

Radiology

- Presents a concise review of pathophysiology and anatomy
- Focuses on the 10 subspecialty content areas
- Prepares for lifelong learning
- Includes sections on MRI and Ultrasound Physics
- 1,000+ Q&As with discussion

CHERI L. CANON

Board Review*

RADIOLOGY

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

PREFACE

In recent years, there has been a paradigm shift in learning, specifically the manner in which information is gathered and ingested. This is particularly notable in subject matter that covers great breadth or is rapidly evolving, such as medicine, and more specifically, diagnostic imaging. Students and residents (and for that matter, practicing radiologists) quickly turn to the Internet to “Google™” unknown factoids, rapidly gathering information, in many cases without source validation. This has created silo learning where tidbits of information are immediately collected, answering the one specific question of concern. However, there is little depth or longevity afforded with this learning process, which in many cases does not drill down to the anatomic or pathophysiologic fundamental principles. As a result, there is a lack of complete understanding, or even worse, misunderstanding, and the information is often retained only long enough to address the question at hand.

This book is an attempt to address the silo learning afforded by the Internet. It is organized according to 10 subspecialties and includes overviews of imaging-based physics for ultrasound, MRI, and nuclear medicine. Content centers on the fundamentals of anatomy and pathophysiology with concise relevant imaging correlation. This, however, is not a text emphasizing image interpretation, as there are countless other references that do this quite well. At the end of each chapter, the reader is challenged with a set of questions written in single best answer, multiple-choice format. Detailed discussions of the answers enhance and enforce the reader's learning experience.

The goal of this text is to provide a firm foundation for learning and reference during residency training, and through lifelong learning. Its intent is to link together common concepts while presenting often complex material in a simple, straight-forward manner, hopefully balanced with enough depth so that fundamental concepts are reinforced so as to avoid piecemeal or silo learning.

ACKNOWLEDGMENTS

I am indebted to the contributing authors for their knowledge, insight, and perseverance. Their expertise has proven invaluable.

I would also like to thank Beth Parker, my assistant, for endless hours of editing and overall coordination of this project. Additionally, thanks goes to Rachel Metcalf, Toni Braddy, Brittany Harris, and Pat Moore for their support and to Tony Zagar for his illustrations. He has drawn clear, understandable figures despite my ambiguous and often conflicting instructions.

Finally, a note of appreciation goes to my fellow members of the Abdominal Imaging Section at the University of Alabama at Birmingham, Department of Radiology. Without your support and encouragement, this book would have never happened. It is a real pleasure to work with you each and everyday.

Section 1

CENTRAL NERVOUS SYSTEM

1 TECHNICAL ASPECTS OF CNS IMAGING

Joseph C. Sullivan III

Imaging used to evaluate the brain, head and neck, and spine primarily incorporates volume acquisition imaging, mainly CT and MRI. Conventional radiography remains useful in central nervous system (CNS) evaluation primarily in the realm of prescreening for indwelling metal foreign bodies and implants in patients undergoing MRI and initial imaging in an emergency setting.

CT

CT uses an x-ray transmission algorithm to mathematically reconstruct a cross-sectional image of the body from relative amounts of x-ray transmission. As the gantry of the CT scans spins around the patient, a narrow beam of x-rays is emitted to an associated row of rotating detectors on the opposite side of the gantry. Relative transmission is calculated and a cross-sectional image is created via computer algorithm. The use of multirow detectors with CT has nearly eliminated conventional (nonhelical) CT, as the speed at which helically acquired CT is now obtained allows for increased areas of coverage without breath-hold or with shorter breath-hold times. High-detail three-dimensional imaging can be obtained via postprocessing. Additionally, the larger number of detectors and overlap of the spiral acquisition nearly eliminates misregistration and volume-averaging artifacts.

The display of data with CT is a computer-based pixel assignment relative to water densities, Hounsfield unit (HU). This scale, named for Sir Godfrey Hounsfield assigns increasing HU to higher density materials with water being 0. Therefore, fat and air have negative HU and bone is highly positive. Brain parenchyma and even CSF,

which is slightly more dense than water, have HU somewhere between that of water and bone.

The basis of the display of this data is relative to the value given to each pixel and the display algorithm that is chosen. The midlevel, or area of interest based on tissue density, is the selected window level. A window width encompassing this level increases or decreases the surrounding variation of shades of gray displayed. Therefore, to evaluate a specific portion of the anatomy, the window is narrowed to a particular width to include the desired surrounding tissues. Therefore, multiple different window-width and window-level settings are used to evaluate for parenchyma (approximately 35–40 HU), blood (approximately 60–70 HU in a normal patient), bone (2000 HU or greater). Dedicated narrow windows are necessary to evaluate for stroke, specifically looking for edema within the parenchyma (25–40 HU); “subdural window” employs more of a soft-tissue window.

Image data can be reviewed in multiple ways and differing planes, allowing for increased information without subjecting the patient to additional radiation. It should be considered, however, that the imaging technique should be tailored for the specific clinical indication. Higher kVp provides improved resolution for more dense material such as bone, versus increased mA to give better resolution of soft tissue.

Ever-increasing multidetector helical acquisition and appetite for improved anatomical resolution must be balanced with risks of increased radiation dosage, particularly in those who are more susceptible to the adverse effects of radiation, that is, infants and children.

CT images are obtained with x-rays and are therefore subject to beam hardening and streak artifacts. As a beam of photons passes through a particular section of anatomy, it is attenuated so that the higher kVp photons are transmitted and registered by the detector on the contralateral side. This results in a misinterpretation by the detector that there was higher transmission than actually occurred, in turn calculated by the computer as an area of low density, thus lower HU. Streak artifact occurs when there are edges of sharp density delineation

between adjacent objects. As the computer sees the large variation in x-ray attenuation, it misinterprets these regions and produces a “star” or a multistreak artifact as the gantry rotates around this interface. Motion artifact occurs when structures change position within the field of view as acquisition of the object changes position relative to the gantry. As the gantry encircles the patient, this causes a misregistration of the object in the field. This may be secondary to normal physiological motion in the case of heartbeat, respiration, vessel pulsation, or bowel gas peristalsis. Although CT scanners have improved in their speed of acquisition to the point this can be nulled or even gated, patient motion remains a continuing problem.

MRI

MRI is a completely different form of volume acquisition. There are different tissue characteristics based on its protons, resulting in differing T1 and T2 relaxation times. The T1 relaxation time is the time it takes for a tissue to become magnetized, while T2 indicates the time for loss of this magnetization. These differing relaxation times are localized within the field of the magnet depending on small variations in the radiofrequency applied and received by tailored antennas known as coils. Tissue within a field of localization may not remain within that field or may pass into that field under normal physiological conditions. Specifically, blood flow may demonstrate a flow void as blood flows through a blood vessel into and out of a magnetized field. Also, in variation with CT, which is acquired in a cross-sectional anatomic demographic plane and reconstructed via postprocessing, MRI can be acquired in multiple planes as the data is acquired volumetrically and presented in planes based on frequency encoding, corresponding to the x-axis, and phase coding, y-axis. Respectively, slice location is determined by slight variations and the gradient intensity along the z-axis.

MR is obtained in multiple varied sequence acquisitions, the primary of which is a spin echo pulse sequence. Standard T1- and T2-weighted images are created using a short time of repetition and time of echo versus longer times, respectively. Proton density sequences use a combination of long repetition time and short echo time, allowing for accentuation of hydrogen density differences between tissues. Variations of spin echo, called multiple spin echo, allow for the reduction of image acquisition time, typically referred to as fast-spin or turbo-spin echo. The trade-off is degradation of signal intensity and increased fat intensity on T2-weighted imaging. Fat-suppression techniques are often used to counter this effect and/or to allow for detection of underlying fluid latent pathology. Inversion recovery pulse sequences emphasize differences between T1 relaxation times as a delayed time of inversion is added to the time of repetition and time of echo; tissues

with short T1 relaxation times such as fat are suppressed and tissues with an unexpected high water content (pathology) are accentuated. Fat-suppression techniques attempt to similarly depress the short T1 signal of fat; however, these are highly sensitive to magnetic field inhomogeneity, and do not work well with low field magnet strength. Fat suppression is performed using a saturation pulse at a resonant frequency of fat applied to each imaging plane. Although this is limited by its sensitivity for field inhomogeneity, this is better for use with postcontrast technique than those of inversion recovery as the latter suppresses all tissues with short T1 including those that may enhance after the administration of gadolinium. Echo planar imaging incorporates fast MR techniques for multislice studies with single radiofrequency excitation. It decreases motion artifact and continues to show improvement in high-resolution techniques such as blood perfusion and functional MR. Gradient recall echo imaging pulse sequences employ multiple short flip angles of less than 90 degrees to decrease the time taken to recover a signal. This, however, creates sensitivity to imperfections in the magnetic field from short T2 relaxation times, also known as T2 star.

Safety of the patient is the foremost concern. Ferromagnetic and magnetic susceptibility of implants, personal items carried by the patient, and support devices inadvertently taken into the field of the magnet must all be considered with each patient. Furthermore, although some implants may not have ferromagnetic components, the components of those implants should be carefully evaluated as wires or loops in a magnetic field can generate electric current. Such radiofrequency current can cause burns or false activation or failure of the implant. The strength of the magnet must also be considered as variations in magnetic field strength can have variable effects on all such devices. Some implants, although considered compatible with MR, may demonstrate artifacts associated with disruption of the magnetic field. This implies the object has some ferromagnetic quality. The safety considerations and compatibility of implants far exceeds the content of this text and should be considered on an individual case-by-case basis.

Motion artifacts in MR are also more prevalent than CT secondary to the longer acquisition time. Multiple techniques such as shorter acquisition time and computer reregistration are used for motion correction.

MYELOGRAPHY

Myelography is a useful tool in those who cannot be imaged adequately or safely with MRI. Although it is not nearly as prevalent as it once was, indications for and usefulness of myelography remain. A lumbar puncture is performed and once a spinal needle is advanced into the thecal sac, at a level that is deemed safe, the stylet is

retracted. Upon the spontaneous return of cerebrospinal fluid, contrast media is carefully injected under direct visualization. Spot fluoroscopic imaging obtained at the time of contrast placement can reveal significant pathologic information by assessing contrast flow. Keeping in mind that all sections of the spinal thecal sac can usually be evaluated from a single puncture, it should be remembered that the density and amount of contrast material greatly varies based upon the clinical question at hand. Careful attention to the location of the contrast in the thecal sac, as this can have clinical side effects based on misplacement and/or its extension into the skull base, and the puncture site, as symptoms of skull-based headaches from cerebrospinal fluid leaks can be detrimental to the patient, must be demonstrated.

Myelographic imaging remains limited in that it only can delineate those things within the thecal sac or that impress upon the thecal sac but not pathology within the cord itself. However, in the patient in whom an MRI is contraindicated, localization of cord swelling or impression upon the cord or other neuroelements may be key to the surgical planning. Further usefulness of myelography is seen with postsurgical patients who have hardware that may not be tolerated in a magnetic field or may create artifacts to the point that evaluation of the adjacent neural elements may be precluded. Provided that the postmyelographic CT does not have substantial artifacts to limit its use, it must be remembered that the acquisition of fluoroscopic spot film at the time of actual myelography can give almost as much information as the postmyelographic CT.

QUESTIONS AND ANSWERS

- What is the result when decreasing CT slice thickness with all other factors constant?
 - Decreased radiation to the patient
 - Decreased noise
 - Decreased resolution
 - Decreased tube heating
 - Decreased motion sensitivity

ANSWER: C. Resolution is decreased in the use of thinner slices if all other factors remain the same (unless kVp and/or mA are increased). A smoothing algorithm may be used to make the images more pleasing which may further limit sensitivity to subtly pathology. Radiation to the patient will increase unless kVp and/or mA is decreased. Tube heating therefore is also increased. The longer scan acquisition time increases risk for motion artifact.

- Which one of the following artifacts is correctly paired with its modality?
 - Beam attenuation-MRI
 - Ring down-CT
 - Streak-MRI
 - Aliasing-MRI
 - Partial-volume averaging-radiograph

ANSWER: D. Aliasing is also known as wrap-around artifact. Ring down occurs with ultrasound. Beam attenuation can occur with any radiation-dependent imaging. Streak artifact occurs on CT at interfaces or secondary to motion at these interfaces.

- What is an imaging benefit of CT versus conventional radiography?
 - Decrease in artifacts
 - Improved resolution
 - Decreased noise
 - Decreased contrast threshold
 - All of the above

ANSWER: D. CT is able to detect lower-contrast differences between tissues than conventional radiography. Radiography has fewer artifacts, better line pair resolution, and less noise than CT.

- What is the basic measure of tissue variation in MRI?
 - K-space
 - Matrix
 - NEX
 - Proton density
 - Proton rotation

ANSWER: D. The variability of T1 and T2 is primarily dependent on the differing density of protons in tissue. K-space is the image space from which an image is calculated from related to the area that is being imaged. The matrix is the rows and column that determine the resolution. NEX is the square root of the number of acquisitions and is related to signal noise. The spin of the protons allows the proton to give off signal as they align and precess in the field.

5. On MRI, what primarily affects the Larmor frequency?
- Strength of the magnetic field
 - Orientation of the magnetic field
 - Location within isocenter of the magnetic field
 - Shimming of the magnetic field
 - Bore size of the magnet

ANSWER: A. Strength and isotope are the primary contributors to the Larmor frequency. Although location within a magnetic field cause a decrease in strength, this should occur while remaining within the isocenter.

6. Why are hydrogen (protons) molecules the ideal isotope for MRI?
- High spin density
 - High tissue density
 - High NMR sensitivity
 - High abundance
 - All of the above

ANSWER: E. Spin and tissue density are the same thing. Protons have a high NMR sensitivity and are highly abundant in tissue as water.

7. What is the Hounsfield unit a measure of?
- Proton density
 - Tissue density
 - Spin density
 - Hemoglobin density
 - Bone density

ANSWER: B. Density of tissue is measured in Hounsfield units (HU). Water is 0 HU. Those tissues less dense than water are given negative numbers, and those tissues more dense than water are positive, respectively.

8. How does increasing image noise impact an imaging study?
- Increased artifacts
 - Increased blur
 - Increased image distortion
 - Decreased low-contrast resolution
 - Increased radiation to the patient

ANSWER: D. Increasing noise makes it more difficult to resolve images at lower contrast.

9. What modality has the best native resolution?
- MRI
 - CT
 - Conventional radiography
 - Ultrasound

ANSWER: C. Although modern CT scanners have improved their resolution capabilities substantially, the line pair resolution for conventional radiography continues to have the best inherent resolution.

10. Image resolution is a direct measure of what?
- Low-contrast objects
 - High-contrast objects
 - Anatomical detail
 - Noisy images

ANSWER: C. Resolution measures blurring associated with clarity of anatomical detail.

11. Of the following, what factor has the most significant effect on the majority of artifacts?
- Matrix size
 - Gradient strength
 - Magnetic field orientation
 - Magnet strength
 - NEX

ANSWER: D. As magnet strength increases, the susceptibility and their respective artifacts also increase. Only motion artifacts may decrease with higher magnet strengths if additional parameters are constant.

2 BRAIN AND SPINE ANATOMY

Surjith Vattoth and Joseph C. Sullivan III

BRAIN ANATOMY

SCALP

The scalp consists of five layers: skin, connective tissue, aponeurosis, loose connective tissue, and pericranium. On T1-weighted images, scalp is hyperintense because of the fatty components.

The skin is attached to the third layer by fibrous septa, so that all three layers move together.

The second layer consisting of fibroadipose tissue lodges the blood vessels of scalp derived mainly from the external carotid artery and cutaneous sensory nerve supply derived from the second and third cervical nerves (the first cervical has no cutaneous branch) and from the trigeminal nerves, with the vessels attached to the fibrous septa. Wounds of the scalp bleed profusely because the vessels, being attached to fibrous septa, cannot retract and constrict. Posteriorly, the skin up to the vertex is supplied by the greater occipital and third occipital nerves (posterior primary rami of C2 and C3), while the skin behind the ear is supplied by the lesser occipital nerve (anterior primary rami of C2). The third layer consists mainly of galea aponeurotica, frontalis muscle anteriorly, and occipitalis muscle posteriorly. The fourth layer is loose areolar connective tissue between the upper three layers that move together and the periosteum of the skull vault. The periosteum or pericranium on the outer surface of the calvarium is continuous with that of the inner surface at the sutural connections between the bones of the skull.

CALVARIUM

The cranium consists of calvarial vault, base of skull, and facial skeleton. The calvarial vault is composed of frontal bone, paired parietal bones, squamous occipital bone, and paired squamous temporal bones. The coronal suture separates the frontal bone from the two parietal bones; the metopic suture seen in neonates separates the frontal bones in the midline which fuses later in life. The sagittal suture separates the two parietal bones, and the lambdoid suture separates the occipital bone from the two parietal bones.

On T1-weighted images, the calvarium is seen as hyperintense, fatty marrow, lined on inside and outside by low signal inner and outer tables of skull, respectively. The evaluation of the calvarial signals on the T1-weighted image is important to assess for marrow infiltrative disorders.

The base of skull and facial skeleton will be dealt with Chapter 13.

MENINGES

The dura (pachymeninges), arachnoid, and pia mater (combinedly called the leptomeninges) form the three meningeal layers covering the brain.

The dura mater has two layers, a superficial layer, which forms the periosteum of the inner skull and a deep

layer, which forms the dura mater proper. The dura separates into two layers at dural reflections, two main dural reflections being falx cerebri and tentorium cerebelli.

The potential extradural or epidural space lies between the skull and dura and is seen as a biconvex space when collections or hematoma develops in this space. Epidural collections do not cross sutures, but may cross the midline. Epidural hematomas usually develop because of arterial bleeding from injury to the skull. The subdural space is a potential space between the dura and the arachnoid and the subdural collections have a concavo-convex appearance. Subdural collections cross sutures, but do not cross the midline. Subdural hematomas occur because of bleeding from the torn bridging veins in the subdural space.

Arachnoid lies inner to the dura and like the dura does not invaginate into the sulci. The subarachnoid space contains CSF and lies between the arachnoid and pia mater. The arachnoid villi are CSF reabsorbing endothelial-lined granulations of arachnoid and subarachnoid space extending into the dural sinuses.

Pia, which is the innermost meningeal layer, unlike the other two layers, invaginates into the sulci. It follows the penetrating cortical arteries into the brain to form the perivascular spaces also known as Virchow-Robin spaces. The subpial space is a potential space between the pia mater and the glia limitans of cortex.

PRACTICAL APPROACH TO IDENTIFICATION OF SULCI AND GYRI

First, at the top axial images, identify the anteroposteriorly oriented superior frontal sulcus joining the transversely oriented precentral sulcus. The premotor cortex of the frontal lobe lies anterior to this precentral sulcus. The central sulcus or Rolandic fissure, which separates the frontal and parietal lobes, is the next transversely oriented sulcus lying immediately posterior to precentral sulcus. The motor cortex of the frontal lobe lies between the central sulcus and precentral sulcus. The inverted omega or horizontal epsilon shaped posteriorly directed knob on the central sulcus/gyrus designates the motor cortex controlling hand function. The motor cortex for facial muscles lies lateral to the hand knob and the leg area lies medially in a parasagittal location. The sensory cortex lies posterior to the central sulcus in the parietal lobe. It is noteworthy that the precentral motor gyrus is thicker than the postcentral sensory gyrus with a mean cortical thickness ratio of 1.54. Also, in axial images, the posterior aspects (pars marginalis) of the right and left cingulate sulci form a horizontal bracket called pars bracket. In 97% of cases, the medial end of the central sulcus lies just anterior to this pars bracket and so it

helps in central sulcus identification. However in 3% of cases, the postcentral sulcus may lie immediately anterior to this horizontal bracket, negating the value of this pars bracket sign.

The sylvian fissure in axial images helps to differentiate the frontal lobe anteriorly from temporal lobe posteriorly. On coronal images, the posterior ramus of sylvian fissure (lateral sulcus) separates the anterior part of parietal lobe superiorly from the temporal lobe inferiorly. Behind the point, where the posterior ramus of sylvian fissure ends (by turning superiorly into parietal lobe), there is no anatomic demarcation between the parietal and temporal lobes. A horizontal imaginary line is drawn posteriorly along the horizontal course of the posterior ramus of sylvian fissure to join another imaginary vertical line drawn between the end of the parietooccipital sulcus on the superomedial margin of the cerebral hemisphere and a notch on its inferolateral margin. This imaginary horizontal line separates the posterior aspect of the parietal lobe superiorly from the temporal lobe inferiorly. The imaginary vertical line separates the occipital lobe posteriorly from the parietal and temporal lobes anteriorly on the lateral parasagittal images. In medial sagittal images, the parietooccipital sulcus demarcates the occipital lobe posteriorly from the parietal lobe anteriorly. The occipital and temporal lobes on the inferomedial surface run into one another with no anatomic structures separating them.

On coronal images, the superior temporal gyrus lies between the sylvian fissure and superior temporal sulcus. The transverse temporal gyrus of Heschl, which is the primary auditory cortex, projects medially from the superior temporal gyrus. The Heschl gyrus can be easily identified in coronal images at the coronal level showing the tent formed by the convergence of fornices and presence of eighth cranial nerves and in axial images at the level of massa intermedia connecting the two thalami. The sensory speech area or Wernicke area is located in the superior temporal gyrus.

On coronal images, the middle temporal gyrus lies between the superior and middle temporal sulci. The inferior temporal gyrus lies between the middle and inferior temporal sulci. Further inferomedially, the fusiform gyrus, which continues posteriorly to join the occipital lobe, lies between the inferior temporal sulcus and collateral sulcus.

The mesial temporal structures of the limbic system lie medial to the collateral sulcus on coronal images with the parahippocampal gyrus inferiorly and hippocampus superiorly. If we follow the hippocampus anteriorly on serial coronal sections, we will reach the hippocampal head at the level of temporal horn of lateral ventricle. The amygdalla lies anterosuperomedial to the hippocampal head. As we follow the hippocampus pos-

teriorly, we can see the head and body of hippocampus followed by its tail. The hippocampal white matter (alveus), which outlines the hippocampal gray matter, continues as fimbria and crus of the fornix on both sides alongside the lateral ventricles. The crura of fornices can in turn be traced anteriorly merging into the column of fornix.

On lateral sagittal images, the frontal lobe anterior to the precentral sulcus is divided by a series of sulci into superior, middle, and inferior frontal gyri. The posterior part of the inferior frontal gyrus is separated from the temporal lobe by the sylvian fissure that has an anterior horizontal and anterior ascending rami. This divides this portion of inferior frontal gyrus into an “M” shaped area, the anterior vertical line of M representing the pars orbitalis, the middle V of M representing the pars triangularis, and posterior vertical line of M representing the pars opercularis. The motor speech area or Broca’s area is located in the opercula and triangular sections of the inferior frontal gyrus.

The lateral sagittal images are also helpful in demarcating the two component gyri of the inferior parietal lobule, namely the supramarginal gyrus and angular gyrus. The posterosuperior end of the posterior ramus of sylvian fissure is surrounded by a horseshoe-shaped gyrus, the supramarginal gyrus. Similarly, the posterior end of the superior temporal sulcus is surrounded by the horseshoe-shaped angular gyrus. The sulcus forming the superior border of these gyri is the intraparietal sulcus and the remainder of the parietal lobe superiorly is the superior parietal lobule.

The medial sagittal images help to demarcate the parietal lobe from the occipital lobe. The parietooccipital sulcus is bounded anteriorly by the precuneus (a parietal lobe gyrus) and posteriorly by the cuneus (an occipital lobe gyrus). Inferior to cuneus in the occipital lobe is the calcarine sulcus and the striate cortex in and around the calcarine sulcus serves as the primary visual cortex. The lingual gyrus of the occipital lobe lies inferior to calcarine sulcus. If we trace further anteriorly, the lingual gyrus becomes continuous with the mesial temporal parahippocampal gyrus. On the inferior surface of the occipital lobe, lateral to the lingual gyrus, lies the fusiform gyrus, which connects the temporal lobe with the occipital lobe. Thus as noted previously, the temporal and occipital lobes on the inferior surface run into one another with no anatomic structures separating them.

The anterior aspect of the medial sagittal images demonstrates the corpus callosum and is well demarcated superiorly by the callosal sulcus, which is continuous posteroinferiorly with the hippocampal sulcus. The cingulate gyrus lies parallel to and above the callosal sulcus and is demarcated superiorly by the cingulate sulcus. Near the region of splenium of corpus callosum, the

cingulate sulcus gives the paracentral branch and marginal branch and then continues as the subparietal sulcus outlining the isthmus of cingulate gyrus (which becomes continuous with parahippocampal gyrus).

In the medial sagittal images, the paracentral lobule is divided by the medial end of the central sulcus into a larger anterior part belonging to the frontal lobe and a smaller posterior part that belongs to the parietal lobe. Anterior to the paracentral lobule lies the superior frontal gyrus and posterior to it lies the precuneus of parietal lobe.

BRAINSTEM

MIDBRAIN

Two large bundles of fibers called crura lie on either side of midline anteriorly divided by the interpeduncular or crural CSF cistern anteriorly and diverge to enter the corresponding cerebral hemispheres superiorly (cerebral peduncles). The third (oculomotor) cranial nerves emerge from the medial aspect of the crus on the same side and exit the midbrain via the interpeduncular cistern on their way to the cavernous sinus and superior orbital fissure to supply the four extraocular muscles, medial rectus, inferior rectus, superior rectus, and inferior oblique. The cerebral aqueduct of Sylvius divides the midbrain into tegmentum anteriorly and tectum or roof posteriorly.

The mesencephalic tegmentum contains the white matter tracts-medial longitudinal fasciculus (oculomotor/vestibular), medial (somatosensory) and lateral (auditory) lemnisci, spinothalamic (somatosensory), and central tegmental motor tract including the reticular formation. The gray matter includes the substantia nigra, red nucleus, periaqueductal gray matter, and third/fourth cranial nerve nuclei. On thin section T2-weighted MRI, the pars compacta of substantia nigra can be seen as a hyperintense band between the hypointense band of pars reticularis of substantia nigra anterolaterally and hypointense nodular red nucleus posteromedially in paramidline location. The pars compacta atrophies in parkinsonian disorders. The third nerve nucleus lies at the superior colliculus level in a paramedian location anterior to cerebral aqueduct and posterior to the red nucleus. The parasympathetic nuclei of the third nerve, Edinger-Westphal nuclei, lie in the periaqueductal gray matter posterior to the third nerve nucleus. The fourth nerve nucleus lies at the inferior colliculus level in a paramedian location anterior to cerebral aqueduct and posterior to medial longitudinal fasciculus.

The tectal plate or quadrigeminal plate is composed of the paired superior colliculi for extraocular muscle

coordination and inferior colliculi for hearing relay. Each colliculus is related laterally to a ridge called the brachium. The superior brachium connects the superior colliculus to the lateral geniculate body and the inferior brachium connects the inferior colliculus to the medial geniculate body on either side. The cistern posterior to the midbrain is called the quadrigeminal plate cistern as it is closely related the quadrigeminal plate. It is important to note that the persistent cavum veli interpositi (CVI) communicates with quadrigeminal cistern. The perimesencephalic or ambient cistern extends from the posterior margin of the interpeduncular cistern to the lateral edge of the midbrain colliculi, around the lateral surface of the upper portion of the brainstem. The ambient cistern mainly contain P2 segment of the posterior cerebral artery, superior cerebellar artery, anterior choroidal artery, basal vein of Rosenthal, and fourth cranial nerve.

Just below the colliculi lies the uppermost part of a membrane called the superior medullary velum, which stretches between the two superior cerebellar peduncles, forming the roof of the fourth ventricle. The fourth (trochlear) cranial nerve, which is the only cranial nerve that exits the brainstem dorsally, courses posteriorly around the cerebral aqueduct and decussates in the superior medullary velum, crosses over in the quadrigeminal cistern, and winds round the opposite side of the midbrain in the ambient cistern to reach its ventral aspect on the way to enter the contralateral cavernous sinus and orbit to supply the superior oblique muscle. During their course, both the third and fourth cranial nerves pass between the posterior cerebral artery and superior cerebellar artery and may be compressed by aneurysms. The superior cerebellar peduncles (brachium conjunctivum) decussate in the midbrain posterior to red nuclei, flank the upper fourth ventricle, and connect the midbrain to cerebellum.

PONS

The ventral surface of the pons is grooved by the sulcus basilaris along which the basilar artery passes. The fifth (trigeminal) cranial nerve emerges from the anterolateral surface of pons and passes through prepontine cistern to be connected to the Gasserian Ganglion in Meckel cave. The bulky middle cerebellar peduncles (brachium pontis) connect the pons with the cerebellum on each side. The sixth (abducens) cranial nerve emerges from the junction of pons and medulla antero-medially, just off the midline above the medullary pyramids, and passes through the prepontine cistern, penetrates dura of basisphenoid to enter the Dorello canal, arches over petrous apex below petrosphenoidal ligament

into posterosuperior cavernous sinus, and then enters superior orbital fissure and orbit to innervate the lateral rectus muscle. The seventh (facial) and eighth (vestibulocochlear) cranial nerves emerge from the pontomedullary junction, laterally above the medullary olives, and enter the cerebellopontine angle cistern on their way to the internal auditory canal. The pons is separated from the cerebellum posteriorly by the fourth ventricle, which is continuous superiorly with the cerebral aqueduct.

The ventral pons, which forms the bellylike anterior projection on sagittal images, contain the longitudinal corticospinal, corticobulbar and corticopontine white matter tracts, and the multiple transverse pontine fibers, which make up the bulk.

The dorsal pontine tegmentum is composed of white matter tracts-medial longitudinal fasciculus (oculomotor/vestibular), medial (somatosensory) and lateral (auditory) lemnisci, trapezoid body (auditory), spinothalamic tract (somatosensory), and central tegmental motor tract including the reticular formation. The gray matter includes the bulk of the motor, main sensory, and mesencephalic nuclei of fifth nerve located in the upper lateral dorsal pontine tegmentum in a location far anterolateral to fourth ventricle. The sixth nerve nucleus is located in lower dorsal pontine tegmentum near midline just anterior to fourth ventricle. The axons of facial nerve loop around the sixth nerve nucleus creating a bulge in the floor (anterior aspect) of the fourth ventricle, called the facial colliculus. The seventh nerve motor, superior salivatory, and tractus solitarius nuclei lie in the lower lateral dorsal pontine tegmentum in a location far anterolateral to fourth ventricle. The medial, lateral, inferior, and superior vestibular nuclei of eighth cranial nerve lie along the lateral aspect of the floor of the fourth ventricle at the pontomedullary junction. The dorsal and ventral cochlear nuclei of the eighth nerve lie dorsally and ventrally on the lateral aspect of the inferior cerebellar peduncle (restiform body) at the pontomedullary junction.

MEDULLA OBLONGATA

The ventral medulla is composed of the medullary pyramids and olives. The pyramids are two paramedian longitudinal projections anteriorly, composed of the corticospinal (pyramidal) tracts, and separated in the midline by ventral median fissure. Posterolateral to the pyramids, separated by the preolivary sulcus from which the rootlets of the twelfth (hypoglossal) cranial nerve exit on each side, lie the medullary olives that consist of inferior olivary nucleus (largest and forms the bulge on the surface of medulla), dorsal and medial accessory olivary nuclei,

and superior olivary nucleus. The postolivary sulcus from which the rootlets of the ninth (glossopharyngeal), tenth (vagus), and eleventh (spinal accessory) cranial nerves exit the medulla lies posterolateral to olive.

The inferior cerebellar peduncle (restiform body) arises from the superior aspect of the dorsal medulla and connects the medulla with the cerebellum. As already stated, the cochlear nuclei lie on the lateral aspect of the inferior cerebellar peduncle at the pontomedullary junction. In the lower aspect of the dorsal medulla lies the paired gracile tubercles formed by the nucleus gracilis, separated in the midline by dorsal median sulcus. Immediately lateral to these lie the cuneate tubercles on each side, formed by the nucleus cuneatus and bounded anterolaterally by the postolivary sulcus. These are connected to the fasciculus gracilis and fasciculus cuneatus, respectively, and white matter tracts that enter the medulla from the posterior funiculus of the spinal cord. The lower part of the medulla, immediately lateral to fasciculus cuneatus, is another longitudinal elevation called the tuberculum cinereum formed by the spinal nucleus of the fifth (trigeminal) nerve. The spinal tract of the trigeminal nerve covers this and they actually extend into the upper cervical canal. The dorsal medullary tegmentum also contains the white matter tracts-medial longitudinal fasciculus (oculomotor/vestibular), medial (somatosensory) and lateral (auditory) lemnisci, spinothalamic tract, spinocerebellar tract (somatosensory), and central tegmental motor tract including the reticular formation. The ninth and tenth cranial nerve nuclei, namely nucleus ambiguus and solitary tract nucleus, lie in upper and middorsal medullary tegmentum laterally. They have sensory fibers that terminate in spinal nucleus of trigeminal nerve. The ninth nerve also has the inferior salivatory nucleus and the tenth nerve has the dorsal vagal nucleus in addition. The eleventh nerve has bulbar nuclei in lower nucleus ambiguus in upper and midmedulla. The twelfth nerve nuclei in the mid-dorsal medullary tegmentum paramedially produces the hypoglossal eminence, which is a bulge in the floor of fourth ventricle. The medulla is separated from the cerebellum posteriorly by the inferior portion of the fourth ventricle (obex), the outlet foramina of which is continuous with the cisterna magna through the Foramen of Magendie posteriorly in the midline, and with the cerebellopontine angles through the paired foramina of Luschka laterally. The obex communicates with the central canal of the spinal cord.

CEREBELLUM

Cerebellum consists of the median vermis and two lateral cerebellar hemispheres. The deepest fissures in the

cerebellum are the primary fissure superiorly, horizontal fissure in the middle, and posterolateral fissure inferiorly. The cerebellar cortex lies superficial to white matter as in the cerebrum. Also, there are deep cerebellar nuclei embedded within the white matter, namely dentate nucleus, emboliform nucleus, globose nucleus, and fastigial nucleus. The white matter of the two sides is connected by a thin lamina of fibers that are closely related to the fourth ventricle. The upper part of this lamina forms the superior medullary velum and its inferior part forms the inferior medullary velum. Both these take part in forming the roof (posterior boundary) of the fourth ventricle. The cerebellar peduncles connecting the cerebellum with midbrain, pons, and medulla are already described in those sections.

Diencephalon

The diencephalon consists of thalamus, hypothalamus, subthalamus, and epithalamus. The thalami lie on either side of the third ventricle. Massa intermedia or interthalamic adhesion connects the two thalami.

The hypothalamus lies around inferior aspect of the third ventricle and consists of the preoptic region adjoining the lamina terminalis, supraoptic region above the optic chiasm, infundibulotuberal region consisting of the pituitary infundibulum, tuber cinereum and the region above it, and mamillary or posterior region consisting of the mamillary bodies and the region above it. Of these, the preoptic region is actually a derivative of the telencephalon.

The subthalamus or ventral thalamus lies behind and lateral to the hypothalamus. Inferiorly it is continuous with the upper ends of substantia nigra and red nucleus of the midbrain and laterally it is related to the lowest part of the internal capsule.

The epithalamus consists of the pineal gland and habenular nuclei. The pineal gland lies anteroinferior to the splenium of corpus callosum and vein of Galen/Internal cerebral vein and posterosuperior to the tectal plate/quadrigenal cistern. Pineal masses elevate the vein of Galen/Internal cerebral veins and depress the tectal plate. The suprapineal recess of the third ventricle extends posteriorly immediately above the pineal gland. The quadrigenal plate cistern lies posterior to the pineal gland and its anterior extension called the velum interpositum lies above the pineal gland/internal cerebral vein and extends anteriorly below the corpus callosum/fornix. The tentorial apex arches above and behind the pineal gland and the course of fourth cranial nerves lies in close relationship. The attachment of the pineal body to the posterior wall of the third ventricle is through a stalk that has two laminae, superior and

inferior. The superior lamina is traversed by fibers of the habenular commissure and the inferior lamina by fibers of the posterior commissure.

Basal Ganglia

The caudate nucleus is a C-shaped mass of gray matter with a head abutting the lateral wall of the frontal horn of lateral ventricle and lies anteromedial to the lentiform nucleus separated by the anterior limb of internal capsule, a body that abuts the body of lateral ventricle, and a tail that continues anteroinferiorly with the lentiform nucleus.

The lentiform nucleus lies lateral to the internal capsule, the anterior limb of which separates it from the caudate nucleus, and the posterior limb from the thalamus. It consists of the globus pallidus medially and the putamen laterally. Laterally, the lentiform nucleus is separated from the claustrum by the external capsule.

Note that the so-called corpus striatum consists of caudate nucleus and putamen and has the main arterial supply from the medial and lateral striate branches of the middle cerebral artery (MCA). Also, their anteriormost parts including the head of caudate nucleus receive supply from the Heubner recurrent artery, a branch of anterior cerebral artery (ACA). Their posterior parts including tail of caudate nucleus also receive blood supply through anterior choroidal artery. The main blood supply of globus pallidus is from anterior choroidal artery. The medialmost part of globus pallidus receives branches from the posterior communicating artery (PCOM).

The claustrum is a thin lamina of gray matter lateral to the external capsule. Laterally, it is separated from the insula by the extreme capsule.

Internal Capsule

The condensed projection fibers white matter structure, internal capsule, has an anterior limb, a genu that connects it to the posterior limb, a retrolentiform part, and a sublenticular part. The upper parts of the anterior limb, genu, and posterior limb are supplied by the lateral lenticulostriate branches of the middle cerebral artery. The lower parts have a different supply—the anterior limb by Heubner recurrent artery branch of anterior cerebral artery, genu by direct internal carotid artery branches/posterior communicating artery branches, and posterior limb by anterior choroidal artery branches. The retrolenticular and sublenticular parts of the internal capsule are also supplied by the anterior choroidal artery.

The internal capsule is continuous inferiorly with the white matter fibers of crus cerebri of the midbrain and superiorly with that of the corona radiata of the cerebral

hemispheres. The corona radiata is continuous superiorly with the centrum semiovale.

CORPUS CALLOSUM

The corpus callosum is a large mass of commissural nerve fibers that connects the two cerebral hemispheres. It has a central body, anterior end bend on itself called the genu, and an enlarged posterior end called splenium. A thin lamina of nerve fibers called rostrum connects the genu to the upper end of lamina terminalis. The under-surface of corpus callosum gives attachment to septum pellucidum and this callososeptal interface is an area to be specifically looked for the dot–dash appearing T2 hyperintense demyelinating plaques in conditions like multiple sclerosis. The corpus callosum forms from anterior to posterior except for the rostrum, which is formed last. In partial callosal agenesis, splenium and rostrum are always missing.

The fibers of the genu run forward into frontal lobes forming the forceps minor and fibers of splenium run backward into occipital lobes forming the forceps major. The forceps major bulges into the upper aspect of occipital horn of lateral ventricles on each side, forming the bulb of the posterior horn. The fibers of the body and some from splenium run laterally and intersect the white matter fibers of corona radiata. As they pass laterally, some fibers of the body and splenium form a flattened band called the tapetum, which is closely related to the occipital and temporal horns of lateral ventricles.

VENTRICLES OF THE BRAIN

LATERAL VENTRICLES

The paired lateral ventricles have a frontal horn, body, atrium or trigone, temporal horn, and occipital horn. The body of lateral ventricle has a roof formed by body of corpus callosum, medial wall formed by septum pellucidum, and body of fornix and floor formed by thalamus medially and caudate nucleus laterally with thalamostriate vein and stria terminalis in between.

The atrium or trigone of the lateral ventricle connects the temporal horn inferiorly, the occipital horn posteriorly, and the body of the lateral ventricle anteriorly.

The frontal horn is bounded anteriorly by genu and rostrum of corpus callosum, roof is formed by anterior aspect of body of corpus callosum, floor is formed mainly by head of caudate nucleus and partially by rostrum of corpus callosum and medial wall by septum pellucidum.

The occipital horn has a roof and lateral wall formed by tapetum (fibers from splenium of corpus callosum)

and a medial wall formed by an upper elevation called bulb of posterior horn (fibers of forceps major), and a lower elevation called calcar avis (white matter pushed in by formation of calcarine sulcus of occipital lobe).

The temporal horn has a roof or lateral wall formed by the tail of caudate nucleus laterally and stria terminalis medially (which extends from the floor of the body of lateral ventricle); the most anterosuperomedial part of roof is formed by amygdalla. The floor or medial wall is formed mainly by the hippocampus along with the alveus and fimbria medially and collateral eminence laterally (produced by inward bulging of collateral white matter lying deep to collateral sulcus).

THIRD VENTRICLE

The third ventricle is the cavity of the diencephalons situated in between the two thalami. It communicates with the two lateral ventricles through the interventricular foramina of Monroe anterosuperiorly just behind the columns of fornix. Posteroinferiorly, it is continuous with the cerebral aqueduct of Sylvius within the midbrain, which connects it to the fourth ventricle. The lateral walls are formed by the thalamus superiorly and hypothalamus inferiorly. The anterior wall is formed mainly by the lamina terminalis; and upper parts by the anterior commissure/columns of fornix. The posterior wall is formed by pineal gland and posterior commissure. The floor is formed from anterior to posterior by the optic chiasm, the hypothalamus including pituitary infundibulum, tuber cinereum and mamillary bodies, the posterior perforated substance, and the midbrain tegmentum. The roof is formed by ependyma stretching across the two thalami, tela choroidea and choroid plexuses. The interthalamic adhesion or massa intermedia pass through the cavity of the third ventricle. The cavity has many recesses including the optic recess that lies just above the optic chiasm, the infundibular recess that extends into the pituitary infundibulum, the pineal recess that lies between superior and inferior laminae of pineal stalk, and the suprapineal recess that lies above the pineal gland.

FOURTH VENTRICLE

The important features of fourth ventricle are already described in the section on brainstem.

TELA CHOROIDEA AND CHOROID PLEXUSES

The tela choroidea is a double-layered fold of pia mater that lies in the roof of the third ventricle. The posterior end of tela choroidea lies in the gap between (transverse

fissure) the splenium of corpus callosum and the posterior part of roof of third ventricle. When traced further posteriorly, the two layers of pia mater separate with the upper layer curving upward over the posterior aspect of the splenium and the lower layer turning downward over the pineal body and tectum. The anterior end of the tela choroidea of third ventricle lies near the interventricular foramina of Monroe and passes through the gap (choroid fissure) between the fornix superiorly and thalamus inferiorly into the body of lateral ventricle on either side. The highly vascular choroid plexuses secrete CSF and are lined by a membrane formed by the fusion of ventricular ependyma with the pia mater of tela choroidea. The choroid plexus of the lateral ventricle extends into the temporal horn. It is noteworthy that the tela choroidea and the choroid plexus do not extend into the frontal horn. The fourth ventricle also possesses its own tela choroidea and choroids plexus, which also extends into the foramina of Magendie and Luschka.

PERSISTENT MIDLINE CSF CAVITIES

During intrauterine life, there are three potential midline cavities related to the cerebral ventricles that regress between the seventh month of intrauterine life and the second year of postnatal life. In adults, if they persist, cavum septum pellucidum (CSP), cavum vergae (CV), and cavum veli interpositi (CVI) occur from anterior to posterior. CSP lies within the two leaflets of septum pellucidum; CV extends further posteriorly and these usually do not communicate with the ventricles or cisterns. CVI is an anterior continuation of quadrigeminal plate cistern.

SELLA AND PITUITARY

The sella is a depression in the basisphenoid bone and contains the pituitary gland and inferior part of its stalk. Its anterior bony wall is called tuberculum sellae and is continuous anterosuperiorly with the anterior clinoid process. Its posterior bony wall is called dorsum sellae and is continuous posterosuperiorly with the posterior clinoid process. The sphenoid sinus lies directly below the sellar floor. The floor has thin bone called lamina dura.

The sella is bounded superiorly by a dural reflection called the diaphragma sellae. Suprasellar cistern above the diaphragma sellae is CSF filled and contains optic nerves/chiasm and upper part of infundibular stalk. The optic chiasm lies in the bony groove that leads to optic canal on each side, called sulcus chiasmaticus, anterior to tuberculum sellae. The hypothalamus and anterior third ventricular recesses lie just above the infundibular stalk. The suprasellar cistern is surrounded by the circle

of Willis. The cavernous sinus lies lateral to the sella on either side and contains the cavernous internal carotid artery and sixth cranial nerve within it. The third, fourth, and ophthalmic and maxillary divisions of the fifth cranial nerve lie in the lateral wall of cavernous sinus.

The pituitary gland lies within the sella and has the anterior adenohypophysis and posterior neurohypophysis. The adenohypophysis, which comprises 75% of the pituitary volume appears isointense to gray matter on T1- and T2-weighted images and is composed of three parts—pars tuberalis (part of the infundibular stalk and median eminence of hypothalamus), pars intermedia, which is very small in humans, and pars distalis, which forms most of the intrasellar adenohypophysis. The posterior neurohypophysis appear-hyperintense on T1-weighted images and hypointense on T2-weighted images.

The height of the pituitary gland varies with age and sex. It measures up to 6 mm in children, 8 mm in males and postmenopausal females, 10 mm with upward bulge in young menstruating females, and 12 mm in pregnant or lactating females. The pituitary stalk measures up to 2 mm in maximum thickness near insertion on pituitary inferiorly and 3 to 3.5 mm near median eminence of hypothalamus superiorly. A rough guide to pituitary stalk thickness is that it should not be thicker than the adjacent basilar artery diameter.

SPINE ANATOMY

GENERAL CHARACTERISTICS

There are 33 spinal vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 to 5 coccygeal. A typical vertebra has a body and posterior elements, namely two pedicles, two transverse processes, two laminae (one on each side), and a spinous process from anterior to posterior. Also the posterior elements have, on each side, articular processes consisting of a superior and inferior articular facet and pars interarticularis. The ligaments include the anterior longitudinal ligament, posterior longitudinal ligament, interspinous and supraspinous ligaments, ligamentum flavum, and the craniocervical ligaments namely alar ligament, transverse/cruciate ligaments, and membrane tectoria. The intervertebral disc is composed of inner nucleus pulposus and outer annulus fibrosus and adheres to the fenestrated hyaline cartilage of vertebral endplates. They are avascular except in children and the peripheral annular fibers in adults. The spine may also be divided into three columns for stability assessment—the anterior column consisting of anterior longitudinal ligament and anterior half of vertebral body, disc, and annulus; the middle column consisting of the posterior half of vertebral body, disc, and annulus

and posterior longitudinal ligament; and the posterior column consisting of the posterior elements, ligamentum flavum, and inter-/supraspinous interconnecting ligaments.

MR SIGNAL INTENSITIES

In young children, the vertebral body has red marrow, which is isointense to paraspinal muscle on T1-weighted images. The marrow shows marked enhancement postgadolinium in those younger than 2 years of age and gradually disappears by around 7 years of age. From 7 years to adolescence, the replacement of hematopoietic red marrow by fatty yellow marrow causes progressive change to hyperintensity on T1-weighted images and relative hypointensity on conventional spin echo T2-weighted images with mixed inhomogeneous signal in between. The intervertebral discs of infants are hyperintense on T2-weighted images except for small central hypointensity of notochord remnants. From the second decade onward, a hypointense band of compact fibrous tissue develops in the centre. In adults, the outer annulus is hypointense on both T1- and T2-weighted images and the inner nucleus pulposus appears hyperintense on T2-weighted images with a low-signal intranuclear cleft. As the disc degenerates, the nucleus pulposus loses its high signal.

VERTEBRAL BODIES

Lumbar: Large, more or less square-shaped vertebral bodies.

Thoracic: Vertebral bodies are slightly wedge-shaped from front to back and gradually increase in size from upper to lower thoracic spine.

Cervical: The typical cervical vertebrae are from C3 to C7 and their bodies gradually increase in size from C3 to C7. They have bilateral posterolateral projections called uncinate processes that form the uncovertebral synovial joints of Luschka with the posterolateral margin of disc/vertebra above. The C2 or axis vertebra has an odontoid process that extends superiorly from its body and articulates anterosuperiorly with the anterior arch of atlas. The C1 or atlas vertebra has no body or spinous process. It has anterior and posterior arches, two lateral masses, and transverse processes. It is a bony ring with oblong or round inferior articular facets that articulate with superior facets of C2 and ellipsoid superior articular facets that articulate with the occipital condyles to form the atlantooccipital joints. The anatomy of the craniocervical junction is described in Chapter 13.

INTERVERTEBRAL DISCS

Lumbar: A normal lumbar disc is slightly concave posteriorly, but appears flat or slightly rounded at L5–S1.

Thoracic: The height of the thoracic discs is less than that of cervical or lumbar discs, but the annulus fibrosus is thicker.

Cervical: The discs are slightly thicker anteriorly than posteriorly.

PEDICLES, LAMINAE, AND SPINOUS PROCESSES

Thoracolumbar spine: The pedicles are thick bony pillars that are directed posterolaterally to join the broad and thick laminae in the thoracolumbar spine. In the lumbar spine, the interpedicular distance widens as we go down the spine, which is reversed in conditions like achondroplasia. The long spinous processes extend posteroinferiorly from the midline where the two laminae fuse.

Cervical spine: The laminae are thin in the cervical spine. The spinous processes are often bifid. C7 has the longest spinous process.

TRANSVERSE PROCESSES

Lumbar spine: Transverse processes project laterally on each side.

Thoracic spine: Transverse processes project superolaterally on each side from the articular pillars between the superior and inferior articular facets. The tip of each transverse process from T1 to T10 has an oval costal facet to form the costovertebral joint with the rib tubercle. Also from T2 to T9, the vertebral demi-facets above and below the disc articulate with the rib head to form the costovertebral joint.

Cervical spine: The transverse processes project anteroinferolaterally from the vertebral bodies. The thin bony bar called costovertebral bar connects the anterior and posterior parts of the transverse process creating the transverse foramen for vertebral artery and vein.

ARTICULAR PILLARS AND FACET JOINTS

The articular pillars consist of the pars interarticularis, which is a bony plate that extends posteriorly from the pedicle and the superior and inferior articular facets that it gives rise to. The synovial facet joints are formed by the anteriorly positioned superior articular process of

the lower vertebra and the posteriorly positioned inferior articular facet of the lower vertebra. A tough fibrous capsule covers the posterolateral aspect of the joint which is deficient ventrally, where the ligamentum flavum covers the joint.

LIGAMENTS

Anterior longitudinal ligament extends from basioccipt to S1, seen as a hypointense band in direct contact with the anterior surface of vertebral bodies and discs.

Posterior longitudinal ligament is a thinner band that extends from C1 to S1 vertebra and does not adhere to vertebral bodies. Epidural fat and veins are interposed between the posterior longitudinal ligament and vertebral bodies. The posterior longitudinal ligament widens laterally at the intervertebral discs attaching firmly to the annulus fibrosus reinforcing the mid-/ paramedian zones of the disc.

Ligamentum flavum arises from the anterior aspect of the lower margin of the lamina of the upper vertebra and attaches to the posterior surface of the lamina below. On axial MRI, it is seen as a hypointense structure that covers the facet joint anteriorly and sometimes filled with fat posteriorly. It thickens and buckles with degeneration and can become fat infiltrated or calcified.

NEURAL FORAMEN AND LATERAL RECESS

The neural foramen lies between the pedicles of the upper and lower vertebrae with the anterior margin formed by the vertebral body superiorly and the disc and posterior longitudinal ligament inferiorly. The posterior boundary is formed by the articular facet and ligamentum flavum. The lumbar nerve root exits the fat-filled foramen through the widest superior part of the foramen and on sagittal T1-weighted MRI looks like a bird's head and beak with the bird's eye formed by the dorsal root ganglion directly below the superior pedicle. The lateral recess is the region of the lumbar canal that is bordered laterally by the pedicle, posteriorly by the superior articular facet and ligamentum flavum, and anteriorly by the vertebral body, endplate margin, and disk margin. Measurements of the bone margins of the lateral recess suggest narrowing with possible root compression when the anteroposterior dimension is below 4 mm. It is important to remember that at the lumbar level, central disc protrusion produces compression of the descending lower nerve root and lateral recess/neural foramen compression impinges the exiting upper nerve root. For example, at L5–S1 level, central protrusion compresses S1 nerve root and lateral recess/neural foramen compression impinges on the L5 nerve root.

In the cervical spine, the nerve roots lie in the inferior aspect of the neural foramen just above the inferior pedicle and the dorsal root ganglia lies outside the neural foramen. This is because the nerve roots exit above the pedicles at the cervical level. At the cervical level, central disc protrusion produces compression of a still lower nerve root than that intervertebral level and neural foramen compression impinges the exiting lower nerve root. For example, at C5–6 level, central protrusion compresses C7 nerve root and neural foramen compression impinges on the C6 nerve root. The C5 nerve root is not compressed by a medial or lateral C5–6 compression.

As already stated, the nerve roots exit above the pedicles at the cervical level and so are seen in the lower aspects of the neural foramina. There are only seven cervical vertebrae, but there are eight cervical nerve roots. The C7 nerve root exits above the C7 pedicle and C8 nerve root exits below the C7 pedicle. From this level downward, the entire thoracic and lumbar nerves exit below the corresponding pedicle and so are seen in the upper aspect of the neural foramina. That is, T1 nerve root exits below T1 pedicle and L1 nerve root exits below L1 pedicle and lies within the upper part of neural foramen. (Remember that the neural foramen is bounded superiorly and inferiorly by the pedicles of the upper and lower vertebrae.)

SPINAL CORD AND CAUDA EQUINA

The spinal cord lies within the thecal sac and is anchored to dura by denticulate ligaments. It has a cervical enlargement for brachial plexus at C3–T2 and a lumbar enlargement at T9–12. The cord ends at the diamond-shaped conus medullaris between T12 and L2–3 (L1–2 being most common). A deep cleft called ventral median fissure is seen in anterior midline, a shallow dorsal median sulcus in posterior midline, paired dorsolateral sulci where dorsal nerve roots enter the cord, paired ventrolateral sulci from where the ventral nerve roots emerge from the cord, and the paired dorsal intermediate sulci separating the gracile and cuneate fasciculi.

Unlike the brain, the H-shaped gray matter of the spinal cord is centrally placed with the white matter superficial to it. The gray matter consists of the shorter thicker ventral horn containing multipolar motor neurons and longer narrower dorsal horn receiving sensory axons from dorsal root ganglia throughout the cord and small lateral horns from the T1 to conus medullaris. The white matter is divided into three columns (funiculi) on each side. The ventral funiculi lie between the ventral median fissure medially and the ventrolateral sulci and the lateral funiculi lie between ventrolateral and dorsolateral sulci. Both these funiculi have descending motor

and ascending sensory tracts. The dorsal funiculi between the lateral funiculi and dorsal median sulcus contain fibers for position and discriminative touch.

After the spinal cord ends, the lower spinal nerve roots exit the conus medullaris and pass inferiorly within the thecal sac forming the cauda equina. On axial sections, the nerve roots lie with the lower sacral roots dorsally and the lumbar roots more anterolaterally.

QUESTIONS AND ANSWERS

- What is the most medially located cranial nerve in the cavernous sinus?
 - II
 - III
 - IV
 - VI

ANSWER: D. Sixth (abducens) nerve lies within the cavernous sinus whereas the third, fourth, and sixth and V2 nerves lie in its lateral wall. The ICA lies further medial to the sixth nerve. The second nerve is not closely related to cavernous sinus.

- What is the blood supply of the anterior hippocampus?
 - ACA
 - MCA
 - PCA
 - Anterior choroidal

ANSWER: D. Anterior choroidal arteries supply anterior hippocampus, lower part of posterior limb/subretrolentiform portions of the internal capsule, globus pallidus, and tail of caudate nucleus. The posterior hippocampus is supplied by PCA branches. The corpus striatum (caudate and putamen) and upper parts of anterior limb, genu, and posterior limb of internal capsule are supplied by lenticulostriate branches of MCA.

- Which of the following best describes the appearance of the pituitary gland on MR imaging?
 - Typically appears flat or with a mild concave anterosuperior surface
 - Enhances less than adenoma
 - Demonstrate early and prominent enhancement
 - Typically dark on T2-weighted images

ANSWER: C. After injection, enhancement is promptly noted on T1-weighted images in the anterior pituitary gland, the infundibulum, and the cavernous sinuses. The posterior pituitary is already high intensity on T1-weighted images. Pituitary microadenomas are generally hypointense compared with the normal gland on T1-weighted images and display variable intensity on T2-weighted images. Postcontrast, microadenomas generally appear initially hypointense to the normal gland; in delayed scanning (>20 minutes), the tumor may appear hyperintense. The pituitary gland can have variable appearance depending on sex and age. On noncontrast MR, the anterior pituitary is isointense to brain on T1- and T2-weighted images. The posterior pituitary is high intensity on T1-weighted images and of lower intensity on T2-weighted images.

- Which one of the following is the motor strip?
 - Calcarine gyrus
 - Precentral gyrus
 - Inferior frontal gyrus
 - Postcentral gyrus

ANSWER: B. Postcentral gyrus of parietal lobe is sensory cortex, inferior frontal gyrus is Broca motor speech area, and calcarine cortex is primary visual cortex.

5. In a child, where does the conus end?
 A. T12
 B. L2
 C. L3
 D. L4

ANSWER: B. The normal level of the conus medullaris in a child is L2. If the conus is below the L2/L3 disc interspace, it should be considered abnormal. In an adult, the cord ends above the L1/L2 disc level.

6. What symptoms would a patient have with far lateral disc herniation at L4-5?
 A. L4 radiculopathy
 B. L5 radiculopathy
 C. S1 radiculopathy
 D. No radiculopathy

ANSWER: A. Above T1, spinal nerves course ABOVE pedicles for which they are named. (e.g., there is a C8 nerve root, but only a C7 vertebral body). Below T1, spinal nerves course below the pedicles for which they are named. Paracentral disk herniation in the lumbar region characteristically strikes the root exiting below the interspace. This is because the disk space is inferior to the exiting root at that level. Thus, an L4-5 disk herniation most often compresses the L5 root. Very lateral herniated disks may compress the upper root; that is, an L3-4 lateral herniation can compress the L3 root; or, in the case of this question, a far lateral L4-5 herniation can compress the L4 root. Larger disks can compress many roots in the thecal sac. Furthermore, disk fragments may migrate superiorly and compress the root exiting at the appropriate interspace. For example, an L3-4 free fragment can compress the L3 root or a combination of the L3 and L4 roots.

7. Which artery supplies the lower aspect of posterior limb of the internal capsule?
 A. Anterior choroidal
 B. Medial lenticulostriate
 C. Lateral lenticulostriate
 D. ACA

ANSWER: A. Anterior choroidal artery originates from ICA. Cisternal segment: Passes through crural cistern, supplies hippocampus, optic tract, lower aspect of posterior limb, retro/sublentiform parts of

internal capsule, globus pallidus, branches to mid-brain, and lateral geniculate nucleus. Plexal segment: Supplies choroid plexus of anterior portion of temporal horn of lateral ventricles.

Lateral lenticulostriate arteries of the MCA supplying basal ganglia structures: Part of head and body of caudate, putamen, lateral aspect of globus pallidus, upper *dorsal* and *ventrostr*al posterior limb, genu, and anterior limb of the internal capsule.

Medial lenticulostriate (Heubner) arteries of the ACA: Supplies the caudate head, lower part of anterior limb of internal capsule, and septum pellucidum.

8. Of the following, what is the most echogenic structure in the fetal brain?
 A. Cerebellar vermis
 B. Corpus callosum
 C. Thalamus
 D. Caudate

ANSWER: A. Cerebellar vermis. Vermis is the most echogenic structure on neonatal head sonogram of the ones listed above, but the glomus of the choroid plexus is the most echogenic structure. Not so echogenic structures are caudate and thalamus. Corpus callosum is a thin echogenic line.

9. What is the cavum veli interpositi?
 A. Anterior continuation of quadrigeminal plate cistern
 B. Posterior continuation of third ventricle
 C. Posterior continuation of cavum vergae
 D. Lies inferior to pineal gland

ANSWER: A. The persistent fetal CSF cavities namely cavum septum pellucidum (CSP), cavum vergae (CV), and cavum veli interpositi (CVI) occur from anterior to posterior. CSP lies within the two leaflets of septum pellucidum; CV extends further posteriorly and these usually do not communicate with the ventricles or cisterns. CVI is an anterior continuation of quadrigeminal plate cistern and lies above the pineal gland/internal cerebral vein and extends anteriorly below the corpus callosum/fornix.

10. Which of the following regarding the fourth (trochlear) nerve is *true*?
 A. Exits the brainstem dorsally
 B. Passes between the posterior cerebral artery and superior cerebellar artery
 C. Each superior oblique muscle is innervated by contralateral trochlear nucleus.
 D. All of the above

ANSWER: D. The fourth (trochlear) cranial nerve, which is the only cranial nerve that exits the brainstem dorsally, courses posteriorly around the cerebral aqueduct and decussates in the superior medullary velum, crosses over in the quadrigeminal cistern, and winds round the opposite side of the midbrain in the ambient cistern to reach its ventral aspect on the way to enter the contralateral cavernous sinus and orbit to supply the superior oblique muscle. During their course, both the third and fourth cranial nerves pass between the posterior cerebral artery and superior cerebellar artery.

