver may simulate a left subphrenic collection. The spleen has a fairly fine-grained echotexture. Unlike the liver, vessels of the spleen are usually not prominent features. In adults, the spleen usually measures no more than 13 cm in length.

SPLENOMEGALY

The spleen may become enlarged in a wide variety of disorders, hence the ultrasound finding of an enlarged spleen is generally nonspecific. However, massive splenomegaly is most often associated with myelofibrosis, a condition in which the bone marrow is replaced by fibrous tissue, resulting in extramedullary hematopoiesis within the spleen. Splenic enlargement is also seen in hematologic conditions such as lymphoma and leukemia, as well as in infectious mononucleosis.

FOCAL SPLENIC LESIONS

Focal lesions are classified as cystic or solid. Cystic splenic lesions include congenital cysts, which are lined by epithelium, and pseudocysts that develop because of infection, trauma, or acute pancreatitis. Whatever their etiology, splenic cysts appear as anechoic or hypoechoic masses with increased through transmission and variable internal echoes. Splenic abscesses have a similar appearance, although they are usually less well defined than other cysts. Lymphangiomas, which are more often seen in children than adults, are rare tumors that are usually cystic, with or without internal septations or debris.

Splenic hemangiomas are said to be relatively common at autopsy, but are rarely encountered sonographically. They may occur in isolation or as part of the Klippel-Trénaunay syndrome. Hemangiomas have sonographic appearances that range from echogenic, similar to hemangiomas in the liver, to hypoechoic or mixed. Metastases to the spleen, which occur most often in patients with malignant melanoma or lymphoma, are typically hypoechoic, and are seen more commonly.

PANCREAS

NORMAL ANATOMY AND APPEARANCE

The pancreas lies obliquely in the retroperitoneum, extending from the duodenal sweep to the splenic hilum. It is divided into four portions—head and uncinate process, neck, body, and tail—that blend imperceptibly with each other and are demarcated chiefly by their relationship to adjacent structures. The splenic vein, which lies deep to the body and tail, is the easiest landmark to identify sonographically, and is often a good starting point for pancreatic sonography. However, it is vital to remember that an axial sonogram that encompasses the splenic vein only includes a portion of the pancreas and that complete visualization requires considerable angulation and movement of the transducer.

The pancreatic duct is most readily identified in the pancreatic body, where its walls lie at right angles to the insonating beam. With high-frequency transducers, the duct appears as thin parallel echogenic lines that course through the pancreatic parenchyma. Its normal diameter is 3 mm or less in the head; the duct tapers toward the body and tail. Pancreas divisum, a congenital abnormality in which the dorsal and ventral pancreatic buds fail to fuse during development, results in separate dorsal and ventral ducts, which may be seen sonographically with meticulous technique.

The echogenicity of the normal pancreas is usually greater than or equal to that of the overlying left hepatic lobe. With advancing age, fatty infiltration of the pancreas may increase its echogenicity considerably, making it very difficult to distinguish from peripancreatic fat. Complete fatty replacement is also seen in patients with cystic fibrosis. Published values for the AP dimension of the normal pancreas vary, but the head usually measures no more than approximately 2.5 cm.

ACUTE PANCREATITIS

Sonography is rarely the primary imaging modality used in patients with acute pancreatitis because of its insensitivity to early changes and complications such as pancreatic necrosis and distant pseudocysts. However, ultrasound is often performed to evaluate patients who present with nonspecific upper abdominal pain or to diagnose associated conditions such as gallstones. In the acute phase, the pancreas becomes edematous and its echogenicity diminishes. Over time, intrapancreatic and peripancreatic fluid collections develop; these are usually complex in appearance, and may contain shadowing gas if they become infected. Pancreatic pseudocysts, which are postinflammatory collections that are bounded

by a fibrous, nonepithelialized wall, are usually discovered at CT, but may be monitored sonographically. As well, ultrasound is often helpful to guide percutaneous placement of drainage catheters. Other complications that may be seen sonographically include pseudoaneurysms affecting the hepatic artery and other regional vessels and splenic vein thrombosis.

CHRONIC PANCREATITIS

Repeated bouts of pancreatitis may result in progressive, irreversible replacement of the pancreas by fibrous tissue, with an associated decline in pancreatic function. The gland may decrease in size, although this change is often difficult to detect sonographically. Pancreatic echogenicity increases as the parenchyma is replaced by fat and fibrosis, but this may also be seen with fatty replacement that occurs with advancing age. Pancreatic echotexture becomes increasingly heterogeneous and ductal dilation is often observed.

Intraductal or parenchymal pancreatic calcifications are the most important distinguishing ultrasound feature. Like calcifications elsewhere, they appear as small, echogenic foci that are accompanied by acoustic shadowing. However, the latter finding may be subtle, and high-frequency imaging with close attention to focal zone placement and other settings is critical.

CYSTIC PANCREATIC MASSES

True pancreatic cysts are uncommon, but may be seen in patients with adult polycystic kidney disease. Most cysts are acquired, and include serous cystadenomas, mucinous cystadenomas, and intraductal papillary mucinous neoplasms. Serous cystadenomas, which are benign tumors that are most common in women in the sixth or seventh decade of life, are often composed of multiple minute cysts that have a solid aggregate appearance. A central scar containing calcifications may be present.

In contrast, mucinous tumors have a malignant potential. Sonographically, they appear as cystic masses of varying complexity that do not communicate with the ductal system. They are also more common in women. The term intraductal papillary mucinous neoplasm is reserved for mucin-producing tumors that involve the main pancreatic duct, its side branches, or both. Conventional ultrasound usually plays little role in the workup of cystic tumors. However, endoscopic sonography is valuable to characterize their internal architecture, gauge their relationship to adjacent vessels and organs, and guide placement of sampling needles.

SOLID PANCREATIC MASSES

As with cystic masses, conventional ultrasound is much less important than endoscopic sonography for the detection and staging of solid pancreatic tumors. Approximately 90% are adenocarcinomas, with endocrine and other primary and secondary tumors comprising the remainder. The most common sonographic appearance is a hypoechoic mass, which may obstruct the pancreatic duct and/or the common bile duct, depending on its location. If ultrasound is the initial imaging modality, it is important to search for signs of unresectability, such as invasion and encasement of major regional vessels and liver metastases.

PANCREATIC TRANSPLANTS

Pancreatic transplantation is most often performed in diabetic patients, often in conjunction with a simultaneous or prior renal transplant. The right lower quadrant is the most frequent site of placement. Initially, bladder drainage via a surgical anastomosis between the pancreaticoduodenal graft and the bladder was the predominant technique. In recent years, enteric drainage, in which the donor duodenal segment is attached to a recipient small bowel loop, has become more popular.

The goal of pancreatic transplant sonography is to look for peripancreatic fluid collections, evaluate the allograft parenchyma, and exclude thrombosis in the transplant vasculature. Although imaging may be compromised by overlying bowel, an attempt should be made to demonstrate intrapancreatic venous and arterial flow, as well as assess the supplying arteries and draining veins. In the bladder drainage technique, both the donor arteries and veins are anastomosed to the recipient iliac vessels; in the enteric drainage procedure, venous drainage is usually to the recipient superior mesenteric vein.

Ultrasound has a limited role in the diagnosis of rejection, as transplant pancreatitis and vascular compromise may have a similar appearance. In patients with transplant dysfunction in whom the diagnosis is in doubt, ultrasound-guided percutaneous biopsy may be performed.

ADRENAL GLANDS

In adults, CT and MRI are usually preferred to evaluate patients with known or suspected adrenal pathology. It is often challenging to visualize the adrenal glands sonographically, particularly on the left side. The normal adrenal glands, which lie superomedial to the upper

renal poles, typically appear hypoechoic, with an echogenic core that represents the medulla.

Adrenal masses often have a nonspecific ultrasound appearance, although it should be possible to diagnose cysts with a high degree of confidence. Similarly, the finding of a highly echogenic mass suggests fat content in a myelolipoma, but confirmation with CT or MRI is recommended. Other masses, including adenomas, pheochromocytomas, and metastases, have a variable ultrasound presentation, ranging from hypoechoic to mixed. In general, however, the concern for malignancy is higher in large heterogeneous masses.

KIDNEYS, URETERS, AND BLADDER

NORMAL ANATOMY AND APPEARANCE

The kidneys are easily visualized sonographically using a coronal or an anterior approach, although a posterior vantage point may be advantageous in patients with copious bowel gas. In adults, they measure approximately 9 to 13 cm in length, have a typical bean-like shape, and are well defined, usually with little or no lobulation. Normal variants include the “dromedary hump,” an apparent bulge in the left kidney caused by impression from the adjacent spleen, the hypertrophied column of Bertin, invagination of cortical tissue between renal pyramids, and persistent fetal lobation, fine indentations along the surface demarcating renal lobes. Other more striking congenital anomalies that may be visible with ultrasound are agenesis, ectopia, and horseshoe kidney.

On ultrasound, normal kidneys have three components: the echogenic central sinus, which includes the collecting systems, vessels, and other supporting tissues, hypoechoic pyramids, and the intermediate echogenicity cortex. The echogenicity of the normal cortex is less than or equal to that of the adjacent right hepatic lobe, an appearance that is accentuated in the presence of hepatic steatosis.

The collecting systems may be mildly distended in the absence of obstruction, particularly if the bladder is distended or if the patient has been hydrated. The normal ureters are rarely visualized. The urine-filled bladder is readily identified as an anechoic structure in the pelvic midline. Wall thickness is usually no more than approximately 5 mm, but varies with the degree of distension. Flow of urine from the ureters into the bladder is often visible as ureteral jets, which may be seen on grayscale or color Doppler imaging. They are thought to result from differences in specific gravity, and are helpful to verify gross ureteral patency.

DIFFUSE RENAL CONDITIONS

Many conditions that affect the kidneys reverse the normal relationship between the renal cortex and the adjacent right hepatic lobe, causing the kidneys to appear echogenic. Cortical echogenicity is particularly increased in certain conditions, including AIDS nephropathy, amyloidosis, and lupus nephritis. However, this appearance, which some term *medical renal disease*, is therefore nonspecific, and biopsy is often required for a definitive diagnosis.

Ultrasound and other imaging modalities usually play little role in patients with uncomplicated *bacterial pyelonephritis*, as management may be guided clinically. The kidneys are usually normal in appearance sonographically, although they may be edematous, and power Doppler interrogation may demonstrate areas of hypoperfusion. In refractory cases, ultrasound is sometimes helpful to detect renal abscesses and guide percutaneous sampling. As well, sonography may suggest the diagnosis of *emphysematous pyelonephritis* in diabetic patients by demonstrating gas within the renal parenchyma or collecting system.

Nephrocalcinosis, which encompasses conditions that result in calcium deposition within the kidneys, is classified as medullary, cortical, or mixed, and has a variety of causes (Table 63-2). The ultrasound appearance of these deposits ranges from faint areas of slightly increased echogenicity to highly reflective aggregates with strong acoustic shadowing. *Medullary sponge kidney*, a developmental condition that is characterized by cystic dilatation of the collecting ducts within one or more medullary pyramids, may have a similar appearance, even in the absence of calculi.

UROLITHIASIS

The sensitivity of ultrasound for detecting stones in the urinary tract depends on a number of factors, including

TABLE 63-2 Causes of Nephrocalcinosis

Medullary	Hypervitaminosis D
	Medullary sponge kidney
	Metastatic carcinoma to bone
	Milk alkali syndrome
	Multiple myeloma
	Primary hyperparathyroidism
	Renal tubular acidosis
	Sarcoidosis
	Acute cortical necrosis
	Alport syndrome
Cortical	Chronic membranous glomerulonephritis
	Congenital oxalosis

the size, location, and composition of the calculus; the patient's body habitus; and the equipment used. The diagnosis rests on the demonstration of an echogenic focus with posterior acoustic shadowing. Unfortunately, the latter may be absent if the stone does not block the ultrasound beam sufficiently because it is too small, the frequency is too low, or the focal zone is set incorrectly. Conversely, other structures in the kidneys, such as calcified vessels, may mimic calculi. In recent years, a color Doppler finding called the twinkling artifact has been applied successfully. This artifact, which appears as a band of alternating color deep to a stone, is related to its surface roughness. Because it improves sensitivity, color Doppler interrogation should be performed routinely when urinary calculi are suspected.

In women with suspected distal ureteral calculi, sensitivity and specificity may be enhanced by endovaginal sonography, which readily visualizes the uretrovesical junctions. In addition, if a bladder calculus is demonstrated via the transabdominal or endovaginal route, turning the patient to one side will cause the stone to move if it is lying freely within the bladder lumen.

OBSTRUCTIVE UROPATHY

Ultrasound is often performed to exclude obstruction in the setting of acute renal dysfunction. While most such examinations are noncontributory (most patients with acute renal failure do not have obstructed ureters), grayscale sonography is certainly capable of demonstrating hydronephrosis when obstruction is present. (The value of the arterial resistive index in determining the presence and severity of ureteral obstruction remains controversial.)

Dilation may be classified as mild, moderate, or severe, depending on the degree of distension of the collecting system and pelvis. As the obstructed collecting system expands, the overlying parenchyma thins, although this is usually a chronic finding. As noted earlier in the chapter, mild dilation may be seen in normal patients with a distended bladder or following aggressive hydration; however, this is usually readily apparent. In any patient with unilateral or bilateral hydronephrosis, an attempt should be made to identify the level and cause of obstruction. Clearly, the likelihood of success depends on the clinical setting, but it should be possible to at least determine if the proximal ureter is dilated in most patients.

Because hydronephrosis predisposes the patient to infection, the sonologist should search for debris within the dilated collecting system. This typically appears as layering material of medium echogenicity that is similar to gallbladder sludge. This finding is highly suspicious

for pyonephrosis, although hemorrhagic debris may have a similar appearance. In addition, immunocompromised patients may develop intraluminal mycetomas that appear as echogenic, nonshadowing filling defects.

CYSTIC RENAL MASSES

Renal cysts are exceedingly common incidental findings in adults with no history of renal disease, and it is vital to distinguish those that do not need follow-up from those that require further imaging with CT or MRI. This determination rests on ultrasound's ability to demonstrate solid elements (septations, mural nodules, or calcifications) within cysts. To a large extent, this mirrors categorization of cysts using the Bosniak classification, which is widely used to guide clinical management of patients with complex renal cysts. However, some features in this classification system, notably septal and mural enhancement, cannot be reliably assessed with grayscale and color/power Doppler sonography, and care should be taken when assigning Bosniak category based solely on these techniques. (The availability of contrast-enhanced ultrasound will likely change this.)

Masses that meet all the sonographic criteria for simple cysts (Table 63-3) need no follow-up or intervention, unless they are symptomatic because of their size or location. Complex cysts present a range of appearances, which include septations, calcifications, mural nodules, and amorphous echoes. Cysts with hairline septations or slight calcification also need no follow-up. With increasing complexity, further evaluation with CT or MRI is usually warranted.

Because of their central location within the kidney, multiple *parapelvic cysts* may be mistaken for a dilated collecting system. Differentiation depends on demonstrating interconnection between the fluid-filled components in the latter condition. *Calyceal diverticula*, which are lined by transitional epithelium and communicate with a calyx or the renal pelvis, also present a diagnostic challenge. The finding of mobile, dependent echoes representing milk of calcium strongly suggests the diagnosis.

Multilocular cystic nephroma is an uncommon cystic mass that occurs in very young children and in adults between 40 and 60 years. The ultrasound appearance is that of a highly complex cystic mass that

TABLE 63-3 Sonographic Signs of a Simple Cyst

Anechoic
Good through transmission
Very thin, sharply defined wall
Round shape

cannot be reliably distinguished from other complex cysts, and excision is often required for a definitive diagnosis.

SOLID RENAL MASSES

Renal cell carcinoma is the most common solid renal tumor in adults. It most frequently presents in the fifth to seventh decade of life, and has an overall 5-year survival of approximately 60%. Clear cell adenocarcinomas predominate, with papillary, chromophobe, and other subtypes occurring less frequently. Predisposing conditions include von Hippel-Lindau disease and hereditary papillary renal cancer, as well as acquired renal cystic disease in dialysis patients.

At ultrasound, renal cell carcinomas usually appear iso- or hypoechoic to the renal cortex. Small lesions tend to be higher in echogenicity. When encountered incidentally, it is important to search for local extension into the perinephric fat, regional adenopathy, or thrombus within the ipsilateral vein or IVC. Doppler sonography may be helpful to distinguish bland from tumor thrombus by demonstrating arterial flow within it.

Angiomyolipomas are composed of blood vessels, smooth muscle, and fat in variable proportion. Lesions with high fat content tend to appear echogenic on ultrasound, particularly when they are small, but reliable differentiation from renal cell carcinoma is often problematic without CT or MRI. The presence of acoustic shadowing suggests fat in an angiomyolipoma, however.

Other primary and metastatic renal neoplasms, including *transitional cell carcinomas*, have a nonspecific ultrasound appearance, and further imaging or biopsy may be required to establish the diagnosis. *Renal lymphoma* is usually secondary, and may cause hypoechoic masses that mimic cysts. However, the degree of through transmission tends to be less than would be expected for a cyst of equivalent size.

POLYCYSTIC AND END-STAGE KIDNEYS

Adult polycystic kidney disease is an autosomal dominant condition that is characterized by replacement of the kidneys by innumerable cysts of varying size. The kidneys are frequently too large to encompass on a single sonographic image unless extended field-of-view techniques are employed, measuring 20 cm or more craniocaudally. The primary role of sonography is to detect complications such as cyst infection or hemorrhage and renal cell carcinomas. Unfortunately, this can be exceedingly difficult owing to the size of the kidneys and the multiplicity of cysts. As in other cysts, mural nod-

ules and thick septations are worrisome. Contrast-enhanced sonography may be helpful in this regard.

No matter what the etiology, chronic renal failure tends to produce a common sonographic appearance in which the kidneys become small and echogenic. Often termed *end-stage kidneys*, they may be difficult or impossible to detect, and exclusion of solid masses within them may not be feasible sonographically.

RENAL VASCULAR CONDITIONS

Verification of gross renal vein patency is usually easily accomplished with color and spectral Doppler ultrasound, although demonstration of nonocclusive thrombi may be challenging, particularly in the longer left renal vein. Ultrasound is also able to detect postbiopsy arteriovenous fistulas and pseudoaneurysms in selected patients.

The role of sonography in the workup of patients with suspected renovascular hypertension is controversial. Some centers tend to reserve ultrasound for patients who cannot undergo contrast-enhanced CT or MRI because of renal failure, on the premise that stenotic accessory renal arteries may be missed sonographically. In other labs, ultrasound is a first-line investigation in hypertensive patients.

Two classes of signs of hemodynamically significant renal artery stenosis have been described. The first group comprises findings within the intrarenal arteries, which can be visualized and interrogated in most patients. These findings include alterations of the normal waveform to produce a so-called tardus-parvus pattern, which refers to a decreased amplitude and rounded configuration of the waveforms.

The second group of signs requires direct visualization of the stenosis, which is more challenging technically, but these signs are more widely accepted. A peak systolic velocity of 200 cm/s is often used as the cutoff for diagnosing significant stenosis. This is combined with calculation of the ratio of the peak systolic velocity in the renal artery to the peak systolic velocity in the proximal abdominal aorta, with 3.5 or more indicating significant stenosis.

RENAL TRANSPLANTATION

The transplanted kidney is essentially identical in appearance to the normal native kidney on ultrasound, although it is usually better seen because of its superficial location. Grayscale imaging is done initially to detect complications that may compromise renal function or transplant survival, including hydronephrosis and adjacent fluid collections. The latter, which include urinomas, hematomas, seromas, and abscesses, have a nonspecific appearance,

although complexity suggests hemorrhage or infection. Sterile collections may be significant if they are large and compress the transplant ureter sufficiently to cause obstruction.

Doppler ultrasound is an important part of the post-transplant examination. Power and color Doppler imaging show an arborized flow pattern that extends to the renal capsule. Spectral interrogation of the interlobar and segmental arteries shows a low medium-resistance pattern with a resistive index of 0.8 or lower.

Timely detection of renal arterial or venous thrombosis is mandatory to avoid graft loss. The main renal artery and vein should be followed to their anastomoses with the iliac vessels, and care should be taken to image accessory arteries. Arterial thrombosis is usually readily apparent, but the diagnosis of renal vein thrombosis may be more challenging. The finding of a very high resistive index (1.0) or reversed diastolic flow is a clue to its presence, although this finding is also seen in patients with acute tubular necrosis, severe rejection, or allograft compression.

The diagnosis of renal artery stenosis is based on the demonstration of high-velocity turbulent flow just beyond the anastomosis, which is the most frequent site of involvement. A peak systolic velocity of 300 cm/s has been recommended as a threshold. The ratio of the velocity in the main renal artery to the velocity in the iliac artery proximal to the anastomosis is also used in some centers, with 2.0 as a suggested cutoff.

Ultrasound is invaluable to guide needle placement for renal transplant biopsy, and it is also helpful to demonstrate biopsy-related complications, including extrarenal flow along the needle track and arteriovenous fistula. The latter often appears as a focal zone of random color assignment within the kidney; spectral Doppler interrogation shows high-velocity turbulent flow.

URINARY BLADDER

OBSTRUCTION, MASSES, AND MISCELLANEOUS CONDITIONS

Because of its fluid content, the urinary bladder is ideally suited to ultrasound evaluation. Despite this, sonography is not often used to detect bladder masses. Nevertheless, bladder tumors, including benign papillomas, transitional cell carcinomas, and squamous cell carcinomas, may be visualized sonographically as masses that project into the bladder lumen. The finding of flow within the lesion with color and spectral Doppler imaging increases the level of suspicion, although cystoscopy is required for a definitive diagnosis. In patients with

hematuria, blood clots within the bladder lumen may mimic masses—turning the patient to elicit movement usually differentiates them.

In patients with suspected outlet obstruction, ultrasound is helpful to estimate the volume of the bladder prior to and after voiding. Many ultrasound scanners include software that computes the bladder volume based on linear measurements obtained in three orthogonal planes. Sonography is also helpful to verify the position of transurethral and suprapubic catheters. *Diverticula*, outpouchings of the bladder wall, are often encountered incidentally. Most are acquired in patients with bladder outlet obstruction.

Cystitis has a nonspecific ultrasound appearance that is characterized by focal or diffuse mural thickening. As in the gallbladder, the presence of shadowing echogenic foci within the wall of the bladder suggests emphysematous cystitis, which is often associated with diabetes. *Fungus balls* may also be seen in patients with diabetes or compromised immune systems.

AORTA, IVC, AND RETROPERITONEUM

The abdominal aorta can be visualized in most patients using an anterior or a coronal approach. Normally, it is smooth in contour and tapers craniocaudally. Spectral Doppler interrogation usually demonstrates a high-resistance waveform.

The primary role of ultrasound is to detect and measure abdominal aortic aneurysms (AAA), which are defined as an outer aortic AP diameter of 3 cm or more. Most are atherosclerotic, with inflammatory and mycotic aneurysms comprising a small minority. Risk factors for atherosclerotic AAA include gender (male > female), smoking, and age. When measuring AAA, care must be taken not to image the aorta obliquely. The ideal plane for measurement of the AP diameter of an aneurysm lies perpendicular to its long axis, which may not parallel the sagittal plane of the patient if the aorta is tortuous.

The relationship of the aneurysm to the renal arteries should be determined, and the presence of any mural thrombus noted. The proximal iliac arteries should be imaged for extension below the bifurcation. Although CT is usually preferred over ultrasound in patients with suspected AAA rupture, sonography may demonstrate retroperitoneal or intraperitoneal fluid. The role of sonography in evaluating patients following endostent placement has yet to be defined, but early studies suggest that contrast-enhanced ultrasound may be helpful.

Abdominal aortic dissections are more often evaluated with CT than ultrasound, in part because identification of the origin of the dissection, which usually is in

the chest, is mandatory to guide management. Hypertension is an important risk factor. On ultrasound, dissection appears as curvilinear structure representing the intimal flap within the aortic lumen. Color flow imaging is helpful to demonstrate flow in the false and true lumens and to determine their relationship to the splanchnic and renal vessels.

The proximal (hepatic) segment of the IVC should be included in every complete abdominal sonogram. Extension of thrombi from the renal veins may be evident in patients with renal cell carcinoma, and IVC filters should be assessed for clot cephalad to them. Visibility of the IVC below the renal veins is variable, depending on the patient's body habitus and the amount of overlying bowel gas.

Most retroperitoneal masses and collections are best imaged with CT or MRI. However, retroperitoneal adenopathy, whether due to lymphoma, metastatic disease, or any other cause, may be visible sonographically, particularly in the upper abdomen. The enlarged lymph nodes are typically hypoechoic, and they may be so confluent that measurement of individual nodes cannot be performed.

GI TRACT AND APPENDIX

Although a detailed description of anatomy is beyond the scope of this chapter, in general, the GI tract has a multi-layered "signature" of alternating echogenic and echopenic bands that is common to all segments. Mural thickness and configuration vary depending on the segment that is being examined, as well as on the degree of distension. Peristalsis is usually readily apparent at real-time imaging. The content of the GI tract also varies widely, ranging from almost hypoechoic to highly reflective.

Many types of bowel pathology may be visualized sonographically. These range from infectious and inflammatory conditions, which tend to cause segmental or extensive mural thickening, to neoplasms, which result in focal masses. Overlap is considerable, however. Sonography occasionally may be helpful to suggest the diagnosis of obstruction in patients who present with nonspecific abdominal pain.

The appendix deserves special mention, as it is often studied with ultrasound. The normal appendix is a blind-ending tubular structure that is typically located in the right lower quadrant. Because loops of bowel often lie between the appendix and the anterior abdominal wall, so-called graded compression sonography, in which gradually increasing pressure is applied to the abdomen, is used. Acute appendicitis should be suspected when the diameter is more than 6 mm, particularly if there is focal tenderness or an appendicolith is visible. The presence of a focal fluid collection or infiltration of periappendiceal fat suggests perforation.

MESENTERIC VESSELS

While technically challenging, Doppler ultrasound is valuable for assessing patients with suspected mesenteric insufficiency. Imaging is performed after a fast to minimize interfering bowel gas. The examination includes visualization and velocity measurements within the abdominal aorta, the celiac axis, the superior mesenteric artery, and the inferior mesenteric artery. As in other vessels, the diagnosis of stenosis is based on the presence of focal high-velocity flow and turbulence; however, there is disagreement concerning appropriate thresholds for peak-systolic or end-diastolic velocities. As a rule of thumb, however, flow rates more than 200 cm/s in the celiac axis or inferior mesenteric artery and 275 cm/s in the superior mesenteric artery are associated with significant stenosis.

PERITONEAL CAVITY AND ABDOMINAL WALL

Ultrasound is quite sensitive for the detection of peritoneal fluid, which is the basis of its role in assessing patients with abdominal trauma. Sonography is also helpful to guide needle or catheter placement in patients who require diagnostic or therapeutic paracentesis. Peritoneal carcinomatosis, in which there are disseminated peritoneal tumor deposits from ovarian or other malignancies, also may be characterized sonographically, although CT is usually more effective in this regard.

The abdominal wall may be assessed for masses, collections, or hernias using a high-frequency linear array transducer. Herniated bowel or omentum is easily recognized if a hernia is large, although small defects may be challenging to demonstrate.

QUESTIONS AND ANSWERS

- Concerning hepatic hemangiomas, which of the following is *true*?

- A. They often possess a hypoechoic halo.
- B. Echogenicity varies with the degree of steatosis.
- C. Through transmission is not seen.
- D. Biopsy is recommended for definitive diagnosis.

ANSWER: B. In the presence of steatosis, hemangiomas, which are usually echogenic, may appear hypoechoic compared to the adjacent echogenic parenchyma.

- Concerning focal fatty sparing, which of the following is *true*?

- A. Pericholecystic location is rare.
- B. Typically echogenic.
- C. May simulate neoplasm
- D. Vessels are usually displaced.

ANSWER: C. Although the location and configuration of focal fatty sparing usually make the diagnosis straightforward, it may occasionally have a mass-like appearance that simulates neoplasm.

- Concerning hepatic tumors, which of the following is *true*?

- A. Cholangiocarcinoma is the most common primary malignancy.
- B. Metastases are less common than HCC.
- C. Lymphoma is usually echogenic.
- D. The presence of flow within thrombus suggests HCC.

ANSWER: D. The finding of flow within tumor thrombus on Doppler ultrasound distinguishes it from bland thrombus, and is highly suggestive of HCC.

- Concerning portosystemic shunts, which of the following is *true*?

- A. Color Doppler ultrasound alone is adequate to assess TIPS.
- B. TIPS stents usually extend from the portal vein to the left hepatic vein.

- C. Goal of shunting is to improve hepatic blood flow.

- D. Absent flow on color Doppler ultrasound does not always indicate thrombosis.

ANSWER: D. Very slow flow in an otherwise patent TIPS may not be detectable sonographically, although it is highly worrisome for impending shunt failure. As well, some types of shunts may be obscured by acoustic shadowing soon after placement.

- Which of the following statements about gallstones is *true*?

- A. Most are cholesterol stones.
- B. Decreasing the ultrasound frequency improves demonstration of acoustic shadowing from small calculi.
- C. Stones are a frequent cause of acute cholecystitis when they become impacted at the gallbladder fundus.
- D. Wall-echo-shadow sign consists of two parallel lines.

ANSWER: A. The majority of gallstones are cholesterol stones.

- Concerning the spleen, which of the following is *true*?

- A. Spleen is larger in myelofibrosis than lymphoma.
- B. Normal adult spleen measures up to 15 cm in length.
- C. Lymphangiomas do not contain internal septations.
- D. Normally the spleen is less echogenic than the liver.

ANSWER: A. Although splenomegaly is encountered in both disorders, it is usually more pronounced in patients with myelofibrosis.

- Which of the following is the most frequent subtype of renal cell carcinoma?

- A. Chromophobe
- B. Papillary
- C. Clear cell
- D. Other

ANSWER: C. Clear cell adenocarcinomas account for 80% of renal cell carcinomas.

- Concerning GU tract stones, which of the following is *true*?

- A. Color Doppler sonography improves sensitivity.
- B. Lowering the ultrasound frequency improves stone detection.
- C. Acoustic shadowing is not related to the beam width.
- D. Most midureteral calculi are easily detectable with ultrasound.

ANSWER: A. The presence of the twinkling artifact on color Doppler imaging helps distinguish stones from other normal echogenic foci, although calcified vessels may still be problematic.

9. Concerning cystic renal masses, which of the following is *true*?

- A. Multilocular cystic nephromas are readily distinguished from other cystic masses.
- B. Assignment of some Bosniak categories may be done with ultrasound alone.
- C. Calyceal diverticula do not contain calcium.
- D. Cysts and lymphomatous masses exhibit similar through transmission.

ANSWER: B. Grade I and II cysts often may be confidently diagnosed with sonography alone.

10. Concerning aortic aneurysms, which of the following is *true*?

- A. AP measurements are best done in the sagittal plane.
- B. Ultrasound is sensitive for the detection of rupture.
- C. AP diameter more than 2.5 cm is considered aneurysmal.
- D. More common in women.

ANSWER: A. Measurements performed in the axial plane may overestimate the AP diameter of the aorta if the plane of section is oblique. Therefore, the AP dimension should be measured in a plane that is perpendicular to the long axis of the aneurysm, which is usually sagittal.

64 FEMALE PELVIC ULTRASOUND

*Arthur C. Fleischer and
Robert S. Morrison III*

INTRODUCTION

The role of pelvic sonography in the evaluation of gynecologic disorders is universal and well accepted by patients and practitioners. It provides clinically important information in a variety of gynecologic disorders such as evaluation of patients for pelvic masses, endometrial or uterine disorders, pelvic pain, and inflammatory disorders.

Pelvic sonography requires that the operator has extensive scanning skills and have interpretation expertise in addressing common and less common clinical questions.

TABLE 64-1 Normal Uterus

Prepubertal	Mostly cervix
Postpubertal	Cervix and corpus/fundus about equal in size
Nulliparous	6–8 cm in length, 3–5 cm in anterior-posterior and transverse axes
Parous	1–2 cm larger than nulliparous
Postmenopause	3–4 cm smaller, thin endometrium

It behooves medical professionals to be up-to-date with current scanning technology and clinical application.

SCANNING TECHNIQUES AND INSTRUMENTATION

When imaging the pelvic structures, two techniques are commonly used. Transvaginal sonography (TVS) provides detailed depiction of the uterus, endometrium, myometrium, ovaries, and cul-de-sac (Tables 64-1 to 64-3). Transabdominal sonography (TAS) provides an overview of these pelvic structures but it has limitations because of the fact that it is degraded by gas-filled bowel and requires that the urinary bladder be distended.

TVS requires an empiric approach to providing optimal images. The first images of the pelvis include long and short axes of the uterus. This requires some anterior angulations of the probe for anteflexed uteri. Retroflexed uteri are imaged without much manipulation of the probe once it is introduced. The endometrial bilayer thickness should be measured in the greatest anteroposterior plane. The ovaries are best delineated in an oblique semicoronal plane. It is important to assess the relative mobility of the ovaries as they are displaced from the uterus with minimal pressure using the probe. Finally, the cul-de-sac and cervix need to be evaluated.

Transabdominal sonography is helpful in the delineation of masses larger than 5 cm, particularly those that are displaced anteriorly or superior to the urinary bladder.

Both TVS and TAS have color Doppler capabilities. The major feeding vessels to the ovaries and some of the larger arcuate and radial vessels can be interrogated with pulse Doppler sonography. The relative impedance (high, intermediate, or low) can be calculated.

Three-dimensional pelvic sonography can be obtained with transabdominal or transvaginal probes that contain a curved array of transducer elements that are automatically swept through a region of interest.

TABLE 64-2 Normal Endometrium

Menstrual phase	Irregular interface representing sloughed endometrium and blood clots, 3–5 mm bilayer
Follicular phase	Isoechoic, 5–6 mm
Periovulatory	Multilayered, 5–8 mm
Luteal phase	Echogenic, 5–12 mm

TABLE 64-3 Normal Ovaries

Premenarche	2 × 2 × 1 cm
Postmenarche	3 × 2 × 1 cm with antral follicles of various sizes
Childbearing	3 × 2 × 2 cm with multiple follicles of various sizes of development
Postmenopause	2 × 2 × 1 cm without follicles

Three-dimensional pelvic sonography provides images in any selectable scan plane and is particularly useful in assessment of endometrial/myometrial disorders.

PATHOLOGY

PELVIC MASSES

Pelvic sonography is the diagnostic modality of choice for evaluation of most pelvic masses. It provides information as to the mass' organ of origin, internal consistency, and vascularity. Each of these parameters is clinically important in determining the most likely diagnosis, whether the mass is most likely benign or malignant and optimal management. (Table 64-4). In most patients, the differential diagnosis can be narrowed to one or two entities based upon the clinical features and laboratory values. There are some relatively specific TVS findings (Table 64-5). Selective use of MR, CT, or PET/CT can further clarify the

TABLE 64-4 Sonographic Differential Diagnoses of Pelvic Masses*

CYSTIC	COMPLEX	SOLID
Completely cystic	Predominantly cystic	Uterine
Physiologic ovarian cysts	Cystadenomas	Leiomyoma (sarcoma)
Cystadenomas	Tubo-ovarian abscess	Endometrial carcinoma, sarcoma

TABLE 64-5 Sonographic Findings of Pelvic Masses

Ovarian Epithelial Tumors	Septated or Nonloculated
Hydrosalpinx	Endosalpingeal folds as echogenic intraluminal projections
Endometriomas	Ground glass internal texture, echogenic foci
Dermoid cysts	Variable appearance can contain echogenic sebum, mural calcifications
Hemorrhagic corpus luteum	Peripheral vascular rim, echogenic interfaces

nature of some masses. These modalities may also be needed when sonography is equivocal or limited.

OVARIAN MASSES

The ovary is the site of a variety of adnexal masses that range histologically from benign to malignant. It is important to correlate the clinical features of each patient to the sonographic findings to provide the most likely diagnosis. For example, physiologic cysts are common in women of childbearing age and uncommon after menopause. Similarly, there are two major peak years for torsion: in the postmenarche girl who begins to ovulate and in the postmenopause woman, secondary to an ovarian epithelial neoplasm acting as a leading mass.

The ovaries are characteristically ovoid structures residing lateral to the body of the uterus. The size of the ovaries changes throughout a woman's life, increasing in size until menarche and then atrophying once menopaual. During the menstruating years, they may vary in size from 1 to 3 cm depending on if they contain mature follicles or corpora lutea. With each menstrual cycle, several follicles begin to develop during the follicular phase. Of these, a dominant follicle (more than 10 mm) forms and contains inside it an oocyte. The cumulus oophorus, which surrounds the maturing oocyte, can occasionally be seen sonographically as a small (1–2 mm) hyperechoic structure along the inner wall of the dominant follicle. At the midpoint of the menstrual cycle, luteinizing hormone surges and the dominant follicle (ranging from 18–25 mm) ruptures, releasing its oocyte and a small amount (3–5 cm³) of free fluid into the cul-de-sac. This dominant follicle subsequently involutes with thickening and serration of the wall and becomes the progesterone-secreting corpus luteum. Occasionally, the dominant follicle will bleed internally and increase in size. This can be seen as a complex intraovarian area termed as hemorrhagic cyst. This hemorrhagic cyst characteristically resolves within one to two menstrual cycles. The remaining nondominant follicles also shrink following dominant follicle rupture. The uterus is primed for implantation; however, if this does not occur, then the follicles will involute and the cycle will begin again.

Cysts within the ovary can range from 3 to more than 20 cm. Most are smooth walled and demonstrate no internal echogenicity. They can be identified as arising from the ovary by recognizing the compressed remaining ovarian tissue surrounding the cystic component. Cystic ovarian masses may contain multiple septations or irregular solid components. Papillary excrescences that arise from the wall usually indicate either a borderline or malignant pathology. Cysts may contain echogenic material, such as sebum, within dermoid cysts or inflammatory debris within a tuboovarian abscess. Mucin within a cyst can be seen in mucinous tumors whereas serous tumors usually have anechoic fluid.

Follicles (functioning cysts) are under the influence of the female sex hormones and thus vary with size depending on the stage of menstruation. A simple cyst that does not change or increase in size between menstrual cycles is considered to be independent from hormonal influence and is termed nonfunctional. If this cyst measures less than 5 cm, then simple observation will suffice as these are almost always benign. However, if a nonfunctional cyst measures more than 5 cm, then the differential for that cyst includes nonphysiologic causes. In these patients, color Doppler sonography (CDS) and three-dimensional sonography can provide useful information as to which patients may be followed is those that may require surgery. Those features which suggest malignancy include papillary excrescences, focal wall irregularity, low-impedance flow within centrally located cluster vessels.

Complex or semisolid ovarian masses are usually dermoid cysts, endometriosis, or in the patient who is febrile, a tuboovarian complex. The greater the degree of variability within a cyst, and in particular the more solid components present, the higher the likelihood for malignancy. For instance, those with increased wall thickness, papillary excrescences, thick septations, and increased echogenicity are significantly more concerning for malignancy. Dermoids are benign neoplasms that are present from birth. These structures contain a myriad of mature epithelial structures, including skin, hair, and teeth. Hydrosalpinges

are typically fusiform but can mimic a cystic ovarian mass. However, the endosalpingal folds within a hydrosalpinx can help identify the cystic mass as arising from the tube and not the ovary. Endometrioma typically contain echogenic internal content termed as ground glass appearance. Occasionally, echogenic foci associated with fibrinolyzed blood products can be seen within the endometrioma. This finding may also be observed in dermoid cysts.

Ovarian tumors typically contain focally thickened walls and papillary excrescences. If the tumor has spread through the capsule of the ovary, intraperitoneal fluid is usually present. On color Doppler sonography, most ovarian neoplasms contain central vessels with low-impedance flow in the morphologically abnormal area, as well as clusters of abnormal vessels (Table 64-6). Three-dimensional sonography can be used to depict papillary excrescence. Additionally, the use of color Doppler sonography may show abnormally branching vessels with an irregular caliber exhibiting focal areas of stenosis and microaneurysm.

PELVIC PAIN

TVS has a vital role in the evaluation of patients presenting with pelvic pain. The main clinical concern is evaluation for adnexal (ovarian and tubal) torsion.

Ovarian torsion is an infrequent but significant cause of lower abdominal pain and accounts for some 3% of operative emergencies in gynecology—the fifth most common cause of gynecologic emergencies. It typically occurs unilaterally in an enlarged ovary and commonly involves torsion of both the ovary and the fallopian tube. Although torsion may occur in a normal ovary (as is common in pediatric patients), it typically involves an adnexa abnormality with an ovarian mass being implicated in almost 60% of all cases. Torsion typically occurs during the early reproductive years; however, it may occur at any stage in a woman's life. The median age for torsion to occur is 28 years.

TABLE 64-6 Sonographic Features of Benign and Malignant Pelvic Masses

	BENIGN		MALIGNANT	
	TVS	CDS	TVS	CDS
Morphology	Smooth-walled, anechoic		Papillary excrescences, mural nodules, irregular solid areas	
Vessels		Regularly spaced		Irregularly spaced, clustered
Impedance		High		Low
Velocity		Low		High
Change in size	Regression or no change		Increase or no change	
Other findings	No ascites; no liver masses or lymphadenopathy		Ascites; liver masses, lymphadenopathy	

TVS: transvaginal sonography; CDS: color Doppler sonography.

In its most common presentation, ovarian torsion presents as the sudden onset of severe unilateral lower abdominal pain that may be intermittent. This sharp stabbing pain often radiates to the back, pelvis, or thigh. Physical examination is relatively nonspecific, but may reveal a tender adnexa or adnexal mass. Given the ovaries intraperitoneal location, examination findings of peritonitis may be present and signify advanced disease. Laboratory studies are of limited value in ovarian torsion; however, a pregnancy test is certainly necessary. TVS is best at helping to identify ovarian torsion but it has limitations in distinguishing torsion from other adnexal masses.

Most frequently, the affected ovary is enlarged and relatively irregular in texture, probably related to intravenous hemorrhage and edema. The increased weight and reduced venous return of the affected ovary precipitates torsion. On color Doppler sonography, the affected ovary and tube typically have reduced to absent venous flow. Arterial flow may be present in less affected portions of the ovary, probably a reflection of the dual arterial supply. Waveforms that demonstrate reversed diastolic flow indicate severe ischemia. The affected adnexa may be surrounded by intraperitoneal fluid.

Another sonographic finding associated with pelvic pain includes pelvic inflammatory disease. In this condition, corpus luteum can become a locus for infection appearing as a hypoechoic mass adjacent to a hydrosalpinx. Guided TVS can provide a means to aspirate the contents of a tuboovarian abscess.

Ectopic pregnancy is an important consideration when considering pelvic pain. By definition, an ectopic pregnancy is one in which the fertilized egg is implanted outside of the endometrial cavity. More than 95% of the time, the improperly implanted embryo can be found within the fallopian tubes; rarely these ova can implant within the adnexa or intraperitoneal surfaces. Clearly, serum beta-hCG testing is necessary to evaluate for ectopic pregnancy in any female with pelvic pain and clinical suspicion. In early healthy intrauterine pregnancies, the serum beta-hCG value should double approximately every 2 days. In the case of an ectopic pregnancy, this doubling rule is not met or may show a beta-hCG value that is slightly decreasing. In practicality, the difficulty with relying on serial laboratory values lies in the delay in establishing a diagnosis. Therefore, ultrasound (US) is often an effective means of helping to identify ectopic pregnancies.

TVS is able to detect an intrauterine gestational sac in cases in which the serum beta-hCG is 1500 to 1800 mIU/mL (approximately 6000 mIU/mL on transabdominal US). If the serum value is at this threshold level and a gestational sac is not visualized within the endometrial cavity, then the pregnancy can typically be considered to be extrauterine.

ENDOMETRIAL DISORDERS

TVS has a vital role in the evaluation of women with suspected endometrial disorders. It provides a means to determine which patients need to be sampled or undergo hysteroscopy versus those who are best managed medically.

It is important to realize that of all postmenopausal women who experience bleeding, only 10% to 15% will have hyperplasia, polyps, or carcinoma. The majority will have endometrial atrophy as the cause of their bleeding.

When assessing a patient's endometrium, it is important to consider their menarchal/menstrual state. For example, a collection of fluid within the endometrial cavity of a fertile woman can be completely normal with menstruation, but in a postmenopausal woman this same finding may be the result of cervical stenosis or an obstructing endometrial or cervical tumor.

In general, an endometrial bilayer less than 6 mm in postmenopausal women who experience bleeding is typically associated with atrophy; those women with a thicker endometrial bilayer are best served by biopsy with management based upon the results. TVS has an important role in recognizing polyps as focal echogenic thickening that with CDS have a feeding vessel. Endometrial cancer can appear as a polypoid lesion, occasionally disrupting the endometrial myometrial junction due to invasion. If there is a question regarding the presence of a polyp, a saline infusion sonohysterogram can be performed to determine the presence of polyps, submucous fibroids, or synechiae.

Another finding to consider when a mass is identified within the endometrial cavity is retained products of conception. These can have various appearances, but should particularly be considered when the patient is known to have recently been pregnant or undergone an elective or nonelective abortion. It is important to identify these products as they may result in uterine infection, synechiae, and metaplasia. One way to help distinguish retained products of conception is through the use of color Doppler sonography, which should show vascular flow to the retained products that have not sloughed. Clots and sloughed tissue typically do not demonstrate flow, however.

UTERINE DISORDERS

By far the most common uterine masses that are seen on sonography are uterine fibroids. They may be submucosal, intramural, or subserosal, and vary from hypoechoic to moderately hyperechoic with echogenic foci consistent with calcification. Additionally, fibroids will show some degree of shadowing particularly arising

from their pseudocapsule. Fibroids are benign soft-tissue masses that have increased frequency in women of African descent and those of middle age. When clinically symptomatic, fibroids often cause pain and vaginal bleeding, which is often disassociated with menstruation. Occasionally, these fibroids will outgrow their blood supply and necrose resulting in an area of hypoechoic or anechoic echotexture present within the solid areas. It is important to document the location of a fibroid relative to the endometrium so that those amenable to intraluminal extraction are distinguished from those that require an open approach.

Adenomyosis is a common cause of excessive bleeding and pain. Sonographically, it appears as an ill-defined disruption of thickened myometrium/endometrium with streaking. This has been described as a moth-eaten appearance that is due to the multiple, small hypoechoic masses seen within the myometrium. As opposed to fibroids that typically exhibit peripheral vascularity, the vascularity associated with adenomyosis is diffuse.

Three-dimensional pelvic sonography provides an accurate means to characterize uterine malformations. Septated uteri can be seen as having a smooth fundal contour and bicornate uteri are noted to have a fundal cleft. Three-dimensional sonography is also useful in assessing the location of an intrauterine contraception device.

MISCELLANEOUS CONDITIONS

TVS has a vital role in the management of gynecologic infertility from follicular monitoring to guided follicular aspiration. Similarly, it is helpful in guided aspiration of tuboovarian abscess and other pelvic fluid collections.

QUESTIONS AND ANSWERS

1. You perform a transvaginal US and identify a pelvic mass with ground glass internal texture. Which of the following is the most likely diagnosis?
 - A. Epithelial ovarian tumor
 - B. Endometrioma
 - C. Dermoid cyst
 - D. Corpus luteum cyst

ANSWER: B. Ground glass appearance is classic for an endometrioma.

2. Which of the following is the most likely etiology for the enlarged ovary seen in torsion?
 - A. Hemorrhagic cyst
 - B. Dermoid
 - C. Hydrosalpinx
 - D. Hemorrhage and edema

ANSWER: D. Although torsion is usually associated with an ovarian mass, ovarian enlargement is thought to be due to hemorrhage and edema, likely from venous outflow obstruction.

3. What does reversed diastolic flow indicate in the setting of torsion?
 - A. Severe ischemia
 - B. Infarction
 - C. Reversibility
 - D. Has no clinical/prognostic significance

ANSWER: A. Reversed diastolic flow suggests severe ischemia.

4. Which of the following is the most common cause of postmenopause bleeding?
 - A. Endometrial carcinoma
 - B. Polyp
 - C. Atrophy
 - D. Cervical carcinoma

ANSWER: C. Atrophy of the endometrium is the most common cause of postmenopause bleeding.

5. How is the vascularity of adenomyosis different from fibroids?
 - A. Fibroids—peripheral; adenomyosis—diffuse
 - B. Fibroids—diffuse; adenomyosis—peripheral
 - C. Their vascularity is identical.
 - D. There is no typical vascular signature of either entity.

ANSWER: A. The vascularity of fibroids is typically peripheral, while that of adenomyosis is more diffuse.

65 OBSTETRICAL ULTRASOUND

Rochelle F. Andreotti, Reagan R. Leverett, and Libby L. Shadinger

FIRST TRIMESTER OBSTETRIC ULTRASOUND

ANATOMY

The blastocyst adheres to the endometrial epithelium on day 6 and is completely surrounded by endometrial epithelium by day 10 of gestation (Fig. 65-1). A normal intrauterine pregnancy will demonstrate the following structures (Fig. 65-2):

- Yolk sac
- Amnion
- Chorion
- Embryo

Note that the chorionic sac may be considered the same as the gestational sac and a portion of it will eventually form the placenta. The yolk sac provides nutrients for the embryo until the establishment of placental circulation and is the first structure identified by sonogram within the gestational sac. A portion of the yolk sac will remain connected to the embryo by the omphalomesenteric duct (secondary yolk sac) and become part of the primitive gut. The amnionic and chorionic membranes fuse at approximately 14 to 16 weeks gestation.

FIRST TRIMESTER SONOGRAPHIC EVALUATION MAY INCLUDE

- Cervix
- Uterus
- Adnexa
- Number and location of gestational sacs
- Number of embryos
- Crown-rump length

- Cardiac activity
- Membranes
- Placenta
- Nuchal translucency

INDICATIONS FOR FIRST TRIMESTER ULTRASOUND

DATING BY SONOGRAPHY

Sonography, if performed early during pregnancy, can greatly enhance the obstetrician's ability to determine the gestational age. The most accurate measurement is the crown-rump length (CRL) when performed between 6 and 12 weeks gestation, confidence level of 95% with a range of 4 to 5 days. The mean sac diameter (MSD) may be used to date the pregnancy if the embryo is not visualized and is equal to the sum of the length, width, and diameter of the gestational sac divided by three.

Clinical dates are calculated from the first day of the last menstrual period with the assumption that ovulation and conception take place on approximately day 14 after the last menstrual period (LMP). It is not uncommon for a patient to be unsure of her dates, have irregular menstrual periods with occasional prolonged cycles, or have some bleeding at the time of implantation of the blastocyst, which is mistaken for a normal menstrual period. The most accurate estimate of gestational age can be made only in patients followed by various clinical methods such as basal body temperatures, luteinizing hormone (LH) surge assays, and ultrasound assessment of follicular growth, while undergoing infertility evaluation.

DETERMINATION OF A LIVE EMBRYO USING TRANSVAGINAL SONOGRAPHY

Using transvaginal sonography (TVS), a gestational sac should be seen by 4.5 weeks, a yolk sac by 5.5 weeks, and an embryo by 6.5 weeks. A yolk sac should be identified by TVS, with a MSD of 8 mm, and an embryo should be seen within a gestational sac of with a MSD of 16 mm or more. The double bleb sign is a transvaginal sonographic sign of a normal intrauterine pregnancy at approximately 5 to 6 weeks, where two cystic structures (the primary yolk sac and amniotic sac) are identified with the developing embryo in between. An embryo with a CRL of 5 mm without cardiac motion is consistent with a failed intrauterine pregnancy (IUP). Note that some radiologists use slightly less strict criteria, typically 8 to 10 mm. A follow-up sonogram may be warranted to ensure that a live pregnancy is not mistaken for a failed pregnancy. A normal early heart rate is greater than 100 bpm. A heart rate of less than 90 bpm has an associated 79% risk of demise.

A saclike structure without a yolk sac or embryo, which appears separate from the endometrial cavity

probably represents a true gestational sac. This may be represented by two important sonographic signs.

- The double decidual sign with the inner decidua being the gestational sac and the outer sac being the endometrial cavity.
- The intradecidual sign is when the sac is eccentrically located with respect to the endometrial cavity within the endometrium.

If no gestational sac is seen within the uterus, the following should be considered:

- Complete or incomplete abortion
- Early IUP (normal or abnormal)
- Ectopic pregnancy

Serial serum beta-human chorionic gonadotropin (hCG) levels are usually obtained to differentiate among these possibilities: a gestational sac should be visualized by 1000 to 2000 mIU/mL (IRP), a yolk sac should be visualized by 7000 mIU/mL, and cardiac activity by 11000 mIU/mL.

VAGINAL BLEEDING

In the first trimester, the earliest bleeding may be secondary to implantation from the blastocyst burrowing into the endometrium, approximate day 20 to 23. Between 5 and 8 weeks gestation, there is sloughing of the decidua capsularis, which covers the chorion laeve, also sometimes referred to as a type of implantation bleeding. Blood may be visualized within the endometrial cavity surrounding the gestational sac giving a "Y" shaped configuration. Retrochorionic hemorrhage occurs following fusion of the chorion with the uterine wall when fluid is demonstrated elevating the chorion from the endometrium and may dissect between chorion and endometrium posterior to the placenta. Prominent vascularity in the region of the cervix may be demonstrated in some patients with vaginal bleeding in the early second trimester in whom no other reason for bleeding has been demonstrated. Other causes of first trimester bleeding include spontaneous abortion, ectopic pregnancy, and gestational trophoblastic disease.

SUSPECTED ECTOPIC PREGNANCY

If the serum hCG is positive, the next step in evaluation of suspected ectopic pregnancy is pelvic sonography. Sonographic confirmation of an IUP effectively excludes ectopic pregnancy because of the extremely low incidence of concomitant ectopic and intrauterine gestations (historically 1/27 000 although the incidence may now be as high as 1/6000 in patients being treated for infertility). An

FIG. 65-3 Diagram of ectopic pregnancy.

SOURCE: Courtesy of Anthony F. Zagar, UAB, Department of Radiology, Birmingham, Alabama.

ectopic pregnancy may be suggested by a hCG of 1000 to 2000 mIU/mL (IRP) and an empty uterus by TVS. In order to confirm an IUP, a sac should be demonstrated within the uterus separate from the endometrial cavity. Although this is a fairly reliable finding, there may still be some confusion between a true sac and fluid within the endometrial cavity (pseudosac), which may be associated with an ectopic pregnancy. A pseudosac of an ectopic pregnancy may be suggested by the presence of an abnormal appearing sac. This would include a sac with angles or a collapsed sac. The absence of the intradecidual and double decidual signs would also warrant a search for an ectopic pregnancy. Adnexal signs vary and may include a living extrauterine pregnancy, a tubal ring, which may contain a yolk sac and/or embryo, a complex cystic or solid adnexal mass, or free fluid, often hemorrhagic in appearance. A tubal ring must be separate from the ovary in order to differentiate it from the corpus luteum.

Doppler imaging may also be of use in identifying an ectopic pregnancy. A tubal ring will appear as a “ring of fire” with color Doppler. Again the “ring of fire” of an ectopic should be determined to be separate from the ovary in order to differentiate it from color Doppler signal that may surround a corpus luteum. Pulsed Doppler may be used to evaluate the tissue surrounding a sac within the uterus. A true gestational sac will have low resistance or high diastolic arterial waveforms, whereas a pseudosac will not. Pulsed Doppler of a tubal ring will demonstrate low resistance/high diastolic arterial waveforms as well, although this is nonspecific because of the presence of the same low resistance waveforms seen in such things as a corpus luteum cyst or ovarian tumors.

The majority (95%–97%) of ectopic pregnancies are tubal, which include both the ampullary and isthmic portions of the fallopian tube. Other types of ectopic

pregnancies are rarely seen although interstitial ectopic pregnancies are the most common of these infrequent locations (Fig. 65-3).

MULTIPLE GESTATIONS

Dizygotic twins (two eggs) are always dichorionic (two placentas) and diamniotic (two amniotic sacs).

Monozygotic twins (one egg) may be

- dichorionic/diamniotic if division is prior to day 3
- monochorionic/diamniotic if division is between days 4 to 8.
- monochorionic/monoamniotic if division is between days 8 to 14.
- conjoined twins if division is after day 14.

DETERMINATION OF AMNIONICITY AND CHORIONICITY

Determining the amnionicity and chorionicity is an important objective for the first trimester sonogram. Important distinguishing signs include the twin peak sign or lambda sign and the T sign. The twin peak sign or lambda sign is a thick intervening membrane and is consistent with dichorionic/diamniotic pregnancy. The T sign is a thin intervening membrane and is consistent with monochorionic/diamniotic twins. No intervening membrane is seen with monochorionic/monoamniotic twins.

NUCHAL TRANSLUCENCY

The nuchal translucency measurement is performed between 11 and 14 weeks gestation and refers to the hypoechoic region along the posterior aspect of the fetal neck. This measurement is part of screening process for chromosomal abnormalities including trisomies 21, 13,

and 18. The pathophysiology of abnormally thickened nuchal translucency is multifactorial, including cardiac dysfunction, venous congestion in the head and neck, altered composition of the extracellular matrix, failure of lymphatic drainage, fetal anemia (because of genetic causes), fetal hypoproteinemia, and fetal infection. Venous congestion in the head and neck may be seen with amniotic rupture, diaphragmatic hernia, and skeletal dysplasias because of obstruction of return of blood to the heart. In trisomies 21, 13, and 18, the etiology is because of altered composition of the extracellular matrix. Fetal infection is more likely if the increased nuchal translucency evolves into hydrops by the second or third trimester. Problematic lymphatic drainage is usually a consequence of hypoplastic lymphatics such as in Turner syndrome.

Measurements vary with gestational age but greater than 3 mm is always considered abnormal. Technique is very important and the unfused amnion should not be mistaken for the fetal skin line. Adding serum two serum markers, pregnancy-associated plasma protein (PAPP-A) and the free beta-subunit of human chorionic gonadotropin (hCG) markers, have also been found to increase sensitivity. According to Malone et al., at 11 weeks of gestation, adding PAPP-A and hCG determinations to measurement of nuchal translucency increases the detection rate of Down syndrome from 70% to 87%, with a 5% false positive rate.

SECOND AND THIRD TRIMESTER OBSTETRIC ULTRASOUND

In the US most women who seek prenatal care receive sonographic evaluation of their pregnancies in the second trimester, usually at around 20 weeks gestational age. While the vast majority of fetuses are structurally normal, sonographic evaluation at this stage enables the patient to make informed choices about the pregnancy and allows for adequate antenatal preparation for delivery and care of infants with a wide variety of anomalies. As fetal surgical interventions continue to advance, early and accurate detection of potentially correctable abnormalities becomes ever more crucial.

In addition to its role in anatomic survey, second and third trimester sonography is a valuable tool in the evaluation of fetal well-being, position, growth, and can help answer clinically relevant questions regarding placenta-tion, umbilical cord configuration and insertion, etiology of vaginal bleeding, status of the cervix particularly as it pertains to preterm labor, and multiple gestations. While first trimester crown-rump length is more precise in pregnancy dating, parameters within the second and third trimesters allow dating with reasonable accuracy.

FETAL ANATOMY

A complete fetal anatomic survey should include examination of the cerebral ventricles, posterior fossa, full length of the spine, stomach, urinary bladder, kidneys, extremities, anterior abdominal wall umbilical cord insertion site, and four chamber views of the fetal heart. If possible, the cardiac outflow tracts should be evaluated.

FETAL NERVOUS SYSTEM

The normal size and configuration of three key intracranial structures can exclude a majority of CNS anomalies: the ventricular atria, cisterna magna, and cavum septum pellucidum. The average measurement of the ventricular atrium is 7 mm; atria over 10 mm are considered abnormal. The choroid plexus may appear to “dangle” in the lateral ventricle. Ventricular enlargement is occasionally seen in normal pregnancies as an isolated finding, but its presence should prompt careful evaluation for underlying hydrocephalus or CNS abnormalities. The presence of a cavum septum pellucidum excludes midline developmental anomalies such as holoprosencephaly and septo-optic dysplasia, and also rules out complete corpus callosal dysgenesis, which is also commonly associated with CNS malformations. Cisterna magna measurements greater than 10 mm may be normal, but should trigger careful analysis for posterior fossa abnormalities.

Hydrocephalus is a common CNS abnormality with a myriad of origins, categorized as obstructive or nonobstructive. Usual underlying etiology is obstructive and causes include spina bifida, aqueductal stenosis, encephalocele, Chiari malformation, and Dandy-Walker syndrome. Nonobstructive causes include intracranial hemorrhage and infection.

Neural tube defects are the most common CNS malformation and have been associated with maternal folic acid deficiency. Maternal serum alpha-fetoprotein level can be elevated in these disorders, which may be the impetus for the sonographic examination. Like many CNS disorders, neural tube defects may be associated with polyhydramnios because of neurologic impairment of swallowing. Neural tube defects include anencephaly, encephaloceles, and Chiari II and III malformations.

Anencephaly is one of the most common fetal CNS anomalies, with a frequency of 1:1000. This lethal anomaly may be detected during first trimester evaluations, but is reliably demonstrated during the second trimester. Ultrasound reveals calvarial absence above the orbits.

Chiari II malformations are complex anomalies affecting the brain, skull, and spinal cord. The most serious neurologic effects are due to the almost invariable

present myelomeningocele as well as the obstructive hydrocephalus caused by anatomic abnormalities of the brain. Radiographic features include a small posterior fossa, herniation of the cerebellar vermis through the foramen magnum, upward herniation of the cerebellum through the incisura (“towering cerebellum”), wrapping of the cerebellum around the pons (“banana” configuration), effacement of the cisterna magna, diminution of the fourth ventricle, beaking of the tectum, corpus callosal dysgenesis, and narrowing of the frontal bone angles which confers a “lemon” shape to the skull. The associated myelomeningocele may be visualized at any level along the spinal cord. Chiari III is defined as the typical findings of Chiari II with an associated encephalocele.

While strongly associated with Chiari malformations, meningocele and myelomeningocele may be found as isolated defects. They occur most commonly in the sacral region and are sonographically identified by splaying of the vertebral body lateral masses with posterior protrusion of a cystic mass of neural elements through the osseous defect. These diagnoses cannot be made with confidence prior to 20 weeks gestation as sacral ossification centers may not be completely ossified earlier in the pregnancy.

Cephaloceles are skull defects that contain herniated neural tissues. They are generally midline and associated with other entities such as Meckel-Gruber syndrome and Chiari III malformations. While 80% are occipital, other locations include parietal, frontal, nasothoracic, sphenoidal, and lateral defects.

Posterior fossa malformations include the spectrum of Dandy-Walker malformation, Dandy-Walker variant, and megacisterna magna. The pathophysiology of Dandy-Walker malformation is thought to be at least partially due to atresia of the foramina of Luschka and Magendie. Radiographically, the entity is characterized by agenesis or hypoplasia of the cerebellar vermis, dilatation of the fourth ventricle, and cystic enlargement of the posterior fossa. Typically, progressive hydrocephalus develops after birth. Dandy-Walker variant, which is more common, has similar findings. However, the posterior fossa is not dilated because of patency of the foramen of Magendie. Megacisterna magna, defined as cisterna magna measurement of greater than 1 cm,

consists of an enlarged posterior fossa with normal cerebellar vermis and fourth ventricle. As an isolated finding, it is usually clinically inconsequential. Its importance therefore lies in differentiating it from the more clinically significant Dandy-Walker malformation.

Aqueductal stenosis is the most common cause of congenital hydrocephalus. It may be congenital, secondary to chromosomal abnormalities, or acquired through in utero infection. Much more rarely, it may be caused by an underlying congenital mass such as germinoma or teratoma. Prognosis depends upon the degree of ventriculomegaly and response to postnatal shunting.

Holoprosencephaly is failure of the embryonic forebrain to divide into right and left cerebral hemispheres. The manifestations of this disorder range from the most severe, alobar form, to the moderate semilobar form, to the milder lobar form. Midline facial anomalies ranging from cyclopia to mild facial dysplasia are common. The severity of these defects correlates with the severity of the holoprosencephaly. Similarly, the clinical expressions of holoprosencephaly, which include developmental delay, seizures, hydrocephalus, and pituitary dysfunction, correspond to the degree of the anomaly. While the radiographic features vary between the alobar, semilobar, and lobar forms, the unifying finding is absence of the septum pellucidum.

Hydrancephaly is characterized by near complete absence of supratentorial structures, particularly the cerebral cortex. The thalami, midbrain, pons, and cerebellum develop normally. While the exact etiology is unknown, an in utero event leading to ischemia or infarction of the anterior circulation bilaterally is suspected. Ultrasound reveals a cystic appearance of the cranial cavity with near absence or total absence of the cortex. Prognosis is uniformly poor, and most infants die within the first year. While the children may appear physically normal at birth, developmental delays quickly become apparent (Table 65-1).

While they are not abnormalities of the CNS, cleft palate, cleft lip, and cystic hygroma should be considered when examining the fetal head and neck. Cystic hygromas are fluid-filled structures caused by lymphatic malformation or obstruction. Their prognosis depends upon size and associated anomalies. Large cervical hygromas are associated with fetal hydrops and intrauterine

TABLE 65-1 Comparisons Between Major Cystic Supratentorial Central Nervous System Abnormalities

HOLOPROSENCEPHALY	HYDRANCEPHALY	SEVERE HYDROCEPHALUS
Cerebral cortex fused across midline	Cerebral cortical tissue absent	Cortical tissue present (thin rim)
Falx absent	Falx present	Falx present
Thalami partially or totally fused	Normal thalami	Normal thalami
Abn karyotypes common (especially trisomy 13)	No association with karyotype abnormalities	± Karyotype abnormalities
Midline facial defects	Normal face and midline structures	Normal face and midline structures

demise. The association with chromosomal abnormalities, especially Turner syndrome, is strong. Cystic hygromas outside the head and neck do not have the same risks of chromosomal abnormalities and adverse outcome. Cleft lip is a superficial soft-tissue abnormality, which is caused by failure of fusion of the maxillary and medial nasal processes during formation of the primary palate. Cleft palate is caused by failure of fusion of the formation of the secondary palate, which is formed by the lateral palatine processes, the nasal septum, and medial palatine processes. Cleft palate is usually accompanied by cleft lip. The two processes may be isolated or may be seen in chromosomal abnormalities or midline neurologic abnormalities such as holoprosencephaly.

FETAL THORAX

CARDIAC ABNORMALITIES

Structural cardiac defects are present in as many as 8/1000 live births. These defects may be difficult to detect because of the small fetal heart size, often confusing fetal orientation with respect to ultrasound scan planes, and rapid fetal heart rates. However, the four-chamber and outflow tract views can allow detection of many abnormalities. M-mode scanning also allows discovery of fetal arrhythmias. Key to interpretation of fetal cardiac images, especially when fetal lie is variable, is understanding that the left atrium should be the chamber nearest the spine. Additionally, the right ventricle must be differentiated from the left. The right ventricle is retrosternal and contains the moderator band. Normally, both ventricles are approximately the same size. The left ventricle is posterior and to the left of the right ventricle, and the mitral valve insertion is just slightly cephalad to that of the tricuspid valve.

Ventricular septal defect (VSD) is common among the cardiac abnormalities, comprising up to 40% of congenital heart defects. It results from abnormal development of or improper resorption of portions of the muscular septum and endocardial cushions. The presence of a VSD allows left-to-right ventricular shunting of blood. While it may be found in isolation, VSD has an association with trisomy 21. It is best detected on the four-chamber view, and Doppler analysis may be helpful in confirming smaller defects.

Endocardial cushion defect, also readily diagnosed on the four-chamber view, is much less common and is caused by failure of the endocardial cushions to fuse. Regurgitation at the atrioventricular valve level is always present. A common atrioventricular valve exists rather than separating tricuspid and mitral valves. The association with trisomy 21 is somewhat higher than that of VSD.

Hypoplastic left heart represents up to 4% of congenital heart defects, and its pathophysiology is largely unknown. A leading theory is that cardiac chamber development is dependent upon chamber blood flow and that some impedance to left chamber blood flow results in a disproportionately small left heart and aorta. The abnormality is best detected on the four-chamber view. The left ventricle appears small, and the mitral valve and aorta appear small. Sustainment of the life of the newborn infant outside of the uterus depends upon the maintenance of a patent ductus arteriosus and shunting through a large atrial septal defect to supply the necessary blood flow to the body beyond the aorta.

Tetralogy of Fallot has four classic features: VSD, overriding aorta, right ventricular outflow tract stenosis, and right ventricular hypertrophy. It is caused by unequal division of the conus resulting from anterior displacement of the truncoconal system. The conus then divides into a smaller anterior right ventricular segment and a larger posterior left ventricular segment, which subsequently gives rise to an overriding aorta and stenosis of the right ventricular outflow tract. This disorder is best visualized on the heart base and outflow tract images, which may demonstrate failure of normal crossing of the great vessels at the base of the heart. The relatively large aorta will override the comparatively small pulmonary artery.

Complete transposition of the great arteries occurs in 0.2 to 0.4/1000 live births. In normal development, the truncus arteriosus divides into a pulmonary artery arising from the right ventricle and an aorta arising from the left ventricle. This division is a result of spiraling of the conal truncal ridge. Caudal growth of the septum without spiraling of the conal truncal ridge results in abnormal relationship between the ventricles and great vessels. The great vessels assume a parallel rather than crossing orientation, apparent on the outflow tract images.

Truncus arteriosus is a less common abnormality, which results when the conal-truncal ridges fail to fuse and descend toward the aortic sac. The truncus arteriosus is formed by the fusion of two opposing ridges in the cephalic portion of the truncus, which grow caudally toward the aortic sac. Normally, these ridges spiral and divide the truncus into the more anteriorly located pulmonary artery and the more posterior aorta. When conal-truncal ridge fusion and spiral fail, a single truncal vessel overrides the ventricular septum. A ventricular septal defect is usually associated. The diagnosis may be made on outflow tract views or on a base view of the heart, which depicts a single vessel originating from the ventricles.

M-mode or Doppler interrogation can be useful for the assessment of fetal arrhythmias. Premature atrial

contractions are the most common fetal arrhythmia. Both premature atrial and ventricular contractions are generally benign and often resolve before birth. Supraventricular tachycardia (heart rate greater than 180 beats per minute) is the most common tachyarrhythmia. A minority of these cases is associated with a congenital heart defect. The clinical importance lies in the possible development of fetal hydrops, and these arrhythmias are often treated medically during the pregnancy. Bradycardia is defined as heart rate less than 100 beats per minute sustained for longer than 10 seconds and is indicative of hypoxic distress. Fetal heart block is highly associated with congenital heart disease as well as maternal systemic lupus erythematosus.

FETAL HYDROPS

Fetal hydrops is defined as the accumulation of fluid within at least two separate fetal body compartments. Suggestive sonographic features include the presence of ascites, pleural effusions, pericardial effusion, subcutaneous edema, placental enlargement, and polyhydramnios. The presence of oligohydramnios in combination with other findings suggestive of hydrops is a very poor prognostic indicator.

Hydrops is categorized into immune and nonimmune causes, which comprise approximately 10% and 90% of cases, respectively. Immune hydrops is usually because of maternal–fetal rhesus (Rh) blood antigen–antibody incompatibility. An Rh– mother develops immunoglobulins during her first pregnancy with an Rh+ fetus. In a subsequent pregnancy with an Rh+ fetus, and antigen–antibody reaction causes hemolysis of fetal red blood cells. This anemia triggers a chain of events, which culminate in fetal hydrops. This immune reaction is largely preventable by the administration of anti-Rh antigen immunoglobulin to Rh– mothers at 28 weeks. In cases in which immune hydrops develops, effective therapeutic intervention is possible by fetal blood transfusion via the umbilical cord.

The more common nonimmune fetal hydrops has a multitude of possible causes and has a relatively poor prognosis as the etiologies are generally not correctable in utero. The majority are cardiac-related. Other causes include chromosomal abnormalities, infection, twin–twin transfusion, and nonimmune types of fetal anemia (Fig. 65-4).

NONCARDIAC THORACIC ABNORMALITIES

Pulmonary hypoplasia may be idiopathic, but is more often a sequela of other malformations. Oligohydramnios, particularly secondary to renal agenesis, may severely impede lung growth by preventing proper lung

FIG. 65-4 Causes of fetal hydrops.

distention. Skeletal abnormalities, such as many forms of dwarfism, which result in decreased thoracic cavity size, may prevent adequate lung expansion. Structural abnormalities such as diaphragmatic hernias and pulmonary adenomatoid malformations can prevent adequate development and maturity of one or both lungs. Congenital diaphragmatic hernia is the herniation of abdominal contents into the thoracic cavity resulting from a failure of closure of the pleuroperitoneal canals. Ninety percent of these hernias are left sided, with most of the remainder on the right. Rarely the entity may be bilateral. While it may be seen in association with abnormal karyotypes, many are isolated anomalies. The outcome of this condition depends upon the severity of consequential events including polyhydramnios caused by bowel obstruction and impairment of swallowing, pulmonary hypoplasia, ascites caused by impeded venous return to the heart, and mass effect upon the heart itself. Herniation of the liver through a right-sided defect also portends a poor prognosis.

Sonographic evaluation demonstrates contralateral displacement of the heart within the thoracic cavity in relation to the diaphragmatic defect. Often the abdominal circumference is decreased as the abdominal contents lie within the thorax. If the stomach and bowel are involved in the hernia, real-time sonography may reveal peristaltic motion of these structures within the chest. The position of the liver may be ascertained by the use of Doppler interrogation of the portal vein to determine its relationship with the diaphragm.

Cystic masses within the chest include bronchogenic cyst, esophageal duplication cyst, congenital teratoma, and congenital pulmonary adenomatoid malformation (CPAM). While the former three entities tend to favor the mediastinum, CPAM is a hamartomatous anomaly found

in the lung parenchyma. It is generally subdivided into three types. Type I CPAMs, which generally have a favorable a prognosis, are composed of one or more cysts which are each 2 to 10 cm in size. Type II includes cysts less than 2 cm. Prognosis is fairly poor as this type has an association with renal and gastrointestinal abnormalities. Type III may appear as a sonographically solid mass which is actually a conglomeration of macroscopic cysts; prognosis tends to be poor.

Bronchopulmonary sequestration is a nonfunctioning nest of pulmonary tissue, which does not communicate with the tracheobronchial tree. It is thought to arise from an accessory lung bud, which migrates caudally from the developing normal lung. Sequestrations are categorized as intralobar or extralobar types, and 80% occur on the left side of the body. Intralobar sequestrations are usually an isolated abnormality. Extralobar types are often associated with other structural abnormalities, particularly congenital diaphragmatic hernias. While both types tend to have a systemic arterial supply, extralobar types typically have systemic venous drainage, while intralobar sequestrations usually drain via pulmonary veins. Extralobar sequestrations are enveloped by a separate pleura, while intralobar are enclosed within the pleura of the adjacent normal lung. Generally, only the extralobar type is prenatally detected. In these cases, ultrasound may demonstrate an echogenic mass at the lung base with systemic vascular supply.

FETAL GASTROINTESTINAL TRACT

Evaluation of the stomach is helpful in detection of upper gastrointestinal tract abnormalities. The stomach should be reliably visualized beyond 20 weeks gestation. Lack of visualization of the stomach beyond this point may imply several abnormalities, including neurologic impairment of swallowing, physical obstruction by an oral, cervical, or thoracic mass, esophageal atresia, or more rarely gastric atresia. Esophageal atresia is often associated with other anomalies, one of which is the VACTERL complex. VACTERL is an acronym that encompasses a constellation of vertebral body anomalies, *anal* atresia, cardiac defects, *tracheoesophageal* fistula, *esophageal* atresia, renal anomalies, and *limb* malformations.

When the stomach and duodenum appear dilated, duodenal obstruction is suspected, often attributable to atresia, stenosis, annular pancreas, or peritoneal bands. The exact etiology may be difficult to elucidate during fetal life. Duodenal atresia has a relatively high association with chromosomal abnormalities, particularly trisomy 21. Multiple dilated loops of small bowel may herald obstructive processes such as volvulus, malrotation, and peritoneal bands.

Echogenic bowel is seen in approximately 1% of second-trimester fetuses. The ultrasound appearance is that of a hyperechoic (isoechoic to bone), nonshadowing mass in the lower abdomen and pelvis. In about 50% of cases, the appearance is an isolated finding that resolves upon subsequent imaging. Differential considerations include cystic fibrosis, intraamniotic bleeding with fetal swallowing of the blood, congenital infections, and chromosomal abnormalities.

The significance of peritoneal calcifications depends upon their location and associated findings. Meconium peritonitis is manifested as scattered peritoneal calcifications which often stud the surface of the liver, and represents the sequela of in utero bowel perforation. Causes of meconium peritonitis include ileal atresia, jejunal atresia, volvulus, microcolon, and cystic fibrosis. A meconium pseudocyst, indicative of contained perforation, is a hypoechoic mass with a calcified wall. Isolated calcifications within the hepatic parenchyma rather than on the peritoneal surface are often of no consequence. However, they may be associated with congenital infections such as toxoplasmosis or cytomegalovirus (CMV) and may rarely be found in conjunction with fetal tumors such as hemangioendothelioma.

Anterior abdominal wall defects are subcategorized into midline and lateral defects (Table 65-2). Midline defects include omphaloceles and Pentalogy of Cantrel, the latter of which is very rare and associated with ectopia cordis. Lateral defects include gastroschisis, limb body wall complex, and amniotic band syndrome. Of these entities, gastroschisis and omphalocele are the most common and the most similar in appearance.

Gastroschisis is generally an isolated defect. Recent research has indicated a slightly increased risk in primiparous teenage mothers. The associated morbidity and mortality are chiefly the result of complications related to bowel obstruction, bowel infarction, or sepsis.

TABLE 65-2 Distinguishing Features of Gastroschisis and Omphalocele

	GASTROSCHISIS	OMPHALOCELE
Location	Right paraumbilical	Midline
Umbilical cord insertion	Lateral to defect	Apex of defect
Size of defect	Small (2–4 cm)	Large (2–10 cm)
Covering membrane	No	Yes
Liver involvement	No	Common
Ascites	No	Common
Bowel thickening	Common at term	Rarely
Bowel atresia	Common	Rare
Bowel ischemia	Common	Rare
Cardiac anomalies	Rare (ASD, PDA)	Common
Associated karyotype abnormalities	No	Often

Ultrasound in the second trimester reveals bowel floating within the amniotic fluid outside the confines of the fetal abdomen, with insertion of the umbilical cord to the right of the defect. An omphalocele is a central abdominal wall fusion defect with a high association with chromosomal abnormalities. The midgut and occasionally the liver, spleen, or gonads are herniated into a translucent sac composed of amnion, peritoneum, and Wharton's jelly. The umbilical cord inserts centrally. The associated morbidity and mortality of omphalocele is chiefly determined by the underlying chromosomal defects.

Amniotic band syndrome is the result of amputations and defects of the abdominal wall and extremities resulting from ruptured bands of amnion within the amniotic fluid. The head may be spared, but occasionally unusually located encephaloceles are seen. The abdominal wall defects are asymmetric, eccentric, and may bear a resemblance to gastroschisis. Limb-body wall complex is a severe form of amniotic band syndrome, which is incompatible with life. The presence of both an omphalocele and severe scoliotic curvature of the fetal spine are suggestive of the diagnosis.

FETAL GENITOURINARY TRACT

The fetal kidneys can be routinely visualized beyond gestation week 16, at which point the bladder begins to fill with urine and empty every 30 to 45 minutes. A potential pitfall in the assessment of the fetal kidneys is that the presence of reniform structures in the flanks may not necessarily signify kidneys as the adrenal glands may enlarge and appear reniform shape in renal agenesis. Thus, lack of visualization of the bladder and oligohydramnios is a more reliable indicator of non-functioning or absent kidneys. Fetal urinary tract anomalies may include obstructive processes as well as functional impairment. The consequences of obstructive processes exist on a continuum from mild hydronephrosis to the nonfunctional multicystic dysplastic kidney.

Renal agenesis results from failure of differentiation of the metanephric blastema during the first month of embryogenesis. The affected kidney, renal artery, and ureter are absent. Unilateral agenesis, which is compatible with normal life, is at least twice as common as the lethal bilateral agenesis. This entity is heritable in approximately 15% of cases. The diagnosis of bilateral agenesis is suggested sonographically by oligohydramnios and lack of bladder filling. Potter's sequence is the clinical syndrome associated with bilateral renal agenesis and the resulting oligohydramnios. Affected infants have a typical facial appearance with a flattened nose, low-set ears, and prominent epicanthal folds. Various

skeletal and cardiovascular malformations may be present. The severe pulmonary hypoplasia is incompatible with life. Bilateral agenesis may be seen in conjunction with chromosomal abnormalities, multicystic dysplastic kidney, or as part of a constellation of complex anomalies such as VACTERL.

Cystic renal diseases include multicystic dysplastic kidney disease (MCDK) and polycystic kidney disease. Polycystic kidney disease exists in two forms: the autosomal recessive (ARPKD) infantile type and the autosomal dominant (ADPKD) later (adult) onset type. The kidneys are enlarged and hypoechoic, and individual cysts cannot be identified sonographically. ARPKD is a spectrum of liver and renal disease; the severity of the hepatic and renal manifestations vary inversely. Renal disease dominates in the severe perinatal form and can result in the Potter sequence.

MCDK, which is the most common neonatal renal mass, is the end result of severe in utero obstruction. The upper third of the ureter is atretic, which prevents the metanephric blastema from producing nephrons. The collecting tubules become dilated. Ultrasound features include a paraspinal mass with numerous cysts of varying sizes. These cysts do not communicate, which allows discrimination from hydronephrosis. Contralateral renal anomalies, most commonly ureteropelvic junction (UPJ) obstruction, are present in 40% of cases. The condition is lethal if associated with contralateral MCDK or renal agenesis. Meckel-Gruber, an autosomal recessive syndrome, requires two of the three characteristic features of bilateral multicystic dysplastic kidney, occipital encephalocele, and polydactyly for the diagnosis. As 95% of the affected fetuses have bilateral MCDK, the condition is generally lethal at birth.

Common obstructive processes include UPJ obstruction, ureterovesicle junction (UVJ) obstruction, and bladder outlet obstruction. UPJ obstruction is the most common antenatal cause of hydronephrosis. Abnormal ureteral recanalization, which normally begins in the midureter and continues proximally and distally, is a leading theory in the pathogenesis of intrinsic UPJ obstruction. Extrinsic causes of UPJ obstruction are most commonly associated with compression of the ureter by aberrant or supernumerary renal vessels, usually by low insertion of a renal artery. Contralateral renal anomalies are not uncommon. Severe obstruction can cause significant mass effect within the thorax and abdomen. Congenital UPJ obstruction may lead to progressive ipsilateral renal impairment.

UVJ obstruction is less common than UPJ obstruction. As with UPJ obstruction, when the process is unilateral, amniotic fluid volume remains unaffected. Underlying etiologies include a duplicated system with obstruction of the ectopic upper pole moiety, primary megaureter, which is a functional obstruction, and distal

ureteral atresia or stricture. If severe, renal function can be affected by urinary stasis and reflux.

Posterior urethral valves (PUV) in a male infant are by far the most common cause of fetal bladder outlet obstruction. A posterior urethral valve is an abnormal membrane which arises during abnormal embryological development of the Wolffian duct. Key sonographic findings include a thickened bladder wall with bladder and posterior urethral dilatation, the appearance of which has been likened to a keyhole. Urinary ascites may develop as a consequence of calyceal rupture caused by extremely high pressures generated by constant urinary reflux and stasis. Outcome depends upon the severity of the resulting renal dysfunction and oligohydramnios.

FETAL MUSCULOSKELETAL SYSTEM

Second and third trimester sonographic evaluation of the osseous structures, particularly the extremities, can be helpful in detection of a host of skeletal dysplasias. Long bone lengths greater than two standard deviations below the mean are highly suggestive of dwarfisms. A small thoracic circumference with associated pulmonary hypoplasia is ominous for lethal skeletal abnormality such as thanatophoric dwarfism, which is the most common lethal dysplasia. The most common nonlethal skeletal dysplasia is heterozygous achondroplasia. Fetuses with the lethal autosomal recessive form of osteogenesis imperfecta, OI type II, lack skull ossification and demonstrate multiple angulated long bone fractures.

Caudal regression is caused by abnormal caudal mesoderm development. While the pathogenesis is largely unknown, up to 20% of cases affect fetuses of diabetic mothers. The entity encompasses a spectrum from complete sacral absence with associated lumbar spine, lower extremity, GI, and GU abnormalities to milder sacral abnormalities without associated defects. Typically, sonographic findings will include absence of one or more vertebrae with fused appearance of the ilia and decreased distance between the femoral heads. The most severe manifestation of caudal regression syndrome is sirenomelia, in which the lower extremities are fused and bilateral renal agenesis or MCKD leads to marked oligohydramnios.

Sonographic evaluation of the hands and feet can provide valuable information about anatomic defects of these extremities, some of which are highly associated with underlying chromosomal abnormalities. The presence of a rocker bottom foot is strongly associated with trisomy 18. Equinovarus talipes, or congenital clubfoot, may be seen in isolation or in combination with other chromosomal abnormalities, neuromuscular disorders, oligohydramnios, amniotic band syndrome, or connective tissue disor-

ders. The foot remains fixed at a right angle to the tibia, and the metatarsal bones are seen in the same imaging plane as the tibia and fibula. Fixed overlapping of the index over the other closed digits is known as clenched fist. The thumb is adducted, and the proximal interphalangeal joint of the index finger flexed. The position is constant during sonographic evaluation and is strongly associated with trisomy 18. Clinodactyly is fixed deviation of the fifth finger in the radioulnar plane. This abnormality is caused by a short middle phalanx, which causes radial angulation of the distal interphalangeal joint. Clinodactyly is associated with trisomy 21 and should prompt a search for other findings suggestive of the diagnosis.

CHROMOSOMAL ABNORMALITIES AND SYNDROMES

A search for sonographic findings supportive of the diagnosis of chromosomal abnormalities may be undertaken in cases of abnormal triple or quadruple screen results, or when a sonographic finding with high association with such anomalies is discovered. Choroid plexus cysts are identified in approximately 1% of pregnancies scanned during the second trimester. The majority will resolve by the third trimester with no implications upon fetal outcome. However, the presence of choroid plexus cysts is a marker for possible increased risk of trisomy 18. Similarly, a single echogenic intracardiac focus is a marker which has been associated with trisomy 21. This echogenic focus correlates with papillary muscle mineralization. With either finding, the fetus should be carefully evaluated as additional abnormalities confer marked increased risk for aneuploidy (Tables 65-3 to 65-6).

DATING AND FETAL GROWTH

While crown-rump measurement in the first trimester is fairly precise for dating of pregnancy, sonographic gestational age assessment becomes increasingly less accurate as pregnancy progresses. Biparietal diameter, head circumference, and femur length are measurements used for dating which, when used in the second trimester, obtain a 95% confidence level of ± 10 to 12 days with the greatest accuracy before 20 weeks gestation. The abdominal circumference measurement has been found to reflect size more so than gestational age, especially in the third trimester. Beyond 26 weeks, ultrasound is much less reliable with a 95% confidence level of ± 3 weeks. Some data suggest that femur length may be the most accurate measurement in the third trimester. The transverse cerebellar diameter has also been reported to be a fairly reliable predictor in the second and third trimester.

Third trimester pregnancy dating can become important in cases in which patients received no previous prenatal care or in cases in which fetal growth disturbances are suspected. Because of difficulty in accurately dating a pregnancy in the third trimester through measurements, investigators have tried to determine fetal age and more importantly, fetal lung maturity, by the appearance of different organ systems, including bowel, lungs, bones, and placenta. These correlations have met with a limited success. For example, a mature appearance of the placenta is usually associated with fetal lung maturity in most low-risk patients, but multiple case reports describe hyaline

TABLE 65-6 Causes of Elevated Maternal Serum Alpha-Fetoprotein Level

Maternal causes

- Subchorionic or retroplacental hemorrhage
- Inaccurate dating of pregnancy

membrane disease in patients with a sonographically mature placenta. More recently, appearance of long bone ossification centers has been studied as a predictor of gestational age. The distal femoral epiphysis is seen by approximately 33 weeks, while the proximal humeral epiphysis is not present before 37 weeks.

SMALL FOR DATES

Patients may be referred for ultrasound examination because of small uterine size for stated menstrual age or because of known fetal or maternal abnormalities which increase risk for intrauterine growth restriction (IUGR). While a fetus below the 10th percentile for weight is at risk for growth restriction, many of these infants are normal. However, true growth restricted fetuses are at high risk for significant morbidity and mortality. Ultrasound is a helpful tool for identifying fetuses at risk with the use of fetal parameters such as abdominal circumference, weight, and body proportionality. In most cases of IUGR, the abdomen is small whereas head circumference is spared. Therefore, abdominal circumference and head circumference ratios are commonly used in the evaluation. These pregnancies are generally followed closely with ultrasound for interval growth assessment, particularly if the gestational age is uncertain.

In some cases, a small uterine size for menstrual dates is due to oligohydramnios. Decreased amniotic fluid volume can be quantitatively diagnosed if the largest vertical pocket of fluid is less than 2 cm or the amniotic fluid index, which adds the largest vertical pocket in each of the four abdominal quadrants, is less than 5 cm. Oligohydramnios may be due to intrauterine fetal demise, bilateral renal anomalies, in utero infection, premature rupture of membranes, postdates pregnancy, and chromosomal abnormalities (Tables 65-7 and 65-8).

LARGE FOR DATES

Sonographic evaluation may also be helpful in cases in which the uterus is clinically large for the patient's gestational age. Fetuses with estimated fetal weight above the 90th percentile or above 4000 or 4500 g, depending on the selected diagnostic threshold, are large for gestational age (LGA). Risk factors include maternal diabetes, maternal obesity, and a previous LGA infant. Most LGA fetuses are symmetrically large. Macrosomic infants are a subset of LGA fetuses in whom the shoulder and body are disproportionately large; these fetuses are at significantly increased risk for shoulder dystocia during delivery. Macrosomia is associated with maternal gestational diabetes (for which it may be the only diagnostic indicator) as well as preexisting insulin-dependent maternal diabetes. Other reported complications of

TABLE 65-7 Causes of Intrauterine Growth Restriction

PLACENTAL CAUSES	MATERNAL CAUSES	FETAL CAUSES
Twin–twin transfusion	Hypertension	Chromosomal abnormalities
Placental abnormalities	Chronic renal disease	Congenital infections
Chronic abruption	Severe diabetes	Multiple gestations
Placenta previa	Hemoglobinopathies	
	Autoimmune disease	
	Smoking	
	Substance abuse	
	Uterine malformations	

LGA fetuses include birth asphyxia, meconium aspiration, neonatal hypoglycemia, and birth trauma.

Other entities which may cause a larger than expected uterus include polyhydramnios, multiple gestations, and uterine leiomyomas. Uterine leiomyomas may significantly enlarge under hormone influences in the second and third trimester, causing marked uterine distortion. Multiple gestations may significantly enlarge the uterus even while the fetuses are individually small.

While many experienced practitioners accurately diagnose polyhydramnios by gestalt, it can be quantitatively defined as a single vertical pocket greater than 8 cm or an amniotic fluid index of greater than 20 cm. In many cases, increased amniotic fluid volume is idiopathic. However, the majority of pregnancies with markedly increased amniotic fluid are associated with underlying congenital abnormalities including fetal hydrops, CNS lesions, thoracic mass, GI obstruction, and twin–twin transfusion. Other causes include maternal diabetes mellitus, congenital infection, and multiple gestations (Table 65-9).

FETAL WELL-BEING

The biophysical profile (BPP) is a powerful predictor of fetal risk hypoxia, distress, and perinatal death. The results may be used to determine the timing of delivery in high-risk pregnancies. The BPP grading system is a binomial system to which scores of 0, 1, or 2 are assigned to the four variables of fetal tone, breathing movements, gross body movements, and amniotic fluid volume. These four variables are combined with the results of nonstress testing for a maximum score of 10. A BPP

Chromosomal abnormalities
Placental insufficiency

score of eight or higher portends a negative predictive value of approximately 99% for normal live outcome within 1 week of the test; a score of two or less is highly predictive of impending fetal demise. The intermediate scores of 4 to 7 have variable outcomes.

Umbilical artery Doppler velocity waveform analysis can further elucidate the risk of fetal morbidity and mortality in cases of suspected IUGR with hypoxemia. An abnormal Doppler ratio indicates compromise of fetal circulation, although the degree of ratio increase generally does not correlate with the severity of the distress. The ratio is obtained by comparing peak umbilical artery systole (A) to end-diastole (B). Normally, A/B ratios progressively decrease throughout the second and third trimesters from mean values of 4.25 at 16 weeks to 2.5 at term. Decreased fetal blood flow may be secondary to increased vascular resistance within the placenta, abnormalities of the fetus itself, or maternal cardiovascular problems. Analysis of the middle cerebral artery Doppler waveform may further characterize the degree of hypoxemia in the fetus with asymmetric IUGR and abnormal umbilical artery Doppler ratios. Initially, the MCA end diastolic velocity will increase, while the pulsatility index (peak systole minus end-diastole divided by the area under the curve of one waveform) will decline as autoregulation preserves brain flow at the expense of blood flow to the remainder of the body. As

the fetal distress worsens and end-diastolic velocity decreases, autoregulation is lost and the pulsatility index rises. The loss of autoregulation is likely due to brain edema.

FETAL PRESENTATION

Sonographic evaluation of fetal lie or presentation is both time-efficient and radiation-free, which are significant advantages over the older radiographic method. At term, the fetal lie may have implications in the management of delivery.

PLACENTATION ABNORMALITIES

In most cases, placental implantation occurs well away from the internal cervical os. In a small minority of cases during the second trimester, the placenta extends to or partially or totally covers the os. Partial and complete previas partially and completely cover the os, respectively. Marginal placentas extend within 2 cm of the os. After the initial detection of these placental abnormalities, the patient is followed with repeat ultrasound early in the third trimester. Placenta previas can regress, so that at term only 0.5% of these abnormalities persist. The apparent regression of the previa has been attributed to more rapid growth of the more cranial uterus as compared to the lower uterine segment and cervical regions during pregnancy. A newer, more widely accepted theory involves involution of the placenta previa owing to lack of vascular support from the cervix (trophotropism). Should the previa or marginal placenta continue, cesarean delivery is planned before the onset of labor to prevent major hemorrhage. Potential pitfalls in the diagnosis of placenta previa include overdistention of the bladder and focal myometrial contractions at the time of the ultrasound evaluation. The patient should be reimaged after bladder emptying if placenta previa or a low-lying placenta is suspected.

In normal placentation, the endometrium prevents placental invasion into the uterine myometrium. Placenta invasion refers to the abnormal penetration of chorionic villi into or even through the uterus. Placenta accreta, which constitutes 80% of such cases, is the adherence of chorionic villi to the superficial myometrium. Approximately 15% involve deep invasion into the myometrium, termed placenta increta. In less than 5% of cases, the villi completely penetrate through the uterus and may invade adjacent organs such as the bladder. Detection of placental invasion is critical as it may result in catastrophic maternal hemorrhage at delivery or infection caused by retained placenta. Prior ce-

sarean section or other surgical intervention of the uterus with subsequent scar formation is a known risk factor. Sonographic diagnosis is based upon demonstration of retroplacental vascularity within or projecting through the myometrium. MRI may be helpful if the diagnosis is equivocal.

UMBILICAL CORD

The normal umbilical cord contains two arteries and one vein. A two-vessel cord with a single artery and vein is associated with karyotype or structural abnormalities in singleton pregnancies; two-vessel cord in multiple pregnancy is less likely to have associated abnormalities. The cord may have only two vessels for portions of its length, but color Doppler imaging of the iliac arteries on both sides of the urinary bladder confirms the presence of two arteries at the fetal level. Evaluation of fetal growth in the third trimester is recommended given the association of two vessel cords and intrauterine growth restriction.

Anomalous umbilical cord insertion into the placenta has potentially critical ramifications. Cord insertion is normal if it occurs anywhere in the placental substance, including its margin. A velamentous cord insertion is insertion beyond the margin of the placenta. The umbilical cord arteries and vein are connected to the placenta by a pedicle and covered only by the amnion and chorion. If undetected sonographically, the vessels can rupture during labor and delivery and cause life-threatening fetal hemorrhage. If these anomalous vessels cross the internal os, the condition is termed vasa previa. Again, catastrophic fetal blood loss can occur at the time of membrane rupture or delivery.

VAGINAL BLEEDING

As previously discussed, the entities of placenta previa, placental invasion, velamentous cord insertion, and vasa previa may lead to major fetal and/or maternal periparturient hemorrhage. Another important cause of vaginal bleeding during the second and third trimester is placental abruption, which is the premature separation of the implanted placenta from the uterus. As 50% of abruptions are sonographically occult, the diagnosis is primarily clinical. Nonetheless, retroplacental hemorrhage on ultrasound is diagnostic.

CERVIX

The average length of the normal cervix at 20 weeks is 3.5 to 4.0 cm as measured along the endocervical canal. Transvaginal, rather than transabdominal, cervical length

evaluation is more reliable and more reproducible. The shortest length observed during sonographic evaluation should be reported. Before 32 weeks, measurements below the 10th percentile, which is 2.5 cm, are generally considered to suggest a risk for preterm labor. Beyond 32 weeks, cervical length becomes less reliable as a predictor of achievement of term pregnancy as cervical effacement generally begins 4 to 8 weeks before delivery.

Incompetent cervix refers to the painless, premature dilatation of the cervical canal. This term is generally applied to cervical dilatation during the first or early second trimesters. Women who have a cerclage placed for incompetent cervix should be followed with serial ultrasound examinations.

MULTIPLE GESTATIONS

Multiple gestations have profound implications upon prenatal, perinatal, and postnatal clinical management. The worldwide incidence of twins is slightly less than one in every 100 births. However, twins and even higher-order multiples are occurring at increased frequency as infertility treatments are introduced and improved. The inherent risks of pregnancy, such as preeclampsia, preterm delivery, growth restriction, and umbilical cord accidents, are significantly increased in multiple gestations.

Differentiation of the different categories of twins is important as the risks for adverse outcome is significantly increased in twinning other than the dichorionic-diamniotic type. One of the feared complications of monochorionic twinning is twin-twin transfusion syndrome (TTS), in which the blood of one twin flows preferentially to the other through a shared placenta. The donor twin becomes hypovolemic and oliguric, and oligohydramnios develops in its amniotic cavity if the twins are diamniotic. Severe oligohydramnios may lead to stuck twin syndrome in which the donor twin may appear fused to the uterine wall. The recipient twin is significantly larger and may develop cardiac failure as a result of volume overload. Polyhydramnios within its amniotic cavity may cause rapid maternal abdomen enlargement. Both twins are at risk for hydrops fetalis. In utero treatments for TTS include reduction amniocentesis of the fluid surrounding the recipient twin. A few medical centers offer laser photocoagulation of chorionic plate vessels to destroy the anastomoses within the placenta allowing the abnormal circulation.

Embolization is a complication of monochorionic twinning in which the death of one twin results in a sudden hemodynamic shift of blood to the remaining twin that ultimately leads to the demise of the latter. Rarer is the acardiac twin, in which a twin with a nonfunctioning heart receives blood supply from a donor twin via arteriovenous anastomoses; the cardiac demand upon the normal twin

may lead to heart failure and death. Monochorionic/monoamniotic twins carry not only the risks inherent to monochorionic pregnancies, but have an extraordinarily high risk of cord entanglement as they are not physically separated by a dividing membrane. The risk of minor and major anomalies involving one or both twins approaches 90%. The risk of intrauterine demise of one or both twins is approximately 50%. Cesarean delivery upon relative lung maturity, usually around 32 weeks gestation, is typical.

QUESTIONS AND ANSWERS

1. Prenatal sonography demonstrates widening of the lateral masses of the lumbo-sacral spine. Which of the following is an associated intracranial finding?
 - A. Effacement of the cisterna magna
 - B. Monoventricle
 - C. Megacisterna magna
 - D. Absence of the cavum septum pellucidum
 - E. Strawberry skull

ANSWER: A. Widening of the lateral masses of the lumbo-sacral spine suggests spina bifida aperta, most likely a meningocele. This type of defect is consistently associated with a Chiari type II malformation of the intracranial posterior fossa, which consists of inferior displacement of posterior fossa structures through the foramen magna resulting in obliteration of the cisterna magna and a small, abnormal-shaped cerebellum (banana sign). A variable degree of ventricular enlargement as well as frontal bossing of the cranial vault (lemon sign) are frequently present. Absence of the cavum septum pellucidum is not a finding associated with spina bifida but would suggest the presence of a midline defect such as agenesis of the corpus callosum or holoprosencephaly, as would monoventricle. Strawberry-shaped skull is associated with trisomy 18.

2. Hydrops is associated with fetal ascites in which of the following?
 - A. Posterior urethral valves
 - B. Cardiac abnormalities
 - C. Duodenal atresia
 - D. Echogenic bowel
 - E. Renal dysplasia

ANSWER: B. Fetal hydrops is defined as the abnormal accumulation of fluid in at least two fetal sites, which include body cavities and soft tissues. The development of hydrops can be explained by an imbalance of intravascular and interstitial fluid compartments. Cardiac failure caused by cardiac anomalies as well as obstruction of venous and lymphatic flow by a mass are two possible mechanisms. Fetal ascites seen without other associated findings of hydrops is usually because of a GI or GU obstruction causing viscous rupture and leakage of urine or bowel contents. Etiologies would include posterior urethral valves and duodenal atresia. Echogenic bowel is considered a soft marker for trisomy 21.

3. Which of the following is used to evaluate fetuses with suspected IUGR?
 - A. Quadruple screen
 - B. Amniocentesis
 - C. Doppler of the middle cerebral artery
 - D. Chorionic villus sampling
 - E. Nuchal translucency

ANSWER: C. When IUGR is diagnosed or suspected, fetal growth and well-being should be monitored for the remainder of the pregnancy since these fetuses are at high risk for mortality and morbidity. Weekly or semiweekly studies are recommended in the third trimester. The biophysical profile score, amniotic fluid volume, and spectral Doppler waveforms

of the umbilical artery and middle cerebral artery are criteria used to evaluate fetal well-being. A worsening trend of these parameters may prompt early delivery. Amniocentesis may be used to evaluate fetal lung maturity but would give no information regarding the status of a fetus with possible IUGR. The quadruple screen, chorionic villus sampling, and nuchal translucency are all used in the detection of probability of chromosomal abnormalities.

4. Which of the following is a sonographic finding associated with renal dysplasia?
 - A. Polyhydramnios
 - B. Cysts
 - C. Mesoblastic nephroma
 - D. Hydronephrosis
 - E. Most often bilateral

ANSWER: B. Renal dysplasia includes a spectrum abnormality, secondary to early renal obstruction. Multicystic dysplastic kidney is the most severe form and is secondary to atresia of the upper one-third of the ureter. Fewer cortical cysts with an echogenic parenchymal pattern is usually the manifestation of renal dysplasia secondary to severe urethral or UPJ obstruction in the first half of pregnancy. Without the presence of large cysts, these kidneys may be abnormally small. Dysplastic kidneys may be mistaken for hydronephrotic kidneys because of their cystic appearance; however, hydronephrosis is not an associated finding. Renal dysplasia is usually associated with oligohydramnios. Mesoblastic nephroma is the most common renal tumor in the fetus and can appear partially cystic, although usually appears as a solid tumor.

5. Which of the following is the most accurate sonographic measurement used for dating pregnancy in the first trimester?
 - A. Biparietal diameter
 - B. Crown rump length
 - C. Humerus length
 - D. Head circumference
 - E. Abdominal circumference

ANSWER: B. Crown-rump length is the most accurate for dating in the first trimester. Biparietal diameter, head circumference, femur length, and humerus length are measurements used for dating which, when used in the second trimester, obtain a 95% confidence level of ± 10 to 12 days with the greatest accuracy below 20 weeks. The transverse cerebellar diameter is reported to be a fairly reliable method in the second and possibly third trimester if well visualized. The abdominal circumference measurement

has been found to reflect size more so than gestational age, especially in the third trimester.

6. Which of the following cardiac anomalies is best detected on outflow tract images of the fetal heart?
- A. Endocardial cushion defect
 - B. Ventricular septal defect
 - C. Hypoplastic left heart
 - D. Tetralogy of Fallot
 - E. Fetal tachyarrhythmia

ANSWER: D. Both Tetralogy of Fallot and transposition of the great arteries are more readily apparent on outflow tract views of the fetal heart, as both the pulmonary artery and aorta should be visualized for confirming these diagnoses. The four chamber view is valuable for evaluation of chamber size (i.e., hypoplastic left heart) and atrioventricular connections so that endocardial cushion defects and ventricular septal defects may be detected. Fetal arrhythmias are detected with M-mode Doppler imaging

7. Which of the following is the most likely etiology of a dilated fetal stomach and duodenum detected upon a 20-week fetal anatomic survey?
- A. Esophageal atresia
 - B. Anterior abdominal wall defect
 - C. Cystic fibrosis
 - D. Duodenal atresia
 - E. Severe hydrocephalus

ANSWER: D. The classic “double-bubble” sign caused by dilation of the fetal stomach and duodenum is highly suspicious for duodenal atresia, which has a relatively strong association with underlying chromosomal abnormalities. Other entities, which may cause a similar appearance indicative of some degree of duodenal obstruction include annular pancreas, high-grade duodenal stenosis, and peritoneal bands. Esophageal atresia is in the differential diagnosis for lack of fluid distention of the fetal stomach after 20 weeks and is associated with the VACTERL syndrome. Severe hydrocephalus and other neurologic defects, which may impair swallowing, may similarly be accompanied by lack of stomach distention. Cystic fibrosis may be associated with echogenic bowel or peritoneal calcifications. Anterior abdominal wall defects are a broad category of herniations of bowel outside the abdominal wall.

8. Dizygotic twinning is most readily confirmed by
- A. Presence of a thick dividing membrane
 - B. Detection of twins of different gender
 - C. Presence of two placentas
 - D. Diagnosis of twin–twin transfusion syndrome
 - E. Presence of two amniotic sacs

ANSWER: B. Twins of different gender confirms that the twinning is dizygotic, or fraternal, rather than monozygotic, or identical. A thick dividing membrane and two placentas are seen in dichorionic–diamniotic twins. While dizygotic twins are always dichorionic–diamniotic, monozygotic twins may be dichorionic–diamniotic, monochorionic–diamniotic, monochorionic–monoamniotic, or conjoined. Their chorionicity and amnionicity is thought to depend upon the timing of the cleavage of the blastocyst into two separate developing embryos. Two separate amnions will be seen in all twins other than monochorionic–monoamniotic and conjoined twins. Twin–twin transfusion syndrome is a complication unique to monozygotic twins.

9. Which of the following is associated with decreased maternal alpha-fetoprotein levels?
- A. Down syndrome
 - B. Neural tube defect
 - C. Intrauterine fetal demise
 - D. Multiple gestations
 - E. Gastroschisis

ANSWER: A. Alpha-fetoprotein is the major circulatory protein of the early fetus. It is formed initially by the yolk sac and the fetal intestine and later by the fetal liver. Screening with maternal serum AFP is performed at 16 to 18 weeks gestation, and values must be corrected for dates, maternal weight, and race. Elevated maternal serum AFP levels are associated with congenital defects including gastroschisis, anencephaly, open spinal defects, omphalocele, renal agenesis, and occasionally proximal fetal bowel obstruction. It may be falsely elevated by incorrect dates, multiple gestations, and intrauterine fetal demise. Low maternal serum AFP levels are seen in incorrect pregnancy dating and trisomy 21.

10. Which of the following is most strongly associated with choroid plexus cysts?
- A. Turner syndrome
 - B. Trisomy 21
 - C. Trisomy 18
 - D. Trisomy 13
 - E. Chiari malformation

ANSWER: C. Choroid plexus cysts will be visible in approximately one-third of patients with trisomy 18 during the second trimester. However, they can be present in up to 5% of normal second trimester fetuses. Visualization of choroid plexus cysts should prompt careful anatomic evaluation for other anomalies. These cysts often resolve in the late second or early third trimester.

AORTA

The aorta and inferior vena cava (IVC) are the largest arterial and venous structures in the body. They are retroperitoneal structures that course through the diaphragmatic hiatus near the midline abdomen. The aorta is typically located to the left of the IVC. The wall of the abdominal aorta is composed of three layers: intima, media, and adventitia. When abdominal aortic aneurysm (AAA) develops, there is expansion of all three layers. This differs from pseudoaneurysm (PSA), which expands the aorta but no longer is contained by all three layers. The first major branch of the abdominal aorta is usually the celiac axis, but paired inferior phrenic arteries may originate cranial to the celiac artery. Both renal arteries originate from the lateral aspects of the aorta and lumbar arteries originate at each vertebral level, L1-4. The celiac artery and superior mesenteric artery supply abdominal organs. At approximately the L4 level, the aorta divides into two common iliac arteries.

In recent years, endostent placement has replaced open repair for AAA. Endoleak into the aneurysm sac around the stent after stent repair of AAA is a common complication.

The most common type of endoleak results from retrograde filling of a branch vessel such as the inferior mesenteric artery, classified as type II endoleak. Ultrasound can detect abnormal flow in the aneurysm sac around the stent and may be used to guide therapy (Table 66-1).

RENAL

RENAL ARTERY STENOSIS

The clinical presentation of renal artery stenosis (RAS) includes refractory hypertension resistant to simultaneous treatment with three or more antihypertensive med-

ications, impaired renal function (azotemia), or acute renal failure after antihypertensive therapy with ACE inhibitors or angiotensin receptor blockers. Hypertension occurs because of effects on the renin angiotensin system. Diagnosis can be made by ultrasound, but invasive techniques like angioplasty are required for treatment. Ultrasound criteria for RAS include peak systolic velocity (PSV) greater than 200 cm/s, ratio of renal artery PSV to aortic PSV greater than 3.5, asymmetry of intrarenal resistive indices compared with contralateral kidney, segmental artery delayed acceleration, and parvus-tardus waveforms.

Beyond the diagnosis of RAS, ultrasound may also suggest which patients will benefit from angioplasty. If the resistive index (PSV-EDV/PSV) is elevated (greater than 0.80), these patients do not benefit from interventional therapy (Rademacher). However, these results have been challenged in subsequent studies.

RENAL VEIN THROMBOSIS

The etiologies of renal vein thrombosis (RVT) are numerous and include nephrotic syndrome, hypercoagulable states, birth control pills, antiphospholipid antibody syndrome/systemic lupus erythematosus, Behcet syndrome, renal neoplasms, trauma, and renal transplant. In infants, dehydration is the most common etiology. In adults, nephrotic syndrome, specifically membranous glomerulonephropathy, is the most common cause. On ultrasound, the kidney can acutely swell and increase in echogenicity. There may be absence of renal venous flow on color Doppler. Arterial waveforms will show high resistance flow. Rapid diagnosis is important if there is to be salvage of renal function.

HEPATIC

PORTAL HYPERTENSION

The etiology of portal hypertension may be prehepatic, intrahepatic, or posthepatic. Cirrhosis is the most common etiology and represents intrahepatic disease. There is normally no significant pressure gradient between the portal venous and hepatic venous systems. In a variety of clinical settings, the gradient may reach 13 mm Hg and lead to variceal formation or ascites. Signs of portal hypertension include dilatation of the main portal vein, monophasic hepatic venous flow, main portal vein or branch reversal, ascites, and varices.

Cavernous transformation occurs when there is collateral vessel formation in the setting of chronic portal vein thrombosis. This has clinical importance since it

TABLE 66-1 Aortic Stent Endoleak Classification

Type I	Attachment site leak at the proximal or distal end of the endostent
Type II	Reversed flow in branch artery
Type III	Modular failure
Type IV	Porosity of the graft
Type V	Expansion of the aneurysm with no endoleak “endotension”

may prevent transplantation. On ultrasound, there will be a tangle of vessels visible in the hepatic hilum, and no normal portal vein is identified. Etiologies of portal vein thrombosis include abdominal malignancies such as hepatocellular and pancreatic carcinoma, hepatic dysfunction because of hepatitis or portal venous hypertension, abdominal infections or sepsis, pancreatitis, severe dehydration, hypercoagulable syndromes, and estrogen therapy.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

The first-line treatment for variceal bleeding is medical management or endoscopic sclerotherapy. In patients who fail, transjugular intrahepatic portosystemic shunt (TIPS) placement is the suggested treatment. A shunt using open mesh or more recently polytetrafluorethylene graft material communicates between the right portal vein and either the right or middle hepatic vein. TIPS can also be used to treat intractable ascites. Although technical success rates are high, TIPS dysfunction is common within the first 2 years and requires surveillance.

Ultrasound is the primary method of monitoring for TIPS dysfunction. TIPS dysfunction may include stenosis, occlusion, infection, hemorrhage, or biliary leakage. On ultrasound, a variety of criteria may suggest stenosis such as low main portal vein velocity less than 30 cm/s, elevated intrashunt gradient greater than 50 to 100 cm/s, intrashunt peak velocity less than 90 cm/s or greater than 190 cm/s, reversal of portal vein branch flow from retrograde to antegrade flow. Interval change (increase greater than 60 cm/s or decrease greater than 40 cm/s) in peak intrashunt velocities compared with baseline may also herald TIPS failure.

ABDOMINAL VISCERAL

Mesenteric ischemia affects patients when there is involvement of at least two of the three major visceral vessels (celiac, superior mesenteric artery, or inferior mesenteric artery). Mesenteric ischemia can be classified as chronic or acute. Chronic mesenteric ischemia usually occurs secondary to long-standing atherosclerotic disease and less commonly caused by vasculitis. Patients typically present with postprandial abdominal pain, termed intestinal angina, and weight loss. Acute mesenteric ischemia is divided into embolic, thrombotic, and nonocclusive (vasoconstrictive and vasospastic) causes, each accounting for approximately a third of acute mesenteric ischemia cases. Patients may

present with poorly localized severe abdominal pain, nausea, vomiting, and possibly prior episodes of intestinal angina. Mesenteric ischemia generally occurs in older individuals secondary to the increased prevalence of atherosclerotic disease, the most common etiology. Unlike atherosclerotic disease, vasculitis affects younger individuals, more commonly women. Sonographic findings include smooth hypoechoic thickening of the vessel wall with a halo appearance. The stenosis may occur at points other than the artery origin from the aorta.

RENAL TRANSPLANT

Transplant renal artery abnormalities are the most common vascular complications associated with renal transplant. Renal artery occlusion is devastating and typically results in allograft failure. Sonographic diagnosis relies on absence of flow in the renal artery and abnormal intrarenal perfusion. There may be persistent venous flow because of capsular arteries or an accessory renal artery supplying a portion of the kidney. RAS most commonly affects the surgical anastomosis. The artery is usually anastomosed to the external iliac artery in an end-to-side fashion, but end-to-end anastomosis to the internal iliac artery is also performed, especially in patients who undergo vascular revision.

Sonographic criteria for transplant RAS include PSV greater than 250 to 300 cm/s, renal artery to iliac artery ratio greater than 1.8, and parvus-tardus waveforms in the segmental renal arteries. Turbulence and mildly elevated velocities may occur in the absence of stenosis because of the angle at which the renal artery takes off from the external iliac artery. In chronic transplant RAS, formation of collateral vessels has been described and may hinder the diagnosis.

TRANSPLANT RENAL VEIN THROMBOSIS

Renal vein thrombosis (RTV) is more common in transplanted kidneys than in native kidneys. It is highly associated with renal allograft failure. RVT is most common in the first month after transplantation and presents with acute renal failure or pain. The kidney will appear swollen and high resistance flow is present on spectral Doppler. Although reversal of arterial diastolic flow is commonly described in RVT, this finding is more commonly because of acute rejection or ATN. Therefore, further evaluation is necessary unless thrombus is identified in the vein. Venous occlusion of the iliac vein will similarly limit outflow and have a similar presentation.

PSEUDOANEURYSM-ARTERIOVENOUS FISTULA

Development of arteriovenous fistula (AVF) occurs in as many as 10% to 15% of transplants after biopsy. Other than biopsy, rare etiologies include infection or trauma. PSA formation can also be related to needle procedure and may be mistaken for renal cyst if Doppler technique is not applied. Extrarenal AVF or PSA are rare and most commonly associated with surgical technical complication or infection. Extrarenal PSA most commonly occur at the anastomotic site.

HEPATIC TRANSPLANT

Hepatic artery thrombosis is a devastating complication that occurs when the artery acutely occludes. Doppler will not identify flow within the hepatic artery in its expected position alongside the portal vein. There may be elevated flow in the portal vein in an effort to compensate. In the setting of progressive development rather than acute occlusion, collaterals may form. The bile ducts are solely supplied by the hepatic artery and are most susceptible to ischemia. In hepatic artery thrombosis, the bile ducts necrose and fill with fluid and gas. Biliary necrosis is severe and may lead to death if transplantation is not again available.

Hepatic artery stenosis is often a precursor to thrombosis, and noninvasive diagnosis by ultrasound is important. Doppler will show focal turbulence and aliasing at the site of stenosis with a 3:1 velocity ratio relative to the upstream artery. Parvus-tardus waveforms beyond the stenosis can confirm the diagnosis but have low sensitivity. Absence of diastolic flow within the hepatic artery is an ominous finding that may predict future thrombosis. The most common location of hepatic artery stenosis is the anastomotic site. Studies have shown that Doppler velocity criteria obtained from the hepatic artery are not useful in the first 48 hours to predict thrombosis as long as diastolic flow is present.

IVC stenosis is difficult to diagnose as the etiology of transplant dysfunction. A 3:1 or 4:1 ratio of stenotic flow versus vena cava inflow suggests abnormality. Absence of transmitted cardiac pulsatility below the narrowing is another indicator of significant abnormality. In many cases, there may be only a kink in the venous structures because of positioning of the liver, but fibrotic strictures can occur.

SCROTAL

Testicular torsion affects young males and usually presents with symptoms of acute testicular pain. The testis is supplied primarily by the testicular arteries, which arise

directly off the anterolateral aspect of the aorta just below the renal artery origins. Testicular torsion can be incomplete or complete, ranging between 90 and 1080 degrees. In partial or incomplete torsion, the degree of spermatic cord rotation is less than 360 degrees. Color Doppler imaging may demonstrate decreased flow and asymmetric arterial waveform as compared with the contralateral testicle. In complete torsion, the rotation is greater than 360 degrees. In 720-degree torsion, the testicle can become nonviable in as early as 6 hours. Rapid diagnosis is important since nearly 100% can be salvaged within 4 to 6 hours but only 70% can be salvaged after 6 to 12 hours, and 20% at 12 to 24 hours. Sonographic findings include absence of flow in the arteries within the testicular parenchyma, absent venous flow, and testicular enlargement. Later findings of hypoechoic echotexture of the testis occur after salvage is no longer possible (see Chapter 67, "The Scrotum").

VARICOCELE

Enlargement of the intrascrotal venous plexus can be symptomatic and palpable. It may be confused for testicular mass, but ultrasound can differentiate the two diagnoses. Intratesticular varicocele (rare) will be a linear anechoic structure with vascular flow on Doppler. However, most are extratesticular. There are two mechanisms of varicocele formation. Type I includes valvular insufficiency and type II is associated with outflow obstruction. Varicocele is more common on the left, and isolated right-sided varicocele should prompt further evaluation for outflow obstruction because of renal mass or adenopathy. Diagnosis of varicocele by ultrasound is based upon identification of dilated veins (greater than 2–3 mm) and engorgement of the veins during Valsalva. There may be persistent reversal of venous flow or reversal only during Valsalva. If there is clinical suspicion, it is important to scan the patient in standing position to increase diagnostic sensitivity for varicocele.

PERIPHERAL VENOUS

Deep venous thrombosis evaluation of the lower extremity is one of the most common Doppler studies performed. Ultrasound is critical since the clinical examination is nonspecific to differentiate cellulitis, thrombophlebitis, and DVT. The exclusion of DVT is necessary since untreated DVT may lead to pulmonary embolism or death. Pulmonary emboli may arise from a variety of sources. Clot in the atrium may dislodge in the setting of atrial fibrillation. However, dislodged clots from the deep venous system of the leg or arm are more common. Upper extremity

DVT is usually associated with venous catheter placement. Chronic occlusion and stricturing are more commonly associated with subclavian catheter placement rather than internal jugular line placement. Unilateral central occlusion will cause arm swelling. Bilateral occlusion results in arm, neck, and facial swelling, referred to as the SVC syndrome. Central venous clot or stricture can be suggested by Doppler, when there is lack of normal phasicity to baseline in the medial subclavian veins.

Lower extremity DVT is most commonly associated with surgery, trauma, and prolonged immobility. Hypercoagulable states increase the risk of thrombosis. Although the deep system above the calf has been most commonly evaluated because of higher embolic risk, intersociety guidelines now recommend calf evaluation. Approximately 50% of DVT occur in the calf veins. Extension into the deep system is the greatest embolic risk of calf clots.

Chronic thrombosis of calf veins can have a less heralded, yet serious, effect on the valves. Fibrosis and tethering of the venous valves can lead to valvular insufficiency and chronic complications characterized by pain and swelling. On ultrasound, reversal of flow greater than 1 second during Valsalva is indicative of venous insufficiency. Since superficial venous insufficiency can have a complex pattern of varices, mapping of the pattern is useful for sclerotherapy planning. The most important venous pathway involves the great saphenous vein. Other named pathways include the vein of Giacomini, which is the intersaphenous vein linking the cephalad extension of the small saphenous vein to the great saphenous veins and perforating veins, which connect the superficial to the deep system. Hunterian perforators are located at the cranial extent of the adductor canal, Dodd perforators at the lower, medial thigh, Boyd perforators at the midcalf, and Cockett perforators at the lower posteromedial calf near the ankle.

QUESTIONS AND ANSWERS

1. What is the most common type of abdominal aortic endoleak?
 - A. Type I
 - B. Type II
 - C. Type III
 - D. Type IV
 - E. Type V

ANSWER: B. Type II endoleak is because of retrograde filling by reversed flow in branch artery is by far the most common endoleak.

2. What is the most common cause of renal vein thrombosis in adults?
 - A. Nephrotic syndrome
 - B. Trauma
 - C. Systemic lupus erythematosus
 - D. Dehydration
 - E. Neoplasm

ANSWER: A. The most common cause of renal vein thrombosis in adults is membranous glomerulonephropathy causing nephrotic syndrome. In infants, dehydration is the most common cause.

3. Which is a criterion for diagnosis of TIPS dysfunction?
 - A. Intrashunt peak velocity >100 cm/s
 - B. Main portal vein velocity >30 cm/s
 - C. Reversal of portal vein branch flow
 - D. Interval decrease in intrashunt peak velocity >40 cm/s
 - E. Hepatic artery reversal

ANSWER: D. All of the following can indicate TIPS dysfunction: portal vein velocity <30 cm/s, intrashunt gradient >50 to 100 cm/s, intrashunt peak velocity >190 cm/s, reversal of portal vein branch flow, and finally, increase >60 cm/s or decrease >40 cm/s in peak intrashunt velocities.

4. What is the most common etiology of mesenteric ischemia?
 - A. Intestinal angina
 - B. Emboli
 - C. Atherosclerosis
 - D. Vasculitis
 - E. Trauma

ANSWER: C. Atherosclerosis is the most common cause of mesenteric ischemia.

5. What is a diagnostic criterion for transplant renal artery stenosis?
- Renal artery-to-iliac ratio <1.8
 - Peak systolic velocity <250 cm/s
 - Resistive index >0.8
 - Tardus-parvus waveforms in segmental artery
 - Resistive index <0.8

ANSWER: D. Resistive index is not a criterion. The “a” and “b” are incorrect (>1.8 and >250 cm/s would be correct).

6. Concerning transplant renal vein thrombosis, which of the following statement is *true*?
- Most common cause of reversal of diastolic flow
 - More common in transplant kidneys than native kidneys
 - Transplant may be acutely shrunken and hypoechoic.
 - Segmental artery waveforms will have low resistive index.
 - Segmental artery parvus-tardus waveforms will be present.

ANSWER: B. Transplant renal vein thrombosis is more common than native vein thrombosis. Parvus-tardus and low resistive indices are findings of renal artery stenosis. Rejection is most common cause of reversal of diastolic flow.

7. Concerning hepatic artery stenosis/hepatic artery thrombosis, which of the following statements is *true*?
- Hepatic artery thrombosis is diagnosed by a 3:1 velocity gradient.
 - Collateral vessels may hinder diagnosis of acute occlusion.
 - Lack of diastolic flow in the first 48 hours is normal.
 - Elevated peak velocity of flow in the first 48 hours is normal.
 - Bile duct necrosis occurs when portal venous flow is also impaired.

ANSWER: D. Elevated peak velocity of flow in the first 48 hours is normal. Bile duct necrosis does not rely on portal venous abnormality since bile ducts are solely supplied by hepatic artery. Hepatic artery stenosis uses a 3:1 ratio. Lack of diastolic flow is always abnormal but peak flow varies in the first 48 hours.

8. After how many hours of torsion does the testicular salvage rate drop to less than 20%?
- 1 hour
 - 2 hours
 - 4 hours

- 6 hours
- 24 hours

ANSWER: E. The salvage rate is 20% after 12–24 hours.

9. Concerning varicocele, which of the following statement is *true*?
- Isolated left varicocele necessitates exclusion of renal hilar mass.
 - Most are intratesticular.
 - Diagnosis is made if vein measures >4 mm diameter.
 - Type II is because of valvular dysfunction.
 - Reversal of venous flow is diagnostic.

ANSWER: E. Reversal of venous flow is diagnostic of varicocele. Isolated right varicocele necessitates renal mass workup. Intratesticular varicocele is rare. Diagnosis relies on 2 to 3 mm threshold. Type I is valvular in etiology. Reversal of venous flow is diagnostic.

10. Which lower extremity venous collateral represents the cephalad extension of the small saphenous vein?
- Hunterian
 - Boyd
 - Giacomini
 - Dodd
 - Cockett

ANSWER: C. Anatomic locations of venous pathways of calf:

Hunterian—cranial adductor canal

Boyd—midcalf

Giacomini—intersaphenous vein

Dodd—lower medial thigh

Crockett—lower posteromedial calf (ankle)

67 SCROTUM

Michelle L. Robbin and Victoria E. Kraft

INTRODUCTION

Although many processes affect the testes and scrotum, in general, the four major areas of clinical concern are infection, tumors, torsion, and trauma. The scrotum is easily assessed with physical examination, but often needs further characterization of the abnormality with ultrasound. Gray scale and color Doppler ultrasound findings are extremely useful in noninvasively determin-

ing the etiology of palpable masses or scrotal enlargement and can sort between the diagnostic possibilities causing scrotal pain, without using radiation. It is highly accurate in differentiating between intra- and extratesticular pathology.

A complete scrotal ultrasound will record the upper, mid, and lower transverse planes and mid, medial, and lateral longitudinal planes of the testis. The testes need to be compared together in a single transverse image to assess for individual differences in echotexture and size. Color Doppler evaluation of testicular arterial flow should be performed in every examination. Assessment of the epididymis and spermatic cords bilaterally, and scrotal contents for abnormalities such as hydrocele and skin thickening complete the examination. If the patient has a palpable focal mass, it is best for the patient to grasp it between his fingers so a transducer can be placed directly over the lesion for further evaluation, as a nondirected examination may miss the questioned abnormality. Because of ultrasound's high spatial resolution, the only other further scrotal evaluation after the physical evaluation is surgical (if necessary).

NORMAL ANATOMY

TESTIS

Testicles are simultaneously gonads that produce spermatozoa and endocrine glands that produce male sex hormones and may thus be categorized under both the reproductive and endocrine systems. The two testicles descend from the abdomen into the scrotum in the fetus, beginning about 36 weeks in utero with the vast majority descended at birth. The testis is a cylindrical, homogeneously medium-level echogenic gland measuring approximately 3 to 5 cm in length, and 2 to 3 cm in both the transverse and anteroposterior planes. A small fingerlike projection called the appendix testis (a mullerian duct remnant) is frequently present off of the cranial portion of the testis, more easily seen with a hydrocele. A tough white fibrous shell, the tunica albuginea, tightly covers the testis. The testis is lined by the visceral layer of the tunica vaginalis everywhere except where the epididymis, spermatic cord, and testis are attached to the posterior scrotal wall. The parietal layer of the tunica vaginalis lines the inside of the scrotum and forms a potential space where fluid can collect, a hydrocele.

The innermost aspect of the tunica albuginea extends as septae into the testicular parenchyma, converging posteriorly to divide the testes into lobules. A lobule comprises multiple seminiferous tubules, which open into dilated spaces within the mediastinum of the testis, termed the rete testes. The rete testis can be identified by

a characteristic extension across the testicle in a cranio-caudal direction toward the mediastinum testis. They can appear more echogenic than the adjacent testicular parenchyma and can be especially prominent when dilated.

The seminiferous tubules are lined with a layer of cells that begin to produce sperm cells at puberty and continue into old age. The sperm travel from the seminiferous tubules to the rete testis located in the mediastinum testis, to the efferent ducts, and then to the epididymis where newly created sperm cells mature. The sperm move into the vas deferens and are eventually expelled through the urethra and out of the urethral orifice through muscular contractions. Between the seminiferous tubules are interstitial cells, where androgens such as testosterone are formed.

The deferential, cremasteric, and testicular arteries make up the three arterial sources of testicular blood flow. The testicular artery originates just below the origin of the renal artery anteriorly off of the aorta, and then progresses through the inguinal canal to the posterosuperior testis, where it arborizes to supply the testis peripherally, perforating into the parenchyma. The deferential artery arises from the inferior vesical artery and progresses to the caudal region of the epididymis, where it forms a capillary network. The cremasteric artery originates from the inferior epigastric artery, then progresses to the tunica vaginalis, where it forms anastomoses with capillaries of other two arteries. The deferential and cremasteric arteries primarily supply the epididymis and scrotal tissues, and anastomose with the testicular artery to provide a small amount of testicular flow. Low resistance velocity waveforms are found in normal intratesticular and capsular arteries. Flow in the epididymis normally has a high vascular resistance. With current ultrasound transducers, flow is always seen in the normal adult testis and can usually be demonstrated even in the pediatric testis using a high frequency (at least a 9–12 MHz) linear array transducer with low flow settings.

EPIDIDYMIS

The epididymis is a narrow, curved, tightly coiled tube that connects the efferent ducts from the rear of each testicle to its vas deferens. The epididymis can be divided into three main regions: the head, the body, and the tail. Spermatozoa formed in the testis enter the head of the epididymis, and then progress to the body and tail of the epididymis, where they are stored. The epididymis is normally iso to slightly hyperechoic to the testis on ultrasound, with a slightly more granular echotexture. The head normally measures approximately 1.0 cm in

diameter, and the body and tail usually measure less than 0.4 cm in diameter. An appendix epididymis may also be seen, typically off of the head of the epididymis, again more easily seen in the presence of a hydrocele.

SPERMATIC CORD AND SCROTUM

The spermatic cord is formed by the cremasteric, deferential, and testicular arteries, lymphatics, nerves, a pampiniform plexus of veins, and the vas deferens. The spermatic cord is enveloped in three layers of tissue: the external spermatic fascia, the cremasteric muscle and fascia, and the internal spermatic fascia and extends down from the abdomen through the inguinal canal. The scrotum develops from a fetal protuberance of abdominal skin and muscle containing the testicles, with fetal peritoneum (processus vaginalis) extending from the abdomen. The function of the scrotum appears to be to keep the testis at a temperature slightly lower than that of the rest of the body. The temperature is controlled by the contracting and relaxing of the dartos fascia in the scrotum and the cremasteric muscle in the abdomen, which moves the testicles closer to the abdomen when it is cold, and away when hot. Skin thickness greater than approximately 0.3 cm is abnormal.

TESTICULAR PATHOLOGY

MASS

The majority of intratesticular masses are malignant, whereas the majority of extratesticular lesions are benign. Risk factors for testicular neoplasm include undescended testicles (cryptorchidism), mumps orchitis, carcinoma in situ, and family history of testicular cancer. Symptoms include a lump in one testis or a hardening of one of the testicles, abnormal scrotal sensitivity (pain or numbness), increasing hydrocele, an increase or significant decrease in size of one testis, blood in the semen, or a dull ache in the lower abdomen or groin.

The goal of scrotal ultrasound in the evaluation of a mass should be to determine intra- versus extratesticular location, size, cyst versus solid, uniform versus heterogeneous, sharply circumscribed or poorly defined borders, and the presence and character of calcifications, as well as determining bilateral versus unilateral location. It is important to compare the testes directly to each other in the same transverse image on ultrasound, so mild changes in testicular echotexture and size because of diffuse tumor infiltration can be appreciated as compared to the normal contralateral testis. Concurrent physical examination can add to the differentiation be-

tween benign and malignant, as a focal tumor mass is likely to be firm and not painful, whereas focal orchitis will be soft and painful to palpation. It is extremely important to recognize that testicular masses should not be biopsied percutaneously through the scrotum. The testicle needs to be approached surgically through the inguinal canal, and the testis brought up through the level of the internal inguinal ring to be resected, or less commonly, biopsied if there is a question of a benign tumor or infection.

MALIGNANT NEOPLASMS

The majority of primary malignant testis tumors occurs in men in their forties and can be divided into seminomatous (50%) and nonseminomatous germ cell tumors (45%). Seminoma is the most common kind of single-cell testicular tumor in adults and in the cryptorchid testes. Seminoma is comparatively less aggressive than the other malignant testicular tumors, and therefore has the most favorable prognosis. Sonographically, it is typically homogenous and hypoechoic and can range from a small (usually well defined) hypoechoic nodule to virtually replacing and enlarging the testis. Rarely, portions of the seminoma can appear cystic because of necrosis.

The more aggressive nonseminomatous germ cell tumors (NSGCT) occur between puberty and age 50, but tend to occur in a younger age group than seminomas. They often invade the tunica albuginea and frequently cause visceral metastases. NSGCT may present with various combinations of teratomas, endodermal sinus or yolk sac tumors, embryonal cell carcinoma, and choriocarcinoma cell types in 40% to 60% of patients. Choriocarcinoma is the rarest form of NSGCT but is highly malignant. Although seminoma may be present in the NSGCT, it does not mean a more favorable prognosis. Sixty percent of endodermal sinus or yolk sac tumors are found in infants younger than 2 years of age and have abnormal alpha-fetoprotein in 95% of cases. Sonographically, NSGCT tumors are heterogeneous, and both cystic areas and large or coarse calcifications are common. They do not have sonographic characteristics that allow further classification other than likely nonseminomatous tumor. Although most testicular tumors are hypervascular, color Doppler by itself is not useful in differentiating tumor types, nor can it definitively distinguish neoplasm from infection.

Some patients have supraclavicular, lung, mediastinal, or retroperitoneal testicular metastases despite a normal testicular physical examination. These primary testicular tumors may be too small to feel, but may still be seen sonographically. Sometimes only a small calcification with or without a soft-tissue mass or just a small

soft-tissue mass may represent the primary tumor, the so-called “burnt out” testicular tumor. It is important to remove this residual tumor, as it can be a source of continued metastasis, although no tumor may be found histologically.

The gonadal stromal tumor generally is made up of Leydig or Sertoli cells and is usually benign. Gonadal stromal tumors may be composed of a single cell type or multiple cell types and account for 3% to 6% of testicular masses, 20% in children. Most stromal tumors are of Leydig cell origin, with some patients presenting with gynecomastia or impotence, while Sertoli cell tumors occur rarely.

METASTASES

Metastatic testicular tumors include lymphoma, leukemia, myeloma, and a small percentage of other metastasis to the testes. The most common bilaterally occurring testicular tumor is lymphoma, nearly always non-Hodgkin type. Lymphoma may not be clinically evident, or disseminated disease may be present. It is the most frequent testicular tumor in men older than 60 years. Patients with lymphoma generally have painless testicular enlargement. Sonographically, the tumor resembles seminoma, with increased color Doppler flow. The tumor is usually large and often replaces the normal testicular parenchyma, but smaller lesions can occur.

Second highest in occurrence in the testes, leukemia metastases are often found (particularly in children) despite bone marrow remission. The blood–testis barrier is thought to decrease the concentration of chemotherapy within the testis, increasing the chance that residual or recurrent cells will be found there. Leukemia metastasis in the testis are hypoechoic and tend to largely replace normal parenchyma. Testicular myeloma can be seen in patients with diffuse myeloma. Other metastases are infrequent and include lung, melanoma, stomach, prostate, pancreas, kidney, and colon. These are usually not clinically symptomatic and occur in patients with diffuse metastatic disease.

BENIGN MASSES

The most common benign mass in the testis is the simple cyst (no perceptible wall, no internal echoes or septations, increased through sound transmission). These are of no clinical significance and do not need to be followed for interval change. More complex cysts require follow-up or may need to be surgically evaluated, as malignant tumors can have cystic areas because of necrosis or hemorrhage. Rarely, a firm palpable nodule may be

an epidermoid cyst. These have variable sonographic appearances, including a swirled onion-skin appearance, or a decreased echogenicity mass with a partially or completely calcified periphery, or central calcification. They may have a nonspecific pattern, however, and need to be surgically evaluated if newly discovered. These tumors are not vascular, in contradistinction to most malignant testis tumors. Care must be taken to avoid misdiagnosing the twinkle artifact from calcifications in an epidermoid cyst for vascular flow, when the lesions are actually avascular.

Cysts in the tunica albuginea are generally single, small and unilocular, and benign. No color Doppler flow is seen in these cysts. Prominent or dilated rete testis can simulate a tumor; the fact that there is a pattern of linearly branching structures converging into the mediastinum of the testis helps to differentiate this normal finding from a tumor. The dilatation may be bilateral and is thought to result from trauma or inflammation. Cystic dysplasia is a rare congenital condition and appears as multiple different interconnecting cysts.

Rarely, sarcoid may cause hypoechoic intratesticular masses. These can be bilateral and may need to go to surgical biopsy for differentiation from tumor. Adrenal rests are another rare cause of testicular mass and usually can be diagnosed correctly with the history of congenital adrenal hyperplasia or Cushing syndrome.

MICROLITHIASIS

Testicular microlithiasis (TM) is relatively uncommon, and the significance of the finding is debated. These findings have been increasingly detected with the current increased resolution of high frequency linear transducers. Small (1–3 mm) echogenic foci, some of which may demonstrate ring down at ultrasound, are seen in testes either unilaterally or bilaterally. In 80% of cases, both testicles are affected. The calcifications are thought to be related to degeneration of seminiferous tubules. It is an asymptomatic, nonprogressive disease that has been classified as limited (less than 5 microliths in a single ultrasound image of the testis) and diffuse (greater than or equal to 5 microliths in a single image). No definite difference between the categories of limited and diffuse microlithiasis and the incidence of malignancy has been noted. An association with TM and testicular malignancy has been suggested, but the validity of the association has been questioned. Most urologists now recommend regular testicular patient self-examination and examination by a urologist, with follow-up ultrasound as needed. This recommendation is altered depending on the patient’s risk profile for testicular cancer,

with increased surveillance in cryptorchidism, infertility, and history of testicular cancer, among others.

TORSION

Testicular torsion occurs when the spermatic cord is twisted, thereby cutting off the blood supply to the testis. Patients typically present with acute onset of severe scrotal pain; if surgically treated within 5 to 6 hours, greater than 80% of testes can be preserved. If surgery is not instituted within 12 hours, only 20% of testes are salvaged. Intravaginal torsion is the most frequent cause of torsion and occurs when the tunica vaginalis (arising from the processus vaginalis in utero) covers the entire testis and epididymis and a portion of the spermatic cord, the so-called “bell-clapper deformity.” This condition is bilateral in greater than 50% of patients. Extravaginal torsion is uncommon and typically seen in neonates. This occurs when an abnormally mobile testis (with normal tunica attachments) rotates together with the epididymis and spermatic cord, twisting at the inguinal ring.

Color Doppler ultrasound of the scrotum can make the diagnosis of torsion with a very high degree of accuracy and sensitivity. Flow is always seen in the normal postpubertal testis (and nearly always in the prepubertal testis), and the absence of flow is diagnostic for torsion given the correct clinical history. The spermatic cord twist may be seen, termed the “whirlpool sign.” The testis may have a normal echotexture initially and is usually enlarged. It later becomes hypoechoic and often is heterogeneous.

When evaluating for torsion, it is important to sample central intratesticular arteries for typical low resistance flow. It should be noted that some peripheral high resistance capsular artery flow can be seen from anastomoses with the deferential and cremasteric arteries in testicular artery occlusion. If only high resistance peripheral arterial flow without central arterial flow is seen, torsion is present. Careful attention to technique using low flow settings with high gain and low pulse repetition frequency along with comparison to the contralateral normal testis is very important. Surgical exploration in the neonate may be necessary if no definite flow can be seen, although further evaluation with testicular scintigraphy could be performed. Scrotal skin thickening and a reactive hydrocele with low-level echoes within may be seen.

Partial torsion (less than approximately two full cord twists) is problematic to diagnose, with arterial flow decreased but not absent; low or no venous outflow may be useful in suggesting this diagnosis. In the unusual setting of detorsion, the testis may be hyperemic, and the sonographic appearance will be similar to epididymo-

orchitis. The appendix testis or epididymis may torsion, causing pain and symptoms similar to testicular torsion. The appendix may be seen as an enlarged, hypoechoic mass without flow adjacent to a testis with normal flow. Central lack of arterial flow in the testis can also be seen in infarction from severe epididymo-orchitis, but these two entities are usually distinguishable clinically.

TRAUMA

Testicular trauma is an injury to one or both testicles, and generally occurs in men between 15 and 40 years of age. Types of injuries include blunt and penetrating, usually from sports injuries, assault and motor vehicle collisions. If an adequate physical examination of the testes cannot be performed because of testicular pain and swelling, and evidence of testicular rupture is compelling or there is a penetrating injury, the patient may be taken to surgery. In less obvious cases of testicular trauma, ultrasound is performed to assess for testicular rupture. If testicular rupture is present, the testicle can be salvaged if repaired within approximately 72 hours. Findings of testicular rupture include protrusion of the seminiferous tubules outside of the testicular contour, an irregular periphery of the testis, and loss of continuity of the tunica albuginea. Color Doppler can be used to assess intratesticular heterogeneous areas for infarction or intratesticular hematoma and assess the overall vascularity of the testicle. The presence of clot overlying the testis in a hematocele should not be mistaken for testicular rupture.

CRYPTORCHIDISM

If the testis fails to descend into the scrotum, it can usually be felt in the inguinal canal. If it cannot be felt, ultrasound is usually the first examination of choice to determine its location and size. MRI is then used if the testis cannot be found. The testis needs to be surgically placed in the scrotum before 1 to 2 years of age to decrease the incidence of both infertility and tumor. There is a large lifetime risk of testicular tumor in the undescended testis, with an increased incidence of tumor in the normally descended testis as well.

EPIDIDYMIS—PATHOLOGY

NEOPLASMS

Most epididymal tumors are benign. The most common type is the adenomatoid tumor, usually located in the tail

of the epididymis. Adenomatoid tumors generally occur singly, in well-defined round or oval shapes, and are variable in echogenicity. Leiomyomas of the epididymis are uncommon; papillary cystadenoma is rare but is frequent in men with von Hippel-Lindau disease. Lymphoma is the most common malignancy that involves the epididymis; metastases are rare.

BENIGN LESIONS

Epididymal cysts and spermatoceles are commonly seen, and are usually of no clinical significance unless they cause discomfort because of size. Epididymal cysts are lined with epithelium, are generally small, and can occur throughout the epididymis. Spermatoceles are seen most commonly in men after vasectomy and contain low-level echoes made up of debris and sperm. These cysts usually occur in the epididymal head and can be quite large. Since both of these cysts are rarely evaluated operatively and appear virtually identical sonographically, common parlance terms them epididymal cysts when the epididymis is seen and they are relatively small, and spermatoceles when little if any normal epididymal head can be detected.

Sperm granulomas can be seen in men postvasectomy and represent a focal, sharply defined lesion that has decreased echogenicity with respect to the adjacent epididymis. These are usually found at the vasectomy site and only rarely cause pain.

INFECTION

Epididymitis is the most common cause for acute scrotal pain in males after puberty. Under 35 years of age, it is usually from sexually transmitted urethritis from *Chlamydia trachomatis* or *Neisseria gonorrhea*. *Escherichia coli* and *Proteus mirabilis* are usually the cause in boys younger and men older than this age range, usually from urinary tract infections (and prostatitis in the older age group). Unusual causes of epididymitis include mumps, tuberculosis, and syphilis. Discomfort while voiding or urethral discharge may develop, along with fever. Scrotal pain is usually present, sometimes radiating to the groin or flank. Epididymitis usually starts in the epididymis tail. Ultrasound findings include an enlarged epididymis with increased epididymal blood flow with respect to the contralateral side. Extension of the infection into the testis, termed epididymo-orchitis, may occur in up to 20%. Patchy (focal orchitis) or diffuse areas of decreased echogenicity along with increased testicular blood flow is diagnostic in the correct clinical setting.

When severe orchitis is present, it may progress to abscess formation and or infarction. Typically, these patients are diabetic and have a spinal cord injury or some other reason for lack of sensation and early detection of the infection. Patients with epididymitis may develop an associated hydrocele, often with low-level echoes or septations within. The infection may be unilateral or bilateral. It is important to note that if a focal testicular mass or masslike area is present in the clinical context of epididymitis or epididymo-orchitis, the patient needs to be reexamined with ultrasound after the epididymitis has resolved to exclude a coexistent tumor.

SCROTUM—PATHOLOGY

VARICOCELE

A varicocele is an abnormal engorgement of the veins that drain the testicle, the pampiniform plexus. The network of veins coalesces into the testicular vein or gonadal vein. Small one-way valves prevent backflow to ensure upward flow of blood in the veins. Defective valves can cause dilation of the veins near the testis, leading to the formation of a primary varicocele. Secondary varicoceles are usually caused by compression of the gonadal vein by extrinsic masses such as from a renal mass or renal hilar adenopathy. Varicoceles are multiple tubular veins greater than 0.2 to 0.3 cm in diameter and usually increase in size with the Valsalva maneuver. They are nearly always found on the left and are usually found near the testis-epididymal head region, extending up into the spermatic cord. They can be bilateral in up to 70% of patients. However, an isolated right-sided varicocele or a new varicocele should raise suspicions for a compressive mass in the course of the gonadal vein and should prompt a renal ultrasound to search for the cause. Color Doppler can definitively characterize the multiple vessels seen on gray scale ultrasound imaging as dilated veins. Rarely, the varicocele can extend into the testis; a dilated tubular structure with venous flow in the testis is diagnostic. Varicoceles that are not palpable still may cause infertility, and thus ultrasound can be important in the evaluation of infertile men.

HYDROCELE

A hydrocele forms in the potential space between the parietal and visceral tunica vaginalis and may result in scrotal swelling. A small amount of fluid is likely physiologic. However, hydroceles may also result from repeated chronic infection, trauma, or tumor. Low-level

echoes, septations, and loculated fluid usually indicate prior trauma or infection and can be seen with torsion.

SCROTAL PEARL

Inflammation or infection in the tunica vaginalis, or torsed appendices of the epididymis or testis may slough off to lie between the parietal and visceral tunica vaginalis. Instead of involuting, this inflammatory tissue may remain, with tissue deposition around a central calcification, termed a scrotal pearl. These are usually mobile and may be palpable and are of no clinical significance.

INGUINAL HERNIAS/OTHER MASSES

Patients occasionally present with groin masses that extend into the scrotum. Ultrasound can be diagnostic, assessing for herniation of bowel, mesentery, or ascites into the scrotal sac. Compression of the inguinal canal may prompt peristalsis. Bowel peristalsis or typical bowel wall contents is diagnostic. Real time evaluation with the Valsalva maneuver is also helpful. If only mesenteric fat is present, only an echogenic mass will be seen. Rarely, a lipoma of the spermatic cord can cause this echogenic appearance; even more rarely, a liposarcoma can be present. CT can be useful for further evaluation of those inguinal and scrotal masses that are not typical bowel containing hernias.

QUESTIONS AND ANSWERS

- Which anatomic structure extends into the testis parenchyma as septae, forming lobules?
 - Epididymis
 - Visceral layer of the tunica vaginalis
 - Parietal layer of the tunica vaginalis
 - Tunica albuginea

ANSWER: D. The tunica albuginea extends into the testis parenchyma to form septae, dividing the testis into lobules. The visceral layer of the tunica vaginalis surrounds the tunica, epididymis, and spermatic cord except where the epididymis and testis is fused to the scrotal wall. The parietal layer of the tunica vaginalis lines the inside of the scrotum. The epididymis is connected to the testis via the rete testis.

- When do most testis descend into the scrotum?
 - 28–32 weeks gestational age
 - 32–36 weeks gestational age
 - 36–40 weeks gestational age
 - First month after birth

ANSWER: C. The testis normally begin their descent from the abdomen into the scrotum at approximately 36 weeks. Nearly all testes have descended into the scrotum by 40 weeks gestation.

- Concerning testicular neoplasms, what is the most common malignancy?
 - Leydig cell
 - Nonseminatous germ cell

- C. Seminomatous germ cell
- D. Sertoli cell

ANSWER: B. Nonseminomatous germ cell tumors are the most common malignant testis tumors, usually with multiple tumor types in the same mass. Seminomatous tumors are the next most common. Leydig and Sertoli cell tumors are both gonadal stromal tumors, uncommon, and usually benign.

4. Concerning testicular masses, what is the most common benign mass?
 - A. Simple cyst
 - B. Tunica albuginea cyst
 - C. Sarcoid nodules
 - D. Epidermoid cyst

ANSWER: A. Simple cysts are the most common benign testicular mass, and of no clinical significance (in contradistinction to complex cysts, which require further investigation). Tunica albuginea cysts are benign and less common. Sarcoid nodules and epidermoid cysts are rare.

5. What is the most common epididymal neoplasm?
 - A. Adenomatoid tumor
 - B. Leiomyoma
 - C. Papillary cystadenoma
 - D. Sperm granuloma

ANSWER: A. The most common neoplasm in the epididymis is benign, the epidermoid tumor. Leiomyomas and papillary cystadenomas are rare. Sperm granulomas are not neoplasms and are usually a focal epididymal lesion seen after vasectomy.

6. Concerning color Doppler of the testes to rule out torsion, which of the following findings is diagnostic for torsion?
 - A. Capsular low resistance arterial flow
 - B. Absence of central arterial flow
 - C. Hypervascular “lesion”
 - D. Absent venous flow

ANSWER: B. Absence of central arterial flow is diagnostic of torsion, in the correct clinical setting, but can also be seen in infarction from severe epididymo-orchitis and trauma. When the testicular artery is torsed, high resistance arterial flow may sometimes be seen in capsular arteries because of collateral flow from the cremasteric and deferential arteries. A hypervascular mass is not diagnostic for torsion, although a testicular tumor can hemorrhage and cause acute testicular pain. If flow is symmetric and normal, torsion is not present. Torsion is rarely bilateral.

7. What is the most common cause of epididymitis in males aged 15 to 35 years?
 - A. Prostatitis
 - B. Sexually transmitted diseases
 - C. Urinary tract infection
 - D. Mumps

ANSWER: B. Sexually transmitted diseases such as *Chlamydia trachomatis* or *Neisseria gonorrhoea* are the most common cause of epididymitis in post-pubertal males to age 35. Prostatitis or a urinary tract infection is usually the cause of epididymitis in males older than 35. Mumps is an uncommon cause of epididymitis.

8. Concerning testicular microlithiasis, which of the following is *true*?
 - A. Microlithiasis causes cancer.
 - B. Risk factors for testicular cancer help determine follow-up.
 - C. Percutaneous biopsy should be performed.
 - D. Calcifications are usually >0.5 cm in diameter.

ANSWER: B. Microlithiasis has an unclear association with testicular tumor, but there is no evidence that it causes testicular cancer. Urologists will typically recommend monthly testicular self-examinations; whether or not follow-up ultrasounds or urologist examinations will be scheduled depends on the patient’s risk factors and urologist preference. Percutaneous biopsy through the scrotal wall should never be performed if tumor is suspected. The microcalcifications seen in microlithiasis range from 0.1 to 0.3 cm in diameter.

9. Concerning an isolated right-sided varicocele, which of the following is *true*?
 - A. Varicocele is easily compressible.
 - B. More common than an isolated left-sided varicocele.
 - C. Need to assess kidney and hilar region for mass.
 - D. Unlikely to cause infertility

ANSWER: C. Isolated right varicoceles are uncommon and are concerning for a mass obstructing the right gonadal vein or its drainage pathway to the IVC (renal vein). If an obstructing mass is present, the varicocele will not be easily compressible nor change significantly with Valsalva. A renal ultrasound to evaluate the kidney for a renal or hilar mass should be performed. Varicoceles, even ones that are not palpable, can be a correctable cause of infertility.

10. Concerning cryptorchidism, what is a common clinical finding?
 - A. Normal-sized testis
 - B. Increased incidence of infertility

- C. Nonpalpable testis
- D. Increased testicular tumor risk only in cryptorchid testis

ANSWER: B. Cryptorchid testes are usually small and located in the inguinal canal and so most are palpable. If no testis is palpable, MRI may be useful to help localize prior to surgery. There is a significantly higher tumor risk in both the cryptorchid testis and the contralateral testis normally located in the scrotum.

68 THYROID, PARATHYROID, AND NECK ULTRASOUND

Mark D. Little and Franklin N. Tessler

THYROID GLAND: NORMAL ANATOMY AND APPEARANCE

The thyroid gland is located in the anterior neck, just below the thyroid cartilage. Sonographically, the gland is homogeneous, slightly hyperechoic, and is contained by a well-defined echogenic capsule. The two lobes of the thyroid gland are positioned on either side of the trachea, bounded anteriorly by the strap musculature, laterally by the common carotid artery and the internal jugular vein, and posteriorly by the longus coli muscle. The lobes communicate across the midline by a thin isthmus of thyroid parenchyma. In addition, up to 40% of patients have a pyramidal lobe lying anterior to the thyroid cartilage, originating from the isthmus. The pyramidal lobe is more often seen in childhood, usually undergoing atrophy with age, but it can be seen in hyperplastic processes such as Graves disease. Arterial supply and venous drainage are via the superior and inferior thyroid arteries and veins, respectively. The recurrent laryngeal nerve passes posterior to the thyroid gland, an important consideration at neck surgery.

The size of the thyroid is highly variable, depending on the patient's age, sex, and physiology. The normal thyroid is larger in males and in endemic areas of iodine deficiency, with a mean longitudinal dimension of approximately 4 to 6 cm and a mean anteroposterior diameter of approximately 1.3 to 1.8 cm. The isthmus measures up to approximately 4 to 6 mm anteroposterior. The estimated mean thyroid volume can be determined clinically or calculated ($\text{height} \times \text{width} \times \text{depth} \times 0.52$), averaging approximately 12 to 40 cm³. In general, however, the normal thyroid dimensions are up to 5 × 2 ×

2 cm. Specifically, the thyroid gland is considered enlarged when the anteroposterior diameter is greater than 2 cm.

CONGENITAL THYROID ABNORMALITIES

Various congenital abnormalities of the thyroid can be assessed sonographically, including complete or partial thyroid agenesis or hypoplasia. Ectopic thyroid tissue can be seen in the tongue or suprahyoid neck, arising along the course of the gland's embryonic descent from the foramen cecum. Ultrasound, however, has limited utility in screening for thyroid ectopia, which is usually evaluated with radionuclide imaging.

MICROSCOPIC ANATOMY AND FUNCTION

The thyroid gland is intimately involved in regulating the body's cellular metabolism and protein synthesis, mediated through the production of thyroid hormones, thyroxine (T₄), and triiodothyronine (T₃). It is composed of spherical follicles that are lined by a simple epithelium surrounding a central cavity that contains colloid. Briefly, the follicular cells accumulate dietary iodide, which is subsequently organified with the amino acid tyrosine and attached to the protein thyroglobulin to produce monoiodotyrosine and diiodotyrosine. Coupling of these precursor proteins results in T₃ and T₄, depending on the number of iodine atoms.

T₃ and T₄ are cleaved from thyroglobulin under the influence of thyroid-stimulating hormone (TSH), which is produced and released by the anterior pituitary gland. The released thyroid hormones predominantly circulate in inactive form, bound to multiple serum proteins, including thyroid binding globulin, albumin, and thyroid binding prealbumin. Only a small percentage (less than 1%) of circulating free T₄ and free T₃ is metabolically active. T₄ is released in greater quantity by the thyroid and is subsequently converted to the more metabolically active T₃ in peripheral tissues. Thyroid hormone production is controlled by a negative feedback loop along the hypothalamic-pituitary axis, mediated through thyrotropin releasing hormone (TRH), which stimulates TSH production by the pituitary.

The thyroid gland also contains parafollicular cells (C-cells), which produce calcitonin, which has opposing effects to parathyroid hormone (PTH) on calcium metabolism. Calcitonin decreases serum calcium by inhibiting osteoclastic activity and reabsorption of calcium by the kidneys and intestine.

DIFFUSE THYROID DISEASE

Thyroid disease can present as focal or diffuse involvement. Diffuse disease is most often characterized by generalized glandular enlargement or hyperplasia. Clinically, patients present as hyperthyroid, euthyroid, or hypothyroid, and the diagnosis is based on the combination of diffuse enlargement and specific laboratory findings. The sonographic appearance is often nonspecific. However, ultrasound is indicated to evaluate coexistent nodular disease or response to treatment.

Diffuse thyroid disease includes multinodular goiter, Graves disease, Hashimoto thyroiditis, subacute thyroiditis, and infectious thyroiditis. The most common worldwide cause of diffuse thyroid enlargement is endemic goiter, secondary to dietary iodine deficiency. Graves disease and thyroiditis are the most common presentations within the United States.

MULTINODULAR GOITER

Multinodular goiter is a common condition that has multiple clinical presentations but is the final expression of a hyperstimulated gland. (The term “goiter” is nonspecific, referring only to an enlarged thyroid gland.) Biochemically, these patients are either hypothyroid-euthyroid or hyperthyroid and are referred to as having nontoxic or toxic multinodular goiter, respectively. Most often, they present with hypothyroidism and palpable neck masses, which occasionally exert mass effect on the trachea.

Sonographically, the thyroid gland appears enlarged with multiple nodules of varying size and complexity with intervening areas of normal or heterogeneous thyroid tissue. These hyperplastic nodules are often nonfunctional and have areas of hemorrhage, necrosis, and colloid. Multinodular goiter is more common in women. In addition, while it was once believed that there was a lower incidence of carcinoma within multinodular goiter, current understanding suggests a similar level of risk. Therefore, suspicious thyroid nodules should be evaluated and biopsied (see below).

GRAVES DISEASE

The most common cause of hyperthyroidism in the United States is Graves disease, an autoimmune, often familial condition that is more common in females. Thyroid-stimulating immunoglobulins bind to and activate TSH receptors, leading to hypersecretion of T3 and T4. Patients present with symptoms of hyperthyroidism, including tachycardia, heat intolerance, fatigue, palpita-

tions, and unexplained weight loss. Twenty-five to thirty percent of patients also have clinical signs and symptoms of Graves ophthalmopathy, such as proptosis, lid retraction, and visual changes. Sonographically, the thyroid gland appears enlarged and heterogeneous and is often diffusely hypoechoic caused by lymphocytic infiltration or loss of parenchymal colloid. On color Doppler sonography, the gland may be diffusely hypervascular, a condition that has been termed “thyroid inferno.”

HASHIMOTO THYROIDITIS

The most common cause of thyroiditis and hypothyroidism within the United States is Hashimoto thyroiditis or chronic lymphocytic thyroiditis. The condition is a result of autoimmune destruction of thyroid cells in the presence of antithyroid peroxidase, antithyroglobulin, and other antibodies, and often presents as a painless enlarged thyroid gland with clinical symptoms of hypothyroidism, including lethargy, cold intolerance, weight gain, dry skin, and fatigue. The condition is more common in young to middle-aged women. Sonographically, the gland may appear enlarged, with numerous 1 to 6 mm hypoechoic nodules with intervening areas of coarsened echogenic fibrous stroma. This appearance is termed micronodulation and is fairly specific for Hashimoto. As the condition progresses, there is increased fibrosis and atrophy of the gland. Because there is an increased risk of carcinoma, enlarging lesions should be evaluated and biopsied. In addition, similar to other autoimmune diseases, patients with Hashimoto thyroiditis are at increased risk for thyroid B-cell lymphoma.

SUBACUTE GRANULOMATOUS THYROIDITIS

The most common cause of a painful thyroid gland is subacute granulomatous thyroiditis, also known as De Quervain thyroiditis. The condition often presents as painful enlargement of the thyroid gland and is thought to be related to viral infection. The clinical course is usually benign and self-limited, but recurrence is possible. Sonographically, subacute thyroiditis is nonspecific and may appear as an enlarged diffusely hypoechoic gland or as focal areas of inhomogeneity.

INFECTIOUS THYROIDITIS

Infectious thyroiditis may be caused by viral, bacterial, or granulomatous etiologies. The involved thyroid gland

may be enlarged, hypervascular, and heterogeneous. Ultrasound has limited utility in the diagnosis of infectious thyroiditis and is used primarily to evaluate for frank abscesses. Sonographically, an abscess appears as an ill-defined, complex, hypoechoic fluid collection with internal echoes, and debris. At times, gas is also present.

NODULAR THYROID DISEASE: GENERAL PRINCIPLES

Nodular thyroid disease has an estimated 50% prevalence within the United States. However, thyroid carcinoma is rare, constituting approximately 1% of all malignancies. Therefore, the vast majority of all incidentally discovered thyroid nodules will be benign. Although clinical features such as rapid growth, hoarseness, and a history of neck irradiation are suspicious for thyroid cancer, ultrasound is the modality of choice to identify nodules that require biopsy. (Nuclear scintigraphy is limited to confirming the presence of hyperfunctioning nodules in selected patients.)

The majority of nodular thyroid disease is secondary to hyperplasia. When individual thyroid acini become hyperplastic, they may undergo micro- or macronodular formation. Hyperplastic nodules have variable sonographic appearances, adding to the diagnostic challenge. Hyperplastic nodules are initially isoechoic to the adjacent parenchyma. As they accumulate colloid, however, their appearance changes. Many undergo cystic or liquefactive degeneration, typified by internal areas of necrosis, hemorrhage, and colloid. They may calcify with eggshell or coarse dystrophic calcification. Most thyroid cysts are usually degenerated hyperplastic nodules, as true epithelial thyroid cysts are rare.

ULTRASOUND ASSESSMENT OF THYROID NODULES

As the use of noninvasive neck imaging has increased, more and more incidental nonpalpable thyroid nodules, termed “incidentalomas,” are being detected. In general, morphologic characteristics are more important than size for determining whether or not a nodule needs to be biopsied. If only the largest thyroid nodule is biopsied, some thyroid cancers will be missed. Similarly, because thyroid cancer appears just as commonly in patients with multiple nodules as in those with solitary lesions, careful sonographic interrogation of all nodules is mandatory.

A significant percentage of nodules contain cystic components. When a thyroid nodule is almost purely cystic, it most likely represents a degenerated benign

TABLE 68-1 Signs of Malignant Thyroid Nodules on Ultrasound

Microcalcifications
Markedly low echogenicity
Irregular margin
Irregular halo
Central flow

adenoma or hyperplastic nodule. On high resolution sonography, however, these hyperplastic lesions often show areas of mural irregularity and layering debris, with or without septations. Since papillary thyroid carcinoma may have cystic components, careful examination with grayscale and color Doppler sonography is recommended to exclude other suspicious characteristics (Table 68-1). Conversely, V-shaped (“comet tail”) artifacts that are associated with colloid microcrystals are found in benign nodules.

The echogenicity of nodules is compared to that of the surrounding thyroid parenchyma. Generally, thyroid carcinomas are hypoechoic. Since most thyroid nodules are benign, the likelihood that an individual hypoechoic lesion represents cancer is unlikely. However, hypoechoic nodules should be interrogated with greater suspicion. Hyperechoic and isoechoic nodules have a lower suspicion for cancer.

Taken in isolation, the marginal characteristics of individual nodules are also nonspecific. While the margins of thyroid carcinomas tend to be irregular and ill defined, this feature has significant overlap with benign nodules. Nevertheless, irregular thyroid lesions that appear to invade surrounding soft tissues or are associated with significant cervical adenopathy should be considered suspicious.

Another helpful feature is the presence or absence of a sonolucent halo. A large percentage of benign hyperplastic thyroid nodules have a peripheral hypoechoic ring that likely represents compressed normal thyroid parenchyma. This sign is present in a minority of thyroid carcinomas. In such instances, the halo may appear irregular or discontinuous.

The presence and, specifically, the pattern of calcification are useful in evaluating thyroid nodules. Approximately 10% to 15% of all thyroid nodules contain calcification. Common patterns include coarse dystrophic, eggshell, and punctate calcifications. While dystrophic calcifications are associated with a somewhat higher risk of malignancy, eggshell calcification is often predictive of a benign lesion. On the other hand, punctate microcalcifications are considered one of the most specific findings for malignant thyroid lesions. Additionally, medullary thyroid cancer may also contain small intralesional echogenic

foci, which can also be seen in adjacent metastatic lymph nodes.

Color Doppler sonography has limited utility in differentiating hyperplastic from malignant nodules. However, hyperplastic nodules tend to show increased peripheral vascularity. In contrast, thyroid carcinoma and adenomas often demonstrate central vascularity. When used in combination with other sonographic findings, color Doppler imaging may be helpful in distinguishing suspicious nodules in need of biopsy.

THYROID NODULE BIOPSY

Fine needle aspiration (FNA) biopsy is a safe, effective technique for evaluating nodules that are felt to be suspicious based on the patient’s clinical history or sonographic findings. Most centers perform FNA using 22 to 25 gauge needles, either using the so-called capillary technique, in which no syringe is employed, or the more traditional syringe suction technique. (Neither technique has been shown to be superior.) Core biopsy is performed rarely.

Although many clinicians perform FNA based solely on palpation, ultrasound guidance increases diagnostic confidence and accuracy. Color Doppler imaging may be helpful to avoid blood vessels, decreasing the likelihood of obtaining a nondiagnostic, bloody specimen. In general, aspirates may be classified as *inadequate* (insufficient cellular material for diagnosis), *benign*, *malignant*, or *suspicious* (follicular or Hürthle cell neoplasm). When the aspirate is insufficient, repeat FNA is recommended, although excisional biopsy may eventually be needed, particularly if the nodule has worrisome sonographic characteristics.

NEOPLASTIC THYROID NODULES

THYROID ADENOMA

Adenomas are infrequent, representing less than 10% of all thyroid nodules. They are approximately seven times more common in females and are usually solitary and nonfunctional. Rare autonomous hyperfunctional adenomas can lead to thyrotoxicosis (Plummer disease). Histologically, these lesions are difficult to distinguish from follicular carcinomas and therefore are usually surgically removed. Sonographically, thyroid adenomas are often hyperechoic, although they can be iso- or hypoechoic, as well. Additionally, they may have a thick peripheral sonolucent halo and demon-

	Anaplastic carcinoma
	Other (lymphoma, sarcoma, carcinosarcoma)

strate internal vascularity in a characteristic spoke wheel distribution.

THYROID CANCER

Thyroid cancer is generally classified as well-differentiated or poorly differentiated (Table 68-2). The former group, which includes papillary and follicular carcinomas, has an overall better prognosis than the latter group.

PAPILLARY CARCINOMA

Papillary thyroid carcinoma is the most common form of thyroid cancer, accounting for approximately 75% of cases. This form of cancer most often presents as a solid, hypoechoic thyroid nodule that contains internal vascularity. These tumors may contain microcalcifications, which represent psammoma bodies. Papillary carcinoma spreads via lymphatics, and metastatic lymph nodes may contain microcalcifications, as well. Early identification and diagnosis of these tumors improves their generally good prognosis. Distant metastases are rare, but when present they are usually to lung or mediastinum.

FOLLICULAR NEOPLASIA

Follicular carcinoma is the second most common type of thyroid cancer. The term “follicular neoplasia,” which includes both benign follicular adenomas and carcinomas, is used because of their nonspecific sonographic and cytological appearances. Both benign and malignant lesions often appear as well capsulated, hyperechoic masses with intrinsic vascularity and a prominent, often incomplete, sonolucent halo. Since FNA cytological analysis cannot reliably differentiate these lesions, the entire nodule must be examined for evidence of capsular invasion and atypia. Therefore, follicular lesions are surgically resected. Overall, prognosis for follicular carcinoma is good. Metastases occur hematogenously and are rare.

MEDULLARY CARCINOMA

Medullary thyroid carcinoma is the next most common subtype. These lesions are distinguished by their inclusion in the multiple endocrine neoplasia (MEN) and familial medullary carcinoma syndromes. They are neuroendocrine tumors and are derived from the parafollicular C-cells. Medullary thyroid cancer is seen in MEN types 2a and 2b. Sonographically, these lesions present as hypoechoic, solid masses, often with internal echogenic foci, typically a coarser appearing calcification than present in papillary cancers. They have a worse prognosis, and distant lymphatic metastases are common at presentation.

ANAPLASTIC CARCINOMA

Anaplastic thyroid carcinoma represents less than 5% of thyroid cancer and is more common in elderly patients. The prognosis is dismal, with local and distant metastases very common at presentation. These tumors are locally aggressive and sonographically appear as large, hypoechoic thyroid masses that commonly demonstrate internal necrosis, calcification, and direct invasion of surrounding neck structures, including the trachea.

LYMPHOMA

Primary thyroid lymphoma is rare and is usually associated with Hashimoto thyroiditis. Typically of the B-cell variety, primary lymphoma has a variable presentation. Sonographically, it may appear as a diffuse or focal hypoechoic mass involving all or part of the gland. More commonly, it appears locally invasive with involvement of adjacent neck structures.

METASTATIC DISEASE

Metastases to the thyroid gland are uncommon, usually from melanoma, breast, or renal cancers. They rarely calcify and may mimic primary thyroid tumors. Sonographically, they are typically hypoechoic and may show internal cavitation or necrosis.

CERVICAL LYMPH NODES

The primary goal of lymph node sonography is to distinguish benign from metastatic adenopathy. Early detection of nodal disease optimizes staging and may direct treatment for many cancers. Ultrasound has

emerged as a sensitive modality for detection of abnormal cervical lymph nodes in need of further evaluation and biopsy.

Targeted ultrasound of the neck usually begins with the lymph nodes associated with the common carotid artery and internal jugular veins. In addition, lymph nodes within the submandibular region and posterior to the sternocleidomastoid should be evaluated. Node size is the only characteristic that can be assessed clinically, however studies have shown that a fair number (20%–40%) of normal-sized lymph nodes may harbor metastases. Conversely, nodal enlargement may be secondary to reactive hyperplasia. Therefore, in addition to size, attention should also be given to morphology.

The normal lymph node usually has a smooth, ovoid, or fusiform shaped hypoechoic cortex with a centrally located echogenic fatty hilum. Often, small blood vessels are seen entering the hilum with color or power Doppler imaging. Metastatic lymph nodes exhibit disruption of the normal architecture, along with development of a more globular shape. Heterogeneity, increased echogenicity, cystic areas, and microcalcifications are all findings that are suspicious for lymph node metastases from thyroid cancers.

POSTTHYROID SURGERY SURVEILLANCE

In recent years, ultrasound has assumed a greater role in the surveillance of patients following thyroidectomy for thyroid cancer. The examination involves evaluation of the thyroid bed for recurrent tumor as well as assessment of the regional lymph nodes for metastases, using the criteria discussed above. Any suspicious findings should be subject to ultrasound-guided FNA biopsy.

PARATHYROID GLANDS

The four parathyroid glands are typically located deep to the upper and lower poles of the thyroid gland and are supplied by branches of the thyroidal arteries. However, ectopic locations, including the substance of the thyroid gland, the retropharyngeal or retroesophageal space, or the mediastinum are not uncommon and supernumerary or absent glands are seen as well.

The parathyroid glands produce PTH, which influences the serum calcium level via several mechanisms. Primary hyperparathyroidism is diagnosed when the serum calcium level is high in the presence of an inappropriately normal or elevated PTH. Symptoms include fatigue, bone pain, and muscle weakness. Most cases are caused by an isolated parathyroid adenoma, although multiple adenomas, hyperplasia, or carcinoma may also

be present. Parathyroid adenomas are also seen in MEN 1 and 2a, with the former predominating. (Primary hyperparathyroidism must be distinguished from the secondary form, which is seen in renal failure patients who develop diffuse or nodular parathyroid hyperplasia.)

Normal parathyroid glands are rarely visible sonographically because of their propensity to blend imperceptibly with adjacent tissues. Parathyroid gland enlargement may be secondary to hyperplasia, adenoma, or carcinoma. In general, it is not possible to distinguish these entities based on their sonographic appearance, as all appear hypoechoic. However, large masses that compress or invade adjacent structures are suspicious for carcinoma, as hyperplastic or adenomatous glands typically conform to their surroundings. Color or power Doppler imaging often demonstrates a vascular arc that partially encircles the gland before penetrating it.

SALIVARY GLANDS: NORMAL ANATOMY AND APPEARANCE

The *parotid gland* is located in the retromandibular fossa, anterior to the ear. It is divided into superficial and deep lobes, of which only the former is well visualized with ultrasound. The *submandibular gland* lies anterior and caudal to the parotid gland in the submandibular triangle, and the *sublingual glands* are located in the floor of the oral cavity. All the salivary glands tend to be homogeneous and at least moderately echogenic.

NONNEOPLASTIC CONDITIONS

Acute infection is most common in children and is usually viral. Ultrasound reveals an enlarged gland with decreased echogenicity. Bacterial infection is more common in elderly and diabetic patients and may proceed to abscess formation. In these cases, ultrasound may be helpful to guide aspiration to determine the causative organism.

Sjögren syndrome, an autoimmune condition that is characterized by chronic inflammation of the salivary glands, results in glands that are very heterogeneous, often showing hypervascularity on color Doppler imaging. These patients have an increased risk of lymphoma, therefore biopsy is recommended for lesions that are larger than 2 cm or that grow rapidly.

Most salivary stones are located in the submandibular gland or Wharton duct, which opens in the floor of the mouth. Sialitis appear as small echogenic foci that exhibit acoustic shadowing, although this feature may be absent with very small calculi. Dilation of the duct proximal to the stone or glandular swelling may be present if the duct is obstructed.

SALIVARY GLAND NEOPLASMS

Pleomorphic adenomas and Warthin tumors are the most common benign neoplasms, which comprise the majority of salivary gland tumors. Both tend to be hypoechoic. Of the malignant neoplasms, mucoepidermoid carcinomas and adenoid cystic carcinomas are the most frequent. They tend to be less well defined than the benign tumors, but there is considerable overlap. Examination of the cervical lymph nodes is essential in these patients.

MISCELLANEOUS NECK MASSES

A variety of cystic and cystlike masses that arise in the neck may be imaged with ultrasound. *Thyroglossal duct cysts* result from persistence of a portion of the thyroglossal duct, which runs from the base of the tongue to the anterior neck. Thyroglossal duct cysts have a sonographic appearance that ranges from simple to complex, and most are infrahyoid. Because thyroid cancer can develop within them, FNA biopsy is recommended if mural nodules are demonstrated and excision is not planned.

Branchial cleft cysts are usually located at the mandibular angle. Most are simple, but proteinaceous or other content may result in an appearance that mimics a solid mass. *Venous malformations* have a complex, multiseptated configuration. Slow flow may be evident on power Doppler imaging or grayscale sonography. Phleboliths, which are echogenic and cast acoustic shadows, are a clue to the diagnosis, but are seen in a minority of cases. Finally, *cervical abscesses* have a sonographic appearance that is similar to abscesses elsewhere, with varying internal debris and gas. Ultrasound is useful to guide percutaneous sampling or drainage.

QUESTIONS AND ANSWERS

- Concerning thyroid physiology, which of the following is *true*?
 - Most thyroid hormone circulates in active form.
 - Production of thyroid hormone is controlled by a positive feedback loop.
 - TRH is secreted by the anterior pituitary gland.
 - T4 is converted to T3 peripherally.

ANSWER: D. T4 is released in greater quantity and is then converted to T3.

- Concerning Hashimoto thyroiditis, which of the following is *true*?
 - Micronodularity is the predominant sonographic feature.
 - Lymphoma is not a recognized complication.
 - Most patients present with hyperthyroidism.
 - It has a male predominance.

ANSWER: A. The thyroid gland in Hashimoto thyroiditis has a micronodular appearance, with multiple, small hypoechoic foci scattered throughout the gland.

- Concerning acute Graves disease, which of the following is *true*?
 - Males are affected more often than females.
 - It is an autoimmune condition.
 - The thyroid gland is small.
 - "Thyroid storm" refers to thyroid hypervascularity on ultrasound.

ANSWER: B. Like Hashimoto thyroiditis, Graves disease is an autoimmune condition that is caused by circulating autoantibodies.

- Which of the following statements regarding thyroid nodules is *true*?
 - They are malignant approximately 20% of the time.
 - Most are hyperplastic.
 - Epithelial cysts are more common than cystic degeneration.
 - Calcifications are rare.

ANSWER: B. Most thyroid nodules are hyperplastic and not neoplastic.

- Which of the following statements about thyroid nodule calcification is *true*?
 - Coarse calcifications are more worrisome than punctate calcifications.
 - If coarse calcifications are present, biopsy is not warranted.
 - Microcalcifications correspond to psammoma bodies in papillary cancers.
 - Colloid crystals cannot be distinguished from microcalcifications by their ultrasound appearance.

ANSWER: C. The microcalcifications in papillary cancers correspond to psammoma bodies seen microscopically. When demonstrated sonographically, they are highly suspicious for papillary thyroid cancer.

- Concerning thyroid cancer, which of the following is *true*?
 - Papillary cancer has a better prognosis than medullary cancer.
 - Papillary cancer is less common than follicular cancer.
 - FNA is sufficient to distinguish follicular adenoma from follicular carcinoma.
 - Thyroid cancer is a common malignancy.

ANSWER: A. Medullary cancer has a worse prognosis than papillary cancer, and nodal metastases are common at presentation.

- Which of the following is a sign of benign thyroid nodules?
 - Central flow on color Doppler
 - Ill-defined halo
 - Microcalcifications
 - Echogenic foci with comet tail artifacts

ANSWER: D. Echogenic foci with comet tail artifacts are representative of colloid, which is often found in benign nodules.

- Concerning cervical lymph nodes, which of the following is suggestive of malignancy?
 - Elongated shape
 - Fatty hilum

- C. Homogeneity
- D. Cystic areas

ANSWER: D. Lymph nodes with cystic areas are suspicious for regional metastases.

9. Concerning thyroid biopsy, which of the following is *true*?
- A. Indeterminate aspirates always require surgical excision for diagnosis.
 - B. Capillary technique is superior to the aspiration technique.
 - C. Core biopsy is required for diagnosis approximately 25% of the time.
 - D. Color Doppler ultrasound is a useful adjunct.

ANSWER: D. Color Doppler sonography may help the radiologist avoid vessels and lessen the likelihood of obtaining a bloody specimen.

10. Concerning parathyroid gland ultrasound, which of the following is *true*?

- A. Normal parathyroid glands are usually visible sonographically.
- B. Adenomas can be reliably distinguished from hyperplastic glands.
- C. Parathyroid adenomas typically have a vessel along their margin.
- D. Parathyroid adenomas are typically more echogenic than the thyroid gland.

ANSWER: C. Parathyroid adenomas usually have a prominent supplying vessel that partially encircles them.

MUSCULOSKELETAL SYSTEM

69 MUSCULOSKELETAL ANATOMY AND BASIC PHYSIOLOGY

*Andrew S. Ferrell and
Matthew C. Larrison*

SUBSTRUCTURE OF BONE

Compact (cortical) bone is the hard outer layer of bone containing very little intervening spaces. This accounts for approximately 80% of total bone weight and provides a significant amount of the strength of bone.

Trabecular bone consists of a porous network found in the center of bones; it contains hematopoietic elements, fat, and vascular structures. Its spongy configuration makes the overall bone lighter.

CELLULAR ELEMENTS OF BONE

Osteoblasts are mononuclear bone-forming cells derived from osteoprogenitor cells. These cells cover the surface of developing osteoid and secrete a protein-rich mixture, predominantly made of type I collagen. They also secrete other matrix proteins, hormones, and prostaglandins, which regulate bone formation. Osteoblasts are stimulated by calcitonin.

Osteoclasts are multinucleated cells responsible for bone resorption and are located in resorption pits called Howship's lacuna. These cells are derived from monocyte precursors and have phagocyte-like activity. They secrete enzymes involved in bone breakdown and turnover. Osteoclasts are stimulated by parathyroid hormone.

Osteocytes originate from osteoblasts trapped within the bone matrix in spaces known as lacunae. These cells are involved in the formation and maintenance of bone,

as well as regulating bones response to stress and mechanical load.

TYPES OF BONES

- Long bones develop by endochondral ossification, and consist of a shaft (diaphysis) with two expanded articular ends (epiphysis). The metaphysis is part of the diaphysis and is the growth zone between the epiphysis and diaphysis during development. The marrow cavity of long bones is within the diaphysis. Long bones include the humerus, radius, ulna, and femur.
- Short bones are composed of an outer layer of compact bone surrounding inner spongy bone and include the carpal and tarsal bones.
- Flat bones consist of two layers of compact bone enclosing spongy bone and marrow (diploic) space. The articular surface of flat bones is lined with fibrocartilage. Ribs, sternum, scapulae, and bones of the skull vault are flat bones.
- Irregular bones include bones of mixed shape, such as those of the skull base and vertebrae.
- Sesamoid bones develop in tendons that cross the surface of long bones such as in the wrist and knee (patella), and they reduce friction.

BONE FORMATION

Endochondral ossification occurs on the foundation of a cartilaginous model and is the type of bone growth that occurs in long and short bones as well as portions of irregular bones. This type of ossification accounts for the majority of growth in childhood as well as some repair following fractures. In fetal life, a primary ossification center develops in the future diaphysis of the cartilaginous model. The perichondrium becomes vascularized and subsequently becomes the periosteum from which undifferentiated cells migrate and become osteoblasts at the primary ossification center. The osteoblasts secrete

osteoid on top of cartilage secreted by chondrocytes and this ultimately calcifies. Osteoblasts secrete additional osteoid that will ultimately lead to trabecular formation. The secondary ossification center occurs in the epiphysis after birth. The epiphysis and diaphysis are separated by a growing transverse band of cartilage known as the physis.

Intramembranous ossification is the formation of bone on or in fibrous connective tissue formed from condensed mesenchymal cells. Unlike endochondral ossification, a cartilage model is not present in intramembranous ossification. Primitive mesenchymal cells proliferate and differentiate into osteogenic precursor cells, which develop into osteoblasts. Osteoblasts begin to lay down osteoid, the inorganic precursor of bone formed of collagen fibrils. The osteoid calcifies to form bone spicules, which unite to form trabeculae. This process creates flat bones such as the mandible and flat bones of the skull, and it is the primary process involved with healing of fractures.

MARROW CONVERSION

In the neonatal period, red or hematopoietic marrow is present throughout the skeletal system. Normal physiologic conversion of red to yellow marrow occurs in a predictable pattern through childhood into adolescence. Conversion begins in the terminal phalanges and progresses proximally. There is a distal to proximal trend within individual bones as well, starting in the diaphysis followed by the distal and ultimately proximal metaphysis. Conversion is completed by age 25, with red marrow remaining primarily within the axial skeleton. Red marrow can be found in the humeral and femoral heads as a normal variant in adults.

FRACTURE HEALING

Fracture healing occurs in three phases. The first is the inflammatory or reactive phase that begins immediately following the fracture with vasoconstriction and formation of localized hematoma and lasts approximately 2 weeks. This hematoma provides limited initial stability of the fracture fragments. The cells in this area will subsequently die allowing fibroblasts to migrate into the area along with small proliferative vessels collectively forming granulation tissue. The second phase is the reparative phase. Periosteal progenitor cells migrate into the fracture gap and form both chondroblasts and osteoblasts that produce hyaline cartilage and woven bone, respectively. Fibroblasts within the granulation tissue itself will also differentiate into hyaline-producing

chondroblasts. This collection of cartilage and woven bone, known as soft callus, serves as the initial connection of the fracture gap and occurs at approximately 2 to 3 weeks. After the immature callus is formed, both endochondral and intramembranous ossification processes convert the hyaline cartilage and woven bone to more organized lamellar bone or hard callus. This occurs at approximately 4 to 8 weeks and is the point at which time the callus becomes radiographically evident. New vessels permeate the lamellar bone and recruit additional osteoblasts, which eventually serve to convert the lamellar bone into trabecular bone. In the final remodeling phase, osteoclasts migrate to create pits known as Howship's lacuna. Osteoblasts will then deposit compact bone within this pit. A balance of osteoblastic and osteoclastic activity will continue until the form of the fracture site is functionally similar to the original bone. This final phase can last for several years.

MUSCLES, TENDONS, AND LIGAMENTS—MACROSTRUCTURE

Skeletal muscles have sites of origin and insertion. Each individual muscle fiber is surrounded by endomysium. Bundles of muscle fibers are surrounded by perimysium and the entire muscle is enclosed by epimysium. Tendons are fibrous bands of connective tissue that connect muscles to bones or cartilage. Ligaments are also fibrous bands of connective tissue; however, they connect bony structures to each other rather than to muscles. Ligaments should be described by their proximal and distal attachments.

TYPES OF JOINTS

Fibrous (synarthroses) joints are held together by fibrous tissue, have no joint cavity, and are immovable. Examples include the sutures of the skull, teeth, and synchondroses. A synchondrosis is a joint of two bones united by cartilage and is seen in the epiphyseal plates in growing children.

Cartilagenous (amphiarthrosis) joints occur where two bones are held together by cartilaginous structures and like fibrous joints have no joint cavity but are slightly moveable. Symphyses are joints joined by fibrocartilage and provide slight mobility and include the symphysis pubis, intervertebral discs, and sacroiliac joints. A syndesmosis is another type of amphiarthrosis where the bony surfaces are united by an interosseous ligament, as in the inferior tibiofibular articulation.

Synovial (diarthrodial) joints are freely moveable joints with thick fibrous capsules containing synovial

fluid produced by a synovial membrane. Articular cartilage (hyaline cartilage) at the ends of the adjoining bones provide for smooth motion and cushioning. The bones are also typically held together by thick ligaments. There are many types of synovial joints based on the shape of their articular surfaces and mechanics:

- Hinge (knee and elbow)
- Ball and socket (hip)
- Pivot (proximal radioulnar and atlantoaxial)
- Condylod or ellipsoid (wrist)
- Gliding (intercarpal and intertarsal)
- Saddle (thumb carpometacarpal)

SPECIFIC JOINTS

SHOULDER

The shoulder is composed of three separate joints: the glenohumeral, acromioclavicular, and sternoclavicular. The glenohumeral joint is the major one and is a ball-and-socket–type synovial joint. It is formed by the articulation of the humerus and lateral aspect of the scapula (glenoid fossa). The shallowness of the glenoid and relative loose connections of the joint capsule and surrounding muscles allow for tremendous mobility; however, this makes this joint prone to dislocation. The capsule is attached superiorly to the glenoid and inferiorly to the anatomic neck of the humerus. The capsule is reinforced by the four muscles and associated tendons of the rotator cuff and five scapulohumeral ligaments (Table 69-1). The rotator cuff circumferentially covers the humeral head and stabilizes, abducts, adducts, and rotates the shoulder. The supraspinatus lies directly over the humeral head attaching to the greater tuberosity and serves to abduct the shoulder through the first 15 degrees of motion. The infraspinatus and teres minor muscles cover the back of the humeral head, both inserting on the greater tuberosity and serving primarily as external rotators. The subscapularis attaches to the lesser

tuberosity and stabilizes the glenohumeral joint as well as functioning as adductor and internal rotator.

Three bursa serve to lubricate the rotator cuff as it moves through the coracoacromial arch (space between the acromion and coracoacromial ligament). The subacromial bursa lies superior to the rotator cuff and facilitates supraspinatus movement beneath the coracoacromial arch. This bursa communicates freely with the subdeltoid bursa, which lies between the deltoid and joint capsule facilitating smooth movement between these structures. A third bursa, the subscapular bursa or recess, lies between the subscapularis tendon and the neck of the scapula. This bursa communicates freely with the synovial joint space, and is therefore normally opacified on arthrograms unlike the subacromial and subdeltoid bursa.

The glenoid labrum is a fibrocartilaginous rim attached around the margin of the glenoid fossa; it protects the edges of bone during motion and deepens the articular fossa. Superiorly, in most individuals, it is continuous with the long head of the biceps (biceps anchor complex). The anterosuperior portions of the labrum are loosely attached to the glenoid while the inferior portion is firmly attached, functioning as an immobile extension of the articular cartilage.

A common normal shoulder variant is a Buford complex, which consists of an absent anterior/superior labrum along with a cord-like thickened middle glenohumeral ligament.

ELBOW

The elbow is a synovial hinge joint formed by three separate articulations. The first two are the humeroradial between the capitellum of the humerus and the radial head and the humeroulnar between the trochlea of the humerus and the trochlear notch of the ulna. These allow for flexion and extension. The third articulation, which allows for supination and pronation of the forearm, is the proximal radioulnar joint between the radial head and radial notch of the ulna. Collectively these three articulations are within a common capsule.

The distal humerus has important medial and lateral epicondyles, the former being larger and the site of origin of the common flexor tendon of the forearm as well as the pronator teres. The lateral epicondyle is the site of origin of the common extensor tendon of the forearm as well as the supinator. The olecranon fossa allows for accommodation of the olecranon along the posterior aspect of the humerus during full extension while the coronoid fossa has a similar role anteriorly during flexion.

Three separate ligaments act to reinforce the elbow, the radial and ulnar collateral ligaments, as well as the annular ligament. The annular ligament is a fibrous band that encircles four-fifths of the radial head, forming a collar securing the radial head to the radial notch of the

ulna at the proximal radioulnar joint. The annular ligament blends with both the radial collateral ligament and joint capsule. The radial collateral ligament is merely a thickening of the joint capsule, which extends from the lateral epicondyle of the humerus to the anterior and posterior margins of the radial notch of the ulna as well as the annular ligament. The ulnar collateral ligament is triangular in its configuration consisting of anterior, posterior, and oblique bands, and extends from the medial epicondyle of the humerus to the coronoid process and olecranon. Additionally, the lateral ulnar collateral ligament is located posterolaterally and prevents posterolateral subluxation of the radial head.

WRIST

The carpal bones are best arranged functionally into proximal and distal rows. The proximal row consists of the scaphoid, lunate, triquetrum, and pisiform, and the distal row consists of the trapezium, trapezoid, capitate, and hamate. The wrist is an ellipsoid joint formed between the radius and the proximal carpal row excluding the pisiform. The triangular fibrocartilage complex attaches the distal radius to the ulna as well as separating the lunate from the distal ulna. Dorsal and palmar radiocarpal ligaments connect the radius and ulna to the proximal carpal row. Radial and ulnar collateral ligaments connect the radial styloid to the scaphoid and the ulnar styloid to the triquetrum and pisiform respectively.

The carpal tunnel is bounded anteriorly by the flexor retinaculum and posteriorly by the carpal bones. The flexor retinaculum extends from the hook of the hamate to the tubercle of the trapezium. The carpal tunnel transmits the median nerve and tendons of the flexor pollicis longus, flexor digitorum profundus, and flexor digitorum superficialis muscles. The extensor retinaculum on the dorsum of the wrist is thinner than the flexor retinaculum and allows passages for the extensor tendons.

HIP

The femoral head articulates with the acetabular cavity, which is an elevated bony rim, incomplete inferiorly at the acetabular notch. The transverse acetabular ligament covers this deficient portion of the acetabulum. The articular surface of the acetabulum is covered by hyaline cartilage and fibrocartilage (acetabular labrum) except centrally at the acetabular fossa that contains fibrofatty tissue and synovium. The femoral head is covered by articular cartilage except centrally at the fovea capitis, a central depression containing the ligamentum teres, which attaches the femoral head to the central aspect of the acetabular cavity at the transverse acetabular ligament.

A strong joint capsule attaches anteriorly and posteriorly to the acetabular rim, creating small paralabral recesses. Superiorly, it also attaches to the labrum creating

a larger paralabral recess. Inferiorly, the capsule attaches to the femoral neck. Anteriorly, the capsule extends to the intertrochanteric line; however, it covers only approximately half of the femoral neck posteriorly. There is a normal communication of the joint cavity with the iliopsoas bursa in approximately 15% of individuals.

KNEE

Three main joints of the knee are the femorotibial, patellofemoral, and proximal tibiofibular joints. The femorotibial articulation is a condylar-type synovial hinge joint between the condyles of the femur and tibia. The patellofemoral joint is a saddle-type joint. The proximal tibiofibular joint is a glide-type joint.

The lateral collateral ligament (LCL) extends from the proximal aspect of the lateral femoral condyle to the lateral aspect of the fibular head. The distal aspect of the ligament merges with tendon of the long head of the biceps femoris as a common attachment. The LCL serves as a stabilizer to varus forces during movement. The iliotibial band is a thickening of the fascia lata, which originates from the iliac crest and attaches to the lateral femoral condyle of the tibia at Gerdy's tubercle. Second fracture is an avulsion fracture of the lateral tibial metaphysis, and is thought to relate to the insertion of the central portion of the lateral capsular ligament, which attaches to the proximal lateral aspect of the tibia.

The medial (tibial) collateral ligament (MCL) can be divided into both superficial and deep components. Anatomically the superficial component has a proximal attachment from the medial femoral condyle just below the adductor tubercle and extends distally to the metaphyseal region of the tibia just beneath the pes anserinus (common tendinous insertion of the sartorius, gracilis, and semitendinosus). The MCL is the primary structure responsible for resistance to valgus stress within the knee. The deep MCL anatomically consists of the meniscofemoral and meniscotibial ligaments. These structures are firmly attached to the meniscus but do not provide significant resistance to valgus force.

The anterior cruciate ligament (ACL) arises from the posteromedial aspect of the lateral femoral condyle and has a broad attachment to the tibia in front of and lateral to the anterior tibial eminence. The ACL is composed of two principle bundles, the anteromedial and posterolateral bands. The anteromedial band is tight in flexion and the posterolateral is tight in extension. The ACL serves to prevent anterior translation of the tibia with respect to the femur. It also serves as a stabilizer during rotational movement.

The posterior cruciate ligament (PCL) originates from the anterolateral aspect of the medial femoral condyle in the intercondylar notch and extends to attach to a recessed shelf posterior and inferior to the articular surface of the tibial plateau. The PCL is approximately twice as strong

and thick as the ACL, therefore it is injured much less frequently than the ACL. It serves as a stabilizer of the knee providing significant resistance to posterior tibial displacement with respect to the femur. The PCL can be divided into anterolateral and posteromedial bundles. The anterolateral bundle prevents hyperflexion while the posterolateral bundle prevents hyperextension.

Medial and lateral menisci are attached to the condylar surface of the tibia. They are separated into body, anterior, and posterior horns. Their superior surfaces are concave and the inferior surfaces are flat. The periphery of the menisci are convex and thick and attached to the joint capsule while the central portion is thinner and only loosely attached to the tibial surface. The peripheral surface is considered nonarticular and usually not involved in tears. Several ligaments also attach to the menisci including the meniscomfemoral, meniscotibial, coronary, and transverse intermeniscal ligaments.

These are mostly avascular structures, except for the peripheral 10% to 25%, supplied by perimeniscal capillary plexus from the lateral and medial geniculate arteries. For this reason, peripheral tears will heal better than central ones.

The medial meniscus has an open C shape and is larger than the lateral meniscus. There is a firm attachment to the deep MCL and joint capsule at the periphery and is therefore more prone to injury. The posterior horn is roughly twice the size of the anterior horn.

The lateral meniscus has a more tight C shape and appears more circular on axial slices. The anterior and posterior horns are roughly equal in size. Unlike the medial meniscus, there is only a loose attachment to the capsule peripherally and there is no direct attachment to the LCL. This makes the lateral meniscus overall more mobile and less prone to injury. Of particular note, the posterior horn is attached to the medial femoral condyle through the ligament of Wrisberg (posterior to PCL) or ligament of Humphrey (anterior to PCL) in one-third of patients. Approximately 3% of people have both.

A common variant of the meniscus is the discoid configuration. This occurs when there is thickening of the central portion of the meniscus extending toward the intracondylar notch. On MRI, this is demonstrated as more than two consecutive sagittal images without a bowtie configuration. This is more commonly seen in the lateral meniscus. Another common variant is meniscal flounce, which is seen as a wavy appearance of the free edge of the meniscus when the knee is in approximately 10 degrees of flexion. This commonly resolves when the knee is fully extended.

ANKLE

While the tibiotalar joint is the true ankle joint, functionally the ankle is composed of four joints: tibiotalar,

subtalar, and the proximal and distal tibiofibular. Interaction of all of these joints is required for proper motion at the ankle.

The tibiotalar joint is a hinge joint with medial and lateral malleoli projecting inferiorly from the tibia and fibula respectively forming the medial and lateral walls. Strong ligaments reinforce the medial (deltoid) and lateral aspects of the joint while the capsule is significantly weaker both posteriorly and anteriorly.

The medial collateral ligamentous complex (deltoid ligament) has several components: tibiotalar, tibiocalcaneal, talonavicular, and the spring ligaments (between the sustentaculum tali and navicular). Functionally, and as seen on imaging studies, the deltoid ligament is best divided into superficial and deep components. The superficial portion arises from the medial malleolus and extends into three separate ligaments. The superficial part of the deltoid primarily resists eversion of the hindfoot. The deep portion arises from the medial malleolus and inserts on the nonarticular surface of the medial talus. The main function of the deep deltoid is to prevent lateral displacement and external rotation of the talus.

The lateral collateral ligamentous complex can be divided into superior and inferior groups. The superior group is composed of anterior and posterior tibiofibular ligaments. The inferior group is composed of anterior and posterior talofibular as well as calcaneofibular ligaments. The anterior talofibular ligament is the most commonly torn ligament of the ankle.

Many important tendons surround the ankle joint. Posteriorly, the Achilles tendon attaches to the posterior aspect of the calcaneus. Of note, the Achilles tendon does not have a tendon sheath but rather a paratenon. Immediately adjacent to the Achilles tendon, along its medial aspect, is the small plantaris tendon. The flexor tendons are located on the medial aspect of the ankle. In successive fashion from medial to lateral and anterior to posterior are the posterior tibial, flexor digitorum longus, posterior tibial neurovascular bundle, and flexor hallucis longus tendon (mnemonic for remembering this is Tom, Dick, and Harry). Laterally there are the primary everters of the foot, the peroneus longus and brevis, which both pass behind the lateral malleolus using this structure as a pulley. Anteriorly from medial to lateral, the main tendons seen are the anterior tibial, extensor hallucis longus, extensor digitorum longus, and peroneus tertius.

QUESTIONS AND ANSWERS

- Where is normal red marrow located in the adult skeleton?
 - Distal femur
 - Skull
 - Vertebral bodies
 - Humeral diaphysis

ANSWER: C. Vertebral bodies. In the neonatal period, red or hematopoietic marrow is present throughout the skeletal system. Normal physiologic conversion of red to yellow marrow occurs in a predictable pattern through childhood and adolescence. Conversion begins in the terminal phalanges and progresses proximally. There is a distal to proximal trend within individual bones as well, starting in the diaphysis followed by the distal and ultimately proximal metaphysis. Conversion is completed by age 25, with red marrow remaining primarily within the axial skeleton. Red marrow can be found in the humeral and femoral heads as a normal variant in adults.

- Which of the following is the most commonly injured ankle ligament?
 - Anterior talofibular
 - Anterior tibiofibular
 - Deltoid
 - Posterior talofibular

ANSWER: A. The anterior talofibular ligament is the most commonly torn ligament followed by the posterior talofibular and calcaneofibular ligaments. These are commonly torn with inversion injuries. In contrast, the medial deltoid ligamentous complex is significantly stronger and seldom tears.

- Which of the following is a component of the Buford complex?
 - Thickened common superior glenohumeral ligament
 - Common superior glenohumeral ligament
 - Thickened superior glenohumeral ligament
 - Common middle glenohumeral ligament

ANSWER: B. A common normal variant seen within the shoulder is a Buford complex, which consists of an absent anterior/superior labrum along with a cord-like thickened middle glenohumeral ligament.

- Between which two muscle tendons is a Baker cyst located?
 - Medial head gastrocnemius and semimembranosus
 - Medial head gastrocnemius and semitendinosus
 - Medial and lateral heads of the gastrocnemius
 - Semitendinosus and semimembranosus

ANSWER: A. A true Baker cyst as originally described lies between the tendons of the medial head of the gastrocnemius and the semimembranosus.

- Second fracture is an avulsion fracture of which of the following structures?
 - Medial capsular ligament
 - Iliotibial band
 - LCLs
 - ACL

ANSWER: C. Second fracture is an avulsion fracture of the lateral tibial metaphysis, and is thought to relate to the insertion of the central portion of the lateral capsular ligament, which attaches to the proximal lateral aspect of the tibia.

- Which of the following is *not* found within the carpal tunnel?
 - Median nerve
 - Flexor pollicis longus
 - Extensor carpi radialis brevis
 - Flexor digitorum superficialis

ANSWER: C. The carpal tunnel is bounded anteriorly by the flexor retinaculum and posteriorly by the carpal bones. The flexor retinaculum extends from the hook of the hamate to the tubercle of the trapezium. The carpal tunnel transmits the median nerve and tendons of the flexor pollicis longus, flexor digitorum profundus, and flexor digitorum superficialis muscles.

- Which of the following is *not* normally opacified on shoulder arthrography?
 - Subscapularis recess
 - Glenohumeral joint space
 - Biceps tendon sheath
 - Subacromial bursa

ANSWER: D. The subacromial and subdeltoid bursas do not normally communicate with the glenohumeral joint space, and opacification of this bursa on routine shoulder arthrography is indicative of a full-thickness rotator cuff tear. The subscapularis recess is a normal inferior extension of the joint space, which can be seen "saddle bagging" over the subscapularis on sagittal images. The long head of the biceps has an intraarticular course, and fluid or

gadolinium is often seen around the tendon within the tendon sheath. Fluid or gadolinium within the tendon itself is indicative of tear.

8. Which of the following structures is found within the tarsal tunnel?
 - A. Anterior tibial nerve
 - B. Extensor hallucis longus tendon
 - C. Sural nerve
 - D. Flexor digitorum longus

ANSWER: D. The tarsal tunnel is on the medial aspect of the ankle and is bordered medially by the bony medial aspects of the distal tibia, calcaneus, and talus and laterally by the flexor retinaculum. Through this tunnel pass the posterior tibial artery and vein; posterior tibial nerve; and tendons of the tibialis posterior, flexor hallucis longus, and flexor digitorum longus muscles.

9. The flexor retinaculum of the wrist extends from which of the following two structures?
 - A. Pisiform to triquetrum
 - B. Hamate to trapezium
 - C. Scaphoid to hamate
 - D. Trapezium to trapezoid

ANSWER: B. The flexor retinaculum extends from the hook of the hamate to the tubercle of the trapezium.

10. Which of the following structure serves to keep the radial head in appropriate location at the proximal radioulnar joint?
 - A. Annular ligament
 - B. Radial collateral ligament
 - C. Ulnar collateral ligament
 - D. Bicipital aponeurosis

ANSWER: A. Three separate ligaments act to reinforce the elbow, the radial and ulnar collateral, as well as the annular ligament. The annular ligament is a fibrous band, which encircles four-fifths of the radial head, forming a collar, which secures the radial head to the radial notch of the ulna at the proximal radioulnar joint. The annular ligament blends with both the radial collateral ligament and joint capsule. The radial collateral ligament is merely a thickening of the joint capsule, which extends from the lateral epicondyle of the humerus to the anterior and posterior margins of the radial notch of the ulna as well as the annular ligament. The ulnar collateral ligament is triangular in its configuration consisting of anterior, posterior, and oblique bands, and extends from the medial epicondyle of the humerus to the coronoid process and olecranon.

70 MUSCULOSKELETAL TRAUMA

*Roderick F. Biosca Jr. and
Matthew Larrison*

CERVICAL SPINE FRACTURES

The cervical spine remains one of the most clinically significant areas of evaluation because of the dire consequences of injury. Injuries of the cervical spine predominantly occur at differing levels based on age. In the pediatric population, cervical injuries tend to involve the proximal cervical spine (C1-2), while in adults, injuries tend to involve the lower cervical spine, specifically C5-6 and C6-7. These differences are believed to be related to the relative size and mass of the child's head with respect to the cervical muscle mass.

The most devastating cervical spinal injury is a flexion teardrop fracture; it is the most common cervical spine fracture with dire consequences. The flexion teardrop fracture results from severe flexion compression that often results in a comminuted fracture of the affected vertebral body, typically C5 or C6 and spinal column. There is posterior dissociation of the upper involved vertebral body. Typically a fragment from the anterior inferior margin of the more cranial affected vertebral body is detached as is the anterior spinal ligament, which remains attached to the fragment. The anterior spinal ligament is disrupted at the level of injury, but also remains attached to the remainder of the spine. The ring of the affected vertebral level is intact and displaces posteriorly, causing marked narrowing of the spinal canal, often with cord impingement, entrapment, and injury. The cord is often struck on the ventral (anterior) surface where the greatest trauma is induced, creating an anterior cord syndrome: diminished motor function with loss of pain and temperature sensation. Proprioception and vibratory sense are intact.

Hyperextension injuries are much more subtle. The uppermost vertebral body is dislocated posteriorly for an instant, but usually self-reduces, limiting findings seen on CT and radiographs. Imaging typically reveals subtle findings, such as prevertebral soft-tissue thickening, mild posterior vertebral body displacement, and widening of the intervertebral disk space.

The most commonly missed significant cervical spine fractures involve the odontoid. Dens fractures are classified by where the fracture plane dissects the dens. Type I is often an avulsion-type injury and only involves the tip and is considered stable. Types II and III are

considered unstable and involve the body of the dens or fracture into the vertebral body of C2, respectively. Findings are often subtle on radiographs, and disruption of the spinolaminar line is classic as a result of the loss of the normal posterior tilt of the dens body with respect to the anterior spinal line.

Axial loading can cause lateral displacement of the lateral masses of C1. Since the atlas is essentially a ring, for the lateral masses to move laterally, the ring has to break in two places. The weakest portion of the atlas is the anterior and posterior arches, where fractures typically occur. Once fractured through both arches, the lateral masses are free to displace laterally, resulting in an unstable injury.

Traumatic spondylolysis, commonly called Hangman fracture, typically results from a hyperextension injury with fractures through neural arches (pedicles or lamina). This injury decompresses itself as the involved vertebral body moves anterior, but the posterior neural arch remains approximately unchanged, thereby actually widening the spinal canal rather than narrowing it. These injuries typically affect C1-2 or C2-3. Disruption of the spinal laminar line is diagnostic.

Jumped, perched, and locked facets occur by a similar mechanism, and are more of a spectrum of the same injury resulting from flexion, distraction, and rotation within the spine. The most common level involved is C4-5 or C5-6.

Three types of occipital condylar fractures are seen. The first type results from axial loading and is a compression-type fracture of the condyle. The second type is unique because it is an extension into or from the occipital bone. The third type of occipital condyle fracture is the most unstable and severe. It involves a simple avulsion of the alar ligament from the occipital condyle. This increases laxity at the skull base and can result in spinal cord compression slightly below the brainstem junction.

THORACIC AND LUMBAR SPINAL INJURY

Thoracic and lumbar spine injuries are unique from cervical spinal injuries because the lower spine has greater structural stability secondary to larger support muscles, thicker ligaments, and larger overall intervertebral disks. Compression and flexion injuries account for 75% of all thoracic and lumbar spinal injuries. The most common thoracic and lumbar fracture in normal bone is an anterior wedging fracture, which usually results in depression and wedging of the superior endplate. If the force load is asymmetric, the injury can simply be a lateral compression fracture.

TABLE 70-1 Grading of Spondylolisthesis

GRADE	DEGREE OF SUBLUXATION OF VERTEBRAL BODY
1	Less than 25%
2	25%–50%
3	50%–75%
4	75% to complete subluxation

Another common thoracic/lumbar fracture is a transverse fracture through the vertebral body with extension through the posterior processes or the intervertebral disk. This injury used to be seen most commonly with a lap belt restraint (Chance fracture). Shoulder belts have decreased these types of injuries significantly to the point that falls from heights are now the most common type of insidious event.

Spondylolysis and spondylolisthesis are considered as a spectrum of injuries that are actually graded based on severity of subluxation. Spondylolysis is actually disruption of one or both pars interarticularis without dissociation or subluxation. This is usually noted by a defect and/or sclerosis of the pars on one or both sides. Spondylolisthesis is the resulting anterior subluxation of the upper vertebral body with respect to underlying level secondary to pars defect(s) disassociation(s). These abnormalities typically occur at the L4-5 or L5-S1 level (Table 70-1).

Within the cervical spine, involvement of the transverse process usually involves the transverse foramina and is associated with injury to the transiting vertebral artery. These injuries commonly occur at C7, and studies have shown that less than 5% of vertebral arteries have entered the transverse foramina at C7, but rather the most common entry level is C6.

PELVIC TRAUMA

Traumatic pelvic fractures usually demonstrate a vertical pattern through the sacrum. Insufficiency sacral fractures are typically horizontal, accounting for the traditional Honda sign on bone scans. As for the most sensitive test for sacral fractures, most references state MRI is slightly more sensitive than conventional bone scan.

Approximately two-thirds of pelvic fractures are stable, that is they are single-break or avulsion-type fractures. One-third is complex and considered unstable.

Hip fractures are one of the most clinically common injuries encountered by radiologists, as they occur in both the young with severe trauma and the elderly with less severe injuries, such as ground-level falls. Hip fractures can be divided into three components based on anatomy: fractures of the acetabula, the femoral neck, and the femoral shaft. The majority of acetabular fractures

can be divided based on which surface is involved—the column, the wall, or a transverse fracture involving both column and wall.

Briefly, the posterior column extends from the obturator foramen through the posterior aspect of the weight-bearing acetabular dome and then obliquely through the greater sciatic notch. Posterior column fractures account for 50% of acetabular fractures and usually occur with a force directed parallel to a flexed femoral shaft. The force is transmitted from the femur onto the posterior acetabular wall, which typically results in either a fracture through the posterior acetabular wall with subluxation or dislocation of the femoral head. If more than 40% of the posterior acetabular wall is involved, the injury is considered unstable and will require surgical fixation. A third injury with more devastating consequences is a posterior acetabular wall fracture with femoral dislocation accompanied by a femoral neck fracture (aka the Bo Jackson). On an AP pelvic radiograph, the ilioischial line is used to evaluate the posterior column for injury. Other associated injuries include sciatic nerve trauma, bladder injury, internal iliac artery injury, and posterior collateral ligament (PCL) tears. Posterior hip dislocations account for 85% to 90% of hip dislocations and patients typically present with the affected lower extremity in internal rotation. Approximately 15% of these injuries result in avascular necrosis.

Anatomically, the anterior column extends from the symphysis pubis and obturator foramen through the iliac crest. The iliopectineal line on an AP pelvic radiograph provides the best evaluation of the anterior column and many fractures involving only the anterior column are associated with anterior hip dislocations. Anterior hip dislocations account for 10% to 15% of traumatic hip dislocations and typically present with an externally rotated lower extremity and only approximately 4% develop avascular necrosis.

The remaining acetabular fractures result from a common mechanism: lateral impaction of the femoral head into the acetabulum. This force results in either a two-column (involving both the anterior and posterior columns) or a T-type fracture. The T-type fracture is a transverse two-column fracture with a third fracture line extending inferiorly into the obturator foramen (and often through the inferior pubic rami). Generally speaking, the T-type injury has a higher prevalence of poor clinical results including nerve injury, osteoarthritis development, and avascular necrosis.

FEMUR FRACTURES

Femoral fractures can be divided into those involving the femoral head, femoral neck, intertrochanteric region, the

femoral shaft, and the femoral condyles. Simple fractures of the femoral head are extremely rare and usually only result from direct-impact trauma like a gunshot wound or some other type of penetrating injury. The other option for a femoral head fracture is slipped capital femoral epiphysis, which is simply an atraumatic fracture through the hypertrophic zone of the physal plate. These fractures are classic Salter Harris type I injuries and are seen bilaterally in 20% of those affected. This injury is associated with rickets, renal osteodystrophy, growth hormone therapy, and obesity. Absence of the line of Klein to intersect the femoral head is diagnostic. Avascular necrosis increases with severity of displacement and attempted reduction.

Femoral neck fractures are a common injury among the elderly and often occur as a result of a fall or less likely as a pathologic fracture. A general trend in femoral neck fractures is the more proximal the occurrence and the more severe the displacement, the higher the chance of developing avascular necrosis. Subcapital, transcervical, and basicervical fractures are similar in mechanism. They all are intracapsular and despite the capsule being sometimes disrupted with more severe fractures, the joint compartment actually can contribute to the increased prevalence of avascular necrosis. Fracture-associated hemorrhage often fills the capsule resulting in increased intracapsular pressure and collapse of the draining venous channels, which in effect can lead to a venous infarct and the development of avascular necrosis. Femoral neck fractures are graded based on the Gardner classification, which has four stages ranging from stage I, incomplete fracture, to stage IV, grossly displaced fracture.

Fractures involving the trochanters are not common, to the point that fractures of the lesser trochanter in an adult is considered pathologic (secondary to a metastasis or primary bone tumor) until proven otherwise. In children, however, a simple avulsion of the lesser trochanter is more common than a pathologic fracture at this same location.

Intertrochanteric fractures typical occur in older individuals and are classified based on the number of fracture fragments. The main fracture line typical runs from the greater to the lesser trochanter, and avascular necrosis and nonunion are uncommon complications.

KNEE INJURIES

Femoral condyle fractures are rare, typically occurring as either direct trauma or as a result of repetitive micro-trauma, which causes a subchondral insufficiency fracture. This subchondral insufficiency fracture is usually located in the medial femoral condyle and classically seen in older women with new onset of knee pain. These injuries often progress to spontaneous osteonecrosis of the knee (SONK) and are associated with a medial

meniscus tear approximately 75% of the time. Rapid subcondylar collapse of the medial anterior weight-bearing femoral condyle is diagnostic.

Patellar fractures are often comminuted and the result of direct impaction. Transverse fractures through the patella are the most common (60%) and often result in distraction of the two fragments by the contracting quadriceps muscle group. The distraction distance varies based on the degree to which the medial and lateral patellar retinacula are disrupted. A single oblique lucency through the upper lateral patella is commonly mistaken for a fracture, but is almost exclusively a bipartite patella. Patellar dislocations are almost exclusively in the lateral direction and associated with tears of the weaker medial retinaculum. A bone bruise within the lateral femoral condyle and a patellar fracture are often seen from impaction of the dislocating patella.

Actual femoral-tibial knee dislocations are rare and can occur in any direction. Because of the immediate proximity of the popliteal artery and tibial nerve, these injuries often have devastating vascular and neurologic consequences, and if not treated promptly can result in limb loss or death because of hemorrhage. The popliteal artery is injured in approximately 30% of cases.

An avulsion fracture involving the anterior lateral proximal tibia slightly below the articular surface is called a Segond fracture. The significance of this injury is its association with tears of the anterior cruciate ligament (ACL, 75%–100%) and either or both menisci (66%–75%).

MENISCUS ABNORMALITIES

The four types of meniscal tears commonly described include vertical, horizontal, radial, and bucket handle tear. The bucket handle tear is more of an extensive/severe configuration of a typical vertical tear. Tears typically appear as linear-increased signal within the meniscus. Degenerative changes within the meniscus cannot be seen on arthroscopy and are not thought to be symptomatic.

LIGAMENT INJURIES

The ACL along with the medial and fibular collateral ligaments are the dominant stabilizers of the knee. The fourth major ligament of the knee, the PCL, was typically not repaired in the past if torn; however, recent data suggest that repair/reconstruction may be preferential. The PCL prevents posterior subluxation/dislocation.

The ACL is the most commonly injured knee ligament often occurring with valgus and anterolateral rotary subluxation. The ACL is the primary stabilizer opposite the PCL, preventing anterior subluxation of the tibia on the

femoral condyles. On physical examination, an ACL tear is diagnosed by the “anterior drawer sign,”—induced tibial anterior subluxation. MRI findings of an ACL tear include swelling/effusion, increased signal within the ACL on sagittal imaging, fiber disruption, and a change in ACL course. These findings have 90% specificity for ACL tear. Other ACL injury–associated findings include hemarthrosis, “kissing contusions” on the anterior lateral aspect of the lateral femoral condyle, and the posterior lateral tibial plateau.

The medial collateral ligament (MCL) is a common accompanier of ACL and medial meniscal injuries (the terrible triad seen commonly in football players). More specifically, an injury to the MCL occurs from a valgus stress often initiated from a lateral blow to the knee. Proximal disruption can result in avulsion of the MCL origin from the medial femoral condyle. Often following a remote MCL injury, posttraumatic ossification develops surrounding the ligament and is known as Pellegrini-Stieda disease.

FORELEG AND ANKLE INJURIES

Blunt trauma to the proximal lateral foreleg, over the fibular head, has the ability to result in traumatic injury to the common fibular (peroneal) nerve, which innervates the extensor muscles of the foreleg, potentially resulting in “foot drop.” Fractures through the proximal fibula can result from two sources: direct blunt trauma and extension of a syndesmotic injury within the distal foreleg exiting through the proximal fibula called a Maisonneuve fracture. Distally this injury can be extremely subtle, most commonly appearing as minimal widening of the ankle mortise. Fractures of the proximal tibia include those from direct blunt trauma and injuries, such as the Segond fracture and avulsion fractures/injuries.

Tendon ruptures and muscle tears most commonly involve the gastrocnemius within either the medial head or the calcaneal (Achilles) tendon. Both injuries are commonly seen in weekend warriors who feel something pop in the back of the foreleg during activity. Achilles tendon injuries typically occur 2 to 6 cm proximal to the calcaneal insertion and result in an inability to plantar flex the foot. The injury to the medial gastrocnemius is often called tennis leg and results in a sharp burning pain in the posterior foreleg. This injury was originally believed to be due to a tear of the plantaris tendon, but has now been correctly identified as an injury to the medial head of the gastrocnemius.

A severe ankle fracture, the plafond fracture consists of a comminuted combined fracture of the ankle and distal tibial metaphysis. It usually has intraarticular extension and is complex approximately 25% of the time. Fractures

TABLE 70-2 Weber Classification of Ankle Fractures

A	Most stable supination, horizontal avulsion fracture below ankle mortise; associated medial malleolar fracture
B	Spiral/oblique fracture at mortise; associated medial malleolar fracture
C	Pronation with external rotation; fibula above mortise; disrupts tibiafibular syndesmosis

of the medial malleolus and the distal anterior and posterior articulating tibial margins are often seen. The fibula can remain intact as much as 25% of the time. The mechanism is one of axial loading, and this injury is often associated with a compression fracture of the lumbar spine (most commonly L1).

Ankle fractures typically involve the medial (tibial) or lateral (fibular) malleolus. Injuries involving the fibular malleolus are graded based on their level and stability (Table 70-2).

Ankle sprains are overwhelmingly inversion injuries that put three ligaments at risk. The first ligament to tear is the anterior talofibular ligament. The second ligament to tear is the calcaneofibular ligament, and rarely the posterior talofibular ligament will be torn.

FOOT INJURIES

Seventy-five percent of talus fractures occur through the neck or body, and because of the tenuous blood supply there is an increased risk of avascular necrosis following fracture.

Fractures of the calcaneus are classified based on the Rowe classification system with type V (a comminuted intraarticular fracture) being the most common. These fractures usually occur from a fall from height (lover's leap fracture) and result in a decreased Bohler angle (normally between 28 and 48 degrees.) Seventy-five percent of calcaneal fractures are intraarticular.

Fractures of the navicular usually occur in the sagittal plane at the junction of the middle and lateral thirds, and an increased risk of avascular necrosis is seen in the lateral fragment of such fractures. Other injuries include stress fractures in runners.

Lisfranc fracture/dislocation results from a rupture of the tarsal-metatarsal ligament complex resulting in lateral subluxation of all the metatarsals (homolateral subluxation) or of the second through fifth metatarsals (divergent subluxation). The mechanism is a result of axial loading on a plantar-flexed foot or the result of a neuropathic (Charcot) joint associated with diabetes.

Jones fracture is a transverse fracture through the base of the fifth metatarsal 1.5 to 2.0 cm distal to the tuberosity. The distance is significant in differentiating

this injury from a similar-appearing injury involving an avulsion of the proximal pole of the fifth metatarsal insertion of the peroneus brevis.

Stress fractures are most commonly seen in the foot, more specifically within the second or third metatarsals, often seen in marching military recruits. Turf toe is an injury resulting in a tear of the first metatarsal phalangeal joint capsule (plantar plate) allowing subluxation and possible dislocation of the joint.

The tibialis posterior muscle function is to maintain inversion of the subtalar joint. When there is paralysis or disruption of the posterior tibialis, the arch flattens and the foot moves into a valgus position as a result of the unopposed peroneus brevis action. Disruption of the posterior tibialis tendon most commonly occurs as the tendon traverses behind the medial malleolus and navicular tuberosity (hypovascular zone of the tendon). Rupture is classically described as acute discomfort and swelling overlying the posteromedial ankle in a middle-aged woman who develops a fallen arch.

UPPER EXTREMITY

SHOULDER

The shoulder is the most dynamic and unstable joint in the body, which also places this joint at risk of several injuries. The most dramatic injury is dislocation, of which 95% are in the anterior direction (the humeral head moves anterior and slightly inferior to the glenoid). Associated injuries include an impaction fracture on the posterior lateral aspect of the humeral head from contact with the inferior glenoid. This injury is called a Hill-Sachs lesion and it typically appears as a wedge-shaped defect. The counterpart to this lesion is a fracture from the anterior inferior rim of the glenoid. This lesion is called the Bankart deformity. Posterior dislocations make up the remaining significant dislocation injuries and are often associated with shock therapy or seizure episodes. The posterior rim of the glenoid is often fractured and displaced with posterior dislocations. Once posteriorly dislocated, the humerus is locked in internal rotation as the subscapularis turns the humeral shaft, unless the lesser tubercle is avulsed by the subscapularis that can occur. The subscapularis inserts on the lesser tubercle, but continues to the greater tubercle as the transverse ligament whose purpose is to contain the long head of the biceps tendon within the intertubercle groove. If the long tendon of the biceps is displaced from this location, the transverse ligament is disrupted and the subscapularis tendon is often torn. Posterior dislocations also put the innervating axillary nerve of the deltoid muscle at risk of injury as it traverses the quadrangular space.

Fractures of the clavicle typically occur through the middle third of the shaft. Fragments are typically displaced by contraction of the sternocleidomastoid, which elevates the proximal clavicular fragment. The distal fragment is typically depressed by the weight of the arm and shoulder. Clavicular articulations are at risk of dislocation with the acromioclavicular joint dislocation occurring more commonly, as this is a focus to release stress with shoulder injuries. The acromioclavicular (AC) joint is a synovial joint tightly vested with connective tissue including the AC ligament and coracoclavicular ligament complex. The weaker AC joint complex is typically disrupted first followed by the coracoclavicular complex with more severe injury. Injuries to the AC joint are graded based on the degree of disruption of the AC joint. Trauma to the distal clavicle has a propensity to develop osteolysis of the distal clavicle.

Labral tears typical occur along the superior margin and track from anterior to posterior, hence the mnemonic SLAP (superior labral tear from anterior to posterior). These lesions typically occur from overhand throwing, such as in baseball pitchers, and are seen in the majority of the elderly population. These lesions often have associated injuries to the biceps tendon as well.

Injuries to the scapula usually indicate direct high-impact blunt trauma with fractures occurring most commonly in the body, neck, glenoid, and acromion. Scapular fractures are often associated with pulmonary contusion, pneumothorax, clavicular fracture (which results in a free-floating shoulder), shoulder dislocation, and because of the proximity to the axillary artery and brachial plexus, arterial and nerve injuries.

Os acromiale is failure of complete ossification of the scapular acromion and is considered a normal variant. This is important as it can be confused with a fracture through the acromion.

HUMERUS

Fractures of the proximal humerus are injuries typically seen in elderly individuals and in those with high-impact trauma. The Neer system is used to grade these injuries based on the number of fracture fragments displaced or angulated from normal anatomic position. Fragments of significance include greater tuberosity, lesser tuberosity, anatomic neck, and surgical neck. Simple surgical neck fractures are the most common proximal humeral fracture in adults and are often associated with osteoporosis. The prognosis is good as the blood supply to the humeral head is usually intact. Anatomic humeral neck fractures are rare and often associated with a poorer outcome as the blood supply to the humeral head is often disrupted. The radial nerve is

commonly injured with humeral fractures and shoulder dislocations.

Fractures through the distal half of the humerus are rare, excluding direct blunt trauma. In children, supracondylar fractures of the humerus are the most common cause of a posterior fat pad sign; in adults, it is a fracture of the radial head.

ELBOW

Radial head fractures are the most common elbow fracture in adults. These fractures are often subtle, but rarely comminuted, and require dedicated imaging to adequately define them. Subtle associated signs include a displaced anterior fat pad and more specifically, a displaced posterior fat pad. The mechanism of injury in most radial head and neck fractures is a fall on an outstretched hand, which drives the radial head into the capitellum resulting in fracture. Injuries associated with a radial head fracture include capitellum fracture, distal radial fracture, triceps tendon rupture, and radial head dislocation. Radial neck fractures are more common in children, and are usually Salter Harris type II fractures in approximately 90% of cases. Radial head and neck fractures have a propensity to develop nonunion and/or avascular necrosis because of a very mobile joint. Operative intervention occurs in more severe fractures and often results on a higher incidence of nonunion or avascular necrosis. In adults with closed physes, a radial head osteotomy is commonly performed. However, in children, this type of procedure can have disastrous consequences.

Supracondylar fractures are the most common pediatric elbow injury. Medial and lateral epicondylar fractures are also seen in pediatric populations. Lateral epicondylar fractures are the second most common elbow fracture in children (20% of pediatric elbow fractures) and result from a fall on an outstretched hand with the forearm abducted and the elbow extended. This injury is unstable and prone to nonunion as the fracture is intraarticular. Medial epicondylar fractures are the third most common pediatric elbow fracture. These injuries are usually extraarticular and usually associated with elbow dislocation. Commonly associated complications include ulnar nerve palsy, avascular necrosis, and nonunion—although this is less common in medial epicondylar fractures than in lateral epicondylar fractures.

RADIUS AND ULNA

As mentioned earlier in the chapter, radial head fractures are the most common adult elbow fracture accounting

for one-half of all elbow fractures in adults. What is less common is a combined fracture of the radius with a dislocation of the adjacent ulna (Galeazzi fracture). Classically this is a radial shaft fracture near the junction between the proximal and middle third along with dislocation of the distal radioulnar joint. The fracture almost invariably occurs slightly above the pronator quadratus. A fracture of the ulnar styloid can be associated. The mechanism is a direct blow or fall on an outstretched hand. The most common distal radial fracture is the result of forced dorsiflexion of wrist, classically seen in a woman older than 50 years falling on an outstretched hand, where the dorsal surface undergoes compression and the volar surface undergoes tension, which results in a fracture with dorsal angulation of the distal radius (Colles fracture). These injuries can have intraarticular extension, scapholunate dissociation, and a triangular fibrocartilage tear resulting in increased carpal osteoarthritis. Smith's fracture is the reverse of Colles fracture, in that the distal radial articulation is angled volar as apposed to dorsal.

A fracture of the radial styloid is known as Chauffeur fracture. It is usually an avulsion fracture and is frequently accompanied by scapholunate dissociation or perilunate dislocation.

There are four main types of ulnar fractures: those involving the coronoid, those involving the midshaft of the ulna, those involving the ulnar styloid, and those associated with radial dislocation (Monteggia fractures). The coronoid is the curved portion of the ulna that articulates with the trochlea of the humerus and it helps to resist posterior subluxation at the elbow joint. Coronoid fractures can vary from a small impaction fracture of the coronoid tip occurring with elbow dislocation, which is usually stable, to a comminuted fracture through the base of the coronoid, which is unstable. The majority is associated with elbow subluxation or dislocation and possible injuries to the anterior band of the ulnar collateral ligament and anterior joint capsule.

Nightstick fractures are blunt-trauma injuries occurring within the ulnar shaft. If they are displaced by greater than 50%, by more than 10 to 15 degrees of angulation, or associated with disruption of the interosseous membrane, they are considered unstable.

The third type of ulnar fracture is the ulnar styloid fracture. This fracture is often associated with other wrist fractures such as Colles, Smith, or Barton or can occur alone. The mechanism is either avulsion or compression.

The last ulnar fracture type is a combined ulnar fracture with radial head dislocation. The mechanism can be similar to that of a nightstick fracture or may result from a hyperpronation or hyperextension injury. The injury was originally described as a fracture through the proximal third of the ulna associated with anterior radial

head dislocation. Associated comorbidities include posterior interosseous nerve or radial nerve injury, nonunion, radial-humeral ankylosis, and recurrent radial head dislocation.

WRIST AND HAND

Carpal bone fractures are uncommon, but can have devastating consequences if untreated, including avascular necrosis and extensive osteoarthritis. The most common carpal bone fractured is the scaphoid, representing approximately 60% to 70% of all carpal bone fractures. Seventy percent of scaphoid fractures occur at the waist and are nondisplaced. Because the scaphoid receives its blood supply in a distal-to-proximal fashion, a fracture involving the proximal pole or waist has an increased risk of vascular disruption resulting in delayed union/nonunion and avascular necrosis. The actual statistics are fairly good in that 90% of scaphoid fractures unite, but some may take up to 2 years to do so. Scaphoid fractures occur by a common mechanism of falling on an outstretched hand.

The second most common carpal bone fracture involves a dorsal avulsion fracture from the triquetrum and usually only seen on lateral views. Lunate fractures are rare, but devastating because of the propensity to develop Kienbock disease, which is lunatomalacia secondary to vascular compromise and avascular necrosis. There is an association between Kienbock and repetitive lunate trauma, which is most commonly seen with negative ulnar variance, which results in increased stress on the lunate. Disruption of the scapholunate ligament complex can result in scapholunate dissociation. The normal distance between the scaphoid and lunate is 2 mm or less. If this distance is widened to 4 mm or more, the diagnosis of scapholunate dissociation can be made. This disruption and displacement can be accentuated by clenching the fist, which will cause the capitate to migrate proximally into the scapholunate interval. This instability results in arthrosis of the lunate capitate space along with narrowing and arthrosis of the radioscapoid space known as scapholunate advanced collapse wrist. Its appearance is identical to changes seen with pseudogout (CPPD).

A lunate dislocation is more severe than a perilunate dislocation, which is more severe than scapholunate dislocation. Fracture dislocations are more common than simple dislocations and are often less stable.

The most common fracture of the hand is a fracture through the distal little or (less commonly) ring finger metacarpal from an axial load along the metacarpal shaft. The common name for this injury is a boxer fracture because a close-fisted blow is the usual mechanism of injury. The distal fracture fragment is often angulated

in a palmar. If left untreated, this may result in limited range of motion.

A mallet fracture is a fracture through the dorsal base of the distal phalanx caused by an avulsion of the common extensor tendon, which occurs from flexion on a forcibly extended finger—often seen in young baseball pitchers. Open surgical repair is required if the fracture displaces more than 40% of the articular surface.

A Boutonniere deformity (buttonhole deformity) occurs when the middle slip of the extensor tendon is disrupted at the proximal interphalangeal joint, which causes flexion of the proximal interphalangeal joint and hyperextension of the distal interphalangeal joint. Surgical correction is required.

There are three main types of thumb injuries. The best-known thumb injury is the gamekeeper's thumb (aka skier's thumb) and it represents an avulsion of the thumb metacarpal phalangeal joint ulnar collateral ligament. This ligament almost always pulls away from the proximal thumb phalanx and results from valgus stress across the thumb.

Bennett fracture is the most common type of thumb fracture. The mechanism is axial loading on a partially flexed first metacarpal, often associated with a fistfight. This results in a fracture dislocation often with an oblique intraarticular fracture of the base of the thumb metacarpal and is unstable. If the intraarticular fracture through the thumb metacarpal is comminuted with dorsal subluxation, this fracture is known as Rolando fracture.

QUESTIONS AND ANSWERS

- On shoulder arthrography, contrast in which of the following locations is considered diagnostic of a complete rotator cuff tear?
 - Along the biceps tendon within the tendon sheath

- Within the subacromion bursa
- Within the subdeltoid bursa
- Overlying the subscapularis
- Both B and C

ANSWER: E. The subacromial and subdeltoid bursae are thought to usually communicate, and hence contrast is often seen occupying both spaces. Contrast in this space is never normal and usually represents a complete (full-thickness) tear of the rotator cuff. Contrast surrounding the biceps tendon is considered a normal variant as long as it is confined to the tendon sheath.

- Which of the following types of acetabular fracture affects both the ilioischial and iliopectaneal lines?
 - Transverse
 - Posterior column
 - Anterior column
 - Posterior wall
 - Anterior wall

ANSWER: A. The iliopectaneal line on an AP pelvis is considered representative of the anterior column. The ilioischial line is considered representative of the posterior column. A transverse fracture involves both the posterior and anterior columns and hence results in disruption of both the ilioischial and iliopectaneal lines.

- Which of the following is *not* associated with Second fracture?
 - ACL injury
 - Lateral capsular ligament injury
 - Meniscal tear
 - Lateral collateral ligament tear

ANSWER: D. Second fracture is an avulsion fracture of the lateral tibial plateau below the articular surface. The mechanism of injury is internal rotation and varus stress, which causes abnormal tension on the central portion of the lateral capsular ligament resulting in avulsion of this attachment. Second fractures are accompanied by other injuries including: ACL tears (75%–100%), medial or lateral menisci injuries (66%–75%), avulsion fracture of the fibular head, and avulsion fracture of Gerdy tubercle.

- In an inversion ankle sprain, which of the following ligaments is most likely injured?
 - Calcaneofibular ligament
 - Anterior talofibular ligament
 - Posterior talofibular ligament
 - Deltoid ligament

ANSWER: B. With inversion ankle sprains, the lateral ankle ligaments tear in a sequential order from

front to back depending on the severity of the inversion. The first and most commonly torn ligament is the anterior talofibular ligament followed next by the calcaneofibular ligament and finally (rarely) by the posterior talofibular ligament.

5. Which of the following shoulder tendons is disrupted with a dislocation of the long head of the biceps tendon?

A. Subscapularis
B. Infraspinatus
C. Teres minor
D. Deltoid
E. Supraspinatus

ANSWER: A. The tendon of the long head of the biceps runs within the intertubercular groove between the greater and lesser tubercles. The greater tubercle is the insertion of three of the four muscles of the rotator cuff, including the teres minor, supraspinatus, and infraspinatus. The lesser tubercle is the insertion of the fourth rotator cuff muscle, the subscapularis. Fibers of this insertion continue across the intertubercular groove as the transverse ligament whose function is to contain the long head of the biceps within the intertubercular groove. Hence if the long head of the biceps is dislocated (almost always anterior), the transverse ligament is disrupted.

6. Which of the following MR findings is *not* associated with a tear of the meniscus?

A. Linear high signal extending to the articular surface
B. Posterior horn appearing smaller than the anterior horn
C. Appearance of a single “bowtie” on sagittal sequences
D. Globular high signal within the meniscal body without extension to the articular surface

ANSWER: D. Globular high signal within the meniscal body without extension to the articular surface can represent one of two normal variants. In the young, this can represent increased vascularity, which is often present into the early twenties, or in older individuals may represent myxoid degeneration, which some believe may put individuals at an increased risk for future tears, but does not currently represent a meniscal tear. The other descriptors listed including a linear focus of high signal extending to the articular surface, blunting of the posterior horn of the meniscus with respect to the anterior horn, and seeing less than two sequential “bowties” on sagittal sequences are all indicative of meniscal tears.

7. A patient has a bone bruise on the anterior aspect of the lateral femoral condyle accompanied by a fracture of the medial patella. This constellation of findings is most consistent with which of the following tears:

A. Medial patellofemoral ligament
B. MCL
C. ACL
D. PCL

ANSWER: A. With a dislocation of the patella (usually laterally), associated injuries include a disruption of the medial patellar retinaculum, disruption of the medial patellofemoral ligament, and often a bone contusion on the lateral femoral condyle from the displaced patella striking the adjacent surface. A osteochondral fracture of the medial facet is also often seen.

8. A middle-aged man felt a pop followed by acute sharp pain behind his knee while playing basketball. Which of the following structures is injured?

A. Medial head of the gastrocnemius
B. PCL
C. MCL
D. Semimembranosis

ANSWER: A. Tennis leg is characterized by the sudden onset of calf pain, often related to an injury incurred because of extension of the knee and forced dorsiflexion of the ankle, as the case would be with an acute change in direction on a tennis or basketball court. Tennis leg is characterized by an injury to one of two structures, the medial head of the gastrocnemius and the plantaris tendon. Rupture of the plantaris tendon at the medial aspect of the calf and rupture of the medial head of gastrocnemius muscle at the musculotendinous junction without concomitant injury to the plantaris tendon have been implicated in the pathogenesis of this condition and are difficult to differentiate on physical examination. MR will show a fluid collection between the aponeuroses of the medial head of the gastrocnemius and the soleus with or without rupture of the medial gastrocnemius muscle.

9. Following reduction of a posterior elbow dislocation in an adult, which of the following is the most common origin of a trapped intraarticular fracture fragment?

A. Radial head
B. Medial epicondyle
C. Lateral epicondyle
D. Olecranon
E. Coronoid process

ANSWER: E. Eighty to ninety percent of elbow dislocations are posterior. In adults, intraarticular

fracture fragments most often originate from the coronoid process, which is often avulsed off the proximal ulna as the humerus moves anterior with respect to the ulna and radius. In children, the medial epicondylar ossification center can avulse and displace into the joint space.

10. What repetitive motion is most often associated with SLAP (superior labrum anterior to posterior) tears?
- Rowing
 - Bench press
 - Swinging a bat or golf club
 - Overhead throwing

ANSWER: D. SLAP tears involve the superior aspect of the glenoid labrum near the origin of the long head of the biceps tendon. These injuries are very common in “throwing athletes,” but are most common in individuals who have fallen or received a blow to the shoulder.

71 INFECTION

James S. Spann Jr. and Robert Lopez-Ben

INTRODUCTION

Infectious processes occurring in the musculoskeletal system can be medical emergencies and important causes of morbidity, and less commonly mortality in the postantibiotic era. Infection can involve bones, soft tissues, and joints. There are often several etiologies and pathogens. Some findings associated with infection can be protean and others more specific. The following discussion highlights the more common infectious processes of the musculoskeletal system and examines the more rare types of infectious processes with brevity.

Musculoskeletal infection occurs by three different routes of inoculation: hematogenous, contiguous spread, and direct implantation. It is important to consider these broad-category etiologies when discussing the various forms of infection involving the musculoskeletal system.

OSTEOMYELITIS

Osteomyelitis simply means inflammation of bone marrow. Although not commonly used, osteitis is a term indicating inflammatory involvement of cortical bone. The term osteomyelitis is essentially synonymous with an infectious process as the etiology.

A brief glossary of several terms regarding osteomyelitis is necessary.

- *Sequestrum* is a necrotic bone fragment separated from living bone by granulation tissue.
- *Involucrum* represents the thick periosteal reaction formed around the cortex of an infected tubular bone.
- *Cloaca* is an opening through the periosteum allowing pus from infected bone to communicate with the soft tissues.
- *Sinus tract* is a channel between infected bone and skin lined by granulation tissue. Sinus tract is different from a *fistula*, which represents a channel between two organs lined by granulation tissue.
- *Phlegmon* is a solid mass of inflammatory tissue, while *abscess* is a cavity lined by granulation tissue and filled with pus. An abscess can be drained if large enough but a phlegmon cannot be drained.

Osteomyelitis caused by hematogenous seeding leads to an immunological response. An organism hematogenously disseminated will initially seed the bone marrow with secondary extension into the cortex and soft tissues. In bone, the host response to the foreign organism leads initially to marrow edema and can progress onward if not treated to involve cortical bone destruction, cloaca formation, periosteal expansion, contiguous spread of infection into the soft tissues, abscess formation, sinus tract formation, bone infarction, and periosteal new bone formation. Abscess formation can be intraosseous within the marrow cavity, periosteal in location, or in the adjacent soft tissues.

Osteomyelitis is commonly divided into three categories: acute, subacute, and chronic. There are characteristic presentations in the infant, child, and the skeletally mature individual.

INFANT (AGE 0–1 YEARS)

In infants, osteomyelitis may be difficult to diagnose and remain clinically silent. Soft-tissue swelling may be the only initial sign. While infections caused by group B *Streptococcus* are more common in the neonate than at other ages, the most common infectious organisms for infants are *Staphylococcus aureus* and group A *Streptococcus*.

The pattern of infection in osteomyelitis can appear different because of variability in the vascular supply to long bones. In the infant, metaphyseal and diaphyseal vessels penetrate the physis, and hematogenously disseminated organisms will often deposit in the epiphyses and/or physis (growth plate). Periosteal elevation because of extracortical spread of infection followed by thick periosteal reaction (involucrum) is common. Periarticular spread is common and occurs with relative ease.

If infection continues to fester, subperiosteal abscess formation can readily occur because of the loose periosteum and subsequent elevation. In the long bones, the subperiosteal abscess can track along the shaft of the bone. Chronic osteomyelitis manifests often as bony sclerosis. In active chronic infection, there will be findings of bone loss, sequestra, and periosteal reaction. Sinus tracts and pathologic fracture are uncommon in the infant.

CHILD (1 YEAR CLOSURE OF PHYSIS)

In the child, vessels typically do not penetrate the physis, and infection will often deposit in the metaphysis because of slow flow in sinusoidal lakes in the metaphysis. Infection does not typically cross the growth plate to involve the joint until later in the course because of contiguous infection. Joint involvement can occur as well as sequestrum and involucrum formation. As in infants, subperiosteal abscess formation is common. A difference in this age group is that sinus tracts can occur.

Subacute osteomyelitis is exemplified by the Brodie abscess, which represents a walled-off fluid collection often with a sequestrum. The fluid in the Brodie abscess can be sterile. It is more common in male children and the metaphysis of the tibia and femur. The physis may be involved by progression of disease and if the lesion is intramedullary, channel-like lucencies may be encountered.

The chronic appearance of osteomyelitis may result in osteosclerosis or a mixed sclerotic and osteolytic appearance. Chronic active infection may manifest as areas of new bone destruction, sequestra, and involucrum. Pathologic fracture is uncommon in this age group. *Staphylococcus aureus* is by far the most common pathogen accounting for approximately 80% of infections. Group A *Streptococcus* is another common source of infection.

ADULT

After physeal closure in the skeletally mature individual, vessels from the diaphysis and metaphysis readily cross the physis, and hematogenous inoculation often results in localization of infection to the subchondral bone plate of the epiphysis. Joint involvement (septic arthritis) can subsequently occur because of contiguous spread. The most common source of infection in the adult is *S. aureus*.

Hematogenously disseminated osteomyelitis is less common in the adult than direct inoculation. When hematogenous dissemination occurs in the adult, it more commonly involves the small bones (hands and feet), pelvis, and spine, rather than the long tubular bones. Joint involvement and sinus tract formation are com-

mon. As opposed to children and infants, formation of involucrum, sequestra, and abscesses are less common. Pathologic fracture, although not common with adult osteomyelitis, can certainly occur in cases of neglect or chronic infection.

ACUTE OSTEOMYELITIS

Initially, bone radiographs are normal in the first week of osteomyelitis of hematogenous origin. The earliest radiographic manifestation of acute osteomyelitis may be deep soft-tissue swelling. This is followed by bone resorption after 1 to 2 weeks (osteoporosis/osteolysis), followed by periosteal reaction. A permeative or moth-eaten appearance because of bone destruction would be a later manifestation of acute osteomyelitis.

MR is excellent for the detection of osteomyelitis because of its high sensitivity but is relatively nonspecific with reported specificities ranging from 53% to 94%. MR has a very useful negative predictive value near 100%. This makes MR an excellent imaging modality, if there is clinical concern for osteomyelitis. Healed osteomyelitis in the adult can be diagnosed after return of normal high T1- and low T2-signal intensity in the marrow representing fatty marrow.

A three-phase bone scan is another excellent tool to evaluate for osteomyelitis if there is clinical suspicion for infection, and as in the case of MR, although sensitive, it lacks specificity. Bone scan imaging findings include increased radiotracer uptake on flow, blood pool, and delayed-phase imaging with technetium-labeled MDP. These findings are specific for osteomyelitis in the absence of recent fracture or surgical hardware/manipulation. The more chronic the infection, flow abnormality is less likely to be seen; however, blood pool and delayed-phase imaging would still probably be positive. More specific nuclear imaging examinations for infection like labeled WBC scans sometimes have decreased sensitivity, especially when infection is chronic.

SUBACUTE OSTEOMYELITIS (BRODIE ABSCESS)

A geographic osteolytic lesion with or without sclerosis and either intramedullary or intracortical in location is the hallmark of subacute osteomyelitis. If intramedullary, channel-like or serpiginous lucencies may be seen. The growth plate can be involved. Periosteal reaction and sequestra may be found. If epiphyses or epiphyseal equivalents are involved by a Brodie abscess, there can be confusion with chondroblastoma. Contrast-enhanced MRI can be useful in distinguishing between the two as the periphery of the lesion enhances in a

Brodie abscess, whereas there is heterogeneous enhancement of chondroblastoma.

CHRONIC OSTEOMYELITIS

Infections of more than 6 weeks duration can be labeled as chronic. Osteosclerosis caused by endosteal thickening, periosteal thickening, thickened intramedullary trabeculae, and cystic changes are common radiographic findings in chronic osteomyelitis. A sequestrum may be present. The most specific sign of active chronic osteomyelitis is a sequestrum, which is best imaged by CT. Other signs of active chronic infection at radiography would include ill-defined and new areas of osteolysis in addition to new areas of periosteal reaction. With CT and MR, findings of active chronic infection would include the presence of sequestrum, intramedullary abscess, cloaca formation, subperiosteal fluid collection, and sinus tract.

CONTIGUOUS SPREAD

When the soft tissues are the site for initial infection (cellulitis), infection that extends into bone is considered to be due to contiguous spread. This type of infection is more commonly seen in the debilitated and immunosuppressed patients, such as diabetic patients and those treated with steroids. The course of disease involves cellulitis followed by periostitis, then osteitis, and finally marrow extension indicating osteomyelitis. This “out to in” pattern of disease progression is opposite that of osteomyelitis because of hematogenous origin where the infection begins in the marrow and spreads in to out.

DIRECT IMPLANTATION

Direct implantation of infectious microorganisms can occur via multiple methods, such as iatrogenic during surgical procedures, open fractures, foreign bodies, or as the result of puncture wounds (dog/cat bites). Rose gardeners can inoculate *Sporothrix schenckii* with thorn punctures (much more prevalent in USMLE Step 1 examination questions than in reality). Human bites are polymicrobial sources of infectious organisms, while animal bites are commonly associated with *Pasteurella multocida*. Interestingly, approximately 5% of dog bites result in infection, whereas slightly less than half of cat bites may result in infection (another reason not to own a cat). Staphylococcal and streptococcal species are other common sources of infection because of animal bites, as many of these species are native skin flora.

The vast majority of cases of osteomyelitis are due to *S. aureus*. *Streptococcus*, *Haemophilus influenzae*, and gram-negative rods are other common pathogens. Several pathogens have increased prevalence in certain patient populations. For example, osteomyelitis secondary to salmonella is more common in patients with sickle cell compared with the background population. However, the overall incidence of *S. aureus* still accounts for the majority of osteomyelitis cases in patients with sickle cell. Pseudomonas is commonly associated with penetrating trauma and intravenous drug abuse. Fracture of the great toe distal phalanx with involvement of the physis is commonly associated with subsequent development of osteomyelitis.

SEPTIC ARTHRITIS

Etiologies for septic arthritis (joint infection) are hematogenous seeding, contiguous spread, or direct implantation of infectious organisms. Osteomyelitis with secondary involvement of the joint and iatrogenic implantation at the time of surgery represents examples of contiguous spread and direct implantation, respectively.

Monoarticular joint involvement represents the overwhelming majority of cases of septic arthritis (~80%). Monoarticular joint inflammation is infection until otherwise excluded. The organism responsible for septic arthritis beyond age 2 years is usually hematogenously seeded staphylococcal or streptococcal species. In the past, *H. influenzae* was one of the leading causes in children younger than 3 years; although it has become rarer in the United States after the implementation of vaccination in 1985. Septic arthritis is polyarticular in 20% of cases. The acromioclavicular, sternoclavicular, and sacroiliac (SI) joints and spine are common sites of infection in intravenous drug users. Atypical infectious etiologies such as tuberculosis and fungi may present more indolent with chronic joint space widening, although other inflammatory-related changes may be seen. The Pheemister triad in TB arthritis includes juxtaarticular osteopenia, peripheral bone erosions, and gradual joint space narrowing.

Pathologically, there is a synovial inflammatory response to the hematogenously seeded organism as evidenced by hyperemia and joint fluid production. Inflammatory-related deposition of fibrin is thought to prohibit cartilage nutrition and WBC release—damaging enzymes such as collagenase. There is pannus formation causing further distention of the joint. Untreated, cartilage and bone destruction ensues.

Radiographically, a septic joint manifests as any inflammatory arthritis may appear: soft-tissue swelling, periarticular osteopenia, uniform joint space narrowing, and bone erosions. Joint space widening may be the

initial finding that is due to joint effusion. In the infant or child hip, septic arthritis is a surgical emergency and the only sign may be a widened hip joint at radiography. An effusion may be seen with ultrasound. The complications of septic arthritis are related to the extent of involvement of the initial infection. Osteonecrosis, slipped epiphysis, growth disturbance, osteomyelitis, and secondary osteoarthritis may result from septic arthritis. Tendon and capsule injury in addition to synovial cyst formation may be found.

CELLULITIS AND OTHER SOFT-TISSUE INFECTIONS

CELLULITIS

Infections involving the soft tissues include cellulitis, septic bursitis, septic tenosynovitis, infectious myositis, and necrotizing fasciitis.

Cellulitis represents acute infection of the subcutaneous fat and dermis associated with pain, erythema, and edema. Cellulitis typically occurs after skin breakdown or a focus of injury allows skin flora or exogenous bacteria to infiltrate into the subcutaneous tissues. Those with peripheral vascular disease, diabetes mellitus, and immunosuppression are at particularly increased risk. Streptococcal and staphylococcal species are common organisms as is *H. influenzae*. The majority of cases of cellulitis are clinical diagnoses, with few cases requiring imaging limited to those who are at high risk of developing more complicated cellulitis, such as those who are immunosuppressed, diabetic and alcoholic patients. Imaging is utilized to assess for inflammatory changes and abscess formation. Uncomplicated cellulitis may mimic anasarca as in heart failure.

SEPTIC BURSITIS/TENOSYNOVITIS

Septic bursitis and septic tenosynovitis are usually the result of direct implantation of infectious organisms as can be seen in penetrating trauma. TB is an alternative consideration. The presence of infectious bursitis or tenosynovitis cannot be distinguished by imaging features from other inflammatory conditions.

PYOMYOSITIS

Infectious myositis (pyomyositis) is infection of muscle and is fortunately very rare, but is now more common in North America because of HIV. Penetrating trauma and hematogenous seeding in intravenous drug users and the

immunocompromised patients account for the majority of cases. Although viruses, fungi, and parasites are sources of infection, bacteria represent the overwhelming majority of cases and most are due to *Staphylococcus* (~75%). Risk factors for development of pyomyositis include HIV/AIDS, strenuous activity, muscle trauma, and rhabdomyolysis. Other risk factors include contiguous spread of skin infections, direct implantation as in intravenous drug use and insect bites, and immunocompromised states like diabetes mellitus. Pyomyositis is more common in the quadriceps muscle, followed by gluteal and iliopsoas muscles, and less common in the upper extremities. Findings can be subtle, and a high degree of suspicion is required, especially in the immunocompromised.

There are three stages of pyomyositis: invasive phase, suppurative phase, and late stage. The invasive stage is characterized by muscle edema and pain while the suppurative phase represents further progression with fever and later abscess formation followed by the late stage indicating sepsis/toxicity, which is potentially life threatening. Findings may include multifocality in approximately 50% of cases, inflammatory muscle expansion, and inflammatory enlargement of intermuscular fascia. Air/gas in muscle tissue is always abnormal and can be due to gas-forming organisms.

Drainage of an abscess and appropriate antibiotic coverage usually leads to complete recovery, although scarring and dysfunction can occur. Untreated cases may evolve into a compartment syndrome or progress onward to septic arthritis and/or osteomyelitis, and if ultimately untreated can lead to death.

NECROTIZING FASCIITIS

Necrotizing fasciitis represents infection and necrosis involving the fascia. Typically, cellulitis (infection of subcutaneous tissues) can progress to involve the fascia where the infectious process can then become rapidly progressive and is associated with a high mortality rate (less than 70%). The incidence of necrotizing fasciitis, although rare, is increasing because of the increase in the numbers of immunocompromised patients, such as those with HIV, diabetes mellitus, cancer, transplants, and alcoholism. Necrotizing fasciitis is a surgical emergency as infection can rapidly spread along fascial planes. Surgical treatment of the necrotizing variety includes fasciotomy and debridement in addition to antibiotics.

Common locations include the perineum, extremities, neck, and face. If the scrotum or penis is involved, it is termed Fournier gangrene. Etiologies for Fournier gangrene include recent genitourinary manipulation, surgery, or trauma, and it is associated with immunocompromised states.

Imaging findings are generally more severe than cellulitis and include skin thickening, sometimes subcutaneous edema/gas, inflammatory fascial thickening, and potentially fluid collections. CT and MR can be used to distinguish cellulitis from necrotizing fasciitis. Lack of enhancement of fascia represents the necrotizing form. Nonnecrotizing fasciitis demonstrates enhancement of inflamed fascia. A sonographic hallmark of Fournier gangrene is subcutaneous gas.

INFECTION OF THE SPINE

Infection of the spine is usually because of hematogenous dissemination of infectious organisms, and the sequence of spine infection is different in adults and children. The adult pattern is characterized by hematogenous seeding of the marrow adjacent to the endplate of the vertebral body (osteomyelitis) followed by rapid spread to the adjacent vertebral disc. Infection spreads sequentially to the next vertebral body. Infection of disc is termed discitis, and when both the bone and the disc are infected it is termed spondylodiscitis. The childhood pattern is characterized by initial seeding of the disc because of the relatively high vascularity of the disc with spread into bone secondarily.

Given the importance of making a diagnosis quickly, MR is the modality of choice for imaging spine infection. At radiography, endplate destruction and loss of disc height may be seen. MR is aptly suited to demonstrate the bone marrow and disc involvement as well as complications related to paraspinal abscess formation and epidural abscess formation. At MR, acute osteomyelitis appears as bone marrow edema, so it is low on T1-weighted images, usually high on T2-weighted images, and will enhance on postcontrast T1 images. Involvement of the disc is usually characterized by high signal on T2-weighted images, and contrast enhancement is variable on postcontrast T1 images.

Paraspinal abscess formation appears as fluid collections typically do—low T1, high T2, and rim-enhancing mass/fluid collection on postcontrast T1 images. The majority of cases of epidural abscess are due to spondylodiscitis and contiguous spread of infection rather than seeding from another site. The earliest stage of contiguous spread may appear as a phlegmon that can progress to abscess.

MISCELLANEOUS AND RARE INFECTIONS

Foot infection is a common source of morbidity in those with diabetes and is usually the result of infection secondary to soft-tissue injury, followed by cellulitis, and

can progress via contiguous spread to osteomyelitis. The presence of microvascular disease and neuropathy create the favorable environment for the development of diabetic foot infection. Pressure points, particularly the plantar surface of the first and fifth metatarsal heads, calcaneal tuberosity, distal toe phalanges, and medial and lateral malleoli, are common sites of infection. Joint effusion, soft-tissue edema, bone marrow edema, and periosteal reaction can be seen in both the neuropathic joint and the diabetic foot infection with osteomyelitis. Therefore, it is helpful to look for other features suggestive of infection such as cortical destruction, sequestrum, and intraosseous abscess in addition to the location to guide the diagnosis of diabetic foot infections. Neuroarthropathy/neuropathy always occurs at the joint, and discriminating features include destruction or fragmentation of bone, joint debris, and dislocation.

Patients with HIV/AIDS are immunosuppressed and are susceptible to common infectious organisms as well as atypical bacterial and fungal infections. As has been previously noted, immunosuppressed patients are at risk for osteomyelitis, septic arthritis, and infectious myositis. Patients with AIDS are susceptible to a rare systemic disease termed bacillary angiomatosis, which can result in osteomyelitis. The causative organisms have been isolated to two gram-negative bacteria, either *Bartonella henselae* or *Bartonella quintana*. This systemic disease results in disseminated nodules including subcutaneous nodules, and multiple osteolytic bone lesions can be seen involving the intramedullary cavity and/or cortex and possibly associated with a soft-tissue mass. Common sites of involvement are the long bones.

Chronic recurrent multifocal osteomyelitis is a form of chronic osteomyelitis, which usually affects children and adolescents, and is associated with SAPHO syndrome because of the common presentation with palmoplantar pustulosis (~40%), but is not necessary for the diagnosis. SAPHO syndrome is characterized by synovitis, acne, pustulosis, hyperostosis, and osteitis. Typical presentations of chronic recurrent multifocal osteomyelitis include symmetric involvement, mixed lytic and sclerotic appearance, and involvement of the metaphyses of the lower extremity and medial clavicle. Bone cultures are often sterile in this disease process, as no definite infectious organism can confidently be attributed to this process. Bone samples often demonstrate plasma cell predominance, and this entity has become known as a “plasma cell osteomyelitis.” Chronic recurrent multifocal osteomyelitis is usually a diagnosis of exclusion.

Chronic granulomatous disease of childhood is another disease characterized by chronic osteomyelitis. Chronic granulomatous disease is a rare X-linked recessive disorder affecting neutrophils leading to susceptibility to catalase-positive organisms (*Staphylococcus*, *Nocardia*, TB).

TB of the musculoskeletal system is increasing in incidence because of the increasing immunocompromised patient population. One to three percent of patients with TB will have musculoskeletal system involvement. If the musculoskeletal system is involved, the majority of cases involve the spine with infection of the digits, joints, bursae, and tendon sheaths, all less common sites of involvement. TB spondylodiscitis is hematogenous in origin via Batson plexus, with L1 being the most frequent site of occurrence usually with more than one vertebral body level affected in a contiguous manner. The infection seeds the subchondral bone plate and is characterized by a slow process resulting in vertebral body destruction and later disc destruction. Paraspinal abscess is commonly associated with this process and the degree of abscess formation with relative sparing of the vertebral body and disc space in comparison with typical bacterial spondylodiscitis makes one think of TB as the etiology. Anterior endplate destruction, especially in the thoracic spine, results in the gibbus deformity.

TB osteomyelitis is rare but can affect any bone, usually at the epiphysis. TB is a less common cause of dactylitis and has a spike-like and puffed full-of-air appearance termed spina ventosa. If TB infects a joint, a monoarticular infection involving a large joint may be seen; it is a slow process/infection because of the lack of proteases. The cartilage is usually spared in TB arthritis, although over time granulation tissue leads to cartilaginous erosion. The Phemister triad appears as juxtaarticular osteopenia, slow joint space loss, and peripheral erosions. A nodular synovial thickening can be seen with joint effusion at MRI.

Leprosy represents the manifestation of infection because of *Mycobacterium leprae* and occurs in the United States (rarely), Africa, South America, and Asia. Infection occurs through the skin and mucous membranes, and there is a long incubation period between 3 and 6 years. Lepromatous leprosy is the more severe and generalized infection due in large part to higher quantities of bacilli, while tuberculoid leprosy has less bacilli, more reaction, and skin and nerve involvement. The dimorphous form features characteristics of both lepromatous and tuberculoid types. Indeterminate leprosy is another form of the disease. A specific sign related to leprosy is a lacelike osseous destructive process involving the phalanges (hands/feet) and nasal bone. Periosteal reaction and bone fragmentation as well as arthritis may be seen. An appearance termed “licked candy stick” has been associated with this disease process because of fracture, bone erosion, and bone remodeling.

Brucellosis is a rare infection that occurs in the United States caused by *Brucella* species, and can involve the spine and joints. Infection with *Brucella* species is rare in the United States because of pasteurization of milk

products as most infections caused by this species occur between livestock/animals, such as cows, goats, and sheep. Infection occurs principally by ingesting contaminated milk or meat sources without adequate preparation. The musculoskeletal system is often the target because of the predilection for marrow involvement (reticuloendothelial system). A septic arthritis can occur with predilection for the knee and shoulder as well as SI joints. Most focal spinal infections that are due to brucellosis occur in the lumbar spine, particularly the L4 vertebral body. The focal form of infection results in a parrot beak osteophyte of the superior anterior endplate and also sclerotic endplate and disc gas. The diffuse form represents severe infection that can mimic osteoarthritis. It is a slow process that is usually characterized by vertebral body height preservation and less tendency to form a paravertebral abscess or epidural abscess. Disc gas can occur and is thought to represent the smoldering progression of the osteomyelitis.

Actinomyces israelii is normal flora in the oral cavity and can also be introduced into other sites of the body because of trauma. Actinomyces infection is known to form sinus tracts and abscesses with common sites of involvement including the mandible, ribs, spine, and pelvis.

Fungal infections involving the musculoskeletal system can be seen in the immunocompromised host. Aspergillosis, blastomycosis, candidiasis, cryptococcosis, histoplasmosis, mucormycosis, and sporotrichosis represent the majority of the fungal infections affecting the musculoskeletal system. Fungal infection is characterized by large lytic and punched-out lesions, often multifocal, and with or without surrounding sclerosis. Blastomycosis is endemic in the Ohio River basin and infection can occur because of inhalation or skin entry from the soil. Coccidioidomycosis is infectious via inhalation, and the organism is endemic in the soil of southwestern parts of the United States and Mexico and can cause bone and joint involvement including a migratory arthritis. Cryptococcosis is another inhaled organism with rare features of musculoskeletal involvement.

Histoplasmosis is the most common fungal organism infection in the United States, is endemic throughout the soil, and infection is spread via inhalation. If musculoskeletal changes are seen, more common sites of involvement include the pelvis, skull, ribs, and small bones. Arthritis can occur with histoplasmosis infection.

Zygomycosis (mucormycosis) infections are encountered mainly in the immunocompromised, burn and uremic patients, and especially those with diabetes, potentially resulting in the feared complication of rhino-orbital-cerebral infection. Mucormycosis is probably the most familiar term but deadly human infection is not limited simply to the *Mucor* family. Other genera include

Rhizopus and *Cunninghamella*. Zygomycetes are a group of fungi that are spore forming and infection typically begins via inhalation with contamination of the nares and sinuses with subsequent tissue invasion. Hyperglycemia and ketoacidosis create the favorable environment for infection. A state of iron overload also fosters growth. Rhino-orbital-cerebral infection results when there is contiguous spread of infection from the sinuses to the soft tissues of the orbit and potentially the brain. It is an angioinvasive fungal infection that can rapidly spread leaving infarcted tissue behind characterized as black eschar. High morbidity/mortality is associated with the disease process.

Sporotrichosis is due to the saprophyte *S. schenckii* and inoculation can occur because of a skin wound (e.g., a rose's thorn) or via inhalation. Disseminated sporotrichosis is highly associated with musculoskeletal changes (~80%) including arthritis and osteomyelitis. The arthritis is typically monoarticular involving the knee or wrist, and osteomyelitis is usually secondary to the arthritis.

Parasitic infections are usually characterized by soft-tissue calcification or other soft-tissue involvement. For example, filariasis results in lymphatic obstruction and elephantiasis. Cysticercosis appears as a linear or oval rice grain of calcification parallel to the long axis of the muscle. *Loa loa* affects the soft tissues with lacelike subcutaneous soft-tissue calcifications. Echinococcal infection usually spares bone but a multiloculated cystic soft-tissue mass may be encountered.

Congenital infections, as in TORCH infections, typically result in metaphyseal lucent bands. Congenital syphilis manifests initially as osteochondritis (metaphyseal lucent bands) and/or osteomyelitis. Proliferative periosteal reaction is most common finding and at the tibia is known as "saber shin." Osteomyelitis is not common with congenital infection. If osteomyelitis occurs, nasal bone involvement can lead to a saddle nose deformity. The majority of cases are not discovered until beyond 10 years. The Hutchinson triad may be encountered characterized by Hutchinson teeth, interstitial keratitis, and sensorineural deafness. Later changes include osteomyelitis and osteitis as well as gumma formation because of caseous bone necrosis.

Lyme disease is the result of infection with *Borrelia burgdorferi* via a tick-borne vector (*Ixodes dammini*) and occurs in endemic areas in the United States (northeast). Skin lesions and joint symptoms are common sequelae. Joint involvement typically involves the knee, though no joint may necessarily be spared. Mono/oligo/polyarticular forms can occur. Soft-tissue swelling and effusion may be seen in MRI with a relative lack of subcutaneous edema. Chronic changes include erosions, joint space loss, and osteopenia.

QUESTIONS AND ANSWERS

- Which of the following is the most common association with fracture of the great toe distal phalanx with physeal involvement?

A. Septic arthritis
B. Early degenerative change
C. Growth arrest
D. Osteomyelitis

ANSWER: D. Occult open fractures can occur after stubbing the great toe because of the proximity of the nail to bone at this location. Although disruption of the growth plate from a fracture can lead to secondary growth arrest and articular incongruity, the best answer is direct implantation of infectious microorganisms leading to osteomyelitis in this location.

- Which of the following is the most likely pathogen in a patient with sickle cell disease and osteomyelitis?

A. *Salmonella* species
B. *Streptococcus* species
C. *Actinomyces* species
D. *Staphylococcus aureus*

ANSWER: D. Although infection with encapsulated organisms like salmonella is indeed much more common in patients with sickle cell disease when compared to other patients, the most common microbial etiology for osteomyelitis in this patient population remains *S. aureus*.

- The presence of gas in which of the following spaces in the absence of trauma implies infection?

A. Disc
B. Intramuscular

- C. SI joint space
- D. Symphysis pubis

ANSWER: B. The vacuum phenomenon appears as a radiolucent area visible in synovial joints, intervertebral discs, and vertebrae. This phenomenon is explained by temporary gas accumulation, mostly nitrogen, related to the negative pressures that can be generated by distraction of the articular surfaces. So the remaining choices are incorrect. Intramuscular gas is not generated by vacuum and is usually due to percutaneous introduction (trauma) or gas-producing organisms.

4. Infection of which anatomic location is more prevalent in intravenous drug users when compared to the general population?
 - A. Acromioclavicular, sternoclavicular, and SI joints, and spine
 - B. Symphysis pubis, facet joints, and short bones of the hand and feet
 - C. Sternomanubrial, humeroulnar, capitellotriquetral, and humeroglenoid joints
 - D. Hip, knee, and shoulders

ANSWER: A. Although the knee is the most common joint involved by infection (greater than 50% in many series), intravenous drug users patients have a predilection for axial joint infection.

5. Which of the following is the hallmark sonographic feature of Fournier gangrene?
 - A. Soft-tissue swelling
 - B. Posterior acoustic enhancement
 - C. Subcutaneous emphysema
 - D. Engorgement of vessels of the pampiniform plexus

ANSWER: C. Ultrasound can help in the early diagnosis of Fournier gangrene by differentiating it from scrotal cellulitis. Soft-tissue swelling would not be specific as it is also identified in cellulitis. Identification of subcutaneous gas with discrete foci of posterior acoustic shadowing is diagnostic of Fournier gangrene.

6. All of the below are associated with an increased incidence of cellulitis, pyomyositis, and necrotizing fasciitis *except*
 - A. HIV
 - B. Diabetes mellitus
 - C. Alcoholism
 - D. Recent organ transplant
 - E. Tobacco abuse

ANSWER: E. All other choices are all examples of immunocompromised hosts who are at higher risk for soft-tissue infections of the musculoskeleton.

Although tobacco abuse can lead to COPD which when treated with chronic corticosteroid use may increase infection susceptibility, it has not been associated with soft-tissue infections in the nonimmunocompromised host.

7. Spondylodiscitis appears different in the child compared to the adult because
 - A. Infection in the child usually begins at the vertebral endplate with direct extension into the disc space via contiguous spread of infection.
 - B. Infection in the child usually begins at the disc space because of hematogenous seeding of the well-vascularized disc with subsequent contiguous spread to adjacent vertebral bodies.
 - C. Paraspinal abscess formation is a prerequisite to vertebral body and disc infection in the child as opposed to the adult.
 - D. Different pathogens are responsible for the infectious process in the child and the adult.

ANSWER: B. Infection of the spine is usually because of hematogenous dissemination of infectious organisms, with *S. aureus* being the most common pathogen for both child and adult. So, choice D is incorrect. The adult pattern is characterized by hematogenous seeding of the marrow adjacent to the endplate of the vertebral body followed by rapid spread to the adjacent vertebral disc. Choice A is thus incorrect for the child. The childhood pattern is characterized by initial seeding of the disc because of the relatively high vascularity of the disc with spread into bone secondarily. So, choice B is the best choice. Paraspinal abscesses are usually secondary to vertebral infection. So choice C is incorrect.

8. Chronic recurrent multifocal osteomyelitis is characterized by all of the following *except*
 - A. Bone specimen demonstrates the majority of cells as plasma cells.
 - B. More common in adolescents and children and is a diagnosis of exclusion.
 - C. Almost always associated with SAPHO syndrome, a prerequisite for the diagnosis.
 - D. Typical presentations include symmetric involvement, a mixed lytic and sclerotic appearance, and involvement of the metaphyses of the lower extremity and medial clavicle.

ANSWER: C. Chronic recurrent multifocal osteomyelitis usually affects children and adolescents. Bone samples often demonstrate a plasma cell predominance. Typical presentations include symmetric involvement, mixed lytic and sclerotic appearance, and involvement of the metaphyses of the lower extremity and medial clavicle. Although it can be

associated with SAPHO syndrome due to the common presentation with palmoplantar pustulosis (~40%), this is not necessary for the diagnosis.

9. Why is septic arthritis/osteomyelitis in the hip of an infant or child a radiological emergency?
 - A. Joint destruction rapidly occurs because of the presence of proteases including collagenase, which leads to cartilage loss and joint space destruction.
 - B. Pyomyositis and/or cellulitis may occur if untreated.
 - C. It is highly associated with left ventricular–infected thrombus and signals the possibility of septic emboli.
 - D. Femoral head is likely to fracture in the first 24–48 hours of infection if the patient is not made non–weight bearing.

ANSWER: A. Joint destruction can occur rapidly due to the release of proteases during the inflammatory response. Pyomyositis is typically not seen after septic arthritis. Although microbial hematogenous dissemination is a common pathway for septic arthritis, it is not highly associated with left ventricular thrombi. Pathologic fracture is a rare complication of bone infection in children.

10. The Phemister triad, which includes juxtaarticular osteopenia, slow joint space loss, and peripheral erosions, is seen with which of the following etiologies?
 - A. TORCH infection
 - B. Loa loa
 - C. Tuberculosis
 - D. *Staphylococcus aureus*

ANSWER: C. The Phemister triad has been classically associated with mycobacterial infection. TORCH infections typically result in metaphyseal lucent bands. Loa loa is a parasitic infection usually of soft tissues and does not involve intraarticular structures. *Staphylococcus aureus* is a virulent organism associated with more rapid joint destruction.

11. Infection by a fungus from the *Zygomycetes* family, associated with the dreaded rhino-orbital-cerebral infection, occurs with which of the following?
 - A. Ketoacidosis and/or hyperglycemia, and iron overload
 - B. Hypoglycemia and copper deficiency
 - C. Hemodynamically significant bilateral common carotid stenoses
 - D. Hospital-acquired pneumonia

ANSWER: A. *Zygomycetes* are a group of fungi that are spore forming, and infection typically begins via

inhalation with contamination of the nares and sinuses with subsequent tissue invasion. Rhino-orbital-cerebral infection results when there is contiguous spread of infection from the sinuses to the soft tissues of the orbit and potentially the brain. Hyperglycemia and ketoacidosis create the favorable environment for infection. A state of iron overload also fosters growth.

72 BONE TUMORS AND TUMORLIKE CONDITIONS

*Matthew C. Larrison and
Gregory S. Elliott*

INTRODUCTION

Differential diagnosis of bone tumors is best determined by conventional radiographs. MRI occasionally will aid in specificity but most often is useful for evaluating extent of disease, staging prior to treatment, and follow-up. The approach to bone tumors is based on evaluating several key factors which will help one to decide if a lesion is aggressive or nonaggressive in appearance and to help narrow the differential diagnosis. These key factors include type of matrix (cartilage, osteoid), zone of transition, presence or absence of soft-tissue mass, location in bone (cortical, medullary, juxtacortical; epiphyseal, metaphyseal, diaphyseal), and the bone involved. The age of the patient is also very important in narrowing the list of diagnostic possibilities.

OSTEOID LESIONS (Table 72-1)

GENERAL

Osteoid lesions demonstrate osseous internal content of varying degrees of maturity. The benign lesions usually contain mature bone elements while the more aggressive lesions contain less mature elements. The radiographic appearance of osteoid matrix is described as fluffy or cloudlike. As with all aggressive or malignant bone lesions, the well-defined lesion will typically have a more favorable biological behavior.

BONE ISLAND (ENOSTOSIS)

Bone islands are a typically incidental finding and are asymptomatic. They are intramedullary in location. The

clinical importance of these lesions is the potential to be confused with sclerotic metastasis or low-grade intramedullary osteosarcoma. Radiographic findings include a densely sclerotic intramedullary lesion, round in shape often with spiculated margins with no or minimally increased activity on bone scan. A giant bone island is defined as greater than 2 to 3 cm in size and is most often found in the pelvis.

OSTEOMA

An osteoma is a benign tumor most often found in the cranium and sinuses. The presence of symptoms depends on size and location but can potentially cause headache or sinus disease. Exophytic lesions arise from the surface of bone/cortex. Osteomas can be associated with Gardner syndrome (Familial polyposis syndrome, also associated with desmoid tumors, and skin lesions). Radiographic findings include a well-defined sclerotic lesion arising from the surface of bone.

OSTEOID OSTEOMA

These lesions typically occur in young male patients (10–25 years of age). The classic history is that of night pain relieved with aspirin. Ten percent occur in the spine and present with “painful scoliosis.” The vast majority of spine osteoid osteomas are in the posterior elements. The most common location is in the diaphyses of long bones with over 50% found in the femur or tibia. Seventy-five percent are cortical and remainder are cancellous in location. The radiographic findings include a cortical lesion with central radiolucent “nidus” surrounded by dense, solid periosteal bone formation. The intra-articular or cancellous lesions often do not have same degree of surrounding sclerosis. MR appearance may be misleading because of degree of bone marrow edema

OSTEOBLASTOMA

This rare tumor occurs in the posterior elements of the spine in 40% of the cases. It occurs in a similar age group as osteoid osteoma (10–30 years of age). Pain is the most common presentation but not as common or severe as with osteoid osteoma. Osteoblastoma can occur in association with aneurysmal bone cyst (ABC) (chondroblastoma are also associated with ABC). Radiographic findings include a lytic lesion with expansion, cortical thinning, or mild destruction. In the posterior elements of the spine, it appears as an expansile mass

greater than in diameter 1.5 cm with associated soft-tissue mass. Osteoblastoma should be included in the differential diagnosis of expansile mass in the spine with any type of matrix.

OSTEOSARCOMA

This lesion is very common, second only to multiple myeloma as the most common primary bone tumor. It can occur as a primary lesion (75%) or secondary to a known precursor, most commonly is Paget disease followed by radiation and osteonecrosis. Primary osteosarcoma is classified as intramedullary (75%) and juxtacortical (approximately 10%) of cases. Rarer classifications include low-grade sclerosing, multifocal, and intracortical. Primary osteosarcoma occurs in younger patients, most commonly in the metaphyses of long bones. The majority produce extensive bony matrix as most are of the osteoblastic type and less than 10% exhibit the fibroblastic histologic pattern. Less common histologic patterns include chondroblastic and telangiectatic.

The radiographic findings depend on the histologic pattern, classification, and whether the lesion is primary or secondary. The classic, primary intramedullary osteosarcoma in children exhibits a dense osteoid matrix (also described as cloudlike) and aggressive periosteal reaction (described as “sunburst,” “hair-on-end,” “Codman triangle”). The majority of these lesions cross the epiphyseal plate. Juxtacortical osteosarcomas have a distinctive appearance and are divided into categories. The two most common in order are:

- Parosteal osteosarcoma: low-grade tumor arising from outer periosteum. Classic location is posterior distal femoral metaphysis.
- Periosteal osteosarcoma: origin is inner layer of periosteum. Broad-based diaphyseal lesion with 85% in femur or tibia. Usually, chondroblastic histology and appear as cortical thickening with erosions and aggressive periosteal reaction that rarely extends into the medullary cavity.

Telangiectatic osteosarcoma is a rare subtype but exhibits a unique appearance when compared with other osteosarcomas. These are expansile lesions, which contain cavities with blood products and necrosis. They can be confused with ABC on radiographs. Similarly, telangiectatic osteosarcomas and ABC both exhibit fluid/fluid levels on MRI. When evaluating osteosarcoma, be sure to evaluate the entire bone, for “skip metastases” or lesions in the same bone separated by normal intervening marrow.

TABLE 72-1 Osteoid Tumors

BENIGN	MALIGNANT
Enostosis: Bone island	Osteosarcoma: Young patients
Osteoma: Cranium, sinuses; Gardner syndrome	Parosteal osteosarcoma: Arises from outer layer of periosteum; posterior femoral metaphysis
Osteoid: Young males; night pain; relieved by aspirin	Periosteal osteosarcoma: Arises from inner layer of periosteum; femur and tibia diaphysis
Osteoblastoma: Young patients; spine; associated with ABC	Telangiectatic osteosarcoma: Multiple cavities; skip metastases

CHONDROID LESIONS (Table 72-2)

GENERAL

Chondroid lesions contain cartilaginous internal elements. The matrix may or may not be calcified. Those lesions that become calcified are described as having a punctuate, flocculent, or arclike pattern of mineralization.

OSTEOCHONDROMA

Osteochondroma occurs in young patients and symptoms are typically related to mass effect, bursa formation, or potential cosmetic effect. They are the only benign skeletal tumor associated with radiation. Osteochondromas have a rare potential of malignant transformation (less than 1% for solitary lesions). The width of the cartilage cap can be measured on MR and is a predictor of malignant transformation to chondrosarcoma. A cap greater than 1.5 cm in a skeletally mature individual is concerning for a malignant lesion. Pain within a previously painless osteochondroma is also ominous.

Hereditary multiple exostosis is an autosomal dominant condition in which patients have multiple osteochondromas (exostosis). This polyostotic variant presents earlier and lesions are said to exhibit a greater incidence of malignant transformation than do solitary osteochondromas. Lesions have a propensity for one side of the body. The femora and tibia are often involved in a characteristic pattern.

Trevor disease is a condition in which osteochondromas develop in an epiphyses causing significant joint deformity. For this reason, these are often treated more aggressively (this is most common in the ankle and knee). Radiographic findings include cortical and medullary continuity. The bone marrow flows freely into the lesion. In long bones, the lesion is metaphyseal and points away from the closest joint. They can be sessile or pedunculated. Look for the cartilage cap with calcification.

ENCHONDROMA

An enchondroma is a rest of hyaline cartilage within cancellous bone. They exhibit lobular growth, producing remodeling and cortical thinning. Common locations include the hands, in particular, the metacarpals. Multiple enchondromatosis is a nonhereditary condition in which polyostotic disease is present. These exhibit increased risk of malignant transformation to chondrosarcomas. Ollier disease is the more common form and presents with varying degrees of severity in childhood. Maffucci syndrome is very rare and is best differentiated from Ollier disease by the presence of multiple soft-tissue cavernous hemangiomas (look for phleboliths on radiographs.) Maffucci syndrome has the added risk of development of other malignancies such as ovarian cancer and glioma.

Imaging findings include incidentally noted, well-marginated, central metaphyseal lesion with chondroid matrix (rings and arcs). Cortical scalloping can suggest a more aggressive process such as developing chondrosarcoma. Typical metaphyseal lesion can mimic bone infarct on radiographs. In the hands, an enchondroma is often expansile and calcified chondroid matrix may be absent or difficult to appreciate. Look for T2 hyperintense lesion with a stippled pattern on MR because of the presence of hyaline cartilage.

JUXTACORTICAL CHONDROMA

This tumor arises just beneath the periosteum in the metaphyses. At least half are found in the humerus, usually in a patient younger than 30 years of age. It can be difficult to differentiate by imaging from juxtacortical chondrosarcoma. Radiographic findings include juxtacortical chondroid mass with cortical erosions, giving a characteristic “saucerization” pattern or long, smooth arc within the metaphysis, occasionally with adjacent sclerosis or periosteal reaction. The soft-tissue mass does not reliably contain chondroid calcification.

CHONDROBLASTOMA

Chondroblastoma is an epiphyseal lesion of children or young adults. At least half will extend into the metaphyses. It is considered an epiphyseal lesion, but do not forget the apophyses (epiphyseal equivalents) such as the greater trochanter can be involved. A small portion (approximately 10%) will be associated with ABC (similar to osteoblastoma). Most common differential diagnosis in a child is infection and Brodie abscess. Radiographic findings include a well-marginated epiphyseal

TABLE 72-2 Chondroid Lesions

BENIGN	MALIGNANT
Osteochondroma: Young patients; hereditary multiple exostosis; Trevor disease	Chondrosarcoma: Primary or secondary (Paget disease, radiation, malignant degenerative of enchondroma or osteochondroma)
Enchondroma: Metacarpals	
Ollier syndrome: Polyostotic; increases risk for chondrosarcoma	
Maffucci syndrome: Polyostotic with hemangioma; risk of other cancers (ovarian, glioma)	
Juxtacortical chondroma	
Chondroblastoma: Children; young adults; epiphyseal	

lesion, often centrally located. Presence of chondroid matrix is not reliable. This is the only cartilage lesion that is not primarily hyaline cartilage and therefore can be intermediate or even dark in signal intensity on T2-weighted images. MR also reveals abundant surrounding edema such as that seen with osteoid osteoma. Fluid/fluid levels on MR suggest an association with ABC.

CHONDROSARCOMA

Chondrosarcoma is a malignant cartilaginous tumor occurring in patients aged 40 to 45 years. Over 50% occur in the femur or pelvis. As seen with osteosarcoma and can be primary or secondary. In addition to Paget disease and radiation, malignant degeneration of enchondroma or osteochondroma can produce a chondrosarcoma. Low-grade chondrosarcoma can be pathologically and radiographically difficult if not impossible to differentiate from enchondroma. Pain suggests chondrosarcoma rather than a benign lesion.

Radiographic findings dependant a great deal on whether the tumor is primary or secondary, the location, and the type (Table 72-3).

1. Intramedullary chondrosarcoma (the most common type) is mixed lytic and sclerotic tumor with chondroid matrix (rings and arcs). Attempts to differentiate from enchondroma are made by assessing the presence of aggressive features such as cortical

scalloping (greater than two-thirds of the normal cortical thickness), expansion, and degree of permeative change.

2. Juxtacortical chondrosarcoma exhibits similar appearance to juxtacortical chondroma but is typically larger (greater than 3–4 cm).
3. Clear cell chondrosarcoma makes up only 2% of chondrosarcomas. These unique lesions are usually epiphyseal and can mimic benign lesions. They contain enough cartilage to remain very bright on T2-weighted imaging (as opposed to other common epiphyseal lesions, such as giant cell tumor and chondroblastoma)

FIBROUS LESIONS (Table 72-4)

FIBROUS CORTICAL DEFECT/ NONOSSIFYING FIBROMA

This is a benign, self-limited, very common pediatric lesion. Over 80% are within the tibia or femur. The term fibrous cortical defect is used when the lesion is small (1–2 cm) and confined to the cortex. Nonossifying fibroma (NOF) extend into the medullary canal. They are clinically silent with the exception of large lesions, which have the potential to pathologically fracture. They can “heal” with sclerosis and then disappear. A healed or sclerotic NOF is termed an ossified NOF. Radiographic findings include a lucent lesion within the cortex of the metaphysis, often with a rim of sclerosis. It can be mildly expansile, but there is no associated soft-tissue mass or aggressive periosteal reaction.

FIBROUS DYSPLASIA

Fibrous dysplasia is a benign developmental anomaly where fibrous tissue and spindle cells replace normal medullary bone. It occurs in children and young adults and can be monostotic or polyostotic. The polyostotic form can be associated with McCune-Albright syndrome (precocious puberty in girls, café au lait skin spots) and endocrine abnormalities (diabetes, hyperthyroidism, and hyperparathyroidism). Polyostotic disease usually presents prior to age 10. Cherubism describes an inherited variant with symmetric involvement of the mandible and maxilla. Monostotic lesions are smaller and usually asymptomatic. Common locations include femur, tibia, calvarium/facial bones, and ribs. A very small fraction are said to undergo malignant degeneration, most commonly to osteosarcoma. The radiographic appearance is varied. “Long lesion in a long bone,” an often-stated quote, explains the most common

TABLE 72-3 Classification of Primary Chondrosarcomas

Intramedullary (most common)
Juxtacortical
Clear cell
Mesenchymal

location and propensity to extend a long segment of the diaphyses. “Ground glass,” is a buzzword to describe the matrix of fibrous dysplasia. Ground glass appearance describes etched glass. Monostotic lesions are typically well marginated with sclerotic borders, often with mild expansion and cortical remodeling. Polyostotic disease yields more significant deformity causing leg-length discrepancies and fractures. “Shepard crook” deformity describes the angled deformity of the proximal femur. In the facial bones, they appear as smooth osseous expansion with typical ground-glass appearance. Frequency of sinus involvement is sphenoid, frontal, maxillary, and ethmoid sinuses in decreasing order. Leontiasis ossea describes “lionlike” faces in patients with extensive facial/cranial bone involvement.

OSTEOFIBROUS DYSPLASIA

This rare pediatric lesion typically occurs in the tibia and/or the fibula. Progression to bowing and fracture is not uncommon. Radiographic appearance includes an elongated, mixed lytic and sclerotic lesion, most commonly in the anterior cortex of the midtibial diaphyses. If large enough, intramedullary extension and cortical remodeling can occur.

ADAMANTINOMA

It is a rare tumor, which is similar in appearance and location to osteofibrous dysplasia. The best discriminator between the two is perhaps age, as adamantinoma occurs in those older than 25 years and osteofibrous dysplasia is rare after the teenage years. This lesion presents with pain and is considered a low-grade malignancy. Radiographic appearance is that of a mixed lytic and sclerotic lesion in the anterior tibial cortex often with expansion and cortical thickening. Often associated with soft-tissue mass.

FIBROMATOSIS: EXTRAABDOMINAL DESMOID

This asymptomatic soft-tissue mass in third to fourth decade, most commonly occurs around the shoulders. It often begins in intermuscular fascia. Treatment is difficult as recurrence is common. Radiographic appearance includes an infiltrative soft-tissue mass that is locally aggressive. MR appearance demonstrates a low T1/T2 signal mass, which enhances homogeneously. There is typically no calcification or bone involvement. The extent of tumor infiltration and neurovascular involvement is best evaluated with MRI.

TABLE 72-4 Fibrous Lesions

BENIGN	MALIGNANT
Fibrous cortical defect: Limited to cortex; common; small; tibia, femur	Malignant fibrous histiocytoma: Older patient; most common soft-tissue sarcoma in adults; primary or secondary (Paget disease, infarct, radiation therapy)
Nonossifying fibroma: Extend to medullary canal; common; tibia, femur	Adamantinoma: Rare; older than 25 years; low grade
Fibrous dysplasia	
McCune-Albright syndrome: Precocious puberty, café au lait skin pigmentation; endocrine abnormalities	
Cherubism: Inherited; mandible and maxilla	
Leontiasis ossea: Facial and cranial bones	
Osteofibrous dysplasia: Rare; young; tibia, fibula	

MALIGNANT FIBROUS HISTIOCYTOMA

This is a common primary bone or soft-tissue tumor occurring in older patients (40–60 years), which can be secondary (just like osteosarcoma and chondrosarcoma) to Paget disease, bone infarct, or radiation therapy. It cannot be distinguished from fibrosarcoma using imaging; however, fibrosarcomas often occur in younger patients (30–50 years). Soft-tissue malignant fibrous histiocytoma (MFH) is the most common soft-tissue sarcoma in adults (Table 72-5). It carries a poor prognosis, as there is a high rate of recurrence and frequency of distant metastases at time of diagnosis. Radiographic appearance of osseous MFH within the diaphyses is an aggressive, permeative lesion with cortical disruption and soft-tissue mass. If it occurs in the diaphyses, the appearance may be less aggressive and does not extend to subchondral bone. The mass is infiltrative and the presence of extension to adjacent bone and cortical disruption is suggestive of MFH.

TABLE 72-5 Soft-Tissue Sarcomas

Rhabdomyosarcoma
Spindle cell sarcoma
Leiomyosarcoma
Synovial sarcoma (least common)

BONE MARROW TUMORS (Table 72-6)

MYELOMA

Myeloma is the most common primary bone tumor. Its distribution is that of red marrow with axial skeletal involvement being most common. Types include multiple (60%), solitary (25%), generalized (15%), plasma cell leukemia (1%), and extraskelatal (0.5%). The most common complication is pathologic fracture. Radiographic findings of multiple myeloma include numerous “punched-out” lytic lesions and “moth-eaten” appearance of the calvarium. These often scallop the inner cortex in the long bones. Plasmacytoma, also known as solitary myeloma, is a bubbly, lytic expansile lesion. A rare variant is the soft tissue or extramedullary plasmacytoma. Ninety percent of extramedullary plasmacytomas occur in the head and neck region. These are most often in the aerodigestive tract such as the nasopharynx or paranasal sinuses. Myeloma most commonly presents as generalized osteopenia (with or without spine compression fractures). MRI can reveal diffuse marrow replacement. Bone scintigraphy may be normal or reveal increased or decreased uptake depending on phase and extent of involvement. Therefore, extent is typically followed with skeletal survey.

PRIMARY LYMPHOMA OF BONE

Primary skeletal lymphoma is rare, making up approximately 5% of primary bone tumors. Almost all are of non-Hodgkin lymphoma. This can occur in any age group. Radiographic findings include an aggressive, permeative appearance, most commonly with associated soft-tissue mass. There is typically no lesional content.

EWING SARCOMA

This is a common malignant tumor in children, ages from 5 to 15 years. Derived from red marrow and histologically related to reticulum cell sarcoma, this tumor is in the category of round blue cell tumors. It typically presents with pain but can clinically mimic infection, presenting with fever, leukocytosis, and elevated sedimentation rate. Most common location is diaphyses or metaphyses of long bones (70% lower extremity). However, particularly in older patients, it is found in the flat bones including the ribs, pelvis, and scapula (locations of red marrow). Radiographic findings typically demonstrate a lytic, permeative lesion with aggressive periosteal reaction (onion-skinning or sunburst appearance) and associated soft-tissue mass. One-quarter is purely sclerotic.

LANGERHANS CELL HISTIOCYTOSIS (EOSINOPHILIC GRANULOMA)

The underlying pathophysiology of this disease is abnormal histiocyte proliferation in the reticuloendothelial system (skeletal and extraskelatal). Occurs predominately in children (first through third decades) and can grow or expand rapidly. Eosinophilic granuloma is the term for localized osseous or pulmonary form of the disease. Clinical presentation, symptoms, and prognosis depend on degree of extraskelatal involvement. Laboratory studies are frequently normal. Isolated skeletal disease has an excellent prognosis. Osseous radiographic findings vary greatly causing this entity to be placed on the differential diagnosis of most pediatric bone tumors. The appearance in part depends on the bone involved. The skull is the most common site of osseous involvement. The tumor involves the inner and outer table to varying degrees giving a “beveled edge” appearance. Occasionally, a cortical lucency will be present with a central density or sequestrum (button sequestrum). “Floating teeth” describes a lytic lesion in the alveolar ridge that gives the impression that teeth are not held in place by bone or are “floating.” Ribs are the second most common site of bony involvement, typically with multiple rib involvement. Ribs become expanded and often have associated soft-tissue mass. Spine lesions can have lytic destruction which when extensive causes vertebra plana (complete collapse of vertebral body). The adjacent disc space heights are typically normal. Pelvis and scapular lesions are often well defined often with sclerotic margins in the pelvis. Langerhans cell histiocytosis cannot be reliably differentiated from malignant lesions such as Ewing sarcoma or infection. Extraskelatal disease can involve the lungs (upper lobe interstitial disease), central nervous system (absent pituitary bright spot, thickened pituitary stalk), and gastrointestinal tract (fibrous polypoid lesion in stomach).

METASTATIC DISEASE

The most common bone tumor is metastatic and occurs as a result of tumor emboli or retrograde venous flow (via Batson Plexus). Breast, prostate, and lung make up the order of frequency of metastatic disease. Pain is the most common complaint but only occurs in two-thirds of patients with metastatic disease. Classically blastic lesions include prostate, carcinoid, and medulloblastoma. Classic lytic “blowout” lesions include renal and thyroid metastases. Bone mets in children are typically because of neuroblastoma, leukemia, lymphoma, or medulloblastoma. Radiographic findings can simulate primary bone tumors and appear both indolent and

TABLE 72-6 Bone Marrow Tumors

Myeloma	Most common primary bone tumor
Lymphoma	Non-Hodgkin type; rare
Ewing sarcoma	Common; children
Langerhans cell histiocytosis	Eosinophilic granuloma; children; skull most common, then ribs

aggressive. Bone scintigraphy is helpful to evaluate extent of disease. PET is also helpful in FDG-avid malignancies.

OTHER BONE TUMORS AND CYSTIC BONE LESIONS

GIANT CELL TUMOR

This adult tumor formed from osteoclast-like giant cells commonly present with pain. Fifteen percent are associated with ABC and ten percent are malignant. The only way to determine if a giant cell tumor is malignant is the presence of metastatic disease. Radiographic findings typically include a lytic, sometimes expansile, epiphyseal lesion commonly extending from the epiphysis and metaphyses. It occurs almost exclusively after fusion of physal plate, is solitary and often eccentric, and exhibits narrow zone of transition with fading sclerosis.

UNICAMERAL BONE CYST

This common pediatric tumor (85% occur in patients younger than 20 years) often presents with pathologic fracture. It is twice as common in males than females and is typically treated with bone graft or curettage. Radiographic findings include a lytic, mildly expansile lesion without periosteal reaction (unless fractured). It is most often in long bones (except in adult patient, where it can reside in the pelvis or calcaneus) and originates at metaphyses. The “fallen fragment” sign describes fragment of bone layering dependently within a fractured unicameral bone cyst.

ANEURYSMAL BONE CYST

This osseous vascular malformation is made up of multiple blood-filled, thin-walled cavities. It occurs in pediatric patients and can occur as a primarily lesion or secondarily within another bone tumor. Associate tumors include giant cell tumor, chondroblastoma, and osteoblastoma. Bone cysts can grow rapidly and cause pain, sometimes with pathologic fracture. Treatment

involves grafting or curettage. Up to 20% will recur, although it has no malignant potential. Radiographic findings include an eccentric, markedly expansile lesion with remodeled but usually intact surrounding cortex (unless in most aggressive phase of growth). Majority are metaphyseal with fewer in diaphyseal location. MRI exhibits multiple cysts with varying degrees of T1 signal intensity (blood products) and fluid/fluid levels.

INTRAOSSEOUS LIPOMA

Usually, this is an incidental lesion, but pain has been reported as a presenting symptom. It is most commonly reported in adults (fourth to fifth decade). Although intraosseous lipoma can occur throughout the skeleton, most common locations include proximal femur (34%) and calcaneus. Radiographic findings include a lucent lesion sometimes with mild expansile remodeling of the medullary canal, fat density and signal characteristics of fat on CT and MR, respectively. Lesion can exhibit central or peripheral ossification. In particular, central calcification in a lucent calcaneal body lesion is essentially pathognomonic for intraosseous lipoma.

EPIDERMOID INCLUSION CYST

Epidermoid inclusion cyst is most common in the third and fourth decades. It is a benign proliferation of epidermal cells. The intraosseous form is usually diagnosed in the terminal phalanx, but can also be found in the skull. Gardner syndrome has an association with epidermoid inclusion cysts. Radiographic findings typically demonstrate a well-defined lucent lesion in the terminal phalanx with surrounding sclerosis.

VASCULAR OR LYMPHATIC TUMORS OF BONE AND SOFT TISSUE

HEMANGIOMA

Hemangioma is the most common vascular soft-tissue abnormality (represents 7% of all soft-tissue tumors). Osseous hemangiomas have a characteristic appearance and are common within the spine in adults. Soft-tissue hemangiomas can be pathologically classified as capillary, cavernous, venous, arteriovenous, and mixed (Table 72-7). An alternate classification schema categorizes high-flow (arteriovenous) or low-flow (capillary, cavernous, venous) lesions.

Maffucci syndrome describes multiple cavernous soft-tissue hemangiomas in the setting of enchondromatosis.

TABLE 72-7 Soft-Tissue Hemangioma Classification

Capillary	Infantile hemangioma; typically involute without treatment
Cavernous	“Vascular birthmark,” deeper than capillary hemangiomas; older children; do not involute spontaneously; most common intraorbital tumor in adults
Venous	Deep structures; abdomen and extremities
Arteriovenous	Persistent fetal capillary bed causes shunting; can be deep or superficial

Klippel-Trenaunay-Weber is a nonhereditary condition of extensive unilateral capillary or arteriovenous hemangiomas in a lower extremity.

Osseous hemangiomas are most common in the vertebral bodies and exhibit vertical striations. In long bones, expansion and bone overgrowth are common. Soft-tissue cavernous hemangiomas are best diagnosed on conventional radiographs with phleboliths, occurring in about one-half of lesions.

GLOMUS TUMOR

This painful, often pulsating tumor commonly occurs in the hand with the majority being subungual in location. Radiographic findings include remodeling of adjacent bone, which is typically along the dorsal margin of the terminal phalanx. Soft-tissue tumor is very bright on T2-weighted images because of vascular nature.

TUMOR-LIKE CONDITIONS AND OTHER SOFT-TISSUE MASSES

SYNOVIAL METAPLASIAS

PIGMENTED VILLONODULAR SYNOVITIS (PVNS)

This idiopathic condition typically presents with pain in the young adult. Treatment is synovectomy. The localized form is also called giant cell tumor of the tendon sheath and is most common in the hand. The diffuse form is seen most commonly found in the hip, shoulder, knee, in decreasing order. Radiographic findings of the diffuse form demonstrate erosions at the joint margins, often with preservation of the joint space and without other findings of arthritis. The localized form often presents as a small soft-tissue mass. Because of presence of hemosiderin (pigmented), these lesions are typically dark on MR sequences.

SYNOVIAL CHONDROMATOSIS

This idiopathic condition presents with joint pain and decreased range of motion. The most common location

is the knee. Males are involved at least twice as commonly as females. Treatment includes synovectomy, but recurrence is common. This condition produces proliferation of metaplastic synovium with eventual fragmentation. These fragments grow and eventually will ossify. Radiographic findings depend on the degree of ossification of the intra-articular bodies. There are typically many more intra-articular bodies present than depicted on radiographs. Tight joints such as the hip will demonstrate earlier erosions and secondary osteoarthritis. In contrast, capacious joints such as the knee often appear essentially normal except for the presence of multiple loose bodies. MR better depicts both the ossific and cartilaginous bodies and the synovial proliferation.

POPLITEAL CYST (BAKER CYST)

Most commonly recognized synovial cyst (herniation of synovial membrane through the joint capsule) resulting from a communication between the knee joint and a distended gastrocnemius-semimembranosus bursa. The most common complication is rupture, which can clinically mimic a deep venous thrombosis. Radiographic findings are best depicted on ultrasound or MR, with fluid signal/cyst extending between the medial head of the gastrocnemius and the semimembranosus tendons.

MYOSITIS OSSIFICANS

Myositis ossificans describes the heterotopic bone formation that occurs most commonly in young adults following trauma, although a significant percentage have no trauma history. In the early stages, this can be confused with an aggressive lesion such as a surface osteosarcoma. Myositis ossificans progressiva is an autosomal dominant condition with dysmorphic skeletal features and an average age of onset of 5 years. Radiographic findings include a focal soft-tissue calcification beginning 2 to 6 weeks following trauma. Over time, this exhibits a pattern of peripheral maturation (dense bone at the periphery of the lesion). CT best demonstrates this maturation pattern, especially early in the course.

SOFT-TISSUE LIPOMA

Lipoma is the most common soft-tissue tumor, a slow growing fatty tumor, surrounded by a thin fibrous capsule. It is usually asymptomatic and presents as a palpable mass. No intervention is required, but these often removed for cosmetic reasons and to exclude liposarcoma. Radiographic findings include a well-circumscribed

TABLE 72-8 Soft-Tissue Sarcomas

Malignant fibrous histiocytoma (MFH)	Most common
Liposarcoma	Second most common; usually painless; extremities; may not contain fat, although many do
Synovial sarcoma	Does not arise from synovium; resembles synovial tissue on microscopy; greater than 90% occur away from a joint; most common sarcoma of the foot and ankle
Rhabdomyosarcoma	Most common soft-tissue sarcoma in children; embryonal is most common type and typically involves the head/neck region or GU tract. The alveolar type is seen more commonly in older children and young adults and involves the extremities more commonly. The pleomorphic type is rare and found in adults

mass that exhibits signal characteristics of subcutaneous fat on all MR sequences but exhibits no significant enhancement. If there are septations, any degree of heterogeneity, or enhancement, then liposarcoma should be considered.

SOFT-TISSUE SARCOMAS (Table 72-8)

Radiographic findings depend on type of sarcoma, however findings relatively nonspecific and often require biopsy or resection to establish diagnosis. MR is most useful in assessing extent of the neoplasm, operative planning, and follow-up. Synovial sarcomas can appear small, cystic, and benign. Enhancement helps to differentiate this lesion from a cyst on MR. On radiographic findings, synovial sarcomas occasionally exhibit “stippled” calcifications. Liposarcomas usually appear as large, enhancing masses with components of fat and soft tissue. Low-grade liposarcomas are difficult to differentiate from atypical lipomas on MR.

1. A popliteal cyst protrudes through which two anatomic structures?
 - A. Semitendinosus and lateral head of the gastrocnemius
 - B. Gracilis and medial head of the pes anserinus
 - C. Semimembranosus and medial head of the gastrocnemius
 - D. Popliteus and the lateral head of the gastrocnemius

ANSWER: C. Popliteal cyst is a synovial cyst, which is a herniation of the joint capsule between the medial head of the gastrocnemius and the semimembranosus.

2. What is the most common soft-tissue sarcoma in the adult ankle/foot?
 - A. Synovial sarcoma
 - B. Malignant fibrous histiocytoma
 - C. Liposarcoma
 - D. Rhabdomyosarcoma

ANSWER: A. Synovial sarcoma is the most common sarcoma in the foot in the adult and often exhibits stippled calcification on plain films. This lesion can appear cystic on MR and therefore enhancement can be very important to verify that a solid lesion is present. MFH is the most common overall sarcoma. Rhabdomyosarcoma is the most common in the pediatric population.

3. Which of the following typically has little or no surrounding edema on MR?
 - A. Osteoid osteoma
 - B. Chondroblastoma
 - C. Intraosseous abscess
 - D. Enchondroma

ANSWER: D. Enchondromas are often incidental findings typically without a great deal of surrounding edema. The other lesions by comparison are known for surrounding edema. In fact, osteoid osteomas and chondroblastomas are occasionally mistaken for more aggressive lesions.

4. Which of the following does *not* help differentiate enchondroma from chondrosarcoma?
 - A. Degree of enhancement
 - B. Pain
 - C. Degree of cortical thinning
 - D. Aggressive periosteal reaction

ANSWER: A. Both tumors can enhance, so this does not help a great deal. Aggressive features such as periosteal reaction and cortical thinning favor

chondrosarcoma. Pain favors a malignant lesion as well.

5. Which of the following is *not* associated with fluid/fluid levels on MR?
- A. Aneurysmal bone cyst
 - B. Eosinophilic granuloma
 - C. Telangiectatic osteosarcoma
 - D. Chondroblastoma

ANSWER: B. ABC and telangiectatic osteosarcoma are known to be associated with fluid/fluid levels on MR and chondroblastoma can be associated with ABC. Eosinophilic granuloma does not have fluid/fluid levels.

6. Which of the following has no or only mild uptake on bone scintigraphy?
- A. Fibrous dysplasia
 - B. Bone island
 - C. Paget disease
 - D. Primary osseous lymphoma

ANSWER: B. Bone islands typically have no or mild uptake. The other lesions are known for marked uptake on bone scintigraphy.

7. Imaging reveals an aggressive bone lesion which exhibits a sequestration and an associated soft-tissue mass. What is the most likely diagnosis?
- A. Chondrosarcoma
 - B. Primary lymphoma of bone
 - C. Multiple myeloma
 - D. Ewings Sarcoma

ANSWER: B. Primary lymphoma of bone has a documented association with sequestra though it is only associated 15% of the time. The other lesions are not associated with sequestration formation.

8. What is the most common risk factor leading to secondary osteosarcoma?
- A. Radiation
 - B. Osteonecrosis
 - C. Paget disease
 - D. Fibrous dysplasia

ANSWER: C. Over 60% of secondary osteosarcomas are diagnosed in patients with Paget disease.

9. Of the synovial metaplasias, which one typically exhibits low signal intensity on all MR pulse sequences?
- A. Lipoma arborescens
 - B. Synovial chondromatosis
 - C. PVNS
 - D. Inflammatory arthropathy

ANSWER: B. PVNS and giant cell tumor of the tendon sheath are pigmented lesions and exhibit hemosiderin. Therefore, they have low signal intensity on MR pulse sequences and, in particular, a gradient sequence. Inflammatory arthropathy is a synovial hyperplasia rather than a metaplasia.

10. Patient presents with an osteolytic, painful lesion at the dorsal aspect of the terminal phalanx. What is the most likely diagnosis?

- A. Enchondroma
- B. Hemangioma
- C. Aneurysmal bone cyst
- D. Glomus Tumor

ANSWER: D. Glomus tumors are vascular lesions that are characteristically subungual in location, painful, and cause osteolysis.

73 ARTHROPATHIES

Mark Sultenfuss and Robert Lopez-Ben

OVERVIEW

Arthritis is most easily approached from an etiologic standpoint. Changes within an articulation can occur from direct injury to the joint, systemic inflammatory processes, or from metabolic abnormalities resulting in deposition of products within and surrounding the joint. The pathophysiology of the underlying disease can explain the radiographic findings. Important distinguishing characteristics include the distribution of involvement, the presence or absence of bony proliferation, and the presence or absence of erosions. Taking these factors into consideration, most forms of arthritis can be accurately characterized.

DEGENERATIVE JOINT DISEASE

Degenerative joint disease or osteoarthritis is a noninflammatory process of synovial joints, resulting from presumably mechanical joint destruction and repair. Degenerative osteoarthritis is considered primary when abnormal forces applied to a normal joint lead to joint disruption, and secondary when normal forces applied to an abnormal joint lead to the same disruptive changes. Degenerative osteoarthritis can affect any articulation, but most commonly affects large weight-bearing joints, such as the hips, knees, and spine. Cartilage disruption

or degeneration within affected joints results in nonuniform joint space narrowing, and subchondral bone fracture and/or collapse. Loss of articular cartilage is accentuated in areas, where there is increased pressure within the joint, accounting for asymmetric joint space loss within an articulation. As the joint is disrupted, joint instability and subluxation occurs, further increasing the abnormal biomechanical forces applied to the articulation. Eventually, the subchondral bone fractures and collapses, and new bone is produced, which is characterized by subchondral eburnation (sclerosis) radiographically. In an attempt to increase the surface area of the articulation and offset the increasingly abnormal forces within the joint, marginal osteophytes are created at low-stress points. Periarticular subchondral lucencies/cysts, which are commonly seen in degenerative osteoarthritis, are thought to occur from extruded synovial fluid into the disrupted subchondral bone and/or bony marrow contusion/involution. The overall lack of inflammation explains the normal bone mineralization and absence of erosions.

EROSIVE OSTEOARTHRITIS

Erosive osteoarthritis is an inflammatory form of degenerative osteoarthritis, most characteristically affecting bilaterally and symmetrically the interphalangeal joints of postmenopausal females. The characteristic central erosions help distinguish this entity from other inflammatory arthritides, which have marginal erosions. Inflammation leads to enzymatic loss of articular cartilage and subsequent collapse of the subchondral bone. The repair process results in marginal osteophyte formation, as seen with degenerative osteoarthritis, another distinguishing feature from other forms of inflammatory arthritis. These marginal osteophytes, in combination with central erosions, can lead to a gull-wing appearance of the interphalangeal joints. Occasionally, new bone formation can result in ankylosis.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is an immune-mediated inflammatory process of synovial joints, thought to occur from a type III hypersensitivity reaction to an unknown antigen. Synovial joints of both the axial and appendicular skeleton are involved. Although any synovial joint can be involved, the hands and feet are most commonly affected. Inflammatory cells target and infiltrate the synovium of these joints, forming granulation tissue known as “pannus.” Immune mediators released from these inflammatory cells stimulate capillary proliferation,

further increasing the inflammatory response and pannus formation. Periarticular osteopenia develops from the resultant hyperemia. Articular bone and cartilage are both directly affected by the inflammatory response. Enzymes released from inflammatory cells create symmetric uniform cartilage destruction, while direct pannus interaction with bone leads to osseous erosions. Since the margins of synovial joints are devoid of articular cartilage, these “bare” areas of bone are affected first, demonstrated radiographically as marginal erosions.

The articular surfaces become incongruous from cartilage and subchondral bone destruction, and the articular capsule and ligaments become weakened from inflammation. As these processes progress, joint laxity and subluxation develop. Subluxations characteristically occur along the ulnar side of the articulation. There is a distinct lack of new bone formation.

Synovium lining the tendon sheaths and bursae can also be affected by the inflammatory infiltration of rheumatoid arthritis, referred to as tenosynovitis and bursitis. The inflammation creates soft-tissue swelling and subjacent bone erosion. Classic examples include ulnar styloid erosion from extensor carpi ulnaris tenosynovitis and posterior calcaneal erosions from retrocalcaneal bursitis. The tendons can spontaneously rupture, contributing to articular subluxation.

JUVENILE RHEUMATOID ARTHRITIS

Juvenile rheumatoid arthritis (JRA) combines five forms of inflammatory arthritis, which occur in children and adolescents. These forms of arthritis include Still disease, polyarticular JRA, seronegative and seropositive JRA, and juvenile ankylosing spondylitis.

Still disease is a systemic process affecting children younger than 5 years. The child presents with fever, anemia, leukocytosis, lymphadenopathy, and polyarticular arthritis. Radiographic changes of arthritis are typically mild and nonspecific.

Pauciarticular disease is the most common form of juvenile arthritis, accounting for approximately 40% of cases. The patients are typically female and are seronegative for rheumatoid factor. One to three joints are involved and usually affect larger joints, such as the knee, elbow, or ankle. Patients can also have a chronic iridocyclitis. Radiographic changes are more pronounced than Still disease, with periarticular osteoporosis, soft-tissue swelling, and a variable presence of joint space loss and erosions.

Polyarticular disease can be seen in both seronegative and seropositive patients. Seronegative polyarticular JRA accounts for about 25% of all JRA patients and is defined as a symmetric arthritis involving multiple articulations in a patient who does not produce rheumatoid

factor. The arthropathy is similar to adult-type RA in distribution and radiographic changes. Some features of long-standing involvement include ankylosis of apophyseal joints in the cervical spine, creating hypoplasia of the cervical vertebrae and discs, as well as ankylosis of the carpal and tarsal bones. Seropositive polyarticular disease accounts for only about 5% of patients and is similar in appearance and distribution to adult-type RA. Symptoms typically begin during the second decade and primarily affect females. Rheumatoid factor is present on serologic examination.

Juvenile ankylosing spondylitis is essentially a young-onset form of adult-type ankylosing spondylitis. There are many similarities between juvenile and adult ankylosing spondylitis, including male predominance, and an association with HLA-B27. Radiographic changes are similar as well, with ankylosis of involved articulations, primarily the sacroiliac joints and spine.

In all forms of JRA, distinguishing features include overgrowth of epiphyses from hyperemia, leading to a ballooned appearance of the epiphysis. Advanced skeletal maturation also occurs from premature physal closure, resulting in shortened limbs. Soft-tissue swelling and metaphyseal osteopenia are also common radiographic findings. Loss of joint space and erosions are typically late manifestations of the disease.

COLLAGEN VASCULAR DISEASES

SCLERODERMA

Scleroderma is an autoimmune collagen vascular disease, which primarily affects the dermis, although many other organ systems, including the heart, GI tract, and kidneys, can be involved. There is a low-grade inflammatory response to an unknown inciting antigen, with inflammatory cells surround the vasculature and depositing collagen. These alterations result in fibrosis of the soft tissues, atrophy of the dermal appendages, and thrombotic occlusion of arterioles. This is most pronounced radiographically within the digits, where resorption and fibrosis of soft tissues results in a sausage-shaped digit. The soft tissues of the fingertips are frequently absorbed and can be associated with osseous erosions of the distal phalangeal tufts, which is termed acro-osteolysis. The tuft can alternatively be sclerotic, which is termed acrosclerosis.

Amorphous calcification of the periarticular soft tissues is also a common feature and is most pronounced in the hands. Infrequently, erosive arthropathy can occur at the interphalangeal joints and the first carpometacarpal joint in patients with scleroderma. A common finding is thickening of the periodontal membrane on mandible radiographs in patients with scleroderma. Although the

erosive changes may resemble those of rheumatoid arthritis, distal interphalangeal involvement may help distinguish scleroderma from RA.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an autoimmune collagen vascular disease of unknown etiology. Arthritis in SLE is a result of autoantibody-induced synovial inflammation and hyperemia, without pannus formation. Changes of soft-tissue swelling and periarticular osteoporosis occur in a bilateral and symmetric distribution. Since there is a lack of pannus formation, cartilage destruction is absent and joint spaces are therefore maintained. Erosive changes are distinctly absent. The inflammation weakens and disrupts tendons, resulting in flexion and extension deformities, as well as ulnar-sided articular subluxations. The metacarpal phalangeal (MCP) joints of the hand and large weight-bearing joints are the most common sites of involvement. Subchondral cysts are thought to occur from the alteration of articular mechanics. Most of these patients require steroid therapy to control the systemic inflammation, which can lead to osteonecrosis.

POLYMYOSITIS/DERMATOMYOSITIS

Polymyositis and dermatomyositis are inflammatory processes involving the striated muscle and dermis respectively. The etiology is unknown, but may be a cell-mediated autoimmune process. Chronic inflammatory cell infiltration of muscle fibers and dermis lead to edema, followed by fibrosis and atrophy. Resulting necrosis leads to soft-tissue calcifications, which are the radiographic hallmark of both disease entities. Articular involvement is rare, with periarticular soft-tissue swelling and calcification seen most commonly. Rarely erosions or articular subluxations can occur.

SERONEGATIVE SPONDYLOARTHROPATHIES

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is a chronic inflammatory arthritis of unknown etiology, likely related to an autoimmune response in patients with HLA-B27 antigen. The disease affects young adults, with a strong male predominance. The low-grade inflammatory process involves both synovial and cartilaginous articulations as well as ligamentous attachment to bone. Involvement is typically

bilateral and symmetric in distribution. Sacroiliitis and a lack of articular subluxations and subchondral cysts are all important features of this disease.

The synovial joints most commonly affected in ankylosing spondylitis are the sacroiliac joints, hips, and shoulders. Inflammation within the synovial joint results in loss of articular cartilage, joint space narrowing, and osseous erosions. The articular cartilage becomes hyperemic from the inflammatory response, with metaplasia of the cartilage occurring over time. The metaplastic cartilage subsequently ossifies, resulting in intra-articular ankylosis.

The cartilaginous joints most commonly affected in ankylosing spondylitis are the intervertebral disc/body junction as well as the symphysis pubis. The inflammation results in cartilage calcification, angiogenesis, and ultimately ossification. These thin bridges of ossification are known as syndesmophytes, which ultimately progresses to bony ankylosis once the bridge across the articulation is complete. The radiographic result is a “bamboo” appearance of the spine.

Inflammation of ligament/tendon attachments to bone (enthesitis) results in subligamentous bone erosion/eburnation, which are termed “shining corner” when it affects the vertebral body. As healing occurs, bony excrescences develop at these ligamentous attachments, which are termed enthesophytes. These inflammatory enthesophytes are nonspecific and can also be demonstrated with reactive arthritis and psoriasis.

REACTIVE ARTHRITIS (FORMERLY TERMED REITER SYNDROME)

This is a triad of urethritis, conjunctivitis, and inflammatory arthritis, most commonly affecting young male patients. The arthritis associated with Reiter syndrome is thought to occur from immune-mediated inflammatory cell infiltration of the synovial membrane. The inflammatory process results in periarticular soft-tissue swelling as well as osteoporosis from associated hyperemia. Inflammatory cartilaginous and osseous changes include joint space narrowing and erosions, which begin at the joint margin and extend centrally. New bone is produced in response to the inflammatory process (periostitis), beginning as cartilaginous fibroplasias/metaplasia, which subsequently ossifies, resulting in intra-articular ankylosis. Reiter’s characteristically involves the small joints of the foot as well as the hand and wrist.

PSORIATIC ARTHRITIS

Psoriasis is a skin disorder, with articular involvement in only a small percentage of patients (less than 30%).

Synovial inflammation and effusions result in fusiform soft-tissue swelling. The degree of synovial inflammatory infiltrate, however, is less than with rheumatoid arthritis. The articular cartilage is destroyed by the inflammatory process, resulting in uniform loss of the joint space. Erosions also develop from direct inflammatory infiltration of bone, beginning at the articular margin and extending centrally. New bone proliferation does occur as an exaggerated healing response, creating excrescences, which accompany osseous erosions.

A characteristic finding is the “pencil-in-cup” deformity, representing telescoping of bone into the central erosion. Arthritis from psoriasis most commonly involves the interphalangeal joints of the hand and foot, MCP and metatarsal phalangeal (MTP) joints, and the calcaneus. Sacroiliac and spine involvement is also common. Psoriatic arthritis is also one of the cause of acroosteolysis or distal tuft erosion. Additionally, the distal tuft can have increased density, termed “ivory phalanx.”

ENTEROPATHIC ARTHRITIS

Articular changes similar to those of psoriasis and reactive arthritis can occur from enteropathic disease processes and infections. Enteric diseases such as ulcerative colitis, Crohn disease, and Whipple disease, as well as enteric infections, such as salmonella, shigella, and yersinia, can all have nonspecific articular changes. These findings include soft-tissue swelling, periarticular osteoporosis, joint space narrowing, and osseous erosions. There is a predilection for larger joints, as opposed to the small joint involvement seen in psoriatic and reactive arthritis.

METABOLIC/BIOCHEMICAL ARTHRITIS

GOUTY ARTHRITIS

Gouty arthritis occurs from the inflammatory response stimulated by sodium monurate crystal deposition in tissues with poor blood supply. Sodium monurate crystals develop from hyperuricemia, either in response to an inborn error of metabolism (primary gout) or from a disease state that creates hyperuricemia secondary to increased production or decreased excretion of uric acid (secondary gout). Radiographic changes are evident in only half of patients with gout, most commonly affecting the MTP of the great toe. Other common areas of involvement include the hands, wrists, elbows, and knees.

Eccentric crystal deposition in the soft tissues, along with the associated inflammatory response, leads to

prominence of soft tissues as well as calcification of the soft tissues over time. These crystal deposits are referred to as tophi. Destruction of cartilage within a joint is asymmetric, usually preserving the joint space until the late stages of disease. Punched-out intra- and juxta-articular erosions, with sclerotic borders, occur at sites of tophus formation. The edges of cortex can create an elevated bony margin, as the bone covers a tophaceous nodule, with bone absorption occurring adjacent to the nodule.

CALCIUM PYROPHOSPHATE CRYSTAL DEPOSITION ARTHROPATHY

Arthropathy from calcium pyrophosphate crystal deposition (CPPD) results from deposition of calcium pyrophosphate crystals into articular tissues. The process can be hereditary, idiopathic or degenerative, or secondary to other diseases, such as hyperparathyroidism, hemochromatosis, hypothyroidism, and many others. Crystals are deposited within the articular cartilage, synovium, articular capsule, and periarticular soft tissues. Deposition of crystal within fibrocartilage accounts for chondrocalcinosis, which is characteristic radiographically. The inflammatory response to intra-articular crystals results in enzymatic destruction of cartilage and ultimately joint space narrowing. Subchondral bone becomes sclerotic and thickened, either from collapse or subchondral new bone formation. Periarticular mineralization remains normal, a finding that suggests a lower-grade inflammatory response and/or the lack of hyperemia within the articulation.

Although findings of CPPD arthropathy seem similar to osteoarthritis, there are several features, which help distinguish the two. The distribution is slightly different; although the knee is most commonly affected, other articulations affected in CPPD, such as the wrists and MCP joints, are less commonly affected by osteoarthritis. Wrist involvement is very distinctive for CPPD, with chondrocalcinosis and degenerative tearing of the triangular fibrocartilage complex. Also, degeneration of the lunate articulations and ligamentous attachments can lead to scapholunate articular collapse (SLAC).

The distribution of CPPD also includes the hands, hips, shoulder, and elbow. When compared with osteoarthritis, CPPD can atypically affect certain areas of the joint, such as selective patellofemoral involvement of the knee. Subchondral cysts that form in the bones of affected articulations are larger and more numerous than those demonstrated with simple osteoarthritis. Destructive changes are more severe and progressive, when compared with osteoarthritis. Finally, osteophyte formation in joints affected by CPPD is variable; some patients may produce exuberant osteophyte formation, while others demonstrate none.

CALCIUM HYDROXYAPATITE CRYSTAL DEPOSITION DISEASE

Calcium hydroxyapatite crystal deposition disease (HADD) is also known as calcific tendonitis/peritendinitis/bursitis. It occurs from deposition of hydroxyapatite crystals into periarticular soft tissues, with subsequent loss of normal soft-tissue structure, mild inflammatory response, and possibly necrosis. The articulations adjacent to these calcific deposits can be normal, or may have non-specific destructive changes such as loss of joint space, subchondral eburnation, and possibly erosions with articular derangement. The etiology is unknown, but local, systemic, and metabolic factors may be contributory.

The shoulder is the most commonly affected joint in HADD, with calcific deposits in the rotator cuff tendons, and other periarticular soft tissues. These deposits stimulate an inflammatory response, leading to subsequent derangement of the joint. Intra-articular involvement of the shoulder with marked loss of articular cartilage, osseous erosions, and rotator cuff degeneration, represent an entity of pain and decreased mobility in elderly patients termed Milwaukee shoulder syndrome. This can sometimes be confused clinically with infection or neuropathic arthropathy. Other joints can also be affected by hydroxyapatite crystal deposition, including the elbow, wrists, hips, and knee. In the cervical spine, soft-tissue swelling, along with amorphous calcium deposition in the prevertebral soft tissues, representing calcific tendonitis of the longus colli muscle, can suggest hydroxyapatite deposition disease.

The periarticular calcification of hydroxyapatite deposition can be simulated by other disease entities. Altered calcium/phosphorous metabolism, such as in renal osteodystrophy, calcinosis in the presence of normal calcium metabolism (idiopathic tumoral calcinosis), and dystrophic calcification in devitalized tissue, can all lead to periarticular calcifications.

HEMOCHROMATOSIS

Hemochromatosis is an iron deposition disorder from either an autosomal recessive inborn error of increased iron absorption (primary hemochromatosis) or iron overload (secondary hemochromatosis). Many years of iron deposition are required for clinical symptoms to occur; therefore, the age of onset is typically the fifth through seventh decades of life.

Arthropathy from iron deposition is more common in patients with primary hemochromatosis, and there is an association of hemochromatosis with CPPD. Iron is deposited within the synovium and cartilage, with calcification of the articular cartilage, either isolated or in

association with CPPD. Osseous changes from iron deposition are similar to those of CPPD arthropathy, including subchondral eburnation and cyst formation.

Distinguishing hemochromatosis from CPPD relies on a few subtle findings. Arthropathy of hemochromatosis primarily affects the second and third MCP joints, with less common involvement of the remaining MCP joints. Hooklike osteophytes along these MCP articulations are also subtle distinguishing radiographic characteristics. Additionally, the radiocarpal articulation is less severely affected by hemochromatosis, when compared with CPPD arthropathy. Finally, the arthropathy of hemochromatosis is less progressive than CPPD arthropathy.

QUESTIONS AND ANSWERS

- Which arthropathy presents with central erosions with marginal osteophyte formation, producing a gull-wing appearance to the interphalangeal joints?
 - Psoriatic arthritis
 - Reactive arthritis
 - Erosive osteoarthritis
 - Calcium pyrophosphate crystal deposition disease

ANSWER: C. Erosive osteoarthritis characteristically has central erosions, along with marginal osteophyte formation to create a gull-wing appearance of the interphalangeal joint.

- Enteropathic arthritis when compared to psoriasis is distinguished by which of the following?
 - Joint space narrowing
 - Periarticular osteopenia
 - Large joint involvement
 - Erosions

ANSWER: C. Soft-tissue swelling, periarticular osteopenia, joint space narrowing, and osseous erosions are common for both psoriasis and enteropathic arthritis, but the latter has more of a predilection for involvement of larger axial joints.

- Seronegative arthropathy is often associated with which of the following?
 - Periostitis
 - Thickening of the periodontal membrane
 - Subcutaneous nodules
 - Hooklike osteophytes

ANSWER: A. Periostitis is another term for reactive new bone proliferation, a common finding in seronegative arthropathies, as well as enthesitis.

- Radiographic findings of advanced scapholunate articular collapse are typically found in which crystal deposition disease?
 - Hemochromatosis
 - Wilson disease
 - Gouty arthritis
 - Pyrophosphate deposition disease

ANSWER: D. Pyrophosphate deposition disease (also known as calcium pyrophosphate deposition disease or CPPD) commonly affects the lunate articulation, with arthropathy and ligamentous disruption, and subsequent radiographic findings of scapholunate articular collapse (SLAC). The other entities are not usually associated with this radiographic finding.

- The most common arthropathy to present as hooklike osteophytes of the second and third MCP joints?
 - Hemochromatosis
 - Osteoarthritis
 - Wilson disease
 - Gout
 - CPPD

ANSWER: A. Second and third MCP joint involvement with hooklike osteophytes is a distinctive finding for hemochromatosis. The other choices do produce this distinctive presentation, although this finding can also be seen sometimes with DJD of the dominant hand in manual laborers. CPPD and hemochromatosis are commonly associated, but CPPD by itself typically does not account for the hooklike osteophytes in these joints.

- A 4-year-old child presents with fever, anemia, lymphadenopathy, and mild polyarticular arthritis. What is the most likely diagnosis?

- A. Juvenile ankylosing spondylitis
- B. Pauciarticular juvenile rheumatoid arthritis
- C. Polyarticular juvenile rheumatoid arthritis
- D. Stills disease

ANSWER: D. Still disease is a mild polyarticular arthritis occurring in children younger than 5 years of age. Systemic symptoms include fever, leukocytosis, lymphadenopathy, and anemia. Although the remaining choices can produce arthritis in children, the presentation is typically more severe than that seen with Still disease.

7. Sclerosis of the anterior margin of the vertebral body is most commonly associated with which of the following?
- A. Rheumatoid arthritis
 - B. Psoriatic arthritis
 - C. Reactive arthritis
 - D. SLE
 - E. Ankylosing spondylitis

ANSWER: E. Ankylosing spondylitis is commonly associated with enthesitis of the ligamentous attachment to the vertebral body, termed “shining corner.”

8. Which of the following arthropathies is associated with calcification in the cervical spine prevertebral soft tissues?
- A. SLE
 - B. Hydroxyapatite deposition disease
 - C. Gout
 - D. Rheumatoid arthritis

ANSWER: B. Hydroxyapatite deposition disease (HADD) is associated with calcific tendonitis of the longus colli muscles, producing calcification in the prevertebral soft tissues. Although SLE is commonly associated with soft-tissue calcifications, this specific involvement is more commonly seen with HADD. Rheumatoid arthritis can affect the cervical spine, but more commonly causes erosive arthropathy, especially at the atlantoaxial articulation.

9. Ulnar subluxation of the MCP joints without significant loss of joint space or destructive arthropathy is most commonly seen with which of the following?
- A. CPPD
 - B. HADD
 - C. SLE
 - D. Hemochromatosis
 - E. Ankylosing spondylitis

ANSWER: C. Articular changes from SLE are primarily derived from soft-tissue derangement. Tendon laxity and rupture allow for subluxation in the absence of significant cartilage and bone derangement.

10. The “pencil-in-cup” deformity is most commonly associated with which of the following?

- A. SLE
- B. JRA
- C. Gout
- D. Psoriasis

ANSWER: D. Pencil in cup deformity results from telescoping of bone into a central erosion of the interphalangeal joint. This is most commonly associated with psoriatic arthritis. The other choices do not commonly demonstrate this abnormality.

74 ENDOCRINE AND METABOLIC BONE DISEASE

Michael A. Bruno and Robert Lopez-Ben

OSTEOPOROSIS

Osteoporosis is a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture. It is the most common metabolic disease of bone and one of the most common skeletal disorders worldwide. Osteoporotic fractures are one of the leading causes of morbidity in the elderly after arthritis.

The most common cause for osteoporosis is primary osteoporosis that can be further classified into type I (postmenopausal) and type II (senile or age-related). In these categories, type I affects women after menopause and is associated with wrist fractures and vertebral crush fractures. Type II is age-related, or senile, osteoporosis, affects men and women older than age 70, and is associated with hip fractures and vertebral wedge fractures.

Involutional changes in bone density happen as both sexes age. This is caused by alterations in the normally coordinated functions of the bone remodeling units of osteoclasts and osteoblasts within the skeleton. The resulting mismatch of the rate of bone resorption to bone formation leads to a decrease in bone mass and abnormal bone morphology. Postmenopausal women will have an accelerated phase of bone loss as compared to age-matched men secondary to the absence of the anabolic effects of estrogen. Because women typically achieve a lower peak bone mass than men during bone growth and formation, they are at higher risk of osteoporosis development because of their increased rate of bone loss and lower starting point for bone mass. There

is predominantly a loss of trabecular bone and not cortical bone. Although serum calcium and phosphorus levels are typically normal, these patients may have increased urine calcium excretion.

Secondary osteoporosis is because of other etiologies that are not related to menopause or aging. It is important to search for these conditions in order to tailor therapy appropriately. These include endocrine causes like hypogonadism in men (like estrogen, testosterone is also a potent anabolic hormone for bone formation and its deficiency can lead to osteoporosis). Other endocrine causes include hyperparathyroidism, hypercortisolism from functioning adrenal tumors, and hyperthyroidism. Prolonged disuse will lead to generalized bone loss. This can be encountered in space travel but closer to earth is seen when patients with chronic illness have prolonged bedrest or neurologic deficits that impede ambulation and weightbearing. Nutritional disorders (such as malnutrition, vitamin D deficiency, scurvy, and alcoholism) and certain medications (predominantly corticosteroids but also anticonvulsants and heparin) can lead to abnormal bone mass and morphology. Congenital causes include osteogenesis imperfecta, homocystinuria, Marfan syndrome, and Gaucher disease.

Osteoporosis is typically asymptomatic but these patients have increased risk of fractures that can occur without significant preceding trauma (bone fragility fractures). Patients may present with a painful fracture or a progressive kyphosis from loss of height because of multiple vertebral compression fractures. Radiographs will show only advanced disease, as greater than 30% to 50% of bone mass needs to be lost to become detected by this technique. There may be cortical thinning and prominence of weight-bearing trabecula present, especially in the hip. Typical vertebral compression fractures are classified as anterior wedging, biconcave endplates, and posterior wedging fracture patterns. MRI is helpful in distinguishing osteoporotic compression fractures from other pathologic fractures because of tumor replacement of the marrow.

Evaluation of bone densitometry is typically done with dual x-ray absorptiometry (DXA). Usually, central areas of bone mineral density (BMD) measurement including the lumbar spine and hip are performed, although peripheral areas like the wrist can also be measured. Other less commonly used methods include quantitative CT and quantitative ultrasound. These BMD measurements are compared to the sex-matched population of young adults at their estimated peak bone mass. A T-score is calculated as the number of standard deviations of the BMD measurements from that young adult mean, which is a good predictor of relative fracture risk when less than 2.5 and is used to diagnose osteoporosis. A “Z” score is also generated when BMD of the patient is compared to a reference

database of BMD from sex and age-matched individuals. This “Z” score helps determine if there are secondary causes of osteoporosis present.

The WHO system is the most often used BMD criteria for the densitometric diagnosis of osteoporosis at central sites. Categories are:

Normal: BMD or bone mineral content (BMC) not more than 1 SD below the young adult mean (T-score above -1).

Osteopenia (or low bone mass): BMD or BMC between 1 and 2.5 SD below young adult mean (T-score between -1 and -2.5).

Osteoporosis: BMD or BMC 2.5 SD or more below the young adult mean (T-score at or below -2.5).

Severe osteoporosis (or established osteoporosis): BMD or BMC 2.5 SD or more below the young adult mean in the presence of one or more insufficiency (i.e., fragility) fractures.

Assessment of fracture risk is possible with densitometry measurements as bone strength correlates with BMD. Each standard deviation decrease in BMD is associated with a 1.5 to 3.0 fold increase in risk of future fracture. Pharmacological therapy including bisphosphonates, estrogen, or selective estrogen receptor modulators has been shown to be effective in preventing future bone loss in this patient population and reducing fracture risk. Therapy can be monitored with DXA, usually performed at 2 year intervals.

DISORDERS OF CALCIUM AND PHOSPHATE METABOLISM

HYPERPARATHYROIDISM

Primary hyperparathyroidism is characterized by the excessive, unregulated excretion of parathyroid hormone and is usually secondary to a hyperfunctioning solitary parathyroid adenoma. In 10% to 20% of cases, it is secondary to a diffuse hyperplasia of the parathyroid glands and in less than 1% of cases, it is caused by a parathyroid carcinoma. It is also associated with MEN syndromes 1 and 2. Ectopic secretion of a parathyroid hormonelike protein can also rarely occur in some paraneoplastic syndromes. Transient hyperparathyroidism of the neonate can occur secondary to maternal hyperparathyroidism but will resolve spontaneously after birth. Secondary hyperparathyroidism is usually secondary to chronic renal insufficiency but can also be seen in certain malabsorption states.

Patients with hyperparathyroidism will have elevated serum calcium and decreased serum phosphorus levels.

This is secondary to parathyroid hormone's effects in increasing calcium mobilization from the skeleton via osteoclast activation, increased gastrointestinal reabsorption of calcium (by promoting conversion of vitamin D to the active metabolite, dihydroxyvitamin D), and increased phosphate excretion from the renal tubules.

Because of the increased use of laboratory blood screening, most patients today with primary hyperparathyroidism are asymptomatic. When skeletal changes are present, the most common (but least specific) finding is generalized osteopenia. These patients will have abnormally decreased BMD when measured with DXA, but as opposed to patient with primary osteoporosis, the areas of bone loss will be more substantial at anatomic sites that contain a higher proportion of cortical bone (like the midradius).

Bone resorption at sites of ongoing mechanical stresses are typically present and can be classified as subperiosteal, subligamentous, subchondral, trabecular, endosteal, and intracortical. Hand radiographs will characteristically show subperiosteal bone resorption of the radial aspects of the middle phalanges of the index and middle fingers, although loss of the distal tufts outline is felt to happen earlier in the disease. Skull radiographs will show typical "salt and pepper" patchy bone resorption and/or patchy bone sclerosis. Subchondral bone resorption can be dramatic in the distal clavicles and sacroiliac joints. Resorption of bone from the margins of joints can lead to an "erosive" appearance atypically. Brown tumors (osteoclastomas) are focal well-circumscribed lytic lesions because of accumulation of giant cells and are seen in both primary and secondary hyperparathyroidism, although they are more commonly seen with primary hyperparathyroidism. Similarly, chondrocalcinosis is predominantly seen in primary hyperparathyroidism.

RENAL OSTEODYSTROPHY

Renal osteodystrophy is a term used to describe the abnormal bone metabolism in the setting of chronic renal failure and is a combination of the above effects of parathyroid hyperplasia but with abnormal low vitamin D levels with resultant osteomalacia. These patients will have increased serum phosphate levels, increased parathormone levels (PTH), and diminished dihydroxyvitamin D levels. The spectrum of renal osteodystrophy includes patients, where the hyperparathyroidism effects are predominant (high bone turnover disease) or osteomalacia effects are more prevalent (low bone turnover disease).

Renal osteodystrophy, when compared to primary hyperparathyroidism, shares a lot of the previously described radiographic findings of parathyroid hormone

mediated bone resorption. However, it may also show more soft-tissue calcification and osseous "sclerosis" secondary to the abnormal deposition of unmineralized osteoid seams in bone because of osteomalacia. In children, typical changes of rickets may be more prevalent. The "rugger jersey" radiographic appearance of the spine in adults is characteristic; there is excess mineralization of excess osteoid at the end plates and resorption of bone from the midportion of the vertebral body, resulting in a horizontal striped or bandlike appearance (hence the rugby jersey analogy) with dense endplates and a lucent central region. Patients with renal osteodystrophy can also demonstrate "Looser zones" and other manifestations of osteomalacia.

HYPOPARATHYROIDISM

Typically results from a deficiency of parathyroid hormone: usually postsurgical from resection of the parathyroid glands during thyroidectomy. These patients will typically have low serum calcium levels, increased serum phosphate levels, and normal renal function.

The imaging appearance is that of widespread osseous sclerosis. This must be distinguished from osteoblastic metastasis, Paget disease, fluorosis, and renal osteodystrophy. Manifestations in the skull include thickening of the calvarium, hypoplastic teeth with blunted roots, and intracranial calcifications, especially within the basal ganglia (these are also seen in pseudohypoparathyroidism [PHP]). Subcutaneous calcifications can be present as well. In the spine, there may be marked calcification of the longitudinal ligaments, which can mimic the appearance of diffuse idiopathic skeletal hyperostosis (DISH).

PSEUDO AND PSEUDO-PSEUDOHYPOPARATHYROIDISM

PHP is because of abnormal tissue receptors for parathyroid hormone. It is sometimes referred to as Albright's hereditary osteodystrophy. Like in patients with hypoparathyroidism, there will usually be serum hypocalcemia and hyperphosphatemia. The imaging findings in PHP are similar to hypoparathyroidism with marked osseous sclerosis and calcifications. These patients will also show other bony abnormalities like cone-shaped epiphyses, exostoses, and shortening of the metatarsal and metacarpal bones, predominantly the fourth. The latter is a nonspecific finding, which can also be encountered in patients with other disorders like Turner syndrome. Pseudo-pseudohypoparathyroidism

(PPHP) is the normocalcemic form; the two syndromes are otherwise indistinguishable.

RICKETS AND OSTEOMALACIA

Rickets and osteomalacia are encountered when there is impaired mineralization of otherwise normal osteoid matrix and a secondary excess of unmineralized osteoid develops. Rickets is basically the occurrence of osteomalacia in an immature skeleton with decreased mineralization of the growth plate. There are three main causes: nutritional, including vitamin D deficiency from any cause (lack of sunlight, drug side-effect, malabsorption, liver disease), vitamin D-resistant rickets (caused by renal tubular loss of phosphate and also seen in certain oncogenic osteomalacia syndromes), and renal osteodystrophy (secondary or “renal rickets”).

The most common imaging finding in a patient with rickets and osteomalacia is generalized osteopenia. Flared metaphyses with widened physal plates are characteristic of rickets and are most commonly encountered in knee radiographs as the distal femur and proximal tibia growth plates have some of the most rapid rates of bone growth in the child. When encountered in the infant rib costochondral junctions, it can lead to the development of *rachitic rosary*. There is secondary bowing of weakened long bones when chronically present. In older children, slipped capital femoral epiphysis can be seen. In adults with osteomalacia, Looser zones are characteristic insufficiency fractures that can occur bilaterally symmetrical in the proximal femurs concave sides, pubic rami, and scapula.

OTHER ENDOCRINE SYNDROMES

ACROMEGALY

Acromegaly is caused by excess human growth hormone (HGH) secretion, usually because of a pituitary adenoma, with secondary bone and soft-tissue growth. This leads to a direct hormonal stimulation of the growth plates and in the skeletally immature patient will present as pituitary gigantism. In the adult, this can lead to enlargement of the *acral* parts (hands, feet, mandible), which is the source of the term *acromegaly*. Fatigue/lethargy is the most common complaint. Proliferation of articular cartilage can lead to widening of joint spaces because of direct stimulation of chondrocytes by HGH and secondarily to osteoarthritis, when the thick cartilage prevents adequate chondrocyte nutrition. Imaging findings include increased thickness of the heel pad with greater than 21 mm thickness felt by some to be pathognomonic. In the hands,

there is marked prominence of the tufts of the terminal phalanges of the fingers and beaklike osteophytes arising from the metacarpal heads. In the spine, there is elongation and widening of the vertebral bodies and this is one of the causes of scalloping of the posterior margins of the vertebral bodies.

THYROID DISEASE

HYPERTHYROIDISM

Excess thyroid hormone secretion will result in both bone resorption and bone formation but bone resorption will be more evident in the patient. This may present as a secondary cause of osteoporosis with secondary insufficiency fractures. Some of the descriptions of hyperthyroid osteoporosis have specifically described cortical striations in the metacarpal bones. Thyroid acropachy in euthyroid patients has been observed after the successful treatment of hyperthyroidism but is also seen in patients with Graves disease and ophthalmopathy. It is polyostotic pattern with asymmetric periosteal new bone formation/thick, shaggy periostitis that can mimic hypertrophic osteoarthropathy. As opposed to hypertrophic osteoarthropathy, soft-tissue swelling and periostitis are mostly in the acral regions—hands and feet, and not in the long bones.

HYPOTHYROIDISM

Hypothyroidism in adults can be because of prior surgery or antithyroid medications as well as iodine deficiency. In children, it is associated with marked osseous deformities and delayed skeletal maturation. Imaging findings include epiphyseal deformities, with “fragmented” epiphyses in childhood. Absence of the epiphyses of the distal femur and proximal tibia in infant is also encountered. In the skull, wormian bones can be seen. Vertebral deformities, including bullet-shaped vertebrae and gibbus deformity, are seen in the spine. SCFE can occur, along with other hip deformities. In adults, only generalized osteopenia is seen.

CUSHING SYNDROME

Cushing syndrome results when there is excess corticosteroid. It may be endogenous from adrenal overproduction or exogenous (as in glucocorticoid therapy). Glucocorticoids can decrease calcium absorption, increase calcium secretion, and have direct effects on osteoblasts and osteoclasts. Endogenous causes include ACTH hypersecretion (Cushing disease) and adrenal hyperplasia. Ectopic ACTH secretion (small cell carcinoma of the lung, carcinoid tumors, etc.) can also be present. The

principal musculoskeletal manifestation will be secondary osteoporosis and/or osteonecrosis.

PAGET DISEASE

Paget disease is a disease of unknown, presumably viral, etiology that is characterized by abnormal remodeling of bone with secondary enlargement. It affects males slightly more commonly than females and is usually seen in patients older than 40 years of age. Paget disease is usually polyostotic but may be monostotic.

Although often asymptomatic and discovered incidentally, patients with Paget disease may have bone pain at sites of involvement. Bowing deformities of the long bones are typical and pathologic fractures are a known complication, as is deafness secondary to cranial nerve compression from an enlarging skull base or direct involvement of the middle ear ossicles. Most pagetic bone fractures heal normally. Spinal canal narrowing and nerve compression similarly is seen with vertebral or skull base involvement. Premature degenerative joint disease secondary to acquired articular incongruities may develop. Secondary osteosarcomas of bone are an unusual but dreaded complication. This should be evaluated for in the patient with long-standing disease and new pain or new focal areas of bone destruction or soft-tissue mass. MRI can be helpful in this setting to evaluate for marrow signal changes and soft-tissue extensions of secondary sarcomas.

There are usually three sequential radiographic stages, although they may coexist occasionally. The lytic phase is usually seen initially, with geographic lesions with well-demarcated borders that can be “flame-shaped” in the tubular bones. The intermediate stage is a mixed pattern between lytic and sclerotic areas, and, lastly, the sclerotic phase will show progressive enlargement and density of the bone.

The most common site of involvement is the lumbar spine. The so-called ivory vertebra appearance of a single sclerotic vertebral body can also be seen in osteoblastic metastatic disease and lymphoma. One important differentiating aspect of the vertebra affected by Paget disease as compared to other etiologies for ivory vertebra is the expansion in size typically present in Paget disease and not usually seen in metastatic disease. The pelvis is another common site of involvement. When present, cortical thickening of the iliopectineal line is very suggestive. In the skull, the initial round lytic phase is termed osteoporosis circumscripta and is very suggestive of Paget. As sclerotic foci appear with disease progression, these are described as “cotton-wool” spots. Basilar invagination can occur in up to one-third of patients. In the tubular bones, the initial lytic phase begins in the subarticular bone with an advancing “blade

of grass” border toward the diaphysis. The exception is the tibia, where the lytic phase may begin in the middle of the diaphysis. In more advanced stages, the bones will appear diffusely sclerotic and enlarged, with both trabecular and cortical thickening present.

QUESTIONS AND ANSWERS

- Which of the following is *not* a cause of secondary osteoporosis?
 - Postmenopausal
 - Hypogonadism
 - Bedrest
 - Malnutrition

ANSWER: A. Secondary osteoporosis is because of etiologies that are not related to menopause or aging. Postmenopausal osteoporosis is classified as primary osteoporosis, type I.

- How much bone loss is necessary to appreciate osteopenia on radiographs?
 - 10%
 - 20%–30%
 - 30%–50%
 - >75%

ANSWER: C. Bones appear lucent on radiographs with loss of cortical thickness as well as trabecula. This requires 30% to 50% bone mass loss to be detectable.

- According to the WHO classification, a person with a T-score of -2.4 is
 - Normal
 - Osteopenic
 - Severe osteopenic
 - Osteoporotic

ANSWER: B. *Osteopenic* (or low bone mass) is diagnosed on bone densitometry, when the BMD or BMC is between 1 and 2.5 SD below young adult mean (T-score between -1 and -2.5). There is no category labeled severe osteopenia.

4. What is the most common cause of primary hyperparathyroidism?
- Parathyroid hyperplasia
 - MEN type 2
 - Parathyroid carcinoma
 - Parathyroid adenoma

ANSWER: D. The excessive secretion of parathyroid hormone in primary hyperparathyroidism is secondary to a hyperfunctioning solitary parathyroid adenoma in approximately 80% of cases. In 10% to 20% of cases, it is secondary to a diffuse hyperplasia of the parathyroid glands and in less than 1% of cases, it is because of a parathyroid carcinoma. Although MEN syndrome type 2a is associated with parathyroid tumors and hyperparathyroidism (as well as pheochromocytoma and medullary thyroid carcinoma), it is not a common clinical occurrence.

5. Patients with primary hyperparathyroidism will typically have what findings in their blood work?
- Decreased parathyroid hormone levels
 - Increased serum phosphate levels
 - Decreased vitamin D levels
 - Increased urine phosphate

ANSWER: D. Hyperparathyroidism patients will have elevated parathyroid hormone levels and subsequent elevated serum calcium and decreased serum phosphorus levels. Parathyroid hormone increases the renal tubular excretion of phosphate.

6. Which findings are more commonly seen in secondary hyperparathyroidism when compared to primary hyperparathyroidism?
- Brown tumors
 - Chondrocalcinosis
 - Soft-tissue calcifications
 - Subperiosteal bone resorption

ANSWER: C. Brown tumors occur in both primary and secondary hyperparathyroidism but are more commonly encountered in primary hyperparathyroidism. Chondrocalcinosis is usually seen with primary hyperparathyroidism. Subperiosteal bone resorption is typically seen in both. Soft-tissue calcifications are usually seen in secondary hyperparathyroidism because of the increased calcium phosphate product leading to metastatic deposits.

7. The radiographic findings of hypoparathyroidism in the spine resemble what other disease process?
- DISH
 - Renal cell carcinoma metastases
 - Hypothyroidism
 - Rheumatoid arthritis

ANSWER: A. The imaging appearance of hypoparathyroidism is of widespread osseous sclerosis. This must be distinguished from osteoblastic metastasis, Paget disease, and renal osteodystrophy. Patients with renal cell carcinoma metastases typically have osteolytic lesions. Adult patients with hypothyroidism will typically show generalized osteopenia. Patients with rheumatoid arthritis will also show generalized osteopenia. In the spine there may be marked calcification of the longitudinal ligaments resembling DISH.

8. Which of the following is *not* associated with acromegaly?
- Fatigue
 - Thickness of the heel pad
 - Joint space widening
 - Acro-osteolysis

ANSWER: D. Acromegaly is associated with fatigue and increased joint space widening and thickness of the heel pads. In the hands, there is marked prominence of the tufts of the terminal phalanges of the fingers, which is the opposite of acro-osteolysis where there is loss of the tuft.

9. Absence of visualization of the epiphyses of the distal femur and proximal tibia in the infant is associated with which endocrine anomaly?
- Cushing disease
 - Acromegaly
 - Hyperparathyroidism
 - Hypothyroidism

ANSWER: D. Hypothyroidism in the infantile and childhood stages is associated with abnormal epiphyseal development, including fragmented epiphyses in the child and stippled or radiographically inapparent epiphyses in the infants.

10. The lytic phase of Paget disease can begin in the middiaphyses of which bone?
- Humerus
 - Radius
 - Tibia
 - Metacarpals

ANSWER: C. In the tubular bones, the initial lytic phase of Paget disease begins next to a joint in the subarticular bone with an advancing "blade of grass" border toward the diaphysis. The exception is the tibia, where the lytic phase may begin in the middle of the diaphysis.

75 HEMATOPOIETIC AND MISCELLANEOUS MUSCULOSKELETAL DISORDERS

*Bhavik N. Patel, Joshua P. Smith,
Matthew C. Larrison, and
Gregory S. Elliott*

HEMATOPOIETIC DISORDERS

Bone marrow is a key component of the hematopoietic system. Disorders of the hematopoietic system, therefore, often exhibit skeletal findings. There is considerable overlap in the appearance of these disorders in part owing to their similar compensatory mechanisms. For example, the “hair-on-end” appearance of the skull is classically discussed with relation to thalassemia and is caused by increased marrow production in the calvarium. However, this hair-on-end appearance is not specific to thalassemia and can be seen in sickle cell disease, hereditary spherocytosis, and Gaucher disease. In the following text, we discuss the most common disorders of the hematopoietic system, which exhibit radiologic findings.

SICKLE CELL DISEASE

Sickle cell trait occurs in approximately 7% of African Americans, and sickle cell anemia is estimated to occur in 0.3% to 1.3% of African Americans. Clinical presentation most commonly involves a painful “crisis” that can begin at age 2 to 3 years. One-third of patients present with dactylitis, or “hand-foot” syndrome. Dactylitis most commonly begins at ages 6 months to 2 years and is said to be a complication of small vessel occlusion. Non-musculoskeletal imaging findings include cholelithiasis (or evidence of cholecystectomy), cardiomegaly, splenomegaly (heterozygous disease), or autosplenectomy with dense, calcified spleen (homozygous disease). Musculoskeletal imaging findings relate to complications of marrow hyperplasia, bone infarction, infection, and complications of treatment. Patients with sickle cell disease are prone to develop osteomyelitis, classically associated with *Salmonella*, but more commonly caused by staphylococci.

Radiographic findings include marrow hyperplasia in the skull that yields thickening of the diploic space with thin inner and outer tables. The “hair-on-end” periosteal new bone formation is more often seen with thalassemia. “Lincoln-log” or “H-type” vertebral bodies

describe the shape of vertebral bodies as demonstrated in the lateral view. Osteonecrosis of the epiphyses is more common in adults than in children and is most commonly seen in the proximal humerus and femur. A bone-within-bone appearance of the long bone diaphyses is caused by diaphyseal infarction. Occasionally, patchy or diffuse osteosclerosis will result from advanced medullary infarction. Osteomyelitis is most common in the long bones and can yield bone abscesses, involucrum formation, and cortical sequestrations.

THALASSEMIA

This group of disorders shares an inherited globin production abnormality. Thalassemia major is the term for the homozygous form and thalassemia minor is the term for the heterozygous form. The major form is significantly more severe. It is most common (and originally described) in those of Mediterranean descent but has been reported in many different populations. Radiographic findings most commonly relate to marrow hyperplasia, but this disorder can also cause growth disturbance as well as pathologic fractures. A “hair-on-end” appearance of the skull is caused by marrow hyperplasia and osseous proliferation of the outer table. Marrow expansion creates an Erlenmeyer flask appearance of the distal femurs, most common in thalassemia. Obliteration of the paranasal sinuses and abnormal facies can result from expansion of the temporal and nasal bones in a child. Marrow hyperplasia leads to diffuse osseous expansion, cortical thinning, and osteopenia. Extramedullary hematopoiesis produces paravertebral, posterior mediastinal, retroperitoneal, and pelvic masses. Osteonecrosis is less common than in sickle cell disease.

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis is an autosomal dominant, inherited disease, most commonly found in those of Northern European descent. Spectrin deficiency causes spherocyte formation, which are trapped in the microcirculation of the spleen, and presents with jaundice and splenomegaly. Radiographic and MR findings are nonspecific showing only bone marrow hyperplasia. Diploic spaces are widened with thinning of the outer table of the cortex.

FANCONI ANEMIA/THROMBOCYTOPENIA ABSENT RADIUS

These two syndromes are often categorized together radiographically as both present with absence or

hypoplasia of the radius. Fanconi anemia is characterized by anemia, congenital anomalies, and brown pigmentation. Thrombocytopenia absent radius (TAR) consists of thrombocytopenia and often results in hemorrhage and more severe skeletal anomalies. TAR often has an earlier presentation (first few months of life) as compared with Fanconi anemia (age 5–10 years). Radiographic appearance of Fanconi anemia includes anomalies of the radius and radial side of the hand ranging from hypoplasia to absence. It is also associated with short stature, developmental hip dysplasia, and renal abnormalities. TAR exhibits bilateral absence of the radius often with hypoplastic ulnae. Absent or small thumbs in Fanconi anemia help differentiate it from TAR. Holt-Oram is a genetic disease that can also present with an absent or small radius.

MYELOFIBROSIS

Marrow replacement by fibrotic tissue is usually diagnosed in the middle-aged to elderly population. This idiopathic condition generally has a poor prognosis. Fibrosis of the bone marrow begins in the locations of active hematopoiesis in adults (spine, pelvis). Compensatory marrow hematopoiesis is then found in the long bones or extramedullary location, but long bones eventually exhibit medullary fibrosis as well. Radiographic findings include osteosclerosis in the axial skeleton and proximal long bones. Prior to osteosclerosis, osteoporosis is demonstrated. Extramedullary hematopoiesis can yield splenomegaly and paraspinal masses. On bone scintigraphy, the resulting diffuse skeletal uptake is one of the causes of a “superscan.”

MISCELLANEOUS DISORDERS

PYKNODYSTOSIS

Pyknodysostosis is a congenital disorder of osteoclast activity which results in deficient bone resorption. Sclerosis of long bones with transverse fractures is also seen. Phenotypically, there are short statures (vertebral segmentation anomalies), shortened hands, and hypoplastic nails. Hypoplasia or aplasia of the distal tufts can also be seen.