3 DEVELOPMENTAL DISORDERS

Surjith Vattoth and Joseph C. Sullivan III

EMBRYOLOGY

Stage 1 (dorsal induction): formation and closure of the neural tube. This occurs during 3 to 5 weeks of gestation, when the neural plate develops on the dorsal surface of the human embryo (approximately 18 days after fertilization). This invaginates forming the neural folds that later oppose in midline forming the neural tube. The tube closure begins in the medulla proceeding rostrally and caudally. Neurulation occurs in two phases in vertebrate embryos: primary and secondary neurulation. Primary neurulation, the formation of the neural plate and subsequent morphogenetic movements that transform it into a neural tube, forms the brain and trunk level of the spinal cord. Secondary neurulation, the formation of an epithelial cord and its subsequent cavitation to form a neural tube, forms the tail spinal cord. Failure of dorsal induction leads to conditions like anencephaly, iniencephaly, cephalocele, Chiari malformations, and spinal dysraphisms.

Stage 2 (ventral induction): formation of the brain segments and face. This occurs during 5 to 10 weeks of gestation, when three primary vesicles namely prosencephalon, mesencephalon, and rhombencephalon form the forebrain, midbrain, and hindbrain, respectively. The prosencephalon divides into telencephalon (future cerebrum) and diencephalon (future thalamic and hypothalamic regions). The rhombencephalon divides into metencephalon (future pons and cerebellum) and myelencephalon (future medulla). Failure of ventral induction leads to condi-

tions like holoprosencephalies, septooptic dysplasia, Dandy-Walker spectrum, arrhinencephaly, cerebellar dysplasias, Joubert syndrome, rhombencephalosynapsis, tectocerebellar dysplasia, and facial anomalies.

Stage 3 (cortical development): neuronal and glial *proliferation* in the germinal matrix located in the subependymal embryologic layers during 2 to 4 months; neuronal *migration* of developing neurons along the radial glial units to the brain periphery during 3 to 5 months and *organization* of migrated neuronal bundles into the six-layered cortex from 5 months onward. Reduced *proliferation* leads to microcephaly and increased nonneoplastic proliferation leads to conditions such as tuberous sclerosis, balloon cell dysplasia (type II Taylor dysplasia), and hemimegalencephaly, whereas increased neoplastic proliferation leads to a dysembryoplastic neuroepithelial tumor (DNET), ganglioglioma, and gangliocytoma. Abnormal neuronal *migration* causes lissencephalies and heterotopias. Abnormal cortical *organization* leads to conditions such as polymicrogyria (PMG), schizencephaly, and nonballoon cell dysplasia (type I Taylor dysplasia).

In this chapter, we will discuss congenital brain malformations in four sections, namely disorders caused by failure of dorsal induction, ventral induction, cortical development, and miscellaneous/neurocutaneous syndromes.

FAILURE OF DORSAL INDUCTION—NEURAL TUBE CLOSURE DEFECTS AND CHIARI MALFORMATIONS

ANENCEPHALY

Anencephaly results from failure of neural tube closure at the cranial end of the developing embryo. The cerebrum and cerebellum are reduced or absent, but the hindbrain is present. Absence of the brain and calvarium may be partial or complete. Anencephaly leads to fetal loss, stillbirth, or neonatal death and is usually not associated with other malformations. Ultrasound diagnosis can be made as early as 20 weeks gestational age and is associated with polyhydramnios and high alpha-fetoprotein.

INIENCEPHALY

Iniencephaly is a rare neural defect involving the occiput and inion (external occipital protuberance) with rachischisis of the cervical and thoracic spine and

retroflexion of the head. The main features of iniencephaly include a variable deficit of the occipital bones that results in an enlarged foramen magnum, partial or total absence of the cervical and thoracic vertebrae with an irregular fusion of those vertebrae that are present, and this is accompanied by incomplete closure of the vertebral arches and bodies, hyperextension of the malformed cervico-thoracic spine with significant shortening of the spinal column because of marked lordosis and an upward-turned face (star gazing fetus on ultrasound), and the mandibular skin being directly continuous with that of the chest owing to the short neck.

CEPHALOCELES

A herniation of cranial contents through a defect in the skull is termed a cephalocele. When the hernia consists of brain and meninges, it is called a meningoencephalocele; the absence of brain tissue characterizes a meningocele. Cephaloceles can be classified according to their location as occipital (between lambda and foramen magnum), parietal (between bregma and lambda), sincipital (at junction of frontal and ethmoidal bones), and basal (at junction of sphenoid and ethmoid bones). Sincipital cephaloceles can be further classified as nasofrontal, nasoethmoidal, and nasoorbital. Basal cephaloceles are subdivided into transethmoidal, sphenothmoidal, sphenoorbital, sphenomaxillary, and transsphenoidal. An atretic cephalocele or meningocele manque, regarded as *forme fruste* of meningoencephalocele, is a skin-covered subcutaneous lesion that consists of meningeal, ectopic glial, or other CNS tissues such as anomalous blood vessels and has high incidence in conditions such as Walker-Warburg syndrome.

CHIARI MALFORMATIONS

The German pathologist Hans Chiari described the Chiari malformations I, II, and III in the 1890s based on autopsy studies. The so-called Chiari IV malformation is a form of severe cerebellar hypoplasia and occurs during a later developmental stage. Some authors reserve the term Chiari IV malformation for severe cerebellar hypoplasia associated with Chiari II.

Chiari I is characterized by herniation of the cerebellar tonsils through the foramen magnum into the cervical spinal canal. Herniation of at least one cerebellar tonsil that is 5 mm or more below the foramen magnum or of both tonsils that are 3 to 5 mm below the foramen magnum, accompanied by certain other features like small, crowded posterior fossa with effaced posterior

fossa CSF cisterns, syringohydromyelia, pointed or peg-like appearance of the tonsils, and elongated but normally positioned fourth ventricle can point to this condition. As cerebellar tonsils ascend with age, the normal upper limit of tonsillar descent varies as follows: up to 6 mm in those aged 0 to 10 years, 5 mm in 10 to 30 years, 4 mm in 30 to 80 years, and 3 mm in 80 to 90 years. Syringohydromyelia seen in 25% (15%–75% depending on the series quoted) is most commonly observed between the C4–6 levels, even though any cord segment may be involved. Most common associated skeletal anomalies are platybasia, basilar invagination (25%–50%), and posteriorly angled odontoid process (26%) with brainstem compression and scoliosis (42%). Other skeletal anomalies include short clivus, short supraocciput, atlantooccipital assimilation, Klippel-Feil syndrome, incomplete C1 ring ossification, increased cervical lordosis, and thoracic kyphosis.

Chiari II malformation, also known as Arnold Chiari malformation, is a complex anomaly with skull, dural, brain, spinal, and spinal cord manifestations, almost always associated with myelomeningocele usually lumbar. The imaging findings in this condition are numerous and can be classified into four categories as skull and dural changes, brain changes, ventricular changes, and other associated changes. The skull and dural changes include lacunar skull or *lückenschädel* (areas of focal calvarial thinning and scooped out appearance that are most prominent near the vertex or torcular herophili, disappearing after 6 months of age), concave posterior aspects of a short clivus and petrous ridges, small posterior fossa and a large, round, gaping foramen magnum, low-lying transverse sinuses and torcular herophili, fenestrated falx with interdigitated cerebral gyri of two sides, hypoplastic tentorium attaching to the occipital bone far caudally just above the foramen magnum, and a heart-shaped tentorial incisura. The brain changes include inferiorly displaced cerebellar vermis through the foramen magnum, medullary spur and kinking inferiorly lying dorsal to the spinal cord, towering cerebellum projecting above the widened tentorial incisura, wrapping of the cerebellum around the brainstem anteriorly and laterally, beaking and inferior displacement of the tectal plate with variable degrees of fusion of the colliculi, and a prominent massa intermedia (interthalamic adhesion). The ventricular changes include a fourth ventricle that is elongated craniocaudally and narrowed in other dimensions, frequently enlarged third ventricle, obliterated posterior fossa cisterns, colpocephaly (enlarged occipital horns and atria of lateral ventricles because of maldeveloped occipital lobes), and anteroinferiorly pointed frontal horns. Hydrocephalus occurs in more than 90%. It is important to understand that the fourth ventricle is normally a thin vertical slit in Chiari

II malformation. A normal appearing or enlarged fourth ventricle in these patients suggests a shunt malfunction or an isolated fourth ventricle that needs CSF diversion. Most frequent associated anomalies include myelomeningocele (88%–100%), corpus callosum dysgenesis (80%–90%), syringohydromyelia (50%–90%), aqueductal stenosis (70%), contracted, narrow gyri or stenogyria (50%), and absent septum pellucidum (40%). Other rarer associated anomalies include heterotopias, diastematomyelia, low-lying tethered cord, and incomplete C1 arch.

Chiari III malformations have high cervical/low occipital encephaloceles that contain cerebellum or occipital lobes and other Chiari II features to a variable extent. They can be considered as Chiari II plus encephalocele.

SPINAL DYSRAPHISMS

Spinal dysraphism occurs in the first 8.5 weeks of fetal life. The neural tube develops from ectodermal cells, while mesoderm forms the bony elements, meninges, and muscle. The skin is separated from the neural tube by the mesoderm. Incomplete separation of ectoderm from the neural tube results in cord tethering, diastematomyelia, or a dermal sinus. Premature separation of the cutaneous ectoderm from the neural tube results in incorporation of mesenchymal elements between the neural tube and skin, which may result in the development of lipomas. If the neural tube fails to fuse in the midline posterior spinal abnormalities such as myelomeningoceles occur. Spina bifida can be divided into two categories, namely spina bifida cystica or aperta and spina bifida occulta.

The subtypes of spina bifida cystica are myelomeningocele, meningocele, rachischisis, lipomyelomeningocele, lipomeningocele, and terminal myelocystocele. *Myelomeningocele* is a condition in which the spinal cord and nerve roots herniate through the bony and musculocutaneous defect into a sac comprising the meninges. The spinal cord often ends in this sac in which it is splayed open, exposing the central canal. It is associated with conditions such as hydrocephalus and Chiari II malformation, intestinal, cardiac, and esophageal malformations, renal and urogenital anomalies. A *meningocele* is simply herniation of the meninges through the bony defect. The spinal cord and nerve roots do not herniate into this closed dorsal dural sac. It does not have associated neurologic malformations such as hydrocephalus or Chiari II. Rachischisis is the most severe form of spina bifida aperta and involves a widely patent dorsal opening of the spine with or without residual cord tissue. *Rachischisis* is usually associated with anencephaly. Lipomyelomeningocele or

lipomeningocele has a lipomatous mass that herniates through the bony defect and attaches to the spinal cord, tethering the cord and often the associated nerve roots. The *lipomyelomeningocele* can envelop both dorsal and ventral nerve roots, only the dorsal nerve roots, or simply the filum terminale and conus medullaris. These lesions do not have associated hydrocephalus but have a more guarded prognosis than simple meningoceles with higher retethering rates following surgery. In *terminal myelocystocele*, the spinal cord has a large terminal cystic dilatation resulting from hydromyelia. The posterior wall of the spinal cord often is attached to the skin, giving rise to a large terminal skin-covered sac. The vast majority of the lesions are dorsal, the most common ventral variant being an anterior sacral meningocele. Posterior meningoceles, lipomyelomeningoceles, and myelocystocele are closed defects and may occur with a skin-covered back mass.

Spina bifida occulta does not have the meninges herniating through the bony defect and is covered by skin. They do not have associated hydrocephalus or Chiari II malformations. Frequently, a skin lesion such as a hairy patch, dermal sinus tract, dimple, hemangioma, or lipoma points to the underlying spina bifida and neurologic abnormality present in the thoracic, lumbar, or sacral region. Presence of these cutaneous stigmata above the gluteal fold signifies the presence of an occult spinal lesion. Dimples below the gluteal fold signify a benign, nonneurologic finding such as a pilonidal sinus.

A *dorsal dermal sinus* is a long, thin, epithelium-lined sinus that extends from the skin surface for a variable distance. This sinus may become symptomatic because of an infection if it has a connection within the thecal sac or compression of neural tissue if associated with a dermoid/epidermoid. An *intradural lipoma* has no anatomic connection with the subcutaneous fat and lies wholly within the dural space. This is similar to a lipomyelomeningocele except that the neural tube closes after the mesenchyme has entered.

A *split notochord* results from abnormal splitting of the notochord, which is usually associated with a persistent tract between the gut and the dorsal skin. The intervening tract may become obliterated at any point to create an enteric cyst, diverticulum, fistula, sinus, *neurenteric cyst*, or enteric duplication cyst.

Diastematomyelia refers to a complete or partial clefting of the spinal cord in a sagittal plane into two symmetric or asymmetric hemicords. The cord usually reunites more distally. Each of the hemicords has its own central canal and dorsal and ventral nerve roots. They are divided into two types: In type A (50%–60%), the hemicords are contained within a single dural and arachnoid lining without a dividing spur. In type B, each hemicord has its own dural and arachnoid sac with a

spur or septum separating the two. The septum may be bony, cartilaginous, or fibrous. The most common site for this anomaly is the thoracolumbar region. Associated cutaneous stigmata at the site of the anomaly, cord tethering, and syringohydromyelia are common and therefore must be looked for in diastematomyelia. Whenever the conus lies below the L2-3 interspace in an infant, cord tethering should be considered. The term *tethered cord* implies that the cord may be attached to vertebral column or subcutaneous tissues by a thickened filum terminale, fibrous band, dermal sinus tract, diastematomyelia, or a lipoma (lipomyelomeningocele).

FAILURE OF VENTRAL INDUCTION—HOLOPROSENCEPHALIES AND POSTERIOR FOSSA MALFORMATIONS OTHER THAN CHIARI

HOLOPROSENCEPHALY

Holoprosencephaly (HPE) is a failure of ventral induction of the brain in which the developing forebrain (prosencephalon) fails to divide into two separate hemispheres and ventricles. They are classified into alobar, semilobar, and lobar subtypes. Midline facial malformations occur in most cases, which are correlated with the degree of HPE and vary from alobar to lobar as cyclopia (single, midline, fused eye beneath a proboscis), ethmocephaly (ocular hypotelorism with a proboscis), cebocephaly (ocular hypotelorism with a single nostril), ocular hypotelorism and midline clefting, or milder facial dysmorphic features. Also, there is a middle interhemispheric variant of HPE, which is associated with solitary median maxillary incisor tooth, prominent vomerine ridge in midpalate, and overgrowth of nasal process of maxilla producing nasal pyriform aperture stenosis.

Alobar HPE is the most severe form in which there is a single ventricle and no separation of the cerebral hemispheres. The interhemispheric fissure, falx cerebri, corpus callosum, septum pellucidum, and fornix are absent. The thalami and basal ganglia are fused.

Semilobar HPE has fused left and right frontal and parietal lobes and the interhemispheric fissure is only present posteriorly. A rudimentary falx may be present, and a primitive occipital horn may develop.

Lobar HPE is the mildest form, in which most of the right and left cerebral hemispheres and lateral ventricles are separated but the most rostral aspect of the telencephalon, the frontal lobes, are fused, especially anteroinferiorly. Sometimes, lobar HPE is limited to an absence of the septum pellucidum.

Septo-optic dysplasia or De Morsier syndrome is the mildest form of lobar HPE in which there is no septum pellucidum and the optic nerves are very atrophic. Schizencephaly may be present in 50% of these cases. Corpus callosum agenesis may also be seen with this entity. They typically present with symptoms of hypothalamic–pituitary dysfunction.

Middle interhemispheric fusion variant (syntelencephaly) of HPE is a condition in which there is fusion of the posterior frontal and parietal lobes/sylvian fissures across the midline and absence of the body of the corpus callosum but presence of the genu and splenium of the corpus callosum. There is incomplete thalamic separation in one-third cases, but the hypothalamus and basal ganglia are usually separated.

ARRHINENCEPHALY

Arrhinencephaly is a condition where there is absence of the olfactory bulbs and tracts. Coronal MRI shows the olfactory sulci, but no olfactory bulbs or tracts. Most cases of HPE are associated with absent olfactory bulbs and tracts. Olfactory aplasia also occurs in Kallmann syndrome, which includes anosmia, hypogonadism, and mental retardation.

DANDY-WALKER SPECTRUM

The Dandy-Walker spectrum classically consists of Dandy-Walker malformation (DWM), Dandy-Walker variant, megacisterna magna. Dandy-Walker malformation is characterized by an enlarged posterior fossa, a high tentorial insertion (lambdoid–torcular inversion) with upward displacement of the transverse sinuses. The floor (anterior part) of the fourth ventricle is present, but the ventricle opens dorsally into a large posterior fossa cyst. There is generalized obstructive hydrocephalus in approximately 80% and colpocephaly (dilated occipital horns of lateral ventricles) if there is associated corpus callosal agenesis, which is seen in 20% to 25% cases. The hydrocephalus is not present at birth and frequently does not become evident until after the neonatal period. There is variable cerebellar vermian/hemispheric aplasia or hypoplasia with the cerebellar remnant everted anterosuperiorly above the cyst. In more severe case, the cerebellar hemispheres can appear winged outward and displaced anterolaterally against the petrous temporal bone. The brainstem may be hypoplastic or compressed. There can be other associated CNS anomalies in up to 70% cases including callosal agenesis, heterotopia, PMG, schizencephaly, and cephaloceles. In the absence of other associated anomalies, these children can have

normal intelligence and lead normal lives if the hydrocephalus is controlled. Also the integrity of normal cerebellar vermal fissures and lobes is important in predicting outcome.

In Dandy-Walker variant, the posterior fossa is characteristically normal in size. There is mild inferior vermal hypoplasia with open communication of the posteroinferior fourth ventricle and cisterna magna through an enlarged vallecule (vallecule is the normal space in between the two cerebellar hemispheres beneath the vermis), producing a keyhole deformity. Some authors prefer to avoid using the term Dandy-Walker variant and describe it as a part of Dandy-Walker spectrum.

Megacisterna magna has a large posterior fossa with normal vermis and fourth ventricle. The cistern is crossed by falx cerebelli and tiny veins. Enlarged cisterna magna communicates freely with fourth ventricle and basal subarachnoid spaces.

Fourth ventriculocele variant of Dandy-Walker malformation is a condition in which the large cyst erodes occipital bone with the encysted fourth ventricle herniating into the occipital encephalocele.

Persistent Blake pouch cyst is a condition in which the inferior aspect of the fourth ventricle herniates through the foramen of Magendie into the vallecule and retrovermal cistern. The persistent Blake pouch cyst also freely communicates with fourth ventricle, but inferiorly under the vermis. The differentiating feature is that the vermis is normal in appearance even though rotated. Also, the basal cisterns are compressed posteriorly or effaced.

Posterior fossa arachnoid cysts are considered a separate entity. The cerebellar vermis is normal in this condition. It can produce scalloping of adjacent calvarium as does the megacisterna magna and also cause mass effect on the adjacent structures when large. It has closed fourth ventricle, not communicating freely with the cyst. The major imaging differentiation on MRI or contrast-enhanced CT scan is that the arachnoid cyst is not traversed by falx cerebelli or tiny veins, whereas the megacisterna magna can be traversed by these structures. True retrocerebellar arachnoid cysts displace the fourth ventricle and cerebellum anteriorly and show significant mass effect. Following instillation of intrathecal contrast in the lumbar subarachnoid space, the megacisterna magna will be readily opacified, whereas the arachnoid cyst will not opacify immediately (even though delayed opacification can occur by diffusion across the cyst membrane).

JOUBERT SYNDROME

In 1969, a French neurologist, Marie Joubert, reported a series of five cases of children with mental retardation,

episodes of abnormally deep and rapid breathing, abnormal eye movements, and ataxia, which were associated with agenesis of the cerebellar vermis. The primary imaging features of Joubert syndrome are absence of the vermis, thickening and reorientation of the superior cerebellar peduncles, and fourth ventricle deformity. The molar tooth sign in axial images, which is considered pathognomonic of this condition, is caused by a lack of normal decussation of superior cerebellar peduncular fiber tracts. A lack of decussation leads to enlargement of the peduncles. Also, the peduncles follow a more horizontal course as they extend perpendicularly to the brainstem between the midbrain and the cerebellum. The absence of crossing fibers is responsible for the decreased anteroposterior diameter of the midbrain and also causes the interpeduncular cistern to be deeper than that in the normal brain. The absence of a normal vermis creates a midline cleft (buttocks sign) between the two normal-appearing cerebellar hemispheres. The fourth ventricle shows a “batwing” appearance at the level of upper pons and a triangular shape at the level of midbrain.

RHOMBENCEPHALOSYNAPSIS

Rhombencephalosynapsis was first described by Obersteiner in 1914 and the first case diagnosed by MRI was reported in 1991. It is characterized by the absence or hypogenesis of the vermis and the midline fusion of the cerebellar hemispheres into a single mass. Unlike other vermal maldevelopment syndromes (such as Dandy-Walker complex, Joubert syndrome, or tectocerebellar dysraphia), there is no disconnection of the cerebellar hemispheres, rather they continue seamlessly through the midline. The most distinctive feature is agenesis or poor differentiation of the vermis, the rostral portion being the most severely affected, while the caudal vermis is better formed, usually with a well-developed flocculonodulus. Cerebellar hemispheres appear midline fused, with no intervening cyst; folia and fissures are transversely oriented (single-lobed cerebellum). Diagnosis is best made by axial images demonstrating the fused hemispheres, while coronal images show horizontal folial orientation. Superior and middle cerebellar peduncles may be fused as well as the dentate nuclei and the inferior colliculi, leading to a characteristic diamond-shaped fourth ventricle (narrowed and posteriorly pointing); however, this finding is not so constant. Olivary nuclei may be hypoplastic or absent. Hydrocephalus is the most frequently found supratentorial anomaly and may be associated with aqueductal stenosis. Other supratentorial findings include fused thalami, fornices and cerebral peduncles, absence of the septum

pellucidum, dysgenesis of the limbic system, cortical malformations, and multiple suture synostoses.

Partial rhombencephalosynapsis is a still rarer entity with only two cases reported that involved the inferior (posterior) cerebellum and one that involved the superior (anterior) cerebellum.

TECTOCEREBELLAR DYSRAPHIA

The extremely rare tectocerebellar dysraphia consists of vermian hypoplasia or aplasia, occipital cephalocele, and dorsal traction of the tectal plate of midbrain, such that the hypoplastic cerebellar hemispheres are rotated around the brain stem to lie ventrolaterally to it.

MALFORMATIONS OF CORTICAL DEVELOPMENT

The malformations of cortical development can be further subdivided into three sections, namely malformations caused by neuronal and glial *proliferation*, neuronal *migration*, and *organization*.

MALFORMATIONS CAUSED BY ABNORMAL NEURONAL AND GLIAL PROLIFERATION

Reduced *proliferation* leads to microcephaly. The craniofacial ratio is reduced, the normal being 5:1 in premature infants, 4:1 in term infants, 3:1 at 2 years, 2.5:1 at 3 years, 2:1 at 12 years, and 1.5:1 in an adult. Primary or genetic microcephaly may have a small but grossly normal brain with gyral simplification or may be associated with cerebellar hypoplasia, pachygyria, lissencephaly, HPE, or hypomyelination. Secondary (nongenetic) microcephaly results from noxious agents that affect the fetal or infant brain growth like hypoxic ischemic encephalopathy, TORCH infection (Table 100-1), fetal alcohol syndrome, and nonaccidental head injury.

Increased nonneoplastic *proliferation* leads to conditions like tuberous sclerosis, balloon cell focal cortical dysplasia (type II Taylor dysplasia), and hemimegalencephaly. Pathologically, all these three have balloon cell proliferation. Balloon cells are giant progenitor cells that have characteristics of both neurons and astrocytes. Balloon cell anomalies typically have high signal intensity on long TR images. MR imaging features of balloon cell focal cortical dysplasia of Taylor include cortical thickening, homogeneous high signal intensity in the subcortical white matter, and abnormal signal intensity that extends to the ventricle and usually has a frontal lobe location. Hemimegalencephaly is a disorder with

lobar or hemispheric enlargement associated with ipsilateral ventriculomegaly, white matter signal intensity changes, heterotopia, and cortical thickening. In cases with dissimilar size of two halves of the brain, it is important to see whether the smaller side or larger side has ventriculomegaly. If the smaller side has ventriculomegaly, it is hemiatrophy of that side whereas if the larger side has ventriculomegaly, then the size discrepancy is because of hemimegalencephaly of that side. Transmantle dysplasia is defined as any disorder with gray matter extending from the ventricular surface to the cortex.

Increased neoplastic *proliferation* leads to dysembryoplastic neuroepithelial tumor, ganglioglioma, and gangliocytoma. Dysembryoplastic neuroepithelial tumor (DNET) has abnormal proliferation of all three cell lines: neuronal, oligodendroglial, and astrocytic. It is a slow-growing benign neoplasm that is occasionally cystic and superficially located mainly in temporal lobe and often involves amygdalla and hippocampus. These are well-demarcated, wedge-shaped, multicystic, bubbly intracortical masses that scallop the inner table of skull and point toward the ventricle. Calcification can be seen in one-fourth cases and faint focal punctuate or ringlike enhancement in one-fifth. These almost always present with partial complex seizure disorders and with no focal neurologic deficit. Histologically, the lesion shows glioneuronal elements, a nodular component, or an association with cortical dysplasia. Gangliogliomas are partially cystic, cortical-based tumors that have a higher incidence of calcification and enhancement (approximately half the cases) than ganglioglioma. Temporal lobe is the most common location, followed by parietal and frontal lobes. They can occur as a circumscribed cyst with mural nodule, a solid tumor that often thickens and expands the gyri or rarely as an infiltrating poorly defined mass.

MALFORMATIONS CAUSED BY ABNORMAL MIGRATION

Abnormal neuronal *migration* causes lissencephalies and heterotopias. Arrest of migration leads to classical type 1 lissencephaly (agyria–pachygyria complex). It is usually associated with chromosome 17-LIS 1 gene mutation or X-linked DCX mutations in boys. Mothers with boys with X-linked lissencephaly who have the X-linked DCX mutation may develop the band heterotopia (double cortex) syndrome. Lissencephaly (smooth brain) or agyria pachygyria complex are terms used to denote brain with absent or reduced sulcation. Complete lissencephaly having a figure of eight or hourglass brain configuration because of smooth brain and shallow

sylvian fissure is synonymous with agyria, whereas incomplete lissencephaly is synonymous with agyria-pachygyria. They are characterized by arrested neuronal migration, pachygyric (thick), four-layered cortex (instead of normal six layer), and smooth brain surface. There can be a cell-sparse white matter layer within the thick abnormal cortex which will be seen as hyperintense line outlined on both sides by lower signal intensity cortex in long TR images and this should not be mistaken for double cortex or band heterotopia. Lissencephaly is found in association with facial anomalies in Miller-Dieker syndrome or as an isolated finding in X-linked lissencephaly. Miller-Dieker syndrome can also have characteristic small midline septal calcification. The brain anomalies because of LIS1 mutation are more severe over the parietooccipital region whereas that owing to X-linked DCX mutation is more severe over the subfrontal and temporal regions. Band heterotopia seen in mothers of boys with X-linked lissencephaly shows symmetric subcortical gray matter ribbons embedded in white matter that parallels the cortex. In this case, the white matter, which separates the cortices, will have normal hypointensity in long TR images. Lissencephaly can also occur secondary to intrauterine cytomegalovirus infection in which case it is associated with periventricular and subcortical white matter calcifications. CMV-related lissencephaly usually does not have a thick cortex and the cortex is often polymicrogyric.

Overmigration results in cobblestone lissencephalies (type 2 lissencephaly). They are usually associated with congenital muscular dystrophy (CMD) subtypes 2, 3, and 4. These hypotonic infants have an abnormal Z-shaped brainstem on sagittal MRI images, which serve as an important diagnostic clue. CMDs comprise a heterogeneous group of autosomal recessive disorders of infancy. The CMDs are classified into four distinctive groups depending on MR imaging, namely CMD1 (merosin positive or negative), CMD2 (Fukuyama CMD), CMD3 (Muscle-eye-brain disease), and CMD4 (Walker-Warburg syndrome). Merosin-positive CMD1 cases have been described to show normal MRI or mild, nonspecific, periventricular white matter changes, cerebellar hypoplasia, or focal PMG. Merosin-negative CMD1 is known to cause bilateral white matter changes. In Fukuyama CMD (CMD2), diffuse central cerebral hypomyelination, cerebellar PMG with or without cysts, frontal PMG, variable degrees of pontine and cerebellar vermian hypoplasia, and occipital cobblestone cortex have been described. In this condition, PMG is seen primarily in frontal lobes and cobblestone lissencephaly is more prominent in occipital regions. Muscle-eye-brain disease (CMD3) is characterised by pachygyria with cobblestone cortex, midline defect, and hypoplastic

pons and white matter changes in patients with muscle-eye-brain disease (CMD3). Patients with Walker-Warburg syndrome (CMD4) have diffuse cerebral cobblestone cortex, hydrocephalus, posterior cephaloceles, severe congenital eye malformations, absence of cerebral and cerebellar myelin, cerebellar PMG with or without cysts, pontine and cerebellar vermian hypoplasia, and variable callosal hypogenesis.

Other lissencephaly variants include X-linked lissencephaly with callosal agenesis and abnormal genitalia (XLAG) because of ARX gene mutation showing posterior agyria and anterior pachygyria. Females with this condition have callosal agenesis. Another lissencephalic variant is that secondary to reelin gene mutation in chromosome 7q22 and is called the Norman Roberts type of lissencephaly. No cell-sparse zone is seen in the thickened cortex. The brainstem and cerebellum are extremely small and hippocampus is incompletely rotated.

Gray matter heterotopia is another major group of migrational anomaly. They can be subependymal, subcortical, and band heterotopias and follow gray matter signal intensity in all MRI sequences. Subependymal nodular heterotopia is the most common subtype and produces a wavy outline of lateral ventricles. Differential diagnosis of the wavy outline of lateral ventricles includes the subependymal tubers of tuberous sclerosis (which have different signal intensity compared to gray matter), posthypoxic white matter loss producing wavy ventricular outline in periventricular leukomalacia, and the extremely rare subependymal metastasis. Subcortical heterotopia may have a thinned and dysplastic overlying cortex if the heterotopia is large. Band heterotopia has already been described along with lissencephaly.

MALFORMATIONS CAUSED BY ABNORMAL CORTICAL ORGANIZATION

Abnormal cortical *organization* leads to conditions like PMG, schizencephaly, and nonballoon cell dysplasia (type I Taylor dysplasia). PMG is a malformation of cortical development characterized by excessive small and prominent convolutions separated by shallow sulci, giving the cortical surface and cortical-white matter junction an irregular appearance. T2-weighted images of patients with PMG reveal two different cortical patterns; one in infants younger than 1 year showing a small, fine, and undulating appearance with normal cortical thickness (3–4 mm), and another pattern in children older than 18 months showing a thick and bumpy cortical appearance (5–8 mm). Pattern 1 seems to evolve into pattern 2 as the brain undergoes myelination. PMG can be associated with clefts and abnormal veins. The cleft

(pial–ependymal seam) of schizencephaly is lined by polymicrogyric cortex. Intrauterine cytomegalovirus infection can cause lissencephaly, periventricular and subcortical calcifications, and PMG. Bilateral perisylvian PMG can be seen in Foix-Chavany-Marie syndrome (congenital bilateral perisylvian syndrome) and Zellweger syndrome.

Schizencephaly or split brain is divided into two types, namely closed-lip schizencephaly in which the cleft walls are in apposition and the more common open-lip schizencephaly in which the cleft walls are separated. The clefts can be located anywhere, but they commonly occur in the perisylvian regions and can be unilateral or bilateral, symmetric or asymmetric. Closed-lip schizencephaly can be identified by looking for the small nipple projecting from ventricle. The clefts are lined by heterotopic/pachy/polymicrogyric gray matter and extend from the pial surface to the ependyma of the lateral ventricle (pial–ependymal seam). The arachnoid membrane covering the cleft can be ruptured easily and hydrocephalus is seen especially in open-lip schizencephaly with ruptured membrane. Large primitive veins may be seen overlying the cleft. The septum pellucidum is absent in 80% to 90% of patients, and schizencephaly may coexist with septooptic dysplasia. In contrast to schizencephaly, the cleft of porencephaly caused by trauma or vascular insult is lined by gliotic white matter in MRI images and not dysplastic gray matter.

Non balloon cell cortical dysplasia (type I Taylor) is seen as a focal thickened area of cortex without underlying white matter changes (as compared to balloon cell type II dysplasia). A focal prominent convexity subarachnoid space overlying the focal area of thickened cortex can sometimes serve as an important diagnostic clue in MRI.

At this point, it would be interesting to review the differences between PMG, cobblestone cortex, and pachygyria in thin section high-resolution MR images. PMG is seen as irregularity of both the outer cortical surface as well as the inner cortical-white matter junction. Cobblestone cortex has a smooth outer cortical surface and an irregular inner cortical-white matter junction. In pachygyria (thick cortex), both the outer and inner margins are smooth, and in some cases, a layer of white matter can be detected in the cell-sparse zone within it.

MISCELLANEOUS/NEURO CUTANEOUS SYNDROMES

AGENESIS OF CORPUS CALLOSUM

The corpus callosum develops from the lamina reuniens in the telencephalon; it begins to appear between the an-

terior and hippocampal commissures at about 10.5 weeks and the adult form is achieved by 17 weeks gestational age. It begins in the genu and the body, progressing posteriorly, but myelinates from posterior to anterior. The anteriormost rostrum is also formed last. Therefore in partial callosal agenesis, the splenium and rostrum are usually absent. In contrast, in the middle interhemispheric variant of HPE, only the body of the corpus callosum is absent.

When the corpus callosum is absent, the third ventricle is often high riding, extending superiorly in between the lateral ventricles. On coronal imaging, a “viking helmet” or “bull’s horn,” “moose head,” or “candelabra” appearance is seen. Probst bundles are longitudinal bundles of white matter seen medial to the lateral ventricles and represent nondecussated callosal fibers. Instead of crossing in the midline, these fibers deviate at the interhemispheric fissure to run along the medial borders of the lateral ventricles from the frontal paraolfactory cortex to the occipital region. Probst bundles are best seen on coronal or axial T1-weighted MRI and appear more slightly T1 hyperintense and T2 hypointense than other white matter. The occipital horns of the lateral ventricles are dilated (colpocephaly) and the frontal horns appear parallel on axial imaging. When the corpus callosum is absent, the cingulate sulcus is absent, and the medial cerebral sulci and gyri radiate toward the midline in a radial configuration. The hippocampal formations are frequently hypoplastic in patients with agenesis of corpus callosum, with resulting mild dilatation of the temporal horns.

The midline cysts associated with callosal agenesis may be a dilated third ventricle or a true arachnoid cyst. At autopsy, the lining of the cyst may contain ependymal or arachnoid cells. On MRI, the cyst may have a high protein content; in these cases, the signal intensity on T1-weighted images is greater than that of CSF. Barkovich et al. have classified these cysts into various subtypes. Type 1 cysts appear to be an extension or diverticulation of the third or lateral ventricles, whereas Type 2 cysts are loculated and do not communicate with the ventricular system. Type 1a cysts are associated with presumed communicating hydrocephalus but no other cerebral malformations. Type 1b cysts are associated with hydrocephalus secondary to diencephalic malformations prohibiting egress of CSF from the third ventricle into the aqueduct of Sylvius. Type 1c are associated with small head size and apparent cerebral hemispheric dysplasia or hypoplasia. Type 2a (multiloculated cysts) are associated with no abnormalities other than callosal agenesis/hypogenesis. Type 2b cysts are associated with deficiencies of the falx cerebri, subependymal heterotopia, and PMG and are almost all in patients diagnosed with Aicardi syndrome. Type 2c cysts are associated

with subcortical heterotopia. Type 2d cysts consist of interhemispheric arachnoid cysts. Other than those with Type 2b cysts, gender predominance was overwhelmingly male. In complex types of multilocular interhemispheric cysts associated with callosal agenesis, a CT cystogram or ventriculogram may be obtained after io-hexol is introduced into the cyst to establish which of the CSF collections communicate with each other or with the ventricular system.

Agenesis of corpus callosum may be associated with a multitude of other conditions including hydrocephalus, cephaloceles, lissencephaly, schizencephaly, gray matter heterotopias, pachygyria, PMG, Dandy-Walker syndrome, Aicardi syndrome, fetal alcohol syndrome, azygous anterior cerebral artery, trisomy 18, and lipomas. Intracranial lipomas result from lipomatous differentiation of the persistent meninx primitiva, the mesenchymal derivative of the embryonic neural crest, which envelops the developing embryo. Interhemispheric lipomas constitute 40% to 50% of intracranial lipomas and are frequently associated with a dysgenetic corpus callosum. Callosal lipomas are of two types: an anterior bulky tubulonodular variety, which is associated with forebrain and rostral callosal anomalies and a more posterior ribbonlike curvilinear lipoma, which is seen with a normal or nearly normal corpus callosum. CT scan shows findings of callosal agenesis with a fatty-density mass that is variably calcified, and on MR, the lipoma follows fat intensity. Prominent vessels often course directly through the more bulky anterior callosal lipomas and the lipomas show variable calcification.

NEUROFIBROMATOSIS TYPE 1 (VON RECKLINGHAUSEN DISEASE)

NF1 is an autosomal dominant phakomatosis with the gene locus on chromosome 17q11.2. NF1 constitutes approximately 90% neurofibromatosis cases. Neurofibromin, the NF gene product, is a tumor suppressor and its inactivation allows cell proliferation and tumor development. The neuroradiological manifestations of NF1 include osseous changes like sphenoid wing dysplasia (producing bare orbit sign in radiographs and causing pulsating exophthalmos because of herniation of temporal lobe with subarachnoid space into orbit), absence of the orbital floor, enlarged orbits, enlargement of cranial foramina, enlargement of orbital margins, sclerosis in the vicinity of the optic foramen because of optic nerve sheath meningioma, dural calcification especially at the vertex, and calvarial defects adjacent to the lambdoid suture. Macrocephaly can occur because of hydrocephalus or increased white matter volume.

Brain abnormalities include foci of abnormal signal intensity, hyperintense on T2-weighted images in the brainstem, cerebellar white matter, globus pallidus, and splenium of corpus callosum. These lesions are isointense on T1-weighted images and usually have no mass effect or edema. These are regions of myelin vacuolization and areas of separation of the layers of myelin as they spiral around the axon. The oligodendrocyte myelin glycoprotein gene is imbedded within the NF1 gene and neurofibromin is required for Schwann cell myelination. The vacuolization may develop in regions where the myelin is inherently dysplastic and the return of normal T2 signal on subsequent examinations later in life may represent myelin repair or remyelination. They become visible between ages 2 and 10 years, then regress by the second decade and are never seen after 20 years of age. If the T2 lesions show enhancement, glioma development should be suspected. Rarely, hyperintensities have been reported in the globus pallidus on T1-weighted images. Optic gliomas are seen in 15% of NF1 cases, and gliomas of other parts of the brain may be seen. Hydrocephalus in NF1 may be because of benign aqueduct stenosis or a glioma of tectum/tegmentum of the mesencephalon. Other intracranial findings include arachnoid cysts, arachnoid pouches, frontobasal meningocele, craniofacial plexiform neurofibromas, vascular intimal proliferation leading to occlusions, moyamoya (puff of smoke) pattern, aneurysms, and AVM.

Spine imaging findings include sharply angled kyphoscoliosis centered at the thoracolumbar junction with the kyphosis more pronounced than the scoliosis, enlargement of the intervertebral foramina and scalloping of the vertebral bodies, lateral thoracic meningocele, cord astrocytoma, and neurofibromas of spinal or peripheral nerves. The target sign showing hyperintensity on T2, with dark collagen centrally is highly suggestive of a peripheral or plexiform neurofibroma on MRI.

NEUROFIBROMATOSIS TYPE 2

The NF2 gene, which functions as a tumor suppressor gene is located in chromosome 22q12 and the gene product is merlin protein. NF2 is also known as MISME denoting multiple inherited schwannomas, meningiomas, and ependymomas. Bilateral eighth nerve schwannomas is a definitive diagnostic criterion of NF2. Other definitive criteria include a first-degree relative with NF2 and either a unilateral CN VIII mass or two of the following: neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity. Extensive calcifications of choroid plexus, cortical surfaces, and ventricular lining may be rarely seen.

TUBEROUS SCLEROSIS

Tuberous sclerosis complex has two distinct gene loci, TSC1 at chromosome 9q34.3 that encodes hamartin and TSC2 at chromosome 16p13.3 that encodes tuberlin. The CNS manifestations include tubers or hamartomas, which are caused by abnormal neuronal and glial proliferation containing balloon cells. Subependymal nodules are seen in 98% of which about half calcify, the calcifications increase with age. About two-thirds of these lie along the striothalamic groove of lateral ventricles near the caudate nucleus, behind foramen of Monro. Subependymal giant cell astrocytomas occur in 15% cases, the majority of which enhance and are seen at the foramen of Monro region and can cause obstructive hydrocephalus. Cortical or subcortical tubers are seen as pyramidal-shaped gyral expansion. Approximately one-fifth of them have a central depression likened to an eye of potato. White matter hyperintensities on T2 are seen along the radial lines of neuronal migration as bands, wedge-shaped lesions, or cystoid brain degeneration. The tubers have high signal intensity compared to the nonmyelinated white matter on T1-weighted images and low on T2-weighted images in the neonate and young child. In older children and adults, the lesions are iso- to hypointense on T1 and hyperintense on T2-weighted images compared to both gray and white matter. There can be enhancement in 12% of cortical and subependymal tubers. Mild nonspecific ventriculomegaly even in the absence of subependymal giant cell astrocytomas can occur in 25% patients. Retinal phakomas occur in 50%. Other intracranial manifestations include aneurysms and vascular stenoses, bone islands in skull, and periosteal new bone formation.

STURGE-WEBER SYNDROME

Encephalotrigeminal angiomatosis or Sturge-Weber syndrome occurs because of a failure of normal fetal cortical venous development and the imaging features reflect chronic venous ischemia. Trigeminal nerve V1 and V2 distribution cutaneous nevus flammeus is seen in the vast majority of patients. Lack of superficial cortical veins leads to formation of enhancing pial angioma in the subarachnoid space and prominent enhancing medullary or subependymal veins and enlarged choroid plexus of that side. Orbital enhancement can be seen including choroidal angioma, periorbital soft tissues and bone. Later, the pial angiomas get burnt out with reduced enhancement and increasing cortical/subcortical atrophy and calcifications. The gyri-form, curvilinear tram track cortical calcifications (not in the pial angioma) are most common in parietal and occipital lobes and are unusual before 2 years of age. It is unilateral in 80% and bilateral in 20%.

VON HIPPEL-LINDAU SYNDROME

Von hippel-lindau syndrome (VHL) gene is located at chromosome 3p25–26 and the CNS manifestations include hemangioblastomas, retinal angiomas, and endolymphatic sac tumors. Hemangioblastomas typically are multiple with half seen in spinal cord, more than one-third in cerebellum, one-tenth in brain stem, and 1% supratentorial in location along optic pathways or cerebral hemispheres. Two-thirds of hemangioblastomas are seen as cysts with an enhancing nodule abutting the pial surface. In one-third cases, they present as solid enhancing tumors. Retinal angiomas cause retinal detachment and vitreous hemorrhages and the VHL patients often present first with visual symptoms. Seven percent of VHL patients will develop endolymphatic sac tumor and if they are bilateral, VHL is present. Endolymphatic sac tumor is seen in CT scans as an aggressive soft-tissue mass that erodes the posterior wall of temporal bone. All of them have central speculated calcifications within the tumor matrix and most of them have a thin rim of calcification along the posterior margin. T1-weighted images shows foci of high signal suggestive of blood along the tumor margin when less than 3 cm in size and within the tumor matrix when larger in size.

HEREDITARY HEMORRHAGIC TELENGECTASIA (HHT OR OSLER-WEBER-RENDU SYNDROME)

The most common intracranial vascular malformation in hereditary hemorrhagic telangiectasia (HHT) is AVM. Capillary telangiectasia can occur in scalp, nasopharynx, orbit, and brain. Multiple developmental venous anomalies (venous angiomas) can also occur in the brain. Brain abscess can occur in these patients with pulmonary AVM because of the right-to-left shunt.

LHERMITTE-DUCLOS DISEASE AND COWDEN SYNDROME

Lhermitte-Duclos disease or dysplastic cerebellar gangliocytoma is an uncommon cerebellar dysplasia with cellular disorganization, hypertrophied granular cell neurons, and axonal hypermyelination in the molecular layer of cerebellum. A nonenhancing mass in the posterior fossa with unilateral hemispheric expansion, hypointense on T1-weighted images, and hyperintense on T2-weighted images, with parallel linear striations on the surface of the lesion producing a tiger striped or corduroy appearance, should be considered specific for Lhermitte-Duclos disease in a middle-aged adult. They have no edema, little mass effect, variable calcification,

and hydrocephalus and very rare enhancement. More than half of the patients with Lhermitte-Duclos disease have Cowden syndrome, which is a syndrome with multiple hamartomas/neoplasia in breast and thyroid, gastrointestinal polyps, mucocutaneous lesions, genitourinary malignancies, cataracts, macrocephaly, extremely high risk of meningiomas, and Lhermitte-Duclos disease.

NEUROCUTANEOUS MELANOSIS

Neurocutaneous melanosis is characterised by giant or multiple cutaneous melanocytic nevi and benign and malignant melanotic lesions of CNS. The melanocytes within the pia mater are responsible for the development of leptomeningeal melanosis. The dura is generally spared.

Diffuse intracranial leptomeningeal, intraspinal leptomeningeal, ventricular ependymal, and choroid plexus involvement also may occur. The cerebral parenchyma may be primarily or secondarily involved. Primary involvement may be caused by melanin-containing macrophages and melanocytes. Parenchymal melanosis usually occurs in the amygdalla, pons, basal ganglia, thalami, dentate nuclei, cerebellar hemispheres, and the basal frontal lobes. Secondary involvement of the cerebral parenchyma occurs from spread via the Virchow-Robin spaces; the deep cerebral parenchyma is usually spared. Malignant melanoma is most common in temporal lobes. Leptomeningeal melanosis show normal or diffuse leptomeningeal enhancement malignant melanoma of leptomeninges show diffuse leptomeningeal enhancement. Parenchymal melanosis shows no enhancement, whereas malignant melanoma shows avid often heterogeneous enhancement. They appear hyperintense on T1-weighted images and iso- to hyperdense on CT. Spinal involvement may be seen in as many as 20% of cases. Diffuse leptomeningeal thickening, arachnoiditis, and secondary syringomyelia may be seen.

QUESTIONS AND ANSWERS

- What is associated with NF2?
 - Café au lait spots
 - Optic gliomas
 - Meningiomas
 - None

ANSWER: C. The diagnostic criteria for NF2 are bilateral eighth cranial nerve masses on CT or MRI or a parent, sibling, or child with NF2 and either a unilateral eighth cranial nerve mass or any two of the following: neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity. The mnemonic is "MISME"—multiple inherited schwannomas, meningiomas, and ependymomas.

- Latex allergy is associated with what disease?
 - Myelomeningocele
 - Dandy-Walker malformation
 - Rhombencephalosynapsis
 - Neurocutaneous melanosis

ANSWER: A. It is thought to happen secondary to the repeated surgeries that children with myelomeningocele undergo, with subsequent sensitization to the latex in the gloves.

- What lines the cleft in schizencephaly?
 - CSF
 - Gray matter
 - White matter
 - Hamartomatous tissue

ANSWER: B. The clefts are lined by heterotopic/pachy/polymicrogyric gray matter and extend from the pial surface to the ependyma of the lateral ventricle (pial ependymal seam). Large primitive veins may be seen overlying the cleft. In contrast to schizencephaly, the cleft of porencephaly caused by

trauma or vascular insult is lined by gliotic white matter in MRI images and not dysplastic gray matter.

4. Which of the following is *not* a feature of tuberous sclerosis?
 - A. Subependymal giant cell astrocytoma
 - B. Angiomyolipoma
 - C. Sphenoid wing dysplasia
 - D. Cardiac rhabdomyomas

ANSWER: C. Sphenoid wing dysplasia is a feature of NF1, not tuberous sclerosis.

5. MRI shows lobar atrophy, pial enhancement, and enlargement of the choroid plexus. What is the most likely diagnosis?
 - A. Sturge-Weber
 - B. Tuberous sclerosis
 - C. NF2
 - D. Osler-Weber-Rendu

ANSWER: A. In Sturge-Weber syndrome, lack of superficial cortical veins leads to formation of enhancing pial angioma in the subarachnoid space and prominent enhancing medullary or subependymal veins and enlarged choroid plexus of that side. Orbital enhancement can be seen including choroidal angioma, periorbital soft tissues, and bone. Later, the pial angiomas get burnt out with reduced enhancement and increasing cortical/subcortical atrophy and calcifications. The gyriform, curvilinear tram track cortical calcifications (not in the pial angioma) are most common in parietal and occipital lobes and are unusual before 2 years of age. It is unilateral in 80% and bilateral in 20%.

6. Which of the following is most likely associated with a midline facial defect?
 - A. Septo-optic dysplasia
 - B. Holoprosencephaly
 - C. Dandy-Walker syndrome
 - D. Tuberous sclerosis

ANSWER: B. Midline defects of the face occur in greater than 80% of cases of holoprosencephaly. Midline facial malformations are correlated with the degree of holoprosencephaly and varies from alobar to lobar as cyclopia (single, midline, fused eye beneath a proboscis), ethmocephaly (ocular hypotelorism with a proboscis), cebocephaly (ocular hypotelorism with a single nostril), ocular hypotelorism and midline clefting, or milder facial dysmorphic features. Also, there is a middle interhemispheric variant of holoprosencephaly, which is associated with solitary median maxillary incisor tooth, prominent vomerine ridge in midpalate, and

overgrowth of nasal process of maxilla producing nasal pyriform aperture stenosis.

7. In neurofibromatosis, what is the cause of pulsatile exophthalmos?
 - A. Sphenoid wing dysplasia
 - B. Enlargement of the optic canal
 - C. Carotid cavernous fistula
 - D. Buphthalmos

ANSWER: A. Sphenoid wing hypoplasia is an osseous manifestation of NF1, which leads to temporal lobe herniation into the orbit. The temporal lobe with subarachnoid space herniation into orbit leads to pulsatile exophthalmos.

8. What is a fetus with small cisterna magna most likely to have?
 - A. Meningomyelocele
 - B. Dandy-Walker syndrome
 - C. Chiari I
 - D. Chiari II

ANSWER: D. Chiari II has abnormal neurulation that leads to a small posterior fossa, including obliteration of the cisterna magna (cerebellomedullary cistern). Chiari I does not cause a small posterior fossa. Myelomeningoceles do not have an association with small cisterna magna, other than being associated with Chiari II. Dandy-Walker syndrome is associated with an enlarged posterior fossa.

9. Which of the following is *not* associated with renal cysts?
 - A. Tuberous sclerosis
 - B. Chronic renal dialysis
 - C. Von Hippel-Lindau
 - D. NF1

ANSWER: D. Renal cystic disease is associated with Von Hippel-Lindau disease and tuberous sclerosis. Patients on hemodialysis also develop renal cysts. Most renal cysts are simple cysts, seen in more than 50% of the population older than 50 years.

10. A child on MRI examination has abnormal high signal in the cerebellum and basal ganglia on T2-weighted images and an enlarged optic chiasm. What is the most likely diagnosis?
 - A. NF2
 - B. Tuberous sclerosis
 - C. NF1
 - D. Septo-optic dysplasia

ANSWER: C. NF1 typically has nonneoplastic hamartomas (80%–90%) that are foci of abnormal signal intensity hyperintense on T2 seen in cerebel-

lar white matter, globus pallidus, and splenium of corpus callosum. These lesions are isointense on T1-weighted images and usually have no mass effect or edema. These are regions of myelin vacuolization, areas of separation of the layers of myelin as they spiral around the axon. The oligodendrocyte myelin glycoprotein gene is imbedded within the NF1 gene and neurofibromin is required for Schwann cell myelination. The vacuolization may develop in regions where the myelin is inherently dysplastic and the return of normal T2 signal on subsequent examinations later in life may represent myelin repair or remyelination. They become visible between ages 2 and 10 years, then regress by the second decade and are never seen after 20 years of age. If the T2 lesions show enhancement, glioma development should be suspected. Rarely, hyperintensities have been reported in the globus pallidus on T1-weighted images. Optic nerve gliomas occur in 15% NF1 patients.

4 CEREBROVASCULAR ANATOMY

Asim K. Bag and Joseph C. Sullivan III

ARTERIES OF ANTERIOR CIRCULATION

INTERNAL CAROTID ARTERY

Neuroradiologists, neurosurgeons, and neurologists now use anatomically correct Bouthillier classification to describe the course of the internal carotid artery. This classification system defines the internal carotid artery (ICA) course using a numerical scale from one to seven in the direction of blood flow. Each segment number identifies the segments of the ICA from its origin to the terminus according to anatomical compartments through which the artery travels, making it very useful clinical communication among clinicians.

CERVICAL SEGMENT (C1)

The cervical segment of the ICA begins at the level of the common carotid artery bifurcation and ends at the entrance of the carotid canal into the petrous bone, anterior to the jugular foramen. The artery ascends perpendicularly upward encased in the carotid sheath with internal jugular vein and vagus nerve.

Branches

No branches from this segment.

Clinical Significance

Atherosclerotic Disease: The origin of the ICA is a very common location for atherosclerotic disease, the major culprit for the ischemic stroke. Carotid artery atherosclerotic disease is treated currently either by carotid endarterectomy or carotid artery stenting.

Management guideline for carotid stenosis (percent stenosis = $1 - \text{minimal diameter/poststenotic diameter} \times 100\%$):

- Low-grade carotid stenosis (stenosis <50% in symptomatic patients and <60% in asymptomatic patients) → medical therapy rather than revascularization.
- Moderate-to severe-carotid stenosis:
In symptomatic patients with >50% stenosis → carotid endarterectomy plus optimal medical therapy, if the patient has high perioperative risk, stenting is an alternative.
In asymptomatic patients with >60% stenosis → carotid endarterectomy plus medical management as long as perioperative risk is low.
- Asymptomatic patients with carotid artery stenosis: stenting is not indicated.
- **Dissection:** May be spontaneous (particularly in women and also if the patient has inherent weakness in arterial wall such as in Marfan or Ehlers-Danlos syndromes) or traumatic. This may be asymptomatic. Typical presentation is partial Horner syndrome with ptosis and miosis, followed by symptoms of transient cerebral/retinal ischemia or stroke, most often in the MCA territory.
- The carotid artery may have a very medial course at the level of nasopharynx, where it may approximate the pharyngeal wall. Any instrumentation or biopsy may injure this segment. Also, pharyngeal infection may cause pseudoaneurysm of the ICA at this level.

PETROUS SEGMENT (C2)

The segment of the ICA within the carotid canal, called the petrous segment, ends at the posterior edge of the foramen lacerum, inferomedial to the Meckel cave. The petrous ICA runs within the periosteum of the carotid canal and is surrounded by areolar tissue, a venous plexus, and postganglionic sympathetic nerves.

Branches

Caroticotympanic and Mandibulo Vidian arteries.

Clinical Significance

Pathologies in this segment are very rare. Aneurysms may occur here, which can be surprisingly large. Dissections

can continue into this segment. Size of the canal can be an indicator of developmental versus more acute pathologies.

LACERUM SEGMENT (C3)

The lacerum segment begins where the carotid canal ends, which is at a vertical line at the posterolateral margin of the exocranial foramen lacerum up to the superior margin of the petrolingual ligament. As in previous compartments, the lacerum segment is surrounded by areolar tissue, a venous plexus, and postganglionic sympathetic nerves.

Branches

Anterior meningeal.

Clinical Significance

This is a very important neurosurgical landmark for exposing Meckel cave through transfacial approach.

CAVERNOUS SEGMENT (C4)

The cavernous segment begins at the superior margin of the petrolingual ligament and ends at the proximal dural ring, formed by the junction of the medial and inferior periosteum of the anterior clinoid process. This segment of the ICA is surrounded by areolar tissue, fat, a venous plexus, and postganglionic sympathetic nerves.

Branches

Meningohypophyseal trunk posteriorly and inferolateral trunk anterolaterally.

Clinical Significance

There is a dangerous communication between the branches from the cavernous segment of ICA and ECA. These arteries may not be visible angiographically, however, utmost care should be taken during ECA branch embolization.

Aneurysms of cavernous carotid account for about 5% of total aneurysm. They are strongly associated with aging and hypertension. Most cavernous aneurysms identified during angiogram are incidental; asymptomatic small lesions usually do not warrant any treatment. When cavernous aneurysms rupture, which is an uncommon event, symptoms related to carotid–cavernous fistula, massive epistaxis, and subdural and much less likely subarachnoid hemorrhage.

More commonly, the cavernous carotid is affected by other sellar and parasellar pathologies that are discussed in a later chapter of this section.

CLINOID SEGMENT (C5)

The clinoid segment begins at the proximal dural ring and ends at the distal dural ring, where the ICA becomes intradural. The clinoid segment is short, coursing obliquely between the anterior clinoid, processing later-

ally and the carotid sulcus of the basisphenoid medially. This segment is not intracavernous.

Clinical Significance

At the end of this segment, the ICA becomes intradural, and also, this segment is closely related to the optic nerve. Ruptured aneurysms may present with subarachnoid hemorrhage (SAH). If the aneurysm is large and compresses the optic nerve, the patient may present with blindness. Because of the anatomic location, aneurysm of this segment is often surgically challenging.

OPHTHALMIC SEGMENT (C6)

The ophthalmic segment begins at the distal dural ring and ends just proximal to the origin of the posterior communicating artery (PCoA). There are two major arterial branches from this segment: the ophthalmic and superior hypophyseal arteries.

Clinical Significance

This is a common site for aneurysm formation.

COMMUNICATING SEGMENT (C7)

The communicating segment begins just proximal to the origin of the PCoA and ends at the ICA bifurcation.

Branches

In addition to the PCoA, this segment gives rise to anterior choroidal artery and occasional perforator branches. Anterior choroidal artery arises more distally and more laterally than the PCoA. The anterior choroidal artery supplied critical brain structures of diencephalon and mesencephalon. It supplies the uncus, piriform cortex, tail of the caudate nucleus, hippocampus, amygdala, thalamus, lateral geniculate body, optic tract, cerebral peduncles, the subthalamic nucleus, genu, and posterior limb of internal capsule.

Clinical Significance

This is also a very common site for intracranial aneurysm formation. As this segment is closely related with the third cranial nerve, aneurysm may present with third nerve palsy.

The ICA terminates by dividing into anterior (smaller branch) and middle cerebral arteries.

VARIATION OF THE INTERNAL CAROTID ARTERY

- *Fetal origin of PCA:* PCA is supplied only from the ICA through the PCoA with absent P1 segment.
- *Persistent trigeminal artery:* This is classified according to the location (medial or lateral) and presence or (Salzman type 2) absence (Salzman type 1) of PCoA. Persistent trigeminal artery can increase the risk of intracranial aneurysm formation. The medial variant is

also very important surgically because it may have a transhypophyseal or intrasellar course.

- **Persistent hypoglossal artery:** This is the second most common anomaly. The persistent hypoglossal artery branches from the ICA as a large extracranial branch and passes through the hypoglossal canal. The basilar artery arises from this artery.
- **Persistent stapedia artery:** The stapedia artery is transiently present in normal fetal development, connecting the branches of the future external carotid artery (ECA) to the ICA. Postembryonic persistence of the stapedia artery is rare and presents as a pulsatile middle ear mass or may be found incidentally during middle ear surgery. This is diagnosed by absent foramen spinosum and soft-tissue prominence in the proximal aspect of the tympanic segment of the facial nerve.
- **Proatlantal intersegmental artery:** They are very rare.
- **Aberrant carotid artery:** Normally, tiny caroticotympanic branch of the internal carotid, a remnant of the embryologic hyoid artery, perforates the carotid plate to enter into the tympanic cavity. The inferior tympanic branch of the ascending pharyngeal artery enters the tympanic cavity through the inferior tympanic canaliculus. The aberrant carotid artery actually represents an enlarged inferior tympanic artery anastomosing with an enlarged caroticotympanic artery when the cervical segment of the ICA is undeveloped/underdeveloped. Consequently, the “aberrant carotid artery” enters the tympanic cavity, courses through the tympanic cavity, and then enters the horizontal carotid canal. This usually presents with pulsatile tinnitus.

ANTERIOR CEREBRAL ARTERY

The anterior cerebral artery (ACA) is the smaller terminal branch of the ICA. After its origin, it traverses anteromedially toward the interhemispheric fissure just above the optic chiasm. In most cases, the ACA joins its contralateral counterpart at the level of interhemispheric fissure through the anterior communicating artery (AComA). The course of the ACA is divided into five segments: A1 is from the origin to the origin of AComA; the A2 segment extends to the junction of the rostrum and genu of corpus callosum, the A3 extends around the genu of corpus callosum until the artery turns sharply posteriorly, and the A4 and A5 segments pass over the corpus callosum separated by the coronal fissure.

NORMAL VARIANT/ANOMALIES OF ACA OF CLINICAL SIGNIFICANCE

Clinical Significance

Bihemispheric ACA: If the A2 segment is hypoplastic, the other A2 divides and supplies both the hemi-

spheres, which may be difficult to differentiate by angiography from true azygos ACA.

Azygos anterior cerebral artery: If the embryonic median artery of corpus callosum persists, an azygos ACA is formed. This is an unpaired median trunk of the ACA, which supplies both the hemispheres. This variant is sometimes associated with the holoprosencephaly.

Unpaired A2 segments can increase the risk of distal ACA aneurysms particularly at the bifurcation of ACA into pericallosal and callosomarginal arteries.

Infraoptic ACA: When the ACA arises early from the intradural course of the ACA, near the origin of the ophthalmic artery, it courses below the optic chiasm and traverses medially and upward to join the normally positioned AComA. This variant has high prevalence of intracerebral aneurysm formation, particularly in the ACA–AComA complex.