OSTEOPOIKILOSIS

Osteopoikilosis is an autosomal dominant, asymptomatic disorder that results in multiple sclerotic foci throughout the skeleton, predominately in a periarticular

distribution in long bones, but also involving the hands, feet, scapula, and pelvis. The sclerotic foci are small, typically well circumscribed, round, or ovoid lesions, somewhat symmetrically distributed. Symmetric distribution helps differentiate it from other disease processes, such as tuberos sclerososis, mastocytosis, or osteoblastic metastases. The lesions may involute or grow on serial radiographs, but do not demonstrate uptake increase on MDP bone scans. They are pathologically similar to bone islands or enostoses. Like bone islands, they can also have thorny spiculations that blend into the surrounding trabeculae. This disorder has been associated with other sclerosing diseases such as melorheostosis.

MELORHEOSTOSIS

Melorheostosis is another sclerosing disease that results in cortical thickening of the long bones, described as “wavy hyperostosis.” Cortical expansion can encroach on the medullary cavity and has a characteristic description of “dripping candle wax” on radiography. This often affects only one side of the bone, involving the periosteum as well as endosteum. The disease can be painful, resulting in contracture, deformities, limb shortening, and circulatory problems. It typically affects a single limb or ray, usually in the lower extremity. This can be associated with other sclerosing diseases such as osteopoikilosis or osteopetrosis. Periarticular soft-tissue calcifications can be seen. Unlike osteopoikilosis, this entity can demonstrate increased uptake on MDP bone scintigraphy.

TARSAL COALITIONS

Tarsal coalitions are ankylosis of the tarsal bones which are most commonly congenital, but can be secondary to trauma/surgery/inflammatory arthropathy. Tarsal coalitions can be osseous, cartilaginous, or fibrous. Classically, the incidence is 1%, though may be more prevalent as many cases go undetected. Bilateral lesions are seen in about 25% to 50% of the cases. Coalitions are more common in males.

Coalition occurs most commonly at the talocalcaneal joint than at the calcaneonavicular joint. These are both greater in frequency than talonavicular, calcaneocuboid, and cubonavicular locations.

The first two entities comprise greater than 90% of all cases, with calcaneonavicular being the most likely to be bilateral. There is a familial inheritance pattern, and the disease can be associated with rare musculoskeletal conditions.

Clinically, patients in their second decade present with painful flatfoot in their second decade. Peroneal spasm may accompany the disorder. Talocalcaneal coalition is typically the most symptomatic. Radiographically, the coalitions can be bony, cartilaginous, or fibrous. Talocalcaneal coalition shows dorsal and anterior osteophyte of the talus at the talonavicular joint (“breaking”) (differential diagnosis includes diffuse idiopathic skeletal hyperostosis and rheumatoid arthritis) and the “C-sign,” where there is continuity between the posterior talus and the calcaneus (sustentaculum tali), forming a C-shape. Radiography is sensitive, but CT is better for talocalcaneal coalitions, especially in cartilaginous or fibrous unions. The coalition most commonly involves the middle facet of the joint. Calcaneonavicular coalitions demonstrate the “anteater sign,” where the anterior process of the calcaneus is elongated and is best seen on 45-degree internal oblique radiographs. Bone scintigraphy can be positive at the joints adjacent to the coalitions, as they are subjected to abnormal forces, as well as at the site of coalition itself. MR and/or joint arthrography is used in cases of nonosseous union.

MADELUNG DEFORMITY

The Madelung deformity is a disorder of growth disturbance (though other etiologies often lead to a similar appearance) of the distal radius. The volar and ulnar tilt of the radius causes the wrist and hand translate to volarly, with a protuberant ulna dorsally at the wrist.

The etiologies are many and the resultant differential diagnoses are numerous (Tables 75-1 and 75-2). Madelung deformity is seen more often in females, in part because of the association with Turner syndrome.

PROXIMAL FEMORAL FOCAL DEFICIENCY

This deficiency is a rare, sporadic, congenital, developmental defect (also having association with toxins, particularly thalidomide), and this disease is characterized by complete or partial agenesis of the proximal femur. This results in obvious deformity, with the distal femur normally formed. There are various degrees of severity, and the most mild form is characterized by nonossified cartilage in the proximal femur persisting long past nor-

TABLE 75-2 Differential Diagnosis of Madelung Deformity

Enchondromatosis
Multiple hereditary osteochondrous
Mucopolysaccharidoses
Achondroplasia
Dyschondrosteosis (Leri-Weill disease: autosomal dominant, varying penetrance, short-limbed mesomelic dwarf. Involves proximal radius, unlike Madelung deformity)

mal, but eventually self-healing through ossification. For this reason, MRI may be the best modality to evaluate this disorder. A dysplastic acetabulum suggests worsening severity, and the shortened femur may pseudoarticulate with the pelvis. The proximal musculature is often normal contributing to the mechanical problems. Despite the name, the abnormality is often associated with other defects in the same limb and can be bilateral in a minority of cases. Treatment consists of a leg-lengthening procedure for mild cases and amputation for more severe cases. A Van Ness rotationplasty can be performed, where the lower leg is rotated 180 degrees and the ankle joint acts as a functional knee. The appearance is fairly pathognomonic, though the mild form could be confused with infantile coxa vara, where the femoral neck angle is less than 120 degrees.

MUCOPOLYSACCHARIDOSES

These autosomal, recessive disorders (Hunter syndrome is the only exception and is X-linked) are a phenotypically heterogeneous group that share a common biochemical abnormality: the inability to break down glycosaminoglycans, found many places throughout the body, but notably in synovial fluid, bones, connective tissue, and tendons. The incomplete breakdown products accumulate in lysosomes, resulting in cellular dysfunction; thus, these are classified as lysosomal storage disorders. Any one of eleven enzymes may be deficient, resulting in different manifestations. The most common are types I, II, II, IV, and VII or Hurler, Hunter, Sanfilippo, Morquio, and Sly syndromes, respectively.

All these diseases have similar manifestation but differ in acuity. Hydrocephalus and mental retardation are often seen, except in Morquio syndrome, where the patients are neurologically normal. Peripheral nerve root compression, corneal abnormalities, and hearing loss are common phenotypic features. Phenotypic appearance includes coarse facial features, coxa vara, hypoplastic odontoid, oar-shaped ribs, and shortened long bones.

TABLE 75-1 Classification of Madelung Deformity

Posttraumatic
Dysplastic
Genetic (Turner syndrome)
Primary (Idiopathic)

SARCOID

Sarcoid is a systemic, immune disorder affecting various organ systems, including the musculoskeletal system. Its exact cause is unknown, and it commonly affects young and middle-aged patients with a higher predilection for African Americans. Diagnosis is made by clinical, radiologic, and histologic findings.

Musculoskeletal involvement of sarcoid is seen with generalized disease. Joint involvement is more common, and rare involvement of muscles and bones typically indicates a prolonged or chronic disease state. Involvement of joints, most commonly knees, ankles, elbows, proximal interphalangeal joints, and wrists, usually presents as inflammatory arthralgia. Articular involvement may manifest as an acute or chronic polyarthritis. Arthralgia in the acute pattern is a result of the effects of inflammatory cytokines on the joints and not as a result of granulomatous change. Tenosynovitis and joint effusion may be detected on ultrasonography. Acute polyarthritis with periarticular ankle joint involvement can be seen as a part of Löfgren syndrome, along with mediastinal lymphadenopathy and erythema nodosum. Granulomatous arthritis with synovitis leading to irreversible joint damage may be seen in the chronic pattern. Acute and chronic sarcoid arthropathy is largely a clinical diagnosis as radiologic evidence of joint involvement is rarely seen.

Skeletal muscle involvement may be of the myopathic or nodular type. Myopathic types have nonspecific findings of symmetric proximal muscle atrophy with fat replacement. They may show hyperintensity on T2-weighted MRI. Sarcoid nodules usually manifest as multiple, bilateral focal intramuscular masses commonly in the lower extremities. They have a characteristic “dark star” appearance on MRI as the central fibrosis appears hypointense on all sequences and the peripheral area of granuloma appears hyperintense on T2-weighted images.

Lesions involving the skeleton are multiple and commonly seen in the hands and feet. Nuclear scintigraphic findings are positive and often precede radiographic manifestations. A combination of cystlike radiolucencies, lacelike honeycomb appearance, bony lytic lesions, and tenosynovitis is diagnostic.

RADIATION-INDUCED INJURY

Radiation-induced injury to the bone may occur as a result of radiation therapy to a metastatic bone lesion or secondarily from inclusion in a radiation field for treatment of adjacent cancer. Radiation effects on the bone include growth arrest, scoliosis, osteonecrosis, and neoplasm formation.

Direct chondrocyte injury and injury to the physal blood vessels from radiation can lead to growth arrest. The epiphysis is the most sensitive to radiation effects, with growth disturbances seen with a total of 20 Gy; the diaphysis, however, is more resistant. Damage to the epiphysis may increase the risk of plate trauma and slipped capital femoral epiphysis. Injury to the metaphysis may lead to bowing, fraying, and sclerosis. When an entire bone is exposed, shaft narrowing and decrease in size can be seen. In a mature skeleton, growth disturbance is seen in the form of osteonecrosis. The necrosis is dose-dependent with radiation osteitis seen at 30 Gy and necrosis at 50 Gy.

Scoliosis from radiation can be seen in the growing spine, especially in children younger than 2 years of age. More frequent and severe deformities have been associated with asymmetric radiation with changes seen with a total of 10 Gy.

Tumor formation can also manifest secondary to radiation administration. Benign tumors are usually seen if the exposure was prior to 2 years of age, whereas in adults, tumors are likely to be malignant. Osteochondromas are the most common tumors in the pediatric population, while osteosarcoma and fibrosarcoma are seen in adults from radiation exposure.

SCOLIOSIS

Scoliosis is marked by lateral curvature of the spine and vertebral rotation. There are several etiologies of scoliosis (Table 75-3). Approximately 80% of scoliosis cases are of the idiopathic type.

Anteroposterior (AP) and lateral views of the entire spine should be obtained in evaluating for scoliosis. Scoliotic curve is assessed in the anteroposterior view. The most common method of assessment is the Cobb method. First, the type of curvature (thoracic, thoracolumbar, lumbar, major double curve) should be noted followed by the presence of any anomalies and spondylolisthesis or spondylolysis.

NEUROFIBROMATOSIS

Neurofibromatosis 1 (NF1), also known as von Recklinghausen disease, is part of the phakomatosis or neurocutaneous syndromes. It is a result of a defect in

TABLE 75-3 Etiologies of Scoliosis

Nonstructural	Postural, compensatory
Transient	Sciatic, hysterical, inflammatory
Structural	Congenital, neuromuscular, neurofibromatosis, mesenchymal disorders, trauma

chromosome 17 and carries an autosomal dominant pattern of inheritance. Specific findings of NF1 involving the musculoskeletal system include sphenoid dysplasia known as the empty orbit sign, pseudarthrosis, ribbon rib deformity, and bowing of long bones. Radiologic findings of NF1 involving the spine include thoracic kyphoscoliosis, vertebral scalloping, enlarged neural foramina, and a lateral thoracic meningocele.

MARFAN SYNDROME

A connective tissue disorder affecting both sexes, Marfan syndrome is commonly seen in athletes with the classic habitus of tall stature, long extremities, and tapered phalanges. It is an autosomal dominant, inherited disorder; however, sporadic mutations have been reported. It affects many organ systems including ocular, cardiovascular, skeletal, pulmonary, central nervous, dermatologic, and musculoskeletal.

Skeletal abnormalities include tall stature, arachnodactyly, hyperextension, scoliosis, pectus deformity, and osteopenia. Hypermobility and subluxation leading to joint deformity, premature arthritis, asymmetric bone growth, arm span greater than for height, and decreased ratio of upper body segment to lower body segment size can also be seen.

Scoliosis is frequently seen in over one-half of patients, with the right thoracic or major double curve being the most common types of curvature. Unlike idiopathic scoliosis, scoliosis in Marfan syndrome can be seen in both sexes and is typically more severe and progressive, often requiring surgery. Scoliosis and straight back can contribute to cardiopulmonary compromise. Dural ectasia can lead to posterior vertebral body scalloping. Many patients have a widened lumbosacral canal with thinned lamina, pedicles, and erosion of the foramina leading to neurologic symptoms. Over two-thirds of Marfan patients have chest wall deformities with pectus excavatum or carinatum from longitudinal overgrowth of ribs. Severe pectus deformity with or without scoliosis can lead to pulmonary function compromise.

EHLERS-DANLOS SYNDROME

Ehlers-Danlos syndrome consists of a group of inherited disorders in which there is a defect in the structure, production, or processing of collagen or defect in the proteins associated with collagen. Symptoms vary from mild-to-severe and result in weakened connective tissue in the skin, bones, blood vessels, and various organs resulting in the clinical presentation of the disorder.

TABLE 75-4 Osteogenesis Imperfecta

TYPE	FEATURES
I	A mild form in which collagen is of normal quality but insufficient in quantity. Findings include blue-gray sclera, loose joints, fragile bones, and early hearing loss
II	Severe form with insufficient quality and quantity and not compatible with life
III	Quantity of collagen is sufficient but the quality is not leading to bone fractures, deformities, short stature, discolored sclera, loose joints, and hearing loss
IV	Similar to type III but without the progressive nature, discolored sclera, and is less severe
V	Similar clinical features as type IV but has a meshlike appearance of bone on histology. Classic triad consists of exuberant callus, radiopaque band adjacent to growth plates, and radioulnar interosseous membrane calcification
VI	Similar clinical features as type IV but has a fish scale appearance of bone on histology
VII	Involves cartilage associated protein
VIII	Associated with the protein leprecan

The most common type is the hypermobility type. The main clinical manifestation is joint hypermobility. Radiologic findings include soft-tissue calcification in the extremities and periarticular regions, recurrent joint or bursal effusions, knee osteoarthritis with chondrocalcinosis, kyphoscoliosis, spondylolysis, spondylolisthesis, and joint malalignment, subluxation, and dislocation.

OSTEOGENESIS IMPERFECTA

Also known as brittle bone disease, osteogenesis imperfecta (OI) is a connective tissue disorder with an autosomal dominant inheritance. The disorder is characterized by inability to produce collagen or production of improper collagen affecting the skeleton, ligaments, skin, and the sclera. There are eight types with type I being the most common (Table 75-4). Short stature may be seen as a result of defective collagen synthesis as well as a result of fractures. Osteopenia is a common radiographic finding along with fractures and deformity as a result of fractures. Multiple fractures in different stages of healing may be seen, and thus child abuse must be excluded. Classic features of OI are blue sclera, fragile bones, Wormian skull bones, and odontogenesis imperfecta.

OSTEOPETROSIS

Also known as marble bone or Albers-Schonberg disease, osteopetrosis is a rare, inherited disorder resulting from defective osteoclastic activity. Findings include dense but brittle bones, stunted growth, pancytopenia, neural foramina stenosis, and deafness. Three clinical

forms exist: benign type (autosomal dominant), malignant type (autosomal recessive), and carbonic anhydrase II deficiency (type III RTA).

SUGGESTED READINGS

- Ejindu V et al. Musculoskeletal manifestations of sickle cell disease. *Radiographics*. 2007;27:1005-1021.

- Newman J, Newberg A. Congenital tarsal coalition: multimodality evaluation with emphasis on CT and MR. *Radiographics*. 2000;20:321-332.

QUESTIONS AND ANSWERS

- What is the most commonly symptomatic tarsal coalition?
 - Calcaneonavicular
 - Talocalcaneal
 - Talonavicular
 - Calcaneocuboid
 - Cubonavicular

ANSWER: B. Talocalcaneal coalitions are the most commonly painful tarsal coalition, though there is some debate as to which is the most common overall, with different sources citing calcaneonavicular versus talocalcaneal. At any rate, these two are much more common than the other rare choices.

- Acro-osteolysis, sclerotic bone changes, and transverse fracture of long bones are identified in a patient. What is the most likely diagnosis?
 - Thermal injury
 - Reflex sympathetic dystrophy
 - Pyknodysostosis
 - Psoriasis
 - Scleroderma

ANSWER: C. Acro-osteolysis is seen in all of the above, but transverse fractures of the bone as well as sclerotic bone changes are seen only in pyknodysostosis, reflecting abnormality of the bone matrix itself.

- Basilar invagination is seen in all of the following *except*:
 - Chiari I malformation
 - Osteogenesis imperfecta
 - Osteopetrosis

- Achondroplasia
- Rickets

ANSWER: C. All of the above can be associated with basilar invagination except osteopetrosis. Sclerosis of the skull base is seen osteopetrosis.

- Posterior scalloping of a vertebral body can be seen in which of the following?
 - Pyknodysostosis
 - Marfan syndrome
 - Osteopetrosis
 - Rare association with tarsal coalition
 - Scoliosis

ANSWER: B. Posterior vertebral body scalloping can be seen in syndromes associated with dural ectasia such as neurofibromatosis, Marfan and Ehlers-Danlos syndromes. Other abnormalities can cause the finding, such as a syrinx or a spinal canal tumor. Congenital disorders associated with this include achondroplasia, the mucopolysaccharidoses, osteogenesis imperfecta, and acromegaly.

- What is the etiology of osteogenesis imperfecta?
 - Inability to properly precipitate hydroxyapatite
 - Delayed enchondral ossification
 - Defect in collagen synthesis
 - Deficient cartilage production

ANSWER: C. The root cause of OI is a defect in type I collagen formation.

- What is the etiology of the chest wall deformity in Marfan syndrome?
 - Rib overgrowth
 - Defect in cartilage production
 - Underlying pulmonary defect
 - Hyperlaxity of joints

ANSWER: A. The chest wall deformity, pectus excavatum, or carinatum is secondary to rib overgrowth. Although these patients have joint hypermobility, this does not contribute to the chest deformity.

- Findings associated with NF1 include all of the following *except*:
 - Sphenoid dysplasia
 - Pseudarthroses
 - Ribbon rib deformity
 - Bowing of long bones with Looser lines

ANSWER: D. While bowing of the long bones can be seen in NF1, Looser lines are not seen and are more commonly associated with rickets. The other findings are commonly associated with NF1.

8. What organism is most commonly implicated in osteomyelitis in patients with sickle cell disease?

A. *Staphylococcus*
B. *Salmonella*
C. *Enterobacter*
D. *Streptococcus*

ANSWER: A. Though *Salmonella* osteomyelitis is more commonly seen in sickle cell disease patients than in the general population, *Staphylococcus* remains the most common etiology.

9. You are presented with a 5-year-old male child with short stature and radiographs revealing an absent radius and thumb. What is the most likely diagnosis?

A. Thrombocytopenia absent radius (TAR)
B. Holt-Oram
C. Fanconi anemia
D. Ellis-van Creveld

ANSWER: C. TAR typically has normal thumbs. Additionally, TAR would typically present at a younger age. Ellis-van Creveld is a syndrome characterized by thoracic dysplasia and death in infancy in 50%.

10. The “hair-on-end” appearance of the calvarium has been reported to occur in all the following *except*:

A. Sickle cell disease
B. Thalassemia
C. Myelofibrosis
D. Gaucher disease

ANSWER: C. The “hair-on-end” calvarium is not a specific sign. It is most severe and commonly reported with thalassemia. However, it is also associated with sickle cell disease and Gaucher’s disease.

76 BREAST ANATOMY AND IMAGING MODALITIES

*Heidi R. Umphrey, Cheryl R. Herman,
and David E. Hogg*

BREAST ANATOMY

The breasts are located within the superficial fascia of the chest wall. The deep layer of the superficial fascia lies on the posterior surface of the breast parenchyma and rests upon the pectoral fascia of the chest wall that overlies the pectoralis major muscle. There is a distinct space between the deep layer of the superficial fascia and the pectoral fascia, termed the retromammary bursa that contributes to the mobility of the breast. Cords of fibrous connective tissue (Cooper ligaments) extend between the deep layer of the superficial fascia and the dermis of the skin.

The breasts are highly modified apocrine sweat glands, derived from ectodermal elements that develop along embryological lines termed the “milk lines,” which extend from the axillary region to the groin. Failure of regression can lead to the development of accessory breast tissue termed polymastia or accessory nipples known as polythelia. Absence of mammary glands is termed amastia. Each breast is composed of 15 to 25 independent secretory units, lobes, which are arranged in a radial pattern around the nipple. The lobes are embedded in adipose tissue that is incompletely subdivided by collagenous septae. A lobe is composed of a main duct system and terminal duct lobular units. Each lobe drains via a main lactiferous duct that has an opening at the nipple and measures 2.0 to 4.5 mm. Just proximal to the opening at the nipple, each main lactiferous duct contains a dilated portion in the subareolar region called a lactiferous sinus. The main lactiferous ducts branch dichotomously eventually forming terminal duct lobular units.

The normal terminal duct lobular unit (TDLU) ranges from 1 to 4 mm in diameter and is composed of an extralobular terminal duct and associated lobule (Fig. 76-1). The extralobular terminal duct is lined by low columnar epithelium with an outer layer of myoepithelial cells and a distinguishing coat of elastic fibers. A lobule is composed of an intralobular terminal duct and ductules (acini). The intralobular terminal duct is lined by a layer of cuboidal epithelium and by an outer layer of myoepithelial cells without surrounding elastic fibers. Ductules are composed of a single layer of cuboidal epithelium with discontinuously interspersed myoepithelial cells. A continuous basement membrane supports the entire glandular epithelium. The lobules are surrounded by intralobular connective tissue. There is cyclic proliferation of TDLU during reproductive age prior to ovulation and cyclic involution during menstruation. TDLU show regression with fatty replacement after menopause. The distinction between the TDLU and larger duct system is essential for understanding breast pathology. The TDLU is the site of origin for ductal carcinoma in situ (DCIS), lobular carcinoma in situ (LCIS), infiltrating ductal carcinoma (IDC), infiltrating lobular

FIG. 76-1 Terminal duct lobular unit (TDLU).

carcinoma (ILC), components of fibrocystic change (microcysts, apocrine metaplasia, adenosis, and epitheliosis), and cysts. The main lactiferous duct and its branches are the origin for intraductal papillomas, papillary neoplasms, and duct ectasia.

BREAST IMAGING MODALITIES

MAMMOGRAPHY

Mammography is primarily a screening tool and will be discussed in detail in the chapter to follow; however, mammographic views in addition to the routine screening views, mediolateral oblique (MLO), and craniocaudal (CC) views have a role in diagnostic imaging. Additional views are obtained to localize a lesion, to characterize a lesion, or to confirm or exclude the presence of a lesion. The location of a lesion is described in a clock-face manner as if the observer is standing in front of the patient (Fig. 76-2).

The straight lateral view is a 90-degree lateral view that can be performed in lateromedial or mediolateral positioning. The location of the lesion is essential when determining a particular view. For example, a lateral lesion would be imaged in the mediolateral view since the lesion would be in closest proximity to the image receptor (film) on this view with compression from the medial aspect. If a lesion is seen on the MLO view only, a true lateral view may be beneficial in triangulating the lesion. A medial lesion moves superiorly on a true lateral view when compared to the MLO view. A lateral lesion moves inferiorly on a true lateral view when compared to the MLO view.

The axillary tail view also known as the Cleopatra view or XCCL view shows the axillary tail (the tail of Spence) of the breast. A cleavage view is a modified CC view that improves visualization of medial and posterior breast tissue.

FIG. 76-2 Breast lesions are described in a clock-face manner. The lateral left breast is at the 3-o' clock position and the lateral right breast is at the 9-o' clock position.

Spot compression views maximally compress and immobilize an area of interest; this minimizes superimposition and geometric blurring. It is important to ensure that the area of interest is included in the field of view. Indications for spot compression views include evaluation of questionable mammographic densities, evaluation of masses, inclusion of tissue excluded from routine screening, correction of technical issues, and localizations.

Magnification views are obtained by moving the breast away from the image receptor, thereby increasing object to image receptor distance by generating an air gap. Grids are not utilized because scatter radiation is eliminated in the air gap. As the object to image receptor distance increases, the magnification factor increases. A magnification factor of $1.5\times$ to $1.8\times$ is common. Magnification is associated with a loss of resolution from the increasing penumbra effect, but this is overcome to a certain degree by utilizing a small focal spot of 0.1 mm. However, a small focal spot increases exposure time, and this may lead to increased motion artifact. Exposure may be increased to decrease exposure time. Indications for magnification views include evaluation of masses, evaluation of calcifications, evaluation of architectural distortion, ductography, and specimen imaging.

Rolled views are performed with lateral or medial rotation of the breast and are helpful in establishing the presence of a lesion or determining the location of a lesion. Rolled views can be utilized to move a lesion away from surrounding glandular tissue to allow for better evaluation. Additionally, rolled views may provide localization information if a lesion is seen only in one view. For example, if a lesion is seen only in the CC view and the superior breast is rotated medially with the inferior breast rotated laterally, a superior breast lesion will move medially as opposed to an inferior lesion which would move laterally. Central breast lesions do not move significantly on rolled views.

Tangential views can be helpful in the evaluation of palpable masses, postsurgical changes, postradiation therapy changes, and in the localization of lesions or calcifications to the skin.

BREAST ULTRASOUND

Sonography is a valuable tool in further characterization of mammographic lesions, clinically palpable breast abnormalities, or for guidance during interventional procedures. Minimal equipment requirements include a linear array transducer with a center frequency of 7.5 MHz and broad bandwidth. Higher frequency transducers are becoming more routinely used, resulting in increased

near-field resolution. A stand-off pad may also increase visualization of superficial structures in the breast. When scanning, the patient should be in the supine, posterior oblique, or lateral decubitus position with the ipsilateral arm raised above the head for optimal visualization. Findings should be evaluated in two orthogonal planes. Color Doppler imaging can be helpful in assessing lesion vascularity and in evaluating the course of surrounding blood vessels for interventional planning. The use of the vocal fremitus technique may also aid in distinguishing true masses from hypoechoic fat lobules. Sonographic images should be labeled in a consistent manner and must include the patient's name, breast laterality, the clock-face position, scan plane (radial, antiradial, transverse, longitudinal), and the distance of the lesion from the nipple. When lesions are present, images with and without measuring calipers are necessary.

A sonographic examination of breast tissue should demonstrate a thin echogenic skin layer (1–2 mm). Fat lobules are hypoechoic, however, fat in the hila of lymph nodes is echogenic. Fibroglandular tissue is hyperechoic with ducts appearing as hypoechoic cylinders or round structures (depending on scanning plane) and Cooper ligaments as echogenic lines. The deep pectoral fascia is a thick echogenic line that separates the breast from the chest wall. Ribs appear as oval or thick linear shadowing hypoechoic structures in the deep portion of the image. The pectoral muscle appears hypoechoic with parallel echogenic lines.

Benign sonographic characteristics include round or oval shapes with thin, well-defined echogenic margins. Benign lesions are anechoic or homogeneously hyperechoic and may have posterior acoustic enhancement. Malignant characteristics include spiculated margins, taller than wide, angular margins, posterior acoustic shadowing, branching pattern, hypoechogenicity, calcifications, duct extension, and microlobulation.

Current indications for breast ultrasound are (1) assessment of palpable mass, (2) assessment of mammographic mass or density, (3) initial evaluation in symptomatic women 30 years or younger, (4) guidance for interventional procedures, and (5) evaluation of the postoperative breast (including implant assessment). A targeted ultrasound examination is performed after palpation of the area. The lesion can be fixed between two fingers to ensure that a palpated lesion correlates with the ultrasound examination. In young patients, an ultrasound examination is performed initially. However, if there is a suspicious finding or no corresponding sonographic finding, a mammogram may be performed as suspicious microcalcifications and subtle areas of architectural distortion may be detected mammographically. Implant rupture may be identified sonographically and will be further discussed in Chapter 81.

Ultrasound has been proven to be a useful adjunct to mammography especially in the high-risk population. The use of ultrasound as a screening tool is still being investigated. Sensitivities for the detection of nonpalpable cancers are increased from 68% with mammography alone to 88% with the addition of sonography in breast tissue of all densities. Cancers detected by ultrasound examination alone have been shown to be similar in size to small (approximately 1 cm) cancers found mammographically.

MAGNETIC RESONANCE IMAGING OF THE BREAST

Magnetic resonance imaging (MRI) of the breast is performed with a 1.5 Tesla magnet, utilizing a dedicated breast coil. The patient is placed in the prone position with the breasts suspended in the coil. Generally, a diagnostic protocol includes a localization sequence; a T1-weighted sequence, which is valuable in evaluating breast and axillary anatomy; a T2-weighted fat-saturated sequence, which is used for characterization of lesions; and postcontrast dynamic imaging, which is used in calculating the signal intensity curves and evaluating lesion enhancement. Two-dimensional (2D) and three-dimensional (3D) imaging has been utilized. The 2D technique acquires images slice by slice, where 3D imaging acquires a tissue volume that provides high resolution with thin slice thickness and allows for manipulation of images into any plane. Postprocessing can include a subtraction series that serves as an additional fat suppression tool. Maximum intensity projection (MIP) images can help localize lesions within the breast and illustrate their relationship to the skin, nipple, and chest wall. Both the morphology and kinetic curves of lesion enhancement are important features in interpretation. Kinetic analysis observes the immediate uptake of contrast within the lesion and the postcontrast phase. Rapid initial uptake, as compared to surrounding normal breast tissue, with plateau or washout of contrast in the late phase suggests a vascular malignant lesion. A slower initial uptake of contrast with a persistent increase in contrast signal suggests a benign process. Morphologic analysis of lesions by MRI is essential for diagnosis including shape, margins, and distribution. Lesions that are round or oval with smooth margins and homogeneous enhancement tend to be benign. An irregular, spiculated mass with heterogeneous, rim or central enhancement or enhancing internal septations is likely malignant. Ductal involvement may be inferred by linear, ductal, or segmental enhancement patterns. Evaluation of

the nipple, skin, pectoral muscle, chest wall, lymph nodes, and visualized lung fields completes the interpretation.

Indications for breast MRI include screening high-risk patients, assessment of extent of ipsilateral disease in newly diagnosed breast cancer patients, assessment of chest wall or pectoralis muscle involvement, evaluation of the contralateral breast, surveillance for residual/recurrent disease after breast conservation surgery, evaluation of response to chemotherapy, further evaluation of mammographic or palpable abnormality, evaluation of axillary carcinoma with unknown primary, and assessment of silicone implant integrity.

A typical imaging protocol for silicone implant rupture would include a localizer sequence, T2-weighted sequence in sagittal and axial planes, and a “silicone bright” STIR with water saturation sequence.

IMAGE-GUIDED BREAST PROCEDURES

CYST ASPIRATION

The indications for cyst aspiration include symptomatic cysts and complex or complicated cysts. Under ultrasound guidance after prep and drape, a needle (22 or 20 gauge) is inserted through the skin adjacent to the transducer and its tip is placed in the center of the cyst. The cyst contents are aspirated. For simple cysts, if they aspirate completely, the fluid may be discarded. Simple cyst fluid may appear straw-colored, yellow, blue, or black. In cases of complex or complicated cysts, bloody aspirate, incomplete aspiration, or intramural nodule, the aspirate is sent for cytology analysis and a core biopsy is obtained from any residual solid component identified. After aspiration, a small bandage may be placed over the entry site and the patient may leave the department without any activity restrictions. Postprocedure complications include pain and bruising. Breast abscesses may also be aspirated if there is poor response to antibiotic therapy and a bacterial culture may provide assistance in selection of antimicrobial therapy or provide acute symptomatic relief. A larger gauge needle may be required (12–14 gauge).

ULTRASOUND CORE NEEDLE BIOPSY

Ultrasound-guided core needle biopsy is a safe, simple, and effective means of sampling any suspicious lesion demonstrable by ultrasound. After ultrasound localization of the lesion, the area is prepped and draped. After local anesthesia (lidocaine with and without epinephrine), a 3-mm dermatomy is made with a scalpel,

slightly away from the transducer (approximately 1 cm) to allow for the shortest biopsy needle trajectory that is still parallel to the chest wall. There are two main types of biopsy devices in use: (1) the 14-gauge automated spring-loaded biopsy gun and (2) the 8- or 11-gauge vacuum-assisted directional biopsy device. The biopsy device is then inserted through the dermatomy, to the periphery of the lesion under ultrasound guidance. “Pre-” and “postfire” images are obtained with the needle adjacent to and subsequently through the lesion. Multiple samples are taken, placed in formalin, and sent to pathology for histologic analysis. At the conclusion of the biopsy, a small metallic marker clip is placed in the biopsy site. Postbiopsy mammogram will reveal the lesion’s location.

Firm pressure is held at the biopsy site. The dermatomy is approximated with steri-strips or Dermabond. An icepack is placed on the breast and the patient is cautioned not to engage in strenuous activity or heavy lifting for the next 2 days. Complications include pain, bruising, hematoma, and infection. Patients that are taking anticoagulants are asked to discontinue aspirin 1 week before the procedure and to discontinue warfarin 3 to 4 days before the biopsy. In the latter group, laboratory tests for coagulation factors including INR obtained on the day of the procedure may be helpful. The patient may resume anticoagulation 2 days after the biopsy. For patients who are unable to discontinue their prescribed medication and have a crucial need for biopsy, preprocedure application of ice to the area and a smaller gauge biopsy needle, such as an 18-gauge spring loaded device can be utilized. Additionally, fewer passes can be made and firm pressure held for a longer period of time to ensure hemostasis.

The biopsy results are correlated with imaging. If concordant and benign, a 6-month follow-up may be scheduled. If concordant and malignant, a surgical consult is recommended. If the pathology results and the imaging are discordant, surgical excision is recommended to further evaluate possible sampling error.

STEREOTACTIC CORE NEEDLE BIOPSY

The indication for stereotactic core needle biopsy is a lesion that is best seen on mammogram. The majority of these lesions are calcifications; however, asymmetric mammographic densities and subtle isoechoic masses may also fall into this category. The prebiopsy mammogram aids in locating the lesion and determining the approach. The patient is placed prone on the stereotactic table. A single direct view and two angled views separated by 30 degrees are taken. The lesion is marked on

the two angled views and its position is calculated. After prep and drape, local anesthesia is injected and a dermatotomy is made. Subsequently, the tip of the biopsy needle is inserted through the skin. “Prefire” and “postfire” images are obtained. On the “postfire” view, the collecting trough of the needle should be through the lesion. Multiple samples are taken. Specimen radiographs are taken to demonstrate the targeted calcifications within the biopsy tissue. The sampled tissue is placed in formalin and sent to pathology for histologic assessment. A marker is placed at the biopsy site in the event that surgical excision is recommended. Post-biopsy and postmarker placement stereotactic images are taken demonstrating the biopsy cavity and satisfactory placement of the clip. Patient management after the procedure is the same as discussed under ultrasound-guided biopsy.

MRI-GUIDED CORE NEEDLE BIOPSY

MRI-guided core biopsy is utilized when lesions are identified on MRI but not seen on other modalities. Before the patient is placed prone in the breast coil, the initial MR examination demonstrating the lesion is reviewed carefully to determine nearby landmarks. The patient is then imaged with a fenestrated grid providing slight compression to immobilize the breast during the procedure. After contrast is injected, lesion conspicuity worsens with time, with the best visualization occurring within the first 2 minutes after injection. Once the location of the lesion is determined on post-contrast imaging, the biopsy needle is inserted through the grid and samples are taken, placed in formalin, and sent to pathology for histologic analysis. Free-hand biopsy, without grid placement may also be performed, however, it is more challenging because of the mobility of the breast. A marker is placed in the biopsy site after samples are obtained. Management after the procedure is the same as discussed under ultrasound-guided biopsy.

MARKER PLACEMENT

Marker placement within a lesion is necessary to provide localization of a lesion for subsequent surgery or for correlation with the mammogram. Markers are made of various metals including stainless steel and titanium. They are also composed of Gelfoam,TM collagen or polyethelen glycol, to enable visualization under ultrasound. Since breast MRI is used more often in staging patients prior to lumpectomy, facilities prefer to use markers with fewer artifacts so not to obscure the lesion.

PREOPERATIVE NEEDLE LOCALIZATION

Preoperative needle localization is utilized to identify a nonpalpable lesion for surgical excision. This is commonly performed with mammographic or sonographic guidance; however, free-hand, stereotactic-guided and MRI-guided localizations are also performed.

For mammographic localization, the shortest distance to the lesion and the length of needle necessary are predetermined. For example, if the lesion is in the superior aspect of the breast, placing the patient in the CC projection will be the initial grid image. Using the alphanumeric grid, the lesion coordinates are determined. The needle is placed through the skin, to the lesion. An orthogonal view is then taken, demonstrating the needle has gone through the lesion approximately 1.0 to 1.5 cm past the targeted lesion. The wire is deployed and a unilateral mammogram is taken with the wire in place for intraoperative use.

For sonographic localization, the needle is placed through the lesion and the wire is deployed under real-time sonographic imaging. A unilateral mammogram is obtained for intraoperative use.

The unilateral mammogram consists of CC and straight lateral views with the lesion clearly marked. A postoperative specimen radiograph is taken to confirm the targeted lesion has been excised. Surgical specimen radiographs document excision of targeted lesion, document removal of localization wire, mark the location of the lesion for the pathologist, detect unsuspected lesions, and give information about the proximity of the lesion to the margins. Specimen radiography is performed with compression and magnification. If the targeted lesion is not identified on the specimen radiograph, additional tissue may be obtained if the procedure has not concluded. Alternatively, a postoperative mammogram should be obtained to evaluate for residual lesion.

DUCTOGRAPHY

Ductography is performed to evaluate spontaneous, unilateral discharge from a single duct. Physical examination can elicit the discharge to assist in guiding the cannula. A 30- or 32-gauge, blunt-tipped cannula is inserted into the discharging duct and approximately 0.5 mL of undiluted, iodinated, water-soluble contrast is injected. Magnification views of the subareolar region are taken in orthogonal planes. Rolled views may also be obtained to separate the ducts for better visualization. Filling defects may be due to ductal debris, hematoma, or mass. Air bubbles may also present as filling defects, but they are sharply circumscribed and mobile. Fibrocystic change will display multiple cystic dilations at the ends of

ducts, while dilated ducts that resume normal caliber away from the nipple represent duct ectasia. Ductography may be useful in localizing intraductal papillary lesions for surgery.

QUESTIONS AND ANSWERS

1. A density in the inferior aspect of the MLO view is not seen on the CC view, but the density is seen more inferiorly on a true lateral view. In what quadrant is the density located?
 - A. Upper inner
 - B. Lower inner
 - C. Upper outer
 - D. Lower outer

ANSWER: D. Lower outer. Lateral lesions are seen more inferiorly on a true lateral as compared with an MLO view, whereas medial lesions are seen more superiorly (Medial lesions = muffins rise; lateral lesions = lead sinks).

2. During ultrasound-guided aspiration, the aspirate from a cystic lesion is bloody. What is the next step in patient management?
 - A. Discard aspirate and follow up in 1 year.
 - B. Send aspirate for cytology, mark lesion, and recommend excisional biopsy.
 - C. Discard aspirate and follow up in 6 months.
 - D. Send aspirate for microbiologic evaluation and place patient on antibiotics.

ANSWER: B. Bloody aspirates should be sent for cytology and excisional biopsy is recommended. A marker may be placed to aid in wire localization for excisional biopsy.

3. There is a spiculated mass in the right breast at the 9-o'clock position. In what aspect of the left breast should one place the transducer for evaluation of an equivalent location?
 - A. Medial
 - B. Superior
 - C. Inferior
 - D. Lateral

- A. Medial
- B. Superior
- C. Inferior
- D. Lateral

ANSWER: D. Lesions are described in a clock-face location as if the examiner were facing the patient. Left lateral breast lesions are at 3-o'clock position and right lateral breast lesions are at 9-o'clock position.

4. What is the appropriate position of the localization wire tip relative to the targeted lesion?
 - A. Immediately proximal to the lesion
 - B. 3 cm past the lesion
 - C. 1 to 1.5 cm past the lesion
 - D. Within the lesion

ANSWER: C. The localization wire tip should be 1 to 1.5 cm past the targeted lesion.

5. What is the optimum prefire position for an ultrasound-guided core needle biopsy?
 - A. Core biopsy needle entirely through the lesion
 - B. Core biopsy needle perpendicular to the chest wall and 5 cm proximal to the lesion
 - C. Core biopsy needle perpendicular to the transducer and at the lesion
 - D. Core biopsy needle parallel to the chest wall and transducer with core biopsy needle tip just proximal to the lesion

ANSWER: D. The optimum prefire core needle biopsy position for an ultrasound-guided biopsy is just proximal to the targeted lesion with the needle parallel to both the transducer and the chest wall.

6. A cluster of amorphous calcifications is seen in the medial breast on CC view but not seen on the MLO view. What additional view would help localize the calcifications?
 - A. Lateral-medial view
 - B. Medial-lateral view
 - C. Cleavage view
 - D. Spot compression

ANSWER: A. A lateral medial view would be optimal as the calcifications would be closer to the image receptor and this view would assist in localization of the calcifications. A cleavage view is a modified CC view that improves visualization of medial and posterior breast tissue. A spot compression view may provide additional information about the character of calcifications but would not improve knowledge of calcification localization.

7. Which of the following is an indication for breast MRI?
- High-risk patient screening
 - Evaluation of silicone breast implants
 - Evaluation of extent of disease
 - Evaluation of response to neoadjuvant therapy
 - All of the above

ANSWER: E. Indications for breast MRI include screening high-risk patients, assessment of extent of ipsilateral disease in newly diagnosed breast cancer patients, assessment of chest wall or pectoralis muscle involvement, evaluation of the contralateral breast, surveillance for residual/recurrent disease after breast conservation surgery, evaluation of response to chemotherapy, further evaluation of mammographic or palpable abnormality, evaluation of axillary carcinoma with unknown primary, and assessment of silicone implant integrity.

8. Which of the following statements is *false*?
- Magnification views are obtained by moving the breast away from the image receptor, thereby increasing object to image.
 - Grids are utilized to eliminate scatter radiation.
 - A magnification factor of $1.5\times$ to $1.8\times$ is common.
 - A small focal spot increases exposure time, and this may lead to increased motion artifact.

ANSWER: B. Grids are not utilized in magnification views because scatter is eliminated through the air gap.

9. The terminal duct lobular unit is the site of origin for all of the following *except*:
- Fibrocystic change
 - Ductal carcinoma in situ
 - Papillary neoplasm
 - Infiltrating ductal carcinoma

ANSWER: C. Papillary neoplasms arise within the main lactiferous duct and its major branches.

10. A round mass is palpated in the axillary tail, which mammographic view is optimal for lesion evaluation?
- XCCL view
 - CC view
 - Cleavage view
 - XCCM

ANSWER: A. An XCCL view optimally images the axillary tail. Cleavage and XCCM views increase visualization of medial breast tissue.

77 BREAST SCREENING AND BREAST IMAGING REPORTING AND DATABASE SYSTEM (BI-RADS) LEXICON

Heidi R. Umphrey, Cheryl R. Herman, and David E. Hogg

BREAST SCREENING

Breast cancer is a leading cause of cancer death, second only to lung cancer in women. Women have a lifetime risk for developing breast cancer of approximately 12.5% (one in eight women). The incidence of breast cancer is approximately 110 cases per 100 000 women. The American Cancer Society (ACS) projects 182 460 new cases of breast cancer in women in 2008 and 1990 cases in men. Several randomized controlled trials have shown a survival benefit for women undergoing screening mammography as compared with control groups. Although mammography has shown proven benefit, it is not a perfect screening test with false-negative rates ranging from 7% to 15%, emphasizing the importance of self-breast examination and annual breast physical examination by a health care professional. Risk factors for breast cancer are listed in Table 77-1.

The ACS recommends annual screening mammography for all women starting at 40 years of age, monthly self-breast examination beginning at 20 years of age,

TABLE 77-1 Risk Factors for Breast Cancer

Gender
Age
Personal or family history of breast cancer
Prior breast biopsy with certain histology (atypical ductal hyperplasia (ADH) or LCIS)
BRCA1 or BRCA2 mutations
History of high-dose chest radiation therapy
Implicated factors
Early menarche
Late menopause
Late first-term pregnancy
Nulliparity
Postmenopausal obesity
Reported associations
Oral contraceptive use
Alcohol intake
Exogenous steroids (after 10 y of use)
Dietary fat intake

and an annual physical breast examination by a health care professional every 3 years (ages 20–39) and annually starting at age 40. The baseline study is no longer part of ACS screening guidelines.

MAMMOGRAPHIC SCREENING

A screening mammography examination usually consists of MLO and CC views of each breast; however, technologists utilize appropriate views to ensure complete imaging of all breast tissue. A marker can be utilized to localize prominent skin lesions. Surgical scars should be documented on an intake history form. In women with breast implants, at least four views are obtained of each breast including CC and MLO views with the implants in view in addition to CC and MLO views with the implants displaced. Usually, kilovolt peak (kVp) ranges from 24 to 32 for molybdenum targets and 26 to 35 kVp for rhodium targets. The average glandular breast tissue dose to an average breast cannot exceed 3 mGy per view for screen–film image receptors. Mammographic images must be labeled appropriately to include patient name, a unique patient identification number, date of examination, radiopaque laterality and projection marker placed closest to the axilla, facility name, facility location, technologist identification, cassette and screen identification number, and mammography unit identification number. Imaging receptors, compression paddles, and cassettes are available in two sizes (18 × 24 and 14 × 30 cm) to accommodate breasts of various sizes.

The angle of obliquity for MLO varies for different patients and is determined by the orientation of the fibers of the pectoralis muscle. The breast tissue in the lateral and inferior quadrants of the breast is mobile, whereas the upper inner breast has little inherent mobility. An adequate MLO view should show the widest aspect of the pectoralis muscle at the axilla, pectoralis muscle extending inferiorly to the level of the nipple, a convex shape to the anterior margin of the pectoralis muscle, an open inframammary fold, and a small amount of upper abdomen. Positioning may be limited because of physical disabilities or absence of the pectoralis muscle termed Poland syndrome.

The pectoralis muscle should be visualized on the CC view in approximately 30% to 40% of patients. Adequate medial breast tissue on the CC view is confirmed by visualization of the pectoralis muscle or cleavage. If neither is seen, the posterior nipple line (PNL) should be measured. The PNL is utilized to determine the adequacy of posterior tissue on a CC view. The distance from the anterior edge of the pectoralis muscle to the nipple is measured. The PNL should be within 1 cm as

measured on MLO and CC views. If tissue extends to the posterolateral aspect of the image on the CC view, then an exaggerated craniocaudal (XCCL) view should be considered. The two indications for XCCL views are when tissue extends to the edge of the image on a CC view or when tissue is seen extending over the upper aspect of the pectoralis muscle in the MLO view.

Image quality must be excellent for adequate mammographic screening. Maximal compression is essential for optimal image quality. As breast tissue is thinned, optimal exposure with lower radiation dose and decreased scatter radiation is obtained. Immobilization of breast tissue minimizes geometric blurring; and as tissue is compressed, superimposition is decreased thereby improving lesion conspicuity. The size of the focal spot for screening mammography is 0.3 mm with smaller focal spot of 0.1 mm utilized in magnification mammography as previously discussed in Chapter 76. High-contrast images are essential for the identification of small breast cancers and malignant calcifications. Final contrast is a function of both subject and image receptor contrast. Subject contrast reflects differences in the radiation absorption of tissues being imaged (malignant masses, glandular tissue, calcifications, or fat) and varies by the quality of radiation beam and the amount of scatter radiation. Film contrast is dependent on subject contrast, scatter radiation, film and screen type used, film orientation in cassette, processing, and photographic density and fog. Screen–film cassettes utilized in mammography have a spatial resolution of 20 line pairs/mm. This high resolution is achieved when a single emulsion film is placed emulsion side down against an image-intensifying screen that is facing upward toward the breast in the film cassette. Most of the screen–film systems have relative speeds of 100 to 270 to produce an OD of 1.0 above base plus fog. Hurter and Driffield curves are plots of the film's optical density as a function of the log of exposure and demonstrate the low exposure latitude of screen–film mammography. However, screen–film mammography has higher resolution and higher film contrast when compared to conventional radiography. Glandular tissue needs to be adequately exposed; therefore, the photocell should be positioned correctly under glandular tissue. As discussed screen–film detectors have a limited dynamic range (25:1), and a highly glandular breast can have an exposure latitude exceeding 200:1 resulting in inappropriately exposed regions of the film. Digital detectors have dynamic ranges exceeding 1000:1 yielding an advantage to digital mammography over screen–film mammography. This advantage overcomes the limited resolution of digital mammography, which is on the order of 6 to 8 line pairs/mm.

MAMMOGRAPHY QUALITY STANDARDS ACT

The Mammography Quality Standards Act (MQSA) was enacted by Congress to ensure women quality mammography that enables the detection of early breast cancers. The MQSA was initially implemented in 1992, with final regulations issued in 1997. Under the Food and Drug Administration (FDA), the MQSA certifies breast-imaging facilities as capable of providing quality mammography. A breast-imaging facility must be accredited by an FDA-approved accreditation body, which includes the American College of Radiology and several states. The Veteran's Administration Facilities are exempt from the MQSA, but have their own mammography quality program whose standards are as strict as those required by the MQSA.

In order to become accredited by an FDA-approved accrediting body, the facility must comply with the following regulations. The physicians who read the mammograms, the mammography technologists who perform the studies and the medical physicists who survey the mammographic units must be properly trained and have adequate experience. This is established by maintenance of copies of diplomas, licensure, certificates, numbers of studies read or performed per period of time, and a log of continuing medical education credits. Specifically, MQSA requirements for interpreting physicians are outlined in Table 77-2. Each facility must have and be able to demonstrate an effective quality control program and must be able to keep certain records including the mammogram films, examination reports to the referring physicians, and the lay letters to the patient. The facility must demonstrate its ability to follow up on significant findings on the mammograms and must have a system in place for tracking biopsy findings that result from abnormal studies. Additionally, a medical audit is performed to evaluate accuracy of mammography and interpretation. Information derived for a medical audit includes the following: true-positive

rate, true-negative rate, false-negative rate, false-positive rate, sensitivity, specificity, positive predictive value, and cancer detection rate. A true positive is defined as breast cancer diagnosed within 1 year after a biopsy recommendation for an abnormal mammogram. A true negative is no known breast cancer diagnosis within 1 year of a normal mammogram. A false positive is no breast cancer diagnosis within 1 year of a biopsy recommendation for an abnormal mammogram (Breast Screening and Breast Imaging Reporting and Database System [BI-RADS] categories 4 or 5), no breast cancer diagnosis within 1 year of an abnormal mammogram, or biopsy with benign findings within 1 year of a biopsy recommendation for an abnormal mammogram (BI-RADS categories 4 or 5). A false negative is a breast cancer diagnosis within 1 year of a normal mammogram. Sensitivity is defined as the probability of detecting cancer when it is present with a goal of better than 85%. It is the number of true positives divided by the sum of the true positives and false negatives. Sensitivity = $TP/(TP + FN)$. Specificity is defined as the probability of a normal mammogram when there is no breast cancer present with a goal of better than 90%. Specificity = $TN/(TN + FP)$. The PPV of abnormal findings at screening mammogram is the percentage of screening studies with abnormal findings that results in a diagnosis of breast cancer. The PPV of biopsies performed is the percentage of all biopsies performed that resulted in a diagnosis of breast cancer. The PPV of recommendations for biopsy is the percentage of patients with a biopsy recommendation that resulted in a diagnosis of cancer. Cancer detection rate is the number of cancers detected per 1000 patients evaluated with mammography. Cancer detection rate is approximately 6 to 8 per 1000 patients for initial screening examination and 2 to 4 per 1000 patients for repeated screening examinations. Interval breast cancers are described as cancers that become clinically apparent after a negative mammogram but prior to the next screening mammogram.

Additionally, the facility must undergo annual inspections by an FDA or State inspector who has completed the required training in the FDA mammography evaluation program. Under the Quality Control requirement, there are many tests that must be performed by the technologist or physicist to ensure optimal performance of equipment and image quality. The schedule of quality control tests performed by the technologists is outlined in Table 77-3.

TABLE 77-2 MQSA Requirements for Interpreting Physicians

Licensure to practice in the state
Certification by an FDA-approved body to certify interpreting physicians or 3 mo full time training in mammographic interpretation, radiation physics, radiation effects, and radiation protection
Completion of 60 h of documented mammography continuing medical education (CME) and 8 h of training in each modality
Read at least 240 examinations in the preceding 6 mo under supervision or have read mammograms under the supervision of a fully qualified physician
Read 960 mammograms over a period of 24 mo
Completion of at least 15 category 1 CME credit in mammography over a 36-mo period, with 6 credits in each modality used

MAMMOGRAPHIC SCREENING EVALUATION

Evaluation of screening mammograms like any radiologic examination should be performed in a standard

TABLE 77-3 Technologists Quality Control Test Schedule for Film-Screen Mammography

TEST	PERFORMED
Darkroom cleanliness	Daily
Processor QC	Daily
Screen cleanliness	Weekly
Phantom images	Weekly
View box cleanliness and viewing checklist	Monthly
Repeat analysis	Quarterly
Fixer retention	Quarterly
Darkroom fog	Semiannually
Screen–film contact	Semiannually
Compression	Semiannually

fashion so that one is prepared to consistently identify abnormalities. First, the images should be assessed for overall quality with criteria previously set forth in this chapter. If the images are of appropriate quality, then the images should be evaluated for overall glandular tissue component. Subsequently, magnification viewing should be performed to evaluate for calcifications. The breasts should be divided into thirds with right to left comparison to evaluate for asymmetry or focal lesions. Specific attention should be directed to the posterior breast tissue. Finally, comparison should be made to previous mammographic images to evaluate for interval change.

MAMMOGRAPHY REPORTING BI-RADS LEXICON

The BI-RADS lexicon is a vocabulary used to describe various mammographic findings in a standardized fashion to ensure effective communication, thereby optimizing patient care. Breast composition is characterized as adipose, small, moderate, and dense. Adipose describes a breast that is predominately composed of fat tissue with a less than 25% glandular component. Small breast density implies a 25% to 50% component of glandular tissue. Moderate breast density implies 51% to 75% glandular tissue, and dense breasts are predominately composed of glandular tissue greater than 75%. Masses are space-occupying lesions that are by definition seen in two different views. Masses are further characterized by shape, margin, and density. Calcifications are further characterized as typically benign, suspicious, and higher probability of malignancy with distribution descriptors. A screening and diagnostic mammogram report should include an assessment category (Table 77-4). Screening mammogram report assessments are usually limited to BI-RADS categories 0, 1, or 2. BI-RADS assessment category 0 (additional evaluation needed) is referred to as a call back as the patient will return for additional imaging evaluation. A call back rate

TABLE 77-4 BI-RADS Assessment Categories

Category 0	Assessment incomplete, need additional evaluation and/or prior mammograms for comparison
Category 1	Negative
Category 2	Benign finding(s)
Category 3	Probably benign, but initial short interval follow-up of 6 mo with 2-y stability (<2% malignancy)
Category 4	Suspicious abnormality, biopsy should be considered (>2% risk of malignancy)
Category 5	Highly suggestive of malignancy, appropriate action should be taken
Category 6	Known biopsy proven malignancy, appropriate action should be taken

of 10% is ideal and will vary with experience. Lesions ascribed a category 3 (probably benign) reportedly have a less than 2% chance of malignancy.

HIGH-RISK BREAST CANCER SCREENING

The ACS describes three strategies to determine women at high risk for breast cancer including evaluation of family history, genetic testing, and review of clinical history. Breast screening in high-risk women is initiated at 30 years of age or 5 years prior to the earliest age of diagnosis of breast cancer in a first-degree relative. Annual MRI screening is recommended in women with a lifetime breast cancer risk of greater than or equal to 25% as predicted by models: women who underwent chest radiation between the ages of 10 and 30 years at dosages above 4 Gy such as for Hodgkin disease, and women who have a hereditary breast cancer syndrome such as Li Fraumeni, Cowden, or Bannayan-Riley-Ruvalcaba. Women with cancer predisposing mutations in either BRCA1 or BRCA2 have an increased risk of both breast and ovarian cancer. Risks of breast cancer in patients with BRCA1 and BRCA2 are 65% and 45% by age 70, respectively. Lobular carcinoma in situ and atypical lobular hyperplasia are both in the spectrum of lobular neoplasia and are associated with an increased risk of the subsequent development of breast cancer with lifetime estimates of increased risk from 10% to 20% (six- to tenfold increased risk). Atypical ductal hyperplasia (ADH) is along the continuum of ductal proliferative lesions ranging from ductal hyperplasia to ADH to ductal carcinoma in situ. ADH is associated with four- to fivefold increased risk of the development of a subsequent invasive breast cancer. The absolute risk of the development of a contralateral breast cancer in women with a personal history of breast cancer is estimated to be 5% to 10% in the 10 years following diagnosis, which is significantly higher than the general population.

QUESTIONS AND ANSWERS

- Which of the following quality control tests are performed weekly for film–screen mammography?
 - Darkroom cleanliness
 - Phantom images
 - Processor QC
 - Darkroom fog

ANSWER: B. Phantom image testing is performed weekly (Table 77-3).

- Which of the following locations is most likely to show motion artifact?
 - Medial aspect of the CC view
 - Central aspect of the CC view
 - Inferior aspect of the MLO view
 - Superior aspect of the MLO view

ANSWER: C. Breast tissue in the inferior and lateral aspects of the breast is mobile. Motion artifact is secondary to inadequate compression, which is more likely to occur in the more mobile aspects of the breast.

- A patient has a negative screening mammogram and 7 months later develops a palpable mass that is biopsied to reveal infiltrating ductal carcinoma. This is termed a:
 - False-positive screen
 - True-positive screen
 - True-negative screen
 - False-negative screen

ANSWER: D. A breast cancer that is diagnosed within a year of a negative screening mammogram is a false negative.

- All of the following are *true* with respect to film–screen mammography versus conventional radiography, *except*:
 - Film–screen mammography has higher resolution.
 - Film–screen mammography has greater exposure latitude.
 - Film–screen mammography has higher film contrast.
 - Film–screen mammography utilizes single emulsion film.

ANSWER: B. Screen–film mammography has narrow exposure latitude. All the other answer choices are correct.

- What is the expected number of cancers if interpreting 1000 initial screening mammograms?
 - 20–30
 - 1–2
 - 6–10
 - None

ANSWER: C. The approximate number of expected breast cancers per 1000 initial screening examinations is 6 to 10. The expected number of breast cancers per 1000 follow-up routine breast screening examination is 2 to 4.

- Over a year, 100 cancers are identified, 92 of these were identified based on biopsy recommendations from screening mammograms and an additional 8 cancers developed after a negative screening mammogram. What is the sensitivity in this population?
 - 8%
 - 80%
 - 91%
 - 92%

ANSWER: D. Sensitivity is defined as a positive test in the presence of true disease. Sensitivity = $TP/(TP + FN)$. $TP = 92$ and $FN = 8$. Sensitivity = $92/(92 + 8) = 92/100 = 0.92$

- A spiculated mass is identified in the left upper outer quadrant on screening mammogram. What is the BI-RADS assessment?
 - BI-RADS 0
 - BI-RADS 1
 - BI-RADS 2
 - BI-RADS 6

ANSWER: A. BI-RADS assessment categories 0, 1, and 2 are utilized in screening mammography. BI-RADS category 0 is incomplete assessment requiring additional evaluation. This finding should be further evaluated with additional mammographic views, ultrasound and biopsy. BI-RADS category 1

is a negative assessment. BI-RADS 2 assessment is benign finding. BI-RADS 6 assessment designates known malignancy utilized in evaluation of response to neoadjuvant therapy or in second opinion cases.

8. What is the typical kVp used in screening mammography?
- 5–15 kVp
 - 24–30 kVp
 - 120–140 kVp
 - 70–90 kVp

ANSWER: B. Kilovoltage peak (kVp) varies dependent on breast size; however, the typical kVp range for mammography is 24 to 30.

9. Which of the following is a risk factor for development of breast cancer?
- Early menopause
 - Early first-term pregnancy
 - Late menarche
 - Cowden syndrome

ANSWER: D. There are numerous syndromes that increase risk for breast cancer, Cowden, Li Fraumeni, Bannayan-Riley-Ruvalcabe. Early menarche (not late) and late menopause (not early), as well as late first-term pregnancy are also risk factors.

10. The posterior nipple line measures 11 cm on the MLO view. What is an acceptable PNL measurement on the CC view?
- 10 cm
 - 6 cm
 - 8 cm
 - 9 cm

ANSWER: A. The PNL measurements should differ no more than 1 cm when comparing MLO and CC views if there is adequate tissue exposure.

78 EVALUATION OF BREAST MASSES

*Heidi R. Umphrey, Cheryl R. Herman,
and David E. Hogg*

BREAST MASSES

Diagnostic evaluation of breast masses may be initiated from findings discovered on screening mammography or from abnormalities identified on self-examination or

on annual physical examination by a health care professional. Each diagnostic evaluation should include a detailed review of patient history with particular attention to presentation and a complete review of patient images. A thorough evaluation is essential to determine the best approach for adequate characterization of breast masses.

Palpable abnormalities should be evaluated with routine mammographic views if the patient is older than 30 years of age and not pregnant. Patients younger than 30 years of age and/or pregnant patients should undergo ultrasound (US) evaluation initially. Masses, architectural distortion, or densities identified on screening mammography should undergo appropriate additional mammographic views and/or US as indicated.

A mass is defined by the BI-RADS lexicon as a space-occupying lesion that is seen in two different projections. The BI-RADS lexicon is employed to describe features of masses including shape, margins, and density. Additional features to consider include associated calcifications, effects on surrounding tissue, architectural distortion, “halo” sign, satellite lesions, multiple lesions, and stability. The characterization of associated calcifications may be helpful in determining benignity or malignancy and are further discussed in Chapter 80. An associated desmoplastic response in adjacent tissue is evidenced mammographically by spiculations and is associated with malignancy. The “halo sign” is a narrowly defined sharp lucency surrounding a mass and is most often associated with benign lesions. Multiplicity is usually associated with benignity; however, breast cancers and metastatic disease may be multifocal and multicentric in nature. Compression, rolled, and magnification views are utilized to further define shape, margins, and density of breast masses. US is useful in further evaluating lesion content and morphology. Additionally, US guidance for core biopsy is a valuable tool.

Mammographic mass shape descriptors include round, oval, lobular, and irregular. The probability of malignancy increases as mass shape progresses from round to irregular. Descriptors for mass margins include circumscribed, microlobulated, obscured, indistinct, and spiculated. The density of a mass may be fat containing or low, equal, or high density as compared to adjacent breast glandular tissue.

US mass shape descriptors include oval, round, and irregular. Margins are described as circumscribed, angular, indistinct, microlobulated, and spiculated. The mass boundary may reveal an abrupt interface or echogenic halo. Internal echogenicity may be anechoic, hyperechoic, complex, isoechoic, or hypoechoic. Posterior acoustic features may be seen and if present may show enhancement, shadowing, or a combination of both. Benign and malignant US features are listed in Table 78-1.

TABLE 78-1 Sonographic Features of Solid Masses

MALIGNANT FEATURES	BENIGN FEATURES
Hypoechoic	Intense homogenous hyperechogenicity
Angulated margins	Four or fewer gentle lobulations
Acoustic shadowing	Thin echogenic pseudocapsule
Microcalcifications	Oval shape
Duct extension	Absence of malignant characteristics
Taller than wide	Parallel to chest wall
Spiculation	
Branch pattern	

When describing masses, the following characteristics should be reported: size and location, mass type and descriptors, presence of associated calcifications, presence of associated findings, interval change, and BI-RADS assessment. Associated findings include nipple retraction and skin thickening. Differential diagnoses for various mass findings are listed in Table 78-2.

BENIGN BREAST MASSES

SKIN LESIONS

Skin masses include nevi, accessory nipples, squamous papillomas, epidermal inclusion (sebaceous) cysts, and neurofibromas. These lesions can often be differentiated

from intraparenchymal lesions by partial or complete outline by air. Placement of skin markers and/or tangential views may also be useful in localizing these lesions to the skin.

EPIDERMAL INCLUSION CYSTS

Epidermal inclusion cysts are common, palpable, well-margined intradermal lesions that may contain calcifications. Mammographically, these lesions are well circumscribed, localized to the skin on tangential views and may contain lucent centered calcifications. Sonographically, epidermal inclusion cysts are hypoechoic round to lobulated lesions localized to the dermis with well- to partially circumscribed margins. Careful sonographic evaluation may reveal a linear hypoechoic tract to the skin surface. A linear transducer may be beneficial in evaluation because of the superficial location. Inflamed epidermal inclusion cysts may have spiculated margins on mammography.

FAT-CONTAINING LESIONS

Fat-containing lesions in the breast are usually benign; masses may be completely fatty and appear radiolucent or have a mixed density. Fat density masses include lipomas and oil cysts. Mixed density masses include intramammary lymph nodes, hamartomas, fat necrosis, galactoceles, and postoperative or posttraumatic fluid collections.

TABLE 78-2 Differential Diagnoses of Masses

Spiculated masses	
Invasive ductal carcinoma	Invasive lobular carcinoma
Tubular carcinoma	Postbiopsy scar
Radial scar	Fat necrosis
Sclerosing adenosis	
Round masses	
Cysts	Fibroadenoma
Invasive ductal carcinoma	Medullary carcinoma
Mucinous carcinoma	Papillary carcinoma
Metastasis	Phyllodes tumor
Papilloma	Lactating adenoma
Epidermal inclusion cyst	
Solid masses with indistinct margins	
Invasive ductal carcinoma	Invasive lobular carcinoma
Lymphoma	Sarcoma
Focal Fibrosis	Pseudoangiomatous stromal hyperplasia (PASH)
Masses containing fat	
Lymph node	Hamartoma
Oil cyst	Lipoma
Liposarcoma	

LIPOMAS

Lipomas can be asymptomatic or present as a palpable mass. Mammographically, a well-circumscribed radiolucent mass with a thin capsule is seen. Sonographically, these well-circumscribed masses are oval to round. Histologically, these lesions are composed of mature adipose tissue with a thin-defined capsule.

OIL CYSTS

Oil cysts can be multiple or solitary. Oil cysts are radiolucent, variable in size, round with a radiodense rim, and evolve over time. Most oil cysts develop mural calcifications resulting in eggshell calcifications. On US, oil cysts are hypoechoic or isoechoic with increased through transmission; they may contain internal echoes. Most are asymptomatic but some may present as palpable lesions.

LYMPH NODES

Intramammary and axillary lymph nodes vary in number, shape, density, and location. Lymph nodes are usually round to oval masses with well-circumscribed margins located in upper outer quadrants. The presence of a fatty hilum seen centrally or peripherally on US or mammography is essential for confirmation. Sonographically, lymph nodes are well-circumscribed, oval hypoechoic masses with an area of hyperechogenicity either centrally or peripherally. Color Doppler can highlight vessels entering this echogenic region also known as the hilum. On MRI, lymph nodes are oval masses with rapid enhancement and washout postcontrast administration; the presence of a fatty hilum on the non-fat-suppressed T1 sequence is important for identification. Benign causes of axillary or intramammary lymphadenopathy include lymphoid hyperplasia, collagen vascular disorders, granulomatous disease, HIV infection, dermatopathic adenopathy, silicone adenopathy, or cat-scratch disease. Interval change is an important tool in the evaluation of lymph nodes particularly in patients with a history of cancer. Interval increase in lymph node size may warrant US-guided biopsy or fine needle aspiration if the patient has a history of malignancy or if the node enlarges by greater than 100%. Spiculated adenopathy may represent extracapsular extension of tumor.

HAMARTOMAS

Hamartomas also termed fibroadenolipomas are characterized by the presence of a pseudocapsule surrounding adipose, glandular, and fibrous elements. Sonographically, these lesions can be distinguished from surrounding breast tissue and are heterogeneous in echotexture. Since these lesions contain glandular tissue, parenchymal changes should always be assessed as elsewhere in the breast.

FAT NECROSIS

Fat necrosis may result from trauma or surgical intervention. In the acute setting, architectural distortion is seen which can be associated with overlying skin thickening and skin retraction. Calcifications associated with fat necrosis are usually dystrophic appearing coarse or lucent centered. Over time, the distortion evolves by decreasing in density, remaining stable to decreasing in size, and occasionally foci may develop into oil cysts. Fat necrosis rarely increases in size or density 1-year posttrauma or surgery, and this change warrants biopsy to exclude malignancy. Sonographic findings include an

area of hyperechogenicity that ranges from well- to ill-defined, with associated cystic spaces or small round areas of hypoechogenicity. Fat necrosis has similar imaging features as malignant lesions, which may prompt biopsy in some cases.

SOFT-TISSUE MASSES

Benign soft-tissue density masses include cysts, adenomas, papillomas, fat necrosis, pseudoangiomatous stromal hyperplasia (PASH), focal fibrosis, sclerosing adenosis, abscess, postoperative fluid collections, vascular lesions, granulomatous disease, radial scar, and granular cell tumor.

CYSTS

Cysts are common breast lesions that occur in women of all ages with some predilection in the perimenopausal years. Without hormone replacement therapy, many cysts resolve or decrease in size after menopause. Patients with cysts can present clinically with one or several palpable abnormalities, focal tenderness, or less often nipple discharge. Cysts are frequently noted in asymptomatic patients on screening mammogram. Mammographically, cysts vary in number, laterality, size, and density. Most cysts are well-circumscribed but can have ill-defined or obscured borders. Calcifications can develop within cyst fluid termed milk of calcium or within the walls of cysts. In the absence of milk of calcium, further sonographic evaluation of internal matrix is necessary to exclude solid mass. Sonographically, cysts are well-circumscribed, anechoic lesions with posterior acoustic enhancement and thin edge shadows. Occasionally, internal echoes are seen within cysts that show mobility. Clusters of cysts can be seen in acini with thin septations and may represent the early stage of cyst development. Although, if there is any question concerning the complexity of a lesion, US-guided biopsy is recommended. Usually, simple cysts decrease dramatically after the first biopsy pass with histology revealing fragments of epithelial and apocrine lined cysts. Cyst aspiration is discussed in Chapter 77.

FLUID COLLECTIONS

Other fluid collections within the breast include galactoceles, postoperative or posttraumatic seromas and hematomas, and abscesses. These lesions may be round, oval, or lobular masses with variable cystic components

and occasionally solid components. Clinical history and presentation are helpful in the diagnosis. Hematomas are related to trauma, and sonography reveals an echogenic mass with cystic evolution and regression at follow-up.

GALACTOCELES

Galactoceles develop in women who are pregnant or lactating. Fluid-fluid levels are often seen.

ABSCESSSES

Mastitis and abscesses are commonly seen during the first 6 weeks of lactation or during weaning, but can affect any woman of any age. Patients present clinically with breast erythema, induration, and pain. Initial treatment is with antibiotics; and if interval improvement is not seen, US may be useful to evaluate for abscess. A complex cystic mass is seen on US. US-guided aspiration can prove therapeutic and diagnostic providing material for microbiologic cultures, which can be useful for antibiotic selection.

FIBROADENOMA

Fibroadenomas are common lesions, particularly in women aging from 20 to 30 years, that show regression postmenopause, resulting in hyalinization with coarse calcifications. Mammographically, these are well-circumscribed, lobulated, or oval masses. Clustered microcalcifications or coarse popcornlike calcifications may be seen within the mass. Sonographically, a well-circumscribed, oval, homogeneous hypoechoic mass is seen that is usually wider than tall or parallel to the skin. On MRI, fibroadenomas have the classic appearance of an enhancing oval or lobulated mass with well-circumscribed borders that contain nonenhancing internal septations with a gradual lesional enhancement pattern. Fibroadenomas are multiple approximately 20% of the time. Complex fibroadenomas contain superimposed fibrocystic changes including cysts greater than 3 mm, sclerosing adenosis, epithelial calcifications, and papillary apocrine changes.

TUBULAR ADENOMAS

Tubular adenomas are seen in women of age 20 to 30 years presenting as palpable mobile masses. Mammographically, a well-circumscribed, round, or oval mass is

seen. Sonographic findings include a well-defined, oval, homogeneous, hypoechoic mass. These masses are indistinct from fibroadenomas. Small closely packed tubular structures with scant surrounding stroma are seen microscopically. The tubules are lined by a single layer of epithelial cells and by a discontinuous layer of myoepithelial cells.

LACTATIONAL ADENOMAS

Lactational adenomas typically occur with pregnancy and may present as a palpable mobile mass that exhibits rapid growth. Sonographically, these masses are lobulated, well-circumscribed, hypoechoic masses with posterior acoustic enhancement. Occasionally, fibrous bands or a cyst may be seen within the mass. Aspiration reveals milky fluid.

PHYLLODES TUMOR

Phyllodes tumors are fibroepithelial neoplasms that are rare and usually benign but metastases have been reported in 3% to 12% of patients. The mean age of presentation is 45 years, and most patients present with a palpable mass. Mammographically, a well-circumscribed, oval, or lobulated dense mass is seen. Increased size and a cystic component may suggest a malignant etiology but no definite imaging features differentiate benign from malignant variants of this tumor. Histologically, the epithelial elements of phyllodes tumors are similar to that of fibroadenomas; however, the stromal cells are monoclonal. Histologic criteria used to differentiate cytologically malignant phyllodes tumors include invasive margins, areas of stromal overgrowth, stromal hypercellularity with atypia, and prominent mitotic activity. Wide local excision is required as recurrence rate is high. Metastatic spread occurs hematogenously, not requiring axillary node dissection.

PAPILLOMAS

Solitary papillomas develop in subsegmental ducts. Women usually present with unilateral spontaneous serous or bloody nipple discharge. Bilateral nipple discharge is usually benign and may be endocrine in nature. Ductography (described in Chapter 77) may reveal round filling defects delineating the number and extent of ductal involvement, and ductography may be useful in surgical planning. Mammographic findings can include a dilated subareolar duct, a well-circumscribed, round, or oval mass possibly with an associated cluster

of microcalcifications or coarse, curvilinear calcifications. Intraductal lesions can be identified on US with ease if the lesion is more proximal to the nipple or associated with ductal dilation. Papillomas are small friable tumors with an epithelial lining that is contiguous with that of the ducts and is differentiated from ductal hyperplasia by the presence of a fibrovascular core. Multiple papillomas can develop in terminal ducts and are similar histologically to solitary papillomas. Mammographic findings include a lobulated mass, multiple peripheral masses of varying sizes, or clusters of punctate calcifications. US reveals multiple solid masses or a combination of intraductal solid masses. These patients may be at an increased risk for breast cancer but data is limited.

GRANULAR CELL TUMOR

A granular cell tumor is a benign tumor likely originating from Schwann cells. US and mammographic findings are similar; a spiculated round mass is seen.

FIBROSIS

Focal fibrosis is usually seen in premenopausal women presenting with a hard palpable mass. Mammographic findings include an oval or round mass with well-circumscribed to ill-defined margins or less commonly asymmetric density, architectural distortion, or spiculated mass. US findings include a hypoechoic mass with well-circumscribed, lobulated, or ill-defined margins. These lesions are frequently biopsied and the histologic diagnosis is congruent with findings when biopsy targeting was accurate. Histologically, a proliferation of stromal tissue is noted with decreased or obliterated ductal and lobular elements. Etiologies include postinflammatory change, involutional change, or hormonal stimulation of fibroelastic tissue.

GRANULOMATOUS MASTITIS

Granulomatous mastitis is a rare disease affecting young premenopausal women. It has been associated with breast-feeding, oral contraceptive use, and may have a possible autoimmune component. Women may present with breast inflammation, mass, induration, or galactorrhea. The mammographic appearance may be highly variable including asymmetric density, focal asymmetry, ill-defined masses, or the absence of findings. US shows focal areas of hypoechogenicity or ill-

defined masses with posterior acoustic shadowing. Evaluation for systemic symptoms should be included in patient history as sarcoid can rarely involve the breast. The malignant imaging findings usually prompt biopsy, which reveals chronic inflammatory cells and granulomas.

BREAST EDEMA

Breast edema is seen as diffuse bilateral or unilateral increased density on mammogram with overlying skin thickening. US imaging may reveal distended hypoechoic dermal lymphatics and subcutaneous edema. Breast edema may have many etiologies and correlation with patient history and additional findings is recommended. For example, breast edema with an enlarged heart and lower extremity edema may be related to congestive heart failure. Diffuse increased breast density may be related to cyclical change associated with hormone replacement therapy but there is no associated skin thickening. Increased breast density may be related to superior vena cava syndrome, but if unilateral changes are present mastitis or inflammatory breast cancer should also be considered.

DIABETIC MASTOPATHY

Diabetic mastopathy is an uncommon entity in premenopausal diabetic women and also in men. Clinically, these patients have a history of juvenile onset insulin-dependent diabetes with other related diabetic complications. Dense tissue is noted mammographically and an intense posterior acoustic shadowing is seen at US. Histologically, dense fibrosis is seen with thick bundles of collagen.

PSEUDOANGIOMATOUS STROMAL HYPERPLASIA (PASH)

PASH can be an incidental finding on breast biopsy or a clinically apparent mass. Symptomatic patients present with a firm, mobile, nontender mass in premenopausal or postmenopausal women on hormone replacement therapy. A noncalcified mass with well- to ill-defined margins is seen mammographically. A hypoechoic mass is noted on US. Microscopically, collagen fibers are noted in an intralobular stroma with slitlike channels that are lined by spindle myofibroblasts that are reactive for CD34 and muscle-specific actin but not factor VIII (an endothelial specific marker).

RADIAL SCARS AND COMPLEX SCLEROSING LESIONS

Radial scars and complex sclerosing lesions are similar histologically differing by size with radial scars being less than 1 cm and complex sclerosing lesions greater than 1 cm. Mammographically, architectural distortion with central fat is seen. The management of these lesions is controversial but most institutions follow a conservative approach with excisional biopsy after core biopsy diagnosis, as adequate sample size is needed to differentiate histologically between radial scar and tubular carcinoma.

GYNECOMASTIA

Gynecomastia is common, occurring in over 50% of men older than 44 years. Gynecomastia is the enlargement of the male breast with secondary branching of the ducts and proliferation of associated stromal tissue. Patients usually present with a palpable subareolar mass. Mammographically, a nodular pattern is characterized by increased tissue focally in the subareolar region. The fibrous pattern shows retroglandular tissue with fibrous extensions projecting into the fatty tissue. Diffuse glandular gynecomastia is similar to a dense glandular pattern seen in the female breast. On US, normal glandular tissue is seen in the subareolar region. Gynecomastia may be idiopathic, secondary to drugs, systemic disorders, estrogen excess, androgen deficiency, or physiologic reasons.

MALIGNANT BREAST MASSES

INVASIVE DUCTAL CARCINOMA

The most common malignant lesion of the breast is invasive ductal carcinoma (IDC) comprising 65% to 75% of breast cancer. Patients may present with a hard, fixed, palpable mass that may cause overlying skin thickening and retraction. If the cancer develops in the subareolar region, nipple retraction may also occur. Infiltration of tumor cells into the dermal lymphatic vessels produces inflammatory skin changes such as peau d'orange. Rarely, patients present with nipple discharge or with an isolated axillary metastasis without evidence of breast lesion. With the advent of screening mammography, patients with IDC are detected prior to clinical presentation. Mammographically, the most common finding is a spiculated mass. However, other mammographic findings include architectural distortion, a round or oval mass with well-circumscribed to

ill-defined margins, focal parenchymal asymmetry, or diffuse increased density with associated malignant-type calcifications. The density of malignant breast lesions is highly variable as well but is usually greater than that of surrounding breast parenchyma. It is important to thoroughly evaluate for malignant calcifications associated with IDC, as an extensive intraductal component has been associated with increased recurrence rate, which may be related to incomplete resection. Sonographic findings include an irregular, ill-defined hypoechoic mass with posterior acoustic shadowing that is taller than wide. Extension of tumor into adjacent ducts can also be seen. When evaluating a suspected IDC, evaluation of both breasts and the ipsilateral axilla by US is essential for defining extent of disease and for staging. Patients with breast cancer are at an increased risk for additional lesions. Multicentric lesions are additional lesions within the same breast but in different quadrants, while multifocal lesions are seen within the same quadrant as the original lesion. Bilateral cancers identified within 6 months of the original diagnosis are synchronous lesions. Metachronous lesions are identified in the contralateral breast more than 6 months after the original diagnosis. MRI findings of IDC include an ill-defined mass with rapid enhancement and early washout; however, other enhancement patterns may be seen.

Infiltration of the epidermis of the nipple or areolar complex by malignant cells resulting in an eczematous reaction on physical examination is known as Paget disease.

Male breast cancer represents less than 0.5% of all breast cancers. Risk factors for breast cancer in men include advanced age, previous chest radiation, cryptorchidism, testicular injury, mumps after age 20, Klinefelter syndrome, family history of breast cancer, Jewish descent, and exogenous estrogen use. Patients usually present with a painless hard mass. Mammographic evaluation reveals a retroareolar, noncalcified round to oval mass with indistinct margins. Sonographically, a hypoechoic mass is seen with variable margins and posterior acoustic shadowing. Ipsilateral axillary nodal evaluation and contralateral breast evaluation is essential to evaluate extent of disease and staging.

INVASIVE LOBULAR CARCINOMA

Invasive lobular carcinoma (ILC) represents less than 10% of breast cancers. Bilateral breast involvement is seen in approximately 20% of patients emphasizing the need for contralateral breast evaluation. The mammographic appearance of ILC is variable. Imaging findings

include noncalcified spiculated mass, unilateral breast atrophy, asymmetric density, or architectural distortion. Sonographic findings include significant posterior acoustic shadowing in large lesions and hypoechoic masses with angular or spiculated margins. The diffuse nature of this lesion is likely related to the single file infiltration of malignant cells through dense adjacent stroma. On MRI, ILC may exhibit early enhancement with washout in a segmental distribution. MRI may be valuable in evaluating the contralateral breast in patients with ILC.

TUBULAR CARCINOMA

Tubular carcinoma is a well-differentiated, slow growing IDC. Mammographically, a small spiculated, round mass is often seen which may be associated with pleomorphic calcifications. These cancers can be multifocal and bilateral and may show stability over time. Sonographically, a vertically oriented hypoechoic mass with irregular margins is seen with posterior acoustic shadowing. Histologically, these lesions may be difficult to distinguish on core biopsy from sclerosing adenosis and radial scars.

MEDULLARY CARCINOMA

Medullary carcinoma constitutes approximately 2% of breast cancers. Medullary carcinomas present clinically as palpable masses with rapid growth rates in young women usually younger than 50 years of age. Occasionally, these cancers present as interval cancers likely secondary to rapid growth rate. Mammographically, round to oval, moderate density masses are seen with well-circumscribed to ill-defined margins. Sonographic findings include hypoechoic masses with microlobulated to irregular margins and variable amounts of posterior acoustic enhancement. Histologically, malignant epithelial cells with pleomorphic nuclei and high mitotic rates are noted with an associated lymphoplasmacytic infiltrate.

MUCINOUS CARCINOMA

Mucinous carcinoma can present at any age but is more commonly seen in postmenopausal women. Typical mammographic presentation is a round mass with well-circumscribed to ill-defined margins. These lesions grow slowly over time. Sonographically, well-defined hypoechoic to isoechoic lesions are seen with variable amounts of posterior acoustic enhancement or shadowing.

PAPILLARY CARCINOMA

Papillary carcinoma is more common in older patients who present with a palpable mass. The mass is often subareolar in location and skin or nipple retraction may be seen. Mammographic findings include an oval, round, or lobulated mass with well-circumscribed margins. Sonographic findings include an isoechoic mass with microlobulations and variable cystic foci. Histologically, these lesions are difficult to differentiate from benign papillary lesions requiring adequate sampling; however, increased nuclear pleomorphism and increased mitotic rate are seen.

LYMPHOMA

Lymphoma can be primary to the breast when extramammary disease is excluded, but the breast is more often involved secondarily. Patients present with single or multiple well-circumscribed to ill-defined masses on mammogram. Occasionally, diffuse increased breast density may be seen. Calcifications are not usually seen. Axillary nodes may be involved. Burkitt-type lymphoma can present during pregnancy or lactation with bilateral breast involvement. Large B-cell lymphoma shows unilateral involvement in a wider age spectrum.

SARCOMA

Breast sarcomas are rare malignant tumors of stromal cells and include malignant phyllodes tumor, sarcoma, fibrosarcoma, malignant fibrous histiocytoma, carcinosarcoma, angiosarcoma, leiomyosarcoma, and liposarcoma. Patients usually present with a palpable mass. Mammographically, a well-defined, round mass is usually seen. On US, a heterogeneous solid mass is seen with variable posterior acoustic features. Axillary nodes are usually not involved as these lesions spread hematogenously.

METASTATIC DISEASE TO THE BREAST

The most common metastatic lesion to the breast is contralateral breast cancer. Extramammary breast metastases spread hematogenously, and lymphoma, leukemia, melanoma, ovarian, colon, renal, stomach, lung, bladder, and cervical carcinoma metastases have been reported. Mammography reveals solitary to multiple, well-defined, round lesions. US reveals hypoechoic lesions with variable posterior acoustic features.

QUESTIONS AND ANSWERS

- All of the following are *true* regarding tubular carcinoma *except*:
 - Can present as a spiculated mass on mammography
 - A well-differentiated slow-growing tumor
 - Multicentric
 - Large rapidly growing mass in young women

ANSWER: D. Tubular carcinoma is a well-differentiated breast cancer that is slow growing and is more often seen in older women. Mammographically, it most commonly presents as a spiculated mass. Tubular carcinoma may be multicentric and bilateral.

- Which of the following enhancement characteristics is most likely associated with a malignant mass on dynamic breast MRI?
 - Early enhancement washout
 - Nonenhancing internal septations
 - Progressive enhancement with delayed imaging
 - Slow gradual enhancement

ANSWER: A. Malignant lesions may show early enhancement with rapid washout or early enhancement that plateaus. Nonenhancing internal septations are seen in fibroadenomas, benign lesions. Slow gradual enhancement is more suggestive of benignity.

- What pathologic finding is responsible for the mammographic appearance of inflammatory breast cancer?
 - Tumor cells invading the dermal lymphatics
 - Inflammatory cells infiltrating the skin
 - Tumor cells infiltrating epidermis of the nipple
 - None of the above

ANSWER: A. Malignant cells invading dermal lymphatics results in overlying skin changes seen in inflammatory breast cancer. Tumor cells infiltrating the epidermis of the nipple are seen in Paget disease.

- An MRI reveals an oval lesion in the right upper outer breast with increased T1 signal centrally and low signal in this region on T2-saturated images. What is the most likely diagnosis?
 - Cyst
 - Fibroadenoma
 - Lymph node
 - Invasive ductal carcinoma

ANSWER: C. The loss of fat signal in the hilum on fat-suppressed sequence is helpful in the diagnosis of lymph node.

- Which MRI finding is most often associated with breast cysts?
 - Increased T2 signal
 - Increased T1 signal
 - Diffuse enhancement
 - Decreased T2 signal

ANSWER: A. Increased T2 signal is seen in most cysts consistent with internal fluid content.

- What disease is characterized by eczematous skin changes around the nipple secondary to tumor cells infiltrating underlying epidermis?
 - Inflammatory breast cancer
 - Paget disease
 - Lobular carcinoma in situ
 - Atypical ductal hyperplasia

ANSWER: B. Paget disease is secondary to infiltration of the areolar epidermis with tumor cells.

- Which of the following lesions is the *least likely* to present as a round mass?
 - Cyst
 - Invasive ductal carcinoma
 - Invasive lobular carcinoma
 - Papillary carcinoma

ANSWER: C. Invasive lobular carcinoma may present as an increased density, architectural distortion, or a spiculated mass.

- Which of the following is *false* regarding phyllodes tumor?
 - Mean age of presentation is greater than 60 years of age.
 - Fibroepithelial tumor
 - Malignancy is rare but can occur.
 - Sonographic findings similar to fibroadenomas

ANSWER: A. The mean age of presentation for phyllodes tumors is 45 years.

9. A patient has a palpable mass on physical examination. What is the *least likely* diagnosis?
- Hematoma
 - Cyst
 - Papillary carcinoma
 - Lobular carcinoma in situ

ANSWER: D. LCIS is usually an incidental finding on biopsy that is associated with an increased risk for breast cancer. Hematoma, cyst, and papillary carcinoma can all present as a palpable abnormality.

10. A well-circumscribed solid mass with fat and soft-tissue density is seen in the inferior right breast on mammogram. What is the next step in management?
- 3-month follow-up
 - 6-month follow-up
 - Excisional biopsy
 - Routine 1-year screening mammogram

ANSWER: D. A well-circumscribed mass with both fat and soft-tissue density is a benign lesion. Differential diagnosis includes hamartoma, intramammary lymph node, fat necrosis, galactocele, and lipoma.

79 EVALUATION OF BREAST CALCIFICATIONS

*Heidi R. Umphrey, Cheryl R. Herman,
and David E. Hogg*

INTRODUCTION

Breast calcifications are highly variable and develop secondary to various etiologies. The majority of calcifications seen on screening mammograms are benign in etiology; however, it is essential to identify malignant calcifications to detect early in situ disease. Calcifications conform to the surrounding tissue. For example, calcifications that form within ducts are rodlike following the distribution of the duct. The calcifications will be larger in subsegmental ducts, smaller in terminal ducts, and round or punctate in acini. Proliferative lesions may indent or truncate calcifications resulting in pleomorphism.

Calcifications identified on screening mammography may require additional imaging evaluation. Additional mammographic views are performed to better define the

calcifications and identify any associated mass lesion. Magnification views provide additional detail about the form, size and density of calcifications. Distribution is usually evaluated on MLO and CC views. Tangential views may also be of assistance in determining the presence of skin calcifications. A lateral 90-degree view may demonstrate calcium suspended in fluid producing a meniscus or teacup appearance.

The ACR BI-RADS lexicon uses several descriptive terms for calcifications organized by the level of concern for malignancy including typically benign, suspicious, or higher probability for malignancy. The distribution of calcifications is an additional important descriptor in evaluation of breast calcifications. Scattered or diffuse calcifications are distributed throughout the breast randomly. Calcifications scattered in a large volume of breast tissue not conforming to a ductal distribution constitute a regional distribution. Five or more calcifications occupying a volume of less than 1 cm³ of breast tissue are termed grouped or clustered. Calcifications distributed in a line are suggestive of ductal deposition but may also be vascular calcifications. A segmental distribution of calcifications is suggestive of extensive ductal involvement, which could be secondary to benign or malignant etiologies.

TYPICALLY BENIGN CALCIFICATIONS

Typically benign calcifications include skin, vascular, coarse, popcorn-like, large rodlike, round, lucent-centered, eggshell or rim, milk of calcium, suture, dystrophic, and punctate calcifications.

Skin or dermal calcifications form in dermal sebaceous glands associated with inspissated sebaceous material. Skin calcifications are round, lucent-centered and may be solitary or clustered. A common location for skin calcifications is posteromedial, projecting over the pectoral muscle on the MLO view and medially in the CC view. Tangential views can localize calcifications to the skin. Calcifications may also develop in association with nevi or other skin lesions. High-density products such as zinc oxide or talc may simulate dermal calcifications.

Calcium can be deposited in the media of arterial walls resulting in dense, linear, tram-track calcifications most commonly seen in postmenopausal women with atherosclerotic disease. Arterial calcifications may be associated with diabetes mellitus when seen in younger women. Discontinuous vascular calcifications may simulate ductal carcinoma in situ (DCIS).

Rarely, tortuous calcifications associated with a venous structure may be seen as sequela of Mondor disease or infection. Mondor disease is an uncommon

self-limiting thrombophlebitis involving a superficial vein of the breast. Patients usually present with palpable tenderness corresponding to a prominent vein. This condition usually resolves spontaneously with supportive care. Mammograms demonstrate a cordlike density that may be associated with subcutaneous thickening. Ultrasound shows a superficial tubular structure with or without Doppler flow in the acute setting.

Dystrophic calcifications are found in stromal fibrous tissue and are variable in size and shape. They are coarse, dense, large, and irregular with associated areas of lucency. These calcifications are associated with benign conditions including fat necrosis, burns, surgery, radiation therapy, and previous trauma or infection. Dystrophic calcifications can also be seen delineating the fibrous capsules of breast implants.

Popcornlike calcifications are dystrophic calcification forming within the hyalinizing fibrous stroma of a fibroadenoma. These calcifications are dense and coarse seen within an associated mass. Ultrasound may confirm an associated oval mass. In benign fibroadenomas, calcifications are usually superficial in location in counterpoint to central calcifications in necrotic malignancies.

Ductal calcifications are the result of the precipitation of calcium salts in entrapped secretions within subsegmental ducts resulting in calcium casts of dilated ducts. These calcifications are cigar-shaped, coarse, smooth bordered, diffuse, and bilateral. These ductal calcifications are directed toward the nipple and central lucencies may be seen. Differential diagnosis includes duct ectasia, secretory disease, and plasma cell mastitis. Histologically, dilated ducts contain amorphous debris, foamy macrophages, and lipid-laden crystals with an associated plasmacytic infiltrate. Ductal epithelial lining is flattened and atrophic.

Round to punctate tightly clustered calcifications may be within acini. These lobular calcifications, when tightly clustered, may reflect sclerosing adenosis. Perilobular stromal proliferation seen in sclerosing adenosis and fibroadenomas may deform acinar spaces causing pleomorphic calcifications, which can be indistinguishable from DCIS and warrant a biopsy.

Lucent centered or eggshell calcifications can be seen within the walls of cysts, oil cysts, and silicone granulomas. Peripheral calcifications less than 1 mm thick are termed rim or eggshell calcifications. Calcium may also be present as a suspension within microcysts termed milk of calcium. These calcifications show characteristic variability on orthogonal views. Milk of calcium has a smudgy, amorphous appearance on CC views; however, this calcium layers in the dependent aspect of the cysts on a 90-degree lateral or MLO view producing

curvilinear calcifications with a meniscus or teacup appearance. Microcysts and milk of calcium can be multifocal and bilateral.

Suture calcifications are coarse and can assume the shape of suture material, knots, or loops. These are more frequently seen in irradiated, postsurgical breast.

Parasites are rare but can localize to the breast and appear as calcifications involving the subcutaneous tissue or skeletal muscle. Trichinosis larvae can enter skeletal muscle such as intercostal muscles or the pectoralis muscle and subsequently encyst and calcify. Mammographically, calcified larvae may appear as linear 1 mm calcifications along the pectoralis muscles. Additionally, parasites reported to involve the breast include hydatid disease, shistosomiasis, and loiasis.

HIGHLY SUSPICIOUS CALCIFICATIONS

Linear, casting, branching, and pleomorphic calcifications are highly suspicious and warrant biopsy. Interval change in calcifications may also prompt biopsy. The differential diagnosis for these type calcifications includes DCIS, early stages of fat necrosis, dystrophic calcifications, fibrosis, and autoimmune disorders. There are several types of DCIS including micropapillary, cribriform, and solid types. DCIS grading is based on nuclear pleomorphism, with higher grades associated with the presence of central necrosis or comedo necrosis. The presence of central necrosis or comedo necrosis is associated with higher grade. It is important to evaluate extent of DCIS. Suspicious calcifications are best seen on mammography and stereotactically biopsied unless an associated mass is seen sonographically. It is essential to confirm the presence of targeted calcifications in specimen radiographs. Documentation of the identification of calcifications in the pathology specimen is important. If targeted calcifications are not documented microscopically by the pathologist, polarized microscopy should be performed. Calcifications composed of calcium phosphate appear basophilic on hematoxylin and eosin staining. Calcifications composed of calcium oxalate are not seen on routine hematoxylin and eosin staining but birefringent crystals can be seen under polarized microscopy. If polarized microscopy is negative, then the paraffin blocks containing the residual biopsy tissue should be radiographed to identify calcifications. It is important to determine concordance of biopsy results with imaging findings. Discordant results may reflect sample error and additional tissue should be obtained. DCIS can have a variable appearance on MRI but washout enhancement patterns following a ductal distribution are suspicious and may prompt MRI-guided biopsy.

QUESTIONS AND ANSWERS

- Which of the following is the highest-grade DCIS?
 - Solid type with comedo necrosis
 - Micropapillary
 - Cribriform
 - Medullary type

ANSWER: A. Comedo necrosis is associated with higher-grade DCIS. Micropapillary and cribriform types are usually low to intermediate nuclear grade. There is no medullary-type DCIS.

- Which BI-RADS lexicon descriptors of calcifications are most associated with malignant pathology?
 - Milk of calcium
 - Lucent centered
 - Popcornlike
 - Fine linear branching

ANSWER: D. Fine linear branching or pleomorphic calcifications have a higher probability of malignancy. Milk of calcium is calcium suspended in microcysts that shows variability on orthogonal views. Lucent-centered calcifications are usually benign and can frequently be seen in skin calcifications. Popcornlike calcifications develop within the hyalinizing stroma of a fibroadenoma.

- Large, coarse rodlike calcifications are seen throughout both breasts without interval change over 2 years. What BI-RADS assessment category is most appropriate?
 - BI-RADS 6
 - BI-RADS 2
 - BI-RADS 4
 - BI-RADS 5

ANSWER: B. This is a typical mammographic presentation of secretory disease or plasma cell mastitis, which is benign.

- Calcifications are seen in the subareolar breast on a CC view and are amorphous or smudgy. A true lateral view demonstrates high-density curvilinear calcifications in the subareolar breast with a teacup appearance. What do these calcifications most likely represent?
 - DCIS
 - Tubular carcinoma
 - LCIS
 - Microcysts

ANSWER: D. The calcifications are milk of calcium seen in microcysts.

- A cluster of pleomorphic calcifications in the left upper outer quadrant is biopsied stereotactically. Biopsy results include LCIS without calcifications. What is the next appropriate step in management?
 - Request polarizing microscopy to evaluate for calcium phosphate.
 - Request specimen radiographs to assess for calcifications.
 - Follow-up 1-year mammogram
 - Follow-up 6-month mammogram

ANSWER: B. Perform radiographs of paraffin blocks to assess for calcifications. Polarizing microscopy should be requested to assess for calcium oxalate as calcium phosphate is seen on routine H&E staining.

- A spiculated mass with associated pleomorphic calcifications is biopsied under US guidance. Biopsy findings are fibrocystic change with associated microcalcifications. What is the next appropriate step in management of this patient?
 - Follow-up routine mammogram in 1 year
 - Follow-up 6-month mammogram
 - Biopsy results are discordant suggesting sampling error; excisional biopsy is recommended.
 - Breast MRI

ANSWER: C. Malignant findings at ultrasound and mammogram are discordant with the benign biopsy results, which likely reflect sampling error. Additional tissue is required to exclude malignancy.

- Punctate clustered calcifications are seen in the left upper inner quadrant that show interval increase in number on screening mammogram. Stereotactic biopsy is performed and fibrocystic changes with birefringent crystals on polarizing microscopy. Which of the following is *true*?
 - Calcifications are likely composed of calcium oxalate.
 - US should be performed.
 - Excisional biopsy is recommended.
 - No calcifications were identified; paraffin blocks should be radiographed.

ANSWER: A. Calcifications composed of calcium oxalate are not seen on routine hematoxylin and eosin staining like calcium phosphate but require polarizing microscopy. Calcifications composed of calcium oxalate are seen within benign processes such as fibrocystic changes. Imaging findings are concordant with biopsy results.

8. An oval mass is seen in the left lower inner quadrant with associated coarse popcornlike calcifications. What is the most likely diagnosis?
- A. LCIS
 - B. ILC
 - C. Hyalinized fibroadenoma
 - D. IDC

ANSWER: C. The findings are consistent with hyalinized fibroadenoma.

9. Lucent centered calcifications are newly seen near the areola. What view would be best for localization to the skin?
- A. Cleopatra views
 - B. Tangential views
 - C. True lateral view
 - D. Craniocaudal view

ANSWER: B. Tangential views are utilized to localize lesions to the skin.

10. What distribution of calcifications is most likely to be benign?
- A. Diffuse
 - B. Linear
 - C. Clustered
 - D. Grouped

ANSWER: A. Diffuse or scattered calcifications are randomly distributed throughout the breast and are likely benign.

80 THE SURGICALLY ALTERED BREAST

*Heidi R. Umphrey, Cheryl R. Herman,
and David E. Hogg*

BREAST BIOPSY

Advances in image-guided biopsy have decreased sampling error over time, reducing the rates of diagnostic excisional biopsies. Mammographic findings after im-

age-guided needle biopsy may include round to spiculated masses in the immediate postbiopsy period, secondary to seroma, hematoma, or fat necrosis. Over time, minimal residual effect is seen mammographically with the exception of biopsy clip markers. Excisional biopsies contain an increased volume of tissue compared to core needle biopsy. Excisional biopsies are performed when there is discordance between the histologic and mammographic findings, suggesting sampling error, or when core biopsy histology reveals a high-risk lesion for breast cancer, such as atypical ductal hyperplasia and even LCIS at certain institutions. Finally, excisional biopsies may be necessary to further define a pathologic condition or exclude a malignant lesion such as radial scar versus tubular carcinoma. Mammographic findings after excisional biopsy include increased density, spiculated to round masses, architectural distortion, and dystrophic calcifications can be seen. High-density lesions can be further evaluated with US to determine if it is a fluid-filled lesion or solid tissue. Fluid collections may include hematoma, seroma, and abscesses. Many of these changes either resolve or evolve over time. If the mammogram reveals interval increase in size or density of postsurgical findings longer than 1 year after surgery, further evaluation with tissue diagnosis is required.

BREAST CONSERVATION THERAPY

The goal of breast conservation therapy is to achieve adequate local control of breast cancer via lumpectomy and radiation therapy with the additional benefit of a good cosmetic result. Mammographic findings after lumpectomy and radiation therapy are variable and evolve over time. In the acute posttherapy period, mammographic changes include increased edema as manifested by skin thickening and prominent trabeculae, usually seen as increased density. Sonographically, dilated dermal lymphatic, skin thickening, and increased echogenicity are seen. Skin thickening may be seen up to 2 years postradiation therapy. Fat necrosis is seen in the lumpectomy site and evolves over time. Initially, fat necrosis may be seen as a spiculated mass or architectural distortion mammographically. Over time, there may be a decrease in the size of distortion or spiculated mass with possible complete resolution over time. With evolution of fat necrosis, oil cysts or dystrophic calcifications may develop within the biopsy site. Fluid collections are seen frequently in postoperative patients within 4 weeks of lumpectomy. A round or oval mass is usually seen on mammogram with well-defined to spiculated margins, which can have variable densities. Sonographically, complex cystic masses are seen with cystic and solid components. Occasionally, fluid collections are slow to

resolve but they usually resolve over 2 years. If the patient is asymptomatic, aspiration is not indicated as many of these collections reaccumulate postaspiration. Follow-up mammography after lumpectomy and radiation therapy varies among institutions. Some protocols require a mammogram immediately before radiation therapy to evaluate for residual calcifications and then perform diagnostic mammography at 6-month intervals for 2 years after breast conservation therapy. However, other facilities may obtain preradiation therapy mammography and instead obtain diagnostic mammograms at 12-month intervals for a longer period of time.

In the first 7 years after breast conservation therapy, recurrences are likely to arise close to the lumpectomy site. After 7 years, recurrences or secondary primary lesions can arise anywhere in the breast. Malignant-type calcifications at a prior lumpectomy site warrant biopsy. Developing masses, increased density, or increased size of distortion within a lumpectomy site also warrant biopsy.

MASTECTOMY

Mastectomy may be performed when there is extensive disease, chest wall involvement, personal choice, or prophylactically. After mastectomy, the chest wall is more easily palpated and recurrences are usually identified on a thorough physical examination. Palpable abnormalities can be further evaluated with US, which can also provide guidance for biopsy if indicated.

BREAST RECONSTRUCTION

Breast reconstruction can be performed at the time of mastectomy. Implants or autologous tissue may be used for reconstruction. Autologous tissue reconstructions are most commonly achieved via a transverse rectus abdominis myocutaneous (TRAM) flap. Mammographic findings after transverse rectus abdominis myocutaneous flap include increased areas of density superiorly and inferiorly. The rectus muscle is seen as a triangular or round density posteriorly. Over time, superior and inferior densities decrease in size. Similar changes of fat necrosis are seen including oil cysts and dystrophic calcifications.

REDUCTION MAMMOPLASTY

Hypertrophic breasts can lead to significant medical as well as psychosocial concerns for women. Medical

morbidity includes postural issues, back pain, breast pain, and intertriginous infections at the mammary folds. Mammographic findings, after reduction mammoplasty include altered distribution of glandular tissue, elevation of the nipple, a swirling pattern of tissue inferiorly on MLO views, fibrotic bands in the subareolar region, distortion, oil cysts, and dystrophic calcifications.

BREAST AUGMENTATION

Breast augmentation is performed with saline, silicone, and dual lumen implants. Implants can be placed between the glandular breast tissue and the pectoralis muscle termed prepectoral or subglandular or they may be positioned posterior to the pectoralis muscle termed retropectoral or subpectoral. The type of implant and position of implant can usually be determined by mammography. Saline implants are less radiodense than silicone implants allowing visualization of wrinkles and valves. As foreign bodies, implants incite an inflammatory response that includes fibrosis and calcifications, producing a capsule. Implant rupture may result from trauma or secondary to aging of the implant and breakdown of the implant shell. While implant ruptures may be either intracapsular or extracapsular; most ruptures are intracapsular. Extracapsular implant rupture results from extrusion of the implant contents outside the capsule. When this occurs in a silicone implant, high-density amorphous material can be seen surrounding the implant or focal protrusion of the implant is seen on mammography. In cases of long-standing implant rupture, silicone may be seen extending into the superior chest wall and taken up by axillary lymph nodes. Sonographically, extravasated silicone may be visualized as specular echoes termed “snowstorm” deep to an echogenic line or as a hyperechoic mass. Extracapsular rupture of saline implants results in deflation of the implant, which can usually be determined by physical examination. Intracapsular rupture of an implant is the disruption of the implant shell with containment of the implant contents by the capsule. Intracapsular rupture is best seen on MRI, although US may demonstrate short linear hyperechoic bands in the central anechoic region of the implant, which are known as the “straw sign”. Fat- and water-saturated series reveal silicone as high signal. Fragments of low signal implant shell are seen floating in the contents of the implant also known as the “linguini sign.” Another finding is the “keyhole” sign, which is a single-layer loop of implant envelope within the lumen.

TABLE 80-1 Imaging Findings Associated with Silicone Implant Rupture

MODALITY	INTRACAPSULAR RUPTURE	EXTRACAPSULAR RUPTURE
Mammography	Negative	Silicone in breast tissue Silicone in axilla Contour deformity of implant
Ultrasound	Stairstep sign	Snowstorm sign
MRI	Linguini sign	Free silicone

This may represent a partial rupture or possible silicone or gel bleed. This must be differentiated from a “radial fold,” which is a double-layer loop of envelope protruding into the lumen and represents normal infolding or wrinkling of the implant envelope (Table 80-1).

QUESTIONS AND ANSWERS

- Which of the following mamographic findings can be seen after reduction mammoplasty?
 - Dystrophic calcifications
 - Oil cysts
 - Elevated nipple
 - All of the above

ANSWER: D. All of the statements are true.

- Extracapsular silicone breast implant rupture can be recognized on US by which of the following?
 - Keyhole sign
 - Linguini sign
 - Snowstorm sign
 - Highway sign

ANSWER: C. The snowstorm sign on ultrasound is seen with extracapsular rupture. The linguini sign is low signal implant shell fragments floating in high signal silicone seen on MRI in cases of intracapsular rupture. The “keyhole” sign is a single layer loop of implant envelope within the lumen that may represent a partial rupture or possible silicone or gel bleed.

- What is a contraindication to breast conservation therapy for newly diagnosed invasive ductal carcinoma (IDC)?
 - Previous excisional breast biopsy with benign findings
 - Previous augmentation
 - Previous reduction mammoplasty
 - Previous radiation therapy

ANSWER: D. Previous radiation therapy is a contraindication for breast conservation therapy.

- Mammography 2 years after right breast conservation therapy for IDC demonstrates interval increased density in the RUO architectural distortion with fine linear and pleomorphic calcifications. What is the BI-RADS assessment?
 - BI-RADS 0
 - BI-RADS 1
 - BI-RADS 2
 - BI-RADS 3

ANSWER: A. Interval change in lumpectomy site at 2 years is suspicious for recurrence. Additional magnification views, ultrasound, and core biopsy should be considered.

- A patient had a right mastectomy 4 years ago for ILC. She now reports a newly palpable mass at the mastectomy site. What is the next appropriate step?
 - US and physical examination
 - Mammogram
 - Follow-up in 6 months
 - MRI

ANSWER: A. The most appropriate next step would be to perform a physical examination and targeted US.

6. What is the most common type of breast cancer?
- A. Invasive lobular carcinoma
 - B. Invasive ductal carcinoma (IDC)
 - C. Tubular carcinoma
 - D. Phylloides tumor

ANSWER: B. IDC is the most common histologic type of breast cancer.

7. The linguini sign of intracapsular silicone breast implant rupture is seen on which imaging modality?

- A. US
- B. MRI
- C. Mammography
- D. All of the above

ANSWER: B. The Linguini sign is seen on MRI. Intracapsular silicone implant rupture cannot be seen on mammography. Extracapsular rupture of silicone implant is seen as the snowstorm on US.

81 **DIAGNOSTIC ARTERIOGRAPHY**

*Heidi R. Umphrey and
Baljendra S. Kapoor*

DIAGNOSTIC ARTERIOGRAPHY

Diagnostic arteriography is an established, safe, and accurate method of evaluating vascular disease. However, imaging of the arterial system is no longer limited to invasive techniques by conventional or digital subtraction angiography (DSA). CT angiography (CTA) and MR angiography (MRA), as well as Doppler ultrasound (US) have largely replaced DSA for diagnostic evaluation of the vascular system. Because of its invasive nature, DSA is now mainly utilized for the confirmation of uncertain findings on CTA, MRA, or vascular US and management of various diseases affecting the vascular system.

CATHETER-BASED ARTERIOGRAPHY: CONVENTIONAL VERSUS DSA

Improvement in the technique of DSA has significantly replaced the conventional film–screen angiography. DSA subtracts images obtained preiodinated-contrast injection “mask” from postiodinated-contrast injection images. DSA provides better contrast resolution, decreased examination time, and lower-contrast dose. Conventional angiography utilizes film–screen imaging in combination with rapid film changers and has the advantage of superior spatial resolution 6 line pairs/mm versus 2 line pairs/mm with DSA. Both angiographic techniques provide information pertaining to the vascular lumens with little information in regard to extraluminal pathology.

CONTRAST AGENTS

Most commonly, iodinated-contrast media is utilized for CTA or DSA. Low-osmolar contrast agents cause less discomfort and have lower incidence of mild allergic reactions such as itching and rashes. No study has demonstrated any significant difference in the incidence of major allergic reactions between low- and high-osmolar contrast agent. Low-osmolar contrast agents should be used in patients who are being treated for severe allergies or asthma and in patients with severe cardiac disease. Patients with previous history of allergic reaction to iodinated-contrast agent should be treated prophylactically prior to angiography, typically with methylprednisolone. Concurrent use of histamine blocker such as diphenhydramine has also been recommended. Patients with pre-existing renal failure are more susceptible to nephrotoxicity by the iodinated-contrast agent and this risk is further compounded by coexisting diabetes mellitus, increasing age, and higher volume of contrast agent. Patients with paraproteinemias such as multiple myeloma are at increased risk of renal failure because of precipitation of proteins in the renal tubules. Adequate hydration, limiting the volume of contrast, and use of low-osmolar contrast agent are some of the strategies that can be utilized to decrease the renal function compromise. Although there is no convincing evidence of their effectiveness, acetylcysteine or fenoldopam have also been utilized to prevent the deterioration of renal function.

Mild reactions such as urticaria are treated by intramuscular or intravenous diphenhydramine, usually in the dose of 25 to 50 mg. For severe reactions, such as anaphylaxis (characterized by hypotension and tachycardia), maintenance of airway and circulation by intravenous fluids are extremely important. Pharmacologic agent of choice is epinephrine 0.3 mL of 1:1000 dilution subcutaneously or 1 to 3 mL of 1:10000 dilution intravenously. For vasovagal reaction, characterized by bradycardia and hypotension, treatment of choice is atropine 0.6 to 2.0 mg intravenously.

An alternative to iodinated intravenous contrast is carbon dioxide (CO₂) in DSA imaging, as CO₂ dissolves rapidly in blood and is completely eliminated in a single pass through the lungs. This contrast agent may be utilized in patients with chronic renal insufficiency or in patients with severe iodinated-contrast allergy history. CO₂ should not be used for arterial imaging in the chest and head and neck secondary to potential neurotoxicity.

TECHNIQUE

For conventional angiography, the most common and safest approach is via the common femoral artery. The common femoral artery is palpated at the level of femoral head with the skin puncture site near the inferior margin of the femoral head to provide a means of compression. After sterile preparation and draping, a local anesthetic (usually lidocaine 1%) is injected in the skin and subcutaneous tissues and a small skin incision is made superficial to the common femoral artery.

While palpating the artery, the opposite hand is used to puncture the artery passing the needle at a 45-degree angle to the skin surface. With the double wall technique, the needle is passed through both walls of the artery. The stylet is removed and the cannula is withdrawn until pulsatile flow is obtained. The single-wall technique involves puncturing the wall with a hollow needle through the anterior wall only.

After brisk pulsatile flow is obtained, a guidewire is carefully passed through the needle and utilized to advance dilators, sheaths, and eventually catheters into the artery. Fluoroscopy is utilized to safely advance guidewires and catheters as to prevent subintimal injury. A test hand injection of contrast through a newly positioned catheter is important to ensure intraluminal position of the catheter within the desired vessel. Catheters are carefully flushed with heparinized saline throughout the procedure to prevent thrombus formation within the catheter. After the procedure is complete, the catheter and sheaths are removed and hemostasis is obtained at the puncture site via manual pressure. Retrograde common femoral puncture is the standard approach for the evaluation of thoracoabdominal aorta and its branches. Retrograde common femoral approach is also utilized for angiographic evaluation of contralateral iliofemoral arteries and lower extremity runoff. Less commonly utilized, antegrade common femoral approach is particularly suited for evaluation and endovascular treatment of infrapopliteal vasculature in the event contralateral approach is not technically feasible. A pulseless femoral artery can be punctured under ultrasound guidance or under fluoroscopy. Presence of calcification and anatomic

location of the common femoral artery at the level of medial and middle third of the femoral head are useful in localizing the common femoral artery.

Advances in axial imaging yield excellent visualization of vessels as well as their relationship to adjacent structures by CT and MR. CTA depicts the vessel lumen accurately and with helical acquisition, multiple reconstructions can be performed from the axial data set without additional contrast or radiation. MR can be utilized to evaluate vascular pathology with or without administration of intravenous contrast. MRA utilizes the inherent contrast produced by nonsaturated protons within flowing blood relative to the stationary saturated protons within soft tissues during time of flight imaging. Additionally, phase-contrast imaging utilizes the property of flowing blood as it interacts with specialized gradients imposed on the main magnetic field. Data can be obtained in the 2D mode (slice mode) or in the 3D mode (slab mode). This data is subsequently postprocessed using maximum intensity pixel algorithms for display in multiple planes. Limitations of MRA include motion artifact, scan time, flow artifacts (which may occur at severe stenoses), and methemoglobin in thrombosed vessels that produces bright signal that could falsely simulate flow. US is an invaluable tool in vascular assessment particularly in the evaluation of the carotid arteries and peripheral arterial system of lower extremities. Additionally, US is a valuable tool for vascular access guidance for interventional procedures.

PREPROCEDURE EVALUATION

Preprocedure evaluation includes clinical history and physical examination of the patient. Prior imaging studies including US, CT, MRI, and so on should be reviewed. Coagulation profile (prothrombin time [PT], partial thromboplastin time [PTT], platelets) and renal function tests (blood urea nitrogen, creatinine) should also be reviewed before angiography. In a heparinized patient, heparin infusion is stopped approximately 4 hours prior to the arterial puncture and heparin may be restarted within 4 to 6 hours after the procedure. A PTT of 1.2 times control is acceptable in the absence of other bleeding abnormalities. If patient is on warfarin sodium (Coumadin), Coumadin should be stopped 5 to 7 days prior to the procedure. Aim is to achieve an INR level below 1.4; however, in certain emergency situations such as acute gastrointestinal bleeding in a patient with coagulopathy, a higher level of INR may be acceptable. Fresh frozen plasma and vitamin K (25–50 mg approximately 4–5 hours prior to the procedure) may be utilized to correct the INR. The platelet count should be greater than 50 000 μ L.

POSTPROCEDURE MANAGEMENT

Traditionally, manual compression of the common femoral artery for 10 to 15 minutes just proximal to the arterial puncture site has been the mainstay of hemostasis. If bleeding recurs, another 10 to 15 minutes of manual compression should be applied. In last few years, the use of arterial closure devices has increased significantly.

Vascular closure devices such as perclose and angioseal can significantly shorten the time to ambulation. These devices utilize a collagen plug or suture.

POSTCATHETERIZATION COMPLICATIONS

Iatrogenic complications from femoral arterial catheterization include hematoma, dissection, thrombosis, pseudoaneurysms, distal embolization, and arteriovenous fistula. Risks factors include anticoagulation, large catheters or sheaths, inadequate compression, or poor access technique. Sonographic evaluation is the imaging study of choice. Hematoma is a mass of varying echogenicity without Doppler flow. A pseudoaneurysm (PSA) communicating with the femoral artery is seen on color Doppler as swirling flow “yin-yang.” Color Doppler can also demonstrate high velocity “to-and-fro” flow at the site of the communication. US-guided thrombin injection is now the preferred mode of managing postcatheterization PSAs. Rarely, US-guided compression of the PSA neck by US transducer is used for thrombosis of the PSA. An AVF is more common after inferior entries, where the artery may lie just superficial to the vein. Arterialized flow is seen within the vein, and there is loss of high resistance triphasic arterial waveforms and low resistance flow (accentuated diastolic flow) within the artery proximal to the AVF.

NONSELECTIVE AORTOGRAPHY

Nonselective arteriography is usually performed with multiple side hole 5F or 4F catheters such as pigtail or omni flush catheter. In pediatric population, a 3F or 4F catheter is usually sufficient. Nonselective arteriography of the arch is routinely performed prior to evaluation of the major arteries arising from the arch in elderly patients because of atherosclerotic disease and potential complication of stroke because of dislodgement of plaque from catheter and guidewire manipulation.

The left anterior oblique (LAO) view provides information about the origins of left subclavian, left common carotid, and the brachiocephalic arteries. The right anterior oblique (RAO) view is utilized for the evaluation of

right common carotid, right subclavian, and origins of both the vertebral arteries.

Abdominal aortography is used to evaluate the abdominal aorta and visceral branches. An approximately 30-degree LAO view provides the best view of origin of renal arteries. The position of the catheter depends on the clinical indication for the procedure. For the evaluation of mesenteric arteries, the catheter is placed at the level of T12 to include origin of the celiac artery. However, for evaluation of renal arterial or infrarenal disease, the catheter is typically placed at L2 to avoid unnecessary filling of the mesenteric circulation. Prior to power injection of the contrast, one must ensure that the pigtail is freely moving in the aorta to avoid injection into a side branch and to minimize the risk of atheroembolism. The most common access for evaluation of the thoracic aorta is via a common femoral artery approach with left axillary or translumbar arterial approaches providing access but is less desirable. For imaging of the thoracic aorta, a pigtail catheter is utilized and placed 1 to 2 cm distal to the aortic valve or within the descending aorta depending on the area of interest. The 45-degree LAO projection best displays the arch and great vessel origins; however, optimum positioning should be individualized with each patient. Contrast is injected at the rate of 20 to 30 mL/s for 2 seconds with rapid filming (frame rate 4–6/s). Extended filming may be necessary for patients with slow flow or suspected dissection. For abdominal aortography, the injection rate is 20 to 25 cm³/s at 4 to 6 frames/s in AP and lateral projections. For the evaluation of atherosclerotic disease involving the pelvic arteries, angulation for the oblique views is individualized in each patient as tortuosity of these arteries varies in every patient; however, as a general rule contralateral oblique opens the ipsilateral internal iliac ostium; and ipsilateral oblique opens ipsilateral common femoral bifurcation.

SELECTIVE ARTERIOGRAPHY

Selective arteriography is performed by selective catheterization of the artery of interest by endhole catheters. Intravascular position of the catheter should be confirmed by aspiration of the catheter or by hemodynamic assessment of the waveform to avoid inadvertent injury to the vessel wall or dislodgement of clot formed at the tip of the catheter.

RENAL ANGIOGRAPHY

Renal arteries typically arise at the level of L2. Occasionally, there may be multiple renal arteries arising from the abdominal aorta. The most frequent indications

for renal arteriography are evaluation of trauma, tumors and renovascular hypertension, and vascular anomalies. Diagnostic, nonselective abdominal aortography is useful to evaluate the orifice and multiplicity of the renal arteries. Catheter selection for renal arteriography includes cobra, SOS, VS1/2, and sidewinder and typical injection rate is 5 to 6 mL/s for a total of 12 to 14 mL. AP or slightly LAO views are usually sufficient to evaluate proximal renal arteries.

MESENTERIC ANGIOGRAPHY

Typical catheter choice is a visceral catheter such as Cobra, RC1/2, or VS1/2. Injection is continued through the venous phase to evaluate patency of portal vein. Some angiographers prefer to start from diagnostic arteriogram in lateral projection to evaluate origins of the mesenteric arteries. This can be particularly useful in elderly patients because of potential stenosis of the ostia by underlying atherosclerotic disease. Intravenous injection of 0.5 to 1.0 mg glucagon before superior mesenteric angiography decreases bowel motility and associated artifact. A typical injection rate for celiac/SMA is 6 to 7 cm³/s for a total volume of 40 to 50 cm³ and for IMA, it is 3 to 4 cm³/s for a total volume of 18 to 20 cm³.

CAROTID AND CEREBRAL ANGIOGRAPHY

Arch aortography with a nonselective pigtail or omni flush catheter optimizes catheter selection for selective carotid and vertebral arteriography. Evaluation of the origins of the major arteries from the aortic arch is particularly important when a patient is being evaluated for underlying atherosclerotic disease. For the carotid arteries, the catheter tip is placed just proximal to the bifurcation and contrast is injected at the rate of 5 to 6 cm³/s with a total volume of 8 to 10 cm³. Provided there is no significant carotid bifurcation disease, the external and internal carotid arteries can be selectively catheterized.

For internal carotid arteries, contrast is injected at the rate of 4 to 5 cm³/s for a total volume of 7 to 8 cm³. Imaging is performed in an AP projection with 10- to -15-degrees cranial angulation, lateral, and 45-degree LAO or RAO views. For evaluation of vertebral arteries, the catheter is placed in the proximal subclavian artery and a test injection is performed. If the origin of the artery is unremarkable, the vertebral artery is selected and contrast is injected at the rate of 5 to 6 cm³/s for a total of 10 cm³. Reflux of contrast into the opposite vertebral artery and filling of its posterior inferior cerebellar artery (PICA) branch is usually desired while evaluating intracranial

circulation to avoid catheterization of opposite vertebral artery. Commonly used catheters for intracranial angiography include the following: 5F-angled glide headhunter (H1, H3, H1 H), Berenstein, vertebral, glide JB-1, JB-2, JB-3, SIM1, SIM2, and SIM3.

UPPER EXTREMITY ANGIOGRAPHY

Common indications for upper extremity angiography are trauma, tumor, atherosclerotic disease, vasculitis, and arteriovenous malformations. A 4F to 5F headhunter or an angled glide catheter is utilized to select the subclavian or axillary artery. Contrast is injected at the rate of approximately 5 to 6 cm³/s with a total volume of approximately 10 to 12 cm³.

LOWER EXTREMITY ANGIOGRAPHY

The most common indication for lower extremity angiography is evaluation of atherosclerotic disease. Pelvic arteriography is performed by placing the pigtail catheter in the distal aorta. AP and both oblique views are obtained by injecting contrast at approximately 10 cm³/s for a total volume of 18 to 20 cm³. Most of the angiographic tables are equipped for bilateral lower extremity runoff. For bilateral lower extremity run off (bolus chase), the typical volume injected is 6 to 10 cm³/s for 10 to 12 seconds. Selective single limb angiography can be performed by crossing over to the opposite side utilizing a 4F or 5F RIM catheter and exchanging it to 4F to 5F Berenstein or JB1 catheter. Angiography is performed by stationary DSA runs at 5 to 6 cm³/s for a total volume of 10 to 12 cm³ of contrast.

ANATOMY AND CONGENITAL VARIANTS

Arteries are composed of three layers including a thin, endothelial lined layer called the intima, a variably thick muscular layer known as the media, and an outer fibrovascular layer termed the adventitia.

THORACIC AORTA

The thoracic aorta extends from the aortic valve to the diaphragmatic hiatus and is divided into three segments: the ascending aorta, aortic arch, and descending aorta. The ascending segment extends from the aortic valve to the origin of the brachiocephalic artery. Proximally, three sinuses correspond to the three aortic cusps; the coronary

arteries arise from two of these sinuses. The left coronary artery arises from the left coronary sinus and the right arises from the right aortic sinus. The ascending aorta has a diameter of 2.5 to 3.5 cm in adults and is normally larger than the diameter of the descending aorta. The aortic arch extends from the origin of the brachiocephalic artery to the attachment of the ligamentum arteriosum with a normal right-to-left course. The arch gives rise to the brachiocephalic, left common carotid, and left subclavian arteries in most individuals. The most common variation in arch anatomy is a common trunk for the brachiocephalic and left common carotid arteries (approximately 20%). The isthmus is the arch between the left subclavian artery origin and the ligamentum arteriosum and is a focus of aortic narrowing. The descending thoracic aorta comprises the remainder of the thoracic aorta and usually gives rise to nine pairs of intercostal arteries. The two upper intercostal spaces are supplied by the superior intercostal artery arising from the costocervical trunk. Bronchial arteries vary but most often arise from the level of T4-7 with the most common pattern consisting of one right and two left arteries.

COLLATERAL CIRCULATION

Obstructive lesions involving the thoracic aorta result in activation of the collateral circulation. The most common obstructive lesion involves the proximal descending thoracic aorta and is seen in coarctation of the aorta. The obstruction at this level results in hypertrophy of the subclavian arteries and their muscular branches, bilaterally. Just distal to the obstruction, there is reversal of flow in the intercostal arteries toward the descending aorta. These intercostal arteries are supplied by the internal mammary arteries. Both internal mammary arteries also provide flow to the lower extremities via the epigastric arteries.

The most frequent arch anomaly is left aortic arch with aberrant right subclavian artery seen in approximately 1% of individuals. The right subclavian artery arises as a fourth branch of the aortic arch, most commonly crossing posterior to the esophagus. Dilation at the origin of the aberrant vessel is termed diverticulum of Kommerell. This anomaly is rarely symptomatic but patients can present with dysphagia (dysphagia lusoria). Associated cardiac anomalies are seen in 10% of patients with coarctation of the aorta and tetralogy of Fallot being most common.

A right arch with mirror image arterial branching occurs in approximately 60% of individuals with right arch anatomy and has no retroesophageal impression. It has a high association with congenital heart disease, most commonly tetralogy of Fallot. A right aortic arch with aberrant left subclavian artery is seen less often and

either the arch or aberrant vessel may cause posterior impression on the esophagus. Associated congenital heart disease is seen in a small percentage of patients with tetralogy of Fallot, including atrial septal defect and coarctation seen most frequently.

Coarctation is a narrowing of the aortic lumen with two classic forms described. An “infantile” form consists of focal distal arch obstruction at the level of the ductus arteriosum with proximal hypoplasia of the aortic arch. This is symptomatic in childhood. The “adult” form is a discrete infolding of the aorta opposite the ligamentum arteriosum. It is seen more often in males and often associated with other anomalies including bicuspid aortic valve, patent ductus arteriosus (PDA), ventricular septal defect (VSD), as well as circle of Willis aneurysms. Coarctation is frequently seen in Turner syndrome (XO) patients.

Clinically, patients may exhibit hypertension of the upper extremities and diminished pulses in the lower extremities. In the young infants, radiographs show enlarged heart because of cardiac failure. In the young child, the chest radiograph demonstrates an enlarged heart with dilated descending aorta distal to the level of coarctation. In the older children and adults, characteristic “3” sign formed by dilatation of the proximal left subclavian artery proximally, an indentation in the contour of the descending thoracic aorta just inferior to the aortic knob in the frontal projection representing the area of coarctation and poststenotic dilatation. Tortuous, dilated intercostal arteries may produce rib notching (ribs 3–9). Acquired coarctation can result from idiopathic inflammatory conditions, radiation vasculitis, rubella syndrome, and neurofibromatosis. MR is the imaging modality of choice for coarctation. Angiography provides extent of aortic involvement and allows for measurement of pressure gradients.

ABDOMINAL AORTA

The abdominal aorta originates at the diaphragmatic hiatus and extends to bifurcate into common iliac arteries at the level of L4. The abdominal aorta normally measures 2.5 cm in diameter proximally tapering to 1.5 to 2.0 cm distally. The major branches of the abdominal aorta include the celiac axis at T12-L1, the superior mesenteric artery at L1-2, and the inferior mesenteric artery at L3-4 arising from the ventral aorta. Paired main renal arteries arise laterally at the level of L2 in most patients. Paired phrenic, adrenal, and gonadal arteries as well as four pairs of lumbar arteries arise from the lateral or posterolateral aorta.

In the event of obstructive aortoiliac disease, there are multiple collateral pathways present in the abdomen and

pelvis to maintain arterial flow distally. Activation of a particular collateral pathway depends upon the site of arterial obstruction. These pathways include the following:

- Superior epigastric to common femoral artery via inferior epigastric artery.
- Lumbar arteries to external iliac arteries via iliolumbar and internal iliac and to common femoral artery via iliac-circumflex artery.
- Inferior mesenteric artery to external iliac artery via hemorrhoidal and internal iliac artery.
- Median sacral artery to external iliac artery via lateral sacral and internal iliac artery branches.
- Internal iliac artery provides collateral flow to opposite internal iliac artery via free anastomosis between the branches of anterior division of internal iliac arteries and lateral sacral artery.
- Internal iliac artery to ipsilateral common femoral artery via iliac circumflex artery and profunda femoris artery.

UPPER EXTREMITY

The right subclavian artery arises from the brachiocephalic artery, and the left subclavian artery arises from the aortic arch. The branches of the subclavian artery include (in order): vertebral artery, internal mammary artery, thyrocervical trunk, and costocervical trunk. The axillary artery extends from the lateral aspect of the first rib and gives rise to the anterior and posterior circumflex arteries. The brachial artery courses along the medial aspect of the upper arm branching into the radial and ulnar arteries just proximal to the elbow. Just distal to the origin of the ulnar artery, it gives rise to the common interosseous artery that usually terminates in the distal forearm; however, continuation of this artery into the hand is termed a persistent median artery and is a common variant. The radial and ulnar arteries form the deep and superficial palmar arches in the hand respectively.

LOWER EXTREMITY

The common iliac arteries originate at the bifurcation and extend to the pelvic brim, subsequently branching into external and internal iliac arteries. The internal iliac artery (hypogastric artery) gives rise to the anterior trunk (branches: superior and inferior vesicle, middle hemorrhoidal, internal pudendal, obturator, inferior gluteal, and prostatic or uterine arteries as well as branches to ductus deferens and seminal vesicles) and the posterior trunk (branches: iliolumbar, lateral sacral, and superior gluteal arteries). The external iliac arteries course to the inguinal ligament giving off the deep cir-

cumflex iliac and inferior epigastric arteries. The common femoral artery bifurcates into the profunda femoris and the superficial femoral artery (SFA) near the inferior margin of the femoral head. The SFA courses in the anteromedial thigh to the adductor canal. The popliteal artery is the continuation of the SFA at the level of the adductor canal coursing through the knee.

The popliteal artery divides inferior to the knee into the anterior tibial (AT) artery and a short tibioperoneal trunk that in short order divides into the peroneal and posterior tibial (PT) arteries. The AT artery passes over the interosseous membrane below the knee descending into the anterior compartment of the leg continuing into the foot as the dorsalis pedis artery. The peroneal artery terminates above the ankle and the PT continues into the foot posterior to the medial malleolus into the plantar aspect of the foot giving off medial and lateral plantar arteries. A persistent sciatic artery is a rare congenital variant seen as an enlarged inferior branch (inferior gluteal) of the internal iliac artery exiting the pelvis posteriorly through the lower portion of the greater sciatic foramen providing dominant inflow to the leg as the proximal SFA may be hypoplastic or absent. This is usually a bilateral finding. Because of its superficial location, this artery is prone to injury and aneurysm.

ATHEROSCLEROSIS

Atherosclerotic plaques are intimal lesions that protrude into vascular lumens producing luminal obstruction, which can be concentric or eccentric in nature. Dystrophic calcification may be seen in the chronic plaques. Risk factors for atherosclerosis include age (more than 60 years), sex (male greater than female), diabetes, hypertension, cigarette smoking, genetic predisposition, and hyperlipidemia. Atherosclerosis can lead to ischemic symptoms that vary based on the artery involved and severity of disease. Associated complications include plaque ulceration, acute thrombosis, and distal embolization. Sudden changes in symptomatology usually indicate an acute complication with clinical findings including diminished pulses, claudication, hair loss or skin changes, rest pain, and gangrene.

Atherosclerosis is a systemic disease and multiple arterial beds can be involved simultaneously. It is usually symmetric and commonly affects arterial bifurcations and ostia secondary to increased turbulence. Imaging shows concentric or eccentric luminal narrowing with occasional poststenotic dilatation. In the lower extremities, the most common artery involved is the SFA followed by the iliac, tibial, popliteal, and common femoral arteries. Arteriography plays a valuable role in preoperative planning and percutaneous intervention

including percutaneous angioplasty, stent placement, and atherectomy. Findings indicating a significant stenosis include greater than 50% luminal narrowing, presence of collateral flow, and peak systolic gradient across the lesion of greater than 10 mm Hg.

Thromboembolism is a common cause of acute arterial occlusion with emboli originating from the heart, proximal aneurysms, or proximal atherosclerotic lesions. The characteristic angiographic appearance is abrupt vessel occlusion with a superior convex meniscus, multiple lesions with emboli at bifurcations, lack of collateral flow, and vasospasm. Arterial thromboembolism results in acute arterial occlusion and threatened ischemia. Clinical presentation includes pain, pulselessness, pallor, paresthesias, and paralysis. Minimizing time from diagnosis to intervention is crucial to prevent tissue or even limb loss.

ANEURYSMS

Aneurysms are localized abnormal dilation of vessel walls and are classified as true aneurysms with all three layers intact or false aneurysms with one or more layers disrupted and containment provided by adjacent extravascular connective tissue. Most thoracic aneurysms are asymptomatic but patients can present with chest pain, stridor, dysphagia, SVC syndrome, and hoarseness. Important risk factors for the development of aneurysms are age, sex (male greater than female), and cigarette smoking.

Chest radiographs demonstrate contour abnormality with aortic tortuosity and vessel wall calcifications. Axial imaging may differentiate aneurysms from other posterior mediastinal masses. CTA and MRA demonstrate wall diameter, mural thrombus, wall calcifications, degree of luminal patency, and mass effect on adjacent mediastinal structures. Ruptured or leaking aneurysms reveal increased soft-tissue density, resulting from mediastinal hematoma and associated left pleural effusion. MR shows signal intensities of blood products within the mediastinum. Angiography is typically reserved for operative planning when it is vital to establish the relationship of the aneurysm to the great vessels, coronary arteries, and vascular supply to the spinal cord. Imaging of the abdominal aorta may also be needed. Angiography is unreliable in evaluation of aneurysms size in the presence of mural thrombus.

Atherosclerotic aneurysms are the result of mild-to-moderate inflammation involving the aortic wall and degradation of structural components of the aorta by matrix metalloproteases. This is combined with impairment of the vasovascular blood supply to the vessel wall resulting in loss of muscular fibers within the media.

Fusiform irregular walls are noted secondary to mural thrombus. Discontinuous curvilinear and plaque-like calcifications are seen. Syphilitic aneurysms are the late sequelae of untreated syphilis resulting from obliterative endarteritis of vasovascularum. Subsequent scarring and retraction of the vessel wall produces wrinkling of the intima known as “tree barking.” Syphilitic aneurysms predominately affect the ascending aorta and aortic arch. Mycotic aneurysms result from weakening of vascular wall from bacterial infection. Patients with bacterial endocarditis, intravenous drug use, aortic surgery, and immunocompromised state are predisposed to these types of aneurysms. These may arise from a septic embolus from endocarditis, vascular wall infection from bacteremia, or direct infectious spread from adjacent structures. These are saccular aneurysms occurring in the ascending and descending aorta. Clinical presentation may include sudden onset pulsatile abdominal mass and fever. CT demonstrates a noncalcified saccular aneurysm with periaortic fluid, gas, or vertebral osteomyelitis. The most common organisms are *Staphylococcus* and *Salmonella* species. Indium-labeled white cell radionuclide imaging is useful in differentiating this from other types of aneurysm. Rupture occurs in as many as 80% of mycotic aneurysms.

Connective tissue disorders such as Marfan and Ehler-Danlos syndrome are associated with abnormal collagen production resulting in cystic medial necrosis and ascending aortic aneurysm formation. The characteristic symmetrical dilation of the sinuses of Valsalva is termed “tulip bulb aorta” and differentiates Marfan from atherosclerotic aneurysms. Ankylosing spondylitis, Reiter syndrome, and relapsing polychondritis are other causes that are associated with thoracic aortic aneurysms.

An abdominal aortic aneurysm (AAA) is defined as dilation of the abdominal aorta greater than 3 cm. They occur in 2% to 6% of the targeted population, most commonly in white males older than 60 years. Most AAA are asymptomatic and are detected on physical examination as a pulsatile mass or incidentally on imaging studies. Clinical presentations can include abdominal pain, abdominal mass, and distal embolic events. Most are infrarenal and are secondary to atherosclerosis. Progressive mural thrombus within the aneurysm may result in occlusion of branch vessels. They tend to be fusiform and enlarge at a rate of 2 to 4 mm per year. Extension into the iliac arteries is common. Complications of AAA include rupture, peripheral embolization, thrombosis, and infection. The incidence of AAA rupture is directly related to increasing aneurysm size (Table 81-1).

US is the imaging modality of choice for initial evaluation, screening, and follow up of AAA. Asymptomatic AAA less than 4 to 5 cm in diameter are followed with serial US until intervention is needed. US can detect

TABLE 81-1 Aortic Aneurysm Diameter and Risk of Rupture

SIZE OF ANEURYSM	RISK OF RUPTURE (%)
<4 cm	10
4–7 cm	25
7–10 cm	45
>10 cm	60

intramural thrombus, accurately size the aneurysm, and detect extension into the iliac arteries. US is limited by patient body habitus, overlying bowel gas, and in evaluation of renal arterial involvement. CTA surpasses US in defining the relationship of the aneurysm to the renal arteries and surrounding structures. CTA with 3D reconstruction is useful for treatment planning. CT is the modality of choice for evaluation of suspected rupture, leaking aneurysm, and perianeurysm fibrosis. Aneurysms are repaired with either endograft or open graft placement procedures. CTA is extremely valuable in evaluation of postendograft repair of AAA particularly in assessment of endoleak and migration of the endograft.

There are five types of endoleak (Table 66-1). A type I endoleak develops secondary to inadequate or ineffective seal at the proximal or distal aspect of the graft thereby allowing a persistent perigraft inflow. A type II endoleak is secondary to persistent collateral retrograde blood flow into the aneurysm sac, commonly from lumbar arteries, the internal iliac artery, or other collateral vessels. A type III endoleak arises when there is a defect within the graft fabric or between segments of a multi-segmental graft. A type IV endoleak is secondary to “bleed-through” or inflow across the pores of a graft. Type V endoleak is endotension; there is no visible contrast or flow in the aneurysm sac but continued expansion. Popliteal artery aneurysms occur in approximately 4% to 10% of patient population with AAA. Imaging of the patients suspected with popliteal artery aneurysm should include the abdominal aorta and popliteal arteries as these aneurysms are bilateral in over 50% of the patient population and approximately 62% of the patients with popliteal aneurysms will also have concomitant AAA. The most common presentation is ischemia because of embolization and rupture is rare. US is 100% sensitive in diagnosing the popliteal artery aneurysm. All symptomatic aneurysms should be repaired and treatment is recommended for asymptomatic aneurysms larger than 2 cm in diameter.

The splenic artery is a common site of visceral artery aneurysm. Most are solitary and localized to the distal two-thirds of the splenic artery. Patients are usually asymptomatic. These are more common in women and have an increased rupture rate during pregnancy

accompanied by a 25% mortality rate. Symptomatic aneurysms, enlarging aneurysms, association with pregnancy or childbearing women, or size greater than 2 cm are indications for intervention.

AORTIC DISSECTION

An aortic dissection is defined as a separation of the layers of the vessel wall creating a false lumen with blood dissecting between and along the laminar planes of the media. The media defect can be acquired or congenital as in the case of Marfan syndrome. Predisposing factors to dissection include hypertension, bicuspid aortic valve, coarctation, pregnancy, scoliosis, pectus excavatum, trauma, prior aortic surgery, and intra-aortic balloon pump. Mortality is usually associated with retrograde dissection into the pericardium causing tamponade, massive aortic regurgitation, or pleural space hemorrhage. Aortic dissection is more common in men between the ages of 40 and 60. Patients may present with sudden severe substernal pain with radiation to the back. Asymmetrical pulses in the upper extremities are often seen when there is such involvement.

There are two classification systems to describe aortic involvement in dissection. The Debakey classification describes three types of dissection (Table 81-2). The Stanford classification is composed of two types of dissections. Type A is the most common type and involves the ascending aorta with variable involvement of the arch and descending aorta. Type B is limited to the arch and descending aorta. Aortic dissection involving the ascending aorta is usually repaired surgically on an emergent basis because of involvement of the aortic root and coronary arteries and a high risk of rupture into pericardial and pleural cavities. A dissection involving the descending aorta is usually managed by conservative medical treatment with aggressive blood pressure control.

CT is excellent for evaluation of dissection with accuracy greater than 90%. The intimal flap is seen as a linear filling defect within the aortic lumen. The true and false lumens may be opacified; although the false lumen may exhibit delayed opacification and late filling of branch vessels arising from the false lumen. The false lumen may compress the true lumen appearing larger and may also contain thrombus. Aortography is rarely

TABLE 81-2 Debakey Classification of Dissection

Type I	Ascending aorta, arch, and variable portions of the descending thoracic aorta
Type II	Ascending aorta, worst prognosis
Type III	Originates near the isthmus distal to the left subclavian artery, does not involve the ascending aorta or the aortic arch, most common type

necessary unless an intervention is planned. The common femoral approach usually allows access to the true lumen as dissections rarely involve the external iliac arteries. Contrast opacification of both the true and false lumens is very important particularly in the cases involving the ascending aorta to determine involvement of the aortic root and coronary arteries. The classic finding is a “double barrel” sign with an interposed intimal flap. The intimal flap usually originates in the anterolateral ascending aorta and spirals to the left posterolateral aspect of the descending aorta to the abdomen. Visceral arteries may be supplied by true or false lumen. The left renal artery is frequently supplied by the false lumen. Symptomatic occlusive complications of aortoiliac dissection can be effectively managed with minimally invasive techniques such as percutaneous fenestration, stent placement, or stent graft placement.

VASCULITIDES

The term “vasculitis” refers to pathologic inflammation and necrosis of the blood vessel wall. Vasculitides are classified based on the vessel size involved. Large vessel vasculitis includes temporal arteritis and Takayasu arteritis. Medium vessel vasculitis includes polyarteritis nodosa and Kawasaki disease. Small vessel vasculitis includes Churg-Strauss syndrome, hypersensitivity vasculitis, Wegeners granulomatosis, and Behcet syndrome.

TAKAYASU DISEASE

Takayasu disease is a granulomatous vasculitis of the medium- and large-sized arteries. The etiology is idiopathic and it primarily affects young (20–40 years) Asian women. It is characterized by marked weakening of the upper extremity pulses known as “pulse less disease.” Fibrous thickening and narrowing of the aorta including aortic arch is classically seen, but branch involvement can also be seen with marked narrowing of arteries supplying the upper body and viscera. The acute stage is characterized by fever, myalgia, arthralgia, and malaise. The fibrotic stage is characterized by pulse deficits, claudication, bruits, and renovascular hypertension. Chest radiographs may show calcifications in the aortic wall. Arteriography shows long or short segment smooth narrowing of the aorta or branch arteries.

GIANT CELL ARTERITIS

Giant cell or temporal arteritis is the most common form of systemic vasculitis in adults. This is more common in

women than men. This is a granulomatous arteritis primarily affecting the temporal arteries but vertebral, ophthalmic arteries, as well as the aorta may also be involved. On clinical examination, patients are generally older than 50 and may also exhibit polymyalgia rheumatica, jaw claudication, and visual loss. Affected arteries may be tender and demonstrate nodular thickening, erythema, and swelling. Laboratory investigation may reveal elevated erythrocyte sedimentation rate and elevated C-reactive protein. On US, a hypoechoic halo with scattered areas of increased peak systolic velocity may be useful in diagnosis. CT, MR, or arch angiography can demonstrate large artery involvement.

POLYARTERITIS NODOSA

Polyarteritis nodosa is a systemic necrotizing vasculitis affecting small- or medium-sized muscular arteries in young adults. Histopathologically, there is transmural inflammation. Inflammatory destruction of the media leads to aneurysm formation. The renal and visceral arteries are frequently affected with relative sparing of the pulmonary vessels. Clinical presentation may include malaise, fever, weight loss, hypertension, and abdominal pain. Hepatitis B infection is reported in approximately 7% of the patients. Diagnosis is based on arteriographic documentation of mesenteric or renal artery aneurysms or biopsy.

KAWASAKI DISEASE (MUCOCUTANEOUS LYMPH NODE SYNDROME)

Kawasaki disease or mucocutaneous lymph node syndrome is an arteritis primarily affecting the coronary arteries seen in infants and young children. Coronary artery involvement results in coronary artery aneurysm formation, which can be seen on echocardiography. It is associated with an acute self-limiting illness including fever, palm, and sole erythema, desquamative rash, conjunctivitis, and cervical lymph node enlargement. Uncommonly, other large, medium, or small arteries may also be involved.

SMALL VESSEL VASCULITIS

Angiography plays a limited role in the diagnosis of small vessel vasculitis. Diagnosis is primarily based on clinical and laboratory findings. Churg-Strauss syndrome or allergic granulomatous angitis usually involves small muscular arteries with eosinophilia and extravascular granulomas in a patient with a history of allergic rhinitis, asthma, or both. Hypersensitivity

vasculitis includes serum sickness, Henoch-Schonlein purpura, and drug hypersensitivity reaction. Wegeners granulomatosis involves a necrotizing granulomatous process of the respiratory tract and kidneys. Laboratory tests are positive for ANCA test but are negative for anti-nuclear antibody test. Behcet syndrome is a multisystem inflammatory disorder characterized by recurrent oral aphthous ulcers, genital ulcers, uveitis, and skin lesions.

BUERGER DISEASE (THROMBOANGITIS OBLITERANS)

Buerger disease is secondary to acute and chronic inflammation of small- and medium-sized arteries characterized by segmental thrombosis. The etiology is unknown with venous involvement occurring occasionally. Nearly all patients are smokers and the great majority are young males. The erythrocyte sedimentation rate and serum C-reactive protein are usually normal. Claudication is a common clinical presentation. The arteries supplying the calf and foot are most commonly affected; however, upper extremity involvement may also occur affecting ulnar or radial arteries. Arteriographic findings include bilateral distal extremity arterial occlusions, intervening normal appearing arteries, multiple corkscrew collaterals, and sparing of larger inflow arteries without any evidence of atherosclerosis.

COLLAGEN VASCULAR DISEASES

Collagen vascular diseases including rheumatoid arthritis, systemic lupus erythematosus, and scleroderma affect the small- and medium-sized arteries of the distal upper extremities. Involvement is typically bilateral and symmetrical with progressive concentric vessel narrowing leading to occlusion with poorly developed collaterals. The vasospastic disorder Raynaud phenomenon is frequently associated.

RADIATION VASCULITIS

Endothelial injury caused by radiation can result in subintimal fibrosis and arterial stenosis or occlusion. The extent of vascular injury corresponds to the area irradiated.

TRAUMA

Aortic transection results from sudden deceleration injury usually in a high-speed motor vehicle collision or penetrating injuries as well as iatrogenic injuries during endovascular or surgical procedures. The laceration may involve one or more layers of the aortic wall. The most common site for injury is the aortic isthmus near the attachment of the ligamentum arteriosum, followed by aortic root and diaphragmatic hiatus injuries. This injury

has more than 90% mortality prior to reaching the hospital and 85% mortality within 24 hours of hospital admission; therefore, prompt diagnosis is essential. Chest radiographs demonstrate widened mediastinum, indistinct aortic knob, abnormal aortic contour, and rightward displacement of the nasogastric tube and/or trachea. CT findings include mediastinal hemorrhage (may be because of bony trauma or disruption of venous structures), abrupt aortic or branch vessel contour change, aortic PSA, intimal flap, pseudocoarctation, and contrast extravasation. Conventional angiography findings include subtle intimal tears, complete transection, traumatic PSA, and posttraumatic coarctation.

Blunt abdominal injury is most often associated with acute deceleration injuries usually related to motor vehicles (seat belt injuries). Injuries to major branch vessels such as renal arteries are commonly associated. Clinical symptoms can be obscured by other intra-abdominal or musculoskeletal injuries; however, absent or decreased pulses as well as embolic events are signs of possible aortic injury. If peritoneal lavage or CT abdomen and pelvis demonstrate intraperitoneal hemorrhage, the patient is sent to operating room for the repair of intra-abdominal injuries. Bleeding in the pelvic retroperitoneum is very difficult to control surgically and surgical decompression of hematoma usually leads to increased blood loss. If the patient remains hemodynamically unstable, emergency angiography and possible embolization of the bleeding artery are required. CT and angiographic findings of arterial injury include intimal irregularity, dissection, laceration with PSA, retroperitoneal hematoma, and thrombosis. Penetrating trauma increases the risk for arteriovenous fistula.

Peripheral vascular injury is usually caused by blunt or penetrating trauma. Patients may present with normal physical examination or reveal a cold, pulseless, ischemic extremity, and/or an expanding pulsatile hematoma suggesting arterial injury. Angiographic findings of peripheral vascular injury include intimal tear, spasm, extrinsic compression, contrast extravasation, occlusion, PSA, and arteriovenous fistula. Posterior knee dislocation should proceed to arteriography, as there is an increased incidence of popliteal artery injury and thrombosis.

TUMORS

Primary vascular tumors are rare and can be classified as benign or malignant. Benign vascular tumors produce vascular channels lined with endothelium without cellular atypia. Hemangiomas are predominately superficial in location but may be found within solid organs. Hemangiomas vary in size from a few millimeters to several centimeters in diameter. Capillary hemangiomas are

the most common subtype of hemangioma and are usually seen in the superficial tissues of children. Most of capillary hemangiomas resolve by age 7. On angiography, pooling of contrast within the vascular spaces of a cavernous hemangioma demonstrates “cotton wool” appearance. Usually, hemangiomas are dark on T1 and very bright on T2 MR imaging. Glomus tumors are benign tumors that are extremely painful. Glomus tumors arise from the modified smooth muscle cells of the glomus body. The glomus body is a specialized arteriovenous anastomosis that is involved in thermoregulation. These tumors usually arise in the distal aspects of the digits most often under the fingernails. Intermediate grade vascular tumors include Kaposi sarcomas (KS) and hemangioendotheliomas. KS have a variable presentation with most tumors being asymptomatic. There is a frequent occurrence of KS in AIDS patients. While many of these lesions are superficial, these tumors may also arise within the viscera and lymph nodes. Hemangioendotheliomas are vascular tumors occurring around medium-sized and large veins in the soft tissues of adults. The differential diagnosis includes metastatic carcinoma, melanoma, and other sarcomas.

The most common primary malignant vascular neoplasms are venous leiomyosarcoma. More than half of the cases of leiomyosarcoma involve infrarenal inferior vena cava (IVC). Other malignant vascular tumors include angiosarcomas and hemangiopericytomas. Angiosarcomas are malignant endothelial neoplasms that occur more often in older adults. While these tumors may occur anywhere in the body, they are more likely to occur in the skin, soft tissue, breast, and liver. Hepatic angiosarcomas are associated with exposure to certain carcinogens including arsenic, thorotrast, and polyvinyl chloride. Angiosarcomas may also arise in the setting of postmastectomy lymphedema for breast cancer. Angiosarcomas show local spread and distant metastases. Hemangiopericytomas are derived from pericytes arranged along capillaries and venules. These tumors may arise in the pelvic retroperitoneum or extremities but can also arise within the CNS extra-axial tissues as well. Approximately two-thirds of hemangiopericytomas have a benign course with the remaining third exhibiting aggressive behavior.

Secondary vascular involvement by a neoplasm is more common than primary vascular tumors. Invasion of veins is more common than the arteries and IVC is particularly prone to invasion by tumor thrombus. IVC involvement is frequently seen with renal cell carcinoma. Vascular invasion is also frequently seen with hepatomas. Diagnosis is usually made by CT or MRI and current CTA and MRA protocols are very sensitive in identifying the vascular invasion by the tumor. Angiography is primarily performed with the intent of embolizing the tumor, if clinically warranted.

Vascular encasement, invasion, and vascular mass are highly suspicious features for malignant neoplasm. Vascular encasement by the malignant tumors tends to be irregular in appearance. Smooth encasement can be caused by malignant neoplasms but can also be seen in benign process such as inflammation. Other common features seen on angiography include distorted angioarchitecture, neovascularity, or tumor blush and arteriovenous shunting. The arteriovenous shunting is characterized by filling of the veins within the mass during the opacification of the arteries in the other areas. Most common hypervascular tumors are leiomyosarcoma, renal cell carcinoma, melanoma, carcinoid, and islet cell tumor. Adenocarcinomas and squamous cell carcinomas tend to be hypovascular.

ARTERIOVENOUS MALFORMATION

Arteriovenous malformations are high flow congenital lesions. These lesions are characterized by one or more tangles of interconnected arterioles and venules representing the “nidus” without normal capillaries. Majority of the AVMs are found in the lower limbs. Large AVMs can clinically present with symptoms of congestive heart failure because of left-to-right shunt, limb hypertrophy, and hemorrhage. Superficial lesions are usually pulsatile. Mainstay of treatment is transcatheter embolization using absolute alcohol, glue, coils, and/or particles. Surgical resection carries a high risk of recurrence.

Venous malformations are congenital low flow lesions, which clinically present with pain and/or swelling because of thrombosis, mass effect, infiltration of soft tissues such as muscle and hemorrhage. These lesions are nonpulsatile. These lesions are comprised of large venous/vascular spaces, which demonstrate slow and delayed filling on angiography. Most commonly these lesions are managed by direct puncture and sclerosis using sclerosing agents such as absolute alcohol and sodium tetradecyl sulfate. Venous malformations can be associated with Klippel-Trenaunay syndrome, a complex usually involving the lower extremities and associated with limb hypertrophy. Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu) is an autosomal dominant disorder characterized by arteriovenous malformations affecting lung, liver, brain and spinal cord, as well as skin and gastrointestinal telangiectasias.

ARTERIOVENOUS FISTULAS

Arteriovenous fistulas are acquired lesions and they usually arise as a result of trauma including iatrogenic trauma, or inflammation/infection. These lesions represent direct

connections between arteries and veins bypassing the capillary network. These lesions can result in high output cardiac failure. Arteriography demonstrates arteriovenous shunting as a result of direct communication of artery with vein without intervening capillary phase. Both the feeding artery and the draining vein are usually hypertrophied. Treatment is usually occlusion of the shunt by endovascular approach (covered stent or coils, if possible) or surgical ligation. Arteriovenous fistulas are also surgically developed for chronic hemodialysis access.

HEMOPTYSIS

Bronchial arteriography is indicated in patients with hemoptysis usually in patients with tuberculosis, cystic fibrosis, and carcinoma. Hemoptysis of more than 300 mL of blood in 24 hours is usually considered as massive hemoptysis. Bronchoscopy is sometimes helpful in localizing the area of interest. Arteriography is performed for the purpose of diagnosis and management of the hemoptysis. A descending aortogram is obtained as a road map. Bronchial arteries typically arise between T4 and T7. Bronchial arteries demonstrate wide variation in their number and origin. The most common variation is two left and one right bronchial artery. Selective injections of the subclavian, intercostal, and internal mammary arteries as well as thyrocervical trunk may be necessary if no clear source of hemoptysis is identified on bronchial arteriography. Hypertrophied bronchial arteries are usually identified on descending thoracic aortogram. There may be abnormal lung parenchymal blush and shunting to pulmonary artery branches and veins. Selective catheterization of the bronchial arteries with a Mickelson, Cobra or Simmons catheter is performed. Typically, embolization is performed using 300 to 700 μ m particles. Complications are uncommon. Most dreadful complication includes inadvertent embolization of artery of Adamkiewicz (arises from the aorta between T8 and L4) resulting in motor spinal cord injury.

Thoracic outlet syndrome is the compression of the brachial plexus or subclavian vessels at the thoracic outlet is usually produced at one of three sites: scalene triangle, costoclavicular space, or pectoralis minor tunnel. The etiologies include cervical ribs, scalenus minimus muscle, anterior scalene muscle, and anomalous first rib resulting in brachial plexus compression causing neurologic symptoms and subclavian artery compression causing ischemic symptoms from distal emboli, claudication, and subclavian vein thrombosis. Acquired lesions include fractures involving clavicle or first rib with large callus formation or nonanatomic alignment and supraclavicular mass. Cross-sectional imaging with CT or MR is useful for evaluating the arteries and surround-

ing structures. Angiography is performed with arm in neutral as well as the position that causes symptoms. Angiography may demonstrate stenosis, aneurysm formation with arteriographic evidence of distal emboli, and presence of thrombus.

Hypothenar hammer syndrome results from chronic repetitive trauma to the hand, at the hook of the hamate where the ulnar artery crosses; this may result in aneurysm formation, occlusion, and distal embolization.

QUESTIONS AND ANSWERS

- How is DSA superior to conventional angiography?
 - Better contrast resolution
 - Decreased examination time

- C. Lower-contrast dose
- D. All of the above

ANSWER: D. DSA provides better contrast resolution, decreased examination time, and lower-contrast dose than conventional angiography.

2. Which of the following is the most common complication of a popliteal artery aneurysm?
 - A. Thrombosis/embolism with limb ischemia
 - B. Rupture
 - C. Popliteal vein thrombosis
 - D. None of the above

ANSWER: A. The most common complication of popliteal artery aneurysm is distal ischemic from thrombosis/embolism.

3. What is the etiology of a type II endoleak?
 - A. Retrograde collateral flow from a patent arterial branch
 - B. Porosity of graft
 - C. Tear in the graft fabric
 - D. None of the above

ANSWER: D. A type II endoleak is secondary to persistent collateral retrograde blood flow into the aneurysm sac, commonly from lumbar arteries, the internal iliac artery, or other collateral vessels.

4. The left bronchial artery most commonly arises from which of the following?
 - A. Pulmonary artery
 - B. Thoracic aorta
 - C. Intercostals artery
 - D. Subclavian artery

ANSWER: B. Bronchial arteries vary but most often arise from the thoracic aorta at the level of T4-7 with the most common pattern consisting of one right and two left arteries.

5. What is the most common site of aortic injury?
 - A. Diaphragmatic hiatus
 - B. Aortic root
 - C. Aortic isthmus
 - D. Descending aorta

ANSWER: C. The most common site for injury is the aortic isthmus near the attachment of the ligamentum arteriosum, followed by aortic root and diaphragmatic hiatus injuries.

6. Concerning Buerger disease, which of the following statements is *false*?
 - A. More common in females

- B. Patients are frequently smokers.
- C. Patients most commonly present with claudication.
- D. Secondary to inflammation of small- and medium-sized arteries

ANSWER: A. Buerger disease is more common in males than females.

7. What is the etiology of a type I endoleak?
 - A. Ineffective seal at the proximal or distal aspect of the graft
 - B. Persistent collateral retrograde blood flows into the aneurysm sac.
 - C. Defect within the graft fabric or between segments of a multisegmental graft
 - D. Endotension

ANSWER: A. A type I endoleak is secondary to an inadequate seal at the proximal aspect of the graft thereby allowing a persistent perigraft inflow.

8. Concerning Kawasaki disease, which of the following is *false*?
 - A. Arteritis that primarily affects the coronary arteries
 - B. Adults older than 70 years
 - C. Fever, desquamative rash, and cervical adenopathy
 - D. Coronary artery aneurysm formation

ANSWER: B. Kawasaki disease is mainly seen in children and infants.

9. Behcet syndrome is a vasculitis characterized by all of the following *except*:
 - A. Oral aphthous ulcers
 - B. Uveitis
 - C. Genital ulcers
 - D. *H. pylori* infection

ANSWER: D. Behcet syndrome is a multisystem inflammatory disorder characterized by recurrent oral aphthous ulcers, genital ulcers, uveitis, and skin lesions. There is no association with *H. pylori*.

10. What is Giant cell (temporal) arteritis?
 - A. Most common form of systemic vasculitis in adults
 - B. More common in women than men
 - C. Granulomatous arteritis
 - D. All of the above are true.

ANSWER: D. Giant cell or temporal arteritis is the most common form of systemic vasculitis in adults. It is more common in women than men. It is a granulomatous arteritis.

82 ARTERIAL INTERVENTIONS

*Anne F. Fitzpatrick and
Souheil Saddekni*

PATHOPHYSIOLOGIC BASIS OF BALLOON ANGIOPLASTY

Since the first angioplasty was performed in 1964, the use of imaging to perform a variety of minimally invasive arterial procedures has grown exponentially. Advantages include diminished pain and recovery time when compared with open procedures. Currently, arterial interventions can generally be divided into two major categories: revascularization (angioplasty, stenting, thrombolysis) and embolization.

ANGIOPLASTY

The majority of cases of arterial occlusive disease are secondary to atherosclerosis. The importance of the effects of atherosclerosis cannot be overestimated, as it is the leading cause of death in the developed world. Risk factors include age, male gender, and genetic predisposition. While these risk factors cannot be reduced by behavior modification, multiple other risk factors can be reduced or eliminated, including hyperlipidemia, hypertension, smoking, and diabetes mellitus.

Vascular injury by any of the above insults causes endothelial dysfunction, which allows smooth muscle cells from the media to migrate into the intima, proliferate, and elaborate extracellular matrix. The result is intimal thickening. In addition, lipids accumulate within the intima. The combination of the thickened intima with lipid deposits gives rise to the characteristic feature of atherosclerotic disease, the fibrofatty plaque, or atheroma. Atheromas have a core composed of cholesterol and cholesterol esters, fibrin and thrombus, as well as lipid-filled monocytes and smooth muscle cells known as foam cells. Overlying this core, there is a fibrous cap, which contains smooth muscle cells, macrophages, lymphocytes, extracellular matrix, as well as small vessels supplying the periphery of the lesion.

The basic atherosclerotic lesion can be complicated by additional changes, including calcification and hemorrhage into the plaque from the small vessels feeding the periphery of the plaque. This hemorrhage, in turn, can induce rupture or ulceration of the plaque. Rupture of the plaque may release thromboemboli of the lipid core contents into the blood stream, while ulceration can expose a thrombogenic surface of the plaque. This

thrombogenic surface may induce platelet deposition and clot formation, which can occlude the lumen of the vessel.

Atherosclerosis affecting the lower extremity vessels may produce chronic lower extremity ischemia, manifested as intermittent claudication. Patients typically present with pain, which is constant in terms of location and relationship to physical activity. This pain resolves with cessation of the inciting activity. Pain location depends on the site of vascular compromise. For example, patients who have mainly distal aortic and/or common/internal iliac artery disease present with pain involving the buttocks, whereas patients who have superficial femoral artery or popliteal artery disease present with calf claudication. Signs of peripheral vascular disease include diminished or absent peripheral pulses, as well as atrophy of the subcutaneous tissues and hair loss on the affected extremity. Patients with suspected peripheral arterial disease are often initially evaluated with measurement of the pressures in their ankle arteries, compared to the pressures in their arms, known as the ankle to brachial index (ABI). A diminished ABI indicates a hemodynamically significant vascular lesion between the heart and the ankle, and the lower the ABI value, the more severe the lesion. An ABI less than or equal to 0.90 in a patient at rest is diagnostic of peripheral arterial disease. More comprehensive noninvasive laboratory testing incorporates ultrasound with Doppler, plethysmography, segmental pressures, and pulse volume recordings and evaluation ABI at rest and after exercise. These tests provide a more specific idea of the severity and location of obstruction.

As the atherosclerotic disease progresses, patients may develop rest pain, described as burning or aching pain localized to the forefoot, which begins after the patient reclines. The pain can usually be relieved by placing the affected extremity in a dependent position. The diagnosis can be confirmed using measurements of pressures in the ankle and toe, with rest pain occurring with an ankle pressure of less than 50 mm Hg or a toe pressure of less than 30 mm Hg. Further progression of the disease leads to ulceration and gangrene. In this clinical setting, an ankle pressure of less than 70 mm Hg or a toe pressure less than 50 mm Hg indicates that the patient's ulceration is because of ischemia (rather than to other etiologies, such as neuropathy). Both rest pain and ulceration indicate that the patient is at risk for limb loss, and because arterial disease in the extremities is often accompanied by generalized atherosclerosis, rest pain and ulceration can also indicate that the patient is also at much higher risk for myocardial infarction and stroke.

Chronic lower extremity ischemia may be managed in several ways. Nonoperative management is acceptable for patients not at risk for limb loss; that is, those

without rest pain or ulceration. Tenets of nonoperative management include smoking cessation and modification of other risk factors, such as hypertension, hyperlipidemia, and hyperglycemia. Exercise is also encouraged, as it not only improves the symptoms of claudication, but also may help in improving cardiovascular health. The importance of improving cardiovascular fitness cannot be emphasized enough, as more than 50% percent of patients with peripheral vascular disease may also have concomitant coronary artery disease. Finally, a variety of pharmacologic agents have been used to improve the symptoms of chronic lower extremity ischemia, including antiplatelet agents and vasodilators. Currently, only pentoxifylline, a methylxanthine derivative which decreases the viscosity of blood and increases the deformability of erythrocytes, and Cilostazol, a phosphodiesterase III inhibitor which results in vasodilation and decreased platelet aggregation, have been approved by the FDA for the treatment of intermittent claudication. However, only cilostazol appears to have a clinically significant effect over placebo in increasing symptom-free walking distance.

Chronic lower extremity ischemia, which results in disabling claudication, meaning that it limits the patient's ability to participate in daily activities or that threatens the limb, is an indication for invasive treatment. Invasive options include percutaneous transluminal angioplasty or surgical bypass.

The first percutaneous transluminal angioplasty was performed in 1964 by Charles Dotter, who dilated a stenosis of the popliteal artery. Expanding the lumen using the "Dotter" procedure relied on passing a large catheter through the stenotic lumen. Therefore, it was limited by the size of the percutaneously introduced dilating catheter approaching the size of the artery itself. This procedure remained in very limited use in the United States. However, some investigators in Europe continued to explore this new technique, which ultimately resulted in Gruentzig introducing a simple modification to the dilating procedure in 1974. Gruentzig's innovation involved using a balloon to dilate the superficial femoral artery, a technique which he then applied to other arteries in the body. Four years after his superficial femoral artery procedure, he published reports of renal and coronary artery balloon dilatation, as had been previously predicted by Dotter. Thus, the Swiss cardiologist's innovation has ignited a remarkable revolution in the treatment of cardiovascular disease, which has continued unabated into the present day. The popularity of the angioplasty technique has prompted major research and development in atherosclerotic disease pathophysiology, plaque formation, and mechanism of action of angioplasty. Additional research has been aimed at eliciting the reasons for success or failure of angioplasty, as well

as in developing stents to reduce the risk of angioplasty failure. As a result, percutaneous angioplasty currently plays a major role in the treatment of occlusive vascular disease.

The improved cross-sectional diameter of the lumen of the vessel achieved with angioplasty was initially believed to be secondary to compression of the plaque along the wall of the vessel. Since that time, however, investigators have determined that the most important contributing factor is actually the disruption of the intima, with extension of the plaque into expanded media. An additional contributing factor (although not as important as the plaque fracture) is stretching of the media.

Much was learned in the first decade of angioplasty. It became clear that not all peripheral atherosclerotic lesions are well-suited to angioplasty. Factors such as lesion morphology, technical constraints, and comorbidities have been reported to influence outcome. This knowledge was helpful in establishing general guidelines, based mainly upon the anatomic location, length of the lesion, and associated calcification. The Society of Cardiovascular and Interventional Radiology (SCVIR, now known as SIR) proposed guidelines including four categories from ideal lesions to those unsuitable for angioplasty. These evolved over a period of more than a decade to a consensus known as the TASC standards, the Trans-Atlantic Inter-Society Consensus Document on Management of Peripheral Arterial Disease, the result of a collaboration between multiple medical societies in Europe and North America. The original document was published in 2000 and was subsequently revised in 2007. Briefly summarized, percutaneous therapy is the standard treatment for TASC A lesions (single stenosis less than 3 cm in length), while TASC D lesions (long complete occlusion of the entire artery) should be treated with surgical intervention. Therapy for category B and C lesions is not quite as structured, although the current recommendation is for percutaneous therapy for B lesions and surgery for C lesions if the patient is a good operative candidate. The Society of Interventional Radiology has established standards of practice governing the evaluation of patients for angioplasty, as well their care, both during and after the procedure.

In general, percutaneous angioplasty is a safe and effective procedure in selected patients, but it does carry certain risks. Major complications are usually related to vascular injury and include hematoma, pseudoaneurysm, or arteriovenous fistula at the access site; distal embolization; occlusion and/or rupture of the angioplastied vessel.

The use of angioplasty is not just limited to treatment of peripheral vascular disease or coronary artery disease. It has also been well-documented in the treatment of vascular disease affecting the renal arteries. Renal artery angioplasty has been used for the treatment of

TABLE 82-1 Atherosclerotic Versus Fibromuscular Dysplasia Stenosis

DISEASE PROCESS	PATIENT POPULATION	LESION LOCATION	DIAGNOSIS	TREATMENT
Atherosclerosis	>50 y, male > female	Primarily ostial	US or MRA/CTA first	Angioplasty and stenting
Fibromuscular dysplasia	Third–fifth decades, female > male	Distal main renal artery	Angiography	Angioplasty alone

renovascular hypertension as well as renal insufficiency secondary to renal artery stenosis. The two most common causes of renal artery stenosis are atherosclerosis and fibromuscular dysplasia (FMD), with the majority of FMD lesions being of the medial fibroplasia with aneurysm subtype. Other causes include Takayasu arteritis, neurofibromatosis, abdominal aortic coarctation, and compression of the renal artery by a mass or hematoma. However, these etiologies are far less common. While both diseases may cause renal artery stenosis, atherosclerotic renal stenosis and FMD differ substantially in affected patient populations, lesion location, diagnosis, and treatment.

Renal artery stenosis, secondary to atherosclerosis typically affects older male patients, in contrast to FMD, which typically affects younger female patients. The two pathologies also differ in their locations. Atherosclerotic lesions are usually ostial lesions, arising from aortic plaque extension into the proximal renal artery. In contrast, FMD is usually located within the mid-to-distal renal artery, with extension into the anteroposterior divisions. Atherosclerosis is also more likely to cause renal insufficiency, uncommon in FMD (Table 82-1).

Diagnosis of renovascular hypertension can be difficult, as it accounts for only 5% of all causes of hypertension. However, certain elements in the patient's hypertensive history are suggestive such as young age, sudden onset (particularly in a woman), severe, hypertension refractory to optimal medical therapy, no family history, abdominal bruit, and the development of renal insufficiency while on an ACE-inhibitor. When renovascular hypertension is suspected, further evaluation is indicated.

Suspected atherosclerotic renal artery stenosis is initially evaluated noninvasively. Workup may include radionuclide renogram with angiotensin-converting enzyme challenge, renal vein sampling to check for renin secretion on the affected side with suppression of secretion on the uninvolved side, or ultrasound. Ultrasound provides anatomic information and renal morphology, evaluating for congenital or acquired medical or surgical renal diseases affecting the kidneys. Ultrasound criteria for greater than 60% stenosis of renal artery stenosis include a peak systolic velocity greater than or equal to 180 cm/s and renal artery peak systolic velocity to aortic peak systolic velocity ratio of greater than or equal to 3.5. The resistive index is also important in the evaluation of renal artery stenosis, as a resistive index of less than

80 suggests that the lesion will be amenable to invasive therapy. MRA and CTA can also be used in the initial evaluation of renal artery stenosis secondary to atherosclerosis. Atherosclerotic renal artery stenosis, which involves the ostium or the proximal renal artery can be reliably depicted in CTA especially with the new generation multidetector CT with postprocessing.

Nonatherosclerotic renal artery stenosis should be suspected in young patients and children with hypertension. Neurofibromatosis, abdominal aortic dysplasia, or midaortic syndrome can involve the aorta and the renal ostia. Main, distal, and branch renal arteries are narrowed in a variety of FMD entities. The desire for less invasive testing in the young is often mitigated by the difficulty in imaging and lack of resolution of the small intrarenal vessels, which frequently necessitate the need for selective arteriography.

The angiographic signs for hemodynamically significant renal artery stenosis include greater than 75% decrease in luminal diameter, poststenotic dilatation, collateral circulation from adjacent lumbar arteries, and ultimately diminished renal mass. When these signs are not clearly seen, a pressure gradient of more than 10 mm Hg across the lesion could be used as an indicator for hemodynamic significance. Renal insufficiency secondary to renal artery stenosis can be diagnosed when there are bilateral significant renal artery stenoses with rapidly deteriorating renal function or loss of renal mass.

Options for revascularization include surgery and percutaneous therapy. Technical success rates for percutaneous therapy are very high, ranging from 80% up to 100%. However, the degree of clinical improvement varies, depending upon the pathology of the lesion (FMD responds better than atherosclerotic ostial lesions) as well as the indication for intervention (i.e., hypertension versus renal insufficiency). In general, outcomes for renovascular hypertension are better than those for azotemia. However, there are certain predictors of success with percutaneous therapy in patients with azotemia, such as bilateral lesions within the proximal renal artery proper (not ostium), serum creatinine less than 3.0 mg/dL. Ostial atherosclerotic lesions traditionally have not been as successful with balloon angioplasty, with significant residual stenosis at the ostium in the majority of cases. Technical success has improved with the advent of stenting, and in fact, many ostial lesions are primarily stented. However, this did not necessarily result in a similar clinical benefit,

because of the multifactorial etiology of hypertension and renal insufficiency in mostly older patients. On the other hand, percutaneous less invasive therapy is a better option than surgery in a patient with diffuse atherosclerotic disease and multiple comorbidities.

Complications of angioplasty include puncture site injuries, such as hematoma, pseudoaneurysm, or arteriovenous fistula formation; flow-limiting dissection; arterial rupture; emboli either to the distal renal artery or the extremities; and renal failure.

STENTING

Despite the many successes of angioplasty alone, some lesions may develop recurrent stenoses or demonstrate a persistent gradient following angioplasty. In addition, angioplasty itself may damage the vessel, causing a flow-limiting dissection. For these lesions, a transcatheter-deployed vascular stent was developed. There are two basic types of stents: balloon-expandable and self-expanding. Balloon-expandable stent diameter is dependent upon the dilating balloon. These stents are less flexible than self-expanding stents, and thus should be avoided across joints (knee or hip). However, they do tend to maintain their diameter better as compared to self-expanding stents. Self-expanding stents, as their name implies, do not require a balloon dilatation for deployment. While they are more flexible than expandable stents, they can also be more difficult to position and less precise.

Stent deployment has become the standard for treating stenoses of the coronary, carotid, subclavian and renal arteries, and has also been described both for celiac and superior mesenteric artery stenoses, particularly ostial lesions, as well as aortic stenoses.

Although, angioplasty alone can be successful in treating short focal stenoses of the iliac and peripheral arteries, it appears that stenting has largely replaced balloon angioplasty. Current indications for iliac artery stent deployment include persistent transstenotic gradient following angioplasty, dissection of the angioplastied artery, stenosis length greater than 3 cm, and following recanalization of a chronically occluded arteries. While stents have been deployed in the femoral and popliteal arteries, the patency rates for these vessels are not as optimal as those with the iliac arteries.

THROMBOLYSIS

Acute thrombosis of a blood vessel results in ischemia in the tissue supplied by that vessel and can have devastating effects upon that tissue. Virchow triad describes

the three factors contributing to pathologic thrombosis: endothelial injury, stasis or turbulent blood flow (as seen with ulcerated atherosclerotic lesions), or hypercoagulable states. Thrombolysis is the delivery of a plasminogen activator to dissolve thrombus and restore blood flow. Prior to the advent of thrombolysis, acute thrombosis of an ischemic limb was treated with surgical mechanical thrombectomy. Thrombolysis, however, not only offers the advantage of restoring perfusion to the affected extremity, but can also help identify any preexisting lesion predisposing to thrombosis.

The pharmacologic basis of thrombolysis is the use of tissue plasminogen activator (t-PA). Tissue plasminogen activator, as its name implies, is an endogenous substance secreted by vascular endothelial cells, which converts plasminogen to plasmin. Plasmin both breaks down the fibrin, which combines with red blood cells and platelets to form thrombus, as well as prevents the propagation of thrombin.

Thrombolytic agents such as streptokinase, urokinase, and t-PA were initially used in clinical settings for treatment of acute large pulmonary embolism and acute myocardial infarction via intravenous systemic delivery. This nontargeted approach with associated major bleeding complications gave way to the more targeted and more effective, rt-PA (Activase) catheter-delivered thrombolytic therapy. Other derivatives such as Reteplase and TNK-tPA are less commonly used, while Streptokinase and Urokinase are no longer in use.

Because of the potentially devastating side effects of thrombolytic therapy, careful patient selection is warranted. Of note, when evaluating for intervention in a patient with acute limb-threatening ischemia (critical limb ischemia or CLI), it is important to establish that the extremity is still viable. Patients who have no sensation or movement in an extremity with no arterial or venous Doppler signals may not have a salvageable limb, no matter what the type of intervention. Absolute contraindications to thrombolysis for peripheral vascular occlusive diseases include cerebrovascular accident (CVA) within the past 2 months, neurosurgery within the past 3 months, or gastrointestinal bleeding within the past 10 days. Relative contraindications include pregnancy, coagulopathy, severe uncontrolled hypertension, and recent major surgery.