Asymmetry of A1: Asymmetry (larger than the opposite side) of the A1 segment has an important impact on likelihood of aneurysm formation in the AComA. The end on hemodynamic impact of pulsatile flow through the larger A1 segment directed against the anterior wall of the A1–AComA junction is thought to explain high incidence of aneurysm formation in this location. This also explains why 70% of the AComA aneurysms are directed anteriorly. Up to 80% of the AComA aneurysms have significant A1 asymmetry.

Branches

Proximal ACA branches

- **Anterior perforating branches:** There are two sets of anterior perforating branches, inferiorly directed and superiorly directed, which arise from the A1, A2 segments, and sometimes also from the AComA. The inferiorly directed branches supply the optic chiasm and optic nerve. Superiorly directed medial lenticulostriate branches are 2 to 15 in number and supply anterior hypothalamus, septum pellucidum, columns of fornix and anterior commissure, genu of corpus callosum, and anterior aspect of striatum.
- **Recurrent artery of Heubner:** A prominent laterally directed lenticulostriate vessel (largest and longest of the perforating vessels) arising most commonly from the proximal A2 segment (may also arise from A1 and AComA). It is usually better demonstrated in the contralateral carotid injection. It supplies anterior aspect of the striatum, anterior limb of internal capsule, and the paraterminal gyrus. This is an important source of preservation of blood supply to the basal ganglia during occlusion of MCA. Occlusion of recurrent artery of Heubner causes hemiparesis that is most prominent in the face and superior extremity.

- **Cortical branches:** Usually do not arise from the precommunicating segment. The first one or two orbital branches (aka orbitofrontal branches) arise from the proximal A2 segment and supply the orbital surface of the frontal lobe. There are also a group of branches arise from the mid A2; the largest one is frontopolar artery.

Distal ACA branches: At the genu of the corpus callosum, the ACA bifurcates into two main vessels, pericallosal artery and callosomarginal artery. Pericallosal artery is rather continuation of the ACA trunk and courses posteriorly for a variable distance above the corpus callosum. The callosomarginal artery is the smaller branch that passes over the cingulate gyrus at the cingulate sulcus. The distal groups of branches, parietal branches, supply the precuneus and adjacent cortex.

Clinical Significance

The pericallosal artery can be compressed posteriorly (A5) in subfalcine herniation, angiographically appears as steplike deformity in the AP projection. The anterior part (A4) is usually displaced to the opposite side rather than being compressed in subfalcine herniation, because the artery is located well below the free margin of falx. Following trauma, there may be distal pericallosal artery pseudoaneurysm formation at the constraints of the free margin of the falx. In severe hydrocephalus, the pericallosal artery is displaced superiorly and takes a smooth curve, best demonstrated in lateral projection.

MIDDLE CEREBRAL ARTERY

The middle cerebral artery supplies most of the eloquent cortex including the somatosensory and motor cortex. The artery is divided into four segments: M1, from ICA bifurcation until the MCA turns superiorly into the insula (the genu); M2 segment extends from the genu to the circular sulcus; M3 extends from circular sulcus to the opercular turn of the branches; and the M4 segments are the branches visible in the lateral convexity of the hemisphere.

The MCA can divide into up to four branching patterns: a single trunk with no main division, a bifurcation, a trifurcation, and a quadrifurcation. The most common branching pattern is bifurcation with a superior and inferior division.

Most (70%) of the MCA aneurysms occur at its bifurcation. Aneurysm of the MCA trunk represents 10% of the aneurysms of this artery.

Branches

Lenticulostriate: There can be roughly 1 to 21 lenticulostriate branches, average being 10. Approximately 80% of the branches arise from the posterosuperior aspect of the MCA trunk, the remaining arise from

the branches of the MCA. They supply the anterior commissure, internal capsule, dorsal aspect of head of caudate nucleus, putamen, lateral globus pallidus, and substantia innominata.

Cortical: The cortical branches supply most of the lateral convexity of cerebral hemisphere, the insular and opercular cortex, the lateral part of the orbital surface of the frontal lobe, and lateral and inferior part of the temporal lobe anteriorly. The borderline region between the distributions of the cerebral arteries is known as watershed zone. These regions are at risk for infarction in the case of severe hypotension, and also, these are the regions for lodging blood-borne diseases (i.e., infection [including mycotic aneurysm] and tumor cell for metastasis).

Frontal lobe branches

- **Orbitofrontal artery:** This branches anteriorly, superiorly, and laterally to vascularize the inferior frontal gyrus. Orbitofrontal branch supplies Broca's area, frontal eye field, and the premotor strip; patients with stroke involving these arteries in the dominant lobe will present with expressive aphasia.
- **Prefrontal arteries:** These arteries fan over the insula and supply the inferior and middle frontal gyrus. Near the superior frontal gyrus, their anastomose with branches of pericallosal arteries.
- **Pre-Rolandic artery:** The artery courses over the media surface of the operculum and supplies the posterior parts of the middle and inferior frontal gyri as well as the lower parts of the precentral gyrus.
- **Rolandic arteries:** The artery supplies posterior precentral gyrus and the inferior portion of the postcentral gyrus coursing inside the central sulcus.

Parietal lobe branches

- **Anterior parietal**
- **Posterior parietal**
- **Angular:** The angular artery is a significant terminal branch of the anterior or middle trunk of the MCA. It emerges from the Sylvian fissure and passes over the anterior transverse temporal gyrus and usually divides into two branches supplying angular and supramarginal gyrus.
- **Temporaloccipital:** This is the longest cortical artery. It courses posteriorly after exiting from the Sylvian fissure parallel to the superior temporal sulcus and supplies the superior and inferior occipital gyri.

Temporal lobe branches

- **Temporopolar**
- **Anterior temporal**
- **Middle temporal**
- **Posterior temporal**

ARTERIES OF POSTERIOR CIRCULATION

VERTEBRAL ARTERIES

Of the two vertebral arteries, the left is the dominant artery in roughly 60% of cases. Both the vertebral arteries are equal in size in 25% of cases. The vertebral arteries are described in four segments. The first segment is from its origin at subclavian artery to its entry into the foramen transversarium usually at C6 vertebral body. The second segment is the course in the foramen transversarium from C6 to atlas. The third segment is a horizontal curvy course in superior surface of posterior arch of atlas. The fourth segment is the intracranial course after this pierces the atlantooccipital membrane and enters into the cranial cavity until the basilar confluence.

Clinical Significance

Vertebral artery injury: Vertebral artery injury occurs most commonly in the foraminal segment.

- Intimal tear: This is the most subtle form of injury. A free flap may be demonstrated within the lumen, or may not be seen in imaging.
- Dissection: When tear of the intima leads to dissection of the blood into the arterial wall.
 - Occlusion: If the blood accumulates between the intima and the media, which is more common, it will compress the arterial lumen.
 - Pseudoaneurysms: If the blood dissects between the media and adventitia, it will cause swelling of the arterial wall or pseudoaneurysm formation.
 - Transection: This is the most severe type, usually fatal.

Atherosclerotic disease: Atherosclerotic disease is common where the artery pierces the dura.

Dissecting aneurysms of the vertebrobasilar system: This is a special group of aneurysm, which involves the vertebral artery, particularly the V1 and V3 segments of the vertebral artery due to defect in the internal elastic lamina and development of a false lumen between internal elastic lamina and media of the arterial wall. The common angiographic findings are focal dilation of the lumen, luminal stenosis or occlusion, string of pearl-like (both occlusion and dilation), and double lumen.

Subclavian steal syndrome: Occurs in cases of proximal subclavian artery stenosis with retrograde flow in the vertebral artery toward the distal subclavian artery causing transient vertebrobasilar symptoms. Color Doppler ultrasound and phase-contrast MRA are useful to diagnose this condition.

Rotational vertebral artery syndrome: Consisting of attacks of vertigo, nystagmus, and tinnitus elicited by

head-rotation-induced compression of the dominant vertebral artery.

Branches

Usually, classified as medial and lateral. Medial branches arise from the distal half of the vertebral artery and supply the anterior medulla and pyramid. The most prominent inferiorly directed medial branch is the anterior spinal artery. The lateral branches are posterior inferior cerebellar artery (PICA) and circumferential branches to the inferior cerebellar peduncle, lateral medulla, and olivary structures.

Clinical Significance

The PICA is the largest branch of the vertebral artery. Stroke involving the PICA territory has a classic spectrum of presentation which is also known as lateral medullary syndrome or Wallenberg syndrome, which includes contralateral deficits in pain and temperature sensation from body (involvement of lateral spinothalamic tract), ipsilateral loss of touch, pain, and temperature sensation from face (involvement of spinal trigeminal nucleus), dysphagia, hoarseness, diminished gag (involvement of nucleus ambiguus), vertigo, diplopia, nystagmus, vomiting (vestibular system involvement), ipsilateral Horner syndrome (descending sympathetic fiber involvement), and ipsilateral cerebellar sign (involvement of the inferior cerebellar peduncle).

BASILAR ARTERY

The basilar artery is formed by fusion of two vertebral arteries at the pontomedullary junction. It is about 32 mm in length and approximately 4 mm in diameter. The narrowest part of the artery is at the level of the origin of superior cerebellar artery, the embryologic junction between the anterior and posterior circulation.

Branches

Brainstem perforators: There may be up to 17 perforator branches from the basilar artery supplying the brainstem. There are two groups of arteries: short median branches, which enter in the pons in the midline in the median sulcus and penetrate up to the floor of the fourth ventricle; the other group encircles the brainstem and enters into the pons more laterally. These branches are very important as they supply the corticospinal and corticobulbar tracts, pontine nuclei, and motor nuclei of midbrain and pons.

Anterior inferior cerebellar artery: It usually arises from the proximal or middle third of the basilar artery. The artery of the internal auditory meatus arises from this artery. For chemoembolization of the posterior fossa tumor, the microcatheter should always be

placed above the level of AICA as some of the chemotherapeutic drugs are toxic to the cochlea and can cause permanent hearing loss. About 8% (error) cases of trigeminal neuralgia due vascular compression of the trigeminal nerve roots is caused by this artery.

Superior cerebellar artery: It supplies the lower midbrain, upper pons, upper vermis, and superior aspect of the cerebellar hemisphere. SCA is the most common artery (50%) to cause trigeminal nerve root compression.

Posterior cerebral arteries (see below)

Clinical Significance

Atherosclerotic disease: Unlike the MCA strokes, which are more commonly embolic in nature, the acute vertebrobasilar strokes are usually thrombotic.

Basilar tip aneurysms: Approximately 10% to 18% of intracranial aneurysms occur in the posterior circulation, of which more than half occur at the basilar tip. These aneurysms are very difficult to approach surgically, particularly if they are directed anteriorly and if there is high basilar bifurcation of the basilar artery in relation to the posterior clinoid process.

POSTERIOR CEREBRAL ARTERIES

In fetal life, the posterior cerebral artery arises from ICA. But most commonly, by birth the main supply to the PCA artery is from the basilar artery.

SEGMENTATION

Like other cerebral arteries, the PCA is also described in three segments: P1 being the segment from the origin of PCA up to the junction of PComA; the P2 segment is from the PComA junction to the posterior aspect of midbrain, and the P3 segment being the lateral aspect of the quadrigeminal cistern around the pulvinar.

Clinical Significance

In the setting of asymmetric mass effect or severe temporal lobe herniation, the midbrain may become compressed against tentorium compressing the PCA or its branches, which normally travel between these two. If the branches are compressed between these two structures, there will be a midline brainstem hemorrhage, also known as Duret hemorrhage.

Branches

Branches to the thalamus and brainstem

- **Thalamoperforator arteries:** There are two groups of thalamoperforator arteries (anterior, 7 to 10 in number and posterior up to 8 in number). The anterior group

supplies thalamic nuclei, posterior aspect of the optic chiasm, proximal part of the optic radiation, posterior hypothalamus, and part of the cerebral peduncle. The posterior group supplies thalamus, subthalamic nuclei, midbrain structures including substantia nigra, red nucleus, oculomotor and trochlear nuclei, the posterior portion of the internal capsule, and the cisternal segment of the oculomotor nerve. When a dominant thalamoperforator artery supplies the thalami bilaterally, it is sometimes referred to as artery of Percheron.

- **Thalamogeniculate arteries:** These may be up to 12 in number. They supply lateral thalamus, posterior limb of internal capsule, and part of the optic tract. Stroke involving these arteries give rise to classic lateral thalamic Dejerine-Roussy syndrome.
- **Peduncular perforator arteries:** These supply the peduncles.

Branches to the ventricles

- **Medial posterior choroidal artery:** This may be multiple in up to 40% of cases. Most commonly, it arises from the P2 segment. On lateral projection, it appears classically as “3” shaped. It supplies the choroids plexus of the third ventricle and may also supply the massa intermedia, stria medullaris, and fornix.
- **Lateral choroidal arteries:** These may be up to nine in number. They arise from P2 segment. They supply the glomus of the choroids plexus of the atrium and the body of the choroids plexus of the lateral ventricle.

Cortical branches

Proximal PCA (P2 segment):

- **Anterior temporal artery:** This is the first cortical branch and anastomoses with the anterior temporal branch of the MCA.
- **Posterior temporal artery:** This is the second cortical branch and arises from the middle of the P2 segment.
- **Distal PCA (P3 & P4 segment):** Distally PCA terminates into two trunks, which ultimately give rise to two sets arteries, medial and lateral:
 - **Medial arteries**
 - **Parieto-occipital:** It supplies the cuneus, precuneus, and lateral occipital gyrus, and may occasionally extend to medial aspects of precentral gyrus and superior parietal lobule.
 - **Calcarine:** This supplies the primary visual cortex and may also supply to the lingual gyrus and cuneus. Unilateral occlusion causes homonymous hemianopsia with varying degree of macular sparing. Bilateral occlusion causes Anton syndrome, sudden bilateral cortical blindness with preserved pupillary reaction and denial of visual loss.
 - **Splenic:** It may arise either from the branches of the PCA or the PCA trunk itself. Sometimes, it is considered as the posterior pericallosal artery.

- Lateral arteries:
 - Anterior inferior temporal arteries.
 - Middle inferior temporal arteries.
 - Posterior inferior temporal arteries.

ARTERIES OF THE CIRCLE OF WILLIS

Circle of Willis is an intercommunicating arcade of collateral arteries (consisting of ICAs, A1 segments, AComA, PComA, P1 segments, and the basilar artery) at the base of the skull before reaching the brain. This arterial arcade balances flow in different regions of the brain. If one portion is hypoplastic, the blood flow is augmented by the collaterals. Complete circle of Willis is present at about one-fourth of the cases. Common variations include hypoplastic PComA, hypoplastic or absent A1, fetal origin of PCA, and infundibular origin of the PComA.

VENOUS SYSTEM OF THE BRAIN

SUPRATENTORIAL

EXTRADURAL

Diploic Veins

These are endothelial-lined vascular spaces within the diploic spaces. They do not have valves.

Dural Sinuses

Superior sagittal sinus (SSS): It is the largest dural sinus. It extends anteriorly from the crista galli to the torcular Herophili, the confluence of SSS, straight sinus, and occipital sinus. The sinus is covered by a fold of falx cerebri. The sinus gradually enlarges in size as it traverses posteriorly and receives numerous tributaries from the superficial veins draining the convexities. There are multiple prominent arachnoid granulations in the posterior aspect of the SSS, which may appear as filling defects in angiography (CTA and MRA) particularly, in old age.

The *inferior sagittal sinus* is much smaller structure than the SSS and runs posteriorly through the free edge of falx and meets the vein of Galen to form the straight sinus. It receives tributaries from the falx, cingulum, and medial hemisphere.

The union of the inferior sagittal sinus and the great vein of Galen form the *straight sinus*. It runs posteroinferiorly down to the torcular Herophili and receives multiple tributaries from the infratentorial veins.

Torcular Herophili is the confluence of SSS, straight sinus, and occipital sinus. It usually drains into two transverse sinuses. These may be equal in size or more often asymmetric, in which case the right transverse sinus is usually larger.

The *transverse sinuses* run anterolaterally from their origin at the torcula and meet the superior petrosal sinus and continue as sigmoid sinus.

Sigmoid sinus is the anteroinferior continuation of the transverse sinus down to the jugular bulb from where it continues as internal jugular vein.

Petrosal sinuses (superior and inferior) are two venous channels, which communicate with the cavernous sinus superiorly down to the ipsilateral sigmoid sinus and jugular bulb, respectively.

The *occipital sinus* is formed at the posterior margin of the foramen magnum by the confluence of the tributaries of the marginal plexus of vein.

Sphenoparietal sinus drains the superficial Sylvian vein into the cavernous sinus along the lesser wing of sphenoid.

Cavernous sinus is located on either side of the sphenoid body extending anteriorly from the superior orbital fissure to the petrous apex posteriorly. This sinus communicates extensively with extracranial and intracranial venous structures and sinuses. The ICA with sympathetic plexus is on the medial wall, the abducens nerve at the center of the sinus lateral to the ICA and medial to the oculomotor and trochlear nerves, as well as the ophthalmic and maxillary divisions of the trigeminal nerve in the lateral wall.

- Communications of the cavernous sinus:

- *Anteriorly*: Receives the superior ophthalmic vein through the superior orbital fissure. Laterally, receives sphenoparietal sinus.
- *Posteriorly*: Communicates with the transverse sinus by means of the superior petrosal sinus; with the internal jugular vein through the inferior petrosal sinus.
- *Medially*: Communicates with each other by means of the anterior and posterior intercavernous sinuses. Also communicates with the pterygoid venous plexus through the foramen Vesalii, foramen ovale and foramen lacerum, and with the angular vein via the ophthalmic vein.

- *Cavernous sinus syndrome*: Cavernous sinus syndrome is symptom complex due to pathologies of the cavernous sinus (carotido-cavernous fistula, carotid artery aneurysm, infection, trauma, tumors, and inflammatory diseases involving the sinus). The symptoms include ophthalmoplegia, chemosis, proptosis, trigeminal sensory loss, and Horner syndrome.

INTRADURAL

Deep

Medullary veins: Numerous angiographically undetectable small deep veins originatings 1 to 2 cm deep to

the cortex, coursing medially through the subcortical white matter, and draining into the subependymal veins that course along the ventricular wall. These veins are prominent in susceptibility weighted imaging and the in the raw images of the perfusion weighted imaging in cases of tumefactive demyelination and also in some low-grade gliomas.

After receiving blood from the medullary veins, the subependymal veins aggregate to form the larger tributaries. The medial group consists of anterior septal vein that drains the deep frontal lobe and runs along the septum pellucidum; lateral group, veins that drain the caudate nucleus, are named as anterior/longitudinal caudate veins which drain into the thalamostriate vein. The anterior septal vein joins the thalamostriate veins at the foramen of Monro, the “venous angle,” to form the internal cerebral vein. Internal cerebral veins are midline paired structures that run posteriorly in the roof of the third ventricle and meet below the tip of the splenium to form the great cerebral vein (of Galen).

The paired basal veins of Rosenthal are each formed in the region of anterior perforated substance by the union of the anterior cerebral veins, deep middle cerebral vein, and striate veins. After its formation, each basal vein passes posteriorly around the cerebral peduncle and terminates into the great cerebral vein (vein of Galen).

The great cerebral vein is a median venous trunk, about 2 cm long and is formed by the union of two internal cerebral veins. After its formation, the trunk abruptly turns upward around the splenium of the corpus callosum and then courses posterior and ends at the anterior end of the straight sinus near the tentorial apex.

Superficial

These include superior cerebral veins, superficial middle cerebral veins, and inferior cerebral veins. As these veins are so variable in number and configuration, most are unnamed.

Superior cerebral veins: About 8 to 10 in number, they collect the blood from superolateral and medial surfaces of the hemispheres and drain into the SSS. The veins course obliquely upward and forward to meet the SSS and drain against the flow of the blood flow in the SSS. This particular orientation helps prevent collapse of the mouth of the cerebral veins during raised intracranial pressure.

Superficial middle cerebral vein: This is a prominent but inconstant vein (or group of veins) that drains blood from the lateral surface of the hemisphere, runs along the posterior ramus and stem of the lateral sulcus, and empties into the cavernous sinus. The superior (vein of Trolard) and/or inferior (vein of Labbe) anasto-

motoc veins connect the superficial middle cerebral veins with the SSS and transverse sinus, respectively.

Inferior cerebral veins: These veins drain the inferior surface and ventral part of the lateral surface of hemisphere. Those from the orbital surface join the sphenoparietal and cavernous sinuses and those from the tentorial surface terminate into the cavernous, superior petrosal, and transverse sinuses.

INFRATENTORIAL

The major infratentorial veins are described as superior (Galenic veins) that drain blood from the median cerebellum and brainstem usually into the vein of Galen; anterior (petrosal), which drain blood from cerebellum, pons, and medulla into the superior petrosal sinus; and the posterior (tentorial) drain blood from the cerebellar hemispheres and drain into the tentorial sinuses.

Venous sinus thrombosis: Venous sinus thrombosis is a relatively rare condition that occurs usually because of a hypercoagulable state but also may be because of slow flow, extrinsic compression or invasion of the sinus, dehydration and pregnancy/postpartum state. It presents with a myriad of clinical symptoms and imaging manifestations (delta sign in noncontrast CT and reverse/empty delta sign in CECT).

QUESTIONS AND ANSWERS

- Which of the following is *true* regarding fibromuscular dysplasia of the carotids?
 - Typically has string sign appearance in internal carotid artery
 - Rarely associated with intracranial aneurysms
 - More commonly involves external carotid artery than internal carotid artery
 - Usually bilateral
 - More common in men

ANSWER: D. Sixty-five percent of cases are bilateral.

2. What is the predominant arterial supply for hippocampus?
- Anterior cerebral
 - Middle cerebral
 - Posterior cerebral
 - Anterior choroidal
 - Recurrent artery of Heubner

ANSWER: C. Hippocampal artery branch of the PCA supplies the hippocampal gyrus.

3. Which artery supplies the posterior limb of the internal capsule?
- Anterior choroidal
 - Recurrent artery of Heubner (Medial lenticulostriate)
 - Lateral lenticulostriate
 - Anterior cerebral

ANSWER: C. The medial lenticulostriate artery supplies anterior limb of internal capsule.

4. A common carotid injection demonstrates occlusion of the ICA immediately above the bifurcation with subsequent filling of the ipsilateral intracranial internal carotid artery. What collateral supply does this most likely represent?
- Collaterals via the AComA
 - Collaterals via the PComA
 - Collaterals via the ophthalmic artery
 - An intact circle of Willis
 - Collaterals via the ipsilateral superficial temporal artery

ANSWER: C. This is one of the common locations of collaterals from external carotid to internal carotid artery.

5. Which one of the following vessels is affected in the Wallenberg (lateral medullary) syndrome?
- Contralateral SCA
 - Contralateral AICA
 - Ipsilateral SCA
 - Contralateral PICA
 - Ipsilateral PICA

ANSWER: E. Ipsilateral PICA typically causes Wallenberg syndrome.

6. You identify an enlarged tentorial branch of the meningohypophyseal trunk. What is the most likely etiology?
- Dural AVM
 - Vestibular schwannoma
 - Posterior fossa glioma

- Jugular paraganglioma
- Cerebellar hemangioblastoma

ANSWER: A. It is unlikely to have blood supply from meningeal branches in other pathologies.

7. Patient presents with neck pain and Horner syndrome on the left after skiing and a fall, what is the most likely diagnosis?
- Vertebral dissection
 - Internal carotid dissection
 - Internal carotid occlusion
 - Cerebral vascular accident
 - Vertebral occlusion

ANSWER: B. Sympathetic nerves supplying the ocular muscles course close to the ICA at the neck. Dissection may paralyze these sympathetic nerves.

8. What is the etiology of subclavian steal syndrome?
- Subclavian stenosis proximal to the origin of the vertebral artery
 - Subclavian stenosis distal to the origin of the vertebral artery
 - Stenosis of the ipsilateral vertebral artery
 - Stenosis of the contralateral vertebral artery

ANSWER: A. Subclavian stenosis proximal to the origin of the vertebral artery “steals” the blood from cranial circulation into the arm during exercise.

9. Which of the following is an example of carotid-basilar communication?
- Ophthalmic artery
 - Posterior meningeal artery
 - Recurrent artery of Hubner
 - Otic artery
 - Temporal artery

ANSWER: D. Other arteries do not have any carotid-basilar communication.

10. A 37-year-old man was painting his roof when he acutely developed left tongue deviation, left facial numbness, ataxia, and right body weakness. What is the most likely diagnosis?
- Carotid artery dissection
 - Vertebral artery dissection
 - Middle cerebral artery infarct
 - Wallenberg syndrome
 - Anterior cerebral artery infarct

ANSWER: B. Prolonged extension of the neck may cause the vertebral artery dissection, which produces these symptoms.

STROKE AND CEREBROVASCULAR DISEASES OF THE BRAIN

*Ahmed Kamel Abdel Aal and
Joseph C. Sullivan III*

STROKE

INTRODUCTION

Stroke is a general nonspecific term that indicates rapid loss of the brain functions because of disturbance in blood vessels. The major causes of stroke in children include congenital heart disease with emboli, dissection, hemorrhage from vascular malformation, idiopathic progressive arteriopathy of childhood, coagulopathy, and drug abuse. In middle-age and old adults, the causes of stroke include arterial thromboembolism, nontraumatic intracranial hemorrhage, intracranial veno-occlusive disorders, hemorrhage from vascular malformation, neoplasms, and coagulopathy.

The risk factors for stroke include hypertension, coronary heart disease, heart failure, atrial fibrillation, diabetes mellitus, high blood lipid levels, cigarette smoking, alcohol consumption, transient ischemic attack (TIA), and asymptomatic carotid atherosclerotic disease.

CEREBRAL ISCHEMIA AND INFARCTION

Ischemia and infarction remain the second most common cause of death worldwide. Cerebral ischemia and infarction have a variety of causes including thrombosis, embolism (from cardiac or noncardiac source), dissection, vasculitis, or generalized hypoperfusion.

The ischemic area consists of a central core of severe ischemia that will progress to infarction and has a cerebral blood flow (CBF) that is less than 12 to 18 mL/100 gm/min. This is surrounded by a peripheral less ischemic region “penumbra,” containing cells that are still viable, but at risk of infarction if not salvaged, and with a CBF less than 20 to 23 mL/100 gm/min.

The most vulnerable parts of the brain to ischemia are the CA1 layer of the hippocampus, the third, fifth, and sixth layers of cortex, and the basal ganglia. Ischemia leads to energy depletion and failure of sodium/potassium pump leading to accumulation of intracellular sodium. High concentration of sodium draws water in-

side the cells by osmosis leading to cell swelling and cytotoxic edema. If the process continues, the cell membrane integrity is lost and the cells rupture leading to disruption and breakdown of the blood–brain barrier and the development of vasogenic edema.

Lacunar infarcts are small deep cerebral infarcts located predominantly in the basal ganglia and thalamus. They result from occlusion of small penetrating arteries in the deep gray matter because of various etiologies. They are strongly related to hypertension, and most of these lacunar infarcts are clinically silent.

Watershed or border-zone infarcts are caused by generalized hypoperfusion and/or hypoxic states resulting in insufficient blood flow and/or oxygenation to meet the metabolic demands of the brain. Causes include severe prolonged hypotension, resuscitation after cardiac arrest, and carbon monoxide inhalation. The process may be so severe involving the whole cerebral hemispheres. In less severe cases, the margins of major arterial territories will be involved. Watershed infarcts can also occur in the deep white matter watershed areas within the centrum semiovale leading to small infarcts in a linear orientation producing “string of pearls” appearance.

In the acute stage (6 hours–3 days), Noncontrast CT mainly serves to exclude hemorrhage as the cause of stroke, which will definitely alter the management of these patients. However, it may help in the diagnosis of infarction since it may show hyperdensity within an artery representing acute thrombus. “Dot sign” may also be seen and represents hyperdense dot in the sylvian fissure caused by thrombus in an MCA branch. Loss of gray–white matter distinction, with obscuration of the deep gray matter nuclei and loss of the cortical ribbon may also be noted. Hypodensity in a specific vascular territory, gyral swelling, and sulcal effacement are less commonly seen.

In the subacute stage (4 days–4 weeks), a wedge-shaped hypodense area is usually seen along the distribution of a vascular territory or in a watershed area depending on the etiology. Gyral swelling will start to decrease at 10 days. Hemorrhagic transformation of the infarcted area can be seen in up to 25% of cases, especially large infarcts, and is primarily because of reperfusion of infarcted areas with disrupted blood–brain barrier. The prognosis in this case is worse than bland infarct.

In the chronic stage (greater than 4 weeks), the infarct becomes more hypodense and there is prominence of the cortical sulci and dilatation of the adjacent portions of the ventricles.

In the acute stage, contrast-enhanced CT will demonstrate enhancement of the cortical vessels because of

TABLE 5-1 CBV, CBF, and MTT Values for Ischemia and Infarction

	CBF	CBV	MTT
Ischemia	Decreased (<20–23 mL/100 gm/min)	Normal	Increased
Infarction	Decreased (12–18 mL/100 gm/min)	Decreased (<2.0–2.5 mL/100 g)	Increased (>6 sec or >1.45% increase over contralateral normal side)

slow antegrade flow or retrograde flow from collaterals. Cortical gyral enhancement begins at 2 days, peaks at 2 weeks, and starts to disappear at 2 months. CT perfusion is done as part of the workup of these patients in some institutions. The cerebral blood volume (CBV), CBF, and mean transit time (MTT) values help determine infarcted areas of the brain as well as the ischemic yet salvageable areas (Table 5-1).

CT angiography (CTA) will show stenosis or occlusion of the different arteries supplying the brain and the presence of collateral flow.

On MRI, diffusion imaging is the most sensitive sequence in detecting hyperacute infarction (<6 hours). Diffusion imaging mainly measures diffusion of water molecules in the extracellular space. In the hyperacute stage, cytotoxic edema leads to reduction in volume of extracellular space and restriction of motion of the water molecules in that space. The area of restricted diffusion is seen as hyperintense on DWI and hypointense on ADC maps. After 7 to 10 days, the cells start to rupture and vasogenic edema develops leading to increase in the volume of the extracellular space and the diffusion abnormalities will revert to normal. This is known as the “pseudonormal” stage and can last up to 4 weeks. The infarcted area will be hyperintense on DWI because of “T2 shine-through” but will be isointense on ADC maps that represent a more accurate measurement of diffusion. Thereafter and in the chronic stage, diffusion is increased because of continued increase in extracellular water, tissue cavitation, and gliosis. The area of restricted diffusion represents irreversible nonsalvageable ischemic area and correlates with the area of final infarct. However, some reports document reversibility of diffusion abnormality, but is not considered the general trend.

The combination of diffusion and perfusion imaging provide more information than either technique alone. In cases of arterial occlusion, areas of decreased diffusion and perfusion represent nonviable tissue or the core of the infarct. The more peripheral areas characterized by normal diffusion and decreased perfusion represent areas of “ischemic penumbra,” which will progress to infarction unless early reperfusion occurs. In the infarcted area, there is decreased rCBV, rCBF, and increased rMTT. In areas of “ischemic penumbra,” the rCBV will be normal or increased. In the subacute stage, the rCBV will increase because of reperfusion hyperemia.

On conventional MRI sequences, acute infarction will demonstrate gyral swelling. The infarcted area may

appear normal in the hyperacute stage, but will be hypointense on T1-weighted images and hyperintense on T2-weighted image and FLAIR images in the acute stage. The presence of signal intensity within the arteries on these sequences indicates occlusion. In the subacute stage, blood products may be seen within the infarct if hemorrhagic transformation occurred, producing variable signal depending on the age of hemorrhage. In the chronic stage, encephalomalacia will ensue, producing CSF-like signal, which will be low on T1, high on T2, and low on FLAIR images. Encephalomalacia will be surrounded by gliosis that demonstrates high T2 and FLAIR signal. GRE images will show hypointense margin around the infarct because of hemosiderin in adjacent gliosis. Wallerian degeneration will lead to abnormal low T1 and high T2 signal along the course of the corticospinal tracts.

Postcontrast T1 images will show different enhancement patterns depending on the stage of the infarct. Intravascular enhancement may occur in the acute stage because of slow flow. In the subacute stage, meningeal and cortical enhancement will be seen and enhancement will start to disappear at 2 month.

MRA is helpful in demonstrating occlusion of large arteries. Conventional (catheter) angiogram is usually reserved for case that will benefit from interventional treatment. Abrupt arterial cut-off or arterial tapering may be seen. There may be slow antegrade flow or retrograde flow from collaterals. Intra-arterial infusion of recombinant tissue plasminogen activator (r-TPA) is used to thrombolysed the clot if the patient presents within 6-hours window. Alternatively, it can be infused intravenously, with a window of 3 hours only. The use of r-TPA significantly improves the outcome and prognosis. The main factors that affect the outcome include administration within the therapeutic window, nonhemorrhagic infarct, and infarct size that is less than one-third of the MCA territory. Devices that retrieve clots are also used but are associated with a high complication rate if clot fragmentation occurred.

NONTRAUMATIC INTRACRANIAL HEMORRHAGE

This accounts for approximately 10% of stroke cases. The causes of nontraumatic intracranial hemorrhage according to different age groups are listed (Table 5-2).

TABLE 5-2 Causes of Nontraumatic Intracranial Hemorrhage by Age Group

AGE GROUP	CAUSES
Premature infants	Germinal matrix hemorrhage
Term infants	Trauma during delivery Hypoxic ischemic injury
Young adults	Aneurysm Vascular malformation Hemorrhagic infarct Hypertensive intracerebral hemorrhage Hemorrhagic neoplasm Drug abuse (e.g., cocaine) Vasculitis
Elderly adults	Hypertensive intracerebral hemorrhage Amyloid angiopathy Hemorrhagic infarct Coagulopathy Hemorrhagic neoplasm

HYPERTENSIVE INTRACEREBRAL HEMORRHAGE

Hypertensive intracerebral hemorrhage is the most common cause of nontraumatic intracerebral hemorrhage in adults accounting for 70% to 90% of cases. The most common location is in the basal ganglia and is because of rupture of lenticulostriate artery aneurysm (Charcot–Bouchard aneurysm). Other less common locations include the thalamus, pons, cerebellum, and white matter.

HEMORRHAGIC INFARCTION

It is usually owing to hemorrhagic transformation of bland infarct as a result of reperfusion. However, arterial infarcts can be primarily hemorrhagic and will usually have an embolic etiology. Venous infarcts are more commonly hemorrhagic and caused by veno-occlusive disease such as dural venous sinus, cortical venous, and deep venous thrombosis.

AMYLOID ANGIOPATHY

It results from extracellular deposition of amyloid in the media and adventitia of small- and medium-sized arteries. Pathologically, there are microaneurysms and fibrinoid degeneration. There is loss of elasticity and increased fragility secondary to replacement of internal elastic lamina by amyloid deposits leading to intracerebral hemorrhage. Amyloid angiopathy accounts for approximately 10% to 20% of nontraumatic intracerebral hemorrhages and is considered the second most common cause in elderly adults. Lobar hemorrhages at dif-

ferent ages may be seen most commonly in the frontal and parietal lobes. Multifocal tiny subcortical hypointensities may also be seen on T2-weighted and GRE images representing chronic microbleeds.

VENO-OCCLUSIVE DISORDERS

These include dural venous sinus, cortical venous, and deep venous thrombosis. A variety of predisposing factors may lead to veno-occlusive disease and are listed (Table 5-3).

DURAL SINUS THROMBOSIS

Thrombosis may involve the dural venous sinus and extend into cortical vein tributaries. The most commonly involved is the superior sagittal sinus, and females are more commonly affected than males.

On noncontrast CT, the thrombosed sinus appears hyperdense, and if the thrombus extends into a cortical vein, a hyperdense linear cordlike structure may be seen. Because of obliteration of the venous drainage of the brain parenchyma, a venous infarct may be seen in 50% of cases, and has a high tendency to be initially hemorrhagic or shows hemorrhagic transformation on follow-up scans. On contrast-enhanced CT, enhancement of the dura surrounding the nonenhancing thrombus will produce the “empty delta” sign which is seen in 25% of cases. With the advent of multidetector CT scanners, CT venography may be performed and will show complete occlusion or intraluminal filling defect within the sinus.

On MRI, the normal flow void within the sinus is replaced by intraluminal thrombus. The signal intensity of the thrombus will depend on its age. It is difficult to detect the thrombus in the acute phase, since deoxyhemoglobin will be isointense on T1-weighted images and hypointense on T2 images and therefore indistinguishable from normal flow voids in most cases. In the subacute stage, the thrombus will appear hyperintense on both T1 and T2 images. The cortical veins may also be involved and will display similar signal intensity to thrombosed venous sinus. Venous infarct may occur producing gyral swelling and T2 and FLAIR hyperintensity in the

TABLE 5-3 Predisposing Factors for Intracranial Venous Thrombosis

Trauma
Neoplasms
Infection: sinusitis, mastoiditis
Pregnancy and oral contraceptives
Dehydration
Metabolic: thyrotoxicosis, cirrhosis
Coagulopathy: factor V Leiden, protein S deficiency
Vasculitis: Behcet

involved brain parenchyma. In case of hemorrhagic infarction or hemorrhagic transformation, the signal intensity will be complex and will depend on the age of hemorrhage. Diffusion imaging may show the infarct earlier than conventional sequences, and unlike arterial infarcts, the signal abnormality is reversible in most cases. Postcontrast images will show peripheral enhancement around the acute thrombus. GRE images will demonstrate blooming in the thrombosed sinus and within a hemorrhagic infarct. In chronic sinus thrombosis, healing by organizing fibrous tissue will produce isointense to hypointense signal in the sinus that will enhance on postcontrast images.

MRV is very helpful in establishing a diagnosis in most cases. 2D or 3D time of flight (TOF) may be used and will show absence of flow in the thrombosed sinus. If there is partial recanalization, the sinus will have a shaggy or frayed appearance. Enlarged collateral venous channels may also be seen. TOF MRV is limited in the subacute stage by the T1 hyperintensity of the thrombus, which falsely appears as patent sinus with normal flow. Therefore, TOF MRV images should always be evaluated alongside the source images and conventional sequences, or alternatively, phase-contrast MRV may be performed, which does not have this limitation.

The 3D contrast-enhanced MRV (CE-MRV) is a more flow-insensitive technique relying on vascular enhancement, after contrast administration, for vessel detection. This technique has shown to provide much better depiction of normal venous structures, better outline of the thrombus, and is much faster relative to TOF MRV. However, its utilization in the diagnosis of chronic thrombosis has been questioned because of possible intense enhancement of the chronic thrombus that will produce an erroneous appearance of a patent sinus.

Catheter angiography may show occlusion of the involved sinus, with slow flow in the adjacent patent cortical veins. Collateral venous channels may also be seen. Partial recanalization in the subacute or chronic stage may produce irregular shaggy outline of the dural venous sinus. Percutaneous catheter directed thrombolysis or mechanical fragmentation can be performed.

CORTICAL VENOUS THROMBOSIS

Thrombosis of a cortical vein may be isolated or result from extension of thrombus from dural sinus. On NECT, the cortical vein will appear as hyperdense linear cord-like structure. Associated hypodensity in the brain parenchyma suggests venous infarct.

CECT and CT venography will show a filling defect within the thrombosed vein and will depict collateral venous channels. However, they have a limited value in chronic cases, since a chronic thrombus will also enhance simulating a patent vein. The appearance of a thrombosed cortical vein on MRI depends on age and is similar to that of a thrombosed sinus described above.

Venous infarction may be seen. Catheter angiography appears to be more sensitive than MRI in the detection of cortical venous thrombosis, and the ability to perform percutaneous treatment is another advantage. This can be achieved by transcatheter administration of thrombolytics and/or mechanically fragmentation of the clot.

DEEP VENOUS THROMBOSIS

This involves thrombosis of the internal cerebral veins, and the thrombus may extend into the vein of Galen, basal veins of Rosenthal, and then into the draining dural venous sinuses. Deep vein thrombosis is more commonly bilateral. If the internal cerebral veins are thrombosed, venous infarcts will involve the thalami and basal ganglia, producing abnormalities on CT and MRI. The imaging features of deep venous thrombosis on CT and MRI are similar to those described above for the dural sinus thrombosis.

CEREBROVASCULAR DISEASES OF THE BRAIN

ATHEROSCLEROTIC DISEASE

Atherosclerotic disease is a major cause of disability and is ranked third among the most common causes of death in industrialized countries. It accounts for 90% of cerebral thromboembolic infarcts. Atherosclerosis affects arteries of all size including the aorta and cerebral microvasculature. A variety of predisposing factors are known including hypertension, diabetes, smoking, high lipid profile, obesity, and old age.

The pathogenesis of atherosclerosis involves injury to the vascular endothelium and LDL deposition in the arterial intima. After a series of changes in the arterial wall, an atherosclerotic plaque is finally formed, which is a complex fibrotic lesion formed of a variety of cells including monocytes, macrophages and smooth muscle cells, as well as connective tissue and lipid deposits. Neovascularization occurs at the center of the plaque. Luminal narrowing occurs because of rupture of neovascularization leading to intraplaque/subintimal hemorrhage. Fracture and ulceration of the fibrous cap and intima at the surface of the plaque invites platelet aggregation and activates the coagulation cascade leading to the formation of thrombus on the surface of the plaque. The thrombus may shower emboli distally, that lodge in smaller arteries leading to infarction. Alternatively, the whole plaque may rupture leading to distal embolization.

The most common location for atherosclerosis is the CCA bifurcation and the proximal ICA. Intracranially, atherosclerotic disease is most commonly seen in the carotid siphons and vertebralbasilar arteries. The clinical presentation is variable and patients may be asymptomatic or present with carotid bruit, TIAs, or stroke.

Sonography is the most important noninvasive technique for visualization of extracranial cerebrovascular atherosclerotic disease. The use of real time gray scale and color Doppler ultrasound (US) provides more information than each technique alone. With gray scale US, the presence of calcification in the plaque can be determined. A hypoechoic plaque will have less calcium and more lipid than content than a hyperechoic plaque and is considered a potential risk factor for embolic stroke. Using peak systolic velocity (PSV) measurement in the CCA and ICA, and obtaining an ICA:CCA PSV ratio, the degree of stenosis can be determined.

Just like any other technique, ultrasound has falsies and disadvantages and is operator-dependant. Estimation of the degree of stenosis based on velocities may sometimes be inaccurate, especially in the presence of tandem severe stenoses, severe stenosis leading to decreased rather than increased PSV, contralateral CCA occlusion, ipsilateral external carotid artery (ECA) occlusion, or cardiac valve disease.

On noncontrast CT, calcification in the involved vessels may be seen. The plaque may display hypodense foci caused by their lipid content. Contrast-enhanced CT will opacify the residual artery lumen and may obscure visualization of calcified plaques on standard brain windows. With the advent of multidetector CT scanners, CTA has become an important tool for visualization of plaques and in determining the degree of stenosis and is a useful alternative for conventional angiography in patients who are at high risk of developing stroke during the procedure or those who refuse to do it. CTA can also characterize the constituents of the plaque by assigning different colors for different densities within the plaque. Plaques with high lipid contents are generally associated with more ischemic symptoms than calcified plaques and are therefore considered potential markers for ischemic stroke.

On MRI, the absence of flow voids in any pulse sequence indicates occlusion of the arterial lumen. T1 appears to be the most helpful sequence in visualizing vessel wall thickening and luminal narrowing caused by plaque formation. Complication of atherosclerotic vascular disease such as large or lacunar ischemic infarcts can also be seen.

Several MR angiographic techniques are used by different institutions. The 2D TOF MRA technique is usually used for imaging the extracranial neck arteries and the degree of stenosis may be determined. However, this technique tends to overestimate the degree of stenosis because of turbulence and eddy currents occurring at the stenotic lesion leading to loss of signal. In case of severe stenosis, there is usually severe loss of signal leading to “flow gap.” Furthermore, blood flowing in a direction parallel to, and in the plane of acquisition, will be subject to saturation and loss of signal, which is known as “in-plane saturation.” Therefore, this

technique cannot be used to image the intracranial cerebral arteries. This technique is also very sensitive to motion artifact that can be caused by arterial pulsation or swallowing.

The 3D TOF MRA technique is usually used for imaging the intracranial circulation. In this technique, thin slices are achievable and the technique is relatively fast. However, similar to 2D TOF MRA, it tends to overestimate the degree of stenosis for two main reasons. One is the presence of turbulence and eddy currents at the stenotic lesion that causes loss of signal. Second is the slow flow, leading to saturation of the fresh blood protons and loss of signal. Severe stenosis will therefore produce significant loss of signal and “flow gap.” The technique also has the disadvantage of poor background suppression of fat and hemorrhage and high sensitivity to motion artifact.

The 3D contrast-enhanced MRA (CE-MRA) is a more flow-insensitive technique relying on vascular enhancement after contrast administration for vessel detection. The center of the K-space is filled first to provide more contrast to the image. Images should be acquired during the arterial phase to avoid venous contamination and therefore timing of image acquisition is important. Several methods such as test bolus or smart prep are therefore used. The tightness of the bolus is also important and is achieved by injection of about 40 mL of gadolinium (at a rate of 2 mL/sec) followed by a bolus of saline. A fast scanner is required since the set of images should be acquired within 10 to 15 seconds. This technique has several advantages. It is a much faster imaging technique, and therefore, several sets of images may be acquired, and the optimum images without venous contamination are selected. It is not affected by “in-plane saturation” as in 2D TOF. It is not affected by saturation because of slow flow as in 3D TOF. Therefore, it is less affected by flow artifacts, and the degree of stenosis is therefore more accurately depicted than TOF techniques. It is performed in the coronal plane with a large field of view that enables visualization of the arterial origins from the aorta as well as the intracranial circulation.

Conventional angiography is the gold standard imaging technique and allows visualization of degree of stenosis and surface of the plaque. Irregularity of the surface of the plaque is usually associated with increased risk of stroke at all degrees of stenosis. North America symptomatic carotid endarterectomy trial (NASCET) criteria are used by most institutions to determine the degree of stenosis. The maximum luminal diameter stenosis is compared to the diameter of a normal distal segment of the ICA beyond the bulb. The greatest value for diameter stenosis of the two standard views is used. According to NASCET, symptomatic patients with luminal diameter stenosis of >70% will benefit from carotid endarterectomy. The asymptomatic carotid atherosclerosis study (ACAS) showed surgical

benefit in asymptomatic patients with luminal diameter narrowing of 60% or more. Angiography has the advantage of assessing collateral circulation and identifying tandem lesions. Interventional procedures, such as angioplasty and stent placement, can also be performed.

NONATHEROSCLEROTIC ARTERIAL DISEASES

There are several congenital and acquired diseases that cause cerebrovascular arterial disease and narrowing (Table 5-4). Vasculopathy is a general term.

HYPOPLASIA OR APLASIA

The A1 and P1 segments of the anterior and posterior cerebral arteries respectively are most commonly seen. The A2 segment is fed by the contralateral anterior cerebral artery via a patent Acom. The P2 segment is fed

through a prominent Pcom, which is known as “fetal origin” of the posterior cerebral artery.

NEUROFIBROMATOSIS

Although uncommonly affects the cerebrovascular circulation, it is considered the most common neurocutaneous syndrome that produce vascular abnormality. In this case, basal arterial stenosis is seen with a Moyamoyalike pattern of collateral blood flow. There are four pathologic types: pure intimal, advanced intimal, intimal aneurysmal, and nodular. Many of the lesions have features of more than one of the pure types. It is proposed that the pathogenesis of all of the types of arterial lesions is proliferation of Schwann cells within arteries with secondary fibrosis.

TUBEROUS SCLEROSIS

It rarely affects the cerebrovascular circulation. There is ectasia and aneurysms of the intracranial circulation seen in these cases.

TABLE 5-4 Nonatherosclerotic Causes of Cerebrovascular Arterial Disease

Congenital	Hypoplasia or aplasia
	Neurofibromatosis
	Tuberous sclerosis
	Idiopathic progressive arteriopathy of childhood (Moyamoya)
Traumatic	Dissection
Vasospasm	Subarachnoid hemorrhage
	Catheter manipulation
	Migraine
Neoplastic	Compression by tumor
	Radiation vasculitis
Hematologic	Sickle cell disease
Infectious vasculitis	Tuberculosis
	Syphilis
	Fungal: aspergillosis
	Viral: Herpes simplex and HIV
	Sarcoid
Noninfectious vasculitis	Collagen vascular disease: SLE, rheumatoid, and scleroderma
	Primary arteritis of CNS
	Polyarteritis nodosa
	Giant cell (temporal) arteritis
	Wegener granulomatosis
	Takayasu arteritis
	Behcet disease
	Drug-induced
	Radiation
	Skull base fracture involving carotid canal
Compressive	Cervical spine fracture or subluxation involving the transverse foramina
	Osteophyte from cervical spine degeneration
	Neoplasm
Idiopathic	Fibromuscular dysplasia

IDIOPATHIC PROGRESSIVE ARTERIOPATHY OF CHILDHOOD (MOYAMOYA)

There is progressive narrowing of the distal supraclinoid ICA and proximal anterior and middle cerebral arteries. The posterior circulation is less commonly involved with stenosis seen in the distal basilar and proximal posterior cerebral arteries. Multiple punctuate hypodensities are seen in the basal ganglia that enhance following the administration of contrast and represent enlarged lenticulostriate and thalamoperforate arteries providing collateral flow. CTA shows the stenotic lesions and collateral flow.

On MRI, the basal ganglia collateral circulation will be seen as flow voids on all pulse sequences. Flow void basal cisternal wormlike filling defects are best seen on T2-weighted images. The sulci will appear bright on FLAIR images because of slow flow within engorged pial collaterals. MRI may also show infarcts. Postcontrast images will demonstrate enhancement of the basal ganglia and leptomeningeal collateral vessels. MRA will show similar findings to CTA. On conventional angiography, the lateral views will demonstrate the lenticulostriate and thalamoperforate collateral vessels appearing as a “puff of smoke” (Moyamoya).

SICKLE CELL DISEASE

It is caused by abnormality in hemoglobin (Hb) synthesis leading to the formation of Hb S, which produces sickling of the RBCs and capillary occlusion leading to ischemia and infarction. Sickle cell disease is the most common cause of infarction in African American children, and the incidence of stroke is significantly decreased by blood transfusion.

Vasculopathy occurs in approximately 50% of cases and involves the distal ICA and proximal ACA and MCA, similar to Moyamoya disease. The adherence of the abnormal sickled RBCs to the endothelium initiates endothelial injury, which is then followed by fragmentation of the internal elastic lamina and degeneration of the media.

The imaging findings are related to two factors: vasculopathy resulting in stenosis, and capillary occlusion leading to ischemia and infarction. On CT, infarctions may be cortical caused by vascular occlusion. Watershed ACA–MCA infarcts may also occur because of vascular stenosis. Multiple punctuate hypodensities are seen in the basal ganglia because of lenticulostriate arteries collateralization and will enhance on postcontrast images. On MRI, cortical and deep white matter watershed infarcts are seen and diffusion imaging better delineates acute infarcts. Basal ganglia collateral circulation will be seen as flow voids on all pulse sequences. The sulci will appear bright on FLAIR images because of slow flow within engorged pial collaterals. MRI may also show infarcts. Postcontrast images will demonstrate enhancement of the basal ganglia and leptomeningeal collaterals. CTA, MRA, and conventional angiography will demonstrate stenosis of the supraclinoid ICA and proximal ACA and MCA, with a Moyamoyalike pattern on lateral views.

PRIMARY ARTERITIS OF CENTRAL NERVOUS SYSTEM

Idiopathic primary vasculitis that is only confined to the intracranial cerebrovascular circulation and characterized by ischemic lesions and small petechial hemorrhages. Pathologically, the presence of mononuclear inflammation with necrosis of the blood vessel wall is characteristic. The disease may involve any vessel (arteries and veins), of any size and can occur in childhood through adulthood. The affected vessels may show alternating stenosis and dilatation, and the degree of vessel narrowing may range from mild stenosis to complete occlusion resulting in infarction. Involvement of the venules may lead to parenchymal hemorrhage.

Areas of infarction are usually seen in the deep gray matter and subcortical white matter on CT and MRI. Patchy areas of enhancement may also be seen, while GRE images may show hypointense areas from petechial hemorrhage. On angiography, alternating areas of stenosis and dilatation are usually demonstrated in the affected vessels; however, long segment stenosis or complete occlusion may also be seen.

VASCULITIS

Vasculitis can be classified as infectious and noninfectious (Table 5-4). It can also be classified according to the size of the involved arteries into large, medium, and small vessel vasculitis (Table 5-5).

TABLE 5-5 Classification of Vasculitis Based on the Size of the Affected Vessel

Large vessel vasculitis (ICA, BA, A1,M1 and P1)	Viral: Herpes simplex type 1, HZV, and HIV Tuberculosis Syphilis Bacterial meningitis Sarcoid Primary arteritis of CNS Scleroderma Takayasu arteritis Giant cell (temporal) arteritis Idiopathic progressive arteriopathy of childhood (Moyamoya)
Medium vessel vasculitis (distal to MCA bifurcation/trifurcation, distal to Acom and Pcom)	SLE Polyarteritis nodosa Kawasaki disease Behcet's disease
Small vessel vasculitis	SLE Rheumatoid Henoch-Schoenlein purpura Wegener granulomatosis Churg-Strauss syndrome

The imaging features of vasculitis include direct and indirect signs. Direct signs include vessel wall thickening and enhancement which is best seen on high resolution thin section contrast-enhanced T1 fat-suppressed images. Evaluation of large vessel vasculitis may be done using this technique, while medium and small vessel vasculitis is usually beyond the resolution of this technique. With thin sections, the walls of the arteries are normally invisible and any thickening in the wall should be considered abnormal. Enhancement is usually restricted to the walls of acutely inflamed arteries; however, it may extend into the adjacent leptomeninges.

Indirect signs include perfusion deficits, multiple infarcts of different ages, intracerebral or subarachnoid hemorrhage, and vascular stenosis atypical for atherosclerosis. Nonspecific patchy areas of enhancement may also be seen. MRI is the imaging modality of choice in these cases and may be supplemented by MR perfusion sequence to detect perfusion deficits. MRA of the neck and brain arteries will demonstrate arterial irregularities or alternating stenosis and dilatations of the affected arteries. Arterial occlusion can also be seen.

Conventional angiography is the technique of choice for medium vessel vasculitis which is usually beyond the resolution of MRA. Irregularity, stenosis, dilatation, and occlusion can be seen in the involved second- and third-order branches. Microaneurysms may be seen in polyarteritis nodosa.

TABLE 5-6 Types of Fibromuscular Dysplasia

TYPE	INCIDENCE	ANGIOGRAPHIC FEATURE
Intimal fibroplasia	1%	Ringlike stenosis Smooth tubular stenosis
Medial fibroplasia: Three subtypes		
a. Medial dysplasia	65%	Alternating webs and aneurysms resulting in classic “string of beads”
b. Perimedial fibroplasia	20%	Alternating webs and aneurysms resulting in “string of beads,” but the beads (aneurysms) are not larger than the diameter of the original vessel
c. Medial hyperplasia	10%	Tubular smooth stenosis
Adventitial fibroplasia	<1%	Tubular smooth stenosis

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia (FMD) is a nonatherosclerotic, noninflammatory arterial disease of unknown etiology. It is a collection of fibrotic disorders that can involve the intima media or adventitia of medium-sized arteries. In the cerebrovascular circulation, the disease more commonly affects the extracranial cervical ICA in 75% of cases. The external carotid artery and the cervical vertebral artery are less commonly involved. Bilateral ICA affection is seen in approximately 65% of cases. The disease is more common in young females. The disease is associated with intracranial aneurysms in 30% of cases and with spontaneous carotid artery dissection in as many as 10% to 20% of cases. Therefore, patients may present with Horner syndrome, TIAs, ischemic stroke, or subarachnoid hemorrhage.

There are five types of FMD (Table 5-6). Medial dysplasia is by far the most common type, and it should be noted that the incidence of the various types of FMD outlined in the table is from large renal studies and may not reflect the incidence of different FMD types in carotid disease.

QUESTIONS AND ANSWERS

- In acute infarction, all the following are *true* except:
 - Noncontrast CT mainly serves to exclude hemorrhage as the cause of stroke.
 - Hyperdensity within an artery on noncontrast CT represents acute thrombus.
 - Loss of gray–white matter distinction, with obscuration of the deep gray matter nuclei are seen on noncontrast CT.
 - Hypodensity in a specific vascular territory is by far the most common finding.

ANSWER: D. Hypodensity in a specific vascular territory is less commonly seen.

- Which of the following is the most correct about enhancement patterns in acute infarction on contrast-enhanced CT?
 - Enhancement of the cortical vessels may be secondary to slow antegrade flow.
 - Cortical gyral enhancement usually begins at 2 weeks.
 - Enhancement of the cortical vessels may be because of retrograde flow from collaterals.
 - Cortical gyral enhancement starts to disappear at 2 months.

ANSWER: B. Cortical gyral enhancement usually begins at approximately 1 week and peaks at 10 days to 2 weeks. This usually subsides by 4 months. As the blood brain barrier breaks down, the tissues and residual supply vessels become leaky. This results in a mix of enhancement and sometimes overlapping laminar necrosis. Laminar necrosis may

have some precontrast hyperdensity from calcification. Enhancement of the vessels in stroke is seen better on MRI (T1 shortening) than CT. On CT, the hyperdense appearance may be from clot and not enhancement.

3. On CT perfusion, which of the following is *true*?
 - A. The CBV and MTT are decreased and CBF is increased in the infarct.
 - B. The CBV, CBF, and MTT are decreased in the ischemic area.
 - C. The CBV and CBF are decreased and MTT is increased in infarct area.
 - D. CBV and MTT are decreased and CBF is normal or increased in ischemic area.

ANSWER: C. The CBV and CBF are decreased and MTT is increased in infarct area. The CBF is decreased, MTT is increased, and the CBV is normal or slightly increased in the ischemic area.

4. On diffusion MRI, which of the following is *false*?
 - A. Diffusion imaging is the most sensitive sequence in detecting hyperacute infarction.
 - B. Cytotoxic edema leads to restriction of motion of the water molecules mainly in the extracellular space.
 - C. After 7 to 10 days, pseudonormalization occurs.
 - D. The area of restricted diffusion is seen as hypointense on DWI and hyperintense on ADC maps.

ANSWER: C. The area of restricted diffusion is seen as hyperintense on DWI and hypointense on ADC maps.

5. Concerning nontraumatic intracranial hemorrhage, which of the following is *true*?
 - A. Intracerebral hemorrhage in adults accounts for 25% of cases.
 - B. The most common location is in the basal ganglia.
 - C. Amyloid angiopathy accounts for approximately 60% of nontraumatic intracerebral hemorrhages.
 - D. Lobar hemorrhages in the same age may be seen most commonly in the occipital and temporal lobes.

ANSWER: B. Intracerebral hemorrhage in adults accounts for 70% to 90% of cases. The most common location is in the basal ganglia. Amyloid angiopathy accounts for approximately 10% to 20% of nontraumatic intracerebral hemorrhages. Lobar hemorrhages are seen in different ages and most commonly in the frontal and parietal lobes.

6. In dural venous sinus thrombosis, which of the following is *false*?
 - A. Most commonly involved is the superior sagittal sinus.
 - B. Females are more commonly affected than males.
 - C. “Empty delta” sign is seen in almost all cases.
 - D. Venous infarct may be seen in 50% of cases.

ANSWER: A. “Empty delta” sign is seen in 25% of cases.

7. In dural venous sinus thrombosis, which of the following is *true*?
 - A. The thrombus can be easily seen in the acute phase.
 - B. In the subacute stage, the thrombus will appear hypointense on both T1 and T2 images.
 - C. In the chronic stage, the thrombus will not enhance on postcontrast images.
 - D. TOF MRV is limited in the acute stage by the T1 hypointensity of the thrombus.
 - E. CE-MRV is limited in evaluation of chronic thrombus.

ANSWER: E. It is difficult to detect the thrombus in the acute phase, since deoxyhemoglobin will be isointense on T1 and hypointense on T2 images and therefore indistinguishable from normal flow voids in most cases. In the subacute stage, the thrombus will appear hyperintense on both T1- and T2-weighted images. In chronic sinus thrombosis, healing by organizing fibrous tissue will produce enhancement on postcontrast images. TOF MRV is limited in the subacute stage by the T1 hyperintensity of the thrombus, which falsely appears as patent sinus with normal flow. The utilization of CE-MRV in the diagnosis of chronic thrombosis has been questioned because of possible intense enhancement of the chronic thrombus that will produce an erroneous appearance of a patent sinus.

8. Regarding atherosclerotic vascular disease, which of the following is *true*?
 - A. It accounts for 50% of cerebral thromboembolic infarcts.
 - B. The most common location for atherosclerosis is the distal ICA.
 - C. CTA can be used to characterize the constituents of the plaque by assigning different colors for different densities within the plaque.

ANSWER: C. It accounts for 90% of cerebral thromboembolic infarcts. The most common location for atherosclerosis is the CCA bifurcation and the proximal ICA. Intracranially, atherosclerotic disease is most commonly seen in the carotid siphons and vertebral arteries.

9. Regarding idiopathic progressive arteriopathy of childhood, which of the following is *false*?
- There is progressive narrowing of the distal supraclinoid internal carotid artery and proximal anterior and middle cerebral arteries.
 - Basal ganglia collateral circulation will be seen as flow voids.
 - The lateral views of conventional angiography will demonstrate the lenticulostriate and thalamoperforate collateral vessels appearing as a “puff of smoke”.
 - FLAIR images will be normal.