There are two basic techniques for thrombolysis pharmacologic and mechanical. Catheter-directed infusion thrombolysis involves crossing the occluded segment with a guidewire, and then placing a catheter with multiple sideholes across the length of the lesion, thus “bathing” the lesion with a continuous infusion of t-PA. This infusion may last from 8 to 24 hours, and the patient will usually require observation in an intensive care unit during this time. An additional mechanical component has been added in the majority of cases in an effort to

TABLE 82-2 Embolization Agents

AGENT	OCCCLUSION TIME	VESSEL SIZE	POTENTIAL USES
Coils	Permanent	Any	Trauma, varicocele
PVA particles/Acrylic spheres	Permanent	Small	Tumors
Gelatin sponge (Gelfoam)	Temporary absorbed over 4–6 wk	Small/medium	Trauma
Glues	Permanent	Any	AVM
Ethiodiol	Permanent	Small	Hepatic chemoembolization
Thrombin	Permanent	Any	Aneurysm, persistent flow following embolization with another agent
Sotradecol	Permanent	Small/medium	Varicose veins
Ethanol	Permanent	Any	AVM, tumor

shorten the length of therapy and enhance the lytic effect by disrupting the clot. Pulse-spray thrombolysis involves positioning a catheter with multiple side holes in the thrombus, and then injecting short bursts of t-PA through the catheter, with the intent to both mechanically disrupt the clot, as well as deliver the t-PA. Power driven mechanical devices use fragmentation and aspiration such as the Amplatz thrombectomy device. The Angiojet and the Trellis are routinely used in conjunction with lytics to achieve thrombolysis within 4 to 6 hours.

The success of thrombolytic therapy in peripheral vascular occlusive disease can be as high as 85% to 95%. Patients who respond within 2 hours of thrombolysis tend to have better outcomes, as do patients with acute occlusions. Patients with chronic occlusions have better long-term results with surgery. Regardless of which treatment modality used, careful search and correction of predisposing underlying stenoses should be corrected to prevent rethrombosis.

The most common complication associated with thrombolysis is bleeding at the puncture site. The risk of this complication is also increased by the simultaneous usage of heparin and/or aspirin, and the risk also increases with the duration of the procedure. Distal embolization is another potentially serious complication. In most cases, the embolus can be resolved with continued infusion. Other complications include pericatheter thrombosis (unusual when the patient is also given systemic heparin), compartment syndrome, renal failure, and infrequent but serious hemorrhage potentially anywhere in the patient.

EMBOLIZATION

In some pathologic states, such as hemorrhage or hypervascularity resulting from a neoplasm, inflammation, or an arteriovenous malformation, the goal of therapy is to disrupt blood flow. While these conditions are not as common as occlusive vascular disease, percutaneous embolotherapy is a well-established and safe method for

addressing these potentially lethal problems. Percutaneous transcatheter embolization involves delivering one or more of various agents via a catheter to a selected vessel in order to induce thrombosis. The agents include metal coils; particulate agents, such as polyvinyl alcohol (PVA) particles, acrylic spheres, and gelatin sponge; and liquids, such as glues, ethiodiol, sotradecol, thrombin, and ethanol. The agent chosen depends upon the indication for the procedure, velocity of flow, the size of the vessel to be embolized, and the desired occlusion time (permanent versus temporary) (Table 82-2).

SPECIFIC INDICATIONS FOR EMBOLIZATION

The use of embolization was first described in the treatment of posttraumatic hemorrhage from a pelvic fracture. Retroperitoneal hemorrhage in the trauma patient with pelvic fractures may result from fractures of cancellous bone, exacerbated by coagulopathy from hypothermia and blood transfusions. In these patients, resuscitation, reduction of the fractures, and external fixation may be sufficient therapy, as these measures can tamponade the bleeding source. However, pelvic fractures can also result in bleeding from the injury to large vessels in the pelvis, in which case, the patient may not respond to external fixation. Patients who remain hemodynamically unstable may benefit from percutaneous embolization. CT usually identifies the general location while a CTA may identify the specific site. Angiography should be performed expeditiously to identify the source of bleeding. Extravasation of contrast from a specific arterial branch identifies the bleeding site, which then can be readily selectively or super-selectively catheterized and the bleeding branch embolized. Appropriately sized coils are commonly used to stop the flow of blood. However, even if no source is identified, bilateral internal iliac embolization should be performed in desperate situation if the patient remains unstable. Bilateral embolization is performed, as cross-pelvic vascular com-

munication can result in continued hemorrhage if only one side is selected.

Embolization has also been widely used in the treatment of splenic injury. While a hemodynamically stable patient with a splenic laceration or hematoma without a large hemoperitoneum may be managed with observation, patients with more severe splenic injury require either splenectomy or splenic artery embolization. While the spleen is not essential to life, it does have an important function in protecting the body from opsonized, encapsulated bacteria. Splenic artery embolization offers the advantage of stopping or preventing further splenic hemorrhage while preserving splenic tissue, although it can result in splenic infarction and/or splenic abscess. Distal embolization is typically performed using coils or PVA particles superselectively into the site of extravasation. More proximal splenic artery embolization may be necessary when distal catheterization is impossible because of tortuosity of the splenic artery, in which case, midsplenic artery embolization is reported to be as effective.

Embolization has also been described in the management of liver injuries. Initially, a hemodynamically unstable patient with a known hepatic laceration is managed with exploratory laparotomy with suture ligation of bleeding vessels and/or packing. This will commonly control both arterial and hepatic or portal venous bleed. However, if bleeding persists, or if the patient is hemodynamically stable with a known hepatic artery pseudoaneurysm, hepatic angiography with embolization is indicated. Because of the extensive hepatic collateral arterial supply, embolization should be as selective as possible, with occlusion of the artery both proximal and distal to the injury. Coils and/or particles may be used. Hepatic infarction is less likely than splenic infarction because of the dual blood supply of the liver.

Angiography with embolization can be used in the diagnosis and treatment of acute gastrointestinal bleeding, which is classified by location of the source: upper (proximal to the ligament of Treitz) or lower (distal to the ligament of Treitz). Upper GI bleeding is more common and is usually secondary to either peptic ulcer disease or gastritis. The initial workup of upper GI bleeding (following stabilization of the patient) is endoscopy, which is both diagnostic and therapeutic. If endoscopy fails, is not available, or is contraindicated, arteriography can be performed. Angiography can detect bleeding of 0.5 mL/min in the upper GI tract. Lower GI bleeding is usually colonic in origin, with diverticulosis and angiodysplasia being the most common causes in patients older than 50 years. The rate of bleeding must be at least 0.5 to 1.0 mL/min before it is detectable by angiography. As a result, only about 50% of angiograms are positive in acute lower GI bleeding. A tagged red blood cell scan is more sensitive in this set-

ting, detecting bleeds of 0.1 mL/min. Therefore, hemodynamically stable patients are better served by initial evaluation with either endoscopy or a tagged red blood cell scan. In contrast, massive hemorrhage may make endoscopy difficult, so arteriography with embolization or intraarterial vasopressin infusion is the procedure of choice in the hemodynamically unstable patient with active lower GI bleeding.

Depending upon the source of the bleeding, either intraarterial vasopressin infusion or embolization can be performed. Vasopressin, or antidiuretic hormone, is synthesized within the hypothalamus and is normally secreted in response to hyperosmolality or diminished circulating blood volume. It results in water retention and vasoconstriction. Administered intra-arterially, it can relieve diffuse mucosal hemorrhage or bleeding from small vessels. It is most commonly used for diverticulosis in the lower GI tract. Because of its effects on diffuse mucosal hemorrhage, it can be used for gastritis as well, although if the patient has a known gastric source of bleeding, embolization of the left gastric artery is usually performed, as the left gastric artery is the source of bleeding in 85% of these patients. Branches of the gastroduodenal artery are a common site of bleeding from duodenal ulcers or complications of pancreatitis. If prior endoscopy has identified bleeding in the duodenum, embolization with particles or coils can be performed imperically even if arteriography fails to demonstrate extravasation. Rich duodenal collaterals prevent ischemic complications. The major contraindication to intra-arterial vasopressin is ischemia; either coronary, gastrointestinal, or peripheral arterial, as the vasoconstriction can worsen ischemia in these vascular beds. The length of therapy and frequent hemodynamic side effects have made intra-arterial vasopressin infusion less desirable and infrequently used intervention.

Embolization, in contrast, is better suited to bleeding from identified extravasated arteries, as with peptic ulcer disease or even colonic bleed if used selectively, as it achieves diminished enough flow to achieve hemostasis without actually inducing ischemia.

Massive hemoptysis is the expectoration of 200 to 600 mL of blood or frankly bloody sputum within a 24-hour period. It has a high mortality rate (up to 75%), with the most common cause of death being asphyxiation, as the blood is very irritating to the airway. As a result, it is a medical emergency and should be managed expeditiously. Initial bronchoscopy is helpful to identify the involved lung or lobe, as well as allow for placement of an intrabronchial balloon tamponade. Intubation may also be necessary for airway protection. While surgical resection of the affected area was traditionally the therapy for hemoptysis, it can be very technically difficult because of the vascularity of the lesions.

Ninety percent of cases of hemoptysis involve the bronchial arteries, with the pulmonary arteries acting as the source only 10% of the time. While normal bronchial arteries are typically diminutive and difficult to select, bronchial arteries involved in massive hemoptysis are often hypertrophied, usually secondary to chronic inflammation, with tuberculosis and aspergillosis being the most common etiologies worldwide, while bronchiectasis is the most common cause in the United States. The bronchiectasis can occur with sarcoid and cystic fibrosis. Pulmonary arterial hemoptysis is usually caused by pseudoaneurysms that develop in the setting of destructive lung disease, such as cavitory aspergillosis or tuberculosis. It should be suspected if an initial bronchial artery embolization is technically successful, but the patient continues to bleed.

The hypertrophied bronchial arteries may be seen on the original arteriogram. However, if patients have a history of prior embolizations or surgery, evaluation of additional arteries, such as the subclavian artery, thyrocervical trunk, and internal mammary artery, is also suggested to eliminate these vessels as potential sources of bleeding.

Embolization is usually performed with particles, as up to 30% of patients have recurrent episodes of hemoptysis. Since coils block the proximal portions of the bronchial arteries, they would preclude further reembolization. The goal of therapy is to reduce flow enough to induce hemostasis, while not causing ischemia. The initial embolization is usually the most technically successful, as smaller, less accessible arteries are recruited in successive episodes of hemoptysis. The most feared complication of bronchial artery embolization is spinal cord injury, as a result of embolization of the anterior spinal artery, so special care is taken for its identification.

While the most common malignant liver lesion in the United States is metastatic colorectal cancer, worldwide, the most common hepatic malignancy is hepatocellular carcinoma. Embolization of both of these lesions with a particulate or liquid can be performed in conjunction with delivery of a chemotherapeutic agent directly to the tumor. The therapy has two mechanisms of action: tumor necrosis because of flow obstruction of the vessel feeding the tumor, as well as the direct delivery of a chemotherapeutic agent to the lesion, at a much higher dose than could be administered systemically. This therapy is possible without causing ischemic necrosis because of the dual blood supply from the hepatic artery and the portal vein, with many malignancies preferentially deriving their blood supply from the hepatic artery.

While surgical resection is the gold standard for treatment of resectable hepatocellular carcinoma, chemoembolization is the therapy of choice for nonresectable lesions and those not amenable to percutaneous ablation therapy. It can also be used to reduce tumor bulk prior to

tumor resection or radiofrequency ablation, or to control tumor growth prior to transplantation. Absolute contraindications to the procedure include tumor unresectability, infection, or advanced liver disease, in which case, chemoembolization may lead to hepatic failure. Relative contraindications include marginal liver function, encephalopathy, renal insufficiency, thrombocytopenia, as well as portal tumoral thrombosis, as embolization of the hepatic artery could then result in liver infarction. However, if hepatopedal collateral flow is still present, the procedure may still be performed.

The usual chemotherapeutic agent to treat hepatocellular carcinoma is Doxorubicin, although it may also be combined with Cisplatin or Mitomycin C. The agent is then combined with Ethiodiol (iodized oil), which is taken up by tumoral cells, and/or particles. The goal of therapy is stasis of flow, thus preventing washout of the chemotherapeutic agent. Therefore gelfoam or PVA particles are often injected with or after the chemo-oil mixture. Postprocedure, the patient may develop the so-called postembolization syndrome, which is associated with abdominal pain, fever, nausea, malaise, and elevated liver function tests. This syndrome usually spontaneously resolves. Other complications include nontarget embolization, hepatic arterial injury, liver failure, gall bladder infarction, as well as complications at the access site.

UTERINE ARTERY EMBOLIZATION

The most common indication for uterine artery embolization is symptomatic uterine leiomyomas (fibroids), although it has also been used for postpartum hemorrhage and palliation of gynecologic malignancies. Leiomyomas are the most common tumors in women (occurring in at least 25% of women), and they respond to estrogen. As a result, involution typically occurs following menopause. However, in a woman of reproductive age, they may lead to menorrhagia (most common indication for embolization), pelvic pain, dyspareunia, bladder outlet obstruction, and miscarriage. Patients can be treated medically with gonadotropin releasing hormone, but have recurrence of symptoms following cessation of the hormone. Symptomatic fibroids can also be treated surgically, either with hysterectomy or myomectomy. However, uterine artery embolization offers the advantages of preserving the uterus, while treating all fibroids at the same time. Embolization can also be an adjunct to surgery, reducing tumor bulk prior to resection.

Initial evaluation should include pelvic ultrasound and/or MRI, as well as a full gynecologic workup to assess for other causes of bleeding. Uterine artery embolization is not recommended for women with pedunculated or mainly submucosal tumors. MRI helps

differentiate between adenomyosis, the extension of endometrial glandular tissue into the myometrium, and leiomyomas, although uterine artery embolization can be used for certain cases of adenomyosis. Contraindications to the procedure include pregnancy, active pelvic inflammatory disease, prior radiation to the pelvis, history of severe anaphylactic contrast reaction, and renal insufficiency.

The procedure is performed with particles. Leiomyomas are well-suited to embolization as they are hypervascular and preferentially receive flow from the uterine artery, with the goal of embolization to diminish flow within the uterine arteries and reduce tumoral hypervascularity. Results vary slightly with the indication for the procedure, with menorrhagia improving in up to 90% of patients. Uterine artery embolization performed for mass effect is slightly less efficacious. Most women report postembolization syndrome, with severe pelvic cramping, which improves over subsequent week. Other complications include premature menopause (more common in women older than 45 years) and infection requiring hysterectomy.

QUESTIONS AND ANSWERS

- Which of the following is *not* a risk factor for arterial occlusive disease?
 - Smoking
 - Age
 - Female gender
 - Diabetes mellitus
 - Hypertension

ANSWER: C. Cigarette smoking, increasing age, diabetes mellitus, and hypertension are all risk

factors for arterial occlusive disease. Female gender does not incur an increased risk for arterial occlusive disease, although male gender does.

2. What is the ABI at or below which peripheral arterial disease is diagnosed?
 - A. 1.00
 - B. 0.90
 - C. 1.20
 - D. 1.40

ANSWER: B. An ABI less than or equal to 0.90 in a patient at rest is diagnostic of peripheral arterial disease. However, more comprehensive noninvasive laboratory testing involves the use of ultrasound with Doppler, plethysmography, segmental pressures, and pulse volume recordings and evaluation ABI at rest and after exercise. These tests give a more specific idea of the severity and location of obstruction.

3. What is the mechanism of action of Cilostazol?
 - A. Decreased blood viscosity
 - B. Increased erythrocyte deformability
 - C. Antiplatelet effect
 - D. Vasodilation and decreased platelet aggregation

ANSWER: D. Cilostazol is a phosphodiesterase III inhibitor, which results in vasodilation and decreased platelet aggregation. Cilostazol has a clinically significant effect when compared to placebo in increasing symptom-free walking distance.

4. What is the *most* important factor in successful percutaneous transluminal angioplasty?
 - A. Compression of the plaque along the vessel wall
 - B. Stretching of the media
 - C. Disruption of intima with extension of the plaque into the media
 - D. Displacement of platelet

ANSWER: C. Investigators have determined that the most important contributing factor in the improvement of cross-sectional diameter of the lumen of the vessel is disruption of the intima, with extension of the plaque into expanded media. Other, much less important factors include compression of the plaque along the wall of the vessel and stretching of the media.

5. What is the therapy of choice for hypertension secondary to renal artery stenosis caused by the medial fibroplasias subtype of fibromuscular dysplasia?
 - A. Angioplasty alone
 - B. Angioplasty with renal artery stent placement
 - C. Surgical revascularization

ANSWER: A. FMD lesions typically respond well to percutaneous angioplasty alone and usually do not require stent placement unless there is a complication associated with the procedure, such as dissection. In contrast, atherosclerotic ostial lesions often require stenting in addition to angioplasty, because the narrowing is usually secondary to extension of aortic plaque into the proximal renal artery, rather than a discrete lesion of the renal artery itself. Surgical revascularization, because of the associated higher morbidity and mortality, is rarely used for the treatment of FMD affecting the renal arteries. Of note, management of the patient with hypertension secondary to FMD should include pharmacologic therapy as necessary to control the patient's blood pressure.

6. What is an absolute contraindication to thrombolysis?
 - A. Acutely ischemic extremity with profound motor and sensory loss
 - B. CVA within past 2 months
 - C. GI bleed within past 10 days
 - D. All of the above

ANSWER: D. An acutely ischemic extremity with profound motor and sensory loss is not viable, and cannot be salvaged, no matter what type of revascularization therapy is chosen. Additional contraindications include GI bleeding within 10 days prior to contemplated thrombolysis, as well as cerebrovascular accident within 2 months of possible thrombolysis, and neurosurgery or intracranial bleed within 3 months of possible thrombolysis.

7. What is the initial treatment of an unstable patient with pelvic fractures?
 - A. Immediate angiography with prophylactic embolization
 - B. Resuscitation, reduction of the fracture, and external fixation
 - C. Emergent operative exploration

ANSWER: B. The initial treatment of an unstable patient with pelvic fractures is resuscitation, reduction of the fracture, and external fixation. If the patient remains unstable despite resuscitation and fixation, and no other source of intraabdominal or intrapelvic hemorrhage is present, angiography with possible embolization may be performed. If no source of bleeding is identified by angiography in a hemodynamically unstable patient, the procedure should be terminated, and the patient taken to the operating room for emergent exploration of the retroperitoneal hematoma.

8. What is the initial diagnostic workup for heme-temesis?
- Upper endoscopy
 - Lower endoscopy
 - Tagged red blood cell scan
 - Angiography

ANSWER: A. The initial workup of upper GI bleeding (following stabilization of the patient) is endoscopy, which is both diagnostic and therapeutic. A stable patient with lower GI bleeding may be evaluated first with a tagged red blood cell scan or endoscopy. An unstable patient with lower GI bleeding should proceed directly to angiography, as heavy bleeding may make endoscopy technically difficult.

9. What is the most common cause of bronchial artery hypertrophy leading to massive hemoptysis?
- Lung cancer
 - Lung abscess
 - Chronic inflammation within bronchiectasis
 - Pulmonary pseudoaneurysm

ANSWER: C. The most common cause of bronchial artery hypertrophy is chronic inflammation resulting in bronchiectasis. This chronic inflammation can result from chronic infection, including tuberculosis, as well as diseases like cystic fibrosis and sarcoidosis. Lung abscesses and lung cancer are less frequent causes of bronchial artery hypertrophy causing massive hemoptysis, and pulmonary pseudoaneurysms from cavitary lung lesions can cause bleeding from *pulmonary* arterial hemoptysis.

10. What is (are) the mechanism(s) of action of hepatic chemoembolization?
- Tumor necrosis secondary to disruption of hepatic arterial blood flow
 - Direct delivery of chemotherapeutic agent
 - Tumor necrosis secondary to disruption of portal vein flow
 - A and B only
 - B and D only
 - All of the above

ANSWER: D. Hepatic chemoembolization is possible because of the dual blood supply of the liver, with many malignancies preferentially deriving their blood supply from the hepatic artery (not the portal vein). Thus, the tumor's blood supply can be embolized, while the liver itself continues to receive blood from the portal vein. In addition, chemoembolization directly delivers chemotherapeutic agents to the tumor, at much higher doses than would be possible if systemically administered.

83 VENOUS DISEASE

Karthikram Raghuram,

Kay M. Hamrick, and Jeffery R. White

VENOUS ANATOMY

UPPER EXTREMITY VEINS

The superficial venous system drains the upper extremities into the deep venous system. There are three major superficial veins: (1) cephalic (radial side), (2) basilic (posterior medial side), and (3) median (anterior forearm). At the level of the cubital fossa, the median cubital vein connects the cephalic, basilic, and median veins.

Veins of the arm drain via the basilic or cephalic system. The basilic vein, embryologic remnant of the postaxial vein, is continuous with the axillary vein. The basilic vein is located along the medial border of the biceps muscle. The brachial artery, accompanying venae comitantes, and brachial plexus lie deep to this vein, under the brachial fascia. The basilic vein pierces the brachial fascia to join the deep veins (brachial veins) at the distal two-thirds of the arm.

The cephalic vein runs between the biceps and brachialis muscles. Proximally, it lies between the pectoralis major and deltoid muscles. The cephalic vein arches deep and drains into the axillary vein deep to the medial border of the pectoralis minor muscle.

The paired brachial veins accompany the brachial artery and are closely related to the median and radial nerves. These veins empty into the basilic vein at the lateral border of the pectoralis major muscle.

The axillary vein lies inferior and anterior to the axillary artery with the brachial plexus between these two vessels. At the lateral edge of the first rib, the axillary vein becomes the subclavian vein.

The subclavian vein lies anterior to the scalenus anterior and unites with the internal jugular vein to form the brachiocephalic vein. The subclavian vein does not contain any valves.

The left brachiocephalic vein (4–6 cm long) runs obliquely downward behind the cranial sternum to the first right costal cartilage where it unites with the right brachiocephalic vein forming the superior vena cava (SVC). In its course, it crosses anterior to the pleura over the left lung. Rarely, the left brachiocephalic vein may take a vertically downward course in the mediastinum before it joins the right brachiocephalic vein. The right brachiocephalic vein (2–3 cm long) begins behind the sternal end of the right clavicle and passes directly inferiorly to join the left brachiocephalic vein.

The internal jugular veins extend from the jugular foramen, enter the carotid sheath coursing lateral to the common carotid artery and anterior to the vagus nerve.

SUPERIOR VENA CAVA

The SVC, remnant of the right anterior cardinal vein, is 7 cm long and 2 cm in diameter. It extends from the level of the first right costal cartilage to the third right costal cartilage. The pericardial reflection/insertion ranges from 1.0 to 5.0 cm and the carina is always located at or above the pericardial reflection and the azygos vein drains into the SVC just above the reflection. A persistent left SVC is the most common anomaly (0.3%) and usually drains into the coronary sinus. A bridging innominate vein may or may not be present.

INFERIOR VENA CAVA

The inferior vena cava (IVC) is formed at approximately the level of L5 by the union of the two common iliac veins, coursing superiorly in the retroperitoneum to the right of the midline anterior to the lumbar and lower thoracic spine. The IVC exits the abdomen through the diaphragmatic hiatus and drains into the inferior and posterior wall of the right atrium. There is some variation to the size of the IVC, which does not contain valves.

EMBRYOLOGY OF THE INFERIOR VENA CAVA

Three pairs of fetal veins are located in the lower chest and abdomen that ultimately form the IVC. These are the posterior cardinal, subcardinal, and supracardinal veins. The posterior cardinal veins disappear completely, however, persistence on the right side can result in a retrocaval right ureter. IVC duplication results from persistence of the left supracardinal vein and regression of the right supracardinal vein results in a left-sided IVC. Unless there is an associated subcardinal vein (suprarenal IVC) anomaly, normal anatomy is restored above the level of the renal veins in all these variations.

The major contributors to the IVC are the hepatic, renal, gonadal, and common iliac veins. Additionally, small lumbar, right adrenal, and phrenic veins drain to it.

RENAL VEINS

Commonly, there is a single renal vein on either side. The left renal vein typically passes anteriorly between the aorta and the superior mesenteric artery and joins the IVC opposite the right renal vein at the L2 vertebral body level. The right renal vein drains directly into the IVC. Up to 40% of individuals may have variations in

renal vein anatomy, including multiple right renal veins (28%), circumaortic left renal vein (5%–7%), and retroaortic left renal vein (3%).

ILIAC AND FEMORAL VEINS

The femoral vein accompanies the femoral artery and receives the profunda femoris vein just below the inguinal ligament along with the great saphenous vein. Above the inguinal ligament, the femoral vein continues as the external iliac vein. At the level of the sacroiliac joint, the external iliac vein joins the hypogastric vein to form the common iliac vein. At the level of the L5 vertebral body, the two common iliac veins unite with each other to form the IVC. The right common iliac vein is nearly vertical and the left iliac vein is longer than the right. The right common iliac artery can course over the origin of the left common vein as it traverses to the right, significantly narrowing the vein under certain circumstances (May Thurner syndrome).

LOWER EXTREMITY VEINS

The dominant superficial veins of lower extremity include the greater saphenous and the lesser saphenous veins. The greater saphenous vein begins from the medial marginal vein on the dorsal aspect of the foot and drains into the femoral vein approximately 3 cm below the inguinal ligament. It ascends in front of the medial malleolus and along the medial side of leg, where it is related to the saphenous nerve. At the knee, it is located posterior to the medial condyle of the femur. It passes upward medially in the thigh. Its dominant tributary is the accessory saphenous vein in the thigh. Just before its entry into the deep femoral vein, it receives the superficial epigastric vein and the superficial circumflex iliac vein. The superficial epigastric vein communicates with the thoracoepigastric vein, an important communication between the femoral and axillary veins.

The lesser saphenous vein is formed behind the lateral malleolus as a continuation of the lateral marginal vein. It ascends along the lateral margin of the Achilles tendon to reach the midline in the back of the leg. The vein runs directly superiorly and perforates the deep fascia in the lower part of the popliteal fossa and drains into the popliteal vein between the two heads of the gastrocnemius muscle. Just before it penetrates the deep fascia, it gives off collaterals that connect to the greater saphenous vein. In the lower part of the leg, the vein is closely related to the sural nerve; in the upper two-thirds, it is closely related to the medial cutaneous nerve of the calf.

The deep veins accompany the arteries and have multiple valves. The posterior and anterior tibial veins are

paired veins that accompany the posterior and anterior tibial arteries. The popliteal vein is formed by the union of the anterior and posterior tibial veins. It receives the lesser saphenous vein just behind the knee joint.

TEMPORARY VENOUS ACCESS

Indications for placing temporary venous access include acute renal failure, failure of permanent graft or fistula in a patient on hemodialysis, chemotherapy infusion, and additional procedures in a patient with difficult venous access. Arteriovenous fistulas (AVFs) require at least 1 month to mature and AV grafts require at least 3 weeks; therefore, obtaining a temporary access for hemodialysis is critical for patients with renal failure. The National Kidney Foundation Dialysis Outcomes Quality Initiative (NKF-DOQI) states that <10% of chronic hemodialysis patients be on temporary access while their permanent access matures. Catheters are designed to achieve 400 to 600 mL/min flow rates. Polyurethane catheters dominate the market over the previously used silicone catheters because of their high tensile strength.

Typical sites for central venous placement include internal jugular veins, subclavian veins, femoral veins, and on rare occasions IVC via translumbar approach. The subclavian vein should be reserved for emergent cases only because subclavian vein stenosis and thrombosis occur at a higher rate than other access sites.

Temporary access can be divided into nontunneled and tunneled. Nontunneled catheters are designed for short periods (no longer than 3 weeks) and have a higher infection rate than tunneled catheters. NKF-DOQI states that a femoral catheter cannot be in place for longer than 5 days. Nontunneled catheters have the advantages at being able to be placed at the bedside and can be placed in a septic individual.

Tunneled catheters are designed for longer time use. The only contraindication is sepsis. Patient must be afebrile and have negative blood cultures for preceding 48 hours. Tunneled catheters have an increased incidence in central vein stenosis and thrombosis.

Complications of placing these catheters include pneumothorax, air embolus, hemothorax, dislodgement of catheter, introduction of infection, and injury to vascular structures. If a catheter is proven to be infected, it should be removed. Another rare complication is formation of fibrin sheath occluding the distal ports. In these cases, the fibrin sheath can be removed by placing a snare around the catheter and gently scraping the sheath away from the catheter tip or by angioplasty. If the catheter becomes thrombosed, injection of tissue plasminogen activator has a high success rate.

Maintenance of these catheters requires a minimal daily heparin flush and heparin infusion into the ports.

Problems with these catheters include inadequate flow rate, infection, leaking, and pain. NKF-DOQI states that no more than 5% tunneled catheters should fail on first dialysis after the procedure. Inadequate flow rates can be treated with exchange of the catheter, repositioning at the atriocaval junction, snaring/stripping fibrin sheath, or thrombolytics.

PERMANENT VENOUS ACCESS

ARTERIOVENOUS FISTULAS

Fistulas account for approximately 20% of the permanent dialysis access. AVFs are favored over AV grafts because of lower incidence of infection, thrombosis, and need for intervention. Some believe that AVFs actually function longer than grafts, but this is controversial. AVF requires at least 1 month to mature before it can be used for hemodialysis.

AVFs are placed surgically and have many different possible locations. The locations can be divided into three general categories: (1) upper extremity (usually radial artery and cephalic vein), (2) upper extremity with transplanted venous return, and (3) lower extremity using femoral artery and saphenous vein.

The preferred location is the radiocephalic (also known as the Brescia-Cimino). As a general rule, the fistula should be made at the most distal possible connection based on the presurgical sonographic examination. Additional possible upper extremity locations include snuffbox (between extensor pollicis longus and brevis tendons), ulnar artery to basilic vein, brachial artery to antecubital vein, and brachiobasilic (Dagher). If the upper extremity vessels do not meet the criteria for fistula creation, then a lower extremity AVF can be created (although a graft is preferred at this location) or, rarely, an anterior chest AVF (axillary/subclavian artery to ipsilateral or contralateral axillary/jugular vein).

Care must be taken in maintaining a functional AVF. On physical examination, a thrill should be palpable along the entire length of the fistula. If the venous limb is occluded, a pulse should be palpable on the arterial limb of the fistula. If a thrill is persistent during the occlusion of the venous limb, then there is flow through large side-branches, which need to be ligated or embolized, usually surgically.

A dysfunctional graft can fall into two major categories: (1) failure to mature and (2) poor function. The NKF-DOQI states that if a radiocephalic fistula fails to support hemodialysis (blood flow >300 mL/min) after 4 months, another type of permanent access needs to be established. AVF failure to mature can be further divided into two categories: (1) inadequate flow and (2) too low

TABLE 83-1 Complications of AVF Intervention

Vein rupture during angioplasty resulting in loss of access	Bleeding can be controlled with external manual compression or an occlusive balloon
Ischemia of the hand	Requires immediate surgical intervention or distal thrombectomy to salvage the hand
Intracranial hemorrhage secondary to thrombolysis	
Myocardial infarction or pulmonary edema	Because these patients have ESRD and are already volume overloaded, care must be taken not to give too much fluids during the procedure
Sepsis	

venous resistance. Inadequate blood flow is most likely secondary to a stenosis either within the native artery proximal to the anastomosis or within the anastomosis itself. These are usually treated with angioplasty; however, care must be taken with the native artery because a dissection, thrombosis, or embolus can be devastating requiring immediate surgery. Inadequate venous resistance causes the venous limb to fail to “arterialize.” This is invariably due to large venous branches, which need to be ligated/embolized.

A poorly functioning AVF (like a graft) is most likely secondary to venous outflow stenosis. A low Kt/V (where, K is total urea clearance of the dialyzer, t is time, V is volume), high recirculation calculation, or elevated venous pressures all indicate venous stenosis. Venous stenosis is treated with angioplasty.

Thrombosed AVF can be treated with either thrombolysis or mechanical thrombectomy. Again, care must be taken since these are the native vessels and not a graft (especially with the arterial limb). Also, the majority of the mechanical thrombectomy devices are FDA approved for grafts and not native vessels. There are several potential major complications when treating a dysfunctional AVF (Table 83-1).

ARTERIOVENOUS GRAFTS

Grafts are more commonly placed than AVF (80%). AV grafts have the advantage over AVF; they can have variable lengths making connection between the arterial and venous limb easier. Originally, there were two different types of grafts: saphenous vein graft (not used anymore) and prosthetic graft. There are two main categories of prosthetic grafts: (1) fabric (Dacron) and (2) synthetic polymers (PTFE). The latter are favored over the fabric grafts, which can fray after multiple needle punctures. In addition, the PTFE grafts are supported by external rings, thereby, decreasing external compression and

kinks. Both types allow ingrowth of tissue, incorporating the graft into the viable tissue.

Grafts can be further subdivided into straight and loop grafts. Originally, loop grafts were thought to be superior to straight grafts; however, over time this topic has become controversial. The locations of the grafts are similar to AVFs, however, extensive repositioning of the native vessels is not necessary. When a graft is placed, it is best to have a wide loop, permitting easier passage of percutaneous catheters and mechanical thrombectomy devices. In addition, if arterial and venous anastomosis are in close proximity to each other, determining the arterial versus the venous limb may be more difficult, especially if the graft is completely thrombosed.

Unique to grafts is a condition called ischemic (or arterial) steal syndrome. This occurs when there is a reversal of the arterial blood flow distal to the graft. This occurs in approximately 2% of the grafts but is not seen with AVF. The symptoms range from a cool sensation of distal extremity to limb-threatening ischemia. Ischemic steal syndrome may be due to diseased native artery proximal or at the anastomosis. Treatment includes angioplasty of proximal arterial stenosis or surgery with ligation of the graft, intentionally narrowing (or banding) the arterial inflow or distal artery ligation (or revascularization) depending on the location of the graft.

Maintenance of a graft is critical to avoid thrombosis. The inflow rate of a graft needs to be at least the same as dialysis pump rate (300 mL/min). On physical examination, the graft (like AVF) should have a thrill in its entirety. If there is a stenosis, the thrill is replaced with a pulse proximal to the stenosis. There will be a thrill or bruit at the stenosis with diminished or no pulse distally. Venous pressure during hemodialysis is the best indicator for graft dysfunction. A venous pressure of greater than 125 mm Hg (via 15-gauge needle at 200–225 mL/min at dialysis) indicates graft dysfunction. Additionally, if the normalized pressure ratio (venous pressure/systolic pressure) is greater than 0.4 mm Hg, this indicates there is a stenosis. If the arterial inflow pressure does not sustain a rate greater than 300 mL/min, then an arterial stenosis is likely. The actual blood flow rate is a poor indicator of graft dysfunction. Sonographic investigation is an excellent modality in detecting stenoses; however, it is not cost effective for routine surveillance. Early thrombosis (less than 6 weeks) is considered a technical or mechanical error while later thrombosis is considered to be secondary to intimal hyperplasia resulting in venous stenosis at the venous anastomosis.

The NKF-DOQI guidelines state that there should be less than 0.5 thrombotic episodes in a graft per patient per year. In addition, graft patency rates should be 70% at 1 year, 60% at 2 years, and 50% at 3 years. There are many causes of graft dysfunction, which include throm-

bosis (most common), infection (the only contraindication for percutaneous intervention), pseudoaneurysm, atherosclerosis of arterial inflow vessels (poor graft thrill), and lymphoceles. Thrombosis, resulting in a decrease in blood flow and increase in graft pressures, most commonly occurs because of a stenosis at the venous outflow anastomosis (80% of dysfunctional grafts). Other causes of thrombosis include altered platelet function, hypercoagulable state, and external compression of the graft.

A pseudoaneurysm is usually caused by a defect in the prosthetic graft, usually due to poor cannulation technique and venous hypertension. These rarely resolve spontaneously and have a risk of spontaneous rupture. Treatment involves covered stent, or thrombin injection directly into the pseudoaneurysm.

A lymphocele is a perigraft collection of ultrafiltrate that weeps across the graft pores, usually near the arterial anastomosis. This collection can develop into a fistula with skin breakdown. Fistulogram will demonstrate no communication with the collection; this allows differentiation from pseudoaneurysm.

Treatment options for dysfunctional graft include both surgical and percutaneous intervention. Patients with a history of right ventricular failure, pulmonary hypertension, right-to-left shunt, or cardiac dysrhythmia are not optimal candidates for percutaneous intervention and should be referred for surgical thrombectomy. In addition, patients should have a satisfactory hematocrit level because mechanical thrombectomy may further decrease the blood volume by mechanical destruction of the red blood cells and too much aspiration.

There are four common steps involved with all percutaneous thrombosed graft treatments. Initial venogram is performed. As stated earlier, the most common site of abnormality for a thrombosed graft is at the venous anastomosis. Secondly, thrombus within both the venous and arterial limbs is removed. Prior to starting, 2000 to 5000 units of heparin are injected. The venous limb is usually cleared of all the thrombi before inserting another sheath and clearing the arterial limb. Then, venous and arterial stenoses are treated. There are two schools of thought about the timing of venous intervention. Traditionally, correction of the venous stenosis is left for the end of the procedure, so the potential pulmonary thrombosis burden will be less, as the stenosis will prevent the emboli from entering the systemic circulation. Others believe addressing the stenosis first, which will decrease intragraft pressure and thereby decrease the risk for arterial emboli. The diameter of the balloon should be 10% to 20% greater than vessel diameter. Finally, the arterial plug, composed of fibrin and packed red blood cells, is dislodged. A compliant balloon (Fogarty) is typically used with care not to injure

the native artery or dislodge emboli into the arterial circulation.

Both mechanical thrombectomy and thrombolysis are common techniques used to declot a graft. There are many different types of mechanical thrombectomy devices on the market. Some have a rotating driveshaft, which makes operating at acute angles difficult. Thrombolysis usually uses a combination of heparin with either urokinase or streptokinase. A “lyse and wait” technique is used when a lytic agent is injected a certain time period prior to the procedure. Complications with percutaneous intervention include arterial emboli, vessel rupture, and arterial rupture. To date, no clinically significant pulmonary embolus has been encountered with these techniques, however, the theoretical risk remains.

VENOUS THROMBOEMBOLIC DISEASE

Venous thromboembolic disease comprises deep venous system thrombosis (DVT), pulmonary thromboembolism (PTE), and venous insufficiency. There are approximately 20 million new cases of lower-extremity and 200 000 to 6 000 000 of upper-extremity DVT yearly. The most critical consequence is a large pulmonary embolism resulting in death. Pathophysiology of venous thrombosis is complex, as described by the Virchow triad (Table 83-2).

Extremity DVT commonly presents with unilateral extremity edema, pain, and warmth. Sometimes, the first presentation is pulmonary embolism. Occasionally, massive DVT involving the entire venous system of the extremity presents as phlegmasia in the extremities with congestion, massive edema, and limb-threatening compartment syndrome. Dilated and prominent collateral veins are sometimes noted. History of antecedent inciting causes such as trauma, prolonged immobilization, and exercise (Paget-Schroetter syndrome in upper extremity) can be useful.

Doppler ultrasound is the mainstay of diagnosis. CT venography in concert with a CT pulmonary angiogram can be performed as a single study to assess for DVT and PTE at the same sitting. MRI has a problem-solving role in lower extremity DVT and is more useful in upper extremity DVT to assess the central veins. Conventional venography is rarely performed, restricted to specific scenarios in-

TABLE 83-2 Virchow Triad

Slow venous flow	External compression, prolonged immobilization
Disruption in vein wall	Trauma from catheters, previous DVT
Hypercoagulable state	Cancer, polycythemia vera, antithrombin III deficiency, protein S or C deficiency, estrogen therapy

cluding evaluation of central DVT in the upper extremities prior to intervention for thrombolysis/thrombectomy, prior to upper extremity permanent dialysis access placement, or prior to placement of a vena cava filter.

Complications of DVT include PTE, phlegmasia cerulea dolens, and postthrombotic syndrome with chronic venous insufficiency. The main principles underlying management are the prevention of PTE and progression of the DVT, both achieved by anticoagulant therapy. An IVC filter addresses only the issue of a possible PTE and does not affect the progression of DVT. Thrombolysis in concert with IVC filter placement addresses both and is the only method that decreases the risk of postphlebotic syndrome and restores venous patency.

The mainstay in the prevention of PTE in a patient with known DVT is the use of anticoagulants, either warfarin or heparin. Warfarin (Coumadin) is the drug of choice for management on an outpatient basis; however, there are certain risks associated with the use of warfarin and maintaining a therapeutic international normalized ratio (2.0–3.0). These include bleeding risks related to preexisting conditions such as ulcer disease, bleeding from minor trauma, hematuria, and intracranial hemorrhage in patients with hypertension. Approximately 20% of patients on Coumadin therapy develop complications that necessitate discontinuing therapy, which often mandates filter placement. There are several indications for filter placement (Table 83-3).

IVC filters are best positioned, with the superior tip exposed to the wash in of blood from both renal veins, thereby reducing the risk of IVC occlusion and maintaining renal vein outflow even if there is a large embolus trapped in the filter. A good quality IVC venogram is mandatory before placing filter. In addition, review of prior cross-sectional imaging studies may help detect unexpected venous variant anatomy. Some of the important variations that could affect the placement include IVC diameter greater than 28 mm (requires OptEase, Bird's nest filter, or the presence of anatomical variations in renal veins [40%]). These variations include multiple renal veins (28%)—usually not an issue as long as they are in close proximity, circumaortic renal vein (5%–8.7%), and retroaortic left renal vein (3%). For the latter two, filter

needs to be placed above the renal veins in most cases. Bird's nest filters are not recommended in a suprarenal location because of the increased risk of prolapse of the coils into the heart. If there is enough distance, the filter could be placed in the IVC below the entry of the circumaortic component.

There can also be caval variations, such as duplicated IVC. Usually the infrarenal segment is duplicated and the left IVC drains into the left renal vein. Filters may be placed in both infrarenal IVCs or in a suprarenal location. There are multiple filters marketed with varying shapes without significant difference in their effectiveness.

RETRIEVABLE FILTERS

The long-term outcomes of filter placement are unknown, and there is risk of caval thrombosis. Also, comparative studies between filter placement alone and anticoagulation demonstrate there is comparable decrease in risk of PTE with greater risk of progressive DVT. Filters are most commonly placed when there is a contraindication to anticoagulation. Retrievable filters are of two types: temporary and optional. Temporary filters are not approved in the United States and consist of the filter attached to a wire or retrievable device that can be left in situ and removed when filtration is no longer desired. Optional filters can be removed either using a snare or an appropriate retrieval device.

These filters are best suited for patients who are at high risk for venous stasis and thromboembolism, such as trauma patients with orthopedic injury and patients undergoing gynecologic surgery.

SUPERIOR VENA CAVA FILTERS

The proposed indications for SVC filter are analogous to those for IVC filter. Contraindications include the following: (1) extensive SVC thrombus; (2) SVC diameter greater than 28 to 30 mm; (3) uncorrectable, significant coagulopathy; and (4) venous pacemaker.

FILTERS CHOICE

Because of the long-term experience with the Greenfield filter, some physicians choose this filter for younger patients. The bird's nest filter is needed for patients with a large vena cava (approved up to 40 cm in diameter). When there is only a short segment of usable IVC, such as when there is a low insertion of a renal vein, placing a Greenfield filter or Gunther Tulip (which can be secured in a small length of cava) may be preferable.

TABLE 83-3 Indications for Caval Filter Placement

Contraindication to Coumadin therapy
Patient is considered unable to maintain the rigorous follow-up required when on Coumadin therapy
Free floating iliofemoral or IVC thrombus
Temporary IVC filtering in patients with increased risk of DVT in the preoperative setting (trauma, gynecologic surgery, etc.)
Patients who have had a prior massive PE or have DVT with limited cardiopulmonary reserve

Knowing the characteristics of each filter will help in choosing the optimal filter for each clinical scenario.

COMPLICATIONS

Complications of filter placement include access site complications such as hematoma, AV fistula, and access vein thrombosis. Complications related to the filter include acute complications such as caval perforation, malposition of the filter, and migration of the filter. Chronic complications include filter migration, fracture, low-grade caval perforation, and IVC occlusion. Additional risks to a jugular/subclavian approach include pneumothorax, air embolism, arrhythmias, and SVC injury with mediastinal/pericardial hemorrhage.

VENOUS THROMBOLYSIS

Catheter-directed thrombolysis is the only method of DVT management that restores venous patency and decreases the risk of postphlebotic syndrome. However, it is underused and is typically reserved for patients with massive acute DVT in the lower extremity (phlegmasia cerulea dolens) or effort thrombosis in the upper extremity (Paget-Schroetter syndrome). There is a relative lack of data from randomized controlled trials comparing catheter-directed therapy with anticoagulation therapy.

Patients with symptomatic acute iliofemoral DVT (less than 10 days) or phlegmasia, diagnosed by conventional venography and/or color Doppler ultrasound who are eligible for thrombolytic therapy and long-term anticoagulation are candidates for this therapy. This subset of patients are often otherwise healthy and may have an underlying obstructive venous lesion such as May-Thurner syndrome. The presence of active internal bleeding, history of a cerebrovascular accident, recent intracranial or intraspinal surgery (less than 1 year), pregnancy, and/or coagulopathy are contraindications. Phlegmasia can also occur in patients with pelvic carcinomatosis or diffuse malignancies, and these patients have limited survival and may not represent ideal candidates for thrombolysis.

There are three general categories of upper extremity DVT. Primary or spontaneous upper extremity DVT occurs in young patients and is due to an underlying mechanical lesion in the costoclavicular space or interscalene triangle. The presence of an anomalous bone, muscle slip, or musculotendinous insertion leads to chronic subclavian vein narrowing. When recurrent occupational or exertional stress is superimposed, intimal damage occurs that results in thrombosis. This is also known as Paget-Schroetter syndrome.

Secondary DVT in the upper extremity results from an identifiable underlying disease processes such as malignancy or hypercoagulable state. Also, mechanical compression by mass or lymph nodes or local invasion by malignancy result in thrombosis.

A third and growing cause of upper extremity DVT is the placement of indwelling central venous catheters. Venous thrombosis in the upper extremity is often clinically silent and may affect up to 30% of patients with central catheters. Symptomatic upper extremity DVT occurs in approximately 3% to 4% of patients. Presenting symptoms include arm pain, swelling, cyanosis, facial edema, and rarely pulmonary embolism.

MANAGEMENT

In the setting of acute primary DVT, anticoagulation and thrombolysis have been used, with the latter method gaining in popularity as it allows the reestablishment of venous patency. A combination of mechanical thrombectomy and thrombolytic infusion have been used with good results. However, there are no randomized controlled trials comparing systemic and catheter-directed thrombolysis. In the case of effort thrombosis, the culprit compressive lesion is best treated by surgery, as the mechanical component of the compression cannot be addressed by endovascular methods. May-Thurner syndrome is treated by stent placement at the left iliac vein stenosis with good long-term success. The incidence of DVT caused by central venous catheters can be reduced by administration of low-dose heparin in selected patients considered to be at a higher risk.

MISCELLANEOUS

SUPERIOR VENA CAVA SYNDROME

SVC syndrome refers to obstruction or occlusion of the SVC with impaired venous return from the upper extremities, head, and neck to the right atrium. Symptoms include facial edema, cough, dyspnea, orthopnea, hoarseness, nausea, headache, plethora, and distention of superficial veins. Life-threatening complications may include cerebral or laryngeal edema. However, mortality is usually secondary to the underlying cause of the venous occlusion. SVC syndrome may result from lung or mediastinal cancer encasing or invading the SVC (80%), mediastinal fibrosis, or from indwelling catheters or cardiac pacer leads causing occlusion. Treatment options for SVC syndrome include surgery, radiation therapy, chemotherapy, and angioplasty with or without stenting. Endovascular therapy

has become the mainstay of treatment for SVC syndrome with stent placement for malignant disease and angioplasty for benign disease. Complications include arrhythmia, acute right heart failure or pulmonary edema from fluid overload, intracerebral hemorrhage secondary to procedural thrombolysis, and acute pericardial effusion and tamponade.

INFERIOR VENA CAVA OCCLUSION

Causes of IVC occlusion include thrombus (extending from an iliac vein, filter placement, trauma, surgery, or placement of an indwelling catheter) or external compression (retroperitoneal mass, pregnancy, adenopathy, or retroperitoneal fibrosis). Tumor infiltration of the IVC is also a culprit.

Acute occlusion presents as bilateral lower extremity edema with or without phlegmasia. More commonly, the occlusion is chronic with development of collaterals. The presence of dilated abdominal wall veins and bilateral lower extremity edema suggests IVC occlusion. Ultrasound, CT, and MRI help in the diagnosis of IVC obstruction and allow identification of an etiology in most cases. Treatment includes thrombolysis in the acute setting and angioplasty with or without stent placement if there is an underlying stenosis.

GONADAL VEIN EMBOLIZATION

Gonadal vein embolization is performed in males for testicular varicocele and in female patients for pelvic congestion syndrome. Varicoceles are encountered in 20% to 40% of male patients with infertility. Treatment is by embolization using coils and sclerosing agents. Technical success rate ranges from 83% to 96%. There is a 12% to 16% rate of recurrence, which is treated surgically.

Veins from the mediastinum testis form the pampiniform plexus, which arises in the scrotum and extends into the spermatic cord. The plexus coalesces into the internal spermatic vein, which passes through the inguinal canal and ascends through the retroperitoneum. Ultimate venous drainage is to the IVC on the right and the renal vein on the left. Ureteric, lumbar, perirenal, and retroperitoneal veins empty into the gonadal veins.

Pelvic congestion syndrome in women represents non-cyclic pelvic pain in the absence of menstruation that is severe enough to cause functional disability. Causes include endometriosis versus pelvic adhesions. This condition usually affects women in the age group of 20 to 30 years. The symptoms are typically exacerbated by standing or lifting and may improve on lying supine. Etiology is considered to be ovarian vein reflux. Ultra-

sound is usually used for detection and quantification of the dilated veins. Treatment includes embolization using coils and sclerosing agents. Technical success rates and potential complications are the same as for varicoceles in men.

ADRENAL VEIN SAMPLING

Adrenal vein sampling localizes a hyperfunctioning adrenal adenoma, secreting either aldosterone or cortisone, when cross-sectional imaging has failed. This procedure differentiates unilateral adrenal adenoma from bilateral adrenal hyperplasia. Simultaneous catheterization of both adrenal veins is performed and samples are obtained concurrent with peripheral venous samples, before and after stimulation with ACTH. The aldosterone–cortisol ratio remains high before and after ACTH stimulation on the abnormal side. On the normal side, the aldosterone–cortisone ratio does not change with ACTH stimulation and remains similar to that in the peripheral femoral vein. In the case of Cushing's syndrome, ACTH stimulation is not required. The treatment for unilateral adenoma is resection. Bilateral adrenal hyperplasia is usually treated medically.

VENOUS INSUFFICIENCY

Venous insufficiency affects 25% of all women (72% of those older than 60 years) and 15% of all men. Risk factors for developing venous insufficiency include hereditary (25% with one afflicted parent; 25% for men and 60% for women with two afflicted parents), lifestyle (27% increased risk with sedentary lifestyle and 36% increased risk with prolonged standing), body habitus (increased BMI for females and increased height for males), and prior history of DVT (50%–60% of the cases).

The pathophysiology of developing venous insufficiency can be divided into three general categories: valvular insufficiency (most common), venous obstruction (DVT or external compression such as pregnancy), and muscle pump dysfunction.

Gravity helps with arterial circulation in the sense that the primary vector of gravity pushes the blood to the distal extremities. This is reverse for venous flow and alternate mechanisms are needed to propel the blood against gravity. This is accomplished first by muscle pump action. As a muscle contracts, the deep vein within that muscle is externally compressed by its surrounding muscle. When this occurs the blood is propelled from that vessel. Valves within the veins are present to prevent the blood from being propelled in the wrong direction. So, any disruption in this mechanism can result in venous insufficiency.

TABLE 83-4 Venous Perforators List

Hunter	Medial thigh
Dodd	Distal thigh
Boyd	Medial knee
Cockett	Posterior tibial

Anatomy specific for venous insufficiency include superficial veins (lesser saphenous, greater saphenous), perforators (connect deep veins to the superficial), reticular veins (tributaries to the saphenous), and capillaries (cause spider veins and telangiectasia). Twenty percent of the population has duplicated saphenous veins. Identifying which vein is dilated will help isolate which valve is incompetent (Table 83-4).

Besides cosmetic appearance, venous insufficiency can result in a various array of symptoms including pain, pruritus, night cramps, fatigue, heaviness, and leg restlessness. Advanced changes include edema, hyperpigmentation, dermatitis, lipodermatosclerosis, and ulceration. There is specific terminology used for the dilated vein. A varicose vein is a dilated, protruding, tortuous, saccular superficial vein in the subcutaneous tissues. A reticular vein is a dilated, tortuous, nonprotruding superficial vein in the subcutaneous tissues. A telangiectasia is a spider appearing, tortuous nonprotruding or dilated vein in the dermis.

Ultrasound evaluation is the modality of choice for evaluating venous insufficiency and etiology of disease. Indication for sonographic examination includes symptomatic or asymptomatic visible varicose veins, symptoms of venous hypertension, or recurrent varicose veins after surgery. Generally, ultrasound is not indicated for telangiectasia. On sonographic examination, incompetent valves, DVT, extent of dilated veins, and reversal of blood flow can be visualized.

Treatment for venous insufficiency can be categorized into four groups: (1) conservative, (2) surgical, (3) sclerotherapy, and (4) endovascular thermal ablation. Conservative therapy includes compression stockings, improve calf muscle function, good skin hygiene, losing weight, regular exercise, and avoiding prolonging periods of standing or sitting.

Surgical option for venous insufficiency involves groin surgery to expose and ligate the diseased great saphenous vein and surrounding tributaries. A stripping tool is inserted at the groin, threaded through the great saphenous vein exiting through the skin just below the knee; the saphenous is then tied to the stripping tool and pulled from below the knee.

Sclerotherapy involves refluxing a sclerosing agent into the saphenous vein. This may be an isolated treatment method or used in conjunction with surgery. There is a high rate of recanalization and symptom recurrence

compared to the other modalities of treatment. Typically, the procedure is performed with ultrasound guidance. Common sclerosing agents include sodium tetradecyl sulfate (Sotradecol), polidocanol, 23.4% saline, 25% dextrose with 10% saline, and sodium morrhuate. Anaphylactic reactions, toxic reactions, hemolysis, and skin necrosis/ulceration are some of the complications associated with sclerotherapy.

Endovascular thermal ablation can involve using a radiofrequency probe, a laser (most common), or cryotherapy probe (poorer results). There is a 98% successful procedure rate with a 93% persistent saphenous vein occlusion. Contraindications to the procedure include dermatitis, cellulitis, severe edema, and allergies to local anesthetics.

Avoiding tight-fitting undergarments and clothing, crossing legs, and sitting and standing for long periods of time will decrease the recurrence of venous insufficiency. In addition, regular exercise, weight loss, and elevating legs at least twice a day will also decrease the rate of recurrence.

QUESTIONS AND ANSWERS

- Which of the following steps would *not* be performed initially during an AV graft declot?
 - Angioplasty the venous stenosis
 - Mechanical thrombectomy
 - Dislodgement of arterial plug
 - Injection of thrombolytics

ANSWER: C. You would never dislodge the arterial plug first as this would increase risk of the embolization into the systemic circulation, possibly resulting in limb-threatening ischemia.

- If a patient has a duplicated IVC, where is an IVC filter usually placed?
 - Infrarenal right IVC
 - Suprarenal IVC
 - Infrarenal left IVC
 - Filter is contraindicated and thrombolysis should be performed.

ANSWER: B. With a duplicated IVC, a suprarenal filter or infrarenal filter in both IVCs is recommended.

- In a circumaortic renal vein, which IVC filter *cannot* be used?
 - Gunther Tulip
 - OptEase
 - Internal jugular vein approached filter
 - Bird's nest

ANSWER: D. With a circumaortic renal vein, IVC filter needs to be placed usually in a suprarenal location. A bird's nest filter has increased risk of prolapse of the coils into the heart.

- What is the standard treatment of malignant SVC syndrome?
 - Stenting
 - Surgery
 - Angioplasty
 - Endovascular treatment is only undertaken with benign disease.

ANSWER: A. In general, stent placement is used for malignant SVC syndrome, as it is permanent. Angioplasty is used for benign disease.

- A perforator vein of the medial thigh, which is fairly consistent in location, is also known as
 - Dodd
 - Boyd

- Cockett
- Hunter

ANSWER: D. Hunter (medial thigh), Dodd (distal thigh), Boyd (medial knee), and Cockett (posterior tibial) are names given to perforators.

- What is a dilated, tortuous, nonprotruding superficial vein in the subcutaneous tissues?
 - Varicose vein
 - Telangiectasia
 - Reticular vein
 - Deep vein

ANSWER: C. A varicose vein is a dilated, protruding, tortuous, saccular superficial vein in the subcutaneous tissues. A reticular vein is a dilated, tortuous, nonprotruding superficial vein in the subcutaneous tissues. A telangiectasia is a spider appearing, tortuous nonprotruding or dilated vein in the dermis.

- What causes Paget-Schroetter syndrome?
 - Presence of an anomalous bone, muscle slip or musculotendinous insertion leading to chronic subclavian vein narrowing
 - Recurrent occupational or exertional stress causing intimal damage resulting in thrombosis
 - Hypercoagulable state secondary to heredity condition
 - Thrombosis secondary to underlying malignancy

ANSWER: B. This is the definition of Paget-Schroetter syndrome.

- Where is the cephalic vein located?
 - Medial border of the biceps muscle
 - Between the biceps and brachialis muscles
 - Lateral border of pectoralis major muscle
 - Pierces the brachial fascia to join the deep veins (brachial veins) at the distal two-thirds of the arm

ANSWER: B. The cephalic vein courses between biceps and brachialis muscles. The basilic vein is continuous with the axillary vein and is located along the medial border of the bicep.

- On physical examination of AVF, where should a thrill be palpable?
 - On the arterial limb only
 - On the venous limb only
 - Throughout the entire graft
 - Only when the venous or arterial limb is occluded.

ANSWER: C. The thrill should be felt throughout the entire graft. With occlusion of the venous side, and pulse should be felt on the arterial side.

10. When are temporary nontunneled catheters contraindicated?
- Sepsis
 - When patient has a nonfunctioning AV graft
 - Hypercoagulable state
 - None of the above

ANSWER: D. Temporary nontunneled catheters are for short-term use (less than 3 weeks). Unlike tunneled catheters, sepsis is not a contraindication.

84 ABDOMEN AND LIVER

Kok C. Tan and Souheil Saddekni

VASCULAR ANATOMY

The liver parenchyma is made up of lobules consisting of sinusoids around a central draining vein, bounded by the portal triad of branches from the bile duct, portal vein, and hepatic artery at the periphery. The liver is mainly composed of hepatocytes, which perform the main metabolic function of the liver and Kupffer cells that form part of the reticuloendothelial system. The liver receives approximately two-thirds of its blood supply from the portal vein and one-third from the hepatic artery. Blood drains via the hepatic veins into the inferior vena cava, and then into the heart.

PORTAL HYPERTENSION

Portal hypertension refers to abnormally high pressure in the portal vein. It is defined as a portal pressure greater than 10 mm Hg, (normal 5–10 mm Hg). Alternatively, it can be defined by the gradient between the wedge hepatic venous pressure (which is an indirect measurement of the pressure in the sinusoids and hence the portal vein) and the free hepatic venous or the inferior vena cava pressure. The normal gradient is less than

5 mm Hg. This gradient is also called corrected sinusoidal portal pressure. Because of great variations of intra-abdominal pressures reflected in a baseline increase of the pressure in the portal vein and inferior vena cava, a more accurate measurement of true portal hypertension is to use the gradient rather than absolute pressures.

Portal hypertension is most commonly encountered in patients with cirrhosis. The common conditions leading to cirrhosis and portal hypertension are alcoholic liver disease and chronic viral hepatitis. Patients in whom a cause cannot be identified are said to have cryptogenic liver cirrhosis. Not all patients with portal hypertension have cirrhosis. Cirrhosis refers to a specific histologic finding of diffused fibrosis and abnormal liver nodularity, resulting from chronic hepatocellular injury.

The causes of portal hypertension can be organized into several categories based upon the level of obstruction: prehepatic, intrahepatic, and posthepatic. Pathologists have further divided the intrahepatic causes into presinusoidal, sinusoidal, and postsinusoidal causes on the basis of histologic findings depending on the predominant location of the fibrosis with regard to the sinusoids (Table 84-1).

Portal hypertension is caused by an increased resistance to blood flow through the liver. Fibrotic changes in the hepatic parenchyma increase the portal pressure by causing an increase in intrahepatic resistance. On a cellular level, the increased pressure results from a combination of deposition of collagen in the spaces of Disse and hepatocyte swelling, both of which increase the sinusoidal pressure and cause a relative resistance to sinusoidal flow.

Resistance to hepatopetal flow through the higher pressure portal system toward and through the liver with increased pressure leads to a backflow and compensation by shunting blood away from the liver (hepatofugal) in a retrograde fashion into the lower pressure systemic circulation. This may occur spontaneously in the form of numerous characteristic collateral venous pathways called varices.

Varices are large, thin-walled veins, which dilate gradually and at a certain point they bleed. Bleeding appears at highest risk in larger varices and with high PV–IVC gradients (greater than 12 mm Hg). Gastroesophageal varices (coronary veins and esophageal

TABLE 84-1 Causes of Portal Hypertension

veins) are most commonly seen at CT. Gastrorenal varices are least commonly seen (Table 84-2).

The spontaneous pathways are often insufficient to decrease portal pressures to normal levels. When variceal bleeding occurs it is considered a medical emergency and the patient should be hospitalized and medically treated to control the bleeding. Supportive measures and vasoactive drugs are used immediately, followed by endoscopy as soon as possible. Endoscopic sclerotherapy is the first line of invasive treatment, which can be effective in the majority of cases. However, recurrence is common and the underlying cause of portal hypertension remains untreated. This can be addressed by the creation of percutaneous transhepatic portosystemic shunt (TIPS) or one of several surgical portosystemic shunt operations.

Ascites is a common and serious complication of cirrhosis and the 2-year survival after ascites develops is approximately 50%. Sinusoidal hypertension is felt to be responsible to a large degree of ascites development. When ascites becomes refractory to medical treatment requiring frequent paracenteses, TIPS should be considered.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

TIPS decompresses the portal system by the percutaneous transjugular intrahepatic creation of a low resistance portosystemic shunt in the liver between the portal vein and the hepatic vein. A stent or stent-graft is placed across the shunt tract in the liver to maintain it open. Self-expanding metal stents were used for almost a decade. Despite the initial success, malfunction of bare metal stents was reported to occur at a high rate

(17%–73% in the first 6 months) requiring frequent revision. Covered e-PTFE stent-graft (Viatorr, W. L. Gore & Associates, Flagstaff, AZ) has practically replaced bare stents and have shown much higher patency rates (80%–84% at 1 year) and lower rebleeding.

The TIPS procedure is usually indicated in patients with variceal bleeding and ascites refractory to medical management. Absolute contraindications to TIPS placement include biliary sepsis, severe hepatic failure, and occluded portal venous system.

A patent portal vein should be documented before TIPS is attempted. This is usually performed with ultrasound interrogation of the liver and a Doppler study of the hepatic and portal venous system. Cross-sectional imaging such as MRI or CT may also provide similar information. Sometimes such imaging may reveal the presence of a mass lesion along the anticipated tract of the shunt, which can alter management decisions.

Prior to TIPS, appropriate blood work should be performed. As general guidelines, platelet counts should be above 50 000 and the international normalized ratio should preferably be below two. In some patients, intubation may be required for airway control. Otherwise, TIPS may also be performed under conscious sedation in experienced hands (fentanyl, midazolam, droperidol). Standard hemodynamic monitoring including ECG, oxygen saturation, and blood pressure should be performed throughout the procedure.

The presence of ascites, especially around the liver, can complicate the TIPS procedure by altering the angle the portal vein makes with the hepatic vein. Therefore, drainage of ascites prior to performing the TIPS procedure is advised.

TECHNICAL CONSIDERATION

The necessary equipment is put together by vendors in special “kits” to facilitate the procedure. The two most commonly used kits for TIPS are the Rosch-Uchida and Ring sets (Cook, Bloomington, IN). The preferred access route is via the right internal jugular vein. The 10F 40-cm-long vascular sheath is then advanced and pressure readings in the right atrium and inferior vena cava are recorded.

A curved multipurpose A (MPA) catheter is then used to select a hepatic vein. The preferable hepatic vein to access is the right hepatic vein, which lies posterior to the right portal vein. Occasionally, tips is performed from the middle hepatic vein and directed posteriorly to the right portal vein. A free hepatic pressure and venogram is obtained. This catheter can also be used to do a wedge hepatic venous pressures and venogram; however, an occlusion balloon catheter such as a Fogarty balloon

catheter is preferable. The balloon is inflated and wedged and hepatic venous pressure is then measured. The intrahepatic portal pressure is expressed as the hepatic vein pressure gradient or the difference between the wedged hepatic venous pressure and the free hepatic or IVC venous pressure. The normal gradient is equal to or less than 5 mm Hg. A gradient larger than 5 mm Hg is indicative of portal hypertension and a gradient above 12 mm Hg is associated with the development of variceal hemorrhage. A wedge hepatic venogram will most likely show reflux of contrast through the sinuses into the portal vein to various degrees depending on the degree of postsinusoidal fibrosis and hepatofugal flow in the portal vein. This reflux is essential to mark the location of the target portal vein in relation to the hepatic vein to be bridged. A wedge venogram using CO₂ rather than iodinated contrast is very useful in this regard as CO₂ is much more likely to reflux much further than iodinated contrast and landmark the location of the portal vein.

The diagnostic MPA catheter is removed and exchanged for a guiding cannula and sheath, which is placed in the hepatic vein. A syringe partly filled with contrast is then attached to the needle hub. When using a right hepatic vein approach, the needle is rotated anteriorly and advanced. The length of the needle pass depends largely on the size of the liver and the relative location of the portal vein. As a general guide, the needle should be advanced approximately 1 cm beyond the expected location of the portal vein. Aspirate the contrast syringe during slow needle withdrawal, and when blood is aspirated, gently inject contrast to identify the vascular structure entered. Once a suitable portal branch is punctured, a glide wire is then manipulated through the portal vein into the splenic vein. The needle is removed and a 5F diagnostic catheter advanced into the splenic vein. Portography is then performed and portal pressures are measured directly.

The entire sheath is then advanced and the parenchymal tract is dilated with 10 mm angioplasty balloon. This is generally the most painful part of the procedure for the patient, and added analgesics are recommended when performing the procedure under conscious sedation. Typically two focal indentations are present on the balloon, which represent the more resilient fibrous tissue of the portal and hepatic veins walls.

An 8- to 12-mm e-PTFE covered stent-graft is then deployed across the newly created transhepatic tract. The first 2 cm is placed in the portal vein are bare (non-covered), while the section that is positioned within the liver tract up into the hepatic vein is covered with impermeable material to prevent bile leaks from entering the shunt tract. Once deployed, we generally use a 10-mm balloon to expand the stent in the tract. For large portal veins and/or treatment of ascites, the use of

12-mm stent grafts and expanding them to full 12 mm with balloon angioplasty may be necessary to reduce the gradient to recommended levels. However, this may increase the incidence of hepatic encephalopathy.

A venogram is performed to document satisfactory positioning of the stent and the pressure gradient across the newly created shunt is determined. Flow in the splenic and portal vein should be antegrade up through the shunt and into the IVC. Significant reduction or cessation in retrograde flow in varices should occur. The portogram may show little or no antegrade flow into right and left portal vein branches indicating reversal of flow (hepatofugal) from the intrahepatic portal veins. Liver perfusion becomes largely hepatic artery dependent.

When TIPS is performed to control variceal bleeding, embolization of the varices should be performed after the TIPS has been created. Coils in the main trunk of the varices may suffice. More distal embolization can be achieved with sclerosing agents.

Following TIPS procedure, the generally desired end point is reduction of the portosystemic gradient to below 12 mm Hg for esophageal variceal bleeding and 8 mm Hg or lower for refractory ascites.

The complication rate from TIPS in experienced hands is less than 5% with a mortality rate of less than 2%. The most serious and potentially lethal complications of TIPS are almost always related to transhepatic puncture. Peritoneal exsanguination can occur from perforation of an extrahepatic portion of the portal vein or from hepatic arterial injury with associated perforation of the hepatic capsule (Table 84-3). Worsening of hepatic encephalopathy after TIPS occurs in 30%. This is believed to be caused by ammonia, a neurotoxin that

TABLE 84-3 Complications of TIPS

	REPORTED RATE (%)
Major complications	3
Hemoperitoneum	0.5
Stent malposition	1
Hemobilia	2
Radiation skin burn	0.1
Hepatic infarction	0.5
Renal failure requiring dialysis	0.25
Death	1
Minor complications	4
Transient contrast induced renal failure	2
Encephalopathy controlled by medical therapy	15–25
Hepatic artery puncture causing clinically apparent injury	1
Fever	2
Entry site hematoma	2

precipitates hepatic encephalopathy, from the gastrointestinal tract. The intact liver normally clears almost all of the portal vein ammonia, converting it into glutamine and preventing entry into the systemic circulation. The increase in blood ammonia following TIPS is a consequence of blood shunting through the TIPS, bypassing the normal liver metabolism.

The technical success rate for TIPS approaches 95%. There is improved survival of patients with refractory ascites when treated with TIPS. Shunt failure in the first 30 days is almost always secondary to acute thrombosis because of improper stent placement or bile duct injury with leakage of bile and mucus into the shunt. Beyond 30 days, intimal hyperplasia can produce narrowing of the stent. Postprocedure TIPS sonography should be performed prior to discharge to serve as a baseline study for outpatient shunt follow-up.

Ultrasound surveillance is recommended and performed routinely periodically by many authors. However, given the infrequent stenosis associated with covered stents, clinical surveillance with elective ultrasound when stent malfunction is suspected could be used effectively especially with the covered stent-grafts.

Based on duplex Doppler findings, shunt stenosis should be suspected and catheterization should be recommended if any of the following direct criteria are present:

- Increase or decrease in peak flow velocity in a similar location within the stent of greater than 50 cm/set relative to the initial baseline study, or
- Absolute peak flow within the stent that is less than 60 cm/s. This has been shown to be greater than 95% sensitive and specific for significant shunt stenosis, or
- Presence of a velocity transition point within the stent through which the velocity is accelerated by a factor of two or more.

Indirect findings that may suggest shunt malfunction and the need for interventional follow-up include the following:

- Decrease in peak velocity in the main portal vein of greater than 33% from baseline
- Reversal of blood flow in the main, right, or left portal vein, or segmental portal vein branch after the initial post-TIPS baseline study
- Reversal to hepatofugal flow in a portosystemic collateral vein, such as a coronary vein or paraumbilical vein, from one study to the next
- Development of retrograde flow in the right hepatic vein, which has been described in the presence of stenosis of the right hepatic venous outflow tract (*Note:* This no longer applies for covered stents and applies only for noncovered stents in the hepatic vein segment.

Covered stents are occlusive to antegrade flow in the right hepatic vein from the time of placement.)

- Developing or worsening ascites or splenomegaly.

Venography combined with pressure measurements represents the gold standard for assessing TIPS patency. This should be performed whenever the screening ultrasound suggests a stenosis or when the patient experiences recurrent ascites or bleeding.

PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAM AND PERCUTANEOUS TRANSHEPATIC BILIARY DRAINAGE

Percutaneous transhepatic cholangiogram (PTC) is the radiographic examination of the liver and bile ducts done by inserting a thin needle through the skin into the liver and injecting contrast medium (cholangiography) in order to visualize the bile ducts. If and when obstruction is documented, percutaneous transhepatic biliary drainage (PTBD) is followed in order to drain the biliary tree and relieve obstruction. The procedure involves placement of a self-retaining tube, which remains in the liver. Bile drains through the tube into the small intestine or into a collection bag outside the body or both.

DUCTAL ANATOMY

Intrahepatic ductal anatomy is modeled after the segmental anatomy of the liver by Couinaud (Fig. 50-1). At the hilum, there are two main hepatic ducts, the right and left, which join to form the common hepatic duct. The right hepatic is formed by the right posterior duct (RPD) and the right anterior duct (RAD). The RAD drains segments 5 and 8 (the anterior segments) and the RPD drains segments 6 and 7. The RPD has a more horizontal course than the RAD, which has a more vertical course. Normally, the RPD courses behind the RAD and joins the RAD on its medial side to form the right hepatic duct. The left hepatic duct courses horizontally and drains segments 2 to 4. It joins the right hepatic duct to form the common hepatic duct and exits the liver at the biliary hilum together with the portal vein and the hepatic artery. The common hepatic duct is joined by the cystic duct to form the common bile duct. The common bile duct measures approximately 8 mm in diameter in normal individuals.

This standard anatomy is present in approximately 57% of patients. Many variations exist but these remain outside the scope of this chapter.

PATIENT PREPARATION

Patient preparation is similar for all transhepatic biliary interventional procedures. Antibiotic prophylaxis is mandatory and in our institution, ciprofloxacin is administered.

Coagulation parameters must be checked carefully and any bleeding tendency must be corrected. Intravenous fluids are started especially for patients with malignant obstruction who have not been eating or drinking well prior to arrival at the hospital. Even when they do arrive at the hospital, they are frequently fasted for a variety of tests and procedures.

TECHNIQUE

PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAM

PTC is performed predominantly from the right side of the patient. The patient is placed supine on the fluoroscopy table. The right flank and right hypochondrium is sterilely prepared. Usually a combination of midazolam and fentanyl is used for conscious sedation.

Under direct fluoroscopy, the patient is asked to inhale deeply and the inferior most point of lung descent is marked. This is to avoid transgressing the pleura.

A suitable location is marked along the mid-axillary line and a 15 cm 22 G Chiba needle is passed from the right flank parallel to the rib toward the vertebral bodies. This should be performed in one smooth motion. The inner stylet is then withdrawn and a syringe containing full strength contrast material is then attached to the needle hub via an extension tubing. The needle is then slowly withdrawn and small aliquots of contrast are injected every 1 to 2 mm until a bile duct is entered.

If a bile duct is not entered on the first pass, successive passes are made in a fan shape down through the liver toward the biliary hilum. It would be prudent not to withdraw the needle fully outside the liver capsule, so that only one hole in the liver capsule is made. This helps to reduce bleeding complications.

When a duct is entered, contrast is injected to outline the biliary system. If stone disease is suspected contrast is diluted down to approximately 200 to 250 mg/mL iodine concentration to avoid obscuring filling defects. Radiographs are obtained in multiple projections in order to delineate ductal anatomy and identify the level of obstruction as well as localize the presence of any filling defects, which may represent stones, debris, or tumor material. Care should be taken not to forcefully inject the biliary system since this can result in an increase in back pressure and reflux into blood circulation causing biliary sepsis.

Success rates for PTC lie between 97% and 100% in experienced hands. As many as 15 to 20 passes can be safely made, but after this, if a bile duct has not been entered, then the procedure is best terminated.

Complications are minimal and occur in some 1% to 2% of patients. These include hemorrhage, sepsis, and bile leak leading to biliary peritonitis.

PERCUTANEOUS TRANSHEPATIC BILIARY DRAINAGE

Percutaneous biliary drainage is usually performed to relieve biliary obstruction. The majority of distal CBD obstructions are diagnosed and successfully studied and stented endoscopically. The role of PTC and PTBD is currently indicated for cases where ERCP and endoscopy has technically failed and/or not possible owing to prior surgical operation (Roux-en-Y).

It is prudent to obtain preprocedure imaging prior to undertaking this procedure. An ultrasound study, CT study, or MRCP may be performed in order to diagnose and ascertain the level of obstruction, to detect the presence of malignant disease, confirm intrahepatic ductal dilatation, and to rule out the presence of ascites.

A right-sided approach is most commonly used. A right-sided PTC is performed as described. When a bile duct is entered, contrast material is injected to opacify the biliary system. If a favorable duct is entered by the initial needle puncture, a 0.018-in guidewire is placed through the needle and manipulated toward the hepatic hilum. If the initial entry was unfavorable, then a second needle would be used to puncture an opacified duct with a more favorable orientation. Once the 0.018-in guidewire has gained reasonable purchase within the duct, a coaxial set (Neff set, Cook, Bloomington, IN) consisting of a 22-gauge metallic cannula inside a tapered 4F dilator inside a 7F dilator is advanced over the wire into the biliary duct. Once good purchase is obtained, the 0.018-in guidewire and inner cannula are removed and a 0.035-in hydrophilic guidewire passed through the outer dilator (which acts as a sheath) into the biliary tree. A 4F catheter is inserted through the sheath and the guidewire is then manipulated across the biliary stricture into the duodenum, followed by the catheter.

Once both catheter are wired safely in the small bowel, the hydrophilic guidewire may be exchanged for a stiff Amplatz wire. The percutaneous track can then be serially dilated to accommodate a biliary catheter with multiple side holes positioned above and below the level of obstruction. All effort should be made to cross the obstruction initially to allow locking the pigtail loop of the catheter in the bowel to avoid dislodgement, which commonly occurs if the catheter is left in

the bile ducts above the obstruction for external drainage. An internal–external biliary catheter is also preferred since drainage can occur both percutaneously into an external bag and internally into the small bowel.

A left-sided approach is technically a little more challenging and is usually done if there is a hilar stricture, which does not allow the left and right ducts to communicate. In general, a segment 3 duct is chosen because it courses inferiorly toward the margin of the left lobe. Again a 22G Chiba needle is used and contrast material used to outline the biliary system. A 0.018-in guidewire is manipulated toward the biliary hilum followed by the Neff set. A hydrophilic wire and catheter are again used to cross the stricture and placed in the small bowel. Once in place a left-sided catheter is actually better tolerated by the patient since it does not go between the ribs and is less likely to dislodge.

PERCUTANEOUS CHOLECYSTOSTOMY

Percutaneous cholecystostomy is a valuable technique for the management of patients with cholecystitis who are critically ill or unfit for surgery. This procedure is a temporizing measure, which buys the patient some time so that definitive surgery can be carried out when the patient has recovered from an acute illness.

Preprocedure workup includes a detailed history and physical examination, baseline studies of serum bilirubin, amylase, lipase, and alkaline phosphatase. A CBC and coagulation profile should also be obtained.

Because bile in disease gallbladders is commonly infected, a broad-spectrum antibiotic such as ciprofloxacin is commonly administered. Ideally, this should be administered 1 to 4 hours prior to the interventional procedure and continued for several days in the presence of cholecystitis or cholangitis.

Percutaneous cholecystostomy can often be performed under conscious sedation. In general, two approaches may be employed—the transperitoneal and transhepatic access routes. Many operators prefer the transperitoneal approach since it is more direct and avoids the necessity of going through the liver. One of the main drawbacks to this approach is that the catheters and wires often buckle outside of the gallbladder because of gallbladder mobility. This could lead to loss of access and bile leak into the peritoneal cavity.

A transhepatic approach can be used to avoid this problem since the entry of the catheter is closer to the attachment of the gallbladder to the liver where the gallbladder is relatively fixed in position.

Using a needle, the gallbladder is punctured under ultrasound guidance. The gallbladder is then opacified

with contrast to confirm position. A guidewire is then inserted through the needle under fluoroscopic guidance. The tract is subsequently dilated and an 8F to 10F self-retaining pigtail catheter is then positioned within the gallbladder lumen. It should be remembered that a mature cholecystostomy tract takes 4 to 6 weeks to develop in debilitated patients and 2 to 3 months in patients who are immunocompromised.

Technical success rates are in excess of 95%. Bile leakage is a feared complication, and cases of massive biliary ascites and chemical peritonitis have been reported. Other complications include intraperitoneal hemorrhage, gallbladder perforation, sepsis, hemobilia, and pneumothorax. The rate of major complication is approximately 6% to 8% while the mortality rate from this procedure is less than 2%.

QUESTIONS AND ANSWERS

- Which of the following is the normal portal venous pressure?
 - 0 to 5 mm Hg
 - 5 to 10 mm Hg
 - 10 to 20 mm Hg
 - None of the above

ANSWER: B. 5 to 10 mm Hg is the normal portal venous pressure. Any value above 12 mm Hg is considered to be portal hypertension. This reflects the noncorrected, absolute pressure. When systemic venous pressures are elevated a corrected sinusoidal pressure or a gradient of PV–IVC is more accurate and 5 mm Hg is the upper limit of normal for gradient.

- All the following represent causes for intrahepatic presinusoidal portal hypertension *except*:
 - Chronic hepatitis
 - Myelofibrosis

- C. Felty syndrome
- D. Budd-Chiari syndrome

ANSWER: D. Budd Chiari is a cause of intrahepatic postsinusoidal portal hypertension. All the others are causes of intrahepatic presinusoidal portal hypertension. Felty syndrome is a complication of rheumatoid arthritis. It is the triad of seropositive (rheumatoid factor positive) rheumatoid arthritis, neutropenia, and splenomegaly.

3. Which of the following is the first diagnostic study of choice for evaluating upper GI bleeding for varices?
- A. Esophagoduodenoscopy (EGD)
 - B. Esophagography
 - C. Diagnostic portal venography
 - D. Nuclear medicine tagged red blood cell scan

ANSWER: A. EGD is the first-line study for evaluation of upper GI bleeding, regardless of etiology. It is both diagnostic and potentially therapeutic.

4. Which of the following is the approximate risk of encephalopathy after TIPS?
- A. 5% to 10%
 - B. 10% to 20%
 - C. 20% to 30%
 - D. >50%

ANSWER: C. The rate of encephalopathy after TIPS is 23% to 29%. Most cases respond to medical therapy. However, 3% to 5% of patients undergoing TIPS have encephalopathy that is refractory to medical treatment.

5. Which of the following Doppler findings suggest TIPS stenosis?
- A. Change in velocity of greater than 20 cm/s in a similar location within the stent compared to baseline
 - B. Maximum velocity within the stent of less than 60 cm/s
 - C. No flow in the TIPS shunt
 - D. All the above

ANSWER: B. A change in velocity of greater than 50 cm/s in a similar location within the stent compared to baseline, and retrograde flow in the right hepatic vein are suggestive of TIPS stenosis. No flow in the TIPS shunt suggests TIPS occlusion.

6. The following are *all* indications for a percutaneous transhepatic biliary drainage *except*:
- A. Relief of biliary obstruction
 - B. Diversion of biliary flow in cases of bile leak

- C. Provide access for biliary intervention
- D. Sphincterotomy

ANSWER: D. PTBD is performed for the relief of biliary obstruction, diversion of biliary flow in cases of bile leak as well as to provide access for biliary manipulation such as brush biopsy. Sphincterotomy is usually performed during an ERCP.

7. Factors that predispose a patient to cholangiocarcinoma include *all* the following *except*:
- A. Inflammatory bowel disease
 - B. Sclerosing cholangitis
 - C. Clonorchis sinensis infection
 - D. Rheumatoid arthritis

ANSWER: D. Inflammatory bowel disease, sclerosing cholangitis, Caroli disease, and clonorchis sinensis infection are the top four factors that predispose an individual to cholangiocarcinoma. Rheumatoid arthritis is not known to be associated with cholangiocarcinoma.

8. What is the incidence of pancreatitis following a PTC procedure?
- A. 1%
 - B. 5%
 - C. 10%
 - D. 15%

ANSWER: A. The incidence of pancreatitis following a PTC procedure is approximately <1%. Other complications include death (<1%), bleeding (<3%), sepsis (<3%), and peritonitis (<2%). Overall major complication rate is approximately ≤8%.

9. Hepatic lobar atrophy caused by cholangiocarcinomas is caused *primarily* by compression of which of the following structures?
- A. Hepatic arteries
 - B. Portal veins
 - C. Biliary ducts
 - D. Hepatic veins

ANSWER: C. The primary cause of parenchymal atrophy is the obstruction of biliary ducts. Cholangiocarcinomas are known to cause segmental atrophy of the liver parenchyma, including, in some cases, entire lobar (left or right) atrophy.

10. *All* the following are indications for a dedicated left hepatic PTC approach *except*:
- A. Extensive neoplastic involvement of the right hepatic lobe by primary or secondary tumor
 - B. Diversion of bile flow in cases of bile leak from the common duct

- C. As part of a combined drainage procedure of both the right and left lobes in cases of hilar obstruction
- D. Obstruction of the main left hepatic duct with no communication between the left- and right-sided ducts

ANSWER: B. All the rest are indications for a left hepatic PTC approach in order to adequately decompress the biliary system. PTC for diversion of CBD leak can be performed from either right or left approach.

85 GASTROINTESTINAL AND BILIARY DISEASE AND INTERVENTION

Kay M. Hamrick and Emily R. Norman

GASTROINTESTINAL BLEEDING

Gastrointestinal (GI) bleeding is the most frequent indication for the angiography of mesenteric vessels. GI bleeding results in approximately 300,000 hospital admissions each year. In approximately 75% of cases of upper GI bleeding and 80% of cases of lower GI bleeding, bleeding will spontaneously cease. However, when bleeding persists or is recurrent, angiography plays an important role in both evaluation and treatment.

The first step in the treatment of GI bleeding is accurate characterization as acute or chronic. This can be usually determined through a detailed history or review of the patient's clinical symptoms and laboratory findings. Tachycardia and hypotension occur when acute blood loss exceeds 500 mL, and hypovolemic shock occurs with a blood loss of 15% or more of the circulating blood volume. The effects of acute blood loss can manifest as failure of multiple systems including cardiac, renal, neurologic, and pulmonary systems, especially in patients in whom bleeding does not cease spontaneously. Most deaths attributable to GI bleeding occur in elderly patients and patients with multiple comorbid conditions exacerbated by blood loss. Probably the most important benefit of arteriography is that it allows minimally invasive intervention such as embolization.

It is important to differentiate between upper and lower sources of blood loss prior to intervention when possible. Nearly 90% of acute GI bleedings occurs in the upper GI tract, which is defined as proximal to the ligament of Treitz (esophagus, stomach, and duode-

num). It is usually suspected in the setting of positive gastric aspirate and melanic stool, though hematochezia can be seen as well. Upper GI bleeding leads to hospitalization in approximately 0.1% of patients each year and carries a mortality rate of approximately 10%. Lower GI bleedings occur distal to the ligament of Treitz (small bowel, colon, and rectum). Lower GI bleeding is less common than upper GI bleeding—approximately 30% of all GI bleeding cases and up to 0.02% of hospital admissions each year. It carries a mortality rate of 3.6%.

Scintigraphy is also used to detect GI bleeding. This method is more sensitive than arteriography and can detect active bleeding at rates as low as 0.05 to 0.1 mL/min. Drawbacks to this technique include poor spatial resolution of scintigraphic images and occasional false-positive results. False-positive results can be minimized using the in vitro technique for erythrocyte labeling.

To diagnose ongoing hemorrhage with arteriography, bleeding must occur at a rate of at least 0.5 to 1.0 mL/min. Angiography has a sensitivity of 63% to 90% and 40% to 86% for upper and lower gastrointestinal bleeding, respectively, with a specificity of up to 100% for both. In case the initial arteriogram is non-diagnostic, a second arteriogram is warranted if bleeding recurs. Extravasation of the contrast material into the bowel lumen is pathognomonic for active gastrointestinal hemorrhage. A “pseudovein” occurs when contrast collects in the dependent portion of the bowel lumen between linear mucosal folds. Extravasation can also be seen as an amorphous contrast collection that persists through the venous phase.

TECHNIQUES

Treatment of GI bleeding, particularly lower GI bleeding, is more frequently using superselective embolization with microcoils or particles.

Particulate embolic agents used in the setting of acute hemorrhage include polyvinyl alcohol (PVA) and absorbable gelatin sponge (Gelfoam). Trisacryl microspheres (Embospheres) are now available in multiple sizes for use in different vascular territories. These must be combined with an iodine-contrast agent for fluoroscopic visualization and then injected through a catheter or more commonly a microcatheter. PVA is available in particle sizes ranging from 100 to 1200 μm . An appropriate range of particle size must be chosen based on the size of the vessels to be occluded. Smaller particles will reach more distal vessels, and it is important to note that this increases the likelihood of necrosis. Generally, particles smaller than 300 μm are not used. Care should be

taken not to reflux the particle–contrast mixture beyond the intended area of embolization. PVA and Embosphere particles are permanent occlusive agents, as are coils, PVA, and collagen spheres.

For more temporary occlusion, Gelfoam can be used, although it can incite an inflammatory response and eventually achieve permanent thrombosis. Once injected, Gelfoam acts as both a mechanical occlusive agent and a thrombogenic agent, occluding the vessel. Gelfoam is available as a sponge, which can either be cut into small pieces called pledgets or from which a slurry can be made.

UPPER GASTROINTESTINAL BLEEDING

The most common cause of nonvariceal upper GI bleeding is ulcer disease. Other causes of upper GI hemorrhage include hemorrhagic gastritis, Mallory-Weiss tear, vascular lesions, neoplasms, and variceal bleeding. Variceal bleeding is discussed in Chapter 84. The number of cases of upper GI bleeding increases with patient's age. In a study performed in the United States, approximately 44.5% of all patients with upper GI bleeding were aged 60 years or older. Morbidity and mortality rates also increased with age; 73.2% of deaths occurred in patients older than 60 years. First-line therapy for upper GI bleeding usually consists of endoscopy with intervention when a bleeding is directly visualized. Transendoscopic treatments of acute bleedings include thermal coagulation, banding, or injection of vasopressin at the bleeding site. Vasopressin injection controls blood loss in approximately 70% of patients. Endoscopy is especially helpful given that gastritis is a condition that is notoriously difficult to evaluate and treat with arteriography given its diffuse nature. However, the more focal lesions of the upper GI tract, such as chronic gastric ulcers, stress-induced gastric ulcers, and Mallory-Weiss tears, are better treated by arterial embolization.

GASTRIC ULCER DISEASE

As previously stated, ulcers are the most common source for upper GI bleedings. Embolization is the preferred method of treatment for hemorrhage from the pyloroduodenal region. Vasopressin can be problematic as its effects are often dampened by the inflammatory changes associated with some duodenal ulcers, which renders nearby vessels. The rich collateral network supplying the duodenum from the celiac and superior mesenteric arteries reduces the risk of infarction following embolization. Some controversy exists as to the best method for upper GI embolization, but Gelfoam is the generally preferred embolic material in most patients

with gastrointestinal hemorrhage. It is associated with a low risk of infarction and does not present the many complications seen with the use of vasopressin. Combinations of different embolic agents may be more effective than embolization with a single agent, and combining Gelfoam with microcoils is often successful and permanent.

HEMORRHAGIC GASTRITIS

Infusion of vasopressin directly into the left gastric artery is effective in 82% of patients with diffuse hemorrhagic gastritis. Vasopressin acts to constrict vascular smooth muscle, particularly at the arteriolar and capillary levels. Vasopressin infusion is begun at a rate of 0.2 U/min for 20 minutes. If bleeding persists, the rate can be increased to 0.4 U/min for another 20 minutes. If this fails, vasopressin infusion is stopped. If, however, the bleeding stops after the 20-minute infusions, vasopressin is continued at the effective rate for 24 hours and then slowly tapered to avoid rebound hyperemia.

Although often successful, this method of treatment may cause serious complications in 8% to 43% of patients. Vasopressin-induced constriction of branches of the inferior phrenic artery can cause ventricular arrhythmias. The antidiuretic effect of vasopressin also limits its use in patients with congestive heart failure, and urine output should be monitored in patients receiving 24 hour drips. More importantly, prior gastrointestinal embolization is a contraindication to the use of vasopressin because of a heightened risk of bowel infarction due to the previous occlusion of some of the arteries that normally serve the area of hemorrhage.

MALLORY-WEISS TEAR

Mallory-Weiss tears are most often seen in the clinical setting of binge drinking followed by repeated vomiting; however, any condition that leads to a sudden rise in gastric pressure may be a cause. Hiatal hernia is a predisposing factor and is seen in as many as 30% to 100% of patients with tears. Bleeding is due to longitudinal lacerations (intramural dissections) at the gastroesophageal junction or cardia. In the majority of cases of (80%–90%), bleeding spontaneously stops and emergency intervention is not needed. When intervention is required, it is usually performed endoscopically. However, when endoscopic treatments fail, vasopressin injection or embolization following subselection of the left gastric artery are valid options, with vasopressin injected more frequently.

NEOPLASM

Carcinoid is a neoplasm of the small bowel, which can occasionally result in upper GI hemorrhage. Patients are most likely to present with chronic, unexplained GI

hemorrhage. Carcinoid syndrome (flushing of the head and neck, asthma-like attacks, and diarrhea) occurs in less than 10% of those patients in whom the disease has spread to the liver. Carcinoid tumors are usually ileal in location and may be seen via barium contrast fluoroscopy, enteroclysis, or CT. The arteriographic features of small bowel carcinoid tumor can also be characteristic. Mesenteric nodal metastasis from primary bowel tumor creates a mesenteric desmoplastic process, which can result in kinking, straightening, and retraction of the mesenteric arteries. Classically, the arteries in the affected mesentery radiate outward from a central nidus of tumor in a stellate or “sunburst” pattern.

LOWER GASTROINTESTINAL BLEEDING

The most common cause of lower GI hemorrhage is diverticulosis (20%–55%). Other causes include angiodysplasia (3%–40%), neoplasms (8%–26%), colitis (6%–22%), and benign anorectal lesions (9%–10%). Lower GI bleeding is much more commonly seen in the elderly patient population.

For evaluating lower GI bleedings, colonoscopy is often the first step. However, if the bleeding is severe, colonoscopic identification of the source of the blood loss may be impossible because of the large amount of blood in the colon. Colonoscopy is most effective in patients with intermittent hematochezia who are clinically stable. Arteriography of lower GI bleedings has been found to identify the source in 40% to 50% of patients when performed while there are clinical signs of active bleeding.

DIVERTICULOSIS

Diverticulosis is a common acquired condition in Western societies. The disease is caused by lack of fiber in the diet. It occurs in approximately 50% of adults older than 60 years. Diverticula are most commonly located in the sigmoid and descending colon, though the source of diverticular bleeding is more often found to be the right colon near the splenic flexure. Diverticular bleeding originates from vasa rectae located in submucosa, which can rupture at the dome or the neck of the diverticulum. Up to 20% of patients with diverticular disease experience bleeding, and the bleeding stops spontaneously approximately 80% of the time. When bleeding does not stop spontaneously, the initial treatment is vasopressin injection using the same technique as described for hemorrhagic gastritis. However, vasopressin injection is associated with all of the aforementioned complications and is also associated with a high rate of rebleeding. Therefore it is used

primarily for temporary stabilization prior to a more definitive treatment.

In rare cases, diverticulosis can cause massive lower GI bleeding, which is defined as the requirement of greater than six units of packed red blood cells replaced in 24 hours. Massive bleedings have an overall incidence of approximately 20.4 per 100 000 patients, with an overall mortality rate of 10%. Once the source of bleeding has been located, the standard of therapy has been surgical intervention with possible bowel resection. Increasingly, however, super-selective embolization of the mesenteric vessels is an alternative treatment. Because of the lack of collateral vessels in the distal bowel, there is an increased risk for ischemia following embolization. Therefore, to prevent this complication, embolization should be performed beyond the marginal artery as close as possible to the bleeding point in the terminal mural arteries.

ANGIODYSPLASIA

Angiodysplasia is the most common vascular abnormality of the GI tract. It is second after diverticulosis as a source of lower GI hemorrhage. The prevalence of angiodysplasia is 0.8% in healthy patients older than 50 years who are undergoing screening colonoscopy. Angiodysplasia is a degenerative lesion composed of a small tangle of abnormally communicating arteries and veins in the mucosa and submucosa of the bowel. Seventy-seven percent of angiodysplasias are located in the cecum and ascending colon, 15% are located in the jejunum and ileum, and the remainder are distributed throughout the alimentary tract. These lesions typically are nonpalpable, small (less than 5 mm), and are typically located on the antimesenteric border of the bowel.

Patients with bleeding angiodysplasias usually present with maroon-colored stool, melena, or hematochezia. Bleeding is usually low grade but can be massive in approximately 15% of patients. Chronic iron deficiency anemia and stools that are intermittently positive for occult blood may occasionally be the only manifestations of angiodysplasia. Bleeding stops spontaneously in more than 90% of cases but is often recurrent.

Arteriography does not usually demonstrate active bleeding. However, the arteriographic appearance of angiodysplasia is pathognomonic, and arteriography is often performed while the patient is asymptomatic. A small tangle of tortuous vessels is visualized during the late arterial and capillary phases. The most diagnostic feature on angiography is the appearance in the arterial phase of a densely opacified vein draining the lesion, appropriately called the “early draining vein.” Arteriographic injections to evaluate for angiodysplasia

should not last longer than 4 seconds in order to minimize the overlap between arterial and venous opacification. Angiodysplasias are usually treated by various endoscopic methods including electrocautery and sclerotherapy, and more severe cases are treated with surgical resection of the affected bowel. Selective mesenteric artery embolization is rarely performed as it has a high complication rate. Therefore, the role of angiography in treatment of angiodysplasias is usually in preoperative localization of small bowel lesions before surgical resection.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease is another fairly common cause of lower GI bleeding and subsequent anemia. Diagnosis is often made via endoscopy or barium contrast studies, but when bleeding occurs before diagnosis has been made, arteriography can play an important role. Most commonly, angiography demonstrates increased contrast staining and early venous return when compared with adjacent bowel loops. This often is accompanied by an increase in caliber of the supplying arteries, and bowel may be affected in the typical “skip pattern.” The two angiographic signs considered to be diagnostic of Crohn disease include the presence of mesenteric neovascularity and the “zoning” sign. The “zoning” sign refers to a double-layer appearance of the bowel wall with a densely staining inner wall representing a hypervascular submucosa and mucosa and a thickened but relatively avascular outer muscle layer. No single finding is thought to be diagnostic of ulcerative colitis. Acute bleedings can be treated by superselection and either vasopressin infusion or coiling.

GASTROSTOMY AND GASTROJEJUNOSTOMY TUBES

Gastrostomy and gastrojejunostomy (G-J) tubes are indicated in patients requiring long-term nutritional support. Gastrostomy tubes have been placed by surgeons since the late 1800s. It was not until 1983 that the technique of percutaneous gastrostomy was described in the radiologic literature. Since that time, numerous papers have described the methods of ultrasonographic and fluoroscopic placement of various types of percutaneous gastrostomy tubes.

Clinical presentations and goals of treatment define the kind of tube that should be placed as well as whether a gastrostomy or gastrojejunostomy should be placed. Patients usually present with inability to swallow, dysfunctional swallowing, or obstruction and are neurologically impaired because of cerebral vascular accident, degenerative CNS disease, or chronic neuro-

logic disorders such as cerebral palsy. Other conditions include head and neck tumors, esophageal carcinoma, and chronic esophageal strictures. Gastric outlet obstruction from tumors necessitate placement of the tube via the stomach into the jejunum. Diabetic patients with gastroparesis also require gastrojejunostomy tubes.

Prior to performing the procedure the patient must be evaluated and any prior imaging must be reviewed. There are few absolute or relative contraindications to gastrostomy and gastrojejunostomy (Table 85-1).

Some patients have a large left lobe of the liver that crosses the midline and may require ultrasonographic marking prior to performing the procedure. As with all procedures, informed consent must be appropriately maintained. A nasogastric tube is placed. Some patients may have difficult nasogastric intubation because of obstructing lesions or severe neurologic dysfunction. A small arterial catheter such as a 5F Berenstein placed with the aid of a hydrophilic wire may be used to intubate the stomach in these patients. Some authors advocate the placement of oral barium contrast agent on the evening prior to the procedure to better image the colon. Intravenous access is necessary so that sedation and analgesia may be performed.

The patient should be fasting for at least 8 hours prior to the procedure. While the patient is in the supine position, the relationship of the stomach to the liver, spleen, large and small bowel must be determined. This is usually possible with the aid of fluoroscopy, and rarely ultrasound is required to mark the left lobe of the liver. Care must be taken to avoid the superior epigastric artery, which runs in the mid portion of the abdominal rectus muscle. Distention of the stomach with air via the nasogastric tube serves to outline the stomach and push the anterior wall to the abdominal wall allowing ready access for percutaneous puncture with a 5F trocar needle. Approximately 600 to 1000 mL of air is instilled in order to decrease the compliance of the stomach wall and to bring it closer to the abdominal wall. The patient is instructed to try to hold the air in the stomach; however, some are unable to cooperate because of comorbid conditions. A dose of 1 mg of glucagon may be given to

TABLE 85-1 Contraindications to Gastrostomy or Gastrojejunostomy Tubes

	Uncorrectable coagulopathy
Relative	Overlying viscera
	Ascites
	Ventriculoperitoneal shunt

decrease the peristalsis of the stomach thereby aiding in gastric distention. This must be given immediately before the procedure because of the short half-life of glucagon: 3 to 5 minutes. Intra-gastric location of the sheathed needle is confirmed with the placement of water-soluble contrast material. Care must be taken to avoid aspiration since the risk is increased with the nasogastric tube and gastric distension. A stiff guidewire is placed with subsequent dilation of the tract with Teflon dilators so that the desired gastrostomy catheter may be placed. The catheter is secured in place and placed to gravity drainage for 24 hours. Feeds may be ordered at one-half strength after the initial 24 hours to be advanced as tolerated after 12 hours.

There has been controversy in the literature regarding the placement of T-fasteners. It is generally accepted that they may be helpful but are not necessary when placement of a gastrostomy is desired. The incidence of complications in percutaneous gastrostomy placement may be increased if with no T-fasteners are used. However, there may be increased pain and skin breakdown associated with the use of T-fasteners. T-tube fasteners must also be used when patients are on steroids in that there is delayed formation of a fibrous tract. Because of the lack of a mature fibrous tract, they are indicated when placement of a jejunal tube via the stomach is desired. Gastrojejunostomy tubes are generally more difficult to place and require increase radiation exposure relative to simple gastrostomy procedures. There may be difficulty crossing the pylorus. These tubes are longer in length and smaller in diameter in the jejunal lumen and therefore more prone to blockage. It is important to determine if gastric decompression is desired so that a double lumen G-J may be placed rather than a single lumen.

Complications include peritonitis, aspiration pneumonia, bleeding, infection, and injury to the liver and spleen. Rarely vasovagal reaction and hypotension may be seen. Complication rates of percutaneous gastrostomy placement of 5.9% have been reported by Wollman et al.—lower than the rates reported by gastroenterologists and surgeons. The use of prophylactic antibiotics is controversial. The incidence of infection is greater for those placed by gastroenterologists, and antibiotics are warranted in these cases. As tubes may occlude, patient and caretaker education is very important. Once occluded, things such as meat tenderizer, cola, and guidewires may be used to re-establish patency. Tube replacement is often necessary.

The technique of direct percutaneous jejunostomy has been described and is indicated in rare cases. These include previous gastric surgery or resection, abnormal stomach position, and duodenal or gastric outlet obstruction. Various techniques have been described.

These include using previously placed tube as has a fluoroscopic target. This can be placed transnasally or via a percutaneous gastrojejunostomy. In either situation, distension of the jejunum with air and the use of T-fasteners is necessary. CT fluoroscopy has also been described as a method of localization. Results compare favorably with those placed via laparoscopy and surgery.

Cecal perforation carries a high mortality. The risk of perforation increases when the diameter is greater than 12 cm. Percutaneous cecostomy is an alternative to traditional surgical techniques for cecal decompression. T-fasteners are used and the technique is similar to that of percutaneous gastrostomy.

Enteric catheters placed radiographically offer the advantage of less sedation and analgesia requirement. Many of these tubes can be placed with local anesthesia only. This is helpful in patients with cardiac and respiratory dysfunction. Costs are also less than those generated in the endoscopy and surgical suites.

PERCUTANEOUS BILIARY INTERVENTION

Percutaneous biliary interventions include percutaneous transhepatic cholangiogram (PTC) with or without external or external-internal drainage, and placement of expandable metallic stents for internal drainage in patients with unresectable malignant disease. PTC has a diagnostic role in patients with failed endoscopic retrograde cholangio-pancreatography (ERCP) or anatomy unfavorable to performing ERCP. Percutaneous cholecystostomy tubes are placed in patients who are not surgical candidates with calculous and acalculous cholecystitis. Retained stones may also be removed percutaneously with or without the aid of lithotripsy; however, T-tube tracts must mature for at least 6 weeks before doing surgery.

PTC has been used for diagnosis and definition of biliary anatomy in patients with biliary obstruction. Presently, definition of anatomy is readily achieved with ultrasound, CT, and MRI. Diagnosis is also made possible with endoscopic techniques. Plastic internal stents can be placed and biopsies performed for tissue diagnosis. In cases of failed ERCP, percutaneous techniques are useful in providing drainage in patients with symptomatic jaundice; patients with prior surgery including biliary enteric anastomosis are not candidates for ERCP.

Prior to performing percutaneous cholangiogram, the patient's history and pertinent laboratory results must be reviewed and informed consent must be obtained. Risks including infection, bleeding, bile leak with possible biliary peritonitis, and pneumothorax must be discussed.

There is a 5% to 10% risk of significant complications associated with this procedure with mortality rate as high as 1% to 2.5%. The patient should be fasting for at least 8 hours prior to the procedure. Intravenous access should be in place for administration of sedation and analgesia. Antibiotics should be given at least 1 hour prior to the procedure, and should be broad-spectrum and provide for gram-negative as well as anaerobic coverage. The risk of infected bile increases in patients with prior surgery. The bile is infected in approximately one-third of patients with malignant disease and two-thirds of patients with benign stricture or stone disease. Once a biliary tube is in place, the bile becomes colonized, thereby making sepsis a possible complication even with simple tube exchanges.

Contraindications for percutaneous biliary intervention include uncorrectable coagulopathy, known vascular tumors, and cystic liver disease. Cirrhosis, ascites, and multiple liver metastases are relative contraindications. Patients should be able to cooperate during the procedure by performing breath holds during passage of the needle.

There is no difference in complication rate regarding a left- or right-side approach. The right approach is from the right midaxillary line. The left is a subxiphoid approach. The most commonly used system is the Neff set (Cook, Bloomington, IN). This consists of a 22-gauge needle, a 5F sheath system and a 0.018-in guidewire. Once the 5F sheath has been placed in the biliary system, a 4F angled catheter such as a Kumpe may be used with a 0.035 in angled guidewire to negotiate the catheter into the duodenum. It is important to fill the biliary tree prior to passage of the level of obstruction as much as possible to avoid pitfalls in diagnosis. Common pitfalls include air bubbles, lack of filling of the left side, (more anteriorly/nonclept located), and false level of obstruction. If the contrast material is too dense, a stone or filling defect may be obscured.

Knowledge of intrahepatic ductal anatomy is necessary when performing percutaneous cholangiogram. Normally the right posterior duct and right anterior duct join together to form the right hepatic duct, which joins the left hepatic duct at the hilum. This is present in 57% of cases. The right posterior duct is more horizontally oriented compared to the right anterior duct. Variations occur with the drainage of the right posterior duct and right anterior duct. Most commonly the right posterior duct may drain into the left hepatic duct, in approximately 21% of cases. The right posterior duct may also drain directly into the main hepatic duct. Rarely the right anterior duct may drain into the left. There may be a confluence of the right anterior duct, right posterior duct, and left duct at the hilum.

Abnormalities seen on cholangiograms may be due to benign disease such as stones or stricture secondary to inflammation. Stones are seen as persistent filling defects. They must be differentiated from blood clots, biliary debris, and polypoid tumors. Patients with sclerosing cholangitis may have extrahepatic or intrahepatic involvement. Most commonly it is diffuse. Appearance may include “beading” or a “shaggy” appearance of the ducts. Primary cholangitis is associated with inflammatory bowel disease, retroperitoneal fibrosis, and cholangiocarcinoma. There is a 70% predominance in the male population. These patients present with chronic or intermittent obstructive jaundice, abdominal pain, and may have fever. Dilatation will usually be present in patients with cholangiocarcinoma. However, because of the different presentations any patient with rapid decline should be considered to have cholangiocarcinoma. Since biopsy is difficult, this diagnosis often remains elusive. Secondary cholangitis may be due to chronic bacterial infection, AIDS cholangitis, and bile duct ischemia. The organisms associated with biliary infection in patients with AIDS are cytomegalovirus and *Cryptosporidium* species.

Tumors affecting the biliary tree produce obstruction by ductal compression either by hilar nodes or hepatic metastases. Evaluation of the distal duct at the ampulla can often be difficult, since inflammatory change and tumor can often have a similar appearance. Biopsy is helpful for further evaluation.

The presence of self-expanding metallic stents has been instrumental in decreasing length of hospital stay. Many institutions place these at the same setting as the initial PTC in patients with known unresectable malignant disease. The currently available 7F delivery systems require no significant additional tract dilatation. Patients with hilar obstruction may be treated with dual stents, one from the right and one from the left. These should be placed simultaneously to avoid the inability to place the contralateral stent. If a safety stent is not left in place, the stent should be balloon dilated. In cases where clot is left in the system, a safety stent should be left in place until bleeding clears.

When long-term internal-external drainage is desired, it is important to secure the tube to minimize movement. Movement occurs with respiratory motion; however, securing the tube decreases the likelihood that a side hole will slip and communicate with a vascular structure or cause a bile leak. Side holes must be proximal to the level of obstruction to allow adequate drainage. If the tube is securely attached at the skin a loop may form between the skin and the liver with respiratory movement. It is advisable to leave a 2 cm distance when suturing the catheter to the skin to avoid this problem.

Tubes must be followed by the interventional team. It is important to perform daily rounds on these patients while in the hospital. Care includes flushing the catheter with 5 mL of sterile saline every shift for the first 48 hours. Antibiotics in coordination with the referring service must be continued for at least 2 to 3 days. If these tubes are to be left in long-term, it is important to educate caretakers with instructions to flush the tube daily and to attach a bag if fever develops. The catheter should be capped prior to patient discharge to ensure this will be tolerated. Catheters must be replaced every 2 to 3 months, sooner if problems develop. Initially an 8F biliary catheter is placed. Once the tract is dilated from respiratory movement, it is best to exchange for a 10 or 12F tube.

Other uses for internal–external biliary drainage catheters include conduits for brachytherapy and a guide for the biliary surgeon when there is a high hilar obstruction. Surgical morbidity and mortality are also decreased with decreasing the bilirubin prior to surgery. PTC also has a role in cases with biliary leak postlaparoscopic cholecystectomy. PTC can define the level of the leak and is often necessary to divert draining bile until the leak has healed. Patients who have had biliary enteric surgery may develop benign strictures. PTC with balloon dilation is often helpful in resolving these strictures. However, these patients must be stented for approximately 6 to 12 months in order for the stricture to resolve.

GALLBLADDER INTERVENTION

Beginning in the 1980s, gallbladder intervention and percutaneous biliary stone retrieval became accepted medical practice. Diagnostic aspiration of the gallbladder in cases of infection has been performed in the past but has been largely abandoned because of the lack of sensitivity. Gallbladder biopsy in cases with gallbladder mass or metastatic disease have been successful in more than 90% of cases. This is performed with a 20- or 22-gauge needle. Currently the most useful gallbladder intervention is that of drainage in patients with cholecystitis.

Patients may present with either calculous or acalculous cholecystitis. Many of these patients have comorbidities, which preclude emergent surgery. In most instances of acalculous cholecystitis drainage with the appropriate antibiotics is satisfactory treatment. Placement of a drainage catheter in patients with calculous cholecystitis may serve as a temporizing measure to surgery. However, once the tract has matured, generally about 6 weeks, stones can be removed percutaneously.

There is controversy concerning the approach for the placement of cholecystostomy tubes. Some prefer to go directly into the gallbladder through the peritoneal cavity while others advocate traversing the liver bare area, where the gallbladder abuts the liver. Both approaches require the use of ultrasound. If the Seldinger technique is used, fluoroscopic guidance is also necessary for wire placements and subsequent dilatations. A Neff system can be used. If the procedure is done at the bedside in the intensive care unit because a patient is too unstable to be transferred, the trocar method may be advantageous. Advantages of going through the bare area of the liver include decreased mobility of the gallbladder and decreased incidence of bile leak into the peritoneal cavity. Disadvantages include an increased risk of bleeding if dilatation is necessary for stone removal. The main advantage of the transperitoneal approach is for subsequent percutaneous stone removal. Disadvantages include the increased mobility of the gallbladder fundus and the possibility of colonic interposition. Technical success rates with both approaches are approximately 100%.

As with any other tube placed by the interventional team, daily rounds must be made. The catheters must be irrigated every shift. Tubes must be left in for a minimum period of 2 to 3 weeks to make sure that a mature tract has formed. A cystocholangiogram must be performed prior to removal to ensure that there is no peritoneal leakage and that the cystic duct is patent.

Complications of percutaneous cholecystostomy are rare, 0% to 8%. Surgical complications are reported as high as 24%. Complications associated with percutaneous treatment include bleeding, hypotension, and biliary peritonitis.

- C. Bleeding esophageal varices refractory to sclerotherapy
D. Prevention of variceal bleeding

ANSWER: C. TIPS is indicated for variceal bleeding refractory to sclerotherapy. It often serves as a bridge to liver transplantation, which is the definitive treatment for cirrhosis and portal hypertension. The first-line treatment of ascites is medical intervention. Sclerotherapy should be attempted to control variceal bleeding prior to TIPS.

2. Which of the following vessel is most commonly affected with Mallory-Weiss tear?
A. Left gastric artery
B. Coronary vein
C. Short gastric artery
D. Phrenic vein

ANSWER: A. A Mallory-Weiss tear occurs at the gastroesophageal junction, which is supplied by the left gastric artery.

3. Which of the following is true?
A. Angiography is more sensitive to occult bleeding than TcRBC-labeled scan.
B. In vivo labeling of RBCs is usually used.
C. In vitro labeling of RBCs decreases false-positive rates.
D. Scintigraphy can detect bleeding rates as low as 0.5 to 1.0 mL/min.

ANSWER: C. TcRBC-labeled scan is ten times more sensitive than angiography for the detection of GI bleeding. Rates as low as 0.05 to 0.1 mL/min can be detected. In vitro labeling decreases false-positive rates.

4. Which of the following procedure is appropriate in the setting of hematemesis?
A. Endoscopy
B. Angiography
C. Abdominal CT with contrast
D. Upper GI examination

ANSWER: A. The first-line evaluation of patients with upper GI bleeding is endoscopy. Often a source will be identified that may be treated with sclerotherapy.

5. Which of the following is the most common angiographic finding in angiodysplasia of the colon?
A. Angiography does not usually show evidence of bleeding.
B. Minimal bleeding
C. Moderate bleeding
D. Massive bleeding

QUESTIONS AND ANSWERS

1. Which of the following is an appropriate indication for TIPS?
A. Definitive treatment of cirrhosis and portal HTN
B. Treatment of ascites prior to medical intervention

ANSWER: A. Angiodysplasia is more often found in elderly patients and patients with hereditary hemorrhagic telangiectasia. These lesions present on the antimesenteric border of the GI tract and demonstrate an early draining vein. These lesions bleed intermittently and are rarely identified by acute hemorrhage.

6. All of the following are *absolute contraindications* to G-tube placement, *except*
- A. Uncorrectable coagulopathy
 - B. Portal hypertension with gastric varices
 - C. Ascites
 - D. Recent ventriculoperitoneal shunt

ANSWER: C. Uncorrectable coagulopathy, anterior gastric wall tumor, gastric varices as well as a recently placed ventriculoperitoneal shunt are contraindications to placement of a gastrostomy tube. Ascites is a *relative* contraindication.

7. What is (are) the advantage(s) of a left-sided PTC via the left lobe of the liver?
- A. Less painful location
 - B. Decreased possibility of pleural complications
 - C. Improved visualization of the entire biliary tree
 - D. A and B
 - E. B and C

ANSWER: D. The advantages of a left-sided approach for a PTC are less likelihood of pleural involvement due to the subxiphoid approach and increased patient comfort due to the placement of the tube anteriorly. Often intercostal pain results from a right-side approach. In addition because of the pleural reflection, the pleural may be crossed.

8. What is the first intervention to try in a patient with persistent hemobilia following placement of a PTC?
- A. Visceral arteriogram
 - B. PTC to look for vascular communication
 - C. Upsize the biliary catheter and flush regularly to clear thrombus
 - D. Remove the catheter and have the patient lay in the right lateral decubitus position

ANSWER: C. The initial treatment in a patient with persistent hemobilia following internal–external drainage is to upsize the tube with the hope that bleeding will tamponade. Once this is done, a cholangiogram may be performed to confirm there is no vascular communication. A visceral arteriogram should not be performed until other measures are exhausted.

9. How are benign biliary enteric strictures best managed?

- A. Balloon dilation and stenting for 4 weeks
- B. Expandable metallic stent
- C. Self-expanding metallic stent
- D. Internal–external drainage for 6 to 12 months

ANSWER: D. Benign biliary strictures require internal–external or plastic tube stenting for 6 to 12 months. Metallic stents are not indicated in patients with a long life expectancy since they eventually become occluded.

10. Which of the following is the most common cause of AIDS cholangiopathy?

- A. *Enterococcus*
- B. *Cryptosporidium*
- C. *Escherichia coli*
- D. Toxoplasmosis

ANSWER: B. The most common causes of biliary tract infection in patients with HIV are CMV and *Cryptosporidium* species.

Rachel F. Oser

INTRODUCTION

Interventional radiology techniques can apply to a wide array of renal and ureteric pathologies. In the past, percutaneous nephrostomy (PCN) for relief of acute obstruction was the most commonly performed intervention. Although PCN is still commonly performed, it has been joined by a host of newer indications and procedures. This chapter will provide a brief overview of techniques and indications.

ANATOMY

An understanding of relevant anatomy is key to the safe and effective performance of any interventional procedure.

Kidneys are paired organs that lie, surrounded by fat, in the retroperitoneal space on either side of the vertebral column between the twelfth thoracic and third lumbar vertebra. Typically, the left kidney is located 1 to 2 cm higher than the right. The axis of the kidney parallels the psoas muscles, with the upper pole located medial and anterior to the lower pole. The pleura attaches to the tenth rib laterally and the twelfth rib medially, and

typically overlaps the upper renal poles increasing the risk of pneumothorax or hydrothorax when upper pole access is required.

The renal hilum contains the renal pelvis, renal artery(ies), and renal vein(s). The renal artery is located posterior to the renal vein and the renal pelvis is located posterior to both the artery and vein. The renal artery divides into anterior and posterior divisions at the renal hilum and then further divides into segmental branches. The segmental renal arteries in turn give rise to the interlobar arteries. The interlobar arteries course around the renal pyramids and give rise to the arcuate and then interlobular arteries. These arteries supply the renal cortex. Renal venous anatomy is more variable. Typically, there are two or three main venous trunks that join to form the renal veins in the renal hilum.

The Brodel line is a relatively avascular plane lying along the posterolateral aspect of the kidney between the anterior and posterior vascular territories. Because of the relative paucity of vessels in this region of the kidney, it is the safest approach for percutaneous interventions. Although, this plane cannot easily be determined on imaging, a posterolateral oblique approach is typically used to minimize bleeding complications. Also, entry into a peripheral calyx or infundibulum rather than the renal pelvis ensures that any vessels crossed are small branches, not a main renal artery or vein.

The ureter courses inferiorly from the renal pelvis along the anteromedial surface of the psoas muscle. At the level of the common iliac artery, it angles medially and then swings posterolaterally into the pelvis. It then courses medially to join the bladder at the ureterovesicular junction. The ureter may have areas of physiologic narrowing at the ureteropelvic junction, the midureter at the level of the common iliac artery, and at the ureterovesicular junction. Vascular supply to the ureters is from ureteral branches of the renal artery; these typically arise from the renal artery in the hilum and appear as fine spiraling vessels that follow the course of the ureters.

The bladder is located in the pelvis behind the symphysis pubis. The dome of the bladder is draped by the peritoneum; the remainder of the bladder is extraperitoneal. Vascular supply to the bladder is from branches of the anterior division of the internal iliac artery, and enters through the posterior and lateral aspects of the bladder.

PATIENT PREPARATION

Any interventional procedure should begin with a thorough review of the patient's past medical history, previous imaging, allergies, and medications. Review of pre-

vious imaging can be especially helpful. Attention should be paid to the level of the kidneys and their relationship to adjacent structures such as colon, liver, and spleen, as well as the diaphragm and pleural reflections. Appropriate laboratory studies, including a coagulation panel and serum creatinine, are obtained. Any coagulation abnormalities should be corrected prior to intervention. Preprocedure antibiotics are indicated if there is a history of infection or pyonephrosis. Specific antibiotics are subject to operator preference. The author typically uses cefazolin (Ancef) 1 g intravenous.

Percutaneous renal interventions are often painful and conscious sedation is almost always indicated. Prior to procedure, airway assessment must be performed and a history of prior pain medication obtained. Patients on chronic pain medications may be difficult for the interventional radiologist to safely sedate. For PCN, the patient will be placed in the prone position. This may create difficulties on ventilation for some obese patients. Positioning can also be problematic in pregnant patients and patients with recent abdominal surgery. If a patient is difficult to sedate or there are airway issues, anesthesia should be consulted for assistance in sedation and airway management.

ANTEGRADE PYELOGRAPHY

Antegrade pyelography is the process of inserting a needle or catheter percutaneously into the renal collecting system and injecting contrast to image the pelvicalyceal system and ureters. Although it was widely used as a diagnostic imaging test in the past, it has been largely replaced by cystoscopy and retrograde urography. Currently, antegrade pyelography is used to guide percutaneous interventions and, less frequently, for performance of the Whittaker test.

TECHNIQUE

The patient is placed in the prone position on the fluoroscopy table. If the goal of the procedure is antegrade pyelography alone, the needle can be directed into the renal pelvis under either fluoroscopic or sonographic guidance. More typically however, antegrade pyelography is a prelude to intervention. In these cases, an approach via a posterior calyx is preferred. The most common landmark for the renal pelvis is the lateral margin of the paraspinal muscles at the level of the L2 transverse process. However, if a direct pelvic access is desired, ultrasound (US) guidance may be simpler.

A 20- to 22-gauge trocar needle is then advanced into the kidney. The author typically uses a 22-gauge

15-cm Chiba needle. A longer or stiffer needle may be needed in obese patients or patients with scarring because of previous interventions. The trocar is then removed from the needle. The needle is slowly withdrawn until urine is aspirated. Contrast is then injected and imaging performed. A tilt table may be helpful in visualizing the distal ureter. It is important to not overfill the collecting system as this may lead to bacteremia and sepsis in patients with infected or colonized urine.

WHITTAKER TEST

The Whittaker test is a ureteral stress test, which is used to assess renal function and determine whether or not a chronically dilated collecting system is obstructed. In the past, this test was used as the gold standard for determining whether or not a ureteropelvic junction (UPJ) obstruction needed treatment. In recent years, nuclear medicine studies such as Lasix renography have replaced the Whittaker test despite a 10% to 15% false-positive rate.

The patient is prepared and positioned as for antegrade pyelography. A needle is placed in the renal pelvis and a Foley catheter is placed in the bladder. Water manometers are attached to the needle in the collecting system as well as the Foley catheter. Opening pressures are obtained in the collecting system and bladder. The ureter is infused with dilute contrast media (20%) at a flow rate of 10 mL/min for 5 minutes. Pressures are rechecked—if no evidence of obstruction is present, the flow rate can be increased to 15 to 20 c³/min and pressures checked again in 5 minutes. The differential pressure is determined by subtracting the bladder pressure from the ureteral pressure (Table 86-1). Finally, the test should be repeated with a full bladder to assess the effect of bladder pressure on the upper collecting system. This may be important with bladder outlet obstruction or bladder dysfunction.

The Whittaker test should be stopped if the urine appears infected or pressure in the kidney is higher than 35 cm H₂O or if the patient experiences pain during the procedure.

TABLE 86-1 Whittaker Test: Normal and Abnormal Pressures Differentials

FLOW RATE (c ³ /min)	PRESSURE DIFFERENTIAL (cm H ₂ O)	DEGREE OF OBSTRUCTION
10	<13	Normal
10	14–22	Mild
10	23–35	Moderate
10	>35	Severe (stop the test)

PERCUTANEOUS NEPHROSTOMY

PCN refers to the insertion of a tube through the skin and renal parenchyma to the collecting system of the kidney. PCN placement is widely used for relief of obstruction, diversion of urine, and accessing the collecting system in preparation for other procedures such as percutaneous nephrolithotomy or stent placement.

Obstruction of the collecting system may be the end result of many disease processes. This includes stone disease, tumor, retroperitoneal fibrosis, surgical mishap, and others (Table 86-2). The end result is complete or partial obstruction of flow from the renal pelvis to the bladder. Important clinical consequences of renal obstruction are sepsis, with or without shock, pain, impaired renal function, and ultimately renal failure. Sepsis is an indication for emergent PCN as septic shock can be fatal. Impaired renal function necessitates urgent, but not emergent, PCN. Renal dysfunction is usually reversible after relief of obstruction.

Diversion of urine is usually indicated to allow healing of renal, ureteral, or bladder leaks or fistulas. Typically urine is diverted as completely as possible away from the area of injury. Usually this involves a combination of PCN, drainage of any fluid collections, and often either an indwelling Foley catheter or suprapubic catheter for bladder drainage.

Percutaneous access to the renal collecting system is often the initial step in many endourologic procedures. Although many of these are primarily performed by the urologist, interventional radiologists are often primary operators in some stent placement, stone removal, and other procedures.

In addition to understanding the indications for nephrostomy placement, the interventionalist should understand when placing a PCN is not indicated.

TABLE 86-2 Causes of Ureteral Obstruction

Intrinsic	Calculi
	Clot
	UPJ
	TB
	Postoperative
	UVJ
	Tumor
	Lymphadenopathy
	Pelvic malignancy
	Pregnancy
Extrinsic	Trauma
	Iatrogenic
	Retroperitoneal fibrosis
	Prostate cancer
	Bladder cancer

True contraindications to PCN are few. Most contraindications are relative and can be corrected over a period of hours to days. Potential contraindications include bleeding diathesis, untreated infection, neoplasia, anatomic variations, and moral/ethical considerations. Because of the vascularity of the kidneys, bleeding is always a serious risk with PCN. Therefore, normal coagulation parameters are imperative prior to PCN. In patients with abnormal coagulation profiles, this should be corrected before proceeding. Patients with acute infection should be treated with antibiotics prior to PCN to decrease the risk of urosepsis. Anatomic considerations such as horseshoe kidney, pregnancy, obesity, scoliosis, colonic interposition, and renal transplant will affect technique and approach. Review of any relevant prior imaging such as CT or US is critical. In patients with an irreversibly obstructed kidney, the nephrostomy catheter cannot be removed without developing a urine leak that may not resolve over time. Therefore, PCN in terminal inoperative cancer patients essentially commits the patient to PCN and routine exchanges for the remainder of their lives. This should be discussed with the patient and family prior to placement.

Preprocedure evaluation is similar to that for antegrade nephrostogram. In addition, the question of what procedure is in the patient's best interest should be considered. In many cases, retrograde drainage (performed by urology) is a better and safer option.

TECHNIQUE

Many different modalities have been successfully used for accessing the renal collecting system. The most commonly used is fluoroscopy, either using bony landmarks or intravenous contrast opacification of the collecting system. US guidance is also popular and is especially helpful with renal transplants and in thin patients. Typically, real-time US guidance is used for the initial access into the system, and the remainder of the procedure is performed under fluoroscopic guidance. Both CT- and MR-guided access have also been described, but both modalities are more cumbersome to use than US and fluoroscopy.

When using either osseous landmarks or real-time US as a guide, the first step is to access the collecting system with a 21- or 22-gauge Chiba needle. The system is then opacified with contrast media and an antegrade nephrostogram performed. Once the collecting system is opacified, the appropriate calyx for intervention is chosen.

Ideally a lower pole posteriorly oriented calyx is chosen as the site of entry. A 20 to 30 degrees posterolateral oblique approach is most likely to keep the entry to the kidney along Brodel avascular zone and minimize the risk of bleeding complications. By choosing a lower pole

calyx and not entering laterally, the risks of pneumothorax and bowel perforation are minimized; however, planned intervention may require a riskier approach. Direct entry into the renal pelvis without passing through renal parenchyma should be avoided, as this approach leads to higher incidence of bleeding and urine leak.

Once an appropriate entry site is chosen, fluoroscopy is used to guide a 21- or 22-gauge Chiba needle into the calyx. Position is confirmed by aspiration of urine and injection of contrast. Only small amounts of contrast should be injected until secure positioning within the collecting system is confirmed to avoid extravasation of contrast around the collecting system, which may obscure the calyces and make subsequent intervention more difficult.

A 0.018-in guidewire is then manipulated through the needle and into the renal pelvis. A conversion system, such as Neff or Accustick system, is then used to upsize the access to allow for placement of a 0.035- or 0.038-in guide wire in the renal pelvis. The wire should then be advanced down the ureter. At our institution, we prefer to use an Amplatz extra-stiff wire for catheter placements. The stiff wire provides good support for interventions and minimizes complications.

The tract is serially dilated and a catheter, typically an 8F or 10F self-retaining pigtail, is placed with the curl in the renal pelvis. Care should be taken during manipulations to not override the wire and perforate the collecting system, as this may lead to catheter malposition and urine leak. There are many brands of catheters available and choice is based on operator preference.

OUTCOMES

PCN is a safe and effective therapy. Success rate is typically more than 98%. In patients with urosepsis, PCN and adequate drainage usually results in clinical improvement within 24 to 48 hours. Patients with obstructive renal dysfunction will demonstrate prompt diuresis and decrease in creatinine. Pain related to obstruction is also usually promptly improved.

COMPLICATIONS

Complication rates for PCN vary widely between published series (Table 86-3). Larger-bore catheters and catheters placed for percutaneous stone removal generally are associated with higher complication rates. On average, complication rates of 4% to 6% are reported. Major complications, such as bleeding requiring surgery or embolization (1%–2%), sepsis (1%–2%), and pneumothorax/hydrothorax (1%), are relatively rare. Minor infection, tube-related issues such as dislodgement,

TABLE 86-3 Complications for Percutaneous Nephrostomy

TYPE	INCIDENCE (%)
Bleeding	
Requiring transfusion	1–3
Associated with vascular injury	0.5–1
Adjacent organ injury	
Bowel	0.1
Pneumothorax/hydrothorax	0.1–0.3
Sepsis	1–3
Mortality	0.05–0.3
Catheter “problems”	2–18

kinking, obstruction and leaks, minor infections, and bleeding not requiring therapy may occur in up to 20% of cases. Arterial injury resulting in pseudoaneurysm or arteriovenous fistula formation can occur in 1% of cases and is usually successfully treated with endovascular therapy such as coil embolization.

As with any major intervention, the key to minimizing complications is good technique and patient selection combined with prompt recognition of complications when they occur. Bloody urine is common after PCN placement. It usually clears within 24 to 48 hours and should not be confused with the rapid bleeding associated with arterial injury. Flank pain is common within the first day after catheter placement and usually abates over time. Adequate pain therapy is critical. A local nerve block may be helpful in patients with persistent catheter-related pain, especially in those patients with intercostal catheters.

CATHETER MAINTENANCE

Self-retaining pigtail-type catheters are most commonly used for PCN. Many manufacturers have designed catheters specifically for this purpose and the choice of brand is dependent on operator and hospital preference. Urologists will often leave a Foley or Council catheter, both of which have a balloon retention system, in place as a PCN catheter. This catheter type is more difficult to place and exchange over a wire and is less favored by interventional radiologists. Typically, catheters should be flushed regularly and have regular dressing changes even after the patient is discharged. The interventional radiology team, including physicians, nurses, residents, and physician assistants, should be available to provide training in catheter care to the patient and family. A printed instruction sheet with contact numbers should be given to the patient and family. Because urine tends to crystallize on and in the tube as well as on the pigtail-retention sutures, routine exchanges are necessary for maintenance of long-term PCN catheters. Patients will require

catheter exchange every 2 to 3 months. Pregnant patients and other patients who form stones quickly may need to be scheduled for more frequent catheter exchanges. Exchanges should be performed over a wire under fluoroscopic guidance, usually in an outpatient setting.

PERCUTANEOUS NEPHROSTOLITHOTOMY

Percutaneous nephrostolithotomy (PCNL) is a treatment option used for removal of renal calculi. Other options include surgery and extracorporeal shockwave lithotripsy. PCNL is most often used for patients with staghorn calculi, unusual anatomy (e.g., horseshoe kidney, calyceal diverticula), or stones limited to the upper collecting system, which are difficult to reach with an ureteroscope. Open stone surgery, once the standard for stone removal, is now rarely performed.

For PCNL, an access is obtained percutaneously in the upper collecting system as for PCN. The entry site is chosen in conjunction with the urologist to maximize access to the stone for subsequent removal. Because of this, the site is often in the upper pole and the risk of complications is substantially higher than with a standard PCN. The initial access is obtained and a wire and catheter are manipulated past the stone to the bladder. Patients with complex anatomy, multiple stones, or staghorn calculi may require more than one access for optimal results.

In patients with large staghorn calculi, maneuvering past the stone may be challenging. In our practice, the urologist places a retrograde ureteral catheter before the patient arrives in interventional radiology. This allows us to identify the best access for intervention and guide our PCN more accurately.

A wire is then placed in the bladder and the tract is dilated to 28F to 34F to allow for placement of a nephroscope directly in the upper collecting system. The stone is then fragmented using ultrasonic or laser lithotripsy. At the conclusion of the procedure, a PCN is left in place, usually a large-bore Council catheter. Although the entire procedure can be performed in the operating room using a C-arm fluoroscopy unit, we prefer to place the access in the radiology department and send the patient to the OR with a percutaneous catheter extending from the access site to the bladder. The tract dilation and stone removal are then performed in the OR under general anesthesia by the urologist.

URETERAL STENTS

Ureteral stents allow for the treatment of many of the same conditions as PCN without the discomfort of an external drainage catheter. They are most frequently placed

for treatment of ureteral obstruction, leaks, before or after lithotripsy for stone disease, and prior to complex pelvic surgery. Although ureteral stents are most frequently placed in a retrograde fashion by a urologist during cystoscopy, they can also be placed in an antegrade fashion either in conjunction with PCN or as primary therapy.

As with PCN, contraindications to ureteral stent placement are most often relative. Untreated urinary tract infections and urosepsis should be treated first with PCN and intravenous antibiotics. Ureteral stent placement can be performed after the initial infection has been treated. When a bladder fistula or leak is present, urinary diversion is required for healing. As ureteral stents drain the urine into the bladder, they are not appropriate in this instance. Ureteral stents are, however, the first line of treatment for ureteral injury or leak. Because the distal end of the stent rests in the bladder, it can cause irritation. Therefore, stents are not recommended for patients with bladder irritability.

TECHNIQUE

The first step in antegrade ureteral stent placement is percutaneous access to the upper collecting system. Preparation and positioning is the same as for PCN. If a previously placed PCN is present, this can be used as access. Otherwise, a new access should be obtained as for PCN placement. A catheter and guidewire are then manipulated across the UPJ, down the ureter, and into the bladder under fluoroscopic guidance. Once access is obtained, extending from the skin to the bladder, stent placement can be performed.

Two types of ureteral stents are available for percutaneous placement. The first is an internal/external stent, which has an external component, a pigtail loop in the renal pelvis, and a second loop in the bladder. The external component can either be left to drainage or capped, allowing for entirely internal drainage with no need for a drainage bag. The advantage to this type of catheter is that it can be exchanged in the interventional radiology suite, without the need for cystoscopy.

Internal stents are favored by patients because they obviate the need for an external catheter and drainage bag; 8F or 10F double-J ureteral stents are the most frequently used sizes. These are manufactured in a range of lengths, although the 26-cm length is generally acceptable in most adults. As for any catheter, several different manufacturers make systems designed for antegrade ureteral stent placement, and the choice of design is left to operator preference. Like external stents, they also need to be exchanged every 2 to 3 months to maintain patency. Unlike external drains or stents, exchange must be performed in the cystoscopy suite by the referring urologist.

Patients with ileal conduit placement after cystectomy can develop stenosis and occlusion at the junction of the ureter and ileal conduit. If untreated, this can lead to hydronephrosis and renal dysfunction. Reoperation is difficult in these patients, and ureteral stenting is often the treatment of choice. Because of the postoperative anatomy, placing a ureteral stent in this group of patients is challenging. Cystoscopy and retrograde stent placement is difficult because of the redundancy of the ileal conduit and variability in location of the implanted ureters. These patients are usually referred to the interventional radiologist for stenting.

Ureteral stenting begins in these patients as in any PCN, with the patient in the prone position. Access is gained percutaneously into the collecting system. The catheter and wire are then manipulated down the ureter and into the ileal conduit under fluoroscopic guidance. In patients with normal anatomy, the ureteral stent is then placed. In patients with an ileal conduit, however, the distal end of the stent will quickly be obstructed with secretions if it is left in the conduit. Because of this, the stent is ideally placed with one end in the upper collecting system and the other end extending outside the patient's conduit with the distal pigtail draining into the ostomy bag. To achieve this, the patient is rolled on their side. The catheter and wire are then manipulated to the ileostomy and pulled outside the patient. This leaves a wire extending from the initial access site in the patient's back and out the patient's front. A double-J ureteral stent can then be passed along the wire in a retrograde fashion and positioned as desired. The wire is then removed. Like any stent, these need to be exchanged under fluoroscopic guidance every 2 to 3 months. Because the stent extends outside the body, this can be done easily in a retrograde fashion, in an outpatient setting with minimal patient discomfort.

SUPRAPUBIC CYSTOSTOMY

Suprapubic cystostomy is typically used to acutely decompress an obstructed bladder or for long-term urinary diversion in patients with chronic bladder outflow obstruction, neurogenic bladder, bladder fistulae, or bladder or urethral injury. Although often performed by urologists, suprapubic cystostomy can be easily and safely performed in the interventional radiology suite.

TECHNIQUE

The procedure is performed in a fluoroscopy suite. Although bony landmarks can be used, we prefer to use US guidance for the puncture. Either trocar or Seldinger

technique can be used. Once in the bladder, contrast should be injected to confirm catheter placement. For initial drainage, a self-retaining 10F pigtail all-purpose drainage catheter is adequate. For long-term drainage, the initial access can be upsized exchanged for a larger Foley catheter once the tract is mature. The Foley catheter can be exchanged by the referring urologist, home health, or a nursing home as needed.

Complications associated with suprapubic cystostomy are minimal, especially with US guidance. Attention should be paid to stick low, just above the symphysis pubis to avoid the peritoneal cavity and overlying bowel loops. A midline puncture will ensure avoiding the inferior epigastric arteries.

SCLEROTHERAPY FOR RENAL CYSTS

Benign renal cysts, either cortical or parapelvic, are found in more than 50% of all people older than 50 years. Typically, these cysts are asymptomatic; however, large, infected, or hemorrhagic cysts may require therapy. Large enough cysts may rarely cause obstruction of the collecting system, urine stasis with stone formation, and renin-dependent hypertension.

Asymptomatic cysts do not require treatment. Symptomatic cysts can be managed with a combination of percutaneous drainage and sclerotherapy. Drainage alone may relieve initial symptoms, but 30% to 80% will quickly reaccumulate fluid. To prevent recurrence, sclerotherapy aims to destroy the epithelial lining of the cysts, following drainage, thus preventing reaccumulation of fluid. A variety of agents have been used as sclerosants including Betadine, absolute alcohol, tetracycline, and sodium morrhuate, among others. Absolute alcohol is the most commonly used agent.

Techniques for cyst sclerosis vary between operators, but the major steps are similar. Initially, the cyst is punctured under US guidance. A small drainage catheter is then placed and fluid aspirated. Contrast should be injected to assess the volume of the cyst and to ensure that there is no communication between the cyst cavity and the collecting system. Contrast is then aspirated and 25% to 50% of the cyst volume replaced with sclerosing agent. The sclerosant is left in place for 15 to 30 minutes. The patient should be encouraged to change position frequently while the sclerosant is in place to allow for maximal contact between the sclerosant and the walls of the cyst. Overdistension of the cyst should be avoided to prevent infiltration of sclerosant into adjacent tissues and vascular structures.

After 15 to 30 minutes, the sclerosant is aspirated. For small cysts, this may be adequate and the catheter can be removed. For larger or recurrent cysts, the

catheter is left to drainage. The procedure may need to be repeated several times until the amount of fluid is less than 5 to 10 cm³. The catheter is then removed.

If the cyst communicates with the collecting system, sclerosant should *not* be injected to avoid formation of strictures. In cases of infected cysts, the infection should be drained and treated with antibiotics before sclerosing. Infection has a strong sclerosing effect, and these cysts may resolve on their own after drainage. Hemorrhagic cysts should be drained and the fluid assessed for possible malignancy. Sclerosis can be performed after the fluid clears.

Outcomes of sclerotherapy for renal cysts are good, with reported success rates of 75% to 100%. Serious complications are rare, but include bleeding, infection, and vascular injury. The sclerosing agents can also be associated with adverse effects, especially if they contact nontargeted tissues. Effects may include local inflammation, fat necrosis, and retroperitoneal fibrosis. Fortunately, these complications can be avoided with careful technique.

BIOPSY

Percutaneous biopsy is indicated both to make a specific diagnosis for renal parenchymal disease in native and transplanted kidneys and to diagnose some tumors. For diffuse parenchymal disease, US is generally used for real-time needled guidance. A 16- to 18-gauge core biopsy gun with a short needle excursion is placed within the periphery of the kidney and several cores obtained. By keeping the biopsy area away from the renal hilum, large blood vessels are avoided minimizing bleeding complications. US performed after removal of the biopsy needle is performed to look for persistent bleeding. If an arterial bleed is seen after biopsy, the patient is referred to angiography for possible embolization of the bleeding artery.

Renal tumors may also be biopsied percutaneously. Most solid renal masses require surgical removal. However, biopsy may be required in debilitated patients, or patients with suspicion for lymphoma, metastases, or other unusual pathologies. Although in the past biopsy of renal masses was not in favor because of concern over tumor seeding of the tract, this appears to not be a major concern. Real-time US guidance and biopsy with an 18- to 22-gauge core biopsy gun is most frequently used. CT guidance is also possible, but is generally more cumbersome in the kidney than US.

Transabdominal or endoluminal US or CT can also guide the biopsy of ureteral or bladder masses. Brush biopsy of ureteral masses can be performed from a percutaneous access as well. However, most masses within the collecting system are biopsied by a urologist under direct visualization at cystoscopy.

For any biopsy, complications are similar to those seen with any percutaneous access at that site. Bleeding is the most commonly seen complication, especially for renal biopsy. Vascular injury may occur with larger-gauge needles, and is readily treated with selective embolization of the injured artery. If untreated, vascular injury that is due to biopsy may lead to pseudoaneurysm or arteriovenous fistula formation. These complications are also readily treated with endovascular therapy. Bleeding complications are minimized by avoiding the larger vessels in the central kidney.

QUESTIONS AND ANSWERS

- Which of the following is *not* an indication for PCN?
 - Renal calculi
 - UPJ obstruction
 - Ureteral obstruction in pregnancy
 - Renal cell carcinoma

ANSWER: D. PCN placement is widely used for relief of obstruction, diversion of urine, and accessing the collecting system in preparation for other procedures such as percutaneous nephrolithotomy or stent placement. Renal cell carcinoma is usually treated with surgical removal.

- Which of the following is an indication for ureteral stenting?
 - Bladder rupture that is due to trauma
 - Ureteral leak after surgery for UPJ obstruction
 - Vesicovaginal fistula
 - Urethral injury

ANSWER: B. When a bladder fistula or leak is present, urinary diversion is required for healing. As ureteral stents drain the urine into the bladder, they are not appropriate in this instance.

- Renal biopsy is required before treating any patient with a solid renal mass.
 - True
 - False

ANSWER: B. Most solid renal masses require surgical removal. However, biopsy may be required in debilitated patients, or patients with suspicion for lymphoma, metastases, or other unusual pathologies.

- Which of the following is the ideal location for accessing a kidney percutaneously?
 - Renal pelvis
 - Any anterior calyx
 - Upper pole posterior calyx
 - Lower pole posterior calyx

ANSWER: D. Ideally a lower pole posteriorly oriented calyx is chosen as the site of entry. A 20 to 30 degrees posterolateral oblique approach is most likely to keep the entry to the kidney along Brodel's avascular zone and minimize the risk of bleeding complications. By choosing a lower pole calyx and not entering laterally, the risks of pneumothorax and bowel perforation are minimized.

- Which of the following is the Brodel line?
 - Most vascular portion of the renal parenchyma
 - Dividing line between the upper and lower ureter
 - Relatively avascular plane between the anterior and posterior vascular divisions of the kidney
 - Most direct access between the skin and the renal parenchyma

ANSWER: C. The Brodel line is a relatively avascular plane lying along the posterolateral aspect of the kidney between the anterior and posterior vascular territories. Because of the relative paucity of vessels in this region of the kidney, it is the safest approach for percutaneous interventions. Although, this plane cannot easily be determined on imaging, a posterolateral oblique approach is typically used to minimize bleeding complications.

- Which of the following is the most commonly used sclerosing agent for renal cysts?
 - Absolute alcohol
 - Sodium morrhuate
 - Tetracycline
 - All of the above

ANSWER: A. A variety of agents have been used as sclerosants including Betadine, absolute alcohol, tetracycline, and sodium morrhuate, among others. Absolute alcohol is the most commonly used agent.

- The renal pelvis is located posteriorly to the renal artery and vein at the hilum.
 - True
 - False

ANSWER: A. The renal hilum contains the renal pelvis, renal artery(ies), and renal vein(s). The renal artery is located posterior to the renal vein and the renal pelvis is posterior to both the artery and vein.

8. Which of the following is an indication for suprapubic cystostomy?
- A. Neurogenic bladder
 - B. Bladder outlet obstruction
 - C. Vesicovaginal fistula
 - D. All of the above

ANSWER: D. Suprapubic cystostomy is typically used to acutely decompress an obstructed bladder or for long-term urinary diversion in patients with chronic bladder outflow obstruction, neurogenic bladder, bladder fistulae, or bladder or urethral injury.

9. Which of the following is a complication of PCN?
- A. Sepsis
 - B. Pneumothorax
 - C. Bleeding
 - D. All of the above

ANSWER: D. Overall complication rates of 4% to 6% are reported. Major complications, including bleeding requiring surgery or embolization (1%–2%), sepsis (1%–2%), and pneumothorax/hydrothorax (1%), are relatively rare.

10. Concerning PCN drainage catheters, which of the following is *true*?
- A. Typically 6F or smaller
 - B. Do not require exchanges because urine is a liquid
 - C. Best long-term option for most patients
 - D. Ideal for relief of acute renal obstruction

ANSWER: D. PCN placement is widely used for relief of obstruction, diversion of urine, and accessing the collecting system in preparation for other procedures such as percutaneous nephrolithotomy or stent placement.

87 PULMONARY ANGIOGRAPHY AND INTERVENTION

Ahmed Kamel Abdel Aal and Bao T. Bui

INTRODUCTION

With great technological advancement in CT angiography (CTA) and the development of multidetector CT

(MDCT) that is greatly expanding in speed and detection, conventional pulmonary angiography (PA) has slowly fallen to the wayside, relegated to problematic and difficult cases in which CT and other techniques have not shown a definitive cause. PA involves the injection of contrast into the pulmonary arteries to obtain radiographic evidence of different pathological processes, and therefore is quite invasive compared to standard CTA techniques. CT is also less operator dependent than angiography and requires less technical expertise. While multidetector helical CTA has steadily become the first test ordered by clinicians to evaluate for patients with symptoms of acute pulmonary thromboembolism (PTE), conventional PA remains the gold standard.

ANATOMY

Pulmonary arterial circulation begins in the heart at the level of the pulmonary valve. The main pulmonary artery arises from the conus arteriosus of the right ventricle extending superiorly and to the left for approximately 5 cm. It is initially anterior to the ascending aorta, and then passes to the left of the ascending aorta as it continues superiorly, to lie in the concavity of the aortic arch.

The main pulmonary artery divides into the right and left pulmonary arteries. The left pulmonary artery is slightly smaller and shorter than the right. It passes anterior to the descending aorta and superior to the left main bronchus. As such, it has a slightly higher position in the chest than the right pulmonary artery. It is attached to the concavity of the aortic arch by the ligamentum arteriosum. It divides into the upper and lower lobar branches.

The right pulmonary artery is slightly larger and longer than the left. It passes anterior to the right bronchus and posterior to the ascending aorta and superior vena cava (SVC). It subsequently divides into two branches: a larger lower branch to the middle and lower lobes and a smaller branch to the upper lobe.

The pulmonary lobar arteries divide into segmental, subsegmental, and lobular branches. Lobular arteries are at the center of the secondary pulmonary lobules, the functional unit of the lung.

There is usually one pulmonary vein from each lobe of the lungs with the right middle and upper lobes uniting to form a common trunk. Four trunks, two from each lung, empty into the left atrium. On both sides, the pulmonary veins are inferior to the pulmonary arteries, except at the level of the hilum where the superior pulmonary veins lie anterior to the right and left pulmonary arteries. The left pulmonary vein is anterior to the descending thoracic aorta. The right pulmonary vein is posterior to the SVC. Anomalous pulmonary venous

drainage can be total or partial and is often associated with congenital heart disease.

The bronchial arteries provide a much smaller portion of the total pulmonary blood flow. They are generally of minor clinical significance and only important in diseases that cause their enlargement, such as cystic fibrosis. In such cases, erosion of these dilated bronchial arteries by the disease process will produce hemoptysis that is often life threatening. Bronchial artery anatomy is very variable and is classified into four types. The most common pattern is two left and one right bronchial artery (type 1). The left bronchial arteries usually arise from the anterolateral surface of the thoracic aorta below the ligamentum arteriosum, while the right bronchial artery usually arises from a common trunk with an intercostal artery (intercostobronchial trunk). However, it is not uncommon to find bilateral single bronchial arteries (type 2), two left and two right bronchial arteries (type 3), or a single left and two right bronchial arteries (type 4). The origins of the bronchial arteries can also be quite variable with some arising from the brachiocephalic, subclavian, or internal mammary artery. It is important to emphasize that, in approximately 5% of the population, the right intercostobronchial trunk contributes to or arises with the artery of Adamkiewicz, which supplies the anterior spinal artery, and needs careful consideration when performing bronchial artery embolization.

TECHNIQUE

PULMONARY ANGIOGRAPHY

INDICATIONS

The main indication for PA is to evaluate for PTE. Classically, pulmonary angiograms are obtained whenever there is an intermediate or high clinical index of suspicion supported by a ventilation/perfusion (V/Q) scan that is interpreted as intermediate or high probability. However, this practice has changed in many institutions, and the standard is to initially obtain a pulmonary CTA for those patients if there is reasonable clinical suspicion. With the advent of MDCT, the entire thorax can be imaged during the first pass of contrast in the pulmonary circulation. This can be achieved during a single breath hold, even in patients with PTE who suffer from dyspnea related to their disease. Pulmonary CTA can detect thrombus in the pulmonary artery up to the third-order branch with optimal technique and contrast timing. CTA also has the advantage of entertaining other diagnoses that can be the cause of the patient's symptoms.

Pulmonary arteriograms are reserved for those cases in which CTA cannot be performed or in cases of mas-

sive or central PTE causing significant hemodynamic compromise and in patients who are potential candidates for thromboembolectomy. Less commonly, pulmonary arteriogram is performed prior to inferior vena cava (IVC) filter placement if documentation of deep venous thrombosis cannot be achieved.

CONTRAINDICATIONS

There is no absolute contraindication to pulmonary arteriograms. The most important relative contraindications are as follows:

- Severe pulmonary hypertension leading to high right ventricular pressure: Systolic pressure more than 70 mm Hg and diastolic pressure more than 20 mm Hg are associated with increased mortality as high as 2% to 3%. In these cases, if pulmonary arteriogram is still indicated, nonionic isoosmolar contrast agents (Visipaque 320 or 270) can be used. Furthermore, subselective-targeted angiograms should be performed to minimize contrast load.
- Left bundle branch block (LBBB): The manipulation of the catheter across the right heart might lead to right bundle branch block. This might lead to complete heart block if the patient had preexisting LBBB. This can be avoided by performing pulmonary arteriogram with the tip of the catheter placed in the distal IVC or SVC to avoid manipulations in the right heart and right bundle branch block. Alternatively, a transvenous pacer can be placed before the procedure.
- Congestive heart failure: This should be preferably treated prior to pulmonary arteriogram.

PROCEDURE

PA is usually performed through a transfemoral approach and occasionally through a transjugular or transbrachial approach. A large pigtail catheter, usually 7F or 8F, is advanced from the puncture site through the right heart and pulmonary valve into the main pulmonary artery. We found that a 5F-angled pigtail catheter allows easy manipulation in the right heart with the aid of a J-wire. The small French size also provides less risk of postprocedure bleeding from the access site. Right ventricular and pulmonary artery pressures should be obtained first, since elevated pressures may influence the performance of subsequent angiograms (see contraindications given in the previous paragraph). PA with the catheter in the main pulmonary artery is then performed. Selective catheterization and angiography of the right or left pulmonary artery can also be performed. Approximately 30 to 50 mL of low-osmolar or isoosmolar nonionic contrast is injected at a rate of 15 to 25 mL/s with filming usually at 4 frames/s. The different projections depend on clinical suspicion, but often an AP and right and left posterior

oblique views of the lung base are performed. Other views are supplemental to the above standard views. Every effort should be made to obtain images during maximum inspiration. Magnified superselective views are sometimes needed to demonstrate a more peripheral thrombus. In this case, balloon occlusion catheters may be used. The balloon should not produce complete occlusion of the catheterized branch and should be deflated immediately at the end of the angiogram.

COMPLICATIONS

Although invasive, the morbidity and mortality of PA are generally low. Complications are mostly related to access technique or contrast-induced nephropathy, ranging from 1% to 5%. Other more serious but less common complications reported include significant arrhythmia, endocardial stain, and right ventricular perforation. Mortality from pulmonary arteriogram is less than 0.5% and is related to acute right ventricular failure in most patients.

BRONCHIAL ANGIOGRAPHY

INDICATIONS

By far the most common indication for bronchial angiogram is hemoptysis. Mild-to-moderate hemoptysis usually requires only clinical monitoring. Massive hemoptysis is defined as more than 300 to 600 mL/24 h, although it varies from 200 to 1000 mL/24 h, according to different authors. The more common causes for hemoptysis include cystic fibrosis and infections such as tuberculosis, bronchiectasis, and bronchogenic carcinoma. Other less common indications for bronchial angiogram include evaluation of bronchial arteries in case of congenital heart disease with interruption of the pulmonary circulation and evaluation of bronchial arteries following lung transplant.

PROCEDURE

The procedure is usually performed through a transfemoral approach. The level of the bronchial arteries is quite variable and ranges from T4 to T9. However, approximately 90% of bronchial arteries arise at the level of T5-6, and the carina acts as a convenient fluoroscopic landmark. In cases of iliac or aortic tortuosity, a long sheath may be used to enhance catheter manipulation. A variety of catheters may be used; the most common and convenient are Mikelson, Simmons I, and shepherd's hook catheters. However, H1, Cobra, and RC2 catheters can also be used. The catheter tip should be directed to a lateral to anterolateral position during the search for the bronchial arteries. Occlusion of the bronchial arteries, especially the intercostobronchial trunk, should be avoided since this may result in cord ischemia. Angiograms are usually performed through

hand injection of 3 to 10 mL of contrast material. Hand injections have the advantage of adjusting the pressure and flow of contrast in the bronchial arteries by the operator to avoid injury and rupture of the small distal diseased branches.

PULMONARY ARTERIAL HYPERTENSION

CLINICAL PRESENTATION AND CONSIDERATION

The mean pulmonary artery pressure ranges from 12 to 16 mmHg. Pulmonary arterial hypertension (PAH) is defined as mean pulmonary artery of more than 25 mmHg during rest or more than 30 mmHg during exercise, although some authors define it as systolic pulmonary artery pressure exceeding 30 mmHg.

Patients with PAH often present with nonspecific signs and symptoms including dyspnea, fatigue, and chest pain. The clinical findings are nonspecific, frequently requiring catheterization and pressure measurements for accurate diagnosis.

Classically, there are two types of PAH: primary and secondary. In primary PAH, the cause is unknown and the disease mostly occurs in middle-aged women. Secondary PAH may be caused by a variety of underlying pulmonary or arterial abnormalities and can be subdivided into four types: pulmonary thromboembolic disease, intra- or extracardiac shunts, chronic lung disease, and left heart failure. The increase flow or obstruction leads to vasoconstriction and remodeling of the pulmonary arterial walls resulting in fibrosis. Elevated right heart pressure is required to pump blood through stiffer pulmonary arteries eventually leading to right ventricular failure.

IMAGING FEATURES

Imaging findings of PAH include enlarged central pulmonary arteries, elevated pulmonary arterial pressure, and marked tapering and attenuation of the peripheral branches. PA is often unable to determine the exact cause or differentiate between the types of PAH and other tests are frequently necessary.

ACUTE PULMONARY EMBOLISM

CLINICAL PRESENTATION

Acute pulmonary embolus is a very common clinical problem and is one of the primary indications for PA. The clinical presentation for acute pulmonary embolism is quite nonspecific, with the minority of patients presenting with classic dyspnea, pleuritic chest pain, and cough. Other nonspecific symptoms include tachypnea and tachycardia. The workup for chest pain, therefore, often involves the exclusion of pulmonary embolus. It

frequently requires a high degree of clinical suspicion. Although clinicians are quite aware of its presence and clinical impact, it is often underdiagnosed.

Patients respond to acute pulmonary embolism differently, depending on their cardiopulmonary reserve. Patients with normal pulmonary and cardiac functions tolerate large emboli well without much morbidity. However, with underlying cardiac or pulmonary disease, small embolus can cause much morbidity and sometimes even death.

The most common source of acute pulmonary embolism arises from lower extremities and pelvic deep venous thrombosis, with the latter occurring more in postpartum patients. The deep veins of the upper extremities are increasingly becoming a cause of embolus, especially in relation to intravenous drug abuse. Superficial veins of the extremities are not known to cause thromboembolic disease to the lungs. Large emboli often break apart as they travel into the central systemic veins and pulmonary arteries, showering smaller emboli into the pulmonary arterial circulation. Pulmonary infarction however is rare, because of dual supply of the pulmonary parenchyma and the fact that most pulmonary emboli lodge more centrally, allowing for collateral flow. Therefore, pulmonary infarction is more commonly associated with peripheral embolus. Large or saddle emboli cause the most significant morbidity and can lead to acute right heart failure secondary to pulmonary hypertension or even death.

IMAGING FEATURES

The most specific signs for pulmonary embolus in any imaging technique whether CT, MR, or conventional PA is intraluminal filling defect, abrupt arterial cutoff, or both. Intraluminal filling defects usually occur at branching points. Suspicious lesions and filling defects should be more carefully examined with different projections and magnification views. A true filling defect should be constant on multiple views. Secondary less specific signs on conventional PA include slow flow or regional oligemia, which are suggestive but not definitive in the diagnosis of acute PTE. Most pulmonary emboli tend to be multiple and bilateral with smaller emboli involving multiple vessels, particularly of the lower lobes.

An advantage of conventional PA over CT includes better visualization of more peripheral embolus. Pulmonary CTA is comparable to conventional angiography in central embolus, and its ability to detect small pulmonary emboli has significantly improved with the development of MDCT. The main limitation remains in its reliable detection of small subsegmental peripherally located pulmonary emboli, although the clinical significance of such small emboli remains debatable. Another advantage of CTA includes its less invasive nature and

the ability to visualize other intrathoracic structures and suggest an alternative diagnosis when available. It is quicker to perform and requires less technical expertise, and therefore is favored by most emergency departments in triaging those patients with clinical presentation suspicious for PTE. Conventional PA currently is reserved for problem solving in patients with clinical suspicion of acute pulmonary embolus but with negative CTA or V/Q scans.

TREATMENT AND PROGNOSIS

The mortality rate for acute pulmonary embolus remains high, reaching approximately 20% in some studies. The classic treatment includes anticoagulation with heparin and long-term warfarin therapy for 6 months or more, while maintaining INR between 2.0 and 3.0. Some patients require lifelong anticoagulation therapy. Anticoagulation will lyse the current thrombus and will prevent recurrence. Most acute emboli will lyse with standard medical therapy; however, a minority of patients will develop chronic pulmonary embolus and PAH, requiring more invasive surgical thromboembolectomy. Patients in whom anticoagulation is contraindicated, placement of an IVC filter to prevent further emboli is necessary.

Sometimes, acute relief of clot burden is required to improve the hemodynamic status of patients on the verge of right ventricular failure. This can be achieved using systemic or catheter-directed thrombolysis. It is important to emphasize that a small decrease in the degree of pulmonary artery obstruction leads to dramatic clinical improvement in most cases. However, thrombolytics are not without side effects and contraindications, and should be used in carefully selected patients to avoid adverse outcomes.

Embolectomy is the last resort for patients with fulminant PE, who failed or have a contraindication for thrombolysis. Surgical embolectomy has very high morbidity and mortality rates. Alternatively, percutaneous embolectomy carries a more favorable outcome in most cases. The catheter-based devices can be divided into those that remove the thrombus versus those that fragment the thrombus into smaller pieces that lodge more peripherally, thus decreasing the pulmonary vascular resistance in the main pulmonary artery. The latter may be followed by catheter-directed thrombolysis.

CHRONIC PULMONARY EMBOLISM

CLINICAL PRESENTATION

Chronic pulmonary embolic disease is often due to recurrent episodes of emboli in patients with underlying disease or condition that predisposes to stasis. Less often, it can occur because of failure of lysis of acute

pulmonary emboli. Clinically, these patients present with nonspecific symptoms of progressive exertional dyspnea, hemoptysis, or fatigue. These patients rarely present emergently, and the workup is often due to other causes.

IMAGING FEATURES

As chronic and unresolved emboli damage and obstruct the pulmonary circulation, remodeling of the pulmonary arterial walls occurs giving rise to the imaging features of chronic pulmonary embolism. The remaining normal pulmonary circulation is diminished leading to increase in pulmonary artery and right heart pressures. Most patients have evidence of PAH during pressure measurements, and show enlarged central pulmonary arteries on chest radiographs and CT with pruning of the peripheral arterial branches. Conventional PA often demonstrates multiple segmental and lobar perfusion deficits consistent with infarcts. Pulmonary artery dilatation and pruning of the peripheral pulmonary arterial branches, irregularities, webs, and stenoses can be seen. Residual linear filling defects resulting from recanalization of prior thrombus can also be seen.

TREATMENT AND PROGNOSIS

Chronic pulmonary emboli do not respond to medical treatment and require surgical thromboembolectomy in most cases. Anticoagulation, however, is still required to prevent further showering of emboli, especially in patients who are clinically unstable. IVC filters are also used for the same purpose.

PULMONARY ARTERY THROMBOSIS

Thrombosis of the main pulmonary artery and its branches can occur in association with parenchymal lung disease, congenital heart disease, thoracic trauma, or because of systemic diseases such as polycythemia vera or sickle cell disease.

On pulmonary arteriograms, the involved vessel will be occluded, yet without the leading edge sign of an embolus. There is usually no peripheral filling beyond the thrombus suggesting intrinsic thrombosis rather than an ill-fitting embolus.

PULMONARY ARTERY ANEURYSM AND PSEUDOANEURYSM

CLINICAL PRESENTATION AND CONSIDERATION

Pulmonary arterial aneurysms are uncommon compared to aneurysms in the systemic circulation. True aneurysms may be congenital or acquired, and PAH plays an

important role in its pathogenesis and formation. Pulmonary artery pseudoaneurysms may be iatrogenic, infectious, or traumatic in etiology. Other less common etiologies include vasculitis, syphilis, tuberculosis (Rasmussen aneurysm), bilharziasis, neoplasms, mycotic emboli, and connective tissue disorders. Patients with pulmonary artery aneurysms or pseudoaneurysms are usually asymptomatic or present with symptoms of their underlying illness. Massive hemoptysis is a common presenting symptom in patients with acute aneurysm rupture and can be life threatening.

In the vasculitis category, Behçet is a landmark. It is a multisystem disease most often seen in men of Mediterranean and Southeast Asian descent who present with oral and genital ulcers, skin lesions, orbital and CNS inflammatory changes, and GI inflammatory symptoms. Hughes-Stovin syndrome is a less well-known cause of pulmonary artery aneurysm and recurrent thrombophlebitis. Iatrogenic perforation of the pulmonary artery during placement of Swan-Ganz catheter is a frequent cause of pulmonary arterial pseudoaneurysms. Conventional PA is both diagnostic and therapeutic in cases of pulmonary aneurysms and pseudoaneurysms.

IMAGING FEATURES

Pulmonary artery aneurysm is easily recognized on both contrast-enhanced CT and PA. Infectious causes including disseminated bacterial infections and tuberculosis tend to be multiple and often peripherally distributed. Syphilitic and vasculitic pseudoaneurysms tend to be more centrally distributed.

TREATMENT AND PROGNOSIS

The treatment for pulmonary artery aneurysm and pseudoaneurysm involves coiling of the lesion itself or the artery feeding the lesion. Pseudoaneurysms are less easily handled since the fragile pseudoaneurysm is prone to rupture during manipulations and coil placement. Ideally, the feeding pulmonary artery should be embolized with coils or Amplatzer vascular plugs.

In certain cases, coils may be gently deployed inside the cavity of the pseudoaneurysm. Even with modern endovascular treatment modalities, the prognosis is often poor owing to the patient's multiple underlying conditions and illnesses.

PULMONARY ARTERIOVENOUS MALFORMATION

CLINICAL PRESENTATION AND CONSIDERATION

Pulmonary arteriovenous malformations (PAVM) are abnormal communications between the pulmonary arteries and veins without intervening capillaries. They

are considered functional extracardiac shunts with blood flowing from the right to left heart without oxygenation or filtration in the lungs. They can occur either as isolated entities or in association with Osler-Weber-Rendu syndrome (otherwise known as hereditary hemorrhagic telangiectasia). In Osler-Weber-Rendu syndrome, patients have arteriovenous malformations in the GI tract, liver, and CNS. Approximately 5% to 15% of Osler-Weber-Rendu syndrome patients have PAVM, while 50% to 60% of patients with PAVM have Rendu-Osler-Weber syndrome. PAVM are multiple in 30% to 50% and bilateral in 30% of cases.

These patients often present primarily with hemoptysis. The resulting right-to-left shunt can cause serious complications related to systemic embolization, such as stroke, transient ischemic attack, and cerebral abscess, reported in up to 40% of patients.

PAVM are classified according to their angioarchitecture as simple and complex. The simple malformations are recognized to have a single segmental artery feeder and include up to three subsegmental arteries. Complex PAVM by definition have two or more different segmental arteries supplying the malformation. Approximately 80% of PAVM are simple and the malformations are usually located in the lower lobes.

IMAGING FEATURES

Contrast-enhanced CT is the preferred imaging modality for PAVM because of its ability to visualize small peripheral lesions. Both lungs should be studied to ensure that small AVM are not missed. PAVM typically appear as multilobulated intensely enhancing masses, with large vessels extending from the mass to the hilum, representing enlarged feeding arteries and draining veins. Volume-rendered three-dimensional reformatted images and multiplanar reformatted images are helpful in planning for percutaneous transcatheter embolization. It must be emphasized that great care should be taken during insertion of intravenous lines and during contrast administration, to avoid introduction of air bubbles.

PA is usually performed to confirm the diagnosis and when percutaneous transcatheter embolotherapy is indicated. Because of the right-to-left shunt, PA in patients suspected with PAVM must be performed with extra care. Careful attention must be paid to the technique to ensure no air embolus will occur. Similar attention should be paid to intravenous line insertion, and the use of filters in these lines is highly recommended. Heparin is often required to prevent thrombus formations around the catheters and guidewires. Pulmonary angiograms will demonstrate enlargement of the feeding artery, with early shunting of contrast during the arterial phase into an enlarged draining vein through an aneurysmal sac. Pulmonary angiogram has the advantage of delineating

the angioarchitecture of the PAVM and the feeding arteries. The size of the feeding artery should be measured since PAVM with feeding artery diameter of more than 3 mm should be treated to avoid paradoxical systemic embolization.

TREATMENT AND PROGNOSIS

In the last decade, percutaneous transcatheter embolotherapy has become the mainstay for most patients with PAVM. Its advantages are that it is less invasive, can be easily repeated in case of recurrence, and a variety of materials are available for embolization. Significant improvements have occurred in catheter techniques, making interventional management simpler and safer. Detachable balloons are historical and were abandoned because of the risk of deflation and paradoxical embolization. Fibered coils are currently used and their diameter should be at least 20% larger than the feeding artery, to avoid paradoxical embolization. The scaffold and anchoring techniques, during placement of coils, have been described in literature to avoid coil embolization into the systemic circulation. More recently, the Amplatzer vascular plug has been used for the treatment of PAVM. The Amplatzer vascular plug is a detachable self-expandable cylindrical device made from a nitinol wire mesh that allows the device to compress inside a delivery catheter and then return to its intended shape to occlude the target vessel. It is recommended to oversize the device by approximately 30% to 50% of the feeding artery diameter to prevent device migration after deployment. The limitation of the Amplatzer vascular plug device is that it requires distal placement of a 5F to 8F guiding catheter, depending on the diameter of the feeding artery to be occluded, which can be technically challenging. Also, the delivery wire of the Amplatzer vascular plug is quite stiff and maneuvering it through tortuous anatomy may be slightly difficult. Recurrence is secondary to recanalization of occluded vessels or interval growth of accessory vessels. Recurrence rates range from 5% to 57%. Recanalization is the most common cause of recurrence, accounting for approximately 90% of recurrent cases. CTA is an excellent modality for follow-up of patients after embolotherapy to evaluate for recurrence. Some patients may need repeat sessions of embolization.

PULMONARY VARIX

Pulmonary varices are focal dilatations of the pulmonary veins that may occur in association with congenital and acquired heart disease or in asymptomatic patients without cardiac abnormality. These lesions are seen as well-defined enhancing structures on CT in

relation to a vessel, and frequently produce a diagnostic dilemma since they have a similar appearance to PAVM. However on pulmonary angiograms, the varix shows delayed-contrast filling on the pulmonary venous phase as opposed to early shunting and venous filling in PAVM.

PULMONARY ARTERY STENOSIS

Pulmonary artery stenosis (PAS) is usually a disease of children and usually associated with congenital heart disease. Children with pulmonary arterial stenosis typically present with dyspnea, fatigue, tachypnea, or tachycardia. In adults, PAS is rare, and vasculitis is the most common etiology. Other causes include chronic PE, post-lung transplant, and extrinsic compression by masses, granulomatous disease, adenopathy, fibrosing mediastinitis, or other intrathoracic processes.

PAS is easily diagnosed with a contrast-enhanced CT of the chest. The main, right, or left pulmonary artery may be small. Conventional PA is rarely required for the diagnosis of PAS, except for documentation of peripheral disease beyond the resolution of axial imaging.

The management of PAS includes angioplasty with possible stent placement or surgery, depending on the anatomy and location of stenosis. Angioplasty is sometimes preferred over stent placement, especially in children where potential mismatch between the deployed stent and the size of the stenosed artery after somatic growth is a concern. Generally the prognosis depends on the underlying congenital heart disease and other associated conditions.

VASCULITIS

CLINICAL PRESENTATION AND CONSIDERATION

Takayasu arteritis is systemic vasculitis affecting large and medium-sized arteries, most commonly involving the aorta and its proximal branches. Pulmonary arterial involvement can occur mostly in the form of arterial occlusion, stenosis, and aneurysm formations. These patients are typically middle-aged women of all racial backgrounds, although it was initially described in Japanese women. Common presenting symptoms can be nonspecific, such as fever, fatigue, and weight loss, or specific symptoms relating to the distribution of the arteries involved. Patients can present with light-headedness or loss of vision because of involvement of the carotid arteries, arm weakness because of involvement of the subclavian arteries, or hypertension because of involvement of the renal arteries. A classic symptom, which gives rise to a more common name of Takayasu arteritis, is “pulseless disease” that is due to subclavian artery occlusions.

IMAGING FEATURES

During PA, pulmonary arterial involvement ranges from stenosis to complete occlusion, although aneurysmal dilatation can also occur. There is no predilection for any side or lobe involvement, and there is no correlation between pulmonary arterial disease and systemic disease. A characteristic feature of active Takayasu’s arteritis is wall enhancement on CT and MRI examinations following administration of contrast.

TREATMENT AND PROGNOSIS

The mainstay of treatment for Takayasu’s arteritis is to control the systemic inflammatory changes using steroids and immunosuppressive drugs. Complications of the disease can be managed as they arise. Long-term prognosis is not known.

HEMOPTYSIS AND BRONCHIAL ARTERY EMBOLIZATION

CLINICAL PRESENTATION AND CONSIDERATION

Mild-to-moderate hemoptysis usually requires only clinical monitoring. Massive hemoptysis, defined as more than 300 to 600 mL in 24 hours, generally requires treatment. In most cases, severe hemoptysis results from a systemic arterial source, rather than from the pulmonary circulation. The most common causes of hemoptysis requiring therapy include cystic fibrosis, bronchiectasis, infections such as tuberculosis, and bronchogenic carcinoma.

Significant bleeding from pulmonary arterial origin is quite rare, usually associated with systemic arterial source, and is commonly seen in cases of destructive pulmonary parenchymal lesions. Examples of such lesions include cavitory tuberculosis, invasive aspergillosis, pyogenic abscesses, and large necrotic tumors. However, it may also occur in case of pseudoaneurysms of various etiologies and in case of PAVM.

CT studies are helpful in determining the probable site of bleeding. Bronchoscopy may show the site of bleeding, especially when performed early in management, and may guide selective intrabronchial balloon tamponade. However, in most cases, bronchoscopy provides no additional information over radiographic studies and should only be reserved for patients in whom radiographic studies failed to localize the site of bleeding. Selective intubation or double-barrel endotracheal tube may be necessary to protect the non-bleeding lung.

IMAGING FEATURES

Bronchial angiography is performed for patients with massive hemoptysis or hemoptysis requiring therapy, as it can be both diagnostic and therapeutic. The

technique of bronchial angiography is described earlier in this chapter. The bronchial artery supplying the source of hemoptysis is usually hypertrophied and tortuous, measuring more than 3 mm. Other angiographic signs suggestive of bronchial arterial source are parenchymal staining, hypervascularity, bronchial-pulmonary shunting, and bronchial artery aneurysms. An important feature that differentiates hemoptysis from acute gastrointestinal hemorrhage is that hemoptysis rarely demonstrates contrast extravasation on bronchial angiograms even if massive or clinically apparent. Collateral pathways to the bronchial arteries from the internal mammary, intercostals, and branches of the subclavian arteries should be clearly delineated, as they can be the source of bleeding in some cases. Pulmonary angiograms are performed if no source is found on bronchial angiogram, and there is strong evidence for pulmonary arterial cause such as pseudoaneurysm or PAVM.

TREATMENT AND PROGNOSIS

The treatment of choice for hemoptysis is embolization. Before embolizing the bronchial artery culprit, a careful search for collateral pathways between the bronchial artery and the anterior spinal artery must be performed. If there is a collateral pathway, extra care must be taken so that spinal cord infarction can be avoided. This is done by superselective catheterization of the bronchial artery using a microcatheter and placing the microcatheter as distal as possible within the artery before injection of embolic material. Spinal cord infarction is a rare complication in the hands of an experienced interventionalist; however, it is a potential significant risk that patients should be aware of and accept prior to performing the procedure. Another potential complication of bronchial angiogram is transverse myelitis manifesting with paraplegia. This is also a rare complication (less than 1%) and the cause is unknown.

Embolization of the bronchial artery is usually accomplished with polyvinyl alcohol (300–900 μm) or Gelfoam pledgets. This is delivered as distal as possible, preferably through a microcatheter. Coils can be used very distally, but not at the orifice of the bronchial artery since it may need to be accessed again in cases of recurrent hemorrhage. If the bronchial artery gives collateral branches to the spinal artery or other critical branches to the trachea and esophagus, embolization should be performed distal to these arteries and using particle size that is essentially larger than 250 μm to prevent nontarget embolization of these critical branches. Follow-up angiograms are performed intermittently during embolization to determine the progress and search for any complication.

The prognosis for patients undergoing bronchial artery embolization is generally good. Complications such as spinal cord infarction, pulmonary infarction, tracheal and esophageal necrosis are rare. Surgically, therapy is considered if bronchial artery embolization is ineffective. In some patients in whom bronchial artery embolization is used to control acute massive hemorrhage, definitive surgical therapy may be necessary to correct the underlying abnormality.

PULMONARY ARTERY TUMORS AND ENDOVASCULAR PULMONARY ARTERY CATHETER-BASED BIOPSY

Primary pulmonary artery tumors are very rare, accounting for less than 15% of thoracic tumors. The most common are sarcomatous tumors, such as leiomyosarcoma and spindle cell sarcoma. Primary tumors commonly have a central location; however multifocal tumors can also occur. Secondary tumors are mostly because of invasion of the pulmonary artery by mediastinal and lung tumors, with bronchogenic carcinoma being the most common.

CT and MRI can clearly demonstrate the tumor and suggest whether it is primary or secondary. Both can show the extent of obstruction of the pulmonary artery lumen. However, the most important aspect of CT and MRI is their ability to distinguish these enhancing tumors from a nonenhancing thrombus. During angiography, pulmonary artery tumors are seen as filling defects in the main pulmonary artery or its branches. Endovascular biopsy of these tumors can be performed using various devices that were originally used for ventricular biopsy, but can also be used in the pulmonary arteries. Forceps are commonly used and can remove a tissue sample of 2 to 5 mL depending on the forceps caliber.

FOREIGN BODY RETRIEVAL

Percutaneous retrieval of intravascular foreign bodies has become the standard of treatment. The majority of cases are due to separated catheter fragment or lost wires during catheter insertion by inexperienced personnel. Foreign bodies may lodge in the SVC, right heart, or pulmonary circulation. Retrieval is usually accomplished using a variety of snares; the most famous and commonly used is the gooseneck snare. Other devices that can be used include a retrieval basket, pigtail catheter and tip-deflecting wire, and grasping forceps. If the foreign body migrates to the distal pulmonary artery, a pigtail catheter may be used to dislodge it into a more proximal position where it can be snared.