ANSWER: D. Basal ganglia collateral circulation will be seen as flow voids on FLAIR. The sulci will appear bright on FLAIR images because of slow flow within engorged pial collaterals.

10. Regarding fibromuscular dysplasia, which of the following is *false*?
- FMD is a nonatherosclerotic, noninflammatory arterial disease of unknown etiology.
 - In the cerebrovascular circulation, the disease more commonly affects the extracranial cervical ICA in 75% of cases.
 - Bilateral ICA affection is seen in approximately 35% of cases.
 - The disease is associated with intracranial aneurysms in 30% of cases.
 - The disease is associated with spontaneous carotid artery dissection in as many as 10% to 20% of cases.

ANSWER: C. Bilateral ICA affection is seen in approximately 65% of cases.

6 INTRACRANIAL ANEURYSMS AND VASCULAR MALFORMATIONS

*Ahmed Kamel Abdel Aal and
Joseph C. Sullivan III*

INTRACRANIAL ANEURYSMS

Aneurysms are usually asymptomatic until they rupture, and they account for approximately 80% to 90% of non-traumatic subarachnoid hemorrhage, resulting in unfavorable outcome in most cases with mortality and morbidity as high as 50%. There are three general types of aneurysms:

saccular (berry), fusiform, and blisterlike aneurysms. Pseudoaneurysms are a pathologically different entity.

SACCULAR ANEURYSM

Saccular aneurysms are rounded berrylike outpouchings, the wall of which is formed only of intima and adventitia. The intima protrudes through a defect in the media and internal elastic lamina. Approximately 95% arise from the circle of Willis (COW), most commonly at the arterial bifurcation or trifurcation, since these areas are subject to high biomechanical shear stress. Approximately 90% arise in the anterior circulation at the ICA, PCOM junction, at the ACOM, or at the ICA bifurcation/trifurcation. Other less common sites include basilar apex aneurysms and PICA, which constitute around 5% to 10% of cases.

Aneurysms are rare in children; peak age is between 40 and 60 years. Multiple aneurysms are seen in approximately 20% of cases. Although there is no evidence for congenital origin of these aneurysms and the proposed etiology is biomechanical arterial wall stress, there is increased incidence among patients with positive family history. Predisposing factors include adult polycystic kidney disease, coarctation of the aorta, fibromuscular dysplasia, Marfan syndrome, Ehler-Danlos syndrome, and connective tissue disorders such as systemic lupus erythematosus.

The most common clinical presentation is SAH secondary to aneurysm rupture. Cranial neuropathy may also be seen and will preferentially involve the oculomotor nerve in case of ICA–PCOM junction aneurysm. The outer fibers of the nerve are affected first, leading to pupillary dilatation. Patients may also present with stroke related to infarction caused by either emboli showering from the aneurysm sac or by SAH-induced vasospasm. Another cause of stroke in these patients is rupture of the aneurysm into the brain parenchyma leading to intracerebral hemorrhage.

The size of the aneurysm ranges from few millimeters to several centimeters. Giant aneurysms are defined as those larger than 2.5 cm in diameter. The risk of rupture depends primarily on the size of the aneurysm. Generally, the risk of rupture is minimal for aneurysms less than 7 mm and is very high for those greater than 2.5 cm. Other factors that predispose to aneurysm rupture include the configuration of the aneurysm, its location, and presence of hypertension. A multilobed aneurysm, the presence of a “tit” or “daughter aneurysm” at its apex, and a sac-to-neck ratio of greater than 1.6 also increase risk of rupture.

On noncontrast CT, ruptured aneurysm may produce regional SAH that helps predict aneurysm location. Predominance of SAH in the suprasellar cistern suggests ruptured ICA–PCOM junction aneurysm, while inter-

hemispheric SAH and sylvian fissure SAH suggest ruptured ACOM and MCA aneurysms, respectively. Other complications include parenchymal hemorrhage, infarction, and hydrocephalus. CTA is the modality of choice for evaluating suspected aneurysms and is positive in roughly 95% of patients with ruptured aneurysms.

The appearance of aneurysms on MRI is more complex and depends on the flow within and the patency of the aneurysm sac. An aneurysm sac with high flow will appear signal void on T1- and T2-weighted images. The partial or complete obliteration of the aneurysm sac will produce a signal abnormality dependent on the age of the clot. Sometimes a laminated appearance is seen corresponding to different ages of layered thrombus. Diffusion imaging may demonstrate infarctions related to SAH-induced vasospasm. Gadolinium-enhanced MR may demonstrate hyperintensity in a patent aneurysm with significantly slow flow. Pulsation artifacts in the phase-encoding direction are helpful in localizing small aneurysms. 3D TOF MRA is valuable in showing patent aneurysms. MRA using spoiled gradient technique appears to be more sensitive than 3D TOF MRA for peripheral, smaller aneurysms, although not routinely performed by many institutions. With the improvements in multidetector CTA, digital subtraction angiography (DSA) is performed only when endovascular treatment using detachable coils is considered. Following coil placement, 3D TOF MRA without and with contrast using short TE and subtraction technique may help show residual lumen on follow-up studies.

FUSIFORM ANEURYSM

Fusiform aneurysm is usually caused by atherosclerosis in older patients. However, other etiologies include collagen vascular disease, HIV, Marfan syndrome, Ehler-Danlos syndrome, and neurofibromatosis (NF) type 1, mostly in young patients. Clinically, patients present with symptoms and signs related to mass effect of the dilated artery. They may also present with stroke from emboli showering from clots formed within the aneurysm.

CTA and MRA reveal a long segment of fusiform arterial dilatation usually involving a nonbranching segment. The basilar artery is more commonly involved. On MRI, the aneurysm will appear as flow void on T1, T2, and FLAIR images, unless a clot is formed giving a laminated appearance. Diffusion imaging helps depict infarction related to embolic complications.

BLISTERLIKE ANEURYSM

These are small broad-based aneurysms arising from the arterial wall, primarily composed of fibrous tissue. The

most common location is the supraclinoid ICA. These aneurysms usually occur in middle-aged patients and tend to rupture at an earlier age and smaller size than saccular aneurysms. CTA shows asymmetric broad-based bulge of the supraclinoid ICA.

PSEUDOANEURYSM

The walls of these aneurysms are formed of organized clot and fibrin without any layers of the normal arterial wall. These are formed by rupture of an artery leading to the formation of a focal perivascular hematoma. The hematoma then cavitates and communicates with the arterial lumen through a narrow neck. The most important etiologies for pseudoaneurysm are infections (mycotic aneurysms), trauma, neoplasm, and drug abuse. They commonly occur at the distal MCA or, less commonly, the distal ACA branches. Pseudoaneurysms can occur at any age of life.

On noncontrast CT, perivascular high-density hematoma can be seen. On CTA, a focal collection of contrast within the hematoma is noted and communicates with the lumen of the adjacent parent artery. The appearance of the perivascular hematoma on MRI is variable and depends on its age. Flow void within the hematoma corresponds to the focal collection of contrast identified on CTA. The hematoma will appear hypointense on GRE images. Diffusion imaging may demonstrate infarction related to emboli showering from clots formed in the pseudoaneurysm. On 3D TOF MRA, the hematoma will appear hyperintense because of T1 shortening and will therefore obscure the pseudoaneurysm. Therefore, CE-MRA or phase-contrast MRA is better in this context.

VASCULAR MALFORMATIONS

Cerebrovascular malformations are a heterogeneous group of congenital anomalies affecting the blood vessels of the brain. The traditional classification of vascular malformations was historically based on their dominant pathologic features, either precapillary or postcapillary vascular malformations. Precapillary vascular malformations include arteriovenous malformations (AVM). Postcapillary vascular malformations include developmental venous anomaly, cavernous malformation, and capillary telangiectasia. With advances in endovascular therapy and the need to identify arteriovenous shunting before intervention, vascular malformations were reclassified. Vascular malformations with arteriovenous shunting include arteriovenous malformation, dural arteriovenous fistula, and vein of Galen malformation. Vascular mal-

formations without arteriovenous shunting include developmental venous anomaly, cavernous malformation, capillary telangiectasia, and sinus pericranii.

ARTERIOVENOUS MALFORMATION

AVM are congenital lesions, although they are rarely diagnosed early in life. There is no familial association or associated specific gene mutation. AVM is most likely caused by dysregulated angiogenesis. Pathologically, this lesion is characterized by large feeding arteries supplying a nidus of thin dysplastic vessels devoid of any capillary bed. The draining veins are enlarged, often with a venous varix or stenosis related to high-velocity blood flow. There is absent normal brain within the nidus. The adjacent brain may show perinidal capillary network as well as hemorrhagic residue.

Approximately 85% AVM occur in the cerebral hemispheres, while 15% occur in the posterior fossa. Multiple lesions are extremely rare and likely seen in hereditary hemorrhagic telangiectasia. AVM is the most common symptomatic vascular malformation, usually presenting between 20 and 40 years of age. Intracranial hemorrhage is the most common presentation occurring in approximately 50% of patients, including intraparenchymal, intraventricular, or subarachnoid hemorrhage. Patients may also present with seizures or other neurologic symptoms.

Spetzler graded these lesions using points for size, location in eloquent brain, and pattern of venous drainage (Table 6-1). Grades 1 to 3 are considered low morbidity for surgical intervention, while grade 6 is considered inoperable. The risk of hemorrhage is increased if there is associated intranidal aneurysm, venous varix, stenosis of the draining vein, central venous drainage, and periventricular location.

Noncontrast CT may show intracranial hemorrhage. The AVM may appear as serpentine isodense or hyperdense lesion without mass effect or surrounding edema. Calcification may also be present, and the lesion will enhance avidly on contrast-enhanced CT. On MRI, the appearance is complex and depends on the flow rate and the presence and age of hemorrhage. Classically, AVM

appears as serpentine flow voids, a “bag of worms,” without mass effect or edema. Adjacent hyperintense gliosis can extend around the lesion, identified on T2 and FLAIR images. GRE images will demonstrate blooming hypointense blood products. Contrast-enhanced images may demonstrate hyperintensity in an AVM with a significantly slow flow. MRA and MRV generally do not provide additional information.

Cerebral angiogram is valuable in delineating the feeding arteries, draining veins, as well as the angioarchitecture of the AVM. It appears as a tightly packed mass of vessels. Arterial feeders could be pial, dural, or both. The presence of intranidal aneurysm, venous varix, or stenosis in the draining vein should be sought in these studies, since these are associated with high risk of hemorrhage. Treatment includes percutaneous embolization, radiosurgery or microvascular surgery, or a combination of the above.

DURAL ARTERIOVENOUS FISTULA

Dural arteriovenous fistula (DAVF) account for only 15% of intracranial vascular malformations and consist of a network of tiny vessels in the wall of a dural venous sinus. Consensus is that these are acquired lesions, likely caused by venous sinus thrombosis, supported by the fact that most cases have a history of prior local trauma or hypercoagulability state. Regardless of the cause, neoangiogenesis occurring in granulation tissue create a network of proliferating capillaries and microstipulae that drain into the dural venous sinus, a cortical vein, or both.

The most common location for DAVF is the transverse (sigmoid) sinus followed by the cavernous sinus (carotid–cavernous fistula). Middle-aged patients are usually affected and the clinical presentation depends upon the location. Transverse sinus lesion presents with pulsatile tinnitus, while carotid–cavernous fistula presents with pulsatile exophthalmus, papilledema, and loss of vision. In severe cases, venous hypertension may ensue leading to thrombosis and ischemia. Intracranial hemorrhage may occur in aggressive lesions. Cognard classified DAVF according to the pattern of venous drainage, which correlates with the risk of hemorrhage (Table 6-2). Barrow classified carotid–cavernous fistulas according to their arterial supply (Table 6-3).

Noncontrast CT is usually normal and contrast CT may show tortuous dural arterial feeders and enlarged dural venous sinus. In carotid–cavernous fistula, the superior and sometimes the inferior ophthalmic veins are enlarged. CTA is valuable in detecting small lesions and demonstrating with greater conspicuity the arterial feeders. Aggressive DAVF can create enlarged cortical veins.

TABLE 6-1 Spetzler Classification of AVM

Size	Small <3 cm = 1
	Medium 3–6 cm = 2
	Large >6 cm = 3
Location	Noneloquent area = 0
	Eloquent area = 1
Venous drainage	Superficial = 0
	Deep = 1

TABLE 6-2 Cognard Classification of Dural Arteriovenous Fistula

TYPE	PATTERN OF VENOUS DRAINAGE	RISK OF HEMORRHAGE (%)
Type I	Drains into the sinus with antegrade flow	
Type II A	Drains into the sinus with retrograde flow into the sinus but not cortical veins	
Type II B	Drains into the sinus with retrograde flow into the sinus and cortical veins	10
Type III	Drains into cortical vein without venous ectasia	40
Type IV	Drains into cortical vein with venous ectasia	65
Type V	Spinal perimedullary veins	

On MRI, thrombosed dural venous sinus will appear hyperintense on T1- and T2-weighted images and will enhance on post contrast images. Tiny flow voids at the wall of the sinus represent DAVF and hyperintensity in the adjacent brain parenchyma on FLAIR images is related to venous hypertension or infarction. The appearance of associated parenchymal hemorrhage depends on its age. MRV shows the occluded sinus and 3D PC MRA, especially when low velocity encoding is implemented and depicts the arterial feeders and the direction of flow in the draining sinuses or veins.

On angiography, multiple arterial feeders are usually identified, supplying “cracklike vessels on a dural venous sinus wall” and draining into the sinus or cortical vein. The most common arterial feeders are the meningeal branches of the ECA. Other arterial feeders may arise from the dural and tentorial branches of the ICA, especially the tentorial branch of the meningohypophyseal trunk (artery of Bernasconi Casinari), and from the vertebral artery. The draining venous sinus is either thrombosed or appears deformed because of recanalization. If the DAVF drains into a cortical vein, the high flow may lead to venous stenosis and hemorrhage. The DAVF may drain into a cortical venous collecting pouch that is separable from the normal venous drainage of the adjacent brain and in such a case it can be amenable to percutaneous transvenous embolization.

TABLE 6-3 Barrow Classification of Carotid–Cavernous Fistula

TYPE	ARTERIAL FEEDERS
Type A	No DAVF Direct flow from cavernous segment of ICA Usually secondary to trauma and skull base fracture
Type B	DAVF supplied by ICA branches
Type C	DAVF supplied by ECA branches
Type D	DAVF supplied by ICA and ECA branches

VEIN OF GALEN MALFORMATION

Vein of Galen malformation (VOGM) is an arteriovenous fistula draining into an aneurysmally dilated median prosencephalic vein of Markowski and is therefore a misnomer. Median prosencephalic vein is part of the fetal venous system that normally drains the choroid plexus and is the precursor of vein of Galen. At about the 10th week of gestation, the cranial aspect of the vein regresses, while the caudal portion persists and joins the internal cerebral veins to become the vein of Galen. Arteriovenous fistula occurs around the 10th to 12th week gestational age and leads to dilatation of the median prosencephalic vein, producing what is known as vein of Galen malformation. The arterial feeders are most commonly the posterior choroidal arteries, followed by the anterior cerebral arteries. In 50% of cases, the dilated median prosencephalic vein drains into a persistent embryonic falcine sinus, and as such, the straight sinus will be absent or severely hypoplastic. High flow within the draining venous sinuses may lead to stenosis or thrombosis.

VOGM is located in the quadrigeminal cistern or velum interpositum cistern. It usually presents in infants and is twice more common in males than females. The high-flow arteriovenous shunt causes cranial bruit and subsequently will lead to high output congestive heart failure. Ischemia or infarction can be seen secondary to arterial steal or because of chronic venous hypertension related to dural venous sinus stenosis. Hydrocephalus may also occur and is also related to impaired drainage caused by dural venous sinus stenosis.

On noncontrast CT, the enlarged venous pouch in the quadrigeminal cistern will appear hyperdense and calcification may be seen. On contrast-enhanced CT and CTA, the feeding arteries appear enlarged; the dilated median prosencephalic vein will appear as a venous pouch that significantly enhances. On MRI, the arterial feeders and dilated median prosencephalic vein will appear signal void. Complex signal is sometimes seen in median prosencephalic vein related to turbulence. Hydrocephalus may be seen and diffusion images are helpful in demonstrating areas of infarction. MRA is also helpful in demonstrating the arterial feeders.

Conventional angiograms are very important in differentiating VOGM from vein of Galen dilatation. In VOGM, there is persistence of the fetal circulation, and the thalamostriate veins will drain into the thalamic and subtemporal veins, which eventually drain in the superior petrosal sinus, producing “epsilon vein” on the venous phase of lateral angiograms. The arteriovenous fistula will drain into median prosencephalic vein that is not connected to the deep venous system. The median prosencephalic vein will drain into transverse sinus or the falcine sinus. In vein of Galen dilatation, there is an AVM

located in the cerebellum, brainstem, or in the deep supratentorial territories that drains into one of the tributaries of the vein of Galen. The vein of Galen is fully developed and drains not only the lesion but also the adjacent brain parenchyma. The dilatation of the vein of the vein of Galen is variable and depends on the outflow obstruction caused by stenosis or thrombosis that usually occurs at the junction of the vein with the straight sinus.

DEVELOPMENTAL VENOUS ANOMALY

Developmental venous anomaly (DVA) is congenital venous vascular malformation resulting from arrest of medullary vein development. It can be viewed as an extreme anatomic venous variant rather than a true vascular malformation. It is the most common of all vascular malformations, representing approximately 60% to 70% of cases. Pathologically, it is formed from multiple medullary veins that are radially oriented forming “caput medusae,” which drain into a larger “collector” vein. The “collector” vein may drain superficially into a dural sinus or cortical vein or may drain deeply into a subependymal vein. The intervening and surrounding brain is normal, and these venous malformations are physiologically important since they provide normal venous drainage. DVA may be complicated by spontaneous thrombosis of the draining vein or sinus leading to parenchymal hemorrhage or infarction of the region of the brain that it drains.

DVA is typically solitary; multiple lesions are extremely uncommon. DVA can occur at any age. Approximately 65% of cases occur in the supratentorial compartment with the frontal lobe being the most common location. Patients are most commonly asymptomatic, and these lesions will be seen incidentally on imaging studies performed for unrelated indications. Occasionally, the patients may present with seizure, headache, or other neurologic deficit, particularly if DVA is associated with other vascular malformation. DVA may be complicated by spontaneous thrombosis of the draining vein or sinus leading to parenchymal hemorrhage or infarction of the region of the brain drained by the anomaly.

Noncontrast CT is usually normal, but may show calcification if DVA is associated with other vascular malformations. On contrast-enhanced CT, the collector vein may be seen as a linear enhancing structure. CTA may show the “caput medusae” near the angle of a ventricle as well as the drainage pathway of the “collector” vein.

The appearance of DVA on MRI is variable depending on the flow rate and will appear classically as linear signal void structure on T1 and T2 in its characteristic location. A thrombosed draining vein or dural venous sinus will appear hyperintense on T1, T2, and FLAIR images, and the resultant parenchymal hemorrhage will

show variable signal depending on the age of the clot. Diffusion images are important in showing early venous infarction also related to draining pathway thrombosis. On postcontrast T1 images, the “collector” vein enhances, since the blood flow is slow enough to produce T1 shortening. In large developmental venous anomaly, the “caput medusae” pattern may be delineated. MRV may be diagnostic, while the venous phase of MRA may show high-flow DVA. On conventional angiography, the arterial phase is usually normal, while the venous phase shows the anomaly and demonstrates its drainage pathway. It is important to emphasize that approximately 10% are angiographically “occult,” with studies completely normal.

CAVERNOUS MALFORMATION

Also known as cavernoma, cavernous malformation is a benign vascular hamartoma. Pathologically, it is formed of large closely packed thin walled vascular channels, lined by endothelium and lacking muscular and elastic layers. There is no normal brain within the lesion. The surrounding brain parenchyma shows a mixture of gliosis and chronic hemorrhagic residue.

Single lesion is seen in approximately 85% of cases; multiple lesions are rare and are thought to be a familial form. The most common associated vascular malformation is developmental venous anomaly, although it may also be associated with café au lait spots and cherry angiomas. The most common location is the subcortical white matter in the supratentorial compartment occurring in approximately 80% of cases. However, it can occur anywhere in the CNS including the spine, nerve roots and dural venous sinuses (especially the cavernous sinus). Patients usually present between 20 and 40 years of age. The most common presentation is seizure occurring in approximately 50% of cases, although patients may present with variable neurologic deficits. The size is variable ranging from 0.5 cm to greater than 6 cm.

On noncontrast CT, calcification may be identified in one-half of the cases, and contrast CT may reveal faint enhancement. CTA is usually negative. MRI is the modality of choice for diagnosis, which is classically described as “popcornlike” lesion. The lesion consists of a central area of multiloculated blood-containing spaces, with mixed hyper- and hypointensity on T1- and T2-weighted images and a peripheral zone of hypointense hemosiderin rim on T2-weighted and FLAIR images. There is no mass effect or surrounding edema. Cavernous malformation may be complicated by hemorrhage. In this instance, signal will depend on the age of hemorrhage. Similar to contrast CT, gadolinium-enhanced T1-

weighted images will demonstrate faint enhancement. GRE shows hypointense blooming lesion and is valuable in demonstrating small lesions that are not well seen on other sequences. MRA and MRV demonstrate no abnormality, unless there are other vascular malformations.

Cavernous malformation is the most common angiographically “occult” lesion and the study is usually normal. Rarely, a faint contrast blush may be seen in the venous phase.

CAPILLARY TELANGIECTASIA

Capillary telangiectasia is the second most common vascular malformation following developmental venous anomaly. Pathologically, capillary telangiectasia represent cluster of ectatic capillaries, which is normal intervening brain parenchyma. The walls of the dilated capillaries are histologically identical to normal capillaries, lacking smooth muscles and elastic fibers. There is no gliosis, calcification, or residual hemorrhagic blood products in pure capillary telangiectasia.

Capillary telangiectasia usually coexist with other vascular malformations, are usually clinically silent and are discovered incidentally with imaging for other indications. Symptomatic lesions are usually associated with other vascular malformation. They can be seen at any age and can be associated with hereditary hemorrhagic telangiectasia. The most common location is in the infratentorial compartment, particularly the brainstem. The spinal cord may also be involved.

CT is usually normal. On CTA, “brushlike” enhancement may be seen. MRI is the modality of choice, and the lesion may be seen as hyperintense on T2 and FLAIR images in about one-half of cases. GRE images are helpful in lesion diagnosis, which appears hypointense, but also serves to identify other smaller lesions that are otherwise occult. Postcontrast T1 images will show faint “brushlike” enhancement.

Similar to cavernous malformations, these lesions are angiographically “occult” in most cases and the study is usually normal. Rarely, a faint contrast blush may be seen in the venous phase.

SINUS PERICRANII

Sinus pericranii represents a communication between a dural venous sinus and the extracranial venous system, either directly (through a transcalvarial vein) or indirectly (through an intervening intracranial cortical vein and transcalvarial vein). Venous varix is usually seen on both sides of the calvarium.

The lesions are secondary to congenital failure of closure of the cranial sutures over venous sinuses or abnormal bone ossification. Those that are acquired may be caused by trauma, skull fracture, and emissary vein tear, or can be spontaneous. Associated abnormalities include systemic vascular malformations and blue rubber-bleb nevus syndrome.

Patients can present at any age, usually with nontender expansile scalp mass that increases in size in the prone position and on Valsalva maneuver and regresses in the upright position. The overlying skin is usually hairless and blue-tinged. There is a potential lifetime risk of hemorrhage and air embolism.

The superior sagittal sinus is most commonly involved, and therefore, sinus pericranii is usually seen in midline or paramedian location. On noncontrast CT, it appears as a soft-tissue mass representing venous varix, adjacent to a well-defined bone defect. Contrast CT and CT venography will demonstrate the enhancing varix and the transcalvarial vein passing through the bone defect. On MRI, the signal in the varix will depend on the flow rate, and classically, signal void is seen in high-flow lesions. The lesions will enhance on postcontrast T1-weighted images. Angiographically, sinus pericranii is identified on the venous phase.

QUESTIONS AND ANSWERS

1. What is the most common clinical presentation of aneurysm?
 - A. Subarachnoid hemorrhage
 - B. Cranial neuropathy involving the oculomotor nerve

- C. Infarction
- D. Intracerebral hemorrhage

ANSWER: A. The most common clinical presentation is SAH that occurs with aneurysm rupture. Ruptured aneurysms account for approximately 80% to 90% of nontraumatic SAH. Cranial neuropathy may also be seen and will preferentially involve the oculomotor nerve in case of ICA–PCOM junction aneurysm.

2. What arterial layer(s) compose(s) the wall of saccular aneurysms?
 - A. Media
 - B. Media and adventitia
 - C. Media, intima and adventitia
 - D. Intima and adventitia

ANSWER: D. The wall of saccular aneurysms is formed only of intima and adventitia. The intima protrudes through a defect in the media and internal elastic lamina.

3. A patient presents with suprasellar cistern haemorrhage on CT. What is the most likely aneurysm location?
 - A. ACA aneurysm
 - B. MCA bifurcation aneurysm
 - C. ICA–PCOM aneurysm
 - D. ACOM aneurysm

ANSWER: C. Predominance of SAH in the suprasellar cistern suggests ruptured ICA–PCOM junction aneurysm, while interhemispheric SAH and sylvian fissure SAH suggest ruptured ACOM and MCA aneurysms, respectively.

4. Which of the following is *not* related to the risk of rupture of saccular aneurysms?
 - A. Size of the aneurysm
 - B. Configuration of the aneurysm
 - C. Location of the aneurysm
 - D. Age of the patient

ANSWER: D. There is no relation between the risk of aneurysm rupture and the age of the patient.

5. What is the most common cause of fusiform aneurysm?
 - A. Marfan syndrome
 - B. Atherosclerosis
 - C. Collagen vascular disease
 - D. Ehler-Danlos syndrome

ANSWER: B. Fusiform aneurysms are usually caused by atherosclerosis in the elderly. However, other etiologies include collagen vascular disease, HIV, Marfan syndrome, Ehler-Danlos syndrome,

and neurofibromatosis (NF) type 1, and these mostly affect young patients.

6. What is the most common location of arteriovenous malformations?
 - A. Midbrain
 - B. Medulla
 - C. Cerebral hemispheres
 - D. Cerebellar hemispheres

ANSWER: C. Approximately 85% AVMs occur in the cerebral hemispheres, while 15% occur in the posterior fossa.

7. According to Cognard classification, what is the type of dural arteriovenous fistula if it drains into an ectatic cortical vein?
 - A. Type I
 - B. Type IIB
 - C. Type III
 - D. Type IV

ANSWER: D. Type IV has 65% risk of hemorrhage.

8. According to Barrow classification, what is the type of a carotid cavernous fistula if it is supplied by the ICA?
 - A. Type A or B
 - B. Type A, B, or C
 - C. Type A, B, or D
 - D. Type D

ANSWER: C. Types A, B, and D have ICA involvement (Table 6-3).

9. What percentage of vascular malformations do developmental venous anomalies constitute?
 - A. 10%–20%
 - B. 30%–40%
 - C. 60%–70%
 - D. 80%–90%

ANSWER: C. DVA is the most common of all vascular malformations, representing approximately 60% to 70% of cases.

10. What is the most common malformation associated with cavernous malformation?
 - A. DVA
 - B. Café au lait spots
 - C. Cherry angiomas
 - D. Capillary telangiectasia

ANSWER: A. The most common associated vascular malformation is DVA, although it may also be associated with café au lait spots and cherry angiomas.

7 HEAD TRAUMA

Ahmed Kamel Abdel Aal and
Joseph C. Sullivan III

INTRODUCTION

Trauma is the most common cause of death in children and young adults, with head injury being the major cause in 50% of cases. Motor vehicle collision is the most common cause of trauma; however, falls in anticoagulated elderly patients and nonaccidental injury in infants and children are other contributors.

PRIMARY MANIFESTATIONS OF HEAD TRAUMA

These include extra-axial manifestations such as epidural hemorrhage, subdural hemorrhage, and subarachnoid hemorrhage, and intra-axial manifestations such as diffuse axonal injury (DAI), cerebral cortical contusion, subcortical injuries, and intraventricular hemorrhage.

EXTRA-AXIAL MANIFESTATIONS

These are because of hemorrhage occurring outside the brain parenchyma.

Epidural hemorrhage is caused by forceful impact. It creates a hematoma that collects between the calvarium and dura (epidural space). Approximately 90% of cases are caused by arterial injury, usually the middle meningeal artery, while the remainders are caused by transgression of one of the sinuses by the fracture, resulting in venous bleed. The epidural hematoma occurs at the impact site (coup). Approximately 95% of cases are unilateral and supratentorial, of which two-thirds will be located at the temporoparietal region because of injury of the middle meningeal artery. Approximately 50% of cases will be associated with other injuries such as cerebral contusions or skull fractures.

About half of the patients will present after asymptomatic “lucid” interval following initial loss of consciousness. On nonenhanced CT, acute epidural hematoma will appear as biconvex or lentiform hyperdense extra-axial collection. If there is active hemorrhage at the time of scanning, mixed hyper/hypodense areas will be seen caused by low-density unclotted blood. Epidural hematoma does not cross the sutures (unless large with diastatic fracture), but will cross the dural reflections including the falx and the tentorium. Vertex epidural hematoma can occur, however it is rare and caused by injury of the superior sagittal sinus. In that case, the fracture is seen crossing the sinus. Subacute and chronic epidural hematoma will be isodense and hypodense on nonenhanced CT and both will demonstrate marginal enhancement following contrast administration. With MR imaging, the appearance of blood products depends on its temporal stage (Table 7-1).

Subdural hemorrhage occurs between the dura and arachnoid meningeal layers and usually results from trauma tearing the bridging cortical veins that cross the subdural space to drain into a dural venous sinus. Other less common causes include vascular malformations, extension of intracerebral hemorrhage into the subdural space, aneurysm rupture, and coagulopathy. The hemorrhage then spreads diffusely over the convexity of the cerebral hemispheres. Approximately 85% of cases are unilateral, and 95% are supratentorial. Nearly two-thirds of cases will be associated with other injuries, more commonly subarachnoid hemorrhage. Similar to epidural hematoma, patients may present after asymptomatic “lucid” interval following initial loss of consciousness.

On noncontrast CT, subdural hematoma appears as a crescent-shaped, extra-axial collection overlying the cerebral convexity. Subdural hematoma may cross the sutures, but will not cross the dural reflections such as the falx and the tentorium (Table 7-2). In the acute stage, the collection appears hyperdense, however, mixed hyper/hypodensity may be seen in cases of active bleeding (producing the “swirl” sign) and in cases of anemia and coagulopathy. In the subacute stage, the collection becomes isodense to the brain parenchyma, making it difficult to identify. Medial displacement of the gray–white matter junction may help in their identification unless the lesions are bilateral and symmetrical. Other signs

TABLE 7-1 CT and MRI Appearance of the Various Stages of Intracranial Hemorrhage

TIME	BLOOD PRODUCT	NECT	CECT	T1	T2	GRE
Hyperacute: 4–6 h	Intracellular oxy-Hgb	Hyperdense		Isointense	Hyperintense	Hypointense
Acute: 6 h–3 d	Intracellular deoxy-Hgb	Hyperdense		Isointense	Hypointense	Hypointense
Early subacute: 4–7 d	Intracellular met-Hgb	Isodense		Hyperintense	Hypointense	Hypointense
Late subacute: 1–4 wk	Extracellular met-Hgb	Isodense	Rim	Hyperintense	Hyperintense	Hypointense
Chronic: >4wk	Hemosiderin	Hypodense	Rim	Hypointense	Hypointense	Hypointense

TABLE 7-2 Epidural Versus Subdural Hemorrhage

EPIDURAL HEMORRHAGE	SUBDURAL HEMORRHAGE
Does not cross sutures	May cross sutures
May cross dural reflections (falx and tentorium)	Does not cross dural reflections
Biconvex or lentiform-shaped	Crescent-shaped
95% Unilateral	85% Unilateral
95% Supratentorial (two-thirds temporoparietal)	95% Supratentorial
90% Arterial bleed (middle meningeal artery)	More commonly caused by tear of bridging veins in the subdural space
10% Venous bleed (lacerated venous sinus)	

that might help in the diagnosis include medial displacement of the effaced sulci (appearing as tiny hypodensities) and medial displacement of the cortical vein together with rim enhancement (seen on contrast-enhanced CT). In the chronic stage, the collection appears hypodense to the brain parenchyma and will demonstrate rim enhancement following contrast administration because of encapsulation by neomembrane formed of granulation tissue. However, they have a high tendency to rebleed from fragile neovascularity formed in the membrane, producing variable complex density. Eventually, the membrane will stabilize and the collection will undergo resorption.

On MRI, subdural hemorrhage will generally follow the usual signal changes seen in any intracranial hemorrhage (Table 7-1). FLAIR images are particularly useful and appear to be the most sensitive sequence capable of detecting small subdural hemorrhage. The appearance of hemorrhage on diffusion images is complex and non-specific and involves many factors including the relative amounts of different blood products; therefore, producing a heterogeneous nonspecific signal in most cases. However, diffusion images are valuable in differentiating subdural hemorrhage from other subdural collections, such as sterile subdural effusion that is most commonly associated with meningitis and shows increased diffusion (hypointense on diffusion-weighted imaging [DWI] and hyperintense on apparent diffusion coefficient [ADC] as well as subdural empyema, which shows restricted diffusion (hyperintense on DWI and hypointense on ADC).

Subarachnoid hemorrhage (SAH) is usually seen in severe head trauma and typically associated with worse prognosis. Bleeding occurs between the pia and arachnoid membranes and results from tearing of veins in the subarachnoid space. Traumatic SAH is more common than nontraumatic causes. It may be associated with other injuries such as subdural hemorrhage and brain contusions.

Traumatic SAH may be complicated by vasospasm leading to ischemia and possibly infarction. It usually

occurs within 3 to 15 days after subarachnoid hemorrhage. Another complication is hydrocephalus because of obstruction of the basal foramina or arachnoid granulations.

On nonenhanced CT, there is high-density blood in the sulci and basal cisterns. This is usually seen adjacent to other traumatic brain lesions such as brain contusions or subdural hemorrhage. Bleeding in the interpeduncular cistern may be the only sign in subtle cases. “Pseudodelta” sign may be seen on nonenhanced CT because of presence of high-density SAH surrounding the hypodense superior sagittal sinus.

On MRI, FLAIR images appear to be the most valuable, and it is very sensitive to detecting subtle SAH that appears hyperintense. On T1-weighted and T2-weighted images, SAH appears isointense to brain parenchyma. Diffusion images are very important to detect early complications related to vasospasm including ischemia and infarction. Angiography may also be helpful to demonstrate SAH-induced vasospasm and offers additional therapeutic advantage through intra-arterial calcium channel blockers (nicardipine) administration.

The differential diagnosis of traumatic SAH includes meningitis, meningeal metastasis (carcinomatosis), gadolinium administration in patients with or without renal failure, oxygen therapy, diffuse cerebral edema (pseudo-SAH), and various causes of nontraumatic SAH (Table 7-3).

TABLE 7-3 Differential Diagnosis of Subarchnoid Hemorrhage on MRI

Nontraumatic SAH	Causative lesion is usually detected, most commonly aneurysm or vascular malformation Other causes include perimesencephalic venous hemorrhage, ruptured dissecting aneurysm, hemorrhagic transformation of bland infarct, and hypertensive intracranial hemorrhage History may suggest coagulopathy
Meningitis	WBCs in the subarachnoid space High FLAIR signal Meningeal enhancement CSF analysis shows infectious pattern
Meningeal metastasis (carcinomatosis)	Malignant cells in the subarachnoid space High FLAIR signal Irregular meningeal enhancement CSF cytology shows malignant cells
Oxygen therapy	Administration of 100% O ₂ High FLAIR signal
Gadolinium administration	In patient with lesions causing blood-brain barrier disruption In patient with or without renal insufficiency High FLAIR signal
Diffuse cerebral edema	Diffusely hypodense brain Relatively hyperdense meninges

INTRA-AXIAL MANIFESTATIONS

These are caused by hemorrhage occurring within brain parenchyma.

Cerebral cortical contusion is injury of the cortical gray matter of the brain caused by impaction of gyri against osseous ridges or dural reflections. The temporal and frontal lobes are therefore more commonly involved. Focal cortical injury may also result from depressed fractures. Cerebral contusions are multiple and bilateral in approximately 90% of cases and can occur in regions of direct trauma (coup) and indirect trauma (countercoup). It is important to realize that the lesion usually starts as a focal area of brain edema showing multiple areas of punctate or linear hemorrhages. Within the next 24 to 48 hours, the size of hemorrhagic component may substantially increase in size and may involve the superficial subcortical white matter, accounting for increased mass effect and clinical deterioration. Therefore, the possible progression of these lesions justifies close follow-up imaging of these patients.

On nonenhanced CT, there are usually patchy cortical hypodense areas of brain edema with small punctate and linear hyperdense foci of petechial hemorrhages. SAH in the adjacent sulci is common. In the next 24 to 48 hours, the petechial hemorrhages may progress to parenchymal hematoma, and new lesions at different locations may also be seen. In the chronic stage, hypodense encephalomalacia is seen with parenchymal volume loss and ex vacuo dilatation of adjacent CSF spaces.

On MRI, T1-weighted images will show heterogeneous hypointense and hyperintense signal in the acute stage, while in the chronic stage hypointense gliosis and parenchymal volume loss will be seen. On T2-weighted and FLAIR images, hyperintense areas of edema and hypointense foci of hemorrhage can be seen. FLAIR images can also show adjacent SAH. On GRE images, just like any other hemorrhage, blood products appear hypointense and will bloom. On diffusion images, there is restricted diffusion (hyperintense on DWI and hypointense on ADC) because of cytotoxic edema and is seen to extend beyond the boundaries of the lesion seen on conventional imaging.

DAI results from high-velocity deceleration injury from high-velocity head impact leading to tear of the neuronal axons and blood vessels. The most common location is at the frontotemporal gray–white matter junction constituting approximately 75% of cases. It can also occur in the body and splenium of the corpus callosum, upper brainstem, and basal ganglia. These patients usually present by loss of consciousness at the time of injury that might progress to a persistent vegetative state.

Nonenhanced CT is usually normal; however, tiny foci of hypodensity (representing edema) or hyperdensity (representing hemorrhage) may be seen at the site of injury. On MRI, T1-weighted images are usually normal, while T2-weighted and FLAIR images will show tiny hyperintense foci in the characteristic locations. If hemorrhage is seen in these lesions, the blood products will produce signal abnormalities dependant on their age (Table 7-1). GRE is the most sensitive sequence in showing DAI, appearing as hypointense lesions even in subtle cases.

Subcortical injury refers to cerebral contusion occurring at the basal ganglia, thalami, and brainstem, secondary to disruption of the penetrating vessels in these areas by shearing forces. Similar to cerebral contusions, these lesions consist of focal areas of parenchymal edema containing linear and punctate foci of petechial hemorrhage. Radiologically, they are similar to cerebral contusions except for the location, but are clinically associated with worse prognosis.

Intraventricular hemorrhages primary hemorrhage within the ventricular system is most commonly because of disruption of the subependymal veins. Less commonly, it can occur because of choroid plexus hemorrhage or can be secondary to rupture of intraparenchymal hemorrhage into the ventricles.

On nonenhanced CT, intraventricular blood appears hyperdense producing CSF-blood level. Bleeding may be extensive, filling and expanding the ventricles. On MRI, the blood products appear hyperintense to the CSF on T1-weighted images, hypointense to CSF on T2-weighted images, hyperintense to the attenuated CSF on FLAIR images, and hypointense with blooming on GRE images.

Shaken baby syndrome refers to nonaccidental brain and skull injuries related to child abuse. There is usually discrepancy between the stated history by parents (minimal trauma) and the degree of brain injury on CT. It can occur at any age but is more common in the first 6 months of life and is more common in males. These children may present with apnea, loss of consciousness, or retinal hemorrhages. These are specific imaging findings suggesting diagnosis (Table 7-4).

TABLE 7-4 Cranial Imaging Findings in Child Abuse

Scalp injuries
Multiple, complex, depressed, diastatic, unexplained skull fracture at different ages of healing
Subdural, subarachnoid, and intraventricular hemorrhage in different stages and locations
Epidural hemorrhage is rare
Cerebral cortical contusions and shear injuries
Global or focal infarction
Other skeletal injuries of different ages and other injuries in the body

SECONDARY EFFECTS OF HEAD TRAUMA

These occur after the initial trauma and represent damage to the neurons caused by systemic physiologic responses to the initial trauma. Secondary effects include cerebral herniation, cerebral edema, cerebral infarction, arterial dissection, and carotid cavernous fistula. Secondary effects of trauma may be more serious and have a worse prognosis than primary effects.

In order to easily understand the concept of brain herniation, it is important to realize that after closure of the skull sutures the intracranial cavity becomes functionally divided by the dural reflections into three compartments: two supratentorial and one infratentorial compartments. Space-occupying lesions such as hemorrhage or neoplasms in one compartment may exert significant mass effect leading to displacement of the brain parenchyma, CSF spaces including ventricles, and blood vessels from one compartment to the other. There are six types of brain herniation.

Subfalcine herniation is the most common type of cerebral herniation and is caused by mass effect on the frontal lobe by a space-occupying lesion. The cingulate gyrus herniates beneath the falx. The ipsilateral ventricle is compressed because of the mass effect, while the contralateral ventricle is enlarged because of obstruction of the foramen of Monro. Severe herniation may occlude the anterior cerebral artery leading to infarction along its territory.

Unilateral descending transtentorial herniation is the second most common type and is caused by mass effect on the temporal lobe due to herniation of the medial temporal lobe through the tentorial incisura. In mild cases, the uncus and parahippocampal gyrus will be displaced medially, partially effacing the suprasellar cistern. The ipsilateral ambient and cerebellopontine angle cisterns will enlarge, as will the contralateral temporal horn because of entrapment. In more severe cases, the suprasellar cistern will be completely obliterated by the herniating brain and the brainstem will be displaced and compressed against the contralateral tentorial margin (Kernohans notch). The oculomotor (III) nerve may be compressed, which in mild cases will manifest with ipsilateral pupillary dilatation because of compression of the parasympathetic fibers, which are located peripherally within the nerve. In more severe cases, the ipsilateral eye globe will be deviated outward and downward because of compression of the motor fibers which are located in the center of the nerve. Severe herniation may occlude the posterior cerebral artery leading to occipital infarction. Duret hemorrhages may occur and these are delayed hemorrhages in the ventral and paramedian aspects of the upper brainstem, resulting in fatal outcome

in most cases. The pathophysiology of Duret hemorrhage remains under debate and can be either arterial or venous in origin. Arterial origin results from stretching and laceration of pontine perforating branches of the basilar artery, while venous origin results from venous obstruction and thrombosis resulting in venous infarction with subsequent hemorrhagic conversion.

Bilateral descending transtentorial herniation is caused by mass effect on both temporal lobes resulting in bilateral herniation of the medial temporal lobes through the tentorial incisura. The thalami, midbrain, optic chiasm, and hypothalamus will be displaced inferiorly and the angle between the midbrain and pons will become more acute. In severe cases the basal arteries may occlude leading to basal infarcts.

Ascending transtentorial herniation is secondary to a space-occupying lesion in the posterior fossa resulting in herniation of the vermis and cerebellar hemispheres superiorly through the tentorial incisura. The quadrigeminal cistern will be effaced and the tectal plate of the midbrain will appear compressed and deformed. The aqueduct may be obstructed leading to hydrocephalus.

Tonsillar herniation is secondary to a space-occupying lesion in the posterior fossa resulting in herniation of the cerebellar tonsils through the foramen magnum into the spinal canal. Patients usually have concurrent ascending transtentorial herniation since both are caused by lesions in the same compartment. There is inferior displacement of the tonsils >5 mm below the foramen magnum, with “peglike” configuration. The tonsillar folia are vertically oriented instead of their normal horizontal orientation. The cisterna magna appears effaced and the fourth ventricle may become elongated and in severe cases may become obstructed leading to hydrocephalus.

Transalar herniation is a rare entity caused by herniation of brain parenchyma and MCA across the sphenoid wing. In ascending transalar herniation, mass effect on the temporal lobe leads to herniation of the anterior temporal lobe and MCA anterosuperiorly over the sphenoid wing, with upward displacement of the sylvian fissure. In descending transalar herniation, mass effect on the frontal lobe leads to posteroinferior displacement of the frontal lobe over the sphenoid wing and posterior displacement of the MCA.

Diffuse cerebral edema occurs in the setting of severe trauma and may lead to diffuse vasogenic and cytotoxic edema, resulting in increased intracranial pressure. The prognosis is usually poor with mortality up to 50%. Diffuse cerebral edema can occur at all ages and is usually associated with other traumatic injuries. Compression of the ventricles and effacement of the sulci are seen. On nonenhanced CT, the cerebral hemispheres appear hy-

podense compared to the cerebellum that appears relatively hyperdense. The surrounding meninges may also appear relatively hyperdense leading to pseudo-SAH appearance. On MRI, the cerebral hemispheres appear hypointense on T1-weighted images and hyperintense on T2-weighted and FLAIR images. MRA and MRV may demonstrate compression and thinning of the arteries or dural sinuses caused by increased intracranial pressure.

A variety of causes may lead to posttraumatic cerebral infarction. These include systemic hypoperfusion, arterial compression secondary to brain herniation, arterial injury (dissection or transection), SAH-induced vasospasm, diffuse cerebral edema causing marked increase in intracranial pressure, and venous compression or thrombosis by epidural hemorrhage. The location of the infarct will depend on the vessel involved, with the posterior cerebral artery being most commonly involved followed by the anterior and middle cerebral arteries in a descending order of frequency. Regardless of the cause, the imaging findings will be those of acute infarction. Nonenhanced CT does not show the infarct in the acute stage, but other signs of brain injury will be evident. CT perfusion may be helpful in cases where infarction is suspected based on clinical or imaging findings, but not evident on nonenhanced CT and will demonstrate decrease in CBF and CBV, with increase in MTT.

On MRI, diffusion images are the most sensitive in detecting early changes related to cerebral infarction. Hyperacute infarcts will show restricted diffusion (hyperintense on DWI and hypointense on ADC maps). On conventional images, infarcts show hypointense T1-weighted and hyperintense T2-weighted and FLAIR signal, and postcontrast images may demonstrate enhancement in the subacute chronic stage. MRA and MRV may be helpful in delineating the occluded vessel or dural venous sinus. MR perfusion has similar role to CT perfusion and demonstrates similar changes in CBF, CBV, and MTT.

Arterial dissection is defined as disruption of the arterial wall continuity by a hematoma in the subintimal or subadventitial planes, splitting the arterial wall and narrowing the true lumen. The traumatic event may be severe as in penetrating injuries or may be very trivial and not recognized by the patient, such as chiropractic maneuvers and violent sneezing and coughing.

Intracranial dissection is the most common location by far is in the vertebral arteries accounting for approximately 75% of cases. Complete disruption of the arterial wall may ensue leading to arterial rupture in the subarachnoid space with resultant subarachnoid hemorrhage. However, the most common complication seems to be

infarction related to narrowing or occlusion of the true lumen. The patient may present with acute or delayed symptoms.

Nonenhanced CT is useful in demonstrating complications (infarction and SAH). CTA is crucial to the diagnosis and should be performed whenever dissection is suspected. Complete occlusion of the artery may be seen in severe cases. In milder cases, there may be fusiform dilatation of the arterial contour with narrowing of the true lumen by an intramural hematoma. Alternatively, an intimal flap may be seen as a filling defect separating the true and false lumens.

On MRI, the absence of flow voids in an artery may suggest the diagnosis. On T1-weighted images, the intramural hematoma appears hyperintense and will be more conspicuous if fat suppressed images were used. Diffusion images and FLAIR are helpful in showing acute infarcts and SAH, respectively. MRA and conventional angiograms may demonstrate arterial occlusion or narrowing. An intimal flap may also be seen as a thin filling defect.

Extracranial dissection can occur in the carotid or vertebral arteries. In the carotid arteries, the most common location is in the cervical segment of the internal carotid artery (ICA), above the bulb to the skull base. In the vertebral artery (VA), it usually occurs at the level of C1-C2. The most common complication of extracranial dissection is infarction related to arterial occlusion or severe stenosis. The patient presents with severe headache in most cases. Horner syndrome may occur and is related to injury of the sympathetic plexus around the ICA from the fusiform dilatation. Underlying vascular abnormalities such as fibromuscular dysplasia, Marfan syndrome, Ehler-Danlos syndrome, cystic medial degeneration, and syphilis may predispose patients to dissection. The imaging findings are similar to intracranial dissection but in extracranial characteristic locations.

QUESTIONS AND ANSWERS

1. What vessel is disrupted in temporoparietal epidural hematomas?
 - A. Superficial temporal artery
 - B. Cortical veins
 - C. Middle meningeal artery
 - D. Sphenoparietal venous sinus

ANSWER: C. Approximately 90% of cases are because of arterial injury, usually the middle meningeal artery, while the remainders are caused by transgression of one of the sinuses by the fracture, resulting in venous bleed. The epidural hematoma occurs at the impact site (coup). Approximately 95% of cases are unilateral and supratentorial, of which two-thirds will be located at the temporoparietal region because of injury of the middle meningeal artery.

2. On T1-weighted and T2-weighted MRI, what are the signal characteristics of subacute hemorrhage?
 - A. Hypointense on T1-weighted and hypointense on T2-weighted images
 - B. Hyperintense on T1-weighted and hypointense on T2-weighted images
 - C. Hyperintense on T1-weighted and hyperintense on T2-weighted images
 - D. Hypointense on T1-weighted and hyperintense on T2-weighted images

ANSWER: B. Subacute hematoma appears isodense on nonenhanced CT. It shows hyperintense signal on T1-weighted and hypointense signal on T2-weighted images because of intracellular methemoglobin. Progression occurs from periphery to center.

3. Which type of extra-axial hemorrhage *does not* cross the skull sutures?
 - A. Epidural hemorrhage
 - B. Subdural hemorrhage
 - C. Subarachnoid hemorrhage

ANSWER: A. Epidural hematoma does not cross the sutures (unless large with diastatic fracture), but will cross the dural reflections including the falx and the tentorium.

4. In cerebral contusion, what is the time frame for progression of the petechial hemorrhages to parenchymal hemorrhage?
 - A. 2–4 months
 - B. 1–2 months
 - C. 1–2 weeks
 - D. 1–2 days

ANSWER: D. The size of hemorrhagic component may substantially increase in 24 to 48 hours, accounting for increased mass effect and clinical deterioration. Therefore, the possible progression of these lesions justifies close follow-up imaging of these patients.

5. What is the most common location for DAI?
 - A. Corpus callosum
 - B. Brain stem
 - C. Frontotemporal gray–white matter junction
 - D. Basal ganglia

ANSWER: C. The most common location of DAI is at the frontotemporal gray–white matter junction constituting approximately 75% of cases. It can also occur in the body and splenium of the corpus callosum, upper brainstem, and basal ganglia.

6. What is the most common cause of intraventricular hemorrhage?
 - A. Disruption of the subependymal veins
 - B. Choroid plexus hemorrhage
 - C. Rupture of intraparenchymal hemorrhage into the ventricle
 - D. Extension from subarachnoid hemorrhage

ANSWER: A. Primary intraventricular hemorrhage is most commonly caused by disruption of the subependymal veins. Less commonly, it can occur because of choroid plexus hemorrhage or can be secondary to rupture of intraparenchymal hemorrhage into the ventricles.

7. What is the location of the mass effect leading to subfalcine herniation?
 - A. Temporal lobe
 - B. Frontal lobe
 - C. Cerebral hemispheres and vermis
 - D. Cerebellar tonsils

ANSWER: B. Subfalcine herniation is the most common type of herniation and caused by mass effect on the frontal lobe by a space-occupying lesion. Descending transtentorial herniation is the second

most common type and caused by mass effect on the temporal lobe. Ascending transtentorial herniation is caused by a space-occupying lesion in the posterior fossa resulting in herniation of the vermis and cerebellar hemispheres superiorly through the tentorial incisura. Tonsillar herniation is caused by a space-occupying lesion in the posterior fossa resulting in herniation of the cerebellar tonsils through the foramen magnum into the spinal canal.

8. Which anatomic structure of the brain herniates in descending transtentorial herniation?
- Cerebellar tonsils
 - Cerebellar hemispheres
 - Cingulate gyrus
 - Uncus and hippocampus

ANSWER: D. In a transtentorial herniation the cingulate gyms descends secondary to it's anatomic location just cephalad and lateral to the tentorial let leaflet.

9. Which vessel is intracranial dissection more likely to involve?
- Vertebral artery
 - Intracranial ICA
 - MCA
 - ACA

ANSWER: A. The most common location by far is in the vertebral arteries accounting for approximately 75% of cases.

10. Extracranial dissection can present with Horner syndrome if it involves which vessel?
- Vertebral artery
 - ICA
 - Subclavian artery
 - ECA

ANSWER: B. Extracranial dissection may present with Horner's syndrome and is related to injury of the sympathetic plexus around the ICA from the fusiform dilatation.

8 SPINE TRAUMA

Joseph C. Sullivan III

MECHANISM OF INJURY

Spine trauma is best described by location (cervical, thoracic, or lumbar) and mechanism. Cervical spine fracture mechanism includes flexion, extension, compres-

TABLE 8-1 Cervical Spine Fracture Types

Flexion fractures	Anterior
	Flexion subluxation
	Facet dislocation (unilateral, bilateral)
	Wedge compression
	Flexion teardrop
Extension fractures	Clay shoveler
	Hangman (traumatic spondylolisthesis)
	Extension teardrop
Compression fractures	Hyperextension dislocation
	Burst
	Jefferson

sion, and complex fractures (Table 8-1). Flexion fractures are further subdivided into anterior, flexion subluxation, and facet dislocation (unilateral or bilateral), wedge compression, flexion teardrop, and clay shovelers fractures. Extension type fractures include hangman (traumatic spondylolisthesis), extension teardrop, and hyperextension dislocation fractures. Compression fractures are further divided into burst fractures and Jefferson fractures. Complex fractures are often seen at the cranio-cervical junction as well as mixed fractures, various combinations of fractures, primarily involving the odontoid process, as well as alanto-occipital junction.

CERVICAL SPINE

With conventional radiography, all seven vertebral bodies should be well seen without motion, limitation of visualization from other anatomical parts, or foreign material obscuring sections of the cervical spine. Additional images, such as a swimmer view or CT may be required. Normal curvature of the spine is lordotic. This however can be reduced even in normal patients depending on positioning, muscular spasm, or in the setting of collar placement. Loss of normal lordosis may be the first indication of a fracture, ligamentous injury, or instability. Multiple papers have described the use of parallel lines to evaluate the cervical spine and its alignment (Fig. 8-1). These lines include the prevertebral space, anterior longitudinal and posterior longitudinal lines, a line along spinolaminar line, as well as a line that may intercede the tips of the spinous processes. An easy way to remember the prevertebral soft-tissue normal thickness is "6 mm at C2 and 2 cm at C6." The pre-dental space should be less than 3 mm in the adult and less than 4 to 5 mm in the child. When evaluating the base of dens at its synchondrosis with the body of C2, a normal variant, os odontoideum may be visualized and should not be mistaken for a fracture line. Lateral masses of C1 and C2 should be symmetric and aligned. The disk spaces should be maintained barring degenerative change. Transverse processes are better evaluated

FIG. 8-1 Evaluation of lateral cervical spine alignment.

on axial and frontal projections, and cervical transverse processes should have a caudal angulation, while thoracic transverse processes angulate slightly cephalad.

Many emergency departments have abandoned conventional radiographs for CT in evaluation of spinal trauma, particularly of the cervical spine. Some, however, obtain an initial lateral view to search for significant fractures. In this scenario, further imaging with CT should be performed unless there is absolutely no clinical indication. If the question is of cord or ligamentous injury, MRI is the modality of choice.

In the setting of anterior subluxation, kyphotic angulation, relative widening of the interspinous space, and facet subluxation should be evaluated. As this can sometimes be difficult to assess in patients realigned by collar placement, voluntary extension films may be obtained for demonstration of stability.

Facet dislocations have a multitude of possible presentations: unilateral or bilateral, complete or perched, and with other associated fractures. When there is a facet dislocation, the associated disk and the posterior longitudinal ligament at the level of fracture might also be injured. The existence of bilateral facet dislocations would indicate disk and posterior longitudinal involvement with concern for an unstable fracture. Some widening of the posterior elements can occur with flex-

ion compression injuries without an associated disk injury. However, these patients, secondary to compression, may be susceptible to traumatic ruptured disk and can present with spinal cord injury without radiologic abnormality (SCIWORA).

A flexion teardrop fracture usually occurs with major shear injury resulting in disrupted ligamentous stability and canal compromise. Conversely, if there is no ligamentous injury or tearing, there may be spinous fractures. Flexion type injuries of such are more likely to cause cord injury as the cephalad fragments sublux over the caudad portions of the vertebral bodies that move relatively posteriorly to impinge upon the canal. By definition, flexion teardrop type fractures are unstable. Clay shoveler fracture is a mild variant of flexion type injury occurring when the cervical spine is in a straightened or flexed position with movement of the body upward relative to a fixed shoulder girdle. This leads to interspinous ligamentous injury and fracture from the downward pull against the spinous processes. As such, it is similar to patients lifting their body while having their arms fixed upon a shovel in the clay, hence the name.

Hangman type fracture is otherwise known as traumatic spondylolisthesis. It is an extension type fracture with a minor flexion variant. As in the setting of a hanging, there is a forward flexing motion of the head de-

pending on the positioning of the knot posteriorly. Today, this is most commonly seen with ejection associated with motor vehicle collisions and an impact of the posterior calvarium on the windshield or roof, creating a traumatic spondylolisthesis at C2 with separation of the posterior elements of the C2 ring. This in effect widens the cervical canal at this level and may actually result in a lower occurrence of cord injury in the event; this is an isolated injury. However, any oblique movement may cause a secondary shearing of the cervical cord. Historically, the hanging knot correctly placed behind one ear would create an oblique motion that would sever the cord in addition to fracturing the spine. However, if the knot was left more posteriorly, it would lead to fracture without cord injury with subsequent death by asphyxiation.

Extension teardrop injuries cause an avulsion of the anterior and inferior corner of the vertebral bodies secondary to hyperextension. This may have a lesser degree of cord injury as the patient extends, and there is some allowance of the posterior elements to collapse upon one another without causing a subluxation posteriorly. This can have a similar appearance as flexion teardrop without the misalignment that is commonly seen with the cephalad portion of the cervical spine moved anteriorly with flexion type injuries. This is not to say that hyperextension dislocation cannot occur, as this being an unstable fracture can also result in cord injury.

In a burst fracture, the vertebral body collapses with multiple fragments that can dislocate posteriorly and impinge the cord. It should be noted that the involvement of two of the three columns of the spine indicates an unstable injury. A compression type fracture involving only the anterior column of the vertebral body is considered stable. One variant of a cervical burst type fracture, Jefferson fracture, occurs in the ringed vertebra of C1. The lateral masses of C1 are laterally displaced, and there can be widening of the predental space, leading to atlanto-axial instability.

Odontoid fractures are classified into three subtypes, depending upon fracture location (Table 8-2). Type I is an avulsion fracture at the superior aspect of the dens; type II is a transverse fracture across the base of the dens; and type III is fractures through the base of C2. A developmental normal variant, os odontoideum, can mimic at type II dens fracture.

Atlanto-occipital dislocation is an unstable ligamentous injury that may not have associated fracture. It results in a stretching of the cord, which may or may not

result in neurologic deficit depending upon the amount of dislocation and degree of cord stretching. Previously, this diagnosis was identified by conventional radiographs when the distance between the basion and the apex of the dens was greater than 12 mm. More recent studies define the distance as 8 to 10 mm with cross-sectional imaging. Magnification on conventional radiographs may explain the discrepancy. Traditionally, the powers ratio was used to describe atlanto-occipital dislocation: distance from the basion to the posterior ring of C1 divided by the distance from the anterior ring of C1 to the opisthion. If this is greater than 1, then dislocation should be suspected. However, trauma patients are often placed in a C-collar, which elevates and aligns the cranium relative to the cervical spine. This may result in a false-negative powers ratio. Cases such as this have been seen in the pediatric population without initial cord injury, suggesting this ratio may not be the best indicator of injury.

THORACIC SPINE

Determining stability is a key feature in imaging of spinal trauma. The spine can be considered in three anatomic columns. If two of the three columns are fractured, then the fracture is considered unstable. The three columns include the anterior and posterior aspects of the vertebral body and the posterior column formed from the posterior elements. The anterior longitudinal ligament stabilizes the anterior column, the posterior longitudinal ligament stabilizes the middle column, and the interspinous and ligamentum flavum ligament stabilize the posterior column.

Because of the stability lent to the thoracic spine by the rib cage, there is a much higher-energy requirement for thoracic spine flexion, extension, and dislocation injuries. Axial loading injury is much more common in the thoracic spine, creating a wedge-type deformity. As a result, most thoracic spinal fractures are usually compression and/or burst fractures. However, Chance fractures secondary to shearing injuries and flexion distraction can also occur, although they require greater impact.

In the setting of compression fractures, flexion associated with axial loading involves only the anterior column resulting in a stable fracture. In the setting of a burst fracture, there is at least anterior and middle column involvement with possible posterior involvement as well, which can be stable or unstable. There can also be posterior longitudinal ligament disruption with associated impingement of the cord by fracture fragments.