QUESTIONS AND ANSWERS

- From which of the following arteries does the bronchial arteries most commonly arise?
 - Thoracic aorta
 - Pulmonary artery
 - Subclavian artery
 - Internal mammary artery

ANSWER: A. The bronchial arteries most commonly arise from the thoracic aorta—the most common pattern of bronchial arteries is two left and one right bronchial artery. They less likely arise from the subclavian, internal mammary, or intercostal arteries, and they are not branches of the pulmonary artery.

- Which of the following is an absolute contraindication to pulmonary angiography?
 - Systolic pressure more than 70 mm Hg and diastolic pressure more than 20 mm Hg
 - Congestive heart failure
 - LBBB
 - None. There is no absolute contraindication to PA.

ANSWER: D. There is no absolute contraindication to PA. Congestive heart failure, LBBB, and severe PAH are all relative contraindications to PA.

- Which of the following is the most specific sign of acute pulmonary embolus on any imaging modality?
 - Regional oligemia
 - Pulmonary arterial stenosis or web
 - Pulmonary infarction
 - Intraluminal filling defect

ANSWER: D. The most specific signs for pulmonary embolus in any imaging technique are intraluminal filling defects, abrupt arterial cutoff, or both.

- Which of the following is the most common cause of pulmonary pseudoaneurysm?
 - Congenital etiology
 - Iatrogenic
 - Neoplasms
 - Vasculitis

ANSWER: B. Most pulmonary arterial pseudoaneurysms are iatrogenic or traumatic in etiology. The other causes are less common.

- Which of the following is the typical clinical presentation of PAVM?
 - Cerebral abscess
 - Stroke
 - Pulmonary abscess
 - Hemoptysis

ANSWER: D. They can present with cerebral abscess and stroke because of right-to-left shunting, which bypasses the filter function of the lung. They almost never present with pulmonary abscess.

- Which of the following is the definition of PAH?
 - Increase right heart pressure
 - There are no accepted criteria—the condition is diagnosed by clinical symptoms
 - Mean pulmonary artery of more than 25 mm Hg during rest or more than 30 mm Hg during exercise
 - Systolic pressure of more than 70 mm Hg or diastolic pressure of more than 20 mm Hg

ANSWER: C. Choice D qualifies as severe PAH.

- Which of the following is the conventional treatment for PAVM?
 - Coils
 - Particles
 - Glue
 - Amplatzer vascular plug

ANSWER: A. Embolization cannot be performed using particles because of the risk of paradoxical

embolization. The Amplatzer vascular plug is an emerging treatment for PAVM. Glue is not used in the treatment of PAVM.

8. Which of the following is the definition of pulmonary varix?
- Focal dilatations of the pulmonary veins
 - Focal dilatation of pulmonary arteries
 - Abnormal communication between pulmonary artery and vein without an intervening capillary bed
 - Abnormal communication between pulmonary artery and bronchial artery

ANSWER: A. Focal dilatation of pulmonary arteries are pulmonary arterial aneurysms. Abnormal communication between pulmonary artery and vein without intervening capillaries are PAVM.

9. Which of the following is a specific imaging characteristic of Takayasu arteritis?
- Pulmonary arterial stenosis or occlusion
 - Wall enhancement on postcontrast CT and MRI
 - Aneurysmal dilatation of the pulmonary arteries
 - Multiple AVM

ANSWER: B. Takayasu arteritis typically occurs in middle-age women. There is no correlation between pulmonary arterial disease and systemic disease.

10. Which of the following are etiologies for hemoptysis that may require bronchial artery embolization?
- Cystic fibrosis
 - Bronchiectasis
 - Neoplasms
 - Infections
 - All of the above

ANSWER: E. All of the above are causes of massive hemoptysis requiring bronchial artery embolization. Cystic fibrosis is the most common cause.

der fluoroscopy or CT) to strengthen the bone and/or for pain relief.

Vertebroplasty has been performed for several decades as an open procedure to augment purchase for pedicle screws and to fill voids from tumor resection. PV was first performed in 1984 in France on a 54-year-old woman who had severe pain from an aggressive C2 hemangioma and her pain was permanently cured. PV was introduced to the United State in 1993.

According to the Osteoporosis Foundation, 10 million people have osteoporosis (Table 88-1), including 45% of white women older than 50 years. An estimated 700 000 osteoporosis-related vertebral compression fractures occur annually (which is higher than the incidence of hip fractures), resulting in 150 000 hospitalizations. Twenty-five percent of women aged 75 years and 50% of women aged 80 years have at least one fractured vertebra. With each osteoporotic vertebral compression fracture, there is a 9% loss in forced vital capacity and 23% increase in mortality.

Size of vertebral bodies varies in direct proportion to overall patient size. Volume of a cervical vertebral body in an average individual is about 7 mL for C5 and 23 mL for L3. Only half of this is fillable volume and with collapse, the volume decreases proportionately. Cement is injected into the intertrabecular spaces of the vertebral body avoiding the large para- and intervertebral veins, and even small volumes of cement can provide relief of symptoms.

Bone mass peaks at 30 years and remains without significant loss till advanced age or menopause. Axial load in the thoracic spine leads to fracture because of natural kyphotic curve in that region. In the cervical and lumbar spine, axial load leads to burst-type fracture. A vertebral compression fracture is defined as 20% or 4 mm reduction of individual vertebral body height. Vertebral compression fracture is generally anterior wedge compression since 75% of body weight is borne by anterior two-thirds of the spine. Posterior cortex is typically maintained in osteoporotic fractures. Single vertebral fracture is more common at any one presentation than multiple fractures. Most fractures are around T12-L1, T7, and T8 being next common location.

Edgar S. Underwood*

PERCUTANEOUS VERTEBROPLASTY

Percutaneous vertebroplasty (PV) is a minimally invasive procedure in which medical grade bone cement is injected into a severely osteolytic or already collapsed vertebra under image guidance (usually un-

Advanced age
Malnutrition
Malignant fracture

Rest, analgesics, and bracing are the mainstay of treatment for osteoporotic fractures. For persistently painful fracture, PV can be used. Certain types of fractures are more likely to be refractory to conventional treatment (Table 88-2). Indications for surgical treatment include cord compression with neurologic deficit, progressive deformity like kyphosis/scoliosis leading to pulmonary compromise, and progressive spinal deformity with imbalance. Relative indications for surgery include pain even after percutaneous therapy or cosmesis. Now even progressive deformity can be treated with vertebroplasty or kyphoplasty, with goals of treatment being pain relief and vertebral body stabilization.

Most vertebral compression fractures occur spontaneously (46%) or after only minimal trauma (36%). Because of lack of a clear history of trauma, correct diagnosis is made in only 43% of first visits to a physician. History and physical examination should be performed to correlate the location of pain and tenderness with the level of the compression fracture and to exclude the presence of focal neurologic deficit or myelopathy. Imaging is an essential part of the workup (Table 88-3). Conventional radiographs are often the first study and may show diffuse osteopenia and often multiple collapsed vertebrae of different ages. MRI is the single best evaluation option; it helps differentiate fractures of varying ages. Acute and subacute fractures less than 30-days-old show characteristic bone marrow edema pattern: hypointense on T1-weighted images and hyperintense on T2-weighted images and STIR sequences. There is a band of T2 hyperintensity adjacent to the frac-

ture endplate in approximately 50%. Additional subacute blood products may be seen in and around the endplate. Healed fractures may show normal marrow signal or can be hypointense on T1-weighted images and T2-weighted images because of sclerosis. If MRI is contraindicated, bone scintigraphy can also be used to differentiate acute from chronic fracture. MRI and bone scintigraphy also have prognostic value and patients with typical MRI findings of acute fracture or positive bone scan have excellent pain relief. CT can demonstrate extension of the fracture line to the endplates or posterior vertebral body, as this increases chances of cement leak and subsequent complications. Otherwise, CT may not be routinely done before percutaneous intervention.

Imaging may also help in differentiating osteoporotic from malignant collapse. In difficult cases tissue can be obtained for diagnosis through the cannula during the procedure. Other preprocedure routine laboratory studies include CBC, PT/INR/PTT. If there is plan to do a venogram prior to the procedure, BUN and serum creatinine levels are needed, although some do not consider it necessary given the small volume (3–5 cm³) of contrast. Preanesthetic workup is essential if general anesthesia is to be used, but this is rarely needed.

There are several indications for PV (Table 88-4), including painful osteoporotic vertebral compression fractures refractory to conventional medical therapy. This indication is also applicable for young patients with osteoporosis because of predisposing metabolic abnormalities such as prolonged steroid use, secondary to inflammatory bowel disease, rheumatoid arthritis, systemic lupus erythematosus, asthma, and prior transplantation. Failure of medical therapy is defined as minimal or no pain relief with administration of physician prescribed analgesics or achievement of adequate pain relief only with narcotic dosage that induces excessive and intolerable sedation, confusion, or constipation. At least 2 weeks of conservative treatment is tried before consideration as medical failure. Best results are obtained

Bony collapse

when vertebroplasty is not delayed beyond 6 months. After this period the efficacy of the procedure in relieving pain decreases. However, there have been reports of intervention after several years of vertebral fracture with good clinical outcome, especially if MRI or bone scan is positive.

Fracture or severe osteolysis from painful metastasis or multiple myeloma with or without adjuvant radiation or surgical therapy is another indication for intervention. Although, there is a theoretical possibility of the injected cement dislodging tumor cells into the vertebral venous system promoting metastasis, there are no reports of this. Because of this theoretical risk, vertebroplasty should be performed after radiation therapy. There are no studies on efficacy of vertebroplasty before or after radiation therapy. Maximal doses of therapeutic radiation do not have an impact on the mechanical or chemical properties of bone cement.

Fracture or severe osteolysis caused by painful benign tumors like vertebral body hemangiomas unresponsive to conservative treatment is a third indication for PV. With aggressive lesions with destruction of the posterior cortex, there is increased risk of cement leak. Eosinophilic granuloma, fibrous dysplasia, and vertebral hemangioma weaken the vertebral body and hence may benefit from PV, hemangioma being the most common benign indication (Tables 88-5 and 88-6). Osteoid osteoma and aneurysmal bone cyst do not need structural reinforcement and hence are not indications for PV.

TABLE 88-6 Indications for Percutaneous Vertebroplasty for Hemangioma

CLINICAL AND RADIOGRAPHIC FINDINGS	VERTEBROPLASTY
Asymptomatic without radiologic signs of aggressiveness	Not indicated
Severe back pain without radiologic signs of aggressiveness	Indicated
Asymptomatic with radiologic signs of aggressiveness	Periodic follow-up; indicated if follow-up not possible
Symptomatic with radiologic signs of aggressiveness (epidural extension or severe pain)	Indicated

TABLE 88-7 Patient Criteria for Vertebroplasty (Must Meet All)

Focused pain in region of fracture
Tenderness on palpation
Absence of radicular pain or cord compression
Acute or subacute fractures less than 1-y-old; older fractures up to 2 y can also be treated in select cases with positive MRI or bone scan indicating incomplete healing
Fracture unresponsive to medical therapy (analgesics, bed rest, immobilization)
Fracture with activity on bone scan or edema on MRI
Pain from fracture negatively impacting mobility and other day-to-day activities

Specific clinical criteria must be met if percutaneous intervention is to be performed (Table 88-7).

There are several absolute contraindications to PV (Table 88-8). Radicular pain or radiculopathy caused by a compressive syndrome unrelated to vertebral body collapse is a relative contraindication. This type of pain is generally not caused by an uncomplicated compression fracture and warrants a thorough search for the cause of pain before attempting vertebroplasty. Retropulsed fragment with greater than 30% spinal canal compromise is also a relative contraindication. Cement injection in such cases can further push the fragments backward and aggravate the cord or root compression; however, this has been done carefully with good results. Tumor extension into epidural space with significant spinal canal compromise is not very amenable to treatment unless accompanied by planned surgical decompression of the spinal canal. Another relative contraindication includes severe vertebral body collapse greater than 80% to 90% (vertebra plana), although a small series of patients with 65% to 70% vertebral body collapse in the lower thoracic/upper lumbar level were treated using the bilateral transpedicular approach with partial or complete pain relief in almost all patients. However, incidence of cement leak was substantial, luckily without any consequence. Stable fractures that do not

TABLE 88-8 Contraindications

Absolute contraindications
Asymptomatic stable fracture
Healed fracture
Patient clearly improving on medical therapy
Prophylaxis in osteopenic patients with no evidence of acute fracture. Currently there is no role for prophylactic vertebroplasty for osteoporotic vertebrae at high risk for collapse
Osteomyelitis of target vertebra
Presence of discitis, epidural abscess, or sepsis
Untreated coagulopathy/hemorrhagic diathesis
Acute traumatic fracture of healthy vertebra
Allergy to any required component

cause pain, fractures greater than 1 year old, and osteoblastic metastasis are also relative contraindications.

The mechanism by which PV relieves pain is not well understood and is at present mostly hypothetical. It is thought that mechanical stabilization of the vertebral body reduces micromotions between the fractured fragments and reduces nerve fiber irritation. Additionally, mechanical injury to tumor tissue, chemical cytotoxic effects of methylmethacrylate (MMA) monomer, and thermal damage to the pain nerve fibers may also contribute to pain relief. The volume of cement needed for PV is much less than the vertebral body volume; as little as 2 to 3 mL of cement in the thoracic and 3 to 5 mL in the lumbar region can provide moderate-to-complete pain relief in most individuals. Stiffness and strength are two important mechanical parameters. The former is associated with pain relief and the latter reduces tendency to refracture. Injection of the appropriate volume of cement is more important than unipedicular versus bipedicular injections. Vertebroplasty generally does not result in significant height restoration, only about 1 or 2 mm, the upper limit being obtained by hyperextending the spinal segment during the procedure. For height restoration, inflatable balloons (kyphoplasty) are used.

EQUIPMENT

PV can be performed under fluoroscopic or CT guidance, the former is the most common. CT is useful especially for severely osteoporotic patients with limited visualization of the bony landmarks, in cases where pedicles are destroyed beyond recognition, in patients with short pedicles (many have advocated biplane fluoroscopy in all above circumstances). In treatment of cervical, high thoracic vertebrae and sacrum, CT is preferred over fluoroscopy. While CT gives good contrast resolution, drawbacks of CT include lack of real-time needle guidance. Single fixed plane fluoroscopy is inadequate; single plane or biplane C-arm fluoroscopy is required.

Needles used for PV are the same ones as those for bone biopsy. They have 11-G trocar and cannula system. Thinner 13-G needles can be used if pedicles are thin. Needles are usually 10 cm long, but if patient is large, a

15-cm needle is recommended. If concomitant bone biopsy is contemplated, a 17-G needle is used. They all have fixed handles that can be introduced by direct hand pressure or by tapping with a mallet.

Ideally, cement should have following properties: easy handling, injectability, high radiopacity, adapted viscosity, nontoxic, nonclotting, and have a relatively long setting time (approximately 15 minutes). Polymethylmethacrylate (PMMA) cements are the most widely used. Many FDA-approved cements are available for PV and kyphoplasty. Barium sulphate is the most common radiopaque agent and added 20% to 30% by weight. Zirconium dioxide, strontium carbonate, and other metals (titanium, tantalum, and tungsten) can also be used as radio-opacifiers.

All patients are routinely given IV antibiotics 30 minutes before the procedure. Adding antibiotics to the cement mixture is disputed. Although it is routinely used in orthopedic cements, infection in PV is far less common, and routine use is justified only in immunocompromised patients. Tobramycin or vancomycin are typically added to the cement mixture in such cases but may adversely affect cement-handling properties.

PV and kyphoplasty are usually performed as outpatient procedures. Conscious sedation administered by a trained nurse is usually sufficient for the procedure. Local anesthesia is also used using lidocaine mixed with 1% sodium bicarbonate liberally and skin, subcutaneous tissue, muscles, as well as the periosteum are infiltrated. General anesthesia is limited to patients who cannot lie flat or prone and agitated patients who cannot lie still. Patients who cannot lie prone can sometimes be managed by lateral positioning with as much prone tilt as possible.

There are several approaches for vertebroplasty (Table 88-9), but transpedicular route is the most common. Most occur from T6 to L5 and pedicles in these regions provide an adequate route. Osteoporotic fractures generally do not involve the cervical spine and most cervical vertebroplasties are done for tumor.

There are several fundamental principles of cement deposition:

- Complete coverage of a vertebral body by cement is not necessary for a good clinical outcome.

TABLE 88-9 Approaches for Percutaneous Vertebroplasty

Cervical	Anterolateral	Lateral approach is not used to avoid injury to the vertebral artery. C2 approach should be behind the angle of mandible. Transoral route is avoided for fear of bacterial contamination
Thoracic	Transpedicular (first choice) or parapedicular (costovertebral)	Transpedicular route can be used from T6 inferiorly. In upper thoracic level, anterolateral or parapedicular approach is used similar to cervical. The costovertebral route can be used if pedicles are absent, not visualized because of severe osteoporosis, or destroyed by tumor
Lumbar	Transpedicular*	
Sacral	Posterior oblique†	

*Transpedicular is the safest approach here.

†Posterior oblique approach is necessitated by sacral anatomy.

- There should be cement in both halves of the vertebral body. In practice however, any cement across the midline is usually sufficient.
- Once cement is distributed across the midline, there is no improvement in clinical outcome in using a bipedicular approach.
- Avoid cement accumulation at the posterior margin of the vertebral body.
- A small amount of cement extravasation into the disc space is frequently unavoidable and is usually asymptomatic.
- Cement extravasation into the disc space theoretically increases the chances of fracture of the adjacent vertebra and hence disc space extravasation should be minimized.
- Cement extravasation into the adjacent perivertebral venous plexus is often inevitable but injection must stop at this point at least temporarily so that a cement embolus is not produced.

Patients are usually monitored for up to 2 hours postprocedure. After this the patient can bear weight with assistance and can be discharged home. Oral analgesics should be satisfactory for pain in the postprocedure pain. If there is severe pain, radiating pain, numbness, bowel bladder dysfunction CT scan should be advised to exclude cement leak and cord or root compression. If there is severe dyspnea, CT angiography or ventilation–perfusion scan of the lungs is recommended to evaluate for pulmonary embolism.

When performed by experienced operators, complication rate is usually low and is around 1% to 3% for osteoporotic fractures, while complication rate for malignant fractures is higher at approximately 7% to 10%. Most significant complications occur from cement leakage, although most leakage is asymptomatic. Other complications most commonly include transient back pain, soreness, and fever. These usually responds well to nonsteroidal anti-inflammatory agents and resolve within 24 hours. Infection is extremely rare, but vertebral osteomyelitis following vertebroplasty or kyphoplasty has high mortality in elderly patients and requires surgical corpectomy and weeks of intravenous antibiotics. Cement or marrow fat emboli can form during PV but are generally asymptomatic because emboli are small. In patients with poor pulmonary reserve, this can result in respiratory compromise. Stroke can occur in patients with right-to-left shunts. Visualization of perivertebral venous plexus is very common during PV and is not a matter of deep concern but rather caution. Injection should be suspended momentarily for cement to solidify. Cord nerve compression is more common following treatment of pathologic fractures resulting from metastasis. Radicular pain caused by cement compression usually responds to analgesics with local

steroid and anesthetic injections. Motor deficits like bowel or bladder dysfunction, which are caused by large volume leaks should prompt immediate CT scan and surgical consult. Pneumothorax is a complication that can occur with procedures at the thoracic level. Death occurs in 1:50000 cases of vertebroplasty or kyphoplasty. It is either caused by severe allergic reaction to bone cement or pulmonary embolism by fat or cement. The risk increases with the number of vertebrae treated at each session. It is prudent not to treat more than three vertebrae in a single session. There have been no reports of true cement failure but two cases of fracture progression, which were because of inadequate cement filling. Cement increases the stiffness of the vertebral body. Earlier reports indicated increased risk of fractures around the treated vertebral body. But later, investigators have refuted this claim. It appears that the same osteoporotic mechanism, which caused collapse of the previous vertebrae, causes collapse of the adjacent vertebra also. However, some controversy still remains.

Pain relief is often immediate but may take 72 hours. In most studies approximately 80% to 90% patients with age-related or steroid-induced osteoporosis experience excellent pain relief. Pain relief is less dramatic with malignant fractures, although at least one-half of patients experience some degree of relief. For optimum outcome, further bone loss should be minimized. Also, modifications in lifestyle are advocated to prevent excess mechanical stress on the spine and further fractures.

KYPHOPLASTY

Vertebroplasty only addresses pain and stability of the vertebral body but does not affect the spinal deformity associated with vertebral compression fracture. Also, cement leak remains a problem. It was thought that if a cavity could be created within the vertebral body and cement was injected into it, cement leak could be reduced. Kyphoplasty (balloon-assisted vertebroplasty) was conceived to address these problems.

Kyphoplasty is a recent modification of vertebroplasty in which usually two balloons are inflated within the vertebral body and a space is created into which cement injection is performed. Indications include the following:

- Spinal canal stenosis because of vertebral body collapse in which height restoration may potentially relieve the symptoms of stenosis.
- Traumatic fracture in which repositioning of the endplate is attempted.
- Difficult vertebroplasties for tumorous indications in which creation of an intravertebral cavity may help in cement injection.

TABLE 88-10 Kyphoplasty Versus Vertebroplasty

Greater restoration of height of the vertebral body
Injection of a more viscous cement
Decreased incidence of extravasation
Lower risk of recurrent fracture

Contraindications for kyphoplasty are usually the same as for vertebroplasty and include extreme vertebral collapse (vertebra plana) in which the superior endplate is below the level of pedicles making it technically difficult/unsuitable for kyphoplasty and carrying the risk of segmental artery injury.

A transpedicular route is used from T10 to L5 level. In the thoracic vertebral bodies from T9 and above the pedicles are narrow and laterally directed, hence an extrapedicular approach is used. Using the posterolateral technique, only one balloon can be placed within the vertebral body but less height is finally achieved than with the double balloon technique. Kyphoplasty is rarely done in the cervical vertebrae, but there are reports of kyphoplasty in the lower cervical vertebrae using an anterolateral approach.

Kyphoplasty can be performed in both acute, 1- to 2-week-old, and chronic fractures. According to some authors, the percentage of height restoration is nearly 100% when fractures are treated within the first 2 weeks. After this the fracture reduction is less predictable. There is considerable controversy as to the definite benefits of kyphoplasty over vertebroplasty (Table 88-10).

Kyphoplasty is more costly and complex than vertebroplasty. Additionally, kyphoplasty is often performed in the operating room with general anesthesia. The patients are commonly kept overnight in the hospital. Thus, total cost of kyphoplasty is approximately 10 to 20 times more than vertebroplasty. Additionally, there is no objective evidence that it is safer or more effective for pain relief.

LORDOPLASTY

A limitation of kyphoplasty is the loss of correction when the balloons are deflated before injection of cement. Lordoplasty is another technique to restore vertebral height by indirect fracture reduction as with an internal fixateur. The fractured and the adjacent vertebrae are cannulated bipedicularly and the adjacent vertebrae are augmented with cement. After injecting cement, the fractured vertebra is reduced by applying a lordotic moment via the cannulas. The pretension is maintained by connecting the cannulae with a bar or fixation clamps, and the fractured vertebra is reinforced with cement in a manner similar to vertebroplasty. Only after the cement has set, are the connections between the cannulas released. Thus, in

lordoplasty in addition to the fractured vertebra, the adjacent vertebrae are also augmented with cement. Lordoplasty can be performed along with kyphoplasty.

SACROPLASTY

Sacral insufficiency fractures can be caused by osteoporosis or by tumor. Patients often complain of low back or buttock pain. Because of the nonspecific nature of symptoms, they are often misdiagnosed or have delayed diagnosis. Conventional imaging is often nondiagnostic, but CT and MRI are excellent. Traditional treatment has been rest and narcotic analgesics. Sacroplasty, analogous to vertebroplasty, was developed to address this use of only fluoroscopy is not optimal as it is often difficult to visualize the sacrum and the fracture precisely resulting in improper needle placement. Likewise, using conventional CT is risky as there is no real-time guidance during actual cement injection, raising the risk of cement extravasation into sacral foramina and nerves and vessels therein. The procedure is best done under CT-fluoroscopy, or if CT is used for used for needle placement, fluoroscopy should be used for cement injection.

QUESTIONS AND ANSWERS

1. What is the most common indication for percutaneous vertebroplasty?

A. Osteoporosis
B. Metastasis
C. Vertebral body hemangioma
D. Multiple myeloma

ANSWER: A. Osteoporosis is by far the most common and most important indication for percutaneous vertebroplasty. It is an important treatment option for pain from osteoporotic fractures resistant to conservative treatment like bracing, rest, and moderate doses of narcotic analgesia. It is not done prophylactically to prevent osteoporotic collapse.

2. Bone cement may contain all *except*:

A. PMMA
B. Barium sulphate
C. Zirconium dioxide
D. Powered Iron

ANSWER: D. PMMA is polymethylmethacrylate. It is supplied in powder form and is mixed with liquid methyl methacrylate (MMA) monomer. It has doughlike consistency and is very biocompatible. But MMA is a tissue irritant. PMMA has a setting time of 15 to 20 minutes. PMMA cements have low intrinsic radiopacity, so exogenous substances are added. The most common is barium sulphate. Others are zirconium dioxide (has minimum interference on properties of cement), strontium carbonate, tantalum, tungsten, and titanium. Iron is not used and would be incompatible with MRI.

3. What percentage of patients will experience, in the near term, pain relief after vertebroplasty for acute osteoporotic fractures?

A. 10%–20%
B. 50%–60%
C. 80%–90%
D. Erratic

ANSWER: C. Approximately 80% to 90% patients with acute osteoporotic fractures experience pain relief after vertebroplasty. Pain relief is slightly less in patients with fractures from malignant disease and other causes (approximately 50% to 80%). Pain relief in hemangioma is higher than metastatic fractures but less than osteoporotic fractures.

4. What is the approach used for vertebroplasty of the cervical spine?

A. Transpedicular
B. Interspinous

C. Lateral
D. Anterolateral

ANSWER: D. In the cervical and sometimes upper thoracic vertebra, the best approach is anterolateral. The transpedicular is used from T6 to L5. Lateral approach is not used in cervical spine to avoid injury to vertebral vessels. Interspinous approach is never used at any level.

5. What is the single best preprocedure evaluation for vertebroplasty of osteoporotic collapse?

A. CT
B. DEXA
C. MRI
D. Bone scan

ANSWER: C. MRI is the single best modality of investigation, as it can differentiate between acute and chronic fractures. This is important because acute fractures respond best to vertebroplasty. Also, it aids in diagnosing other causes of back pain. A bone scan can be performed in patients in whom MRI is contraindicated. It can also differentiate acute from chronic fractures. CT should be used when there is a suspicion of posterior cortex breach or to evaluate complex fractures. Irrespective of these advanced tests, all patients should have frontal and lateral radiography of the spine.

6. What is the best modality to direct sacroplasty?

A. CT
B. MRI
C. Fluoroscopy
D. CT-fluoroscopy

ANSWER: D. Use of fluoroscopy alone is not optimal as it is often difficult to visualize the sacral fracture precisely, resulting in improper needle placement. Likewise using conventional CT is risky as there is no real-time guidance during actual cement injection. The procedure is best done under CT-fluoroscopy. MRI is not typically used.

89 PRINCIPLES OF TUMOR ABLATION

*Clinton R. Smith and
Edgar S. Underwood*

INTRODUCTION

Numerous advances have occurred in the oncologic application of interventional radiology techniques. Catheter-based therapies for primary and metastatic

neoplasms of the liver, as well as percutaneous imaging-guided chemical and thermal ablative therapies have seen growth and show promising results.

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide, related to the increasing number of patients with hepatitis B and C. It is an aggressive tumor, which frequently occurs in those patients who have developed cirrhosis, although it can occur in noncirrhotic livers as well. Hepatic resection and transplantation are the primary treatments in appropriately selected patients; however, a majority of patients are poor surgical candidates (because of medical comorbidities, limited hepatic reserve, or hepatic lesions too numerous or too large), and there are a limited number of organs available for transplant.

Metastasis to the liver from colorectal carcinoma and other neoplasms is also a significant clinical problem. Surgical resection is considered the treatment of choice for isolated hepatic metastasis. As with HCC, few patients meet criteria for resection.

Renal cell carcinoma (RCC) accounts for approximately 85% of renal tumors. Promising results have been demonstrated with radiofrequency ablation (RFA) and cryoablative therapies in patients who are poor candidates for nephron-sparing surgery. Percutaneous treatment of RCC is also proving beneficial in patients with hereditary syndromes such as von Hippel-Lindau, as well as nontraditional indications such as palliation and pain control, transfusion-dependent hematuria, post-biopsy bleeding, and transitional cell carcinoma.

Primary lung cancer is the most common cause of cancer death in the United States and accounts for approximately 29% of all cancer deaths. For early-stage non-small cell lung carcinoma, surgical resection is the treatment of choice. The lungs are the second most common organs for metastasis of solid organ malignancies. Minimally invasive percutaneous therapy has become an option in patients with primary or metastatic lung cancer who are not surgical candidates or have failed chemotherapy and external-beam radiation.

TRANSARTERIAL CHEMOEMBOLIZATION

HEPATOCELLULAR CARCINOMA

Only 30% to 40% of patients with HCC are candidates for curative therapy (resection, transplantation, or percutaneous ablation); therefore, most patients are only suitable for palliative or locoregional therapy. Improved survival (as compared to optimal supportive care) with chemoembolization has been shown in recent trials. This is related to the fact that approximately 80% of the

blood supply to HCC and liver metastases is derived from the hepatic artery. About three-fourths of blood supply to normal liver is portal venous. Therefore, therapeutic agents infused or injected directly into the hepatic artery preferentially target tumor rather than normal hepatic parenchyma.

The most commonly used chemotherapeutic agents are doxorubicin alone, or a mixture of doxorubicin, mitomycin C, and cisplatin. This cocktail is mixed with Lipiodol, an iodized ester derived from poppy seeds that acts as a carrier. This mixture is selectively taken up and retained by HCC and some metastatic liver lesions. With addition of embolic particles or gelatin foam as well as Lipiodol, arterial inflow is reduced, leading to decreased drug washout. Concentrations of chemotherapy drugs of up to 100 times that of systemic intravenous administration can be achieved.

A variety of embolic agents have been described in combination with the Lipiodol/chemotherapeutic cocktail (Gelfoam powder or pledgets, embospheres, starch and glass microspheres, and polyvinyl alcohol particles). Despite the tumor necrosis expected after particle embolization when combined with the cytotoxic effect of the chemotherapeutic agents, many tumors do not develop extensive necrosis. This raises the question of whether the embolization stimulates upregulation of certain molecular factors, which could inhibit cell death and stimulate vascular growth.

For unresectable HCC not amenable to percutaneous ablation (usually because of large size), transarterial chemotherapy (TACE) is currently the favored treatment. It is considered palliative, but can be an adjunctive therapy to resection or a bridge to transplantation or combined with ablation for palliation. However, many patients are not suitable candidates for TACE because of poor liver function. In patients with reduced hepatic reserve, this therapy may accelerate liver failure and negate the desired antitumoral effect or survival benefit.

Absolute contraindications include tumor resectability, severe hepatic disease (Child-Pugh, class C), and intractable infection. Relative contraindications include, but are not limited to, serum bilirubin more than 2 mg/dL, LDH more than 425 U/L, AST more than 100, tumor burden more than 50% of the liver, portal vein thrombosis, uncorrectable coagulopathy or thrombocytopenia, cardiac or renal insufficiency, ascites or recent variceal bleeding, poor performance status, extrahepatic metastases, encephalopathy, and extensive arteriovenous shunting through the tumor. Patients with functional compromise of the sphincter of Oddi (prior hepaticojunostomy, sphincterotomy, or biliary stent) are at increased risk of hepatic abscess after TACE.

The technique involves preprocedural care including hydration, broad-spectrum antibiotics, and antiemetics.

A prolonged arteriogram of the superior mesenteric artery evaluates for variant anatomy and portal vein patency. A celiac axis injection is then performed followed by selection of the desired hepatic artery branch.

The chemotherapeutic agent(s) with Lipiodol is then injected followed by an embolic agent. A chemotherapy-resistant (metallic) three-way stopcock is required. Embolization should occur beyond the gastroduodenal artery, and attention should be given to other regional arteries to avoid nontarget embolization, usually performed with distally placed microcatheters. However, if there are multiple tumors in one lobe, hepatic lobar chemoembolization can be performed. Whole liver chemoembolization should be avoided to reduce risk of severe liver injury.

Postprocedural care includes hospital admission with continued aggressive intravenous hydration, analgesia with PCA pump, antiemetics, and continued antibiotics. Patients are usually discharged within 2 days when pain is controlled and oral intake is sufficient. Some authors recommend continued outpatient antibiotics of up to 5 days.

Follow-up imaging and laboratory evaluations should be performed after at least 4 to 6 weeks and at 3-month intervals thereafter. Reduction in tumor size is the optimal result of any chemoembolization according to the World Health Organization and Response Evaluation Criteria in Solid Tumors (RECIST). Assessment of size alone may not be reliable because of initial increase in size from necrosis with edema and/or hemorrhage. In addition to contrast-enhanced CT, some authors recommend a perfusion-diffusion MRI to evaluate for free water content (indicating cell death). Also, MRI can overcome the limited ability to discern true enhancement versus retention of Lipiodol within the tumor on CT.

Complications from TACE include postembolization syndrome (pain, nausea, fatigue, fever, and/or leukocytosis), liver abscess, tumor rupture, irreversible liver failure, hepatorenal syndrome, septicemia and nontarget embolization including gallbladder infarction.

One recent meta-analysis found that no chemotherapeutic agent or combination of agents was significantly superior. Also, there is no evidence of benefit with Lipiodol. Gelatin foam is the most commonly used embolic agent, but polyvinyl alcohol may be better; bland transarterial embolization appears as good as transarterial chemoembolization for metastases but chemoembolization is better than bland for HCC.

Other variations of TACE include drug-eluting microspheres and radiation-emitting microspheres. The drug-eluting microspheres can be loaded with doxorubicin, and the sustained release over a longer period is potentially an advantage over standard TACE. ⁹⁰Yttrium-labeled microspheres are also available for treatment of HCC and liver metastases. For this treatment,

the gastroduodenal artery and sometimes other regional arteries are embolized to prevent reflux, which could cause severe radiation-induced gastrointestinal ulceration. Also, hepatopulmonary shunting must be excluded prior to administering the ⁹⁰Y-bearing spheres. This is done by an initial angiogram and ^{99m}Tc-labeled MAA injection followed by nuclear medicine lung scan to calculate a hepatopulmonary shunt fraction.

HEPATIC METASTASES

In similar fashion, liver metastases from colorectal carcinoma and neuroendocrine tumors can be embolized with or without chemotherapeutic agents. There is much less experience with TACE for colorectal carcinoma metastases than for HCC. Most trials for colorectal metastasis involve a surgically placed hepatic artery infusion pump, that is, infusional hepatic intraarterial chemotherapy. For neuroendocrine tumors, the benefit of TACE over bland transarterial embolization is not certain. One recent study suggests that adding chemotherapeutic agents to transarterial embolization is not beneficial in patients with carcinoid tumor, but does improve outcome in patients with islet cell tumors.

PERCUTANEOUS ETHANOL/ACETIC ACID INJECTION

ETHANOL

Percutaneous ethanol injection (PEI) is probably still the most widely used method for HCC tumor ablation worldwide. PEI is a highly effective, inexpensive, and easy-to-perform method for treatment of small HCC. PEI can easily be performed in areas of the world where HCC is endemic and health care resources are limited. Its mechanism involves small vessel thrombosis, denaturation of cellular proteins, and cytoplasmic dehydration. The resulting coagulative necrosis is not distinguishable from thermal ablation.

Chemical ablation works better for HCC than for liver metastatic disease. The ethanol injection into the tumor has a more uniform distribution for HCC ("soft" tumor in a "hard" cirrhotic liver). For metastatic disease, the ethanol distribution is less favorable (hard tumor in a soft normal liver). However, local recurrence is more common in tumors larger than 5 cm in diameter. As a result, PEI is not recommended for large lesions. Ideally, PEI is used for tumors smaller than or equal to 3 cm in diameter and adjacent to thermally sensitive areas such as central bile ducts and bowel. Other selection criteria include unresectability, no extrahepatic disease, and

poor surgical candidates. Patients with advanced liver disease (Child-Pugh class C) are poor candidates for PEI, as no survival benefit has been demonstrated. Other contraindications include portal vein thrombosis, tumor burden more than 30% of total liver volume, coagulopathy, and platelet count less than 40 000/mm³.

Real-time ultrasound (US) or CT guidance can be used to perform PEI. This can be done as an outpatient for smaller lesions, but multiple separate injection sessions may be necessary. Alternatively, a “one-shot” method with general anesthesia and hospital admission can be performed. Under US visualization, slow injection is done with a multiside hole needle. The area of ethanol injection becomes echogenic, and the injection should be stopped if bile ducts, hepatic vessels, or gallbladder fills. Historically, a tumor volume calculation was performed to estimate the amount of ethanol needed for ablation. In general, 1 to 8 mL of 95% ethanol is injected for a staged approach for four to twelve sessions. The one-shot technique involves injecting 60 to 150 mL in multiple injections over 30 minutes.

Complications are infrequent and usually well-tolerated using the staged approach, including ethanol intoxication, local pain, and transient fever. Rarely, severe hemorrhage has been reported, as has seeding of the needle tract. For the one-shot method, complications can be more frequent and severe, including portal venous thrombosis, hemoperitoneum, variceal bleeding, liver failure, and transient renal insufficiency.

PEI has shown similar survival rates as surgical resection in small lesions. Tumor size more than 3 cm has been shown to be most predictive of local recurrence. Histologic grade, Child-Pugh score, and size/number of lesions are the most important factors related to survival after PEI for HCC. RFA has been compared with PEI, with the results of one study showing fewer treatment sessions to achieve the same degree of tumor necrosis, and a slightly higher complication rate with RFA.

ACETIC ACID

Percutaneous acetic acid injection (PAI) is also an effective method for ablation of small HCC. A 50% solution of acetic acid and sterile water is prepared and injected in similar fashion as PEI. The advantage of PAI is that the septa and capsule of tumors can be infiltrated to a greater degree than with PEI. A smaller volume and fewer treatment sessions are needed to achieve the same ablative effect as ethanol. Only one-third of the volume of acetic acid is needed as compared to 95%

ethanol. In one randomized prospective trial, significant and substantial differences in cancer-free and overall survival rates were observed favoring PAI. Side effects and complications unique to PAI include metabolic acidosis with renal toxicity as well as transient hemoglobinuria.

RADIOFREQUENCY ABLATION

RFA creates thermal injury by depositing electromagnetic energy within the patient. A high-frequency alternating current moves from an electrode tip into surrounding tissue. Because of high resistance of the tissue, the ions attempt to follow the alternating current and create frictional heat by their movement. The tissue temperature and duration of heating are important factors related to tissue necrosis. Tissue heated to 50°C to 55°C for 4 to 6 minutes causes irreversible cellular damage. Between 60°C and 100°C, near-instantaneous tissue coagulation is produced with irreversible damage to mitochondrial and cytosolic enzymes. At 100°C to 110°C, tissue carbonizes and vaporizes, which actually acts as an insulator and reduces efficacy. Therefore, the goal of RF ablation is to achieve and maintain approximately 50°C to 100°C for 4 to 6 minutes. In reality, longer applications must be used because of relatively slow thermal conduction through tissues.

To increase the volume of tissue ablated, multitined probes have been developed, which allow for destruction of the tumor and an acceptable margin (usually defined as 360 degrees, 1 cm surrounding each tumor). An important concept is that of heat efficacy (optimized heat deposition and minimized heat loss) and the bio-heat equation described by Pennes, and simplified by Goldberg and colleagues (coagulation = energy deposited × local tissue interactions – heat loss). Tissue heterogeneity and regional blood flow causing tissue cooling (“heat sink” effect) are therefore important causes of incomplete coagulation.

RFA can be performed with percutaneous CT, MR, or US guidance, and can be done under conscious sedation, but general anesthesia is sometimes required. Open or laparoscopic RFA with US guidance is also used for liver lesions. In tumors larger than 2 to 3 cm, multiple overlapping spheres or cylinders of ablation are needed to treat the tumor with an acceptable margin. In addition to larger and multitined probes, other methods have been developed to increase the ablation volume and decrease number of overlapping sections. These include internally cooled electrodes, cluster electrodes, more powerful electric generators, perfusion or injection of liquid agents (saline, ethanol or acetic acid), and reduction

of blood flow with preablation transcatheter embolization.

LIVER

Selection of patients for RFA includes nonresectable HCC with a single tumor smaller than 5 cm or up to three lesions, each smaller than 3 cm. Additionally, there can be no evidence of extrahepatic disease, vascular invasion, severely impaired liver function (Child-Pugh class C), or a performance status test of 0. For nonresectable colorectal carcinoma liver metastasis, lesions must be confined to the liver or have limited pulmonary metastatic involvement. Most centers prefer to treat patients with four or fewer hepatic lesions, but excess of this number is not an absolute contraindication. The tumor size is the most important factor in predicting outcome, and for metastatic lesions, the tumor should not exceed 3 to 4 cm in greatest diameter.

Most authors agree that the heat sink phenomenon is most significant adjacent to vessels 3 mm and more in diameter. In the liver, this offers some protection for lesions adjacent to large hepatic vessels; however, subcapsular lesions adjacent to gastrointestinal structures should be avoided for percutaneous treatment. The colon appears to be at greater risk than the stomach or small bowel. Laparoscopic approach or use of hydrodissection (percutaneous injection of 5% dextrose in water to displace adjacent structures) should be used. Central bile ducts and gallbladder are also at risk for lesions ablated near the liver hilum. Needle tract seeding is also a concern, particularly for subcapsular lesions, but some devices offer a “track ablation” mode for coagulation at the time of withdrawal of the probe.

RFA is relatively well-tolerated, but severe and fatal complications have been reported. These include liver failure, portal vein thrombosis, GI perforation, liver abscess, pneumothorax, pleural effusion, skin burns, subcapsular hematoma or hemoperitoneum, acute renal insufficiency, and needle tract seeding. Also, a postablative syndrome of pain, fever, and malaise has been reported and is self-limited and reportedly less common than with TACE.

For treatment of HCC, RFA has essentially supplanted PEI because of several recent studies showing superior long-term survival and recurrence rates. As previously mentioned, some studies showed a higher complication rate with RFA, but this did not result in increased mortality. Although resection remains the gold standard in patients meeting criteria for resection, two recent reports showed comparable overall and disease-free survival rates for RF compared to resection in solitary HCC less than 5 cm in diameter. Although recur-

rence rates after RFA are higher than resection, this does not appear to change long-term survival.

For patients with resectable metastatic liver disease from colorectal carcinoma, surgical resection remains the gold standard. However, RFA has become the most widely accepted ablative technique for treatment of nonresectable colorectal carcinoma metastases. There is indirect evidence that RFA is preferred over chemotherapy regimens and improves survival in selected patients with limited liver metastatic disease. Local recurrence and intrahepatic progression appear to affect long-term survival with unresectable CRC metastasis, unlike with HCC. Recurrence rates appear to increase dramatically with increase in tumor size between 2.5 and 3.0 cm.

Combined therapies: Several studies have been conducted regarding a combination of the previously described therapies (TACE, PEI and/or RFA), the most common combination of which includes TACE and RFA. The most recent of these studies has data to suggest that in selected patients, a combination of TACE/RFA was significantly better than either alone. Benefit was seen in patients with unifocal and multifocal disease. Median survival and tumor response were superior in the combined therapy group, and benefit was not offset by adverse effects on liver function.

KIDNEY

The greatest success in RFA of renal lesions has been reported in tumors less than 3 to 4 cm in greatest dimension. Patients who are not candidates or choose not to have nephron-sparing surgery typically belong to one of two categories. One group has sporadic RCC (solitary tumor of 3 to 4 cm and otherwise normal renal function) and can be treated more aggressively with a wider tumor margin in hopes of preventing recurrence. The other group has hereditary syndrome (such as VHL) predisposing to multiple recurrent RCC. These patients are at long-term risk of renal impairment, and as such, a less aggressive approach is recommended to extend good renal function for as long as possible.

There are several unique technical aspects of performing RFA of renal lesions as compared to liver RFA. Placing the patient in lateral decubitus or semiprone positioning helps shift bowel loops out of the way, and the use of hydrodissection can be quite useful. Adjacent bowel, ureters, adrenal gland, and several nerves and muscles are at increased risk for thermal injury. Acute hypertensive crisis can result from injury to the adrenal gland.

Also, cortical lesions are more amenable than medullary lesions because of less heat sink effect, as well as some proposed “oven effect” of surrounding fat

for exophytic lesions. There is considered to be more of a heat sink effect in the kidney as compared to the liver, given that the kidney has five times greater blood flow per gram of tissue. However, since the kidney is an end organ without the dual blood supply as in the liver, this can be advantageous by first ablating the more central portion of larger lesions. This “deep first” technique can significantly decrease peripheral blood flow.

Complications of renal RFA include infection, hemorrhage, and tumor seeding. Since a postablation abscess can mimic tumor recurrence, some authors advocate prophylactic antibiotics. As described previously for the liver, tract ablation can be performed to minimize risk of tumor seeding. Although hemorrhage is a complication of RFA, the risk of significant bleeding is less than that of partial nephrectomy. In fact, RFA has been used to treat life-threatening transfusion-dependent hematuria and hemorrhage after partial nephrectomy.

LUNG

In addition to primary lung cancer and metastatic lung disease, thermal ablation can be used for treatment and/or palliation of chest wall masses or other thoracic skeletal metastases. Currently, RFA and other thermal ablative methods are most useful for early-stage lung cancer in nonsurgical candidates, small and favorably located pulmonary metastatic disease, and for symptomatic palliative treatment of late-stage malignancies. Patient selection for lung RFA is therefore directed by the ultimate goal, whether for potential cure, prolongation of survival, or palliation of symptoms.

Most patients who are candidates for percutaneous lung biopsy are able to undergo lung RFA. There are few absolute contraindications, including bleeding disorders and recent anticoagulant use. In fact, pulmonary RFA can be done safely in patients with only one lung. Caution should be used in patients with emphysema and pulmonary fibrosis, and some authors recommend pulmonary function testing prior to the procedure with a threshold FEV₁ more than 400 mL. Many patients also have cardiac pacemakers and defibrillators which are susceptible to energy interference in the RF and microwave frequencies. Coordination with cardiac electrophysiologists or use of an alternative ablative therapy such as laser or cryoablation should be considered.

Complications include postablation syndrome (pain, fever, chills, anorexia and/or malaise), pneumothorax, sympathetic pleural effusion, hemoptysis, bronchopleural fistula, hemorrhage, skin burns (because of inappropriate grounding pad placement), injury to adjacent mediastinal organs/nerves, infection/abscess formation or acute respiratory distress syndrome. Pneumothorax is most common

and typically occurs in 30% to 60% of cases, but requires aspiration or tube placement only in approximately 20% of patients. Creative methods to avoid some of these complications have been developed, including the previously discussed hydrodissection technique, as well as intentional pneumothorax creation to separate peripheral lung lesions from the parietal pleura and mediastinal structures. One unique risk of pulmonary RFA is systemic embolization with possibility of stroke that is due to microbubbles from tissue heating at “roll-off” temperatures.

To date, no randomized and controlled clinical trial exists comparing thermal ablation techniques alone, or in combination, to established therapy for lung malignancies. Preliminary data suggest that RFA may prolong survival in patients with medical comorbidities who have a resectable lesion but are not able to undergo surgery. It is clear that complete ablation is most likely in tumors ≤ 3 cm.

CRYOABLATION

Cryoablation is another effective thermal ablative modality that has been studied in liver (HCC and metastasis) and RCC primarily, but also shows promise for treatment of other cancers. Because of the large size of the initial cryoprobes, this technique was usually done via an open or laparoscopic approach. However, with development of argon gas-based units and much smaller probes (11–17 gauge), percutaneous approach with imaging guidance is gaining popularity and showing safety and efficacy comparable to surgical approaches. The mechanism of tumor ablation involves rapid expansion of argon gas at the probe tip resulting in temperatures reaching -100°C over a few seconds. This freezing initially causes extracellular ice formation with subsequent movement of intracellular water, changes in pH, protein denaturation, and mechanical disruption of cell membranes; also, local microvascular injury leads to diminished perfusion and delayed cell death.

For percutaneous approaches, imaging guidance with US, CT, and MRI are all feasible options, although the first two are most commonly used because of more availability. The technique used for ablation is similar whether for treatment of nonresectable primary or metastatic liver and lung tumors, renal neoplasms, or other lesions such as prostate cancer or skeletal metastases. Patient selection for cryoablation in the setting of HCC is similar to that of RFA (single mass less than 5 cm or up to three masses less than or equal to 3 cm in diameter); however, larger tumors might possibly be treated more effectively with cryoablation, as discussed later in the chapter. For hepatic metastases, some authors recommend treating up to five lesions with diameter of approximately 4 cm. In patients with RCC, cryoablation is considered for a single tumor less than

4 cm in diameter, but multiple lesions can be treated in a single session for hereditary syndromes such as VHL.

After appropriate patient selection and preprocedure preparation, including correction of any coagulation or platelet abnormality, percutaneous cryoablation can usually be performed with conscious sedation. If needed, a biopsy can be performed prior to the ablation, but caution should be exercised because bleeding from the biopsy can occasionally obscure the lesion for cryoprobe placement. Because of relatively small ablation volume per probe, multiple probes are often needed to cover the entire lesion with an acceptable surgical margin. A commonly used guideline is the “2 to 1 rule,” in which probes are positioned within a given lesion no more than 2 cm apart and no more than 1 cm from the margin of the lesion. This allows for optimal temperatures between -20°C and -40°C to ensure tumor killing, and the synergistic effect of multiple probes leads to much colder isotherms centrally within large ice balls. The outer edge of the ice ball should extend several millimeters beyond a lesion because the outer isotherm (0°C) is not absolutely cytotoxic.

Similar to the heat sink effect seen with RFA, a “cold sink” effect occurs with cryoablation adjacent to larger vessels, and this should be considered for probe placement. Injury to collagenous structures of blood vessels is unlikely with cryoablation, and the 2 to 1 rule can be modified adjacent to vascular structures. One author recommends placing a probe within 5 mm of the lesion edge on the vessel side, with no more than 1 cm between probes. Also, thermodissection methods such as injection of air, carbon dioxide, water, or balloon placement can be used to separate adjacent critical structures. For renal cryoablation, circulation of warm saline through retrograde ureteral stents has been described to offer some protection to the ureter and central renal collecting system.

Once the cryoprobes are adequately positioned, the ablation is usually performed in a double freeze-thaw cycle of 8 to 12 minutes each. This double cycle causes more complete and confluent cell death with synergistic cytotoxic effect as compared to a single freeze cycle. Active thawing can be achieved performed if needed by instillation of helium rather than argon gas through the probes.

A comparison of percutaneous cryoablation and RFA reveals several relative advantages and disadvantages of these modalities. Compared to RFA, cryoablation is much less painful and able to be done with conscious sedation on an outpatient basis more frequently. Better visualization of the ice ball by CT allows for more precision and confidence that the lesion has been adequately covered; however, if US is used, the far side of the ice ball cannot be completely visualized because of acoustic

shadowing. Another advantage described for cryoablation is that it may be safer to treat central lesions, whether hepatic or renal. Animal studies suggest less damage to the renal collecting system than the heat-based modalities. Larger areas (up to 8–10 cm) can be treated because of simultaneous placement of multiple probes, and the size and shape of the ablation zone can be modeled to some degree, because of adjustable settings for each probe.

A disadvantage of cryoablation includes the lack of cauterization effect seen with the heat-based techniques. This may put patients at a slightly higher risk of bleeding immediately post procedure, although the majority of these will stop with conservative management, and few patients have clinically significant bleeding requiring further intervention. Also, compared to RFA, the zone of ablation for each cryoprobe is smaller (approximately 2 cm diameter), thus requiring multiple probes be placed.

Two complications unique to cryoablation of liver lesions also have been described, but are fortunately uncommon. One is that of liver “cracking,” which can result in rapid and massive hemorrhage. This usually occurs during the thawing phase and was previously thought to be due to the air-ice interface encountered in open procedures, but has been seen with percutaneous treatments as well. Another unique complication is “cryoshock,” which is a severe systemic response similar to tumor lysis syndrome, which results in severe coagulopathy, thrombocytopenia and DIC, and multiorgan failure. This has been reported after RFA and cryoablation, but more frequently with the latter. This possibly occurs because of the lack of immediate coagulative effect seen with RFA and the absorption of necrotic debris during reperfusion of the ablated zone after cryotherapy.

Other complications of liver and renal cryoablation include postablation syndrome, tumor seeding, injury to adjacent structures (or central biliary structures in the case of liver cryoablation), abscess formation (rare unless compromise of sphincter of Oddi), arteriovenous fistulas, or pneumothorax.

Regarding treatment of small renal masses, there is question as to whether a surgical or percutaneous approach is preferable. The percutaneous route is relatively newer because of the recent advent of small probes with the argon gas-based systems. One recent meta-analysis concluded that percutaneous ablation is safer and equally effective as a surgical approach, but more than one session may be necessary for complete treatment. Also, there has been no definitive conclusion regarding whether RFA or cryoablation of small RCC is preferable. Another recent meta-analysis suggested that cryoablation results in better local tumor control, less need for treatment, and may be associated with a lower

risk of progression to metastatic disease as compared with RFA. However, in this report, it was noted that the differences in metastatic progression were marginally significant and that most of the cryoablations were performed laparoscopically rather than percutaneously.

MICROWAVE ABLATION

Microwave ablation (MWA) for HCC causes tissue death by coagulation necrosis using electromagnetic energy with frequencies greater than or equal to 900 MHz. Dipole water molecules oscillate billions of times per second at the same frequency as the microwave electric field which causes friction and heat. The MWA system is composed of a microwave generator, flexible coaxial cable, and microwave antenna (probe). This can be performed with open or laparoscopic surgery, or percutaneously with US, CT, or MR imaging. Patient selection criteria and technique are similar to RFA for HCC.

There are several theoretical advantages of MWA as compared to RFA. MWA can provide larger tumor ablation volumes, faster ablation times, and more complete tumor kill. Also, the heat sink effect is less than that for RFA. MWA tissue heating is primarily active (rather than passive) as seen with RFA. This gives a larger zone of active heating and does not rely on electrical conduction (no grounding pads). Tissue desiccation and charring is not a major concern with MWA; therefore, consistently high temperatures can be achieved within a tumor. Another advantage is the ability to create complete necrosis despite presence of fibrous tissue or a septum. The majority of experience with MWA for HCC is from Asia, and comparable long-term survival rates with surgery have been reported for tumors less than or equal to 4 cm in selected patients.

LASER INTERSTITIAL THERMAL THERAPY

Optical range or near-infrared wavelength light emitted from a bare 400- μ m laser fiber can be conducted into a targeted lesion causing heat and coagulative necrosis. An Nd:YAG laser is used most frequently, and this laser has also been used to treat lesions in the esophagus, colon, stomach, and bronchial tree. The laser interstitial thermal therapy system consists of multiple optical fibers placed into a tumor through cannulated needles positioned under US, CT, or MR imaging guidance. Although there have been promising results for treatment of HCC, experience is limited and

no clear advantage over other ablative techniques has been documented.

Venook AP. Nonsurgical treatment strategies for colorectal cancer liver metastases. UpToDate Online Resource; updated March 14, 2008.

QUESTIONS AND ANSWERS

1. Why is transarterial chemoembolization a safe and viable palliative therapy for liver tumors?
 - A. Most tumors are supplied by the hepatic artery, and a normal liver has its main blood supply from the portal vein.
 - B. Doxorubicin mixes well in Lipiodol.
 - C. Tumor necrosis is induced by embolization with microspheres.
 - D. Embolization may stimulate upregulation of factors which can stimulate vascular growth.

ANSWER: A. As the normal liver receives most of its blood from the portal vein embolization of the hepatic artery will not cause liver necrosis of normal parenchyma. The other statements are true as well but not unique to hepatic artery embolization.

2. What is the best clinical indication for tumor ablation using chemical injection (alcohol or acetic acid)?
 - A. Tumors >5 cm in diameter
 - B. Colon cancer metastases in an otherwise normal liver
 - C. Primary HCC in a cirrhotic liver
 - D. Endocrine metastasis

ANSWER: C. These tumors frequently have a “pseudocapsule,” which acts to contain the chemical agent in the tumor allowing greater and more localized tumor necrosis. Tumors larger than 5 cm in diameter are not optimally treated with ablation, and local injection should not be done for neuroendocrine tumors. Also, metastases in an otherwise normal liver may allow diffusion of the chemical agent with less tumor necrosis and more damage to surrounding structures.

3. Regarding RFA versus cryoablation, which of the following is *true*?
 - A. Cryoablation is safer because there is less chance of postprocedure bleeding.
 - B. RFA is preferred because it causes less pain.
 - C. RFA is easier to monitor with CT guidance.
 - D. Cryoablation is less painful than RFA, and, therefore, can usually be done without general anesthesia.

ANSWER: D. There is less pain during the ablation process using cryoablation. There may be a higher incidence of bleeding with cryoablation. The ablation zone is harder to define on CT during RFA but will be demarcated during cryoablation.

4. What is the advantage of using MWA over RFA?
 - A. It causes tumor necrosis without thermal energy.
 - B. It is faster than RFA and can ablate a larger area.
 - C. There is no risk to surrounding structures with microwave.
 - D. There is no postablation syndrome with microwave.

ANSWER: B. Ablation can be accomplished in less time and to one larger area with microwave than with RFA. All ablative procedures can cause postablation syndrome and can damage surrounding structures. Also, microwave causes ablation by the generation of heat.

5. Which of the following is the most common *severe* complication of ablative therapy?
 - A. Hemorrhage
 - B. Postablation syndrome
 - C. Infection
 - D. Stroke

ANSWER: A. Bleeding is the most common severe complication though it is rarely life threatening. Postablation syndrome occurs but is usually easily manageable. Infection can be severe but is usually easily treated. Stroke has been rarely reported with lung ablation because of microbubbles, but is very uncommon.

90 RADIATION SAFETY, INSTRUMENTATION, AND QUALITY CONTROL

Jon A. Baldwin and Kok C. Tan

INTRODUCTION

Imaging in nuclear medicine is significantly different than those in most other imaging modalities in radiology. Rather than passing a beam of energy through a patient and measuring its attenuation, radioactivity is injected into a patient, and the distribution of that radioactivity is captured by a specialized imaging system. Many of the radioactive substances in use in nuclear medicine are composed of two substrates: the radionuclide and a ligand to which the radionuclide is “tagged” to, creating a radiopharmaceutical. Occasionally, the radionuclide in its “native” chemical and physical state is the radiotracer used (e.g., Na^{123}I , Na^{131}I , ^{133}Xe , $\text{Na}^{99\text{m}}\text{TcO}_4$). Radiotracers each have a unique biodistribution and imaging appearance, which is then altered in particular disease processes. As such, nuclear medicine imaging is more about the imaging of physiology or function, rather than that of anatomy. In this chapter, we will begin by reviewing some basic physics, such as characteristics of radioactive decay, including production of commonly used radionuclides, and how their decay affects image quality and patient dose. We will then discuss how images are generated, and what type of quality control is performed, and when to assure proper image reconstruction. Finally, some of the basic Nuclear Regulatory Commission (NRC) guidelines pertinent to diagnostic and therapeutic nuclear medicine are reviewed.

PHYSICS OF NUCLEAR MEDICINE

Radioactivity is a random process by which unstable atoms emit energy and/or particles in an attempt to

become more stable. The way a particular atom will decay at a particular instant cannot be known for certain, but can be expressed by a percentage based on observational evidence. For the purposes of this review, there are essentially two forces at work in a nucleus—the electromagnetic, which is repulsive between protons, and the strong nuclear force, which is attractive between nucleons (protons and neutrons) over small distances. In stable (nonradioactive) isotopes of lighter elements, the proportion of protons to neutrons is 1:1. As elements get larger, the repulsive force from the large numbers of protons present needs to be counteracted by the strong nuclear force. The proportion of protons to neutrons approaches 1:1.5. To move toward this proportion, the atom can undergo decay. Alpha (α) decay, beta minus (β^-) decay, positron decay (β^+), or electron capture decay (EC) are processes that look to balance the electromagnetic and strong forces (Table 90-1).

α DECAY

This form of decay tends to occur in heavier unstable atoms. A charged (+2) α particle, which in reality is a helium nucleus (^4He), is emitted. The daughter’s mass (A) is decreased by four, and the atomic number (Z) is decreased by two. Photonic energy, in the form of a gamma (γ) ray, is also usually emitted as part of this process. Currently, radionuclides that decay by α decay are not used in nuclear medicine.

TABLE 90-1 Radionuclides and Their Modes of Decay

TYPE OF DECAY	RADIONUCLIDES
β^- emitter, no imageable γ produced	^3H , ^{14}C , ^{32}P , ^{89}Sr , ^{90}Y
β^- emitter, imageable γ produced	^{99}Mo , ^{131}I , ^{133}Xe , ^{153}Sm
β^+ emitter	^{11}C , ^{13}N , ^{15}O , ^{18}F , ^{68}Ga , ^{82}Rb
Electron capture	^{67}Ga , ^{111}In , ^{123}I , ^{201}Tl
Isomeric transition	$^{99\text{m}}\text{Tc}$, $^{113\text{m}}\text{In}$

β^- DECAY

In this form of radioactive decay, a β^- particle, which is in essence a nuclear-formed electron (e^-), is emitted from the nucleus. One can think of it as a neutron being “transformed” to a proton. The daughter’s mass is unchanged, but the atomic number is increased by one. This decay occurs in “neutron rich” radionuclides. The β^- particle will travel a short distance, and then come to rest. This particle has the potential to damage DNA, and is the basis of radionuclide therapy with ^{32}P , ^{89}Sr , ^{90}Y , ^{131}I , and ^{153}Sm . Certain radionuclides also have γ photonic emissions that occur and can be imaged.

β^+ DECAY

In positron decay, a β^+ particle, which is a nuclear-produced “positive” electron, is emitted from the nucleus. A proton is thus “transformed” into a neutron. The daughter’s atomic mass is unchanged, and the atomic number is decreased by one. This decay occurs in “proton rich” radionuclides, but only when enough energy (1.02 MeV) is available for positron decay. The particle will travel a short distance before it comes to rest, at which time it will contact a “negative” electron and annihilate, giving off two 511 keV γ photons approximately 180 degrees apart. These emissions are imaged in positron emission tomography (PET). Radionuclides important to nuclear medicine that decay by positron emission are usually produced by a cyclotron (the exception being ^{82}Rb , a cardiac PET perfusion agent produced in a generator system). β^+ decay often competes with electron capture decay, even when enough energy is available for positron emission. For example, ^{18}F decays by β^+ 87% of the time, and by EC 13% of the time.

ELECTRON CAPTURE DECAY

This form of decay occurs in “proton rich” radionuclides, when there is not enough energy available for positron decay. The atom captures an orbital electron, “transforming” a proton into a neutron. The daughter’s atomic mass is unchanged, and the atomic number is decreased. γ Photons can also be emitted and imaged. In addition, the orbital electron vacancies will be filled by electrons from adjacent orbits, resulting in either characteristic x-ray emissions or Auger electron emission. Sometimes it is the characteristic x-rays that are more abundant or advantageous for imaging, as is the case in decay of ^{201}Tl ; it is the characteristic x-rays of the ^{201}Hg daughter that are imaged. These radionuclides are also cyclotron produced.

ISOMERIC TRANSFORMATION

A radionuclide in an excited state (an “isomer”) will get rid of excess energy by emitting γ photon. These isomers are generally of very short duration, except in the case of a metastable radionuclide. These have a measurable interval before emitting their photon. These radionuclides are designated with an “m” by their atomic mass number (e.g., $^{99\text{m}}\text{Tc}$). This process competes with internal conversion, in which the excess energy is transferred to an orbital electron, which is then ejected from its orbit. Orbital vacancies will be filled by electron from adjacent orbits, resulting in characteristic x-rays or Auger electron emission.

It is important to remember that radioactive decay is a random process. One cannot know for sure how a particular atom in a sample will decay, and what the energies of the resultant particles/photons will be. β^- and β^+ particles will have a E_{max} and a mean E . Energy is “randomly” distributed among the particles, γ photon and the antineutrino or neutrino. The average energy of a particle is approximately one-third of its maximum energy ($E_{\text{ave}} = 1/3 E_{\text{max}}$). Also remember that internalized particulate emissions are much more damaging to biologic structures, and contribute more to patient dose than do internalized or externalized photonic emissions. β^+ and β^- particles do not travel far before they deposit their energy and “do their damage”; they can be shielded against with plastic or plexiglass (in fact, it is important to avoid using lead shielding with β^- emitters, as penetrating bremsstrahlung x-rays will be produced). Photon emissions are much more penetrating, and must be shielded with denser materials such as tungsten or lead. Of the five processes by which photons interact with matter (coherent scattering, photoelectric absorption, Compton scattering, pair production, and photodisintegration), the two that are important in nuclear medicine are photoelectric absorption and Compton scattering. The end result of either of these processes is the production of an ion pair: an ejected electron from the atom, and a positive ion (due to the loss of the electron), which will then ultimately interact with tissue and potentially damage it. Additionally, photoelectric absorption will result in either characteristic x-rays or Auger electron emission as the inner electron shell is filled. Compton scatter will have a “scatter photon,” the γ photon with decreased energy resulting from its interaction with an outer shell electron. Tables 90-1 and 90-2 summarize radionuclide decay and production.

RADIONUCLIDES AND RADIOPHARMACEUTICALS

With an understanding of how different radionuclides decay, it is possible to use that information to under-

TABLE 90-2 Sources of Radionuclides

SOURCE OF RADIONUCLIDE	RADIONUCLIDE
Reactor	^{99}Mo , ^{131}I , ^{133}Xe , ^{137}Cs
Cyclotron	^{11}C , ^{13}N , ^{15}O , ^{18}F , ^{111}In , ^{123}I , ^{67}Ga , ^{201}Tl
Generator	^{68}Ga , ^{82}Rb , $^{99\text{m}}\text{Tc}$, $^{113\text{m}}\text{In}$

stand some of the properties of radiopharmaceuticals used in diagnostic and therapeutic nuclear medicine. Several factors go toward making an ideal *diagnostic* radiopharmaceutical. First, the photons emitted have to be within a range that lends itself to being recorded onto a usable image. The ideal range of photon energy for nuclear medicine camera systems is between 100 and 200 keV. Although energies above or below this can be imaged, the image quality and resolution is not ideal. Second, the radionuclide should have no particle emissions, as this increases the dose to the patient, without contributing to the image. Third, the half-life of the radionuclide has to be such that there is adequate time for the radiopharmaceutical to localize in the organ of interest. Unnecessary long half-lives, however, will generally result in larger doses to the patient (assuming the activity is not removed from the body by some biologic process). The chemical properties of the radionuclide are also important. If the radionuclide is not going to be used in its natural form, but rather “tagged” to a ligand that will allow proper localization, its chemistry must be such that it will permit it to be incorporated stably within the radiopharmaceutical. The radiopharmaceutical itself should be nontoxic to the patient, and be sufficiently resistant to degradation for the duration of the diagnostic study. Therapeutic radiopharmaceutical criteria share some of these criteria, but β^- particle emission is required. Half-life of the radiopharmaceutical can vary, but should be long enough to treat the condition in question, but not to cause excessive harm to normal structures. A few therapeutic agents (e.g., ^{131}I , ^{153}Sm) can be imaged, so as to observe areas being treated and discover unsuspected disease. Other therapeutic radionuclides do not emit photons that can be imaged (Table 90-1).

The workhorse radionuclide of diagnostic agents in nuclear medicine is $^{99\text{m}}\text{Tc}$. It fulfills the majority of the criteria cited above. An additional factor that makes $^{99\text{m}}\text{Tc}$ appealing is that it is obtained from a generator system, enhancing its availability. Radionuclide generators consist of a radionuclide with a relatively long half-life, with a relatively short-lived daughter. The daughter typically can be easily removed from the parent due to different chemical properties. Examples include the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator system, in which ^{99}Mo ($T_{1/2} = 67$ hours) decays to $^{99\text{m}}\text{Tc}$

($T_{1/2} = 6$ hours); the $^{82}\text{Sr}/^{82}\text{Rb}$ generator system, in which ^{82}Sr ($T_{1/2} = 25$ days) decays to ^{82}Rb ($T_{1/2} = 75$ seconds); and the $^{113}\text{Sn}/^{113\text{m}}\text{In}$ generator system, in which ^{113}Sn ($T_{1/2} = 115$ days) decays to $^{113\text{m}}\text{In}$ ($T_{1/2} = 1.7$ hours).

$^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ GENERATOR

In this system, ^{99}Mo is adhered to an alumina column. As it decays, the daughter $^{99\text{m}}\text{Tc}$ is not bound as tightly to the column. Physiologic saline is washed across the column, and $^{99\text{m}}\text{Tc}$ is eluted from the column in the form of sodium pertechnetate ($\text{Na}^{99\text{m}}\text{TcO}_4$). $\text{Na}^{99\text{m}}\text{TcO}_4$ is in a +7 valence state, and must be reduced to a suitable form to label the chelates. This is usually accomplished with stannous ions. If there are errors in the reduction process, insoluble impurities may be introduced. In addition, before it is injected into the patient, the radiopharmaceutical should be sterile and pyrogen free. All of these steps require quality control testing to ensure that the radio-tracer is in compliance with set guidelines.

RADIONUCLIDE PURITY

Radionuclide purity is expressed as the percentage of activity present that is due to the radionuclide of interest. ^{99}Mo is a long-lived nuclide with particle emission and high energy photons. These factors can increase the dose to patient and degrade the patient's images. To test for the presence of ^{99}Mo , the sample is shielded with lead, with the test based on the different photopeaks of the radionuclides. It is important that the ^{99}Mo be assayed first, and in the special lead shield supplied by the manufacturer of the dose calibrator. $^{99\text{m}}\text{Tc}$ is then assayed directly in a plastic sleeve. The basis of the test is that the high energy ^{99}Mo photons will not be attenuated by the lead, but the 140 keV $^{99\text{m}}\text{Tc}$ photons will be attenuated. Activity of ^{99}Mo (in μCi) is divided by activity of $^{99\text{m}}\text{Tc}$ (in mCi) to obtain a ratio. The NRC allows no more than 0.15 μCi of ^{99}Mo per 1 mCi of $^{99\text{m}}\text{Tc}$ at the time of administration. As a rule of thumb, if the ratio is less than 0.038 at the time of elution, the material will be suitable for injection for at least 12 hours.

CHEMICAL PURITY

The column inside the generator is made of aluminium oxide (Al_2O_3). For this reason, alumina can be eluted from column. This can form colloids with $^{99\text{m}}\text{Tc}$, which would show up as liver activity, or can cause sulfur colloid aggregation, which would lead to lung uptake on a liver-spleen scan. The test performed is similar to the colorimetric test performed with pH paper; excessive alumina will change the color of the paper. The permissible amount is 10 mg Al^{3+} per 1 mL $^{99\text{m}}\text{Tc}$ eluate.

RADIOCHEMICAL PURITY

The assessment of the radiochemical purity of the ^{99m}Tc radiopharmaceutical is determining the degree of successful tagging of the ^{99m}Tc to the biological component contained in the kit. The $\text{Na}^{99m}\text{TcO}_4$ obtained from the generator is added to the reaction vial. This vial contains stannous chloride (SnCl_2 , the reducing agent), the pharmaceutical to be tagged, preservatives, and is purged with N_2 gas (to prevent reduction of Sn by O_2 in the air). Instant thin layer chromatography (TLC) is usually performed to assess the chemical purity of the radionuclide. To check for the presence of free pertechnetate, the radiopharmaceutical is placed on the chromatographic strip and acetone solvent is used; acetone will move with the solvent front. To check for insoluble impurities, such as hydrolyzed reduced technetium, saline is used. The insoluble impurity will not move with the solvent front. If the radiotracer is itself insoluble, there is no test available to check for the presence of hydrolyzed reduced technetium in that sample, so the possibility that it is present is ignored. The United States Pharmacopeia (USP) has limits of acceptability for radiochemical purity. The limits are 95% for $\text{Na}^{99m}\text{TcO}_4$, 92% for ^{99m}Tc sulfur colloid, and 91% for all other ^{99m}Tc radiopharmaceuticals.

Particle size of certain compounds may also be checked by a hemocytometer as part of the quality control procedure.

MISCELLANEOUS TESTING

The USP maximum diameter recommendation for macroaggregated albumin (MAA) is $150\text{ }\mu\text{m}$, with 90% of the particles between 10 and $90\text{ }\mu\text{m}$. The sterility of a compound must also be tested, either by incubating the radiopharmaceutical on agar media, or by the Bactec system. This system uses ^{14}C labeled glucose, and in the presence of bacteria, $^{14}\text{CO}_2$ is released. If the radiopharmaceutical is to be used for cisternography, it must also be pyrogen free. Endotoxins may be evaluated by the limulus amoebocyte lysate test. This material is derived from the amoebas present in the tail of the horseshoe crab, which in the presence of an endotoxin, will form an opaque gel.

Once the radiopharmaceutical is made and meets NRC and USP standards, it is ready to be administered to the patient. The route of administration is typically intravenously, but some are administered subcutaneously, and some are ingested. One now needs an imaging system that can localize and record the distribution of the radiotracer. This system is the gamma scintillation camera.

BASIC INSTRUMENTATION

The gamma scintillation camera converts photons emitted by the radionuclide in the patient's body into a light pulse,

which is then subsequently converted into a voltage signal, which is then used to form an image. This is true for both "conventional" nuclear medicine scintigraphy, as well as for imaging with positron emitting radionuclides. In this section, we will first discuss non-PET imaging. The basic components of a gamma camera system are the collimator, the scintillation crystal, the photomultiplier tube array, the pulse height analyzer (PHA), and the control console with computer integration. Each of these components contributes to the accurate localization of the radiotracer distribution within the patient. The radiopharmaceutical used and its time to desired/optimized biodistribution will determine some image parameters—the timing of the image acquisition, the type of collimator used, and the photopeak window setting.

COLLIMATOR

Ideally, the concentration of photons arriving at a radiation detector would be proportional to the number of photons emitted in the respective body part being imaged. However, unwanted photons can arise from background activity in tissues in front, behind, or to the side of the body part being imaged. These photons reduce image contrast and may distort the data analysis. Secondly, photons arising from the organ of interest may travel "off axis" since radiation is given off equally in all directions. Thirdly, Compton scatter can degrade the image. Recall that Compton scatter arises from photons that originate in or adjacent to the organ of interest and then interact with a loosely bound orbital electron resulting in image degradation. The collimator is the first portion of the gamma camera system that the emitted photon encounters. It is made of perforated lead and is interposed between the patient and the scintillation crystal. It is designed to reduce scatter and allows the gamma camera to correctly localize radionuclide events in the patient's body. It does this by discriminating against unwanted photons on the basis of their direction of travel. The collimator cannot, however, distinguish between photons of different energy. This is done by the PHA (discussed later). A *parallel hole collimator* is the workhorse collimator in clinical practice. It consists of thin lead dividers interspersed by thousands of uniformly distributed gaps or holes. The choice of parallel hole collimator would depend on the photon energy level of the isotope being imaged, and the sensitivity or resolution desired. The thickness of the lead septa and the interspace distance between the lead dividers determines the optimized photopeak for the collimator. A low-level energy collimator is conventionally used for radiotracers with photon energies of 1 to 200 keV (e.g., ^{99m}Tc , ^{123}I , ^{133}Xe , ^{201}Tl). Medium energy collimators are designed for radiotracers with maximum photon

energies of 200 to 400 keV (e.g., ^{67}Ga , ^{111}In) by having thicker lead septa than the low energy collimators. Photons with lower energies are unlikely to pass through the thicker lead septa. High-energy collimators have been designed for radiotracers with maximum photon energies more than 400 to 600 keV. ^{131}I falls into this category; even though the principle imaged photon is “medium energy,” there are 19 possible different γ rays emitted, some of which (7% abundance) have a 637 keV photon. Sensitivity and resolution of an image, in regard to the collimator, is related to the length of the lead septa. There is an inverse relation between these two parameters, and improving one comes at the cost of worsening the other. High-resolution collimators have long septa. This significantly reduces the chance that a photon coming at an oblique angle will strike the crystal face. This, however, means that fewer photons will strike the crystal face and the sensitivity suffers. Put another way, if the length of the septa is increased, the count rate decreases and the resolution increases. The difference between a general collimator and a high sensitivity collimator of the same energy (low, medium, or high) is that high sensitivity collimators may allow approximately twice as many counts to be imaged, but the spatial resolution will also be degraded accordingly. High-sensitivity collimators are important in the use of dynamic acquisitions, for example, in the flow phase of a bone scan, and in other instances when a low count density is expected. It should be noted that in parallel hole collimators the distance of the patient from the camera face will not affect the sensitivity. As the distance between the two increases, counts reduced by the effect of the inverse square law are compensated for by the increased field of view the increased distance affords. The net effect is that count rates are unchanged. Resolution, however, is significantly decreased as the distance between patient and collimator increases. The septa are no longer able to eliminate photons coming from an oblique angle to the crystal face. A *pinhole collimator* behaves in much the same way as a pinhole camera. As such, the field of view increases with distance and the resulting image is magnified and inverted. Its main clinical purpose is to image small parts objects such as the thyroid and the bones of the hands and feet. *Converging hole collimators* are used to magnify the image, without image inversion as in pinhole collimators. These collimators have holes that converge toward a point approximately 50 cm in front of the collimator. As the patient moves away from the collimator up to the focal point, sensitivity increases. Beyond the focal point, however, sensitivity decreases. Resolution decreases with distance. A *diverging collimator* is one whose holes and lead septa point away from the crystal surface, minimizing the image. They permit imaging of a larger area of the body on a small crystal face than is possible

with a simple parallel hole collimator. The diverging collimator can increase the area to be imaged by approximately 30%. Resolution and sensitivity both decrease as the patient is moved away from the collimator. An important thing to remember about nonparallel hole collimators is that since they are magnifying or minimizing a three-dimensional object, image distortion can occur.

SCINTILLATION CRYSTAL

Once the photon emerges from the patient, and gets past the collimator, it will interact with the crystal. This crystal is made of sodium iodide doped with thallium. The photon interacting with the iodide will cause an ejection of an orbital electron, producing a pulse of fluorescent light. The amount of light produced varies directly with the energy of the photon striking the crystal. Photomultiplier tubes (PMT) behind the crystal surface detect the light and amplify it. The likelihood of a photoelectric event and consequent complete energy absorption in the sodium iodide crystal is greater at low energies and decreases at higher energies, because the probability of Compton interaction increases at higher energy levels. Approximately 30% of the light from each event reaches the PMTs. The thickness of the crystal will affect the efficiency of gamma ray detection and spatial resolution of the image. The thicker the crystal, the more likely events are to be captured. However, with a thicker the crystal, the spatial resolution worsens, as the PMTs are further away from scintillation event. The relationship of crystal thickness and energy of the photon emitted from the patient also has an impact on sensitivity and resolution. The higher the photon energy, the more likely the photon will pass through the crystal without producing a scintillation event. For example, there is near-100% efficiency of detection for $^{99\text{m}}\text{Tc}$, ^{123}I , ^{133}Xe , and ^{201}Tl photons with a $\frac{1}{2}$ -in crystal. That same crystal has only about a 25% efficiency for detecting ^{131}I photons. As with collimators, sensitivity is sacrificed for spatial resolution. For thinner crystals, sensitivity decreases $\sim 10\%$ as more photons pass through, but there is $\sim 30\%$ increase in spatial resolution. This is due to the PMTs being closer to the scintillation event, and the light pulse can be localized more accurately. Thicker crystals do better for detecting higher energy photons.

PHOTOMULTIPLIER TUBES

PMTs detect light pulses produced by the crystal, amplifies them and converts them into an electrical signal of measurable magnitude. Usually, an array of PMTs are aligned behind the crystal for event localization. The

number of PMTs used affects the ability of the system to localize where the pulse originated from; therefore, more PMTs will increase resolution. A scintillation event in the crystal is invariably recorded by one or more PMTs, and the final image is determined by the amount of light sensed by each tube, thus affecting the pattern of PMT voltage output. For each event, the summation signal is then formed by weighing the output from each tube. Two kinds of signal processing take place. The summed pulse typically called the Z pulse is related to intensity of the output. This is used to determine if the detected event falls within the desired energy range and should be accepted into the formation of the image. If it does not fall into the desired energy range, it will be rejected by the PHA. Simultaneously, the signal from each scintillation event is localized spatially to an x and y coordinates in a Cartesian plane. It should be noted that a potential source of image degradation lies within the circuits of the PMTs. The electronics of the PMTs are such that there may be variations in how an individual PMT perceives a light impulse of specific intensity. This can result in an inhomogeneous distribution of activity across the image. This can be corrected for through the use of computer correction factors. This parameter, called field uniformity, will be discussed in more detail below in the quality control section.

PULSE HEIGHT ANALYZER

The basic principle of the PHA is to discard unwanted signals, so that only photons with the photopeak of the radiotracer used in the study are being imaged. The photopeak is the characteristic energy of photons emitted by a particular radionuclide. Imagine a plot was made of the photon energy (x-axis) versus number of counts (y-axis) for ^{99m}Tc , as imaged with gamma camera system. ^{99m}Tc emits a gamma ray with an energy of 140 keV when it decays to ^{99}Tc , so one might expect all of the counts to be located at that energy. In fact, when imaged by the scintillation camera, the highest number of counts would have a Gaussian distribution on either side of this main photon energy of the radiotracer. Other peaks would be found as well, however, as a result of the different interactions of the 140 keV photons with other components of the imaging system. These include the iodine escape peak, the backscatter peak, lead x-ray peak, and Compton edge. The iodine escape peak is the result of the interaction of a ^{99m}Tc photon with the K shell electron of the iodine near the edge of the sodium iodide crystal. The energy of that ejected electron is then lost, shifting the peak to the left ($140\text{ keV} - 28\text{ keV} = 112\text{ keV}$). Another peak results from the interaction of the ^{99m}Tc photon with the K shell electrons of the lead in the collimator. The characteristic x-rays produced from this interaction

produce a peak in the range of 75 to 88 keV. A third peak occurs when a ^{99m}Tc gamma ray first undergoes 180 degrees scatter and is subsequently absorbed by the sodium iodide crystal. The resulting loss of energy from the scatter event results in the backscatter peak ($140\text{ keV} - 50\text{ keV} = 90\text{ keV}$). Finally, the effect of Compton scatter of the 140 keV photon within the crystal gives a peak from 0 to 50 keV (Fig. 90-1).

The above mentioned peaks are seen if one considers only a source of ^{99m}Tc interacting with the camera system. The plot of counts versus energy are different when the ^{99m}Tc photons are escaping from a patient who has been injected with a ^{99m}Tc radiopharmaceutical. There is still a sharp peak at 140 keV with a Gaussian distribution; however, to the left of the peak there is a large broad peak resulting from Compton scatter of the 140 keV photons within the patient. These scattered photons will then strike the crystal with energies from approximately 90 keV to just less than 140 keV. These energies will mask the iodine escape peak and backscatter peaks (Fig. 90-2). Compton scatter from the patient significantly degrades the images obtained from the patient.

Other radiotracers will have distinct “plots” based on the energies of the photons they emit and their interactions with the camera system. In addition, there may be multiples of these photopeaks in radiotracers that have several abundant photon energies (^{67}Ga and ^{111}In being the most important in nuclear medicine). Finally, unwanted photons can arise from background activity, from scattered radiation, or radiation from interfering isotopes. The PHA determines which events occurring in the crystal will be displayed and which will be rejected. It is able to do this because the energy deposited by a scintillation event in the crystal bears a linear rela-

FIG. 90-1 Plot of a point source ^{99m}Tc photon energy, as imaged by a gamma camera system. The peak at 140 keV is the energy resulting from the decay of ^{99m}Tc to ^{99}Tc . The peak at 112 keV is the iodine escape peak. The peak at 90 keV is a combination of the backscatter and Pb x-ray peaks. The Compton edge is at 50 keV, with Compton scatter seen from 0 to 50 keV.

FIG. 90-2 Plot of ^{99m}Tc photon energy emitting from a patient, as imaged by a gamma camera system. Compton scatter occurring within the patient accounts for the broad peak from 90 to 140 keV.

tionship to the voltage signal emerging from the PMT. Signal intensity information is then matched against a voltage discriminator otherwise known as a “window.” The window has an upper and lower limit that defines the window width. This allows energy related to the desired isotope photopeak to be recorded. Any signal higher or lower than this range will be rejected. Some cameras have several PHAs, which allow several photopeaks to be used at once. This is useful for radionuclides with multiple photopeaks such as ^{67}Ga and ^{111}In , or in doing dual tracer studies, where two radiopharmaceuticals with different energies are imaged at the same time. A classic example of this is performing a ^{99m}Tc bone scan and an ^{111}In tagged WBC to assess for osteomyelitis. One can simply change the window setting to see if there is congruent or noncongruent uptake at a suspected site. This cannot be accomplished with all radiotracer combinations, however, because of a phenomenon called “downscatter.” More energetic photons can spill into a window of a less energetic photon emitter, especially when Compton scatter within a patient is occurring. Some clinical examples are performing a V/Q scan with ^{133}Xe and ^{99m}Tc MAA, or a bone scan with ^{99m}Tc MDP followed by a ^{67}Ga scan for suspected vertebral osteomyelitis. ^{133}Xe has a photopeak of 81 keV. Recall that Compton scatter of ^{99m}Tc within a patient has an approximate range of 90 to 140 keV, which is close to the ideal window of ^{133}Xe . If the ^{99m}Tc MAA portion of the V/Q scan was performed first, when the ^{133}Xe was imaged, there would be interference in image quality from scattered ^{99m}Tc photons. A similar phenomenon occurs with ^{99m}Tc and ^{67}Ga (^{67}Ga has photopeaks of 93, 184, 300, and 393 keV). In both cases, the portion of the study that uses the lower energy photon must be done first to avoid downscatter. This is especially important when using ^{67}Ga , which has a half-life of 78 hours; if done first, one would have to wait at least

a week for activity from the ^{67}Ga (physical half-life, 78 hours; effective half-life ~ 50 hours) to clear sufficiently to perform the ^{99m}Tc study! Also in regard to ^{67}Ga , an astute observer would no doubt have discerned that part of the reason that ^{67}Ga has poor imaging characteristics is the downscatter phenomenon that is present even when used by itself, because of its multiple photopeaks.

Once the impulses from the PMT have been processed by the PHA, depending on voltage signal it is either accepted or rejected based on the window setting selected by the technologist. Once sufficient accepted signals, with their x and y coordinate information, have been obtained, this data is then used to assemble a diagnostic image. The image can then be recorded by photographic or electronic means.

TYPES OF IMAGE ACQUISITIONS

Nuclear medicine images acquired by a gamma camera system can be obtained as a “static” image for a predetermined number of counts, or for a set time. In addition, a dynamic acquisition can be acquired, with the camera capturing and recording the distribution of radiotracer as it moves through the patient over short time intervals. When improved spatial resolution is needed to make the proper diagnosis, a SPECT acquisition can be performed. A camera or cameras are rotated either 180 or 360 degrees around the patient, typically moving 3 to 6 degrees at a time. Orbits can be circular or elliptical. The more projections obtained, for a longer period of time, the better the image quality. However, as patients often cannot tolerate remaining motionless for long periods of time, compromises must be made. Patient motion can severely degrade image quality. Combinations of number of camera stops and time per stop that result in acquisition times less than 30 minutes are favored. Another important imaging parameter is image matrix size—the number of pixels over the imaging surface. A matrix size of 128×128 has better resolution than a matrix size of 64×64 , but comes at a cost of increased acquisition time, increased processing time, and reduced count density per pixel, which adversely impacts image contrast. Once the study is acquired, the data can be processed to construct a three-dimensional image of the organ or body part scanned. This is done by mathematical techniques called filtered back projection or iterative reconstruction. Mathematical filters are used before or after image reconstruction to help eliminate noise in the image, smooth the image, and improve resolution. These filters will allow predetermined frequencies to “pass” through—contribute to the final image—while disregarding other frequencies. Images can be degraded by attenuation from within the patient. This can be corrected for by passing a

photon through the patient (whether from a radionuclide like ^{153}Gd or a CT scanner) and measure its attenuation through the patient. This attenuation map can then be used to “reassign” counts based on the probability of their being attenuated. This method is most commonly used in SPECT myocardial perfusion imaging. The final reconstructed image can be viewed in a rotating three-dimensional view and can be sectioned into the three orthogonal planes for review.

QUALITY CONTROL FOR GAMMA CAMERAS

As seen from the above discussion, there are numerous components involved in generating a diagnostic quality image. If any of these fails, image quality may suffer. Several parameters are tested at specified intervals to ensure that the camera system is working properly (Table 90-3). Of the listed parameters, window setting, uniformity, spatial resolution, and linearity are checked most frequently.

FIELD UNIFORMITY

This parameter requires daily assessment and measures the uniformity of the response of the gamma camera across its entire field of view. As discussed previously, individual PMT can assign slightly different voltages to the same photon energy because of differences in their internal electronics, as well as slight variations in crystal thickness. To make certain that the computer corrections

are functioning to ensure that uniformity remains within accepted percentages (2%–5%; as low as 1% if SPECT is to be performed). If measurements are made with the collimator in place, extrinsic uniformity is being tested. Measurements without the collimator are testing intrinsic uniformity. For extrinsic field uniformity, most nuclear medicine facilities use either a phantom filled with a uniform solution of $\text{Na}^{99\text{m}}\text{TcO}_4$ in water or a permanent disk source of uniformly distributed ^{57}Co (half-life of 270 days). $^{99\text{m}}\text{Tc}$ flood sources have the advantage of being easily available and relatively cheap. However, with its half-life of 6 hours, it has to be refilled daily. Thorough mixing is imperative, so that uniform distribution of radiotracer is presented to the crystal face (watch out for air bubbles!). Contamination of a department by $^{99\text{m}}\text{Tc}$ from a dropped flood source has ruined many a nuclear medicine technologist’s morning. The ^{57}Co sheet source avoids this complication by being uniformly distributed throughout a plastic matrix. Sheet sources cost more, and do eventually have to be replaced. The ^{57}Co photopeak (122 keV) approximates that of $^{99\text{m}}\text{Tc}$. The image obtained should be inspected carefully. A highly uniform appearance is expected, although very minor mottling from the PMTs is acceptable. A failure of a PMT can be recognized as an area of decreased activity. Cracked crystals are also readily identified, and damage to the collimator system can be detected (when performing an extrinsic test). For testing uniformity, one does not have to do *both* extrinsic and intrinsic tests daily, either check is sufficient. However, it is wise to do the check that is not performed daily

TABLE 90-3 Quality Control for Gamma Cameras

PARAMETER	FREQUENCY OF TESTING	METHOD OF TESTING
Window setting	Each patient	Verify correct energy window setting for radionuclide used
Uniformity, extrinsic	Daily, before first patient	$^{99\text{m}}\text{Tc}$ flood/ ^{57}Co sheet source, collimator in place
Uniformity, intrinsic	Daily, before first patient	$^{99\text{m}}\text{Tc}$ point source at the proper distance from crystal face; collimator removed
Spatial resolution	Weekly	$^{99\text{m}}\text{Tc}$ flood/ ^{57}Co sheet source covered by bar phantom
Linearity	Weekly	$^{99\text{m}}\text{Tc}$ flood/ ^{57}Co sheet source covered by bar phantom
SPECT calibration floods	Per manufacturer, usually monthly	High activity $^{99\text{m}}\text{Tc}$ flood source
Center of rotation (SPECT)	Per manufacturer, usually monthly	SPECT acquisition of a $^{99\text{m}}\text{Tc}$ point source
Tomographic resolution (SPECT)	Quarterly	Obtain $^{99\text{m}}\text{Tc}$ line source SPECT and planar acquisition and compare resolution; cannot exceed 10% of planar value
Tomographic uniformity (SPECT)	Quarterly	Image cylindrical tomographic phantom
Collimator performance	Annually*	$^{99\text{m}}\text{Tc}$ flood/ ^{57}Co sheet source, collimator in place, for 1 million counts
Energy resolution	Annually*	Various radionuclides used, FWHM calculated
Count rate capability	Annually*	Two sources of $^{99\text{m}}\text{Tc}$ counted, one higher in activity than the other. Look for count rate that causes a 20% data loss (while using a 20% window)
Sensitivity	Annually*	Count rate for per μCi (using 20% window), for each collimator

*Parameters that are checked annually can be checked more frequently if a problem is suspected.

periodically to assure that parameter is within specifications (i.e., if intrinsic uniformity is checked daily, extrinsic uniformity could be checked weekly). If the camera being tested for uniformity performs SPECT acquisitions, a much higher count image (at least 30 million counts instead of 1 million) is acquired at least quarterly. Nonuniform fields can lead to “bull’s eye” or ring artifacts on acquired images.

WINDOW SETTING

This should be checked before the acquisition of each patient. If the improper window setting is used, image degradation can occur from improper photopeaks being accepted by the camera system. The most common approach to this is to use a symmetrical window centered at the energy peak of the radionuclide label being used in the imaging process. For ^{99m}Tc , the recommendation is to use a 20% window centered around a 140 keV photopeak. Using a narrower window of 10% to 15%, or an asymmetric window (i.e., centered slightly more than 140 keV) will improve resolution.

SPATIAL RESOLUTION AND LINEARITY

Bar phantoms containing lines with differing degrees of interspacing are routinely used to evaluate image resolution and linearity in the clinical setting. With modern imaging equipment, a weekly assessment is sufficient. Resolution is defined as the ability to discriminate between two distinct points. It is expressed subjectively in terms of the smallest bar pattern visible on the image. All groups in the bar phantom should also appear straight and parallel (linearity). Some distortion at the edge of the field of view is acceptable. The spatial resolution of a gamma camera is expressed quantitatively as the full width at half maximum (FWHM) of a line spread function. A narrower FWHM indicates better spatial resolution. In modern cameras, intrinsic resolution approaches 3 mm FWHM.

POSITRON EMISSION TOMOGRAPHY IMAGING

PET imaging shares many of the same principles as imaging with non-PET radiotracers. In fact, before the advent of PET-specific imaging systems, PET studies were (and occasionally still are) imaged with the standard gamma camera. Even with a thicker crystal and high energy collimator, image quality is poor, as the 511 keV photon is not optimally imaged with a NaI crystal. Cameras are now available that utilize the char-

acteristics of positron emitters to reconstruct high quality, high resolution images. As discussed earlier, positron emitters decay by releasing a positron—a positive electron—that travels a short distance before it comes to rest. When it does so, and comes in contact with a negative electron, an annihilation reaction occurs, giving off two 511 keV photons approximately 180 degrees apart. Using a full ring of detectors (or in the case of the gamma camera, two rotating camera heads), one can detect these “coincidence” events striking the camera face at the same time, and use that line of response to ultimately generate an image. PET-specific imaging devices typically incorporate a full ring of crystals, so that events will less likely be lost. The crystals have been designed to more effectively harness the energy of the 511 keV photon to cause a scintillation event. These crystals are denser than NaI, with a higher effective Z (atomic number) for better “stopping power.” The most commonly used crystals are bismuth germinate oxide (BGO), lutetium oxyorthosilicate (LSO), and gadolinium oxyorthosilicate (GSO), with effective Z of 74, 66, and 59, respectively. The last two crystals have superior light output and time resolution compared to BGO. Light from the photoelectric interaction of the 511 keV photon and the crystal is taken up by PMTs that are optically coupled to the crystals. Using the properties of the annihilation event, if there are two scintillation events that occur in paired detectors (detectors that share an arc across from a particular detector) that are recorded within a brief time window (10 nanoseconds), these are recorded as a true event. This effectively represents collimation, not by a physical lead device, but by electronics. This leads to excellent sensitivity (since photons are not physically lost). A few imaging systems do include collimation in the form of removable septa that can slide in and out between detectors to shield against “crosstalk” from activity outside the plane of interest. When the septa are inserted, it is called a two-dimensional acquisition. When the septa are not in place, it is referred to as a three-dimensional acquisition. The three-dimensional acquisition has the benefit of increased sensitivity, but suffers from increased misregistered events. Spatial resolution is much better than in SPECT, on the order of 7 mm in clinical imaging. Some resolution is lost because of the fact that a positron will travel a short distance (approximately 6 mm for the cardiac perfusion agent, ^{82}Rb ; approximately 2 mm for ^{18}F) before it comes to rest and annihilates, leading to uncertainty as where the decay actually occurred. In addition, because of the kinetic energy of the positron, not all annihilation events result in photons that are 180 degrees; this noncollinearity can lead to loss of resolution on the order of 1 to 2 mm. Other problems include misregistered events owing to Compton

scatter of photons or false events from two single events that strike the crystal within the 10 nanosecond window. Images are typically corrected for attenuation by either a ^{153}Gd transmission scan or with CT.

OTHER RADIATION DETECTORS

There are several other instruments that are commonly used in nuclear medicine departments. Some of these have direct clinical applications, whereas some are used to detect radiation in a sample or the environment. The Geiger-Mueller (GM) counter is a device used to detect small amounts of radioactive contamination. The probe is a gas-filled chamber wherein the enclosed gas becomes ionized when exposed to radiation. There is a high voltage between the anode and cathode of the detector, such that a single ionization event causes a propagation of additional electrons, amplifying the effect. The result is a device that is extremely sensitive for the detection of even small amounts of radiation. The drawback to using this device is that it is easily overwhelmed in high radiation fields—it takes some time for the charge in the detector chamber to dissipate, leading to “dead time” before it can detect another event. The maximum exposure rate reliably detected with a GM counter is 100 mR/h. Ionization chambers are used when higher dose rates are expected. They solve the dead time problem by applying a lower voltage across the anode to the cathode, so there is no large propagation of electrons as in the GM counter. Ionization chambers can detect exposure rates of 0.1 to 100 R/h. The dose calibrator used in nuclear medicine departments to assay the radiopharmaceutical activity is an ionization chamber. When a dose is placed in the chamber, and the radionuclide being measured is input into the selector (i.e., the reading will change depending on if the radiotracer being measured is $^{99\text{m}}\text{Tc}$ versus ^{67}Ga or ^{131}I), a readout of the activity is made in mCi. The range that can be measured is from 30 μCi to 2 Ci. Periodic quality control to determine constancy (dose is within 5% of computed activity; checked daily), linearity (accurate readout for activities over the whole range of potentially encountered activities; checked quarterly), accuracy (radiotracer standard measured and compared to what the activity should be; performed at installation and annually), and geometry (the correction for different positioning/sample size of the dose in the chamber; performed at installation). A third device that is commonly found in nuclear medicine departments is a sodium iodide well counter. In essence, this is a small gamma camera with a single PMT and PHA. In this case, the scintillation crystal surrounds the sample; a

hole is present in a block of NaI crystal (hence the name well counter), which is encased in shielding material. Surrounding the sample with detector increases the efficiency of detection of radiation manifold. However, this efficiency leads to a problem with dead time. If the activity in the sample exceeds approximately 5000 counts per second (much less activity than a μCi), the reading will likely be significantly underreported. A modified version of a NaI well counter is the thyroid probe used to calculate thyroid uptake values. The probe also has NaI crystal surrounded by shielding, a PMT and a PHA. The opening in the shielding is pointed at the patient’s neck at a precise constant distance, and readings are taken. A summary of selected radiation detectors is listed in table (Table 90-4).

RADIATION SAFETY AND NRC REGULATIONS

There is no safe dose of radiation, as in theory it takes only a single photon or particle to cause damage to DNA resulting in a genetic alteration. Of course, we know that the higher the dose of radioactivity one is exposed to, the more likely biological harm is to occur. With that in mind, efforts have been made to assure both the general public and workers that may be exposed to radiation that any exposure they may receive is *as low as reasonably achievable*—the basis of the ALARA program that will be found at any medical facility that utilizes radiation for clinical and research uses. Most of these directives can be found in the Code of Federal Regulations (CFR) part 19 (deals with inspections and instructions to workers), part 20 (deals with radiation protection standards), and part 35 (deals with human use of radioisotopes). The NRC is the governing body that has been charged with the enforcement of these directives. Individual States can reach an agreement with the Federal government to regulate directives regarding use of radioactivity in their state. The directives of these “Agreement States”

TABLE 90-4 Summary of Ancillary Nuclear Medicine Devices for Detection and Quantification of Radioactivity

DEVICE	DOSE RATE RANGE RELIABLY DETECTED	COMMENT
GM counter	<100 mR/h	Dead time a factor at high dose rates
Ionization chamber	0.1 mR/h–100 R/h	Dose calibrator is a type of ionization chamber (range 30 μCi –2 Ci)
Well counter	<1 μCi	Dead time a factor at high dose rates

can be more strict than those of the NRC, but cannot be less so.

RADIATION SAFETY RADIOACTIVE CONTAMINATION

No matter how much care is taken to ensure that radiopharmaceuticals do not end up contaminating objects in a department, accidents do occur from time to time. It is important to remember that if a spill or contamination event occurs while a patient is in distress, the needs of the patient outweigh containment concerns. Once the patient has been stabilized and is no longer in danger, then containment procedures become the priority. When it is first realized that a spill has or potentially has occurred, efforts should be made to confine the spill to the area. Gloves and shoe covers (if available) should be worn. Absorbent materials should be placed over the area where the spill took place. The radiation safety officer (RSO) should be notified as soon as possible, to help manage and coordinate efforts. The location should be “cordoned off” to help prevent accidental tracking and spreading of material to uncontaminated areas. It would be best if the RSO were the one to clean the spill, but if that is not possible, use damp absorbent materials to clean the spill, working inwards toward the center of the spill. Use of tongs or forceps is preferred to handle the absorbent material, if available. Proper protective equipment should be worn (gloves, shoe covers, and face shield/mask), as should be a personal dosimeter/film badge. When the cleanup is completed, and counts have fallen to a few times of background or less, items used during the cleanup will need to be either surveyed or presumed to be contaminated, and held with other contaminated objects until they have decayed to safe levels (as a rule of thumb, 10 half-lives of the radionuclide). After this time they can be returned or discarded as regular trash.

Those individuals who were in the area at the time of the spill and are potentially or known to be contaminated will need to be surveyed by the RSO in a different area (to avoid counting interference from the spill itself). Because of the inverse square law, this does not have to be a large distance away. Care should be taken to make sure contamination is not present on their shoes before they are moved to a different area. If there is contamination on an individual, its location is noted. If it is an article of clothing that is contaminated, that clothing is removed and (usually) will be held by the RSO in a safe area until the activity has decayed to safe levels. If the skin of an individual is contaminated, the area is washed thoroughly with soap and water, taking care to not damage the skin (abrasions may allow the contamination to enter the body).

RADIOIODINE THERAPY

^{131}I therapy for nonmalignant and malignant thyroid disease is both safe and efficacious. Many precautions must be taken, however, to protect the patient, their family and friends, and the general public from unnecessary radiation exposure. Whether a patient must be confined to a hospital room for his/her therapy is dependent on the measured activity at a specified distance from their chest. Some agreement States have the limit as 5 mR/h at 1 m from chest (which equates to approximately 30 mCi of activity of ^{131}I). The NRC has the limit as 7 mR/h at 1 m from chest (which equates to approximately 33 mCi of residual activity of ^{131}I). Activities that exceed these limits will necessitate confinement of the patient to a hospital room until these rates are achieved. The precautions that a patient need to take related to the fact that they are being made radioactive with an energetic long-lived (physical half-life, 8 days; effective half-life varies with thyroid uptake and renal function, but is usually quoted as 7.6 days), and the ways that the body seeks to eliminate the ^{131}I that is not taken up by the thyroid gland/thyroid malignancy. ^{131}I is eliminated from the body mainly through urine, but is also excreted in feces, saliva, sweat, and breast milk. In terms of radioactivity emitting from a source, exposure to individuals is reduced through three main factors: time, distance, and shielding. We do not send patients home with lead shielding, so time and distance are utilized to mitigate exposure. Patients are encouraged to increase the distance between themselves and other individuals, particularly pregnant women and children. The amount of time the patient spends around any one particular individual should also be limited. This is of course easy to control while the patient is in a private hospital room—visitors are discouraged or not allowed, and nursing staff are instructed to limit time spent in the room. Once the patient is discharged, or if they have received an outpatient therapy, they are told to sleep alone for the first 3 days after treatment or release. During this period, they should avoid kissing, sexual intercourse, and prolonged physical or intimate contact. When considering the ways ^{131}I is eliminated from the body, the remaining precautions will make sense. The patient is encouraged to drink plenty of fluids and to urinate frequently. This will hasten the elimination of ^{131}I not taken up by the thyroid or malignancy. Good bathroom hygiene is critical. Ideally, the patient should have sole use of a bathroom. Toilets should be flushed twice to assure that potential contamination is removed. Males are encouraged to be seated during urination to limit splashing of urine. Washing hands thoroughly with soap and water after urinating or defecating will help prevent spreading contamination. When eating, some

recommend that disposable utensils and plates be used; if they are not, utensils and plates should not be shared and washed separately. Clothes and linens used by the patient should also be washed thoroughly and separately. The majority of the above precautions should be observed for at least 3 days after release from the hospital or after administration of an outpatient therapy. Lactating mothers should NOT receive ^{131}I therapy, unless there is an absolute medical necessity—there would be an increased radiation burden to the breasts because of the hyperemia from the breast-feeding; breast-feeding will need to be discontinued at any rate to prevent radioiodine being passed to the nursing child. Because of an increased risk of miscarriage after ^{131}I therapy, female patients should not attempt to become pregnant for 6 to 12 months after therapy.

Precautions also have to be taken for the administrators of the therapy, as well as the facility where high-dose recipients will be confined. The administrator must keep distance from the patient to minimize personal radiation dose. Everyone involved with patient must wear personal dosimeter/film badge. Gloves must be used by the dose administrator. A mask to prevent inhalation of aerosolized ^{131}I is sometimes worn by the patient, the administrator, or both. Every participant in therapy must have his/her thyroid counted 24 hours after the therapy is performed. The room in which the patient stays will have to be prepared before the patient arrives. Signs informing the public and staff that the room is a radiation area must be posted. Absorbent material is taped to the floor, around the commode in the bathroom at a minimum, but usually throughout the room. This is very important, as iodine binds very well to many floor surfaces, particularly linoleum, making it difficult to remove contamination. Many facilities will wrap in plastic items like a phone, remote control or other device that a patient will frequently handle. Alternatively, a patient can wear gloves to handle these devices. Once the patient has been released, the RSO will have to survey the room before housekeeper can enter it to clean it, and before it can be used by another patient.

REGULATIONS GENERAL PUBLIC

According to the CFR part 20, each licensee shall conduct operations so that there is an annual dose limit of 100 mrem for members of the public, and that the dose in any *unrestricted area* does not exceed 2 mrem in any 1 hour. General radiation safety rules (no smoking, eating, drinking, etc.) must be posted in each laboratory in which radioactive materials are used. In addition, State/NRC regulations and telephone numbers must be

posted conspicuously in each nuclear medicine department. In addition, signage must be placed indicating which type of radiation area one may expect to encounter: “Radiation Area”—an accessible area where an individual could receive a dose equivalent in excess of 0.005 rem (0.05 mSv) in 1 hour at 30 cm from the radiation source or from any surface that the radiation penetrates; “High Radiation Area”—an accessible area where an individual could receive a dose equivalent in excess of 0.1 rem (1 mSv) in 1 hour at 30 cm from the radiation source or from any surface the radiation penetrates; “Very High Radiation Area”—an accessible area where an individual could receive an absorbed dose in excess of 500 rads (5 grays) in 1 hour at 1 m from a radiation source or from any surface that the radiation penetrates.

OCCUPATIONAL EXPOSURE DOSE LIMITS

According to the CFR part 20, the licensee shall control the occupational dose to individuals older than 18 years to 5 rem total body effective dose equivalent per year, 15 rem to the lens of the eye per year, 50.0 rem total organ dose equivalent per year, and 50 rem to the extremities per year. Additionally, the Licensee shall reduce the dose that an individual may be allowed to receive in the current year by the amount of occupational dose received while employed by any other person or facility (i.e., these doses are inclusive for *all* facilities where an individual works at). Additional limits apply to the embryo/fetus of a declared pregnant woman. This declaration consists of formally notifying the employer of the pregnancy *in writing*, and providing an estimated date of conception. The limit of the dose to the embryo/fetus over the entire 9-month period of gestation is 0.5 rem. This dose should be delivered at a fairly uniform rate over the entire gestation period and not delivered in a few large doses. The dose equivalent to the embryo/fetus is the sum of the deep-dose equivalent to the declared pregnant woman, and the dose equivalent to the embryo/fetus resulting from radionuclides in the embryo/fetus and radionuclides in the declared pregnant woman. This rule permits additional 0.05 rem if the declared pregnant worker has greater than 0.45 rem at the time of notification. Monitoring of employees is required if an individual is likely to receive a dose greater than 10% of limits (500 mrem/y), receive an intake greater than 10% of the annual limit on intake (ALI: the derived limit for the amount of radioactive material taken into the body of an adult worker by inhalation or ingestion in a year), and/or an individual is

entering a high or very high radiation area. Summation of internal and external doses is necessary if both internal and external doses are required to be monitored. Every employer is responsible for informing each employee on an *annual basis* of the worker's cumulative radiation dose.

RECORDABLE AND REPORTABLE EVENTS

There have been a few changes in recent years regarding misadministration terminology and definitions. The NRC no longer requires that administered doses be within 10% of the prescribed dose; this has now changed to 20%. Many states still have the 10% rule in place, however. In addition, the NRC has changed its terminology in regards to diagnostic reportable events, and it is now termed a "Medical Event." The corresponding criteria are incorrect radiopharmaceutical administered to patient, diagnostic dose differing from prescribed dose by greater than 20%, or administration of radiopharmaceutical by an unprescribed route. The difference between a diagnostic recordable event and a diagnostic medical event essentially is governed by the amount of dose that a patient receives as a result of the error. A recordable event is one in which the whole-body dose is *less than* 5 rem and any single organ dose is less than 50 rem. In a diagnostic medical event, the whole-body dose exceeds 5 rem and any single organ dose is greater than 50 rem. A therapeutic medical event occurs if the administered dose was not within 20% of prescribed dose. Medical events/reportable events require documenting the details of the error and notifying the NRC/state in writing of the misadministration, its effect, if any, on the individual(s) who received the misadministration, and that the referring physician and affected individual was notified of the error. Also to be included are what actions, if any, have been taken or are planned to prevent a recurrence. This should be reported to the NRC no later than the next calendar day after discovery of the medical event. Recordable events require documenting details of the event as above and keeping a record of it for 3 years.

RECEIVING, STORING, AND DISPOSING OF RADIOACTIVE MATERIALS

Most nuclear medicine departments have their radiopharmaceuticals delivered to them. These packages must be received and surveyed according to NRC regulations. In addition, every package containing radioisotopes must be logged in appropriately. This includes recording the radionuclide, the product name, the chemical form, the physical form, and the lot number. The time, date, and activity at time of calibration also

needs to be recorded, as does the time, date, and activity at time of receipt, shipper's package identifying number, and initials of person receiving the package. These packages need to be monitored for contamination if the package bears DOT radioactive material labels, or the package is crushed, damaged, or leaking. The recipient must immediately notify final delivery carrier and the NRC regional office if removable contamination limits are exceeded and/or external radiation exposure rate limits are exceeded. If your license requires you to survey every package received by your department, results of this monitoring must be recorded in a logbook. Radiation surveys are conducted both with a GM counter and via wipe tests. The GM counter tests are performed at the surface of the package and at 1 m above the surface. Wipe surveys are performed on all sides of the container. Security of nuclear medicine departments is a focus of inspectors. Areas that store radioactive materials must employ some sort of security (locked doors, keycard access, etc.) to prevent theft or access to unauthorized individuals. Items that are contaminated with or have residual amounts of radioactivity on them can be held behind lead shielding until they decay to background levels (generally 10 half-lives of the radionuclide), at which time they can be thrown away as regular trash.

SUGGESTED READING

Chandra R. *Nuclear Medicine Physics: The Basics*. Lippincott Williams & Wilkins; 2004.

QUESTIONS AND ANSWERS

1. A patient is suspected to have multinodular goiter of the thyroid gland. Which of the following radionuclides is best suited to image the thyroid gland?
A. 5 mCi Na^{131}I
B. 5 mCi Na^{123}I
C. 5 mCi $\text{Na}^{99\text{m}}\text{TcO}_4$
D. 5 mCi ^{201}Tl Chloride

ANSWER: C. $\text{Na}^{99\text{m}}\text{TcO}_4$. ^{131}I is not used for routine diagnostic imaging of patients with a thyroid gland. The imaging characteristics of ^{131}I are poor, due to its 364 keV photon. More importantly, if the dose listed in choice A was administered, it would have resulted in a dose of approximately 5000 rads to the thyroid gland (1000 rad per mCi of ^{131}I). Although it can be used to image the thyroid gland, ^{123}I is not used at this dose in a routine diagnostic

scan, as it would also give a high dose to the thyroid gland, albeit less than ^{131}I (10 rad per mCi of ^{123}I). The 159 keV photons emitted by ^{123}I are ideal for the gamma camera imaging system, and a thyroid uptake can also be performed with the same dose. The usual dose of ^{123}I for imaging of the thyroid gland is 200 to 400 μCi . $\text{Na}^{99\text{m}}\text{TcO}_4$ results in the lowest dose to the thyroid gland of the thyroid imaging agents (1 rad per 5 mCi of $\text{Na}^{99\text{m}}\text{TcO}_4$), and also has excellent imaging characteristics. It is technically challenging to do a thyroid uptake with $\text{Na}^{99\text{m}}\text{TcO}_4$, so a small amount of ^{131}I or ^{123}I is used for the uptake portion of the study (if performed). It should be noted that dose to the thyroid per unit of activity quoted above assumed a normal thyroid uptake. ^{201}Tl is not used to image the thyroid, although it is sometimes used in parathyroid adenoma imaging.

2. The patient in the prior question is indeed diagnosed with multinodular goiter. The ordering clinician asks that you treat the patient with a therapeutic dose of radioactive iodine. Which of the following is the correct dose rate and distance to avoiding having the patient confined to the hospital?
 - A. 5 mR/h at 1 m from chest
 - B. 10 mR/h at 1 m from the chest
 - C. 5 mR/h at 3 m from the chest
 - D. 10 mR/h at 3 m from the chest

ANSWER: A. 5 mR/h at 1 m from chest.

3. A technologist asks you to review at a bone scan. The image quality is severely deficient, with poor resolution and contrast. Which of the following is the *least* likely explanation for the described appearance?
 - A. Nonfunctional PMT
 - B. Patient too far away from collimator
 - C. Incorrect collimator used

ANSWER: B. A solitary nonfunctional PMT would give a focal round (or possibly hexagonal) defect within the field of view. All other choices can result in “diffuse” poor image quality.

4. What is the allowable limit of $^{99\text{m}}\text{Mo}$ in an eluate of $^{99\text{m}}\text{Tc}$ at the time of administration?
 - A. 10 mg per 1 mL of $^{99\text{m}}\text{Tc}$
 - B. 10 mCi per 1 mCi of $^{99\text{m}}\text{Tc}$
 - C. 0.15 μg per 1 mL of $^{99\text{m}}\text{Tc}$
 - D. 0.15 μCi per 1 mCi of $^{99\text{m}}\text{Tc}$

ANSWER: D. 0.15 μCi per 1 mCi of $^{99\text{m}}\text{Tc}$. The permissible amount of Al^{3+} is 10 mg per 1 mL of $^{99\text{m}}\text{Tc}$.

5. Which of the following parameters is tested with a point source of $^{99\text{m}}\text{Tc}$?
 - A. Extrinsic uniformity
 - B. Intrinsic uniformity
 - C. Spatial resolution
 - D. Linearity

ANSWER: B. Intrinsic uniformity is performed with the collimator removed from the imaging system, and a point source located a predetermined distance from the crystal face (on the order of 1–2 m). All other choices use a sheet/flood source.

6. Which of the following is an acceptable amount of radiation exposure in 1 hour for an area declared as an unrestricted area?
 - A. 10 mrem
 - B. 5 mrem
 - C. 2 mrem
 - D. 1 mrem

ANSWER: C. 2 mrem in 1 hour.

7. You are preparing to perform an ^{89}Sr therapy on a patient with painful osseous metastases from prostate carcinoma. A helpful colleague recommends that you shield the ^{89}Sr dose with lead shielding. You respond.
 - A. Lead shielding is not necessary, as β^- particle emissions from the radiopharmaceutical are not very penetrating.
 - B. Lead shielding is not necessary, as it may increase the dose of radiation that you will receive.
 - C. Thank you very much, that is very thoughtful of you. Lead shielding is just what I was looking for.
 - D. How could you possibly have made partner before me?

ANSWER: B. Lead shielding is in fact not desired, as it can cause penetrating bremsstrahlung x-rays to be produced. Although D may be a valid observation, it is not the best choice for this question.

8. A V/Q scan has been ordered for a patient suspected of having pulmonary thromboembolism. As the patient has severe COPD, you opt to use ^{133}Xe as your ventilation agent. Which of the following statements is *true*?
 - A. Vents should be positioned at or near the ceiling.
 - B. Ventilation portion of the study should be performed first.
 - C. Ventilation portion of the study should be performed in a positive pressure room.

D. Ventilation portion of the study is best imaged in the anterior projection.

ANSWER: B. The ventilation portion of the study should be performed first. If the perfusion portion was performed first, the downscatter phenomenon would degrade the ^{133}Xe ventilation images. ^{133}Xe studies should be performed in a *negative* pressure room (to keep a spill from exiting the room). Because ^{133}Xe is heavier than air gas, vents for “cleaning up” a spill are best situated close to the floor. ^{133}Xe ventilation studies are acquired in the posterior projection, as pulmonary thromboembolisms are more likely to go posteriorly. Attenuation of ^{133}Xe ’s 81 keV photon from overlying breast or chest wall also lessens the utility of the anterior projection.

9. Concerning adult workers, which of the following is correct regarding occupational dose limits?

- A. 50 rem total body effective dose equivalent per year
- B. 50 rem to the lens of the eye per year
- C. 50 rem to the extremities per year
- D. 50 rem total body effective dose per year at each facility they work

ANSWER: C. Adult workers are allowed 50 rem to the extremities per year. In addition, adult workers are allowed 5 rem total body effective dose equivalent per year, 15 rem to the lens of the eye per year, and 50 rem total organ dose equivalent per year. These doses are for inclusive for ALL facilities that an individual works at.

10. A patient presents to your clinic for a stress myocardial perfusion study. When the patient reaches peak stress, the technologist administers the radiotracer, and the stress portion of the study is completed as per the protocol. When the patient is imaged 1 hour later, no cardiac activity is seen but solely osseous structures. Which of the following steps do you now need to take?

- A. Document details of the occurrence
- B. Notify the NRC/state in writing of the misadministration
- C. Notify the NRC/state of plans for preventing recurrence
- D. All of the above

ANSWER: A. Document details of the occurrence. This is a recordable event, not a medical event (the former “reportable event”); the wrong radiopharmaceutical was administered, but the whole-body dose would be less than 5 R and single organ dose would be less than 50 R.

91 SKELETAL NUCLEAR MEDICINE

Pradeep G. Bhambhani

INTRODUCTION

Bone scan has been available and used for decades to image the skeletal system. It is very sensitive for pathology; but lacks specificity. It can image the entire skeletal system at a relatively low cost and therefore, remains popular for skeletal imaging. Bone scintigraphy the normal bone response to pathology and not the disease itself.

RADIOPHARMACEUTICALS

The radiotracer most commonly used for bone scan is Tc-99m methylene diphosphonate (MDP), where technetium-99m is the radioactive component and MDP the biological component. MDP binds to the hydroxyapatite present in the osteoid matrix. Tc-99m MDP can be prepared from a simple kit, where free pertechnetate is added to a vial containing MDP, stabilizers and stannous ion, the latter helps with reducing the valence state of technetium and thereby helps binding of technetium-99m with MDP. Free pertechnetate results when there is inadequate stannous ion available to reduce technetium and is evident as tracer activity in the salivary glands, thyroid gland, and stomach. This results in poor quality images and therefore reduces the sensitivity of the bone scan. After IV injection, the Tc-99m MDP is taken up by the osteoid matrix of the bone and also at other sites of calcification. Approximately 50% of the dose is taken up by bone and the remaining gets excreted by the kidneys. Peak bony uptake occurs 1 hour after injection, and imaging is usually done 2 to 4 hours after tracer injection for optimal skeletal-to-background ratios. Tracer uptake is directly proportional to the amount of osteoid matrix and blood flow. Additional radiotracers are available for imaging the skeletal system including Gallium-67, Samarium-153, and F-18, the latter is used in PET imaging.

IMAGING PROTOCOL

Typical bone scan done for evaluation of skeletal metastases involves IV injection of radiotracer and subsequent delayed imaging 2 to 4 hours later. An average dose for adult is 20 mCi (740 mBq). Patients are encouraged to

keep themselves well hydrated and void frequently to minimize radiation to the urinary bladder. Whole-body scan and planar images are obtained for suspicious or symptomatic regions. Additional SPECT (single photon emission computed tomography) can be obtained of specific areas of interest to improve image contrast resolution, and accurate lesion localization, as in imaging of the spine and facial bones. In instances where skeletal infection, trauma, prosthesis loosening and RSD are clinical concerns, a three-phase bone scan can be done. The “flow” phase involves the first minute of imaging after tracer injection over the area of concern. The “pool” phase involves imaging the soft tissues in the regions of interest 5 to 15 minutes after tracer injection and the “delayed” phase is conventional delayed imaging of the osseous structures done 2 to 4 hours after tracer injection.

NORMAL AND ABNORMAL BIODISTRIBUTION

In a normal bone scan, the radiotracer uptake is essentially symmetrical. Careful patient positioning is necessary to avoid apparent asymmetry. Most pathological states involving the bone invoke an osteoblastic response, seen on a bone scan as increased uptake of Tc-99m MDP. This is usually seen as sclerotic lesions on radiographs, although the scintigraphic findings frequently precede the radiographic findings. Diminished uptake can be seen in areas of bone destruction associated with aggressive metastases, although usually even with lytic lesions, there is increased blood flow and attempt at reactive bone repair, seen as areas of increased radiotracer uptake.

In a child, intense uptake is seen in the growth plate complex, which diminishes with advancing age until fusion of the epiphyseal plate occurs. Frequently child immobilization is required to obtain satisfactory images. Attention to the region of the growth plate is necessary as there is a tendency of infection and metastasis to favor the metaphysis. The growth plate complex appears globular in infants and as the child begins to walk, it appears more linear. Metabolic dysfunction resulting from chronic kidney disease and chronic steroid therapy may result in decreased growth plate uptake.

The sacroiliac joints appear to have increased uptake, thought to be due to weight bearing. Altered weight bearing and stress patterns may result in abnormal tracer accumulations in the asymptomatic extremity. Correlation with history is necessary in such instances.

The skull is very variable in appearance. Persistent visualization of the skull sutures in adult life may be

normal, however when marked, can be seen in renal osteodystrophy. Diffuse uptake in the calvarium, especially in the frontal region can be seen in benign hyperostosis frontalis interna. In infants, the base of the skull has increased uptake.

Focal uptake at the sternal manubrial junction is a normal finding and does not indicate pathology. Sternal foramina described in the lower sternum appear as uniform circular regions of radiotracer activity surrounding an area of central photopenia is also a normal variant.

In the lower thoracic and lumbar spine, the vertebrae are better identified, when compared to the cervical, upper and mid-thoracic vertebrae. Also the normal curvature of the spine causes portions of the spine closer to the detector to appear hotter than other regions.

Increased uptake in the patellae is commonly seen in the bone scan and usually ascribed to degenerative change.

In women, mild and diffuse uptake in breasts and uterus may be normally seen, although focal uptake may be indicative of pathology.

Arthritic changes involving the weight-bearing joints in the lower extremities and also the sternoclavicular and acromioclavicular joints can be seen.

External artifacts from metallic and other objects, like belts, coins, breast implants, pacemakers may appear as regions of decreased uptake/photopenia.

Renal and urinary bladder activity is normally seen, as the tracer is excreted by the kidneys. Reduced kidney activity and persistent background activity may be an indication of kidney disease, although more often poor visualization of the kidneys is a result of increased tracer accumulation in the skeletal system, associated with the “superscan,” seen in diffuse skeletal metastatic disease, or metabolic bone disease such as renal osteodystrophy, severe thyrotoxicosis, or acromegaly. In some instances, the kidneys may be low lying or pelvic in location, as after renal transplant or with horseshoe-shaped kidneys. Prominent radiotracer pelvic/iceal accumulation in the upright position may be an indication of obstructive uropathy. If the renal cortical activity is greater than or equal to the lumbar spine, consider drug therapy or iron overload, as in hemochromatosis or after multiple blood transfusions.

Significant bladder activity will limit complete evaluation of the pelvis and therefore voiding is a must prior to imaging.

External urinary contamination is usually evident on imaging without much difficulty.

SPECT imaging of the pelvis may result in streaking artifacts because of increasing urinary bladder activity during image acquisition.

Bisphosphonates therapy results in diffusely decreased skeletal uptake of Tc-99m MDP.

Radiation therapy is also associated with decreased radiotracer uptake at the site of skeletal radiation. Knowledge of radiation history is necessary in such cases.

Soft tissue accumulation of Tc-99m MDP is well reported in various disease entities, like neoplasms, hematomas, heterotopic bone formation or myositis ossificans, in the myocardium in amyloidosis, in splenic infarcts, pleural effusions, ascites, and at sites of dystrophic and metastatic calcification. Diffuse uptake can be seen in normal breasts and gynecomastia; however focal regions of activity in the breast can be associated with benign and malignant etiologies. Tracer uptake in visceral organs, like in the lungs and stomach is seen in metabolic disorders like hyperparathyroidism.

EVALUATION OF METASTATIC BONE DISEASE

Bone metastases are commonly associated with several malignancies. Malignancies involving breast, prostate, lung, and kidneys represent the source of approximately 80% of all osseous metastases. Patients present without symptoms or with bone pain, fractures and sometimes as spinal cord compression. Bone metastases occur via direct, lymphatic or hematogenous dissemination. Batson's plexus is a mesh of vertebral veins that connect with veins of the brain, skull, ribs, viscera and the vertebral column; they have been implicated in skeletal metastases associated with breast and prostate cancer.

Bone scan is much more sensitive than radiographs in detecting skeletal metastases, with the reported sensitivity between 62% and 100%. Bone scan can detect as little as 5% to 15% in bone turnover, whereas it requires a 50% loss in bone mineral content before the lesion can be seen on radiographs. The sensitivity is lower in detection of purely osteolytic cancers like multiple myeloma and other osteolytic skeletal metastasis. Lytic lesions associated with multiple myeloma are detected approximately half the time on bone scan, as compared to 80% detection on skeletal survey. Therefore, skeletal surveys are preferred in evaluation of osseous involvement in patients with multiple myeloma. This is a reflection of relative absence of reactive bone repair, possibly due to the production of an osteoblast inhibitory factor in this condition. Patterns of uptake in multiple myeloma would include normal, cold or photopenic areas or occasionally focal areas of increased uptake. Bone scan may also be normal in instances where the metastases are localized to the bone marrow. Occasionally in cases of aggressive tumors, there may be an absence of a reparative response and a cold or photopenic lesion is noted. Approximately 90% of patients with skeletal metastases present with multiple lesions of varying size, shape, and intensity. Only 10% of

patients with cancer present with a solitary bone metastasis. The percentage increases to 35% when two new lesions were detected, and reaches 100% when five new lesions were identified. Specifically a solitary rib lesion has approximately a 10% probability of representing a metastasis in a patient with known malignancy. Approximately 80% of all osseous metastatic lesions are in the axial skeleton. In the spine, sensitivity of lesion detection increases with use of SPECT, which may also be helpful in distinguishing benign from malignant processes, based on patterns of uptake on bone scan, specifically with uptake in the body itself favoring malignancy.

FLARE PHENOMENON

The flare phenomenon, which indicates a good response of bone metastases to treatment, is associated with increasing intensity and/or number of lesions on bone scan. It can be seen with bone scan as well as F-18 PET scan. Patients are typically asymptomatic and corresponding radiographs usually show sclerosis of the lesions. The phenomenon is usually seen between 2 weeks to 3 months following treatment, but can occasionally be seen as late as 6 months after treatment. Continued increase in the number and intensity of lesions beyond 6 months after treatment completion is usually indicative of disease progression. In general, it is appropriate to wait for approximately 3 months following completion of treatment regimen prior to repeating the bone scan. The diagnosis of flare phenomenon requires two criteria:

1. Increased intensity and/or number of lesions on bone scan (thought to be secondary to increased osteoblastic activity associated with healing of bone metastasis) and
2. Subsequent decreased uptake in these lesions on repeat bone scan after 3 months.

PROSTATE CANCER

Bone metastases are commonly seen in prostate cancer, and occur in up to 85% of patients dying of prostate cancer. Also patients who have bone metastases on scintigraphy at presentation have a higher mortality than those without. Bone metastases are uncommon (less than 1%) in patients with PSA less than 10 ng/mL and proportionally increase in incidence with rising PSA values, although PSA values are unreliable for assessment of metastases in those patients who have undergone androgen deprivation therapy. The incidence of osseous metastasis is also directly proportional to increasing Gleason histological grades, as all patients with a

“superscan” appearance of widespread metastases have high histological grades.

LUNG CANCER

Many patients with lung cancer present with disseminated metastatic disease including skeletal metastases, especially those with small cell and anaplastic cancer. Interestingly arterial metastases are more commonly seen with lung cancer, as these tumors can easily invade the vasculature. Thus involvement of the appendicular skeleton is more commonly seen in lung cancer.

In addition to the focal lesions noted in bone scan associated with osseous metastases, lung cancer may be notable for hypertrophic osteoarthropathy (HOA). Hypertrophic osteoarthropathy occurs in up to 10% of patients with lung cancer and involves clubbing of the fingers and toes, and periostitis of the long bones. Patients may have pain and swelling about the wrists and less commonly the ankles and knees. Radiographs may reveal periosteal new bone formation. Bone scan is notable for increased activity along the periosteum of long bones (“tramline sign”). Hypertrophic osteoarthropathy tends to resolve following tumor resection. It can also be seen in other chronic illnesses including, bronchiectasis, cystic fibrosis, mesothelioma, pneumoconiosis, cyanotic heart disease, and inflammatory bowel disease.

BREAST CANCER

The skeleton is the most common site of distant metastases in breast cancer. Detection of skeletal metastasis with bone scintigraphy precedes radiographic detection, by an average of 4 to 6 months. In breast cancer patients, there is a low positive yield for the bone scan in patients with asymptomatic stage I disease and those with small primary tumors (less than 2 cm), therefore the routine use of preoperative bone scanning in these patients is probably unnecessary. Approximately 5% of patients present with stage IV disease (distant metastases), and those with only bone metastases have a significantly better survival when compared to those with bone and extraskelatal metastases. Women with breast cancer, present with bone metastasis at the time of diagnosis, have a markedly worse prognosis. In patients with breast cancer, 21% of patients relapsed with a solitary bone metastasis, the most common location being the spine. However, an isolated sternal lesion, which is usually a benign finding in the setting of breast cancer, has a 75% to 80% likelihood of being an osseous metastasis.

NEUROBLASTOMA

It is one of the most common extracranial solid tumors in children and is frequently associated with skeletal metastasis. Frequently the primary tumor is seen on the bone scan. Lesions are typically multifocal in the metaphysis, commonly in the proximal humeri, distal femurs, and proximal tibiae, although involvement of the skull, vertebrae, ribs, and pelvis is also commonly seen. Imaging with I-123 or I-131 MIBG is more sensitive than bone scan for metastatic evaluation, though a combination of both imaging is complementary.

OTHER TUMORS

There is decreased sensitivity in detection of bone metastases from kidney tumors, as they are associated with “cold or photopenic” lesions, and are therefore better assessed with skeletal survey or MRI.

Focal or diffuse uptake may be seen in Hodgkin’s lymphoma, although presently lymphomas are best evaluated with F-18 FDG PET-CT.

Focal or diffuse abnormalities may be seen in systemic mastocytosis, a condition associated with tissue mast cell infiltration. Patients complain of bone pain, abdominal pain, flushing, diarrhea, and skin rashes.

A spectrum of scintigraphic findings are seen in histiocytosis, including focally increased uptake noted in unifocal eosinophilic granuloma, negative scans, and cold lesions, some with a peripheral rim of activity.

PRIMARY BONE TUMORS

There is a limited role of bone scintigraphy in evaluation of primary bone tumors, as MRI provides additional information regarding soft tissue involvement and tumor margins. Bone scan is useful in evaluating skeletal metastatic spread and response to therapy in these instances.

OSTEOGENIC SARCOMA

It is the most common primary malignant bone tumor. It occurs most commonly in the second decade of life, in the metaphysis of long bones, with 50% of cases occurring about the knee. Tracer accumulation is increased with patchy areas of decreased uptake within the overall increased region of activity. The major use of bone scintigraphy is in detection of skip lesions in the medullary bone adjacent to the primary tumor and

detection of distant skeletal metastases. Local evaluation after limb amputation is important, as increased activity in the stump after 6 months may indicate local recurrence.

EWING SARCOMA

It is the second most common primary bone tumor after osteogenic sarcoma. More than 80% of the Ewing sarcomas occur in patients younger than 20 years, and interestingly blacks are rarely affected. The tumor usually arises in the diaphysis of a long bone (humerus, femur, tibia, or fibula), but 20% arise in the pelvis and lesions in the pelvis are associated with a worse prognosis. The most common presenting symptoms are pain and swelling. Patients may complain of systemic symptoms such as fever, anorexia, weight loss, and fatigue, and the clinical presentation may be confused with chronic osteomyelitis. The lesion usually produces a “moth-eaten” pattern of bone destruction on plain film radiographs and the lesion is typically “hot” on blood flow, pool, and delayed bone scan images. Bone scan is useful to assess for skeletal metastasis and monitoring therapy. The incidence of distant metastasis at the time of presentation ranges from 10% to 40%, most commonly to the lungs and bone. On follow-up, the skeleton is the first site of metastatic disease in approximately 25% of patients.

OSTEOID OSTEOMA

Osteoid osteoma is a benign bone tumor that occurs most commonly in adolescents and young adults, with 90% of cases seen in patients younger than 25 years. The osteoma is most commonly cortical but can be medullary, periosteal, or intracapsular in location. Typical clinical presentation is localized bone pain, worse at night and relieved with aspirin. The proximal femur and tibia account for a majority of the cases. When the lesion occurs in the spine (10% of cases), it nearly always occurs in the posterior elements (50%) and is frequently associated with a painful scoliosis with the convexity of the curve oriented away from the side of the lesion. The most common location of a spinal lesion is the lumbar spine.

On plain films, the very vascular nidus of the osteoid osteoma is lucent and is surrounded by dense, reactive sclerosis. MRI demonstrates decreased signal intensity because of the reactive bony sclerosis, but the nidus may produce a brighter signal.

On bone scan, the lesion is hot on all three phases. On delayed images, the nidus may be seen as a focal area of

even greater activity within the diffuse abnormality. A normal bone scan virtually excludes the diagnosis of an osteoid osteoma. Bone scan is also useful in the follow-up of these patients after treatment, as persistent scintigraphic abnormality may be indicative of residual disease. SPECT is very useful for precise localization. Intraoperative localizing probes and monitoring radioactivity of removed bone fragments have been used during surgery.

FIBROUS DYSPLASIA

Usually there is intense tracer activity associated with monostotic or polyostotic fibrous dysplasia.

HETEROTOPIC OSSIFICATION

This is also referred to as “myositis ossificans,” which is usually seen after trauma, other etiologies of heterotopic ossification include after paralysis or spinal cord injury, or hip joint replacement. Serial bone scans are useful to evaluate the maturity or the degree of inflammatory activity in myositis ossificans. Recurrence of heterotopic ossification is decreased when mature calcification is excised. Decreasing MDP uptake is seen as the heterotopic ossification matures. Three-phase bone scanning is very sensitive for the early detection of myositis ossificans.

OSTEOMYELITIS

Osteomyelitis is infection localized to bone or the bone marrow. It can occur as a result of hematogenous seeding, contiguous spread of infection to bone from adjacent soft tissues and joints, or direct inoculation of infection into the bone as a result of trauma or surgery. In long bone hematogenous osteomyelitis, the most common site of infection is in the metaphysis. The major blood vessel to long bones usually penetrates the mid-shaft of the bone and then travels toward both ends, forming metaphyseal vascular loops just before it hits the epiphyseal plates. Slowed blood flow in these loops along with the absence of basement membranes predisposes the metaphysis to osteomyelitis. For the same reason osteomyelitis involving the epiphysis is uncommon. In the setting of osteomyelitis, inflammatory exudate in the marrow leads to increased intramedullary pressure, with subsequent extension of exudate into the bone cortex where it can rupture through the periosteum. If this occurs, the periosteal blood supply is interrupted, leading to necrosis. The resulting pieces of separated dead

bone are known as “sequestra.” New bone formation in regions of periosteal damage is known as an “involucrum.” Acute osteomyelitis is infection in bone prior to development of sequestra, whereas after the formation of sequestra, the infection is considered to be chronic. In children the femur and tibia are the most common sites of osteomyelitis.

Hematogenous osteomyelitis is usually monomicrobial, while contiguous osteomyelitis may be either polymicrobial or monomicrobial. *Staphylococcus aureus*, coagulase-negative staphylococci, and aerobic gram-negative bacilli are the most common organisms; other pathogens implicated include streptococci, enterococci, anaerobes, fungi, and mycobacteria. Acute osteomyelitis typically presents with dull pain at the involved site, with or without movement, local tenderness, warmth, erythema, swelling, and fever. Acute osteomyelitis can also present as septic arthritis. Chronic osteomyelitis presents with pain, erythema, or swelling, sometimes in association with a draining sinus tract. If exposed bone is present, osteomyelitis is very likely.

Establishing an accurate and early diagnosis of osteomyelitis is critical, since the infection can require prolonged antibiotic therapy and/or aggressive surgical intervention. The gold standard for diagnosis is isolation of bacteria from a bone biopsy sample obtained via sterile technique, and histological findings of inflammation and osteonecrosis. Laboratory tests are usually nonspecific. Radiographs are limited by their sensitivity and specificity. In early infection, radiographs may be normal, whereas in chronic osteomyelitis; typical findings include cortical erosion, periosteal reaction, mixed lucency and sclerosis. MRI is very sensitive for the detection of acute osteomyelitis. It is useful in delineating the extent of cortical destruction and evaluating the bone marrow and associated soft tissue inflammation, as in the setting of cellulitis or myositis. Additionally it can also demonstrate sinus tracts, fistulas, and abscesses.

Scintigraphy is especially useful early on when radiographic abnormalities are not evident, and initiation of early treatment prevents irreversible bone damage. Sensitivity greater than 90% is described in several series for diagnosis of osteomyelitis. Characteristic finding in a “three-phase bone scan” is increased activity in the blood flow and pool phases and intense focal uptake in the involved bone in the delayed phase. However, these findings are not specific for infection as similar findings have been described in neuropathic joints, fractures, including stress fractures, gout, rheumatoid arthritis, etc. SPECT is very useful in evaluating the skull or the spine. In the absence of underlying bone disease, the overall sensitivity for a three-phase bone scan is 94%

and the specificity 95% for detection of osteomyelitis. In instances where bone remodeling may be present, the sensitivity is 95%, but the specificity declines to 33%. In an adult a negative bone scan essentially rules out infection.

In children symptoms can be unreliable and infection could be multifocal, therefore it is important to perform a whole-body scan. Subperiosteal pus/edema, joint effusion, or vasospasm can decrease vascularity to the infected area. Therefore, in a child, increased blood flow may be absent, even when there is a clear abnormality on delayed images. Positioning is extremely important especially in children, as activity in the growth plates may mask the focus of infection in the neighboring metaphysis, if the camera is not perpendicular to the physis and subtle asymmetric activity may be the only indicator of an early osteomyelitis. Photopenic (cold) defects on delayed images are uncommon but may be seen particularly in the very early stages of the infection. Therefore in children, if the bone scan is normal initially and if there is sufficient clinical suspicion, a repeat examination should be repeated in 2 to 3 days, or a gallium examination may be performed. As the condition evolves into the sub acute phase, hyperemia rather than ischemia becomes the dominant finding.

MRI is probably the modality of choice when evaluating patients for suspected vertebral osteomyelitis. Gallium scan combined with bone scan, has a 86% accuracy in the detection of vertebral osteomyelitis, can be done in those patients who cannot tolerate MR. Indium 111 leukocyte imaging is not as sensitive for infection of the spine as for other musculoskeletal infections and may be falsely negative in up to 80% of cases.

NEUROPATHIC FOOT

Neuroarthropathy develops most commonly in the tarsal and tarsometatarsal joints (60%) followed by the metatarsophalangeal joints (30%) and tibiotalar joints (10%). The most common cause of Charcot joints is diabetes mellitus. It predisposes these patients to infection because of underlying neuropathy, vasculopathy, and leukocyte dysfunction. Loss of pain sensation and proprioception, facilitated by vasculopathy and WBC dysfunction, leads to repeated trauma, ulceration, and infection. The most frequent sites of infection are pressure points over bony prominences, including the metatarsal heads, phalanges, and the calcaneus. Diagnosis of osteomyelitis complicating the neuropathic joint is very challenging, as the combination of arthropathy, ulceration, and soft tissue infection results in increased activity on all phases of the bone scan,

resulting in low specificity. Radiographs are poorly sensitive in this situation. Combined tagged WBC and Tc-99m sulfur colloid marrow imaging is the procedure of choice for the evaluation of patients with Charcot joints, as it can better identify those patients with true osteomyelitis, where one would typically see accumulation of labeled WBCs and lack of or decreased marrow activity. MRI complements scintigraphy in evaluation of suspected osteomyelitis in the Neuroathic foot.

PROSTHESIS EVALUATION

Approximately 500 000 hip and knee arthroplasties are performed annually in the United States. Complications can arise after surgery, including infection, aseptic loosening, joint dislocation, heterotopic ossification, and fracture. Differentiating infection from aseptic loosening, the most common complication of arthroplasty is challenging. Because the treatment of these entities is radically different, accurate differentiation is very important. Treatment of loosening is usually a single step revision arthroplasty, whereas for infection, treatment involves removal of hardware, prolonged antibiotic therapy, and eventual revision arthroplasty.

Bone scan finding of periprosthetic activity is very nonspecific. The increased periprosthetic activity reflects increased bone mineral turnover, which can be seen in infection as well as other conditions like aseptic loosening. Up to 1 year after hip arthroplasty, patterns of periprosthetic uptake are variable, beyond 1 year in case of cemented hip prosthesis, most asymptomatic patients have a normal scan; however, up to 10% of asymptomatic patients will have some periprosthetic uptake despite no complications. In case of cementless or porous coated hip arthroplasty, where bony ingrowth occurs into the porous coating applied to the prosthesis surface, persistent uptake beyond 1 year is even more prevalent. Similar observations have been made with knee arthroplasty. Although not commonly done, a baseline study done with serial imaging would be more useful in following these patients. Typically, there is diffusely increased periprosthetic activity associated with infection, as opposed to aseptic loosening in which there is a focal uptake noted around the prosthesis. However, these findings are not specific and significant overlap of findings exists in infection and loosening. Conventional bone scan has a sensitivity of 65%, specificity of 70%, and an accuracy of 70% for the diagnosis of infected prosthesis. However bone scan is useful as a screening examination because a normal scan essentially rules out a prosthesis complication. Combined leukocyte–marrow imaging is helpful to

overcome issues created by variable marrow distribution postoperatively and should be used regularly in evaluating a painful arthroplasty. It is based on the observation that infection stimulates the accumulation of tagged WBC and suppresses the uptake of sulfur colloid in the bone marrow. The reported sensitivity, specificity and accuracy with combined imaging are greater than 90%.

BONE MARROW SCINTIGRAPHY

This procedure is performed with Tc-99m sulfur colloid in patients with sickle cell anemia, to demonstrate marrow expansion and marrow infarctions. It is however unable to differentiate between acute and chronic marrow infarction. In infection, it is used along with labeled WBC to evaluate osteomyelitis and in evaluation of a painful prosthesis to differentiate infection from aseptic loosening.

METABOLIC BONE DISORDERS

HYPERPARATHYROIDISM

Primary hyperparathyroidism in most patients will have a normal bone scan. In general, only severe cases of the disorder demonstrate findings on the bone scan. Scintigraphic findings include increased activity on delayed images can be seen in the axial skeleton, the long bones, the mandible, the skull, the acromioclavicular joints, hands, and the sternum (areas which frequently demonstrate demineralization on plain film). Focal abnormalities may be seen with Brown tumors, or compression fractures. Soft tissue tracer activity has been reported in sites of metastatic calcification (often the lungs, kidneys, and stomach).

In secondary hyperparathyroidism, unlike primary hyperparathyroidism, the bone scan is usually abnormal. There is diffusely increased skeletal activity, with decreased renal activity producing a “superscan” appearance in severe renal osteodystrophy. This is due to the generalized increase in bone turnover and not just tracer retention caused by renal failure. Absence of bladder activity makes it more likely that the superscan appearance is from renal osteodystrophy rather than metastatic disease or other metabolic diseases. Additional findings seen include the beading of activity along the costochondral junctions (“rosary bead appearance”), diffuse calvarial uptake, mask-like periorbital accumulation, uptake in the maxilla, mandible, and sternum. Brown tumors may also produce focal abnormalities.

OSTEOMALACIA

The bone in this condition is inadequately mineralized. It results from dietary insufficiency of calcium, phosphorus, and/or Vitamin D, GI malabsorption or inadequate Vitamin D synthesis. Bone scan is reliable in detection of Looser zones or pseudofractures, seen frequently and symmetrically in the ribs.

PAGET DISEASE OF BONE

Paget disease or osteitis deformans is a benign disorder of bone remodeling and affects between 3% and 4% of the population older than 40 years and up to 10% to 11% after age 80 years. The exact cause of Paget disease is not known; a viral etiology has been postulated. Pathologically, there is an increased osteoclastic resorption of bone followed by intense osteoblastic activity and increased vascularity. The most commonly involved bones are of the axial skeleton, spine (30%–75%), skull (25%–65%), pelvis (30%–75%), and proximal long bones (25%–35%, femur and tibia). Monostotic disease occurs in 10% to 35% of patients and is more often seen in the axial skeleton. Polyostotic disease (65%–90%) occurs more commonly. Paget disease can be asymptomatic, and is often found incidentally when working up increased serum alkaline phosphatase or abnormal radiographs done for other reasons. Clinical features include local pain, tenderness, bowing deformities, kyphosis of the spine, and bone expansion.

Classically, there are three phases to this disorder—lytic phase, mixed phase, and blastic phase. Initially, intense osteoclastic activity produces the lytic or incipient active phase. The scintigraphic appearance is fairly typical with intense radiotracer accumulation throughout the affected bone, with the exception of the lytic phase more commonly seen in the skull, where the uptake is mainly noted at the margins of pagetic involvement (osteoporosis circumscripta) and also after therapy. In the long bones, the process begins in the subchondral region of the epiphysis and extends along the shaft in a characteristic V shaped (“flame” or “blade of grass”) appearance. Additional patterns and signs have been described including the “Mickey Mouse sign,” in a pagetic vertebra, with a typical pattern of an inverted triangle of three dots indicating involvement of the transverse processes and the “Abe Lincoln sign” with monostotic mandible involvement, etc. Differential diagnosis on bone scan includes malignancy, where typical uptake is more focal and circular, without bony expansion, although sometimes differentiation between Paget disease and skeletal metastasis is very difficult. Scintigraphy is more sensitive than plain films for disease detection during the

lytic phase. Scintigraphy is also useful to monitor disease progression while on therapy, where response is associated with regression of scintigraphic abnormalities, although changes in alkaline phosphatase and urinary hydroxyproline and N-terminal telopeptide better monitor response to treatment.

Sarcomatous degeneration occurs in less than 1% of patients with Paget disease. Patients with severe polyostotic disease and males have an increased risk for degeneration. New focal pain and swelling are the most common clinical complaints. The most common location is the hip, pelvis, and shoulder. The most common neoplasm is an osteosarcoma (50%–60% of cases), but pleomorphic sarcoma, chondrosarcoma, fibrosarcoma, giant cell tumor, and malignant fibrous histiocytomas have all been reported. Radiographs may show a new, enlarging lytic lesion. Bone scan commonly reveals decreased uptake of tracer within the lesion in comparison to the adjacent Pagetoid bone, however, increased activity may also be seen. Increased gallium accumulation associated with relatively decreased Tc-99m MDP activity suggests malignant degeneration.

AVASCULAR NECROSIS

There are several etiologies for avascular necrosis, including trauma (most common), idiopathic, steroids, ETOH abuse, sickle cell disease, caisson disease, vasculitis (SLE), pancreatitis, bisphosphonate use, radiation therapy, polycythemia, and Gaucher disease. In children, Legg-Calve-Perthes disease results in avascular necrosis of the femoral head epiphysis. Bone scan findings depend on the time since the vascular insult. With acute interruption of blood flow, infarcted bone is seen as a cold or photopenic region. Once bone repair begins, increased tracer uptake is initially noted at the margin of infarction, which progressively increases into the infarcted zone and eventually normalizes once healing is complete.

COMPLEX REGIONAL PAIN SYNDROME OR REFLEX SYMPATHETIC DYSTROPHY

Complex regional pain syndrome includes a spectrum of motor, sensory, and autonomic findings predominantly affecting the extremities. Clinical findings include pain, swelling, vasomotor changes, functional impairment, and muscle wasting. It can occur after trauma, CVA and other acute illnesses. The classic finding in bone scintigraphy includes increased uptake in the blood flow and blood pool phases reflecting increased vascularity and

periarticular uptake in the delayed phase. However, abnormality in all the three phases is seen in less than 50% of patients. The periarticular uptake in the delayed phase has very high sensitivity (greater than 95%), but specificity is decreased in patients with diabetes and foot infections. Bone scan findings vary depending on the time of onset of the syndrome, with the classic findings seen in the initial 5 months. Thereafter the increased flow is not seen and the periarticular uptake may be decreased, normal, or persistently increased.

SKELETAL TRAUMA

Bone scan has an important application in detection of occult skeletal trauma in both children and adults. It allows for detection of trauma at a very early stage predating the radiological findings. Approximately 80% of bone scans will show increased activity at the site of fracture by 24 hours, and 95% by 72 hours, although the elderly and debilitated patients may not show activity for several days. In the latter instances repeat imaging approximately 7 days later is recommended. The time a fracture takes to heal to result in a normal bone scan is variable. Approximately 60% to 80% of nondisplaced and uncomplicated fractures revert to a normal bone scan in 1 year and greater than 95% in 3 years. However in cases where the joint is involved, posttraumatic arthritis can confound or result in indefinite increased uptake on a bone scan.

STRESS FRACTURES

Stress fractures occur because of repetitive activity applied on normal bone. The involved bone reacts to the repetitive stress by internal osseous remodeling, which strengthens the bone to withstand the particular stress. However during the remodeling process, there is a period when bone resorption exceeds bone formation, which temporarily weakens the cortex. Microfractures can result if the stress is continually applied to the bone and eventually an overt fracture may result if these microfractures are not allowed to heal. Bone scan is very sensitive in these instances and will typically show increased activity, 1 to 2 weeks before radiographic abnormality is apparent. The sensitivity of bone scan for the diagnosis of stress fracture approaches 100%. Typically, increased activity is seen in the blood flow, pool, and delayed images. The metatarsals and the posterior medial cortex of the tibia are the most common locations for stress fractures.

In the sacrum, stress fractures are associated with osteoporosis or prior radiation therapy to the pelvis. This

characteristic sacral insufficiency fracture has a “butterfly” or “Honda sign” appearance with fracture lines running vertically through the left and right sides of the bone just medial to the sacroiliac joints, and a transverse fracture just below the level of the sacroiliac joints. Radiographs are typically normal, but may show sclerosis in sacral ala.

Shin splints (stress periosteal reaction) are characterized by abnormal linear (nonfocal) tracer activity along the posteromedial tibial cortex. It is usually seen in runners and results from tearing of muscle fibers anchoring the muscle to the periosteum, resulting in a periosteal reaction. Patients present with exercise-induced pain in the posteromedial distal leg. The radionuclide uptake is usually superficial and mild to moderate in intensity along the distal and posteromedial tibial cortex. No significant increase in blood flow is seen with shin splints, unlike stress fractures.

OSTEOPOROSIS

Osteoporosis is a skeletal condition characterized by low bone mass, which is associated with reduced bone strength and an increased risk of fractures, particularly at the spine, hip, wrist, humerus, and pelvis. Osteoporosis is commonly identified in postmenopausal women most likely related to the decrease in estrogen secretion. Other causes of osteoporosis include corticosteroid use, Cushing’s disease, prolonged inactivity, and nutritional deficiencies. Skeletal scintigraphy has very limited role in detection and follow-up of osteoporosis. Bone mineral density is the most important determinant of bone fragility and risk of fracture. Quantitative assessment of bone mineral density (BMD) using Dual energy x-ray absorptiometry is the most common clinically used modality in evaluation of osteoporosis. The normal value for BMD is within one standard deviation of the young adult reference mean (T-score). The WHO has defined osteopenia as a BMD T-score between 1 and 2.5 standard deviations below the young adult reference mean. Osteoporosis is defined as a T-scores, 2.5 standard deviations below the young adult mean.

QUESTIONS AND ANSWERS

1. In nuclear imaging of the musculoskeletal system, what advantages does SPECT offer over planar imaging?
 - A. Better spatial resolution
 - B. Faster imaging time
 - C. Better image contrast resolution

ANSWER: C. SPECT imaging offers the advantage of improved image contrast resolution and accurate lesion localization in the three planes over planar imaging. Target to background ratio is improved by removing the overlying tissues, which is not possible in planar imaging. Spatial resolution is degraded with SPECT imaging.

2. Superscan can be seen in all the following conditions *except*:
 - A. Osseous metastases
 - B. Renal osteodystrophy
 - C. Bisphosphonate therapy
 - D. Hyperparathyroidism

ANSWER: C. Diffusely increased skeletal uptake is a unique scintigraphic pattern referred to as “superscan.” The renal activity/kidneys are not clearly seen or absent in a superscan. They can be seen in diffuse skeletal metastatic disease, primary hyperparathyroidism, and renal osteodystrophy. Poor skeletal uptake of tracer may be an indication of chronic bisphosphonate therapy.

3. Presence of gastric activity in a whole-body bone scan is suggestive of free pertechnetate, if the following is also seen:
 - A. Pulmonary activity
 - B. Thyroid activity
 - C. Renal and urinary bladder activity
 - D. Cerebral activity

ANSWER: B. Free pertechnetate results when there is inadequate stannous ion available to reduce the technetium ion. The free technetium is evident as activity in the salivary glands, thyroid gland, and the stomach. Technetium tagged to MDP is the isotope used in bone scintigraphy. It is predominantly excreted via the kidneys and as a result renal and urinary bladder activity is normally seen in bone scans. Pulmonary, gastric, and renal uptake can be seen in metabolic disorders such as hyperparathyroidism.

4. What is the most common complication following primary joint replacement surgery?
 - A. Aseptic joint loosening
 - B. Infection
 - C. Fracture
 - D. Heterotopic ossification

ANSWER: A. By 10 years after arthroplasty, 50% of prostheses have radiographic evidence of loosening and 30% require revision. Its pathogenesis includes pseudomembranous structure made of histiocytes, giant cells, lymphocytes, plasma cells, and sometimes neutrophils, which develops at the cement bone interface, and osteolysis induced by unsuccessful attempts at phagocytosis induced by particulate debris from component degradation and secretion of cytokines and enzymes. These damage the bone and cartilage leading to osteolysis and prosthesis loosening. The rate of infection following primary joint replacement surgery is approximately 1% for hip prosthesis and 2% for knee joint prosthesis. Following revision surgery, the rates of infection are higher, approximately 3% for hip replacements and 5% for knee joint replacements. Differentiating aseptic loosening, the most common complication of arthroplasty, from infection is challenging.

5. The combined WBC/bone marrow scintigraphy protocol performed for evaluation of osteomyelitis is based on the fact that infection:
 - A. Is associated with accumulation of tagged WBC and decreased accumulation of the Tc-99m sulfur colloid in the bone marrow scan

- B. Stimulates accumulation of Tc-99m sulfur colloid and decreases accumulation of tagged WBC
- C. Stimulates accumulation of both tagged WBC and Tc-99m sulfur colloid
- D. Decreases accumulation of both tagged WBC and Tc-99m sulfur colloid

ANSWER: A. Leukocyte imaging may be false-positive because of normal WBC activity in the bone marrow or healing bone, in evaluations of osteomyelitis. Therefore it is used in combination with marrow imaging, where congruent uptake in leukocyte and marrow imaging is consistent with physiologic marrow uptake, but incongruence, where there is WBC uptake and corresponding absence of marrow uptake, is suggestive of infection.

6. What is the most likely etiology for a solitary rib focal lesion on bone scan?
- A. Solitary skeletal metastasis
 - B. Rib fracture
 - C. Infection
 - D. Osteoid osteoma

ANSWER: B. Approximately 90% of patients with skeletal metastases present with multiple lesions. Only 10% of patients with cancer present with a solitary bone metastasis. The most common etiology in this instance is related to trauma. In a published trial evaluating solitary focal rib lesions in extraskelatal cancer, only 12% of patients were attributed to have solitary bone lesion on bone scan, the remaining 88% were from benign reasons. Ribs are an unusual location for osteoid osteomas, which are usually seen in the femurs.

7. Which of the following entities is *least likely* to show uptake on bone scan?
- A. Bone island
 - B. Osteoid osteoma
 - C. Osteomyelitis
 - D. Paget disease.

ANSWER: A. All the above except bone island are associated with increased flow and bone repair and therefore increased activity on a bone scan. Mild focal uptake may be occasionally seen in bone islands, reflecting the mild metabolic activity of the bone island, usually associated with larger and metabolic bone islands.

8. Which of the following joints is most commonly involved with Charcot arthropathy?
- A. Knees

- B. Tibiotalar
- C. Tarsal and tarsometatarsal
- D. Metatarsophalangeal

ANSWER: C. Neuroarthropathy develops most commonly in the tarsal and tarsometatarsal joints (60%) followed by the metatarsophalangeal joints (30%) and tibiotalar joints (10%). The most common cause of Charcot joints is diabetes mellitus. It predisposes these patients to infection because of underlying neuropathy, vasculopathy, and leukocyte dysfunction. Loss of pain sensation and proprioception, facilitated by vasculopathy and WBC dysfunction, leads to repeated trauma, ulceration, and infection. The most frequent sites of infection are pressure points over bony prominences, including the metatarsal heads, phalanges, and the calcaneus. Diagnosis of osteomyelitis complicating the neuropathic joint is very challenging, as the combination of arthropathy, ulceration, and soft tissue infection results in increased activity on all phases of the bone scan, resulting in low specificity. Radiographs are poorly sensitive in this situation. Combined radio labeled WBC and Tc-99m sulfur colloid marrow imaging is the procedure of choice for the evaluation of patients with Charcot joints as it can better identify those patients with true osteomyelitis, where one would typically see accumulation of labeled WBC and lack of or decreased marrow activity. MRI complements scintigraphy in evaluation of suspected osteomyelitis in Charcot arthropathy.

9. What is the most common organism responsible for prosthetic joint infection?
- A. *S. aureus*
 - B. *Staphylococcus epidermidis*
 - C. *E. Coli*
 - D. *Pseudomonas aeruginosa*

ANSWER: B. *S. epidermidis* (30%) and *S. aureus* (20%) are the most common offending organisms implicated for prosthetic joint infections. Approximately one-third of joint infections occur within 3 months of the arthroplasty, a third occur within 1 year of implantation and the remainder after 1 year of surgery.

10. Vertebral uptake in a bone scan with SPECT is suggestive of bone metastases when there is involvement of the:
- A. Vertebral body
 - B. Lamina
 - C. Articular facets
 - D. Spinous process

ANSWER: A. More than 50% of all skeletal metastases are found in the vertebral column; however, several other benign entities can cause increased uptake in the spine on bone scan, for example, arthritis and confound interpretation. Patterns of uptake in the vertebral column, seen on SPECT can help distinguish between benign and malignant etiologies. It is a well-known fact that skeletal metastases have a tendency to localize in the marrow containing axial skeleton. A majority of the spine metastases will therefore initially lodge in the bone marrow contained in the vertebral body prior to extension into the surrounding bone. Uptake in the posterolateral elements, like the lamina and spinous processes and the anterolateral aspect of the vertebral body with substantial sparing of the vertebral body usually indicate a benign process.

92 PULMONARY SCINTIGRAPHY

Pradeep G. Bhambhani

PULMONARY EMBOLISM

Acute pulmonary embolism (PE) is a common and frequently fatal condition. It is obstruction of the pulmonary artery or one of its branches by thrombus that originated elsewhere in the body. Other materials such as tumor, air, or fat are also well-known causes of PE. Its clinical presentation is variable and nonspecific, which makes accurate diagnosis difficult. It can be classified as acute or chronic. Patients with acute PE typically develop symptoms and signs immediately after obstruction of the pulmonary vessels. In contrast, those with chronic PE tend to develop slowly progressive dyspnea over a period of years because of pulmonary hypertension. PE is associated with a mortality rate of approximately 30% without treatment, primarily the result of recurrent embolism. However, accurate diagnosis followed by effective therapy with anticoagulants decreases the mortality rate to between 2% and 8%.

Risk factors for PE include immobilization, surgery within the last 3 months, stroke, prior history of venous thromboembolism, malignancy, central venous instrumentation within the last 3 months, chronic heart disease, obesity, and heavy cigarette smoking (more than 25 cigarettes per day).

In the Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II), the most common symptoms associated with PE were dyspnea at rest or with exertion (73%), pleuritic pain (44%), cough (34%), greater than 2-pillow orthopnea (28%), calf or thigh pain (44%), calf or thigh swelling (41%), and wheezing (21%). The most common signs were tachypnea (54%), tachycardia (24%), rales (18%), decreased breath sounds (17%), an accentuated pulmonic component of the second heart sound (15%), and jugular venous distension (14%). Circulatory collapse was uncommon (8%). Massive PE may be accompanied by acute right ventricular failure. Symptoms or signs of lower extremity deep venous thrombosis (DVT) were common (47%).

The radiological diagnostic tests commonly employed in the evaluation of a patient with suspected PE include chest radiography, radionuclide ventilation–perfusion (V/Q) scan, pulmonary CT arteriography (CTA), and pulmonary angiography. Pulmonary angiography is the definitive diagnostic modality or reference standard in the diagnosis of acute PE; it has a sensitivity of 98% and a specificity of 97%. However, it is infrequently done as it is invasive and expensive compared to other modalities.

Chest radiographic abnormalities are common in patients with PE; however, they are not helpful diagnostically, because they are also seen in patients without PE. In a large prospective study, atelectasis and/or a pulmonary parenchymal abnormality was noted in 69% and 58% of patients with and without PE, respectively. Pleural effusion was detected in 47% and 39% of patients with and without PE, respectively, and approximately 12% of the chest radiographs in patients with pulmonary emboli were interpreted as normal. Various signs described including Westermark sign (attenuation of the pulmonary vessels distal to the embolus), the Fleischner sign (prominence of the proximal pulmonary artery from the embolus), and Hampton hump (pleural-based density resulting from infarction) are rare radiographic findings in acute PE.

Because of its widespread availability, pulmonary CTA is being increasingly used to diagnose patients with suspected PE. The benefit of CTA in addition to faster scan times is the ability to detect alternative etiologies that may explain the patient's clinical presentation. Reported data suggests that CTA is not inferior to V/Q scanning for ruling out PE. However, CTA requires concomitant pretest clinical probability assessment (Table 92-1) to be an effective diagnostic tool for confirming or excluding PE. Discordant CTA and clinical findings should prompt additional testing. Conventional pulmonary angiography is often required in this setting to definitively exclude pulmonary embolism. The PIOPED II trial concluded that there was increased sensitivity in diagnosis of suspected PE when CTA was combined with CT

TABLE 92-1 Clinical Probability of PE (Well Criteria)

CLINICAL FEATURES	SCORE (POINTS)*
Clinical signs and symptoms of DVT (objectively measured leg swelling and pain with palpation)	3.0
Heart rate >100 beats/min	1.5
Immobilization ≥ 3 consecutive days (bed rest except to access bathroom) or surgery in previous 4 wk	1.5
Previous objectively diagnosed PE or DVT	1.5
Hemoptysis	1.0
Malignancy (cancer patients receiving treatment within 6 mo or receiving palliative treatment)	1.0
PE as likely as or more likely than alternative diagnosis (based on history, physical examination, chest radiograph, electrocardiogram, and blood tests)	3.0

DVT, deep venous thrombosis; PE, pulmonary embolism.

* <2.0 Low probability; 2.0–6.0 Moderate probability; >6.0 High probability.

venography to assess the iliac, femoral, and popliteal veins for acute DVT with similar specificity when compared with CTA alone. Compression sonography has been reported elsewhere to be similarly accurate for evaluation of DVT. It is worthwhile to note that CTA is associated with significantly greater radiation burden to the body (absorbed radiation dose is between 8 and 10 mSv), particularly to the female breast as compared to the V/Q scan (absorbed radiation dose is approximately 2 mSv), although in a pregnant woman the consensus evidence points toward a lower fetal radiation dose with shielded CTA as compared to the V/Q scan. V/Q scan is the modality of choice in instances of renal insufficiency and contrast allergy, which preclude use of CTA.

The diagnostic accuracy of CTA appears to vary widely between institutions, which may be due to differences in the experience of radiologists interpreting the images and also image quality. Clinicians should consider their institution's experience and the pretest probability of PE when deciding whether to use CTA and/or whether to pursue other additional diagnostic testing.

VENTILATION–PERFUSION SCINTIGRAPHY

V/Q scintigraphy involves use of radioactive tracers, which map the ventilation and perfusion of the lung fields. The perfusion scan uses microscopic radioactive particles that are trapped in the pulmonary capillary system, whereas the ventilation examination uses an inhaled radiopharmaceutical.

Normal pulmonary ventilation (V) and perfusion (Q) are matched, with a normal gradient, that is, the lung apices are less ventilated and perfused compared to the lung bases. In PE, a thrombus occludes the pulmonary artery or one of its branches and reduces distal pulmonary arterial perfusion. The lung parenchyma in this setting usually remains perfused from the bronchial artery circulation, usually preventing pulmonary infarction. This results in a state where the pulmonary perfusion is reduced coupled with normal ventilation, resulting in a V/Q mismatch, the hallmark finding of pulmonary embolic disease.

RADIOPHARMACEUTICALS

PERFUSION RADIOTRACERS

Tc-99m macroaggregated albumin (Tc-99m MAA) is the radiotracer most commonly used today. The radioactive label is technetium-99m and the biological component is macroaggregates of albumin particles. The particles range in size from 10 to 100 μm . The diameter of the pulmonary capillaries ranges from 7 to 10 μm . Withdrawal of blood into the syringe with the radiotracer, prior to injection should be avoided to avoid clumping of the Tc-99m labeled MAA particles. After intravenous injection, the Tc-99m MAA particles travel to the right heart and are eventually trapped in the pulmonary capillaries. Regions of decreased perfusion are seen as photopenic or cold areas. It is important to note that not only absent but also diminished activity can be a pattern seen in PE. The MAA particles have a biological half-life of approximately 4 to 6 hours.

In general, the perfusion scan is safe examination. A minimum of 100 000 particles are required for a satisfactory adult perfusion scan. In clinical practice, between 200 000 and 500 000 particles are usually administered. The number of particles is reduced in pulmonary hypertension, pregnancy, right-to-left shunts, neonates, and children younger than 5 years. Decreasing the number of particles is not synonymous with decreasing the level of radioactivity, and this has to be kept in mind when formulating the radiotracer.

VENTILATION RADIOTRACERS

Two different classes of radiotracers are available for ventilation imaging: the radioactive gases (xenon 133, xenon 127, and krypton 81 m) and the radio aerosols (Tc-99m DTPA and Technegas). Xenon 133 and Tc-99m DTPA are presently available in the United States.

Xenon 133

Xenon 133 is the only radioactive gas available commercially in the United States. It is very sensitive for

detection of chronic obstructive pulmonary disease. It has a physical half-life of 5.3 days and a biological half-life of 30 seconds during washout; therefore, only one view (usually posterior) can be obtained using a single detector. With dual detectors, an anterior view can be also obtained. Additionally, images with xenon-33 are of poor resolution owing to its low photopeak of 80 keV, which mandates that it be done before the Tc-99m MAA (photopeak 140 keV) perfusion study. Phases of the procedure include wash-in (single maximal inspiration of xenon 133 and breath hold), equilibrium (normal breathing of xenon 133 and room air) and washout (normal breathing of room air). Decreased uptake in any of these phases is considered to be abnormal. Persistent pulmonary xenon activity in the washout phase is indicative of air trapping. Abnormal accumulation of xenon in the right upper quadrant can be seen in patients with hepatic steatosis because of its fat solubility.

Tc-99m DTPA

Aerosol ventilation with Tc-99m DTPA is widely used in the United States. It requires patient cooperation because of the need of breathing via a mouthpiece with a nose clamp in place for several minutes. Like with xenon 133, ventilation examination with Tc-99m DTPA should be completed before the perfusion study, as the counts achieved are much lower than the perfusion examination. Multiple images are obtained as with the perfusion study, these include anterior, posterior, right and left lateral, right and left posterior, and anterior obliques, to enable complete visualization of the lung fields. With radioaerosols, activity may be seen in the mouth, pharynx, large airways, and the stomach (from swallowed activity). Clumping in the central airways most commonly occurs in bronchial asthma, chronic obstructive pulmonary disease, or in patients who are unable to comply with deep breathing.

INTERPRETATION

Normal V/Q scan should have homogenous distribution of tracer throughout the bilateral lung fields. Areas of normal attenuation include the hilar structures, cardiac silhouette, spine, sternum, pacemakers, and other implanted devices. Images obtained should be preferably in the same position for the ventilation and the perfusion components of the examination. Correlation with a recent chest radiograph is necessary. The sine qua non of acute PE in a V/Q scan is multiple, moderate-to-large, wedge-shaped perfusion defect(s) in area(s) of normal lung ventilation. However, several other etiologies including prior or unresolved PE, fat, air, septic embolism, vasculitis, may result in unmatched V/Q defects. The probability of PE increases with increasing number of mismatched perfusion defects. Infrequently

in PE there may be pulmonary infarction, which will result in a ventilation defect that is usually smaller than the perfusion defect along with a corresponding radiographic abnormality (triple match).

Perfusion defects are described in terms of their size and location. Defects are considered large if they involve more than 75% of the lung segment, moderate if involve between 25% and 75% of the lung segment (counted as being approximately half of a large defect), and small if involvement is less than 25% of the lung segment. The defects are additionally described in terms of being segmental and nonsegmental, that is, corresponding to one or more bronchopulmonary segments. A nonsegmental defect is one that does not conform to the segmental anatomy and is less likely to be a consequence of an acute PE, for example, defects secondary to pneumonia, pacemaker artifact, tumor, adenopathy, and cardiomegaly. Often the defects are difficult to characterize on the basis of their segmental anatomy.

Many patients, especially those with chronic obstructive pulmonary disease and bronchial asthma, have multiple perfusion and ventilation abnormalities that are usually matched. The perfusion abnormality in these instances is a consequence of compensatory vasoconstriction in response to hypoxia. "Reverse mismatch" refers to a state where there is ventilation abnormality accompanied by normal perfusion or a perfusion abnormality, which is smaller than the ventilation abnormality. Reverse mismatched defects are seen in pleural effusions, lobar pneumonia, lung atelectasis, gross cardiomegaly, acute exacerbation of chronic obstructive pulmonary disease, and acute partial bronchial obstruction. In these conditions, the hypoxia driven vasoconstriction fails or is incomplete.

The PIOPED study, a multi-institutional study, funded by the National Institutes of Health has been the most comprehensive study evaluating the accuracy of V/Q scintigraphy. V/Q scans are essentially reported as normal or abnormal. Abnormal scans are in turn reported based on size, number, matched/unmatched ventilation and perfusion defects, and the findings of chest radiographs. The abnormal scans are categorized as being very low probability, low probability, intermediate probability, or high probability for an acute PE (Table 92-2).

A normal perfusion scan irrespective of the ventilation scan and radiographic findings effectively excludes pulmonary embolism (likelihood of PE less than 5%). A low probability scan carries a likelihood of 10% to 20% of acute PE. Usually this results when the perfusion defect is less than 25% of the segment, irrespective of the appearance of the ventilation scan or the chest radiograph or when the V/Q defects are matched or when the radiographic abnormality is larger than the corresponding perfusion defect. The high probability scans, in the appropriate clinical setting, carry a high likelihood of

TABLE 92-2 Modified PLOPED Criteria for Diagnosis of Pulmonary Embolism

High probability (>80% likelihood for PE)	Greater than or equal to 2 large mismatched segmental perfusion defects or the arithmetic equivalent in moderate or large defects with a normal chest radiograph Any perfusion defect substantially larger than the radiographic abnormality
Intermediate probability (20%–80% likelihood for PE)	One moderate to less than two large mismatched perfusion defect(s) or the arithmetic equivalent in large and/or moderate defects Single moderate to large matched ventilation–perfusion defect with normal chest radiograph Triple matched defect in the lower lung field Difficult to categorize as low or high probability
Low probability (< 20% likelihood for PE)	Any perfusion defect with a substantially larger chest radiographic abnormality Any number of small perfusion defects with a normal chest radiograph Nonsegmental perfusion defects (e.g., cardiomegaly, enlarged or ectatic aorta, enlarged hila, elevated diaphragm) Multiple matched V/Q abnormalities, with a normal chest radiograph
Normal	No perfusion defects or perfusion exactly outlines the shape of the lungs seen on the chest radiograph (note that hila and aortic impressions may be seen and the chest radiograph and/or ventilation study may be abnormal).

acute PE (greater than 80%) and include either two or more large unmatched perfusion defects with a normal chest radiograph or a combination of defects that add up to two or more large defects, with at least one of the defects being moderate or large. The intermediate probability scan carries a 20% to 80% probability for an acute PE, includes those that do not meet the criteria of low or high probability scans. Typically these include a single unmatched perfusion defect of at least moderate size or a triple matched defect in the lower lung fields where there are corresponding abnormalities in the V/Q scans and the chest radiograph. Triple matched defects in the upper and midlung fields are categorized as being low probability. The updated PLOPED II recommendations have introduced the very low probability category (Table 92-3), which carries a likelihood of less than 10% for acute PE, and includes nonsegmental defects, perfusion defect smaller than radiographic defect, stripe sign, etc.

SPECIAL SIGNS AND SITUATIONS

“Stripe sign” refers to presence of stripe of radiotracer activity at the periphery or base of the wedge-shaped

TABLE 92-3 Criteria for Very Low Probability of PE in PLOPED II

Nonsegmental perfusion abnormalities. These include enlargement of the heart or hilum, elevated hemidiaphragm, linear atelectasis, or costophrenic angle effusion with no other perfusion defect in either lung
Perfusion defect smaller than corresponding radiographic lesion
≥2 matched V/Q defects with regionally normal chest radiograph and areas of normal perfusion elsewhere in the lungs
1–3 small segmental perfusion defects (<25% of a segment)
Solitary triple matched defect (defined as a matched V/Q defect with associated matching chest radiographic opacity) in the middle or upper lung zone confined to a single segment
Stripe sign, which consists of a stripe of perfused lung tissue between a perfusion defect and the adjacent pleural surface (best seen on a tangential view)
Pleural effusion equal to one-third or more of the pleural cavity with no other perfusion defect in either lung

perfusion defect, representing perfused lung tissue between the perfusion defect and the adjacent pleural surface. It usually indicates a very low probability for an acute PE.

“Fissure sign” refers to the curvilinear perfusion defects representing pleural fluid in the interlobar pulmonary fissures; it usually indicates the presence of a pleural effusion but can also be seen in the presence of fissural pleural thickening and also in chronic obstructive pulmonary disease. In the supine position, pleural fluid layers dependently, resulting in an appearance where one lung is diffusely hypoperfused in case where the pleural effusion is unilateral.

Solitary lobar or solitary whole-lung perfusion defects are unusual findings associated with acute PE and can be associated with hilar mass, hypoplastic pulmonary artery, and mediastinal fibrosis. A large saddle embolus could result in unilateral diffuse hypoperfusion, but is very uncommon.

A perfusion defect with a corresponding substantially larger radiographic abnormality is suggestive of low probability, while perfusion abnormality with a similar or smaller radiographic abnormality is referred to as intermediate probability when in the lower lung fields and low probability when in the upper and midlung fields.

Pleural effusions may produce reverse mismatched defects or triple matched defects. According to the PLOPED data, matched defects caused by small pleural effusions (blunting of the costophrenic angle) should be classified as “intermediate” probability, while defects caused by larger effusions should be classified as low probability; however, it is important to note that PE is associated with pleural effusions of all sizes, and thus all pleural effusion–related triple matches should be assigned an intermediate probability. It is worth

remembering that a pleural effusion in acute PE is rarely seen without other perfusion defects.

In chronic obstructive pulmonary disease, both segmental and nonsegmental matched ventilation and perfusion defects can be seen, while in pulmonary hypertension, V/Q scan may be normal or notable for multiple, small, and unmatched, usually nonsegmental perfusion defects. In contrast, acute PE causes multiple large unmatched, segmental perfusion defects. Mucous plugs in the airways usually result in matched V/Q defects.

In small and medium vessel pulmonary vasculitis, V/Q scans may show focal matched defects or evidence of pulmonary infarctions, unless the patient has known pulmonary thromboembolism like in systemic lupus erythematosus associated with antiphospholipid antibodies. Large and medium vessel vasculitis such as Takayasu's arteritis can result in scans indistinguishable from acute PE. Depending on the anatomic location, bronchogenic carcinoma may compress a major pulmonary artery resulting in a unilateral nonperfused lung or lobe of the lung with associated normal ventilation.

ACCURACY OF V/Q SCAN

In the PIOPED trial, the sensitivity of a high probability V/Q scan was only 41%, while the specificity was 97%. This means that a majority of patients with PE had a low or intermediate probability V/Q scan and those with a high probability V/Q scan almost always have a PE. Another finding of the PIOPED trial and many others is the low likelihood of adverse clinical outcomes in patients with normal and low probability V/Q scans (less than 1%).

FOLLOW-UP V/Q SCAN IN ACUTE EMBOLISM

One of the most common causes of a false-positive V/Q scan is an unresolved prior PE. Usually the perfusion defects become smaller or may disappear altogether. Sometimes new defects appear from fragmentation of larger, central thrombi that move distally. However, up to 35% of acute emboli do not completely resolve; these are usually larger defects and seen in the elderly. After a high-probability V/Q scan, a follow-up V/Q scan in 3 months after the initial scan is recommended to establish a new baseline and allow time for resolution of the initial defects. Perfusion defects that persist at 3 months are likely to remain unresolved.

QUANTITATIVE V/Q SCAN

Ventilation and perfusion scintigraphy can provide estimation of the extent of pulmonary parenchymal disease

and therefore help predict the consequences of lung resection and radiation therapy. It is useful in the preoperative evaluation prior to planned lung surgery for pulmonary malignancy, lung volume reduction surgery in chronic obstructive pulmonary disease and prior to lung transplantation. Differential right and left lung function is obtained by acquiring anterior and posterior images of both lung fields and drawing regions of interest around each lung field and calculate the geometric mean which is the square root of anterior counts times the posterior counts to correct for attenuation. Additional calculations can be made by dividing each lung into upper, middle, and lower lung zones.

QUESTIONS AND ANSWERS

1. Which of the following chest radiographic findings is most commonly seen in patients with an acute pulmonary embolism?
 - A. Pleural effusion
 - B. Normal
 - C. Atelectasis
 - D. Westermark sign

ANSWER: C. Radiographic abnormalities are commonly seen in patients with PE; however, they are not helpful diagnostically because they are also found in patients without PE. In the reported literature, atelectasis and/or a pulmonary parenchymal abnormality was noted most commonly in patients with PE. Approximately 12% of the chest radiographs in patients with pulmonary emboli were interpreted as normal. Various signs described including Westermark sign (attenuation of the pulmonary vessels distal to the embolus), the Fleischner sign (prominence of the proximal pulmonary artery from the embolus), and Hampton hump (pleural-based density resulting from infarction) are rare findings in acute PE.

2. Quantitative Lung Perfusion scan done for a patient with idiopathic pulmonary fibrosis, prior to lung transplant, is reported as

Right lung anterior = 22 000 counts/min
Right lung posterior = 16 000 counts/min
Left lung anterior = 28 000 counts/min
Left lung posterior = 22 000 counts/min

Using the geometric mean technique, what is the percentage perfusion to the right and left lungs, respectively?

- A. 43% and 57%
- B. 38% and 62%
- C. 35% and 65%
- D. 45% and 55%

ANSWER: A. Geometric mean is the square root of anterior counts multiplied by posterior counts. In this case, it is 18 762 for the right lung field and 24 819 for the left lung field. The sum of both the right and left lung field geometric mean would be 43 581. On dividing the geometric mean of the right lung field by the sum of the geometric means of both lung fields, the differential perfusion of the right lung field is 43%, while for the left lung field is 57%. Quantification of differential lung ventilation and perfusion can help predict the consequences of lung resection and radiation therapy and is useful in the preoperative evaluation prior to planned lung surgery for pulmonary malignancy,

lung volume reduction surgery in chronic obstructive pulmonary disease, and prior to lung transplantation.

3. What is the most common cause of false-positive V/Q mismatches for acute pulmonary embolism?
 - A. Vasculitis
 - B. Tumor
 - C. Previous pulmonary embolism
 - D. Bronchial asthma

ANSWER: C. Of the potential causes of false-positive V/Q scans, previous PE or unresolved PE is the most common cause. After a high probability V/Q scan, a follow-up V/Q scan in 3 months after the initial scan is recommended to establish a new baseline and allow time for resolution of the initial defects.

4. Visualization of the kidneys on a lung perfusion image is more likely due to an anatomic right-to-left shunt if activity is also seen in which of the following other organ?
 - A. Stomach
 - B. Liver
 - C. Brain
 - D. Thyroid

ANSWER: C. Nuclear perfusion study using macro aggregates of albumin demonstrates the presence of right-to-left shunt, as presence of cerebral and renal activity. Scintigraphy cannot distinguish between intracardiac and intrapulmonary shunt. After injection the MAA particles enter the systemic circulation, evident as visualization of the brain and kidney activity. Renal activity can also be seen in instances of free pertechnetate or following absorption of Tc-99m after the ventilation study. However in neither of these instances is cerebral activity seen, which is a typical finding of a systemic right-to-left shunt. Free pertechnetate is notable for presence of gastric, salivary glands, thyroid, and renal activity.

5. What is the most appropriate Tc-99m labeled radiopharmaceutical for a right-to-left shunt study?
 - A. Macroaggregates of albumin (MAA)
 - B. Sestamibi
 - C. DTPA
 - D. Sulfur colloid

ANSWER: A. MAA particles attached to a radioactive label, Tc-99m are used most commonly for perfusion lung scan, evaluation of a right-to-left shunt, and to determine shunt severity. Scintigraphy cannot distinguish between intracardiac and

intrapulmonary shunt. The MAA particles, which vary in size between 10 and 100 μm , normally get trapped in the pulmonary capillary bed and give an image of distribution of blood flow in the lung fields. In instances of right-to-left shunts, these particles are able to enter the systemic circulation evident as visualization of the brain and kidney activity. Renal activity can also be seen in instances of free pertechnetate or following absorption of Tc-99m after the ventilation study. However, in neither of these instances is cerebral activity seen, which is a typical finding of a systemic right-to-left shunt. Free pertechnetate is notable for presence of gastric, salivary glands, thyroid, and renal activity.

6. When correlating the V/Q scan with chest radiograph, which of the following statements is true?
 - A. When the size of the defect in the lower lung field equals that of the radiographic abnormality, the probability of PE is low.
 - B. When the size of a perfusion defect in the lower lobe is larger than the radiographic abnormality, the probability of PE is low.
 - C. When the size of the lower lung field perfusion defect is less than the size of the radiographic abnormality, the probability of PE is intermediate.
 - D. When the perfusion scan is normal and the radiograph has evidence of bilateral pulmonary infiltrates, it essentially excludes the diagnosis of an acute pulmonary embolism.

ANSWER: D. Any perfusion defect with a substantially larger chest radiographic abnormality is considered low probability. On the other hand, a perfusion defect that is much larger than the radiographic abnormality is high probability. Matched ventilation, perfusion and radiographic findings are referred to as a triple match. A triple match in the upper and mid lung fields is said to represent a low probability for an acute PE, whereas a triple match in the lower lung field is considered to indicate an intermediate probability for an acute PE.

A “normal” perfusion scan essentially rules out an acute PE, irrespective of the radiographic findings.

7. Which of the following can cause platypnea-orthodeoxia?
 - A. Hepatopulmonary syndrome
 - B. Hepatorenal syndrome
 - C. Cirrhosis
 - D. Ischemic cardiomyopathy

ANSWER: A. “Platypnea” is defined as an increase in dyspnea induced by the upright position and re-

lieved by recumbency, whereas “orthodeoxia” refers to arterial oxyhemoglobin desaturation upon assuming an upright posture, which is also improved by recumbency. Orthodeoxia in patients with liver disease is strongly suggestive of hepatopulmonary syndrome, although it can be seen in a number of other diseases, including postpneumectomy, recurrent pulmonary emboli, atrial septal defects (including patent foramen ovale), and chronic lung disease. In general, the diagnosis of hepatopulmonary syndrome is confirmed when the following exist: liver disease, an elevated alveolar-arterial gradient while breathing in room air, and intrapulmonary vascular dilations, latter resulting in a large right-to-left shunt. Intrapulmonary vascular dilations are presently detected using contrast-enhanced echocardiography, technetium-99m-labeled MAA scanning (perfusion lung scan), and pulmonary arteriography. Nuclear perfusion scan using Macroaggregates of albumin demonstrates the right-to-left pulmonary shunt, evident as presence of cerebral and renal activity. Scintigraphy is used to quantify the shunt, but cannot distinguish between intracardiac and intrapulmonary shunt. Liver transplantation is presently considered the most effective treatment in hepatopulmonary syndrome associated with severe hypoxemia.

8. Regarding perfusion scintigraphy with Tc-99m MAA particles, which of the following statements is true?
 - A. Patients with one lung are at increased risk of complications from the test.
 - B. Renal activity is highly suggestive of a right-to-left shunt.
 - C. If 50 000 particles of MAA are administered in an adult, the image quality will likely be poor.
 - D. Normally the ratio of administered particles to the number of pulmonary capillaries is 1:50.

ANSWER: C. Tc-99m labeled MAA particles is the most commonly used radiopharmaceutical in perfusion scintigraphy today. Approximately 200 000 to 500 000 particles are injected IV for the perfusion scan. There are approximately 280 billion pulmonary capillaries, which normally result in a particle-to-capillary ratio of approximately 1:1 million. A minimum of 100 000 particles are required in adults to obtain a satisfactory examination. In certain conditions such as pulmonary hypertension, pregnancy, right-to-left cardiac shunt, and in children, the number of particles given for the scan is reduced. In general the perfusion scan is safe examination, even in right-to-left cardiac shunts, where

the MAA particles enter the systemic circulation, evident as visualization of the brain and kidney activity.

9. Geometric mean is calculated using the following formula, where A = Anterior Counts and B = Posterior Counts.
 - A. $(A + B) (A + B)$
 - B. Square root of $A \times B$
 - C. Square root of $A + B$
 - D. Square root of $(A + B) (A + B)$

ANSWER: B. Geometric mean = Square root of $A \times B$ is applied in quantification of differential lung ventilation and perfusion, which is useful in the preoperative evaluation prior to planned lung surgery for pulmonary malignancy, lung volume reduction surgery in chronic obstructive pulmonary disease, and prior to lung transplantation. Anterior and posterior images of bilateral lung fields are obtained, regions of interest are drawn around both lung fields and geometric mean is calculated for attenuation correction.

10. Your obstetrician colleague calls for advice regarding choice of imaging in a 22-year-old female patient in her second trimester of pregnancy with normal kidney function and complains of shortness of breath. There is clinical concern of an acute pulmonary embolism. What would be your recommendation?
 - A. Ventilation and perfusion lung scan
 - B. Chest radiography
 - C. Pulmonary CTA
 - D. Ultrasound duplex Doppler of the lower extremities

ANSWER: C. Pregnant women have a fivefold increased risk for venous thromboembolism including acute PE and DVT. Clinical examinations are unreliable, and imaging the patient is essential. An evaluation to rule out PE during pregnancy is especially challenging because of concerns regarding fetal radiation exposure. Radiographic abnormalities are commonly seen in patients with PE; however, they are not helpful diagnostically, because they are also found in patients without PE. V/Q scanning has traditionally been associated with less radiation exposure to the fetus than CTA. However, there is published evidence suggesting CTA is actually associated with a lower average fetal radiation dose than V/Q scanning during all trimesters. One drawback, however, of CTA is that it exposes maternal breast tissue to relatively high doses of radiation, much higher than that associated with V/Q scanning. Ultrasound examination of the lower extrem-

ity venous system is helpful in diagnosis of DVT and not acute PE, although the both entities are sometimes seen together and often managed similarly.

GASTROINTESTINAL MOTILITY

GASTRIC EMPTYING STUDIES

INTRODUCTION

Gastric emptying studies (GES) using radionuclides are performed to evaluate gastric motor function. They are often considered the “gold standard,” and “most physiologic” examinations, because of their noninvasive nature, use a physiologic liquid or solid meal, and the resultant quantitative information. Radionuclide GES are very reproducible and serial examinations after therapeutic interventions can help establish their effectiveness. Typical indications for GES are evaluation of symptoms such as (postprandial) nausea, vomiting, or abdominal pain, gastroesophageal reflux disease, difficult glycemic control in diabetic patients, suspected or known gastroparesis, and assessing response to therapy.

TECHNIQUE

Patient preparation includes a fast of at least 4 hours prior to the procedure. Some experts recommend performing GES in premenopausal women on day 1 to 10 of the menstrual cycle to prevent possible effects of hormonal variation on gastric emptying.

GES can be performed using a solid (solid gastric emptying studies [SGES]) or liquid (liquid gastric emptying studies [LGES]) meal. In addition, dual phase/dual isotope studies with different radionuclides for the solid and liquid meal have also been used for the simultaneous evaluation of both liquid and solid emptying. The current consensus is that SGES are more sensitive than LGES. Therefore, patients should undergo SGES if possible when evaluation of gastric motility is warranted. Nevertheless, there is emerging data that a number of patients may have normal solid and abnormal liquid gastric emptying. The radiopharmaceuticals used to label (solid or liquid) meals most commonly are ^{99m}Tc sulfur colloid (0.2–0.5 mCi) and, less frequently, Indium 111 (0.1–0.3 mCi) (Table 93-1). There is a variety

TABLE 93-1 Radiation Dosimetry for GI/Hepatobiliary Imaging Agents in Adults

RADIOPHARMACEUTICAL	ADMINISTERED ACTIVITY (mCi)	RADIATION DOSE TO TARGET ORGAN (rad/mCi)	EFFECTIVE DOSE (rem/mCi)
99mTc sulfur colloid po (gastric emptying)	0.2–0.5	0.41 (large intestine)	0.089
In 111 po (gastric emptying)	0.2–0.5	2.0 (large intestine)	0.3
99mTc sulfur colloid IV	4–6 mCi (liver spleen scan), 10 mCi (GI bleeding study)	0.27 (spleen)	0.052

Tc-99m mebrofenin	1.5–5.0	0.41 (gallbladder)	0.089

Data modified from the Society of Nuclear Medicine Procedure Guidelines. www.snm.org.

of (especially solid) GES protocols, including different approaches to meal composition, patient positioning, and imaging protocol. It is important that normal gastric emptying rates are established for each specific protocol. In addition, the stability of the radiolabel of a solid meal in gastric juice must be established. For liquid gastric emptying studies, almost any liquid can be used, such as water, orange juice, or milk (usually 300–500 mL). Solid meals may consist of eggs (scrambled, whole, egg whites, or egg substitute), or beef stew, or liver, and/or toast. The radiolabeled solid meal should be ingested promptly, ideally within 5 to 10 minutes. The technologist should record any deviation from the standard procedure, such as any portion of the meal that was not eaten or if it took longer than 10 minutes to finish the meal. Imaging should begin immediately after ingestion of the meal. Images may be obtained standing, sitting, or supine, but should not change during the study. Planar images should include the distal esophagus, the stomach, and the proximal small bowel in the field of view. To account for movement of the meal from posterior to anterior (gastric fundus to antrum) and differences in attenuation, imaging in the anterior and posterior view and subsequent calculation of the geometric mean (square root of the product of counts in the anterior and posterior region of interest [ROI]) is recommended. Alternatively an LAO view may be used (especially for LGES). The exact type of imaging (continuous dynamic, intermittent data acquisition) and duration varies per specific protocol, nevertheless the study usually takes at least 30 minutes for LGES and at least 90 minutes for SGES (often longer [2–4 hours]). Continuous dynamic imaging (i.e., at a rate of 30–60 s/frame) is more useful for LGES and, when used for solid emptying studies, has the advantage of more accurately determining the gastric emptying half times and lag phase. For SGES, intermittent imaging that determines the percent retention (or emptying) at certain time points may be more efficient.

Follow-up studies should always be done under the same conditions as the baseline study. Of note, a most recent procedure guideline from the society of Nuclear Medicine makes specific recommendations of a standard meal based on consensus guideline.

INTERPRETATION

A region of interest is drawn around the radiotracer activity in the stomach and time activity curves are obtained. Solid gastric emptying usually demonstrates a so-called “lag phase” (a period during which food is grinded to small particles in the stomach and no emptying into small bowel occurs) followed by emptying in a constant, linear fashion. Liquid gastric emptying begins immediately after ingestion (no lag phase) and usually has a (mono)exponential characteristic.

Gastric emptying can be measured and quantified in several ways, for example, as half emptying time (the time it takes to reach half the maximum counts), or emptying rate (%/min), or percent emptying (or retention) at specific time points (e.g., 1–4 hours; end of study). Gastric emptying data obtained is compared to normal values (again, normal values must be established and validated for each specific protocol). Normal values for SGES vary, depending on the protocol. A normal half time for liquid emptying is approximately less than 10 to 20 minutes. There are a variety of factors that may affect gastric emptying (Table 93-2). Sources of error include poor labeling of the solid meal, nonstandard meal or procedure, significant variation in the environment (noise, temperature, etc.), vomiting, fasting status less than 4 hours, esophageal retention, gastroesophageal reflux, overlap of small bowel and stomach in the ROI, and meal not eaten entirely or over a prolonged period of time (greater than 10 minutes). Review of (dynamic) images should be done to assess for incidental findings such as gastroesophageal reflux and for quality control (correct ROI, overlap of small bowel, and stomach in the ROI).

ESOPHAGEAL TRANSIT SCINTIGRAPHY

Esophageal transit scintigraphy may be useful in the evaluation of esophageal motility disorders. Although esophageal manometry is the main diagnostic tool for the diagnosis of esophageal motility disorders and barium radiography can provide qualitative assessment of (impaired) motility, the scintigraphic technique provides quantitative information. This could be particularly useful in the evaluation of therapeutic interventions. Esophageal transit scintigraphy is noninvasive, quantitative, and relatively easy to perform. After an overnight fast, the patient consumes a radiolabeled (Tc-99m sulfur colloid) liquid or semisolid meal in the upright or supine position (protocols vary). Dynamic imaging is performed while the patient is eating and continued for a

period of time thereafter (15–30 minutes), ROI are drawn around the radiotracer activity in the esophagus (as well as the stomach) and time activity curves can be derived. Esophageal transit time and/or residual esophageal activity can be quantified.

GASTROINTESTINAL BLEEDING

INTRODUCTION

Gastrointestinal (GI) bleeding can be divided into upper or lower GI bleeding depending on its origin (proximal or distal to the ligament of Treitz). Causes of upper GI bleeding include esophageal varices, gastric or duodenal ulcers, gastritis or duodenitis among other. Lower GI bleedings are caused by diverticula, neoplasm, angiodysplasia, and inflammatory bowel disease. Both endoscopy and angiography may be able to identify the cause of bleeding; in addition, they may also be able to provide therapeutic control. The goal of GI bleeding scintigraphy is to localize the source of GI bleeding with the hope that the patient can be triaged to the appropriate therapeutic intervention (angiography, endoscopy, surgery) or next diagnostic test. With radionuclide techniques, GI bleeding with bleeding rates as low as 0.1 mL/min may be detected (or 2–3 mL of blood total). Radionuclide studies for the evaluation of GI bleeding are usually performed using Tc-99m labeled red blood cells (RBC), although Tc-99m sulfur colloid may be used as well.

GASTROINTESTINAL BLEEDING SCINTIGRAPHY USING TC-99M LABELED RBC

There are essentially three techniques of RBC labeling with Tc-99m pertechnetate (Table 93-3): the so-called in vivo, modified in vitro, and in vitro techniques. The techniques vary not only in technical complexity but also labeling efficiency (which relates to image quality). In vitro labeling is recommended for GI bleeding scintigraphy, although a modified in vitro technique may also be acceptable. In vivo labeling is not recommended. When RBCs are used, strict adherence to procedures such as correct patient identification and handling of blood products is mandatory to prevent administration of one patient's blood into another patient.

Imaging is begun after injection of the radiotracer (an initial “flow” or “radionuclide angiography” phase is optional). Because movement of a GI bleeding can be fast (due to stimulation of peristalsis), frequent dynamic images (10–60 s/frame) are recommended to accurately localize the site of bleeding. Duration of initial imaging is usually 60 to 90 minutes. The field of view should include the entire abdomen and pelvis in the

Image quality	+	++	+++
Cost			(More costly)

anterior view. Additional views such as a lateral view of the pelvis or a postvoid image may be helpful to avoid misinterpretation due to overlying bladder activity. Delayed (dynamic and/or static) images (2–24 hours after initial radiotracer injection) may be useful if no bleeding is detected on initial images. These images should be viewed with caution as they may (more often than initial studies) result in incorrect localization of bleeding site. If the patient continues to show signs and symptoms of active GI bleeding, starting a new study by injecting labeled RBC again may be more useful than just obtaining delayed images. Pharmacologic interventions such as glucagons or heparin administration are not widely used.

Normal RBC biodistribution includes the vascular space of the heart/great vessels, liver, spleen, and kidneys. Some of the radioactivity is excreted into the urine, and the bladder is usually seen.

RBCs that extravasate into the bowel lumen are identified as radiotracer activity that appears rather suddenly, increases in intensity over time, and/or that moves in a pattern consistent with lumen of the small or large bowel (this may be antegrade or retrograde). Small bowel bleeding can be distinguished from large bowel bleeding by its swift serpiginous movement. To definitely distinguish small bowel from large bowel bleeding or accurately localize the bleeding, it may be necessary to continue imaging after the bleeding was detected scintigraphically—until a distinctive pattern of movement is noted.

Sources of error include intermittent nature of bleeding (bleeding stopped by the time the scan was acquired), technical error such as failure to image the entire abdomen/pelvis or insufficient frame rate of dynamic images. In addition, blood pool activity in (abdominal) vessels (especially if abnormal such as ectatic aorta or varices), hemangiomas or genitalia, or radio-

tracer accumulation in a hydronephrotic kidney or hydroureter or transplant kidney may be mistaken for an area of active bleeding. A full urinary bladder may obscure a lower (rectal) bleeding. If excess free pertechnetate is present, gastric mucosal activity may be very prominent and may mimic bleeding. If this is suspected, extra views of the thyroid/salivary glands can confirm the presence of free pertechnetate.

GASTROINTESTINAL BLEEDING SCINTIGRAPHY USING TC-99M SULFUR COLLOID (SC)

The usual dose of Tc-99m sulfur colloid is 10 mCi. Because of the short residence time within blood pool (serum half-life of 3 minutes), dynamic imaging of the entire abdomen and pelvis (similar to the RBC technique) is obtained for only 20 to 30 minutes. Normal biodistribution includes the liver, spleen and bone marrow. Similar to the labeled RBC technique, the hallmark of GI bleeding is a new site of abnormally increased radiotracer uptake that demonstrated motion in an intraluminal pattern. Fixed areas of uptake may be related to ectopic spleen, or asymmetric bone marrow.

Disadvantages of the sulfur colloid technique compared to RBC imaging are related to the fast clearance by the reticuloendothelial system: bleeding must be active at the time of injection, as imaging for greater than 30 minutes or delayed images are not useful. In addition, bleeding sites in the upper abdomen (e.g., stomach, hepatic and splenic flexures) may be obscured by physiologic uptake in the liver and spleen. On the other hand, the shorter preparation and acquisition time may be advantageous since reinjection and reimaging is an option. The fast blood pool clearance results in an excellent target to background ratio for the mid and lower abdomen if a bleeding is visualized. Overall, Tc-99m sulfur colloid is nowadays rarely used.

MECKEL SCAN

A Meckel diverticulum is a remnant of the omphalomesenteric duct located in the ileum, approximately 50 to 80 cm proximal to the ileocecal valve. Approximately 50% of Meckel diverticula contain gastric mucosa. Bleeding secondary to Meckel diverticula may be secondary to ulceration of the adjacent small bowel mucosa. Because one of the properties of Tc-99m pertechnetate is to accumulate in gastric mucosa (particularly in the mucin cells), it is used in patients (typically young children) having unexplained GI bleeding due to a suspected Meckel diverticulum. Meckel scintigraphy should be performed when the patient is not actively bleeding. If active bleeding is present, the most appropriate radionuclide technique is a GI bleeding scintigraphy (using labeled RBC). Prior to the procedure, the patient should fast for 6 hours. Pharmacologic pretreatment is not considered mandatory when performing Meckel scintigraphy, nevertheless it may be considered (especially if there is continued clinical suspicion despite a negative study result). Pretreatment with pentagastrin, H₂ (histamine) blockers, and/or glucagons has been reported to improve the accuracy of Meckel scintigraphy. Pentagastrin for example enhances the uptake of pertechnetate by the gastric mucosal cells and has been shown to increase rapidity, intensity, and duration of pertechnetate uptake. On the other hand, it also stimulates GI motility, which could potentially reduce the activity at ectopic sites. H₂ blockers such as cimetidine and ranitidine block the secretion of pertechnetate from the gastric cells and increase uptake in gastric mucosa leading to more intense and prolonged uptake. Oral cimetidine (300 mg qid $\times$ 2 days in adults) is the preferred choice of histamine blockade. Glucagon, an antiperistaltic agent, relaxes the smooth muscles of the GI tract and may delay or prevent washout from pertechnetate both from the stomach and from the ectopic site. Other interventions reported to improve accuracy of the examination is placing the patient in a left lateral decubitus position during imaging and nasogastric tube suction (both may prevent secretions from the stomach to enter the small bowel). With the patient supine (or left lateral decubitus), dynamic planar images of the anterior abdomen and pelvis (30–60 s/frame) are obtained for 30 to 60 minutes. Additional oblique, lateral, or posterior projections including a postvoid image may be helpful. Radiotracer uptake in the ectopic gastric mucosa generally appears as a distinct focus that is seen at the same time as the normal gastric mucosa (usually within the first 5–10 minutes). The diverticulum may be located anywhere in the abdomen, although the right lower quadrant is the typical location. Sources of

error are radiotracer activity in the kidneys, ureter, or bladder; or radiotracer excreted by normal gastric mucosa that enters the small bowel. False-positives may be caused by bowel irritation from recent endoscopy or laxatives. In addition, any lesion with increased blood pool, such as ulceration, inflammation, tumor, or intussusceptions may be confused with the Meckel diverticulum. On the other hand, Meckel diverticula that are small in size or those that have an ischemic or necrotic component may appear later than the normal gastric mucosa or are not visualized at all. False-negative examinations may also be caused by attenuation from recent barium study, recent in vivo labeling of RBC, or perchlorate.

HEPATOBIILIARY IMAGING

INTRODUCTION

Hepatobiliary scintigraphy described radionuclide studies that evaluate the function and integrity of the hepatobiliary system by visualizing the production and flow of bile from the liver through the biliary system into the intestinal tract. Common indications are suspected acute cholecystitis, common bile duct obstruction, chronic cholecystitis (also sometimes called biliary dyskinesia), bile leak, postcholecystectomy syndromes, and congenital abnormalities of the hepatobiliary tree.

PATIENT PREPARATION

The patient should be fasting for 4 to 24 hours for gallbladder visualization. If the patient has been fasting for greater than 24 hours, the gallbladder may not be able to fill (in this circumstance, the patient may be treated with sincalide, see below). To avoid effects of opioid medication, the scan should be delayed by more than 4 hours after the last opioid medication dose.

RADIOTRACERS

Tc-99m labeled IDA (iminodiacetic acid) analogs are used for hepatobiliary scintigraphy. They have similar uptake (carrier mediated), transport (active membrane transport), and excretion mechanisms as bilirubin. Nevertheless IDA are neither conjugated nor metabolized. Tc-99m labeled disofenin (DISIDA) or mebrofenin (BRIDA) are the radiopharmaceuticals of choice. They are injected intravenously at a dose of 1.5 to 5 mCi for adults. Higher doses (up to 10 mCi) may be necessary in hyperbilirubinemia. Mebrofenin may also have an advantage over disofenin in this circumstance because of its higher hepatic extraction. Dynamic images of the anterior abdomen are performed immediately after the radiotracer administration. An initial

blood flow phase is optional. If performed, the liver is typically visualized several seconds after other abdominal organs (spleen or kidney) are seen because the blood supply of the liver is predominantly by the portal vein (and not arterial). Images are generally obtained for 60 minutes (or less if gallbladder and bowel are clearly visualized). Additional views, especially a right lateral and left anterior oblique views, may be helpful to clarify anatomy and confirm gallbladder visualization. When the gallbladder is not visualized at 60 minutes, 4 hour delayed images or images after morphine augmentation may be performed. Delayed images (up to 24 hours) may be necessary in patients who have severe hepatocellular dysfunction, suspected common bile duct obstruction or biliary atresia. Delayed images at 2 to 4 hours (along with patient positioning maneuvers) can also be helpful if bile leak is suspected. Any drainage catheters and bags ought to be included in the field of view.

INTERVENTIONS

Sincalide

Sincalide, a synthetic C-terminal octapeptide of cholecystinin (CCK), stimulates gallbladder contraction and relaxes the sphincter of Oddi. It is given in doses of 0.01 to 0.02 $\mu\text{g/kg}$ body weight over 30 to 60 minutes. Faster injections (3–10 minutes) can be used but may result in gallbladder spasm and more frequent side effects. Sincalide can be given prior to the injection of the radiotracer if the patient is NPO > 24 hours. Other indications are the assessment of gallbladder ejection fraction (GBEF) and excluding common bile duct obstruction. The GBEF can be determined after gallbladder contraction stimulated by sincalide. For that purpose, sincalide is infused after the gallbladder has filled on initial imaging (usually at 60 minutes). Dynamic acquisition is continued for an additional 30 or 60 minutes. GBEF can be calculated using the immediate presincalide image and the postsincalide data. ROI are drawn around the gallbladder and GBEF is calculated as follows:

$$\text{GBEF (\%)} = [(\text{maximum GB count} - \text{minimal GB counts}) / \text{maximum GB count}] \times 100$$

Normal values of GBEF that have been established depend on the specific protocol (total dose, dose rate, length of infusion) and range from >0% to >40%. A normal GBEF excludes acute acalculous cholecystitis (if the gallbladder fills initially) and chronic Cholecystitis. Bowel visualization after sincalide administration helps to differentiate common duct obstruction from normal variant.

Fatty meal

Fatty meal stimulation may be performed to assess gallbladder contractility if sincalide is unavailable or cannot be given (lack of intravenous access for example).

Phenobarbital

Phenobarbital is given in infants suspected of having biliary atresia (5 mg/kg/d divided in two doses) for 3 to 5 days prior to hepatobiliary scintigraphy. This stimulates hepatic cells and may increase the excretion of radiotracer, decreasing the false-positive rate.

Morphine augmentation

Morphine sulfate (MSO_4), given at doses of 0.04 –to 0.1 mg/kg body weight, can be administered if acute cholecystitis is suspected and the gallbladder is not visualized at 1 hour as an alternative to delayed imaging. The thought is that morphine increases the tone of the sphincter of Oddi, thus “forcing” the radiotracer into the gallbladder if the cystic duct is indeed patent. Morphine should only be given if radiotracer is seen in the small bowel (patent common bile duct). If the liver and intra- and extrahepatic biliary tree have only minimal residual radiotracer present, a “booster dose” of radiotracer (1 mCi) may be given in conjunction with morphine. Imaging is continued for an additional 30 minutes following morphine administration. Attention to possible contraindications (allergy, respiratory compromise, acute pancreatitis) is important.

IMAGING FINDINGS

Normal

Normal hepatobiliary scintigraphy is characterized by prompt visualization of the liver, followed by transit of radiotracer activity into the intra- and extrahepatic biliary tree, gallbladder, and small bowel. Gallbladder and small bowel are seen within an hour in most normal studies.

Acute cholecystitis

Acute cholecystitis is scintigraphically characterized by gallbladder nonvisualization on (4 hour) delayed images or after morphine augmentation (nonvisualization at 60 minutes could be acute cholecystitis, chronic cholecystitis or normal variant). The so-called “rim sign” describes a band of increased radiotracer uptake in the hepatic tissue adjacent to the gallbladder fossa that is related to increased blood flow and inflammation. It is more often associated with severe gangrenous or phlegmonous cholecystitis and is associated with a higher frequency of complications and poorer prognosis. Overall sensitivities are reported to be 95% to 100% with specificities of 91% to 99%. Potential causes of false-positive results are insufficient

fasting (less than 4 hours), prolonged fasting (greater than 24 hours), severe hepatocellular dysfunction or intercurrent illness, high grade common bile duct obstruction, rapid biliary to bowel transit, severe chronic cholecystitis, and previous cholecystectomy. False-negative examinations are extremely rare but may be encountered if radiotracer activity in or near the gallbladder fossa (overlying bowel loop, bile leak, congenital abnormalities, activity in the kidneys) is mistaken for gallbladder visualization.

Chronic cholecystitis

In chronic cholecystitis, the gallbladder is usually visualized within 1 hour after radiotracer administration. The hallmark of chronic cholecystitis is an abnormally reduced GBEF. A decreased GBEF may also be seen in acute acalculous cholecystitis, certain nonbiliary conditions (acute intermittent illness, diabetes mellitus, obesity, pancreatic insufficiency, sickle cell disease), and several medications (morphine, atropine, calcium channel blocker, progesterone, histamine blockers among other).

Common bile duct obstruction

Common bile duct obstruction is usually suspected when there is no or severely delayed (>60 minutes) biliary to bowel clearance. With acute, complete, or high-grade obstruction, there is usually prompt liver uptake, but no visualization of the biliary tree and gallbladder (because of “back pressure” from the obstruction preventing excretion of radiotracer from the liver). With prolonged obstruction, hepatocellular dysfunction is eventually seen, which makes interpretation of lack of small bowel activity more difficult. Nonvisualization of small bowel at 60 minutes may also be seen in up to 20% of normal individuals. In these cases, the gallbladder (if present) is usually seen, and administration of sincalide or delayed images should be obtained to differentiate normal variant from obstruction.

Biliary atresia

Hepatobiliary scintigraphy in infants can help differentiate between neonatal hepatitis (biliary to bowel clearance demonstrated) and biliary atresia (no biliary to bowel clearance). Both entities usually have persistent liver uptake due to poor hepatocellular function. Delayed images are often necessary and should be obtained for 24 hours if necessary. Premedication with phenobarbital to stimulate hepatic enzymes is recommended. If an initial scan was performed without premedication and is consistent for biliary atresia (bowel not visualized), a repeat study

after appropriate premedication is recommended. Radiotracer activity in the urinary tract or diaper may be confused with bowel activity and can lead to false interpretation.

Bile leak

A biliary leak is likely present when radiotracer accumulates in locations other than the liver, biliary tree, gallbladder, bowel, or urine. Accuracy of detection by hepatobiliary scintigraphy depends on the severity and location of the leak. Delayed images, additional views, changes in patient positioning, and correlation to anatomic imaging (location of fluid collections, postsurgical (blind) bowel loops, etc.) are all useful.

Postcholecystectomy pain

There are several reasons for pain after cholecystectomy including sphincter of Oddi dysfunction which has the scintigraphic appearance of (partial) common bile duct obstruction. Pretreatment with sincalide to increase bile flow may improve accuracy of the study for that indication. Visual and (semi)quantitative parameters taking into account clearance of radiotracer from the liver parenchyma and common bile duct, timing of small bowel visualization, and appearance of intra- and extra-hepatic ducts have been employed.

Other findings

Enterogastric (duodenogastric) reflux may be incidentally seen during hepatobiliary scintigraphy. It may possibly be an alternative explanation of the patient's symptoms (epigastric/abdominal discomfort).

HEMANGIOMA IMAGING

Liver blood pool imaging using ^{99m}Tc labeled RBCs is performed for the detection of hepatic hemangiomas. A typical clinical situation would be a liver lesion detected on anatomical imaging (ultrasound, CT, and MRI) that has some but not all typical characteristics of hemangioma, and clarification is felt necessary. Blood flow (“radionuclide angiography”) and immediate blood pool images are optional for hepatic blood pool imaging. Delayed blood pool images at 30 minutes to 3 hours are mandatory. The study should be obtained in multiple views (anterior, posterior, and lateral) including the view most likely to reveal the lesion (based on anatomic imaging). When the lesion is small (less than 2 cm), or when multiple lesions are present, and/or when planar imaging is unrevealing, SPECT or SPECT/CT (if available) imaging is recommended. Markedly increased

radiotracer activity on delayed blood pool of a hepatic lesion is very specific for a cavernous hepatic hemangioma (the lesions usually have no increased (arterial) blood flow or immediate blood pool uptake). Hemangiomas >2 to 3 cm are generally always identified on planar images, whereas SEPCT is useful for lesions smaller than that (lesions as small as 0.5 cm may be detected with SPECT imaging). Other tumors of the liver (i.e., angiosarcomas) could possibly also have increased uptake during the delayed blood pool phase (yet they also have increased flow). False-negatives may be encountered in hemangiomas with partial fibrosis or thrombosis. Lesion location (i.e., lesions adjacent to the heart, great vessels, and kidney) can also affect accuracy.

LIVER SPLEEN SCAN

Liver spleen scintigraphy is not frequently used nowadays, since most liver lesions can be characterized with newer types of imaging (ultrasound, CT, and MRI). Liver and spleen radionuclide imaging may still be used in selected liver lesions (e.g., suspected focal nodular hyperplasia), to assess for functioning splenic tissue (suspected asplenia, residual splenic tissue in patient with thrombocytopenia postsplenectomy, accessory spleen, and masses). For liver spleen scans, 4 to 6 mCi of ^{99m}Tc sulfur colloid (small colloid particles: 0.1–1.0 μ m) is injected intravenously. After injection, sulfur colloid is quickly phagocytized by the reticuloendothelial system. Imaging is begun after more than 15 to 20 minutes when blood pool clearance has occurred. Planar images of the abdomen in the anterior, posterior, lateral, and oblique views are usually obtained. SPECT (or SPECT/CT) imaging may be useful. Extra views with (size) markers for measuring liver and spleen size and for identifying anatomical landmarks may also be helpful in certain circumstances. Normal biodistribution includes the liver (85%), spleen (10%), and bone marrow (5%). The so-called colloid shift describes increased radiotracer uptake in the spleen and bone marrow relative to the liver. This phenomenon can be observed in hepatic dysfunction and portal hypertension, hypersplenism, or bone marrow activation (i.e., cytopenia). Diffuse pulmonary activity is nonspecific and could be secondary to cirrhosis, infection, neoplasm, coagulopathy, estrogens, trauma, or excess aluminum in colloid. Sources of error may be related to anatomic variations, respiratory motion, and colloid size (i.e., smaller particles may be localizing preferentially in the bone marrow, larger particles in the spleen).

SPLENIC IMAGING USING HEAT DAMAGED RED BLOOD CELLS

Heat-damaged red blood cells are cleared by functioning splenic tissue. Therefore radionuclide (^{99m}Tc pertechnetate) labeled heat damaged RBC can also be used for splenic imaging. Heat damage is accomplished generally by heating RBCs in a waterbath at 49°C to 50°C for 20 minutes. Imaging is begun 30 minutes to 2 hours after reinjection of the heat damaged RBCs. If ectopic splenic tissue is suspected, images of the entire abdomen (or chest depending on the situation, i.e., prior trauma) are obtained. SPECT (or SPECT/CT) may be useful. Sources of error may be secondary to the degree of damage to the red blood cells.

OTHER IMAGING TECHNIQUES

HEPATIC PERFUSION STUDIES

Hepatic perfusion imaging following the injection of ^{99m}Tc macroaggregated albumin through a hepatic artery catheter is performed to determine the biodistribution of agents to be administered via the catheter (i.e., chemotherapy, radiolabeled microspheres). This helps to assure that the catheter is correctly placed to deliver the therapeutic agent to the liver tumor and to avoid perfusion of normal extrahepatic tissue such as the lungs or GI tract. Multiple planar views of the abdomen as well as images of the lungs are obtained after radiotracer injection.

Images should be reviewed for the presence of radiotracer accumulation within the liver (masses) and uptake outside the liver (i.e., lung, stomach, small bowel). Significant lung uptake caused by right-to-left shunting can also be quantified.

QUESTIONS AND ANSWERS

1. Which of the following statements about gastric emptying studies is *true*?
 - A. Solid meals are usually labeled with Tc-99m DTPA.
 - B. Liquid gastric emptying is typically exponential.
 - C. Liquid gastric emptying is abnormal if solid emptying is impaired.
 - D. Patient should ingest a nonlabeled test meal just prior to the radiolabeled meal to make sure he/she tolerates the meal.

ANSWER: B. Solid (or liquid) meals are usually labeled with Tc-99m sulfur colloid (In 111 is an alternative). Liquid gastric emptying may be normal when solid gastric emptying is impaired. It is certainly not always abnormal. No test meal is necessary; in fact the patient needs to be fasting for at least 4 hours. It is nevertheless good practice to inform the patient about the procedure (including the meal) beforehand, and ensure there are no intolerances or dietary restrictions.

2. Differences between GI bleeding scintigraphy using labeled RBC and studies using Tc-99m sulfur colloid include.
 - A. Studies with labeled RBCs are typically shorter.
 - B. Radiation dose to the spleen is higher in labeled RBC studies.
 - C. Sensitivity for bleedings in the upper abdomen is higher in sulfur colloid studies.
 - D. False-positives studies from blood pool activity in abnormal vascular structures (abdominal varices) are not usually encountered with sulfur colloid imaging.

ANSWER: D. Given the fast clearance of sulfur colloid from the blood pool, false-positives examinations from blood pool activity in abnormal vascular structures are not usually encountered with sulfur colloid imaging, although it is a problem with RBC scintigraphy. Studies with sulfur colloid are typically shorter because of the fast clearance. The radiation dose to the spleen is higher in sulfur col-

loid studies. Target organ for labeled RBC studies is the heart. The sensitivity for bleedings in the upper abdomen is lower in sulfur colloid studies because of the overlying intense uptake of the liver and spleen.

3. Regarding labeling of red blood cells with Tc-99m pertechnetate, which of the following statements is *true*?
 - A. In vivo technique requires venous blood sampling.
 - B. In vitro technique has the highest labeling efficiency.
 - C. Image quality is not effected by the type of labeling technique.
 - D. Labeling techniques are robust and not influenced by medications.

ANSWER: B. The in vivo technique does not require venous blood sampling. The in vitro technique has the highest labeling efficiency, followed by the modified in vitro technique. The in vivo technique has the poorest labeling efficiency. Since image quality has to do with labeling efficiency, it is affected by the labeling technique. Labeling may be affected by multiple factors including medications (heparin, doxorubicin among other), iodinated contrast, antibodies (e.g., from transfusion), too much or not enough stannous ion used during labeling, or incorrect incubation time intervals during labeling.

4. All of the following medications have been used to enhance the accuracy of Meckel scintigraphy, *except*.
 - A. Sincalide
 - B. Pentagastrin
 - C. Glucagon
 - D. Cimetidine

ANSWER: A. Sincalide has no role in Meckel scintigraphy. It is used in hepatobiliary imaging (see above). Pentagastrin enhances the uptake of pertechnetate by the gastric mucosal cells, resulting in a more rapid and intense and durable pertechnetate uptake. Cimetidine is a histamine blocking agent that blocks the secretion of pertechnetate from the gastric cells and increases uptake in gastric mucosa again leading to more intense and prolonged uptake. Ranitidine is another H₂ blocker that can be used. Glucagon relaxes the smooth muscles of the GI tract and may delay or prevent washout from pertechnetate from the Meckel diverticulum.

5. Hepatobiliary scintigraphy using ^{99m}Tc mebrofenin is performed in a 50-year-old woman with right upper quadrant pain and gallstones visualized on ultrasound. After 60 minutes of imaging, the gallbladder and common bile duct is visualized, yet no radiotracer is seen in the small bowel. What is the most likely diagnosis?

A. Acute cholecystitis
 B. Normal variant
 C. Acute complete common bile duct obstruction
 D. False-negative finding from prolonged fasting

ANSWER: B. Visualization of the gallbladder implies a patent cystic duct and therefore, excludes acute cholecystitis with a high degree of certainty. The hallmark of acute complete common bile duct obstruction is nonvisualization of the intra-/extra-hepatic biliary tree, gallbladder, and small bowel. Prolonged fasting status may affect visualization of the gallbladder (possibly leading to false-positive examinations); it has no influence on initial biliary to bowel clearance. The differential diagnosis for the above finding (nonvisualization of the bowel at 1 hour despite activity in the gallbladder and common bile duct) includes partial common bile duct obstruction and normal variant (may be seen in 20% of normal patients).

6. What would *not* be an appropriate next intervention in the patient described before?
- A. Infuse sincalide intravenous over 30 minutes and continue imaging
 B. Delayed images at 4 hours
 C. Imaging after having eaten a fatty meal
 D. Administer morphine sulfate intravenous and continue imaging for another 30 minutes

ANSWER: D. To differentiate between obstruction and normal variant, sincalide infusion, which stimulates gallbladder contraction and relaxes the sphincter of Oddi, would be the best next step. Alternatively, imaging after stimulation with a fatty meal or just delayed images may also be an option. Morphine is not indicated. In fact, it is contraindicated if small bowel is not visualized. Morphine is used in suspected acute cholecystitis if the gallbladder is not visualized at 60 minutes as an alternative to delayed imaging.

7. A diabetic patient with postprandial abdominal discomfort underwent a solid phase gastric emptying study that demonstrated delayed gastric emptying. Possible sources of error or confounding factors for this result include all of the following *except*:
- A. Poor, unstable radiolabel of the solid meal
 B. Hyperglycemia

C. Overlap of small bowel in the region of interest
 D. Patient did not eat the entire meal.

ANSWER: A. Poor, unstable radiolabel of a solid meal may result in more rapid gastric emptying than expected (the Tc-99m sulfur colloid may bind to gastric secretions (fluids) resulting in mixed liquid/solid emptying characteristics). Diabetic patients may suffer from diabetic gastroparesis from autonomic dysfunction. In addition, acute hyperglycemia can cause delayed gastric emptying. It may be of value to have blood sugars monitored in patient with diabetes and instruct them to bring medication/insulin on the day of the study. Overlap of small bowel in the region of interest leads to overestimation of total counts (and therefore falsely prolonged gastric emptying). Gastric emptying depends on meal volume (larger meals empty faster than smaller meals), so if the patient did not eat the entire meal, gastric emptying may be prolonged compared to standard normal values for that meal.

8. A patient has a 1.5 cm liver lesion that demonstrates atypical characteristics for a hemangioma on contrast-enhanced CT. A labeled red blood cell study is requested for further evaluation. Which of the following statements is *true*?
- A. Increased early arterial flow and immediate blood pool images will confirm that the lesion is a hepatic hemangioma.
 B. If the lesion is “cold” on the RBC study, it will confirm that the lesion is malignant.
 C. SPECT imaging should be considered.
 D. Performing the scan with heat damaged red blood cells improves accuracy.

ANSWER: C. Increased delayed blood pool (at 30 minutes–3 hours) is the hallmark of a hepatic hemangioma. Typically, the lesions do not have increased early arterial flow and immediate blood pool. A “cold” lesion on a RBC study is very non-specific and is seen in most lesions, benign or malignant, other than hemangiomas. SPECT imaging should be considered since it improves lesion localization if the lesion size is less than 2 to 3 cm. Red blood cells used for hemangioma imaging are never heat damaged. Heat-damaged red blood cells have been used for imaging splenic tissue.

9. Which of the following statements regarding hepatobiliary scintigraphy for the evaluation of infants with persistent hyperbilirubinemia is *true*?
- A. Should never be performed without pretreatment with phenobarbital.

- B. Imaging for up to 12 hours is sufficient.
- C. Biliary atresia is excluded if radiotracer is seen in the intestinal tract.
- D. Disofenin with a maximal dose of 0.1 for infants is the preferred radiopharmaceutical.

ANSWER: C. Biliary atresia is excluded if radiotracer is seen in the bowel. Careful inspection of dynamic and static images to ensure that other radiotracer activity (GU tract, contamination) is not mistaken for bowel activity is important. On the other hand, nonvisualization of bowel is consistent with biliary atresia, but may also be caused by severe hepatocellular dysfunction from any cause. The scan may be performed without pretreatment with phenobarbital. Nevertheless, if a scan performed without phenobarbital pretreatment does not show biliary to bowel clearance, the examination should be repeated after appropriate pretreatment (phenobarbital: 5 mg/kg/d divided in two doses, for 3–5 days). Although some experts suggest checking phenobarbital levels prior to HIDA scanning, this is not mandatory. Imaging for up to 12 hours may not be sufficient. Images up to 24 hours are often necessary. Mebrofenin is preferable to disofenin in this circumstance (hyperbilirubinemia) because of its higher hepatic extraction. The dose for infants and children is weight based (0.05–0.2 mCi/kg), with a minimum recommended activity of approximately 0.5 mCi.

10. Areas of focally or regionally increased radiotracer uptake within the liver during scintigraphic procedures can be seen in which of the following conditions?
- A. Liver hemangioma – HIDA scan
 - B. Focal nodular hyperplasia – sulfur colloid scan
 - C. Hepatic adenoma – labeled red blood cell scan
 - D. Budd Chiari syndrome – quadrate lobe of the liver on sulfur colloid scan

ANSWER: B. There are only a few focal hepatic lesions that have somewhat typical appearance on certain radionuclide studies (most lesions are usually “cold” or have such variable patterns that scintigraphic examinations have very limited predictive value). The most important one is hepatic hemangioma, which is essentially the only liver lesion that would demonstrate increased delayed blood pool activity. Another hepatic lesion is focal nodular hyperplasia (FNH), which contains hepatocytes and Kupffer cells. FNH may demonstrate sulfur colloid uptake equal or greater than the liver in approximately 50% to 60%. Therefore, normal or increased sulfur colloid uptake in a liver lesion is

very suggestive of FNH. Of note, a regenerative nodule in a cirrhotic liver may also have increased sulfur colloid uptake. There are also several vascular abnormalities that can lead to differences in regional hepatic perfusion and thus cause areas of increased radiotracer uptake (on either HIDA or sulfur colloid scan), such as Budd Chiari syndrome (hepatic outflow obstruction such as hepatic vein thrombosis), which leads to increased uptake in the caudate lobe (the caudate lobe has separate venous efferent blood flow directly to the inferior vena cava). Occlusion of the superior vena cava can lead to increased uptake (on HIDA, sulfur colloid, or other scans) in the quadrate lobe of the liver because of collateral venous pathways (if the tracer was injected in the upper extremity) (occlusion of the inferior vena cava may lead to the same pattern in the lower extremity were chosen for injection of the radiotracer).

94 GENITOURINARY NUCLEAR MEDICINE

Jon A. Baldwin

The primary role of nuclear medicine is in the functional analysis of the genitourinary system (Table 94-1).

RENAL IMAGING AGENTS

Selection of the renal radiopharmaceutical is dependent on the parameter one wishes to assess. Twenty percent of total renal function is the result of glomerular filtration; the remaining 80% is the result of tubular secretion. ^{99m}Tc diethylenetriamine penta-acetic acid (^{99m}Tc DTPA) is almost entirely filtered through the glomerulus, and therefore is an agent used to determine

TABLE 94-1 Indications for Radionuclide Study of GU Tract

Renal perfusion
Quantitative and differential function of native kidneys
Evaluation for obstruction (Lasix renography)
Screening for renovascular hypertension (captopril renography)
Quantitative and differential function of allograft kidneys
Radionuclide cortical imaging
Screening for and evaluation of vesicoureteral reflux
Evaluation of testicular torsion

glomerular filtration rate (GFR). Approximately 5% to 10% of ^{99m}Tc DTPA is bound to plasma proteins once injected, which will result in a slight underestimation of GFR. ^{99m}Tc DTPA can demonstrate renal perfusion (radionuclide angiogram), renal parenchymal abnormalities, and assesses the renal collecting system and bladder for obstruction. It is not the ideal agent for assessment of the renal parenchyma itself, as it has a brief nephrogram phase; the cortical imaging agents described later in the chapter are superior for this task. In addition, the extraction fraction is approximately 10% to 20%, which somewhat limits the utility of ^{99m}Tc DTPA in patients with poor renal function or longstanding/high-grade obstruction, when compared to other radiopharmaceuticals with higher extraction fractions. Peak cortical uptake usually occurs by 3 to 5 minutes. One-half of the peak cortical activity is reached at 15 to 20 minutes. Bladder activity typically appears by 6 minutes at the latest. Ureter activity may not be seen in normal subjects.

Prior to 1986, the radiopharmaceutical that measured tubular secretion was ^{131}I orthoiodohippurate (^{131}I OIH). ^{131}I OIH is primarily (80%) cleared by tubular secretion, with the remainder filtered at the glomerulus. ^{131}I OIH is no longer commercially available in the United States. Tubular secretion and, by extension, the measurement of effective renal plasma flow (ERPF), is now primarily measured by the radiotracer ^{99m}Tc mercaptopyruvate (^{99m}Tc MAG3). Because the radionuclide label is ^{99m}Tc , a larger radiotracer dose may be used than with ^{131}I OIH. The 140-keV photons emitted are far superior to those of ^{131}I OIH for rendering images used to interpret morphology of the kidneys and generate time activity curves. ^{99m}Tc MAG3 is predominately cleared by the proximal tubules, with less than 5% filtration. The overall clearance of ^{99m}Tc MAG3 is approximately 60% that of ^{131}I OIH, because of slower plasma clearance and higher proportion of protein binding. In truth, ^{99m}Tc MAG3 measures the clearance of ^{99m}Tc MAG3, *not* ERPF; a correction factor is necessary to compute an ERPF when using this agent. It is a better agent to use in patients with renal dysfunction, as its extraction fraction (40%–50%) is superior to that of ^{99m}Tc DTPA.

Imaging of the renal cortex can be achieved with one of two agents. Both agents are fixed to proximal renal tubular cells via sulfhydryl group binding. The most commonly used radiopharmaceutical is ^{99m}Tc dimer-captosuccinic acid (^{99m}Tc DSMA). Approximately 40% of the dose is ultimately concentrated in the renal cortex. Because of its slow clearance rate, a delay of 1 to 3 hours is necessary for optimal imaging. Once this delay is met, however, the image quality is very good, with an excellent target-to-background ratio. ^{99m}Tc glucohepto-

TABLE 94-2 Renal Radiopharmaceuticals Used in Renal Imaging

RADIONUCLIDE	DOSE (mCi)	PARAMETER ASSESSED	CRITICAL ORGAN
^{99m}Tc DTPA	10–20	GFR	Bladder
^{99m}Tc MAG3	5–10	ERPF	Bladder
^{99m}Tc GH	10–20	GFR and cortical	Bladder
^{99m}Tc DSMA	1–5	Cortical	Kidney

nate (^{99m}Tc GH) is also used for cortical imaging. A radiolabeled carbohydrate, a smaller percentage of this radiotracer is bound to the cortex when compared to ^{99m}Tc DSMA. ^{99m}Tc GH is also filtered, so it can be imaged after injection to assess renal flow, the collecting system, and the bladder. Table 94-2 summarizes commonly used renal radiopharmaceuticals.

QUANTITATIVE AND DIFFERENTIAL RENAL FUNCTION

It should be noted that no imaging of the radiopharmaceutical need be performed to quantify either GFR or ERPF in certain circumstances. Some institutions use a plasma-sampling technique that generates a “superior” result in terms of accuracy and reproducibility than a camera-based technique. The drawback to this method is having to handle blood products, as well as additional laboratory training and credentialing. For the purposes of review, an outline of the plasma sample technique will follow. Before the patient is injected with the radiopharmaceutical, the dose is placed in a dose calibrator and the reading is recorded. The patient is injected with the radiopharmaceutical, and if imaging is to be performed, the camera is started. The syringe is again placed in the dose calibrator, and a “residual” is measured. This number is subtracted from the original reading, and the difference is the dose that the patient actually received. At a specific time, a blood sample will be taken from the patient. The time used is based on data beyond the scope of this discussion; suffice to say that it is approximately 45 minutes for ^{99m}Tc MAG3 and at 60 and 180 minutes ^{99m}Tc DTPA (because of its slower plasma clearance). The sample is spun in a centrifuge, and the plasma is subsequently placed in a well counter (along with a radiopharmaceutical standard) and counted. This result is then decay corrected. Knowing how much radiopharmaceutical was injected into the patient, and how much remains in the plasma at a fixed time period, one can use this information to calculate GFR or ERPF (depending on the radiopharmaceutical used). A critical assumption in this method is that the full dose was delivered intravascularly. The presence of

a dose infiltration at the injection site could artificially increase or decrease the measured renal function parameter if the infiltration is relatively “loculated” (activity is not in the plasma because of it being sequestered, artificially inflating the result) or gradually reenters the circulation via the lymphatics, respectively.

Most facilities have found that a camera-based method of determining renal function is sufficiently accurate and reproducible for their needs. Care should be taken when using this method, however, as differences in positioning and processing can cause wide variations in results, as will be described. Before the patient is injected, the dose is imaged at a precise geometry and distance from the camera’s collimator for a set time, usually 1 minute. Meticulous attention to detail is crucial when positioning the dose for reproducibility. The patient is then injected with the radiopharmaceutical, and sequential images are obtained for a set time (typically 6 minutes for ^{99m}Tc DTPA). These images are then processed, and regions of interest are drawn around the kidneys, as well as outside the kidneys for background correction. The background-corrected counts for each kidney can then be compared as a percentage to the injected dose. Attenuation must be corrected for by using the patient’s weight and height using standardized formulae. Potential sources of error for this method include dose infiltration, imprecise positioning of the radiotracer syringe, inclusion of a blood pool structure (such as the liver or spleen) in the background correction region of interest (ROI), and imprecise “attenuation correction” because of variability in kidney depth in patients.

The majority of functional renal imaging performed in the United States is performed with ^{99m}Tc MAG3. The review in the remainder of this section will assume that ^{99m}Tc MAG3 is the radiopharmaceutical being used; if there are significant differences in normal values or pathologic findings when using ^{99m}Tc DTPA, they will be described.

For the purposes of the study of renal function, the patient and camera are positioned in such a way as to minimize attenuation from overlying structures and ensure that the kidney is centered in the field of view. The camera is situated posterior to the supine patient for the study of native kidney function, and the camera is situated anterior to the supine patient for the study of renal allograft function. Anterior camera positioning is also preferred for imaging of horseshoe kidneys. ROIs are drawn around the kidney(s), and time activity curves are produced. Once the patient is injected, the radiotracer transits through the kidney in three phases: vascular, concentration, and excretory (Fig. 94-1). The vascular phase represents renal perfusion. It begins approximately 15 to 20 seconds after injection, and within 4 to 6 seconds after aorta visualization. This peaks at

FIG. 94-1 Three phases of the renogram.

approximately 30 seconds and levels off. Because of the quick nature of this process, dynamic serial images are made for every 1 to 5 seconds for 1 minute. ROIs are drawn around both kidneys and the aorta, taking care not to include the spleen or liver (Fig. 94-2). Activity within the kidneys is ideally symmetric and approximately equal to slightly less intense compared to the peak of the aorta activity. An injection with a good bolus is imperative for reliable data. Table 94-3 lists common causes for patterns of altered perfusion, in addition to some pathologies which do not have an altered perfusion phase. The next phase of uptake is the cortical uptake phase, also known as the parenchymal phase. It typically lasts 1 to 5 minutes. In this phase, the tubular secretory accumulation of the radiopharmaceutical predominates. The slope of this uptake correlates with global renal function; a steep slope is indicative of good renal function, while a more gradual increase is indicative of poor renal function. It is during this phase that true differential function of the kidneys is best determined. If one waits much beyond 3 minutes, they run

FIG. 94-2 Time-activity curve for renal perfusion.

TABLE 94-3 Renal Perfusion Findings

Symmetric decreased perfusion	Poor bolus/injection technique
Asymmetric decreased perfusion	Renal artery thrombosis
	Renal vein thrombosis
	Avulsion of renal artery
	Acute pyelonephritis
	Acute rejection (allograft)
	Longstanding high-grade obstruction
Asymmetric/focal increased perfusion	Renal artery aneurysm
Normal perfusion	Acute tubular necrosis
	Interstitial nephritis
	Cyclosporine toxicity

the risk of excreted radiotracer in the renal pelvis contributing to the counts within the ROI of the kidneys. Our facility has chosen 1 minute as the time at which differential function is determined. This, of course, presupposes that the injection was performed as a bolus, and that the camera was initiated at the time of injection. Improper timing of camera operation can alter not only differential function values, but peak time (typically 3–5 minutes) and 20/3 ratio values as well. As the study progresses, the final phase, the excretory phase, is entered, which lasts for the remainder of the study. During this phase, the excretion of radiotracer should exceed the uptake of radiotracer in normal patients. There is a gradual downsloping of activity, with radiotracer entering the renal pelvis and collecting systems on its way to the bladder. Approximately half of the peak counts is reached at approximately 7 to 10 minutes in normal patients. A way to quantify whether a patient has retention or not is to compare the number of counts within the ROI at 20 minutes to the number of counts at either peak activity, or at 3 minutes. This is called the 20/peak or 20/3 ratio, respectively. Please note that while these ratios are often used as a measure of cortical retention, the number would also be increased in obstruction, in which case the majority of the counts would be coming from the renal pelvis as opposed to the cortex. One must carefully inspect the images to attempt to conclude where the counts are coming from. Another potential source of error is the hydration status of the patient. If the patient is not adequately hydrated, this may lead to delays in excretion of radiotracer from the tubules. Table 94-4 summarizes normal ^{99m}Tc MAG3 findings.

TABLE 94-4 Summary of Normal ^{99m}Tc MAG3 Renal Scan Findings

PEAK TIME	DIFFERENTIAL FUNCTION	20/PEAK	20/3
3–5 min	50% + 6%	0.3	≤ 0.8

DIURETIC RENOGRAPHY

Intravenous-contrast urography and renal ultrasound provide excellent anatomic structural information in the evaluation of renal obstruction, but do not provide functional urodynamics. Renal scans performed without diuretics may demonstrate decreased perfusion to the affected kidney, the severity of which is dependent on the chronicity of the obstruction. The appearance of the concentration and excretory phases are also related to the chronicity of the obstruction, and the amount of preserved renal function. If the obstruction is indeed longstanding, the typical renogram appearance will reflect poor and asymmetric uptake, with a flattened renogram curve. An acute or subacute obstruction, however, will have continuously accumulating radiotracer, with a markedly delayed time to peak in the affected kidney (Fig. 94-3). This appearance can also be seen in a patient with a dilated collecting system as in nonobstructive hydronephrosis from a variety of causes: prior obstruction now reversed, vesicoureteral reflux (VUR), urinary tract infection, lax pelviureteral muscle, and congenital malformations.

The use of a diuretic such as Lasix will help differentiate between the conditions mentioned previously and mechanical obstruction. It is given intravenously over 1 to 2 minutes, and has a quick onset of action. Increasing renal flow by diuresis, radiotracer may be forced from the collecting system to the bladder. There are several variations as to how much and when to give the radiotracer. Most institutions will administer 40 mg of Lasix to its adult patients (1 mg/kg for the pediatric population, with maximum of 40 mg). If the patient has renal insufficiency, the dosage of Lasix can be increased to try to compensate for the decreased renal function. Likewise, as GFR is affected more by longstanding obstruction than is ERPF, ^{99m}Tc MAG3 should be used in patients with poor renal function. If renal function is

**FIG. 94-3** Time-activity curve in an acutely obstructed kidney.

preserved, ^{99m}Tc DTPA will perform as well as ^{99m}Tc MAG3. Variations in timing of Lasix administration include prior to, at the time of, and after radiopharmaceutical injection. Administration prior to or at the radiopharmaceutical injection is preferred in patients with poor renal function, as this will give additional time for the Lasix to work. If given after the radiopharmaceutical, most institutions try to give it near peak activity, anywhere from 10 to 20 minutes after radiotracer injection. If there is no obstruction present, in less than 10 minutes there should be less than half of the counts remaining than were present at the peak. This is a normal time to half peak after Lasix administration. A transient slight upward deflection or plateau is not unusual in the renogram curve in normal patients. This represents diuretic-induced increased flow before clearance from the collecting system. When there is no response to Lasix, or there is continued accumulation of radiotracer within the renal pelvis, and the half peak has not been reached by 20 minutes after Lasix administration, the obstruction is present. Time to half peak between 10 and 20 minutes (15–20 minutes according to some authors) is indeterminate for obstruction. The most common cause for this finding is a very dilated renal pelvis with a subsequent reservoir effect. Numerous conditions can lead to a false positive for obstruction. In addition to the cause just listed, poor hydration status can contribute to a lack of response of Lasix; in this study, adequate hydration is imperative. Poor renal function can also lead to a poor response to Lasix administration. In these cases, the amount and timing of Lasix can be adjusted as listed to maximize the effect. Pressure from a full or neurogenic bladder may prevent the flow of radiotracer from the renal pelvis. In these cases, making sure the patient voids before the study (or self-catheterizes, in the case of neurogenic bladder) may help to prevent this phenomenon. In some cases, a Foley catheter may be needed in place during the study. Diuretic renography findings and false positives are summarized in Tables 94-5 and 94-6.

RENOVASCULAR HYPERTENSION

Only approximately 10% of patients with hypertension have a discernable cause for their high blood pressure;

TABLE 94-5 Diuretic Renography Findings

TIME TO HALF PEAK AFTER LASIX ADMINISTRATION	DIAGNOSIS
>10 min (15 min, some authors)	Not obstructed
Between 10 (15) and 20 min	Indeterminate for obstruction
>20 min	Obstructed

Inadequate patient hydration
Poor renal function
Massively dilated renal pelvis
Rigid/noncompliant renal pelvis
Full/neurogenic bladder
Neonate—(functionally immature kidneys)

the majority of this population have “essential hypertension.” Of those individuals who do not have essential hypertension, a significant number have renovascular hypertension (RVH). Risk factors for the presence of RVH include malignant/resistant hypertension, abrupt onset of hypertension, early or late onset of hypertension, and worsening renal function after initiation of angiotensin-converting enzyme (ACE) inhibitor therapy. The two main causes of RVH are atherosclerosis and fibromuscular dysplasia. The decrease in perfusion pressure in the afferent arterioles caused by the presence of either of these conditions is detected by the juxtaglomerular apparatus. In an effort to preserve perfusion pressure across the glomerulus, the cells of the juxtaglomerular apparatus release renin. Renin converts circulating angiotensinogen to angiotensin I, which is subsequently converted by ACE into angiotensin II, the active form. Angiotensin II increases perfusion pressure in the glomerulus and thereby GFR by preferential constriction of the efferent arteriole. Angiotensin II also increases sodium and water retention by decreasing peritubular hydrostatic pressure (as a consequence of efferent arteriole constriction) and by increasing aldosterone secretion from the adrenal gland. The administration of an ACE inhibitor would reduce these effects, and is the basis of radionuclide screening for RVH with an ACE inhibitor, such as captopril.

Several factors must be taken into account in regard to patient preparation. To increase the sensitivity of the study, the patient should stop ACE inhibitors prior to the renal study. The length of time to stop ACE inhibitor therapies varies with the duration of effect of the particular drug (3–5 days if the patient is taking captopril). Since patients with true RVH have high blood pressure that is difficult to control, this may not always be feasible; these patients may have the study using their dose of the ACE inhibitor as the pharmacologic agent. If the patient is to receive captopril as the pharmacologic agent for the renal scan, they should not have eaten for at least 4 to 6 hours to promote GI uptake of the drug (this precaution is unnecessary if an IV ACE inhibitor like enalapril is used). The patient should be well hydrated, however, dehydration can cause errors in interpretation. Before administration of the ACE inhibitor, it

is wise to review the patient's history and medications. This will help guide you as to the best dose of ACE inhibitor to use (usually 25–50 mg captopril PO; 5 mg enalapril IV). Using a lower dose may be more prudent on patients who are on large doses of other antihypertensive medications (to avoid inducing hypotension in the patient). Ideally, an IV should be placed before administration of the ACE inhibitor should the patient become hypotensive, and IV hydration become necessary. A baseline blood pressure should be checked, and periodic blood pressure measurements should be taken over the course of an hour to make sure the patient does not become hypotensive. After this uptake period, the patient will be ready to receive their radiopharmaceutical dose. Many facilities also administer IV Lasix at the time of radiopharmaceutical administration. This will promote collection system clearance, so as to not confound interpretation (i.e., counts emanating from renal pelvis retention rather than cortical retention).

The appearance of renal artery stenosis (RAS) will vary depending on the radiopharmaceutical chosen. If ^{99m}Tc DTPA, a GFR agent, is used, the affected kidney will demonstrate asymmetric decreased uptake and flow in that kidney because of the loss of perfusion pressure across the glomerulus along with a decrease in GFR of greater than 10%. However, ^{99m}Tc MAG3, a tubular agent, will have asymmetric marked cortical retention in the affected kidney. The curve has the appearance of the one given for renal obstruction (Fig. 94-3), with the counts in the ROI resulting from cortical retention as opposed to retention within the collecting system. If the study does not have the classic marked cortical retention appearance for RAS, a baseline study can be performed to compare to the ACE inhibitor study. Other findings that can be seen (compared to baseline) are a delay in time to peak of more than 2 minutes, delay in collecting system visualization by more than 2 minutes, and a 15% increase in cortical retention. If bilateral cortical retention is seen, it typically does not represent bilateral RAS, but rather the presence of hypotension or dehydration. Table 94-7 summarizes diagnostic criteria and the

resulting interpretations. A “high probability for a hemodynamically significant RAS indicates there is a 90% chance that RAS is present. Low probability indicates the chance of RVH from RAS is less than 10%.

RENAL ALLOGRAFT FUNCTIONAL IMAGING

The study of allograft function is performed identically to that of the study of native kidney function, except that the camera is placed over the anterior pelvis for imaging. ^{99m}Tc MAG3 is typically used for imaging, although ^{99m}Tc DTPA can be used. ^{99m}Tc MAG3 is preferred because of its higher uptake and better target-to-background appearance. When used in conjunction with knowledge of the type of allograft implanted (cadaveric, living related, or living unrelated donor) and the time from implantation, a renal scan of the renal transplant is a good screening test to help differentiate conditions that can frequently occur in allografts, including accelerated acute rejection, acute rejection, chronic renal allograft nephropathy (chronic rejection), acute vasomotor nephropathy (AVN; less precisely referred to as acute tubular necrosis, ATN), and drug toxicity. Renal scans can also help detect surgical complications.

NONSURGICAL COMPLICATIONS

Hyperacute rejection is extremely rare, secondary to HLA immunologic screening. If preformed antibodies were present in the recipient's circulation, this type of rejection would result. This is an immediate response, typically too quick for imaging, and if imaging is performed, the allograft would appear as a photopenic area in the pelvis. The allograft cannot be saved.

Accelerated acute rejection can occur in patients who have had prior transplantations or other conditions that can cause increased antibodies in the circulation

TABLE 94-7 Summary of ACE Inhibitor Renal Study Findings and Interpretations

ACE INHIBITOR RENAL STUDY FINDING	STUDY INTERPRETATION
Unilateral decrease in uptake and clearance with ^{99m}Tc DTPA	High probability for a hemodynamically significant renal artery stenosis
Global decrease in GFR >10% when compared to baseline	
Unilateral marked cortical retention with ^{99m}Tc MAG3	
Change in function or symmetry present, but <10% compared to baseline	
Bilateral cortical retention	Intermediate probability for a hemodynamically significant renal artery stenosis
Baseline study changes/asymmetric poorly functioning kidney on both studies/baseline poor global renal function	
Symmetric function with normal renogram curves	Low probability for a hemodynamically significant renal artery stenosis

(e.g., multiple blood transfusions, pregnancy). This will typically occur as early as 3 days after implantation. If the patient had a normal baseline renal scan, one would expect an increase in time to peak and cortical retention (increased 20/3 ratio). As this is the scan appearance for acute vascular nephropathy, this can be differentiated on the basis of a normal baseline study and its early manifestation (3–5 days) after transplantation. If the initial study had the appearance of AVN, superimposed accelerated acute rejection or acute rejection can be suspected on the basis of renal function not improving over time (as typically occurs in AVN).

Acute rejection is more frequent in incidence than accelerated acute rejection. It has an imaging appearance similar to accelerated acute rejection (delayed time to peak, increased 20/3 ratio). Perfusion to the allograft will be delayed, if initial dynamic perfusion images are obtained. The time frame for the manifestation of acute rejection is longer than accelerated acute rejection, with its appearance typically occurring postoperative day 7 to 10. It is a common complication within the first 3 months of transplantation, although it can occur after this time frame in patients who have discontinued immunosuppressive therapy. AR can be mediated by either cell-mediated or humoral processes, although cell-mediated processes tend to predominate. Both accelerated acute rejection and AR often respond to medical therapy.

Despite the advances in immunosuppressive therapy, chronic allograft nephropathy/chronic rejection is the inevitable fate for a renal allograft. This manifestation can be delayed for many years with good therapy. The risk for hastened chronic rejection (appearing in 6–12 months) is increased if the allograft has had severe AVN, prior severe acute rejection, and immunosuppressive drug (cyclosporine and tacrolimus) toxicity. Imaging features include normal to mildly delayed time to peak, relatively decreased uptake, and minimal to no cortical retention. If measured, ERPF or GFR demonstrate a steady decline in function over time.

Acute vascular nephropathy, also referred to as ATN, is typically a complication of cadaveric donor kidneys, although living donor kidneys can have this complication if there is a long delay before implantation. Typically, there is a delay in uptake and time to peak, delay in appearance of radiotracer within the bladder and cortical retention leading to an increased 20/3 ratio. If dynamic renal allograft initial perfusion imaging is performed, it is usually normal. This condition is present in the baseline renal scan, and improves on subsequent studies. If the appearance does not resolve, superimposed acute rejection should be considered.

Cyclosporine and tacrolimus, although important for mitigating immune reactions that would lead to acute

rejection, are known culprits for long-term decrease in allograft function, with longstanding use ultimately leading to chronic allograft nephropathy. Scintigraphic appearance of cyclosporine toxicity mimics the appearance of acute vascular nephropathy, with normal initial dynamic perfusion and cortical retention. Of course, the appearance of this cortical retention would not be present on the initial postoperative study, but only after weeks of therapy. Long-term use would lead to a chronic allograft nephropathy appearance. Given new immunosuppressive regimens, and lower doses of cyclosporine prescribed, this is now a less common complication.

SURGICAL COMPLICATIONS

Urine extravasation (urinoma) can be seen in both leakage from the ureterovesical anastomosis and damage to the transplant ureter. If present, this condition will lead to radiotracer outside the allograft or bladder, although delayed imaging may be necessary to demonstrate this. Care should be taken in interpretation of delay images when ^{99m}Tc MAG3 is used, as over time this is excreted into the bowel and may confound the picture for urinoma.

Ureteral obstruction can be the result of extrinsic compression from overlying hematoma or lymphocele or from ischemic scarring of the ureter and/or anastomosis. Diuretic renal scan, performed as described earlier in the chapter, can help detect this condition and differentiate it from a dilated collecting system. As the renogram curve can appear similar in obstruction, acute vascular nephropathy, and acute rejection, the images should be carefully scrutinized to determine whether the counts are coming from the cortex or the collecting system.

Lymphocele and hematoma will typically present as perinephric photopenic areas on a renal scan.

Arterial thrombosis is an extremely rare complication; this may be the result of difficulties related to implanting the allograft anastomosis into the patient's iliac artery. A renal scan of this condition would demonstrate no flow or function. If only a segmental arterial branch is obstructed, the scan may demonstrate an area of infarction within the allograft.

Venous thrombosis is usually a consequence of autoimmune complications, which occurs within the first few days to weeks of transplantation. This frequently will lead to loss of an allograft. As there are no collaterals within the allograft, the venous congestion will ultimately lead to a lack of flow in the allograft. Scintigraphic appearance is similar to arterial thrombosis, with a photopenic defect in the patient's pelvis surrounded by background activity.

RAS can occur in a transplanted kidney if there is constriction at the arterial anastomosis site (most commonly) or distal to the anastomosis site. An ACE inhibitor renal scan can be performed when this condition is suspected. When using ^{99m}Tc MAG3, if there is no cortical retention on the renal scan after ACE inhibitor, then there is a low probability that a hemodynamically significant RAS is present. If, however, there is marked cortical retention after ACE inhibitor administration, one should perform a baseline study without an ACE inhibitor, to eliminate the presence of acute vascular nephropathy or acute rejection, which would have similar scintigraphic appearance. If ^{99m}Tc DTPA is used, one would expect a marked decrease in flow and clearance in the presence of an ACE inhibitor. This would reverse on the baseline study without an ACE inhibitor.

RADIONUCLIDE CORTICAL IMAGING

The agents for renal cortical imaging are ^{99m}Tc DMSA and ^{99m}Tc GH. Although ^{99m}Tc DMSA results in a higher dose to the patient's kidney, the dose to the gonads is less than that of ^{99m}Tc GH, and for this reason, as well as its superior resolution, it is preferred for cortical imaging in the younger pediatric population. Renal cortical imaging is most often used to detect the presence of acute pyelonephritis in the pediatric population, in both symptomatic individuals, and in those with known VUR. ^{99m}Tc DMSA cortical imaging is more sensitive than ultrasound. An additional indication is differentiation of prominent column of Bertin from a malignant renal mass (a renal mass will not have ^{99m}Tc DMSA uptake, but column of Bertin will). The patient is imaged in the supine position at 1 to 3 hours after injection. A high-resolution parallel-hole collimator is used. A minimum of posterior planar views is acquired, although anterior and oblique views are preferred. Magnified views of the kidneys with a pinhole or converging collimator are recommended. SPECT images of the kidneys can also be performed, but this is sometimes difficult to accomplish in a nonsedated pediatric patient. If ^{99m}Tc GH is used, imaging is similar, but a flow phase is also acquired initially. Acute pyelonephritis can appear as a single focal ill-defined area of decreased uptake, multifocal areas of decreased uptake, or as diffuse decreased uptake in an otherwise normal-sized kidney. The first and second appearances can also be seen in tumors and scars as well. While a scar will typically have volume loss and contraction, leading to irregular contour, a mass may not. Correlation with ultrasound is recommended. The last appearance is indicative of a diffuse inflammatory process. Other "artifacts" that

can cause inhomogeneous radiotracer distribution are overlying attenuation in the superior poles from liver and spleen, fetal lobulation, or relative decreased counts centrally from the collecting system. ^{99m}Tc DMSA is useful for following the course of the patient, and when the defect resolves or progresses to scar. It is recommended that there is an interval of 3 to 6 months between scanning.

RADIONUCLIDE CYSTOGRAPHY

The majority of cases of acute pyelonephritis in the pediatric population are the result of VUR of infected urine from the bladder into the kidneys. While radiographic-contrast cystography gives good anatomic information, and can detect the presence of posterior urethral valves in males, radionuclide cystography is the favored method for evaluation and follow-up for VUR. Radionuclide cystography is the more sensitive of the two modalities, being able to detect reflux volumes as low as 1 mL. In addition, the radiation dose to the gonads is substantially less than with the radiographic study, with anywhere from 50 to 150 times less exposure. The drawback is the loss of anatomical information because of resolution limitations; the usual radiographic system of grading cannot be applied.

The patient is placed in the supine position, with the camera posterior to the patient and positioned such that the bladder and kidneys will be in the field of view. The bladder is catheterized and connected to a 500-mL bag of normal saline 25 cm above the table; 0.5 to 1.0 mCi of ^{99m}Tc sulfur colloid (^{99m}Tc SC) is added to the bag of saline. ^{99m}Tc SC is preferred, because sodium pertechnetate ($\text{Na}^{99m}\text{TcO}_4$) or ^{99m}Tc DTPA may be absorbed by the bladder wall, especially in the presence of inflammation and excreted by the kidneys. The radiotracer is instilled into the bladder during a dynamic acquisition of images until the bladder is filled. Any reflux seen will be graded (Table 94-8). After bladder capacity is reached, the patient is preferably placed in the sitting position (with the camera posterior) as the patient voids. If the patient cannot void on request, supine positioning with the patient voiding into a diaper or towel can be performed. Dynamic imaging is performed during voiding as well, once again looking for the presence of reflux. A static postvoid image is also obtained, and can be used for the determination of postvoid residual volume. Given the amount of activity present in the bladder, it is possible that subtle reflux into the proximal ureter may be missed, but this is usually of little clinical consequence.

TABLE 94-8 Grading of Vesicoureteral Reflux

RADIOTRACER ACTIVITY	RADIONUCLIDE CYSTOGRAPHY "GRADE"	EQUIVALENT CONTRAST CYSTOGRAPHY GRADE
Confined to ureter	Mild/scintigraphic grade I	Grade I
Reflux into renal pelvis	Moderate/scintigraphic grade II	Grade II/III
Reflux into renal pelvis with clearly dilated collecting system/ureter	Severe/scintigraphic grade III	Grade IV/V

TESTICULAR IMAGING

The radionuclide imaging of testicular flow has almost entirely been relegated to historical interest with the availability, sensitivity, and specificity of ultrasound imaging. When performed, it is a good study for the differentiation of acute testicular torsion from other causes such as epididymitis. The radiotracer used is $\text{Na}^{99\text{m}}\text{TcO}_4$. The patient is imaged supine, with the camera anterior to the scrotum. The penis may be taped to the abdominal wall to keep it out of the field of view. A lead shield behind the testicles may help eliminate background activity from the thigh. It is helpful to have a marker placed on the affected side. A normal study will have symmetric low-level flow within the scrotum. The interpretation of abnormal studies will not only depend on the appearance, but also on clinical information, such as time from onset of pain and side of the pain.

Flow images may be normal in early acute testicular torsion. Abrupt termination of flow may be seen at the site of the torsion ("nubbin sign"). On the blood pool phase, focal absent activity can sometimes be seen at the affected testicle.

Delayed torsion: Although previously called "missed torsion," in these litigious times, delayed torsion has become the preferred term. For this condition, the torsion has been in place for some time, and the likelihood of testicle salvage is small. The most common appearance is a halo of increased activity (from hyperemia) around a central area of photopenia (testicle with no flow). While this is the typical appearance of delayed torsion, the appearance of testicular abscess is similar.

Findings in acute epididymitis include increased flow and blood pool activity to the painful side caused by the increased hyperemia of inflammation.

QUESTIONS AND ANSWERS

- Of the following appearances, which is *least* likely to represent a diagnosis of acute pyelonephritis in a $^{99\text{m}}\text{Tc}$ DMSA renal study?
 - Focal cortical defect
 - Irregular renal contour
 - Multifocal cortical defects
 - Diffusely decreased uptake unilaterally

ANSWER: B. Focal cortical defect with irregular renal contour. Scarring from a previous infection usually results in volume loss and contraction, which can lead to an irregular renal contour. Admittedly, in practice this may be difficult to distinguish. All of the other appearances can be seen in the presentation of acute pyelonephritis.

- A patient with suspected RVH has a baseline renal scan, which is reported as normal. A renal scan performed with captopril demonstrates marked asymmetry in function, with normal function on the right and marked decreased function on the left. Which of the following radiopharmaceuticals was used in this study?
 - $^{99\text{m}}\text{Tc}$ DTPA
 - $^{99\text{m}}\text{Tc}$ MAG3
 - $^{99\text{m}}\text{Tc}$ DMSA
 - $\text{Na}^{99\text{m}}\text{TcO}_4$

ANSWER: A. $^{99\text{m}}\text{Tc}$ DTPA. The presence of RAS is associated with cortical retention in the affected kidney when $^{99\text{m}}\text{Tc}$ MAG3 is used as the radiotracer. $^{99\text{m}}\text{Tc}$ DTPA would demonstrate an asymmetric decrease in function in the affected kidney, because of the decrease in perfusion pressure across the glomerulus ($^{99\text{m}}\text{Tc}$ GH—not listed—would likely demonstrate the same effect on the renogram portion of the study). $^{99\text{m}}\text{Tc}$ DMSA is a cortical imaging agent, not used for the detection of RAS. $\text{Na}^{99\text{m}}\text{TcO}_4$ is not used for functional renal imaging.

- Which of the following statements regarding radionuclide cystography is *true*?
 - $\text{Na}^{99\text{m}}\text{TcO}_4$ is the preferred radiopharmaceutical for this study.
 - Reflux grading system is same as for contrast-voiding urethrocytography.

- C. Dose to the patient's gonads is approximately 10–15 times less than received from a radiographic contrast-voiding urethrocytography.
- D. Radionuclide cystography can detect reflux volumes as low as 1 mL.

ANSWER: D. Radionuclide cystography can detect reflux volumes as low as 1 mL. $\text{Na}^{99\text{m}}\text{TcO}_4$ is not usually used, as it can be absorbed through an inflamed bladder wall and excreted by the kidneys. $\text{Na}^{99\text{m}}\text{Tc SC}$ is the radiotracer of choice. Because of resolution limitations, scintigraphic grading of reflux is typically described as minimal (equivalent to radiographic grade I), moderate (equivalent to combined grades II and III), and severe (equivalent to combined grades IV and V). The dose to the gonads is substantially less than with the radiographic study, with anywhere from 50 to 150 times less exposure.

- 4. A pediatric patient has a prior history of vesiculoureteral reflux, pyelonephritis, and renal calculi. The patient now presents with left flank pain and temperature of 100.1°F. The pediatrician has asked for a renal scan to narrow his differential. Assuming all of the following radiotracers are available at your facility, which of the following agents would give the most information about possible causes for the clinical appearance?
 - A. $^{99\text{m}}\text{Tc DTPA}$
 - B. $^{99\text{m}}\text{Tc MAG3}$
 - C. $^{99\text{m}}\text{Tc GH}$
 - D. $^{99\text{m}}\text{Tc DMSA}$

ANSWER: C. $^{99\text{m}}\text{Tc GH}$. The point of this question is to remind you that $^{99\text{m}}\text{Tc GH}$ has the ability to image flow of the kidneys, as well as to do delayed cortical imaging. With the history of prior renal calculi and flank pain, the patient could be presenting with obstruction, which the flow phase of the study could assess for. With the histories of vesiculoureteral reflux and pyelonephritis, $^{99\text{m}}\text{Tc GH}$ can assess for the presence of pyelonephritis. All of the other listed radiotracers could only definitively investigate for one of these conditions, not both.

- 5. Your facility employs a plasma-sampling technique to determine global renal function (using $^{99\text{m}}\text{Tc MAG3}$) in addition to imaging to determine differential function. When performing a renal scan on a patient, the technologist started the camera late, after the time of the radiotracer injection. Which of the following findings would still be accurate?
 - A. Peak time
 - B. Differential function

- C. ERPF
- D. GFR
- E. 20/3 ratio

ANSWER: C. ERPF. All of the choices listed except for GFR are dependent on the computer analysis of the data obtained from the images obtained. Peak time would be delayed. As differential function is determined at a specific point in the renogram curve, this would also be inaccurate, as counts from the excretory phase would be in the ROI. 20/3 ratio would also be inaccurate because of the timing error. Plasma sampling is not affected by camera errors. GFR is not measured by $^{99\text{m}}\text{Tc MAG3}$.

- 6. Which of the following findings is most consistent with a finding of acute testicular torsion?
 - A. Asymmetric increased flow and blood pool to the painful side of the scrotum
 - B. Asymmetric decreased flow and blood pool to the painful side of the scrotum
 - C. Asymmetric increased flow with central photopenia to the painful side of the scrotum
 - D. Symmetric flow and blood pool within the scrotum

ANSWER: B. Asymmetric decreased flow and blood pool to the painful side of the scrotum. Increased flow and blood pool to the affected side is consistent with an inflammatory condition, such as epididymitis. Increased flow with central photopenia is the typical appearance of delayed torsion. Symmetric flow and blood pool will sometimes be seen in the earliest phases of acute testicular torsion, but more likely represents a normal study or torsion of a testicular appendage.

- 7. Which of the following agents has the highest dose to the kidneys?
 - A. $^{99\text{m}}\text{Tc DTPA}$
 - B. $^{99\text{m}}\text{Tc MAG3}$
 - C. $^{99\text{m}}\text{Tc GH}$
 - D. $^{99\text{m}}\text{Tc DMSA}$

ANSWER: D. $^{99\text{m}}\text{Tc DMSA}$. The critical organ for all other listed radiopharmaceuticals is the bladder.

- 8. Which of the following parameters is most useful in differentiating acute rejection of a renal allograft from acute vascular nephropathy (ATN)?
 - A. Time from implantation
 - B. Peak time
 - C. ERPF
 - D. 20/3 ratio

ANSWER: A. Time from implantation. Of the listed responses, this is the most helpful in differentiating acute rejection from ATN (acute vascular nephropathy). ATN is more likely to be present initially, with gradual improvement over time. Acute rejection typically begins to arise 10–14 days after transplantation. Renal perfusion (not listed) would also help differentiate these conditions. ATN has preserved perfusion, whereas acute rejection typically has decreased perfusion. Peak time is delayed in both conditions, and 20/3 is increased in both as well. ERPF may be low in both conditions.

9. Which of the following time to half peak after Lasix administration values is most consistent with obstruction?
- 8 minutes
 - 10 minutes
 - 15 minutes
 - 20 minutes

ANSWER: D. Time to half peak after Lasix administration less than 8 or 10 minutes is not compatible with obstruction; 15 minutes is indeterminate for obstruction.

10. In which of the following conditions would you expect the renal perfusion (vascular phase) to be normal?
- Acute pyelonephritis
 - ATN of a cadaveric renal allograft
 - Acute rejection of a cadaveric renal allograft
 - Renal vein thrombosis

ANSWER: B. ATN. Of the listed conditions, acute tubular necrosis is the only one, which is likely to have preserved perfusion.

95 CENTRAL NERVOUS SYSTEM SCINTIGRAPHY

Jon A. Baldwin

INTRODUCTION

Radionuclide imaging of the central nervous system (CNS) is one of function, rather than of anatomy. Most commonly requested studies are brain SPECT studies that assess regional cerebral blood flow (rCBF) and brain PET studies that assess glucose metabolism (with ^{18}F -FDG PET). Less commonly requested neurological studies include planar radionuclide angiography and cisternography. Diversionary shunt patency studies are also infrequently ordered. Table 95-1 lists radiopharmaceuticals used in nuclear medicine imaging of the CNS.

SPECT IMAGING OF THE BRAIN

One of the earliest agents used to image rCBF was ^{123}I iodoamphetamine (IMP). IMP is a lipophilic amine derivative able to cross the blood-brain barrier (BBB), and temporarily binds to amphetamine receptors. It is not fixed in the neurons and tends to wash out over time. This is a historical agent that is no longer clinically available in the United States. Another agent that can demonstrate rCBF is the noble gas ^{133}Xe . It also is readily diffusible across the BBB. It is quickly cleared, so the study can be repeated often. It is a technically challenging agent to use, and has poor imaging characteristics (the 81-keV photon is easily attenuated and scattered, and is below the ideal imaging window of 100–200 keV). ^{133}Xe has been

TABLE 95-1 CNS Radiopharmaceuticals

RADIOPHARMACEUTICAL	IMAGE ACQUISITION	APPLICATION IMAGED
$^{99\text{m}}\text{Tc}$ diethylenetriaminepenta-acetic acid ($^{99\text{m}}\text{Tc}$ DTPA)	Dynamic planar	Radionuclide angiography and cisternography; diversionary shunt patency
$^{99\text{m}}\text{Tc}$ hexamethylpropyleneamine oxine ($^{99\text{m}}\text{Tc}$ HMPAO)	Dynamic planar, SPECT	Radionuclide angiography and rCBF
$^{99\text{m}}\text{Tc}$ ethyl cysteinate dimer ($^{99\text{m}}\text{Tc}$ ECD)	Dynamic planar, SPECT	Radionuclide angiography and rCBF
^{133}Xe	SPECT	rCBF
^{15}O H_2O	PET	rCBF
^{201}Tl chloride	SPECT	Tumor imaging (tumor recurrence versus radiation changes)
^{18}F -fluoro-2-deoxyglucose (^{18}F -FDG)	PET	Glucose metabolism
^{18}F -fluoro-L-dopa (^{18}F -FDOPA)	PET	Presynaptic dopaminergic function
^{18}F -fluorothymidine (^{18}F -FLT)	PET	DNA synthesis/tumor imaging
^{18}F -misonidazole (^{18}F -MISO)	PET	Measure tumor hypoxia
^{111}In -DTPA	Dynamic planar	Radionuclide cisternography; diversionary shunt patency

mostly relegated to research applications. The workhorses of SPECT imaging of rCBF in clinical applications are the ^{99m}Tc radiotracers hexamethylpropyleneamine oxime (^{99m}Tc HMPAO—Ceretic) and ethyl cysteinate dimer (^{99m}Tc ECD—Neurolite). Both are neutral and lipophilic, and are relatively fixed in the neuron; there is, however, slow washout of ECD over time ($\sim 6\%$ per hour). Both also have a high first pass extraction (^{99m}Tc HMPAO $\sim 80\%$, ^{99m}Tc ECD $\sim 60\%$ – 70%). They accumulate in the cortex in proportion to blood flow, both slightly underestimating true rCBF. As they are essentially fixed in the neurons, SPECT imaging can be delayed with both radiotracers. Delay can be anywhere from 15 minutes to 2 hours with ^{99m}Tc HMPAO, without loss of image quality or information. Since blood clearance is faster with ^{99m}Tc ECD than ^{99m}Tc HMPAO, early ^{99m}Tc ECD images are superior to delayed ^{99m}Tc ECD images. Delayed ^{99m}Tc ECD images are also inferior to delayed ^{99m}Tc HMPAO images, because of the slow washout, resulting in considerable loss of activity from the cortex as time from injection increases. For both radiotracers, the uptake is predominately within the cortex. There is relative increased uptake in the caudate and lenticular nuclei, the thalami, and the cerebellum. White matter has much less uptake when compared to gray. Ventricles have near-absent to absent uptake. In addition, there are differences in normal biodistribution between the two radiopharmaceuticals: ^{99m}Tc HMPAO accumulates more in the frontal lobes, thalamus, and cerebellum; ^{99m}Tc ECD demonstrates slight preferential uptake in the parietal and occipital lobes. These slight differences can make comparison studies difficult between the two radiopharmaceuticals. The ^{99m}Tc rCBF radiotracers are used in numerous applications, including differentiating dementias, seizure localization, evaluation of vascular parameters, and tumor imaging. As the patterns of uptake in dementias and in seizure foci are similar regardless of whether ^{18}F -FDG or ^{99m}Tc rCBF radiotracers are used, those topics will be discussed after the section on PET imaging. The least common SPECT clinical application is for tumor imaging. The rCBF radiotracers typically are not used for this purpose. If tumors are evident at all, they may demonstrate nonspecific focal hypoperfusion (^{99m}Tc ECD can occasionally present as focal increased uptake). SPECT radiotracers used for imaging include ^{201}Tl chloride and ^{99m}Tc sestamibi. ^{99m}Tc sestamibi is uncommonly used. ^{201}Tl chloride is a potassium analog taken up by the Na^+/K^+ pump. Its distribution relates to blood flow, the presence of BBB breakdown, and the metabolic activity of the lesion. Although inflammatory conditions can also take up ^{201}Tl , tumors will have more intense uptake than infections. Abnormalities will have uptake greater than that of the scalp. Occasionally there may be a need to draw a region of interest around the abnormality and the

contralateral normal side, and then compare intensities. Alternatively, one can compare the intensity to normal scalp activity; activity twice that of scalp activity is considered high. The main utility of this technique is differentiation of recurrent glioma from radiation therapy changes. A recurrence would have much higher uptake than radiation changes. ^{201}Tl can also help grade gliomas, but ^{18}F -FDG PET is preferred for this application.

SPECT IMAGING OF ^{99m}Tc rCBF RADIOTRACERS IN VASCULAR APPLICATIONS

Two studies are used to evaluate vascular reserve and/or collateral blood flow in the brain: carotid artery balloon occlusion studies and the acetazolamide (Diamox) challenge study. Certain conditions (e.g., carotid body tumor, intracranial aneurysm) may call for the sacrifice/occlusion of one of the internal carotid arteries. Preoperative testing with ^{99m}Tc rCBF radiotracers has a very significant positive impact on patient morbidity and mortality. These patients are taken to the neurointerventional suite, and a balloon is temporarily inflated in the selected carotid artery. Radiotracer is injected while the balloon is inflated. SPECT images are performed after the patient is out of the recovery room. Images are compared for relative asymmetry in radiotracer distribution. If collateral flow from the circle of Willis is not sufficient, there will be significant asymmetry in rCBF. Markedly asymmetric patients are at increased risk of stroke after carotid artery sacrifice, and would benefit from carotid artery bypass. The second test can assess the presence of ischemia within the brain. Diamox is a carbonic anhydrase inhibitor that causes vasodilatation. After it is administered (1 g, intravenous), one can look for areas of decreased vascular reserve. It is convenient to think of the study as an adenosine stress test for the brain. Diseased vessels are already maximally dilated in an attempt to meet the vascular constraint, and cannot further respond to Diamox. Normal vessels, however, can respond by vasodilating. Ischemic areas will appear as relative defect at “stress,” and are at risk for future infarction. When a baseline study without Diamox is performed, these areas would tend to be isointense to the Diamox intensity or demonstrate improvement. Portions of the cortex that have already infarcted will appear with absent or near-absent activity on both studies.

Accurate interpretation of cerebral flow studies requires an understanding of the relationship between perfusion and metabolism in regard to imaging with rCBF agents and ^{18}F -FDG. These two parameters are often matched or “coupled,” which is to say that areas that are metabolically active require adequate perfusion. Instances in which this relationship is “uncoupled” occur during

evolution of a stroke. Initially in the face of an insult, and lasting for approximately 48 to 72 hours, the metabolism of brain tissue will be preserved despite the decrease in perfusion. This is the so-called misery perfusion. The area of decreased perfusion (on SPECT images) may be greater than the lesion seen if the patient had a CT scan, indicating there is additional tissue that is at risk for infarction. If therapy can be initiated to relieve ischemia, some brain tissue may be salvaged. If no intervention is made, over time this mismatch cannot be maintained. Damage to the tissue vessels can result in excessive blood flow, or the so-called luxury perfusion (lasting approximately 1–3 weeks after onset). By this time, though, the ischemia is progressing to infarct and metabolism declines.

Crossed cerebellar diaschisis is another finding that can be seen in both SPECT rCBF and PET ^{18}F -FDG imaging. When a lesion with decreased uptake is present in the cerebral cortex, either from tumor, infarct/ischemia, or trauma, a decrease is often also seen in the contralateral cerebellar cortex. This is especially true if the cerebral supratentorial lesion involves the motor cortex. As the cerebellar neurons of the corticopontocerebellar pathways are not “stimulated” because of loss of cerebral cortical function, blood flow is shunted away from this area, leading to decreased metabolism as well.

PET IMAGING OF THE BRAIN

Depending on the radiotracer, PET imaging can assess perfusion as well (e.g., ^{15}O - H_2O), but usually evaluates metabolism of a particular substrate. Glucose metabolism is the most commonly used, but in reality, the potential for PET imaging is limitless in terms of metabolic pathways (Table 95-1). ^{18}F -FDG PET, a glucose analog, is ideally suited to assessing regional brain metabolism, as the brain is an obligate glucose user. ^{18}F -FDG crosses the BBB by glucose transporters and is phosphorylated in neurons, which effectively traps it so that the activity cannot redistribute. Peak uptake in brain is approximately 35 minutes. Renal clearance is rapid, giving good target to background ratio. The normal pattern of uptake is similar to that of the $^{99\text{m}}\text{Tc}$ rCBF radiotracers: relative increased uptake in the caudate and lenticular nuclei, the thalami, and the cerebellum. White matter has much less uptake when compared to gray, and ventricles have near-absent to absent uptake. Resolution is better with PET imaging (on the order of 5 mm) than SPECT (order of 7 mm). It is important to remember that distribution can be altered by external conditions (as is true for SPECT brain imaging as well). For instance, bright lights in the room at time of injection can increase occipital lobe uptake. It is better to have intravenous access before the injection of the dose to decrease painful stimuli, which may increase uptake in

pain centers. When using a glucose analog like ^{18}F -FDG, it is best if the patient's glucose is less than 200 mg/dL; otherwise, competition from increased glucose pool may lead to less uptake of the radiotracer. Common indications for imaging with ^{18}F -FDG PET include dementia, seizure localization, and tumor imaging.

TUMOR IMAGING WITH ^{18}F -FDG PET

Most oncology patients are imaged from the skull base to midhigh, with the exception of head and neck cancers and melanoma. Part of the reasoning behind this is the variable uptake that ^{18}F -FDG can have with metastases. Because the brain is an obligate glucose user, background activity can obscure metastases. Metastases can appear hypermetabolic (usually an anaplastic or relatively dedifferentiated cancer), isointense, or hypometabolic (often the result of edema, although can represent glucose metabolism less than that of adjacent cortex). An application that has some utility is grading gliomas, as well as determination of recurrent gliomas versus radiation necrosis. High-grade gliomas typically have brisk ^{18}F -FDG uptake while radiation changes do not.

PATTERNS OF UPTAKE IN DEMENTIAS (TABLE 95-2)

One of the most common indications for SPECT or PET imaging of the brain is to evaluate dementia. Because of

TABLE 95-2 Dementia Pattern on SPECT and PET Imaging

PATTERN OF DECREASED UPTAKE	DEMENTIA
Frontal and temporal lobes	Frontotemporal dementia/Pick disease
Superior posterior parietotemporal lobes	Alzheimer disease
Frontal, parietal, and temporal lobes with motor strip and occipital sparing; parietotemporal decrease > frontal decrease	Advanced Alzheimer disease
Posterior parietotemporal and occipital lobes, slight relative sparing of mesial temporal lobe	Lewy body disease (Parkinson dementia has similar appearance)
Global rCBF decrease, frontal predominance; presence of scattered cortical defects and/or decrease in a vascular territory (such as ICA, MCA) aids in diagnosis	Vascular dementia
Heterogeneous appearance, with scattered cortical/subcortical decreased perfusion; focal increased perfusion possible	AIDS-dementia complex

the coupling of perfusion and metabolism, patterns of uptake in dementias are similar, whether the radiotracer is ^{18}F -FDG or one of the $^{99\text{m}}\text{Tc}$ rCBF radiotracers. Sensitivity and resolution of PET imaging is better than SPECT imaging; otherwise, the preference of whether to use PET or SPECT is based on availability and preference.

Symmetric decrease of uptake in the frontal and temporal lobes is seen in frontotemporal dementias: rare Pick disease, familial frontotemporal dementias, and primary progressive aphasia. Other conditions that can cause a symmetric frontal decrease include schizophrenia, depression, and progressive supranuclear palsy. The most commonly encountered dementia is Alzheimer dementia (also known as senile dementia, Alzheimer type). The classic appearance of Alzheimer dementia is symmetric decrease in uptake involving the cortex of the superior posterior temporal and parietal lobes. Variations on this appearance can occur. In early Alzheimer dementia, the decreased uptake can appear as asymmetric involvement of the posterior parietotemporal cortex. In advanced Alzheimer dementia, there is symmetric involvement of the frontal cortex as well, although the degree of decrease is still greater in the posterior parietal and temporal lobes. Typically there is sparing of the motor strip, occipital lobe, and basal ganglia, even in advanced Alzheimer dementia.

Lewy body dementia (LBD) has an appearance similar to Alzheimer dementia, with decreased uptake within the posterior parietal and temporal regions. In LBD, however, there is involvement of the occipital lobe as well. Some decrease can also be seen in the cerebellum. There may be relative sparing of the hippocampal regions in comparison to Alzheimer dementia. The pattern of uptake in Parkinson dementia is virtually the same as LBD.

Acquired immunodeficiency syndrome (AIDS)-dementia complex can have a heterogeneous pattern uptake, predominately with focal decreased uptake, although focal increased uptake can sometimes be seen. The defects are typically seen in frontal, temporal, and occipital lobes, as well as the basal ganglia.

Vascular dementia is typically a diagnosis of exclusion. There are various presentations, from a global de-

crease with a frontal predominance to scattered cortical defects (the result of thromboembolic disease) to a major vascular territory decrease. Combinations of these patterns can also be seen.

PATTERNS OF UPTAKE IN SEIZURE LOCALIZATION STUDIES (TABLE 95-3)

SPECT and PET imaging for localizing seizures play an important role in evaluating for and directing of surgical resection. At the very least, it can direct optimal placement of intracranial EEG leading to more discrete seizure localization prior to resection. The pattern of uptake is more dependent on the type of study performed rather than the radiotracer used. If radiotracer is injected while the patient was actively seizing, focal increase uptake would be seen at the seizure focus, using either a perfusion or metabolism agent. Because of complexity of timing of ictal seizure localization studies, these are usually performed at specialized centers. Antiseizure medications are typically discontinued, and the patient undergoes continuous video-monitored EEG. ^{18}F -FDG is usually not used because of shorter half-life and higher cost. $^{99\text{m}}\text{Tc}$ HMPAO or ECD is injected within seconds of seizure onset, although actual imaging can occur later. When the study is interpreted, it is important to know that the injection was performed at the correct time. Additional helpful information include clinical and EEG findings at the time of the seizure (lateralization and localization) and if it was "typical." A positive ictal study will appear as a focal area of increased uptake, most commonly the temporal lobes, since most seizures are the result of mesial temporal sclerosis. The ictal SPECT study is the most sensitive and specific of the nuclear medicine studies for seizure localization.

Since the majority of facilities do not perform ictal SPECT studies, most seizure localization is performed during the interictal state, with either ^{18}F -FDG or a $^{99\text{m}}\text{Tc}$ rCBF radiotracer. The findings for a positive study are the same regardless of the radiopharmaceutical: a focal area of relative decreased uptake. Of the two interictal studies, interictal PET with ^{18}F -FDG is more sensitive for the detection of the seizure focus,

TABLE 95-3 Summary of Seizure Localization Studies

STUDY	FINDINGS	COMMENT
Ictal SPECT with $^{99\text{m}}\text{Tc}$ rCBF agent	Focal increased uptake at seizure focus	Most sensitive study for seizure localization
Interictal PET with ^{18}F -FDG	Focal decreased uptake at seizure focus	Better sensitivity than interictal SPECT study
Interictal SPECT with $^{99\text{m}}\text{Tc}$ rCBF agent	Focal decreased uptake at seizure focus	

especially in cases of extratemporal epilepsy. Although unlikely, if a patient was injected with ^{18}F -FDG at or near the time of a seizure, it would appear the same as an ictal SPECT study.

PLANAR NUCLEAR MEDICINE CNS STUDIES

There are several nuclear medicine studies of the CNS that do not require SPECT or PET acquisitions. They include cerebral radionuclide angiography in cases of suspected brain death, radionuclide cisternography to assess for a suspected communicating hydrocephalus (such as normal-pressure hydrocephalus) or cerebral spinal fluid (CSF) leak, and diversionary shunt patency studies.

RADIONUCLIDE ANGIOGRAPHY

Although the diagnosis of brain death is primarily a clinical one, radionuclide angiography may aid in the diagnosis, especially when the EEG and clinical criteria are equivocal. Accuracy and speed in diagnosis is critical, especially when organ donation is being considered. Edema, softening, necrosis, and autolysis of brain tissue lead to increased intracranial pressure. As pressure rises, it prevents intracranial perfusion. Lack of blood flow to the brain on a radionuclide angiography study is diagnostic of brain death. Historically, this study was performed with $^{99\text{m}}\text{Tc}$ DTPA. It is cleared rapidly from blood, so repeat study can be performed if necessary. Interpretation can be difficult, however, as poor bolus technique and/or overlying scalp activity can confound the dynamic flow portion of the study. Scalp tourniquet was advocated to reduce interfering scalp activity, although use of a tourniquet is contraindicated in children, as it increases intracranial pressure, and has the potential for creating a false-positive study. With the newer $^{99\text{m}}\text{Tc}$ agents, use of a tourniquet has fallen out of favor. With $^{99\text{m}}\text{Tc}$ DTPA on delayed static images, the presence of the major venous sinus suggests of intracranial blood flow, but this is not reliable. Because of these difficulties, $^{99\text{m}}\text{Tc}$ HMPAO or $^{99\text{m}}\text{Tc}$ ECD are more commonly used. Positive blood flow can be determined on the initial flow images, as well as the delayed images, since both cross the BBB. Good bolus is important for an accurate flow study. A positive study will have no flow above the base of the skull. There may be increased focal increased uptake at the nose (“hot nose sign”), as flow is shunted to the external carotid artery because of increased intracranial pressure. Delayed static im-

ages will confirm no uptake within the cortex. It is prudent to image injection site and the liver for confirmation purposes. This ensures that decreased flow is not due to a dose infiltration or to a hypotensive state (i.e., liver uptake proves systemic perfusion is adequate), respectively.

CISTERNOGRAPHY (TABLE 95-4)

For evaluation of CSF dynamics, approximately 500 μCi of sterile and pyrogen-free ^{111}In DTPA is injected into the subarachnoid space via lumbar puncture. Imaging of the injection site is recommended to check for “loculation” and ensure ascent of the radiotracer through the spinal canal. Anterior and lateral planar images of the head are obtained at 6, 24, 48, and 72 hours as needed. Activity usually reaches the basal cisterns at 1 to 4 hours in normal adults, shortly followed by the frontal poles and sylvian fissure and interhemispheric cisterns. At this point, the anterior images have a trident-like appearance. At 24 hours, there should be complete ascent over the cerebral convexities and the parasagittal region, with relative clearance from the basal cisterns. The presence of early and persistent radiotracer activity in the lateral ventricles is abnormal (communicating hydrocephalus) giving a heart-shaped appearance, although some investigators say transient entry at 4 hours that clears by 24 hours is a normal variant. Additional findings suggesting communicating hydrocephalus include a delay of more than 24 hours in the ascent of activity over the convexities, and delayed clearance of activity. Patients with significant cortical atrophy may have a delay in this ascent, although they will not have ventricular activity. In patients with a

TABLE 95-4 Scintigraphic Appearance of CSF Dynamics

SCINTIGRAPHIC APPEARANCE	POSSIBLE CAUSES
“Trident sign” at 1–6 h, radiotracer activity over the convexities at 24 h, good clearance of activity at 24 h	Normal dynamics Noncommunicating hydrocephalus
Delayed transit over the convexities, but no ventricular activity seen	Cerebral atrophy Evolving/early communicating hydrocephalus
Delayed transit over the convexities, presence of ventricular activity (“heart-shaped” appearance), poor clearance/persistent activity at more than 24 h	Communicating (normal-pressure) hydrocephalus

noncommunicating hydrocephalus, the pattern of uptake is typically normal.

Cisternography may also be used to localize intermittent rhinorrhea or otorrhea. When imaging a patient with a suspected CSF leak, one may use ^{99m}Tc DTPA instead of ^{111}In DTPA. Since the duration of imaging is likely to be less than in the investigation of suspected hydrocephalies, the shorter half-life of ^{99m}Tc DTPA should not be an issue. The better imaging characteristics of ^{99m}Tc DTPA may also aid in the detection of subtle leaks. The study is performed like cisternography examination, but imaging of the presumed site of leak is performed at 1 and 3 hours. Some advocate placing the patient in Trendelenburg position to aid the flow of activity to the basal cisterns. If a particular position is thought to promote leak, the patient should be placed accordingly. The use of pledgets in the nares or ears can significantly increase identification and localization (anterior vs. posterior rhinorrhea) of leaks. A blood sample, with plasma centrifuged out, can be placed in the well counter along with the pledgets. This will help determine if the pledget activity represents absorbed activity from the plasma versus a true leak. A true positive study will have a high ratio of activity when comparing pledget to plasma.

DIVERSIONARY SHUNT PATENCY

As these studies are also typically of short duration, one can use ^{99m}Tc DTPA (~ 1 mCi) as in the CSF leak studies. Injection is typically done by the neurologist or neurosurgeon with aseptic technique. Patient is imaged in the supine position, although upright positioning may be necessary if flow appears obstructed. Dynamic images are obtained of the injection site and reservoir, and activity is followed as it descends to its destination, which is frequently the peritoneum or right atrium, but could also be the pleural space. If it is a patent ventriculoatrial shunt, in addition to following the activity to the heart, one will see kidney and bladder activity, as ^{99m}Tc DTPA is a renal imaging agent. Patent ventriculoperitoneal and ventriculopleural shunts will demonstrate activity coating the peritoneum and pleura, respectively. If the shunt is not patent, activity will remain in the ventricles or may abruptly terminate at the obstruction. As it is difficult to gauge where the activity terminates within the patient, it is often helpful to place radioactive markers on anatomical landmarks (suprasternal notch, xyphoid process, etc) or place a sheet source behind the patient to outline the body habitus. Delayed static images for up to 24 hours may be beneficial.

APPROACH TO UNKNOWN BRAIN CASES (FIG. 95-1)

Distinguishing different radiotracers can be difficult, but there are a few defining concepts. Overall, ^{18}F -FDG images have relatively better resolution. Perfusion and metabolism patterns are often the same. ^{18}F -FDG assesses glucose metabolism in the brain and ^{99m}Tc HMPAO assesses rCBF; these processes are coupled such that the appearances of many disorders are similar. There are few conditions that demonstrate focal increased uptake; a focal unilateral hot spot in a temporal lobe usually indicates an ictal SPECT scan. Differential considerations for focal increased uptake outside the temporal lobe include an extratemporal seizure focus (if an ictal SPECT study), a hypermetabolic metastasis (if a FDG PET study), a recurrence of glioma (if a FDG PET study, or in a ^{201}Tl chloride study as well. In the latter case, image quality would be poor), and AIDS-dementia complex (SPECT uptake would be heterogeneous, with predominately focal areas of hyperperfusion, occasional focal hyperperfusion). If there are no focal areas of increased uptake, then look for areas of focal or regional decreased uptake. Focal unilateral decrease in the temporal lobe suggests a seizure focus on interictal SPECT or PET. A solitary focus of unilateral decreased uptake outside temporal lobe can represent an extratemporal seizure focus on an interictal SPECT or PET study, ischemia/infarct, or malignancy (remember, it has to be very FDG avid to be noticeably hot on PET). Focal scattered cortical defects suggest a thromboembolic phenomenon, such as multiinfarct dementia. If the decreases appear more “regional,” assess if they are symmetric or asymmetric. Symmetric frontal and temporal decrease is consistent with frontotemporal lobe dementia or Pick disease. If the decrease involves the bilateral posterior parietal and temporal lobes, then consider Alzheimer dementia (realizing, of course, that early Alzheimer dementia can have some asymmetry in uptake). If there is bilateral frontal, parietal, and temporal lobe decrease with motor strip and occipital lobe sparing, this suggests advanced Alzheimer dementia. If, however, there is bilateral posterior parietal/temporal with occipital involvement, consider Lewy body disease or Parkinson dementia. When the “regional” decrease is asymmetric and confined to a vascular territory, consider a vascular ischemia (or dementia in the proper clinical setting), or a balloon occlusion study. Finally, the appearance of vascular dementia can vary, and is typically a diagnosis of exclusion. One can see a global rCBF decrease with a frontal predominance. Often there are scattered focal areas of hypoperfusion or an ICA/MCA regional defect to aid in the diagnosis.

QUESTIONS AND ANSWERS

1. A patient undergoes SPECT imaging of the brain with ^{99m}Tc HMPAO. The images demonstrate symmetric relative decreased uptake in the frontal, temporal, and parietal lobes. You note that there is sparing of activity within the motor strip and occipital lobe. Which of the following is the most likely diagnosis?
 - A. Pick disease
 - B. Alzheimer dementia
 - C. Lewy body disease
 - D. Vascular dementia
 - E. Seizure localization

ANSWER: B. This constellation of findings is typical for advanced Alzheimer dementia (Table 95-2).

2. A patient undergoes SPECT imaging of their brain with ^{99m}Tc HMPAO. The images demonstrate global decreased cortical uptake, with bilateral scattered focal cortical and subcortical defects. Which of the following is the most likely diagnosis?
 - A. Pick disease
 - B. Alzheimer dementia
 - C. Lewy body disease
 - D. Vascular dementia
 - E. Seizure localization

ANSWER: D. Scattered cortical defects in the setting of global decreased rCBF is most consistent with vascular dementia (Table 95-2).

3. A patient undergoes PET imaging of the brain with ^{18}F -FDG. The images demonstrate symmetric frontotemporal lobe decreased activity. Which of the following is the most likely diagnosis?
 - A. Pick disease
 - B. Alzheimer dementia
 - C. Lewy body disease

- D. Vascular dementia
- E. Seizure localization

ANSWER: A. Symmetric frontotemporal lobe decrease is typical of a frontal lobe dementia such as Pick disease Table 95-2.

4. A patient undergoes SPECT imaging of the brain with ^{99m}Tc HMPAO. The images demonstrate focal increased uptake within the left mesial temporal lobe. Which of the following is the most likely diagnosis?
 - A. Pick disease
 - B. Alzheimer dementia
 - C. Lewy body disease
 - D. Vascular dementia
 - E. Seizure localization

ANSWER: E. A seizure focus appears as a focal area of increased uptake on an ictal SPECT study. Very few other conditions have focal increased uptake on ^{99m}Tc HMPAO imaging.

5. A patient undergoes PET imaging of the brain with ^{18}F -FDG. The images demonstrate relative decreased uptake in the posterior parietotemporal and occipital lobes. Which of the following is the most likely diagnosis?
 - A. Pick disease
 - B. Alzheimer dementia
 - C. Lewy body disease
 - D. Vascular dementia
 - E. Seizure localization

ANSWER: C. LBD and Parkinson dementia usually have occipital lobe involvement. Advanced Alzheimer dementia usually spares the occipital lobe.

6. Regarding the appearance of CSF flow dynamics in radionuclide cisternography, which of the following patterns is *normal*?
 - A. Persistent intensity of activity at 24 hours
 - B. Flow of radiotracer over the convexities at 24 hours
 - C. "Trident-shaped" pattern of uptake at 24 hours
 - D. "Heart-shaped" pattern of uptake at 24 hours

ANSWER: B. Lack of clearance or no change in activity over time suggests that there is an abnormality in the reabsorption of CSF. By 24 hours, there should be migration of activity over the convexities. "Trident" pattern (delay in ascent, no ventricular activity) can be seen in cerebral atrophy. Persistent activity in the ventricles is not normal, and is seen in normal-pressure hydrocephalus.

7. Concerning radionuclide cerebral angiography for determining brain death, in which of the following

situations is the use of a scalp tourniquet *most* indicated?

- Radionuclide cerebral angiography performed with ^{99m}Tc DTPA in a child
- Radionuclide cerebral angiography performed with ^{99m}Tc HMPAO in a child
- Radionuclide cerebral angiography performed with ^{99m}Tc DTPA in an adult
- Radionuclide cerebral angiography performed with ^{99m}Tc HMPAO in an adult

ANSWER: C. Use of a tourniquet is contraindicated in a child, as there is fear that the tourniquet may raise intracranial pressure, leading to a false-positive study. A flow phase is not as critical when using ^{99m}Tc HMPAO, since it crosses the BBB. If intracranial flow is present, one need only look at the delayed images for confirmation. A tourniquet is not an absolute requirement when using a blood pool agent such as ^{99m}Tc DTPA, but as there is no crossing of the BBB, the flow images are more critical.

- Which of the following choices listed below correctly lists the sensitivity and specificity of radionuclide studies for the detection of a seizure focus in descending order?
 - Ictal SPECT with ^{99m}Tc HMPAO, interictal PET with ^{18}F -FDG, interictal SPECT with ^{99m}Tc HMPAO
 - Interictal PET with ^{18}F -FDG, interictal SPECT with ^{99m}Tc HMPAO, ictal SPECT with ^{99m}Tc HMPAO
 - Interictal SPECT with ^{99m}Tc HMPAO, ictal SPECT with ^{99m}Tc HMPAO, interictal PET with ^{18}F -FDG

ANSWER: A. Ictal SPECT is the most sensitive and specific for seizure localization. If a facility cannot do ictal SPECT, ^{18}F -FDG interictal PET is the best study available, followed by interictal SPECT.

- Which of the following situations is the *most* helpful in detecting a CSF leak in radionuclide cisternography?
 - Use of ^{111}In DTPA instead of ^{99m}Tc DTPA as the radiotracer
 - Use of pledgets
 - Imaging the patient in the supine position
 - Imaging the patient in Trendelenburg position

ANSWER: B. The use of pledgets may detect an occult leak as well as better localize the leak (i.e., anterior vs. posterior nose). There is no advantage in the use of ^{111}In DTPA instead of ^{99m}Tc DTPA in the setting of cisternography for CSF leak. The half-

life of ^{99m}Tc DTPA is usually sufficient for detection of the leak, which is typically demonstrated in less than 4 hours. Many centers will place patients in Trendelenburg position after the intrathecal injection to promote movement to the basal cisterns, but once that occurs, the patient is positioned in such a way as to promote CSF leakage.

- Which of the following statements is *true* regarding diversionary shunt patency studies?
 - Patient should be imaged in Trendelenburg position.
 - Imaging for up to 48 hours is recommended.
 - ^{111}In DTPA is the imaging agent of choice.
 - ^{99m}Tc DTPA is the imaging agent of choice.

ANSWER: D. Imaging is performed in the supine position, and if need be, in the upright position. Imaging in Trendelenburg position may actually impede flow. As the study is typically performed with ^{99m}Tc DTPA, imaging at 48 hours is not possible. One *could* use ^{111}In DTPA for the study, but the cost and imaging characteristics of ^{99m}Tc DTPA are better.

Sibyll Goetze

MYOCARDIAL PERFUSION IMAGING

OVERVIEW

Myocardial perfusion can be evaluated with SPECT (most commonly performed) or PET perfusion tracers. Common indications include evaluation of chest pain, (re)evaluation of known coronary artery disease, heart failure, and preoperative testing. To differentiate between normal, ischemic, and scarred myocardium (Table 96-1), patients undergo stress testing, which can be achieved using physical exercise or pharmacologic intervention and will be described in this chapter.

TABLE 96-1 Pattern in Myocardial Perfusion Imaging

	STRESS	REST
Normal	Normal	Normal
Ischemia	Abnormal (↓)	Normal
Infarct	Abnormal (↓)	Abnormal (↓)

SPECT MYOCARDIAL PERFUSION IMAGING

RADIOPHARMACEUTICALS

Thallium-201

Thallium-201 (Tl-201) decays by electron capture with a physical half-life of 73 hours (the principal photon energy is 69–83 keV [from mercury x-ray]). The usual dose is 2 to 4 mCi. Being a potassium analog, Tl-201 is taken up by myocardial cells via active transport (Na^+/K^+ -ATPase). After injection, Tl-201 concentration in the myocardium reflects myocardial blood flow. The extraction fraction of Tl-201 is relatively high (approximately 85% at first pass during resting flow conditions) and proportional to myocardial blood flow over a wide range of flow rates. Over time, Tl-201 undergoes washout, with relatively rapid washout from normal myocardium and slower washout from abnormal (ischemic) myocardium. This phenomenon is called “redistribution,” and may lead to normalization of myocardial perfusion defects over time (therefore, imaging needs to be performed no later than 5–10 minutes after injection of the radiotracer for stress imaging). Thallium is cleared though the kidneys (which is also the target organ).

Tc-99m LABELED AGENTS

Tc-99m-labeled agents include Tc-99m-sestamibi, Tc-99m tetrofosmin (which have similar properties), and Tc-99m-teboroxime. The use of the latter agent (Tc-99m teboroxime) in clinical practice is very limited because of rapid washout from the myocardium.

Tc-99m Methoxyisobutylisonitrile (Sestamibi)

Tc-99m sestamibi (an isonitrile) is a lipophilic cation, which enters the myocardial cells via passive diffusion. Within the cell, it localizes to mitochondria. The extraction fraction of sestamibi (40%–50% at first pass) is lower than that of thallium or teboroxime. Sestamibi practically does not redistribute. Imaging is usually delayed for at least 15 minutes (after exercise) to 30 to 90 minutes (at rest and after pharmacologic stress) to allow for liver washout and better target-to-background ratio. Clearance of sestamibi is via the hepatobiliary system. The target organ is the colon.

Tc-99m Tetrofosmin

Tc-99m tetrofosmin (diphosphine agent) has very similar characteristics compared to sestamibi, except for slightly higher heart/liver ratios allowing for relatively earlier imaging.

Tc-99m-Teboroxime

Tc-99m-teboroxime has the highest extraction fraction of all SPECT imaging agents (more than or equal to 90% at resting flow rates), but is not widely used in current practice.

IMAGING PROTOCOLS

There are various imaging protocols, including 1- or 2-day; stress-only, rest-stress, or stress-rest; single- (i.e., Tc-99m-labeled agent at both stress and rest) or dual-isotope (Tl-201 at rest and Tc-99m-labeled agent at stress) protocols, which can be used depending on patient characteristics, imaging laboratory preference, and logistics. For same-day single-isotope protocols, a low dose (8–10 mCi of sestamibi) is used initially followed by a three times higher dose (24–30 mCi of sestamibi) for the second portion of the study. For 2-day protocols, full doses (24–30 mCi of sestamibi) can be administered each day.

STRESS TESTING

Exercise Stress

Physical exercise increases cardiac workload and thus myocardial oxygen demand. This may reveal areas of significant coronary artery stenosis, because these areas are not able to vasodilate to meet the increased oxygen demand. There are several methods for exercise stress testing, with a variety of treadmill exercise protocols (the Bruce protocol is commonly used) as well as supine and upright bicycle exercise. It is important to be aware of contraindications to and endpoints for exercise testing (Tables 96-2 and 96-3). Vasodilator stress testing can

TABLE 96-2 Contraindications to Exercise Testing

ABSOLUTE	RELATIVE
Acute myocardial infarction (within 2 d)	Left main coronary stenosis
High-risk unstable angina	Moderate stenotic valvular heart disease
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise	Electrolyte abnormalities
Symptomatic severe aortic stenosis	Severe arterial hypertension (SBP >200 mm Hg and/or DBP >110 mm Hg)
Uncontrolled symptomatic heart failure	Tachyarrhythmias or bradyarrhythmias
Acute pulmonary embolus or pulmonary infarction	Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
Acute myocarditis or pericarditis	Mental or physical impairment leading to inability to exercise adequately
Acute aortic dissection	High-degree atrioventricular block

TABLE 96-3 Indications for Terminating Exercise Testing

ABSOLUTE INDICATIONS	RELATIVE INDICATIONS
Drop in systolic blood pressure of >10 mmHg from baseline blood pressure despite an increase in workload, when accompanied by other evidence of ischemia	Drop in systolic blood pressure of (≥ 10 mmHg from baseline blood pressure despite an increase in workload, in the absence of other evidence of ischemia
Moderate to severe angina	ST or QRS changes such as excessive ST depression (>2 mm of horizontal or downsloping ST-segment depression) or marked axis shift
Increasing nervous system symptoms (e.g., ataxia, dizziness, or near-syncope)	Arrhythmias other than sustained ventricular tachycardia, including multifocal PVCs, triplets of PVCs, supraventricular tachycardia, heart block, or bradyarrhythmias
Signs of poor perfusion (cyanosis or pallor)	Fatigue, shortness of breath, wheezing, leg cramps, or claudication
Technical difficulties in monitoring ECG or systolic blood pressure	Development of bundle-branch block or IVCD that cannot be distinguished from ventricular tachycardia
Subject's desire to stop	Increasing chest pain
Sustained ventricular tachycardia	Hypertensive response (SPB >250 mm Hg and/or DBP >115 mm Hg)
ST elevation (≥ 1.0 mm) in leads without diagnostic Q waves (other than V_1 or a VR)

ACC/AHA 2002 guideline update for exercise testing: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Exercise Testing). 2002. Available at: http://www.acc.org/qualityandscience/clinical/guidelines/exercise/exercise_clean.pdf

be considered if exercise is contraindicated. Adequate exercise is defined as reaching more than or equal to 85% of the maximal age predicted heart rate ($220 - \text{age}$) and/or a “double product” ($\text{HR} \times \text{SBP}$) of at least 25 000. Exercise can be continued further once a patient has reached at least 85% of age-predicted maximal heart rate if they remain asymptomatic and no other indications for terminating the test exist.

Although left bundle branch block (LBBB) is not a contraindication to exercise testing per se, it should be avoided in patients undergoing SPECT imaging. Perfusion defects can occur in approximately 50% of patients with LBBB if the heart rate increases (as it does with exercise). These patients should undergo vasodilator stress.

PHARMACOLOGIC STRESS TESTING

Vasodilator

Dipyridamole and adenosine are both vasodilators used for stress myocardial perfusion imaging if a patient is unable to undergo exercise testing.

Adenosine

Adenosine is an (nonselective) A_2 receptor agonist. It is given via continuous infusion ($140 \mu\text{g/kg/min}$) over 5 or 6 minutes (radiotracer is injected at 3 minutes). Through activation of the A_2 A receptor, it causes coronary vasodilation, increasing myocardial blood flow by three- to fourfold. Stenotic coronary arteries are less able to vasodilate, which results in less radiotracer uptake in regions of the myocardium supplied by the stenotic artery. Contraindications and indications for terminating the test early are presented in Table 96-4. Possible side effects are AV block, peripheral vasodilation (hypotension,

headache), and bronchospasm. Chest pain is common (25%–30%) and not necessarily related to CAD. Because of the very short half-life of adenosine (less than 10 seconds), most side effects resolve after discontinuation of the infusion, and aminophylline is rarely required.

Dipyridamole

Dipyridamole (Persantine) increases the levels of adenosine by preventing reuptake and deamination of adenosine. It is administered as an IV infusion (0.56

TABLE 96-4 Contraindications and Indications for Early Termination of Vasodilator Pharmacologic Stress Testing

CONTRAINDICATIONS	EARLY TERMINATION CRITERIA
Asthma (with ongoing wheezing)	Severe hypotension (SBP <80 mmHg)
Unstable acute MI/unstable angina less than 1 d	Development of symptomatic, persistent second-degree or complete heart block
AV block greater than first degree or sick sinus syndrome without PM	Wheezing
Recent (less than 24 h) of caffeine-containing products, dipyridamole-containing medications, theophylline, aminophylline	Severe chest pain associated with CT depression of ≥ 2 mm
SBP less than 90 mmHg	Signs of poor perfusion (cyanosis or pallor)
Profound sinus bradycardia (<40 bpm)	Technical difficulties in monitoring ECG or SBP
Hypersensitivity to adenosine	Patient's request to stop

Modified with permission from Henzlova MJ, Cerqueira MD, Taillefer R, et al. ASNC Imaging Guidelines for nuclear cardiology procedures. *J Nucl Cardiol*. In press. Copyright © Elsevier.

mg/kg over 4 minutes), and the radiotracer is injected 4 minutes after the infusion is stopped. Side effects and contraindications are similar to adenosine. Aminophylline (50–250 mg IV) is more frequently administered for reversal of side effects given the longer half-life of dipyridamole.

Regadenoson

Regadenoson is an A_{2A} adenosine receptor agonist. The recommended dose is 5 mL (0.4 mg regadenoson). It is given in a rapid (bolus) IV injection followed by saline flush. The radionuclide is administered 10 to 20 seconds after the saline flush. Side effects and contraindications are similar to adenosine. Aminophylline may be administered for reversal of side effects.

Dobutamine

Dobutamine stimulates beta-1 and beta-2 receptors resulting in an increase in heart rate, blood pressure, and myocardial contractility. It is infused at an initial rate of 5 to 10 $\mu\text{g/kg/min}$ IV and increased in 10 $\mu\text{g/kg/min}$ increments every 3 minutes to a maximum of 40 $\mu\text{g/kg/min}$. Its half-life is approximately 2 minutes. Similar to exercise testing, achieving more than or equal to 85% of the maximal age-predicted heart rate is a marker for adequate stress. If this is not achieved with maximum dose of dobutamine, atropine (0.5–2 mg IV) can be given in the absence of contraindications (prostatic hypertrophy, glaucoma). Side effects of dobutamine are palpitations, chest pain, headache, and dyspnea. Significant supraventricular or ventricular arrhythmias occur in 10% of patients, ischemic ST-segment depression is noted in roughly one-third of patients. Administration of a short-acting beta-blocker IV (e.g., Esmolol) may be necessary for severe side effects (Table 96-5).

COMBINATION OF VASODILATOR AND LOW-LEVEL EXERCISE STRESS

The combination of vasodilator and low-level exercise stress (treadmill or handgrip) can be safely performed. Advantages are significant reduction in side effects of the vasodilator (i.e., hypotension) as well as improved image quality (i.e., less liver uptake of the radiotracer).

IMAGE ACQUISITION

PLANAR IMAGING

With the advantages of SPECT imaging, planar imaging is infrequently performed, usually if SPECT imaging cannot be obtained (because of patient's body weight, claustrophobia).

TABLE 96-5 Contraindications and Indications for Early Termination of Dobutamine Pharmacologic Stress Testing

CONTRAINDICATIONS	EARLY TERMINATION CRITERIA
Recent (less than 1 wk) myocardial infarction	Similar to those for exercise testing
Unstable angina	
Hemodynamically significant left ventricular outflow tract obstruction	
Severe aortic stenosis	
Atrial tachyarrhythmias with uncontrolled ventricular response	
Prior history of ventricular tachycardia	
Uncontrolled hypertension (SBP >200 mm Hg and/or DBP >110 mm Hg)	
Aortic dissection or large aortic aneurysm	
Beta-blocker (heart rate and inotropic response to dobutamine will be attenuated)	

Modified with permission from Henzlova MJ, Cerqueira MD, Taillefer R, et al. ASNC imaging guidelines for nuclear cardiology procedures. *J Nucl Cardiol* 2009. Copyright © Elsevier.

Planar images usually including the left anterior oblique, anterior, and left lateral views can be acquired ungated and gated.

SPECT Imaging

Myocardial SPECT imaging is usually performed from an RAO to LPO angle covering 180 degrees (i.e., with a dual-headed camera, each camera head covers 90 degrees). Images are further processed, and the myocardium is reconstructed in the short axis (apex to base), vertical long axis (septum to lateral wall), and horizontal long axis (inferior to anterior wall). SPECT imaging has a superior spatial resolution compared to planar imaging and is more sensitive for detecting and localizing perfusion defects.

Gated Imaging

With gated SPECT acquisition, data collection is triggered by the QRS complex of the patient's ECG (i.e., R wave). The cardiac cycle is divided into a certain number (usually 8 or 16) of frames (of equal duration), each frame representing a specific phase of the cardiac cycle. Over time, data from several hundreds of cardiac cycles are obtained, and corresponding frames (1, 2... n) from all cardiac cycles are stored sequentially in their specific frame "bin" (1, 2... n). After the acquisition is completed, each frame bin contains the summed data of the specific phase of the cardiac cycle. These summed frames (which contain the data of the entire study all added into one cardiac cycle) can then be displayed in a cinematic fashion. Consequently, left ventricular wall

thickening and wall motion can be assessed, and LVEF (LV volumes at end diastole and end systole) can be calculated. Left ventricular function adds important information to perfusion imaging, and helps differentiating perfusion defects from artifacts. LVEF obtained by myocardial perfusion SPECT (MPS) is very reproducible and reasonably accurate. Especially in patients with relatively small ventricles, volumes (especially in end systole) maybe underestimated. The minimum number of frames for reliable LVEF assessment is 8. More frames (16, 24, or more) would improve temporal resolution, but the trade-off would be less favorable count statistics and/or a lengthier acquisition. A regular heartbeat is a prerequisite for gated imaging. Significant arrhythmias (atrial fibrillation, frequent ectopic beats) can lead to significant problems obtaining diagnostic quality images. Other difficulties may be artifact from skeletal muscle, pacemaker, or prominent T waves.

IMAGING RESULTS

NORMAL

With normal myocardial perfusion there is homogenous radiotracer uptake in the entire LV myocardium. The lateral wall may appear slightly brighter than the septum. Especially the basal septal wall has relatively decreased uptake (reflecting the membranous portion near the valve plane). The apex may have a small area of de-

creased uptake (so-called apical thinning). In addition, the areas of right ventricular (RV) insertion (7-o'clock and 11-o'clock positions on the short axis view) may also demonstrate slightly less uptake.

ABNORMAL

Stress myocardial perfusion imaging can differentiate between normal myocardium (normal perfusion at stress and rest), myocardial ischemia (so-called reversible defect: abnormal perfusion at stress which normalizes at rest) and myocardial scar (fixed defect: abnormal perfusion at stress that remains abnormal under resting conditions). Some stress perfusion defects are noted to be partially reversible at rest, meaning they show some but not complete normalization. Those defects may be a combination of scar and ischemia, or very severe ischemia, or a combination of ischemia and artifact. Besides evaluating for reversibility, characterization of a perfusion defect should include its location and extent (size and/or severity).

The location of a perfusion defect can be described according to vascular territory, myocardial wall, or segments involved (Table 96-6). The LAD typically contributes blood flow to the anterior, anteroseptal wall, and apex; the RCA supplies the inferior and inferoseptal wall; and the LCX the lateral wall. There is variability in blood supply of the posterior (inferolateral) wall depending on dominance (RCA vs. LCX), the apex (LAD vs. RCA), and anterolateral wall (LAD, LCX, or

ramus intermedius). Evaluation of the extent/severity of a perfusion defect can be done based on visual assessment. In addition, there are several (semi)quantitative parameters (available from most software programs). The percentage of LV myocardium underperfused can be computed. The so-called summed stress score (SSS) applies scoring of the radiotracer uptake (Table 96-7). The lowest SSS is 0 (normal myocardium) and the most abnormal score is 68 (no radiotracer uptake in any segment). Using the SSS, a perfusion defect can be characterized as small (4–8), moderate (9–13), or large (greater than 13). Other parameters that have been used to describe the extent of myocardial perfusion abnormalities are the number of vascular territories involved (small: 0–1, moderate: 1–2, large: 2–3) as well as the percent of the left ventricular myocardium involved (small: less than 10%, moderate: 10%–20%, large: greater than 20%).

LOW-RISK PARAMETERS

Overall, patients with normal or near-normal myocardial perfusion images have a very low (less than 1%) annual cardiac event rate.

HIGH-RISK PARAMETERS

Several parameters observed during MPS are associated with a higher risk of cardiac events (greater than 5% per year). These include large stress-induced myocardial perfusion defects, perfusion defects in more than one vascular territory, substantial degree of reversibility of stress-induced perfusion defect, abnormal postexercise LVEF, transient left ventricular dilatation, abnormal rest LVEF (less than 40%), and increased lung uptake of thallium (lung/heart count ratio greater than 0.5). Thallium uptake in lungs is thought to reflect elevated LVED left ventricular dysfunction (importantly, lung uptake on a sestamibi scan does not have the same association). Other possible causes of thallium (or sestamibi) lung uptake could be inflammatory, infectious, or malignant conditions.

ACCURACY

Depending on the exact imaging technique/protocol, patient population, and gold standard used, reported sensitivities, specificities, and normalcy rates of MPS are 80% to 85%, 65% to 81%, and 80% to 93% respectively.

ARTIFACTS

Several artifacts can be observed in MPS. They can affect image quality and therefore diagnostic performance. The most frequent artifacts will be discussed as follows.

Attenuation

Attenuation describes the loss of photon signals when photons pass through tissue (lungs, soft tissue, bone) from the organ of interest (myocardium) to the detector. This can result in loss of count density (intensity) in the picture. Attenuation can be uniform or focal, depending on the patient's body habitus. Diaphragmatic attenuation may lead to inferior wall defects, whereas breast attenuation can affect the anterior (or apical, or lateral) wall. Attenuation artifacts are commonly present on both rest and stress images (fixed defects). To differentiate them from other forms of fixed defects (scar), one can either employ attenuation correction if available or review the gated images: a scar demonstrates abnormal wall motion, whereas attenuation artifacts will show normal motion and thickening. Imaging the patient in a different position (i.e., prone imaging) may also be helpful.

Motion

Patient motion (from respiratory variations, coughing, or inability to hold still) can be recognized by reviewing the raw projection images for unexpected steps or bouncing. Typical artifacts on the reconstructed tomographic slices are opposed defects on the contralateral walls (180 degrees apart), indistinct myocardial borders, or distortion of the heart shape with tails of radiotracer activity emanating from edges of a defect (this is sometimes called “hurricane sign”). If preventive measures (comfortable patient positioning, good immobilization, clear instructions, and sufficient delay of imaging after exercise) fail, one can apply motion correction or, if unsuccessful, repeat imaging.

Noncardiac Radiotracer Uptake

Noncardiac radiotracer uptake (namely, intense radiotracer uptake in the liver or GI tract adjacent to the myocardium) can lead to interfering hot spots. These hot spots can lead to hot spots in the adjacent myocardium itself by scattering radiotracer activity. Noncardiac radiotracer activity can also lead to cold spots in the myocardium when a ramp filter is used for reconstruction (a ramp filter applies negative values adjacent to [count dense] projection profiles to eliminate the star artifact). Therefore, intense noncardiac radiotracer uptake may lead to artificial perfusion defects or may mask actual perfusion defects or decrease reader confidence. Several measures to reduce or eliminate these artifacts are to delay imaging for better biliary and GI clearance, have the patient drink fluids, consider low-level exercise with pharmacologic stress testing, reimaging (possibly prone), or reprocessing.

PET MYOCARDIAL PERFUSION IMAGING

RADIOPHARMACEUTICAL

Several PET radiotracers are used for myocardial perfusion imaging, including rubidium-82 chloride (Rb82), ^{13}N ammonia, and O-15 water. Rubidium-82 is produced from an $^{82}\text{Sr}/^{82}\text{Rb}$ generator. It has a half-life of only 76 seconds. The usual dose is in the range of 30 to 60 mCi. Rb82 is a monovalent cation (potassium analog) that is taken up by the myocardial cells, similar to thallium, via active transport (Na^+/K^+ ATPase). An on-site cyclotron is needed for the production of ^{13}N ammonia (half-life 10 minutes) that is given at doses of 10 to 30 mCi. Another cyclotron-produced agent is O-15 water (half-life 2 minutes), which is only used in research settings.

TECHNIQUE

Similar to SPECT imaging, there are various imaging protocols for myocardial perfusion with PET (rest/stress, stress/rest, etc). Cardiac PET perfusion studies can also be performed gated to assess for LV function and wall motion. Nevertheless, there are some general differences to SPECT imaging, mostly related to the short half-life of the currently available PET tracers and logistics involved. For example, pharmacologic stress is performed since exercise stress testing is typically not feasible; PET imaging can be performed with similar doses for the rest and stress studies (especially for Rb82); imaging can be completed in a shorter period of time overall; and a true peak stress LVEF can be calculated. Another advantage of PET is that attenuation correction is applied.

INTERPRETATION

Like in SPECT imaging, PET perfusion studies are reviewed for the presence, reversibility, location, extent, and severity of perfusion defects.

ACCURACY

Sensitivity of PET myocardial perfusion imaging is 90% (range, 83%–100%) with a specificity of 89%

(range, 73%–100%). With PET, a true peak stress LVEF can be obtained (therefore, changes in LV function from rest to peak stress can be evaluated). Quantification of myocardial perfusion (in milliliter per minute per gram of tissue) and coronary flow reserve is feasible with PET, which may be particularly useful in patients with fairly balanced three-vessel disease or in the research arena.

MYOCARDIAL VIABILITY

CLINICAL BACKGROUND

In patients with coronary artery disease, left ventricular function/wall motion may be abnormal (ischemic cardiomyopathy). There can be various reasons for myocardium to be dysfunctional (Table 96-8). Hibernating myocardium is severely ischemic dysfunctional myocardium that is viable (meaning the abnormal contractility can be improved or even reversed when blood flow is restored). A myocardial scar on the other hand (which also demonstrates abnormal wall motion and perfusion) is nonviable (wall motion does not improve if blood flow is restored). If blood flow is not restored to an area of hibernating myocardium, it will eventually become a scar. Both hibernating and scarred myocardium (which have abnormal perfusion) should be distinguished from so-called stunned myocardium (which has normal perfusion). Stunned myocardium is myocardium with persistent wall motion abnormality following a period of ischemia despite restoration of perfusion. It is important to identify patients with hibernating (viable) myocardium. Patients with ischemic cardiomyopathy and viable myocardium have a better prognosis with revascularization (compared to medical therapy only). In most of these patients, revascularization improves wall motion (increased LVEF), and may also lead to increased survival, reduced cardiovascular events, arrhythmias, as well as relief of symptoms. Several imaging techniques are available to assess myocardial viability, including several nuclear medicine imaging procedures, echocardiography, and MRI.

TABLE 96-8 Myocardial Viability Pattern

	WALL MOTION	PERFUSION	FDG
Normal	Normal	Normal	Present*
Stunned	Abnormal	Normal	Present*
Hibernating	Abnormal	Abnormal	Present
Scar	Abnormal	Abnormal	Absent

*FDG uptake in normal or stunned myocardium may be variable. Both entities are not ischemic (perfusion is normal/preserved); therefore, FDG uptake does not add any information.

NUCLEAR IMAGING TECHNIQUES

THALLIUM

The underlying principle of viability imaging using thallium is the preservation of cell integrity needed for thallium uptake via active transport in viable myocardial cells. Although initial thallium uptake after injection is proportional to blood flow (normal myocardium has normal uptake, scar or hibernating myocardium has no/decreased uptake), thallium redistributes over time, meaning that myocardial Tl-201 is continuously exchanged with systemic Tl-201 as long as cells are viable. Thus, reversibility of a perfusion defect over time is a marker of viability. Several different protocols of assessing viability with thallium exist: initial imaging may be performed at rest or after stress; the redistribution image could be done at various time points after initial imaging (usually 3–4 hours after injection). Modifications are further delayed images (at 12, 24, or even 72 hours after injection). In addition, thallium reinjection to boost the available systemic thallium pool is an option. Although the PPV (if redistribution is observed, myocardium is indeed viable) is as high as 88%, the NPV is relatively poor, and a fixed defect does not necessarily rule out viability. Nevertheless, thallium SPECT imaging remains a commonly used technique because of its wide availability and overall good accuracy.

Tc99m SESTAMIBI

The uptake of sestamibi is a marker of viability, because it requires certain degree of myocyte cell (membrane) and mitochondrial integrity for localization. For example, the degree of sestamibi uptake in dysfunctional myocardium compared to the maximum myocardial sestamibi uptake (using a cutoff of 50%–60% of maximum intensity) has been used to differentiate between viable myocardium and scar. This can be performed with or without nitroglycerin administration, but the latter may improve accuracy. Overall, sestamibi is less accurate than thallium (and FDG PET) imaging, and similar to thallium imaging, it underestimates the amount of viable myocardium.

F18 FLUORODEOXYGLUCOSE

In ischemic myocardium, metabolic substrate preference is shifted toward glucose (relative to fatty acid or lactate). Therefore F18-FDG, a marker of glucose metabolism, identifies preserved metabolic activity in regions of underperfused and dysfunctional myocardium.

TECHNIQUE

F18-FDG is a PET tracer with a half-life of 109 minutes. 18F-FDG is used to image metabolism of glucose (see Chap. 98 for details). The usual dose for cardiac imaging is 5 to 15 mCi. Normal myocardium preferentially utilizes free fatty acids in the fasting state, and the uptake of glucose (FDG) is usually low, although fairly variable. Therefore, when it comes to cardiac imaging with FDG, the goal is to stimulate the myocardium to utilize primarily glucose (take up FDG), which is usually accomplished by elevating glucose and insulin levels. For cardiac FDG imaging, patients fast for 6 to 12 hours. If the baseline blood glucose is less than 110 mg/dL, a standardized glucose load is administered (25–200 g, usually orally, although IV glucose is an alternative). In a normal individual, this stimulates the endogenous insulin response, and glucose is driven into the myocardial cells. Patient's blood glucose is monitored, and if it is less than 130 mg/dL approximately 1 hour after glucose load, FDG is administered IV. This protocol can be challenging in diabetic patients who may be unable to achieve a sufficiently low fasting blood glucose level, or have too high blood glucose levels after glucose administration. In these circumstances, exogenous insulin may be administered with further monitoring of blood glucose. FDG may be injected when blood glucose is trending down. Imaging is generally performed 45 to 60 minutes after FDG administration.

INTERPRETATION

Myocardial FDG uptake is assessed for its presence, distribution, and extent. Most importantly, comparison of FDG uptake (metabolism) and myocardial perfusion is performed to assess for areas of decreased or absent perfusion with concordant absence of FDG uptake (match) or discordant FDG uptake (mismatch). For such comparison, either a PET or SPECT myocardial perfusion study can be used.

ACCURACY

Reported sensitivities for FDG imaging to identify viable myocardium are 88% to 92%, with specificities of 73% to 89%, PPV of 68% to 100%, and NPV of 75% to 100%. Technical advantages of PET imaging (over SPECT) include reliable attenuation correction and very good spatial resolution. Disadvantages are relative limited availability of the technique and expertise, relative high cost, and challenges in diabetic patients. Viability imaging with FDG PET is rather extensively validated and currently the best (most sensitive) method in nuclear medicine and by many considered the gold standard.

OTHER IMAGING TECHNIQUES

ECHOCARDIOGRAPHY

Echocardiographic techniques assess myocardial wall thickness and motion. Viable myocardium demonstrates maintained contractile reserve (i.e., improvement in segmental wall motion with infusion of dobutamine). The hallmark of hibernating myocardium is a biphasic response during dobutamine infusion: after an initial improvement in segmental wall motion with infusion of low-dose dobutamine, worsening function during higher doses of dobutamine is observed (when the myocardium becomes more ischemic). Like SPECT imaging, it is frequently used because of the wide availability of the technique.

MRI

MRI allows evaluation of myocardial function, perfusion, and contrast enhancement. Scarred (nonviable) myocardium may demonstrate early hypoenhancement (perfusion defects on first-pass imaging), but the hallmark of scar tissue is late enhancement. Hibernating myocardium on the other hand is defined by the lack of late hyperenhancement.

RADIONUCLIDE VENTRICULOGRAPHY

Radionuclide ventriculography, also called gated blood pool study, radionuclide angiography, or multiple gated acquisition (MUGA) scan, is performed to evaluate global and regional ventricular function. Techniques include first-pass radionuclide angiography (FPRNA) and equilibrium radionuclide angiography (ERNA).

FIRST-PASS RADIONUCLIDE ANGIOGRAPHY

Overall, FPRNA is not frequently performed. It requires a fast compact bolus injection immediately followed by very rapid acquisition of data while the radiotracer passes through the central circulation. The main advantage of first-pass imaging is a more accurate assessment of RV function (compared to ERNA), since there is no overlapping radiotracer activity in other structures. Typically, images are obtained in the RAO view to assess the RV. Although FPRNA could be done with virtually any radiopharmaceutical (providing enough counts), it is usually performed in conjunction with ERNA (labeled red blood cells) or MPS (Tc99m sestamibi). For

repeated acquisitions (i.e., baseline and peak stress), a tracer that is easily cleared, such as Tc-99m sulfur colloid or Tc-99m DTPA, may be preferable.

EQUILIBRIUM RADIONUCLIDE ANGIOGRAPHY

The radiopharmaceutical typically used for ERNA is Tc99m-labeled red blood cells (usual dose 10–20 mCi). Several methods for labeling of red blood cells exist (Chap. 93). In vivo labeling is sufficient for radionuclide ventriculography. Gated images are obtained in the left anterior oblique (this is usually not a fixed angle, but the view that allows for the best septal separation between RV and LV), anterior, and left lateral views (see gated imaging technique given earlier). Images are reviewed for visual assessment of chamber (LV, RV, atria) size, and function. At the state of equilibrium, radiotracer activity from a cardiac chamber is proportional to its volume. Therefore, ventricular function (LVEF) can be quantified. Regions of interest (ROI) are drawn either automatically or manually around the left ventricle at end systole (frame with fewest counts) and end diastole (frame with maximum counts). The left ventricular ejection fraction is calculated as follows:

$$\text{LVEF} = (\text{LVED} - \text{LVES}) / (\text{LVED} - \text{background})$$

The background ROI is usually a crescent shape adjacent to the LV. If a relatively hot structure (i.e., spleen) is included in the background ROI, the LVEF is falsely high (Table 96-9). A normal resting EF is usually $\geq 50\%$ (50%–80%). The RVEF (normal 46%–70%) is usually slightly less than LVEF. Besides global ventricular function, regional wall motion is assessed. Wall motion is normally greatest in the apex and the free walls (and less in the septum). When wall motion is abnormal, the abnormality should be further described as akinesis (absence of motion), hypokinesis (diminished wall motion, which could be further classified as mild, moderate, or severe), or dyskinesis (paradoxical wall motion). Nowadays, exercise MUGA is rarely indicated. A normal response to exercise is an increase in LVEF by 5% or more. A failure to increase the LVEF by 5%, a decrease of LVEF from baseline, or the development of wall motion abnormalities (with or without chamber dilatation) indicates an abnormal response.

Quantitative (Fourier phase) analysis of a MUGA study reduces four-dimensional information for each

TABLE 96-9 Possible Sources of Error During Gated Blood Pool Imaging

pixel into a two-dimensional image. These parametric images may be useful in evaluating regional variations of ventricular contractions. The so-called amplitude image shows cardiac contractility (how much each pixel moved during the cardiac cycle) color coded. In a normal patient, the LV should have a fairly uniform color. The phase image reflects the timing (sequence) of contraction (i.e., when each pixel moved in relationship to the R wave or other marker). The phase can be displayed as a color-coded image (the LV should have a fairly uniform color) or as a histogram (where a cardiac cycle is transformed into 360 degrees on the x-axis and number of pixels on the y-axis). This histogram should show the ventricles as a fairly narrow bell-shaped curve (widening would reflect abnormal wall motion); the ventricles and atria should be 180 degrees apart. The paradox image is the ED frame subtracted from the end-systolic frame (ES–ED). In a normal patient, the area of the LV should be a void. Any visible areas of the LV reflect dyskinetic areas. MUGA studies should be carefully reviewed for incidental findings such as splenomegaly, or a circular area of photopenia around the heart (which may be related to pericardial effusion).

CLINICAL APPLICATION

One of the main clinical applications nowadays is the assessment of patients who receive cardiotoxic therapy (specifically anthracyclines). Unfortunately, there are no universally excepted guidelines on how to follow these patients (i.e., how frequently to reassess LVEF, when/how to alter or discontinue therapy). Therefore there is some interinstitutional variation. Nevertheless, most people would agree that therapy should not be started if the baseline LVEF is less than 50% and that therapy should be discontinued if the LVEF falls to less than 50%. A decline in LVEF by more than 10% to 20% is also concerning. Other indications for gated blood pool studies are to follow patients with cardiomyopathy, especially if the LVEF is difficult to assess by other techniques or if the EF was borderline with another imaging technique prior to ICD implantation.

QUESTIONS AND ANSWERS

- Which of the following radiopharmaceuticals for myocardial perfusion imaging has the highest extraction fraction?
 - Thallium-201
 - Tc-99m sestamibi
 - Tc-99m tetrofosmin
 - Tc-99m teboroxime

ANSWER: D. Extraction fractions are as follows: Tc-99m teboroxime (>90%) > Tl-201(85%) > Tc-99m sestamibi(Tc-99m tetrofosmin) (55%–70%). (The most physiologic myocardial perfusion tracer with an extraction fraction of nearly 100% is O-15 water, a PET tracer.)

- A 72-year-old male with chest pain and left bundle branch block presents for stress myocardial perfusion imaging (MIBI). He has a history of hypertension, diabetes, peripheral vascular disease (bilateral below the knee amputation). He received aspirin and metoprolol to manage his chest pain within the last 2 hours. Upon auscultation you notice wheezing. Concerning his stress test, which of the following is the best next step?
 - Reschedule the test
 - Perform the test using adenosine
 - Perform the test using exercise
 - Perform the test using dobutamine

ANSWER: A. The test needs to be rescheduled. Certainly a patient with bilateral below the knee amputation would be unable to exercise. Vasodilator

stress (adenosine) is contraindicated given active wheezing. Dobutamine is not an option because the patient recently received a beta-blocker dose and has a LBBB (this can lead to perfusion defects when the heart rate increases).

3. A 43-year-old diabetic female suffered an acute LAD myocardial infarction, which was treated with emergent stent. Besides occlusion of the proximal LAD, coronary angiogram at that time revealed mild to moderate disease in the LCX and RCA. Six months later, she presents with chest pain. Myocardial perfusion imaging reveals a stress-induced perfusion defect involving the lateral wall that is reversible at rest. LVEF is 50%. Which of the following is the best explanation for this finding?
 - A. Acute LAD stent thrombosis
 - B. Interval LCX infarct
 - C. Interval progression of disease with ischemia in the LCX
 - D. Interval progression of disease with ischemia in the LAD distal to the stent

ANSWER: C. This is the only answer correctly describing the territory involved (the lateral wall receives blood supply from the left circumflex artery) and the nature of the perfusion defect (a stress-induced defect that is reversible at rest is ischemia). Especially in diabetic patients, coronary artery disease can progress relatively rapidly. An interval infarct may have been suspected if a fixed (nonreversible) defect was seen. LAD disease should involve the anterior, septal, or apical wall. Acute stent thrombosis usually occurs shortly after stent placement (not several months later).

4. A patient presents for exercise stress testing to evaluate for coronary artery disease. Baseline BP is 140/80 mmHg, HR 67 bpm, normal baseline ECG. At stage 2 of the BRUCE protocol, BP is 170/80 mmHg, HR 150 bpm. You proceed to stage 3. Which of the following is an absolute indication to terminate exercise stress testing?
 - A. SBP decreases to 160 mm Hg, patient asymptomatic
 - B. DBP decreased to 60 mmHg
 - C. ECG shows 2 mm ST elevation in leads I, II, V1-V4.
 - D. Greater than 10 PVCs per minute

ANSWER: C. Absolute indications for early termination of exercise stress testing are decrease in SBP of greater than 10 mm Hg from baseline despite an increase in workload, when accompanied by other evidence of ischemia (not when asymptomatic, a false), ST elevation (≥ 1 mm) in leads

without diagnostic Q waves, sustained ventricular tachycardia (not only several PVCs per minute). A decrease in DBP is a normal physiologic response to exercise.

5. Which of the patients described below does *not* have a high-risk myocardial perfusion scan pattern?
 - A. A 35-year-old female with perfusion defects in the anterior and inferior wall and LVEF of 50%
 - B. A 65-year-old male with lung/heart ratio of 0.3
 - C. A 50-year-old male with moderate-sized anterior wall scar and LVEF of 30%
 - D. A 42-year-old female with an SSS of 20

ANSWER: B. Parameters that are associated with a high risk of cardiac events include stress-induced large myocardial perfusion defects (patient D), perfusion defect in more than one vascular territory (patient A), abnormal rest LVEF ($<40\%$) (patient C), and increased lung uptake of thallium (lung/heart ratio >0.5). (option B is correct). Other high-risk parameters are large reversibility of stress-induced perfusion defect, abnormal postexercise LVEF, and transient left ventricular dilatation.

6. You review a radionuclide ventriculography on a patient with lymphoma and notice that the background ROI includes part of the spleen. The LVEF is likely
 - A. underestimated
 - B. overestimated
 - C. not affected

ANSWER: B. LVEF by ERNA is as follows: $LVEF = (LVED - LVES) / (LVED - \text{background})$.

If a relatively hot structure (e.g., spleen) is included in the background ROI, the LVEF is overestimated. If a relatively photopenic area is included (i.e., stomach or large hiatal hernia), the LVEF is underestimated.

7. A patient with ischemic cardiomyopathy (LVEF 25%) undergoes sestamibi myocardial perfusion and FDG PET imaging. The MIBI scan shows severely decreased perfusion in the apex, anterior, septal, and inferior walls, and normal perfusion of the lateral wall. FDG uptake is noted in the anterior, anteroseptal, and lateral walls, and no FDG uptake is seen in the inferoseptal, inferior wall, and apex. Which of the following does this indicate?
 - A. LAD scar, LCX hibernating, RCA scar
 - B. LAD normal, LCX normal, RCA scar

- C. LAD hibernating, LCX normal, RCA hibernating
- D. LAD hibernating, LCX normal, RCA scar

ANSWER: D. The LAD territory (anterior wall and septum) has decreased perfusion, but preserved FDG uptake (viable); therefore it is hibernating. The LCX supplies the lateral wall, which has normal perfusion (normal). The RCA territory (inferior wall) has absent perfusion and no FDG uptake (match) indicating that this area is a scar. A matched defect involving the apex may indicate that it receives blood supply from the RCA (normal variant) or that there is a small distal LAD scar (nevertheless, most of the LAD territory is viable).

8. A patient with a baseline EF of 55% by MUGA received doxorubicin. A high-quality follow-up MUGA scan reveals an LVEF of 40%. Which of the following is the next best step?
 - A. Confirm findings with transthoracic echocardiography
 - B. Continue therapy with reduced dose and regular follow-up
 - C. Continue therapy with same dose and short-term follow-up
 - D. Discontinue doxorubicin

ANSWER: D. Unfortunately there are no universally accepted guidelines on anthracycline cardiotoxicity; most people would agree that therapy should be discontinued if the LVEF falls below 50% (and no technical problems with the examination are identified). It is also important to use the same imaging technique (e.g., echocardiography or MUGA) for follow-up that was used for the baseline evaluation.

9. On a myocardial perfusion SPECT study, you notice decreased radiotracer uptake in the anterior wall at rest and stress (fixed defect) in a female patient. Gated images reveal preserved wall motion and thickening in the anterior wall. What does this represent?
 - A. LAD ischemia
 - B. LAD scar
 - C. Attenuation artifact
 - D. Gating artifact

ANSWER: C. A fixed defect could represent a myocardial scar or an attenuation artifact. Breast tissue can lead to attenuation involving the anterior wall. To differentiate attenuation from scar, one can apply attenuation correction if available (attenuation artifacts should normalize, scar should not), or one can review gated images. A myocardial scar is associ-

ated with abnormal wall motion and thickening. Ischemia leads to reversible (not fixed) defects. There is no indication in the case that there is a gating problem.

97 THYROID AND PARATHYROID SCINTIGRAPHY

Sibyll Goetze

THYROID

INTRODUCTION

Patients with hyperthyroidism, thyroid nodules, or thyroid cancer are referred to the nuclear medicine department for the diagnosis and treatment of thyroid disease. Procedures performed in these patients may include thyroid (radioiodine) uptake, thyroid scintigraphy, and radioiodine therapy.

DIAGNOSTIC PROCEDURES

THYROID SCINTIGRAPHY

Thyroid scintigraphy refers to a nuclear medicine procedure where images of the thyroid gland (or other thyroid tissue) are obtained after injection of a radiopharmaceutical that localizes to thyroid tissue, such as Tc-99m sodium pertechnetate (TcO_4^-) or radioiodine. Common indications for thyroid scintigraphy are to evaluate for typical patterns of radiotracer distribution in patients with hyperthyroidism (usually in combination with radioiodine uptake measurement), to investigate selected patients with a thyroid nodule, to locate ectopic thyroid tissue, assess neck or substernal masses, or to further investigate congenital hypothyroidism. Prior to the procedure, it is important to ensure that patients have not been exposed to interfering medications or agents (Table 97-1). Female patients must not be pregnant or nursing.

During thyroid scintigraphy, the patient is in the supine position with the neck extended. A gamma camera equipped with a pinhole collimator is typically used. A “distant” anterior image that includes the salivary glands and superior mediastinum is obtained first. Marker views to outline anatomical landmarks such as sternal notch, angle of the mandible, or other may be useful. Then with the camera centered over the thyroid

TABLE 97-1 Medications Potentially Interfering with Thyroid Imaging/Radioiodine Therapy and Recommended Time of Withdrawal

MEDICATION	TIME OF WITHDRAWAL
Antithyroid medications (PTU, methimazole)	>3–4 d
Thyroid hormone replacement	
Thyroxine	3–4 wk
Triiodine thyronine	2 wk
Multivitamins	1 wk (6 wk for thyroid cancer patients)
Topical iodine	2–3 wk (6 wk for thyroid cancer patients)
Amiodarone	>3–6 mo
Radiographic contrast media	
Intravenous water soluble (CT, angiography)	4 wk
Lipophilic agents	>1 mo
Lugol's solution, SSKI, Kelp, other	2–3 wk (6 wk for thyroid cancer patients)

bed, “close” images are obtained in the anterior and bilateral anterior oblique views. For the evaluation of thyroid nodules, marking of a palpable nodule should be performed. Interpretation of the examination should include an estimate of the overall intensity (compared to the salivary glands or background) and uniformity of radiotracer uptake within the thyroid gland. The presence, number, size, and location of any areas with significantly increased “hot” or decreased “cold” uptake are noted. Correlation with the patient's history, physical examination, laboratory values, and other imaging procedures is crucial. Sources of error are possible contamination (skin, hair, or clothing), interfering food, medications, technical errors, and esophageal activity (to clear radiotracer from the esophagus, patients may drink some water prior to imaging).

Tc-99m Sodium Pertechnetate (TcO_4)

Tc-99m pertechnetate (photopeak: 140 keV, half-life: 6 hours) is injected intravenously. Images are usually obtained 15 to 30 minutes after injection. Tc-99m pertechnetate is less expensive and more readily available than I-123. In addition, scintigraphy with pertechnetate can be completed in a shorter period of time (usually within 1 hour). Disadvantages of pertechnetate are that it is not organified by the thyroid cells (which may limit the evaluation of thyroid nodules) and activity in adjacent structures (esophagus, blood vessels) may be confusing. Images of the injection site to assess for dose infiltration should be obtained if the uptake in the thyroid gland is low.

Radioiodine

There are two forms of radioiodine used in nuclear medicine: I-123 (photopeak: 159 keV, half-life: 13 hours)

and I-131 (photopeak: 364 keV, half-life: 8 days). Unlike pertechnetate, radioiodine is not only trapped by follicular thyroid cells, but also organified and incorporated into thyroid hormone, which reflects thyroid physiology somewhat more accurately. Radioiodine is administered orally. Since food may interfere with the procedure by slowing the absorption of radioiodine, it is recommended that patients fast for 2 hours before and after the radioiodine administration. After ingestion of I-123, imaging is typically performed at 4 to 6 hours. Since images are obtained several hours after radiotracer ingestion, the procedure using I-123 is longer compared to pertechnetate. Although I-123 is more expensive and less readily available than pertechnetate, it has several advantages including a more accurate characterization of thyroid nodules, better visualization of retrosternal thyroid tissue and more accurate/robust quantification of uptake (which is often requested in those patients). Beta-particle emission, high photon energy, and long half-life of I-131 all lead to a relatively high radiation dose to the thyroid (100 times more than I-123, Table 97-2). Therefore, I-131 should not be used for thyroid scintigraphy, unless radioiodine therapy is subsequently performed. It may also be useful in the evaluation of substernal masses (high-energy photons are even less attenuated by osseous structures).

Whole-Body Radioiodine Scans

Whole-body radioiodine scans are performed for the detection of residual thyroid and/or tumor tissue in patients with differentiated thyroid cancer. Patients are rendered hypothyroid (goal TSH greater than 30 mIU/L) to stimulate any potential thyroid or tumor tissue to trap radioiodine, which is nowadays often accomplished by administration of recombinant TSH (rTSH). Alternatively, thyroid hormone replacement therapy can be withdrawn (patient must discontinue T3 for 10–14 days and/or T4 for 3–4 weeks prior to imaging). Patients should also follow a low-iodine diet for 7 to 14 days. Diagnostic scans are performed with a relatively low dose of radioiodine. It has been suggested that higher doses of radioiodine (especially I-131) cause “stunning” of thyroid tissue (decreased uptake and efficacy of treatment doses of I-131 because of cell death or dysfunction). Planar anterior and posterior images from the top of the head to the lower extremities are usually obtained 24 hours (6–48 hours) after oral ingestion of 0.5 to 5.0 mCi of I-123 or 48 hours (24–72 hours) after 1 to 4 mCi of I-131. Spot images of the neck and as well as marker images to delineate anatomic structures (i.e., sternal notch, angle of the mandible) can be useful. SPECT or SPECT and CT may improve localization of iodine-avid tissue. Physiologic uptake includes the salivary glands, the oro- and nasopharynx, bowel, and bladder. There are

TABLE 97-2 Radiation Dosimetry for Thyroid and Parathyroid Imaging Agents in Adults

RADIOPHARMACEUTICAL	ADMINISTERED ACTIVITY (mCi)	RADIATION DOSE TO TARGET ORGAN (rad/mCi)	EFFECTIVE DOSE (remmCi)
Patients with thyroid gland (assuming 15% uptake)			
I-131 NaI	0.05–0.2 (scan) 0.004–0.01 (uptake)	780 (thyroid)	24.0
I-123 NaI	0.2–0.6 (scan) 0.1–0.3 (uptake)	7.0 (thyroid)	0.28
Tc-99m TCO ₄	2–10 (scan and uptake)	0.23 (large intestine)	0.048
Patients after thyroidectomy (0% thyroid uptake)			
I-131 NaI	1–5	3.0 (bladder wall)	0.41
I-123 NaI	0.5–5.0	0.33 (bladder wall)	0.048
Other			
18 F-FDG	10–20	0.59 (bladder wall)	0.07
Parathyroid imaging			
201 Tl chloride	2.0–3.5	2.0 (kidney)	0.85
99mTc sestamibi	5–25	0.14 (gallbladder)	0.031

Data modified from the Society of Nuclear Medicine procedure guidelines www.snm.org.

multiple pitfalls that should be kept in mind when interpreting radioiodine scans, the most common ones including contamination, breast, and thymic uptake. In addition, there are inflammatory conditions, other tumors, and even effusions or renal cysts that may also cause false-positive examinations and correlation with thyroglobulin (Tg) levels and other imaging procedures is often necessary. Diagnostic (low-dose) scans should be distinguished from posttherapy scans, which are obtained several days after radioiodine ablation/therapy. In addition to salivary glands, oro-/nasopharynx, bowel and bladder, the biodistribution of posttreatment scans includes mild diffuse uptake in the liver (secondary to metabolism of thyroid hormones). If a diagnostic whole-body scan is negative (no radioiodine-avid lesions identified), radioiodine-avid tissue/lesions may be detected on a posttreatment scan.

RADIOACTIVE IODINE UPTAKE TEST

Radioactive iodine uptake (RAIU) is the measurement of the fraction of an administered radioiodine dose that accumulates in the thyroid gland. It is performed in patients with hyperthyroidism, especially to differentiate etiologies that may be treated with radioiodine (Graves disease, multinodular goiter (MNG), and hyperfunctioning adenoma) from those that can be followed clinically (thyroiditis, and iodine-induced hyperthyroidism). In patients who are deemed candidates for radioiodine therapy, the uptake measurement is frequently used to determine the individual patient treatment dose.

Similar to thyroid imaging, it is important to ensure that patients have not been exposed to interfering medica-

tions or agents (Table 97-1). Female patients must not be pregnant or lactating/nursing. Thyroid uptake measurements can be obtained with I-123 or I-131. To calculate a thyroid uptake, counts of the patient's neck at certain time point(s) after the dose administration in addition to counts of a calibrated standard (or patient dose) in a neck phantom, counts of the patient's thigh (patient background) and room background are necessary. Measurements can be taken early (2–6 hours) and/or late (18–24 hours). RAIU is calculated as follows (all in counts per minute).

$$\text{RAIU} = (\text{patient neck counts} - \text{patient background}) / (\text{administered or standard counts} - \text{room background}) \times 100\%$$

Reference normal values of RAIU are obtained from historical data and range from 5% to 15% at 4 hours and 10% to 35% at 24 hours. In most euthyroid patients, the uptake at 24 hours is greater than the 4-hour uptake. The historical reference values should not be strictly used since uptake may vary depending on laboratory (equipment used at different institutions) and specific population (varying levels of dietary iodine intake in different geographical regions). Radioiodine uptake values obtained should always be interpreted in the clinical context.

Although a thyroid uptake can also be determined with 99mTc pertechnetate using a gamma camera technique (drawing regions of interest over thyroid gland and background), this requires careful validation and is overall felt to be less accurate. Therefore it should be used with caution only in selected cases. Images of the injection site to assess for dose infiltration should be obtained if the uptake in the thyroid gland is low.

Radiation doses to target organs and effective doses are detailed (Table 97-2). It should be noted that the radiation dose increases with radioiodine avidity of the thyroid gland (i.e., the dose to the thyroid gland increases to 1300 rad/mCi of I-131 if the uptake is 25%). Effective doses are also higher in children compared to adults.

RADIOIODINE THERAPY

Therapy with I-131 in the form of sodium iodide given orally has been used for many years to treat benign (hyperthyroidism secondary to Graves disease, multinodular goiter, or autonomous adenoma) and malignant (thyroid cancer) conditions in adults and children. Regulations related to radioiodine therapy (licensure to administer I-131, release of patients after therapy, etc.) vary between jurisdictions.

PATIENT PREPARATION AND PREREQUISITES

Prior to radioiodine therapy, patients must discontinue all potentially interfering medications (Table 97-1). For patients with hyperthyroidism, the avidity of the thyroid gland for radioiodine must be established, which is done by performing a radioiodine uptake test. Patients at increased risk for radioiodine-induced “thyroid storm” (patients with large thyroid glands, very high radioiodine uptake, patients receiving large amounts of radioiodine, and elderly patients with cardiovascular disease) will likely benefit from prophylactic beta-blocker therapy. Especially patients with thyroid cancer should follow a low-iodine diet 1 to 2 weeks prior to therapy. For female patients, a serum pregnancy test must be obtained. Breast-feeding must be discontinued at least 4 weeks prior to radioiodine therapy (to reduce radiation to the breast) and cannot be resumed after treatment for that child.

SIDE EFFECTS AND ASSOCIATED RISKS

Side effects and associated risks must be discussed with the patient by the performing physician, and informed consent must be obtained. Patients treated for hyperthyroidism will almost universally become hypothyroid (usually over a period of several months) and appropriate follow-up and lifelong thyroid hormone replacement therapy will be necessary. (Patients with thyroid cancer are usually already hypothyroid after thyroidectomy.) For patients with hyperthyroidism, other important possible side effects are related to radiation-induced thyroiditis and include transient hyperthyroidism (possible thyroid storm) and local tenderness (which may require steroid therapy in severe cases). In addition, patients with Graves orbitopathy may experience worsening of the eye disease, and prophylactic steroid administration should be considered.

It is possible that the initial radioiodine treatment is not completely efficient and a repeat treatment may be

necessary. In patients with hyperthyroidism, the first treatment is usually effective in greater than 90% of patients. For thyroid cancer patients, the likelihood of subsequent radioiodine therapies depends on the stage and aggressiveness of the tumor. Thyroid remnant ablation in low-risk patients is successful with one treatment in more than 80% of patients.

For higher doses of radioiodine (thyroid cancer therapy), possible side effects also include mucositis, sialadenitis, and loss of taste. This is usually transient, but can be permanent in rare cases potentially leading to sicca syndrome (dry mouth and dry eyes) and increased risk of dental caries. Higher doses of radioiodine have also been associated with transient cytopenia, and high cumulative doses of I-131 (approaching 1 Ci) may lead to permanent bone marrow depression.

In male patients, temporary decrease in sperm counts has been observed following high doses of I-131. If cumulative doses exceed 400 mCi, sperm banking should be discussed with male patients. There has been no observed definite adverse effect of radioiodine treatment on female fertility and future pregnancies. All female patients are usually advised to avoid pregnancy for 6 months following radioiodine therapy to allow for time to achieve a stable euthyroid stage and to ensure that no repeat radioiodine therapy is necessary. Although there may be an increased risk of secondary malignancies (colon, bladder, breast cancer, and leukemia) after high doses of radioiodine, there is no definite threshold of I-131, and no recommendation of more intensive cancer screening other than usual age-appropriate screening is felt to be necessary.

RADIATION SAFETY PRECAUTIONS

Following radioiodine therapy, patients must follow precautions to protect any family members and the public from excess radiation. This includes increasing physical distance to other people (sleeping in separate beds), limiting time spent with others, and paying special attention to personal hygiene (prevent exposure of other people to body fluids that may contain I-131) following I-131 therapy.

I-131 DOSE DETERMINATION

I-131 dose for Thyrotoxicosis: In general, multinodular goiter and autonomous adenomas are more resistant to radioiodine therapy than Graves disease. Therefore, multinodular goiter or single adenomas may require higher doses of I-131, and are more likely to require a second treatment. There are two different approaches to selecting I-131 dose for hyperthyroid patients. One is to empirically select a dose (5–10 mCi for patients with Graves disease and 15–29 mCi for patients with nodular goiters and adenomas). Another method is to determine

a dose based on individual patient characteristics (size of the thyroid gland on physical examination and 24-hour radioiodine uptake) and desired activity to be delivered to the thyroid tissue as follows:

$$\text{Treatment dose (mCi)} = (\text{thyroid gland size [g]} \times \text{desired dose to be delivered to the thyroid [mCi/g]}) / (24\text{-hour radioiodine uptake})$$

The desired dose to be delivered to the thyroid gland depends on the underlying condition and ranges from 80 to 200 $\mu\text{Ci/g}$ of thyroid tissue, with doses at the higher range selected for conditions that may be more resistant to I-131, such as nodular glands or very large goiters.

I-131 dose for Thyroid Cancer: Treatment doses are usually selected empirically based on clinical/histopathologic characteristics. While a dose of 75 to 100 mCi (or even as low as 30 mCi) should be administered for postsurgical remnant ablation in low-risk patients, patients at risk for residual/recurrent disease should be treated with higher doses (100–200 mCi). Metastatic disease is usually treated with I-131 doses of at least 150 mCi (locoregional metastasis) or 150 to 300 mCi (for distant metastasis). Alternatively, dosimetry may also be applied to determine a treatment dose. Although not frequently done, it may help to determine the highest possible dose that can be given without exceeding radiation to critical structures or to ensure that critical structures (lung or bone marrow) do not receive excess radiation with usual empiric doses (patients with extensive lung or bone metastasis). Radiation dose to the bone marrow should be less than 200 rads (whole-body retention at 48 hours less than 120 mCi). Whole-body retention at 48 hours should be less than 80 mCi in patients with diffuse lung metastases to prevent radiation pneumonitis and fibrosis.