In the setting of a Chance fracture, transverse forces result in spinal injury (bone and/or ligamentous) that involves all three columns at either a single level or multiple levels. Keep in mind that fracture lines can extend

TABLE 8-2 Odontoid Fractures

Type I	Superior dens
Type II	Base of dens; mimicks os odontoideum
Type III	Base of C2

from the vertebra body through the pedicles into the posterior elements, giving a so-called “open mouth” appearance at the pedicle.

Flexion distraction injuries tend to occur with a higher-energy injury, resulting in instability at all three columns with anterior wedge abnormality of the inferior vertebral body as well as middle and posterior column instability with possible rotational axis posterior to the anterior longitudinal ligament.

LUMBAR SPINE

The lumbar spine undergoes similar mechanisms of injury as the thoracic spine with a slightly more common occurrence of flexion–distraction injuries. However, compression type injuries remain substantially more common because of the stability provided by the chest, rib cage, and muscular abdominal girdle. Higher mass load is placed on the lumbar spine as it is the fulcrum between the upper and lower body and because of the higher weight of the more cephalad body.

Direct injury to the cord can result in injury to small blood vessels, tears of the pia, or axial disruption. Indirect injury includes reactive effects of venous congestion, perivascular edema, and subsequent decreased blood flow resulting in necrosis or hemorrhage. Not all injuries are immediately visible (SCIWORA). There tends to be improvement in the amount of neurologic deficit over time in the setting of purely edematous cord and/or those with mixed edematous and hemorrhagic changes, with less improvement in the setting of primarily hemorrhagic injury. When there is extradural impingement of the canal, it is important to remember that not all cord injuries occur at the level of the osseous abnormality. It is also important to note that injuries can occur as the spine returns to its normal alignment. This can occur in the setting of hematomas, disks herniations, or when bony fragments impinge on the cord at the time of reduction.

Spine trauma should initially be evaluated via conventional radiography even in today's setting of MDCT. Radiographic evaluation should quickly progress to cross sectional imaging if the mechanism of trauma is such or there are unexplained neurologic deficits. Concomitantly in the setting of head trauma, there is a strong possibility that there will be related cervical injury. CT imaging can quickly establish normal alignment of the vertebral bodies as well as maintenance of the normal vertebral heights, vertebral disk space heights, and appropriate perispinal soft tissues. MR imaging can further contribute with additional information of cord injury or edema indicating microinjuries, or the osseous elements or ligamentous instability, which can be obscured by collar placement. This is aided by the

use of inversion recovering imaging. MRI can diagnose epidural hematoma or traumatic disk injuries, and gradient recall echo imaging increases sensitivity of diagnosis of hematomyelia and bone or disk fragments within the canal. T1-weighted imaging delineates anatomy and identifies cord swelling and hematomas, while fast and echo T2 techniques essentially provide an MR myelogram pattern for evaluation of cord and canal.

In the setting of spinal injuries, the perispinal soft tissues should be evaluated for adjacent ligamentous, muscular, and vascular abnormalities, with consideration of the energy and mechanism of injury. This can help identify an underlying malignant process complicating spinal fracture. In the setting of single level injury, the location of the fracture should be considered; for example, pedicle fracture is more likely a malignant process. A compression fracture will maintain the normal volume of the bone, whereas a pathologic fracture may present itself as an expanse of soft tissue at the level of compression.

Follow-up imaging is indicated if there are continued or new neurologic symptoms or if there are persistent symptoms of compression post/reduction. This is best performed with MRI as cord changes can be evaluated and/or posttraumatic progressive myelopathy can be diagnosed. The latter includes myelomalacia and syrinx formation. Subarachnoid cysts, scarring, and/or fibrosis can also be seen. These complications can be delayed in onset with progressive motor and sensory loss. Specifically, syrinx and/or syringomyelia onset can be as late as 10 to 15 years after the initial injury.

Imaging in spinal trauma continues to advance as reconstruction techniques improve and increased scanner speed decreases motion artifacts and increases patient throughput. MRI imaging also continues to improve with decreased acquisition times and improved signal to noise ratio with the smaller fields of view needed for the spine.

QUESTIONS AND ANSWERS

- Which of the following fractures is most likely to be stable?
 - Jefferson
 - Hangman
 - Occipital condyle avulsion
 - Unilateral facet dislocation
 - Flexion teardrop

ANSWER: D. Only a single column is likely to be involved in unilateral facet dislocation, and there is no definite ligamentous injury.

- Which of the following fractures is most likely to cause neurologic deficit?
 - Jefferson
 - Hangman
 - Occipital condyle avulsion
 - Unilateral facet dislocation
 - Flexion teardrop

ANSWER: E. Flexion injuries are more likely to cause cord injury, and the remainder, although unstable, are less likely to impinge in the cord.

- With MRI finding suggests increased likelihood of traumatic cord injury?
 - Increased T1; increased T2
 - Increased T1; isointense T2
 - Isointense T1; increased T2
 - Isointense T1; hypointense T2
 - Hypointense T1; hypointense T2

ANSWER: C. Isointense signal with T1-weighted images and increased T2 signal imply only edema and not hematomyelia, which usually show improvement as the edema abates.

- Which of the following is *not* an indication of ligamentous injury?
 - Asymmetry of the dens in the C1 ring
 - Widening of the posterior elements
 - Unilateral facet dislocation
 - Occipital condyle avulsion
 - Widening of the basion-odontoid interspace

ANSWER: C. Bilateral facet dislocation implies ligamentous injury. Unilateral does not.

- When dealing with compression fractures, which of the following is a good indicator of benignity?
 - Nitrogen formation in the adjacent disc
 - Paraspinal soft-tissue thickening
 - Complete midline collapse
 - Isointense signal on STIR imaging
 - Mild enhancement soon after the believed compression causing event

ANSWER: A. Gas in the absence of infection, juxtaposed to a fracture most likely indicates a degenerative collapse.

- Which of the following is the best indication for MR imaging of the cord?
 - High-speed MVC in an inebriated patient
 - Patient with seat belt sign on their neck
 - Patient with pain 2 days after the accident
 - Patient with parasthesia and normal CT examination
 - Patient with micturition at the scene of the accident

ANSWER: D. Unexplained deficit, even with normal CT, may indicate cord injury. MRI may also be unimpressive in mild cord injuries.

- Which of the following is most likely to demonstrate a vertebral artery injury?
 - Patient with seat belt sign to the neck
 - Patient with fracture involvement of the sixth foramen transversarium
 - Patient with C3-4 grade II traumatic listhesis without other fracture
 - Patient with hangman fracture
 - Patient with atlantal occipital dislocation

ANSWER: C. The vertebral artery is likely to be injured by the pulling caused by separation of the C3 and C4 transverse components.

- Which vertebral level fracture implies the greatest force of injury?
 - C1
 - C2
 - C4
 - T4
 - L4

ANSWER: D. T4 is the most supported vertebral body listed. It is reinforced by the rib cage.

CENTRAL NERVOUS SYSTEM NEOPLASMS

Asim K. Bag and Joseph C. Sullivan III

INTRODUCTION

The incidence of primary neoplasm of brain in the United States is 14.4 per 100 000 persons. Women are affected slightly more than men. Pathologists classify

brain tumors according to histopathologic behavior, but tumors can be heterogeneous and have different histologic elements. For purposes of this chapter, classification will be based on location and epidemiology.

In adult patients, the most common primary intra-axial supratentorial neoplasm tumor is glioblastoma multiforme, and metastasis is the most common tumor in the posterior fossa. In pediatric population, brain tumors are exceedingly common among all tumors. These are the second most common site of tumor after leukemias. Tumors in the first year of life may be congenital or de novo and usually of high grade. In the prepubescent child, the most common tumors are infratentorial, 75% involve the cerebellum and 25% arise from the brain stem.

ADULT BRAIN TUMORS

INTRAPARENCHYMAL

SUPERFICIAL CORTICAL

- Ganglioglioma/gangliocytoma: More common in children.
- Pleomorphic xanthoastrocytoma: More common in children.
- Dysembryoplastic neuroepithelial tumor: More common in children.
- Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos syndrome): Holohemispheric cerebellar hamartoma is composed of dysplastic ganglion cells. This is a very rare tumor associated with Cowden disease, and usually presents in adults with dysmetria. On T2-weighted sequences, it appears as hyperintense mass with thickened folia and heterogeneous hyperintense stripes.
- Desmoplastic infantile ganglioglioma: Only in infants.

DIFFUSE CORTICAL

Astrocytoma

Astrocytoma is the most common type of primary brain tumor in adults. The most consistent finding of this tumor both histologically and on imaging is heterogeneity. The natural history of this tumor is a continuous evolution from most benign tumor to most malignant tumor. It is very difficult to identify the transition period of this tumor with imaging and also sometimes histologically. The tumor grade depends upon the most malignant part of the tumor. If most of the tumor histology is grade II and one corner shows features of grade III tumor, the tumor is labeled and treated as grade III tumor.

Diffuse astrocytoma is a diffuse, benign slow-growing tumor of young adults occurring predominantly in

the supratentorial cortex. It is composed of mature astrocytes but over time dedifferentiates into anaplastic astrocytoma and ultimately to glioblastoma. It accounts for 10% to 15% of all astrocytic tumors and most commonly occurs in the 30 to 40 years age range. There is a slight male predominance. It can occur in any part of the neural axis but most commonly occurs in frontal and temporal lobes, with the most common presentation of seizures.

Diffuse astrocytoma is a grade II tumor. The histological signature of grade II tumors is cellular atypia (variation in nuclear shape or size associated with hyperchromasia). Pathologically, they may be fibrillary (most common type), gemistocytic, and protoplasmic (rare).

Diffuse astrocytoma is usually a homogenous mass in the cerebral hemispheres, hypodense in CT, and hyperintense on T2-weighted images. There may be a focal area of heterogeneity. It usually has well-defined margins; however, there is microscopic infiltration of the peritumoral areas not identified by the MR. There may be infrequent intratumoral calcification, usually not evident in MR. Classically, it does not enhance; however, subtle enhancement may occur occasionally. There is no correlation between tumor enhancement and tumor grade. Diffusion restriction and increased rCBV indicate higher-grade tumors. These sequences should be included to guide prebiopsy primary brain tumors imaging to identify the most aggressive part of the tumor.

Anaplastic astrocytoma is a diffuse and malignant tumor. The average age at diagnosis is 45 to 51 years. It preferentially involves the cerebral hemisphere but can occur anywhere. Symptoms are similar to those of diffuse astrocytoma.

Anaplastic astrocytoma is a grade III tumor. The histological signature of grade III tumors is cellular atypia, anaplasia, and unequivocal mitotic activity. These tumors may evolve from grade II diffuse astrocytoma or de novo without any evidence of a less malignant precursor lesion. These tumors have an inherent tendency to dedifferentiate into glioblastoma.

CT is not useful in differentiating grade II from grade III tumor. There are a few MRI features that suggest a more malignant tumor. (Again it is difficult to differentiate anaplastic astrocytoma from glioblastoma.) This tumor is heterogeneous without the features of necrosis. Contrast enhancement is extremely variable in extent and pattern. As described earlier in the chapter, there is no correlation between tumor enhancement and tumor grade. There is a significant area of peritumoral T2 signal hyperintensity that is a mixture of edema, tumor infiltration, and rarely demyelination. On diffusion imaging, it may show diffusion restriction. On perfusion imaging, there may be focal area of increased rCBV compared to

the contralateral normal-appearing white matter. MR spectroscopy may show a low NAA peak and high choline peak usually not associated with a lipid/lac peak. An intratumoral focus with low ADC value, high rCBV, and high choline peak is the best place for biopsy.

Glioblastoma multiforme is the most common primary brain tumor, with mean age of presentation between 45 and 75 years. This tumor most commonly occurs in cerebral hemispheres predominantly in the subcortical white matter with slight preference for the temporal and frontal lobe.

The clinical history is short (less than 3 months). The usual clinical features are headache, nausea/vomiting, seizures, and/or papilledema and may include other localizing signs depending upon the location of the tumor.

Glioblastoma multiforme is a grade IV tumor with all the histologic features of grade III tumors and microvascular proliferation, necrosis, and vascular thrombosis. Most commonly, it is a rapidly developing *de novo* tumor. Less commonly, it secondarily develops into low-grade tumors.

Glioblastoma multiforme is usually a cerebral hemisphere tumor but may involve brain stem, cerebellum, and rarely even spinal cord. It may cross the midline to involve the opposite lobe usually along myelinated structures such as the corpus callosum and fornices. This tumor may be very large and extremely heterogeneous on T2 associated with necrosis, focal area of hemorrhage, and hypercellularity. The hypercellular area appears as relatively hypointense in T2 than the rest of the well known tumor and shows diffusion restriction in DWI because of compromised extracellular space. The necrotic area is hypointense in T1, hyperintense in T2, and shows facilitated diffusion in DWI. There is extensive peritumoral T2 signal hyperintensity because of mixture of tumor infiltration and edema. There may be signal void in the T2 demonstrating hypervascular tumor. Neoangiogenesis, the hallmark of the glioblastoma, is reliably identified in perfusion imaging. This consistently shows high rCBV in the region of the neoangiogenesis (development of new tumor blood vessel). One important concept is that there is no strong correlation between neoangiogenesis and enhancement in T1. Contrast enhancement is due to the T1 shortening of the tissue by the leaked gadolinium in the tissue through the disrupted blood brain barrier. High rCBV in the area of neoangiogenesis is due to high blood vessel density. In fact, contrast leakage may paradoxically lower the rCBV value. Intratumoral hemorrhage is not uncommon and is best evaluated by susceptibility-weighted imaging. However, GRE and T2 are also sensitive to detect the hemorrhage.

Gliomatosis cerebri is a diffuse glioma with exceptionally extensive infiltration of a large region of the

CNS, with at least three-lobe involvement, usually bilateral. The age range varies from neonatal period till ninth decade of life, the peak incidence being fifth to sixth decade. Any part of the brain may be involved by this tumor. The most common areas of involvement are cerebral hemispheres, mesencephalon, pons, thalamus basal ganglia, cerebellum, and medulla, in descending order of frequency. The spinal cord can also be involved by this tumor.

Presentation depends upon the site of involvement. It may be changes in the mental status, seizures, pyramidal symptoms, cranial nerve dysfunction, and signs of increased intracranial pressure.

The involved areas of brain are edematous, firm, and blurred distinction of grey–white matter interface. They most commonly express an astrocytic phenotype, but oligodendroglioma can also present with a gliomatosis growth pattern. Glioblastoma cerebri is a grade III tumor.

These are Poorly differentiated hypodense lesions with little mass effect and mild blurring of grey–white differentiation. MR imaging shows extensive white matter T2 hyperintensity, with minimal mass effect. Contrast enhancement is not a typical feature unless there is dedifferentiation. However, irregular small enhancement in parts of the tumor is not uncommon. Sometimes the diagnosis may be confused with diffuse demyelinating or dysmyelinating diseases. Presence of subtle mass effect, diffuse sulcal, or ventricular effacement should prompt thought of this diagnosis instead of demyelination.

Oligodendroglioma

Oligodendroglioma is a diffusely infiltrating, well-differentiated tumor of oligodendroglial lineage of adults, typically located in the cerebral hemispheres. It comprises 2.5% of all brain tumors and 5% to 6% of all gliomas. The majority of these tumors occur in adults, with peak age of presentation being 40 to 45 years. It preferentially occurs in the cortex and white matter of cerebral hemispheres. The frontal lobe is involved in 50% to 65% of cases, followed in decreasing order of frequencies by temporal, parietal, and occipital lobes. If the tumors of oligodendroglial lineage show focal or diffuse features of malignancy (cellular atypia, mitoses, vascular hypertrophy, pleomorphism necrosis, and so on), they are called anaplastic astrocytoma. They are approximately 20% to 35% of all the oligodendrogliomas. Very rarely, tumors may have mixed astrocytic and oligodendroglial lineage; such tumors are called oligoastrocytoma. Oligoastrocytomas do not have any specific clinical or radiological findings.

Concurrent deletion of the 1p and 19q chromosomal arms constitutes the genetic hallmark of oligodendroglioma, which may be found in up to 80% of cases. Most tumors show losses of one entire copy of 1p and

19q as a result of unbalanced translocation. Tumors with 1p/19q loss have distinct clinical, histologic, and radiological findings from those tumors without. The following characteristics are more commonly found in tumors with 1p/19q loss:

- Better response to chemotherapy.
- More indolent clinical behavior.
- Longer-lasting response to radiotherapy.
- Tumors with 1p/19q loss occur more commonly in frontal and parietal lobes compared to the temporal lobe and diencephalon.
- Usual oligodendroglial morphology instead of mixed oligoastrocytic component.
- More indistinct border in MRI and heterogeneous appearance on T1 and T2.
- Diffuse patchy enhancement instead of ring enhancement and necrosis.
- Median survival is improved.

Approximately two-thirds of patients will present with seizures. Other common presenting symptoms are headache, signs of increased intracranial pressure, focal neurological deficit, and cognitive or mental changes.

Oligodendroglioma is diffusely infiltrating tumors of moderate cellularity with oligodendroglial lineage. An important histological finding is presence of microcalcification. Classically, it is a grade II tumor.

Peripheral location, presence of characteristic calcification (linear or nodular or clumped), and occasional findings of modeling defect of the adjacent calvaria are suggestive of diagnosis. Calcification may be seen in 70% to 90%. It is heterogeneous in T2-weighted sequence. The intensity is less compared to the astrocytoma of similar grade because of high cellularity. The most specific MR feature is cortical infiltration and marked thickening, which usually is not seen in astrocytoma. Small cystic changes and intratumoral hemorrhage are common. Contrast enhancement is common but does not have any specific morphology. Oligodendroglioma may be confused with dysembryoplastic neuroepithelial tumors in young adults, but it is more hyperintense and homogenous in T2.

Primary CNS Lymphoma

By definition, primary CNS lymphoma arises in the CNS with no systemic disease. The incidence of primary CNS lymphoma has increased in the past few years. It can occur in immunologically intact and immunocompromised patients. Before HAART therapy, the tumor was highly prevalent in the end-stage HIV infection/AIDS. This tumor also occurs in posttransplant patients. This tumor can occur at any ages with a peak incidence in immunocompetent patient being sixth to seventh decade and a male predominance. In immunocompromised patients, it may

occur much earlier in life. Immunodeficiency, either acquired or congenital, predisposes to primary CNS lymphoma. Epstein-Barr virus plays a significant role in the development of the tumor. Approximately 60% of the tumors are supratentorial and can involve cerebral cortex, deep gray matter, and periventricular region. Approximately 10% to 25% of the tumors are multiple (60%–85% in AIDS). Secondary meningeal spread occurs in roughly 25% of patients. Secondary lymphoma, however, predominantly involves the meninges. Around 50% to 80% of these lymphomas present with focal neurological signs. Neuropsychiatric symptoms are also common.

The classic imaging finding is intensely and homogeneously solid-enhancing mass in the earlier mentioned locations. In AIDS patients, it may appear as multiple ring-enhancing lesions with peritumoral T2 signal hyperintensity, which is often difficult to distinguish from toxoplasmosis. The presence of subependymal spread is in favor of lymphoma rather than toxoplasmosis. CNS lymphoma usually follows the signal intensity of the cortex. However, it may be hypo- or hyperintense on T2-weighted images. Peritumoral T2 signal hyperintensity is much less intense than that of gliomas. There is usually no tumor infiltration beyond the tumor margin. It causes moderate severe diffusion restriction because of severely compromised extracellular space secondary to hypercellularity. One other common presentation is perivascular enhancement. Both extra-axial and parenchymal sarcoidosis mimic primary CNS lymphoma.

Metastatic Tumors

Metastatic tumors are the most common CNS neoplasms. Brain metastases occur in approximately 25% of patients who die of cancer, leptomeningeal metastases occur in 4% to 15% of patients, and dural metastases occur in 8% to 9% of patients. The most common source of brain metastasis is the lung followed by breast, melanoma, and cancer of unknown primary source. More than 80% of the tumors are located in the cerebral hemispheres at the gray–white matter interface secondary to abrupt change in the caliber of the arterioles in this location. Usually all metastatic foci have significant peritumoral vasogenic edema. There is also no infiltration of the tumor beyond the tumor margin.

On CT, they are usually hypodense ring-enhancing masses with significant peritumoral vasogenic edema. On MR, they present similar to that on CT. The edema associated with the tumor usually does not cross the corpus callosum. Cortical metastasis may not have any edema. One characteristic feature of melanoma metastasis is T1 hyperintensity in precontrast imaging because of paramagnetic melanin content. Metastases from melanoma, small cell lung carcinoma, thyroid cancer, choriocarcinoma, and renal cell cancer are prone to have intratumoral hemorrhage.

INFRATENTORIAL

MEDULLOBLASTOMA

See “Pediatric Brain Tumors” section.

PILOCYTIC ASTROCYTOMAS

See “Pediatric Brain Tumors” section.

HEMANGIOBLASTOMA

Hemangioblastoma is a relatively uncommon tumor. It may occur sporadically or may have familial association with von Hippel-Landau (Table 9-1). It usually occurs in adults, in the fifth to sixth decade of life. If it is associated

TABLE 9-1 Familial Tumor Syndromes Involving the CNS

NF1	CNS tumors: Neurofibroma, malignant peripheral nerve sheath tumor, optic nerve glioma, astrocytoma Other tissue involvement: Iris hamartoma, osseous lesions, pheochromocytoma, leukemia, café au lait spots, axillary freckling
NF2	CNS tumors: Bilateral vestibular schwannoma, peripheral schwannoma, meningioma, meningiomatosis, spinal ependymoma, astrocytoma, glial hamartomas, cerebral calcification Other tissue involvement: Posterior subcapsular ventricular opacities, retinal hamartomas
von Hippel-Landau syndrome	CNS tumor: Hemangioblastoma (brain and retina) Other tissue involvement: Renal cell carcinoma, pheochromocytoma, visceral cysts
Tuberous sclerosis	CNS tumor: subependymal giant cell astrocytoma (SEGA), cortical tubers Other tissue involvement: Cardiac rhabdomyoma, adenomatous polyps of the duodenum and the small intestines, cysts of the lung and kidney, lymphangioleiomyomatosis, renal angiomyolipoma, cutaneous angiofibroma, subungual fibroma
Li-Fraumeni syndrome	CNS tumors: Astrocytoma, PNET Other tissue involvement: Breast cancer, bone and soft-tissue sarcoma, adrenocortical carcinoma, leukemias
Nevoid basal cell carcinoma syndrome (Gorlin)	CNS tumor: Medulloblastoma Other tissue involvement: Jaw cysts, ovarian fibroma, skeletal abnormalities, basal cell cancer of skin
Turcot syndrome	CNS tumors: Glioblastoma medulloblastoma Other tissue involvement: Adenomatous colon polyps, café au lait spots
Cowden disease	CNS tumors: Dysplastic cerebellar gangliocytoma, megalencephaly Other tissue involvement: Hamartomatous polyps of the colon, thyroid neoplasm, breast cancer, multiple trichilemmoma, fibroma
Rhabdoid tumor predisposition syndrome	CNS tumors: AT/RT Other tissue involvement: Bilateral renal rhabdoid tumors

Abbreviations: PNET, primitive neuroectodermal tumors.

with von Hippel-Landau, it may occur in much younger patients. Sporadic tumors are usually single and occur in the cerebellum. Tumors associated with von Hippel-Landau may be multiple and may involve cerebellum, brain stem, and/or spinal cord. They may present with cerebellar symptoms. They frequently cause hydrocephalus by obstructing cerebrospinal fluid (CSF) outflow.

Pilocytic astrocytomas are well-demarcated cystic lesions with a highly vascular nodule in the wall. They are composed of large vacuolated cells and vascular cells. They are grade I tumors.

Pilocytic astrocytomas are usually large, sharply marginated cystic masses of the cerebellar hemisphere with a pial-based mural nodule with very minimal to no peritumoral edema. There is usually no calcification. A cystic posterior fossa mass, brightly enhancing pial-based nodule, and a prominent vessel (flow void) within or adjacent to the tumor on MR, in combination, are consistent with hemangioblastoma. The mural nodule produces intense blush in angiography. The cyst fluid may appear hyperintense to normal CSF because of presence of hemorrhage and protein contents.

Dysplastic Cerebellar Gangliocytoma

This is a childhood tumor. See “Pediatric Brain Tumors” section.

INTRAVENTRICULAR

LATERAL VENTRICULAR

Ependymoma

This is more common among children (See “Pediatric Brain Tumors” section).

Subependymoma

Subependymomas are WHO grade I tumors and are usually asymptomatic. They are more common in males with peak age of presentation being the fourth through sixth decade. They are well-circumscribed, lobulated intraventricular masses. The most common locations are the foramen of Monro and the fourth ventricle. Subependymomas of the foramen of Monro or at the region of aqueduct may obstruct CSF flow and can present with hydrocephalus. They are hypodense in CT with or without calcification. They are hyperintense to gray matter in T2, with no enhancement.

Central Neurocytoma

Central neurocytomas are rare, benign intraventricular tumors attached to the septum pellucidum and/or the lateral ventricular wall often arising from the region of the foramen of Monro. They usually occur in early adulthood. On microscopy, they look like oligodendroglioma. Calcification is a common finding. Their enhancement is variable but common.

Xanthogranuloma

They are benign choroid plexus masses. They are usually bilateral and typically occur in adults.

Meningioma

See “Meningeal” section.

Metastasis

See “Intraparenchymal” section.

ANTERIOR THIRD VENTRICLE**Subependymal Giant Cell Astrocytoma**

This is usually a tumor of pediatric age group (Table 9-1).

Colloid Cyst

Colloid cysts are well-capsulated neuroepithelial cysts in the roof of the third ventricle found almost exclusively in the anterior part of the third ventricle right behind the foramen of Monroe. They occur in both sexes and are frequently asymptomatic. Sometimes they present with headache. They may obstruct the foramen of Monroe and can cause hydrocephalus. There are reported cases of sudden death after acute onset hydrocephalus.

On CT they are usually well-capsulated and round. They are typically hypodense, but if there is higher protein concentration, these may be hyperdense of variable degree. The capsule may enhance. On MR, they are hypointense in T1 unless they contain highly proteinaceous fluid, blood products, or cholesterol crystal when they become hyperintense. They are typically hyperintense on T2, unless they contain blood products or highly proteinaceous fluid. Endoscopic removal is the treatment of choice.

Metastases of the anterior third vehicle are benign, unilocular, smooth, round, epithelial-lined (derived from endoderm), mucin-containing cysts of the anterior third ventricle between the columns of fornix. They represent the most common type and location of neuroepithelial cysts. They may present with headache, sudden transient paralysis of lower extremity, incontinence, and personality changes. Hydrocephalus, which may be positional and intermittent, is also common. They are usually seen in young adult and middle-age patients. They are hyperdense in CT. The MR signal characteristics are variable depending upon the protein content and also frequent presence of different paramagnetic substances. The signal intensity may vary from markedly hypointense to markedly hyperintense in T2. They can also be of high or low signal intensity on T1. Rarely, there may also be rim enhancement. Solid enhancement should suggest other diagnoses.

SELLAR/PARASELLAR/SUPRASELLAR**PITUITARY ADENOMA**

Pituitary adenomas are slow-growing tumors arising from the adenohypophysis. They are the most common tumor

of the sella turcica. They are primarily tumors of adults. Only about 3% occur in children less than 18 years. They can be of variable size from less than a centimeter up to several centimeters. Tumors less than 10 mm in size are known as microadenoma. Most of the functional adenomas are prolactin secreting. Prolactinomas occur predominantly in women. ACTH-secreting adenomas constitute 15%. Approximately 25% tumors are nonfunctional.

Prolactinomas in women cause presenting clinical symptoms like menstrual irregularity and galactorrhea. Women tend to seek medical attention much earlier than men, thus explaining the comparatively smaller tumor size in women. The clinical symptoms in men can be subtle (decreased libido) precluding early tumor detection. Symptoms owing to mass effect on adjacent structures (visual field defect, ptosis) are more common in men. Growth hormone-secreting tumors present with gigantism in children; in adults, they present as acromegaly. ACTH-secreting tumors present with Cushing syndrome, predominantly in women. Nonfunctional adenomas are usually clinically silent until they become large enough to impinge the adjacent structures.

The best imaging modality is MRI as the soft-tissue resolution is greatly superior to CT, and there are no bone artifacts. Coronal plane is the best plane for evaluation of the pituitary/sella. Almost 80% of tumors present as focal T1 hypointensity and T2 hyperintensity with or without contour abnormality of the gland. Tumoral calcification is rare. The best sequence for evaluation of microadenoma is coronal postcontrast dynamic T1-weighted sequence. As the tumors uptake contrast at much slower rate than the normal pituitary tissue, tumors appear as focal hypointense defect. A laterally located tumor may displace the pituitary stalk; if the tumor is large enough it may invade the cavernous sinus and impinge on the internal carotid arteries and surrounding cranial nerves, which is of great importance in preoperative planning. There are many MR signs described for detection of the invasion of the cavernous signs. The definite signs of noninvasion are normal pituitary tissue between the tumor and cavernous sinus, less than 25% of the ICA encasement, and intact medial venous compartment. A large tumor may show demineralization of the adjacent bone. Intratumoral hemorrhage can occur in 20% to 30% of adenomas, mostly in macroadenomas. Most of the time the hemorrhage is subclinical but may also present as pituitary apoplexy. The incidence of hemorrhage is higher in patients treated with bromocriptine.

CRANIOPHARYNGIOMA

In adults, papillary craniopharyngiomas are more common. They are solid, without calcification. Unlike the adamantinomatous form, they are encapsulated with absent desmoplasia and are easily separable from the

adjacent structures. This also explains less recurrence after surgery compared to the adamantinomatous form. They frequently involve the third ventricle.

RATHKE CLEFT CYST

Rathke cleft cysts are usually incidental on autopsy findings. They are rarely symptomatic, except when they are large and compress the adjacent structures. They may appear with variable signal intensity in both T1- and T2-weighted sequence depending upon the protein concentration of the cyst. They may be T1 hyperintense and T2 hypointense compared to the cortex, if the protein concentration is very high. They are usually hypodense in CT but may be hyperdense as well. They usually do not enhance.

MENINGIOMA

Approximately 10% of meningiomas occur in the parasellar region. See “Meningeal” section.

CHORDOMA

The clivus is the most common site of cranial chordomas. Chordomas originate from the embryologic remnant of the notochord or ectopic cordal foci. They usually present in the sixth decade. They are benign, locally aggressive masses causing extensive bony destruction. If large enough, they may cause compression of the visual pathways, cranial nerve palsies, and brain stem compression. If they grow laterally, they can present as a CP angle mass or inferiorly; they can present as pharyngeal mass. They are hypointense in T1 with replacement of the normal high T1 signal intensity of fat within the bone marrow. Characteristically, they are moderate to severely hyperintense in T2. They may be heterogeneous because of calcification and bone destruction.

SUPRASellar GERMINOMA

This is a tumor of childhood. See “Pediatric Brain Tumors” section.

HYPOTHALAMIC HAMARTOMA

A disease of childhood. See “Pediatric Brain Tumors” section.

DERMOID CYSTS

Dermoid cysts are ectodermal inclusion cysts, which usually occur at midline or near the midline. They may have epidermal derivative like hair and sweat glands. They usually occur in the third decade. Midline structures such as the vermis or fourth ventricle are the most common locations of this tumor followed by sellar/suprasellar region and frontobasal regions. The cysts usually contain lipid material, and that is why they appear as hypodense mass in CT and very bright in noncontrast T1-weighted sequence. One important feature of dermoids is that they

may rupture and spread in the CSF spaces. This can result in chemical meningitis with seizures, which can be fatal. Headaches and seizures are common presenting features. They usually do not enhance with contrast.

Dermoid cysts constitute approximately 8% of the primary intracranial tumors. The most common site is the intracanalicular portion of the vestibular division of the eighth nerve complex with or without extension into the CP angle. They are associated with NF2.

Pathologically, dermoids are well encapsulated and arise from the outer nerve sheath layer and grow eccentrically outward and this is the reason they most commonly present with hearing loss due to compression of the cochlear division by the growing tumors. They more commonly arise from the sensory nerves. Histologically, they may be of two types: Antoni A cell type with compact stroma and Antoni B type with loose matrix. They usually appear as heterogeneously T2 hyperintense mass with bright enhancement in the postcontrast images. The Antoni B type is usually hyperintense in T2-weighted sequence. High-resolution heavy T2-weighted sequences (CISS, FIESTA) allow excellent delineation of the tumor.

HYPOTHALAMIC AND CHIASMATIC GLIOMA

See “Pediatric Brain Tumors” section.

CEREBELLAR PONTINE ANGLE

ACOUSTIC NEUROMA

MENINGIOMA

See “Meningeal” section.

EPIDERMOID CYSTS

Epidermoid cysts may be congenital and acquired. Congenital tumors occur as an inclusion cyst. They probably arise from the ectopic epithelial inclusion at the time of neural tube closure. Acquired tumors arise after trauma. They are soft tumors that have an inherent tendency to insinuate along the CSF spaces rather than compress the surrounding structures. They usually contain squamous epithelium, keratin debris, and sometimes cholesterol crystal. Unlike dermoid, they lack dermal elements and are usually off midline rather than midline. They are more common than dermoid cysts. They usually occur in the fourth or fifth decade of life. Usual symptom is headache.

Epidermoid cysts follow the CSF density and intensity in CT and MR respectively. Rarely, there may be mural calcification. They usually do not enhance in the post contrast scan. The most consistent and characteristic finding is diffusion restriction in DWI. Unlike arachnoid cysts, they appear hyperintense in FLAIR.

CRANIAL NERVE SCHWANNOMAS

These are benign nerve sheath tumors that arise from myelin support cells. These displace but do not invade the nerve.

METASTASIS

See “Meningeal” section.

MENINGEAL**MENINGIOMA**

Meningiomas arise from the meningotheial cells. They account for approximately 30% of the primary intracranial tumors. There is an association with NF2 (may be multiple) (Table 9-1). This is a tumor of adulthood, with peak age being the sixth and seventh decades. There is a slight female predominance. Spinal meningiomas show a marked female predominance. Radiation to the head is known to cause meningiomas. Sex hormones may also have some role. The most common location is over the cerebral convexities, often parasagittal (Table 9-2). Others common locations are olfactory groove, sphenoid ridges, sellar/parasellar region, optic nerve sheaths, petrous ridge, posterior fossa. The predilection to these common sites may be explained by the predominance of the arachnoid granulations in these locations.

Meningiomas are slow-growing tumors, usually present with headache, and may also be associated with seizures and nerve palsies. They are mostly WHO grade I tumors, but may also be grade II or III. There are numerous pathologic subtypes. The most common type is the meningotheial subtype.

On conventional radiograph, there may be bone erosion, localized bone thickening, enlarged vascular channels, and enlarged paranasal sinuses (in skull-base meningiomas).

On noncontrast CT, meningiomas are usually homogeneously isodense or can be hyperdense (to brain parenchyma). They are well-circumscribed dural-based masses. There may be calcification in approximately 25%

of cases. Hyperostosis is a common finding. Contrast-enhanced CT shows intense homogenous enhancement (as these tumors develop from dura which does not have blood–brain barrier).

On MR, the tumor is isointense to cortex in T1 and isointense to cortex in T2 in 50% and hyperintense to cortex in 50%. These tumors enhance brilliantly after contrast administration. The CSF cleft is commonly seen. There may be vasogenic edema in the adjacent cortex. There is no definite imaging finding to differentiate typical meningiomas from atypical meningiomas.

HEMANGIOPERICYTOMA

These are soft tissue sarcomas that originate from the pericytes of blood vessels. They can appear similar to a vascular aggressive meningioma on imaging.

METASTASIS

The most common type of metastasis to the dura is from breast cancer. Other common primary sites are lungs, lymphoma, prostate, and less likely neuroblastoma. Very rarely, extensive dural involvement with or without multiple cranial nerve palsies, carcinomatous meningitis, may occur. They usually appear as enhancing lesions of the dura with or without thickening.

LYMPHOMA/LEUKEMIA

Their involvement of the meninges is primarily from metastatic or cranial extension.

SARCOIDOSIS

Secondary intracranial involvement in sarcoidosis is not uncommon. Intracranial sarcoidosis may be of two types: granulomatous meningitis (more common) and parenchyma space-occupying lesions. The leptomeningeal involvement may involve the cranial nerves causing cranial nerve palsy. The facial nerve is the most common. Leptomeningeal lesion present as an irregular thickening/lobular dural mass, which is isointense in T1, hypointense in T2, and brightly enhancing in T1+c. Parenchymal lesions are rare.

PEDIATRIC BRAIN TUMORS**TUMORS IN THE FIRST YEAR OF LIFE****TERATOMA**

These are tumors containing all three germ cell lines.

ATYPICAL TERATOID AND RHABDOID TUMOR

Although these represent only 32% of CNS pediatric tumors, they are one of the more common solid CNS childhood malignancies, with roughly two-thirds occurring in the posterior fossa. See “Supratentorial” section.

TABLE 9-2 Imaging Findings in Favor of Extra-Axial Tumors

A CSF cleft around the tumors
Vessel interposed between brain and tumor
Displaced/Compressed (with or without edema) gray matter between white matter and the mass
Enlarged CSF spaces, particularly at the margins of the tumor
In posterior fossa mass, compression and displacement of the brain stem opposite to the tumors
Peripheral broad dural based

Abbreviations: CSF, cerebrospinal fluid.

DESMOPLASTIC INFANTILE GANGLIOGLIOMA AND ASTROCYTOMA

The tumors listed here are large cystic tumors of infants that involve the superficial cerebral cortex and leptomeninges with a favorable prognosis. They are rare tumors of infancy and early childhood. They usually present within the first year of life. They always arise in the supratentorial region and usually involve more than one lobe, preferentially the frontal and parietal lobes.

These tumors of childhood usually present with increasing head circumference, tense and bulging fontanelles, and lethargy. They are huge tumors that are mostly cystic and almost always associated with a focal hyperenhancing superficial solid portion. The solid portion is primarily extracerebral and involves the leptomeninges and superficial cortex. This solid portion is hyperdense to cortex in CT and isointense to cortex in T1 and T2.

Choroid Plexus Cancer/Papilloma

Choroid plexus cancer/papilloma constitutes approximately 10% to 20% of all brain tumors in the first year of life.

EARLY ADULTHOOD TUMORS

PARENCHYMAL TUMORS

Infratentorial

Medulloblastoma

Medulloblastomas are malignant tumors of cerebellum presenting in early childhood and with an inherent tendency to metastasize via CSF pathways. They comprise 15% to 20% of intracranial tumors in children and 30% to 40% of infratentorial tumors in early childhood. The peak age at presentation is 7 years. There is a slight male predominance. Two-thirds of childhood medulloblastomas arise in the vermis and project into the fourth ventricle. Involvement of the cerebellar hemispheres increases with age. This tumor is associated with basal cell nevus syndrome.

Medulloblastomas usually present with cerebellar signs and signs of increased intracranial pressure. The duration of symptoms is usually short because of the aggressive nature of the tumor. In infants, there may be enlarged head circumference due to hydrocephalus. Spinal metastasis is present at the time of initial diagnosis in 30% of tumors.

Medulloblastomas are composed of densely packed, primitive, undifferentiated small round cells with cellular signature of high-grade tumors. Homer-Wright rosettes are seen in 40% of tumors. They are WHO grade IV tumors with multiple histologic variants.

On CT, medulloblastomas typically appear as well-circumscribed hyperdense masses involving only vermis, or vermis and cerebellum. More peripherally lo-

cated tumors may have exophytic growth pattern and may extend to the CP angle. Calcifications may be seen in 20% and intratumoral cysts are found in about half of the cases. The mass appears heterogeneous in both T1 and T2. The solid portion is isointense to grey matter in T1 and hypo- to isointense in T2. CSF metastasis is common with the most common location as the basilar cisterns and in the ependyma of lateral ventricles. In the spinal cord, the most common location is the dorsal surface of the thoracolumbar spinal cord (intradural extramedullary or intramedullary). The caudal most part of the thecal sac is also a common location. Complete imaging of the spinal cord at diagnosis is always required for assessment of disease burden.

Cerebellar Astrocytoma

Cerebellar astrocytoma constitutes 5% to 6% of all gliomas. This is the most common glioma in children, occurring most commonly in the cerebellum. The most common supratentorial site in children is visual pathways/hypothalamus. This tumor most commonly develops in the first two decades of life. This tumor can arise from any part of neural axis containing glial tissue. Common locations are the optic nerves (optic nerve glioma), hypothalamus, thalamus, basal ganglia, hemispheres, cerebellum (cerebellar astrocytoma), brain stem (dorsal exophytic glioma). Intracranial visual pathway PAs are often associated with NF1 (Table 9-1).

Clinical features depend upon the location of the tumor. Cerebellar astrocytoma usually does not present with seizures as it infrequently involves the cerebral cortex. Posterior fossa tumors present with cerebellar symptoms, such as clumsiness, problems in balance and coordination. Tumors involving the optic pathways present with visual difficulty. Tumors of the sella usually present with endocrinologic abnormality or cranial nerve palsies.

Cerebellar astrocytoma is well circumscribed, partially cystic, often with a mural nodule of solid vascular tissue. The cause of cyst formation within the tumor is not known but may be proteinaceous. This is a WHO grade I tumor and does not show features of a high-grade tumor. There is low to moderate cellularity with loose-textured cells and microcysts.

The cystic part appears as hypodense (denser than CSF because it contains protein) on CT, hypointense in T1, and hyperintense in T2 (may be more hyperintense than CSF if it contains protein). Intratumoral calcification is not common. Mural nodule is slightly hyperintense in T2 and hypointense in T1 in comparison to normal brain tissue and enhances brightly and homogeneously in the postcontrast images. The wall of the cyst may or may not enhance (as most of the time the wall is the compressed normal brain tissue or reactive glial tissue). The solid portion of the tumor is usually homogenous and

isointense to normal brain on T2. It displaces and therefore compresses the fourth ventricle. Visual pathway gliomas may be completely solid without any cystic component. Brain stem pilocytic astrocytomas are usually dorsal, exophytic with variable enhancement instead of symmetric pontine enlargement as seen in diffuse fibrillary astrocytomas.

Ependymoma

Ependymomas constitute 8% to 12% of all primary pediatric CNS tumors. They may occur at any age, but the mean age at presentation is 6.4 years. There is a second peak in the fourth and fifth decades. They can occur at any ventricle and the spinal cord. The most common location is the fourth ventricle (both from the roof and floor of the fourth ventricle with frequent extension into the foramen of Luschka and Magendie) and the spinal cord followed by the lateral and third ventricles. Supratentorial ependymomas occur particularly in children and they are usually parenchymal.

Presentation depends upon the location, but fourth ventricle ependymomas usually present with hydrocephalus and signs of raised intracranial pressure.

Ependymomas arise from the ependymal cells. They are so-called plastic tumors that fill the fourth ventricle and emerge out of the fourth ventricle through the foramen of Luschka and Magendie. There are many histologic subtypes of the tumor. They are usually WHO grade II tumors. In 10% to 12% cases, there may be CSF spread. CSF spread is usually associated with higher-grade tumors (grade III or ependymblastoma).

The typical CT appearance is iso- to hyperdense fourth ventricular mass with both solid and cystic component, calcification, heterogeneous enhancement, and extension through the foramen of Luschka and Magendie. On MR, the mass is extremely heterogeneous with solid portions, cystic portions, calcification, and hemorrhage. In preoperative evaluation, spinal MR should be included to exclude the possibility of CSF dissemination.

Brain Stem Tumor

Brain stem tumors represent 15% of all pediatric tumors and about one-third of all posterior fossa tumors. The peak age at presentation is between 3 and 10 years, although they can present at any age. Brain stem tumors are broadly classified as medullary, pontine, mesencephalic, and tumors associated with NF1 (Table 9-1). Although brain stem tumors may be of any histology, astrocytoma is the most common.

Medullary tumors may be of pilocytic astrocytoma variety, which typically involve dorsal medulla with exophytic growth, or it may be diffuse fibrillary astrocytoma involving pons rostrally and cervical cord caudally with or without enhancement.

Pons is the most common location of brain stem tumor. The usual histology is high-grade fibrillary glioma. It usually presents with multiple cranial nerve palsy and cerebellar signs. It is hypodense to cortex on CT and hypointense to cortex on T1 and hyperintense on T2 and FLAIR with expansion of the pons. There is a blurry margin of pons with subtle or no enhancement. The imaging appearance is so typical that biopsy is not required to start treatment. However, the presence of any atypical sign (marked enhancement before treatment or presence of hemoglobin degradation product) should always be carefully searched for alternate diagnosis.

Hemangioblastoma

Usually this tumor occurs in the older age group (Table 9-1). See “Infratentorial” section.

Supratentorial

Astrocytoma

The presentation, clinical feature, and imaging features are similar to that of adult astrocytoma. See “intraparenchymal” section.

Ganglioglioma/Gangliocytoma

Ganglioglioma/gangliocytoma represents 1.3% of all brain tumors. The age of presentation is wide ranging: from 2 to 70 years of age, with a mean age of presentation 8.5 to 25 years. They can occur in any part of the CNS but occur mostly at the supratentorial superficial cortex. The most common location is the temporal lobe (greater than 70%). Parietal and frontal lobes are the next most common location.

Tumors of the cerebrum present with refractory seizures. They are the most common tumors presenting with seizures.

Gangliogliomas/gangliocytomas are well-differentiated slowly growing tumors containing neoplastic mature ganglion cells and glial cells. They are usually solid/cystic lesions with minimal mass effect. They are usually WHO grade I tumors and may be rarely of higher grade.

Typically ganglioglioma/gangliocytoma is well circumscribed and solid or partially cystic often with focal calcification. There is no specific imaging sign. Usually it is hypodense in CT and heterogeneously T2 hyperintense tumors of varying sizes and varying contrast enhancement with little mass effect. On rare occasions, there may be remodeling of the adjacent bone, confirming the slow-growing nature of the tumor. Sometimes the tumor cannot be differentiated from the gangliocytoma both histologically and by MR. When this occurs, they are loosely called as ganglion cell tumors.

This lesion presents as a central solid mass with multiple surrounding large cysts. It usually presents in the first 24 months and involves more than one lobe of the cerebrum.

Desmoplastic Infantile Astrocytoma and Ganglioglioma Dysembryoplastic Neuroepithelial Tumor

Dysembryoplastic neuroepithelial tumors are uncommon benign supratentorial intracortical tumors that occur preferentially in children and young adults, mainly at the temporal lobe.

Typically, these tumors present with drug-resistant partial seizures, with or without secondary generalization, and no neurological deficit.

Dysembryoplastic neuroepithelial tumors are grade I tumors containing glioneural elements; the histologic hallmark is the column of tumor cells perpendicular to the cortical surface. Focal cortical dysplasia is associated in 80% of cases.

Classically, these tumors selectively involve the cortex. There may be enhancement in approximately 20% of cases. They are hypodense on CT. There may be calcification in about one-third of patients. In some lesions, there may be focal remodeling changes in the adjacent calvarium. On MRI, there may be multiple small focal intratumoral cysts.

Pleomorphic Xanthoastrocytoma

Pleomorphic xanthoastrocytoma is a relatively rare tumor that accounts for approximately 1% of all astrocytic tumors. This is a tumor of children and young adults. Seventy-five percent of tumors present in persons less than 18 years. This is a superficial cortical tumor and involves the meninges. It is almost always supratentorial, and the most common location is temporal lobe.

As this tumor preferentially involves the cerebral cortex, the most common presentation is long-standing seizures.

Pleomorphic xanthoastrocytomas are frequently associated with cysts (in 50%) and a mural nodule. Pleomorphic refers to variable histologic appearances. Xanthoastrocytoma refers to presence of xanthomatous cells showing intracellular lipid accumulation. They are WHO grade II tumors.

Typical imaging appearance is well-circumscribed peripheral temporal lobe mass with cystic and solid component without any calcification. The solid portion is isodense to gray matter in CT and isointense to gray matter in T1 and T2. The solid portion enhances homogeneously but may be heterogeneous if there are microcystic changes. There is usually no peritumoral T2 signal hyperintensity. The tumor frequently invades the leptomeninges. Like other superficial tumors, this tumor may also produce bony remodeling in the adjacent calvarium.

Gliomatosis Cerebri

Subependymal giant cell astrocytoma is a specific tumor that is characteristically associated with tuberous sclerosis. It occurs in 5% to 10% of tuberous sclerosis patients. The tumor may occur at any age but the median

age at diagnosis is 5 to 10 years. It typically arises from the wall of the lateral ventricle near the foramen of Monro and frequently present with hydrocephalus by obstructing the foramen. The tumor is most likely originated from the subependymal hamartomas of tuberous sclerosis because they are identical histologically. It is hypo- to isodense in CT (hypo- to isointense in MR) with frequent calcification, and enhances homogeneously with contrast.

Primitive Neuroectodermal Tumor

Primitive neuroectodermal tumors (PNET) are embryonal tumors of undifferentiated or poorly differentiated neuroepithelial cell origin with capacity for divergent differentiation. Ninety to 95 percent of tumor cells are undifferentiated or poorly differentiated. Histologically, they are similar to medulloblastoma, pinealoblastoma, and peripheral neuroblastoma.

Exact incidence is not known, as there is frequent overlap with above-mentioned pathologies. The tumor may occur between 4 weeks and 20 years of life but median age of presentation is 5.5 years. They usually occur in the deep cerebral white matter of cerebrum.

The clinical presentation depends upon the location of the tumor. Most are very large at presentation and contain poorly differentiated cells. PNET are WHO grade IV tumors. They can metastasize outside CNS.

They are an extremely heterogeneous tumor, usually located either in the cerebral hemisphere or in the lateral ventricles. They may be mixed having solid and cystic components, and solid tumors with central necrosis with frequent calcification. The solid portion of the tumor is hyperdense in CT (isointense to gray matter in T2 and FLAIR). There is frequent enhancement in postcontrast images.

Supratentorial Ependymoma

Supratentorial ependymomas constitute 20% to 40% of childhood ependymoma. They usually occur early in childhood with a slight male predominance.

Presentation depends upon the location of the tumor, but seizure is a common presenting symptom.

These tumors are histologically identical to the infratentorial counterpart. The imaging appearances are variable. They may be completely solid and/or containing cystic component and calcification. They are iso- to hyperdense on CT (usually follow the signal characteristics of grey matter in T1, T2, and FLAIR images). The heterogeneity and peritrigonal location raises the suspicion of this tumor. Oligodendroglioma is rare in children, and constitutes 1% of all pediatric brain tumors.

Atypical Teratoid/Rhabdoid Tumor

Atypical teratoid/rhabdoid tumors are highly malignant rare tumors of early childhood (Table 9-1). They rarely occur in patients older than 6 years of age, median age

of presentation is 2 years. They may be both supra- and infratentorial, supratentorial being slightly more common. The usual supratentorial location is cerebral hemispheres. They can involve the cerebellum, CP angle, and brain stem infratentorially.

The clinical presentation depends upon the tumor location, size, and age at presentation. Usual presentations are lethargy, failure to thrive, and signs of increased intracranial pressure.

Atypical teratoid/rhabdoid tumors are grade IV tumors containing rhabdoid cells and any type of cells arising from the ecto-, endo-, and mesoderm. They are usually large at presentation. Typically, they are angry-looking solid tumors with heterogeneous enhancement and variable necrosis. The solid portion is usually hyperdense to normal gray matter in noncontrast CT owing to hypercellularity. Sometimes they are difficult to differentiate from primitive neuroectodermal tumors.

VENTRICULAR TUMORS

Choroid Plexus Papilloma/Carcinoma

Choroid plexus papillomas (CPP) are intraventricular papillary tumors. They represent 2% to 4% of brain tumors in children younger than 15 years of life. Approximately 80% of the lateral ventricle tumors present before 20 years of age. The fourth ventricle tumor can occur at any age. CPP occurs more commonly in males, but there is no sexual predilection in choroid plexus carcinoma (CPC). The tumor involves the lateral ventricles in approximately 50% (the trigone is the most common location), the fourth ventricle in 40%, and third ventricle in 5%.

Typically, the child presents with hydrocephalus because of obstruction of CSF flow and/or overproduction of CSF.

CPPs are cauliflower-like masses of the ventricle that may involve the ventricular wall. They do not involve the adjacent brain tissue unlike CPC. CPP is a WHO grade I tumor. If there is an atypical feature, it is considered to be grade II. CPC is grade III tumor.

On CT, the typical papilloma appears as a multilobulated intraventricular hypodense mass with occasional calcification but almost always with intense enhancement. Occasionally the papilloma grows through the ependyma and involves/infiltrates periventricular white matter. CPC usually invades and infiltrates adjacent white matter with extensive T2 signal hyperintensity. Usually CPC are heterogeneous with loss of lobulation in appearance and also they enhance heterogeneously. The central portion of the tumor is hypointense to the grey matter in T2. Intratumoral hemorrhage is common and can be identified on MR. Based on imaging appearances, most of the time it is impossible to correctly identify CPP versus CPC. However, CPP may have aggres-

sive features, and the malignant looking mass may turn out to be an atypical CPP in histology.

Ependymoma

See "Infratentorial" section.

Colloid Cyst

See "Anterior Third Ventricle" section.

PINEAL REGION TUMORS

Germinoma

There is geographic variance in incidence. Germinomas are more common in Far East Asia. They account for 2% to 3% of all primary CNS neoplasms and up to 15% of all pediatric tumors in Japan. The respective numbers for the west is 0.3% and 3% to 4%. Approximately 90% of CNS germ cell tumors occur in patients younger than 25 years with a peak age of incidence 10 to 14 years. There is an interesting sexual distribution of the tumor. The great majority of the pineal germinomas occur in boys, but the suprasellar tumors are common in girls. Of all the germinomas, teratomas occur in males in approximately 90% of cases. The majority of the germinomas arise around the third ventricle. The most common location is pineal region followed by suprasellar region.

The clinical presentation and duration of symptoms depend upon the histology and the location of the tumor. The pineal region tumor presents with progressive hydrocephalus owing to compression of the aqueduct. If the tumor involves the tectal plate, characteristic paralysis of upward gaze and convergence (dorsal Parinaud syndrome) occur. Suprasellar germinomas may compress the optic chiasm producing characteristic bitemporal hemianopsia. They also frequently present with hormonal disturbances (diabetes insipidus, pituitary failure) owing to interference with hypothalamic-pituitary functions. Precocious puberty is also a known manifestation because of secretion of hCG.

Germinomas are predominant in the suprasellar compartment. Nongerminomatous germ cell tumors predominate in other locations. Multifocal germinomas usually involve the pineal and suprasellar region either simultaneously or sequentially. Characteristic CT finding is a midline pineal/suprasellar mass containing both fat and calcification with variable contrast enhancement. On MR, the lesion is heterogeneous in both T1- and T2-weighted images because of different contents. However, germinomas can present as homogenous soft-tissue density/intensity mass with variable contrast enhancement in the typical location and typical age group. A more malignant variant may be associated with vasogenic edema.

Pineal Parenchymal Tumors

Pineal parenchymal tumors are less common than germinomas. They may be of two types: pineocytomas and pinealoblastomas. Pineocytomas are rare in childhood, but pinealoblastomas usually present in the pediatric

age group. Pineocytomas are well-circumscribed, non-invasive slow-growing tumors composed of differentiated cells and pinealoblastomas are highly malignant, invasive tumors composed of small round undifferentiated cells. Pineal parenchymal tumors commonly disseminate through the CSF. Imaging features are like that of primitive neuroectodermal tumors in the pineal region.

SELLAR/SUPRASellar TUMORS

Craniopharyngioma

Craniopharyngioma is partially cystic epithelial tumor of the sellar region. These tumors account for 1.2% to 4.6%. The incidence is higher in Japan and Nigeria. Craniopharyngioma may be of two types: adamantinomatous and papillary. There is a bimodal age distribution of the adamantinomatous form with peaks in children 5 to 15 years and adults aged 45 to 60 years. Papillary craniopharyngioma occurs almost exclusively in adults with mean age of presentation 40 to 55 years. The most common location is suprasellar cistern with a minor intrasellar component.

Clinical features are nonspecific and depend on the involvement of the adjacent structures caused by mass effect. It may present with visual field defects (most common presentation) because of compression of the optic chiasm/nerve/tract and endocrine abnormality because of interference with hypothalamic-hypophyseal functions. Cognitive impairment and personality changes are also common.

Typically, they are lobulated cystic masses with solid component in adamantinomatous variety. On sectioning, there is a typical greenish-brown liquid like “machine oil.” They often extend beyond anatomic confinement and produce dense desmoplasia causing superficial brain penetration and adhering to the adjacent vessels and nerves. They are very difficult to resect surgically. On the other hand, papillary variety is well-circumscribed solid, rarely cystic tumor with absence of calcification. They are WHO grade I tumors.

The imaging appearance depends upon the histologic type. Adamantinomatous form appears as a mixed solid and cystic mass with calcification in most. The CT density of the cyst may be hypo-, iso- or hyperdense to cortex. The calcification may be circumferential at the wall or dense calcification in the solid portion. There is variable enhancement in most. A cystic or solid/cystic enhancing mass with calcification at the suprasellar region with intrasellar extension is consistent with a craniopharyngioma. Large tumors may extend to middle/anterior/posterior cranial fossa.

Rathke Cleft Cyst

See “Sellar/Parasellar/Suprasellar” in “Adult Brain Tumors” section.

Pituitary Adenoma

See “Sellar/Parasellar/Suprasellar” in “Adult Brain Tumors” section.

Hypothalamic Hamartoma

Hypothalamic hamartomas are congenital lesions of the normal neuronal tissue involving the hypothalamus and pituitary stalk. There is a markedly male predominance. The most common presentation is isosexual precocious puberty. Usual presentation is less than 2 years. The other common clinical presentation is seizure, typically of gelastic type. They are well-defined masses from the hypothalamus extending down to suprasellar cistern following the density/signal intensity of normal gray matter without any enhancement.

Chiasmatic/Hypothalamic Astrocytomas and Optic Nerve Tumor

Astrocytomas at these locations constitute approximately 10% to 15% of the supratentorial tumors. Once the tumor grows beyond the margin of the primary location, it is difficult to identify the exact origin. Males and females are affected equally. Usual age of presentation is 2 to 4 years. One interesting behavior of the astrocytomas of the optic nerve and chiasm is that they can resolve spontaneously over time. This is true both with and without the setting of the NF1.

The usual clinical presentation is visual field defects, optic atrophy, and short stature. If the tumor is large, it can present with hydrocephalus and signs of increased intracranial pressure.

Up to 50% of the astrocytomas at this location are associated with NF1. The majority of the tumors at this location are pilocytic astrocytomas; the pathology and imaging findings are similar to the pilocytic astrocytomas of the cerebellum.

Bone artifacts in the CT scan prevent accurate evaluation of the tumor extent. MRI is very helpful for defining the extent of the tumor and also involvement of the optic pathways. The tumor primarily arising in the optic nerve causes fusiform enlargement of the optic nerve. Astrocytomas of this location are almost always hypodense to brain on CT and hypointense to gray matter in T1-weighted sequence and hyperintense to gray matter in T2-weighted sequence. In postcontrast images, the tumor enhances heterogeneously to a variable extent. The sagittal plane is optimal for evaluation of the optic nerve and coronal plane is very good for evaluation of the chiasm and brain involvement.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a heterogeneous group of tumors and tumorlike masses composed of histiocytosis. LCH shows features of dendritic Langerhans cells, whereas most of various non-LCH show

macrophage lineage. LCH is a disease of childhood and presents most commonly as a solitary lytic lesion of the skull bones. The mean age of presentation is 12 years. If there are multifocal lytic bony lesions associated with involvement of the hypothalamus, it is known as Hand-Schüller-Christian disease. Histiocytosis of the lymph node, skin, and viscera without brain involvement is otherwise known as Letterer-Siwe disease.

The most common intracranial location is at the involvement of the pituitary stalk. Diabetes insipidus is a known clinical feature and can occur from 5% to 50% of cases. Usually the first deposit is in the subarachnoid space, but gradually the pituitary stalk is involved. In the later stage of the disease, there is granulomatous involvement of the brain parenchyma too. The hypothalamic involvement may vary from slight thickening of the stalk to a frank mass. There is usually enhancement of the pituitary stalk/mass. One characteristic finding is absent T1 bright signal in the posterior pituitary.

Suprasellar Germ Cell Tumor

Unlike pineal region germ cell tumors, suprasellar germ cell tumors are more common in girls.

QUESTIONS AND ANSWERS

1. What is the most likely location of a lesion that causes homonymous hemianopsia?
 - A. Optic nerve
 - B. Optic chiasm
 - C. Lateral geniculate body
 - D. Postchiasmatic optic pathways

ANSWER: D. Homonymous hemianopsia can occur as a result of lesions anywhere in the postchiasmatic visual pathways including optic tract, lateral geniculate body, optic radiation, and visual cortex. Lateral geniculate body is correct and is a better option because it includes all possible causes and is more appropriate. The nasal fibers, responsible for the temporal visual fields, decussate at the optic chiasm. Lesions in the optic chiasm cause bitemporal hemianopsia. Unilateral optic nerve lesions cause unilateral visual disturbances.

2. Where is intraventricular meningioma most commonly located?
 - A. Frontal horn
 - B. Fourth vent
 - C. Atria of the lateral ventricle
 - D. Third ventricle

ANSWER: C. Intraventricular meningioma arises from the choroid plexus stromal cells. Choroid plexus is voluminous at the atria of the lateral ventricles, explaining this is to be the most common location.