CLINICAL SCENARIOS

THYROTOXICOSIS

There are many forms of thyrotoxicosis. Depending on the etiology, therapy and prognosis can vary. Sometimes, the etiology of thyrotoxicosis can be established based on clinical evaluation alone. If this is not the case, patients may be referred to the nuclear medicine department for further evaluation. For example, thyroid uptake helps to differentiate entities with increased radioiodine uptake (Graves disease, multinodular goiter, and autonomous adenoma) from thyrotoxicosis with decreased uptake (thyroiditis). This is important since thyroiditis is a benign self-limiting condition that usually does not require any specific treatment. Radioiodine uptake may be within the normal reference range, nevertheless it is in-

appropriately high in the setting of a recent low or suppressed TSH. This may be the case in patients with multinodular goiter and single adenoma, since there are areas of relatively hyperfunctioning and suppressed tissue, and the overall uptake can occasionally be normal. It may be difficult to distinguish these patients from patients with recovering thyroiditis (when radioactive iodine uptake returns to normal), and correlation with clinical data (duration of disease, TSH) and follow-up may be useful. In patients with Graves disease, uptake is typically well above the normal range. If further differentiation of the radioiodine-avid forms of thyrotoxicosis is necessary, a thyroid scan may help (diffuse uptake in Graves disease, heterogenous uptake in multinodular goiter, and a single hot focus in autonomous adenoma).

Graves disease, also called diffuse toxic goiter, is caused by IgG antibodies directed against TSH receptors on the cell surface of follicular thyroid cells. These antibodies stimulate the thyroid cells to increase the production of thyroid hormones (T4 and T3 are elevated, and TSH suppressed through feedback mechanism). Since iodine is needed for the thyroid hormone synthesis, radioiodine uptake is increased. In most patients, the 24-hour uptake is higher than the 4-hour uptake. On occasion, the 4-hour uptake may be higher than the 24-hour uptake. This is due to rapid turnover of radioiodine by the thyroid glands, usually in patients who are markedly hyperthyroid with very elevated radioiodine uptake (greater than 65%) at 4 hours. The autoimmune process is generally diffuse, leading to diffuse increased uptake on a thyroid scan. Treatment options for Graves disease are radioiodine therapy, antithyroid medications and, in selected patients (i.e., marked thyromegaly, or tracheal compression), surgery. Marine-Lenhart syndrome, a variant of Graves disease, basically represents Graves disease with coexistent multinodular goiter (also called nodular Graves disease). Radiotracer distribution on thyroid scintigraphy may be heterogenous.

Toxic autonomous nodule refers to thyrotoxicosis caused by one (or two) hyperfunctioning nodule that is no longer under the control of the pituitary-thyroid control mechanism and autonomously produces excessive amounts of thyroid hormone (T4/T3 increased/TSH low). Radioactive iodine uptake is usually mildly to moderately increased. Thyroid scan shows one (or two) distinct focus of increased radiotracer uptake, which may, or may not, suppress radiotracer uptake in the remainder of the normal thyroid tissue. I-131 therapy or surgery are treatment options.

Toxic multinodular goiter is a multinodular goiter associated with thyrotoxicosis. It is thought that several nodules of a multinodular goiter become hyperplastic and eventually function autonomously (T4/T3 normal to

increased/TSH low). Radioactive iodine uptake is mildly to moderately increased, and the thyroid scan usually shows very heterogeneous uptake with several areas of relatively increased and decreased uptake. Radioiodine therapy, surgery, or antithyroid therapy may be a treatment option.

Subacute thyroiditis (also called granulomatous thyroiditis, de Quervain thyroiditis, or giant cell thyroiditis) is presumed to be secondary to preceding viral infection. It may be associated with fever, systemic symptoms, thyroid tenderness/pain (erythrocyte sedimentation rate may be elevated). Inflammation of the thyroid gland leads to destruction of the follicular cell integrity with release of thyroid hormone (T4/T3 increased/TSH low) into the circulation. Radioactive iodine uptake is very low in the hyperthyroid phase because the follicular cells are damaged and unable to transport or organify iodine. The condition is self-limiting (resolving within several months), and symptomatic treatment with antiinflammatory medications may help. Silent thyroiditis (also known as painless thyroiditis, subacute lymphocytic thyroiditis, or atypical thyroiditis) may be a painless variant of subacute granulomatous thyroiditis or Hashimoto thyroiditis. If it occurs in the postpartum phase, it is called postpartum thyroiditis (5%–10% of pregnancies). An autoimmune process leads to destruction of the thyroid cells. The condition, although it can be recurrent, is self-limited, usually resolving within weeks to months. Radioactive iodine uptake is very low in the hyperthyroid phase secondary to cell damage. In the recovery phase of thyroiditis (after the acute thyrotoxic phase), radioactive iodine uptake (thyroid cell integrity) recovers and may be normal or even slightly elevated.

Iodine-induced hyperthyroidism is one end of the spectrum of iodine-induced thyroid disease (hypothyroidism is more common) and may be encountered following exposure to large amount of iodine, such as contrast agents or iodine-containing medication. The exact mechanism of iodine-induced thyrotoxicosis is not entirely understood, yet it may be related to underlying areas of autonomous nodular activity that are stimulated by the iodine to synthesize thyroid hormone. This is also called Jod-Basedow phenomenon. Radioactive iodine uptake is low, secondary to excess iodine saturating the thyroid gland.

Thyrotoxicosis secondary to extrathyroidal thyroid hormone can be seen in factitious thyrotoxicosis from (self) administration of excess thyroid hormone, metastatic thyroid cancer if the metastatic tissue produces sufficient amounts of thyroid hormone to cause thyrotoxicosis (very rare), or struma ovarii, a rare ovarian tumor that contains functioning thyroid tissue,

which in rare cases produces excessive amounts of thyroid hormone.

THYROID NODULES

It is important to understand that thyroid scintigraphy does not identify a nodule per se. It simply represents (differences) in radiotracer uptake (function) of thyroid tissue. Thyroid nodules can be diagnosed by physical examination or ultrasound (US), or other anatomical imaging. It is therefore wrong to interpret scintigraphic findings as nodules, unless proper correlation is made. In addition, thyroid scintigraphy has a very limited role in patients with thyroid nodules found on palpation or imaging tests. Thyroid scintigraphy may be useful if the TSH is low (to evaluate if the nodule is a hyperfunctioning adenoma) or if US-guided fine needle aspiration (FNA) was indeterminate and the clinical suspicion for cancer is not high (hot nodules could be followed). US is the imaging modality of choice to evaluate thyroid nodules.

If patients with a thyroid nodule are referred for scintigraphy, marking of a thyroid nodule is often necessary in addition to the routine thyroid scintigraphy procedure outlined earlier in the chapter. This helps to accurately correlate the scintigraphic findings/characteristics (decreased, normal, or increased uptake) with the palpable abnormality. For marking, palpation of the thyroid gland should be performed. If a palpable nodule remains palpable with the patient supine on the imaging table, a radioactive (hot) or radioopaque (cold) marker is placed exactly over the palpable nodule. Marker images should be obtained with the nodule/marker in the center of the field of view to avoid distortion from parallax effect. Duplicate views without the marker should also be obtained. Solitary nodules can be characterized depending on the intensity of radiotracer uptake compared to normal thyroid tissue as hot (increased), warm (isointense) or cold (decreased). Warm nodules are sometimes called equivocal. Hot nodules are almost certainly benign and most often represent a hyperfunctioning adenoma (malignancy rate less than 1%). Hyperfunctioning (hot) nodules may completely or partially suppress radiotracer uptake in normal thyroid tissue. Most solitary hypofunctioning (cold) nodules (90%) are benign and represent nonfunctioning adenomas, cysts, localized fibrosis, or thyroiditis. Nevertheless, up to 10% of solitary cold nodules are malignant and therefore require further evaluation. A dominant cold nodule in a multinodular gland could also be malignant (although less likely than a solitary cold nodule in an otherwise normal gland). Occasionally, a nodule will appear *not* cold (warm, or rarely hot) on a pertechnetate scan but in fact be cold on a radioiodine scan. This is when the lesion, although it can trap pertechnetate (or iodine), lacks the ability to organify

iodine—it is called discordant nodule. Since very few nodules are discordant nodules, most experts feel that this does not warrant the routine use of I-123 in thyroid scintigraphy, given all the other advantages of Tc99m pertechnetate.

THYROID CANCER

Introduction

Although an increasing incidence of thyroid carcinoma has been observed in recent years (at least partially secondary to early detection of disease), it remains a relatively infrequent entity. The typical presentation is a thyroid nodule incidentally found on examination or diagnostic imaging (US with FNA are generally used to establish the primary diagnosis), although patients may seek attention because of local symptoms or signs of metastatic disease. Thyroid carcinoma can be divided into several histologically different entities: differentiated tumors (including papillary and follicular carcinoma) are most common (70%–90%) with generally very good long-term prognosis. The remaining 10% to 30% are medullary carcinoma, anaplastic carcinoma, lymphoma involving the thyroid gland and metastases.

Differentiated Thyroid Cancer

Initial management for patients with differentiated thyroid cancer is typically total thyroidectomy. Usually postoperative radioiodine remnant ablation is performed several weeks after surgery. The treatment goals of radioiodine ablation/therapy (I-131 Rx) are to facilitate surveillance with iodine scans and stimulated Tg and decrease the risk of locoregional recurrence and cancer-related mortality.

TSH Stimulation

For radioiodine therapy (as well as for iodine scans), residual thyroid tissue needs to be maximally “stimulated” to take up iodine, which is usually achieved by making the patient hypothyroid (goal of TSH greater than 30 IU/mL). This can be reached either by thyroid hormone replacement withdrawal or by administration of rTSH in selected patients.

Whole-Body Iodine Scans

Pretherapy whole-body radioiodine scans are not generally recommended, but may be useful in patients in whom the extent of thyroid remnant tissue is unknown or when the results of the scan would alter the decision about I-131 Rx or the I-131 dose to be given. The use of I-123 or low-dose I-131 (3–5 mCi) is recommended for diagnostic whole-body radioiodine scans.

Posttherapy whole-body radioiodine scans (usually 7 days [3–14 days] after therapy) should be performed in

all patients since it may detect new or additional metastases, alter staging or affect further management (in up to 15% of patients). In long-term management (6–12 months after I-131 therapy), diagnostic whole-body iodine scans may be of value in the follow-up of patients with high or intermediate risk of persistent disease. Low-risk patients clinically free of disease, negative stimulated Tg, and cervical US do not require routine iodine scans.

I-131 Dose for Ablation/Treatment

For initial (postsurgical) radioiodine ablation/treatment, a minimum effective dose (30–100 mCi) should be chosen, especially in low-risk patients, while a higher dose (100–200 mCi) may be appropriate for residual microscopic disease or a more aggressive tumor (e.g., tumor size greater than 1.5 cm, unfavorable histology [tall cell, sclerosing, and other variants], multifocal disease, lymphatic/vascular invasion, or positive margins). For lymph node and distant metastasis (lung bone), a dose of 150 to 200 mCi (or even 300 mCi) may be given. Radioiodine therapy doses can be selected empirically or calculated by dosimetry (this may be beneficial for pulmonary metastasis to limit radiation to the lung tissue). Since metastatic lesions may be stimulated after radioiodine is given, glucocorticoids should be administered prophylactically for patients with osseous or brain lesions that may predispose to increased risk for fractures or neurological compromise. In addition to I-131 therapy, other treatments such as surgery or external radiation should be considered in selected patients (local aerodigestive tract invasion, bone or brain metastasis). Persistent, recurrent, or metastatic disease can be treated with radioiodine (every 6–12 months) as long as disease continues to be radioiodine avid (visualized on posttreatment scans) and continues to respond to therapy (decrease in size of lesions, or declining Tg levels).

Long-Term Management

Following thyroidectomy and thyroid remnant ablation, disease-free status is defined by no clinical evidence of tumor, no imaging evidence of tumor, and undetectable serum Tg levels during TSH suppression and stimulation. Therefore, initial follow-up for low-risk patients should be based mainly on TSH-suppressed Tg and cervical US, followed by TSH-stimulated Tg (if the TSH-suppressed Tg is undetectable). Serum Tg levels (together with thyroglobulin antibodies [TgAb]) should be measured every 6 to 12 months. US of the thyroid bed and locoregional lymph nodes should be performed depending on patient's risk for disease and Tg status. Diagnostic whole-body iodine scans may be useful in a few selected patients.

Tg positive is defined by any detectable suppressed Tg level or a stimulated Tg more than 2 ng/mL (in the absence of interfering antibodies). Recommended evaluation for Tg-positive patients includes imaging of the neck (US) and chest (high-resolution noncontrast CT). If both are negative, empiric I-131 therapy should be considered; if either US or CT are positive, treatment options depend on results (surgery with or without I-131 therapy). Radioiodine can be repeated until the tumor is eradicated, no longer responds to treatment, or is no longer radioiodine avid. When disease is not radioiodine avid (negative posttreatment I-131 scan), patients may benefit from F18-FDG-PET (especially if suppressed Tg greater than 10 ng/mL).

MEDULLARY THYROID CANCER

Medullary thyroid cancer (MTC), a neuroendocrine malignancy originating from parafollicular C cells in the thyroid gland, is usually (75%) sporadic, although it can be seen as part of multiple endocrine neoplasia or isolated familial medullary thyroid cancer. It is usually managed surgically. After surgery, patients are followed with serum calcitonin and CEA levels. Imaging is obtained if these results are abnormal or if symptoms arise. Various imaging modalities have been used to evaluate medullary thyroid cancer including US, CT, MRI, as well as nuclear techniques, such as somatostatin receptor imaging with ^{111}In -pentetreotide and ^{131}I - or ^{123}I -MIBG. MIBG scintigraphy has a sensitivity of approximately 30%, while the sensitivity of somatostatin receptor imaging is in the range of 25% to 71%. Other radiopharmaceuticals (^{201}Tl , $^{99\text{m}}\text{Tc}$ -sestamibi, radiolabeled anti-CEA antibodies) are generally not used because of unsatisfactory results. The role of FDG-PET in patients with MTC is not established with reported wide ranges of accuracies and conflicting results. It may be useful in selected patients (serum calcitonin levels more than 1000 pg/mL, or if other imaging modalities are negative).

Anaplastic Thyroid Cancer

Anaplastic thyroid cancer is a very rare but very aggressive malignancy affecting mostly elderly patients. The use of nuclear (and other) imaging procedures for following patients with anaplastic thyroid cancer is very limited as the results do not change outcomes, which is typically quite poor.

ECTOPIC THYROID TISSUE

When the thyroid gland fails to completely descend to its location during embryologic development, thyroid tissue may remain along the course. Thyroid scintigraphy may be useful in confirming the presence of ectopic thyroid tissue, such as a lingual thyroid, thyroglossal duct remnant, or pyramidal lobe. For this indication, ra-

dioiodine is preferred over pertechnetate, given less salivary gland activity and higher tissue specificity.

In addition, thyroid scintigraphy may confirm that a mediastinal mass represents substernal goiter. For this indication, radioiodine is also preferred over pertechnetate because of less blood pool activity and higher-energy photons (less attenuation). Sometimes, the goitrous substernal tissue has impaired function (and is not very radioiodine avid) resulting in equivocal studies.

NEONATAL HYPOTHYROIDISM

When the TSH screening test is abnormal in a neonate, thyroid scintigraphy may help differentiate between agenesis of the thyroid gland (nonvisualization of the thyroid gland), lingual thyroid or other ectopic tissue, and dysmorphogenesis (markedly increased radio-tracer uptake by the thyroid gland).

PARATHYROID IMAGING

CLINICAL BACKGROUND

The most common cause of primary hyperparathyroidism is hyperfunctioning adenoma (80%–85%), followed by multiple gland hyperplasia (12%–15%), and parathyroid carcinoma (1%–3%). Parathyroid scintigraphy has been employed to localize parathyroid adenomas or other abnormal parathyroid tissue prior to surgery. Localizing imaging procedures are especially useful in patients who present with recurrent or persistent hyperparathyroidism after surgery, and patients at high surgical risk or presenting with life-threatening adenomas. Imaging is also helpful when minimally invasive surgery is considered.

IMAGING PROTOCOLS

DUAL-PHASE SESTAMIBI IMAGING

Dual-phase imaging describes the acquisition of early and delayed images after injection of $^{99\text{m}}\text{Tc}$ sestamibi. Sestamibi localizes to tissue with relatively high blood flow (parathyroid adenomas are hypervascular) and localizes in mitochondria (oxyphil cells of parathyroid adenomas are rich in mitochondria). The principle of dual-phase Sestamibi imaging is that Sestamibi demonstrates faster washout from normal thyroid (and normal parathyroid) tissue, than from abnormal parathyroid glands. Therefore, abnormal parathyroid tissue becomes (more) prominent over time. Planar images of the neck and mediastinum are obtained early (approximately 10–15 minutes) and late (approximately 2–4 hours) after radiotracer injection. Additional images with a pinhole or converging collimator

may be useful. SPECT (or SPECT/CT) imaging has become increasingly popular because of more precise anatomical localization. The accuracy of dual-phase Sestamibi parathyroid scintigraphy in the evaluation of parathyroid adenoma is greater than 90%. Relatively small size (500 mg or less) of a parathyroid gland may cause false-negative examinations. In addition, a number of parathyroid adenomas (as well as hyperplastic glands) have relatively fast washout characteristics. False-positive examinations may be caused by other lesions that have persistent Sestamibi uptake, such as thyroid nodules, other head and neck cancers, lymphadenopathy, or brown adipose tissue. Sestamibi can also be used for intraoperative lesion detection using a handheld gamma probe.

DUAL-ISOTOPE (SUBTRACTION) IMAGING

With dual-isotope or subtraction imaging, two different radiopharmaceuticals are used. One of the radiotracers utilized is taken up by both thyroid and parathyroid tissue (201-thallium chloride [half-life: 72 hours, photopeak: 69–83 keV], or 99mTc sestamibi) and the other radiotracer only accumulates in the thyroid gland (99mTc pertechnetate, or I-123). Similar to dual-phase Sestamibi imaging, images of the neck and mediastinum are obtained. The image of the thyroid specific tracer is subtracted from the thallium or sestamibi image—any remaining focus of radiotracer activity could represent a parathyroid adenoma. In addition to the sources of errors mentioned earlier in the chapter, patient motion/ misregistration is a particular problem with the subtraction imaging technique and may cause false-positive or negative examinations. Another potential problem may be agents interfering with thyroid scintigraphy (such as iodinated contrast). There is no clear consensus that dual-phase imaging is better than subtraction imaging technique.

OTHER IMAGING PROCEDURES

US has been used to localize parathyroid adenoma (hypervascular hypoechoic lesion). Advantage of US is that it is able to evaluate for coexisting thyroid abnormalities prior to neck surgery. Disadvantages are the inability to localize ectopic parathyroid glands (i.e., in the mediastinum) and difficulties in evaluating postsurgical neck.

CT and MRI may be useful in selected cases.

QUESTIONS AND ANSWERS

- Which of the following is an appropriate I-131 dose for a 39-year-old female after total thyroidectomy with a 7-mm papillary (unifocal) thyroid carcinoma without clinical or imaging evidence of metastatic disease?
 - 20 mCi
 - 75 mCi
 - 200 mCi
 - Should be determined by dosimetry

ANSWER: B. This patient (small unifocal papillary thyroid cancer) is at low risk for occult metastatic or recurrent disease. In these cases, a minimum dose that ensures effective thyroid remnant ablation should be chosen and is usually 75–100 mCi, although doses as low as 30 mCi have been utilized in selected patients. For this patient, 20 mCi would be inappropriately low and 200 mCi too high (200 mCi is usually used for patients with metastatic disease). Dosimetry is not necessary for this patient. It is usually applied in patients receiving doses of I-131 greater than 200–300 mCi or those who have extensive metastatic disease (lung, bones) to ensure that critical organs do not receive exceedingly high amounts of radiation.

- Which of the following radiopharmaceuticals is *not* clinically used for thyroid scintigraphy or uptake measurements?
 - Iodine-123
 - Iodine-124

- C. Iodine-131
- D. ^{99m}Tc pertechnetate

ANSWER: B. Iodine-124 is a radioisotope of iodine. Although it could be used for PET imaging (half-life of 4.18 days), it is currently not clinically used for thyroid scintigraphy.

3. A clinically and biochemically euthyroid patient was found to have a 2-cm nodule when palpating the thyroid gland. Which of the following is the most appropriate imaging procedure for further evaluation?
 - A. Contrast-enhanced CT
 - B. F18 FDG-PET
 - C. US
 - D. I-123 scan

ANSWER: C. US is the imaging modality of choice for evaluating thyroid nodules. It can confirm the palpated abnormality is indeed a thyroid nodule, assess for the presence of other nodules (which may not be palpable), and assess the characteristics of the nodule (cystic component, calcifications, etc.). FNA may be performed with US guidance. Thyroid scintigraphy with I-123 may be useful if the patient is thyrotoxic, or if US-guided FNA was indeterminate and the clinical suspicion for cancer is not high. CT and PET have no role in the initial evaluation of a recently diagnosed thyroid nodule.

4. Which of the following is *not* a possible side effect of radioiodine therapy in a female patient with Graves disease?
 - A. Hypothyroidism
 - B. Infertility
 - C. Worsening of ophthalmopathy
 - D. Transient worsening of thyrotoxicosis

ANSWER: B. Treatment doses of I-131 for hyperthyroidism do not cause infertility in women. Radioiodine treatment can cause radiation-induced thyroiditis in the short term (transient worsening of thyrotoxicosis, neck pain) and hypothyroidism in the long term. Graves ophthalmopathy may develop or worsen in patients (especially smokers), and steroid prophylaxis or treatment may be necessary.

5. Which of the following statements about dual-phase Sestamibi parathyroid scintigraphy is *true*?
 - A. Early images are obtained at 4 hours, delayed images at 24 hours.
 - B. Should be considered in patients with recurrent hyperparathyroidism after parathyroidectomy.

- C. Thyroid carcinoma may result in false-negative examinations.

- D. An important step in the interpretation is the computer subtraction of the early from the delayed image.

ANSWER: B. Localization of an abnormal parathyroid gland is especially important prior to repeat surgery. Scintigraphic techniques (e.g., dual-phase Sestamibi imaging) are especially useful since an ectopic parathyroid adenoma may be found, and other imaging techniques may have limitations in the postsurgical neck. Early images are obtained at 10 to 15 minutes, delayed images at 2 to 4 hours. Thyroid carcinoma or adenomas may result in false-positive examinations. Using dual-phase Sestamibi imaging, no computer subtraction is necessary. Subtraction is performed when dual-isotope techniques are used.

6. Which of the following medications does *not* need to be discontinued prior to thyroid scintigraphy?
 - A. Levothyroxine
 - B. Methimazole
 - C. Propranolol
 - D. Propylthiouracil

ANSWER: C. Propranolol is a beta-blocker and does not need to be stopped prior to thyroid scintigraphy or radioiodine treatment.

7. Which of the following statements about Graves thyrotoxicosis is *true*?
 - A. Radioiodine uptake is typically uniformly increased.
 - B. Surgery is preferred over radioiodine therapy.
 - C. It is characterized by elevated levels of T4 and antinuclear antibodies.
 - D. It is a very rare cause of thyrotoxicosis.

ANSWER: A. Graves disease is a fairly common cause of thyrotoxicosis caused by stimulating TSH receptor antibodies (*not* antinuclear antibodies). Antithyroid medications and I-131 therapy are the main treatment modalities, and surgery is rarely indicated.

8. Which of the following combinations of clinical scenario and radioiodine uptake is correctly matched?
 - A. Factitious hyperthyroidism – normal
 - B. Graves disease – low
 - C. Silent thyroiditis – low
 - D. Struma ovarii – high

ANSWER: C. Radioiodine uptake is low in silent (lymphocytic) thyroiditis, subacute thyroiditis, factitious hyperthyroidism, iodine-induced hyperthy-

roidism, and ectopic hyperfunctioning tissue (struma ovarii). Radioiodine uptake is high in Graves disease. Radioiodine uptake is usually (inappropriately) high in toxic MNG and autonomous adenoma. *Caveat:* Radioiodine uptake could be normal in recovering thyroiditis.

9. A patient with locoregionally advanced papillary thyroid cancer (T3N2M0) presents 9 months after total thyroidectomy and radioiodine treatment (150 mCi). His stimulated Tg level is now 50 mg/dL. Cervical US shows nonspecific findings; noncontrast chest CT is negative. He receives 150 mCi I-131 for therapy. His posttreatment scan is negative. Which of the following would be the next most appropriate step?
- MRI of the neck
 - Repeat CT of the chest with contrast
 - FDG-PET
 - Follow up in 6–12 months with Tg levels

ANSWER: C. In a patient with elevated Tg levels and negative posttreatment iodine scan, FDG-PET is the most appropriate next step. The goal is to localize disease that could be managed by surgical resection or other local therapy (external radiation therapy (XRT), radiofrequency ablation, chemo/alcohol embolization). FDG-PET has sensitivities of 45% to 100% and specificities of 90% to 100% for the diagnosis of recurrent thyroid cancer. PET/CT fusion imaging appears superior to PET alone. FDG-PET–positive patients who cannot be surgically treated, thyroid hormone suppression, chemotherapy, or monitoring without additional therapy may all be options. FDG-PET negative patients can be followed with serial FDG-PET and serial Tg measurements. Whether FDG-PET scanning (similar to radioiodine whole-body scans) should be performed under TSH stimulated conditions has not yet been definitively established. FDG-PET also has prognostic information: Patients with FDG-avid disease have a worse outcome compared to patients with negative FDG-PET scans.

10. Which of the following radiotracer combinations not appropriate for dual-isotope subtraction imaging in parathyroid scintigraphy is correctly matched?
- ^{99m}Tc pertechnetate – ^{99m}Tc sestamibi
 - I-123 – ^{99m}Tc sestamibi
 - Thallium – Pertechnetate
 - ^{99m}Tc pertechnetate – I-123

ANSWER: D. The principle of dual-isotope imaging is that a tracer that localizes in both thyroid and parathyroid glands (e.g., sestamibi, thallium) and a tracer that localizes to thyroid only are used. Images

are obtained, while the patient remains in the same position, and are later computer subtracted. There are various combinations of radiopharmaceuticals, with doses varying depending on which one is used first and whether tracers with a different or similar photopeak are used. Pertechnetate and I-123 localize only to thyroid gland.

PET IMAGING

RADIOPHARMACEUTICAL: F18 FDG

^{18}F fluorodeoxyglucose (FDG) is cyclotron produced. It has a (physical) half-life of 109 minutes. The radioactive component, ^{18}F , decays via beta-positive emission to ^{18}O . Like with any other positron emitter, upon annihilation of the positron with an electron, two gamma photons with energy of 511 keV are released. ^{18}F -FDG is used to image the metabolism of glucose. It is a good imaging agent for applications in oncology because many tumor cells have increased glucose metabolism and therefore will demonstrate increased FDG uptake. FDG is injected intravenously and is taken up by the cells similar to glucose. Once intracellular, FDG undergoes phosphorylation by hexokinase to FDG-6-phosphatase. FDG-6-phosphatase cannot be metabolized further and is “trapped” in the cells (Fig. 98-1). Normal biodistribution of FDG includes the brain, the myocardium (which in the fasting state demonstrates variable FDG uptake), liver, spleen, GI tract, blood pool, lymphoid tissue, salivary glands, and testes. Since FDG is excreted through the urine, the urinary bladder (which is also the target organ) and renal collecting system accumulate FDG. Bowel uptake is thought to be secondary to uptake in smooth muscle, metabolically active mucosa, lymphoid tissue, swallowed secretions or FDG uptake by colonic bacteria or

FIG. 98-1 Comparison between glucose and F18-FDG metabolism.

any combination—and therefore can be very variable in extent, intensity and overall pattern. Normal variants of FDG uptake are frequent and include uptake in muscles, bone marrow, breasts and ovaries (depending on patient's age, menstrual cycle), thymus and lymphoid tissue (especially in younger patients) among many others

(Table 98-1). Uptake of FDG in the so-called brown adipose tissue (BAT), which can occasionally interfere with the assessment of the neck and thorax if intense, maybe reduced by keeping the patient in a warm room 30 to 60 minutes before injection, administration of a benzodiazepine like lorazepam or diazepam, or a beta blocker.

Data modified from Delbeke D, Coleman RE, Guiberteau MJ, et al. Procedure guideline for tumor imaging with 18F-FDG PET/CT 1.0. *J Nucl Med.* 2006;47(5):885-895.

PATIENT PREPARATION AND IMAGING

To optimize uptake of FDG by the target (tumor), it is important that

- glucose which competes with uptake of FDG is kept within the normal range, and
- as much FDG as possible is available for uptake to the tumor (and not “shifted” to other organs).

Therefore, patients should be in a state of normal glucose and insulin levels since hyperinsulinemia would cause redistribution of glucose/FDG to muscle and myocardium. To achieve this goal, patients are asked to fast for at least 4 hours prior to the examination. Blood glucose (BG) is checked prior to injection of FDG and if BG >150 to 200 mg/dL, rescheduling of the patient should be considered. Patients should neither exercise nor perform strenuous activities for 24 hours prior to the examination to avoid uptake of FDG in musculature, reducing availability of FDG for tumor uptake. After injection of FDG (the usual dose for an adult ranging from 10–20 mCi for whole-body imaging), patients are resting quietly in a warm room for at least 45 minutes (usually 60–90 minutes) before imaging. For most applications in oncology, whole-body imaging from the skull base to the proximal thighs is performed. For cancer types with a high likelihood of lesions in the head or lower extremities, adjustments can be made. Increasingly, hybrid PET/CT machines (in contrast to standalone PET cameras) are used to ensure optimal fusion of physiologic (PET) and anatomic (CT) information. This leads to higher accuracy because it allows for better differentiation of FDG uptake by normal structures versus uptake by tumor. Besides aiding in the localization of FDG uptake, CT is also used for attenuation correction.

STANDARDIZED UPTAKE VALUE

For most clinical purposes, it is sufficient to assess the presence (and intensity) of FDG uptake visually and describe the intensity of uptake as mild, moderate, or intense in relation to background uptake (for example, in normal liver parenchyma). Nevertheless, for research purposes and certain clinical circumstances (for example, assessing solitary pulmonary nodule [SPN] or response to therapy), it may be useful to include semiquantitative description of FDG uptake by tumor. Commonly used is the standardized uptake value (SUV). The SUV is defined as follows:

$$\text{SUV} = \frac{\text{activity in region of interest in tumor (mCi/mL)}}{\text{injected dose [mCi]/body weight [g]}}$$

SUV can be expressed as maximum or mean SUV, and it can be adjusted for lean body mass (or BSA), which

maybe preferably for circumstances where there are significant changes in body weight (e.g., follow-up of head and neck cancer patients under or after treatment). One should be careful in interpreting SUV since many factors influence its accuracy and reproducibility, such as the accuracy of the calibration of the PET scanner itself, strict adherence to clinical protocols, dose infiltration, time to imaging after radiotracer administration, type of reconstruction algorithm and attenuation map, the size of the selected region of interest, changes in uptake in other organs (e.g., bone marrow), and method of analysis (maximum vs. mean). The accuracy of the SUV also depends on the lesion size itself, and in lesions smaller than 1 cm FDG uptake maybe underestimated. There is no SUV value that definitely confirms or excludes malignancy. Fairly extensively evaluated is the value of SUV in the characterization of SPNs, where an SUV of less than 2.5 may best distinguish benign from malignant lesions. Nevertheless, this cannot be necessarily applied to other structures (liver, bone marrow, etc), and also depends on the prevalence of other (FDG-avid) disease processes.

CLINICAL APPLICATIONS

SOLITARY PULMONARY NODULE

SPN is defined as an approximately round lesion, less than 3 cm in diameter that is completely surrounded by lung parenchyma without other abnormalities. Overall 10% to 70% of these nodules maybe malignant. FDG imaging maybe helpful to characterize SPNs. For example, in low-risk patients (clinical likelihood of malignancy 20% or less), the negative predictive value (NPV) of a non-FDG-avid SPN is very high (decreasing the risk of malignancy to approximately 1%); nevertheless in high-risk patients, further evaluation of a SPN maybe necessary. An expert panel recently did not support the use of specific “quantitative thresholds.” Several studies have used a cutoff of maximum SUV of 2.5 to differentiate benign from malignant nodules. Several studies have shown that FDG PET is useful for the evaluation of SPN with a sensitivity of 95% and specificity of 81%. There appears to be no major difference in accuracy whether visual assessment or SUV threshold was used. The positive predictive value (PPV) of FDG PET is higher than that of CT in characterizing a lesion as malignant. Specificity is affected by prevalence of other potentially FDG-avid disease such as histoplasmosis or fungal infections (Table 98-1).

LUNG CANCER

In patient with non-small cell lung cancer (NSCLC), FDG PET is currently used for staging, restaging, evaluating recurrent disease, and assessing response to therapy. NSCLC is staged by the TNM system. Correct

initial staging is important to determine treatment options (especially surgery) and prognosis. FDG PET is especially useful in evaluating nodal (N stage) and distant (M stage) metastasis. For example, normal-sized lymph nodes by CT maybe malignant and some enlarged lymph nodes maybe in fact benign. As far as correct staging of nodal status is concerned, PET has a sensitivity of 88% and specificity of 91% (compared to CT with a sensitivity of 63% and specificity of 76%). The fact that the specificity for PET is less than 100% is mostly related to FDG uptake in inflammatory nodes. One main impact of FDG PET is that surgery maybe avoided in patients who are “upstaged” when advanced disease is identified. Unsuspected metastatic disease has been found in 14% to 29% of patients with NSCLC undergoing FDG PET. Overall FDG PET seems to be reliable enough for the evaluation of bone metastasis that a bone scan (in addition to PET) is only recommended in special circumstances. One should keep in mind that FDG PET is not optimal for the evaluation of the T stage. In some cases, for example, FDG PET cannot clearly detect the level of invasion of adjacent structures, and CT (or MRI) is necessary in evaluating involvement of chest wall, mediastinum, pleura, and vascular structures. There are certain subtypes of NSCLC that may not be particularly FDG avid, such as bronchoalveolar cancer as well as carcinoid tumor. Although small cell lung cancer (like many aggressive cancer types) is FDG avid, PET imaging is not used in patients with small cell lung cancer because the disease tends to be advanced at the time of diagnosis. Therefore, therapy choices are usually limited, and curative treatment such as surgery is generally not an option.

LYMPHOMA

FDG PET imaging is used for both Hodgkin lymphoma and non-Hodgkin lymphoma (NHL). All grades and cell types may take up FDG with a substantial overlap of level of FDG uptake (therefore, PET imaging cannot replace histological grading). Especially low-grade lymphomas (MALT, marginal zone lymphomas, and small lymphocytic lymphomas) maybe less FDG avid. Nevertheless, PET maybe useful in individual patients with low-grade lymphoma suspected to have transformation to a more aggressive type to detect transformation and guide biopsy. For Hodgkin lymphoma and NHL, FDG PET is used for initial staging, monitoring response to therapy, detecting relapse and restaging. As far as initial staging is concerned, PET detects more lesions than CT (i.e., disease in lymph nodes that are not enlarged by CT). It changes staging and/or impacts patient management in 8% to 48% of patients in Hodgkin lymphoma and NHL. Overall hybrid PET/CT is more accurate than PET alone (accuracy of 84% and 94%, respectively). Splenic involvement may present as diffusely increased uptake or focal FDG-avid

lesions. As far as the evaluation of bone marrow (BM) infiltration is concerned, FDG PET is complementary to bone marrow biopsy. Bone marrow biopsy and PET are concordant in 80% of cases. FDG-avid bone marrow lesions may need to be assessed by directed biopsy, while routine bone marrow biopsy is still necessary even if there are no FDG-avid lesions detected on PET imaging (since it maybe false negative). It has been shown that FDG detected BM disease that would have been missed by routine biopsy in 8% of patients, while 5% of patients had a positive bone marrow biopsy without abnormal FDG uptake (this may happen in lower-grade and non-FDG-avid lymphomas, or relatively less bone marrow involvement). Assessing response to therapy is more accurate with PET compared to CT mostly because of higher specificity (PET 86%, CT 31%) and better PPV (PET 100%, CT 42%). One of the strengths of PET is that it more correctly characterizes residual masses or enlarged lymph nodes as inactive disease if they are not FDG avid following treatment. FDG PET information has now been incorporated in *Revised Response Criteria For Malignant Lymphoma*, for example, defining a complete response as PET negative (of note, there are recommendations on how to standardize imaging techniques/interpretation and what exactly constitutes a “negative” PET). PET imaging also provides prognostic information: patients who have residual FDG-avid disease after therapy have a worse outcome in terms of overall survival than patients who have no detectable disease. Following therapy, an interval of 2 to 3 weeks (for chemotherapy) and 8 to 12 weeks (for radiation therapy) is recommended before obtaining a PET scan to avoid false-negative (“stunning” of viable cancer cells) and false-positive (from inflammatory response) results. The use of “midtherapy” (after several cycles of chemotherapy) PET scanning has been evaluated for Hodgkin lymphoma and NHL. It has been found that it is related to posttherapy scan results as well as event-free survival. In fact, presence (or absence) of FDG-avid disease was a stronger prognostic factor than any clinical parameter. With the information of midtherapy PET scans, therapy can be altered (intensified therapy for PET positive patients versus deescalation [avoiding toxicity] for PET-negative patients) with overall improved event-free survival.

COLORECTAL CANCER

Colorectal cancer is the third most common malignancy comprising 13% of all cancers. Similarly to lung cancer, the strength of FDG PET imaging is the evaluation of distant metastases, which may not be seen by conventional imaging. FDG PET is mostly used to stage patients with recurrent colorectal cancer. In this setting, it has a sensitivity of 97% and specificity of 76%. Patients with liver metastasis who are considered for curative

resection should undergo PET to exclude other metastatic disease (to avoid futile surgery). FDG PET may detect unsuspected disease in 27% of patients (leading to changes in therapy in 37%), mostly avoiding surgery in patients who would not benefit from it. Another indication for PET is the evaluation of patients with elevated CEA levels and negative conventional imaging. In addition, FDG PET may also help differentiate between local recurrence (in the colon) and postsurgical scarring. False-negative studies may be seen in patients with predominantly mucinous tumors. While FDG PET has no role in the screening/primary diagnosis of colorectal cancer, incidentally detected colorectal cancer during whole-body FDG imaging has been reported. Even though FDG uptake in the GI tract is very variable, focal intense uptake which can be seen in approximately 3% of patients requires further workup (e.g., colonoscopy) since there is a high likelihood of precancerous or cancerous lesions.

BREAST CANCER

FDG PET should be added to conventional imaging to evaluate breast cancer patients with a clinical suspicion of metastatic disease or those with disease recurrence. FDG PET has currently no role for breast cancer screening and initial diagnosis of breast cancer or evaluation of breast masses; in fact there appears to be a high risk of false-negative results, for example missing early stage (small) lesions. Mammography and MRI (and US) are more accurate for these indications. In addition, FDG PET is usually not beneficial in assessing axillary lymph node involvement, and it cannot replace sentinel lymph node biopsy.

HEAD AND NECK CANCER

Although overall a fairly rare malignancy, head and neck cancer is increasing in frequency, possibly related to its association with human papilloma virus. It is also linked to tobacco and alcohol use. FDG PET certainly has limitations in the evaluation of primary head and neck tumor (compared to contrast-enhanced CT or MRI), especially in defining the exact extent of the primary tumor and invasion of adjacent structures. Nevertheless, FDG PET is helpful in detecting nodal and distant metastasis and should be added to conventional imaging for staging head and neck cancer as well as for patients suspected to have recurrent disease. Even though the postsurgical neck is more difficult to evaluate given asymmetry of physiologic structures (muscles or salivary glands) and nonspecific inflammatory FDG uptake, PET appears more accurate than CT in this setting to assess for recurrent disease. FDG PET may also be useful in the detection of clinically suspected unknown head and neck primary tumors if conventional workup is

negative. In this setting, if FDG-avid lesions are identified, directed biopsy should be performed, and if FDG PET is negative, further workup is required (e.g., biopsy of at risk sites or tonsillectomy).

ESOPHAGEAL CANCER

FDG PET is very beneficial in staging of esophageal cancer because of its usefulness in detecting metastasis (M stage). Its accuracy for nodal disease (N stage) is only modest: the detection of local lymph node metastasis depends not only on the intensity of FDG uptake in the primary lesion and the involved lymph node but also the proximity of the lymph node to the primary lesion (intense FDG uptake in primary tumor may obscure the uptake in paraesophageal nodes). Overall accuracy for nodal staging with PET is 48% to 86%, while for CT/EUS it is 69% to 90%. FDG PET also lacks accuracy in evaluating the T stage with potential-false positive (secondary to FDG uptake in inflammatory lesions in the lower esophagus) as well as false-negative cases (small tumors, T1 stage). Endoscopy with EUS and/or contrast-enhanced CT is preferred for T and N staging. On the other hand, accuracy for detecting metastatic disease with FDG PET is 82% to 86%, while for CT it is 62% to 73%. PET is also used to assess response to therapy and to evaluate patients suspected (or known) to have recurrent disease.

MALIGNANT MELANOMA

Although FDG PET does not have a role in screening and diagnosis of melanoma and does not replace sentinel lymph node biopsy, it has a role in evaluating for metastatic disease. FDG PET has a sensitivity of approximately 96% and specificity of 87% for the detection of metastatic disease. Therefore, FDG PET should be considered in staging patients with “high-risk” melanoma (Breslow skin depth more than 1.5 mm, or metastatic disease at time of diagnosis), as well as for restaging at time of recurrence (especially with local recurrence if further surgery is considered an option). There are currently conflicting data on the routine use in patients with a positive sentinel lymph node biopsy. There are also emerging data on the usefulness of FDG PET in patients with elevation of S 100B markers. It should also be noted that MRI may perform better than PET in assessing metastatic lesions in the brain, liver, or bone marrow, and that small pulmonary lesions could possibly be more accurately detected by CT.

THYROID CANCER

For the most part FDG PET is not useful for the diagnosis, follow-up, or surveillance of patients with differentiated thyroid carcinoma. FDG PET is currently recommended for patients with differentiated thyroid cancer

(papillary or follicular cancer), after thyroidectomy and radioiodine ablation in the setting of detectable thyroglobulin levels (greater than 10 ng/mL), and a negative whole-body (posttreatment) radioiodine scan (with the goal of identifying patients who may benefit from specific treatment such as surgical excision or external beam radiation of FDG-avid disease). In this clinical setting, sensitivities of 45% to 100% and specificities of 90% to 100% for the diagnosis of recurrence were reported. FDG PET also reflects prognostic information: patients with FDG-avid disease have a worse prognosis compared to patients with negative FDG PET scans. Patients with Hürthle cell carcinomas (a rare, histologically distinct variant of follicular thyroid cancer) and patients with medullary thyroid cancer (a neuroendocrine malignancy that originates from parafollicular C cells of the thyroid gland) may benefit from FDG PET imaging in certain circumstances. Please see Chap. 97 for thyroid imaging.

Incidental Thyroid Uptake of FDG

Although FDG PET has no role in the detection/initial diagnosis of thyroid cancer or in the workup of thyroid nodules, focal FDG uptake in the thyroid gland is sometimes found incidentally (incidence of 1%–4%). If focal FDG uptake is detected in the thyroid gland, further evaluation (thyroid ultrasound with FNA or biopsy) is usually required, since there is a high likelihood of malignancy (up to 50% or more). Diffuse FDG uptake within the thyroid gland is seen in approximately 3% of patients undergoing FDG PET imaging. This phenomenon is most often benign and related to autoimmune (Hashimoto) thyroiditis or existing (or developing) hypothyroidism.

BRAIN TUMORS

FDG PET has been helpful in differentiating between radiation necrosis (no FDG uptake) and persistent brain tumor (uptake), especially if other imaging is equivocal. FDG uptake has also been found to be related to the histological grade in certain tumors, providing noninvasive tumor grading and prognostic information. FDG PET may also facilitate guiding biopsy of brain tumors/ intracranial lesions. Because of the high physiologic FDG uptake in the brain, PET is relatively insensitive for the detection of intracranial metastasis, as metastasis may be hyper- or hypo- or isometabolic. Amino acid PET tracers are more sensitive than ¹⁸F-FDG in imaging recurrent brain tumors, particularly low-grade tumors, in addition to differentiating between recurrent tumor and treatment-related changes.

UNKNOWN PRIMARY TUMOR

If the anatomic origin of a biopsy-proven malignancy remains unidentified after diagnostic evaluation, it is called an unknown primary tumor. This may account for 2% to 7% of all malignancies. Approximately 25% of

primary tumors are eventually localized by conventional imaging/workup. PET/CT maybe beneficial in the detection of occult primary lesions.

OTHER TUMORS

Data about the use of FDG PET in many other cancers are evolving and various malignancies (pancreatic, cholangiocarcinoma, ovarian, endometrial cancer) maybe (and are) imaged using this technique. On some cancer types, data are insufficient at this point to make any specific recommendations about the use of FDG PET, such as sarcomas. Where PET is not universally advantageous are usually slow growing or well-differentiated tumors, such as differentiated thyroid cancer, neuroendocrine tumor, and prostate cancer. Other tumors are not FDG avid because of histologic characteristics (e.g., mucinous or clear cell tumors). Hepatocellular carcinoma (HCC) has varying degree of glucose-6-phosphatase and does not reliably retain FDG intracellularly (up to 59% of HCC are not FDG avid). Transitional cell cancer of the GU tract is potentially very FDG avid; nevertheless because of its location in the GU tract and the normal excretion of FDG in urine, imaging with PET is generally not useful (Table 98-1).

BONE METASTASES

Since FDG PET is useful for the detection of distant metastatic disease in many cancer types, the question whether bone scintigraphy remains necessary for the evaluation of osseous metastatic disease arises. This question is not an easy one to answer. Certainly for malignancies where disease may be primarily located in the bone marrow space (lymphoma or multiple myeloma), FDG PET is more accurate than bone scintigraphy. For NSCLC, there appears to be enough evidence to support that bone scintigraphy is not necessary if a patient already undergoes PET imaging. For other cancers, for example breast cancer, FDG PET and bone scintigraphy are still complementary. Overall FDG PET/CT has a PPV for osseous metastatic disease of 61% to 98% (depending if lesions are concordant or discordant between the FDG and CT portion). Similar to bone scintigraphy, FDG PET has a lower PPV for solitary bone lesions, and further workup (MRI, biopsy) maybe necessary. Another PET tracer used to assess osseous metastatic disease is F-18 sodium fluoride. It has been found to have increased accuracy and efficiency (imaging 15–30 minutes after injection, duration 15–30 minutes) with a similar dosimetry compared to ^{99m}Tc-MDP. This tracer maybe more widely used in the future.

INDIUM-111 OCTREOSCAN

In-111 pentetreotide (Octreoscan) is the most commonly used agent for somatostatin receptor imaging. It

can be useful in imaging patients with neuroendocrine tumors, such as carcinoids (80%–100% detection rate), gastrinomas, insulinomas, neuroblastomas, pheochromocytoma, paraganglioma, Merkel cell tumors, lymphomas, certain CNS neoplasms, small cell lung cancer, and medullary thyroid carcinoma. In-111 is chelated to octreotide, a somatostatin analogue using DTPA to form In-111 pentetreotide (Octreoscan). There are five somatostatin receptor subtypes (all of which bind somatostatin), but only subtypes 2 and 5 bind with pentetreotide. Pentetreotide has been shown to bind to somatostatin receptors on both tumor and nontumor sites throughout the body. Because 80% of enteropancreatic neuroendocrine tumors express subtype 2 receptors, a majority of these tumors are Octreoscan positive. The usual adult dose of In-111 pentetreotide is approximately 6 mCi. Normal uptake of In-111 pentetreotide occurs in the thyroid gland, liver, gallbladder, spleen, kidneys, urinary bladder, and the GI tract. SPECT is very useful in cases where the tumor is in the abdomen. Imaging is done usually at 4 and 24 hours. Early 4-hour images have the advantage of less or absent bowel activity; 48-hour images maybe done to clarify if abdominal activity is of GI origin. Uptake of octreotide is thought to be decreased with concurrent therapeutic somatostatin use, and may need to be discontinued prior to the scan.

METAIODOBENZYLGUANIDINE IMAGING

Metaiodobenzylguanidine (MIBG) is taken up by adrenergic tissue, as it is an analog of noradrenalin and guanethidine, and therefore the MIBG scan is considered as the first-choice imaging procedure in the evaluation of neuroendocrine tumors like pheochromocytoma, paraganglioma, and neuroblastoma. MIBG can be labeled with either I-131 or I-123. I-123 MIBG is preferable because it has a more favorable dosimetry and provides better image quality, while I-131 MIBG is cheaper, more easily available and has a longer half-life, therefore delayed images can be obtained, if needed. Certain medications interfere with the uptake and/or vesicular storage of I-MIBG, and include tricyclic antidepressants, sympathomimetic drugs (e.g., decongestants), antihypertensives including Labetalol, possibly calcium channel blockers and ACE inhibitors and certain antipsychotics. These drugs should be discontinued after consulting the referring physician for an adequate time prior to imaging. The thyroid gland needs to be blocked with Lugol iodine or perchlorate to prevent inadvertent radiation to the thyroid gland from bound and unbound I-131 or I-123. The usual dose given is 500 μ Ci of I-131 or 3 to 10 mCi I-123 labeled

MIBG. Whole-body and spot images are obtained over 24 to 72 hours. SPECT images can be obtained if indicated. Normal biodistribution of MIBG includes the liver, spleen, urinary bladder, colon, salivary glands, heart, lung, and the thyroid gland. The adrenal glands maybe faintly visualized normally, more frequently with I-123 MIBG than with I-131 MIBG. Pheochromocytoma is seen as a focal area of MIBG accumulation in the adrenal gland or elsewhere. MIBG detects most of the adrenal and extraadrenal pheochromocytoma with an overall sensitivity of 80% to 90% and a specificity of 90% to 100%. Pheochromocytomas are known by the rule of “ten,” 10% are malignant (tend to be larger lesions), bilateral, occur in pediatric patients, and are extraadrenal. The overall sensitivity and specificity of MIBG in the detection of neuroblastoma is approximately 90% and 94%, and MIBG is superior to MDP bone scan for detecting the presence of skeletal metastases in this condition, yet both studies maybe complementary.

GALLIUM-67 IMAGING

Gallium-67 had been used for many years in oncology imaging; however with improved technology in CT, MRI, and PET, uses of gallium in oncology have dramatically been curtailed. It has a half-life of 78.1 hours after intravenous injection gets bound to plasma proteins primarily transferrin. Its uptake in tumor tissue is thought to be related to presence of transferrin receptors on the tumor cells, which bind the Ga-67-transferrin complex. Normal biodistribution includes the nasopharynx, salivary glands, lacrimal glands, bone marrow, breast tissue, liver, spleen, bowel, and thymus. Kidneys and bladder may be seen in the initial 24 hours. Usual dose is 10 mCi for oncology imaging. Whole-body and spot images are usually obtained at 48 hours; additional images can be obtained in 24-hour intervals. SPECT imaging increases the sensitivity of lesion detection. Prior to the advent of PET, gallium-67 was widely used in the evaluation and follow-up of lymphoma.

RADIOIMMUNOTHERAPY

Radioimmunotherapy involves the use of monoclonal antibodies directed against specific tumor antigens labeled with a beta-particle emitting–radioisotope to deliver radiation directly to the tumor. The CD20 antigen on B lymphocytes is the target for the currently used radioimmunotherapies: yttrium-90, ibritumomab tiuxetan (Zevalin), and I-131 tositumomab (Bexxar) in refractory NHL.

PREREQUISITES TO THERAPY

The prerequisites to therapy include a platelet count more than 100 000, neutrophil count more than 1500 cells/cm², bone marrow involvement on biopsy less than 25%, no prior history of hypersensitivity reactions to murine antibodies, and satisfactory pretherapy biodistribution. Patients with prior myelotoxic therapies associated with autologous bone marrow transplantation or peripheral stem cell rescue and those with a history of prior external-beam radiation to more than 25% of the active marrow should be excluded at this time.

ZEVALIN (YTTRIUM-90 IBRITUMOMAB TIUXETAN)

Ibritumomab is an IgG1 kappa-monoclonal antibody directed against the CD20 antigen found on normal mature B lymphocytes and on more than 90% of malignant B lymphocytes in patients with B-cell NHL. The CD20 antigen is an ideal target for immunotherapy because it is absent from hematopoietic stem cells. Zevalin is a radiolabeled antibody therapy approved for treatment of relapsed or refractory, or CD20⁺ transformed NHL. It has an overall response rate between 67% and 83%, with 15% to 37% of patients achieving complete remission. Zevalin consists of a murine monoclonal antibody attached to a metal chelator (Y-90). Y-90 is a pure beta-emitter that has a half-life of 64 hours. Unlike with I-131 Bexxar, no imaging can be performed as Y-90 has no gamma emission. The treatment is given on an outpatient basis, as the radiation exposure risk to family members is minimal. Unbound agent accumulates in bone so a stable antibody attachment is very important to limit bone marrow toxicity. Materials with a low atomic number, such as plastic or acrylics, are used for shielding so that the emitted beta particles will be completely absorbed in approximately 1 cm of these materials.

PROTOCOL

A dose of unlabeled rituximab is used to block CD20-binding sites on B cells in the circulation and in the spleen thereby optimizing biodistribution of the radiolabeled agent. In-111 ibritumomab tiuxetan (5 mCi) is given IV to obtain a diagnostic scan for assessment of biodistribution. A whole-body scan is obtained between 48 and 72 hours following tracer administration, with subsequent optional scanning as needed. The normal biodistribution on the initial scan is good uptake in the blood pool, moderately high to high uptake in the normal liver and spleen, and moderately low to low uptake in the lungs, kidneys, and urinary bladder. Altered biodistribution is suggested when blood-pool activity is not visualized and when lung uptake exceeds liver activ-

ity, renal activity exceeds liver activity on posterior images, and greater uptake in the bowel than the liver. When altered biodistribution is suspected, whole-body images should be obtained at 90 to 120 hours to exclude delayed clearance or other abnormalities. Patients with altered biodistribution should not be treated with ⁹⁰Y-ibritumomab tiuxetan. If the biodistribution appears normal, then patients can be treated with ⁹⁰Y-ibritumomab tiuxetan. Dosing is calculated by patient body weight and baseline platelet count. The dose is 0.4 mCi/kg in patients with platelet counts greater than 150K, and 0.3 mCi/kg if the platelet count is between 100K and 150K. The maximum dose given is 32 mCi.

TOXICITY

The primary adverse event is hematologic toxicity. The blood count nadir is usually between 7 to 9 weeks and counts normalize by 9 months posttreatment. Up to one-third of patients may later transform to an aggressive lymphoma. It is unclear if this represents therapy toxicity or the natural progression of the disease. Myelodysplasia or acute myelogenous leukemia has also been reported in a small minority (1.4%) of treated patients.

I-131 BEXXAR (I-131 TOSITUMOMAB)

Tositumomab is a murine monoclonal antibody that binds to the CD20 antigen expressed on the surface of malignant B lymphocytes. It is used in the treatment of rituximab refractory CD20⁺ follicular NHL. Unlike Zevalin, the I-131 gamma emission is useful to evaluate the biodistribution of the agent and to calculate the treatment dose. Pretreatment with SSKI or Lugol's iodine is required to block thyroid uptake of I-131 that maybe released from the antibody. The patient is first treated with unlabeled tositumomab to block the excess CD20 sites and prevent unnecessary uptake in the reticuloendothelial system. Thereafter, a low dosimetry dose of I-131 tositumomab (5 mCi) is given; serial scans are obtained to calculate how fast the activity clears from the body. This along with platelet counts helps with calculating the therapy dose, which is given after repeat pretreatment of unlabeled tositumomab. The most common toxicity is hematologic; blood count nadir is reached between 3 to 7 weeks after therapy. Myelodysplasia can occur as can hypothyroidism from free I-131 effects on the thyroid gland. Approximately 63% of patients refractory to rituximab have some response to I-131 Bexxar and 29% have complete response.

SENTINEL NODE DETECTION

A sentinel node according to Morton's definition is a lymph node that receives afferent lymphatic drainage di-

rectly from a primary tumor. The purpose of lymphoscintigraphy in sentinel node detection is therefore to demonstrate the drainage pathway of the neoplasm. It is currently widely used in the evaluation of melanoma and breast cancer. Other indications of reported use include penile, vulvar, testicular, oral, urinary bladder, laryngeal cancers, and GI malignancies. Tc-99m sulfur colloid particles are most commonly used in North America for lymphoscintigraphy. The visualization of the sentinel node depends on the transport of the sulfur colloid particles from the injection site to the lymphatics, which drain into the sentinel node. In the node, these particles are trapped and phagocytosed by macrophages. The optimal particle size is between 10 and 50 nm. If the particles are too small, they enter the systemic circulation, and if they are too large, they are unable to enter the lymphatics.

MELANOMA

The incidence of melanoma metastasis depends on the skin depth of tumor involvement. Node dissection is not usually required or does not make much sense for tumors less than 1 mm deep or more than 4 mm deep. Less than 1-mm deep tumors are seldom associated with lymphatic metastases, while 4 mm or deeper lesions are usually associated with distant metastases. In those with tumor depth between 1 and 4 mm, there is a high incidence of occult lymph nodal metastasis and a possible survival benefit associated with nodal dissection, therefore sentinel node detection is done. An intradermal injection of tracer is made at four or more sites surrounding the melanoma or the excisional biopsy scar; dynamic imaging and static images are acquired to identify the sentinel node followed by its localization and skin marking. The lymphatic drainage is usually predictable in the extremities, axillary, and inguinal in case of the upper and lower extremities. Popliteal nodes can be seen with melanoma on the calf, heel, or the lateral foot, while epitrochlear nodes are occasionally seen draining lesions on the forearm or hand. The drainage patterns are very unpredictable in case of the head and neck and trunk, where the drainage patterns may be bilateral, and in cases involving the trunk, drainage to the axilla, neck, or groin can be seen. An intraoperative gamma probe detector is frequently used to accurately localize the sentinel node at the time of surgery.

BREAST CANCER

In addition to the size and grade of the primary breast tumor, the status of the axillary lymph node is an important factor for accurate staging and determines the need for adjuvant therapy. Clinical examination has a poor predictive value for the determination of axillary nodal involvement, and therefore histological examination of the lymph nodes is required for identification of metastatic

disease. The axillary sentinel node can be accurately identified in 90% to 100% of patients with use of an intraoperative gamma probe and blue dye. Most of the breast lymphatic system drains to the axillary lymph nodes. Approximately 3% drains to the internal mammary chain nodes (usually from the medial portion of the breast), and a very small percentage drains to the posterior intercostal nodes. The standard surgical treatment in the past for breast cancer used to be radical mastectomy and axillary nodal dissection. The latter comes with a significant morbidity including pain, swelling, restricted range of motion, and paresthesias; also a majority of patients have no axillary metastasis and therefore have no benefit of this invasive surgical procedure. Sentinel node biopsy in the axilla involves removal of the sentinel node and other suspicious nodes. It is associated with less morbidity, shorter length of stay, and improved staging when compared with axillary nodal dissection. Tracer injection with Tc-99m sulfur colloid on the day of or even the day before could be superficial or deep. Superficial injections include intradermal, subcutaneous, periareolar, or subareolar. Deep injection techniques involve peritumoral (most common) and intratumoral approaches. Massaging the injection site facilitates migration of the sulfur colloid particles and aids in detection of the sentinel node. Prior to surgical biopsy, blue dye is also commonly injected around the margins of the tumor to aid in intra-operative detection of sentinel node.

QUESTIONS AND ANSWERS

1. A 65-year-old male with history of refractory non-Hodkin lymphoma involving the mediastinal and

retroperitoneal nodal regions is referred for (Zevalin) Y-90 Ibritumomab therapy. Which of the following is a prerequisite to proceed with therapy?

- A. Platelet count more than 100 000/ μ L
- B. Renal activity greater than that of liver on the pretherapy indium scan
- C. 10% bone marrow involvement with lymphoma
- D. Uptake of Indium-111 ibritumomab in the mediastinal and retroperitoneal adenopathy

ANSWER: A. Zevalin is indicated in the treatment of refractory NHL. It is contraindicated if lymphoma involves greater than 25% of the bone marrow, if platelet count is less than 100 000, and if absolute neutrophil count is less than 1500 cells/ cm^2 . Prior to therapy with Y-90 Zevalin, a whole-body scan is obtained with In-111 ibritumomab to check for presence of altered biodistribution, which includes increasing activity in the lung, liver, heart, kidneys, and bowel. Although uptake of the tracer in involved lymph nodes can be seen occasionally, it is *not* a prerequisite.

2. Which of the following radiopharmaceuticals may be useful for localizing a pheochromocytoma?
 - A. I-131 meta-iodo-benzyl-guanidine
 - B. Gallium-67 citrate
 - C. I-131 tositumomab
 - D. Tc-99m mercaptoacetyl triglycine (MAG-3)

ANSWER: A. Neuroendocrine tumors including adrenal (pheochromocytomas) and extraadrenal paragangliomas arise from specific cells that originate from the embryonic neural crest. Most pheochromocytomas produce both epinephrine and norepinephrine, and clinically present with hypertension, headache, diaphoresis, tachycardia, and anxiety. Pheochromocytomas may occur as part of MEN-2A or 2B syndromes and are also seen with von Hippel-Lindau syndrome and neurofibromatosis. I-131 MIBG and In-111 pentetate are useful in imaging these tumors, though I-131 MIBG is the most common radiopharmaceutical used for adrenomedullary scintigraphy and detects most of the adrenal and extra adrenal pheochromocytomas. It is the preferred agent used for imaging adrenal pheochromocytomas, although there are some data to suggest that In-111 pentetate is more sensitive in detecting head and neck paragangliomas.

3. In cases of lymphoma, what is the implication of mild metabolic activity in the thymus gland on FDG PET-CT imaging?
 - A. Before treatment indicates a poor prognosis
 - B. Before and after treatment maybe a normal finding

- C. After treatment indicates disease progression
- D. Prior to treatment indicates involvement with lymphoma

ANSWER: B. Low-level thymic activity is commonly seen in young patients. Normal thymic activity is triangular or 'V' in configuration. Thymic hyperplasia or rebound represents an immunologic phenomenon seen following chemotherapy, especially in young patients. It is seen in up to 75% of children and in 5% to 16% of adults. Thymic activity is abnormal when the uptake is very focal, intense (some sources have suggested maximum SUV > 4) or when the typical triangular or V configuration is distorted.

4. A 45-year-old male has been recently diagnosed with a right lung mass, and bronchial carcinoid is suspected. Which of the following radiotracers should be employed for definitive diagnosis?
 - A. In-111 pentetate (Octreoscan)
 - B. F-18 FDG
 - C. Ga-67 citrate
 - D. Tc-99m sestamibi

ANSWER: A. Neuroendocrine tumors are derived from the cells of the embryonic neural crest. They have the ability to synthesize peptide hormones and neurotransmitters. Examples of these tumors include pituitary adenomas; medullary cancer of the thyroid gland; small cell lung cancer; pheochromocytomas (adrenal and extraadrenal); neuroblastomas; enteropancreatic tumors like gastrinomas, insulinomas, and carcinoid tumors. A variety of radiotracers are available to image these tumors. In-111 pentetate is widely used for somatostatin receptor imaging to evaluate several neuroendocrine tumors including carcinoid.

5. Which of the following statements regarding I-131 MIBG scanning in patients with suspected pheochromocytomas is *true*?
 - A. Usual dose of I-131 MIBG is 12 mCi.
 - B. Thyroid uptake of I-131 is blocked by Lugol iodine, which also reduces tumor uptake of I-131 MIBG.
 - C. Propranolol reduces tumor uptake of I-131 MIBG.
 - D. Over-the-counter decongestants (sympathomimetics) decrease tumor uptake of I-131 MIBG.

ANSWER: D. Sympathomimetics including over-the-counter decongestants like phenylpropanolamine, pseudoephedrine, and phenylephrine deplete the storage vesicles in the adrenergic tissues and therefore

interfere with the uptake of MIBG and need to be discontinued prior to the MIBG scan. Additionally blood pressure medications like calcium channel blockers and labetalol also interfere with MIBG uptake and need to be discontinued prior to the examination. Lugol's iodine is given to saturate the thyroid gland with iodine and prevent uptake of I-131 by the thyroid gland. It however has no effect in the tumor uptake of MIBG. The usual dose of I-131 MIBG is 0.5 mCi.

6. A 56-year-old smoker is referred for a whole-body PET-CT scan for evaluation of a 1.5 cm left upper lobe SPN. Hypermetabolic activity (maximum SUV 3) is seen in the lung nodule at 60 minutes after 18-FDG injection, which increases to maximum SUV of 4.5 at repeat imaging performed 2 hours after tracer injection. Which of the following statements is accurate?
 - A. Baseline SUV less than 1.0 is concerning for malignancy.
 - B. Increasing SPN FDG activity is suggestive of an underlying malignancy.
 - C. Increasing interval SUV is due to patient eating a snack in between the two images.
 - D. Respiratory motion does not affect the standard uptake value.

ANSWER: B. Improved detection of malignant lesions has been reported by performing "dual time point imaging." This technique is based on the observation that more commonly, tracer activity will washout of inflammatory or benign lesions, while malignant lesions retain or increase in FDG activity over time (although some inflammatory lesions occasionally also show increase over time). Lesions with a baseline SUV of less than 1 have a very high likelihood of being benign, and dual time point imaging is not required as it may result in false-positive examinations. Respiratory motion may produce lesion blurring and an apparent increase in lesion size. This results in a decrease in the activity concentration per pixel within the lesion and an underestimation of SUV.

7. All the following lung tumors may be falsely negative in an 18-FDG PET-CT scan with the exception of the following:
 - A. Carcinoid
 - B. Bronchoalveolar cell
 - C. Adenocarcinoma
 - D. Mucinous

ANSWER: C. FDG PET scanning is not 100% sensitive in detection of tumors. Noteworthy exceptions include bronchoalveolar cell lung carcinoma (BAC), which may have a lower FDG uptake value

and can result in a false-negative FDG PET-CT. Other pulmonary neoplasms that frequently have no significant uptake increased FDG include carcinoid and mucinous tumors. Carcinoid tumors are usually slow growing and well differentiated, therefore have low FDG retention while BAC and mucinous tumors have a low proportion of tumor cells within the matrix of fibrosis and mucin, resulting in decreased FDG retention. Lung cancer with the above exceptions is usually FDG avid.

8. A 60-year-old male with past history of colorectal cancer, postcurative resection 3 years ago, is noted to have gradually increasing CEA levels. 18-FDG PET-CT scan is done to evaluate for suspected recurrent disease. Which of the following is the most likely site for tumor recurrence?
 - A. Within the abdomen/pelvis including the liver
 - B. Lungs
 - C. Skeletal system
 - D. Brain

ANSWER: A. Recurrent colorectal carcinoma occurs in 37% to 44% of patients within 2 years of curative resection. Local tumor extent and the presence or absence of adenopathy are important variables for determining prognosis and the risk for tumor recurrence. Serum levels of carcinoembryonic antigen (CEA) are frequently used as a tumor marker to monitor for the presence of recurrent tumor. However, the CEA test cannot localize the site of recurrent disease. Locoregional recurrence is more commonly encountered with rectal carcinoma, while colon carcinoma recurrence is more commonly seen in the liver or abdomen. FDG PET is also useful in distinguishing local tumor recurrence from postoperative scar.

9. Which of the following is the histological hallmark of Hodgkin lymphoma?
 - A. Reed-Sternberg cell
 - B. Schistocytes
 - C. Smudge cells
 - D. Plasmacytoma

ANSWER: A. The characteristic histological finding in Hodgkin lymphoma, a B-cell neoplasm, is the Reed-Sternberg cell. These are large cells with a characteristic clear area surrounding the nucleoli, giving an "owl-eye" appearance to the nuclei, seen in the lymph node surrounded by a dense inflammatory infiltrate. Patients usually present in their third or seventh decades with palpable adenopathy and constitutional symptoms (B symptoms) of fever, night sweats, pruritus, and weight loss. There are four subtypes of Hodgkin disease: nodular sclerosis

(most common form), mixed cellularity, lymphocyte predominant (favorable prognosis), and lymphocyte depleted (worst prognosis). PET-CT is useful in staging, restaging, and monitoring of response to therapy in lymphoma and also in directing site of diagnostic biopsy. It has replaced gallium-67 in the evaluation and follow-up of patients with lymphoma, because of its higher sensitivity and specificity, resolution, and favorable scan times (takes several days for completion of the gallium scan). Plasmacytomas are tumors containing plasma cells such as multiple myeloma. Smudge cells are histologically seen in chronic lymphocytic leukemia, while schistocytes are noted in hemolytic conditions like DIC and TTP.

10. Which of the following is a contraindication to the surgical treatment of NSCLC?
- Ipsilateral hilar adenopathy
 - Tumor which is larger than 2 cm from the carina, without carinal invasion
 - Ipsilateral peribronchial adenopathy
 - Ipsilateral supraclavicular adenopathy

ANSWER: D. Surgical resection is the treatment of choice of early stages of NSCLC and therefore accurate staging is crucial. The decision about resectability of NSCLC is based among other variables on which lymph nodes are involved with the tumor. In general, ipsilateral adenopathy (N2 disease) is an acceptable indication for surgical resection of tumor, while contralateral involvement (N3 disease) or metastatic cervical and supraclavicular adenopathy are contraindications to surgical treatment.

99 LABORATORY NUCLEAR MEDICINE AND MOLECULAR IMAGING

Jon A. Baldwin

INTRODUCTION

This chapter first reviews two nonimaging studies performed in nuclear medicine laboratories—measurement of thyroid uptake and the Schilling's test. (Laboratory measurements of ERPF and GFR are discussed in Chap. 85.) A brief outline and review of the concepts of molecular imaging follow. The end of the chapter contains summary charts and tables that residents will find to be

useful for preparing for written and oral board examinations.

NUCLEAR MEDICINE LABORATORY STUDIES

THYROID UPTAKE

Measurement of radioactive iodine uptake is a useful test to help differentiate nonmalignant thyroid diseases, and to determine the amount of ^{131}I that will be used to treat a condition such as Graves disease. In this test, a small amount of either ^{123}I (50–100 μCi) or ^{131}I (5–10 μCi) is administered orally to the patient. If 200 to 400 μCi of ^{123}I is used, imaging of the thyroid gland can also be performed. Recall that because of the dose to the patient and poor imaging characteristics, ^{131}I is not used in routine diagnostic imaging of the thyroid gland. Sodium pertechnetate is generally not used to determine thyroid uptake because of technical challenges and near-universal preference for the radioiodine method. Regardless of which radiotracer is used, the device which most commonly measures the thyroid uptake is the same—a thyroid probe, which operates on the same principle as an NaI well counter. A gamma camera can be used to determine thyroid uptake, as well as perform whole-body dosimetry (i.e., to estimate doses to particular organs), but is not terribly practical in most clinical applications.

Before radioiodine is administered to the patient, several patient preparation factors should be considered. The patient should be NPO for at least 4 hours to promote GI absorption of the radiotracer. More importantly, it should be verified that the patient has been off any medications that can interfere with thyroid uptake for the proper amount of time. The length of time these medications must be discontinued varies with the physiologic duration of their effect on the thyroid gland. In general, these medications will decrease radioiodine uptake. A list of some common medications, and the length of time they should be discontinued before a thyroid uptake study is attempted, is listed in Table 99-1. Once it is established that these patient preparations have been followed, the probe is used to count the background radiation in the room. The radioiodine sample is usually contained within a capsule, but can be in liquid form. Capsule is preferred to avoid aerosolization or loss of the dose, and it can also easily be placed in the neck phantom. The radiotracer is placed in a Lucite neck phantom, and that phantom is counted for 1 to 2 minutes. The probe is placed at a distance of 25 to 30 cm from the surface of the phantom. The dose is administered to the patient, and the patient will have their neck counted at a specified time after administration. The “gold standard”

TABLE 99-1 Drugs Affecting Radioiodine Uptake, and the Amount of Time They Should Be Discontinued Before Radioactive Uptake Study Is Performed

MEDICATION	TIME MEDICATION SHOULD BE DISCONTINUED
Propylthiouracil (PTU)	3–5 d
Methimazole (Tapazole)	5–7 d
Triiodothyronine (Cytomel—T ₃)	2–3 wk
Iodinated contrast	2–4 wk
Amiodarone	2–4 wk
Lugol's solution or SSKI	2–4 wk
Thyroxine (Synthroid—T ₄)	4–6 wk
Iodine supplements	4–6 wk

is to have the neck counted at 24 hours, but many centers will count their patients at anywhere from 2 to 6 hours. Whenever the patient is counted, room background will be again counted (before the patient is in the room). Counts of the patient will be performed for 1 to 2 minutes with the probe 25 to 30 cm anterior to their neck. Counts of the patient's thigh will also be performed, to correct for the background within the patient (i.e., to “subtract” counts in the neck that are coming from structures other than the thyroid). The formula used to compute radioiodine uptake is counts per minute, or cpm.

$$\frac{\text{Neck counts (cpm)} - \text{thigh counts (cpm)}}{\text{Administered counts (cpm)} - \text{room background counts (cpm)}} \times 100\%$$

The administered counts in the denominator are decay corrected for the amount of time that has elapsed since the neck phantom was counted. In the past, this was accomplished by counting a “standard” of similar activity in the phantom at the time the patient was counted. In most facilities, the radioiodine probe systems have computer software that will make this calculation automatically.

Normal radioiodine uptake values will vary based on the time that is chosen to count the patient. The normal values at 4 hours as reported by the Society of Nuclear Medicine's *Procedure Guideline for Thyroid Uptake Measurement* are 6% to 18%; at 24 hours, the normal values are 10% to 35%. These values will vary from institution to institution. Causes for abnormally high or low radioiodine uptake values are summarized in Table 99-2.

SCHILLING TEST

This nuclear medicine study does not require imaging. The patient is given a radioactive substrate, and a sample is taken from the patient at a set time after its administration and measured. The Schilling test is an effective physiological method of assessing cobalamin (vitamin B₁₂) absorption, although it is not performed very often anymore (Table 99-3). The cobalamins have a cobalt-containing corrin ring, a nucleoside base projecting off one face of the ring, and a beta-group of variable composition attached to the cobalt on the opposite side of the ring. The four varieties of vitamin B₁₂ in tissue are the metabolically active forms methylcobalamin and deoxyadenosylcobalamin, and hydroxocobalamin and cyanocobalamin. The last two are converted in vivo into active metabolites. All mammals require vitamin B₁₂ in their diet; none can synthesize it in vivo. There are only two reactions in humans known to require vitamin B₁₂. It is required in specific metabolic pathways responsible for deoxyribonucleic acid (DNA) synthesis and for the integrity of myelin. Methylcobalamin is an essential cofactor for the enzyme that produces tetrahydrofolic acid, which is required for the conversion of deoxyuridine monophosphate to deoxythymidine monophosphate. Vitamin B₁₂ is involved in the isomerization of methylmalonyl coenzyme A to succinyl coenzyme A. Vitamin

TABLE 99-2 Causes of Increased or Decreased Radioiodine Uptake

INCREASED RADIOIODINE UPTAKE	DECREASED RADIOIODINE UPTAKE
Hyperthyroidism	Subacute thyroiditis
Graves disease	Drug induced
Multinodular goiter	Increased iodine pool
Solitary hyperfunctioning adenoma (RAIU often normal)	Iodinated contrast
Hashitoxicosis	Lugol's/SSKI
Iodine deficiency	Iodine/mineral supplements
Recovery phase of subacute thyroiditis	Amiodarone
Tumors secreting TSH-like substances (rare)	Interference with thyroid function
Pituitary adenoma	PTU/Tapazole
Hydatidiform mole	Cytomel/Synthroid
Trophoblastic tumors	Hypothyroidism (primary or secondary)
Choriocarcinoma	Ectopic secretion of thyroid hormone (rare)
Metastatic thyroid carcinoma	Struma ovarii

TABLE 99-3 Interpretation of Findings in Schilling Test

FINDING	CAUSE
Part I Shilling test: Urinary excretion $\geq 6\%$ –9%	Dietary insufficiency
Part I Shilling test: Urinary Excretion $< 6\%$ –9%	Pernicious anemia Intestinal malabsorption Generalized (e.g., sprue) Specific to terminal ileum (e.g., Crohn disease) Pancreatic insufficiency
Part II Shilling test: Urinary excretion $\geq 6\%$ –9%	Pernicious anemia
Part II Shilling test: Urinary excretion $< 6\%$ –9%	Intestinal malabsorption Pancreatic insufficiency

B₁₂ deficiency leads to increased levels of methylmalonate, which can lead to formation of abnormal fatty acids; these may be incorporated into neuronal lipids, leading to a predisposition to myelin breakdown. Vitamin B₁₂ is plentiful in meat and dairy products, and only minute quantities are sufficient for biological processes (only a few micrograms per day are needed). Body stores are typically 3 to 4 mg. One is unlikely to have a deficiency based on inadequate intake (sometimes seen in strict vegans). Deficiency therefore is usually due to absorption problems, and is typically insidious in onset. Patients with vitamin B₁₂ deficiency typically have moderate to severe megaloblastic anemia, leukopenia with hypersegmented granulocytes, mild-to-moderate thrombocytopenia, and neurologic changes related to involvement of the posterolateral spinal tracts. These can present as spastic paraparesis, sensory ataxia, and severe paresthesias in the lower limbs. Initially the vitamin B₁₂ is released from its protein-bound form in animal foods by the action of pepsin in the acidic environment of the stomach. The liberated vitamin B₁₂ is bound to salivary vitamin B₁₂-binding proteins (“R binders”). These R binders protect the vitamin B₁₂ from degradation by stomach acid. The R binder is dissolved by pancreatic proteases in the duodenum. Vitamin B₁₂ next binds to intrinsic factor (IF), which is produced by parietal cells in the stomach, forming an IF-vitamin B₁₂ complex. This complex is transported to the ileum, where it adheres to IF receptors on the ileal cell membranes. It is then transported in the plasma bound to transcobalamin II. There are several steps along this process in which vitamin B₁₂ absorption can be interfered with. The Schilling’s test is used to differentiate if vitamin B₁₂ deficiency is due to lack of IF (pernicious anemia) or malabsorption. It can be performed as either a two-step procedure (with ⁵⁷Co-vitamin B₁₂) or a one-step procedure (with ⁵⁷Co-vitamin B₁₂ and ⁵⁸Co-vitamin B₁₂). In preparation for the Schilling test, the patient should be

NPO after midnight, and remain fasting for 2 hours after oral administration of the test dose. This is because the amount of vitamin B₁₂ in a meal can significantly affect the fractional absorption of the test dose. The patient should not receive parenteral vitamin B₁₂ for at least 3 days before the study. Biliary excretion of that parenteral vitamin B₁₂ into the GI tract may also significantly affect the fractional absorption of the test dose. It is also important to be aware if the patient has had other recent radionuclide studies, particularly if these radio-tracers are excreted through the kidneys. The patient is administered a 0.5 mCi dose of ⁵⁷Co-vitamin B₁₂ orally. The radiolabeled vitamin B₁₂ dose ranges from 0.5 to 2.0 μ g—you do not want to saturate the limited IF-mediated mechanism for cobalamin absorption. The patient is given 1 mg intramuscular nonradioactive vitamin B₁₂ between 0 and 2 hours. This promotes blocking of vitamin B₁₂-binding sites (i.e., transcobalamin), which will lead to excretion of a large portion of the radioactive vitamin B₁₂ into the urine. The patient will collect their urine for 24 hours following administration of the ⁵⁷Co-vitamin B₁₂. Ideally the urine collection should be at least 1 L. Patients with poor function (Cr ≥ 2.5) will require longer collection times of 48 or 72 hours. The patient’s urine sample, a standard, and a background sample will be counted. If radioactive cobalamin excretion is normal ($\geq 6\%$ –9% of administered dose is recovered in urine), there is no evidence of malabsorption, and dietary deficiency is suspected. If excretion is diminished, then the patient should proceed with phase II Schilling test. The procedure for the phase II study is essentially the same, except now IF is given orally with the radioactive vitamin B₁₂. This serves to differentiate IF deficiency from IF-independent causes of malabsorption. If the excretion is still more than 6% to 9%, then IF deficiency is not the cause. If a cause such as pancreatic insufficiency, bacterial overgrowth, tapeworm infection, or if interfering medications are suspected, phase III and phase IV Schilling tests can be performed after oral pancreatic enzymes are added and antibiotic therapy is completed, respectively. Needless to say, this is rarely performed. There are several pitfalls in this test, the most important of which is urine collection. Improper urine collection (e.g., insufficient volume) can falsely lower results. Several sources of error can stem from patient preparation. Another drawback is if the excretion percent is low, then more testing has to be done determine the cause. To help avoid doing a phase II study, a dual isotope Schilling test can be performed. This can be done because the two radioactive cobalts used have different photopeaks (⁵⁷Co, 122 keV; ⁵⁸Co, 811 and 511 keV—one must correct for the downscatter from the ⁵⁸Co into the ⁵⁷Co window). In this procedure, the patient is given a capsule containing 0.25 μ g of 0.8 mCi

radiolabeled ^{58}Co -vitamin B_{12} and 0.25 μg of 0.5 mCi ^{57}Co -vitamin B_{12} bound to IF. The patient preparation and collection procedure is the same. If the B_{12} -IF to B_{12} ratio is greater than 1.4, the cause is IF-dependant vitamin B_{12} deficiency. In this study, one is more interested in the IF-bound vitamin B_{12} to free vitamin B_{12} ratio, so urine collection errors are not as important as in phase I Schilling's test. Another benefit of the dual isotope test is it is a shorter test, and generally additional testing is not needed. The drawbacks include greater dose to patient, increased cost, and potentially performing a test with IF that was not needed. Falsely low B_{12} without true B_{12} deficiency can be caused by folate deficiency, myeloma, aplastic anemia, pregnancy, oral contraceptives, and transcobalamin I deficiency. Falsely normal B_{12} with true B_{12} deficiency can be seen with liver disease, chronic myelogenous leukemia, transcobalamin II deficiency, and recent B_{12} injection.

MOLECULAR IMAGING

Molecular imaging is the ability to characterize and quantify biological processes in living organisms at the cellular or even subcellular level. Based on how much molecular imaging is being touted at national meetings and in the literature, one might think that molecular imaging has only been around for a short time. This is not the case, as in the strictest sense molecular imaging has been around as long as nuclear medicine has been in existence. Following the distribution of radioactive Na^{131}I , $^{99\text{m}}\text{Tc}$ MDP, ^{18}F -FDG, or numerous other radiotracers in physiologic and pathophysiologic processes is molecular imaging that has been around for decades. What has changed in recent times are the scale and the targets of the processes being imaged. As technology has improved, the ability to deliver, image, and resolve smaller molecules has become reality. In addition, the understanding of genetics and molecular biology has aided us in where to target our probes to best image a disease process. This section will review the basic genetic structure and function, as well as the basic design of molecular probes that can target the different processes in the expression of genetic expression.

GENETIC STRUCTURE AND THE CENTRAL DOGMA

It has been more than 50 years since Watson and Crick first determined the molecular structure of DNA, which was known as early as the 1940s to be the primary repository of our genetic information. Four nucleotide bases—adenine, cytosine, guanine, and thymine—are

the building blocks of DNA structure. It is these four bases that are arranged in long sequences to form our genetic code. These bases are made up of a phosphate group, a cyclic deoxyribose sugar, and either a purine base (adenine and guanine) or pyrimidine base (cytosine and thymine). The purine and pyrimidine bases are able to form hydrogen bonds with a specific partner: adenine with thymine and cytosine with guanine. Two strands of nucleotides with complementary base pairs are twisted into shape of double helix. This double helical configuration is achieved through base pair interaction and stacking. It is the sequence of these base pairs in particular locations on the DNA strand, called genes, that are expressed to elude the information contained within the DNA into a functional structure to interact with its environment. Genes make up a genotype, or the hereditary constitution of an organism. These genes, when expressed, lead to the phenotypical appearance of an organism, as a result of the interaction of its genotype and its environment. In the eukaryotic cell, the genetic information is contained within the nucleus. The enormous amount of genetic material (more than three billion base pairs) in the human genome is organized into nucleosomes, the basic unit structure chromosomes. DNA strands are wrapped around positively charged proteins called histones (which are attracted to the negatively charged phosphate groups on the DNA molecule) to ultimately form the nucleosomes. These structures are unwound and compacted as needed for the processes of replication and transcription.

DNA replication typically occurs during the S phase of the cell cycle. The DNA strand itself is unwound and separated by the enzyme DNA helicase. DNA replication is said to be semiconservative, which is to say that each of the two strands of DNA is used as a template for the formation of a new complementary DNA strand. During replication, deoxyribonucleide triphosphates (dATP, dCTP, dGTP, and dTTP) complementary to the template are added sequentially. The growth occurs only in the 5' to 3' direction. DNA polymerases facilitate these reactions. The DNA strand that is read in the 3' to 5' direction is called the leading strand, because replication can grow in the complementary 5' to 3' direction without interruption. The original complementary DNA (in the 5' to 3' direction), however, must be read as a short sequence at a time because of its direction. This is the lagging strand, and its replication results in so-called Okazaki fragments, that are later spliced together by DNA polymerase ϵ . Despite the enormity of the task, there is excellent fidelity in the replication process, with only about 1 error per 10 to 100 billion bases.

The "central dogma" of molecular biology is that DNA is transcribed to RNA, which is then translated to protein. The information contained in the genetic code of DNA

will ultimately be expressed as proteins, which contributes to the structure or function of the organism. As one can imagine, control of this process is intricate and complex.

DNA is sequestered in the nucleus of the cell (there is some extranuclear DNA in the cell, located in the mitochondria—its control and function is beyond the scope of this review). Protein synthesis occurs outside the nucleus, in the ribosome. To deliver the genetic message to this protein factory, the cell will make a copy of a portion of its DNA, but make that copy with RNA. In transcription—the message is the same, it is written in a slightly different “language.” RNA is similar to structure to DNA, the differences being that ribose is the cyclical sugar (as opposed to deoxyribose in DNA), and that pyrimidine base uracil is used instead of thymine. The process of transcription itself is accomplished by RNA polymerases. RNA polymerase II is the polymerase that will produce the RNA template—messenger RNA, or mRNA—that will ultimately lead to protein production. RNA polymerase II will also produce snRNA, which will aid in the processing of mRNA. RNA polymerase I will transcribe DNA to produce particular subunits of ribosomal RNA (rRNA), while RNA polymerase III will transcribe DNA to produce other rRNA subunits and transfer RNA (tRNA). Transcription begins when the RNA polymerase binds to the promoter site, a specific sequence of DNA bases located upstream of the DNA to be transcribed. After this, the DNA is unwound, and transcription can begin. Only one strand of the DNA is used in the transcription process; it is called the template or antisense strand. The other complementary DNA strand is called the coding or sense strand. This strand will have the same code as the transcribed mRNA (with the appropriate thymine—uracil substitutions, of course). The RNA polymerase moves in the 3' to 5' direction. In eukaryotic cells, there are a host of other DNA-binding sites, as well as proteins called transcription factors that interact with RNA polymerase and adjacent areas within the chromatin, that contribute to the process of transcription. There are sequences on the DNA upstream of the main promoter that will bind proteins to further promote and enhance transcription. These enhancers will increase the level of transcription. There are also sequences that will reduce the amount of transcription called repressor sequences.

The mRNA that results from the process of transcription is not the mRNA that will leave the nucleus to be translated into protein. Instead, this “pre-mRNA” must first be processed to its final form. First, a cap (in the form of 7-methylguanosine) is placed on the 5' end of the pre-mRNA to make it resistant to degradation. Next, a polyA tail (numerous adenine residues) is added to the end of the transcript. This pre-mRNA as originally transcribed consists of areas that will ultimately be used (exons)

and ultimately discarded (introns). This splicing will be accomplished by the spliceosome—a complex of numerous proteins and snRNA. Specific nucleotide sequences in the intron key the spliceosome as to where to cut. Splicing must be precise, as the leaving behind or deletion of even one nucleotide can change the protein that would be ultimately produced. Where the splice does occur can change in a tightly regulated process depending on the needs of the cell, enabling many different proteins to be produced from a particular sequence of DNA.

Once transcribed and modified, this mRNA is free to leave the nucleus and travel to the ribosome. It will be translated there into the language of amino acids and proteins. It is interesting to contemplate that the incredible complexity of an organism is in essence the result of precise combinations of just 20 amino acids (and that these are directed by sequential combinations of four bases). The proteins produced either provide cell and organ structure, or will catalyze reactions as enzymes to further the function and form of the organism.

The “interpreters” that translate the mRNA message are the ribosomes. Ribosomes are a combination of proteins and rRNA. There are different subunits that come together to form a complete ribosome: in the eukaryotic cell they are the 60 S and 40 S subunits (where S represents the Svedberg unit, a measure of sedimentation coefficient). The complete ribosome has binding sites for mRNA and for tRNA. There are two binding sites for tRNA in the ribosome, the so-called P (for *peptidyl*) site and A (for *aminoacyl*) site. These sites are adjacent to each other, allowing the reading of two adjacent codons. The tRNAs are the molecules that carry individual amino acids. There is a specific tRNA for each possible codon (triplets of bases read from the mRNA), except for the three stop codons. There is only one start codon, and this codon codes for the amino acid methionine. Beyond the 4 just mentioned, there are 60 other possible triplet combinations. Recall that there are only 20 amino acids—more than 1 codon can code for a particular amino acid. In this way, the genetic code is said to be “degenerate.” The degeneracy is located at the third position in the codon—for example, UGU and UGC both code for the amino acid cysteine. Amino acids are added to their specific tRNA by the enzyme aminoacyl-tRNA synthetase to form aminoacyl-tRNA.

In order for the process of translation to begin, recognition of the start codon by the ribosome, as well as an additional specific sequence near the start codon, must be achieved. Once the mRNA-ribosome-methionine-tRNA complex is formed, additional factors are needed to begin and continue the process of translation. These factors are initiation factors, elongation factors, and termination (or release) factors. Once the initiation complex is formed, and the methionine-tRNA occupies the P site of the ribosome, the tRNA with the complementary

anticodon to the next mRNA codon finds its way to the A site on the ribosome. A combination of elongation factors and enzymes present in the ribosome will form a peptide bond between the two amino acids. Once this occurs, additional enzyme/factors will eject the tRNA at the P site, while passing its amino acid to the aminoacyl-tRNA at the A site. This complex is then moved to the P site, and the mRNA is moved one codon. This process repeats itself until a stop codon is reached. At that time, release factors will recognize the stop codon, and the polypeptide chain is transferred to a water molecule. The mRNA is released, to be either translated again or degraded.

As purine and pyrimidine bases were the unit structures of DNA and RNA, amino acids are the unit structures of proteins. They all have a central carbon atom, to which is attached a hydrogen, a carboxyl group, and an amino group. Where they differ is at the fourth position, the side chain. These are grouped into nonpolar, polar, acidic, and basic side chains based on their chemical properties. The chain of amino acids, called a polypeptide, will eventually form a particular three-dimensional structure. There are four levels of structure in a protein. The first is the amino acid sequence itself. This will ultimately determine the form the polypeptide will have in the aqueous environment of the cell. The secondary level of protein structure is determined by hydrogen bonding between the amino and carboxyl groups of nearby amino acids. The most common forms of secondary structure in proteins are the alpha-helix and the beta-pleated sheet. The R side chain interactions, along with folding and interacting of the alpha-helices and the beta-pleated sheets, will contribute to the three-dimensional shape, or tertiary structure, of the polypeptide. Quaternary structure of a protein is the result of interactions of multiple polypeptides.

Once a protein is formed, it can be further modified by the apparatus of the cell. Disulfide bonds can be formed to strengthen tertiary or quaternary structure; sugars and/or lipids can also be added to specific amino acid residues in posttranslational modification of the protein. These proteins can then be used in the cell as enzymes or structural proteins, incorporated into the cell membrane for a variety of functions, or secreted from the cell.

MOLECULAR IMAGING PROBES

In general, current imaging for disease processes requires that the pathologic process be of a sufficient macroscopic size (usually on the order a few millimeters), or sufficiently disruptive of function (e.g., altered blood flow leading to contrast enhancement), that it can be detected by conventional imaging modalities. It

would be considerably better for the patient if the disease process could be found before it led to these macroscopic changes. If a way could be found to target mutations in genetic material for a particular disease, one could potentially catch a disease at an earlier stage, where treatment could be more effective. Of course, the next logical step would be to tailor a treatment to fix or eradicate that same aberrant gene or genes. First things first, though, although there have been many advancements in a relatively short time, there is still progress that needs to be made in the development of probes for a particular target, delivery systems to the target, and systems capable of imaging these probes. Molecular imaging can be defined as is the *in vivo* visualization of normal and abnormal cellular processes at a molecular or genetic level of function. It is used to provide characterization and measurement of biological processes in both spatial and time relations. Targets that can be imaged range from genes to mRNA to proteins. While it might seem to make the most sense to target a particular gene directly, there are many more copies of the transcripts or translations of that gene available for the probe to attach to. The molecular target that has the most copies available is the protein. The protein target may be a membrane receptor, an intracellular receptor, an enzyme, or a transporter. Some examples of this are already widely used in nuclear medicine. ^{111}In pentetreotide (Octreoscan) is a chelated peptide that targets somatostatin receptors, ^{111}In capromab pendetide (ProstaScint) is a monoclonal antibody that targets the prostate-specific membrane antigen, and ^{111}In ibritumomab tiuxetan (Zevalin) is a monoclonal antibody that targets the B-lymphocyte CD20 receptor (and is used as part of a regimen to treat non-Hodgkin lymphoma). ^{18}F FDG is transported across a cell's membrane by GLUT-1 transporter. Once inside the cell, it is phosphorylated to ^{18}F -FDG-6-phosphate by hexokinase. Further metabolism of this substrate is not possible by the cell; it is trapped inside the cell. ^{18}F -FDG therefore is used to measure glucose metabolism, "targeting" the increased expression and activity of the GLUT-1 transporter and hexokinase. Targeting is in quotations, as unlike the first two examples, it is not directed at a particular object, but rather is the nonspecific process of glucose metabolism, which can be seen in physiologic, inflammatory, or malignant processes. Targeted probes are specific in that they bind with high affinity with the substrate of interest. Ideally, they are cleared from background tissues quickly (giving good target-to-background ratio) and have minimal nonspecific or random binding.

Radiopharmaceuticals listed in the chapter demonstrate the common configuration that all molecular probes share, whether in nuclear medicine, or using

other imaging modalities. First, there has to be a substrate that will bind to or otherwise interact with the target to properly localize the event that one wishes to image. The second part of the probe is the “beacon,” a substrate that can send a signal to allow for localization within an organism. In nuclear medicine, this is a radionuclide, but chelated Gd^{+3} (for T1 contrast) or superparamagnetic iron oxide nanoparticles have been used in molecular beacons in MRI. It is also possible to make molecular probes for optical imaging. Optical imaging uses fluorescent and bioluminescent probes that emit radiation in the visible or near-infrared wavelengths, which can be scanned by optical cameras. Unfortunately, light can travel only a few millimeters through tissue so it is limited to imaging skin, breast, and small animals (for research applications), as well as in surgical and endoscopic procedures. Near-infrared fluorescence is preferred, as there is the least absorption from tissues at this wavelength. Fluorescence from the tissues themselves is minimal at this wavelength as well. This wavelength can penetrate a depth of a few centimeters.

As of now, targeted molecular probes in ultrasound remain in the realm of research. However, nontargeted microbubbles made of lipids or proteins, and filled with a nonreactive gas that has low solubility in tissues, can be used in clinical practice to determine parameters such as blood flow and volume (e.g., tumor angiogenesis) in particular structures. By placing, for example, antibodies on the surface of the microbubbles, one can gain the specificity for a particular process or substrate to make it a targeted molecular probe.

So-called smart probes have been developed that will only function when particular parameters are met, such as the presence of a particular enzyme to catalyze a reaction. These smart probes are frequently used in optical imaging, although some MRI smart probes have been developed. The beacon does not “light” until acted on by a particular physiologic condition (e.g., change in pH) or more often, until a particular enzyme is present. Because of this, there is excellent target-to-background ratio. The most common example is the use of a smart probe to detect a particular protease. When this protease has not been expressed by the cell or organism, there is no detectable signal. If, however, the protease is present, it will cleave a specific site on the probe, removing a “quencher” and allowing the fluorescent molecule to become visible.

REVIEW MATERIALS

The last four tables in this chapter are charts that have been put together for both radiology and nuclear med-

icine residents to help summarize the myriad radionuclides and studies they struggle to master over the course of their residency. Table 99-4 is a list of acronyms used in nuclear medicine. Table 99-5 summarizes common radionuclides used in nuclear medicine, listed in alphabetical order. It includes half-lives, photopeaks, and chemical forms of the radionuclides. Table 99-6 is sorted by nuclear medicine study, and includes radiopharmaceutical used, route of administration, and other information specific to the study. Table 99-7 lists ^{99m}Tc radiopharmaceuticals and their applications.

TABLE 99-4 Acronyms Used in Nuclear Medicine

Instrumentation/Terms	
ADC	Analog-to-digital converter
AOR	Axis of rotation
COR	Center of rotation
CPU	Central processing unit
CRT	Cathode ray tube
DICOM	Digital communication standard
EDTA	Ethylenediaminetetra-acetic acid
ERPF	Effective renal plasma flow
FWHM	Full width at half maximum
LEAP	Low-energy all-purpose (collimator)
MUGA	Multigated acquisition
PET	Positron emission tomography
PHA	Pulse height analyzer
PMT	Photomultiplier tubes
RAM	Random-access memory
ROM	Read-only memory
ROR	Radius of rotation
SDAT	Senile dementia, Alzheimer's type
SPECT	Single-photon computed tomography
Radiotracers	
18-FDG	18-F fluorodeoxyglucose
DMSA	Dimercaptosuccinic acid
DTPA	Diethylenetriaminepentaacetic acid
EDC	Ethylene L-cysteinate dimer (Neurolite)
HMPAO	Hexamethylpropyleneamine oxime (Ceretek)
IDA	Iminodiacetic acid
MAA	Macroaggregated albumin
MAG3	Mercaptoacetyltriglycine
MDP	Methylene diphosphonate
MIBG	Metaiodobenzylguanidine
MIBI	Sestamibi (Cardiolite)
OIH	Orthiodohippurate
SC	Sulfur colloid

TABLE 99-5 Common Radionuclides Used in Nuclear Medicine

NUCLIDE	Z	P*	T1/2	DECAY†	MAJOR EMISSIONS§	CHEMICAL FORM(S)	USES
Carbon-11	6	A	20 m	β+	γ 511 keV, β+ .96 MeV	¹¹ C acetate; ¹¹ C palmitate; ¹¹ C carfentanil	PET metabolic agents; receptor binding
Chromium-51	24		27.8 d	EC	γ 320 keV	⁵¹ Cr EDTA	Red cell mass
Cobalt-57	27	A	272 d	EC	γ 122 keV	⁵⁷ Co vitamin B ₁₂	Schilling test
Fluorine-18	9	A†	109 m	EC, β+	γ 511 keV; β+ .64 MeV	¹⁸ F- fluorodeoxyglucose; ¹⁸ F sodium fluoride	Metabolic/tumor agent Metabolic agent
Gallium-67	31	A	78 h	EC	γ 93, 184, 296, 388 keV	Gallium citrate	Inflammatory disease detection; tumor localization
Gallium-68	31	G†	68 m	EC, β+	γ 511 keV	Gallium citrate	
Indium-111	49	A	67 h	EC	γ 172, 247 keV	Labeled WBC; labeled antibodies, proteins and peptides ¹¹¹ In pentetreotide (OctreoScan) ¹¹¹ In DTPA	Inflammatory disease detection; tumor localization Somatostatin receptor analog Cisternogram; liquid phase gastric emptying
Iodine-123	53	A	13 h	EC	γ 159 keV	Sodium iodide	Thyroid scintigraphy; thyroid uptake/function
Iodine-131	53	R	8 d	β−	γ 284, 364, 637; β− 0.19 MeV	Iodoamphetamine Sodium iodide Tositumomab (Bexxar)	Cerebral perfusion scintigraphy Thyroid CA scintigraphy; thyroid uptake/function Treatment of relapsed/refractory NHL
Molybdenum-99	42	R	66.7 h	β−	γ 181, 740, 778 keV	NP-59, MIBG Ionically bound to alumina (Al ₂ O ₃) column	Adrenal imaging Technetium 99 m generator
Nitrogen-13	7	A	10 m	β+	γ 511 keV	¹³ N ammonia; ¹³ N glutamate	PET perfusion agent; metabolic agent
Oxygen-15	8	A	124 s	β+	γ 511 keV	¹⁵ O- CO ₂ , ¹⁵ O- water; ¹⁵ O- oxygen	PET perfusion agents; metabolic agent
Phosphorus-32	15	R	14 d	β−	β− 695 keV, 1.7 MeV	Sodium phosphate	Palliation of bone metastases; PCV therapy
Rubidium-82	37	G†	1.3 m	EC, β+	γ 511 keV, 777 keV	⁸² Ru chloride	PET cardiac perfusion agent
Samarium-153	62	A	1.9 d	β−	β− 233 keV; γ 103 keV	¹⁵³ Sm- leixidronan/ ¹⁵³ Sm- EDTMP	Palliation of bone metastases
Strontium-89	38	R	50.5 d	β−	β− 1.46 MeV	⁸⁹ Sr- chloride	Palliation of bone metastases
Technetium-99 m	43	G	6 h	IT	γ 140 keV	Multiple	Variable
Thallium-201	81	A	73 h	EC	69–81 keV¶	Thallous chloride	Myocardial perfusion scintigraphy; tumor imaging
Xenon-133	54	R	5.3 d	β−	γ 81 keV	Inert gas	Pulmonary ventilation scintigraphy
Yttrium-90	39	R	64.2 h	β−	β− 937 keV	⁹⁰ Y- ibritumomab tiuxetan (Zevalin)	Treatment of relapsed/refractory NHL

*Produced: A = accelerator; G = generator; R = reactor.

†Given the fact that this isotope is generator produced and/or has a (relatively) long half-life, a cyclotron need not be on premises for use of this nuclide.

‡β+ = positron; β− = negatron or beta decay; EC = electron capture; IT = isomeric transformation.

§Underlined value is the commonly imaged photopeak(s).

¶Major emissions are characteristic x-rays of daughter product, mercury-201 (²⁰¹Hg).

TABLE 99-6 Brief Summary of Nuclear Medicine Study Parameters

STUDY	RADIOPHARMACEUTICAL	ADMINISTERED	DOSE TO IMAGE TIME	SPECIAL
Adrenal medullary	^{131}I MIBG/ ^{123}I MIBG	IV	24–72 h	Lugol solution for patient
Bone marrow	$^{99\text{m}}\text{Tc}$ sulfur colloid	IV	Immediate	
Bone scan	$^{99\text{m}}\text{Tc}$ MDP	IV	Immediate (3 phases), 2–3 h	
Brain death	$^{99\text{m}}\text{Tc}$ HMPAO or ECD	IV	Flow and immediate static	
Brain SPECT	$^{99\text{m}}\text{Tc}$ HMPAO or ECD	IV	15 min or later	
Cardiac PET	^{18}F -FDG	IV	45–60 min	Cardiac viability; glucose loading + insulin needed
Cardiac PET	^{82}Rb	IV	Immediate	Cardiac perfusion
Cardiac SPECT	$^{99\text{m}}\text{Tc}$ sestamibi	IV	1–4 h	Planar—increase dose
Cardiac SPECT	$^{99\text{m}}\text{Tc}$ tetrofosmin	IV	30 min–1 h	Planar—increase dose
Cardiac SPECT	^{201}Tl chloride	IV	Immediate (poststress), 3–4 h	Cardiac viability, 4- to 24-h delays
Cisternogram	^{111}In - DTPA	Subarachnoid	2, 6, 24, 48, 72 h as needed	Pledgets for CSF leak
Gallium	^{67}Ga citrate	IV	48–72 h	Use 5 mCi for infection, image at 24 h
Gastric emptying	$^{99\text{m}}\text{Tc}$ sulfur colloid	PO(with egg)	Immediate, image 1 h	Use ^{111}In DTPA for liquid phase
GI bleed	$^{99\text{m}}\text{Tc}$ tagged RBCs	IV	Immediate (3-h delay if needed)	Can also use $^{99\text{m}}\text{Tc}$ SC
Hemangioma	$^{99\text{m}}\text{Tc}$ tagged RBCs	IV	Immediate	SPECT improves sensitivity
HIDA	$^{99\text{m}}\text{Tc}$ DISDA or mebrofenin	IV	Immediate (3-h delay if needed)	Vary dose with bilirubin
LeVeen shunt	$^{99\text{m}}\text{Tc}$ MAA	Intraperitoneal	Immediate, 1-h delay (lungs)	
Liver/spleen	$^{99\text{m}}\text{Tc}$ sulfur colloid	IV	20 min	Rib margin marker on AP images
Lung perfusion	$^{99\text{m}}\text{Tc}$ MAA	IV	Immediate	Lower dose if done before vent.
Lung ventilation	^{133}Xe	Inhaled	Immediate	Posterior views
Lung ventilation	$^{99\text{m}}\text{Tc}$ DTPA aerosol	Inhaled	Immediate	
Lymph Node scintigraphy	$^{99\text{m}}\text{Tc}$ filtered sulfur Colloid	Intradermal	Immediate up to 1 h	Identify sentinel LN
Meckel's	$^{99\text{m}}\text{Tc}$ Na pertechnetate	IV	Immediate	
MUGA	$^{99\text{m}}\text{Tc}$ tagged RBCs	IV	Immediate	Gated images
Octreotide	^{111}In pentetreotide	IV	4 h and 24 h	SPECT improves sensitivity
Parathyroid	$^{99\text{m}}\text{Tc}$ sestamibi	IV	15 min, 2 h (and 4 h if needed)	Pinhole or SPECT improve detection
PET oncology	^{18}F -FDG	IV	1 h	
ProstaScint	^{111}In capromab pendetide	IV	96 h	Will need $^{99\text{m}}\text{Tc}$ tagged RBC too
Renal-cortical	$^{99\text{m}}\text{Tc}$ DMSA	IV	1–3 h	Also $^{99\text{m}}\text{Tc}$ glucoheptonate
Renal-GFR	$^{99\text{m}}\text{Tc}$ DTPA	IV	Immediate	
Renal-tubular	$^{99\text{m}}\text{Tc}$ MAG-3	IV	Immediate	Used to approximate ERPF
Testicular	$^{99\text{m}}\text{Tc}$ Na pertechnetate	IV	Immediate and 15 min delayed	
Thyroid scan	$^{99\text{m}}\text{Tc}$ Na pertechnetate	IV	15–30 min	Trapped but not organified
Thyroid scan	Na^{123}I	PO	4–24 h	Trapped and organified
Thyroid uptake	Na^{131}I	PO	4 h and 24 h if needed	If probe used, no pictures obtained
Thyroid uptake	Na^{123}I	PO	4 h and 24 h if needed	If probe used, no pictures obtained
Thyroid WB	Na^{131}I	PO	24–72 h	Withdraw Sythroid or give rTSH
Thyroid WB	Na^{123}I	PO	24–48 h	Withdraw Sythroid or give rTSH
Thyroid WB	Na^{131}I	PO	7 d	Post high-dose therapy
WBC scan	$^{99\text{m}}\text{Tc}$ HMPAO	IV	1 and 4 h (24 h if needed)	Also ^{111}In WBC

TABLE 99-7 Nuclear Medicine Studies Sorted by Technetium Agent

^{99m} Tc AGENT	APPLICATION*
^{99m} Tc arcitumomab (CEA scan)	[Monoclonal antibody for colorectal cancer evaluation]
^{99m} Tc bicisate (Ethylene L-cysteinate dimer or ECD) [†]	SPECT cerebral perfusion imaging
^{99m} Tc bromotriethyl IDA (Mebrofenin)	Hepatobiliary scintigraphy
^{99m} Tc diethylenetriamine-pentaacetic acid (DTPA)	Lung ventilation (aerosol), renal scintigraphy, GFR, cisternography, shunt patency [brain scintigraphy; blood volume]
^{99m} Tc dimercaptosuccinic acid (DMSA)	Renal cortical scintigraphy
^{99m} Tc diphosphonate (MDP)	Skeletal scintigraphy
^{99m} Tc disopropyl IDA (DISIDA)	Hepatobiliary scintigraphy
^{99m} Tc exametazime (HMPAO) [‡]	SPECT cerebral perfusion imaging, tagging agent for WBC studies
^{99m} Tc glucoheptonate	Renal scintigraphy [brain/CSF]
^{99m} Tc macroaggregated albumin (200–600 k particles)	Pulmonary perfusion scintigraphy
^{99m} Tc mercaptoacetyl triglycine (MAG3)	Renal scintigraphy, ERPF
^{99m} Tc red blood cells	GI bleeding detection, ventriculography (MUGA), hepatic hemangioma detection
^{99m} Tc sestamibi (Cardiolite)	Myocardial perfusion imaging {15–30 mCi (2-d protocol); 8–10 mCi rest/20–30 mCi stress (1-d protocol)}; parathyroid scintigraphy [breast cancer imaging]
^{99m} Tc sodium pertechnetate	Thyroid gland scintigraphy, Meckel diverticulum detection, testicular imaging [salivary gland scintigraphy]
^{99m} Tc sulfur colloid (filtered particle size .3 to 1.0 μm)	Liver/spleen (RES) scintigraphy, GI bleeding detection (tagged RBC is preferred method), gastric emptying, bone marrow scintigraphy
^{99m} Tc sulfur colloid (filtered particle size .03 to .1 μm)	Lymphoscintigraphy
^{99m} Tc tetrofosmin (Myoview)	Myocardial perfusion imaging (see sestamibi protocols)

*Applications in square brackets, “[]”, indicate rarely used or historical uses of the agent. Numbers in set brackets, “{ }”, are ranges of activity for adult patients; pediatric doses are often weight based.

[†]Neurolite (trade name)

[‡]Hexamethylpropylenamine oxime or Ceretec (trade name)

QUESTIONS AND ANSWERS

1. A patient has laboratory findings consistent with hyperthyroidism, with an elevated T₄ and suppressed TSH. When a radioactive iodine uptake test is performed, the uptake is 4%. Which of the following conditions does the patient likely have?
 - A. Graves disease
 - B. Toxic multinodular goiter
 - C. Toxic hyperfunctioning adenoma
 - D. Subacute thyroiditis

ANSWER: D. Subacute thyroiditis. It is not unusual that by the time the patient has the radioactive iodine uptake study, the T₄ released as a result of the thyroiditis has caused a feedback decrease in TSH secretion. This would lead to decreased radioiodine uptake. All of the other choices would most likely result in an elevated radioiodine uptake.

2. Of the following agents, which will interfere with radioactive iodine uptake for the *longest*?
 - A. Propylthiouracil
 - B. Thyroxine
 - C. Intravenous iodine contrast
 - D. Triiodothyronine

ANSWER: B. Thyroxine (Synthroid), which is T₄, will interfere the longest.

3. What is the purpose of administering 1-mg intramuscular nonradioactive vitamin B₁₂ immediately after administering the radiolabeled vitamin B₁₂?
 - A. This promotes radiolabeled vitamin B₁₂ uptake in the gut.
 - B. This interferes with radiolabeled vitamin B₁₂ uptake in the gut.
 - C. This promotes urinary excretion of radiolabeled vitamin B₁₂.
 - D. This will stimulate IF production in the patient.

ANSWER: C. This promotes urinary excretion of radiolabeled vitamin B₁₂. If the patient was given vitamin B₁₂ within 3 days before the test, this may decrease the fractional absorption of the test dose. This is due to biliary excretion of that parenteral vitamin B₁₂ into the GI tract.

4. When handing you the results of a patient's radioactive iodine thyroid uptake, the technologist tells you that he just realized that he forgot to include the counts from the patient's thigh in his calculations. How would this affect the computed radioiodine uptake value?

A. Result will be underestimated compared to the true value.
B. Result will be overestimated compared to the true value.
C. Will not affect the result
D. Cannot know what effect it will have on the result

ANSWER: D. Cannot know what effect it will have on the result. In this situation, the only body part counted in the patient is the neck. The thigh counts are used to account for activity in the neck that is not coming from the thyroid gland, but rather from background activity in the other structures of the neck. If the thyroid uptake was high, then you in essence have thyroid counts/(standard in phantom – room background) and there would be a slight underestimation. If the thyroid uptake is low, then patient background would be high, meaning there would be counts coming from the neck that were not really coming from the thyroid, overestimating the uptake.

5. Which of the following will *not* result in an abnormal part I Schilling test?
- A. Dietary deficiency
B. Pernicious anemia
C. Crohn's disease
D. Sprue

ANSWER: A. Dietary deficiency. Pernicious anemia would cause the uptake of ^{57}Co vitamin B₁₂ to be low in the part I test; it would be normal in part II, when IF is provided. Malabsorption from either Crohn's disease or sprue would interfere with ^{57}Co vitamin B₁₂ uptake in the ileum.

6. A referring physician calls you to ask how long their patient should discontinue their methimazole. What would your response be?
- A. No need to discontinue
B. 1 day
C. 1 week
D. 1 month

ANSWER: C. 1 week.

7. The genetic code is said to be degenerate because
- A. Error rate of DNA is 1 in each 10–100 million bases.

B. More than one triplet can specify the same amino acid.
C. Only 1% to 2% of the three billion base pairs in the human genome encodes for proteins.
D. It probably will never amount to much.

ANSWER: B. More than one triplet can specify the same amino acid. Fidelity in DNA replication is excellent, with 1 error per 10 to 100 billion bases. While it is true that only 1% to 2% of the base pairs in the human genome encode for proteins, this is not why the code is called degenerate.

8. The central dogma of molecular biology is that:
- A. DNA is transcribed to mRNA, which is translated to protein.
B. DNA is translated to mRNA, which is transcribed to protein.
C. DNA is translated to rRNA, which is transcribed to protein.
D. The genetic code is degenerate.

ANSWER: A. DNA is transcribed to mRNA, which is translated to protein.

9. ProstaScint is a type of molecular probe used to detect prostate cancer. It is a monoclonal antibody that targets _____, and uses _____ as its beacon.
- A. Prostate-specific antigen (PSA); ^{111}In
B. Prostate-specific membrane antigen (PSMA); ^{111}In
C. Prostate-specific antigen (PSA); $^{99\text{m}}\text{Tc}$
D. Prostate-specific membrane antigen (PSMA); $^{99\text{m}}\text{Tc}$

ANSWER: B. ProstaScint is a monoclonal antibody directed against a glycoprotein expressed by prostate epithelium known as prostate-specific membrane antigen (PSMA). It uses ^{111}In as its radionuclide.

10. Which of the following wavelengths is the best choice for optical imaging molecular probes?
- A. All wavelengths are equally useful
B. Ultraviolet
C. Visible light
D. Near-infrared

ANSWER: D. Near-infrared has the least absorption by organs and tissues, and has better penetration in tissues.

*Brenton D. Reading and
Robert P. Nuttall*

DEVELOPMENTAL/IDIOPATHIC ABNORMALITIES

BLOUNT DISEASE

Blount disease is a developmental deformity of the tibia, also known as tibia vara. Its etiology uncertain but it is likely caused by sequelae of developmental bowing, which does not correct. Normal bowing is seen up to 3 years of age, which then progresses to genu valgum in 3 to 5 years of age. Subsequently, normal posture should be achieved. If not, surgical correction with epiphysiodesis is often required to correct the persistent bowing.

DEVELOPMENTAL DYSPLASIA OF THE HIP

Developmental dysplasia of the hip (DDH) can range from mild acetabular dysplasia to irreducible dislocation of the femoral head. The incidence is approximately 1:1000 and is more common in girls than boys (8:1). The left hip is much more commonly affected than the right hip (70%–75%). There is bilateral involvement in 5% of patients. Ultrasound is the study of choice in children younger than 6 months of age as radiographs are not very useful. However, after 6 months of age, ossification of the femoral head makes ultrasound less useful. High-risk patients include those with a family history of DDH, breech delivery, oligohydramnios, as well as neuromuscular and foot abnormalities. Physical findings include positive hip click with dislocation and relocation

(Barlow and Ortolani maneuvers respectively), shortened leg with decreased abduction, and asymmetric gluteal folds.

Radiographic features of DDH include late or asymmetric femoral head ossification (normal femoral head ossification typically occurs between 3 and 7 months, earlier in girls; 90% are ossified by 7 months); positioning of the femoral head lateral to the Perkins line and superior to the Hilgenreiner line; and abnormal curve of Shenton line. The Hilgenreiner line is a horizontal line drawn through the triradiate cartilage; the Perkins line is drawn perpendicular to the Hilgenreiner line at the outer acetabular edge; the Shenton line is a sinuous arch extending along obturator foramen to the medial femoral neck. US indicators of DDH are an alpha angle less than 60 degrees and a shallow acetabulum.

JUVENILE RHEUMATOID ARTHRITIS (JUVENILE IDIOPATHIC ARTHRITIS)

Juvenile rheumatoid arthritis (juvenile idiopathic arthritis) is a chronic polyarthritis, most commonly involving large joints such as the knees and wrists. This most commonly presents within the first 5 years of life and is more common in females than males. Erosion of the dens and atlantoaxial subluxation can occur. The systemic form is called Still disease, with symptoms including polyarthritis, splenomegaly, myocarditis or pericarditis, lymphadenopathy, and fever.

LEGG-PERTHES

Legg-Perthes is an idiopathic avascular necrosis of the femoral head. It usually presents with knee pain and limp. It is more frequent in boys than girls (5:1), and it is bilateral approximately 15% of the time. Onset before 6 years of age usually results in better outcome. Early radiographic findings include a patchy trabecular pattern, widening of the joint space, crescent sign, marrow

edema on MRI, and contrast enhancement. Chronic findings include coxa plana and coxa magna, fragmentation/collapse of the capital femoral epiphysis, physeal growth arrest, and short femoral neck.

NEWBORN PERIOSTEAL REACTION

Newborn periosteal reaction may be normal or pathologic. Physiologic periosteal reaction is usually symmetric and commonly occurs in the first few months of life, typically involving the long bone diaphyses. Prostaglandin use and TORCH infections (Table 100-1) can cause periosteal reaction. Caffey disease is an idiopathic, self-limiting condition usually occurring in the first few months of life with periosteal new bone and adjacent soft-tissue swelling. The areas involved include the mandible, ribs, scapula, clavicles, femurs, humerus, radius, and ulna. In addition, metastatic disease, especially from neuroblastoma must also be considered as a cause for diffuse periosteal reaction.

OSGOOD-SCHLATTER DISEASE

The etiology of Osgood-Schlatter disease is controversial. The most likely cause is related to traction on the tibial tuberosity during growth resulting in microfractures with avulsion and tearing at the insertion of the patellar tendon. The tibial tubercle region is commonly irregular with multiple bony fragments.

PROXIMAL FOCAL FEMORAL DEFICIENCY

Proximal focal femoral deficiency is a congenital abnormality involving variable degrees of deficiency of the proximal portions of the femur. This can also involve the acetabulum and the femoral head in severe cases. The patient presents with leg-length discrepancy. The fibula may be absent and the foot is often deformed.

TABLE 100-1 TORCH Infections

Toxoplasmosis
Hepatitis B
Syphilis
Varicella-Zoster
HIV
Parovirus
Rubella
Cytomegalovirus
Herpes virus

SCOLIOSIS

Congenital scoliosis is secondary to congenital spinal anomalies such as hemivertebra and butterfly vertebra. Neuromuscular scoliosis is common in cerebral palsy. It is typically a C-shaped scoliosis without a compensatory curve because of the lack of weightbearing. Idiopathic scoliosis has a typical S-shaped curve, consisting of a thoracic dextroscoliosis and a lumbar levoscoliosis. Multiple forms of idiopathic scoliosis exist including infantile, juvenile, and adolescent types. Adolescent is the most common type and frequently occurs in females. Surgical treatment is generally reserved for greater than 40-degree curvature. Nonidiopathic scoliosis has numerous causes including spinal pathology such as tethered cord, syrinx, and tumor; spinal bony lesions such as osteoid osteoma and osteoblastoma; metastatic disease; osteomyelitis; Langerhans cell histiocytosis; neurofibromatosis; postirradiation changes; and leg-length discrepancy.

SLIPPED CAPITAL FEMORAL EPIPHYSIS

Slipped capital femoral epiphysis (SCFE) is similar to a Salter-Harris I fracture involving the proximal femoral physis which presents in adolescents with hip or knee pain. It is twice as common in males and is usually idiopathic or occasionally posttraumatic. Bilateral involvement is not rare but often presents in an asynchronous pattern. There is increased incidence in renal osteodystrophy, hypothyroidism, and hypopituitarism, as well as obesity. Femoral head displacement is posterior and medial. A frogleg view is crucial for diagnosis; the neutral view can appear normal. A line drawn tangential to the lateral cortex of the femoral neck should intersect a portion of the femoral head; if not, SCFE is likely. Surgical intervention involves pin fixation. Avascular necrosis, premature osteoarthritis, and chondrolysis are potential complications.

TALIPES EQUINOVARUS (CLUBFOOT)

The frequency of clubfoot is approximately 1 to 4:1000, with occurrence in males approximately twice that in females. The feet are affected bilaterally approximately 30% to 50% of the time. Clubfoot presents with hindfoot equinus with a decreased lateral talocalcaneal angle less than 35 degrees, hindfoot varus with a decreased talocalcaneal angle less than 20-degrees AP, and forefoot varus with medial displacement of first metatarsal relative to the long axis of the talus. Clubfeet may be corrected with manipulation, casting, and splinting alone. Cases that respond poorly to splinting and manipulative treatment require operative management.

TOXIC SYNOVITIS

Toxic synovitis is a diagnosis of exclusion. It is most common in children younger than 10 years. Joint effusion is present but no evidence of bacteria, virus, or inflammatory change is identified. The etiology is likely viral. The associated pain usually subsides with rest.

INFECTION

DISCITIS

Discitis is often secondary to hematogenous seeding and commonly involves adjacent vertebral endplates. It is most common in children from 6 to 10 years of age and is most common in the lumbar region. Vertebral body osteomyelitis is more common in adults since adult disks are avascular.

OSTEOMYELITIS

The typical locations of osseous infection are age-related. In infants, the primary site is metaphyseal with potential extension to the epiphyses. Epiphyseal involvement can occur up to approximately 18 months of age, at which time the appearance of epiphyseal ossification centers prevents access to these regions. In children up to the age of skeletal maturity, a metaphyseal location is most common because of slow blood flow in this region. The femur is the most frequently affected bone, followed by the tibia and humerus. Multifocal involvement can be seen in neonates and infants.

Bony changes may not be seen for 10 to 14 days or routine radiographic analysis. A nuclear medicine bone scan is more sensitive in this time period. Modes of transmission include hematogenous; direct extension secondary to cellulitis and sinusitis; and direct implantation secondary to open injury, foreign body penetration, and postoperative complications. Common pathogens include *Staphylococcus aureus*, group B *streptococcus*, especially in neonates, as well as *Salmonella* or *Strep pneumoniae* in sickle cell patients. Fungal or mycobacterial involvement can also be seen in immunocompromised patients. Joint space involvement can occur with intra-articular metaphyses, such as the hip, elbow, and shoulder. Brodie abscesses are chronic, circumscribed areas of osteomyelitis which most commonly occur in the femur or tibia and are more commonly metaphyseal than diaphyseal.

SEPTIC ARTHRITIS

Septic arthritis is bimodal in distribution typically occurring in infants or teenagers and most cases occur in children younger than 3 years of age. The most commonly affected joints are the hip and knee. Septic arthritis presents with pain on joint movement and refusal to walk. *S. aureus* and group A *streptococcus* are the most common agents. There is significant potential for joint destruction. Spread is typically from the adjacent metaphysis with hematogenous seeding of the synovial vasculature. Radiographic findings are related to effusions and synovial inflammation. Findings at the hip include an increased teardrop distance measured from medial cortex of femoral metaphysis to “teardrop” of acetabulum. A distance of greater than 2 mm compared with the uninvolved hip is worrisome.

METABOLIC BONE DISEASE

RICKETS

Rickets in children is the result of a disruption in the pathway of either vitamin D or phosphate metabolism. Defective mineralization in developing bone causes osteomalacia. The most common cause is a vitamin D deficiency. A diet lacking in calcium or phosphorus may also produce rickets. Widening and cupping of the metaphyses is noted, most prominent at the knee because growth is most rapid in this location. Noncalcified osteoid along the shaft leads to the appearance of periosteal lifting. Coarsening of trabeculae is noted in contrast to the ground glass osteopenia of scurvy. Bones may become bowed because of softening and weight-bearing as well as green stick type fractures. Similar findings are seen in pediatric renal osteodystrophy and secondary osteopenia.

NEOPLASMS

BENIGN OSSEOUS LESIONS

For benign osseous lesions, see Tables 72-1 to 72-3.

ENCHONDROMAS

These are benign cartilaginous growths, most frequently seen between 10 and 40 years of age. The radiographic findings of an enchondroma consist of a pathognomonic pattern of a lucent lesion with calcifications in rings and arcs. However, radiographs may not depict the calcified matrix, particularly in the hands and feet. Enchondromas are the most common cystic lesion involving the

phalanges, but are most commonly seen in the humerus and femur.

FIBROUS CORTICAL DEFECT

This is a nonaggressive fibrous lesion of bone, which is referred to as nonossifying fibroma (NOF) if larger than 3 cm. The lesions are most commonly seen in the distal femur and proximal tibia and are estimated to be present in 30% to 40% of all children. These lesions are typically well-defined, eccentric, lucent lesions with a sclerotic margin that may not extend around the entire lesion. The lesions should not be painful and there should be no periosteal reaction unless a pathologic fracture is present. The natural course is gradual regression, often associated with increasing sclerosis without treatment. These are considered “do not touch” lesions, as no further imaging or intervention is indicated.

FIBROUS DYSPLASIA (LICHTENSTEIN-JAFFE DISEASE)

This is a fibro-osseous lesion in which medullary bone is replaced by fibrous tissue. It is usually seen in the lower extremities although skull involvement is not uncommon. Fibrous dysplasia is most frequently seen in pediatric patients between 5 and 20 years of age and may be associated with hyperparathyroidism and hyperthyroidism. Radiographic findings include lucent osseous lesions (often in the diaphysis or metaphysis) with a smooth and homogeneous matrix “ground glass” appearance, endosteal scalloping, lack of periosteal reaction, and expansion of outer cortex with cortical thinning in skull lesions. There is a low risk of malignant transformation. Monostotic fibrous dysplasia is the most common type (85%), most frequently involving the skull, ribs, and femurs.

LANGERHANS CELL HISTIOCYTOSIS (HISTIOCYTOSIS-X)

There are multiple forms of this disease process ranging from systemic disease to focal lesions. Eosinophilic granuloma (EG) is the most common presentation and has the best prognosis. Findings include lytic lesions most commonly involving the skull (punched-out lesions), mandible (floating teeth), and vertebral bodies (vertebra plana). EG should always be included in the differential diagnosis for a pediatric lytic lesion of bone as these lesions may at times be aggressive in appearance with periosteal reaction, pain, and associated soft-tissue involvement. Letterer-Siwe generally presents prior to age 2 years with multisystem involvement and is often fatal. Associated findings include, cutaneous rash, hepatosplenomegaly, lymphadenopathy, and pulmonary disease. Hand-Schüller-Christian usually presents by age 5 with high morbidity and approximately 15% mortality. There is chronic diffuse involvement of the skull

and orbits with associated findings of diabetes insipidus, hepatosplenomegaly, and marrow involvement.

OSTEOCHONDROMA

This is a cartilage-capped exostosis, which grows away from the joint. There is cortical and medullary continuity with the parent bone. Growth continues until the growth plate closes. These are typically metaphyseal and tend to occur in long bones such as the femur and tibia. However, many other locations are possible especially when multiple lesions are present. These are more common in males than females and are not intrinsically painful but associated mass effect on adjacent structures can be symptomatic. These lesions are most commonly seen in the first three decades of life.

OSTEOID OSTEOMA

Most common in teenagers, and more frequent in males than females, these are cortically based lesions which present with night pain relieved by aspirin. The femur and tibia are common locations. Plain films may show a sclerotic focus with or without the more lucent cortical nidus, which is clearly demonstrated on CT. Nuclear medicine may also be helpful. Surgical excision or thermal ablation is curative if the nidus is completely treated.

OSTEOBLASTOMA

Osteoblastoma (giant osteoid osteoma) lesions are also more common in males than females and most frequently occur in the second and third decades. A common location is the posterior elements of the spine. The main symptom is pain and the treatment is surgical curettage.

MALIGNANT OSSEOUS LESIONS

EWING SARCOMA

This is the second most common primary bone malignancy in children, often presenting in the second decade with a 2:1 male-to-female ratio. Metastatic disease to the lung, lymph nodes, and bones is common at presentation. Flat bones and long bones such as the femur, pelvis, and ribs are commonly involved with a permeative pattern of bone destruction. Aggressive (onion skin) periosteal reaction is commonly seen and there is usually a prominent soft-tissue component.

OSTEOSARCOMA

This is the most common primary pediatric bone malignancy. The age range is 10 to 25 years with typical symptoms of pain and swelling. Fifty to seventy-five percent are found in the region of the knee with the proximal humerus also being a common site. These are pearly metaphyseal lesions with aggressive periosteal

reactions. Approximately 15% of affected individuals present with bony metastasis at the time of diagnosis. Multiple types exist, including the classic medullary type, as well as parosteal, periosteal, telangiectatic, multifocal, and radiation- or chemotherapy-induced osteosarcoma.

TRAUMA

ELBOW TRAUMA

Supracondylar fractures are the most common elbow fractures in skeletally immature patients; while radial head fractures are more common in skeletally mature young adults. Lateral condyle fractures are the second most common type of pediatric elbow fracture.

There are six ossification centers at the elbow joint. It is important to understand that these centers ossify in a specific sequence. A mnemonic to remember the order is CRITOE: Capitellum, Radial head, Internal (medial) epicondyle, Trochlea, Olecranon, External (lateral) epicondyle. Knowing this order is particularly helpful in recognizing a medial epicondyle avulsion fracture, the third most common pediatric elbow fracture. The fracture fragment may become trapped in the joint and could be misinterpreted as the trochlear ossification center if the order of I (medial epicondyle) before T (trochlea) was not remembered.

Elbow fractures may be difficult to see. Elevation of the posterior fat pads is consistent with a joint effusion and should cause high suspicion for a fracture. If a fracture is not seen, repeat films in 7 to 10 days may be helpful. If the anterior humeral line does not pass through the middle one-third of the capitellum, supracondylar fracture is suspected.

Nursemaid elbow is a very common injury in infants and small children in which the radial head slips from the annular ligament and no longer aligns with the capitellum. This typically presents as refusal to move the arm with no associated history of trauma.

GROWTH PLATE INJURIES

The growth plate is the weakest part of the bone and is therefore susceptible to injury. Accounting for approximately 15% to 20% of all pediatric fractures, physeal injuries are more common in males than females. Five types are commonly discussed as described by Salter and Harris (Table 100-2). Types I, II, and III have an excellent prognosis; types IV, and V can disrupt the growth plate or cause asymmetric growth, possibly leading to limb shortening or angulation. Osteochondritis dissecans is an osteochondral injury that can be considered a type VII fracture, involving only the epiphysis.

TABLE 100-2 Salter-Harris Fracture Classification

Type I	Growth plate (slipped capital femoral epiphysis)
Type II	Growth plate and adjacent metaphysis; most common growth plate injury (50%–75%)
Type III	Growth plate and the epiphysis; most commonly in the distal tibia (juvenile Tillaux fracture)
Type IV	Growth plate, metaphysis, and epiphysis; common sites are the distal humerus and tibia
Type V	Crush-type injury

NONACCIDENTAL TRAUMA

Skeletal findings are only present in about one-third of child abuse cases. However, skeletal findings are the most commonly discovered radiologic manifestation of child abuse. Once suspicion of abuse has been raised, a skeletal survey is the primary method of evaluation. Nuclear medicine bone scan can also be useful, especially when a skeletal survey is negative but clinical suspicion remains high. The fractures most suspicious for abuse involve the posterior ribs; long bones in nonambulatory children, especially the femur; metaphyseal corners; scapula; and sternum. Fractures with moderate specificity include complex skull fractures, fractures of different ages, and multiple bilateral fractures. Fractures with low specificity involve the skull (linear), clavicle, and long bones in ambulatory children. Periosteal reaction usually appears within 10 days of the original insult and is nonspecific; however, in possible nonaccidental trauma, it should be viewed with suspicion. Conditions, which can mimic child abuse include osteogenesis imperfecta (OI), rickets, scurvy, and infantile cortical hyperostosis (Caffey syndrome).

OTHER DISTINCT PEDIATRIC FRACTURES

Because of relatively compliant bones, pediatric fractures may not completely traverse the bony shaft. Bowing fractures have no visible fracture line and are most common in the forearm. Greenstick fractures disrupt only one cortex and are fairly uncommon. Buckle or torus fractures are common cortical fractures frequently occurring in the distal forearm cortical deformity. These fractures demonstrate angulation of the bone and are often only evident on one view, most commonly the lateral view. Toddler fracture is a nondisplaced tibial fracture, usually in the distal third, and typically presenting between 9 months and 3 years. These fractures are often spiral or oblique and may be seen well on only one projection. Toddlers with this fracture often present with a refusal to walk and therefore an evaluation of the entire extremity is often required to exclude other pathology. Pediatric stress fractures of the calcaneus and cuboid may also occur.

SKELETAL DYSPLASIAS

ACQUIRED SKELETAL DYSPLASIAS

Acquired disorders are more common than congenital dysplasias. For normal osseous development, growing bones require physiologic muscle tension and gravitational loading. Any process that interferes with this normal stress may lead to osseous dysplasia. Examples of disease processes causing acquired skeletal dysplasia include paraplegia or quadriplegia, chronic bedrest (leukemia, juvenile chronic arthritis, etc.), and neuromuscular diseases (cerebral palsy, Duchenne muscular dystrophy, poliomyelitis, etc.). Affected individuals may demonstrate extremely gracile (long and thin) bones, coxa valga, pelvic malformation, and diminished muscle mass. While the clinical distinction between the etiologies for acquired skeletal dysplasias is generally straightforward, in the absence of specific findings such as articular erosions to suggest juvenile rheumatoid arthritis, the radiographic appearance may be very similar and clinical history is key. Poorly healed fractures or postoperative deformities can also appear severely dysmorphic and should be on the differential for acquired bone dysplasias.

CONGENITAL SKELETAL DYSPLASIAS

The congenital skeletal dysplasias are a group of more than 200 disorders consisting of abnormalities in cartilage and bone growth. The overall incidence of skeletal dysplasias is approximately one case per 4000 to 5000 births. The most common congenital skeletal dysplasias are achondroplasia, osteogenesis imperfecta (OI), and thanatophoric dysplasia (TD). In general, no racial predilections are described. Other than the X-linked recessive disorders, males and females are equally affected by most skeletal dysplasias.

ACHONDROGENESIS

Achondrogenesis is an autosomal, recessive, lethal chondrodystrophy characterized by the following triad: severe micromelic dwarfism, craniomegaly with normal-to-decreased calvarial ossification, and poor vertebral body ossification. Achondrogenesis is divided into two main categories: type I (Houston-Harris syndrome and Parenti-Fraccaro disease) with abnormal enchondral and membranous ossification and type II (Langer-Saldino syndrome) with abnormal enchondral ossification.

The prognosis of all types of achondrogenesis is very poor with death occurring either in utero or shortly after birth because of respiratory failure. The differential considerations include homozygous achondroplasia, short rib-polydactyly syndromes, and TD.

ACHONDROPLASIA

The most common nonlethal form of chondrodysplasia is achondroplasia. This rhizomelic form of dwarfism is autosomal dominant in inheritance and *de novo* mutations account for 75% to 80% of cases. Affected individuals generally have normal intelligence and motor function. However, because of the narrowing of osseous foramina, neurologic deficits may occur.

The diagnosis is based on typical clinical and radiologic features. The radiologic features are best evaluated with a skeletal survey. Radiographic findings include a contracted skull base with small foramen magnum, normal trunk length, rhizomelic shortening of the limbs with trident hands and brachydactyly, thoracolumbar gibbus in infancy, large calvarial bones in contrast to the small cranial base and facial bones, limited elbow extension, progressive interpedicular narrowing at the lumbar spine, short pedicles (which can cause spinal stenosis), genu varum, short femoral necks, metaphyseal flaring, dysplastic ilium, narrow sacroiliac groove, and flat-roofed acetabula. The prognosis of achondroplasia is generally good with a long life expectancy. The potential differential diagnosis list includes achondrogenesis, thanatophoric dwarfism, and chondroectodermal dysplasia (Ellis-van Creveld syndrome).

ASPHYXIATING THORACIC DYSTROPHY (FAMILIAL ASPHYXIATING THORACIC DYSTROPHY, JEUNE SYNDROME)

Jeune syndrome, a potentially lethal congenital form of dwarfism, is a rare genetically heterogeneous disorder with autosomal recessive inheritance. The classic findings of Jeune syndrome include a narrow thorax and micromelia, respiratory and renal manifestations (associated with bilateral microcystic kidney disease), and retinal degeneration.

The most common cause of death in Jeune syndrome is respiratory failure with 60% to 70% fatality among affected individuals in infancy and early childhood. However, respiratory symptoms vary widely ranging from respiratory failure and infantile death to latent phenotype with respiratory symptoms. In affected individuals with respiratory failure, alveolar hypoventilation is caused by impaired chest expansion as a result of short ribs. The few patients who survive into early adolescence face an increased risk for development of chronic renal failure. The differential considerations include TD, short-limb polydactyly syndrome, and achondroplasia.

CAMPOMELIC DYSPLASIA (CAMPTOMELIC DYSPLASIA)

Campomelic dysplasia is an autosomal, recessive disorder with occasional sporadic autosomal dominant mutations, which results in bowing of the long bones. The

most characteristic radiographic sign is marked anterior bowing of the femur and tibia. At times, bowing may be so severe that the angulation can mimic fracture. Additional findings include bell-shaped narrow chest, hypoplasia of the midthoracic vertebral bodies, scoliosis, and talipes equinovarus.

Polyhydramnios and anomalies of the central nervous, cardiac, and renal systems are also associated with campomelic dysplasia. The prognosis is poor with death generally occurring before 5 months of age related to respiratory insufficiency.

CHONDRODYSPLASIA PUNCTATA

Chondrodysplasia punctata is a group of syndromes with characteristic osseous sclerotic calcifications near the articulations from birth. Associated findings include short limb segments, dysmorphism with hypoplastic nose, skin lesions, and cataracts. Other associated anomalies vary depending on the subtype. The types can be divided into five groups: autosomal dominant (including dysplasia epiphysealis congenital, stippled epiphyses, chondrodysplasia punctata dominant type, chondrodysplasia epiphysealis punctata, and chondrodystrophia calcificans congenital); autosomal recessive; X-linked dominant (Conradi-Hunermann syndrome); X-linked recessive, and Sheffield type.

The autosomal dominant form is the most common type and most cases are the result of a *de novo* mutation. The major criteria for diagnosis include craniofacial dysmorphism, symmetric frontal bossing, flat nasal bridge, dysplastic auricles, mongoloid palpebral fissures, hypertelorism, and high arched palate. Other associated abnormalities include ocular abnormalities, cutaneous abnormalities, skeletal abnormalities (e.g., asymmetric mild shortening and bowing of long bones, vertebral anomalies, and clubfoot deformity), and miscellaneous abnormalities (e.g., pulmonary artery stenosis, ascites, and polyhydramnios). Although occasionally associated with mild mental retardation, the prognosis is excellent and affected individuals usually have a normal lifespan and intelligence.

The autosomal recessive or rhizomelic type results in radiologic findings of symmetric shortening of the proximal bones, punctate calcific deposits in infantile cartilaginous skeleton, and coronal clefts in the vertebra. This type is associated with mental retardation. The prognosis is poor as most fetuses die in utero or shortly after birth, and the few that survive longer suffer severe debility and profound mental retardation. Death then ensues in the first decade of life.

The X-linked dominant type (Conradi-Hunermann type subgroup B) is a very uncommon syndrome with

possible lethality in the hemizygous male. The prognosis is extremely variable ranging from neonatal death to near undetectability of the disorder in the adult. The X-linked recessive type is a very rare disorder with radiologic findings resembling the nonrhizomelic type. The Sheffield type or chondroplasia punctata mild form is also very rare. The clinical manifestations include failure to thrive, mental retardation, and typical facies with flattened tip of the nose and depressed nasal bridge.

CHONDROECTODERMAL DYSPLASIA (ELLIS-VAN CREVELD SYNDROME)

Ellis-van Creveld syndrome is an autosomal, recessive form of acromesomelic dwarfism with an increased incidence among individuals of Old Order Amish descent. The clinical tetrad of Ellis-van Creveld syndrome consists of chondrodystrophy, polydactyly, ectodermal dysplasia, and cardiac anomalies. Chondrodystrophy affects the tubular bones leading to a disproportionate dwarfism with progressive distal limb shortening of the forearms and lower legs. In addition, congenital cardiac anomalies occur in 50% to 60% of patients.

The radiographic findings include acromesomelia, which is most prominent in the hands, ulnar postaxial polydactyl, syndactyly, short ribs with thoracic narrowing, delayed bone maturation, valgus deformity of the knee, and clinodactyly of the fifth finger. The prognosis is poor with death occurring in the first month of life in up to 50% of cases because of respiratory/cardiac complications. The differential includes asphyxiating thoracic dysplasia and short rib polydactyly syndromes.

CLEIDOCRANIAL DYSOSTOSIS (CLEIDOCRANIAL DYSPLASIA)

Cleidocranial dysostosis (cleidocranial dysplasia) is an autosomal dominant disorder, which results from an abnormality in membranous and enchondral bone formation with a tendency to affect midline structures. Common findings include macrocephaly with delayed suture closure, wormian bones, hypertelorism, a small face, dental dysplasia, hypoplasia/aplasia of the clavicles, narrow pelvis, and spinal anomalies. Despite the tendency to affect midline structures, other bones are often involved including the ossicles of the ear and the extremities. The prognosis is good with a normal life expectancy. Possible complications associated with this syndrome include dental anomalies, hearing loss, scoliosis, and dislocations of the shoulder, radial head, or hip.

CRANIOSYNOSTOSIS

Sagittal stenosis is the most common type resulting in a boat-shaped calvarium referred to as dolichocephaly/scaphocephaly. Coronal synostosis is often associated with a so-called Harlequin eye, with elongation of the superior/lateral orbit. A brachiocephalic contour of the calvarium is present if bilateral synostosis occurs. This condition can be seen with associated abnormalities, such as Apert syndrome (coronal synostosis with syndactyly) and Crouzon disease (coronal synostosis with craniofacial dysostosis). Metopic synostosis results in a pointed forehead (trigonocephaly). Lambdoid synostosis results in brachycephaly if bilateral and plagiocephaly if unilateral. Kleeblattschädel (cloverleaf skull) results from pansutural synostosis.

ENCHONDROMATOSIS

Enchondromas are ectopic hyaline cartilage rests within intramedullary bone. Multiple enchondromas may occur in three distinct disorders: Ollier disease, Maffucci syndrome, and metachondromatosis. Ollier disease is a nonhereditary disorder with multiple enchondromas, which can grow large, become disfiguring, and generally occur in a unilateral distribution. There is an increased risk for degeneration to chondrosarcoma in affected individuals. Maffucci syndrome is also nonhereditary and is less common than Ollier disease, presenting with both multiple hemangiomas and enchondromas. The soft-tissue hemangiomas typically have numerous phleboliths, visible on radiographs. There is an increased risk for degeneration to chondrosarcoma as well as increased risk for other malignancies of the CNS and abdomen. Metachondromatosis is autosomal dominant in transmission and presents with multiple enchondromas and osteochondromas. However, these osteochondromas differ from conventional osteochondromas in that they point toward rather than away from the joint. Although in most cases, chondrosarcoma has aggressive features, low-grade chondrosarcoma may be indistinguishable from an enchondroma and if symptomatic then concern for chondrosarcoma is increased.

POLYOSTOTIC FIBROUS DYSPLASIA (MCCUNE-ALBRIGHT SYNDROME)

Polyostotic fibrous dysplasia may involve any bone but most commonly affects the long bones, ribs, and skull. Females are much more commonly affected than males. Lesions range from asymptomatic areas detectable only by bone scan to markedly disfiguring lesions. The larger lesions can result in frequent pathologic fractures and impingement on vital nerves. McCune-Albright

syndrome is described with café au lait skin pigmentation and autonomous endocrine hyperfunction. In this syndrome, adrenocorticotrophic hormone (ACTH)–independent Cushing syndrome results in growth failure and hypertension in infancy, hyperthyroidism typically occurs because of one or more autonomous hyperfunctioning nodules, and growth hormone excess from somatotroph adenomas in the pituitary can occur resulting in gigantism and/or acromegaly. Precocious puberty is a result of gonadotropin-independent autonomous ovarian or testicular function and girls as young as 4 months with McCune-Albright syndrome can have breast development or vaginal bleeding. Excess estrogen can result in a marked advancement in skeletal maturity.

The craniofacial form of fibrous dysplasia (Leontiasis Ossea) occurs in 10% to 25% of patients with the monostotic form and in 50% with the polyostotic form. The frontal, sphenoid, maxillary, and ethmoidal bones are the most commonly affected and involvement of the occipital and temporal bones is less common. Lesions in the maxillofacial bones and skull base may result in neurologic deficits related to narrowed cranial foramina. Cherubism (familial fibrous dysplasia) is an autosomal dominant variant with variable penetrance, which occurs in children and is more severe in males. The findings consist of a broad and protruding jaw with symmetric fibrous dysplasia involving the maxilla. Regression of this form may occur after adolescence.

When assessing for polyostotic fibrous dysplasia with a skeletal survey, total radiation exposure can be decreased if a focused skeletal survey is preceded by a bone scan. The differential considerations are broad and include Paget's disease, fibrous cortical defect/nonossifying fibroma, hyperparathyroidism, giant cell tumor, EG, and hemangioma.

GAUCHER SYNDROME

Often occurring in Ashkenazi Jews, this autosomal, recessive disorder has no gender predilection and results in accumulation of sphingolipids in the reticuloendothelial cells. The result is hepatosplenomegaly and osseous infarcts because of increased intramedullary pressure causing occlusion of the intramedullary veins. In approximately 50% of patients, osteonecrosis may also develop in a subchondral location such as the femoral head, leading to subchondral collapse and early arthrosis. Other osseous findings include flaring in the metaphyses (Erlenmeyer flask deformity), possibly related to packing of Gaucher cells. Affected individuals may also be at increased risk for osteomyelitis. The usual form of the disorder is associated with a normal life span, although infantile and juvenile forms may result in mental retardation and early mortality.

HYPOPHOSPHATEMIC RICKETS (X-LINKED HYPOPHASPHATEMIA)

This X-linked dominant syndrome is caused by a hereditary defect of the renal tubules, which causes decreased reabsorption of phosphate and reduced serum phosphate levels. This decreased reabsorption does not respond to usual amounts of vitamin D. The disorder exhibits rachitic epiphyseal and metaphyseal abnormalities predominantly in the lower limbs. Affected individuals may also demonstrate a generalized bone remodeling abnormality causing short, squat bones.

MARFAN SYNDROME

Marfan syndrome is an inherited connective tissue disorder transmitted as an autosomal dominant trait, which primarily involves the eye, skeleton, and cardiovascular system. Although sporadic cases occur, most cases are owing to autosomal dominant gene with a high degree of penetrance. Affected individuals are characteristically tall and thin with disproportionately long limbs in respect to the trunk, greatest peripherally with the appearance of “arachnodactyly.” Ocular abnormalities are common and associated cardiac and vascular abnormalities lead to a shortened life expectancy.

METAPHYSEAL CHONDRODYSPLASIAS

This heterogeneous group of intrinsic dysplasias is characterized by flaring in the metaphyses of the short and long tubular bones (Erlenmeyer flask deformity), while the epiphyses remain normal. The osseous deformity is caused by abnormal, physeal, proliferative, and hypertrophic zones. Hypercalcemia is commonly seen and these disorders are also associated with neutropenia, lymphopenia, immunodeficiency, pancreatic exocrine insufficiency, Hirschsprung’s disease, and intestinal malabsorption. The metaphyseal chondrodysplasias are often recognized in early childhood with waddling gait, lumbar lordosis, genu varum, short stature, retardation, joint contractures, and exophthalmic eyes. Radiographic findings include enlarged metaphyses and widened cupped physes (similar to rickets), and coxa vara without associated bowed femur.

Multiple epiphyseal dysplasia is predominantly autosomal dominant in transmission and is related to imperfect articular cartilage that is unable to withstand normal loading. Involvement of the hips must be differentiated from Perthes’ disease and unlike Perthes’, there is generally symmetric involvement and the acetabulum is often irregular. However, there may be superimposed osteonecrosis (AVN) of the hip. In Schmid type, affected individuals demonstrate mild short stature; greater involvement of the

lower extremities with leg pains, varus deformities of the knees and ankles, and genu varum, which may be severe. Jansen type is an extremely rare, progressive disorder with variable range and severity of symptoms, most commonly occurring because of random spontaneous de novo mutations. Pyle disease is a mild form of metaphyseal dysplasia and affected individuals are often tall and asymptomatic. The McKusick type is autosomal recessive and presents with sparse brittle hair, light pigmentation, shortening of long bones, cupped widened metaphyses, and widened costochondral junctions.

Differential consideration primarily includes rickets. Many affected individuals will initially be thought to have a hypophosphatemic vitamin D-resistant rickets, which can lead to the inappropriate administration of vitamin D.

MULTIPLE HEREDITARY EXOSTOSIS (FAMILIAL OSTEOCHONDROMATOSIS)

Multiple hereditary exostosis (familial osteochondromatosis) is an autosomal dominant disorder. The average age at diagnosis is 3 years. Numerous sites are affected simultaneously. Malignant transformation is a significant risk. Chondrosarcoma has been reported in up to 20% of cases in some series. The lesions at greatest risk for sarcomatous degeneration are those occurring near the pelvis, scapula, proximal humerus, proximal femur, and spine. A change in size of the exostosis or onset of pain in an affected skeletally mature individual is cause for concern and investigation. Growth abnormalities caused by joint involvement as well as mass effect on adjacent vessels and nerves can be significant. Multiple cartilaginous exostoses are seen arising from the metaphyses, pointing away from epiphysis, and extending down the diaphysis during growth. The osteochondromas may increase in size and number with growth, but generally become latent at maturity. In over 90% of cases, the distal tibia, proximal tibia, proximal femur, and proximal humerus are involved. Other common sites of involvement include the iliac crests, scapulae, and ribs. Clinical problems include pathologic fracture, pressure of exostosis on surrounding soft tissues, and neurovascular compromise.

NEUROFIBROMATOSIS

This autosomal dominant disorder affects the bones, the nervous system, soft tissue, and the skin. There are two genetic disorders with at least eight different clinical phenotypes. Neurofibromatosis 1 (NF1) is the most common subtype and is referred to as peripheral NF. The characteristics of NF1 include six or more café au lait macules larger than 5 mm in diameter prepubertal and larger than 15 mm postpubertal, two or more neurofibromas or one plexiform

neurofibroma, axillary/inguinal freckling, optic glioma, two or more Lisch nodules, a distinctive osseous lesion (sphenoid dysplasia or thinning of the long bone cortex) with or without pseudoarthrosis, and a first-degree relative with NF1. Neurofibromatosis 2 (NF2) or central NF characteristics include bilateral masses of the eighth cranial nerve seen with appropriate imaging techniques (e.g., CT, MRI), a first-degree relative with NF2, and either a unilateral mass of the eighth cranial nerve or two of the following: neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular opacity.

The skeletal findings of NF include pseudoarthrosis of the tibia; bowing of the long bones, orbital defects; dysplasia of the sphenoid wings with resulting herniation of the temporal lobe through the enlarged superior orbital fissure and pulsating exophthalmos; thoracic cage asymmetry with flaring or prominence of the inferior ribs; and abnormalities of cortical diaphyseal structure, density, and metaphyseal modeling. The mortality rate is higher than that of healthy population because of increased potential for malignant transformation of diseased tissues and the development of neurofibrosarcoma.

OSTEOGENESIS IMPERFECTA

OI is an autosomal dominant congenital syndrome with increased bone fragility. The sclera ranges from white to blue. Type I OI is the mildest form. Affected individuals generally have no long-bone deformity. Over a lifetime, the numbers of fractures can range from 1 to 60. Affected individuals have a high tolerance for pain. Other possible findings include kyphoscoliosis, hearing loss, premature arcus senilis, and easy bruising. Type II OI is the most severe form and is often lethal. All patients have in utero fractures, which may involve the skull, long bones, and/or vertebrae. The cause of death is usually related to the extreme fragility of the ribs resulting in pulmonary hypoplasia or occasionally cranial injury with CNS hemorrhage. Individuals with type III OI may have joint hyperlaxity, muscle weakness, chronic unremitting bone pain, and skull deformities (e.g., posterior flattening) caused by bone fragility during infancy. In utero fractures are common. Limb shortening and progressive deformities can occur. Type IV OI is not clearly defined. Dentinogenesis imperfecta may be present. Fractures usually begin in infancy, but in utero fractures may occur. The long bones are usually bowed.

OSTEOPETROSIS

This clinical syndrome is characterized by failure of osteoclasts to resorb bone, resulting in skeletal fragility de-

spite increased bone mass. Osseous overgrowth may also cause hematopoietic insufficiency, disturbed tooth eruption, nerve entrapment syndromes, and growth impairment. This is a heterogeneous disorder with different molecular lesions and a range of clinical features. However, all forms share a single pathogenic etiology in the osteoclast. If untreated, infantile osteopetrosis usually results in death by the first decade of life owing to severe anemia, bleeding, or infection. Adults with osteopetrosis are usually asymptomatic and have good long-term survival rates. Radiologic features are usually diagnostic and include generalized osteosclerosis, uniformly sclerotic bones, alternating sclerotic and lucent bands in the iliac wings and near ends of long bones, bone within bone appearance (endobone), thickened and dense skull especially at the base, small and underpneumatized sinuses, and extremely dense vertebrae with alternating bands (Rugger-Jersey sign). Pycnodysostosis is a rare, autosomal, recessive syndrome with similar presentation because of failure of osteoclasts to resorb bone.

SHORT-RIB POLYDACTYLY SYNDROME

This is a group of autosomal recessive lethal skeletal dysplasias with micromelic dwarfism, short-ribbed narrow thorax, and ulnar/fibular polydactyly. The prognosis is poor with death occurring in utero or shortly following birth because of respiratory failure. Four types are described: type I (Saldino-Noonan syndrome), type II (Majewski syndrome), type III (Verma-Naumoff syndrome), and Beemer-Langer syndrome. Other associated findings include poorly ossified vertebral bodies with notchlike ossification defects, cleft lip/palate, widened metaphases (type III), syndactyly, as well as cardiac, GI, and GU malformations. Differential considerations include TD, camptomelic dysplasia, and OI.

THANATOPHORIC DYSPLASIA

This is the most common form of lethal skeletal dysplasia in the neonatal period. This severe rhizomelic (micromelic) dwarfism is most commonly caused by de novo dominant mutations. TD is nearly always lethal in the neonatal period because of respiratory insufficiency secondary to reduced thoracic capacity or related to compression of the brainstem. There are two clinically defined subtypes. TD type 1 is the most common subtype with a normally shaped skull and curved long bones shaped like a telephone receiver. The femurs are most affected. TD type 2 presents with a cloverleaf-shaped skull (kleeblattschädel) and straight femurs. Radiographic findings include narrow chest, small scapula,

normal clavicles, short ribs with flared ends, rhizomelic shortening of the long bones, telephone receiver-shaped femurs, flattened vertebral bodies with wide intervertebral spacing, and enlarged skull. The prognosis is poor with death often occurring in utero or shortly after birth because of respiratory failure. Differential considerations include homozygous achondroplasia, short-rib polydactyly syndrome, and achondrogenesis

THROMBOCYTOPENTA-ABSENT RADIUS SYNDROME

This is a rare condition with bilateral radial aplasia and episodes of thrombocytopenia, which begin in the neonatal period. There are associated abnormalities in some affected individuals involving the lower extremities, heart, and face. Differential considerations include VACTERL, Holt-Oram syndrome, and Fanconi syndrome.

QUESTIONS AND ANSWERS

1. What is the most common form of skeletal dysplasia?
 - A. Achondroplasia
 - B. Thanatophoric dysplasia
 - C. Acquired skeletal dysplasia
 - D. Osteogenesis imperfecta

ANSWER: C. Acquired skeletal dysplasias are the most common cause for skeletal dysplasias, more common than all of the congenital skeletal dysplasias combined. Achondroplasia is the most common congenital skeletal dysplasia. Thanatophoric dysplasia is the most common skeletal dysplasia, which is lethal in the neonatal period.

2. An 8 month-old male infant is greater than three standard deviations below normal size with the following radiographic findings: contracted skull base with small foramen magnum, rhizomelic shortening of the limbs with trident hands and brachydactyly, progressive interpedicular narrowing at the lumbar spine, short pedicles, and flat-roofed acetabula. What is the most likely diagnosis?
 - A. Achondrogenesis
 - B. Chondroectodermal dysplasia
 - C. Thanatophoric dysplasia
 - D. Achondroplasia

ANSWER: D. The described findings are classic for achondroplasia. The other congenital skeletal dysplasias listed are generally fatal in the neonatal period. The clinical tetrad of chondroectodermal dysplasia (Ellis-van Creveld syndrome) consisting of chondrodystrophy, polydactyly, ectodermal dysplasia, and cardiac anomalies was not described.

3. What is the most common cause of death in Jeune syndrome?
 - A. Craniocervical junction impingement
 - B. Intracranial hemorrhage
 - C. Respiratory failure
 - D. Electrolyte imbalance
4. What is the most common etiology of rickets?
 - A. Vitamin D deficiency
 - B. Low dietary intake of calcium
 - C. Low dietary intake of phosphorus
 - D. Decreased renal tubular reuptake of phosphorus

ANSWER: A. Vitamin D deficiency is the most common cause of rickets. Low dietary intake of calcium and phosphorus may also cause rickets. Decreased renal tubular uptake of phosphorus is the cause of hypophosphatemic rickets (X-linked hypophosphatemia).

5. Which of these fractures is most likely to result in asymmetric growth?
 - A. Displacement of the distal radius epiphysis through the growth plate
 - B. Fracture through the distal femoral physis extending through the metaphysis
 - C. Fracture through the lateral distal tibial physis extending through the epiphysis

D. Lateral condylar physeal fracture extending through the capitulotrochlear groove

ANSWER: D. A lateral condylar physeal fracture extending lateral to the trochlea through the capitulotrochlear groove is a SH type IV fracture. SH type IV and V fractures have the highest risk of growth disturbance. The remaining fractures are types I to III.

6. What region of the bone is usually initially involved in pediatric osteomyelitis?

- A. Epiphysis
- B. Metaphysis
- C. Physeal plate
- D. Diaphysis

ANSWER: B. Pediatric osteomyelitis most commonly begins in the metaphysis because of rich vascular supply and slow blood flow in this region. The epiphysis may be involved up until ossification occurs at approximately 18 months of age.

7. A patient with sickle cell disease presents with osteomyelitis. What is the most likely organism?

- A. *Staphylococcus aureus*
- B. *Streptococcus pyogenes*
- C. *Pseudomonas aeruginosa*
- D. *Salmonella*

ANSWER: A. Although *Salmonella* osteomyelitis is frequently associated with sickle cell disease, the most common etiology for osteomyelitis remains *Staphylococcus aureus*.

8. Which of these fractures is most characteristic of nonaccidental trauma?

- A. Linear skull fracture
- B. Clavicular fracture
- C. Posterior rib fractures
- D. Complex skull fracture

ANSWER: C. Highly suspicious fractures for abuse include posterior rib fractures, long bone fractures in nonambulatory children, metaphyseal corner fractures, scapular fractures, and sternal fractures. Fractures with moderate specificity include complex skull fractures. Fractures with low specificity include linear skull fractures and clavicle fractures.

9. Which of the following lesions should be biopsied?

- A. Painful lucent lesion with calcifications in rings and arcs
- B. Sclerotic cortical lesion with a central nidus and pain at night relieved by aspirin
- C. Well-defined proximal tibial, eccentric, lucent lesion with a sclerotic margin

D. Cartilage-capped exostosis that grows away from the joint with open physes

ANSWER: A. An enchondroma cannot be differentiated radiographically from a low-grade cartilaginous neoplasm and pain suggests the possibility of low-grade chondrosarcoma. A sclerotic lesion with a central nidus suggests an osteoid osteoma. A well-defined lucent lesion in the proximal tibia likely represents a nonossifying fibroma. A cartilage-capped exostosis growing away from the joint is consistent with an osteochondroma and the possibility of sarcomatous degeneration is raised with continued growth after skeletal maturity.

10. Which of the following does *not* increase the risk for developmental dysplasia of the hip?

- A. Breech delivery
- B. Male infant
- C. Oligohydramnios
- D. Family history of DDH

ANSWER: B. High-risk patients include those with a family history of developmental dysplasia of the hip, breech delivery, oligohydramnios, as well as neuromuscular and foot abnormalities. Females are affected more commonly than males.

101 PEDIATRIC CHEST

Christopher J. Guion*

NEONATAL CHEST

TUBES AND LINES

Evaluating the placement of all the various support devices is an important function of the pediatric radiologist. Some line placement is unique to the neonatal period.

Both the umbilical arterial and venous catheters enter through the umbilicus. The course of the umbilical artery catheter is from the umbilical artery to the internal iliac artery (hypogastric artery) to the aorta. The tip of the catheter can be left high (T6–T9) or low (L3–L4). These positions are chosen so as to avoid the origins of the celiac axis, superior mesenteric artery, and the renal arteries. The course of the umbilical venous catheter is from the umbilical vein to the left portal vein, then through the ductus venosus to the inferior vena cava to the right atrium. The correct position of the tip is above

the right diaphragm projected over the right atrium. Beware of common malpositions of the umbilical venous catheter. The catheter tip overlying the right upper quadrant and directed toward the patient's right indicates right portal vein placement. An abrupt caudad reversal of the catheter below the level of the diaphragm indicates middle hepatic vein placement. Advancement beyond the right atrium frequently crosses through a patent foramen ovale into the left atrium. From the left atrium, the tip can actually enter a pulmonary vein.

Extracorporeal membrane oxygenation (ECMO) is used as pulmonary bypass. ECMO is a therapy of last resort for patients with a reversible disease and a chance of survival. There are two forms: venovenous and arteriovenous. With venovenous ECMO, a single, large cannula is seen with its tip overlying the right atrium. Blood is removed from the right atrium, travels through a membrane oxygenator, and is returned to the venous system. With the arteriovenous form, two cannulas are seen. The arterial catheter is placed into the right carotid artery with its tip overlying the aortic arch. The venous catheter is placed via the right internal jugular vein to the right atrium. The right common carotid artery and right internal jugular vein are sacrificed during arteriovenous ECMO.

In general, the endotracheal tube tip should be placed in the center of the trachea halfway between the inferior margins of the clavicles and the carina. In the term, newborn ideal endotracheal tube placement equates to 2 cm above the carina. Keep in mind that in this early stage of life, the trachea is quite short. Helpful phone calls to the intensive care unit regarding tube malposition should be reserved for a tube tip terminating above the thoracic inlet, within the main bronchi, or an esophageal intubation.

AIR LEAK IN THE NEONATE

Air leak is used as a general term to describe rupture of the alveolus or pulmonary interstitium, generally resulting from an increase in alveolar pressure with some type of air block. The term includes pneumothorax, pneumomediastinum, pneumopericardium, and pulmonary interstitial emphysema. Infants are imaged supine; therefore, pleural air in a pneumothorax collects anteriorly and medially. A pleural line is often very difficult to see. The majority of neonatal pneumothoraces are noted medially. They may appear as a lucency along the cardiac margin. One should suspect a pneumothorax when there is a hyperlucent lung or a "deep sulcus sign." Pneumomediastinum can be recognized when there is uplifting of the thymus causing a "sail sign." Cross-table lateral or decubitus imaging may help to differentiate an ante-

rior pneumothorax from a pneumomediastinum. On cross-table lateral imaging, air will often surround the thymus, while on decubitus imaging, air will rise and outline the pleural surface. With pneumomediastinum, air can appear to surround the heart, creating the "continuous diaphragm sign." In pneumopericardium, air outlines the heart. The air is limited superiorly by the pericardial reflection of the great vessels.

Pulmonary interstitial emphysema results from barotrauma, which causes alveolar tears. Air then tracks into the perivascular spaces and lymphatics. Pulmonary interstitial emphysema is seen as well-defined, linear, and bubblelike lucencies, which can be either focal or diffuse. These lucencies may coalesce into cystic air collections. Findings are typically transient but serve as a warning for possible impending pneumothorax or pneumomediastinum.

PULMONARY PATHOLOGY ASSOCIATED WITH THE NEONATE

Respiratory distress syndrome (RDS) (also referred to as hyaline membrane disease or surfactant deficiency) is a disease of the premature infant caused by the inability of the premature type II pneumocytes to produce enough surfactant. Surfactant coats the alveoli and lowers the surface tension. A deficiency or lack of surfactant leads to alveolar collapse and decreased pulmonary compliance. Classically, the chest radiograph demonstrates low lung volumes and diffuse, bilateral granular opacities. Since the larger bronchi do not collapse, air bronchograms are visualized. Severity is inversely proportional to gestational age. RDS is rarely seen after 36 weeks gestation. Treatment is with intratracheal administration of exogenous surfactant. Possible complications of surfactant therapy include pulmonary hemorrhage and increased risk of developing a patent ductus arteriosus.

Bronchopulmonary dysplasia (BPD) (also referred to as chronic lung disease of infancy) is a common complication of prematurity and was initially described by Northway et al. as having four stages. Because of changes in therapy, the four stages are not typically seen today. Mechanical ventilation and oxygen toxicity are felt to be the cumulative agents in the development of BPD. Premature infants requiring prolonged ventilatory support are most at risk for developing BPD. By the beginning of the third week of life, hazy densities are seen throughout the lungs. Over weeks to months, coarse lung markings, bubbly lucencies, and areas of asymmetric aeration develop.

Transient tachypnea of the newborn (TTN) (also referred to as retained fetal fluid and wet lung disease) is a

condition seen in near-term, term, and postterm infants. The condition results from delayed clearance of the fetal pulmonary fluid. Conventional wisdom holds that the thoracic squeeze during passage through the birth canal helps expel this fluid from the lungs. Therefore, infants delivered by cesarean section are at increased risk. This condition is also seen following maternal sedation and also in infants of diabetic mothers. The typical clinical course is the onset of respiratory distress by 6 hours after birth, peaking of symptoms at around 24 hours after birth, and resolution of symptoms by 48 to 72 hours after birth. Radiographically, a proximal humeral head ossification center is seen in these term or postterm infants. There are prominent interstitial markings, indistinct pulmonary vasculature, fluid in the fissures, and pleural effusions. The heart size is usually normal.

Meconium aspiration syndrome is seen in the term or postterm infant. Meconium is usually passed during the first 24 hours after birth. Intrapartum or intrauterine aspiration of meconium can result from advanced gestational age, fetal distress, preeclampsia, maternal drug abuse, and placental insufficiency, among others causes. The thick meconium causes airway obstruction, surfactant insufficiency, and chemical pneumonitis. The radiograph demonstrates areas of asymmetric hyperinflation, as well as, atelectasis. "Ropey" perihilar densities can be seen. As these are term or postterm infants, the proximal humeral head ossification center will be present. Air leak phenomena including pneumothorax or pneumomediastinum can be seen. Severe cases may require ECMO. Fatalities still occur from this condition.

Persistent pulmonary hypertension of the neonate (also referred to as persistent fetal circulation of the neonate) is a physiologic condition in which there is continuation of high pulmonary vascular resistance and failure of the normal transition to low pulmonary vascular resistance. Persistent pulmonary hypertension of the neonate occurs as an idiopathic primary form and a secondary form related to hypoxemia (seen with meconium aspiration syndrome, congenital diaphragmatic hernia, and neonatal pneumonia). Right-to-left shunting may occur through the foramen ovale or ductus arteriosus. The chest radiograph may be normal or show pulmonary oligemia. There can be mild cardiomegaly and hepatomegaly.

Patent ductus arteriosus results from delayed closure of the ductus arteriosus. The normal ductus arteriosus typically closes by day 2 after birth, but it may remain patent in hypoxic infants. Initially, there is right-to-left shunting, but as the pulmonary vascular resistance begins dropping at the end of the first week, a left-to-right shunt develops. The radiograph shows an increase in heart size

and prominent pulmonary vascularity. The vessels start to become ill-defined as the interstitial edema increases. The prostaglandin inhibitor, indomethacin, is used to close the ductus. Transcatheter occlusion or surgery may be required.

Chylothorax is the most common cause of a large pleural fluid collection in the newborn period. Initially, lymph accumulates in the pleural space, becoming chylous after the ingestion of lipids in milk or formula. Most affected infants will have developed symptoms by the end of the first week of life. The majority of cases occur on the right; however, bilateral cases are encountered. There is a male gender predilection. While the etiology is usually unknown, thoracic duct rupture is the presumed causative agent. Chest radiograph demonstrates a pleural fluid collection. In extreme cases, there is complete opacification of the hemithorax with contralateral shift of the mediastinal contents. Widening of the ipsilateral ribs may be seen. Treatment is by thoracentesis.

CONGENITAL TRACHEOBRONCHIAL ABNORMALITIES

Tracheal atresia is a rare condition in which there is usually absence of the entire trachea. The bronchi or, if present, the distal trachea connects to the esophagus. Chest radiograph may show absence of the tracheal air column.

Tracheal stenosis can be congenital or acquired. The rare congenital form is because of complete cartilaginous rings. Congenital tracheal stenosis may be either focal or diffuse. The VACTERL association (Vertebral anomalies, Anal atresia, Cardiac anomalies, Tracheo-esophageal fistula, Renal anomalies, and Limb anomalies) may be seen in these patients. The acquired form may result from intubation or traumatic suctioning.

Bronchial atresia is most often seen in lobar or segmental bronchi. There is an upper lobe predilection. In the neonatal period, a fluid density "mass" is seen in one of the upper lobes. There is an association with other bronchopulmonary foregut malformations.

A tracheal bronchus (also referred to as a pig bronchus) is present in a small percentage of the population. In this condition, the entire right upper lobe segment or the apical segment of the right upper lobe is supplied by a bronchus arising directly from the trachea. Complications include recurrent pneumonia, atelectasis, and/or air trapping within the portion of the right upper lobe supplied by the ectopic bronchus.

CONGENITAL PULMONARY ANOMALIES

In pulmonary agenesis, there is complete absence of the lung. An equal frequency of occurrence is seen between

the left and right lung. Right lung agenesis has a higher association with cardiac anomalies than does left-sided agenesis. In cases of true agenesis, no bronchus is present on the affected side. In cases of aplasia, a small atretic bronchus is present. Chest radiograph reveals a small, opaque hemithorax with mediastinal shift toward the affected side. In addition to cardiac anomalies, there are multiple other associated anomalies, including renal agenesis and imperforate anus.

There is a specific form of right lobar agenesis/aplasia called scimitar syndrome or venolobar syndrome. An abnormal pulmonary vein drains into the superior vena cava, creating the so-called scimitar shadow seen in the right chest. The right pulmonary artery is either small or absent. There is systemic arterial supply to the abnormal lung from the aorta. There may be absence of the inferior vena cava.

Pulmonary hypoplasia classically involves the right lung. There is typically a small or absent pulmonary artery. The chest film reveals a small hemithorax with mediastinal shift toward the affected side. In classic right-sided pulmonary hypoplasia, the lateral view demonstrates a soft-tissue stripe anterior and/or posterior to the lung. This stripe is created by extrapleural areolar soft tissue. This areolar tissue also leads to a loss of the right heart border on the frontal view.

Congenital lobar emphysema is a condition in which there is progressive hyperexpansion of a lobe. The left upper lobe is most commonly affected, followed by the right middle lobe, followed by the right upper lobe. The lower lobes are much less commonly involved. The etiology remains elusive. While there is over distension of a lobe, no true alveolar wall destruction occurs. Initially, a soft-tissue density is seen in the affected lobe secondary to fetal fluid. As the fetal fluid begins to clear, progressive hyperexpansion of the lobe is seen. Treatment is by lobectomy.

Congenital cystic adenomatoid malformation (also referred to as congenital pulmonary airway malformation) is an intrapulmonary mass consisting of a proliferation of hamartomatous tissue. These masses have both solid and cystic components. The cysts usually communicate with the tracheobronchial tree. There would appear to be no lobar predilection, as upper and lower lobe preference have been reported by different authors. The commonly used classification system is based on cyst size at imaging. In common parlance, there are three types (Table 18-1). Type I lesions have at least one dominant cyst greater than 2 cm in diameter. Type II lesions contain numerous small cysts of more uniform size measuring up to 2 cm in diameter. Type III lesions are the least common and are solid in appearance, being composed of microcysts. Type I lesions are rarely associated with other congenital malformations. Type II

lesions are associated with other congenital malformations in approximately 50% of the cases. The prognosis in type III congenital cystic adenomatoid malformation is poor. Depending on the age at imaging (presence or absence of retained fetal fluid) and the type, there is a varied appearance. The lesion can be cystic, mixed cystic and solid, or solid. These lesions have the potential for malignancy in the form of rhabdomyosarcoma and are therefore resected.

Pulmonary sequestration is a congenital mass of abnormal pulmonary tissue, which receives its blood supply from the systemic circulation and has no normal communication with the bronchial tree. The systemic arterial supply is from the aorta. There are two forms of sequestration: intralobar and extralobar. Differentiation of the two forms cannot be reliably made by imaging. In general, the characteristics of intralobar sequestration include no separate pleural covering, venous drainage by way of pulmonary veins, the vast majority being in the lower lobe (left greater than right), and an uncommon association with other anomalies. Extralobar sequestration has its own pleural covering, the majority are left-sided, and venous drainage is to the azygous. Diagnosis is earlier than the intralobar form. Extralobar sequestration has a greater than 50% association with other anomalies. Radiographically, the lesion first appears as a radiopaque mass. Once infection has occurred gas may be present, giving a multiloculated cystic appearance. In both types, the lesion is most commonly seen in the left lower lobe.

Bronchogenic cysts occur with equal frequency within the lung parenchyma and the mediastinum. They initially appear as smoothly marginated, thin-walled, homogeneous masses of soft-tissue density. Once infected, gas may be seen within the lesion.

PEDIATRIC CHEST INFECTION

Growth of the airway occurs throughout fetal development and for years after birth. The development of the terminal bronchi has occurred by the 16th week of gestation. The aveoli develops between the 16th and 24th weeks of gestation and continues through 8 years of age, although the majority have developed by 3 years. Although the tracheal cartilage is developed at birth the posterior noncartilaginous aspect of the trachea, the pars membranacea, may allow for compression of the posterior tracheal air column. This allows for the appearance of near AP collapse of the trachea in a crying infant with expiration. On inspiration the tracheal air column should be easily recognized on chest radiographs. The course of the trachea may change with inspiration and expiration in infants, buckling away from the aortic arch with expiration.

LARYNGEAL AND SUBGLOTTIC INFLAMMATORY DISEASE

Croup occurs often with parainfluenza virus and causes subglottic edema and narrowing. The term encompasses laryngotracheobronchitis. It is common in young children from 6 months to 3 years of age. Tracheal bacteria infections may cause crouplike symptoms and are frequently staphylococcal in origin. Epiglottitis is associated with *Haemophilus influenzae* type B. This often occurs during winter months and predominately affects the 3- to 6-year-old age group. Swelling of the epiglottis and aryepiglottic folds may cause life-threatening airway obstruction, whereas croup is less likely life threatening. Retropharyngeal hemorrhage caused by trauma may have a similar appearance. Foreign bodies most commonly produce more distal bronchial occlusion rather than upper airway obstruction. These entities may be exacerbated in smaller children because of the small caliber of the upper airway.

Masses within the subglottic airway of young children may be secondary to manipulation such as intubation or tracheostomy causing granulation tissue. Entities such as airway papillomatosis are secondary to infection with papilloma virus, which can be acquired at birth. Soft-tissue mass such as subglottic hemangioma may involute similarly to cutaneous hemangiomas over several years.

AGE-RELATED RESPIRATORY INFECTION

Respiratory infections affect about one-quarter of children younger than 2 years of age. Several respiratory infections are age related. Tracheobronchitis and

bronchiolitis peak at 6 to 12 months of age. Entities such as cytomegalovirus may be acquired in utero. Infectious agents such as group B streptococcus and chlamydia may be acquired at birth. Respiratory syncytial virus may cause bronchiolitis in neonates and young infants. Parainfluenza and croup are more commonly seen in 2- to 3-year-old. *Mycoplasma pneumoniae* is more common in schools-age children. Many radiologists note it is difficult to differentiate bacterial and viral pneumonia, as there is considerable overlap in appearance. Some patterns may be helpful. Central parabronchial edema and atelectasis is more suggestive of a viral etiology or entities such as mycoplasma or chlamydia infection. Diffuse fluffy infiltrates, which extend to the lung periphery or lobar consolidations, are more commonly seen with bacterial infection.

Recurring pneumonia should suggest evaluation for chronic conditions. Cystic fibrosis, immunodeficiency congenital or acquired, and conditions such as chronic granulomatous disease, asthma, asplenia, or sickle cell disease with functional asplenia may be considered. Congenital anomalies such as pulmonary sequestration, congenital cystic adenomatoid malformation, or anomalous bronchi are also in the differential diagnosis. Extrinsic compression by mass or intrinsic obstruction such as foreign body needs to be excluded (Table 101-1).

VIRAL DISEASE

Viral bronchiolitis continues to be one of the most common indications for imaging in children with airways disease. Hyperinflation with peribronchial edema and areas of subsegmental atelectasis are common. Hilar lymphadenopathy may be present and does not have the

TABLE 101-1 Respiratory Infection

ominous significance when seen in the adult setting. The etiology of upper respiratory infection is viral in 95% of preschool children younger than 5 years of age. Although viruses are still most common in school-age children older than 5 years, *M. pneumoniae* may be seen in up to 30% of cases and streptococcal pneumoniae has been seen more frequently. Pleural effusions are relatively uncommon in viral lower airways disease. Respiratory syncytial virus is highly contagious and more severe in children younger than 2 years of age. It accounts for 60% of respiratory infections below the age of 5 years and is known to peak in the late fall and winter months. Respiratory infection associated with measles is less common in developed countries with immunization. Children with measles pneumoniae may be prone to superimposed infection with *H. influenzae*, *Staphylococcus aureus*, and *Streptococcus pyogenes*.