3. CT scan demonstrates focal calcifications at the junction of the optic nerve and the globe in a patient with unilateral papilledema. Which of the following is the most likely diagnosis?
 - A. Retinoblastoma
 - B. Optic glioma
 - C. Drusen
 - D. Hemangioma with phleboliths

ANSWER: C. Calcification classically occurs at this location in Drusen. Calcification retinoblastoma occurs within the tumor of the retina. Optic glioma usually does not calcify. Hemangioma usually does not involve the optic nerve.

4. Which of the following is the most likely cause of drop metastases?
 - A. Epidermoid
 - B. Medulloblastoma
 - C. Dysgerminoma
 - D. Oligodendroglioma
 - E. Hemangioblastoma

ANSWER: B. Medulloblastoma is the most common to drop metastasize. Rarely, oligodendroglioma

can have drop mets. Other tumors do not produce drop metastasis.

5. Which of the following is the most likely diagnosis of a high-density mass on head CT?
 - A. Lymphoma
 - B. Astrocytoma
 - C. Schwannoma
 - D. Paraganglioma

ANSWER: A. Because of densely packed cells, lymphomas appear hyperdense on CT.

6. Which of the following is *not* associated with renal cysts?
 - A. Tuberous sclerosis
 - B. Chronic renal dialysis
 - C. von Hippel-Landau
 - D. Neurofibromatosis I

ANSWER: D. The other three conditions are known to be associated with renal cysts.

7. Imaging reveals cerebellar lesion with increased T2 signal involving the cerebral peduncles and optic nerves. Which of the following is the most likely diagnosis?
 - A. Neurofibromatosis II
 - B. Neurofibromatosis I
 - C. Tuberous sclerosis
 - D. von Hippel-Landau

ANSWER: B. NF1 typically causes multiple astrocytomas. Cerebellum and optic nerve are common locations of astrocytomas in the setting of NF1.

8. Which of the following is the most likely cause of an enhancing suprasellar mass in a 1-year-old?
 - A. Neuroblastoma metastasis
 - B. Glioma
 - C. Craniopharyngioma
 - D. Pituitary adenoma
 - E. Dysgerminoma

ANSWER: C. Of all these, the incidence of craniopharyngioma is much higher than other pathologies.

9. A 34-year-old female presents with sudden-onset headache. MR shows fluid-fluid level in sella. Which of the following is the most likely diagnosis?
 - A. Pituitary apoplexy
 - B. Pituitary abscess
 - C. Carotid aneurysm
 - D. Lymphocytic hypophysitis

ANSWER: A. Pituitary apoplexy classically presents acutely in women. On imaging it shows enlarged pituitary with or without intragland hemorrhage, which appear as fluid-fluid level on MR. The other three conditions usually do not present so acutely.

10. A 1-year-old boy develops ataxia and vomiting. MRI shows enhancing mass in the cerebellar vermis extending into the fourth ventricle. Which of the following is the most likely diagnosis?
 - A. Medulloblastoma
 - B. Glioma
 - C. Ependymoma
 - D. Brain stem glioma

ANSWER: A. This is the classic age, location, and imaging appearance for the medulloblastoma.

10 INTRACRANIAL INFECTIONS

*Ahmed Kamel Abdel Aal and
Joseph C. Sullivan III*

CONGENITAL/NEONATAL INFECTIONS

Although the causative organisms might be somewhat similar, the radiological presentation of intracranial CNS infections in neonates is significantly different than adults (Table 10-1).

INTRODUCTION

The gestational age of the fetus at the time of infection is the most important determining factor that will eventually dictate the degree and type of brain damage. If the fetus is infected during the first two trimesters, a resulting congenital brain malformation is likely to ensue. If the fetus is infected thereafter, the brain is likely to undergo an encephaloclastic response that will ultimately lead to brain destruction.

The TORCH infections refer to the most common organisms involved in congenital/neonatal infections and include toxoplasmosis, rubella, cytomegalovirus (CMV), and herpes simplex virus type 1 (Table 100-1). With the increased prevalence of human immunodeficiency virus (HIV) in the general population, congenital HIV infection has also become a common pathogen in CNS infections.

TABLE 10-1 Comparison of Neonatal Infections

	CMV	TOXOPLASMOSIS	RUBELLA	HSV TYPE 2	HIV
Incidence	Most common	Second-most common	—	—	—
Mode of transmission	Hematogenous, transplacental	Hematogenous, transplacental	Hematogenous, transplacental	During transvaginal delivery	Hematogenous, transplacental, during delivery, and during lactation
Increased frequency	—	Late in pregnancy	During early pregnancy	Maternal genital disease at delivery	High maternal viral load
Increased severity	—	Infection during early pregnancy	—	—	—
Calcification	Periventricular	Basal ganglia	Cortical and basal ganglia	Superficial and deep gray matter	Basal ganglia
Microcephaly	Present	Present	Present	Present	—
Enhancement	—	—	—	Cortical	Basal ganglia
Cerebellar hypoplasia	Present	—	—	—	—
Migrational anomalies	Present	—	—	—	—

CYTOMEGALOVIRUS

CMV has been implicated as the most common cause of congenital CNS infections, at least three times as frequent as toxoplasmosis, which is the second most common organism. The virus affects about 1% of newborns. The virus is transmitted in utero through hematogenous/transplacental route. In the neonatal period, the virus can be acquired from the mother during delivery or thereafter through breast milk. It is to be noted that about 40% of mothers who acquire the infection during pregnancy transmit the virus to their fetuses.

CMV has a predilection for the germinal matrix as well as the capillary endothelium, producing periventricular tissue necrosis, thrombosis, ischemia, and subsequently periventricular dystrophic calcification. When fetal infection occurs at an early age, migrational abnormalities are likely to occur including lissencephaly, heterotopias, and cortical dysplasia.

On nonenhanced CT, the most common finding is periventricular subependymal calcification occurring in 40% to 70% of cases. Microcephaly as well as ventricular dilatation secondary to white matter loss are also noted. Migration anomalies as previously described can be seen together with cerebellar hypoplasia. On MRI, tiny periventricular pseudocysts can be seen together with focal white matter areas of high T2 signal representing gliosis.

TOXOPLASMOSIS

Toxoplasmosis is the second most common CNS infection following CMV. It is caused by a parasite, *Toxoplasma gondii*. Maternal infection occurs following

direct or indirect contact with oocytes in cat feces or ingestion of undercooked meat containing tissue cysts.

The fetus acquires infection through hematogenous/transplacental spread. The disease is transmitted more frequently in the later stages of pregnancy, while the severity and prognosis of the disease are related to disease transmission in early pregnancy.

On nonenhanced CT, punctate calcification can be seen predominantly in the basal ganglia. As with CMV, microcephaly is a predominant feature. On MRI, hydrocephalus caused by aqueduct stenosis, porencephaly, and hydranencephaly can be seen.

RUBELLA

Fetal infection usually occurs if maternal infection occurs during pregnancy. Infection with rubella virus has significantly declined following the widespread use of rubella vaccine. The frequency and severity of the disease are greatest if infection occurs in the first trimester. Similar to CMV, it has a predilection for the germinal matrix and vascular endothelium resulting in tissue necrosis.

On nonenhanced CT, cortical and basal ganglia calcification can occur but appear less prominent than other TORCH infections. Microcephaly, ventriculomegaly, and brain atrophy can also be seen. On MRI, focal high T2 signal might be seen in the white matter related to vasculopathy and ischemic injury.

HERPES SIMPLEX VIRUS

There are two types of herpes simplex virus. Type 1 account for 10% of neonatal infection, while type 2

accounts for 90%. The virus is transmitted during delivery by contact of the fetus with vaginal or cervical maternal herpetic lesions, and therefore, the frequency of infection is higher if genital disease was present during delivery. Unlike adults, the virus does not have a predilection to the limbic system, but usually involves the endothelial cells resulting in thrombosis and hemorrhagic infarction with subsequent encephalomalacia and atrophy.

On nonenhanced CT, superficial and deep gray matter punctate calcification is noted. Patchy white matter hypodensities are also seen that demonstrate edema pattern (low T1 and high T2) on MRI. Following administration of contrast, there is patchy cortical enhancement on CT and MRI.

HUMAN IMMUNODEFICIENCY VIRUS

Infection is caused by HIV type 1 virus, encountered during pregnancy, at delivery, or through breast-feeding. Thirty percent of mothers infected with HIV transmit the infection to their newborns. The risk of transmission is proportional to maternal viral load. In infants and children, CNS manifestations are primarily caused by HIV encephalitis and less commonly caused by secondary infections or tumors.

On nonenhanced CT, there is brain atrophy predominantly in the frontal lobes. There is faint basal ganglia enhancement seen on CT and MRI preceding the appearance of basal ganglia calcification.

ACQUIRED INFECTIONS

EXTRA-AXIAL PRESENTATIONS

Extra-axial presentations are caused by a variety of organisms and include meningitis, subdural empyema, and epidural abscess.

MENINGITIS

Inflammation of the meningeal coverings of the brain is the most common CNS infection and is divided into three general categories: acute pyogenic meningitis (usually bacterial), lymphocytic meningitis (usually

viral), and chronic meningitis that could be infectious (as in tuberculosis [TB] and fungal infections) or noninfectious (sarcoidosis) (Table 10-2).

Acute pyogenic meningitis is the most common organism causing acute pyogenic meningitis and varies according to the age of patient. In neonates, it is most commonly caused by Group B streptococcus and *Escherichia coli*, which in addition to meningitis, can also present with cerebritis, ventriculitis, vasculitis, and subdural empyema. In infants and children, the most causative organism is *Neisseria meningitidis*. In adults, *Streptococcus pneumoniae* is by far the most common organism involved.

The various organisms may reach the meninges through various routes. Hematogenous spread appears to be the most common route. Direct extension from adjacent foci of inflammation such as otitis media, mastoiditis, and sinusitis is the second most common. Other possible routes include penetrating head trauma, neurosurgery, extension of intra-axial infectious process such as cerebritis or brain abscess, or extension through a preexisting congenital communication with the CSF space (as in dermal sinus).

Complications include venous thrombosis caused by stasis and thrombophlebitis, arterial vasospasm that may result in infarctions, subdural sterile effusion that is more commonly seen in infants, epidural empyema, ventriculitis/ependymitis, choroid plexitis, obstructive (communicating or noncommunicating hydrocephalus), cerebritis, and abscess formation.

Acute lymphocytic meningitis is most commonly caused by enteroviruses such as echoviruses and coxsackie viruses. Viral meningitis occurs more frequently in adults and children and is uncommon in neonates.

Chronic infectious meningitis is most commonly caused by tuberculosis. Other frequent causative organisms include cryptococcosis (especially in immunocompromised patients) and coccidioidomycosis.

Chronic noninfectious meningitis is most commonly caused by sarcoidosis. Others include histiocytosis, Wegner granulomatosis, and rheumatoid meningitis.

On nonenhanced CT, there is hardly any abnormality. Effacement of the basal cisterns may be noted. On contrast-enhanced CT, dural or leptomeningeal enhancement may be noted along the brain convexities or

TABLE 10-2 Causative Organisms and Etiologies in Different Types of Meningitis

ACUTE PYOGENIC	ACUTE LYMPHOCYTIC	CHRONIC INFECTIOUS	CHRONIC NONINFECTIOUS
Neonates: Group B streptococcus <i>E. coli</i>	Enteroviruses (echoviruses and coxsackie viruses)	Tuberculosis	Sarcoidosis
Infants and children: <i>N. meningitidis</i>		Fungal infections (cryptococcosis and coccidioidomycosis)	Histiocytosis
Adults: <i>S. pneumoniae</i>			Wegners granulomatosis
			Rheumatoid pachymeningitis

basal cisterns, although it is much less apparent in case of acute lymphocytic meningitis related to viral infection. MRI is more sensitive than CT in detecting meningitis as well as early complications. The exudate appears isointense on T1 and hyperintense on T2 and FLAIR images. There is thickening and enhancement of the meninges following administration of contrast. Diffusion images are useful in detecting infarcts related to vasospasm, and gradient images will show hypointense blood products in the setting of hemorrhagic infarcts related to venous thrombosis. Superior sagittal sinus thrombosis may be recognized as a central triangular nonenhancing thrombus surrounded by enhancing meninges and flowing blood producing the “delta sign” on contrast-enhanced CT. On MRI, this will appear as hyperintensity along the course of the superior sagittal sinus on noncontrast T1 images. MRA and MRV are also helpful and may be obtained if arterial and venous complications are evident or clinically suspected. Other complications such as hydrocephalus, abscess, and extra-axial collections/empyema are also evident. The imaging features of tuberculous and cryptococcal meningitis will be discussed separately later in this chapter.

Subdural empyema is more common than epidural abscess and usually caused by a penetrating wound or following surgery. Less commonly, it may result from extension of infection from nearby focus such as otitis media, mastoiditis, sinusitis, or meningitis. The most common causative organisms are *S. pneumoniae* and *Staphylococcus aureus*. It is to be noted that meningitis in infants may be complicated by sterile subdural effusions that might later become infected producing subdural empyema. Complications are seen in 10% of cases and include cortical venous and dural venous thrombosis that may result in infarction. Adjacent parenchymal abscess/cerebritis is also a potential complication. In general, complications are more commonly seen in subdural empyema than in epidural abscess.

Subdural empyemas follow the same rules as subdural hemorrhage and will cross the dural attachments at cranial sutures but will not cross the falx. On nonenhanced CT, crescentic extra-axial collection is noted that might be hyperdense compared to CSF. Sterile effusions will appear isodense to CSF if not secondarily infected. On contrast-enhanced CT, peripheral rim enhancement will be evident. On MRI, the extra-axial collection may appear hyperintense to CSF on T1 and FLAIR images and will show restricted diffusion. Similar to CT, post-contrast MR images will show strong peripheral enhancement and possible loculation caused by internal fibrous septae. MRA and MRV may show arterial and venous complications.

Epidural abscess, together with subdural empyema, account for 30% of intracranial infections. The routes of infections are similar to that of subdural empyema. In contrast to subdural empyema, it can cross the falx but cannot cross the dural attachment at cranial sutures, abiding by the same rules as epidural hematoma. Apart from being lentiform (lens) shaped, it usually follows the same signal intensity and pattern of enhancement as subdural empyema. On T2-weighted images, the collection may be seen displacing the hypointense dural line inward.

INTRA-AXIAL INFECTION

Intra-axial infections are caused by a variety of organisms and include cerebritis, abscess, and ventriculitis/ependymitis.

Cerebritis is the earliest stage of intra-axial purulent parenchymal infection and in most cases will progress to abscess formation if not treated early. Routes of infection include hematogenous spread, direct spread from nearby focus of infection, penetrating trauma, neurosurgery, right-to-left shunts such as congenital cardiac or pulmonary arteriovenous malformations, or extension through a preexisting congenital communication with the CSF space (as in dermal sinus).

Early cerebritis (during first week) presents as a low-density lesion at the gray/white matter junction on CT, that shows low T1 and high T2 signal on MRI. There is minimal or no enhancement on both CT and MRI. As such, the appearance is similar to low-grade gliomas, and distinction should be based on clinical presentation. In late cerebritis (1–2 weeks), there is usually patchy or ill-defined peripheral enhancement on CT and MRI scans.

Pyogenic abscess results from progression of cerebritis, which was not treated or was unsuccessfully treated. The routes of infection and location (at the gray/white matter junction) are therefore the same as cerebritis. The causative organism is usually polymicrobial including streptococci, staphylococci, and anaerobes. Risk factors include diabetes, immunosuppression, septicemia, and infective endocarditis.

In the early stages of abscess formation (greater than 2 weeks), a central necrotic core surrounded by a well-defined collagen capsule is noted. The capsule is surrounded by edema and gliosis. In the late stages (weeks to months), the cavity shrinks, the collagen capsule thickens, and the surrounding edema decreases.

Early abscess demonstrates hypodense epicenter on CT, with well-defined, thin, smooth-enhancing capsule, which appears thinner toward the ventricles. On MRI, the abscess shows a hypointense center compared to

TABLE 10-3 Early and Late Appearance of Cerebral Abscess on CT and MRI

	EARLY ABSCESS				LATE ABSCESS			
	CECT	T1	T2	T1+C	CECT	T1	T2	T1+C
Epicenter	Hypodense	Hypointense	Hyperintense	—	Smaller			
Capsule	Thin enhancing	Iso-/hyperintense	Hypointense	Thin enhancing	Thick and irregular, decreased T2 hypointensity, decreased enhancement			
Edema	Hypodense				Decrease			

brain parenchyma (yet hyperintense when compared to CSF) on T1-weighted images, with a thin peripheral rim of isointense to hyperintense signal compared to brain parenchyma representing the capsule (Table 10-3). On T2-weighted images, the center will definitely appear hyperintense to brain parenchyma, while the capsule will appear hypointense. The T2-weighted shortening of the capsule is explained by the presence of collagen and, the paramagnetic effect of free radicals resulting from macrophage activity. Postcontrast T1-weighted images demonstrate smooth, thin-enhancing capsule. Diffusion imaging shows restrained diffusion within the central area of necrosis, which helps differentiate it from other ring-enhancing lesions. MR spectroscopy will show high concentration of lactate, and PET FDG will demonstrate increased metabolism.

Late abscess will show decrease in size of the central cavity on both CT and MRI, with thickening and slight irregularity of the surrounding capsule. With resolution of the abscess, the surrounding edema will diminish as will the T2 hypointensity of the capsule. Enhancement of the capsule may persist for several months but will definitely decrease on serial scans.

Ventriculitis/ependymitis describes inflammation of the ependymal lining the ventricles. It usually results as a complication of shunt procedures, intraventricular surgery, or intrathecal chemotherapy; however, it can also occur as a complication of meningitis or abscess. The incidence is by far more common in young age especially neonates and infants. Causative organisms include a variety of bacterial, fungal, and parasitic infections. In shunt procedures, staphylococci and streptococci seem to be the most common organisms, while in neonates, *E. coli* is the commonest. In the immunocompromised patients, a variety of fungal and parasitic infections may be involved, the most common of which is CMV.

On contrast-enhanced CT, there is thickening and enhancement of the ventricular wall with faint hypodensity seen in the surrounding periventricular brain parenchyma. There may be intraventricular fluid/fluid level caused by layering of debris. On MRI, periventricular T1 hypointensity and T2/FLAIR hyperintensity is noted with thickening and enhancement of the ventricu-

lar wall. Choroid plexitis is rare and is seen as enlarged and markedly enhancing choroid plexus. Obstruction at the level of the basal foramina or aqueduct by debris may occur and lead to hydrocephalus. Obstruction of the foramina of Monro may lead to entrapment of either or both lateral ventricles. Septations or adhesions may be noted that eventually lead to loculated areas within the ventricles.

INFECTIONS WITH SPECIFIC PRESENTATIONS

TB has been increasing in the last decade as a result of immunocompromised states, intravenous drug abuse, resistant strains, and increased crowding in certain populations such as prisons, nursing homes, and similar facilities. It is to be noted that 20% of patients with HIV have TB, while 30% of patients with TB have HIV. CNS infection is mostly caused by mycobacterium tuberculosis and results from hematogenous spread of pulmonary TB or less likely from GI or GU tracts. In the pediatric population, the infection is typically primary, while in adults, it is mostly because of reactivation/reinfection. In CNS, TB presents with meningitis or tuberculoma that may progress to tuberculous abscess.

Tuberculous meningitis is the most common presentation, with the same imaging features as meningitis, but it has a predilection for basal cisterns and may be associated with dystrophic calcification. Rarely T2 hypointense nodules can be seen along the meninges representing granulomas. On FLAIR images, there is increased intensity in the basal cisterns and sulci because of proteinaceous exudate. Enhancement of the basal meninges is seen on postcontrast images with minimal nodularity.

Tuberculoma is a localized parenchymal infection, usually multiple, supratentorial at the gray–white matter junction. Tuberculomas may be noncaseating, caseating with nonnecrotic center, or caseating with a necrotic center (Table 10-4).

Vasculitis caused by basal meningitis and extension of infection into the perivascular space may lead to

TABLE 10-4 CT and MR Imaging Features of Tuberculoma

	CECT/T1+C	T1	T2
Noncaseating	Nodular enhancement	Hypointense to brain	Hyperintense to brain
Caseating with nonnecrotic center	Ring enhancement	Iso-/hypointense to brain	Isointense center with hypointense rim
Caseating with necrotic center	Ring enhancement	Hypointense center with isointense rim	Hyperintense center with hypointense rim

thrombosis and infarction. The lenticulostriate and thalamoperforate arteries are frequently involved producing punctate or linear basal ganglia enhancement on post-contrast MR images. Diffusion images are helpful in detecting infarctions related to vasculitis.

Herpes and other encephalitides: encephalitis is a diffuse brain inflammation characterized by increased water content of the brain parenchyma. It can be caused by various organisms although usually viral (Table 10-5). Viruses spread to the brain hematogenously or through cranial nerves (as in case of HSV). Most viral encephalitides will present radiologically with nonspecific imaging appearance with high T2-weighted signal in the gray and/or white matter and variable enhancement. As such, the diagnosis is usually based on the clinical presentation and laboratory findings.

The exception to this rule is HSV, which has a specific radiological appearance on brain imaging that helps distinguish it from other similar disease processes. In adults and children HSV type 1 (orofacial herpes) is involved, as compared to HSV type 2 (genital herpes) in neonates, which shows different radiological features than type 1 (see neonatal infections). Initial infection occurs in the oronasopharynx through infected secretions. The virus then travels in retrograde fashion along the lingual branch of the mandibular division of the trigeminal nerve to the trigeminal ganglion, where it remains dormant. Reinfection or reactivation (because of im-

munosuppression) will cause the virus to become active causing hemorrhagic necrotizing encephalitis. Mortality rate is as high as 70% if untreated. PCR of CSF samples is usually performed to establish the diagnosis. However, the PCR protocols and quality control vary tremendously from laboratory to laboratory. A negative CSF result cannot absolutely exclude HSV. Therefore, if MRI shows compatible temporal lobe findings and no alternative diagnosis is established, early and continued treatment with acyclovir should be strongly considered.

HSV has a predilection to involve the limbic system (temporal lobes, subfrontal area, cingulate gyrus, and insula). Cerebral convexities, especially the occipital cortices, are less commonly involved. Bilateral involvement is common but usually asymmetric. Rarely, the virus might involve the brainstem.

On CT, there is usually hypodensity and mild mass effect in the medial temporal lobes, with patchy or gyri-form enhancement after contrast administration. MRI is more sensitive and specific in diagnosing HSV, because of higher ability to outline involvement of different structures of the limbic system. On T1 images, there is edema with mild mass effect of the involved regions. High signal intensity on T1 indicates hemorrhage, which can also be demonstrated as hypointensity on GRE images. High T2 and FLAIR signal in typical areas is seen and involves the cortex and subcortical white matter. Postcontrast images will show patchy or gyri-form enhancement, with meningeal involvement and enhancement. Diffusion images will show restricted diffusion in involved areas. Differential diagnosis of HSV encephalitis is broad (Table 10-6).

Lyme disease is caused by *Borriella burgdorferi*, a tick-borne spirochete. The intermediate hosts are deer and mice. Clinically, it presents with arthralgia, erythema chronicum migrans, adenopathy, and facial nerve symptoms with or without Bells palsy. Periventricular white matter hypodense lesions are seen on CT that might enhance after contrast administration. On MRI, these lesions are best seen on T2-weighted and FLAIR sequences. Gray matter lesions are rarely seen. Meningeal involvement is less common and can be detected as meningeal enhancement on postcontrast images. Facial nerve thickening and enhancement correlates with clinically symptomatic facial neuritis. Diagnosis is usually confirmed by ELISA or PCR. Differential diagnosis

TABLE 10-5 Location of Brain Abnormalities in Encephalitides

CAUSATIVE ORGANISM	LOCATION OF ABNORMALITY
HSV-1	Limbic system (see below)
CMV	Periventricular white matter
VZV (Varicella)	Cortex
VZV (Herpes zoster)	Cortex, brainstem, and cranial nerves
Eastern equine virus	Basal ganglia and thalami
Coxsackie and polio viruses	Midbrain and anterior spinal cord
St Louis virus	Substantia nigra
West Nile virus	Substantia nigra, brainstem, cerebellum, and anterior spinal cord
Japanese virus	Cortex, thalami, brainstem, cerebellum, and spinal cord
Listeria	Brainstem and cerebellum
Rabies	Cortex, white matter, hippocampus, hypothalamus, and brainstem

TABLE 10-6 Differential Diagnosis of Herpes Encephalitis

Limbic encephalitis	Paraneoplastic syndrome Limbic system involved Bilateral and symmetric Insidious onset
Glioma	Low-grade gliomas: Unilateral Gliomatosis cerebri: Bilateral and asymmetric Insidious onset
Infarction	MCA distribution More acute onset
Status epilepticus	Active seizures Unilateral
Syphilis	Involve medial temporal lobes, meninges, and arteries

includes multiple sclerosis, vasculitis, lacunar infarcts, and age-related white matter changes.

Rocky Mountain spotted fever is also a tick-borne rickettsial disease caused by *Rickettsia rickettsii*. Similar to Lyme disease, it has a predilection to involve the white matter and cauda equina. The white matter lesions appear similar to those of Lyme disease on CT and MRI, with similar enhancement of the lower thoracic cord and cauda equine roots.

Neurocysticercosis is caused by the helminthic cestodes *taenia solium* and *taenia saginata*, and the intermediate hosts are pigs and cattle, respectively. Infection is transmitted to human beings by eating undercooked pork or beef. It is considered the most important cause of acquired seizures. The most common location is the convexity subarachnoid space, basal cisterns, brain parenchyma, and ventricles in a descending order of frequency. Amongst all, those located in the basal cisterns carry the worst prognosis since they incite vasculitis and leptomeningitis, resulting in communicating hydrocephalus.

There are four pathologic stages that correlate with the imaging findings (Table 10-7). In the vesicular stage, the larva is alive and seen as a small marginal nodule in a

small cyst with clear fluid. There is little or no inflammation around the cyst. It can remain in that stage for years before it degenerates. In the colloidal vesicular stage, the larva dies and the cyst starts to degenerate exciting inflammation and edema in the surrounding tissue. The cyst shrinks and its contents become turbid and the capsule thickens. In the granular nodular stage, the shrinkage of the cyst and thickening of the capsule progresses, and the surrounding inflammation and edema start to subside and the scolices begin to calcify. In the nodular calcified stage, the cyst becomes small and completely calcified with resolution of the adjacent inflammation.

FUNGAL INFECTIONS

A variety of fungal infections can involve the CNS such as aspergillosis, candidiasis, histoplasmosis, and coccidioidomycosis. Although immunocompromised states are the major predisposing factors for fungal infection, they still can occur in immunocompetent patients. The only manifestation may be diffuse brain edema. The lesions are usually multiple and widely distributed throughout the brain parenchyma. They appear as discrete solid-enhancing or ring-enhancing lesions that are low on T1 and high on T2 and FLAIR images. Meningeal involvement is also typical. Fungal infections are often seen to cause vasculitis with subsequent thrombosis or infarction, which can be seen on diffusion images and MRA. Cryptococcosis is discussed separately with HIV infection.

CNS MANIFESTATIONS OF HIV INFECTION

Approximately 40% to 50% of patients with AIDS have neurologic symptoms throughout their life span. Approximately 5% to 10% of patients with AIDS present

TABLE 10-7 CT and MRI Appearance of Stages of Neurocysticercosis

	VESICULAR	COLLOIDAL VESICULAR	GRANULAR NODULAR	NODULAR CALCIFIED
NECT	Well-defined, thin-walled cyst	Hyperdense cyst	Cyst shrinks and wall thickens	Small calcified lesion
CECT	Minimal or no capsule enhancement	Thick, ring-enhancing capsule	Cyst shrinks and wall thickens	No enhancement
T1	Isointense to CSF, scolex may show eccentric hyperintensity	Slightly hyperintense to CSF and capsule thickens	Cyst shrinks and wall thickens	Calcified lesion of variable intensity
T2	Isointense to CSF	Hyperintense to CSF	Cyst shrinks and wall thickens	Calcified lesion of variable intensity
FLAIR	Isointense to CSF (oxygen therapy increase conspicuity)	Hyperintense to CSF	Cyst shrinks and wall thickens	Calcified lesion of variable intensity
T1+C	Minimal or no capsule enhancement	Thick, ring-enhancing capsule and enhancing eccentric scolex	Cyst shrinks and wall thickens and enhances	Calcified lesion +/- persistent enhancement
GRE	Hypointense calcified scolex			Hypointense calcified lesion

initially with CNS disease. CNS disease in AIDS is primarily infectious or neoplastic. Infections are the most common pathologies in patients with AIDS, with HIV infection being the most common. The most common opportunistic infection in patients with AIDS is toxoplasmosis, and the most common fungal infection is cryptococcosis. Other common infections include JC papovavirus causing progressive multifocal leukoencephalopathy (PML) and CMV. Uncommon infections include a variety of other fungal organisms, TB, syphilis, HSV and varicella-zoster virus. Neoplastic lesions in AIDS include primary and secondary lymphoma which unlike their appearance in immunocompetent patients have imaging findings similar to some of the AIDS infections. Other less common neoplastic lesions include glioblastoma multiforme, plasmacytoma, and Kaposi's sarcoma. Radiologically, CNS manifestations of HIV infections have two distinct presentations, diffuse or patchy white matter abnormalities and/or focal or multifocal lesions.

Diffuse or patchy white matter abnormalities can be seen in HIV encephalitis, PML, and CMV infection. Less commonly these can be due to vasculitis caused by neurosyphilis or a variety of viral and fungal infections such as varicella-zoster virus, candidiasis, or aspergillosis (Table 10-8).

HIV encephalitis is caused by HIV type 1, which is the most common infectious agent in AIDS patients followed by toxoplasmosis and cryptococcosis. Approximately 50% of adult patients and 40% of pediatric patients with AIDS have HIV encephalitis. Usually, it affects AIDS patients with CD4 counts less than 200/mm³; clinically, it presents with AIDS dementia complex, which is a triad of cognitive, motor, and behavioral dysfunction.

On CT, there is typically generalized cerebral and cerebellar atrophy with diffuse or patchy white matter hypodensities. On MRI, T1-weighted images usually show no abnormality, while T2 and FLAIR images will demonstrate the high signal diffuse or patchy white mat-

ter changes. These lesions do not enhance following contrast administration on either CT or MRI. Similar lesions in the basal ganglia, brainstem, and cerebellum may be seen later in the disease.

PML is caused by JC virus (named after the first patient diagnosed with PML), which belongs to the papovavirus group. PML occurs in 5% of AIDS patients, usually with CD4 counts less than 50/mm³.

On CT, there is usually single or multiple areas of white matter hypodensity in the subcortical frontal or parieto-occipital lobes without mass effect. On T1 images, the lesions appear hypointense as opposed to the normal T1 images in HIV encephalitis. On T2 and FLAIR images, the lesions appear hyperintense, with predilection for the subcortical U-shaped fibers. Usually, the lesions do not enhance, although faint enhancement can be rarely seen. Multiple lesions may enlarge along the course of the disease and later become confluent. Even when the lesions are multiple and bilateral, they are asymmetric differentiating them from the white matter lesions in HIV encephalitis. Although the lesions are more common in the white matter, any myelinated areas can be affected, and the lesions can be seen less commonly in the basal ganglia, thalami, brainstem, and cerebellum, with the later presenting with a comma-shaped lesion, caused by sparing of the dentate nucleus.

CMV belongs to the herpes virus family. In addition to encephalitis and ependymitis, the virus can produce myelitis, vasculitis, cranial neuritis, peripheral neuritis, and chorioretinitis in AIDS patients.

On CT, there is usually generalized cerebral and cerebellar atrophy, with periventricular low-density lesions. On MRI, these lesions appear hyperintense on T2 and FLAIR images. There will be ependymal enhancement seen on CT and MRI following contrast administration. Table 10-9 lists the causes of ependymal enhancement in AIDS patients.

Neurosyphilis is a sexually transmitted disease caused by the spirochete *treponema pallidum*. There is

TABLE 10-8 White Matter Abnormalities in Patients with HIV

	HIV ENCEPHALITIS	PML	CMV	NEUROSYPHILIS
Location	Diffuse deep WM	Fronto-parieto-occipital subcortical WM (U-fibers)	Periventricular WM	No specific predilection
Distribution	Bilateral symmetric	Bilateral asymmetric	Bilateral symmetric	Bilateral
T1 Signal	Normal	Hypointense	Hypointense	Hypointense
Enhancement	No enhancement	May show faint enhancement	Ependymal and subependymal enhancement	Enhancement of parenchymal lesions (gummas)
Brain atrophy	Cerebral and cerebellar		Cerebral and cerebellar	
Other locations	Basal ganglia, brainstem, and cerebellum, later in the disease	Basal ganglia, thalami, brainstem, and cerebellum (sparing the dentate nucleus)	None	Gray matter, meninges, cranial nerves, and cord

TABLE 10-9 Etiology of Ependymal Enhancement in Patients with AIDS

Lymphoma	Thick, irregular, and nodular ependymal enhancement and ring-enhancing lesions Tumoral enhancement.
Intraventricular spread of infection	TB or pyogenic
Glioblastoma multiforme	

an association between HIV and syphilis infections since both have the same predisposing factors and routes of infection. Although it is still unclear whether AIDS increases the risk of acquiring syphilis, it is usually seen at a younger age and is more aggressive in AIDS patients. The most common intracranial manifestations of syphilis are encephalitis and meningovascularitis. In the later, there is small- and medium-sized artery involvement.

On imaging, there may be white matter lesions that appear hypodense on CT and hyperintense on T2 and FLAIR images related to vasculitis. Discrete, enhancing lesions can also be detected in the brain parenchyma representing gummas. These lesions are peripherally located and may show adjacent meningeal thickening and enhancement. MRI is more sensitive in showing cranial neuritis particularly optic and vestibulocochlear neuritis. Diffusion images are useful in showing infarcts that more commonly occur along the distribution of the middle cerebral artery and are related to vasculitis.

FOCAL OR MULTIFOCAL LESIONS

Toxoplasmosis is caused by the protozoan parasite *toxoplasma gondii* that is acquired through ingestion of undercooked meat containing the cysts or exposure to cat feces. Approximately 70% of the general population has positive serology. The parasite later reactivates when the host immunity is decreased. It is the most common opportunistic infection in patients with AIDS.

On CT, there is single or multiple isodense or hypodense ring-enhancing lesions located in the basal ganglia or gray–white matter junction, particularly of the frontal lobe, with surrounding edema. The lesions are usually 1 to 3 cm in diameter (smaller than lymphoma) (Table 10-10) and may show intralesional hemorrhage especially after treatment. On MRI, the lesions appear hypointense on T1 and hyperintense on T2 and diffusion images. MR perfusion studies shows decreased cerebral blood volume (CBV) in toxoplasmosis which may help differentiate these lesions from lymphoma, since the later usually show increased CBV, although recent reports have shown decreased CBV in lymphoma as well. Thallium-201 SPECT shows increased tracer uptake in lymphoma but not in toxoplasmosis. Despite the efforts to differentiate these two entities using various imaging modalities, clinicians usually administer a course of antitoxoplasma therapy initially and reimagine the patients to see the response.

Cryptococcosis is the most common fungal infection in patients with AIDS, although it may occur in immunocompetent patients, usually with underlying chronic illness such as diabetes, alcoholism, collagen

TABLE 10-10 Imaging Findings of Toxoplasmosis Versus Lymphoma in Immunocompromised Patients

	TOXOPLASMOSIS	LYMPHOMA
Size	Smaller 1–3 cm	Larger, greater than 3 cm
Number	Single or multiple. If multiple, more numerous	Mostly multiple and less numerous
Location	Basal ganglia, gray–white matter junction at the frontal lobe	Periventricular with subependymal extension
CT	Isodense or hypodense	Hyperdense in one-third of cases
T1	Hypointense	Isointense/hypointense
T2	Hyperintense	Isointense/hypointense (because of high nuclear:cytoplasmic ratio)
FLAIR	Hyperintense	Isointense/hypointense
DWI	Hyperintense	Hyperintense
Enhancement	Less than 1 cm: 75% solid More than 1 cm: 75% ring	Less than 1 cm: 75% solid More than 1 cm: 50% ring +/- ependymal enhancement
Hemorrhage	More common, usually after treatment	Less common, usually after steroid or radiotherapy
Thallium-201 SPECT	Decreased tracer uptake	Increased tracer uptake
PET	Hypometabolic	Hypermetabolic
MR perfusion	Decreased CBV	Increased or decreased CBV

vascular disease, or neoplasms. It ranks the third after HIV and toxoplasmosis as a cause of CNS infection in AIDS and is seen in approximately 10% of patients. It is caused by *Cryptococcus neoformans*, a fungus that enters the body through the respiratory tract. Following entry, the organism spreads hematogenously to the CNS. As a result of the host immune response, the organism becomes encapsulated with acidic polysaccharide capsule that produce mucoid deposits. The most common presentation is meningitis that usually affects the base of the brain. The infection can spread along the perivascular spaces that become dilated with mucoid material forming gelatinous pseudocysts. Further spread may cause parenchymal lesions, particularly in the basal ganglia, thalami, and midbrain, known as cryptococcomas.

On CT, hypodense lesion can be seen in the basal ganglia representing cryptococcomas. These lesions appear hypointense on T1-weighted and hyperintense on T2-weighted and FLAIR images and may show ring enhancement especially in immunocompetent patients. Leptomeningeal enhancement is the most common presentation. Dilated perivascular spaces that follow CSF intensity may also be seen, representing gelatinous pseudocysts, which do not enhance since they are extra-axial and do not compromise the blood-brain barrier.

QUESTIONS AND ANSWERS

- What is the most common cause of congenital CNS infection?
 - CMV
 - Toxoplasmosis
 - Rubella
 - Herpes

ANSWER: A. CMV is the most common cause of congenital CNS infection, and toxoplasmosis is the second.

- In which of the following infections are cerebellar hypoplasia and migration anomalies most common?
 - HSV
 - Toxoplasmosis
 - CMV
 - Rubella

ANSWER: C. CMV has a predilection for the germinal matrix as well as the capillary endothelium, producing periventricular tissue necrosis, thrombosis, ischemia, and subsequently periventricular dystrophic calcification. When fetal infection occurs at an early age, migrational abnormalities are likely to occur including lissencephaly, heterotopias, and cortical dysplasia.

- In which neonatal infection is basal ganglia calcification most commonly seen?
 - Rubella
 - Toxoplasmosis
 - HIV
 - All of the above

ANSWER: D. In neonatal toxoplasmosis and HIV, calcification is usually seen in the basal ganglia. In neonatal rubella infection, calcification is usually seen in the cortex and basal ganglia.

- What is the most common causative organism of acute pyogenic meningitis in adults?
 - E. coli*
 - N. meningitides*
 - S. pneumonia*
 - S. aureus*

ANSWER: C. *E. coli* is the most common agent in neonatal pyogenic meningitis, while *N. meningitides* is common in infants and children.

5. What are the MRI characteristics of a pyogenic abscess in its early stage?
- Thin and well-defined
 - Irregular
 - Hyperintense on T2-weighted images
 - Hypointense on T1-weighted images

ANSWER: A. Early abscess shows thin, well-defined enhancing capsule that appears iso/hyperintense on T1-weighted and hypointense on T2-weighted images. The T2-weighted hypointensity of the capsule is explained by the presence of collagen and the paramagnetic effect of free radicals resulting from macrophage activity.

6. What is the most common intracranial presentation of TB?
- Noncaseating tuberculoma
 - Caseating tuberculoma with nonnecrotic center
 - Caseating tuberculoma with necrotic center
 - Tuberculous meningitis

ANSWER: D. Tuberculous meningitis is the most common presentation, with the same imaging features as meningitis but it has a predilection for basal cisterns and may be associated with dystrophic calcification.

7. All of the following regions of the brain are involved in herpes virus infection, *except*
- Insula
 - Cingulate gyrus
 - Temporal lobes
 - Cerebellum

ANSWER: D. HSV has a predilection to involve the limbic system (temporal lobes, subfrontal area, cingulate gyrus, and insula). Cerebral convexities, especially the occipital cortices, are less commonly involved. Bilateral involvement is common but usually asymmetric. Rarely the virus might involve the brainstem.

8. What is the most commonly affected cranial nerve in Lyme disease?
- Optic nerve
 - Occulomotor nerve
 - Facial nerve
 - Vestibulocochlear nerve

ANSWER: C. Facial nerve is the most commonly involved cranial nerve. Facial nerve thickening and enhancement correlate with clinically symptomatic facial neuritis.

9. In which stage of neurocysticercosis is the larva alive?
- Vesicular stage
 - Colloidal vesicular stage

- Granular nodular stage
- Nodular calcified stage

ANSWER: A. In the vesicular stage, the larva is alive and seen as a small marginal nodule in a small cyst with clear fluid. In the colloidal vesicular stage, the larva dies and the cyst starts to degenerate.

10. What is the most common opportunistic infection in AIDS?
- Toxoplasmosis
 - Cryptococcosis
 - CMV
 - TB

ANSWER: A. The most common opportunistic infection in patients with AIDS is toxoplasmosis, and the most common fungal infection is cryptococcosis.

11 NEURODEGENERATIVE AND WHITE MATTER DISEASES

Ritu Shah and Joseph C. Sullivan III

WHITE MATTER DISEASES

White matter diseases are conventionally classified into “demyelinating” and “dysmyelinating” disorders. Demyelination refers to the destruction of normally formed myelin, whereas dysmyelination indicates a defect in the formation or maintenance of myelin. In the following text, we will focus primarily on disorders of myelination while briefly mentioning other processes that may also cause white matter lesions. White matter lesions can be further categorized as multifocal (Table 11-1) or diffuse (Table 11-2).

MULTIFOCAL WHITE MATTER LESIONS

Age-related white matter hyperintensities are subcortical, central, and periventricular, commonly identified on T2-weighted MR scans in an otherwise healthy elderly patient. Cognitive function is not related to the presence or absence of the white matter hyperintensities. Patients with hypertension, diabetes, hyperlipidemia, and heart disease have more white matter hyperintensities compared to patients without these risk factors.

Virchow-Robin spaces (perivascular spaces) are found in the basal ganglia and centrum semiovale in patients of all ages and are considered a normal anatomic variant. These become more frequent and larger with

TABLE 11-1 Differential Diagnosis of Multifocal White Matter Lesions

Common	Age-related white matter hyperintensities (also known as microangiopathic changes) Virchow-Robin spaces Multiple sclerosis Lacunar infarcts Reversible posterior leukoencephalopathy syndrome
Less common	Acute disseminated encephalomyelitis Cerebral arteritis caused by collagen vascular or granulomatous disease Migraine Traumatic shear injuries Osmotic demyelination syndrome PML

advancing age. Virchow-Robin spaces appear as round or linear smoothly margined foci that follow CSF on all pulse sequences on MRI.

Lacunar infarcts result from occlusion of deep perforating arteries in the basal ganglia, thalami, and brainstem. These are usually less than 1 cm in diameter, hypointense on T1-weighted images, and hyperintense on T2 and FLAIR images. Acute lesions may enhance.

Multiple sclerosis (MS) is the most commonly acquired demyelinating disease. Its precise etiology remains unknown although it is believed to be due to autoimmune-mediated demyelination in genetically susceptible individuals. Onset of disease is usually between 20 and 40 years of age with a female-to-male ratio of 1.7–2:1. In children, there is no sex predominance.

On the basis of the natural history, multiple sclerosis is classified as relapsing-remitting (85%), secondary-progressive, primary-progressive (5%–10%), and progressive-relapsing types.

Presentation with a single episode of neurologic deficit such as optic neuritis, transverse myelitis, or brainstem syndrome is also common. Progression to multiple sclerosis occurs in approximately 57% of patients with isolated brainstem syndrome and in 42% of patients with spinal cord syndrome. Risk of developing

MS following optic neuritis has been estimated to be 75% or more. Presence as well as number of asymptomatic lesions on MRI markedly increase the risk of progression. Seventy percent of patients have elevated CSF IgG levels and approximately 90% have elevated oligoclonal bands.

MRI FINDINGS

- Ovoid and periventricular lesions oriented perpendicularly to the long axis of the brain and lateral ventricles are characteristic of MS. These lesions are present in 85% of patients and are believed to represent inflammatory changes along long axis of medullary vein (Dawson fingers).
- The calloseseptal interface is involved in 50% to 90% of patients; it is optimally imaged on the sagittal FLAIR images. Calloseseptal lesions have 93% sensitivity and 98% specificity in differentiating MS lesions from vascular diseases.
- Ten percent of MS plaques in adults are infratentorial, mostly located in the brainstem or surrounding the fourth ventricle. In children, posterior fossa involvement is more common.
- Enhancement can be solid or ringlike and represents active demyelination. An open-ring pattern of enhancement is considered characteristic for MS. Delayed imaging (15–60 minutes following injection) and triple dose of gadolinium (0.3 mmol/kg versus 0.1 KG/kg) increases detection of enhancing MS lesions.
- Acute lesions can demonstrate restricted diffusion.
- MR spectroscopy: ↓ NAA, ↑ Cho. Abnormalities also present in normal-appearing white matter.
- Magnetization transfer is decreased in MS plaques and in normal-appearing white matter. Magnetization transfer ratio is highest in homogeneously enhancing lesions, lower in nonenhancing lesions, and lowest in central portion of ring-enhancing lesions.
- Uncommonly, multiple sclerosis may appear as a large mass, which can be mistaken for a neoplasm (tumefactive MS). However, this mass effect is usually relatively less than expected for the size of the lesion. Tumefactive MS lesions have leading edge of enhancement and an incomplete horseshoe-shaped ring. Veins are displaced by neoplasm but course through MS lesions. Perfusion is not increased. Single-voxel MR spectroscopy utilizing a PRESS protocol with a short echo time (30 milliseconds) has been reported to demonstrate elevation of glutamate/glutamine peaks, which can aid differentiation of tumefactive demyelinating lesions from tumors.
- Solitary spinal cord involvement is seen in 5% to 24% of patients; however simultaneous brain and spinal cord involvement is more common. Sixty percent of

TABLE 11-2 Differential Diagnosis of Diffuse or Confluent White Matter Lesions

Common	AIDS encephalopathy Advanced, deep white matter ischemia
Uncommon	Radiation injury Chemotherapeutic toxicity Severe PRES Leukodystrophies (adrenoleukodystrophy, Krabbe, globoid cell, Alexander disease, Canavan disease, etc.) Gliomatosis cerebri Lymphoma

spinal cord lesions are in the cervical region. Spinal cord lesions in MS tend to be peripherally located, do not respect white and gray matter boundaries, and the overwhelming majority are less than two vertebral body segments in length. Associated spinal cord swelling occurs in 6% to 14% of patients and atrophy in 2% to 40% of patients.

MRI criteria for diagnosis of MS suggested by Fazekas and colleagues include three or more lesions with presence of at least two of the following lesion characteristics:

1. Size greater than 5 mm
2. Periventricular
3. Infratentorial

MULTIPLE SCLEROSIS VARIANTS

Devic disease, or neuromyelitis optica, consists of both transverse myelitis and optic neuritis, which can occur simultaneously or be separated by days or weeks. It is controversial whether this represents an acute variant of multiple sclerosis or a separate demyelinating disease.

Balo concentric sclerosis represents lesion with alternating concentric regions of demyelination and normal brain.

Schilder disease is an acute, rapidly progressive form of MS with bilateral, relatively symmetric demyelination. It is seen in childhood and rarely after the age of 40 years and is characterized by large confluent areas of demyelination involving supra- and infratentorial parenchyma.

Marburg variant is a fulminant form affecting younger patients. It has a febrile prodrome and poor prognosis with death in months.

Persons younger than 40 years and with migraine can have high signal abnormalities predominantly in the centrum semiovale and subcortical white matter, which extend into the deeper white matter at the level of the basal ganglia.

Acute disseminated encephalomyelitis (ADEM) is a monophasic demyelinating disease, usually caused by infection, vaccination, or exanthematous diseases of childhood. Suspected etiology is based on an allergic or autoimmune cross-reaction with a viral protein. MRI findings in ADEM include multiple large T2-hyperintense lesions, which enhance in a nodular or ring pattern. However, enhancement is usually mild or spotty in nature. Bilateral but asymmetric involvement of peripheral gray-white matter junction is seen. Lesions do not usually involve callosal interface. No new lesions should appear on MR after 6 months from initial diagnosis of the disease.

Acute hemorrhagic leukoencephalitis (Hurst disease) is a fulminant form of ADEM with rapid progression

from confusion to stupor and coma in less than a week. The hemorrhages although seen on autopsy may not be seen on MRI. There is massive brain swelling and high intensity on T2WI. Enhancement may not be prominent.

Progressive multifocal leukoencephalopathy (PML) is caused by JC virus infecting the oligodendrocyte. It is associated with immunosuppressed state (most commonly AIDS) but can also be seen in autoimmune diseases, cancer, immunosuppressive therapy, lymphoproliferative disorders, myeloproliferative disorders, sarcoid, transplantation, tuberculosis, and Whipple disease. The prognosis is poor with death within 6 months to 1 year after onset. However with highly active antiretroviral therapy (HAART), longer survival has been reported. MRI typically reveals T1-hypointense and T2-hyperintense nonenhancing lesions without mass effect with predilection for parietooccipital region and posterior fossa. Brainstem and cerebellar regions are involved in approximately one-third of patients. The disease eventually becomes multifocal and confluent. Sparing of cortical ribbon and deep gray matter is common. Uncommonly, mass effect and enhancement can be seen especially as a result of immune reactivation after HAART therapy.

Reversible posterior leukoencephalopathy or posterior reversible encephalopathy syndrome (PRES) is associated with hypertension, immunosuppressive and chemotherapeutic agents (including cyclosporine, ARA and ARA-C, tacrolimus and cisplatin), preeclampsia-eclampsia, renal disease, systemic lupus erythematosus, cryoglobulinemia, hemolytic-uremic syndrome, and severe hypercalcemia. Patients present with headaches, seizures, confusion, and visual disturbances. MRI reveals reversible bilateral asymmetric cortical and subcortical white matter edema in the parietal occipital region, which can extend into temporal and frontal lobes, pons, and cerebellum. Typically, these are not restricted on diffusion, although small areas with restricted diffusion can be seen in up to 17% of cases. These may reverse or continue onto infarction. Minimal gyriform enhancement and hemorrhage are less common.

Many other diseases, including collagen vascular diseases, sarcoidosis, Lyme disease, Behcet disease, and vasculitis, result in multifocal white matter lesions that can mimic MS.

DIFFUSE OR CONFLUENT WHITE MATTER LESIONS

In advanced stages, all multifocal white matter diseases can progress to a more diffuse, confluent pattern. However, there are other conditions that more frequently have a confluent pattern of white matter abnormality.

TABLE 11-3 CNS Abnormalities Produced by Drugs and Toxins

AGENT	PATHOLOGIC FINDINGS
Heroin inhalation	Symmetric signal abnormality in cerebellar and posterior cerebral white matter and posterior limb internal capsule
Cocaine	Increased T2/FLAIR hyperintensities, hemorrhagic and ischemic stroke
Amphetamines	Hemorrhage, vasculitis, infarcts, pseudoaneurysm information
Alcohol	Chronic vermian atrophy and generalized atrophy; Wernicke encephalopathy: mamillary body, medial thalamus, hypothalamus, and periaqueductal gray signal abnormality and enhancement; Marchiafava-Bignami syndrome: signal abnormality, swelling, and enhancement involving the genu and splenium of the corpus callosum; restricted diffusion may occur in the acute form
Methanol	Optic nerve atrophy, hemorrhagic putaminal and subcortical white matter necrosis, less commonly caudate in hypothalamus
Ethylene glycol	Thalamus and pons showing T2 hyperintensity
Toluene	Cerebrum, corpus callosum, and cerebellar vermis atrophy; diffuse white matter T2 hyperintensity
Carbon monoxide	Globus pallidus, white matter, and hippocampus

CNS insults from a wide variety of recreational drugs and toxins affect white matter. The imaging abnormalities encountered often include but are not limited to the white matter (Table 11-3).

Radiation-induced demyelination is seen as T2 white matter hyperintensity and atrophy, conforming to the radiation portal. Other radiation-induced findings include hemosiderin deposition, telangiectasia, and mineralizing microangiopathy seen as calcification affecting basal ganglia and subcortical white matter. Young age at the time of treatment is associated with worse prognosis.

Disseminated necrotizing leukoencephalopathy results in diffuse demyelination after cranial spinal radiation in combination with intrathecal methotrexate for leukemia in children and adults, bone and soft tissue sarcoma, and small cell carcinoma of lung. Progressive decline in mental status and seizures are seen. MRI findings include diffuse T2 hyperintensity throughout the white matter with predilection for periventricular region and centrum semiovale with sparing of U fibers. Enhancement is rarely reported.

Postanoxic encephalopathy is an allergic demyelination caused by exposure to a myelin antigen during anoxic injury. It occurs after a severe anoxic episode,

followed by recovery in 24 to 48 hours and then precipitous decline within a 2-week period. MRI findings reveal diffuse T2 hyperintensity throughout the white matter, particularly involving corpus callosum, subcortical U fibers, and internal and external capsules. Restricted diffusion is seen. Similar findings can be produced by carbon monoxide exposure but with a propensity for bilateral symmetric globus pallidus lesions.

Osmotic demyelination syndrome occurs in alcoholic, malnourished patients, who have rapid correction of hyponatremia. It is also associated with chronic renal failure, liver failure, diabetes mellitus, rapid dialysis, and syndrome of inappropriate antidiuretic hormone secretion. In children, this syndrome has been associated with orthotopic liver transplantation, acute myelogenous leukemia, Hodgkin disease, Wilson disease, and craniopharyngioma. T1 hypointense and T2 hyperintense nonenhancing signal abnormalities are seen on MRI in pons with sparing of periphery and descending corticospinal tracts. Involvement of extrapontine structures, including basal ganglia; internal, external, and extreme capsules; amygdala and cerebellum, is also seen. No mass effect or enhancement is typically present. Features of some common dysmyelinating disease have been described in Table 11-4.

TABLE 11-4 Dysmyelinating Diseases

DISEASE	INHERITANCE/ENZYMATIC DEFICIENCY	DISTINGUISHING FEATURES
Metachromatic leukodystrophy	Autosomal recessive, arylsulfatase A deficiency	Symmetric diffuse white matter hyperintensity in cerebrum and cerebellum
Adrenoleukodystrophy	X-linked or autosomal recessive, acyl-coA synthetase deficiency	Parietooccipital white matter abnormalities progressing anteriorly, enhancement along leading edge; can have enhancement in major white matter tracts
Alexander disease	Unknown	Megalencephaly in infantile form; diffuse white matter abnormality; enhancement early in course of disease
Canavan disease	Autosomal recessive, N-acetylaspartoacylase deficiency	Megalencephaly, diffuse white matter signal abnormality, high levels of NAA on MR spectroscopy
Krabbe disease	Unknown, beta-galactocerebrosides deficiency	Diffuse cerebral and cerebellar white matter signal abnormality; symmetric thalamic hyperdensity can be seen; optic nerve enlargement reported
Pelizaeus-Merzbacher disease	X-linked, unknown	Diffuse white matter signal abnormality and atrophy; iron deposition in lentiform nuclei, substantia nigra, dentate nuclei and thalamus, tigroid pattern

NEURODEGENERATIVE DISORDERS

Alzheimer disease (dementia Alzheimer type or DAT) accounts for 60% to 90% of the dementing disorders. Vascular dementia (15%–30%) and alcohol are the second and third most common causes of dementia, respectively. Senile plaques and neurofibrillary tangles are the diagnostic pathologic features. Abnormal accumulation of tau protein is thought to play a key role. Five to ten percent of cases are familial, and early onset of familial Alzheimer disease is associated with mutations in amyloid precursor protein gene on chromosome 21, presenilin-1 gene on chromosome 1, and presenilin-2 gene on chromosome 14. Late onset of familial and sporadic forms of Alzheimer disease is associated with ApoE- ϵ 4 allele on chromosome 19.

Parietal and temporal cortical atrophy with disproportionate hippocampal volume loss is identified on cross-sectional imaging. Temporal horn dilatation of more than 3 mm is seen in more than 65% of patients with Alzheimer type dementia. Width of the temporal horn is also found to be the most sensitive discriminator. Subiculum of the parahippocampal region is most severely affected. In absence of cardiovascular risk factors, white matter changes are less frequent in patients with Alzheimer-type as compared to normal age-matched controls. MR spectroscopy reveals decreased NAA and increased myoinositol levels and is useful to follow progression of disease by monitoring decrease in NAA. With MR perfusion, relative values of temporoparietal CBV (as a percentage of cerebellar rCBV) are reduced by 20% in patients with DAT compared to normal controls.

Multi-infarct dementia (vascular dementia) is the second most common cause of dementia. It is clinically characterized by a progressive, episodic, stepwise decline. MRI shows cortical infarcts, with white matter ischemia and lacunar infarctions, in patients with long-standing hypertension or other risk factors for atherosclerotic disease.

Multisystem atrophy, progressive supranuclear palsy, cortical-basal ganglionic degeneration, and dementia with Lewy bodies are together known as Parkinson-plus syndromes. They also share the findings of pars compacta atrophy with Parkinson disease. Globus pallidus internus and subthalamic nucleus are usually targeted for stereotactic stimulator implantation in Parkinson disease. Table 11-5 describes unique clinical and MRI features of Parkinson syndromes, and other uncommon dementias.

AIDS–dementia complex is characterized by atrophy and white matter hyperintensity without mass effect in an AIDS patient. MR spectroscopy shows decrease in NAA and elevated choline. HAART therapy can reverse cognitive decline; however, imaging response is often delayed and may even progress initially before stabilizing eventually. Basal ganglia and brainstem manifestations respond to the greatest degree.

Binswanger disease (subcortical arteriosclerotic encephalopathy) is a demyelinating disease affecting patients older than 55 years. It is associated with hypertension (98%) and lacunar infarction. Patients may present with acute stroke followed by declining mental status or a slow, insidious decline. MRI shows broad regions of T2-hyperintense abnormalities in white matter

TABLE 11-5 Distinctive Clinical and MRI Features of Other Idiopathic Dementias

DEMENTIA	DISTINCTIVE CLINICAL FEATURE	DISTINCTIVE MRI FEATURE
Frontotemporal dementia (FTD)	Early behavioral changes with intact visual and spatial skills	Frontal and temporal lobe atrophy
Pick disease	Same as FTD, but this term is reserved for pathological variant with cytoplasmic inclusion “Pick bodies”	Anterior temporal and frontal involvement with posterior temporal and parietal sparing; “knife-like gyri”
Parkinson disease	Bradykinesia, shuffling gait, rigidity and involuntary tremors, which precede onset of dementia by >1 y	Decrease in width of pars compacta of substantia nigra on T2WI
Multisystem atrophy (MSA)	Autonomic system dysfunction and parkinsonian symptoms; dementia is usually not a prominent component of MSA	Marked cerebellar atrophy; abnormal iron deposition (T2 hypointensity) in putamen and caudate nucleus; “hot-cross bun sign” in pons on T1 and T2
Progressive supranuclear palsy	Supranuclear ophthalmoplegia (impaired downward gaze) and pseudobulbar palsy after onset of parkinsonian symptoms	Midbrain atrophy (diameter on axial scans <17 mm), enlargement of the interpeduncular cistern, third ventricular dilatation, atrophy of superior colliculi, periaqueductal high intensity
Cortical-basal ganglionic degeneration	Postural instability, dystonia, akinesia, apraxia, myoclonus, bradykinesia, and limb rigidity	Asymmetrical atrophy involving posterosuperior frontal and parietal regions (“knife blade” atrophy)
Dementia with Lewy bodies	Dementia preceding or accompanying parkinsonism, visual hallucinations, cognitive fluctuation	Brainstem and substantia nigra atrophy is seen; greater degree of cortical atrophy than the Parkinson disease; SPECT scans show occipital hypoperfusion

or frontal–parietal–occipital regions in the centrum semiovale with sparing of subcortical U fibers.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an inherited disease caused by mutations of Notch 3 gene on chromosome 19. The disease onsets in the fourth decade, with mean age of death being 59. Recurrent transient ischemic attacks, strokes, dementia, and depression characterize this neurodegenerative disorder. It mainly affects frontal, temporal lobes, and insula. T2-hyperintense and T1-hypointense white matter lesions are seen typically with involvement of subcortical U fibers in anteroinferior temporal lobes and inferior frontal lobes.

Creutzfeldt-Jakob disease (CJD) is a rare dementing disorder thought to be due to a prion. The sporadic form is mostly seen more commonly and presents with rapid cognitive decline and cerebellar dysfunction. A new variant Creutzfeldt-Jakob disease (nvCJD), a human disease thought to be due to the same infectious agent as for bovine spongiform encephalopathy, or mad cow disease, presents at young age with more frequent psychiatric and sensory abnormalities. Prognosis is poor with 1-year survival rate of only 10%. CSF 14-3-3 is 95% sensitive and 93% specific in diagnosis of sporadic CJD.

CT studies may be normal or show atrophy. FDG PET may show cerebral hypometabolism even before MRI abnormalities are seen. Bilaterally symmetrical increased T2 hyperintensity in putaminal and caudate nuclei and cortex is seen on MRI in sporadic CJD. Restricted diffusion in cortex and basal ganglia is usually the earliest abnormality. The pulvinar sign (bilaterally symmetrical hyperintensity of the pulvinar of the thalamus) and “hockey stick” sign (symmetrical pulvinar and dorsomedial thalamic nuclear FLAIR hyperintensity) are characteristic of nvCJD.

Other related prion diseases include kuru in brain-eating cannibals, scrapie in New Guinea sheep, and Gerstmann-Straussler-Scheinker disease, which manifests with severe cerebellar dysfunction.