M. pneumoniae has a variable appearance and may be reticular nodular, interstitial, or involve a single lobe, making it difficult to distinguish from viral or bacterial infections. Hilar lymphadenopathy may be common and pleural effusion is uncommon. Pneumonia associated with cytomegalovirus and Varicella Zoster commonly affects immunosuppressed patients.

BACTERIAL PNEUMONIA

Round pneumonia may appear as a well-defined, round opacification and may simulate a mass but should not cause mass effect on adjacent structures. This is often seen in up to 8 years of age and is commonly *S. pneumoniae*. *S. aureus* and *H. influenza* are also commonly seen. *Pneumocystis carinii* and *pertussis* would be atypical. In this age group, the collateral pathways of air circulation (channels of Lambert and Pores of Kohn) are not well developed. This decreases the spread of infection giving the “round” appearance. Although the differential diagnosis may include entities such as foregut duplication cyst, or even neuroblastoma in the posterior mediastinum, these may cause mass effect. Pneumonic complications may result, depending upon the severity and distribution. Abscess, pneumatocele, cavitory necrosis, or bronchopleural fistulas may occur. Cavitory necrosis is currently most commonly seen with *S. pneumoniae*. A retrocardiac opacity needs to be differentiated from a hiatal hernia or entities such as foregut malformation, or neurogenic tumors.

In bacterial infection, pleural effusions are seen in approximately 20% of *S. pneumoniae* and are more common in younger children. Pleural effusions may be seen in up to 80% of *S. aureus* pneumonia. Suppurative complications of pneumonia may require CT to help differentiate complex fluid collections, cavitory necrosis, lung abscess, or pericarditis. Lung infection associated

with a chest wall mass may occur with both infection and neoplasm. Differential may include such as actinomycosis, blastomycosis and tuberculosis, or neoplastic lesions such as Ewing sarcoma, rhabdomyosarcoma, or PNET. Rib osteomyelitis may be seen with both bacterial infection and tuberculosis. In cases of multiple lung abscesses, septic emboli must be considered as well as children with aspiration and/or periodontal disease.

TUBERCULOSIS

Tuberculosis is seeing a comeback in children with decreased immunizations and resistant strains. It is still a major cause of morbidity and mortality in developing countries and may complicate HIV infection. Primary tuberculosis in children is acquired through droplet infection usually from adults with cavitory disease. Children younger than age 5 are more susceptible and a more disseminated form is seen in children younger than 2 years of age. Primary tuberculosis may heal with calcified hilar lymphadenopathy (Ranke complex). Bronchial compression from adjacent lymphadenopathy may be seen. Both pleura effusion and thin walled cavitation is common. Rib and chest wall involvement is usually from hematogenous spread rather than direct extension. Hematogenous dissemination is most common in the 3 to 6 months age group. Tuberculous meningitis is common. Pneumonia associated with lymphadenopathy should raise the concern for TB testing. CT is more sensitive than plain radiographs for demonstrating findings of primary tuberculosis.

Histoplasmosis may cause granulomatous disease simulating pulmonary tuberculosis. It is a fungus found in the soil most commonly in the Mississippi river Delta and South Western United States. Long-standing infection, which crosses lung and pleura to involve chest wall should raise the specter of other fungal entities such as blastomycosis, actinomycosis, and aspergillosis.

QUESTIONS AND ANSWERS

- Which of the following is most likely to communicate with the tracheobronchial tree?
 - Sequestration
 - Congenital lobar emphysema
 - Bronchogenic cyst
 - Abscess

ANSWER: B. Congenital lobar emphysema communicates with the bronchial tree at birth. Bronchogenic cysts may develop a communication with the airway caused by infection. Sequestration and abscess do not have a normal connection to the bronchial tree.

- Concerning umbilical arterial catheter placement, which of the following is *incorrect*?
 - Line placement between T6 and T9
 - Line placement between T9 and L2
 - Line placement between L3 and L4

ANSWER: B. The UAC is placed either high (T6–9) or low (L3–4) in order to avoid the origin of the celiac axis, superior mesenteric artery, and the renal arteries.

- Pulmonary interstitial emphysema serves as a warning for what possible impending condition?
 - Necrotizing enterocolitis
 - Heart failure
 - Pneumothorax
 - Pneumonia

ANSWER: C. PIE serves as a warning for possible impending pneumothorax or pneumomediastinum.

- What is the typical clinical course of transient tachypnea of the newborn?
 - Onset of respiratory distress by 6 hours after birth, peaking of symptoms around 24 hours after birth, and resolution by 48 to 72 hours
 - Onset of respiratory distress by 24 hours after birth, peaking of symptoms around 48 hours after birth, and resolution by 4 days

- Onset of respiratory distress by 48 hours after birth, peaking of symptoms around 3 days after birth, and resolution by 1 week

ANSWER: A. Transient tachypnea of the newborn is also referred to as retained fetal fluid or wet lung disease and is seen in postterm infants. It is because of a delayed clearance of fluid with onset of respiratory distress within 8 hours of birth, peaking around 1 day, and resolution by 48 to 72 hours.

- What is the most common cause of a large pleural fluid collection in the newborn period?
 - CHF
 - Congenital lobar emphysema
 - Pneumonia
 - Chylothorax

ANSWER: D. Chylothorax is the most common cause of a large pleural effusion in the newborn period, usually within the first week of life. It is usually right-sided but can be bilateral.

- A 6-week-old infant presents with fever, hyperinflation of the lungs, and peribronchial cuffing. What is the most likely diagnosis?
 - Chlamydia
 - Parainfluenza
 - Staphylococcus pneumoniae*
 - Streptococcus pneumoniae*
 - Mycoplasma pneumoniae*

ANSWER: B. Viral pneumonia and parainfluenza commonly present with the above symptoms in this age group. Effusion may occur. Consolidation is rare. Bacterial pneumonia in the neonate is often caused by *Streptococcal pneumoniae*.

- What causes membranous croup?
 - Staphylococcus aureus*
 - Hemolytic influenza
 - Parainfluenza
 - Streptococcus*
 - Pseudomonas*

ANSWER: A. Membranous croup or exudative tracheitis is a bacterial infection, most commonly *staphylococcal* in etiology. Membranous croup is an uncommon bacterial inflammation involving the larynx, trachea, and bronchi. Patients are generally older and sicker than children with viral croup. Viral croup or laryngotracheobronchitis is commonly parainfluenza.

- What is the most common cause of round pneumonia in children?
 - S. aureus*
 - Streptococcus*

- C. *Pseudomonas*
- D. *Klebsiella*

ANSWER: B. *Streptococcus* and *staphylococcus* are both causes of round pneumonia. *Streptococcus* is more common in the young age ranging from 1 to 3 years. Round pneumonia appears round because of poorly developed collateral pathways (pores of Kohn and channels of Lambert). With time, initial round pneumonia may develop in more typical consolidation.

102 PEDIATRIC CARDIOVASCULAR DISEASE

Eric J. Howell

CHEST RADIOGRAPHY

HEART SIZE

The heart size is often difficult to assess on the frontal image because of the relatively large thymus in infants and small children and poor inspiration, as a result, the cardiothoracic ratio is of little use. In older children, this ratio is usually less than 50%. The lateral view is more useful in evaluation of cardiac size; posterior cardiac margin approaching the spine suggests cardiac enlargement. Gross cardiomegaly is seen in volume overloading of the heart, as in severe valve regurgitation (Ebstein anomaly), cardiomyopathy, pericardial disease, and mediastinal masses.

PULMONARY VASCULATURE

Pulmonary vasculature is also often difficult to assess considering the frequent supine positioning and expiratory phase. Normally, the pulmonary artery branches are the same size as the accompanying bronchi. The right descending pulmonary artery should be the same or less than the width of the trachea, and no pulmonary vessels should be seen in the peripheral one-third of the lung. Normal vasculature can be present in valvular defects without shunting, in small-to-moderate shunts, and in balanced complex congenital heart disease.

Increased vasculature is seen in pulmonary to systemic shunts greater than 2:1. Decreased pulmonary vasculature is seen in cyanotic lesions with right-to-left

shunt. Pulmonary venous hypertension is another pattern recognized by hyperinflation of the lungs, perihilar vessels that are poorly defined, septal lines, and frank alveolar edema. Asymmetrical pulmonary flow can be seen with pulmonary arterial stenosis or hypoplasia and disturbances in ventilation with secondary vasoconstriction.

AORTA

Identifying the side and size of the aorta is often difficult secondary to overlap from the thymus. The trachea usually deviates away from the side of the aortic arch, which may help. A prominent ascending aorta is usually abnormal in children.

SITUS

The position of the stomach and liver should be assessed on chest radiographs when there is concern for congenital heart disease.

BONE ABNORMALITIES

Abnormalities such as scoliosis, segmentation anomalies, and rib anomalies are often associated with congenital heart disease. Rib notching is present in older children having coarctation of the aorta and intercostal collateral vessels. A bifid manubrial ossification center may be present in Down syndrome (80% trisomy 21, 20% normal children).

CT ANGIOGRAPHY

ADVANTAGES

CT offers the best global assessment of intrathoracic structures including the lungs and airways. Sedation is less often needed relative to MR vascular imaging; CT can be performed with support devices such as pacemakers. Images can be reconstructed in multiple planes.

DISADVANTAGES

CT results in relatively high radiation doses to the pediatric patient. CTA has a similar dose to routine chest CT; however, functional evaluations using gated CT have a greater dose than limited diagnostic catheter angiography

or nongated CTA. CT also requires use of intravenous contrast, which carries a small risk of significant adverse reactions.

CONTRAST

Low osmolar, nonionic iodine, 300 mgI/mL is typically used. The dosage is 1.5 mL/kg with maximum total volume 125 to 150 mL. If additional scanning is needed, the study can be repeated with an additional 1 to 1.5 mL/kg.

The suggested rates of administration are 1.5 mL/s with a 24-gauge angiocath, 2.0 to 2.5 mL/s with a 22-gauge angiocath, and 3.0 to 4.0 mL/s with a 20-gauge angiocath. The use of a power injector is preferable for optimal bolus formation. The timing of the delay in scanning relative to contrast administration is empiric in small children, usually 6 to 7 seconds after the onset of contrast administration. For large children, the delay is 50 seconds or alternatively, bolus tracking may be used.

SCAN TECHNIQUE

The highest possible number of detector rows and the thinnest reconstructed slice thickness should be employed. The pitch is 1.3 to 1.75. The tube current varies depending on patient size and as many units automatically modulated base on patient thickness. The peak kilovoltage is 80 kVp for infants, 100 kVp for young children, and 120 kVp for older children.

MAGNETIC RESONANCE IMAGING

FUNCTIONAL ASSESSMENT

MR is used to assess the ventricles, specifically end-diastolic and end-systolic volumes, ejection fraction,

stroke volumes, cardiac output, cardiac index, and shunt sizes.

TECHNIQUES

A combination of spin echo and gradient echo imaging is used to assess morphology. Recently, double inversion recovery morphologic imaging with flowing blood having signal void has been used. Another common technique used is gadolinium-enhanced magnetic resonance angiography with time of flight SPGR sequence. The steady-state free precession sequence (SSFP) is used for evaluating cardiac motion and function.

INDICATIONS

Most lesions are not evaluated with MR initially. Postop MR can be useful to assess the repair of transposition and evaluate various shunts (Glenn and Fontan) for patency or stenosis. MR has been used to evaluate right ventricular arrhythmogenic dysplasia. It can help demonstrate myocardial fat deposition, focal myocardial thinning, and microaneurysm formation. Wall motion abnormalities are also well shown by MR. The evaluation of the peripheral pulmonary arteries, which is difficult by echocardiography, is well shown by MR. MR is also a useful tool in diagnosing aortic abnormalities, such as coarctation, aneurysm, and vascular rings.

PATHOLOGY

ACYANOTIC CONGENITAL HEART DISEASE

All left-to-right shunts have increased pulmonary blood flow (Table 102-1).

TABLE 102-1 Acyanotic Congenital Heart Disease

Atrial septal defect (ASD)	Right-sided enlargement; secundum defect most common
Ventricular septal defect (VSD)	Right-sided and left atrial enlargement; membranous most common
Patent ductus arteriosus (PDA)	Right-sided, left atrium and aortic enlargement
Endocardial cushion defect (ECD)	Right-sided enlargement; trisomy 21
Aortic stenosis	Valvular most common
Aortic coarctation	“3” sign; associated with Turner syndrome
Pseudocoarctation	High aortic arch
Cor triatriatum	Ventricular enlargement with edema
Pulmonic stenosis	Dilatation of main and left pulmonary artery with right ventricular hypotrophy
Absence of the pulmonic valve	Dilatation of main and right pulmonary; Tetralogy

ATRIAL SEPTAL DEFECT

With atrial septal defect, there is right-sided enlargement, but no left atrial enlargement. The secundum defect at the foramen ovale is the most common type, accounting for approximately 80% of ASD. The primum defect, which is below the foramen ovale, is less common, accounting for approximately 10% of cases. The sinus venosus type, posterior to the foramen ovale, accounts for the remaining 10%. Sinus venosus type ASD is associated with partial anomalous pulmonary venous return of the right lung.

VENTRICULAR SEPTAL DEFECT

In ventricular septal defects, there is right-sided enlargement and left atrial enlargement. The membranous type is the most common (75%–80%), followed by muscular (10%–15%), and supracristal or conal (5%–10%). VSD may be isolated or associated with other complex congenital heart malformations.

PATENT DUCTUS ARTERIOSUS

There is an increased incidence of PDA in premature infants, infants with asphyxia, and congenital rubella. Radiographic findings include enlargement of the aorta and left atrium, in addition to right-sided enlargement. Indomethacin can be used to treat this defect. Transcatheter closure can be used for small-to-moderate lesions in term infants. Surgery is usually reserved for large defects in term infants and defects in preterm infants.

ENDOCARDIAL CUSHION DEFECT

This type of defect results from abnormal development of the endocardial cushions. The defect can be partial (ostium primum ASD and cleft mitral valve) to complete atrioventricular (AV) canal (primum ASD, large VSD beneath AV valves, common AV valve with five leaflets). There is right-sided enlargement secondary to interatrial or interventricular shunting. Left atrial enlargement may be present if there is mitral insufficiency. The defect is associated with trisomy 21, and 40% of these patients have congenital heart diseases and of these 40% have ECD. This subset of patients more commonly develops pulmonary hypertension with this defect.

OUTFLOW OBSTRUCTION LESIONS

Aortic Stenosis

Valvular aortic stenosis is the most common type of outflow obstruction. Seventy-five percent of these patients have a normal chest radiograph. A dilated ascending aorta may be identified, and there may be an abnormal number of leaflets or stenosis of a normal

valve. Supravalvular stenosis is uncommon (1%–2%). This form is associated with Williams syndrome. Muscular subvalvular stenosis accounts for 8% to 20% of cases.

Aortic Coarctation

Aortic coarctation has narrowing of the descending thoracic aorta adjacent to the site of the ductus arteriosus and just distal to the left subclavian artery origin. There is always a juxtaductal discrete narrowing, but there may also be varying degrees of tubular hypoplasia of the transverse arch and isthmus. Associated anomalies are frequent, and there is an inverse relationship between age at presentation and presence of other lesions, such as bicuspid aortic valve, VSD, PDA, and other left-sided obstructive lesions. There is an increased frequency of coarctation associated with Turner syndrome.

There are two theories for the development of aortic coarctation. The ductal sling theory postulates that there is an abnormal extension of contractile ductal tissue that forms a shelf. The blood flow theory describes decreased blood flow through the aortic isthmus in fetal life, secondary to left-sided obstructive lesions and as a result, there is abnormal aortic development and coarctation. Radiographic findings include the “3” sign upper convexity of the dilated aorta, narrowing at the coarctation and the lower convexity representing poststenotic dilatation. A “reverse 3 sign” is seen with a barium-filled esophagus. Occasionally, rib notching can be seen in children older than 5 years, as a result of dilated intercostal arteries. Both CT and MRI can assess coarctation and collateral blood flow. There is controversy regarding treatment of native coarctation with balloon angioplasty with stent or surgery. The former is the preferred procedure for recurrent coarctation.

Pseudocoarctation

There is a high aortic arch in pseudocoarctation. Though the thoracic aorta is kinked, it is not obstructed.

COR TRIATRIATUM

Cor triatriatum is a rare lesion and is associated with other lesions in 12% to 50% of cases. It results from an anomaly of pulmonary vein development in which the pulmonary veins connect to an accessory chamber of the left atrium. The accessory chamber is separated from the true left atrium by a fibromuscular septum that has a small, obstructed opening. An ASD may be present. There is pulmonary venous obstruction. On radiographs, there is right ventricular enlargement, pulmonary edema, and a large left atrial shadow representing both chambers. MR can be used to show the left atrial anatomy and the size and course of pulmonary veins.

PULMONIC STENOSIS

Radiographs may be normal in pulmonic stenosis if there is only mild narrowing. More severe narrowing creates poststenotic dilatation of the main and left pulmonary artery, right ventricular hypertrophy with elevation, uplifting of the cardiac apex on the frontal film, and filling in of the upper retrosternal clear space on the lateral view. The main pulmonary artery may be prominent in adolescence and there needs to be a correlation between imaging findings and clinical examinations.

ABSENCE OF THE PULMONIC VALVE

Absence of the pulmonic valve may be isolated or occur with other lesions, most commonly tetralogy of Fallot (TOF). Regurgitant blood flow results in aneurysmal dilatation of the main, right and left pulmonary arteries with compression/narrowing of the central and peripheral tracheobronchial tree. CTA and MRA studies can assess both the vascular abnormality and associated caliber and compression of the tracheobronchial tree.

CYANOTIC CONGENITAL HEART DISEASE

TETRALOGY OF FALLOT

TOF is the most common cyanotic congenital heart disease and is associated with trisomy 21, DiGeorge syndrome, and Alagille syndromes (Table 102-2). There is a right aortic arch in 25% of cases. Tetralogy

has four components: right ventricular outflow tract obstruction, right ventricular hypertrophy, VSD, and overriding aorta. There is a normal to slightly enlarged heart size with a boot shape on radiographs as the right-sided changes elevate the cardiac apex. The main pulmonary artery segment is concave, creating a left heart margin concavity. Pulmonary vascularity is diminished to a varying degree depending on morphology and can be disorganized if multiple systemic to pulmonary collaterals are present. Preoperative CT and MR can be helpful in delineating the pulmonary artery anatomy and caliber and systemic to pulmonary collaterals. Cardiac MR assesses right ventricular size and function.

TRICUSPID ATRESIA

In tricuspid atresia, there is an absence of the tricuspid valve with no blood flow from the right atrium to the right ventricle. Associated lesions include transposition, pulmonary hypoplasia/stenosis, coarctation of the aorta, ASD, patent foramen ovale, and VSD. Seventy percent of cases have ventriculoarterial connections that are concordant with severe pulmonary or subpulmonary stenosis. Thirty percent of cases have ventriculoarterial connections that are discordant with transposition and associated mild pulmonary stenosis and aortic obstruction. There is variable radiographic appearance depending on the type and associated lesions. The heart is usually normal to mildly large with normal-to-decreased pulmonary vascularity. CT and MR are useful postoperatively to evaluate patients after Fontan repair.

TABLE 102-2 Cyanotic Congenital Heart Disease

Tetralogy of Fallot	Most common cyanotic defect; trisomy 21, DiGeorge and Alagille syndromes 1. Right ventricular outflow tract obstruction 2. Right ventricular hypertrophy 3. VSD 4. Overriding aorta
Tricuspid atresia	
Pulmonary atresia with intact ventricular septum	
Pulmonary atresia with VSD	Severe tetralogy of Fallot
Ebstein anomaly	Abnormal tricuspid valve
Transposition of the great vessels	D- and L-types; “egg-on-a-string”
Truncus arteriosus	CATCH 22 syndrome
Total anomalous pulmonary venous return	
Double outlet right ventricle	
Hypoplastic left heart	Males; under development of left ventricle w/ obstruction of inflow and outflow.

PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

In this entity, there is right ventricular outflow obstruction with variable development of the right ventricle. The central pulmonary arteries and branching pattern are normal. There are variable tricuspid valve abnormalities with severe stenosis and insufficiency. These patients may have massive cardiomegaly if insufficiency is present.

PULMONARY ATRESIA WITH VSD

Pulmonary Atresia with VSD is felt to represent the most severe form of TOF.

EBSTEIN ANOMALY

The development and positioning of the tricuspid valve leaflets are abnormal in this anomaly. There is apical displacement of the septal and posterior valve leaflets into the right ventricle, resulting in partitioning of the right ventricle into an atrialized upper segment and

apical outflow chamber. The anterior leaflet is normal in position, but redundant. Almost all patients have ASD or a patent foramen ovale. Tricuspid insufficiency leads to elevated right atrial pressure and right-to-left shunting at the atrial level with cyanosis. The classic radiographic appearance shows a globular-shaped heart with normal-to-diminished pulmonary vascularity. MR reveals valve position, evaluates right ventricular function, and assess degree of shunting and regurgitation.

TRANSPOSITION OF THE GREAT VESSELS

In transposition, there is an abnormal relationship between the great vessels and the ventricles.

There are two main types of transposition: d-transposition and l-transposition. In d-transposition, the ascending aorta is anterior and to right of the main pulmonary artery. The aorta is connected to the right ventricle and the main pulmonary artery to the left ventricle. The coronary arteries arise from the ascending aorta. There are resulting parallel circuits, which require mixing of blood to maintain life. The cardiac apex is usually left-sided, and there is atrial situs solitus. Fifty percent of patients have simple transposition of the great vessels with a patent foramen ovale and/or PDA and no other anomalies. Twenty-five percent of patients have VSD. Twenty-five percent of patients have VSD and pulmonary stenosis or subpulmonary left ventricular outflow tract obstruction. Right aortic arch is present in 4% of simple lesions and in 16% of patients with VSD. There are variable radiographic findings. The classic appearance is described as an “egg on a string” heart with narrowed superior mediastinum from thymic atrophy and altered great vessel arrangement. Pulmonary vasculature is normal in neonates, then increases, as pulmonary vascular resistance decreases unless pulmonary stenosis is present. MR can be useful in evaluating older switch procedures. CTA is also useful in evaluating postoperative stenosis.

In l-transposition (congenitally corrected type), there is ventriculoarterial discordance and ventricular inversion. There is leftward and anterior positioning of the aorta relative to the pulmonary artery. The anatomic left ventricle is to the right of the anatomic right ventricle. In 20% to 50% of patients, mesocardia or dextrocardia is present. Most patients have additional abnormalities, including VSD (80%), pulmonary stenosis (30%–50%), abnormal tricuspid valve, conduction abnormalities, coarctation, and ventricular hypoplasia. On radiographs, there may be an abnormal straightening of the mid and upper left heart border because of the position of the aorta.

TRUNCUS ARTERIOSUS

This is a conotruncal defect with a single vessel arising from the ventricles, which overrides a VSD that supplies the systemic, pulmonary, and coronary circulations. There is one semilunar valve with two to four leaflets that are often abnormal. One-third of cases are associated with deletions in the genes of chromosome 22q11. This has been linked with the CATCH 22 syndrome, which has cardiac anomalies, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia. There is an increased incidence of truncus arteriosus in infants of diabetic mothers and retinoic acid exposure.

The truncal valve insufficiency and/or regurgitation lead to heart failure. Radiographs reveal a large heart with increased vascularity, pulmonary edema, right aortic arch, and thymic atrophy. Most patients are adequately assessed with echocardiography without the need for CT or MR. The Collett and Edwards classification is used to describe the specific truncal abnormality (Table 102-3).

TOTAL ANOMALOUS PULMONARY VENOUS RETURN

In this anomaly, all pulmonary veins connect to the systemic venous circulation or directly to the right atrium rather than the left atrium. The four pulmonary veins may form a common pulmonary vein or connect separately. The male-to-female ratio is 3 to 4:1. One-third of cases have been associated with other cardiovascular malformations, especially heterotaxia syndromes.

Darling classification is an anatomic-based description of location of the pulmonary venous drainage (Table 102-4). All type III lesions are obstructed, while only 50% of type I lesions are obstructed. Without venous obstruction, the physiology is similar to a large ASD. In type I lesions, there is a widened mediastinum with increased blood flow through the vertical vein, left brachiocephalic vein, and SVC. This gives the classic “snowman” heart in older children. There is cardiomegaly and increased pulmonary vasculature. With

TABLE 102-3 Collett and Edwards Classification of Truncus Arteriosus

Separate origins from lateral aspects of the truncus	6%–10%
Separate origins of pulmonary arteries directly from the posterior surface of the truncus	29%–48%
Short main pulmonary trunk arising from the left side of the truncus	48%–68%
Pseudotruncus: pulmonary atresia with bronchial collateral vessels off the descending aorta (complete sixth arch development failure)	

TABLE 102-4 Darling Classification

I, Supracardiac	50% of patients with TAPVR Four pulmonary veins form a common pulmonary vein behind the left atrium. This empties into a left vertical vein, which goes to the left innominate vein, which leads to the right-sided SVC
II, Cardiac	20% Pulmonary veins drain to the right atrium or as a common pulmonary vein to the coronary sinus
III, Infracardiac	20% Veins form a common pulmonary vein, which courses below the diaphragm to empty into the portal vein, ductus venosus, hepatic vein, or IVC
IV, Mixed type	10% All patients have a patent foramen ovale or ASD which maybe small and contribute to obstruction. This obstruction may be intrinsic or extrinsic

obstructive lesions, pulmonary venous hypertension and congestion are seen. There is an edema pattern with normal-sized heart, pleural effusions, thymic atrophy, and lung hyperinflation. CT and MR are useful in depicting the pulmonary veins and connections.

DOUBLE OUTLET RIGHT VENTRICLE

Double outlet right ventricle results from a conotruncal defect. The aorta and pulmonary artery arise from the right ventricle. A VSD is present and is the outlet from the left ventricle. A classification system has been developed based on VSD position. In the subaortic, type accounting for 50% of lesions, the blood from the left ventricle preferentially enters into the aorta. One-half of these patients also have pulmonary stenosis. Subpulmonary (Taussig-Bing) type accounts for 30% of cases. In this type, the blood from the left ventricle preferentially enters into the pulmonary artery. Thirty-five percent of these cases have associated aortic obstruction. Doubly committed accounts for 5% of lesions. In this type, the VSD is beneath the aortic and pulmonary valves with blood flow from the left ventricle to both the aorta and pulmonary artery. Noncommitted accounts for the remaining 10% of cases. The VSD is remote from the outflow and not committed to either great artery. There is no classic pattern on radiograph for all forms of double outlet right ventricle. The clinical presentation, physiology, radiographic appearance is dependant on the VSD position and associated stenosis. It may resemble VSD, TOF, or transposition.

HYPOPLASTIC LEFT HEART

There is a spectrum of anomalies associated with hypoplastic left heart syndrome. These include underde-

velopment of the left ventricle with obstruction or atresia of the inflow and outflow of the left ventricle. Two-thirds of cases occur in males. Findings include a hypertrophied left ventricular myocardium with a small chamber, hypoplastic ascending aorta, aortic valve atresia or stenosis, mitral atresia or stenosis, and a PDA. There often is a patent foramen ovale or ASD. Coarctation is present in 80% of cases. Both pulmonary and systemic circulations depend on the right ventricle. When the ductus constricts, there is decreased systemic perfusion, myocardial ischemia, and shock. Radiographic findings are variable ranging from normal to marked cardiomegaly. There may be an edema pattern in the lungs. MR may be useful to assess the anatomy if a two-ventricle repair is being considered. Treatment involves a staged reconstruction procedure, usually a Norwood procedure, followed by a bidirectional Glenn shunt, and then a Fontan shunt. Alternatively, cardiac transplantation has been used.

OPERATIVE PROCEDURES FOR CONGENITAL HEART DISEASE

BLALOCK-TAUSSIG SHUNT

The original Blalock-Taussig shunt operation created an end-to-side subclavian artery to pulmonary artery anastomosis. The modified procedure is a graft between the subclavian artery and PA.

GLENN SHUNT

The Glenn shunt is a unidirectional connection from the superior vena cava to the right pulmonary artery. The right pulmonary artery is divided from the main and left pulmonary artery. The bidirectional Glenn shunt is an end-to-side anastomosis of the superior vena cava to the right pulmonary artery, which remains in continuity and therefore provides blood flow to both sides.

FONTAN PROCEDURE

The classic Fontan procedure is a connection of the right atrium to the main pulmonary artery with a direct anastomosis or conduit. The new modified procedure has an anastomosis between the inferior vena cava and pulmonary arteries with a conduit or lateral atrial tunnel patch. The Fontan procedure is used for treatment of single ventricles and tricuspid atresia. Complications with this procedure include elevated systemic venous pressures, right heart chamber thrombosis, pulmonary arterial-venous malformation, arrhythmias, and protein losing enteropathy.

JATENE ARTERIAL SWITCH

The arterial switch procedure is used to repair d-transposition. The pulmonary artery and aorta are returned to

normal position after transection above the valves and switching. The coronary arteries are transplanted to the systemic vessel.

MUSTARD/SENNING PROCEDURE

Prior to the use of the switch procedure, the Mustard/Senning procedure was used to repair d-transposition, but is rarely used today. In this procedure, the systemic blood flow is redirected from the superior and inferior vena cava through a baffle or tunnel into the left (pulmonary) ventricle. The Mustard procedure uses a pericardial baffle and the Senning uses a right atrial flap. Pulmonary venous blood flow is redirected into the right (systemic) ventricle. Complications include baffle obstruction and leak, right ventricular failure, arrhythmia, and tricuspid insufficiency.

RASTELLI PROCEDURE

The Rastelli procedure is used in patients with d-TGV and a large VSD. An external conduit connects the right ventricle to the pulmonary artery. Blood flows from the LV to the ascending aorta through a VSD.

NORWOOD PROCEDURE

The Norwood procedure is used in hypoplastic left heart syndrome. The Norwood procedure has several components, which include atrial septectomy, transection of the pulmonary trunk proximal to the pulmonary bifurcation, and anastomosis of the pulmonary trunk to the aorta. A patch homograft is used to augment the ascending aorta and aortic arch. The patent ductus is ligated and a modified Blalock-Taussig shunt is placed to provide pulmonary blood flow.

ROSS PROCEDURE

The Ross procedure is used in aortic stenosis for severe dysplasia or insufficiency. There is translocation of the pulmonary valve to the aortic position as an aortic root replacement and then use of a pulmonary homograft.

CARDIAC AND VISCERAL MALPOSITION

ABNORMALITIES OF VISCERAL SITUS

Situs solitus is the normal arrangement in the body. In situs inversus, there is a mirror image of normal. This arrangement has a slightly increased incidence of congenital heart disease (3%–5%), such as right aortic arch, atrioventricular discordance, and transposition of the great vessels. Situs ambiguous or heterotaxy encompasses all other arrangements. It is typically divided into right (asplenia) and left (polysplenia) isomerism. Radiographs, CT, MR, and US are used for evaluation.

Asplenia

Asplenia is more common in males. There are bilateral trilobed lungs with bilateral minor fissures and eparterial bronchi. There are bilateral systemic atria. The liver is horizontal and centrally placed. Bowel malrotation is common with the stomach in an indeterminate position. The spleen is absent. The abdominal aorta and inferior vena cava are located on the same side of the spine. There is complex congenital heart disease in all patients, typically single ventricle, transposition, common atrioventricular canal, and pulmonary outflow obstruction.

Polysplenia

Polysplenia is more common in females and has a better prognosis than asplenia. There are bilateral bilobed lungs with hyparterial bronchi, with bilateral pulmonary atria. The liver is central in the abdomen. Bowel malrotation is common with the stomach in an indeterminate position. There are multiple spleens present in the upper right or left abdomen. There is interruption of the inferior vena cava with azygous continuation. Cardiac anomalies are present in 50%, typically anomalous systemic venous return, ASD, VSD, atrioventricular canal, double outlet right ventricle, and total or partial anomalous venous return.

VASCULAR RINGS AND SLINGS (GREAT VESSEL ANOMALIES)

LEFT AORTIC ARCH WITH ABERRANT RIGHT SUBCLAVIAN ARTERY

This is the most common aortic arch anomaly with a 0.5% incidence. It is typically asymptomatic. There is a posterior impression on the esophagus as evidenced on esophagography.

INNOMINATE ARTERY COMPRESSION

In this condition, the innominate artery originates to the left of midline and passes in front of the trachea. There is an anterior tracheal impression 1 to 2 cm above the carina. No esophageal impression is seen on esophagography. It rarely causes symptoms of respiratory obstruction.

RIGHT AORTIC ARCH, MIRROR IMAGE BRANCHING

Congenital heart disease is present in almost all patients; typically the lesions are cyanotic. The arch anomaly itself is not symptomatic.

RIGHT AORTIC ARCH WITH ABERRANT LEFT SUBCLAVIAN ARTERY

This type of right aortic arch is rarely associated with congenital heart disease. A ring exists that is completed

by the ligamentum arteriosum. There may be a diverticulum of Kommerell giving origin to the aberrant left subclavian artery. The vascular ring is typically loose and many patients have only mild or no symptoms.

DOUBLE AORTIC ARCH

In this anomaly, there are bilateral patent arches or atresia of one arch. Two vessels arise from the ascending aorta, joining posteriorly and having a left descending aorta in 80% of cases. The right arch is usually more superior in location, posterior, and larger, and there usually are no associated cardiac anomalies.

PULMONARY ARTERY SLING

In pulmonary artery sling, an anomalous vessel originates from the right pulmonary artery, passes between the trachea and esophagus, and supplies the left lung. It is accompanied by hypoplasia or dysplasia of the tracheobronchial tree in 65% of cases. It creates an indentation on the anterior wall of the esophagus at the level of the carina on esophagography. Initially, the right lung is opaque, but in older neonates and children, it becomes hyperlucent.

QUESTIONS AND ANSWERS

- Which type(s) of atrial septal defect is *not* commonly associated with anomalous pulmonary venous return?
 - Primum
 - Secundum
 - Sinus venosus
 - All types of atrial septal defect can be associated with anomalous pulmonary venous return

ANSWER: B. The sinus venosus type is associated with anomalous connection of the right pulmonary veins especially the upper lobe veins to either the

right atrium or superior vena cava. The ostium primum defect is associated with multiple other anomalies including total anomalous venous return.

- What is the most common type of ventricular septal defect?
 - Conal
 - Membranous
 - Supracristal
 - Muscular

ANSWER: B. Approximately 80% of VSD occur in the membranous septum.

- Which type of aortic stenosis is associated with Williams syndrome?
 - Valvular
 - Subvalvular
 - Supravalvular
 - None of the above

ANSWER: C. Williams syndrome is a sporadic genetic condition associated with distinctive facies and behavior, hypercalcemia, hyperacusis, and cardiovascular anomalies especially supravalvular aortic stenosis.

- What is the proposed mechanism for development of coarctation?
 - Reduced blood flow
 - Abnormal cardiac looping
 - Ductal sling
 - Both A and C

ANSWER: D. Although neither theory has been proven to be definitive, both the reduced blood flow and ductal sling have been proposed as mechanisms in formation of coarctation.

- What percentage of patients with hypoplastic left heart have coarctation?
 - 25%
 - 50%
 - 80%
 - 100%

ANSWER: C. Aortic coarctation is present in 80% of patients with hypoplastic left heart syndrome.

- Which of the following is *not* a component of tetralogy of Fallot?
 - ASD
 - VSD
 - Right ventricular hypertrophy
 - Pulmonary outflow obstruction

ANSWER: A. Tetralogy of Fallot consists of a defect in the anterior ventricular septum, obstruction of the right ventricular outflow tract, overriding aortic root above the VSD, and right ventricular hypertrophy.

7. Which of the following is the most common type of cyanotic congenital heart disease?
- Truncus arteriosus
 - Tetralogy of Fallot
 - Transposition of the great vessels
 - Tricuspid atresia

ANSWER: B. Tetralogy of Fallot is the most common accounting for nearly 10% of all congenital heart lesions.

8. Massive cardiomegaly can be seen in all of the following *except*:
- Pericardial effusion
 - Ebstein anomaly
 - Pulmonary atresia with an intact septum
 - Total anomalous pulmonary venous return with obstruction

ANSWER: D. Total anomalous venous return with obstruction. With this lesion there is normal cardiac configuration and size. The other lesions listed can have massive enlargement of the heart shadow.

9. Which of the following is associated with right aortic arch?
- Truncus arteriosus
 - Tetralogy of Fallot
 - Ebstein anomaly
 - Both B and C
 - Both A and B

ANSWER: E. Truncus arteriosus and tetralogy of Fallot have right-sided aortic arch usually the mirror image branching type as an associated anomaly.

10. Which of the following is *not* a procedure used for treating transposition?
- Jatene switch
 - Mustard
 - Senning
 - Ross
 - Rastelli

ANSWER: D. The Ross procedure is used in treating aortic stenosis.

103 PEDIATRIC GASTROINTESTINAL TRACT

Martha M. Munden and

Daniel W. Young

CONGENITAL DIAPHRAGMATIC HERNIAS

A Bockdalek hernia is a large, posterolateral defect in the diaphragm, with an estimated frequency of 1 per 2 to 5000 births. These occur more often on the left than the right side. Bowel can occupy the chest, shifting the heart and mediastinal structures to the opposite side, and ipsilateral and contralateral pulmonary hypoplasia is associated because of this space-occupying process. The pulmonary hypoplasia is more severe on the ipsilateral side. However, there are new developing theories that congenital diaphragmatic hernia is secondary to disruption of normal mesenchymal differentiation, with abnormal formation of the diaphragm affecting bronchial development, thus the pulmonary hypoplasia. Pulmonary hypertension commonly complicates congenital diaphragmatic hernias. Extracorporeal membrane oxygenation (ECMO) may be implemented in the newborn period (The other frequent reasons for ECMO are meconium aspiration and persistent pulmonary hypertension in the newborn).

A Morgagni hernia is a congenital anterior diaphragmatic hernia. This form of congenital hernia is much rarer than the Bockdalek hernia. The Pentology of Cantrell is a rare, associated condition (Table 103-1).

A hiatal hernia is an upward extension of cardia and fundus of the stomach into the chest through the diaphragmatic hiatus.

ESOPHAGUS

Gastroesophageal reflux (GER) can lead to symptoms and/or pathologic changes, which are referred to as

TABLE 103-1 Pentology of Cantrell

Omphalocele
Anterior diaphragmatic hernia
Sternal cleft
Ectopia cordis
Intracardiac defect: either a ventricular septal defect or a diverticulum of the left ventricle

TABLE 103-2 GERD Symptoms

Poor growth (decreased nutritional intake from vomiting)
Irritability or refusing to feed because of pain
Blood loss from esophagitis
Breathing problems and recurrent respiratory illness
Globus sensation
Acidic or sour taste in the mouth (water brash)
Dysphagia

gastroesophageal reflux disease (GERD). GER is a normal part of life in the newborn to some extent. There are many, varied symptoms of GERD (Table 103-2).

Most healthy infants have GER within the first 6 months of life, with prevalence decreasing with age, and spontaneous resolution is typical. The incidence is higher in premature infants. Those with neurologic disorders also have an increased incidence, partly because of reduced lower esophageal pressures with elevated intracranial pressure and abnormal esophageal peristalsis because of CNS dysfunction. In normal infants, transient relaxation of the distal esophagus occurs with the passage of food content and is initiated by peristalsis. The high-pressure zone of the intra-abdominal esophagus is important to prevent reflux. The integrity of the high-pressure zone depends on an adequate length of intra-abdominal esophagus, normal diaphragm, an intact phrenoesophageal ligament, and adequate gastric emptying. Anatomic predisposition to GER includes hiatal hernia, tracheoesophageal fistula, and esophageal atresia.

The Nissen fundoplication is the most commonly performed procedure out of the antireflux procedures and creates a 360-degree wrap of the gastric fundus around the distal esophagus creating an antireflux “valve.” This is now being performed laparoscopically on a more routine basis. Complications can arise when the esophageal wrap slips above the diaphragmatic hiatus, or there may be partial slippage above the diaphragm with a paraesophageal hernia. These conditions are associated with a reoccurrence of GER and dysphagia. The wrap is intended to be below the level of the hemidiaphragm. Additional problems include gastric bloat related to the inability to belch after the fundoplication, dysphagia, recurrent reflux, and others.

Esophageal atresia is highly associated with tracheoesophageal fistula (TEF). Esophageal atresia commonly presents with proximal esophageal atresia with distal TEF. The dilated proximal pouch is classically associated with tracheomalacia. The surgical repair usually occurs on the side opposite from the aortic arch. Therefore, since most patients have a left-sided aortic arch, a right

thoracotomy is most often performed. This entity is associated with VATER/VACTERL (Vertebral defects, Anorectal malformations, Cardiovascular defects, Tracheoesophageal defects, Renal anomalies, Limb deformities [radial ray abnormalities]). The distal esophageal segment in primary esophageal repair is known to have diminished peristaltic properties. There is usually stenosis at the site of primary anastomosis, which can cause obstruction of large foreign bodies or food. Balloon dilatation therapy is frequently performed to treat the narrowing at the anastomotic site. Proximal esophageal atresia with a distal TEF occurs in 82%, with proximal and distal esophageal atresia present in 9%, “H” type fistula with no esophageal atresia in 6% of patients, esophageal atresia with proximal and distal TEF in 2% and esophageal atresia with proximal fistula in 1%.

Swallowed foreign bodies can lodge at the level of the aortic arch or the thoracic inlet in the normal esophagus. Most small foreign bodies that reach the stomach pass out of the GI tract without harm in the fecal stream. Foreign bodies that need special mention include batteries and multiple magnets. Any time, more than one swallowed magnet passes beyond the stomach, they can attract each other through walls of adjacent loops of intestine, leading to obstruction with reported cases of necrosis and perforation. These foreign bodies may need endoscopic or surgical removal. Another concern is the penny minted after 1982 with a high zinc content. If it becomes lodged in the stomach, it may corrode because of a reaction of zinc with hydrochloric acid. Therefore, swallowed foreign objects should be monitored to ensure passage within about 2 days. Also of concern are the small disk batteries, which can cause mucosal injury if lodged in the esophagus in as short a time as 1 hour.

It is possible to perforate the back of the pharynx at the site of Killian dehiscence with a nasogastric tube. One should realize that patients with esophageal atresia have a proximal pouch that terminates near the T3 level or above. If the nasogastric tube cannot pass and is below the T3 level, consider traumatic perforation of the esophagus. Instillation of air through the tube with radiography can be helpful in diagnosing this condition.

STOMACH, SMALL BOWEL, AND COLON

A bezoar consists of an accumulation of undigested foreign material within the stomach. It is classified by the type of accumulated foreign material within the stomach (Table 103-3). It occasionally leads to obstruction.

TABLE 103-3 Bezoar

Lactobezoar	Congeaed milk or formula. This is the most common bezoar of infants
Trichobezoar	Swallowed hair
Phytobezoar	Plant fibers, persimmon fibers

Bezoars can be seen occasionally on conventional radiographs UGI examination, US, and CT.

Duodenal atresia can result in obstruction of the proximal duodenum and is associated with the “double-bubble” sign on radiographs. Duodenal atresia has a high association with Down syndrome but is not associated with a microcolon.

Jejunal and ileal atresia results in complete obliteration of the lumen. Proximal atresias may have a normally formed colon because of the passage of the succus entericus. Ileal atresia and distal jejunal atresia are frequently associated with microcolon. Ileal atresia may be seen in cases of complicated meconium ileus.

Meconium ileus presents with inspissated thick black enteric material in the distal small bowel and has a high association with cystic fibrosis. It can be treated with careful water-soluble contrast enemas. The hyperosmolar properties of water-soluble contrast allow water to be drawn into the GI tract to facilitate passage of meconium. Complications with meconium ileus occur in 30% to 50% of cases and include volvulus, perforation, atresia, peritonitis, and pseudocyst.

Meconium peritonitis is secondary in utero GI tract perforation in which meconium is expelled into the peritoneum. The meconium calcifies and can be a tell-tale sign. Meconium peritonitis is highly associated with meconium ileus. It is important to remember that calcifications may be seen in the scrotum in this condition because of the concomitant presence of a patent processus vaginalis.

Meckel diverticulum (omphalomesenteric duct remnant) is an antimesenteric outpouching of distal ileum, which has a fibrous connection with the umbilicus. These fibrous bands may be associated with internal hernia and volvulus. The Meckel diverticulum can bleed if it contains a sufficient amount of gastric tissue, which is diagnosed with the technetium-99m pertechnetate scan. The bleeding occurs on the wall opposite from the Meckel diverticulum due to ulceration resulting from acid production.

Small intramural nodules of lymphoid tissue are seen in the small bowel in patients with lymphoid hyperplasia. There is an association with IgA immunodeficiency.

Necrotizing enterocolitis (NEC) is an inflammatory condition of premature neonates and infants characterized by intramural air (pneumatosis intestinalis). There

can be portal venous gas and free intraperitoneal air associated with GI tract perforation. NEC has no definitive known cause but is strongly associated with prematurity. A combination of factors including prematurity with the immaturity of the immune system, alteration in mesenteric blood flow, and feeding may be associated, as NEC is usually seen after, not before, the beginning of feeding. It often presents with increased residuals, distention of the abdomen, and bloody stools.

Hirschsprung disease implies aganglionosis of the colon, resulting in a transition zone. The distal bowel is frequently of normal to slightly small caliber with a transition to dilated proximal bowel. There may be irregular contractions in the distal segment; the most common transition zone is near the recto sigmoid junction, which is deficient in submucosal and intramural ganglion cells of neural crest origin. There is an association of Hirschsprung disease with other neurocristopathies such as neuroblastoma, Ondine curse (central hypoventilation syndrome), and Waardenburg syndrome (white forelock, deafness). With total colonic aganglionosis, the entire colon and parts of the distal small bowel may be void of ganglion cells. If a newborn has a perforated appendicitis, one should suspect total colonic aganglionosis.

Meconium plug syndrome is a form of colonic dysmaturity in which meconium plugs obstruct the colon. Hirschsprung disease needs to be excluded in order to make this diagnosis. A suction rectal biopsy is usually sufficient. This disorder may also be seen in patients whose mothers have received magnesium sulfate for eclampsia.

Neonatal small left colon syndrome is a form of colonic dysmaturity and has an association with infants of diabetic mothers. No surgery is needed, as this condition is typically outgrown. Colon atresia is a rare cause of microcolon.

Cystic fibrosis is the most common autosomal, recessive disorder of whites. (Sickle cell disease is the most common autosomal, recessive disorder of African Americans.) Cystic fibrosis occurs secondary to a sodium chloride transport gene regulation abnormality and is associated with cirrhosis of the liver, pancreatic insufficiency; sinusitis, increased sweat chloride, sinusitis, infertility, and increased incidence of pneumonia, bronchiectasis, and tracheobronchiomegaly. Embolotherapy may be necessary in patients who have uncontrolled hemoptysis. Fifteen percent of patients have a history of meconium ileus. Fibrosing colonopathy can be seen in patients with cystic fibrosis that receive pancreatic enzyme replacement therapy. Distal intestinal obstruction syndrome, formerly called meconium ileus equivalent, is a condition in which stool fecal material becomes so viscous that it causes

TABLE 103-4 VACTERL/VATER Syndrome

Anorectal malformations
Cardiovascular defects
Tracheoesophageal defects
Renal anomalies
Limb deformities

bowel obstruction. A water-soluble contrast enema may be used therapeutically to treat this.

Imperforate anus is classified: as high, intermediate, or low. High imperforate anus is anal atresia with the point of atresia above the levator sling muscles. High imperforate anus is associated with rectourethral fistula in the male and rectovaginal fistula in the female. Patients with rectourethral fistula may have intraluminal meconium calcification. This is thought to be because of an alteration of pH secondary to the mixture of urine and meconium. High imperforate anus is treated by colostomy and a subsequent rectal pull through procedure. A fistula closure may also be required. Low imperforate anus may be treated with anoplasty. Intermediate imperforate anus occurs when the patient has external signs of a low lesion with a fistula to the urethra. Imperforate anus is associated with VACTERL/VATER (Table 103-4) and Currarino triad (Table 103-5).

HETEROTAXY

The term “situs solitus” refers to the normal arrangement of the systemic atria on the right, a right-trilobed lung, right-sided liver, and IVC. Situs inversus refers to the mirror image of situs solitus with the systemic atria on the left, a left-sided trilobed lung, left liver, left IVC, right-sided cardiac apex, stomach, spleen, and aorta. Heterotaxy, or “situs ambiguous,” refers to malpositioning of the viscera with indeterminate atrial arrangement. A variety of terms are used to describe the “ambiguous” visceral arrangement such as asplenia, right isomerism, bilateral right-sidedness and polysplenia, bilateral left-sidedness, or left isomerism. There is a high association of congenital heart disease with heterotaxy (50%–100%).

TABLE 103-5 Currarino Triad

Imperforate anus
Presacral mass, such as anterior meningocele
Teratoma
Rectal duplication
Sacral anomaly

Classic heterotaxy with asplenia has been used to describe bilateral trilobed lungs with bilateral minor fissures and eparterial bronchi, bilateral systemic atria, and central/midline liver. The stomach may be midline and small. The IVC and aorta are on the same side of the spine. These patients commonly have complex, severe cardiac anomalies and carry a worse prognosis.

Heterotaxy with polysplenia typically indicates bilateral bilobed lungs, bilateral pulmonary atria, a midline liver, stomach in variable position (though always on the same side as the spleen), and multiple spleens. The IVC may be interrupted with azygous or hemiazygous continuation. Heterotaxy with polysplenia tends to have less common and less severe cardiac anomalies. There is some association with biliary atresia. Both asplenia and polysplenia can be associated with midgut malrotation. Cardiac ECHO, abdominal US, MRI, and even CT may be indicated to define the full extent of the visceral and cardiac anomalies in these patients as the features of situs ambiguous are inconsistent.

EMERGENT PEDIATRIC ULTRASOUND

HYPERTROPHIC PYLORIC STENOSIS

Idiopathic hypertrophic pyloric stenosis (IHPS) was first described in 1627, though the etiology remains unknown. Infants with IHPS are clinically normal at birth and develop projectile, nonbilious emesis over a short time interval. IHPS typically occurs within the first 2 to 12 weeks of life. The incidence is two to five per 1000 births per year in the white populations and is less common among African Americans and Asian populations. It occurs more frequently in males, with ratios varying from 2.5:1 to 5.5:1. While there is a known hereditary link, it is likely polygenic with male and female children of affected mothers carrying an increased risk of developing IHPS. The risk is less for those children of an affected father.

The muscle in IHPS has been found to be deficient in the number of nerve terminals and markers for nerve-supporting cells, nitric oxide synthase activity, messenger RNA production for nitric oxide synthase, interstitial cells of Cajal, with increased insulin-like and platelet-derived growth factors. The abnormal muscle innervations may lead to failed relaxation of the muscle with secondary hypertrophy and obstruction. Interestingly, these levels return to normal months after surgical treatment.

The symptoms develop over a short period of time, progressively worsening until projectile emesis occurs after all feedings. The gastric contents are nonbilious, but may be blood-tinged with protracted vomiting caused

by gastritis. Eventual hypochloremic alkalosis develops with sodium and potassium deficits. With delayed diagnosis, extensive weight loss can occur. In severe cases, an emaciated infant may present with visible vigorous peristalsis noted in the epigastric region.

When IHPS occurs, the normal pyloric ring is no longer present, replaced by an elongated channel lined by thickened muscle that abruptly changes caliber from the normal 1 mm thickness of the gastric wall. The muscle wall thickness ranges from 3 to greater than 6 mm. Normal muscle wall thickness is less than 2 mm. There is also a redundant gastric mucosa associated with IHPS, which obstructs the elongated, thickened pyloric channel. The channel length is variable and can measure from 1.5 to well over 2 cm.

An experienced pediatric surgeon can palpate the “olive,” which represents the thickened, elongated pyloric channel. However, this is an art that is slowly being lost with increasing reliance on radiologic diagnosis. While the UGI examination was the mainstay in years past, it is now more of an accidental finding when the symptoms suggesting IHPS were not elicited prior to its performance. Typically, if suspicion is high, or a preliminary abdominal radiograph shows a distended stomach, US is performed, as it is a rapid diagnosis when positive.

Pylorospasm is a transient spasm of the pylorus. Similar to IHPS, patients present with emesis. However, upper GI examination and US show antral narrowing with delayed, intermittent, gastric emptying, not obstruction. On US, the single muscle wall thickness is normal as is the channel length.

Prostaglandin E therapy is used to maintain the patency of the ductus arteriosus in ductal dependent cardiac lesions and can lead to hyperplasia of the gastric mucosa. This can result in gastric outlet obstruction and an elongated pyloric channel on upper GI. However, on US, the muscle thickness will be normal and the obstruction is caused by mucosal hyperplasia. This disappears when the prostaglandin E therapy is discontinued.

Midgut malrotation occurs with a variety of abnormal rotations of the gut, which result in a foreshortened mesentery. The abnormal short mesenteric base allows excessive mobility of the small bowel and can result in midgut volvulus, where the small bowel rotates around the superior mesenteric artery (SMA) axis. Volvulus of the midgut or Ladd bands (which cross the third portion of the duodenum) can lead to obstruction. While upper GI is the primary mode for diagnosis, findings can be seen on US. With malrotation, the third portion of the duodenum is malpositioned anterior to the SMA, not in its normal retroperitoneal location. The normal anatomic position of the third portion of the duodenum

is between the SMA and aorta. In malrotation with midgut volvulus, the sonographic whirlpool sign is seen, representing a branch of the jejunal vein wrapping clockwise around the SMA. Demonstration of the normal retromesenteric position of the third portion of the duodenum between the SMA and aorta sonographically has been shown to be a reliable finding that the bowel is in its normal anatomic position.

DUPLICATION CYSTS

Congenital duplication cysts are a relatively uncommon but well-known congenital abnormality. They can occur anywhere along the digestive tract along the mesenteric side with the small intestine the most frequent site: ileum, then jejunum, and then duodenum. (Small intestine: approximately 45%, colon, 15%; gastric, 7%; duodenum, 5%; thoracic, 4%). Duplication cysts are firmly attached to the intestine, sharing a common wall and mesenteric blood supply with the gut. They can present with obstructive type symptoms or a palpable abdominal mass. A duplication cyst can be complicated by intussusception, volvulus, perforation, and rarely malignancy (frequency highest with those occurring within the colon in adults). US is probably the most common imaging modality and a duplication cyst has the characteristic sonographic appearance of the echogenic inner mucosal layer with hypoechoic outer muscular layer (the “gut signature”). The wall gut signature may not be circumferential as the layers are not uniform in thickness. If seen during a barium study, the cyst will show mass effect extending into the lumen of the portion of bowel. Gastric mucosa occurs in a reported 17% to 36% of duplication cysts and can lead to ulceration and GI bleeding. Those containing gastric mucosa can be demonstrated using Tc-99m sodium pertechnetate, similar to the uptake within a Meckel diverticulum. Sensitivity of Tc-99m imaging is reported to be 75%. At CT, a duplication cyst will be seen as a nonenhancing cystic mass. Fluid within the lumen typically has low Hounsfield units unless complicated by hemorrhage or proteinaceous material. Treatment is surgical excision.

GALLBLADDER

The incidence of gallstones in pediatrics is approximately 1.5%. Some of the more common etiologies of cholelithiasis in pediatrics include Lasix therapy, malabsorption, TPN, sickle cell disease, spherocytosis, thalassemia, and cystic fibrosis. Imaging findings are the same as those for adults. The normal gallbladder length in the neonate and young infant is less than 3 cm

and the width is less than 1 cm. From 2 to 16 years of age, the length is less than 8 cm and width is less than 3.5 cm. Wall thickness is 3 mm or less. The common bile duct is significantly smaller in children than adults. The common bile duct is less than 1.2 mm in children 3 months of age and younger, less than 2 mm in infants up to 1 year of age, and less than 4 mm in older children.

Kawasaki disease (mucocutaneous lymph node syndrome) is associated with a hydropic gallbladder and focal artery dilatation, most worrisome being the coronary arteries.

Ascending cholangitis is a common finding in patients who have had the Kasai procedure, caused by the lack of a sphincter preventing the upward migration of bowel organisms into the biliary system.

Alagille syndrome (also known as arteriohepatic dysplasia) is an autosomal dominant (variable expression) disorder with characteristic facial features including a pointed chin, elongated nose, and broad forehead. Patients typically present with cholestatic jaundice in early infancy. Elevated serum bile acids often result in severe pruritis and xanthomas. Additional associated abnormalities include pulmonary stenosis, butterfly vertebrae, growth and mental retardation, eye and kidney involvement, as well as hypogonadism.

The histologic finding in liver biopsy in Alagille syndrome an increased portal tract to bile duct ratio reflecting the bile duct paucity. The bile paucity may not be present in the newborn and the clinical picture may suggest neonatal hepatitis. Other features of the syndrome help in making the diagnosis. Treatment of the cholestasis includes choleretic agents, partial external biliary diversion when indicated for severe pruritus and xanthomas, and liver transplant when indicated for end-stage liver disease.

BILIARY ATRESIA AND NEONATAL HEPATITIS

Biliary atresia and neonatal hepatitis are common causes of conjugated hyperbilirubinemia. Neonatal hepatitis is a nonspecific hepatic inflammation with different etiologies including infection (CMV, toxoplasmosis, spirochetes, rubella, herpes, syphilis, protozoa), metabolic defects (such as alpha-1 antitrypsin deficiency, galactosemia, and glycogen storage disease), familial recurrent cholestasis, and errors of metabolism such as nesidioblastosis (idiopathic hyperinsulin hypoglycemia of infancy). Both biliary atresia and neonatal hepatitis present around 3 to 4 weeks of age with jaundice. Biliary atresia is characterized by obliteration or disruption of the extrahepatic biliary system with obstruction to

bile flow. The perinatal subtype form of biliary atresia is seen in 65% of cases and has isolated biliary atresia, while approximately 35% have the fetal subtype with multiple congenital abnormalities including polysplenia, malrotation, azygous continuation of IVC, situs inversus, preduodenal portal vein, bilobed right lung, complex congenital heart disease, choledochal cyst. Additional subtypes based on location of involvement include type I biliary atresia, which is rare with focal involvement. In type II, uncommon as well, there is atresia of the intrahepatic bile ducts and in type III (by far the most prevalent seen in greater than 90%), there is atresia of the right and left hepatic ducts to the level of the portal hepatis.

Distinguishing between biliary atresia and neonatal hepatitis is important, as biliary atresia requires early biliary diversion and neonatal hepatitis is managed medically. If the distal common bile duct is obstructed, an anastomosis between the extrahepatic biliary tree and intestine is performed. However, the majority require the Kasai procedure in which a portion of small bowel is attached to the portal region to allow bile drainage. The success of the Kasai procedure is 90% when performed in infants younger than 2 months and 50% when performed between 2 and 3 months of age, dropping even further after 3 months; thus the importance of a rapid diagnosis. Both entities may have some coarsening and increased echogenicity of liver parenchyma at US. With biliary atresia, the “triangular cord” sign, representing the fibrous remnant of the bile duct at the portal hepatis in extrahepatic biliary atresia, is fairly specific if present. Also, in biliary atresia the gallbladder is typically small or absent, though can be normal in about 10% of patients. Often with biliary atresia, the gallbladder is shrunken and irregular with poorly developed gallbladder wall, measuring less than 15 mm in length. Change in gallbladder size after a milk-feeding, indicating patency of the common bile duct is seen only with neonatal hepatitis. Scintigraphic examination will show tracer uptake by hepatic parenchyma, but no excretion in biliary atresia, while parenchymal uptake is decreased in neonatal hepatitis, but there will be excretion.

CHOLEDOCHAL CYST

Choledochal cyst is an uncommon cause of obstructive jaundice, more frequently seen in females and Asian infants, thought to be related to an abnormal insertion of the common bile duct into the pancreatic duct with reflux of pancreatic enzymes into the pancreatic duct causing chemical cholangitis and subsequent dilatation

of the common bile duct. Some may present with the classic triad of pain, jaundice, and a right upper quadrant mass while some are asymptomatic. Choledocal cyst is typed according to the Todani classification (Table 51-1).

INSPISSATED BILE SYNDROME

Inspissated bile syndrome is an uncommon cause of jaundice in neonates. Inspissated bile is echogenic but does not cause shadowing. It can obstruct extrahepatic bile ducts. Inspissated bile may be associated with TPN, cystic fibrosis, massive hemolysis, and increased enterohepatic circulation with Hirschsprung disease intestinal atresias, and intestinal stenoses.

Spontaneous perforation of the extrahepatic bile ducts is a rare entity, affecting infants younger than 3 months of age presenting with jaundice and ascites. The perforation is usually at the junction of the cystic and common hepatic ducts. At US, ascites and a loculated fluid collection at the portal hepatis are typical. Scintigraphy confirms the bile leakage.

PORTAL HYPERTENSION

Portal hypertension results from an increase in pressure gradient between the portal venous system and the hepatic veins or IVC. Most often, it is caused by intrinsic liver disease, but can be because of posthepatic etiology such as right-sided heart failure, constrictive pericarditis, and Budd-Chiari syndrome. Prehepatic causes include portal vein thrombosis (such as those resulting from umbilical venous catheter induced thrombus), portal mass effect by adjacent tumors. An uncommon etiology in portal hypertension is an underlying arteriovenous malformation. Imaging findings in portal hypertension include an enlarged portal vein (normal for children younger than 10 years is 8.5 ± 2.7 mm and 10 ± 2 mm from 10 to 20 years of age), decreased or reversal of portal venous flow (normal velocity is between 20 and 30 cm/s with respiratory variation), increased flow within hepatic artery, varices, splenomegaly, a thick lesser omentum, and ascites. Hemorrhage from varices is an important complication of portal hypertension. The left gastric vein drains the distal esophagus and proximal stomach and courses through the lesser omentum, entering the portal venous system near the splenoportal junction. The normal lesser omentum lies behind the left lobe of the liver and contains the left gastric artery and vein. The diameter of the lesser omentum in children is nearly constant. The lesser omental AP diameter can be related to the diameter of the aorta and

does not exceed 1.7 times the adjacent aortic caliber. In the absence of fatty infiltration or adenopathy (other contents within the lesser omentum), if the lesser omental/aorta ratio exceeds 1.7:1, portal hypertension should be considered.

Portal vein thrombosis can result from thrombosis induced by umbilical vein catheters, sepsis, dehydration, or tumor invasion (usually hepatoblastoma). Acutely, the portal vein is enlarged and can be easily demonstrated by US, CT, or MRI. Chronic portal vein thrombosis results in periportal collateral vein formation (cavernous transformation). Cavernous transformation has been shown to develop within 6 to 20 days after an acute thrombosis. A mass of collateral vessels around the main portal vein forms with intrahepatic extension of collaterals in some patients. Portosystemic collaterals form mainly through the left gastric and perisplenic veins and portoportal from the periportal or pericholecystic venous channels to the intrahepatic portal veins. Despite the recruitment of collaterals, portal hypertension usually occurs.

BUDD-CHIARI SYNDROME

Budd-Chiari syndrome is an uncommon, yet potentially fatal if untreated, condition resulting from acute hepatic vein obstruction and is characterized clinically by ascites, abdominal pain, jaundice, tender hepatomegaly, and liver failure. Etiologies include tumor thrombus extension from Wilms tumor radiation, chemotherapy, coagulation disorders, congenital webs. Obstruction of large or small caliber veins leads to hepatic congestion, causing hepatocellular injury. Type I Budd-Chiari syndrome is obstruction at the IVC level, type II is obstruction at the level of the major hepatic veins, and type III is obstruction at the level of the small centrilobular venules (veno-occlusive disease). Imaging by CT or US shows occlusion of hepatic veins, increased caudate enhancement, and patchy enhancement of the remaining hepatic segments. Ascites and gallbladder wall edema are present.

VENO-OCCLUSIVE DISEASE

Veno-occlusive disease consists of occlusive fibrosis of small, intrahepatic, centrilobular, and sublobular venules. Hepatic veins and IVC are patent. It is one of the most frequent serious complications after stem cell transplantation, occurring in 5% to 60% in children who have had stem cell transplant. The primary site of injury is the sinusoidal endothelial cells of hepatic venules with eventual complete venular obliteration, hepatocellular necrosis,

and widespread fibrous change. Veno-occlusive disease has a high-associated morbidity and mortality in post-transplant patients. Those at increased risk include those with preexisting liver disease, second myeloablative stem cell transplant, prior certain chemotherapy agents, prior conditioning with busulfan, melphalan, or both, and osteopetrosis. The principle cause in most cases is the toxicity of the preparative regiment for bone marrow transplant. Early symptoms include weight gain, tender hepatomegaly, ascites, and edema. The diagnosis can be challenging, as there are a lack of sensitive laboratory and imaging diagnostic studies. The imaging study of choice is abdominal Doppler with findings including slow or reversed portal venous flow (hepatofugal flow), decreased or reversal of diastolic flow in the hepatic arteries (increased resistance), ascites, hepatomegaly, and a thick gallbladder wall.

HENOCHE-SCHONLEIN PURPURA

Henoch-Schonlein purpura is an IgA-mediated vasculitis of small vessels that affects the bowel, skin, joints, and kidneys. Patients often present with abdominal pain with a rash. Hemorrhage into the bowel wall resulting in thickening can act as a lead point for intussusceptions. Seventy-five percent of cases occur between the ages of 2 and 11 years. Bowel wall thickening, ascites, and secondary intussusceptions can be seen sonographically.

APPENDICITIS

The role of the appendix, thought for years to be a troublesome vestigial remnant, is now being studied in the etiology of ulcerative colitis and for its role in the development of gut associated lymphoid tissue. Some hypothesize that appendicular lymphoid tissue may contribute to the development of colitis. Inflammation of the appendix is the most common cause for emergent abdominal surgery in childhood. The use of ultrasound in the evaluation of underlying appendicitis is well documented throughout the literature.

Inflammation of the appendix results from luminal obstruction caused by lymphoid hyperplasia of submucosal follicles, obstruction caused by an appendicolith or hard concretions, and rarely foreign bodies, parasites, and so on. Mucus production increases intraluminal pressure, bacteria proliferate, and the appendix distends. Venous congestion, edema ensues and by about 12 hours, inflammatory process may become transmural. If untreated, arterial flow is reduced causing ischemia and eventual necrosis with perforation. Perforation typically

will occur within 48 to 72 hours with complications that include abscess formation, peritonitis, sepsis, infertility, adhesions, and even death.

The lifetime risk for appendicitis is approximately 7% in females and 9% in males and appendicitis is much more common in developed countries. The peak incidence of appendicitis is highest in males from 10 to 14 years of age and 15 to 19 years in females. The classic symptoms of periumbilical pain that migrates to the right lower quadrant accompanied by anorexia, mild nausea, and several episodes of emesis, only occurs in around one-third of patients. In the very young, those younger than 3 years of age, when idiopathic intussusception is a common etiology for abdominal pain, the diagnosis of appendicitis is more difficult than in the child who can provide a history of pain in the right lower quadrant. Most children present with perforation younger than 3 years of age.

In clinically equivocal cases, imaging can improve the accuracy of diagnosis. Prompt diagnosis is necessary to prevent delay in treatment, perforation, and its complications. Plain films are nonspecific and insensitive in the diagnosis of appendicitis and can be normal or show decreased gas in the right lower quadrant, scattered air-fluid levels, an indistinct psoas margin, or mildly dilated small bowel loops. The presence of a calcified appendicolith has a high-positive predictive value for appendicitis in the presence of abdominal pain, but can be detected on plain films in only around 5% to 10% of cases. Most consider plain films to be of little value for routine evaluation.

US and CT have served to reduce the false-negative rate of appendectomies, with rates of 20% to 30% now around 4% to 8%. While CT does have an overall increased sensitivity and specificity compared to US, CT does not come without the cost of ionizing radiation and can be difficult to interpret in the very young child with little or no intra-abdominal fat. Limited and low-dose CT is being utilized to expedite the diagnosis of appendicitis in clinically equivalent cases. However, with the lack of fat in the young pediatric patient, most would agree that US, in experienced hands, is the best route for initial examination for suspected appendicitis in the infant and nonobese pediatric patient.

The use of graded-compression US in the diagnosis of appendicitis was first described by Puyleart in 1986. A high-resolution linear transducer is placed at the site of maximal tenderness indicated by the patient to compress and displace bowel loops to identify the appendix. The location of the appendix is highly variable and the anatomic position determines the symptoms and site of tenderness when the appendix is inflamed, thus the importance in examining the region indicated by the

patient. Graded compression is utilized to locate either a normal or inflamed appendix to exclude or confirm the diagnosis of appendicitis. The normal appendix, which is a blind-ending tubular structure that compresses, is usually found anterior to the psoas muscle. The normal appendix has a thin, echogenic inner layer of mucosa and submucosa surrounded by a peripheral hypoechoic layer of muscularis propria. It is important to follow the suspected appendix back to the cecum, where the appendix arises about 1 to 2 cm below the terminal ileum and follow it along its length to the tip to ensure that an inflamed terminal ileum is not mistaken for an inflamed appendix. This is also necessary to include those with inflammation limited to the tip of the appendix. The abnormal appendix is identified as a blind ending, non-compressible, tubular structure measuring greater than 6 mm in maximum transverse diameter. In early appendicitis, the echogenic line, which corresponds to the mucosa and submucosa, is maintained. Loss of this echogenic line may be one of the earliest signs of perforation. With increasing inflammation, the appendix becomes hyperemic and increased flow can be seen by color Doppler. Signs of perforation include increasing echogenicity of the surrounding inflamed fat, adjacent fluid with varying degrees of increased echogenicity, as well as widespread echogenic fluid, abscess formation, and secondary small bowel obstruction.

Absolute exclusion of appendicitis by US is more difficult and the drawback for performing ultrasound to diagnose appendicitis is the operator dependency and the increasing incidence of obesity in childhood. In experienced hands, ultrasound has reported negative predictive value of 96%, but the overall reported sensitivity varies widely. In a recent publication of a study of sonographic techniques by Lee et al. in diagnosing acute appendicitis in a group, which included pediatric and adult patients, they were able to visualize the appendix in 98% of their control group and 99% in their patient group. In addition to the upward-graded compression, using a linear transducer to push the cecum and appendix out of the pelvis, they utilized several additional maneuvers to increase the visibility of the appendix. A forced extrinsic compression by the examiners left hand on the posterior aspect of the cecum, while graded compression with the linear transducer anteriorly was used. They also increased their sensitivity by turning the patient into the left lateral oblique decubitus position to displace the cecum and appendix medially.

The patient with a short history of signs and symptoms suggesting appendicitis, but an inconclusive US examination, can undergo a repeat limited US examination within a short period of time. This is in accordance to the ALARA principle.

Obesity in childhood has become an increasing problem in the US and can severely limit the ability to evaluate for appendicitis sonographically. Hormann et al showed that the higher the body mass index-for-age percentile (BMI-FAP), the more difficult it was to detect the appendix, not an unexpected finding. Age is not adequate to use for a cut-off in the decision as to whether to use US or CT in the clinically inconclusive patient as even the very young can be extremely obese; while, an older, thin patient may be an ideal candidate for an US examination. A significant decrease in US sensitivity occurs beyond a BMI threshold of 25. The decision of whether to proceed with CT or to attempt a limited US in a larger patient is dependent on the resources of the individual institution.

Pitfalls in the diagnosis of appendicitis by ultrasound include the inability to identify inflammation localized to the tip of the appendix, thus the importance of searching for the tip. With a recent perforation, the appendix may reseal at the tip or rupture such that no appendix can be identified, another cause for a false-negative examination. Presentation too early in the course of inflammation, such as in the patient with only 6 to 8 hours of pain, may lead to a false-negative US examination. In this case, if there is continued clinical suspicion and an inconclusive examination, the patient can be held for observation with repeat limited scan of the right lower quadrant within about 8 to 12 hours because appendicitis usually “declares” itself in 24 to 36 hours.

Omental infarction, an entity becoming more prevalent with the increasing incidence of childhood obesity, can lead to a confusing examination with echogenic, inflamed omentum at the site of tenderness, which may decrease the ability to find a normal appendix. Adnexal pathology including pelvic inflammatory disease, ovarian torsion, and hemorrhagic ovarian cysts can mimic appendicitis clinically and the inflammation related to pelvic inflammatory disease can extend to the appendiceal region. Mesenteric adenitis (a cluster of three or more ileocolic nodes measuring greater than 5 mm short axis diameter with a normal appendix) and even an inflamed Meckel diverticulum can mimic appendicitis. A dilated ureter obstructed by a distal stone may be mistaken as the appendix by the inexperienced sonographer.

False-positive studies can result from bowel inflammation adjacent to the normal appendix. It is important to follow the complete course of the appendix to prevent terminal ileum thickening from Crohn disease from mimicking appendicitis. The bowel wall thickening associated with Henoch-Schonlein purpura can be confused with appendicitis. The vasculitis of Henoch-Schonlein

purpura can cause intramural thickening, which can be difficult at times to differentiate from both appendicitis and intussusception. Bowel wall thickness usually ranges from 5 to 8 mm with Henoch-Schonlein purpura. In addition, the appendix in cystic fibrosis can be of much greater diameter and incompressible because of mucoid material in its lumen without being related to appendicitis.

INTUSSUSCEPTION

Intussusception occurs when a loop of bowel (intussusceptum) invaginates into a more distal loop of bowel (intussusciens). Idiopathic intussusceptions generally occur from about 3 months of age to 2 years, with males affected about three times more frequently than females. Classic symptoms occur in only about 50% and include intermittent severe abdominal pain with interval periods of lethargy, palpable abdominal mass, and “currant jelly” stools. While only about half have the classic triad of symptoms, most (75%) have stools that test positive for occult blood.

The large majority of idiopathic intussusceptions are ileocolic or ileoileocolic and occur secondary to lymphoid hyperplasia within Peyer patches in the terminal ileum, leading to the intussusceptum invaginating into the intussusciens. The mesentery is drawn with the intussusceptum, which becomes compressed causing compromise of venous drainage with subsequent bowel edema, possible ischemia, obstruction, and infarction. Ischemia of the mucosa causes bleeding and mucus outpouring, resulting in the “currant jelly.” If treated, mortality is only 1% to 3%. Delayed treatment leads to bowel necrosis and even death. Recurrence rates range from 5% to 20%.

Predisposing illness leading to lymphoid follicular hyperplasia include recent URI or diarrheal illness, particularly adenovirus, and enterovirus, thus the more seasonal variation in presentation with idiopathic intussusception. Intussusception with underlying lead points (less than 5%) is uncommon in infants and more common in neonates and children older than 5 years, as well as those with small bowel intussusceptions. Intussusceptions within small bowel can be associated with Henoch-Schonlein purpura, indwelling gastric or gastrojejunostomy tubes, polyps in Peutz-Jeghers syndrome, and recent intraperitoneal or retroperitoneal resection. Lead points also include duplication cysts, Meckel diverticula, lymphoma, and even trauma.

The consequence of missing the diagnosis of intussusception can be disastrous for the patient. Plain film findings include small bowel obstruction, decreased

gas in the right lower quadrant, a gasless abdomen, findings, which are generally nonspecific. The “target sign” is more specific, representing a soft-tissue mass containing a circular area of lucency representing the mesenteric fat of the intussusception. This is often seen in the right upper quadrant. The meniscus sign consists of a crescent of gas within the colon lumen outlining the intussusception. Plain films are often not useful in the diagnosis of intussusceptions. However, plain films can be useful to evaluate for complications of intussusception such as small bowel obstruction or intestinal perforation.

Ultrasound is readily available and has become the imaging modality of choice to evaluate for intussusception, along with other suspected etiologies of acute abdominal pain in the emergency department setting. Sensitivity in detection of intussusception is reported to be 98% to 100%. In a prospective study, Verschelden et al. reported ultrasound to have a negative predictive value of 100%, meaning no patient having a negative US examination was found to have an intussusception by enema. This applies in the case of ileo and ileoileocolic intussusception where the peripheral location of the colon is easily evaluated sonographically. In the case of intussusceptions limited to the small bowel, these numbers do not necessarily apply given the limitation of central detail by bowel gas, especially in the postoperative patient.

On US examination, the typical findings of an intussusception are a mass from 3 to 5 cm or greater in size located in the distribution of the colon, usually on the right side. In the study of Verschelden et al., most of their examinations were performed by third and fourth year residents who had completed several months of training. Use of high frequency linear transducers is recommended for optimal bowel detail. An excellent description of the appearance of an intussusception on transverse and longitudinal imaging is provided by del-Pozo et al. Transversely, an intussusception produces a target sign with multiple hypoechoic concentric rings of alternating layers of collapsed intussusceptum lumen and the bowel wall signature of the intussusceptions surrounding an echogenic center of the mesenteric fat often containing lymph nodes, or the “doughnut” sign with echolucent outer ring surrounding an echogenic center. In longitudinal views, the intussusception has been characterized as having a “pseudokidney” sign, where the intussusciens has a hypoechoic rim and the more central intussuscepting mesenteric fat is more echogenic, similar to the kidney.

Clearly defined echogenic/echolucent alternating rings correspond to less edematous bowel and typically better success of reduction. Enlarged mesenteric lymph nodes are commonly seen in children with gastroenteritis

and following various viral syndromes. These mesenteric nodes are commonly pulled with the mesentery into the intussusception and are commonly seen sonographically within the central echogenic mesentery at US. The mesentery is dragged between the loops and is maximum at the base of the intussusception and absent at the apex. Sonographic signs associated with irreducibility include interloop fluid with a thickened outer hypoechoic ring with “doughnut” pattern and absence of blood flow in an intussusception. This pattern holds true, both with ileocolic and small bowel intussusceptions. The lymph nodes, along with edematous mesentery, are thought to impede the exit of the intussusceptum. Identification of a lead point is valuable information provided sonographically for decisions in further management of the patient.

Not only should the right lower quadrant and distribution of colon be studied with abdominal pain, but small bowel should be briefly studied as well. Often transient small bowel intussusceptions are found incidentally and complete resolution should be documented. CT and US studies have shown that benign, transient small bowel intussusceptions tend to be less than 3.5 cm in length; nontransient ones are often associated with lead points. Their appearance is similar, though more midline in location, and they can be multiple in patients with polyps associated with Peutz-Jeghers syndrome. Symptoms are often more chronic than acute, not the classic signs of idiopathic intussusception.

INTUSSUSCEPTION PITFALLS

Causes of the occasional false-positive US examination include any condition leading to bowel wall thickening, such as vasculitis leading to intramural hematoma in Henoch-Schonlein purpura. The characteristic appearance on transverse imaging of eccentric, hyperechoic mesenteric fat, and lymph nodes should not be present in these conditions, which can serve to differentiate bowel wall thickening from an intussusception.

In conclusion, if a child has all three classic signs and symptoms of an intussusception, the most cost-effective approach for the next evaluation would be to perform a contrast enema examination, as this has the potential both to confirm the diagnosis and to treat the problem. However, if the diagnosis is less straightforward, ultrasound is the ideal modality to identify which children would be appropriately treated by enema reduction for an intussusception. Ultrasound also has the advantage of identifying an underlying lead point when present and can serve to help one judge the reducibility of an intussusception by its appearance.

QUESTIONS AND ANSWERS

- What is the most important anatomic landmark in the pediatric upper GI examination?
 - Gastric fundus
 - Duodenojejunal junction
 - Pyloric channel
 - Gastric antrum

ANSWER: B. The location of the duodenojejunal junction, which determines if there is midgut malrotation and therefore risk for midgut volvulus.

- Which of the following diagnoses is suggested with bilious vomiting?
 - Hypertrophic pyloric stenosis
 - Biliary atresia
 - Midgut volvulus
 - Gastric volvulus

ANSWER: C. This can be an important clue of the possible diagnosis of malrotation—and midgut volvulus. Bilious vomiting suggests the diagnosis is located distal to the ampulla, as in midgut volvulus. Gastric outlet obstruction, such as from pyloric stenosis or gastric volvulus would have nonbilious vomiting.

- What is the best test for the diagnosis of malrotation?
 - UGI examination
 - Ultrasound
 - CT
 - MRI

ANSWER: A. Upper GI, because it specifically locates the duodenojejunal junction.

- What is a sonographic finding of malrotation?
 - Predoduodenal portal vein
 - Short pancreas

- C. Microgastria
- D. Inversion of the SMA/SMV relationship

ANSWER: D. Inversion of the SMA/SMV relationship. A “whirlpool” sign can be seen with midgut twisting around the vessels, midgut volvulus.

5. What would be the safest contrast material to use to evaluate the proximal pouch in a patient with esophageal atresia and distal tracheoesophageal fistula?
 - A. Gastrografin
 - B. Barium agent
 - C. Air
 - D. Non-ionic water-soluble contrast

ANSWER: C. Air. Instill a few cubic centimeters of air into the Replogal catheter used to drain or decompress the proximal pouch.

6. Which one is associated with microcolon?
 - A. Meconium ileus
 - B. Scarring
 - C. Infants of diabetic mothers
 - D. Midgut volvulus

ANSWER: A. A microcolon is a small unused colon and is seen in the setting of meconium ileus, ileal atresia, colonic atresia, and megacystis-microcolon-hypoperistalsis syndrome. Jejunal atresia may not be consistently included on this list since the succus entericus produced by the small intestine may be associated with a normal caliber colon.

7. Intraperitoneal calcifications are identified in the abdominal cavity and scrotum. What is the most likely diagnosis?
 - A. High imperforate anus
 - B. Meconium peritonitis
 - C. Hypercalcemic state
 - D. Hyperparathyroidism

ANSWER: B. Meconium peritonitis. This implies that there has been a GI tract perforation in utero and scrotal calcifications prove patent processes vaginulus.

8. If a contrast enema is being used to treat meconium ileus, what contrast should be used?
 - A. Barium
 - B. Air
 - C. Water-soluble contrast
 - D. Lipiodol

ANSWER: C. Water-soluble contrast media, such as contrast media used for VCUG. Its hypertonicity draws fluid into the bowel lumen, helping cleanse the inspissated thick, black material.

9. What are contraindications to the performance of an air or contrast enema to reduce ileocolic intussusceptions?
 - A. Pain
 - B. Small bowel obstruction
 - C. Perforation and peritonitis
 - D. Hypothermia

ANSWER: C. Perforation and peritonitis.

10. If a patient is felt to have meconium plug syndrome, what underlying disorder should still be considered?
 - A. Cystic fibrosis
 - B. Meconium ileus
 - C. Meconium peritonitis
 - D. Hirshprung disease

ANSWER: D. Meconium plug syndrome is a form of colonic dysmotility and is transient. Clinically, it can be indistinguishable from Hirshprung disease, which is a permanent motility disruption due to segmental absence of colonic ganglion nerve cells.

104 PEDIATRIC GENITOURINARY TRACT

Jeremy T. Royal and Stuart A. Royal

ADRENAL GLAND

Neonatal adrenal hemorrhage is associated with coagulopathy, birth trauma, sepsis, and asphyxia and can typically be seen in infants of diabetic mothers who are large for gestational age. It is bilateral in 10% and more common on the right (85% in one study). Typical sonographic features include nonvascular hematoma that involutes over months to years and may develop calcification. Adrenal insufficiency is extremely rare.

Neuroblastoma is the most common solid, extracranial childhood malignancy with a peak age of 2 years. Three-fourths occur in the abdomen, with two-thirds of these occurring in the adrenal medulla. One-third of these occur in the extra-adrenal retroperitoneum, with 20% in the posterior mediastinum, 3% in the presacral pelvis (Table 104-1), and 5% in the neck. Neuroblastoma encases adjacent upper abdominal arteries and extra-adrenal neuroblastoma invades the epidural space via the neural foramina. Metastases (50% at diagnosis) are common to the liver and bone, though extremely rare

TABLE 104-1 Pediatric Presacral Mass

Cystic sacrococcygeal teratoma	Solid sacrococcygeal teratoma
Duplication cyst	Neuroblastoma
Anterior meningeal cyst	Rhabdomyosarcoma
	Primary sacrococcygeal bony tumors

to lung. Calcification in abdominal neuroblastoma is seen in 85% via CT scanning and 30% via radiography. Radionuclide bone scan demonstrates uptake in the primary mass in 75% and is performed at diagnosis in addition to radiographic bone survey. MIBG has uptake in 70%. Ultrasound and CT of the primary area with supplemental MR is typically utilized for complete staging. Stage IV-S neuroblastoma is seen in infants younger than 1 year of age with skin, liver, and bone marrow but no osseous cortical abnormality. Multiple syndromes are classified based upon metastasis (Table 104-2).

The overwhelming majority of patients have elevated catecholamines at diagnosis. Better prognosis includes lower stage, stage IV-S, thoracic primary, Shimada histologic grade, high-DNA index, low N-MYC amplification, and age younger than 1 year.

KIDNEYS

CONGENITAL ABNORMALITIES

Ureteropelvic junction (UPJ) obstruction is the most common form of urinary tract obstruction in pediatrics. It is four times more common in newborn boys than girls and bilateral in 10% to 20%. It is seen in association with horseshoe kidney, inferior renal ectopia, and the lower pole of a complete duplex collecting system. Patients may be diagnosed prenatally with sonography. Postnatally, UPJ obstruction is the most common cause of a palpable abdominal mass. Patients may

present with urinary tract infection (UTI), intermittent abdominal pain, vomiting, or hematuria. On nuclear scans with a diuretic challenge, a T1/2 washout from peak activity greater than 20 minutes is diagnostic of obstruction. A T1/2 washout of 10 to 20 minutes is indeterminate.

Multicystic dysplastic kidney (MCDK) is a nonfunctioning kidney, which is replaced by multiple, noncommunicating cysts with intervening dysplastic parenchyma. It is the most common cause of a unilateral, cystic kidney in a neonate, and it is the second most common abdominal mass in a neonate. The classic form results from pelvoinfundibular atresia. Up to 40% of these patients have a contralateral abnormality, commonly contralateral UPJ obstruction, and 25% have contralateral reflux. In 85%, the affected kidney tends to involute over time. MCDK is typically diagnosed with ultrasound, but nuclear scintigraphy can be helpful to confirm the diagnosis by demonstrating absence of renal function.

Renal ectopia represents normal renal tissue in an abnormal location. Kidneys that fail to ascend, generally maintain some degree of anterior orientation. Variations of renal ectopia include horseshoe kidney, crossed fused ectopia, pelvic kidney, iliac (ptotic) kidney, and thoracic kidney. Pelvic kidney is the most common form of ectopia, accounting for about 60% of cases. Malpositioned kidneys are at a higher risk for vesicoureteral reflux (20%–30%), trauma, obstruction (usually UPJ), infection, stones, and a slight increase in the incidence of Wilms tumor. Aberrant and multiple renal arteries and veins are also common. Horseshoe kidney may be associated with genital anomalies, VACTERL anomalies (vertebral, anorectal, cardiac, tracheoesophageal, renal, limb abnormalities), and Turner syndrome, among others.

Renal agenesis may occur bilaterally or unilaterally. Bilateral renal agenesis is lethal. Males are affected three times more often than females. This condition produces profound oligohydramnios, and the kidneys, which can usually be seen by the 15th week of gestation by ultrasound, are not present. If the diagnosis is not made until birth, the child will manifest with Potter syndrome: pulmonary hypoplasia (usually with spontaneous pneumothoraces), abnormal facial features, and deformity of the limbs. Unilateral renal agenesis may be detected prenatally, postnatally, or may be silent until puberty, when associated genital tract anomalies become apparent. The association of unilateral renal agenesis with genital tract anomalies in females, especially the absence or hypoplasia of the vagina, is called Mayer-Rokitansky-Kuster-Hauser syndrome. Seminal vesical cyst can be seen in males with unilateral renal agenesis. Unilateral renal agenesis is frequently seen in association with anomalies of the cervical and lumbosacral

TABLE 104-2 Metastatic Neuroblastoma Syndromes

Hutchinson syndrome	Primary adrenal neuroblastoma Skeletal metastases (skull) Proptosis Bone pain
Pepper syndrome	Primary adrenal neuroblastoma Hepatomegaly secondary to metastases
Blueberry-Muffin syndrome	Primary adrenal neuroblastoma Multiple metastatic skin lesions

spine, and/or anorectal anomalies. The contralateral kidney should be measured to evaluate for compensatory hypertrophy.

Autosomal recessive polycystic kidney disease (ARPKD) is a genetic disorder characterized by bilateral, symmetric cystic renal disease involving the distal convoluted tubules and collecting ducts. The kidneys are typically bilaterally enlarged and hyperechoic with poor corticomedullary differentiation and may fill the flanks and displace adjacent organs. Small, discrete cysts (less than 1 cm) may or may not be visible. There is usually a history of oligohydramnios. Small biliary ductal ectasia and liver fibrosis are always present, with Caroli disease seen in a small number of patients. Twenty to forty-five percent of patients with ARPKD present in the second decade of life with renal failure and require dialysis or renal transplantation. Late complications include portal hypertension secondary to hepatic fibrosis.

Autosomal dominant polycystic kidney disease (ADPKD) is a genetic disorder characterized by bilaterally macrocystic kidneys and is associated with other systemic abnormalities. The kidneys are typically within two standard deviations of normal in size at diagnosis in childhood. The cysts tend to be larger than 1 cm in size. Occasionally, pediatric patients with ADPKD may have diffusely hyperechoic kidneys similar to ARPKD. Cysts may also involve the liver (50%) and the pancreas (9%). Noncystic manifestations include cardiac valvular disorders, hernias, colonic diverticula, and congenital “Berry” aneurysms (15%). Tuberous sclerosis can rarely have renal cystic disease, which is similar in appearance to ADPKD. Patients with ADPKD most commonly present in the fourth or fifth decade of life with renal failure or hypertension.

RENAL TUMORS

Wilms tumor is the most common abdominal tumor of childhood with a peak age of 3 years. Typical triphasic pathology occurs with epithelial, blastemal, and stromal elements, though anaplasia is a high-risk histologic feature. Staging includes CT imaging of the chest. Bone metastases are uncommon so that bone imaging is not usually performed. Stage V includes bilateral synchronous tumors, which are associated with nephroblastomatosis. Calcification is present in 9% of radiographs and 15% of CT examinations. Pulmonary metastases are present in 20% of children at time of diagnosis. Nephroblastomatosis, secondary to persistent metanephric blastema in the kidneys, is a risk for developing Wilms tumor. Perilobar nephroblastomatosis is located in the subcortical region and is associated with Beckwith-Wiedemann syndrome (also at risk for hepatoblastomas and adrenal carcinoma), hemihypertrophy, Perlman syndrome, and trisomy 18 (Table 104-3). Intralobar nephroblastomatosis is located deep within the kidney and is associated with Drash syndrome, sporadic aniridia, WAGR syndrome, and has a high risk for degeneration into Wilms tumor. Imaging includes evaluation of the inferior vena cava, as extension into the renal vein is common and alters surgical approach. Follow-up imaging for metachronous tumor in the contralateral kidney (10%) and pulmonary metastases is key. Screening recommendation for the follow-up of Wilms tumor in high-risk patients is renal ultrasound at 3-month intervals up to 8 years of age.

Congenital mesoblastic nephroma is the most common solid renal tumor less than 3 months of age. This benign lesion should not metastasize and is unilateral. A cellular variant can have a more aggressive clinical course. The gross appearance is similar to a uterine fibroid. Entrapped normal renal tissue can mimic function in these lesions.

TABLE 104-3 Wilms Tumor Versus Neuroblastoma

	WILMS TUMOR	NEUROBLASTOMA
Frequency	Most common abdominal solid tumor	Most common overall extracranial solid tumor
Metastasis	Pulmonary	Bone cortex
Prognostic indicators	Anaplasia-worse	Shimada class, better with age <1 y Increased DNA index, Low N-MYC, thoracic primary
Unique staging parameters	Stage V-bilateral kidneys	Stage 4S-bone marrow but no bony cortex metastasis. Ninety percent resolve spontaneously
Associated syndromes	Beckwith-Wiedemann, DRASH, Sporadic Aniridia, WAGR	None
Calcification	15% on CT	50%–85% on CT
Vascular invasion	40% Renal Vein/IVC	Rare

Clear-cell sarcoma is the bone-metastasizing renal tumor of childhood, so that bone imaging is required at diagnosis and in follow-up. Features are similar to Wilms tumor otherwise.

Rhabdoid tumor is a highly aggressive, usually fatal primary renal tumor that occurs in children typically younger than 1 year of age. It is associated with hypercalcemia and is associated with CNS tumors most common in the posterior fossa, usually PNET.

Renal cell carcinoma is typically seen in adolescents, where 50% of primary renal tumors are Wilms tumor and 50% are renal cell carcinoma. Appearance and workup is otherwise typical for Wilms tumor.

Multilocular cystic nephroma is a multicystic focal mass in the kidney, which can encompass benign lesions such as multilocular cyst to cystic Wilms tumor (cystic partially differentiated nephroblastoma). Imaging cannot distinguish a benign multicystic primary renal mass from a malignant one, so that removal of the lesion is required. They can occasionally herniate into the renal pelvis.

Renal medullary carcinoma occurs in adolescents with sickle cell trait and is highly aggressive and usually fatal.

ACQUIRED ABNORMALITIES

Renal vein thrombosis, more common in the left kidney, is most common in dehydrated or septic infants and infants of diabetic mothers. The thrombosis starts in the intrarenal venules and propagates centrally. Ultrasound demonstrates heterogeneous echogenicity of the enlarged kidney, poor corticomedullary differentiation, and may show focal hemorrhages. Renal artery Doppler demonstrates reversed diastolic flow.

Urolithiasis in childhood is most commonly caused by idiopathic hypercalciuria. Important other causes include type I renal tubular acidosis (RTA), furosemide treatment for bronchopulmonary dysplasia (BPD), stasis with hydronephrosis, Lesch-Nyhan syndrome with uric acid stones, metabolic diseases such as cystinuria, xanthinuria, oxalate stones, cystic fibrosis, Crohn disease, and infection stones (struvite–calcium magnesium ammonium phosphate). Medullary nephrocalcinosis (Table 104-4) can give an increased echogenic pyramid

appearance with a differential diagnosis including medullary cystic disease, ARPKD, Beckwith syndrome, Sickle cell disease, Bartter syndrome, acute renal failure, and protein deposition such as Tam-Horsfall proteinuria and hemoglobinuria/myoglobinuria.

URETERS, BLADDER, AND URETHRA

Vesicoureteral reflux (VUR) is common, with lower incidence in African Americans. It is thought to occur secondary to a shortened submucosal tunnel within the bladder with a lateralized ureteral orifice. Children with VUR have twice the incidence of pyelonephritis. Since VUR is seen in approximately 25% of asymptomatic siblings of affected children, screening of siblings is recommended. There is a correlation of renal scarring and lack of spontaneous resolution of reflux with increasing grade of reflux. VUR is graded as follows:

Grade I-reflux into a ureter that does not reach the renal pelvis.

Grade II-reflux reaching the pelvis but not blunting the calyces.

Grade III-reflux reaching the calyces causing mild blunting.

Grade IV-reflux reaching the calyces causing moderate blunting.

Grade V-dilated and tortuous ureter with complete calyceal blunting.

Radiographic voiding cystourethrography (VCU) is recommended in boys with their first UTI and with complex anatomy (suspected duplex collecting system). Radionuclide cystogram is recommended in first time UTI in girls, follow-up male and female for known reflux, postoperative reflux assessment, and sibling reflux screening. Ultrasound is the most common method of upper tract assessment in UTI evaluation. Radionuclide cystogram has a 1/100 radiation dose compared to fluoroscopic VCU. Eighty percent of children with grade I to II reflux spontaneously resolve with age. Reflux and infection are felt to be independent phenomena though may affect one another. Similar statements for bladder outlet obstruction related to reflux can be made. Postnatally, sterile VUR typically does not cause scarring. Complications of renal scarring include hypertension, renal insufficiency, and proteinuria. If the patient is non-compliant, develops resistant infection, has high-grade reflux, or develops progressive scarring, treatments consist of ureteral reimplantation or advancement procedures, or STING procedure (subureteric transurethral injection).

With acute pyelonephritis, 30% to 50% are associated with vesicoureteral reflux. Scarring occurs most

TABLE 104-4 Hyperechoic Renal Medulla

Bartter syndrome
Acute renal failure
Sickle cell disease

commonly in children younger than 1 year of age and is rare after onset greater than 3 years of age. DMSA scanning, CT, and MRI are more sensitive than sonography or IVP for this diagnosis. Acute pyelonephritis most commonly appears as a wedge-shaped, segmental defect, less commonly rounded, and is frequently polar where compound calyces occur. Ultrasound is used initially in hospitalized UTI patients to exclude an obstructed infected system (pyonephrosis).

Ureteral duplication is the most common anomaly of the urinary tract and may be partial or complete. In complete duplication, the ureter draining the upper pole of the kidney inserts into the bladder inferior and medial to the ureter draining the lower pole (Weigert-Meyer rule). The upper pole ureter tends to obstruct (75% from a ureterocele). The lower pole ureter has a short submucosal tunnel and tends to reflux. Complete duplication is bilateral in approximately 25% of cases. Ultrasound and VCU are the first-line imaging modalities for diagnosis. MR urography with heavily T2-weighted sequences can occasionally be a supplemental tool for imaging the ureters. In symptomatic patients, the type of surgery depends on the function of the upper pole.

Posterior urethral valves (PUV) is a form of chronic urethral obstruction secondary to fusion and prominence of the plicae colliculi, normal concentric folds of the urethra. It occurs exclusively in males and is the most common cause of congenital bladder outlet obstruction. The diagnosis is typically made on VCUG and demonstrates an abrupt transition from a dilated posterior urethra to a small, bulbous urethra at the level of the valves. Bladder wall trabeculation/muscular hypertrophy is commonly seen. PUV is associated with vesicoureteral reflux (50%), urinary ascites, and urinomas in newborns. Despite increased prenatal detection and improved surgical interventions, approximately one-third of patients will eventually develop renal insufficiency.

Ureterocele is congenital cystic dilation of the distal submucosal portion of the ureter. An intravesical ureterocele occurs when the ureterocele is completely contained within the bladder. An extravescicle ureterocele occurs when part of the cyst extends to the urethra, bladder neck, or perineum. An orthotopic (simple) ureterocele has its orifice located in a normal anatomic position at the trigone of the bladder and is usually seen in single systems. An ectopic ureterocele has its orifice located anywhere else, though the ureterocele presents as an intravesicle mass. Ectopic ureterocele is five times more common in girls than boys, is bilateral in 10% of cases, and is the most common cause of bladder outlet obstruction in girls. Cecoureteroceles are a subtype of ureterocele, which is elongated by tunneling under the trigone and the urethra. Treatment of ureteroceles includes cystoscopic fenestration of the ureterocele

and/or resection and reimplantation of the ureterocele or heminephroureterectomy depending on upper pole function. Ureteroceles are best seen with ultrasound, which also evaluates the ureters and kidneys. With VCUG, early filling images are essential for demonstrating ureteroceles.

An ectopic ureter is one that drains outside the posterolateral angle of the trigone, either within the bladder or extravescically. It is associated with ureteral duplication anomalies in 80% of cases. In cases of an ectopic ureteral insertion, the ureter may insert infrasphincteric in girls and lead to chronic wetting. In boys, the ectopic ureter is suprasphincteric and does not lead to wetting, but may insert into the epididymis, vas deferens, or spermatic cord and cause epididymitis.

Primary megaureter is a dilated ureter, which is secondary to functional obstruction of the distal, adynamic, normal caliber ureteral segment. The functionally obstructed ureter may be associated in 20% of cases with coexisting vesicoureteral reflux. This entity can lead to decreased renal function, but renal function is usually more preserved than in other cases of congenital obstructive uropathy. Primary megaureter is associated with ipsilateral and contralateral UPJ obstruction.

Urachal anomalies are secondary to persistence of the midline connection between the bladder dome and the umbilicus, which is a remnant of the fetal allantoic stalk. A urachal fistula (patent urachus) is an open channel from the bladder to the umbilicus through which urine can leak. A urachal sinus is persistence of a superficial segment of the channel opening onto the skin surface. A urachal diverticulum is persistence of the deep segment creating a diverticulum of the anterosuperior bladder. A urachal cyst is persistence of the intermediary segment with a fibrous attachment to the bladder wall and umbilicus. The urachal remnant is treated with resection secondary to a small risk of malignant conversion to adenocarcinoma, not transitional cell carcinoma. Associated abnormalities include prune-belly syndrome, PUV, urethral atresia, and cloacal anomalies.

Bladder diverticulum is a protrusion of the mucosa of the bladder through a defect in the muscular wall (pseudodiverticula). A "Hutch" diverticulum occurs in a periureteral location, typically laterally and cephalad to the ureteral orifice. It may be associated with single system VUR, infection, hematuria, or stone formation. Primary diverticula are idiopathic and may be seen with several syndromes including cutis laxa, Menkes, and Ehlers-Danlos syndrome. Secondary bladder diverticula are the result of chronically increased intravesical pressure with hypertrophy of the bladder musculature and may be seen in patients with severe lower urinary tract obstruction, such as PUV, and in patients with neurogenic bladders. VCUG is the best imaging modality for diagnosis.

Prune-belly (Eagle-Barrett) syndrome occurs in boys with laxity of the abdominal wall musculature, urinary tract dilation, and cryptorchidism. It is thought to be because of mesodermal arrest. The posterior urethra is dilated secondary to prostatic hypoplasia. Varying degrees of hydronephrosis and renal dysplasia may be seen. Pulmonary hypoplasia secondary to oligohydramnios can be an important component in severe cases. VCUG may show posterior urethral dilation or urethral diverticulum (persistent prostatic utricle) without PUV.

Neurogenic bladder (most commonly related to myelodysplasia in children) can be classified into two types:

1. Hyperreflexic contractile bladders—Trabeculated, thick wall with normal to small volumes and bladder sphincter dyssynergia.
2. Overflow neurogenic bladder—Smooth wall large capacity bladder, frequently with incontinence because of sphincteric weakness.

The key treatment protocol is to establish bladder emptying, either with intermittent catheterization or spontaneous voiding. Without success, 50% have upper tract deterioration with hydronephrosis, infection, and eventual chronic renal failure. Differential diagnosis of the hyperreflexic neurogenic bladder includes William syndrome, Menkes syndrome, and cutis laxa or Ehlers-Danlos. There is an increased incidence of urolithiasis and autonomic dysreflexia. Other treatment options include medications, bladder augmentation surgery, and operations for continence. Patients with dysfunctional voiding (severe form with nonneurogenic, neurogenic bladder-Hinman syndrome) have a form of bladder sphincter dyssynergia, which can mimic neurogenic bladders of defined etiologies. The “spinning top” urethra is a typical morphology for dysfunctional voiders, especially in females.

Urethral duplication is a rare, congenital anomaly that occurs more often in males than females. In the epispadiac type, an incomplete accessory channel has a dorsal opening in the phallus and ends blindly. The complete or partial form originates from the bladder or proximal urethra and courses through the dorsal aspect of the penis to end in an epispadiac position anywhere between the glans and the root of the penis. The ventral urethra, which is always associated with the urinary sphincter, is normally positioned and ends in the glandular meatus. In the hypospadiac type, an incomplete accessory channel has a ventral opening in the phallus and ends blindly in the periurethral tissue similar in appearance to a urethral diverticulum or Cowper duct. Hypospadias is associated with cryptorchidism.

The prostatic utricle is in the midline verumontanum and is associated with hypospadias, prune-belly syndrome, imperforate anus, and Down syndrome. The prostatic utricle fills with contrast during VCUG. A Mullerian duct cyst is rare and is a large mass originating from the verumontanum and does not communicate with the urethra on VCUG.

TUMORS

Rhabdomyosarcoma originates most commonly in children in the head and neck. Genitourinary tract (GU) is the second most common location and extremities the third. The GU tumors most commonly involve the bladder (sarcoma botryoides), the prostate in periadolescent males, and rarely the vagina and the uterus. Another rare location includes the retroperitoneal pelvis. Spread is local, lymphatic, and hematogenous to lungs, liver, and bone. The bladder tumors have a typical intraluminal polypoid extension. Rare associations include neurofibromatosis, Li-Fraumeni syndrome, Beckwith Wiedemann syndromes, and postradiation. The majority of patients are younger than 5 years of age.

Sacroccygeal teratoma can present as a presacral mass with typical imaging features of teratoma, and the classification is type I primarily external (47%), type II dumbbell (34%), type III (9%) primarily within the abdomen and pelvis, and type IV (10%) entirely internal. The more cystic varieties are typically benign, while solid components indicate malignancy. Alpha-feta protein produced in endodermal sinus components should be measured to gauge malignancy. Surgical resection requires coccygeal removal to prevent recurrences. These can be associated with the Currarino triad (presacral mass, anorectal stenosis, sacral anomalies), which has an autosomal dominant inheritance pattern and can present with polyhydramnios or high output cardiac failure from arterovenous shunting.

MALE GENITAL TRACT

Testicular torsion is twisting of the testis and spermatic cord within the scrotum, resulting in vascular occlusion or infarction. It is most commonly seen between 11 and 18 years of age. The testicle twists medially in two-thirds of cases, and the axis of the testes may change from a vertical to horizontal orientation. Diagnosis is made on ultrasound by demonstrating decreased or absent blood flow within the testicle. Extratesticular flow may be increased. In recent torsion, the testicle parenchyma may be completely normal. Otherwise, the testicle may be enlarged and demonstrate a heterogeneous or hypoechoic

echotexture. Hydrocele may be seen. Testicular torsion is associated with an abnormally high attachment of the tunica vaginalis, resulting in a “bell-clapper” deformity. Prenatal testicular torsion almost invariably presents with testicular infarction. Viable torsed testes undergo orchiopexy, while nonviable testes are removed. Preventative orchiopexy is typically performed on the contralateral, nontorsed testis. Surgical salvage rates are 80% to 100% if the patient is found within 6 hours of pain and quickly decline after 12 hours.

Torsion of the testicular appendage is spontaneous twisting of one of the pedunculated vestigial remnants of tissue extending from the testicle or epididymis, causing ischemia and pain and is typically treated nonsurgically. It occurs most commonly between 6 and 12 years of age. Ultrasound shows an enlarged appendage (greater than 5 mm), spherical in shape, with periappendiceal hyperemia but no flow in the appendix. A reactive hydrocele is common. The “blue dot” sign of an ischemic appendage is seen through the scrotal wall in a minority of patients.

Epididymo-orchitis is infectious inflammation of the epididymis, testicle, or both. On ultrasound, there is enlargement of the affected tissue with accompanying hyperemia and a small reactive hydrocele. It is most often caused by *Staphylococcus aureus*, *E. coli*, or viruses, especially mumps. It is the most common cause of acute, painful scrotum in the postpubescent male. Elevation of the affected hemiscrotum relieves the pain of epididymitis (Prehn sign) and exacerbates torsion.

If the newborn has an enlarged scrotum and multiple calcifications around the testes, meconium peritonitis with a patent processus vaginalis should be a strong consideration.

MALE GENITAL TUMORS

Testicular neoplasms are unusual in infants and children, representing around 1% of all childhood malignancies. Of those that occur in children, 60% occur at age 2 or younger. These tumors typically present as painless, nontender, firm scrotal masses of weeks to months duration. Scrotal ultrasound typically demonstrates a mass, which can be confused for infarct, granuloma, and focal orchitis. Reactive hydroceles may be seen in 15% to 20% of cases. Color Doppler typically demonstrates increased vascularity.

Germ cell tumors represent around 70% of all testicular tumors in children. Yolk sac tumors are by far the most common germ cell tumor in children, representing 80% to 90% of cases. Of those, 75% are diagnosed by 2 years of age. These tumors are frequently complicated by hemorrhage. Serum alpha-fetoprotein levels are

elevated in 90% of affected patients. Testicular teratoma is the second most common germ cell tumor in children, usually developing between 3 months and 5 years of age. This appears as complex solid and cystic mass on ultrasound and is derived from elements of all three germ cell layers. Bony elements/dental structures are hyperechoic with posterior shadowing and are often visible on conventional radiographs. Prepubertal teratomas are typically benign (85%), while postpubertal teratomas are more frequently malignant, with elevated serum hCG levels.

Gonadal stromal tumors are almost always benign and represent around 25% of pediatric testicular masses. Leydig cell tumors and Sertoli cell tumors are the most common gonadal stromal tumors of childhood. Leydig cell tumors represent 45% of these and are the most common testicular neoplasm in African American children. These are typically diagnosed in 2- to 9-year-old, but may be associated with hormone production and premature virilization if androgens are produced and gynecomastia if estrogen is produced. Sertoli cell tumors represent 20% of nongerm cell tumors, half are diagnosed by the first year of life, and gynecomastia caused by estrogen production may occur.

FEMALE GENITAL TRACT

CONGENITAL ABNORMALITIES

In hydrometrocolpos, there is dilatation of the vagina and/or uterus either secondary to imperforate hymen (no associated anomalies) or vaginal atresia (high incidence of renal anomalies and other anomalies). This presents as a mass prolapsing through the introitus (imperforate hymen) or abdominal/pelvic mass between the bladder and rectum. Secondary hydronephrosis is an important complication. Echogenic debris within the dilated vagina can be related to mucus secretion or infection. Rare peritoneal calcification is related to reflux of secretions out the fallopian tubes. A key imaging feature is to identify the small uterus attached to the top of the vagina in hydrometrocolpos to distinguish from other pelvic masses. Hydrometrocolpos has a bimodal age presentation, either in infancy or in periadolescent age group. In adolescents, it presents with monthly pain associated with lack of menstrual periods. It can have associated vertebral and cardiac anomalies in addition to müllerian duct fusion anomalies.

Patients with intersex disorders and ambiguous genitalia benefit from a complete evaluation including chromosomes, gonadal assessment, external and internal genital anatomy, hormonal assessment, rearing, and psychosocial orientation. Ultrasound is helpful to

demonstrate the infantile uterus, and ovaries can frequently be identified. VCUG and vaginogram are important to demonstrate the anatomy of the bladder, the urethra, vagina, and urogenital sinus. MRI occasionally is utilized to identify the internal genital anatomy. The most common etiology for female intersex is congenital adrenal hyperplasia. Other causes include maternal androgen ingestion or masculinizing ovarian tumor in the mother. Male intersex or pseudohermaphroditism is frequently from testicular feminization or lack of Mullerian regression factor secretion. Deficiency of enzymes such as 5- α -reductase deficiency can produce this syndrome. Gonadal dysgenesis such as XY gonadal dysgenesis is a variant of Turner syndrome producing ambiguous genitalia. In the Drash syndrome (gonadal dysgenesis, nephropathy, and Wilms tumor), ambiguous genitalia are present. True hermaphroditism is rare, where both testicular and ovarian tissue occur in the same patient.

Precocious puberty occurs in females developing signs of puberty before 8 years of age and in males before 9 years of age. Isosexual precocious puberty can be related to hamartoma of the tuber cinereum. These patients can also present with gelastic seizures. Rare other CNS tumors can provoke precocious puberty. Females with precocious puberty can have autonomous ovarian cysts stimulating estrogen secretion, rare estrogen secreting adrenal tumors, and McCune-Albright syndrome associated with polyostotic fibrous dysplasia, cafe-au-lait spots, and precocious puberty.

Males with isosexual precocious puberty are evaluated for hypothalamic hamartoma (a mass at the base of the hypothalamus, which is isointense to gray matter on T1 and T2 images and does not enhance). Rare androgen-secreting adrenal carcinomas or testicular tumors in males occur. Males can have congenital adrenal hyperplasia that mimics sexual precocity. Leydig tumors of the testes and rare HCG secreting tumors can occasionally cause precocious puberty in boys. HCG secreting tumors occur in hepatoblastomas, some teratomas of the mediastinum and the retroperitoneum, intracranial germinomas, and pinealoblastomas.

Ovarian torsion is also termed adnexal torsion including torsion of the ovary, fallopian tube, or both. It produces unilateral enlarged ovary with peripheral cysts, typically best seen on ultrasound though also seen on CT or MR, which can also show additional fallopian tube twisting or thickening. This entity in pediatrics is most common without underlying mass or tumor and is in the differential diagnosis of right lower quadrant pain including appendicitis. Salvage of the ovary is more common than in testicular torsion.

FEMALE GENITAL TUMORS

Ovarian dermoid tumor (two germ cell lines) and teratoma (three germ cell lines) are the most common ovarian tumors. They can be bilateral in up to 25% and malignant degeneration in approximately 10%. CT, MR, and ultrasound can demonstrate calcifications, fat, hair, teeth, and cysts. Teratomas are most commonly sacrococcygeal (7%) and gonadal (29%) with ovarian more common than testicular. Complications include torsion and spontaneous rupture and malignant degeneration.

Rhabdomyosarcoma of the vagina is typically botryoides and extend out the introitus (interlabial mass) (Table 104-5), producing a differential diagnosis with hydrometrocolpos, prolapsing ureterocele, urethral prolapse, and urethral cyst. Vaginal primaries are more common than the rare uterine primary tumors. It is included as one of the small blue round cell tumors including neuroblastoma, Ewing sarcoma/PNET, and leukemia/lymphoma. Endodermal sinus tumor is a rare vaginal tumor of infancy. Clear cell adenocarcinoma of the vagina (also termed mesonephroma) can present in a patient with or without exposure to DES and mimic rhabdomyosarcoma.

Sixty percent of pediatric ovarian neoplasms are germ cell tumors (70% teratomas, 25% dysgerminomas—most common pediatric ovarian malignancy, and 5% endodermal sinus tumors). Twenty percent are epithelial neoplasms including cystadenoma (80%) and cystadenocarcinoma (10%) and 10% are sex cord tumors. Granulosa cell tumors are the most common ovarian cause of isosexual precocious puberty in females. One-third of pediatric ovarian neoplasms are malignant. Most do not have specific imaging features and are best initially evaluated with ultrasound. CT and MRI scanning are helpful for evaluation of peritoneal involvement, lymphatic spread, or hematogenous pulmonary metastases.

Ovarian cystadenoma is the second most common ovarian neoplasm in children after mature teratoma. It may arise in dysgenetic gonads but less commonly than gonadoblastoma. Leydig cell tumors rarely produce androgens causing virilization in females.

The most common intra-abdominal neonatal mass in a female is an ovarian cyst caused by placental hormonal stimulation of the in utero ovary. These may torsion or infarct and are followed clinically with occasional surgical intervention. Ovarian cysts greater than or

TABLE 104-5 Bulging Mass at the Introitus

Ectopic ureterocele
Hydrometrocolpos
Rhabdomyosarcoma
Urethral cyst/Skene gland cyst
Urethral prolapse

equal to 3 cm in size in older children and adolescents can be symptomatic alone or with torsion occasionally. Hemorrhage into ovarian cysts will produce echogenic material with fluid–fluid level or debris on ultrasound and can mimic appendicitis in presentation.

QUESTIONS AND ANSWERS

1. A newborn presents with an enlarged scrotum. On ultrasound, multiple irregular calcifications are noted within the scrotum. Which of the following is the most likely diagnosis?

- A. Neuroblastoma
- B. Tuberculous peritonitis
- C. Teratoma
- D. Meconium peritonitis
- E. Hemangiomatosis

ANSWER: D. Meconium peritonitis (typically secondary to in utero bowel perforation) can lead to scrotal calcifications in the case of a patent processus vaginalis. Noting that this surrounds the testicle and is not within the testicle would exclude testicular teratoma, and this is not a location for neuroblastoma. Tuberculous peritonitis is rare and would be unlikely to have this appearance. Hemangiomatosis could be considered if there were phleboliths present.

2. What is the most likely testicular tumor in a 1-year-old?
 - A. Seminoma
 - B. Mixed germ cell tumor
 - C. Yolk sac tumor
 - D. Embryonal tumor
 - E. Teratoma

ANSWER: C. Yolk sac tumor is the most common testicular tumor in a young boy. Teratoma is the second most common testicular tumor. Other germ cell line tumors are less common. Stromal tumors are less common overall than germ cell tumors.

3. A newborn infant has bilaterally enlarged, hyperechoic kidneys on ultrasound and a history of oligohydramnios. What is the most likely diagnosis?
 - A. Autosomal dominant polycystic kidney disease
 - B. Autosomal recessive polycystic kidney disease
 - C. Multicystic dysplastic kidney
 - D. Wilms tumor
 - E. Lymphoma

ANSWER: B. Autosomal recessive polycystic kidney disease is the most common etiology of bilaterally enlarged, hyperechoic kidneys. ADPKD kidney would rarely present in the newborn period and would most commonly have multiple, enlarged cysts. Bilateral MCDK is a fatal disease. Wilms tumor and lymphoma do not present in the newborn period.

4. What is the most common location of GU obstruction in a neonatal male?
 - A. Bulbous urethra
 - B. Prostatic urethra
 - C. Ureterovesicle junction

- D. Distal ureter
- E. Ureteropelvic junction

ANSWER: E. Ureteropelvic junction obstruction is the most common cause of hydronephrosis in the newborn male. PUV and UVJ obstructions are less common.

5. A 2-year-old girl presents for the first time with burning micturition, fever, pyuria, and flank pain. What is the most appropriate study?
 - A. Renal ultrasound and radionuclide cystogram
 - B. MR Urography and fluoroscopic voiding cystourethrogram
 - C. DMSA scan and radionuclide cystogram
 - D. Contrast-enhanced CT and voiding cystourethrogram
 - E. Intravenous pyelogram and radionuclide cystogram

ANSWER: A. Renal ultrasound and radionuclide cystogram is the most appropriate combination of studies in a young girl with a first-time UTI or suspected acute pyelonephritis. Radionuclide cystograms are preferred to fluoroscopic VCUs because of radiation concerns. MR urography, DMSA, and contrast-enhanced CT are occasionally used as supplemental tests in this scenario. IVP is not used in this setting.

6. In a 3-month-old, what is the most likely etiology of an echogenic renal mass?
 - A. Multicystic dysplasia
 - B. Wilms tumor
 - C. Neuroblastoma
 - D. Mesoblastic nephroma
 - E. Rhabdoid tumor

ANSWER: D. Mesoblastic nephroma is the most common solid renal mass in early infancy. Multicystic dysplasia should be detected either in utero or perinatally. Wilms tumor occurs at an older age. Neuroblastoma, though the most common solid extracranial tumor of childhood, is not a renal mass. Rhabdoid tumor is rare compared to mesoblastic nephroma.

7. What is the most likely etiology of a mass between the rectum and bladder in a 1-day-old female?
 - A. Rectal duplication
 - B. Sacrococcygeal teratoma
 - C. Hydrometrocolpos
 - D. Neuroblastoma
 - E. Rhabdomyosarcoma

ANSWER: C. Hydrometrocolpos with an enlarged vagina presenting as a mass between the rectum and

bladder would be the best diagnosis. Rectal duplications are rare and usually occur retrorectal. Sacrococcygeal teratoma and neuroblastoma occur in the presacral space. Congenital rhabdomyosarcoma would be extremely rare.

8. In a 3-year-old female with isosexual precocious puberty and an echogenic ovarian mass, what is the most likely etiology?
 - A. Brenner tumor
 - B. Granulosa cell tumor
 - C. Krukenberg tumor
 - D. Benign ovarian cyst
 - E. Dysgerminoma

ANSWER: B. Granulosa cell tumor. This is the most common pediatric tumor causing isosexual precocious puberty in a female. Brenner tumor, Krukenberg tumor, and dysgerminoma do not produce precocious puberty. Autonomous ovarian cysts can produce isosexual precocious puberty though would not be an echogenic mass.

9. What condition has surveillance imaging because of high risk for Wilms tumor?
 - A. Hereditary aniridia
 - B. Beckwith-Wiedemann syndrome
 - C. Neurofibromatosis type I
 - D. Horseshoe kidney
 - E. Infants of diabetic mother

ANSWER: B. Beckwith-Wiedemann syndrome. Sporadic aniridia, not hereditary aniridia, requires surveillance imaging for high-risk Wilms tumor. Although neurofibromatosis type I and horseshoe kidney statistically have a slight increased incidence of Wilms tumor, we do not use surveillance imaging for them. Infants of diabetic mothers are not at risk for Wilms tumor.

10. What disorder has increased medullary echogenicity in a newborn?
 - A. Fanconi syndrome
 - B. Tamm-Horsfall proteinuria
 - C. Multicystic dysplastic kidney
 - D. Caroli disease
 - E. Autosomal dominant PCKD

ANSWER: B. Tamm-Horsfall proteinuria. This causes transient oliguria in the newborn because of Tamm-Horsfall protein deposition in the tubules causing a medullary hyperechoic appearance. This does not occur in Fanconi syndrome, multicystic dysplastic kidney, Caroli disease, or ADPKD (could be seen in ARPKD).

105 PEDIATRIC NEUROIMAGING

*Shyamsunder B. Sabat and
Yoginder N. Vaid*

PEDIATRIC BRAIN

NORMAL MYELINATION

At term birth, the white matter is largely unmyelinated. Myelination of the brain proceeds from posterior to anterior, central to peripheral, and inferior to superior directions. Also, sensory pathways myelinate earlier than motor, projection pathways earlier than association, and proximal pathways earlier than distal. Until 6 months of age, T1-weighted images and after 6 months, T2-weighted images are best for assessment of myelination. On T1 images, myelination is complete by 8 months and by 18 months on T2-weighted images.

CONGENITAL ANOMALIES

SCHIZENCEPHALY

Schizencephaly refers to gray matter-lined clefts extending from the cortical surface to the ventricles. It can be unilateral (60%) or bilateral (40%). The clefts can be open lip (65%–85%) or closed lip (15%–35%) depending on their position (focally or throughout). Most clefts occur around the pre- and postcentral gyrus. Patients present with seizures, hemiparesis, and variable developmental delay. Bilateral cases have more severe symptoms. Unilateral closed type has the best developmental outcome. Optic nerve hypoplasia and consequent blindness are present in one-third of patients with schizencephaly. The septum pellucidum is often absent in cases of bilateral schizencephaly. Thus, many patients with schizencephaly (especially bilateral) have septo-optic dysplasia. While open lip schizencephaly is easy to diagnose, closed lip may mimic transmantle heterotopia and deep infoldings of polymicrogyria. A dimple on the lateral ventricular wall, where the cleft opens into the ventricle may help identify such subtle cases.

POLYMICROGYRIA

Polymicrogyria is a disorder of neuronal organization, resulting in formation of multiple small gyri. It can be focal, multifocal, or diffuse, and unilateral or bilateral. The posterior portion of the Sylvian fissure is the most common location, followed by parietal and temporal

locations. The commonest syndrome associated with polymicrogyria is congenital bilateral perisylvian syndrome consisting of bilateral opercular polymicrogyria presenting with pseudobulbar palsy, seizures, and developmental delay.

LISSENCEPHALY (“SMOOTH BRAIN”)

Lissencephaly (“smooth brain”) refers to paucity of gyral and sulcal development on the brain surface. Agyria (classic lissencephaly) is complete lack of sulcation and pachygyria (incomplete lissencephaly) is decreased sulcation with few broad, flat gyri. The latter is more common than the former. The sulci in pachygyria are normal with corresponding anatomic names, while the ones seen in polymicrogyria do not correspond to established anatomic sulci. Also in pachygyria, the cortex-white matter junction is smooth, while in polymicrogyria it is irregular. Lissencephaly is associated with various gene mutations such as LIS1, DCX, and syndromes such as Miller-Dicker, Walker-Warburg. Lissencephaly can also be caused by in utero CMV infection. There is a “figure-of-eight” appearance on cross-sectional images because of shallow, vertical sylvian fissures. Cobblestone lissencephaly has a characteristic pattern with irregular cortical projections into the white matter and is seen in various congenital muscular dystrophies (Walker-Warburg syndrome, Fukuyama muscular dystrophy).

HETEROTOPIA

Heterotopia is ectopic gray matter in locations other than the cortex or other normal anatomic locations. Patients almost always present with seizures, variable delay, and motor weakness. Heterotopic gray matter is isointense to gray matter on all MRI pulse sequences.

Heterotopia falls into one of three types. Subependymal heterotopia occurs along the inner ventricular lining and must be differentiated from subependymal nodules of tuberous sclerosis. Focal subcortical heterotopia is subcortical and results in overlying cortex being thin with shallow sulci. It can have mass effect mimicking tumor but does not enhance or have edema. It is often associated with abnormalities such as callosal dysgenesis and dysplastic basal ganglia. Mantle heterotopias is a subtype, which has linear gray matter deposit extending from cortex to ventricular margin but lacks the characteristic dimple on the outer ventricular margin seen in schizencephaly. Band heterotopia (double cortex) is more common in females (90%). It can be complete around the cortex or partial, commonly in the frontal region. Overlying cortex shows normal thickness with shallow sulcation. This heterotopia is hypermetabolic on FDG-PET and shows increased blood flow on BOLD imaging.

Focal cortical dysplasia presents with seizures. Focal cortical dysplasia with balloon cells (Taylor-type dysplasia) shows focal cortical thickening with blurring of gray-white matter junction. Focal cortical dysplasia without balloon cells most commonly appears as a region of thin cortex with volume loss and T2 hyperintensity of underlying white matter. Focal retraction of the cortex with prominent overlying vein (cortical vein sign) if present, aids in the diagnosis of focal cortical dysplasia.

HEMIMEGALENCEPHALY

Hemimegalencephaly describes hamartomatous overgrowth of part or whole cerebral hemisphere. Imaging features include dysplastic cortex with broad gyri, shallow sulci, ipsilateral enlarged ventricle, white matter signal abnormalities, and heterotopias. It is seen in many disorders like epidermal nevus syndrome, Proteus syndrome, NF1, Klippel-Treunaunay-Weber syndrome, and tuberous sclerosis.

HOLOPROSENCEPHALY

Holoprosencephaly describes a group of heterogeneous disorders characterized by failure of cleavage of the cerebrum by varying degrees. It is mostly caused by maternal diabetes or by genetic syndromes like trisomy 13 (Patau syndrome) and trisomy 18 (Edward syndrome). Depending on increasing levels of cleavage, it can be divided into alobar, semilobar, and lobar types. In global holoprosencephaly, the cerebrum is pancake-like with no Sylvian or interhemispheric fissure, and no falx cerebri, septum pellucidum, or corpus callosum. Also absent are the optic tracts, olfactory bulbs (arrhinencephaly), internal cerebral veins, vein of Galen, superior and inferior sagittal sinuses. The thalami and basal ganglia are fused and the third ventricle is absent. There is a single monoventricle with wide communication with a large dorsal cyst filling most of the posterior cranium. The cerebellum and brainstem are relatively normal. Discrete middle and anterior cerebral arteries are usually absent, and when present, the latter are fused to form a single azygous anterior cerebral artery. Facial abnormalities can include a cyclopia (single midline orbit, arhinia, and proboscis: a fleshy appendage in forehead), cebocephaly (hypotelorism, single-nostril nose), and ethmocephaly (hypotelorism, proboscis, absent nose). In semilobar holoprosencephaly, there is partial separation of cerebral hemispheres with rudimentary temporal and occipital lobes. The frontal lobes are fused. There is a monoventricle with a partial falx present posteriorly. Septum pellucidum is absent and thalami are partially fused. The corpus callosum consists of only the splenium (only brain anomaly with presence of splenium in absence of anterior corpus callosum). Facial

anomalies are mild, like cleft lip and palate. In the lobar form of holoprosencephaly, brain appears normal but frontal horns are fused with absent septum pellucidum. Bodies of lateral ventricles are apposed closely. The falx is present although it is hypoplastic anteriorly; thalami are separate. Face often has only hypotelorism. Lobar holoprosencephaly may be a spectrum of septo-optic dysplasia.

SEPTO-OPTIC DYSPLASIA

Septo-optic dysplasia is believed to be a mild form of lobar holoprosencephaly; it consists of absent septum pellucidum with hypoplasia of optic nerve/optic chiasm and of the hypothalamus. It may be associated with Chiari II malformation, aqueductal stenosis, schizencephaly, and corpus callosum agenesis. Hypothalamic pituitary dysfunction is present in two-thirds of patients with septo-optic dysplasia (Demorsier syndrome).

HYDRANENCEPHALY

Hydranencephaly is an encephaloclastic porencephaly presumably because of in utero occlusion of bilateral internal carotid arteries. It is thought secondary to infection such as CMV or caused by a genetic cause. A midline falx is present. Differential diagnosis includes severe hydrocephalus in which a thin rim of cortical mantle is present and alobar holoprosencephaly in which falx is absent and thalami are fused.

AGENESIS/DYSGENESIS OF CORPUS CALLOSUM

Corpus callosum has rostrum, genu, body, and splenium, which develop from anterior to posterior direction beginning with the genu. Rostrum develops last. Partial agenesis may result in variable formation of anterior structures (except rostrum). Imaging features of complete agenesis include absent cingulate sulcus with gyri appearing to radiate from a high-riding third ventricle. The lateral ventricles are parallel, nonconverging with dilated occipital horns (colpocephaly). There is medial concavity of the frontal horns because of indentation by the bundle of Probst (longitudinal tracts which would have crossed over) and enlargement of the temporal horns. Pericallosal lipomas and interhemispheric cysts, which may or may not communicate with the high-riding third ventricle may be found. Associated malformations include Dandy-Walker syndrome, cephalocele, heterotopia, and coloboma. Callosal agenesis can be seen in Aicardi, Klinefelter, and fetal alcohol syndromes.

DANDY-WALKER SYNDROME

The Dandy-Walker complex consists of posterior fossa cystic malformations, which includes Dandy-Walker malformation, Dandy-Walker variant, megacistern

TABLE 105-1 Dandy-Walker Complex

Megacistern magna
Dandy-Walker variant
Dandy-Walker malformation
Blake pouch cyst

magna, and Blake pouch cyst (Table 105-1). The Dandy-Walker malformation consists of an enlarged posterior fossa with high position of the tentorium, hypo- or agenesis of the cerebellar vermis and cystic dilatation of the fourth ventricle. The foramina of Magendie and Luschka are absent. Male-to-female ratio is 1:3 and hydrocephalus is often present. Associated malformations may include with dysgenesis or lipoma of the corpus callosum, heterotopias, polymicrogyria, holoprosencephaly, and occipital encephalocele. The Dandy-Walker variant is more common and has variable inferior vermian hypoplasia and varying enlargement of the fourth ventricle but posterior fossa volume remains normal. Megacistern magna consists of a normal vermis but an enlarged cisterna magna. Blake pouch cyst represents posterior ballooning of the inferior medullary velum (posteroinferior wall of the fourth ventricle) into the cisterna magna and is secondary to failure of perforation of the foramen of Magendie. There is no vermian hypoplasia and the posterior fossa is enlarged. The above malformations may be difficult to differentiate from each other but the outcome is related not to the nature of the malformation but the degree of cerebral abnormalities and hydrocephalus.

A large posterior fossa arachnoid cyst, although developmentally unrelated, can mimic the above entities. Posterior fossa is usually enlarged and the vermis is not hypoplastic. It can also be differentiated from Dandy-Walker complex by the fact that it does not communicate with the fourth ventricle (as seen on thin heavy T2-weighted images and CSF flow studies).

CHIARI MALFORMATIONS

Chiari I malformation consists of downward herniation of peg-like cerebellar tonsils through the foramen magnum into the upper cervical spine. It is secondary to short, flat clivus with small posterior fossa. Patients have occipital headache on straining and sometimes have downbeat nystagmus. It can be associated with craniovertebral junction anomalies like basilar invagination, occipitalization of C1, and Klippel-Feil syndrome. Patients can develop hydrocephalus and syringohydromyelia. Tonsillar ectopia because of chronic intracranial hypotension can be differentiated by a sagging third ventricle, enlarged dural sinuses and marked dural enhancement.

Chiari II (Arnold-Chiari malformation) also shows a very small posterior fossa, downward tonsillar and vermian herniation, caudal displacement of the fourth ventricle, and medulla, forming a characteristic cervicomedullary kink. MRI also reveals upward cerebellar herniation with wrapping of cerebellar tissue around the brainstem, midbrain collicular fusion into a beak-like projection (tectal beaking), and fenestrations of falx. Skull films show Luckenschadel or lacunar skull, (which disappears by 6 months of age), scalloped clivus, and absent/hypoplastic posterior arch of C1. Associated abnormalities include lumbar myelomeningocele (90%–100%), dysgenesis of corpus callosum (80%–85%), absence of septum pellucidum (40%), aqueductal stenosis, obstructive hydrocephalus (60%–90%), and syringohydromyelia. It is the single most common cause of hydrocephalus in children constituting approximately 40% of all hydrocephalus.

Chiari III malformation consists of a midline occipital bone defect/posterior spina bifida at C1, C2 with a high cervical/low occipital encephalocele with many of the other intracranial features of Chiari II.

CEPHALOCELES

Cephalocele is a term given to herniation of intracranial contents through defects in the skull. They are named for the location of bone defects through which they pass. Occipital (70%), parietal (10%), frontoethmoidal (9%), and nasopharyngeal (1%) are the commonest types. Frontoethmoidal is the commonest in Southeast Asia. They are identified as meningoceles if they contain CSF-filled meninges and encephaloceles if they contain brain tissue. MRI shows the contents of the sac and CT depicts the exact osseous defects. Atretic cephaloceles are involuted true cephaloceles and present as subscalp palpable masses in the midline in parietal or occipital regions with focal bone defect. Persistent falcine sinus, a normal accessory sinus, usually obliterated by birth is usually present. Occipital cephaloceles are associated with Chiari malformations, Dandy-Walker malformation, callosal anomalies, heterotopias, and imaging is indicated to pick up these, as well as the relation of the cephalocele to the dural sinuses. Frontoethmoidal cephaloceles show contiguous brain tissue/CSF within it with an absent crista galli. These should be differentiated from other midline masses like nasal dermoid and nasal glioma. Nasal dermoid is bright on T1, suppresses on fat suppression, and shows a split crista galli. Nasal glioma (a misnomer; actually nasal cerebral heterotopia) is dysplastic brain tissue in the nasal cavity or subcutaneous tissue with no intracranial connection. There is no split in the crista galli. Sphenoidal cephaloceles

are rare and present as a nasopharyngeal mass. Coronal CT shows midline split in the sphenoid body.

NEURO CUTANEOUS SYNDROMES

A heterogeneous group of disorders affecting nervous system and other ectodermally developed structures. Common ones are neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, and von Hippel-Lindau disease. All are autosomal dominant except Sturge-Weber syndrome, which is developmental and not hereditary. Neurofibromatosis is associated with mutation in chromosome 17. Neurofibromatosis type 1 has multiple peripheral nerve neurofibromas (hypointense on T1, hyperintense on T2/FLAIR, and show homogenous enhancement), cranial nerve schwannomas (mostly fifth), craniofacial plexiform neurofibromas (pathognomonic for neurofibromatosis), optic nerve gliomas, cerebral gliomas (tectum, brainstem), CNS hamartomas (unidentified bright objects on T2-weighted images), occlusion/stenosis of distal ICA/proximal MCA with Moya-Moya phenomenon, dumb-bell neurofibromas of spinal nerves with widening of neural foramen, lateral/anterior thoracic meningoceles, dural ectasia with posterior vertebral body scalloping. Skeletal manifestations include orbital dysplasia with bare orbit sign (because of lateral displacement of the innominate line on frontal skull radiograph), perilambdoid skull defects, kyphoscoliosis, pseudoarthrosis of tibia, multiple nonossifying fibromas, and hemihypertrophy. Other systemic manifestations include lower lung interstitial fibrosis, pheochromocytoma, parathyroid adenomas, renal artery stenosis/aneurysms, neurofibromas in wall of intestine, Lisch nodules (hamartomas) in iris, café-au-lait spots, and axillary freckling in skin. Neurofibromatosis type 2 is associated with deletion in chromosome 22. It has multiple meningiomas, bilateral vestibular schwannomas, schwannomas of other cranial nerves, and spinal ependymomas.

Tuberous sclerosis presents as seizures and mental retardation. CNS imaging shows multiple subcortical and subependymal hamartomas (hypodense, nonenhancing on CT and hypointense on T1, hyperintense on T2/FLAIR, calcify after first year of life). Subependymal giant cell astrocytoma is a growing hamartoma at the foramen of Monroe with astrocytic neoplastic transformation and resultant hydrocephalus. It shows uniform enhancement. Interval growth (not enhancement) is the definitive sign of neoplastic transformation. Other manifestations include skin angiofibromas, ash-leaf patch, shagreen patch, gingival fibromas, renal angiomyolipomas (fat-containing tumors), multiple renal cysts, cardiac rhabdomyomas, bone islands, thick periosteal reaction in distal phalanges, lymphangiomyomatosis, and repeated pneumothorax/chylothorax.

Sturge-Weber syndrome presents as seizures, bupthalmos and unilateral facial angioma in distribution of V1 and V2 segments of trigeminal nerve (port wine stain). Imaging shows ipsilateral leptomeningeal venous angioma with or without gyral calcification, overlying calvarial thickening, atrophy of underlying brain parenchyma because of vascular steal and enlargement of adjacent choroid plexus.

Von Hippel-Lindau disease consists of single or multiple cerebellar and/or spinal hemangioblastomas (can be cystic with solid enhancing mural nodule/only cyst/only enhancing nodule; tubular flow voids in the nodule are common). Multiple hemangioblastomas are pathognomonic. Other imaging manifestations are retinal angiomas, endolymphatic sac carcinomas, renal cell carcinomas, renal cysts, pheochromocytomas, pancreatic islet cell tumors/cysts/cyst adenomas, epididymal cystadenomas, and cysts in liver, spleen, adrenal, lung, and bones.

AQUEDUCTAL STENOSIS

It is the most frequent cause of congenital hydrocephalus. Occlusion occurs at the level of superior colliculus or intercollicular sulcus. Most common cause is postinflammatory (50%), secondary to perinatal infections such as TORCH, mumps, influenza, syphilis, or intracranial hemorrhage. It can also be developmental because of aqueductal forking (a condition in which it branches into dorsal and ventral channels and the dorsal in turn divides into several ductules) or aqueductal web. Neoplastic occlusion of the aqueduct can result from tectal/quadrigenal or pineal masses. MRI shows loss of CSF flow void in the aqueduct. MRI with or without CSF flow studies can be used for diagnosis.

CRANIOSYNOSTOSIS

Craniosynostosis refers to premature fusion of the cranial sutures and can be primary as a developmental anomaly or secondary to lack of brain growth. More than three-fourths involve a single suture and are non-syndromic. The skull shape depends on the suture that prematurely fuses as follows (Table 105-2). CT reveals sutural sclerosis and bony bridging of the sutures.

TABLE 105-2 Craniosynostosis

INVOLVED SUTURE	CEPHALIC SHAPE
Sagittal	Dolichocephaly
Metopic	Trigonocephaly
Unilateral coronal	Anterior plagiocephaly
Unilateral lambdoid	Posterior plagiocephaly
Bilateral coronal with lambdoid	Brachycephaly/turricephaly
Bilateral coronal with lambdoid	Oxycephaly
All sutures	<i>Kleeblattschädel</i> (cloverleaf skull)

Three-dimensional shaded-surface reconstruction is superior to conventional radiographs and CT for diagnosis. Raised ICT, hydrocephalus, proptosis, and optic atrophy are important complications.

INFECTIOUS/INFLAMMATORY DISORDERS

TORCH INFECTIONS

Table 100-1.

Congenital CMV is the most common serious viral infection among newborns and results from transplacental infection. Early second trimester infection results in microcephaly, lissencephaly, cerebellar hypoplasia, delayed myelination, hydrocephalus, extensive periventricular calcifications, and lenticulostriate vasculopathy. The latter is seen on US as perivascular calcification along lenticulostriate arteries. In mid second trimester infections, the cortical abnormality is polymicrogyria and all the other above findings, but slightly milder. In late gestation infection, there are no neuronal migrational abnormalities and other findings are milder.

Toxoplasmosis is also acquired transplacentally and imaging shows microcephaly, periventricular and intraparenchymal calcifications, hydrocephalus (often severe), porencephaly, and hydranencephaly (if severe). Unlike CMV infection, cortical malformations are rare.

Rubella is extremely rare in the developed world and can have similar imaging features as toxoplasmosis.

Herpes simplex infection in newborns is acquired while passage through the birth canal and is caused by HSV type 2. There is a diffuse necrotic meningo-encephalitis without predilection for the frontal and temporal lobes unlike in adults. Imaging shows mild meningeal enhancement and signal abnormalities beginning in the white matter which spread to the gray matter over 2 days. Diffusion-weighted MRI shows the earliest changes. Fifty percent have deep gray matter involvement, hemorrhage or cerebellar involvement. Eventually, there is multicystic encephalomalacia and diffuse cerebral atrophy.

BACTERIAL MENINGITIS

It is the most common CNS infection in children. Group B *streptococci* and *Escherichia coli* are the most common organisms in neonates, while *Haemophilus influenzae* type 2, *Streptococcus pneumoniae*, *E.coli* and *Neisseria meningitidis* are the culprits in the postneonatal period. Imaging is useful when the diagnosis is in doubt or to identify complications like hydrocephalus (communicating), venous thrombosis (empty delta sign), venous infarcts (do not show restricted diffusion like arterial infarcts), arterial infarcts (seen in basal ganglia, brainstem and is because of arteritis), subdural effu-

sions, and empyemas (empyemas show restricted diffusion while effusions do not), cerebritis, abscess, postmeningitic deafness (for evaluation for cochlear implant; calcification in the cochlea/cochlea stenosis is a poor indicator for success).

CEREBRITIS AND BRAIN ABSCESS

Both cerebritis and brain abscess have similar imaging characteristics as in adults, including restricted diffusion. The frontal lobe is the most common location for brain abscess in children. The temporal lobe and cerebellum are preferred sites for otogenic abscesses. Brain abscess in infants has poor capsule formation resulting in rapid enlargement and relatively large size. Also, they are commonly periventricular with high incidence of intraventricular rupture.

TUBERCULOUS MENINGITIS

Tuberculous meningitis is uncommon in United States and is commonly secondary to miliary tuberculosis. Imaging demonstrates hydrocephalus with marked enhancement of the basal cisterns because of extensive basal exudates. Intraparenchymal tuberculomas (tubercular abscesses) may be seen and the cerebellum is a common location.

ACUTE POSTINFECTIOUS ENCEPHALITIS

Acute demyelinating encephalomyelitis/ADEM is autoimmune in nature and can occur after common trivial bacterial/viral upper respiratory or gastrointestinal infection or even vaccination. Mortality rate is 10% to 20%. Imaging shows restricted diffusion and scattered T2/FLAIR hyperintensities in bilateral cerebral white matter and also in the thalami and basal ganglia. Sparing of the corpus callosum and deep gray matter involvement distinguish it from multiple sclerosis. Brainstem, cerebellum, and spinal cord are involved in one-third to one half of the cases.

HIV INFECTION

Approximately 90% of HIV infection is acquired by vertical transmission. Median age of disease onset is approximately 8 months. Imaging shows global atrophy, basal ganglia calcifications, and subcortical white matter calcifications (most common in frontal lobes). As opposed to adults, intracranial neoplasms and infections are relatively rare. Lymphoma is the most common neoplasm, typically involving the basal ganglia/thalamic region and often associated with systemic disease. CMV disease and progressive multifocal leukoencephalopathy are the most common infections. HIV vasculopathy can manifest as vascular ectasia, (seen at base of the brain), vasculitis, and thrombosis. Acquired HIV disease has similar manifestations as in adults.

RASMUSSEN ENCEPHALITIS

Rasmussen encephalitis is chronic localized encephalitis of unknown origin and one of the most important causes of intractable partial seizures. There is T2/FLAIR hyperintensity in the cortex and subcortical white matter involving a part (frontal/temporal) or the whole hemisphere with no contrast enhancement. Eventually, there is atrophy/encephalomalacia of the affected region with progressive dilatation of the adjacent ventricle. MR spectroscopy shows reduced NAA in the affected white matter. FDG-PET imaging reveals diffusely decreased activity in the region. It is treated by antiepileptics and subtotal/total hemispherectomy.

NEOPLASMS

MEDULLOBLASTOMA

Medulloblastoma arises from the cerebellar vermis and is the most common posterior fossa tumor in children, accounting for 15% to 20% of all intracranial tumors and 30% to 40% of all posterior fossa tumors. They are the most common brain tumor in 6 to 11 year age group with male to female ratio of 3:1. CSF dissemination is very frequent; most common intracranial locations include the vermian and basilar cisterns. Spinal “drop metastasis” are seen in 40% of patients, most commonly in the thoracic and lumbosacral levels. Systemic metastasis can rarely occur to the bones, lymph nodes, and lung. On noncontrast CT, the tumor is slightly hyperdense (best diagnostic sign); on T2-weighted images, the solid portion is isointense to gray matter. Calcifications are seen in 20%; solid portion enhances, and cystic/necrotic areas are seen in up to 50% of cases. Hemorrhage is rare.

ASTROCYTOMA

It is the most common brain tumor in children, comprising of 40% to 50% of all brain tumors. Forty percent occur in the cerebellum, 20% in the brainstem and the remaining 40% are supratentorial. Most of the cerebellar astrocytomas are juvenile pilocytic astrocytomas, WHO grade 1. Cerebellar astrocytomas occur in the cerebellar hemisphere and approximately two-thirds of these tumors are cystic with a solid well-enhancing mural nodule. The remaining one-third are solid, enhancing with central nonenhancing cystic region. Supratentorial astrocytomas have varying WHO grades with variable solid/cystic components; they often involve the deep nuclei and have a worse prognosis than cerebellar pilocytic astrocytoma.

EPENDYMOMA

Ependymoma comprises 8% to 15% of posterior fossa tumors. It arises from the floor/roof of the fourth ventri-

cle and has a tendency to grow through the midline foramen of Magendie into the cisterna magna (a specific sign seen in 60%) or through the lateral foramina of Lushka into the CPA cisterns. It is a predominantly solid mass with calcifications in approximately 50% and small cysts in 20%. Hemorrhage and CSF dissemination occur in approximately 10%. On CT it is iso to mildly hyperdense and isointense to gray matter on T2-weighted images. They show moderate heterogeneous enhancement.

BRAINSTEM GLIOMAS

Brainstem gliomas comprise approximately 15% to 20% of brain tumors and 20% to 30% of posterior fossa tumors. They are most commonly located in the pons, cause expansion of the brainstem and thus present with multiple cranial nerve palsies. Two-thirds have indistinct margins; correspond to WHO grade III/IV and show minimal or no enhancement. One-third are focal and are either grade I/II.

CRANIOPHARYNGIOMA

Craniopharyngiomas account for 50% of suprasellar tumors in children. Ninety percent have cysts, 90% with calcification, and 90% have contrast enhancement (peripheral rim enhancing). They may erode into the dorsum sellae or may grow into the sella with widening of the sella.

PRIMITIVE NEUROECTODERMAL TUMORS

Primitive neuroectodermal tumors are large tumors that occur in deep cerebral white matter and have distinct margins. The solid portion is hypodense on CT and isointense to gray matter on T2/FLAIR images; cystic areas and punctate calcification are common. When a large, solid, and sharply delineated mass is seen in a young child, the diagnosis of PNET is most likely, particularly when the mass is markedly heterogeneous.

DYSEMBRYOBLASTIC NEUROEPITHELIAL TUMOR (DNET)

Dysembryoblastic neuroepithelial tumor (DNET) is seen in children or young adults. It presents with long-standing, refractory epilepsy. Sixty percent occur in the temporal lobe and 30% in the frontal. Imaging demonstrates a well-demarcated, lobulated cortical mass, hypodense on CT, hypointense on T1-weighted, and hyperintense on T2-weighted images with cystic or microcystic components in 30% to 40% of the cases. Calcification is present in 30% of cases. Scalping of the inner table of the calvarium may be seen. Enhancement, usually patchy, can be seen 30% of tumors. They are metabolically inactive with no significant activity on FDG-PET.

CHOROID PLEXUS PAPILLOMA

Choroid plexus papilloma occur mainly in infants, cause severe secretory hydrocephalus, and have marked male predominance. It is a lobulated intraventricular mass, most commonly in the atrium of the lateral ventricle. The surface of the mass has papillary appearance on MRI that differentiates it from other intraventricular tumors like meningioma and ependymoma, which have a smooth surface. It is iso-/mildly hyperdense on CT with punctate foci of calcification and homogeneous contrast enhancement. The central portion is hypointense on T2-weighted images. Choroid plexus carcinoma has a tendency to invade the ventricle walls with adjacent vasogenic edema.

PINEAL TUMORS

Germinomas account for more than 50% of all pineal tumors. Male to female ratio is 10:1. Peak occurrence is in later part of second decade. It presents as a round/lobulated mass with iso-to hyperdensity on CT, T2-weighted/FLAIR hypointensity on MRI, and shows homogeneous contrast enhancement. CSF dissemination to the brain and spine is common.

Pineocytomas are uncommon in children. Pinealoblastoma is the second most common tumor of the pineal gland in the pediatric age group. They are highly malignant and can invade the cerebellar vermis, the walls of the third ventricle, and often have CSF dissemination. There usually iso-to-hyperintense on T2-weighted/FLAIR images. Necrotic or cystic areas may be present in larger pineoblastomas. Typically, there is intense but heterogeneous contrast enhancement. They are larger, more irregular and show more heterogeneous enhancement than pineocytomas or germinomas.

METABOLIC DISORDERS

DEMYELINATING/DYSMYELINATING DISORDERS

Metachromatic leukodystrophy, typically presents between infancy and 5 to 7 years of age. There is diffuse demyelination with subcortical white matter sparing. Krabbe disease (mean age 3–6 months) shows bilateral hyperdense thalami, caudate nuclei, corona radiata, and cerebellar dentate nuclei with T1 hyperintensity in these structures. Enhancement of cranial nerves and the cauda equina may be seen. Adrenoleukodystrophy is an X-linked disorder, affecting males 5 to 7 years of age and shows predominately bilateral occipital white matter and splenium of corpus callosum involvement. Canavan disease (neonatal period) is commonly seen in Ashkenazi Jews and presents with macrocephaly with diffuse white matter disease and early involvement of subcortical U fibers. MRS shows a very high NAA peak, which

is highly specific for this disorder. Alexander disease (infancy) also shows macrocephaly with predominately frontal white matter involvement associated with involvement of bilateral caudate nuclei and parietal white matter. MELAS (Mitochondrial myopathy Encephalopathy with Lactic Acidosis and Stroke) shows fluctuating T2 hyperintensities involving both gray and white matter predominantly in the occipital and parietal lobes, evolving into well-defined strokes, or resolving completely. MRS shows elevated lactate peak. Leigh disease is a mitochondrial disorder with characteristic, bilateral, nonenhancing, putaminal CT hypodensities and T2 hyperintensities with elevated lactate levels in basal ganglia.

MISCELLANEOUS DISORDERS

Mucopolysaccharidosis shows patchy white matter T2 hyperintensities in bilateral cerebral hemispheres and corpus callosum with prominent perivascular spaces. Hallervorden-Spatz disease shows markedly T2 hypointense globus pallidus with central hyperintensity (eye of the tiger sign). Wilson disease reveals CT hypodensity and T1 hyperintensity in bilateral basal ganglia, while phenylketonuria shows nonspecific periventricular white matter hyperintensity on T2.

TRAUMA

CT scan is the modality of choice in imaging acute head trauma. Epidural hematoma in children is the result of tear of dural veins rather than arterial injury. Epidural and subdural hemorrhages have imaging characteristics similar to adults.

NONACCIDENTAL HEAD INJURY

Nonaccidental head injury (NAHI) is the most common cause of severe head injury in infants. Children younger than 3 years are most vulnerable and shaking is the most common mechanism. Characteristic imaging findings include bilateral subdural hemorrhages, subarachnoid hemorrhage, interhemispheric subdural hemorrhage, subdural hemorrhage of various ages, and severe head injury in absence of fracture, diffuse axonal injury, and cerebral atrophy in later stages. Bilateral retinal hemorrhages are frequent; macrocephaly, bilateral posterior rib fractures, and metaphyseal fractures can also be seen. Skull fractures are common and are frequently located at the vertex, communicated, depressed, and often cross sutures. Husbands, boyfriends, and caretakers are the most common perpetrators, and greater than three-fourths of the perpetrators are unemployed. History frequently is insufficient to explain the severity of injury. Coagulopathies need to be ruled out. Glutaric aciduria

type 1 can mimic NAH1 and also has macrocephaly, bilateral subdural effusions, and retinal hemorrhages, but neuromotor abnormalities are almost always present.

VASCULAR DISORDERS

VEIN OF GALEN ANEURYSM/MALFORMATION

Aneurysm is a misnomer. Vein of Galen aneurysm/malformation is a central AVM occurring between intracranial arteries, usually choroidal, thalamoperforate, and anterior cerebral arteries and the vein of Galen and is probably secondary to intrauterine straight sinus thrombosis with recanalization. Male to female ratio is 2:1. It is detectable in utero after 30 weeks gestation as a hypoechoic aneurysmally dilated vein of Galen. Rim calcification with variable thrombus can be seen on CT and MRI. It usually presents as intractable neonatal heart failure, macrocrania with obstructive hydrocephalus or headaches and intracranial hemorrhage beyond infancy. There can be areas of encephalomalacia secondary to steal and ischemia. Neonatal heart failure, if present has a high mortality despite treatment.

MOYA-MOYA SYNDROME

Is characterized by progressive occlusion of terminal internal cerebral and proximal middle cerebral arteries with development of multiple collaterals consisting of thalamoperforate and lenticulostriate arteries giving rise to the classic “puff of smoke” appearance on angiography. Various diseases can give rise to moyamoya type of circulation: NF1, tuberous sclerosis, mucopolysaccharidoses, recurrent thromboembolism, Down syndrome, radiation therapy, sickle cell disease, glycogen storage disease type Ia, and HIV. MRI shows multiple flow voids in the basal ganglia, thalami, and base of brain with subarachnoid hemorrhage and cerebral infarcts.

SICKLE CELL DISEASE

CT contrast agents may precipitate sickling and are to be avoided. MR contrast agents are however safe. Imaging in sickle cell disease reveals thickened calvaria, infarctions, encephalomalacia from previous ischemic episodes, and moyamoya type of circulation.

JUVENILE ANGIOFIBROMA

Juvenile angiofibroma occurs in the adolescent males and presents as recurrent, often refractory epistaxis. Imaging shows a nasopharyngeal mass with multiple flow voids and intense enhancement. The mass often causes bowing of the lateral wall of the maxillary sinus (antral sign). Epistaxis is controlled by endovascular embolization.

HEREDITARY HEMORRHAGIC TELANGIECTASIA (OSLER WEBER RENDU DISEASE)

Multiple tiny telangiectasias in the nasal mucosa cause recurrent and refractory epistaxis and are often the initial presentation in patients with Osler-Weber-Rendu disease, usually manifesting in the second decade. Control of epistaxis is best done by endovascular means.

HYPOXIC ISCHEMIC INJURY IN THE NEWBORN

Hypoxic ischemic injury in the newborn in premature manifests as either germinal matrix hemorrhage or periventricular leukomalacia. Germinal matrix hemorrhage occurs in newborns younger than 34 weeks in the region of the caudothalamic groove. There may or may not be intraventricular extension, hydrocephalus, or less commonly, intraparenchymal extension. This type of hemorrhage is hyperechoic on US. Periventricular leukomalacia is ischemia occurring in frontal white matter near foramen of Monroe or in peritrigonal location. Subsequent cavitation occurs in approximately 3 weeks. Before cavitations, periventricular leukomalacia appears as indistinct, globular hyperechoic areas. Subsequent cavities are typically tiny and clustered. CT and MRI later reveal T2/FLAIR hyperintensity with paucity of periventricular white matter and ventriculomegaly.

In full-term newborns, mild-to-moderate hypotension causes ischemia in the watershed territories of ACA-MCA and MCA-PCA (called parasagittal injury). Profound hypotension irrespective of age infarcts the basal ganglia, thalami, and perirolandic cortex, which are the most metabolically active areas of the brain.

PEDIATRIC SPINE

CONGENITAL ANOMALIES

APLASIA OR HYPOPLASIA OF ODONTOID

Complete failure of formation of dens results in aplasia while partial formation is referred to as dens hypoplasia. Aplasia of os terminale results in a notch at the tip of the odontoid process. Os terminale appears at 6 years of age and fused with rest of dens by 10 to 12 years. During this age group, it should not be confused for a fracture.

OS ODONTOIDEUM

Os odontoideum is felt to be a variant resulting from enlargement of the os terminale part of odontoid, associated with enlarged anterior arch of C1. It also mimics a fracture of odontoid. Instability at cranio-cervical junction and C1-2 should be checked by flexion extension views. There is an association with Down, Morquio, and Klippel-Feil syndromes.

SEGMENTATION ANOMALIES

Block Vertebra or failure of sclerotome segmentation results in fused vertebrae at one or multiple levels, lumbar more common than cervical spine, which is more common than thoracic spine. Narrowing (waist) at the level of rudimentary disc and fused posterior elements are typical findings. Differential diagnosis includes postsurgical changes, juvenile chronic arthritis, postdiscitis and ankylosing spondylitis. There may be associated other anomalies: hemivertebra, butterfly vertebra, rib fusion anomalies, and posterior arch anomalies. This can be an isolated finding or associated with syndromes like Klippel-Feil syndrome.

KLIPPEL-FEIL SYNDROME

Klippel-Feil syndrome includes failure of segmentation of cervical somites creating block vertebra at one or multiple levels in cervical spine. Clinically, patients present short neck with limited neck motion and low posterior hairline (40%–50%). There is an association with Sprengel shoulder (20%–30%), congenital scoliosis (60%), and neurologic problems such as synkinesia (20%).

VATER ASSOCIATION (VACTERL ASSOCIATION)

Nonrandom association of anomalies of multiple organ systems (except brain) is referred to VATER syndrome: Vertebral, Anorectal/auricular, Tracheoesophageal fistula, Esophageal atresia, Renal/radial/rib, limb anomalies. It is diagnosed when three or more of these coexist.

Vertebral anomalies including block vertebra, hemivertebra, and butterfly vertebra are associated with sickle sacrum, caudal regression, and cardiac anomalies (VSD (30%), PDA (26%), ASD (20%).

SPINAL DYSRAPHISM

Congenital anomalies of spine are usually associated with tethering of spinal cord. Nonoccult includes meningocele (only meninges) and myelomeningocele (meninges and spinal elements). Occult anomalies are skin covered or nearly skin covered with dimple, dermal sinus tract, lipoma, skin tag (tail), tuft of hair, or hemangioma.

Underlying cord abnormalities include tethered cord, split cord (diastematomyelia), and terminal myelocystocele. Rarely cord may terminate high (stump ending). Intrathecal lesions can include dermoid, epidermoid, hemangioma, and anterior meningocele. Spinal ultrasound is best for initial screening, and MRI is further definitive evaluation.

DIASTEMATOMYELIA

Diastematomyelia (split cord malformation) is a type of occult dysraphism. It occurs as a sagittal split of the cord by a fibrous, cartilaginous, or osseous (less than 50%)

bar. There may be associated segmentation anomalies, widened interpediculate distance. Most are located in the lumbar or lower thoracic spine. Split cord may reunite or stay split, and a syrinx is identified in up to 50% of cases. The cord abnormalities will need to be untethered, and there is good prognosis following spur resection with untethering.

CAUDAL REGRESSION SYNDROME

Caudal regression syndrome describes a series of anomalies, including partial or complete agenesis of sacrum, thoracic, and lumbar spine. It is secondary to defective induction of caudal cell mass before seventh week of gestation and occurs in 1% of all diabetic pregnancies. There is an association with VACTERL.

CURRARINO TRIAD

Currarino triad includes partial sacral agenesis (scimitar sacrum), imperforate anus, and anterior meningocele. It may be associated with teratoma, or cyst in presacral region.

INFLAMMATORY DISORDERS

Discitis is an inflammatory process of disc space. *Staphylococcus aureus* is the most common agent. Initially, patient presents with low back pain and typically have negative radiographs. Bone scan is usually positive at presentation revealing increased uptake in bodies on either side of the disc. Radiographic findings will eventually include a narrow disc with endplate irregularity of the vertebral bodies.

MRI reveals low T1 signal in marrow on adjacent bodies, decreased disc space, and loss of cortical low signal. T2-weighted images demonstrate high signal in marrow, loss of high signal of disc, and edema of paravertebral tissues. Gadolinium confirms the diagnosis with enhancement of the vertebral bodies and disc margins as well as the paravertebral soft tissues.

TUBERCULOUS SPONDYLITIS

Although, rare in the United States, incidence is on rise with increasing immigration from Southeast Asia and Latin America. Caudal thoracic or lumbar spine is the most common site of involvement. Anterior vertebral body initially affected with spread to the disc and adjacent vertebra. Posterior elements are relatively spared (gibus deformity).

Radiographs reveal lytic lesion in anterior body with disc narrowing. Multiple vertebral bodies may be affected, and the disc space and posterior elements may be

spared. Paraspinal soft tissue with cold psoas abscess is the classic finding. Contrast-enhanced MRI depicts the extent of disease more accurately, specially the soft-tissue abscesses.

NEOPLASMS

EWING SARCOMA

Ewing sarcoma is a malignant lesion of primitive neuroectodermal (small blue cell tumor) origin, arising from vertebral body with almost purely destructive nature. There is usually associated soft-tissue mass. Patients may present with localized pain, fever and leukocytosis.

Radiography shows permeative destruction, vertebra plana, and multiple vertebral bodies may be involved. MRI is the best modality for staging. Differential considerations include Langerhans cell histiocytosis, osteomyelitis, other small blue cell tumors and sarcoma.

METASTASES

Metastatic disease to the spine is usually from leukemia, lymphoma, rhabdomyosarcoma, neuroblastoma, Wilms tumor, and PNET. Langerhans cell histiocytosis will have similar appearance. Radiography reveals lytic or sclerotic lesions, compression of vertebral bodies, and paraspinal masses. On MRI, there is variable signal on T1-weighted and increased signal on T2-weighted images. Fat suppressed, postcontrast images demonstrate the tumor infiltration.

Leukemia is the most common malignancy of childhood. Acute lymphoblastic leukemia is much more common than acute myeloblastic leukemia. Imaging findings are nonspecific, characterized by osteopenia, compression deformities, and pathologic fractures. Soft-tissue masses (chloromas) in the paraspinal region are more commonly seen in acute myelogenous leukemia.

Imaging findings in Hodgkin and non-Hodgkin lymphoma are also nonspecific in nature with multiple focal lesions, usually lytic and rarely sclerotic nature. Soft-tissue masses in the paraspinal region and adenopathy may be helpful additional findings.

ANEURYSMAL BONE CYST

Aneurysmal bone cyst (ABC) is a benign cystic expansile mass with loculated appearance on conventional radiography. Up to one-third occur in the spine, usually arising in the posterior elements and may extend into the body. Absent spinous process or pedicle on frontal radi-

ograph and expansile mass in the lamina on lateral view are classic findings. CT demonstrates multiple fluid/fluid levels because of hemorrhage. There is natural zone of transition. Septal enhancement may be seen on post-contrast CT. MRI demonstrates the products of hemorrhage more clearly.

OSTEOBLASTOMA

Osteoblastoma (giant osteoid osteoma) is an expansile lesion arising in the posterior elements of spine. It is greater than 2 cm in size, characterized by single lytic with and variable sclerosis of its margins. It may be difficult to identify on conventional radiographs. CT demonstrates narrow zone of transition. The appearance is similar to a large osteoid osteoma. MR demonstrates variable signal on T1- and T2-weighted sequences. Rarely fluid/fluid levels similar to aneurysmal bone cyst may be seen. Enhancement on postcontrast scan is variable. The patient may present with painful scoliosis.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis is a nonneoplastic condition characterized by monoclonal proliferation of Langerhans cells. There is vertebral body involvement sparing the adjacent discs (thoracic greater than lumbar greater than cervical spine). On electron microscopy, cytoplasmic inclusion bodies (Birbeck granules) are identified.

Imaging features include severe compression deformity of the vertebral bodies, resulting in vertebra plana. The posterior elements, usually spared, are more commonly affected in cervical region. Small paraspinal soft-tissue mass can be seen. Commonly affected regions include the skull, spine, pelvis, and extremity bones. Lytic lesions with variable sclerosis are seen.

Conventional skeletal survey is more sensitive than bone scan. MRI demonstrates that spinal soft-tissue masses and mass effect on the spinal cord more accurately. The disc shows no involvement in this condition, even in the presence of extensive compression deformity of adjoining vertebral bodies.

TRAUMA

Fractures and dislocations of the spine are less common than in adults but are important to diagnose, as they are associated with significant morbidity and mortality. Developmental structures can mimic trauma. Primary centers of ossification begin to appear after

8 weeks of gestation. Secondary centers appear around puberty and fuse by 25 years of age. The atlas has one ossification center for its anterior arch and two for the posterior arch. Anterior arch is seen only in 20% of patients in first year. The axis has five primary centers, one for body, one for each neural arch, and two for the dens. The subdental synchondrosis should not be confused for a fracture. It begins close after 3 years of age in girls and by 5 years of age in boys. The terminal center for dens appears by 6 years of age and fuses by 10 to 12 years. C3 through C7 have three primary ossifications centers (one for body and one for each arches). The synchondroses fuse by 3 to 6 years of age.

Each vertebra has five secondary centers, one for transverse process, one for spinous process, and one for superior and inferior epiphyseal ring. They appear by puberty and close by 25 years of age. Horizontal orientation of the facet joints makes the spine in younger children susceptible to subluxation and dislocations. After 8 to 11 years, the nature of injuries becomes similar to adults. Pseudosubluxation of C2 over C3 and C3 over C4 can be seen up to age 11. Normal alignment of the posterior spinolaminar line helps to differentiate from the true subluxation. Injuries in the upper cervical spine are more common, because of higher fulcrum in younger children (C2–3) than adults (C5–6). Heavier head and poorer support by weaker ligaments make upper cervical spine more susceptible to distraction, subluxation, and dislocation. Spinal cord injuries without radiographic abnormalities (SCIWORA) is more common in children than in adults.

Atlanto-occipital dislocation is seen in young children involved in high-speed motor vehicle collisions. Typically, there is anterior displacement of the skull relative to the spine. On lateral view of the cervical spine, the dens to basion distance (DB) should be between 5 and 12 mm. Powers ratio (BC/OA) should be less than one.

SPONDYLOLYSIS/SPONDYLOLISTHESIS

Spondylolysis is a break in pars interarticularis, felt to be a stress- or trauma-related. L5 and L4 are the commonest sites. Most are bilateral (less than 15% unilateral). This is best demonstrated on an oblique view of the spine as a break in the “Scotty dog’s neck.” Bone scan with SPECT is the most sensitive modality for initial diagnosis. Axial and sagittal CT is used for anatomic localization. MRI shows low signal on T1-weighted and high signal on T2-weighted images through the region of pars interarticularis.

MISCELLANEOUS

SCHEURMANN DISEASE

Scheurmann disease (juvenile kyphosis) is a disease of children characterized by kyphosis with pain in the thoracolumbar region. Children between the age of 13 and 16 years are most commonly affected. Etiology is uncertain, but pathologically, there is osteochondrosis of the secondary centers of ossification of the vertebral bodies. Metabolic, mechanical, and endocrine causes have been proposed. Males are affected more than females, and it may be hereditary, autosomal dominant.

Radiographs demonstrate thoracic kyphosis, wedging of the vertebrae, irregular end plates of the vertebral bodies because of herniation of the nucleus pulposus (Schmorls nodes). Limbus vertebra may also be seen. Diagnostic criteria: (Sorenson) include hyperkyphosis greater than 40 degrees, with irregular upper and lower vertebral endplates, loss of disc space height, wedging of 5 degrees or more in three consecutive vertebrae. Differential considerations include congenital kyphosis, trauma, Langerhans cell histiocytosis, osteoporosis because of chronic glucocorticoid steroid therapy, ankylosing spondylitis, and generalized skeletal dysplasia.

SCOLIOSIS

Scoliosis is defined as lateral curvature of spine greater than 10 degrees. It is idiopathic, characterized by dextrocurvature of the thoracic spine with levocurvature of the lumbar spine. Females are affected seven times more commonly than males. Atypical idiopathic scoliosis has levothoracic and dextrolumbar curvature. Congenital scoliosis is caused by segmentation or formation anomalies or a combination of the two. It is typically characterized by short segment acute scoliosis. Neuromuscular scoliosis is typically C-shaped. Infections of tuberculous or pyogenic origin, benign and malignant tumors, trauma, and radiation therapy are other common etiologies for scoliosis.

Conventional radiography best demonstrates the nature of scoliosis. Method of Cobb is utilized for measurement: the angle between two lines drawn perpendicular to the endplates of the terminal vertebrae is measured. MRI may be used to rule out underlying spinal cord anomalies including tethering, tumor, syrinx or infection among etiologies. CT and three-dimensional reconstruction are useful for surgical planning.

INTERVERTEBRAL DISC CALCIFICATION

Intervertebral disc calcification is of unknown etiology. Infection and trauma have been implicated. Typically patients present with fever, neck pain, elevated sedimentation rate, and leukocytosis. Biochemical abnormalities of the nucleus pulposus and abnormal vascular

supply of the disc are also proposed mechanisms of disease. Cervical and thoracic spine are most common sites of disc calcification, and C6-7 is the most common site for symptomatic disc calcification. Overall, it is a self-limiting condition, rarely requiring surgical intervention.

Radiographs readily demonstrate disc calcification. CT or MR is used to demonstrate mass effect on the cord. Of the symptomatic patients, a little more than one-third of the patients may demonstrate posterior disc protrusion.

SACROCOCCYGEAL TERATOMA

Sacroccocygeal teratoma is a germ cell tumor containing elements of all three germ cell layers located in the coccyx. It usually presents as a large mass in distal end of body in a newborn or diagnosed on prenatal sonography. Males are affected four times more than females. Eighty percent are benign. Tumors are staged based upon the tumors' relative location (inside, outside) the body (Table 105-3).

Radiography reveals a soft-tissue mass, many with calcifications. Ultrasound reveals a complex cystic/solid mass. CT and MRI show complex mass with cystic, solid, hemorrhagic and calcified components and heterogeneous enhancement. Differential considerations include anterior meningocele, neuroblastoma, rhabdomyosarcoma, and rarely chordoma.

ASTROCYTOMA OF CORD

Astrocytoma of cord is the most common intramedullary primary tumor of cord of childhood; most are low-grade gliomas, although subarachnoid spread has been seen. It is associated with NF 1 and 2. It is an asymmetric infiltrating mass with homogeneous enhancement and no tendency for hemorrhage. Differential considerations include other tumors of cord, syringohydromyelia, acute inflammatory myelitis, cord ischemia, vascular malformations.

EPENDYMOMA OF CORD

Ependymoma of the cord most commonly occurs in cervical region as an expansile intramedullary mass with hemorrhagic features. It is slow growing with widening of osseous canal, increased interpediculate

distance, and posterior vertebral scalloping. Symmetrical expansion of cord is typical. Myxopapillary ependymoma is a separate entity that arises from filum terminale. It is an enhancing mass that is also slow growing with expansion of bony canal similar to intramedullary type. It has a much better prognosis than intramedullary type.

NEUROBLASTOMA

Neuroblastoma arises from primitive neural crest cells and has variable differentiation and malignant tendency. Ganglioneuroma is the most differentiated and most benign; ganglioneuroblastoma, a mixture of neuroblasts and ganglion cells; neuroblastoma, most poorly differentiated and most malignant therefore, it presents as paraspinal abdominal mass with weight loss, fatigue, irritability (paraneoplastic syndrome). Neuroblastoma accounts for 65% to 70% intra-abdominal paraspinal masses. Radiography shows paraspinal soft-tissue widening with calcifications and osseous bony destruction. MRI shows paraspinal enhancing mass with or without intraspinal extradural extension and cord compression. MRI is best for diagnosis; presurgical planning incorporates PET with FDG. Bone scan is also good for staging while MIBG is good for staging as well as postsurgical surveillance.

NEUROFIBROMA

Type 1 neurofibromatosis (NF1), an autosomal dominant (chromosome 17) mesodermal dysplasia associated with nerve root neurofibroma, plexiform neurofibroma or malignant peripheral nerve tumors is more common in children (1/5000). Spinal manifestations include, kyphoscoliosis, multiple nerve root tumors and lateral meningocele (dural ectasias).

Type 2 neurofibromatosis (NF 2) is more common in adults, (1/50 000), and is an autosomal dominant (chromosome 22) dysplasia characterized by multiple inherited schwannomas (nerve VIII most common), intraspinal meningiomas and intramedullary ependymomas. More than 80% have intraspinal tumors at diagnosis.

HYDROSYRINGOMYELIA

A general radiographic term used to describe a cavitary lesion of cord in (hydromyelia) or around (syringomyelia) the spinal central canal. Patients present with loss of pain and sensation with preservation of proprioception, position, and light touch. Etiologies include Chiari malformation I or II, trauma, infection, and spinal cord tumor. Imaging reveals a linear, cystic, sometime septated lesion. Contrast enhancement is useful in differentiation and demonstration of associated tumor.

TABLE 105-3 Staging of Sacro/Coccygeal Teratoma

STAGING	TUMOR RELATIVE TO BODY
I	Primarily external (47%)
II	Dumb-bell shaped, equally external and internal (34%)
III	Primarily internal (9%)
IV	Totally internal (10%), mostly malignant

QUESTIONS AND ANSWERS

- What is the normal progression of myelination in a newborn?
 - Cranial to caudal
 - Posterior to anterior
 - Motor to sensory
 - Peripheral to central

ANSWER: B. Myelination characteristically occurs from posterior to anterior, caudal to cranial, and central to peripheral. Also, sensory and projection pathways myelinate before association pathways.

- Which of the following can mimic child abuse?
 - Canavan disease
 - Phenylketonuria
 - Homogentisic aciduria
 - Glutaric aciduria

ANSWER: D. Glutaric aciduria type I shows characteristic signs of child abuse head injury like bilateral subdural effusions, large head, and bilateral retinal hemorrhages. The most striking finding on brain imaging is the presence of very wide CSF spaces anterior to the temporal lobes and within the sylvian fissures. Widening of the sylvian fissures is a very characteristic finding in this disorder. Abnormal neuromotor development is almost always present and is a clue to the diagnosis.

- Which of the following is closely related to septo-optic dysplasia?
 - Hydranencephaly
 - Lobar holoprosencephaly
 - Lissencephaly
 - Colpocephaly

ANSWER: B. Septo-optic dysplasia is closely related lobar holoprosencephaly and shares many of its features. In fact many consider many cases of lobar holoprosencephaly to be a subtype of septo-optic dysplasia.

- What is most commonly associated with corpus callosal agenesis?
 - Dandy-Walker malformation
 - Holoprosencephaly
 - Lissencephaly
 - Schizencephaly

ANSWER: A. The most common malformation associated with callosal agenesis is Dandy-Walker malformation. Syndromes in which callosal agenesis is seen are Aicardi syndrome, fetal alcohol syndrome. Lissencephaly is commonly seen in congenital muscular dystrophies. Holoprosencephaly is seen in Edward and Patau syndromes.

- In which of the following is CSF dissemination *not* seen?
 - Ependymoma
 - Medulloblastoma
 - Choroid plexus papilloma
 - Pinealoblastoma

ANSWER: C. CSF dissemination is seen in all except in choroid plexus papilloma. Germinomas that occur typically in suprasellar/pineal region can also have CSF dissemination. CSF dissemination is most commonly present at the time of presentation in medulloblastoma.

- In which of the following diseases are Hyperdense thalami seen on CT?
 - Metachromatic leukodystrophy
 - Alexander disease
 - Wilson disease
 - Krabbe disease

ANSWER: D. Krabbe is an autosomal recessive sphingolipidosis. The thalami, central white matter, and cerebellum, which show hyperdensities on CT are seen on MR as decreased signal intensity on T2-weighted images and increased on T1-weighted images. These findings are attributed to alterations in the ratio of lipids, water, and proteins in response to

breakdown of myelin and the associated astrogliosis with fine microcalcifications.

7. In which of the following diseases can Moya-moya disease be seen?
- A. Sickle cell disease
 - B. Amyloidosis
 - C. Myelofibrosis
 - D. Multiple myeloma

ANSWER: A. Moyamoya is seen in sickle cell disease. It is associated with nonatherosclerotic intimal thickening and occlusion of terminal ICA, proximal MCA, and ACA. It can also be seen in NF1, protein C/S deficiency, radiation injury, Down syndrome, systemic lupus erythematosus, and polyarteritis nodosa.

8. Which of the following diseases are spinal ependymomas associated with?
- A. Chiari II malformation
 - B. NF2
 - C. Von Hippel-Lindau disease
 - D. Tuberous sclerosis

ANSWER: B. NF2 has associated multiple meningiomas, bilateral eighth nerve and multiple cranial nerve schwannomas, spinal cord ependymomas, multiple paraspinal schwannomas/neurofibromas. The ependymomas usually occur in the cauda.

9. In what percentage of patients with Chiari II malformation Myelomeningocele is seen ?
- A. 0%–10%
 - B. 10%–20%

- C. 50%–60%
- D. 90%–100%

ANSWER: D. Myelomeningocele is seen in almost all cases of Chiari II syndrome and is located in the lumbar region. The cord is low lying and tethered. Lipomyelomeningocele can also be found. Other spinal dysraphisms can also be associated.

10. Children born to diabetic mothers are at risk for which of the following diseases?
- A. Sacrococcygeal teratoma
 - B. Diastematomyelia
 - C. Caudal regression syndrome
 - D. Hydromyelia

ANSWER: C. Caudal regression syndrome is a congenital defect, characterized by the absence of the sacrum and defects of variable portions of lumbar spine. Majority of cases are sporadic, and it occurs in up to 1% of pregnancies of women with diabetes and up to 22% of cases of CRS are associated with either type 2 or type 2 diabetes. Femoral hypoplasia, clubbed feet, and flexion contractures of the lower extremities are also commonly seen. Additionally, caudal regression syndrome is often associated with anomalies of the gastrointestinal tract, genitourinary tract, and heart, as well as with neural tube defects. Sirenomelia, which was thought to be the most severe form of caudal regression syndrome (today it is considered a different entity), is the main differential diagnosis. Fusion of the lower extremities is a typical finding of sirenomelia and is absent in caudal regression syndrome.