Amyotrophic lateral sclerosis (ALS) is a degenerative upper motor neuron disease causing progressive loss of motor, facial, limb, and diaphragmatic musculature. MRI findings reveal signal abnormality in the corticospinal tract at the level of the internal capsules. Abnormalities may extend through the full length of the corticospinal tracts from motor cortex to posterior limb of internal capsule, cerebral peduncles, and brainstem. Atrophy of anterior horn cell region of the spinal cord can also be seen.

Cerebrotendinous xanthomatosis is an autosomal recessive disorder affecting the bile acid synthesis pathway as a result of deficiency of sterol 26-hydrox-

ylase. Mental retardation, epilepsy, polyneuropathy, and spasticity result from neurologic involvement. Combination of cataract, symmetric deep gray matter lesions and a posterior column involvement in a young individual suggests diagnoses. Focal areas of T2 hyperintensity in the globus pallidus and supratentorial white matter structures (especially corticospinal tracts in the cerebral peduncles) are identified on MRI and dentate nucleus calcification on CT. Enlargement of Virchow-Robin spaces in the spine can be seen; posterior and lateral columns may be selectively affected.

DEGENERATIVE DEEP GRAY NUCLEI DISORDERS

Unlike the cortical neurodegenerative disorders described above, these disorders usually present with movement disorders and incoordination.

Huntington chorea is an autosomal dominant genetic disorder resulting from a defect in the short arm of chromosome 4. Severe memory impairment and involuntary choreoathetoid movements are seen. It results in selective atrophy of the caudate nuclei resulting in dilated frontal horns of lateral ventricles. Increased signal intensity on MR in putaminal and globus pallidus has been described in the juvenile form of Huntington disease and frontal atrophy is usually present.

Hallervorden-Spatz syndrome is an autosomal recessive disorder associated with involuntary movements, spasticity, and progressive dementia. On MRI, T2 hypointensity in globus pallidus, red nuclei, and substantia nigra results from iron accumulation. Although normal iron deposition in these structures can be seen with increasing age, its presence in a young adult with bradykinesia, muscle rigidity, and choreoathetoid movements of the body is suggestive of the disease. “Eye of the tiger sign” is described as an area of linear high signal in a dark globus pallidus on T2WI and is considered characteristic but can be also seen in other diseases as well.

Wilson disease (hepatolenticular degeneration) is an autosomal recessive disorder caused by abnormal ceruloplasmin metabolism. Classic Kayser-Fleischer rings due to copper deposition are identified in cornea on ophthalmologic examination. CT reveals caudate nuclei and brainstem atrophy and hypodensity in basal ganglia and thalami. Bilateral symmetric FLAIR hyperintensity in caudate nuclei and putamina, T1 hyperintensity in putamina, and caudate nucleus atrophy are typical MR findings. Signal abnormalities in the midbrain on T2WI have been described as “face of the giant panda” sign. Table 11-6 given the differential diagram of T1 hyperintense in basal ganglia.

TABLE 11-6 Hyperintense Basal Ganglia on T1-Weighted Imaging

Common	Hepatic encephalopathy
	Parenteral nutrition
	Calcium-phosphate metabolic disorders (hyperparathyroidism, hypoparathyroidism, pseudohypoparathyroidism, pseudopseudohypoparathyroidism)
	Hypoxic ischemic encephalopathy
	Neurofibromatosis type I
Uncommon	Japanese encephalitis
	Wilson disease
	Hallervorden-Spatz syndrome
	Carbon monoxide poisoning
	AIDS
	Fucosidosis

METABOLIC DISORDERS

Metabolic disorders affecting the brain comprise of a large number and variety of diseases, which include mucopolysaccharidoses, lipidoses, mitochondrial defects, aminoacidopathies, and lysosomal disorders.

MUCOPOLYSACCHARIDOSES

Mucopolysaccharidoses (MPS) clinically manifest as mental retardation, peculiar facies, and musculoskeletal deformities. MRI findings include diffuse atrophy, enlargement of Virchow-Robin spaces, white matter signal abnormality with cribriform appearance, and dural thickening. Arachnoid cysts due to deposition of glycosaminoglycans in the meninges can be seen. Macrocrania can be seen with Hunter syndrome (MPS II). Atlantoaxial subluxation and cord compression due to ligamentous hypertrophy can be seen in Morquio (MPS IV) and Maroteaux-Lamy (MPS VI) syndromes.

LIPIDOSES AND OTHER STORAGE DISORDERS

Cerebellar atrophy and ataxia are seen with Tay-Sachs disease and Niemann-Pick disease. Bilateral thalamic hyperdensity on CT is characteristic of Sandhoff disease and Tay-Sachs disease. Fabry disease is an X-linked recessive disorder caused by deficiency of α -galactosidase A. It is characterized by angiokeratoma, corneal and lenticular abnormalities, acroparesthesia, renal and cardiac dysfunction, and stroke. Imaging findings include multiple infarcts, vascular stenoses and thromboses, and lacunar infarcts. T1 hyperintensity in the pulvinar likely representing calcification has been described as pathognomonic of Fabry disease.

MITOCHONDRIAL DEFECTS

Leigh disease (necrotizing encephalomyelopathy) is caused by pyruvate carboxylase/dehydrogenase deficiency. Majority of patients present by age of 2 with psychomotor delay/regression and progressive brainstem and basal ganglia dysfunction. Elevated blood and CSF lactate levels aid diagnosis. Diagnosis is made by mitochondrial analysis of muscle biopsy or cultured skin fibroblasts. MRI features include increased T2/FLAIR hyperintensity in the putamen and periaqueductal gray matter. Substantia nigra and dorsomedial nuclei of thalami can also be involved. MR spectroscopy demonstrates increased choline and decreased NAA with presence of lactate.

MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes) is characterized by onset of strokelike episodes in childhood/early adulthood with mean age of onset at 15. Male-to-female ratio is 2:1. CSF lactate is elevated. MRI findings in the acute stage include gyriiform cortical swelling, not limited to vascular territories. In the chronic stage, multiple lacunar infarcts and atrophy are seen. MR spectroscopy is useful in demonstrating elevated lactate doublet peak at 1.3 ppm in 60% cases.

Other less common mitochondrial disorders also include MERRF syndrome, Kearns-Sayre syndrome, Alpers disease, Leigh disease, Menkes kinky hair disease, Zellweger syndrome, and Refsum disease.

QUESTIONS AND ANSWERS

1. What is a characteristic feature of multiple sclerosis plaques in the cord?
 - A. Less than two vertebral segments in length
 - B. Solitary

- C. Central cord involvement
- D. Cord swelling

ANSWER: A. Plaques in MS typically involve peripheral cord and are less than 2 vertebral segments in length.

2. Which MRI feature supports the diagnosis of tumefactive multiple sclerosis rather than tumor?
 - A. Mass effect excessive for the size of the lesion
 - B. Increased perfusion
 - C. Elevation of glutamate/glutamine peak on single-voxel MRS using PRESS
 - D. Absence of enhancement

ANSWER: C. Tumefactive MS lesions have less mass effect relative to size of lesion, decreased perfusion, and have an open-ring pattern of enhancement, which aid differentiation from tumor. Absence of enhancement can be seen with low-grade tumors or demyelinating lesions and does not support one diagnosis over the other.

3. What causes progressive multifocal leukoencephalopathy in AIDS patients?
 - A. Autoimmune reaction to HIV
 - B. JC virus infection of oligodendrocyte
 - C. Prion reactivation
 - D. Toxicity due to HAART therapy

ANSWER: B. PML is caused by JC virus infecting the oligodendrocyte.

4. A 59-year old diabetic woman presents with a 2-month history of rapid cognitive decline and ataxia. MRI shows restricted diffusion and T2 hyperintensity in bilateral caudate nuclei and putamina. What is the most likely diagnosis?
 - A. Hypoxic-ischemic encephalopathy
 - B. Viral encephalitis
 - C. Creutzfeldt-Jakob disease
 - D. Uremic encephalopathy

ANSWER: C. While hypoxic-ischemic encephalopathy, hypoglycemia, and encephalitis can all result in bilateral basal ganglia showing T2 signal abnormalities, the history together with MRI findings makes CJD the most likely diagnosis.

5. Which dysmyelinating disorder is characterized by elevated levels of NAA on MR spectroscopy?
 - A. Alexander disease
 - B. Canavan disease
 - C. Adrenoleukodystrophy
 - D. Metachromatic leukodystrophy

ANSWER: B. Canavan disease has elevated levels of NAA on MR Spectroscopy.

6. What is the most likely diagnosis in a patient with parkinsonian features and “hot cross bun” sign on MRI?
 - A. Idiopathic parkinson disease
 - B. Multisystem atrophy
 - C. Progressive supranuclear palsy
 - D. Corticobasal degeneration

ANSWER: B. “Hot-cross bun” sign is considered characteristic of multisystem atrophy in a patient with parkinsonian symptoms.

12 SELLA AND PARASELLAR PATHOLOGY

Joseph C. Sullivan III

CAVERNOUS SINUS ANATOMY

The sella is essentially formed by the base of the sphenoid bone and its more medial wings, with a reflection of dura surrounding this, as it encompasses the inferior hypothalamic region of the brain and the medial cranial fossa. It is bordered inferiorly by the sphenoid sinuses and anteriorly by clinoid processes at the posterior aspect of the ethmoid bone. The orbital plate also lends structure to the anterior aspect of the sella and parasellar regions. Within the cavernous sinus, there is essentially a mixed plexus of venous sinusoidal components encircling the anatomical structures, which reside and traverse the cavernous sinus. The pituitary gland proper is a central point within this sinus. Its infundibulum traverses inferiorly from the hypothalamus bordered on its anterior aspect by the posterior optic chiasm. The internal carotid arteries essentially occupy four corners of the cavernous sinus when viewed in a coronal plane (Fig. 12-1). The inferior aspects of the cavernous portions of the internal carotid artery course anteriorly after coming cephalad past the foramen lacerum from the petrous segment extending into the vertical portion. ICA it then turns anteriorly in the horizontal cavernous aspect before coming to an anterior genu, which curves the internal carotid artery more posteriorly. This gives off branches, including the meningohypophyseal trunk as well as the inferior lateral trunk. They supply the meninges. More superiorly, the ophthalmic and superior hypophyseal arteries branch off as the internal carotid artery turns more vertically at the anterior genu and then more posteriorly as it penetrates the dura.

- 2 Optic chiasm
- 3 CN III
- 4 CN IV
- 5 CN V₁ & V₂
- 6 CN VI
- 7 ICA

FIG. 12-1 Anatomy of cavernous sinus, coronal plane.

In the coronal plane, the cranial nerves horizontally traverse through the cavernous sinus, with the sixth cranial nerve the most medial. Lesions in the central portion of the central cavernous sinus, may present with a sixth nerve palsy before impinging the more lateral cranial nerves. In a cephalad to caudad arrangement, the third, fourth, and first two components of the fifth cranial nerve course along the lateral aspect of the cavernous sinus. Another difference is that these lateral cranial nerves are encircled by a membranous layer of internal and external dural reflection. It should also be noted that the second component of the fifth cranial nerve may actually reside inferiorly in an extended reflection of the dura anterior to Meckel cave. Therefore, lesions occurring within the lateral intradural wall of the cavernous sinus, such as schwannoma, epidermoid, or less likely metastatic disease and to have a more smooth contour and shape with medial displacement of the intracavernous components and normally occur without internal carotid involvement, unless the lesion is aggressive. This is in contrast to lesions that occur in a more medial intracavernous sinus, such as meningioma or adenoma, which actually *encase* the carotid arteries.

PITUITARY GLAND

The pituitary gland itself is essentially divided into anterior and posterior lobes. The anterior lobe is further subdivided into the pars distalis, pars intermedia, and pars tuberalis more cephalad at the insertion at the infundibulum. The pars distalis is the more anterior portion with the pars intermedia being the more posterior

portion of the anterior lobe abating the posterior lobe. The pars intermedia is felt to be the origin for Rathke cleft cysts, whereas pars distalis is the primary component of hormonal secretion and therefore the source of most functioning microadenomas. However, the pars tuberalis can also be a source for adenomas and may actually function after transsphenoidal hypophysectomy of the pars distalis and the pars intermedia. This may present as an adenoma, which appears to be above the diaphragma sella at the roof of the sella above the pituitary. The posterior pituitary gland or neurohypophysis is further subdivided into an infundibulum or stem, a more medium eminence, and a posterior (neural) lobe. The posterior lobe has a more direct arterial supply. The meningeal hypophyseal trunk and the inferior hypophyseal arteries arise directly from cavernous internal carotid artery. This may explain the near immediate enhancement of the posterior lobe while there is a delayed, more portal supply, enhancement of the anterior lobe. This further explains why the anterior lobe is more susceptible to ischemia and infarction, such as in the postpartum setting (Sheehan syndrome). Sheehan syndrome is a variation of pituitary apoplexy, which occurs with acute onset of infarction, necrosis, and hemorrhage into the pituitary gland. This is secondary to an adenoma in true pituitary apoplexy. Although the patient history may differ, clinical onset, however, is very similar with the acute onset of headache, visual changes, nausea, and possible ptosis. MRI is the modality of choice for diagnosis.

CONGENITAL AND DEVELOPMENTAL LESIONS

Congenital and developmental lesions consist of cyst and midline abnormalities including lipoma, teratoma, and dermoid/epidermoid. As previously mentioned, the Rathke cleft cyst develops most commonly from the pars intermedia. This is felt to be a remnant of a pouch with diverticulum from the stomodeum or primitive buccal cavity as it extends cephalad to meet the inferior migrating portion of neuroectoderm, which will form the posterior pituitary. It is this remnant connection with the oral cavity that is felt to be trapped and form a Rathke pouch cyst. However, debate remains whether this may be similar or the same lesion of a more ventral cyst of neuroectodermal origin. There can also be a continuous tract called the craniopharyngeal canal extending into the sphenoid sinus in a very small number of individuals. Similarly, there can be entrapped arachnoid-forming arachnoid cysts. Other developmental lesions such as midline lipomas or mixed mesodermal origin lesions can form as they do in other parts of the neuroaxis. Another congenital variant may be ectopic

pituitary in which there is focal pituitary-enhancing tissue most commonly just at the posterior aspect of the optic chiasm at the upper infundibulum without identifiable connection into the sella. These patients may present with an overall delayed hormonal development.

NEOPLASM

Adenomas are divided into two subgroups: functioning and nonfunctioning. The functioning or hormonally active adenomas tend to present with smaller size because of their overt clinical signs secondary to abnormal hormonal effect. These can be difficult to visualize on MRI, even with the use of dynamic contrast evaluation. These adenomas have a slight delay in enhancement, resulting in a relative hypointense signal character on T1-weighted postcontrast MRI. However, again, their small size may preclude identification. Nonfunctioning adenomas tend to exert mass effect on local tissues, such as the optic chiasm, presenting with classic bitemporal hemianopsia or sixth nerve palsy with lateral rectus palsy because of this sixth cranial nerve's medial location within the sella. The macroadenoma may distort the local anatomy displacing the infundibulum to the contralateral direction as it still remains attached to the normal pituitary tissue. Even in the setting of macroadenoma, diagnosis can be difficult with CT. Secondary signs such as extension into the sphenoid sinus via erosion of the floor, bulging of the cavernous sinus at the lateral walls, or mass effect on the chiasm, infundibulum or hypothalamus may be the first imaging signs.

Glioma (astrocytoma) can arise along the optic pathways or the hypothalamus. The differentiation between a parasellar lesion with local extension versus hypothalamic origin of a tumor is critical. It should also be evaluated in the correct clinical setting because hamartomas of the tuber cinereum can have a similar appearance but a different clinical presentation consisting of gelastic seizures and possible precocious puberty. Although fairly different in appearance, a germinoma can have a similar appearance early on in young adults.

Cancer can invade (or metastasize) to the cavernous sinus. Metastasis to the anterior skull base is more commonly seen with breast and lung carcinoma but can also be seen with prostate cancer. While prostate metastases tends to be more osteoblastic and lung metastasis more lytic, breast carcinoma, although more commonly lytic, has variable presentations within the skull base. Other lesions within the clivus can be mistaken for metastasis, such as chloromas in patients with leukemia, chordomas, or even Wegener granulomatosis. Inflammation from the petrous apex, Gradenigo syndrome, can

spread to the lateral petroclival junction. Chondroid lesions such as chondrosarcoma or chondroid chordomas can also occur at the petroclival junction, usually presenting with a sixth nerve palsy as this nerve traverses Dorello canal. There can also be spread of tumor from below in the inferior skull base sinuses in the younger patients. Juvenile angiofibroma is an aggressive vascular lesion usually presenting in young male patients. It can extend into the cavernous sinus via the pterygopalatine fossa.

Other paracavernous lesions or lesions that extend into the cavernous sinus, such as meningiomas, may be difficult to initially evaluate based on their location. These should be traceable to a central aspect from a localized clinoid process, reflection of dura across the diaphragma sellae, or extending from the clivus or planum sphenoidale. Lesions such as these tend to cause symptoms secondary to mass effect more than infiltration. Schwannomas rising along the cranial nerves may traverse through the cavernous sinus. If involved in the third, fourth, or first two sections of the fifth cranial nerves, they may have more of a rounded tubular appearance because of their location in the lateral cavernous dural sheath. In contrast, if these lesions are in the sixth cranial nerve, they may appear elongated and compressed, secondary to their resistance to expansion because of their more medial location within the sella. The cranial nerves should be evaluated for perineural spread from craniofacial lesions. Most frequently, this occurs with the more common squamous cell carcinoma, although adenoid cystic carcinoma has a greater propensity for perineural spread earlier in the course of the disease.

INFLAMMATION AND INFECTION

There are a multitude of inflammatory and infectious processes that can affect the pituitary gland. The sella and cavernous sinus can be affected by infectious processes within the intracranial vault of the meninges, such as basilar infectious processes from contiguous extent into the sella and cavernous sinus from the sinuses. The sella and cavernous sinus can also be affected by idiopathic inflammatory processes, such as the so-called Tolosa-Hunt syndrome. Such processes can present alone or in concert with involvement with surrounding structures such as thrombosis of the cavernous sinuses or its drainage pathways. These are of interest because their diagnostic dilemma is the entity of eosinophilic granuloma, which can present as a simple thickening of the infundibular stalk. This, as well as adenomas, can be confused with lymphocytic hypophysitis, which is an inflammatory process involving the pituitary gland or the infundibulum. This is most

often seen in the classic postpartum setting; however, it can also occur in men. The enlarged pituitary gland and/or stalk may regress spontaneously or with steroid treatment. Other granulomatous processes such as giant cell granulomas and sarcoidosis can have a similar appearance as any other pituitary lesion and may also appear even similar to an adenoma of the pituitary gland. Diagnoses are often made in association with other extracranial findings. It should also be noted that although uncommon, in the correct clinical setting (immunosuppression or postoperative state), abscesses could exist in this location.

MISCELLANEOUS

In discussing the postoperative appearance within the sella and cavernous sinus and its juxtaposed sphenoid sinuses, fat saturation imaging is critical for the evaluation of the postsurgical fat patch, which is used during transsphenoidal hypophysectomy. It is also important to evaluate the optic pathways for tethering or scarring after reduction removal of large sella and suprasellar lesions.

Similar in appearance, although separate in etiology, the empty sella may occur with dehiscence of diaphragma sellae. This can be associated with increased intracranial pressure of an idiopathic nature or so-called pseudotumor cerebri. Careful attention to the optic nerve sheaths and optic heads, which can be other signs of increased intracranial pressure, should be paid when the sella appears pancaked inferiorly within the sella. Careful attention should also be paid to the native size of the sella itself so as not to mistake this appearance with previous disease.

QUESTIONS AND ANSWERS

- Which of the following clinical signs would *not* indicate the possibility of a sella/cavernous lesion?
 - Unilateral in turned eye
 - Unilateral jaw pain
 - Anisocoria
 - Inability to close one eye
 - Amenorrhea

ANSWER: D. Bell palsy of the seventh cranial nerve. This is a common presentation of Bell palsy and should not be confused for the presentations seen with impingement of the cranial nerves: III supplies pupillary and upper eye lid opening, which may cause anisocoria; IV supplies the superior oblique muscle, which contributes to the ability to look down and medially; V is responsible for sensation to the face; VI supplies the lateral rectus, which is used for abduction of the globe. Amenorrhea could imply a lesion with pituitary involvement.

- Which of the following is a lesion *least* likely seen in a parasellar distribution?
 - Metastasis
 - Schwannoma
 - Adenoma
 - Glioma
 - Epidermoid

ANSWER: E. Epidermoid is more typical in the cerebellar pontine angle or fourth ventricle. Cholesteatoma, a lesion similar to an epidermoid, can be seen in the petrous ridge. A schwannoma can involve the nerves traversing the cavernous sinus. Gliomas can involve the hypothalamic axis of the optic distributions.

- Which of the following about craniopharyngiomas is *not* true?
 - Tend to have a cystic and solid component.
 - Childhood type (adamantinomatous) is more amenable to resection.
 - Cyst contains a mixed proteinaceous material.
 - Enlarging cyst may be symptomatic.
 - Recurrences can occur with both types.

ANSWER: B. The adamantinomatous type tends to be more adhesive to normal structures as opposed to the squamous-papillary type thought to be a cause for its said greater rate of recurrence. The

squamous-papillary type, which occurs more commonly in adults, is said to be less lobulated with smaller, more watery cysts.

4. Which of the following is *not* true about aneurysms in the parasellar cavernous sinus distribution?
- Ophthalmic complaints may be the only presenting sign.
 - If they rupture distal to the ophthalmic segment, they will present with subarachnoid hemorrhage.
 - Anisocoria can be caused by a posterior communicating aneurysm.
 - If they rupture within the cavernous sinus, it will likely tamponade.
 - Any of the cavernous cranial nerves can be affected by an ICA aneurysm.

ANSWER: D. Rupture into the cavernous sinus most often results in a C-C fistula. This will result in arterialized flow within the ophthalmic veins, presenting with ophthalmic symptoms. This is as opposed to the subarachnoid hemorrhage that occurs once the ICA penetrates the dura. Anisocoria can be caused by impingement of the pupillary control running along CN III by a PComm origin aneurysm.

5. Which of the following about schwannomas is *true*?
- It expands from the central nerve.
 - Often seen in the cavernous sinus.
 - Tubular shape indicates a lateral cavernous nerve involvement.
 - Usually detected early.
 - Primarily presents with vascular occlusion.

ANSWER: C. The tubular nature is caused by restriction of the dural reflection in the lateral cavernous sinus. It originates from the support Schwann cells along the nerve. It is not that common within the cavernous sinus and when it does, Schwannomas can be silent for some time because of the dura reflection encasing the lateral cranial nerves within the cavernous sinus. They tend to present from neuronal compression.

6. What is the most sensitive imaging study for pituitary adenoma?
- Dynamic post-gadolinium T1 imaging
 - Thin section T2-fast spin echo
 - Delayed postcontrast T1-fat saturation imaging
 - Evaluation of secondary signs (infundibular displacement)
 - Coronal thin section inversion recovery imaging

ANSWER: A. Dynamic postcontrast imaging uses the delay in enhancement to demonstrate the late

enhancing adenoma. The anterior pituitary lobe is supplied primarily by a portal system. The adenoma will see a delayed contrast enhancement as well as a slightly slower wash out of contrast. This is useful for finding microadenomas as well as differentiating normal gland displaced by large macroadenomas.

7. Which of the following is *true* about pituitary hemorrhage?
- Only occurs after pregnancy
 - More likely to occur in the posterior pituitary gland
 - More likely to occur in an adenoma
 - Usually presents with subarachnoid hemorrhage
 - Usually presents with acute onset of sixth nerve palsy

ANSWER: C. It occurs more often in adenomas as a result of a more tenuous blood supply with a classic presentation of acute onset of blindness and headache. Although it is more often described in pregnant women, it can occur in nonpregnant women or even men.

8. Which of the following is *true* about postoperative imaging of the sella/pituitary?
- If the chiasm is tethered, the patient will have visual defects.
 - Delayed contrast enhanced T1-fat saturation imaging is the key.
 - Dynamic gadolinium enhanced T1 imaging is the most beneficial for recurrence.
 - Infundibulum will point toward the removed lesion.
 - Sinuses do not need to be included for examination.

ANSWER: B. As fat packing is usually used after transsphenoidal hypophysectomy, fat saturation should be used. The patient does not always have visual defect with tethering of the chiasm. Dynamic T1-postcontrast imaging may be difficult with the packing in the sella and sphenoid sinuses.

9. Which of the following is the most common cranial nerve affected by a pituitary macroadenoma?
- CN III
 - CN IV
 - CN V
 - CN VI
 - CN I

ANSWER: D. Although the optic nerve (CN II) is commonly the nerve impinged by a macroadenoma at presentation, it should be remembered that CN VI is the most medial one in the cavernous sinus.

Commonly, a degree of lateral rectus palsy can be detected on examination at the time of presentation with visual symptoms. It is not covered by a reflection of dura unlike those cranial nerves in the lateral cavernous sinus.

10. What is the most common isolated cranial nerve palsy secondary pathology outside of the cavernous sinus to of those that traverse the cavernous sinus?

A. CN I
B. CN III
C. CN IV
D. CN V
E. CN VI

ANSWER: E. The sixth cranial nerve traverses the longest distance and is more tethered than other cranial nerves that traverse the cavernous sinus. It travels cephalad from a long course within the brainstem, exiting at the caudal pons and turns anterosuperiorly at Dorello canal at the petroclival junction. This means that it is susceptible to subtle mass effect on the brainstem as well as a multitude of skull base processes.

13 FACE AND NECK ANATOMY

Surjith Vattoth and Joseph C. Sullivan III

FACIAL SKELETON: THE BUTTRESS CONCEPT

The facial skeleton can be conceptualized as four transverse and four paired vertical buttresses, which is important from a surgeon's perspective. The buttresses represent areas of relative increased bone thickness that support the functional units of the face, including muscles, eyes, dental occlusion, and airway, in an optimal relation and define the form of the face by projecting the overlying soft-tissue envelope. As structural units that support the face, the buttresses must either directly or indirectly interface with the skull base or cranium as a stable reference. Any significant buttress displacement is treated surgically using reduction and rigid internal fixation. Transverse buttress reduction restores facial profile and width while vertical buttress reduction restores facial height. Buttress reduction establishes a functional support for the teeth and globes.

The upper transverse maxillary buttress runs from the squamous temporal bone, across the zygomatic arch and the inferior orbital rim, to the nasofrontal junction.

The orbital floor is the posterior extension of this buttress. The lower transverse maxillary buttress runs along the maxilla above the alveolar ridge. The hard palate is the posterior extension of this buttress. The paired lateral vertical midface buttresses are the columns of bone from above the posterior maxillary molars across the zygomaticomaxillary suture and body of the zygoma, extending superiorly along the lateral orbital rim and across the zygomaticofrontal suture to the frontal bone. The posterior projections of these buttresses include the lateral orbital wall and the lateral wall of the maxillary sinus. The paired medial maxillary buttresses are the columns of bone from the anterior nasal spine, extending along the rim of the piriform aperture, up the frontal process of the maxilla, and across the nasofrontal junction to the frontal bone. The posterior projection of these buttresses includes the medial orbital wall and the anterior projection includes the lateral nasal wall. The paired posterior maxillary buttresses are the columns of bone at the pterygomaxillary junction where the pterygoid processes of the sphenoid join the posterior maxilla.

Naso-orbitoethmoid (NOE) fractures involve the central upper midface, disrupting the confluence of the medial maxillary buttress with the upper transverse maxillary buttress as well as their posterior extensions along the medial orbital wall and floor. The eyelids insert around the lacrimal fossa through the medial canthal tendon. Even if the frontal process of the maxilla, which is the superior portion of the medial maxillary buttress, is anatomically reduced, there can still be a residual rotation deformity that splays the posterior extension of this buttress resulting in telecanthus and globe malposition. It is important to note that in axial CT scan sections, the frontal process of maxilla lies immediately posterior to the lacrimal bones and it is a common mistake to describe these as nasal bones. Radiologic reports of NOE fractures should describe the degree of comminution of the medial vertical maxillary buttress, specifically in the region of the lacrimal fossa, where the medial canthus attaches. The distance between the two lacrimal fossae in the coronal plane is also important for the surgeon to assess the need for a medial canthoplasty. NOE fractures include damage to the ethmoid sinus and walls. If there is bilateral comminution and displacement in this region, the nasofrontal ducts that drain the frontal sinus are also likely disrupted. Although the frontal sinus may not be directly injured, if the nasofrontal ducts are disrupted, then frontal sinus surgery is needed to prevent a mucocoele in the future. NOE fractures can include orbital damage. NOE fractures are distinguished from simple nasal fractures by posterior disruption of the medial canthal region, the ethmoids, and the medial orbital walls.

The two major buttresses of the zygomaticomaxillary complexes are the upper transverse maxillary (across the zygomaticomaxillary and zygomaticotemporal sutures) and the lateral vertical maxillary (across the zygomaticomaxillary and frontozygomatic sutures). The zygomaticomaxillary complexes relate to the temporal bone, maxilla, frontal bone, and skull base and are therefore a quadripod (not truly a tripod) structure. Fractures typically occur across these three buttress-related sutures, leading to the term tripod fracture. Tripod fractures consist of fracture of the zygomatic arch, the lateral orbital wall, and the inferior orbital floor. This term fails to recognize the posterior relationship of the zygoma with the sphenoid bone of the skull base and its extension inferiorly down the lateral wall of the maxillary sinus. A displaced zygomaticomaxillary complex (ZMC) fracture is a quadripod fracture. If the two buttresses of the zygoma are reduced and fixated, it is still possible to have a rotational deformity of the zygoma about the zygomaticosphenoid suture. Fractures of the zygomatic complex frequently result in sensory disturbances in the infraorbital nerve because fractures generally occur in the vicinity of the infraorbital foramen and canal.

Another accepted system of facial fracture description is the Le Fort classification. It is easy to identify the Le Fort fractures if we know the following anatomic concepts. Pterygoid process fracture is common to all Le Fort fractures, and it is rare for the pterygoid processes to be fractured in the absence of a Le Fort fracture. Each of the Le Fort fractures has a unique component. Le Fort I fracture is the only one that involves the anterolateral margin of the nasal fossa just above the maxillary alveolar process. This fracture of the anterolateral margin of the nasal fossa is easily seen on coronal or three-dimensional CT images of the face. If the pterygoid processes are broken and this portion of the maxilla is broken, a Le Fort I fracture most likely is present. If the anterolateral margin of the nasal fossa is intact, a Le Fort I fracture is excluded. Le Fort II fracture is the only one that involves the inferior orbital rim. The inferior orbital rim is also easily seen on coronal or three-dimensional CT images of the face. If the pterygoid processes are broken and the inferior orbital rim is broken, a Le Fort II fracture is probably present. If the inferior orbital rim is intact, a Le Fort II fracture is then excluded. Le Fort III fracture is the only one that involves the zygomatic arch. The zygomatic arch is easily seen on axial or three-dimensional CT images of the face. If the pterygoid processes are broken and the zygomatic arch is broken, probably a Le Fort III fracture is present. If the zygomatic arch is intact, a Le Fort III fracture is excluded.

NASAL CAVITY AND PARANASAL SINUSES

The nasal cavity has a roof formed by the cribriform plate of ethmoid; a floor formed by the palate; lateral walls formed by the turbinates/meatuses; and a midline septum formed by the perpendicular plate of ethmoid posterosuperiorly, vomer posteroinferiorly, and septal cartilage anteriorly. The meatuses of the lateral walls lie below the respective turbinates. The superior meatus receives drainage from the posterior ethmoidal air cells at the sphenoethmoidal recess. The vertical lamella of middle turbinate attaches superiorly to the cribriform plate of ethmoid and its basal lamella or ground lamella attaches posterolaterally to the lamina papyracea (lateral ethmoid sinus wall/ medial orbital wall) and forms the junction of anterior and posterior ethmoid sinuses. The surgical relevance is that the anterior ethmoid cells drain into the hiatus semilunaris of the middle meatus, while the posterior ethmoid cells drain into the superior meatus. The classical anatomy of dividing the ethmoid sinus into anterior, middle, and posterior group of cells is no longer surgically relevant. The hiatus semilunaris of the middle meatus also receives the drainage from the maxillary sinuses. The inferior meatus receives drainage from the nasolacrimal duct anteriorly.

Concha bullosa is a pneumatized middle turbinate and sometimes may be large enough to cause obstruction in the middle meatus or the infundibulum. The middle turbinate usually curves medially toward the nasal septum. However, in one-fourth of patients, the convexity is directed laterally resulting in a paradoxical middle turbinate.

The frontal sinuses are funnel-shaped cavities with a central septum dividing the frontal sinus into two parts but several septa may also be seen. The frontal recess is the drainage pathway of the frontal sinus bordered by the agger nasi cell anteriorly, lamina papyracea/agger nasi/ethmoid bulla laterally, and middle turbinate medially. It drains directly into the anterior aspect of middle meatus if the uncinate process inserts on lamina papyracea. Alternatively, the frontal recess drains into the ethmoid infundibulum and then to the middle meatus if the uncinate process inserts on middle turbinate or skull base. On coronal CT, the frontal recess is seen superior and medial to the agger nasi. Reconstructed sagittal images are the best to see the frontal recess.

The posterior limit of the frontal recess is defined by the location of the anterior ethmoidal artery. The anterior ethmoidal artery is a branch of the ophthalmic artery. From the orbit, it passes through a canal into the anterior ethmoid sinus just posterior to the frontal recess. It then crosses the sinus and enters the anterior cranial fossa before exiting and reentering the nasal cavity via the cribriform plate.

Frontal recess (Kuhn) cells are the cells that extend from the anterior ethmoid labyrinth into the frontal recess posterosuperior to the agger nasi.

1. Type I cell is a single frontal recess cell above the agger nasi but below the floor of the frontal sinus.
2. Type II cells are a tier of cells in the frontal recess above the agger nasi that might extend into the frontal sinus.
3. Type III cell is a single massive frontal recess cell that pneumatizes superiorly into the frontal sinus.
4. Type IV cell is a single isolated cell within the frontal sinus. Intersinus cell is derived from the frontal sinus, seen between the frontal sinuses, and can have mass effect on the frontal recess.

Agger nasi (meaning nasal mound in Latin) cells lie anterior and inferior to the frontal recess. They are constant extramural cells and represent the most anterior ethmoid cells. On coronal CT, they appear inferior to the frontal recess and lateral to the middle turbinate and form important surgical landmarks. When inflamed, the agger nasi cells may obstruct the frontal recess causing isolated opacification of frontal sinus without involving anterior ethmoid or maxillary sinuses. Opening these cells at endoscopic surgery usually gives access to the frontal recess.

Haller (infraorbital ethmoid) cells are ethmoid cells that extend along the floor of the orbit. They lie lateral to ethmoid (maxillary) infundibulum and when inflamed can obstruct the infundibulum producing isolated maxillary sinus disease sparing the ethmoid sinuses, the so-called infundibular pattern of sinus disease.

Onodi (sphenothmoid) cells are posterior ethmoid cells that extend lateral and superior to the sphenoid sinus and abut the optic nerve with an endoscopically visible bulge of the optic canal.

Supraorbital cells arise from the anterior ethmoid air cells and extend between the medial orbital wall and ethmoid roof resulting in pneumatization of the orbital plate of frontal bone posterior to frontal recess and lateral to frontal sinus.

The ethmoid roof is formed by the fovea ethmoidalis of the frontal bone laterally and the lateral lamella of cribriform plate of the ethmoid bone medially. The medial aspect is 10 times thinner than the lateral aspect. Because of the delicate attachment of the middle turbinate to the cribriform plate anteriorly, surgery in this area should be performed carefully as detachment of the middle turbinate may damage the dura, resulting in cerebrospinal fluid leak. Keros has classified ethmoid roof into three types, according to the vertical height of the lateral lamella with the resultant depths of olfactory

fossa. Keros type I: olfactory fossa is 1 to 3 mm deep, lateral lamella is nearly nonexistent; type II: olfactory fossa is 4 to 7 mm deep; and type III: olfactory fossa is 8 to 16 mm deep with the longest vertical height of lateral lamella of cribriform plate. Keros type III has the highest risk for iatrogenic injury to the lateral lamella of the cribriform plate at endoscopic surgery. Also the anterior ethmoidal artery is vulnerable to injury at the cribriform plate, which may cause catastrophic bleeding into the orbit.

The ostiomeatal unit is the complex anatomic region superolateral to the middle meatus where drainage of frontal, anterior, ethmoid, and maxillary sinuses occurs. It includes the superomedial maxillary sinus, maxillary sinus ostium, ethmoid (maxillary) infundibulum, hiatus semilunaris, ethmoid bulla, anterior ethmoid cells, and the frontal recess. The ethmoid infundibulum is bound laterally by the inferomedial wall of the orbit, superiorly by the hiatus semilunaris and ethmoid bulla, and medially by the uncinate process. As the maxillary sinus ostium opens into the floor of the ethmoid infundibulum, it is not possible to see the ostium endoscopically without removing the uncinate process. If an ostium is seen endoscopically, it is most likely to represent an accessory ostium. The hiatus semilunaris runs obliquely in a posteroinferior direction between the uncinate process and the ethmoid bulla and is best seen on parasagittal reconstructions. On CT, it is bound superiorly by the ethmoid bulla, laterally by the medial bony orbit, inferiorly by the uncinate process, and medially by the middle meatus. The gap between the tip of the uncinate process and the ethmoid bulla constitutes the hiatus semilunaris. In short, the maxillary sinus ostium opens into the inferior aspect (floor) of the ethmoid (maxillary) infundibulum, which runs superomedially to drain into the hiatus semilunaris, which in turn is continuous into the middle meatus of nasal cavity.

The uncinate process forms the upper medial maxillary sinus wall. It can be seen attached inferiorly to the inferior turbinate with the free edge representing the posterior free margin. Superiorly, the uncinate process may be attached to the lamina papyracea, the skull base, or the middle turbinate. As already stated, if the uncinate process is attached superiorly to the skull base or the middle turbinate, the frontal recess opens into the ethmoid infundibulum on its way to the middle meatus and infection in the infundibulum may affect the frontal sinus, resulting in the involvement of the frontal, ethmoid, and maxillary sinuses. Alternatively, if the uncinate process inserts into the lamina papyracea, the frontal recess drains directly into the anterior aspect of middle meatus, the ethmoid infundibulum being closed superiorly by a blind-ending pouch known as recessus terminalis. Therefore, ethmoid infundibular inflammation does not result in concomitant frontal sinusitis. The free edge

of the uncinate process may be deviated medially, which may narrow the middle meatus, or deviated laterally, which may obstruct the ethmoid infundibulum. Pneumatization maybe seen in a minority, but this uncinate process variant rarely compromises the infundibulum. A bent uncinate process may simulate a double middle turbinate on endoscopy. An atelectatic uncinate process is a condition in which the edge of the uncinate process approximates the orbital floor or the inferior aspect of the lamina papyracea and is usually associated with a hypoplastic ethmoid bulla or maxillary sinus. Uncinectomy may therefore result in injury to the orbital contents.

The ethmoid bulla is a dominant anterior ethmoid cell that protrudes inferomedially into the ethmoid infundibulum and upper middle meatus. The degree of pneumatization varies considerably ranging from failure of pneumatization (torus ethmoidalis) to a giant ethmoid bulla insinuating between the middle turbinate and uncinate process, displacing the uncinate process medially. The ethmoid bulla is bordered inferomedially by the hiatus semilunaris and ethmoid infundibulum, laterally by the lamina papyracea, and posterosuperomedially by the basal or ground lamella of middle turbinate, with the aerated gap called the sinus lateralis in between.

The sphenoid sinus is situated in the body of the sphenoid bone below the sella turcica. Its ostium is seen in the anterosuperomedial portion of the anterior sinus wall and communicates with the sphenoethmoidal recess and the posterior portion of the superior meatus. The carotid artery is related to its lateral walls, the optic nerve lies superolaterally, and the Vidian canal in its floor. The carotid artery may bulge into the sinus in approximately two-thirds of patients and rarely, the thin sinus wall separating the two may be absent. The intersphenoid septum is often deflected to one side and may be attached to the bony wall covering the carotid artery predisposing it to injury when the septum is avulsed during surgery. The maxillary (V2) nerve is closely related to the lateral aspect of the roof of the sphenoid sinus and hence, sphenoid sinusitis can produce trigeminal neuralgia. The posterior ethmoid sinus has a variable relationship with the sphenoid sinus and is intimately related to the optic nerve. The sphenoid sinus need not be directly posterior to the posterior ethmoid sinus, and the posterior ethmoid cell may extend laterally or superiorly beyond the anterior wall of the sphenoid sinus and may lead to the potential injury to the optic nerve at endoscopy. Also, there may be complete bony dehiscence of the optic canal exposing the nerve to injury.

ORBIT

The orbital roof, the floor of the anterior cranial fossa, and the frontal sinus are formed by the orbital plate of

the frontal bone. The orbital surface of the zygomatic bone and greater wing of the sphenoid constitute the lateral orbital wall. The medial wall is made from anterior to posterior by the frontal process of the maxillary bone, the lacrimal bone, and the lamina papyracea of the ethmoid bone with a small contribution by the lesser wing of the sphenoid. The floor is formed by the orbital surfaces of the zygomatic bone and maxilla as well as minimally by the palatine bone medially. Medially, the superior orbital rim ends in the spine of the lacrimal bone lying posterior to the infraorbital margin, which ends in the spine of the maxillary bone. The fossa of the lacrimal sac is between these two spines. Note that the lacrimal gland lies in the lacrimal fossa, a recess of the frontal bone anterolaterally in the orbit.

The extraocular muscles are comprised of four rectus muscles, the levator palpebrae superioris and the inferior and superior oblique muscles. Other than the inferior oblique muscle, which originates at anteroinferior orbital rim, all other extraocular muscles arise from a common fibrous ring, the annulus of Zinn, which overlies the optic foramen and the medial end of the superior orbital fissure. All four rectus muscles insert into the globe behind the limbus or sclerocorneal junction. The superior oblique muscle passes medially along the roof of the orbit to the trochlear, a tendinous sling attached to the orbital roof posterior to the superomedial orbital rim. It then passes posterolaterally between the superior rectus and globe where it inserts into the sclera in the middle of the globe. The inferior oblique arises from the medial orbital floor lateral to the lacrimal sac, passing posterolaterally beneath the inferior rectus and between the lateral rectus and globe to insert into the sclera adjacent to the superior oblique. The levator palpebrae superioris is not always identified discretely from the superior rectus on conventional imaging and the two muscles are often referred to as the superior muscle complex. Extraocular muscle thickness based on CT data are inferior rectus 4.8 mm, medial rectus 4.2 mm, superior rectus 4.6 mm, and lateral rectus 3.3 mm. The muscular cone divides the orbit into an extraconal, a conal, and an intraconal compartment.

The optic foramen is formed by the lesser wing of sphenoid and is separated inferomedially from the superior orbital fissure by the optic strut, which may have high signal marrow, seen separating the optic nerve from the oculomotor and other cranial nerves (CN) on high-resolution T1-weighted MRI of the orbital apex. The superior orbital fissure is limited by the lesser wing of sphenoid superomedially and the greater wing of sphenoid inferolaterally and connects the orbit and the middle cranial fossa via the cavernous sinus. The superior orbital fissure contains ophthalmic division of trigeminal nerve; CN III, IV, and VI; superior ophthalmic

vein; orbital branch of the middle meningeal artery; and sympathetic fibers. The oculomotor nerve (III) divides into superior and inferior divisions within the superior orbital fissure. The superior division supplies the superior rectus and levator palpebrae superioris, lying deep to their respective muscles. The inferior division has three branches supplying the medial and inferior rectus and the inferior oblique. The trochlear nerve (IV) lies above the oculomotor nerve in the orbital apex. It enters the orbit lateral to the annulus of Zinn above the frontal division of V1, runs medially between the superior muscle complex and the orbital periosteum, and then along the superior oblique muscle, which it supplies. The sensory ophthalmic division of the trigeminal nerve divides into three branches (frontal, lacrimal, and nasociliary) within the distal cavernous sinus before entering the orbit. The abducens nerve (VI) supplies the lateral rectus muscle.

The inferior orbital fissure lies between the floor and the greater wing of sphenoid. It communicates with the pterygopalatine fossa (PPF) and the masticator space (MS) and contains infraorbital nerve and zygomatic branch of the maxillary branch of the trigeminal nerve and emissary veins between inferior ophthalmic vein and pterygoid plexus. The infraorbital groove traverses the orbital floor, ending in the infraorbital canal and foramen.

The optic nerve sheath complex is formed by the optic nerve and the dural and leptomeningeal coverings. The intracanalicular portion of the optic nerve enters the orbit through the optic foramen with the ophthalmic artery lying inferiorly. The ciliary ganglion lies between the optic nerve and the lateral rectus muscle, usually lateral to the ophthalmic artery. The ophthalmic artery lies inferolateral to the intracanalicular optic nerve within the dural sheath. It leaves the dura inferiorly, crossing perpendicularly above the optic nerve from lateral to medial sides. In contrast, the ophthalmic vein crosses with lesser obliquity, enabling the distinction from the ophthalmic artery. The central retinal artery arises from the ophthalmic artery as it winds around the nerve and runs centrally within the optic nerve. The superior ophthalmic vein is larger and lies lateral to the superior oblique muscle anteriorly, passing backward over the optic nerve and beneath the superior muscle complex where it can be seen on coronal imaging. The inferior ophthalmic vein lies on the orbital floor between the lateral and inferior rectus muscles. It communicates through the inferior orbital fissure with the pterygoid venous plexus and the PPF.

PTERYGOPALATINE FOSSA

PPF is a fat-filled space between maxillary sinus anteriorly and pterygoid bone posteriorly. Its contents are

pterygopalatine ganglion, maxillary nerve (V2) entering via foramen rotundum, and distal internal maxillary artery entering via pterygomaxillary fissure.

Pterygomaxillary fissure is the lateral opening of PPF into nasopharyngeal MS. Sphenopalatine (nasopalatine) foramen is its medial opening into superior meatus of nose, covered by mucosa. This is the region where nasopharyngeal angiofibromas arise. Inferior orbital fissure is its anterosuperior opening into orbit, which transmits infraorbital nerve (V2 branch) and artery. Foramen rotundum is the posterosuperolateral canal along which intracranial maxillary nerve (V2) passes into PPF. It can be easily identified if we search for the canal connecting the PPF to middle cranial fossa at the lateral wall of cavernous sinus. Vidian canal (running through the body of sphenoid bone) is a posteroinferomedial canal below foramen rotundum, connecting PPF to foramen lacerum. (Remember that the foramen lacerum is the anteroinferomedial cartilaginous floor of horizontal petrous previously defined ICA canal, between sphenoid and temporal bones).

Pterygopalatine canal is the inferior canal leading from PPF through greater palatine foramen to hard palate. Lesser palatine foramen, another communication of PPF to palate, is posterior to greater palatine foramen.

JUGULAR FORAMEN AND HYPOGLOSSAL CANAL

The double eagle appearance of the occipital condyles of both sides is an important landmark, which can be easily identified in coronal sections roughly at the level of the dens. The eagle's head and beak is formed by the jugular tubercle. The hypoglossal canal passes through the occipital condyle along the undersurface of the beak. The beak separates the inferomedial hypoglossal canal from the superolateral jugular foramen. The jugular foramen actually lies between the occipital and temporal bones and is anteriorly connected with the petrooccipital fissure. The carotid space (CS) extends directly up to jugular foramen.

The jugular foramen has two parts partially divided by the jugular spine, the smaller anteromedial pars nervosa and the larger posterolateral pars vascularis. The pars nervosa transmits the ninth (glossopharyngeal) cranial nerve, Jacobson nerve, and inferior petrosal sinus. The pars vascularis transmits the tenth (vagus) and eleventh (spinal accessory) cranial nerves, Arnold's nerve, jugular bulb, and posterior meningeal artery. The hypoglossal canal transmits the twelfth (hypoglossal) cranial nerve and can be seen in contrast-enhanced MRI as linear low signal-intensity structures surrounded by enhancing high signal basiocciput venous plexus. As

soon as the nerve exits the hypoglossal canal, it immediately enters the nasopharyngeal CS to join CN IX, X, and XI, which come from the jugular foramen. Both the hypoglossal canal and jugular foramen empty into the cephalad-CS and therefore, the upper CS contains CN IX to XII and the internal jugular vein (IJV).

CRANIOCERVICAL JUNCTION

The articulations of the craniocervical junction include the middle atlantoaxial joint, which consists of two synovial compartments that surround the dens and allow rotation of C1 and C2 with respect to each other and the paired lateral atlantoaxial and atlanto-occipital articulations. These joints are bound and supported by several ligaments, including the anterior longitudinal ligament, the anterior atlantoaxial and atlanto-occipital ligaments, the cruciform ligaments, the alar ligaments, the apical ligament, and the tectorial membrane, which extend cranially as the cephalic extension of the posterior longitudinal ligament. The alar ligaments can be identified in coronal thin section T2/PD MRI as they extend from the lateral surface of tip of dens to anteromedial occipital condyles on each side. The transverse fibers of the cruciate ligament called the transverse atlantal ligament can be seen in T2 W axial images extending between the lateral masses of C1 passing behind the dens. On the open-mouth anteroposterior view of the craniocervical junction, the lateral masses of C1 should align exactly with the lateral margins of C2 when degenerative spurring is ignored. The posterior axial line is a line drawn along the posterior cortex of the body of the axis and extended cranially. The basion axial interval is the distance between the basion and this line and measured in the midsagittal plane. The basion axial interval is difficult to reproduce on CT images. The basion-dens interval is the distance from the most inferior portion of the basion to the closest point of the superior aspect of the dens in the midsagittal plane. In plain radiographs, 95% of adults have the basion-dens interval less than 12 mm and in 98%, the basion is situated no more than 12 mm anterior or 4 mm posterior to the posterior axial line. An abnormal distance between the dens or posterior axial line and the basion suggests failure or insufficiency of the alar ligaments, tectorial membrane, or both. In a recent CT scan series, 95% of the population was found to have a basion axial interval less than 8.5 mm with a maximum of 9.1 mm, compared with 12 mm on data from plain radiographs. The power ratio is obtained by dividing the distance between the tip of the basion to the spinolaminar line of the atlas by the distance from the tip of the opisthion to the midpoint of the posterior aspect of the anterior arch of C1. It is normal when the value is less

than 1 and there is no significant difference compared with data obtained by plain radiographs. Power ratio is only sensitive in the evaluation of anterior atlanto-occipital dissociation. A posterior dissociation or vertical distraction injury could result in a normal value and consequently go undiagnosed. The atlantodental interval is measured by drawing a line from the posterior aspect of the anterior arch of C1 to the most anterior aspect of the dens at the midpoint of the thickness of the arch in cranio-caudal dimension in the midsagittal plane. In plain radiographs, enlargement of the predental space, which should be less than 5 mm in children younger than 9 years of age and less than 3 mm in adults, points to injury of the transverse atlantal ligament. In CT scan, 95% of the population was found to have an atlantodental interval less than 2 mm, compared with 3 mm, the previously accepted plain radiograph measurement. The atlanto-occipital interval is calculated by drawing a line perpendicular to the articular surfaces of the occipital condyle and the lateral mass of C1, drawn at the center of the articulation by correlating the sagittal and coronal images. Measurements of the AOI are performed bilaterally and the values averaged. The atlanto-occipital interval in 95% of the population ranged between 0.5 and 1.4 mm.

The important lines and indices used for assessment of basilar invagination are Wackenheim line, Welcher basal angle, Klaus index, Chamberlain line, McGregor line, McRae line in lateral projection and atlanto-occipital joint angle in anteroposterior projection. The Wackenheim line is drawn along the posterior surface of clivus. The dens should lie anteroinferior to this line normally and any intersection of dens by this line is abnormal. The Welcher basal angle is the angle between the line drawn along the posterior surface of clivus and a line drawn anteriorly along the plane of sphenoid bone. Normal measurement is less than 140 degrees and signifies platybasia above that. Klaus index measures the perpendicular height from the tip of the dens to the twining's line. The twining's line is an anteroposterior line drawn from the tuberculum sellae to the internal occipital protuberance. If the Klaus posterior fossa height index is less than 30 mm, it suggests platybasia and basilar invagination. Chamberlain (palato-opisthion) line is drawn between hard palate and opisthion, the posterior margin of foramen magnum. Odontoid tip lying more than 5 mm above this line is abnormal. McGregor (palato-suboccipital) line is drawn from the hard palate to base of occipital bone. odontoid tip lying more than 7 mm above this line is abnormal. McRae line is drawn between the anterior and posterior margins of foramen magnum, that is, basion and opisthion. It is normally 35 mm in diameter and dens does not extend above it. In the frontal view, the angle formed at the junction of the lines traversing atlanto-

occipital joints of both sides normally measures 125 to 130 degrees. It may reflect occipital condyle hypoplasia if the angle is less than 124 degrees.

TEMPORAL BONE

The external auditory canal which is a slightly S-shaped canal measuring approximately 2.5 cm in length has a fibrocartilaginous lateral third and bony medial two-thirds, without periosteum, formed mainly by the tympanic portion of temporal bone. The external auditory canal is lined by closely adherent skin, which contains hair follicles, ceruminous and sebaceous glands at the cartilaginous portion. Medially, the canal ends at the tympanic membrane, which separates the external ear from the middle ear cavity. The membrane slants inferomedially at an angle with the floor of the external auditory canal, stretching superiorly from the thin sharp-edged scutum down to the tympanic annulus. The scutum is one of the bony structures eroded or blunted early by a cholesteatoma. The tympanic membrane consists of an upper pars flaccida and a larger lower pars tensa. The pars tensa consists of an outer thin layer of squamous cells, an intermediate layer of fibrous tissue, and an inner layer of mucosal cells continuous with the middle ear cavity. The pars flaccida lacks the intermediate fibrous layer. The scutum, the tympanic membrane, and the tympanic annulus are best demonstrated on coronal images at the mid bony portion of the external auditory canal.

The middle ear cavity is divided into three compartments in the coronal plane. A line drawn from the lower edge of the scutum to the tympanic portion of the facial nerve divides the superior compartment, the epitympanum (attic), from the middle compartment, the mesotympanum (tympanic cavity proper). A line drawn parallel to the floor of the external auditory canal further divides the mesotympanum from the inferior compartment, the hypotympanum. On the axial images lines drawn parallel to the anterior and posterior walls of the external auditory canal are also used to divide the middle ear cavity into three compartments, from anterior to posterior, the protympanum, the mesotympanum, and the posterior tympanum.

The epitympanum contains the head of the malleus, the malleoincudal articulation, and the body and short process of the incus, which are best demonstrated on axial images at about the level of the vestibule. The roof of the epitympanum forms an important bony landmark, the tegmen tympani, which separates the middle ear cavity from the middle cranial fossa and is best evaluated on coronal images. The space situated between the scutum and pars flaccida laterally and the neck of the

malleus medially is called the Prussak space or the lateral epitympanic recess. This is the site where the pars flaccida cholesteatoma arises and is best seen on the coronal plane. Posteriorly, the epitympanum opens into the mastoid antrum via the aditus ad antrum, which is well demonstrated on both the axial and coronal images. The Koerner septum separates the mastoid antrum medially from squamous portion of the mastoid air cells laterally. The medial wall of the epitympanum is the bone overlying the lateral semicircular canal and is an area to evaluate for fistula in cholesteatoma in the epitympanum. The tympanic portion of the facial nerve runs posterolaterally inferior to the lateral semicircular canal. In this area, the bony floor of the facial nerve canal is very thin and may not be visualized on coronal CT scan images. The tympanic segment of the facial nerve can also be identified on the axial images running from the anterior genu posterolaterally, just below the lateral semicircular canal, to the posterior genu. Coronal CT scan images at the lateral semicircular level shows three important landmarks from superior to inferior, namely, lateral semicircular canal, tympanic segment of facial nerve, and oval window. Below the oval window on coronal scan are the mesotympanic structures, namely cochlear promontory and the round window.

The mesotympanum contains the rest of the ossicular chain. On coronal images, the long process of incus is vertically oriented parallel to the malleus manubrium, continuing as the rounded lenticular process with the “hockey stick” appearance and with the facet to articulate with the head of the stapes. The stapes consists of the head and the neck (hub), the anterior and posterior crura, and a footplate. The stapes neck and crura are best demonstrated on axial images at the level of the oval window. The stapes footplate sits in the oval window niche. Both the malleoincudal and the incudostapedial articulations are synovial joints and may be afflicted with diseases involving other synovial joints of the body. At the posterior wall of the mesotympanum is a bony protuberance called the pyramidal eminence where the stapedius muscle exits to its tendinous attachment at the head or posterior crus of the stapes. Lateral to the pyramidal eminence is the facial recess which contains the descending (mastoid) segment of the facial nerve. Medial to the pyramidal eminence is the sinus tympani which may be a blind spot for the surgeon during transmastoid cholesteatoma surgery. The oval window is seen just anterior to the sinus tympani in axial images. Anteriorly just above the entrance into the eustachian tube is the bony canal for the tensor tympani muscle which inserts to the malleus. Both the stapedius and tensor tympani muscles serve to dampen the effect of high-intensity sound waves. The tensor tympani muscle is supplied by the mandibular branch of the trigeminal

nerve (V3), while the stapedius muscle is supplied by the facial nerve. There is a bony prominence on the medial wall of the mesotympanum called the promontory which is caused by protrusion of the basal turn of the cochlea. Above the promontory is the oval window and posteroinferior to which is the round window niche; these relationships are well seen in coronal images through the cochlear promontory. The round window is seen at the posterolateral aspect of the basal turn of cochlea in axial images.

Anatomy of ossicular chain can be adequately evaluated in temporal bone CT scan by assessing three axial levels and a coronal level as follows. Axial section at epitympanum (attic) shows an ice cream cone appearance with the malleus head forming the anterior ice cream and the incus body/short process forming the posterior cone. Axial section at mesotympanum shows two parallel lines with the tensor tympani tendon leading to malleus neck forming the anterior line and the incus lenticular process, incudostapedial joint, and stapes head forming the posterior line. Axial section of the mesotympanum at the oval window level shows the anterior and posterior crura of stapes and its footplate fitting into the oval window. A coronal section of mesotympanum should show the ossicular "L" or hockey stick formed by the vertically oriented long process of incus and horizontally oriented lenticular process of incus.

The inner ear includes the membranous labyrinth within the bony labyrinth. The membranous labyrinth consists of the utricle, saccule, cochlear duct, and the membranous channels within the semicircular canals and the endolymphatic duct. The membranous labyrinth contains endolymph and is surrounded by perilymph, which together appear as low attenuation on CT and high-fluid signal on T2-weighted images. Perilymph connects to subarachnoid space via cochlear aqueduct, which is seen in the medial wall of temporal bone inferior to the internal auditory canal (IAC) in axial images. The bony labyrinth consists of the cochlea, the vestibule, the semicircular canals, and the cochlear and vestibular aqueducts. The cochlea consisting of two and half turns contains the organ of Corti and is the auditory end organ receiving sound waves transmitted by the ossicular chain. The base of the cochlea is at the lateral end of the IAC. The basal turn opens into the round window niche. Cochlear implants are inserted through a new opening made into the basal turn of cochlea just anterior to the round window niche. The opening to cochlea from the IAC is called the cochlear aperture. Modiolus is the central bony axis of cochlea, which lodges the spiral ganglion containing cell bodies of cochlear nerve. The osseous spiral lamina is a thin bony plate projecting to basilar membrane from modiolus and provides support

and allows organized transmission of cochlear nerve fibers to each segment of the cochlea. The cochlea has three spiral chambers, namely, the perilymph containing ascending anterior spiral called scala vestibuli, the perilymph containing descending posterior spiral called scala tympani, and the endolymph containing scala media (cochlear duct) in between. The scala media is separated from the anterior scala vestibule by the vestibular (Reissner) membrane and from the posterior scala tympani by the basilar membrane on which sits the organ of Corti.

The vestibule is the largest component of the membranous labyrinth. It consists of the superior utricle and the inferior saccule. The semicircular ducts open into the utricle. There are three semicircular canals, namely, the superior (anterior), lateral (horizontal), and posterior semicircular canals. They are perpendicular to each other. The plane of the posterior semicircular canal is parallel to the petrous ridge while that of the superior semicircular canal is perpendicular to it, although both are in the vertical plane. All the semicircular canals join the vestibule with posterior limbs of the superior and posterior canals sharing a common crus. The vestibule is separated from the middle ear cavity by the oval window niche. The superior semicircular canal forms a bony ridge at the roof of the petrous bone called the arcuate eminence giving a landmark to the surgeon entering through the middle cranial fossa. The subarcuate canal is an osseous canal seen just below the superior semicircular canal passing through its arch and contains the subarcuate artery, which is a branch of labyrinthine artery, from basilar artery or anterior inferior cerebellar artery. It connects the subarachnoid space of IAC to the mastoid antrum and is a potential route of spread of infection. The subarcuate canal should not be mistaken for a congenital lesion in a child or fracture in an adult. As already stated, the cochlear aqueduct contains the perilymphatic duct and runs inferiorly to the IAC from the basal turn of the cochlea to the subarachnoid space superomedial to the jugular foramen. The vestibular aqueduct contains the endolymphatic duct and the intraosseous portion of the endolymphatic sac. It arises from the posteromedial aspect of the vestibule and runs first posterosuperiorly and then posteroinferiorly in an arc to open at the posterior aspect of the petrous temporal bone. The extraosseous portion of the endolymphatic sac lies outside the vestibular aqueduct between the layers of the posterior fossa dura.

The IAC contains the facial nerve, the cochlear nerve, the superior vestibular nerve, the inferior vestibular nerve, and the artery of the IAC. The medial opening of the IAC is called the porus acousticus. The IAC is divided at its most lateral end by the horizontal crista falciformis and the vertical crests (Bill's bar) into four compartments.

The facial nerve is in the anterosuperior compartment, the cochlear nerve is in the anteroinferior compartment, while the superior and inferior vestibular nerves are in the posterior superior and inferior compartments respectively. The facial nerve from the lateral end of the IAC enters the petrous bone as the labyrinthine portion running anterolaterally, superior to the cochlea, and toward the anterior genu (geniculate ganglion) where it makes an abrupt turn to then run posterolaterally along the medial attic wall beneath the lateral semicircular canal as the tympanic portion toward the posterior genu at the fossa incudis. It then turns inferiorly as the descending (mastoid) portion to exit at the stylomastoid foramen. Coronal images just posterior to the plane of the geniculate ganglion will show both the distal labyrinthine (medial) and proximal tympanic (lateral) portions in tangent giving the “cobra-eye” sign. The greater superficial petrosal nerve arises from the geniculate ganglion and supplies secretomotor fibers to the lacrimal gland and taste fibres from the palate. The chorda tympani nerve arises from the descending segment of the facial nerve running anterosuperiorly passing through the tympanic cavity to transmit taste fibres from the anterior two-thirds of the tongue to the lingual nerve as well as secretomotor fibres to the submandibular and sublingual glands. The singular canal is a tiny canal in the temporal bone seen parallel and posteroinferior to the IAC in axial CT scan and contains a branch of the inferior vestibular nerve that travels to posterior semicircular canal.

ORAL CAVITY

Oral cavity is the area of the suprahyoid neck below the sinonasal region and anterior to the oropharynx. It is separated from the oropharynx by soft palate, anterior tonsillar pillars, and circumvallate papillae. Note that the lingual and palatine tonsils are both contents of oropharynx, not oral cavity. The oral cavity consists of four distinct regions, namely, oral mucosal space, sublingual space, submandibular space, and root of tongue. There is no fascia covering the oral cavity regions, except the submandibular space, which is lined by superficial layer of deep cervical fascia. Also, no fascia separates the posterior submandibular and sublingual spaces from inferior parapharyngeal space (PPS).

The oral mucosal space extends from skin-vermilion junction of lips to junction of hard and soft palate above and to line of circumvallate papillae below. It includes the mucosal lip, upper and lower alveolar ridge mucosal surface, retromolar trigone, buccal mucosa, mucosal surface of floor of mouth, mucosal surface of hard palate, and mucosal surface of anterior two-thirds of the tongue (oral tongue). The posterior one-third of the

tongue (base of tongue) contains the lingual tonsil and is a part of the oropharynx, not oral cavity. The retromolar trigone is a triangular mucosal area posterior to last mandibular molar tooth that covers the anterior surface of lower ascending ramus of mandible. Beneath the mucosa of the retromolar trigone lies the pterygomandibular raphe, which is a thick band of middle layer of deep cervical fascia extending between posterior border of mandibular mylohyoid ridge inferiorly and hamulus of medial pterygoid plate superiorly. The pterygomandibular raphe provides superior and inferior routes of early spread of squamous cell carcinoma involving the retromolar trigone. If carcinoma spreads directly into mandible from retromolar trigone, anterior perineural spread along inferior alveolar nerve in the mandibular inferior alveolar canal may occur. The mucosal surface of the floor of the mouth overlies the mylohyoid and hyoglossus muscles. Its posterior boundary is the base of anterior pillar of tonsil. It is divided into two sides by the frenulum of the tongue and has ostia of submandibular and sublingual salivary ducts.

Root of tongue is the undersurface of oral tongue at its junction with the anterior floor of mouth and mandible. It includes the lingual septum, inferior portion of genioglossus muscles, and geniohyoid muscles. It ends superiorly at the intrinsic tongue muscles, inferiorly at mylohyoid sling, and anteriorly at mandibular symphysis.

The sublingual space includes part of the oral tongue between mylohyoid muscle inferolaterally and geniohyoid muscle of root of tongue medially. The non-fascia-lined sublingual spaces of either side communicates anteriorly under the frenulum of tongue. Posteriorly, the sublingual space communicates with the submandibular space and inferior PPS at the posterior margin of mylohyoid muscle. Lesions of sublingual space may also extend to the anterior submandibular space in front of submandibular gland through the variably sized cleft at the junction of anterior one-third and posterior two-thirds of the mylohyoid muscle. The posterior aspect of the sublingual space is divided into medial and lateral compartments by the hyoglossus muscle attaching to the side of tongue. The lateral compartment lateral to hyoglossus and medial to mylohyoid contains hypoglossal nerve, lingual nerve, sublingual glands and ducts, deep portion of submandibular gland, and the submandibular (Wharton's) duct. The medial compartment of the posterior sublingual space medial to hyoglossus muscle and lateral to genioglossus muscle of root of tongue contains glossopharyngeal nerve, lingual artery and vein.

The submandibular space lies inferolateral to mylohyoid muscle sling, deep to platysma muscle, and superior to hyoid bone. It continues inferiorly into infrahyoid neck as anterior cervical space. Its contents include anterior belly of digastric muscle, superficial portion of

submandibular gland, submandibular and submental lymph nodes, facial artery and vein, fat, and inferior loop of the hypoglossal nerve on its way to the tongue muscles. The tail of parotid gland may sometimes hang down into the posterior submandibular space.

PHARYNX

The pharynx is a musculomembranous tube extending from the skull base to the level of the cricoid cartilage. It is subdivided into the nasopharynx, oropharynx, and hypopharynx. The wall of the pharynx is composed of circular constrictor muscles—the superior, middle, and inferior constrictors—and inserts posteriorly in the midline on a median raphe, which is attached superiorly to the pharyngeal tubercle at the skull base. The other muscles of the pharynx include the salpingopharyngeus, stylopharyngeus, palatopharyngeus, tensor veli palatini, and levator veli palatini, all of which aid in movement of the pharynx during swallowing. The junctional zone between the hypopharynx and esophagus is demarcated by the cricopharyngeus muscle at C5-6 level, which is approximately 1 cm wide and attaches like a sling to the lamina of the cricoid cartilage and is the major element to the upper esophageal sphincter.

The boundaries of the nasopharynx are the basisphenoid and clivus superiorly, the retropharyngeal and prevertebral space (PVS) posteriorly, the nasal choanae anteriorly, the oropharynx inferiorly, the PPS laterally. Anteriorly, the soft palate separates the nasopharynx from the oropharynx with the posterior side of the soft palate belonging to the nasopharynx and its inferior side to the oropharynx. Posteriorly, there is no clear separation between the nasopharynx and oropharynx; on imaging studies, this separation can be made by drawing a horizontal line along the superior edge of the anterior arch of C1 or through the atlantoaxial articulation. The nasopharyngeal mucosa consists of epithelium delineating the pharyngeal mucosal space (PMS). The submucosal space also contains lymphoid tissue, accessory salivary glands, cellular notochord remnants, and tensor and levator veli palatini muscles. There are two main mucosal-lined recesses, namely, the eustachian tube orifice, just in front of the torus tubarius, and the lateral pharyngeal recess or fossa of Rosenmüller, located posterosuperior to the torus tubarius. Because of the configuration of the torus tubarius, the fossa of Rosenmüller appears posterior on axial images and superior on coronal images to the eustachian tube orifice.

The oropharynx contains the palatine (faucial) tonsils bound by anterior and posterior tonsillar pillars. The anterior tonsillar pillar is formed by mucosa over the palatoglossus muscle and the posterior tonsillar pillar is

formed by mucosa over the palatopharyngeus muscle. The soft palate, posterior oropharyngeal wall, and the posterior third of the tongue (tongue base) posterior to the circumvallate papilla extending inferiorly to the vallecula, containing the lingual tonsils, are the other components. The epiglottic vallecula is the air space seen anterior to the free superior margin of epiglottis and pharyngoepiglottic folds divided in the midline by the glossoepiglottic fold and are considered a part of oropharynx.

The adenoids or pharyngeal tonsils, which are prominent in children, consist of lymphatic tissue located midline in the roof of the nasopharynx.

The fascia covering the outside of the posterior of the pharynx is the buccopharyngeal fascia (that is continuous with the fascia covering buccinator muscle). The interior fascia is the pharyngobasilar fascia. The pharyngobasilar fascia is a tough aponeurosis that surrounds the pharynx and attaches to the skull base, anteriorly to the medial plate of the pterygoid process and superiorly to the inferior part of the petrous apex. The foramen ovale is lateral to this fascia while the foramen lacerum is within the attachment of this fascia to the skull base. Posteriorly, the pharyngobasilar fascia attaches to the occipital pharyngeal tubercle and the prevertebral muscles. The eustachian tube and levator veli palatini muscle enter the nasopharynx through a posterolateral defect of the pharyngobasilar fascia, which is known as the sinus of Morgagni. The strong pharyngobasilar fascia limits tumor spread, but this protection is weak at the foramen lacerum where skull base and intracranial spread may occur despite the closure of this orifice by a fibrocartilage and at the sinus of Morgagni where posterolateral spread may occur.

Hypopharynx is the caudal continuation of the PMS between the oropharynx and esophagus and extends from the level of glossoepiglottic and pharyngoepiglottic folds superiorly to cricopharyngeus muscle at the inferior cricoid cartilage level inferiorly. The roof of the hypopharynx is formed by the glossoepiglottic fold in midline anteriorly and paired pharyngoepiglottic folds on each side laterally at the axial level of hyoid bone. These folds connect the free upper margin of epiglottis to the tongue and lateral pharyngeal walls respectively. Note that the epiglottic vallecula is the air space seen anterior to the free superior margin of epiglottis and pharyngoepiglottic folds divided in the midline by the glossoepiglottic fold.

The hypopharynx consists of three regions: paired pyriform sinuses, which are its anterolateral air containing outpouchings, posterior wall of hypopharynx, which is continuous inferiorly with the esophagus, and post-cricoid region, which is the anterior wall of lower hypopharynx continuous inferiorly with the larynx. The

anteromedial wall of pyriform sinus is formed by the aryepiglottic fold, which is actually a supraglottic laryngeal structure and has been referred to as marginal supraglottis. The pyriform sinus apex extends further inferiorly and is seen at the axial level of true vocal cords of the glottis.

LARYNX

The larynx has three subunits, namely, supraglottis, glottis, and subglottis. Embryologically, the supraglottic larynx develops from the primitive buccopharyngeal anlage and has rich lymphatics. The laryngeal ventricle separates it from the glottic and subglottic larynx, which forms from tracheobronchial buds and has few lymphatics.

The supraglottis consists of epiglottis, aryepiglottic folds, false vocal cords, and laryngeal ventricles. Epiglottis is a leaf-shaped cartilage with an upper suprahyoid free margin and a lower infrahyoid fixed portion. The aryepiglottic folds project superiorly from the upper tip of arytenoid cartilages to the inferolateral margin of epiglottis. As already stated, they form the superolateral margin of the supraglottis, separating it from pyriform sinuses of the hypopharynx on each side. The air-filled laryngeal ventricle separates the false vocal cord of supraglottis above from the true vocal cord of glottis below, which is well seen on coronal CT reconstructions. When a tumor crosses laryngeal ventricle to involve true and false vocal cords, it is called transglottic spread and has important treatment implications.

The glottis consists of true vocal cords, anterior commissure, and posterior commissure. During quiet respiration, the larynx is open and the anterior commissure is well demonstrated. The anterior commissure connecting the true vocal cords of two sides should not be more than 1 mm in thickness normally. In breath-hold CT scans, the vocal cords adduct and the laryngeal airway is closed. The subglottis extends from the undersurface of true vocal cords to inferior surface of cricoid cartilage.

The laryngeal cartilages include thyroid cartilage, cricoid cartilage, and paired arytenoid and corniculate cartilages. The thyroid cartilage shields the larynx. The cricoid cartilage has posterior lamina and anterior arches. It forms the inferior margin of the larynx and is the only complete laryngeal cartilage ring. The paired arytenoid cartilages are seen on the superior edge of posterior cricoid lamina. The vocal ligament attaches to the vocal process of arytenoid cartilage and marks the level of the true vocal cord. The thyroarytenoid muscle forms the bulk of the true vocal cord. Its medial fibers constitute the vocalis muscle. The corniculate cartilage lies on top of superior process of arytenoid cartilage within the aryepiglottic folds.

The paraglottic space of the glottis (true cord level) shows soft-tissue density on CT that is due to the thyroarytenoid muscle and the paraglottic space of supraglottis (under the mucosa of false cord) shows low-density fat. The preepiglottic space is a fat-filled space anterior to epiglottis and is contiguous with the paraglottic space. These spaces cannot be seen on endoscopy and imaging is required to detect occult masses.

SUPRAHYOID NECK SPACES

Suprahyoid neck spaces other than the already described sublingual and submandibular spaces are PMS, retropharyngeal space (RPS), PVS, PPS, CS, MS, parotid space, and buccal space.

There are two main fascial layers in the suprahyoid neck, namely, superficial cervical fascia that covers the subcutaneous tissues and the deep cervical fascia. The deep cervical fascia in turn has a superficial layer, a middle visceral or pharyngomucosal layer, and a deep prevertebral layer. In the suprahyoid neck, the middle visceral or pharyngomucosal layer of the deep cervical fascia encloses the pharynx. Thus the oropharynx and nasopharynx are collectively called the visceral or pharyngeal mucosal space. In the infrahyoid neck, the visceral fascia also encircles the hypopharynx, larynx, and thyroid gland and these structures are also components of visceral space.

The RPS is located directly behind the pharynx. It is a potential space bound anteriorly by the visceral fascia and posteriorly by the prevertebral fascia. The RPS is divided into anterior and posterior compartments by a very thin fascial layer called alar fascia, which may be identified in patients with edema of RPS following radiation therapy. The anterior compartment located between the visceral fascia and alar fascia is the true RPS. This space extends from the skull base to the location where the alar fascia fuses with the visceral fascia, which varies between C6 and T4. The posterior compartment between the alar fascia anteriorly and prevertebral fascia posteriorly is referred to as the danger space. This space extends from the skull base to the diaphragm and provides a direct pathway for head and neck infections to spread to posterior mediastinum. Fat and retropharyngeal lymph nodes (nodes of Rouviere), which may extend from skull base to C3 level, are the main contents of RPS. The retropharyngeal lymph nodes which are contained in the true RPS can be divided into a lateral group that overlie the prevertebral fascia at the level of transverse processes of upper cervical vertebrae and a median group that are smaller and not consistently present. The lateral nodes are more commonly involved by pathology especially from

squamous cell carcinomas of nasopharynx, oropharynx, nasal cavity, and hypopharynx and present as rounded mass more than 1 cm diameter. There are no RPS lymph nodes in the infrahyoid neck. It is important to note that an RPS abscess does not elevate the prevertebral muscles, whereas PVS abscess does so.

The PVS is enclosed by prevertebral fascia. It lies directly posterior to RPS. The contents in suprahyoid neck are prevertebral muscles longus colli capitis, vertebral body, cervical intervertebral disc, spinal canal, vertebral artery, and phrenic nerve. Large rhabdomyosarcomas arising in PVS may cause diagnostic confusion with large neuroblastomas arising in CS. Erosion of adjacent anterior portion of vertebral body favors a PVS tumor and erosion along the lateral aspect of vertebra favors neuroblastoma.

The PPS lies anterior to styloid process and extends from skull base to approximately hyoid bone level. Its contents are fat, small branches of mandibular nerve, internal maxillary artery, ascending pharyngeal artery, pharyngeal venous plexus, and less commonly lymph nodes and ectopic minor salivary gland rests. Most common lesions in PPS result from extension of pathology from adjacent spaces like deep extension of tonsillar carcinoma or abscess from PMS or medial extension of odontogenic infection arising in MS. A primary PPS mass typically displaces the lateral wall of the PMS medially, the deep lobe of parotid gland laterally, and the contents of the CS posteriorly. It is important not to confuse a primary PPS mass with a mass arising from the deep lobe of parotid gland. A deep lobe of parotid mass may be surrounded medially by a thin rim of parotid tissue and may extend to superficial lobe of parotid. PPS masses are usually unifocal and parotid masses may be multifocal. Also, a primary PPS mass should not be confused with a primary MS lesion. Primary PPS masses arise medial to medial pterygoid muscle. Large masses may displace the medial pterygoid laterally, but usually do not invade it. A mass that appears to replace the medial pterygoid and involve the PPS is likely to be a MS mass that has extended into the PPS.

The CS is the poststyloid PPS that extends from the jugular foramen superiorly to the aortic arch inferiorly. It is bound anteriorly by the styloid process and PPS, laterally by the posterior belly of digastric muscle and parotid space, and medially by the lateral margin of RPS. Its contents are ICA, IJV, and CN IX and XII in the nasopharyngeal CS. Only the tenth (vagus) cranial nerve is seen from the oropharyngeal CS inferiorly. The vagus nerve is seen in the posterior notch between ICA and IJV. The sympathetic plexus runs outside the CS closely attached and medial to CS and lateral to RPS. The suprahyoid neck CS lesions typically displace the PPS

fat anteriorly, styloid process anterolaterally, and the posterior belly of digastric (which separates it from the deep lobe of parotid gland) laterally. The carotid sheath is made up of components of all three layers of deep cervical fascia.

The MS contains the muscles of mastication, namely, medial and lateral pterygoids, masseter and temporalis, ramus of mandible, and the mandibular division of fifth cranial (trigeminal) nerve as it passes from the cranial cavity through foramen ovale into suprahyoid neck. The superficial layer of deep cervical fascia splits to enclose this space. The space extends inferiorly to the attachment of medial pterygoid and masseter muscles onto the mandible, superomedially abuts the skull base with the foramen ovale and foramen spinosum included in this space, and superolaterally extends high along parietal calvarium up to where the temporalis muscle inserts. The suprazygomatic MS or temporal fossa contains only the belly of temporalis muscle and the infrazygomatic MS or nasopharyngeal MS or infratemporal fossa is the MS proper.

The parotid space contains the parotid gland, retromandibular vein, external carotid artery, and intra-parotid lymph nodes. The parotid gland is divided into superficial and deep lobes by the plane of the facial nerve, the location of which can be suggested on imaging, as it is situated just lateral to the retromandibular vein. The external carotid artery is the smaller, medial vessel of the two vessels seen within the parotid gland just behind the mandibular ramus and the retromandibular vein is the larger lateral vessel. The PPS is directly medial to parotid space, the CS posteromedial, and the MS anterior to it. A mass of the deep lobe of parotid gland displaces the PPS medially with widening of the stylomandibular gap. The upper parotid space is separated from the CS by the posterior belly of digastric muscle.

The buccal space is bound medially by the buccinator muscle, which attaches to the outer cortex of maxillary alveolar ridge, posteriorly by the MS, laterally by the parotid space, and anteriorly by the superficial muscles of facial expression and the investing fascia and inferiorly it blends imperceptibly with the submandibular space. The buccal space does not have complete fascial coverings that separate it from adjacent spaces and therefore easy spread of infections occurs. Its contents are minor salivary glands; parotid duct; lymph nodes; facial vein; facial, angular, and buccal arteries; and buccal branches of facial and mandibular nerves. The parotid (Stenson) duct emerges from the anterior parotid gland, runs along the surface of the masseter muscle, arches through the buccal space to pierce the buccinator muscle, and opens into oral cavity at the level of upper second molar tooth. The facial artery and vein that lie

just anterior to the buccal segment of the parotid duct divide this space into anterior and posterior compartments. The fat of deep buccal space is a special form of adipose tissue *syssarcosis*, a remnant of succatory fat pad in infants, which appear on CT to have lower attenuation compared with fat of anterior buccal space and subcutaneous tissue of face.

INFRAHYOID NECK SPACES

Infrahyoid neck spaces are mainly extensions of the suprahyoid spaces, including the visceral space, CS, RPS, and perivertebral space. Other spaces are the posterior cervical space, which is a posterolateral fat containing neck space extending from mastoid tip to clavicle on both sides, and the anterior cervical space, which is the inferior continuation of the submandibular space lying lateral to the visceral space on both sides. The eleventh (spinal accessory) cranial nerve and dorsal scapular nerve lie in the floor of the posterior cervical space. Spinal accessory nodes are the main components of this space. The visceral space, which is the largest infrahyoid neck space, contains hypopharynx, larynx, trachea, esophagus, thyroid, and parathyroid glands.

NECK LYMPH NODE CLASSIFICATION

Level I nodes are submental and submandibular nodes. Level IA represents the submental nodes that lie between the medial margins of the anterior bellies of the digastric muscles. Level IB represents the submandibular nodes that lie posterior and lateral to the medial edge of the anterior belly of the digastric muscle, and anterior to a transverse line drawn on each axial image tangent to the posterior surface of the submandibular gland on each side of the neck.

Level II nodes are suprahyoid internal jugular nodes. It extends from the skull base, at the lower level of the bony margin of the jugular fossa, to the level of the lower body of the hyoid bone. Level II nodes lie anterior to a transverse line drawn on each axial image through the posterior edge of the sternocleidomastoid muscle and lie posterior to a transverse line drawn on each axial scan through the posterior edge of the submandibular gland. If a node situated within 2 cm of the skull base lies anterior, lateral, or posterior to the carotid sheath, it is classified as a level II node. If the node lies medial to the ICA, it is classified as a retropharyngeal node. Caudal to 2 cm below the skull base, level II nodes can lie anterior, lateral, medial, and posterior to the IJV. Level IIA nodes are upper internal jugular nodes that lie posterior to the IJV and are inseparable from the vein or that

lie anterior, lateral, or medial to the vein. Level IIB nodes are upper spinal accessory nodes that lie posterior to the IJV and have a fat plane separating the nodes and the vein.

Level III or midjugular nodes lie between the level of the lower body of the hyoid bone and the level of the lower margin of the cricoid cartilage. These nodes lie anterior to a transverse line drawn on each axial image through the posterior edge of the sternocleidomastoid muscle. Level III nodes also lie lateral to the medial margin of either the common carotid artery or the ICA. On each side of the neck, the medial margin of these arteries separates level III (lateral) nodes from level VI (medial) nodes.

Level IV or low jugular nodes lie between the level of the lower margin of the cricoid cartilage arch and the level of the clavicle on each side as seen on each axial scan. These nodes lie anterior and medial to an oblique line drawn through the posterior edge of the sternocleidomastoid muscle and the posterolateral edge of the anterior scalene muscle on each axial image. The medial aspect of the common carotid artery is the landmark that separates level IV nodes (lateral to this artery) from level VI nodes (medial to this artery).

Level V nodes are posterior triangle nodes that extend from the skull base, at the posterior border of the attachment of the sternocleidomastoid muscle, to the level of the clavicle as seen on each axial scan. Level V nodes all lie anterior to a transverse line drawn on each axial scan through the anterior edge of the trapezius muscle. Between the levels of the skull base and the bottom of the cricoid arch, these nodes are situated posterior to a transverse line drawn on each axial scan through the posterior edge of the sternocleidomastoid muscle. Between the axial level of the bottom of the cricoid arch and the level of the clavicle, level V nodes lie posterior and lateral to an oblique line through the posterior edge of the sternocleidomastoid muscle and the posterolateral edge of the anterior scalene muscle. Level VA (upper level V) nodes lie between the skull base and the level of the lower margin of the cricoid cartilage arch, behind the posterior edge of the sternocleidomastoid muscle. Level VB (lower level V) nodes on each side lie between the level of the lower margin of the cricoid cartilage arch and the level of the clavicle as seen on each axial scan. They are behind an oblique line through the posterior edge of the sternocleidomastoid muscle and the posterolateral edge of the anterior scalene muscle.

Level VI and VII nodes are anterior neck nodes. Level VI or visceral nodes lie inferior to the lower body of the hyoid bone, superior to the top of the manubrium, and between the medial margins of the left and right common carotid arteries or the ICAs.

Level VII nodes lie caudal to the top of the manubrium in the superior mediastinum, between the medial margins of the left and right common carotid arteries. These superior mediastinal nodes extend caudally to the level of the innominate vein.

Supraclavicular nodes lie at or caudal to the level of clavicle, lateral to carotid artery, above and medial to the ribs. The nodes seen lateral to the ribs represent axillary nodes.

QUESTIONS AND ANSWERS

- Which of the following is *true* regarding orbital anatomy?
 - Trochlear nerve innervates the inferior oblique muscle
 - Trochlea of superior oblique muscle is in the lateral wall
 - Ophthalmic vein is superior to ophthalmic artery
 - Annulus of Zinn separates the anterior and posterior compartments
 - Superior orbital fissure contains the maxillary division of the trigeminal nerve

ANSWER: C. Superior ophthalmic vein is superior to the ophthalmic artery. The trochlear nerve supplies the superior oblique muscle. The trochlea for the superior oblique muscle is in the medial wall. Other than the inferior oblique muscle, which originates at anteroinferior orbital rim, all other extraocular muscles arise from a common fibrous ring, the annulus of Zinn; the anterior and posterior compartments are not defined. The superior orbital fissure contains ophthalmic division of CN V; CN III, IV, and VI; superior ophthalmic vein; orbital branch of the middle meningeal artery; and sympathetic fibers. The maxillary division of CN V exits through foramen rotundum. CN III innervates all extraocular muscles except lateral rectus (supplied by CN VI) and superior oblique muscle (by CN IV).

- A patient with head and neck carcinoma presents with a submental node. According to the Sloan-Kettering classification, which of the following is the nodal station?
 - I
 - II
 - III
 - V
 - VI

ANSWER: A. Sloan-Kettering classification groups are (I) submental and submandibular, (II) internal jugular nodes above hyoid including jugulodigastric (upper pharyngeal node adjacent to posterior belly of digastric muscle), (III) jugular between hyoid and cricoid cartilage, (IV) jugular below cricoid (most nodes will be in group II–IV), (V) posterior triangle (deep and posterior to the sternocleidomastoid and above the clavicle), (VI) anterior jugular visceral chain in front of the thyroid. See text for more details on imaging classification of cervical lymph nodes.

- Which of the following statements is *false* regarding the position of the facial nerve in the IAC?
 - Anterior to the vestibular nerve
 - Above the crista falciformis
 - Below the crista falciformis
 - Superior to the cochlear nerve

ANSWER: C. The IAC is separated into four quadrants by the transverse crista falciformis and vertically by Bill's bar. The facial nerve is in the anterosuperior compartment, the cochlear nerve is in the anteroinferior compartment, while the superior and inferior vestibular nerves are in the posterior superior and inferior compartments, respectively.

4. Regarding the facial nerve, all are *true* except:
- A. Superior to cochlear nerve
 - B. Can enhance on MR
 - C. Goes through stylomastoid foramen
 - D. Separates superficial and deep portions of parotid
 - E. Innervates posterior two-thirds of tongue

ANSWER: E. Taste from the anterior two-thirds of the tongue is carried by the chorda tympani—a branch of the seventh cranial nerve that runs with fibers of the third division of CN V as the lingual nerve. Fibers run through the otic and geniculate ganglion to end at the cell bodies in the nucleus solitarius. The posterior one-third is supplied by CN IX. These fibers run through the petrosal ganglion to also reach the cell bodies of the nucleus solitarius. The facial nerve courses through the middle ear after entering the IAC. It exits through the stylomastoid foramen. It may normally show some enhancement at the geniculate ganglion and its horizontal and descending portions. Seventy-six percent enhance in one or more portions and this may be very asymmetric. Enhancement in the IAC is always abnormal. The normal enhancement is thought to be caused by a circumferential arteriovenous plexus, which is not present in the intralabyrinthine and extracranial portions. Bell palsy tends to enlarge and enhance the nerve.

5. What sinuses are involved in the ostiomeatal sinus occlusion pattern?
- A. Frontal
 - B. Ethmoid and maxillary
 - C. Maxillary and frontal
 - D. Frontal, anterior ethmoids and maxillary sinuses

ANSWER: D. Blockage of just the maxillary sinus ostium will result in obstruction of the maxillary sinuses, but obstruction of the hiatus semilunaris in the middle meatus will affect the frontal, maxillary, and anterior and middle ethmoids. The ostiomeatal unit is the complex anatomic region superolateral to the middle meatus where drainage of frontal, anterior ethmoid and maxillary sinuses occurs. It includes the superomedial maxillary sinus, maxillary sinus ostium, ethmoid (maxillary) infundibulum, hiatus semilunaris, ethmoid bulla, anterior ethmoid cells, and the frontal recess. Haller (infraorbital ethmoid) cells are lateral to ethmoid (maxillary) infundibulum, and when inflamed can obstruct the infundibulum producing isolated maxillary sinus disease sparing the ethmoid sinuses, the so-called infundibular pattern of sinus disease. When inflamed, the agger nasi cell may obstruct the frontal recess causing isolated

opacification of frontal sinus without involving anterior ethmoid or maxillary sinuses. The posterior ethmoid sinuses and sphenoid sinus opens via the sphenothmoidal recess into the superior meatus nose.

6. A lesion in which of the following areas will not cause in homonymous hemianopsia?
- A. Lateral geniculate body
 - B. Anterior to the chiasm
 - C. Posterior to the chiasm
 - D. In the occipital lobe

ANSWER: B. Homonymous hemianopsia is defined as a visual field defect involving one-half of the visual field in both eyes. Interruption of the optic tract as well as injury to the lateral geniculate nucleus results in homonymous hemianopsia. Injury to the optic nerve causes ipsilateral monocular blindness. Damage to the middle of the chiasm will cause bitemporal hemianopsia and damage to the lateral edge will cause ipsilateral nasal hemianopsia. Injury to the occipital lobe will also cause contralateral homonymous hemianopsia, but with macular sparing. Thus, an injury posterior to the chiasm will cause homonymous hemianopsia. Lesions anterior to the chiasm will cause either blindness of one eye if affecting the optic nerve or bitemporal or ipsilateral nasal hemianopsia if affecting the anterior chiasm.

7. What is the caudal extent of imaging in a patient with left vocal cord paralysis?
- A. Thyroid gland
 - B. Thoracic inlet
 - C. Aortopulmonary window
 - D. Subclavian artery level

ANSWER: C. Recurrent laryngeal nerves which are branches of X (vagus) cranial nerve loop under the aortic arch (ligamentum arteriosum) on the left and under the subclavian artery on the right. They supply all laryngeal muscles except for the cricothyroid, which is innervated by the external laryngeal branch of the superior laryngeal nerve (a vagal branch in the neck). Above the vocal folds the sensory innervation of the larynx is via the internal laryngeal branch of the superior laryngeal nerve. Below the vocal folds it is by way of branches of the recurrent laryngeal nerve.

8. Which of the following is *true* regarding hypopharynx?
- A. Vallecula is a part of hypopharynx.
 - B. Aryepiglottic folds are hypopharyngeal structures.

- C. Cricopharyngeus muscle forms the junctional zone of hypopharynx with esophagus.
- D. Pyriform sinus apex is seen at the level of oropharynx.

ANSWER: C. The hypopharynx consists of three regions the names of which start with the letter “p”—the paired pyriform sinuses, which are its anterolateral air containing outpouchings, posterior wall of hypopharynx, which is continuous inferiorly with the esophagus, and postcricoid region, which is the anterior wall of lower hypopharynx continuous inferiorly with the larynx. Note that the epiglottic vallecula is the air space seen anterior to the free superior margin of epiglottis and pharyngoepiglottic folds divided in the midline by the glossoepiglottic fold and is considered a part of oropharynx. The anteromedial wall of pyriform sinus is formed by the aryepiglottic fold, which is actually a supraglottic laryngeal structure and has been referred to as marginal supraglottis. The pyriform sinus apex extends further inferiorly and is seen at the axial level of true vocal cords of the glottis. The junctional zone between the hypopharynx and esophagus is demarcated by the cricopharyngeus muscle at C5-6 level, which is approximately 1 cm wide and attaches like a sling to the lamina of the cricoid cartilage. It is the major element to the upper esophageal sphincter.

- 9. Which of the following is *true* regarding the epitympanum?
 - A. Tegmen tympani form the floor of epitympanum.
 - B. Prussak space is the medial epitympanic recess.
 - C. Tympanic portion of facial nerve runs superior to lateral semicircular canal.
 - D. Medial wall of epitympanum is formed by the bone overlying lateral semicircular canal.

ANSWER: D. The roof of the epitympanum forms an important bony landmark, the tegmen tympani, which separates the middle ear cavity from the middle cranial fossa and is best evaluated on coronal images. The space situated between the scutum and pars flaccida laterally and the neck of the malleus medially is called the Prussak space or the lateral epitympanic recess. This is the site where the pars flaccida cholesteatoma arises and is best seen on the coronal plane. Posteriorly, the epitympanum opens into the mastoid antrum via the aditus ad antrum, which is well demonstrated on both the axial and coronal images. The Koerner septum separates the mastoid antrum from squamous portion of the mastoid air cells. The medial wall of the epitympa-

num is the bone overlying the lateral semicircular canal and is an area to evaluate for fistula in cholesteatoma in the epitympanum. The tympanic portion of the facial nerve runs posterolaterally inferior to the lateral semicircular canal.

- 10. Which of the following is *true* regarding suprahypoid neck spaces?
 - A. Anterior belly of digastric muscle separates the parotid space from CS.
 - B. A mass of the deep lobe of parotid gland displaces the PPS medially with widening of the stylomandibular gap.
 - C. A primary PPS mass typically displace the lateral wall of the pharyngomucosal or visceral space laterally.
 - D. An RPS abscess elevates the prevertebral muscles.

ANSWER: B. A mass of the deep lobe of parotid gland displaces the PPS medially with widening of the stylomandibular gap. The upper parotid space is separated from the CS by the posterior belly of digastric muscle. The anterior belly of digastric muscle is seen in submandibular space. A primary PPS mass typically displace the lateral wall of the pharyngomucosal or visceral space medially, the deep lobe of parotid gland laterally, and the contents of the CS posteriorly. An RPS abscess does not elevate the prevertebral muscles, whereas a PVS abscess does so.

14 HEAD AND NECK PATHOLOGY

Asim K. Bag and Joseph C. Sullivan III

TEMPORAL BONE

PETROUS APEX

Asymmetric marrow: This is an asymmetric aeration of one petrous apex with nonpneumatized marrow on the opposite side, which appears as a pseudomass, particularly in T1-weighted images.

Cholesterol granuloma: This is due to inflammatory response caused by the cholesterol crystal deposition in a trapped apical air cell in the petrous apex probably from recurrent subclinical hemorrhage. This may present with sensorineural hearing loss and tinnitus. Most common imaging appearance is well-defined

expansile lesion in the petrous apex with high signal in both T1- and T2-weighted images. Large lesions may extend to the clivus medially, carotid canal anteriorly, and internal auditory canal (IAC) posteriorly.

Cholesteatoma: Cholesteatoma in this location arises either from the embryonal epithelial cell rest or from extension from the middle ear cavity. They are smooth expansile masses. The most common presentation is sensory neural hearing loss. They usually follow the cerebrospinal fluid (CSF) signal, and there is prominent diffusion restriction in DWI.

Cephalocele: This is usually due to lateral prolapse of Meckel cave into the petrous apex caused by dehiscence of bone. This is usually an incidental finding; however, this may present with recurrent meningitis.

Apical petrositis: This is due to extension of the middle ear cavity/mastoid infection in the aerated petrous apex typically with meningeal involvement. This usually presents with deep pain and otorrhea. The classic clinical triad of Gradenigo syndrome (otalgia as a result of fifth nerve involvement, lateral rectus palsy as a result of sixth nerve involvement, and otomastoiditis) is rarely present.

Internal carotid arteries aneurysm: This is a very rare location for internal carotid arteries aneurysm. As this aneurysm usually does not produce any symptom, it may be surprisingly large at presentation with thrombus in the aneurysm sac.

INNER EAR

CONGENITAL

Labyrinthine aplasia: There is absence of the entire inner ear structure. There is amorphous bone in place of the cochlea, vestibule, and semicircular canal. Usually the IAC is small, but in severe cases the entire IAC may be absent. Facial nerve canal is prominent.

Cochlear aplasia/hypoplasia: The entire cochlea is absent. The vestibule and semicircular canals may be normal, hypoplastic, or with cystic changes.

Cystic common cavity of inner ear: There is fluid-filled cystic cavity in the region of the semicircular canal and cochlea that is due to incomplete development and presents with congenital sensory neural hearing loss.

Incomplete partition and dilatational defect: In this condition, there is only the basilar turn of cochlea and a dilated cavity in the region of the middle and apical turn. It may be associated with other inner ear abnormalities.

Isolated semicircular canal aplasia/hypoplasia: Aplasia/hypoplasia is a very rare congenital anomaly.

The lateral semicircular canal is most commonly involved.

Endolymphatic hydrops: Endolymphatic hydrops is an abnormal dilation of the endolymphatic space because of failure of the endolymphatic sac to reabsorb the endolymph, resulting in dilation of the sac with or without communication between endolymph with perilymph. This can be congenital or acquired or idiopathic. Any congenital malformation can ultimately lead to the endolymphatic hydrops, the most common being the large vestibular aqueduct syndrome (dilated endolymphatic duct [greater than 1.5 mm in the mid bony aqueduct] and sac, presenting with hearing loss and vertigo). Any inflammation and infection of inner ear can also end up with hydrops. Ménière disease is the idiopathic form of the hydrops presenting with fluctuating SNHL with or without vertigo. This is most often unilateral, and there may be enhancement of the endolymphatic sac in the post contrast scan.

INFECTION AND INFLAMMATION

Labyrinthitis: Labyrinthitis is an inflammation of the membranous labyrinth, mostly caused by virus but can also be immune and drug mediated. There is enhancement of the cochlea and semicircular canals on the postcontrast T1-weighted scans. The enhancement on the postcontrast T1 images may not be well appreciated because of high precontrast T1 signal from the proteinaceous inflammatory exudates. Postcontrast FLAIR may be helpful in these cases.

Labyrinthitis ossificans: There is ossification of the membranous labyrinth as a healing response to inflammation or trauma. They usually occur in children in the age 2 to 18 months after an episode of acute meningitis. The most common presenting symptom is bilateral sensorineural hearing loss with or without vertigo.

Otosclerosis: Otosclerosis is a disorder of bony labyrinth and stapes. This is bilateral in 80% of cases and presents with slowly progressive disorder affecting predominantly females. It typically presents with hearing loss with or without tinnitus. The hearing loss is predominantly conductive with or without sensorineural component. The disease has two distinct presentations:

- **Fenestral:** Typical presentation of this condition is slowly progressive conductive hearing loss. Conductive hearing loss is due to impingement of the footplate with the oval window. The most common location is just anterior to oval window at the fissa ante fenestram. Pathologically, there is initial resorption of the bone followed by deposition of

spongy vascular bone in the early stage. In the late stage of the disease, there is restoration of bone density due to sclerosis. In otoscopy, there is normal tympanic membrane and no sign of middle ear inflammation. There may also be a pink hue in the otoscopy reflecting the vascularity of the abnormal bone. On CT, there is subtle focal demineralization of otic capsule at the region of fissula ante fenestram (a small focus anteromedial to the oval window). With progression of disease, the demineralized bone enlarges and encroaches and causes narrowing of the oval window and ultimately the footplate of stapes is thickened and fixed to the oval window. Rarely, in late stage, the bone density gradually returns and then demineralization may not be identified in CT.

- *Retrofenestral*: This is a more severe condition with extensive demineralization of around the cochlea in addition to the involvement of the fissula ante fenestram. HRCT is required for the diagnosis. There are multiple radiolucent arcs in the otic capsule. There is almost always a sensorineural component in the hearing loss. The disease is bilateral symmetric in almost all cases. There is no definite MR feature of this condition.

TUMORS

Endolymphatic sac tumor: This tumor is usually locally invasive and large at presentation. This may be solitary, but more frequently is associated with von Hippel-Lindau. This presents with sensorineural hearing loss with or without facial nerve dysfunction. The presentation may be acute as a result of intratumoral hemorrhage or chronic as a result of progressive local invasion. This is heterogeneous on T2-weighted images and enhances with contrast.

Schwannoma: This may be in the seventh or eighth nerve with usual appearance.

Squamous cell carcinoma (SCC)/adenoid cell carcinoma: They are rare primary tumors.

Rhabdomyosarcoma: It may involve the soft tissue.

MIDDLE EAR/MASTOID

Otitis media (OM) is a common childhood disease. Acute OM with effusion is an infection of the middle ear with fluid in the middle ear cavity. The infection of the upper airway secondarily involves the middle ear, mastoids, and pneumatized petrous bone as they are interconnected to each other with the eustachian tube. In most cases, OM is treated with antibiotics with no need for imaging. The usual pathogens are *Streptococcus*, *Hemophilus*, *Moraxella*. Acute OM may go on to the chronic phase. By definition, if there is persistent fluid in the middle ear cavity for more than 3 months, it is consid-

ered as chronic. Chronic suppurative OM is otorrhea more than 6 weeks.

COMPLICATION OF ACUTE OM

Coalescent mastoiditis: This is defined as erosion of mastoid septae with or without intramastoid abscess.

Facial nerve palsy: Mostly caused by inflammation of the tympanic segment.

Dural sinus thrombosis: Bony defect/dehiscence in mastoid exposes the infected material to sigmoid sinus and dura, which may result in thrombophlebitis or thrombosis of the sinus. This may progress and secondarily involve the other sinus. This may appear as “empty delta sign” on contrast-enhanced CT when involving the sagittal sinus.

Venous infarction: This infarction occurs secondary to sinus thrombosis causing venous hypertension and ultimately venous infarction.

Meningitis: Meningeal infection occurs either from bony defect/osteomyelitis or venous thrombophlebitis. They may be complicated with empyema, subdural abscess, or brain abscess.

Otitic hydrocephalus: This is secondary to sinus thrombosis probably caused by obstruction in the arachnoid granulation.

Labyrinthitis: The bacteria or endo-/exotoxin may spread either through the oval or round window. The membranous labyrinth may enhance after contrast on postcontrast T1.

Cholesteatoma: Cholesteatoma is a sac of exfoliated debris of growing skin in a wrong place. It may be either congenital or acquired. The congenital cholesteatoma (same is epidermoid in other places) of the temporal bone due to epithelial cells rests of embryonal origin. Acquired disease is by far more common than congenital disease and most commonly occurs in Prussak's space secondary to perforation of the pars flaccida of tympanic membrane either secondary to chronic OM or trauma. The growing cholesteatoma medially displaces the malleus head, laterally erodes the scutum, posteriorly extends into the incudal space and posterolateral attic, and from there to mastoid through aditus ad antrum.

Pars tensa cholesteatoma: This is less common and has a tendency to grow medially. The inner ear structures are involved early and more commonly in this variant. The hallmark of imaging manifestation is bone erosion along the line of the growth of the tumor. This frequently erodes the middle ear ossicles, approximately 75% in pars flaccida cholesteatoma and approximately 90% in pars tensa cholesteatoma. The long process of incus is the most

common segment of the ossicular chain eroded by both the two types.

Labyrinthine fistula: This is another severe complication where the lateral semicircular canal is most commonly involved. The growing lesion also involves the facial nerve canal, most commonly the tympanic segment, in 1% of cases. There may be erosion of the tegmen tympani and sigmoid sinus plate increasing the chance of sinus thrombosis and intracranial complications as described before.

TUMORS

Glomus tympanicum is a small paraganglioma of the middle ear cavity. It is very small at the time of presentation.

EXTERNAL EAR

INFECTION/INFLAMMATION

Necrotizing External Otitis

Necrotizing external otitis is a locally aggressive infection of the external ear usually from the pseudomonas. The usual predisposing factors are older patients with diabetes and AIDS. Usually the infection starts insidiously at the osteocartilaginous junction as a focal ulcer. The tympanic membrane is resistant to infection. The infection spreads through the cartilaginous part into the soft tissue and ultimately involves all structures of the base of the skull. CT and MRI both are necessary for evaluation of the disease extension. CT is required for evaluation bony changes. MRI is needed for evaluation of the soft-tissue involvement.

Diffuse Petrous Diseases

Osteogenesis imperfecta is a disease of abnormal type I collagen formation. The typical presentation is fragile bone, blue sclera, and deafness. CT shows thickened bone around the otic capsule and narrow middle ear cavity with the footplate of stapes embedded in the dysplastic bone. The facial nerve canal may also be obstructed. The imaging appearance is similar to the retrofenestral otospongiosis but the demineralization is more extensive.

Osteopetrosis: Osteopetrosis is a rare hereditary defect of bone remodeling caused by abnormal osteoclastic activity resulting in thick, dense fragile bone. There is increased density of the temporal bone with absent mastoid air cells. The internal auditory canal is shortened. The middle ear ossicles may be thickened and enlarged.

Paget disease: Paget disease can be a uni- or multifocal disease caused by exaggerated bony remodeling. Temporal bone Paget disease presents with hearing loss, which may be conductive, sensorineural, or mixed. Facial nerve dysfunction may also occur as a

result of compromised facial nerve canal. In temporal bone, the disease begins in the petrous apex. The otic capsule is the last structure to be involved. The stapedial footplate may be thickened.

Fibrous dysplasia: Fibrous dysplasia is a disease of unknown cause in which the normal bone is replaced by fibro-osseous tissue. This may be mono-/polyostotic. In fibrous dysplasia of temporal bone, there is increase in the size of the temporal bone causing compression of the bony foramina and ostia. It usually presents with progressive hearing loss. The facial nerve may be entrapped. The common CT finding is increased bone thickness and loss of trabecular pattern.

SKULL BASE

ANTERIOR SKULL BASE

CONGENITAL

Cephaloceles: By definition, cephaloceles are congenital herniations of intracranial contents through cranial defects. There are various developmental concepts. They may arise because of incomplete separation of neural and surface ectoderm at the site of final closure of the anterior neuropore during the final phase of neurulation in the fourth week of gestation. Another theory is excess outgrowth of the surface ectoderm might act as an outward vector to the attached neuroectoderm and may drag out the neuroectodermal tissue. They can be classified according to the contents of the sac.

- **Meningocele:** If there is herniation of meninges and CSF.
- **Meningoencephalocele:** If there is herniation of CSF, meninges, and brain.
- **Glioceles:** If the glial-lined cysts contain CSF only.
- **Atretic cephalocele:** This is forme fruste of cephalocele consisting of dura, fibrous tissue, and dysplastic neural tissue.

The most common location is occipital region, followed by frontonasal, basal cephaloceles, in descending order of frequency. Cephaloceles may be associated with microphthalmos, anomalies of the corpus callosum, interhemispheric lipomas/arachnoid cyst, migrational anomalies, and so on. They usually present as externally visible frontonasal masses in newborns or infants with broadening of the nasal bridge and hypertelorism. They commonly enlarge with crying and with jugular compression (Furstenberg sign). They may also present with nasal obstruction, CSF leakage, or meningitis. Basal cephalocele may mimic an intranasal polyp or other nasal masses.

MR is the preferred method for evaluation. Continuity of herniated tissue and/or fluid with the brain is crucial to the diagnosis. On T1-weighted images, they are isointense to grey matter and also CSF signal. On T2-weighted images, they are hyperintense due to gliosis and CSF signal. They do not enhance with contrast.

Developmental cysts: Incomplete separation of the dura from the skin elements can result in pulling in the dermal contents with the involuting dural diverticulum and result in dermal sinus, congenital dermal inclusion cysts (epidermoid and dermoid), and tumor (teratoma). The peak age of presentation is 23 months. Roughly one half of these children of these children have a dimple or pit over the nasal bridge. Occasionally hairs/sebaceous discharge emanate from the pit. A palpable mass is found in 30% of children. Broad nasal bridge and hypertelorism are in 50% of children. They may be associated epidermoid and/or dermoid cysts and are usually extracranial. Rarely, they may present with infection.

MR is the preferred modality of evaluation. Epidermoid follows the signal intensity of CSF but appears as a lightbulb in DWI. Dermoid cyst is variably hyperintense in both T1 and T2; hence it does not show up in DWI. Subtle dermal sinus may be detected well by highly T2-weighted sequences (also known as MR cisternography). A bifid crista galli or enlarged foramen cecum, if present, can be a clue.

Nasal glioma: Developmentally, nasal glioma can be conceptualized as cephaloceles with lost intracranial connection. By definition, they do not contain any CSF-filled space that is connected with subarachnoid space/ventricles. Histologically, they are congenital masses of glial tissue that occur intra-/extranasally at or near nasal root. They resemble reactive gliosis instead of any glial proliferation.

They constitute approximately 4.5% of nasal masses. They occur sporadically with no familial tendency. There is no sexual predilection. Up to 15% may have associated cerebral heterotopias. Of all the lesions, 60% are extranasal, 14% to 30% are intranasal, and 10% to 14% are mixed (with both intra- and extranasal component). They usually present early in infancy as nonpulsatile skin-covered mass, which does not change size with Valsalva, and tends to grow along with the child. Intranasal heterotopias present as polypoid mass typically medial to middle turbinate and attached to the turbinates. They may cause blockage of NLD. They are commonly confused with inflammatory polyps.

MRI is the preferred method of evaluation. The nasal glioma is typically well circumscribed, rounded, or

polypoid in shape; hypointense in T1-weighted images; and hyperintense in T2-weighted images. On postcontrast scan, they do not enhance but may have peripheral enhancement.

INFECTION/INFLAMMATION

Sinusitis: Complicated sinusitis can involve the anterior skull base.

Epidural abscess/empyema: Epidural empyema is the collection of pus between dura and skull and occurs secondary to sinusitis at this location. The falx and dural sinuses may be displaced. Hypointense peripheral rim is seen in T2, which reflects the inflamed edematous dura, which shows moderate enhancement in postcontrast scan.

TUMORS

SCC of sinuses: Invasive frontal and ethmoid sinus cancer, which can involve the anterior cranial fossa.

Meningioma: Olfactory groove, sphenoid wing, and optic pathway meningioma are common in this location.

Metastasis: Usual primary are sinonasal, breast, lung, prostate, and vascular mets.

Rhabdomyosarcoma: Head and neck are the most common location of this tumor. They usually involve nasal cavity, paranasal sinuses, orbit, and nasopharyngeal musculature. They are highly malignant masses with local invasion and distal lymph nodal metastasis. These are the most common extracranial masses invading the skull base in children. They are heterogeneous masses isodense to brain parenchyma. They enhance moderately with contrast.

Sinonasal undifferentiated cancer (SNUC): This is a highly malignant mass of nasal cavity and paranasal sinuses.

Lymphoma: The usual primary mass is in the nasopharynx. The sphenoid can secondarily be involved.

Esthesioneuroblastoma: These are the tumors of the primitive neuroectodermal tumor family.

Plasmacytoma: This is an extramedullary tumor.

CENTRAL SKULL BASE

CONGENITAL

Cephalocele in this location is very rare.

INFECTION/INFLAMMATION

Sinusitis: Sphenoid sinus infection and complications involve the central skull base.

Langerhans cell histiocytosis (LCH): LCH frequently involves calvarial bones; however, the skull base may also be involved. The lesions are typical

“punched out” with sharp margin. CT is best to demonstrate the typical punched out lesion. On MRI, they are usually associated with T2 hyperintense soft tissue.

TUMORS

Squamous cell cancer of sinuses: Invasive squamous cell cancer can involve the central skull base.

Meningioma: Sphenoid wing is a common location.

Pituitary adenoma: Pituitary macroadenoma can be surprisingly large and can involve the sphenoid bone. Usually there is demineralization of the involved bone.

Chordoma: Clival chordoma frequently involves the central skull base.

Chondrosarcoma: When large in size, they frequently encroach the central skull base from the petroclival junction.

Aneurysmal bone cyst: Aneurysmal bone cysts are occasionally seen in the sphenoid bone. They frequently hemorrhage and have characteristic multiple intratumoral hemorrhagic cysts and fluid-fluid levels which are easily identified on MRI.

Giant cell tumors: Giant cell tumors can involve the sphenoid bone.

POSTERIOR SKULL BASE

TUMORS

Nasopharyngeal cancer (NPC): Advanced-stage NPC involves the sphenoid bone with bony lysis.

Chordoma: Chordoma is a tumor of remnant notochord elements. The most common location is the sacrum. The clivus is the most common cranial location. They are locally aggressive masses of the posterior and central skull base with a tendency to involve anterior structures, like the nasopharynx. The peak age at presentation is 20 to 40 years with a male predominance. They are highly vascular tumors with frequent destruction of the bone and also with frequent tumoral calcification. They are hypointense on T1-weighted images and heterogeneously hyperintense on T2-weighted images with bright enhancement with contrast. Combined CT and MR evaluation is required in some cases where there is only subtle contrast enhancement.

Chondrosarcoma: Chondrosarcoma also predominantly arise at the posterior skull base at petroclival junction. They are similar to chordoma both on imaging and on histology. The typical location is off midline in the region of petroclival synchondrosis. They can occur at any age but the usual age of presentation is fifth to sixth decade. The clinical presentation is headache

and the symptoms related to the secondary involvement of structures by the tumors (like multiple cranial nerve palsies). The CT finding is variable. Typically they are slightly hyperdense (to surrounding muscles) with variable enhancement. Chondroid matrix with typical chondroid calcification is the characteristic finding but may not be found always. They are usually very bright on T2-weighted images with moderate enhancement. If there is dense calcification, the tumor may appear as heterogeneous.

Plasmacytoma: Plasmacytoma is a rare tumor of this location.

Meningioma: CP angle meningioma and meningioma around the foramen magnum may involve the posterior skull base.

JUGULAR FORAMEN

CONGENITAL

High-riding jugular bulb: Jugular bulb is considered “high riding” when it extends to the middle ear, above the level of the floor of the IAC or tympanic annulus.

Dehiscent jugular bulb: There is absence of the bony margin separating the jugular bulb from the posteroinferior aspect of the jugular foramen causing forward displacement of the jugular bulb into the tympanic cavity. They usually present with pulsatile tinnitus.

INFECTION/INFLAMMATION

LCH may involve the jugular foramen with usual features.

TUMORS

Paraganglioma: Paragangliomas in this location have different names according to the nerve involved. Glomus tympanicum is small paraganglioma of the middle ear cavity arising from the nerve of Jacobson. Glomus jugulare is the paraganglioma of the jugular foramen and skull base arising from paraganglia of the adventitia of the jugular bulb. Glomus vagale (paraganglioma of the vagus nerve) are tumors arising from the vagus nerve and they are usually parapharyngeal masses.

Paragangliomas usually present between the fourth and fifth decades of life. They are more common in women. Rarely they are familial. The clinical presentation is myriad and depends upon the infiltration of the adjacent structure and also chemical activity of the tumor. The usual presentations are pulsatile tinnitus, conductive hearing loss, jugular foramen syndrome with or without involvement of

the hypoglossal or facial nerve. Acoustic symptoms are more frequent than the lower cranial nerve palsies. The size of the tumor at the time of diagnosis varies from a few millimeters (glomus tympanicum) to several centimeters. The glomus tympanicum most commonly occurs at the promontory, but can be anywhere along the course of the Jacobson's nerve at the medial wall of the middle ear cavity. The extension of the tumor involving surrounding bone is evaluated better in CT but MR is much better for appreciation of contrast enhancement. The earliest imaging feature of glomus jugulare is erosion of the anterior bony wall of the jugular foramen. This tumor sometimes becomes very large and can grow along the course of the jugular vein and even obstructs the vein either partially or completely. They usually enhance intensely with contrast. Sometime it is difficult to differentiate a small tumor from the normal jugular bulb in CECT. On T2 images, there may be "salt and pepper" appearance because of the signal voids from the tumor vessels.

Metastasis: Metastasis at this location is usually from renal or thyroid.

Schwannoma/neurofibroma: Schwannoma at this location arises from the ninth and tenth cranial nerves and spinal accessory nerve. The tumor may be predominantly intracranial or may be predominantly at the jugular foramen. Intracranial tumors present with cerebellar symptoms but predominantly jugular foramen masses present with jugular foramen syndrome (aka Vernet syndrome), which includes paralysis of the ninth and tenth cranial nerves and spinal accessory nerve. They usually expand the foramen and can appear like CP angle schwannoma.

ORBIT

VASCULAR LESIONS

ORBITAL CAVERNOUS MALFORMATION

Orbital cavernous malformation is the most common vascular abnormality of the orbit in adults. It usually occurs in the second to fourth decade of life. There is a gradually enlarging mass (usually intraconal), presenting as gradual-onset painless proptosis. Histologically, they are enlarged vascular space lined by endothelium, with no feature of endothelial proliferation. They are sharply margined, lobular homogenous soft-tissue mass of increasing density with variable enhancement. Phlebolith is not common. They are usually isointense to muscles and enhance variably.

CAPILLARY HEMANGIOMA

Capillary hemangioma is primarily diseases of the first year of life and slightly more common in girls.

Microscopically, there is endothelial and capillary proliferation. They enlarge rapidly in the initial 6 to 18 months and usually after 1 year they start to regress. They are mostly extraconal mass of varying sizes with well-/ill-defined margin and variable enhancement.

VENOLYMPHATIC MALFORMATION

The term lymphangioma is not technically correct, as there is no cellular proliferation. The best term to describe this condition is lymphatic malformation or venolymphatic malformation as this condition is often mixed with vessels with venous characteristics. They are relatively large, progressively enlarging, ill-defined extra-/intraconal masses of childhood or young adulthood. They are frequently associated with intracranial vascular abnormality, most common being developmental venous anomaly. They are not well encapsulated and may infiltrate surrounding structures. They are heterogeneous in density/intensity. The enhancement is also heterogeneous. On MR, fluid-fluid levels and hemorrhages of different ages could be identified. If the lesion is purely lymphatic, it does not enhance with contrast.

ORBITAL VARIX

Primary orbital varix may involve a vein, a small segment of a vein, a tangle of venous structures with massive dilation that is due to weakness of the venous wall. There is painless intermittent proptosis, which enlarges with Valsalva. Orbital varix may be associated with intracranial AVM. Supine CT scan or MR may be normal. In suspicious cases, scan in prone position is required. Sometimes scanning during Valsalva is required for demonstration of varix. There may be phleboliths.

CAROTID-CAVERNOUS FISTULA

Carotid-cavernous fistula can present with pulsating exophthalmos, chemosis, venous engorgement, and restricted ocular motility. It may occur because of trauma or surgery or may occur spontaneously. On imaging, there is engorgement of the superior ophthalmic vein with or without engorgement of the extraocular muscles. Angiogram is often needed for exact localization of the fistula and planning of treatment.

INFLAMMATORY AND INFECTIOUS LESIONS

THYROID ORBITOPATHY

Dysthyroid ophthalmopathy (of Grave disease) is the most common cause of both unilateral and bilateral proptosis. The average age at presentation is the fifth decade of life; women are commonly involved but

involvement in men is more commonly severe. Thyroid orbitopathy is an autoimmune process with infiltration of the ocular muscles and retrobulbar compartment presenting with proptosis, limitation of the eye movement, and upper and lower lid retraction. This occurs in patients with hyperthyroidism but may also occur in the setting of hypothyroidism, euthyroidism, and also in Hashimoto thyroiditis.

In the acute stage, there is bilateral swelling of the retrobulbar contents and enlargement of the extra ocular muscles (best visualized in coronal planes) sparing the tendons. The enlarged muscles are hypodense in CT and shows increased signal intensity on T2-weighted images.

IDIOPATHIC ORBITAL INFLAMMATORY DISORDER

Idiopathic orbital inflammatory disorder, aka orbital pseudotumor, is nongranulomatous inflammation of the eye/orbit, which can present acutely or may present as subacute and chronic disorder. This is the second most common ophthalmologic disorder after thyroid orbitopathy. This condition can be bilateral in up to one-third of cases. It usually presents acutely with orbital pain, restricted ocular movement, proptosis, visual abnormality, conjunctival/scleral congestion. Histologically, there is polymorphous infiltration of the inflammatory cells into the involved areas. Depending upon the location they are described as follows:

- *Anterior orbital inflammation:* There is involvement of the anterior orbit and the globe. The symptoms are usual with conjunctival hyperemia and lid swelling. MRI is better than CT to identify the scleral thickening. There may be accumulation of fluid in Tenon's capsule, which can be easily picked up by ultrasound. There is enhancement of the thickened sclera and also the optic nerve junction. In some cases there may be retinal detachment.
- *Diffuse orbital inflammation:* Diffuse orbital inflammation was classically described as orbital pseudotumor. There is diffuse infiltration of the retrobulbar fat with polymorphous inflammatory cells. This diffuse infiltration causes proptosis and surrounds the globe without any deformation. There is enhancement of the entire infiltrated areas. The presentation may be acute or subacute.
- *Orbital myositis:* Orbital myositis is an idiopathic inflammation of the extraocular muscles. This may be acute, subacute, or recurrent in presentation, usually present with painful extraocular movement, diplopia, and proptosis. The superior muscle complex and the medial rectus are the most common muscles to be involved. The involvement can be bilateral. The close differential diagnosis is dysthyroid involvement of the muscles. In thyroid myopathy, the onset is painless, slowly progressive, and usually with systemic stigmata

of hyperthyroidism. In idiopathic myositis, the enlargement extends anteriorly to involve the tendons with ragged and ill-defined margin of the enlarged muscle. The fat plane between the muscle cone and periosteum is also lost because of inflammation/infiltration. There may inward bowing of the muscle belly immediately posterior to the globe.

- *Perineuritis and periscleritis:* This condition can mimic the clinical presentation of optic neuritis. Pressing the globe may exacerbate the pain. There is enlargement of the optic nerve sheath complex with irregular margin. There may be involvement of the retrobulbar fat adjacent to the nerve.
- *Lacrimal:* Isolated involvement of the lacrimal gland is also possible. It can mimic viral adenitis. There is pain in the superolateral compartment of the orbit. On imaging, there is enlargement of the gland and enhancement with contrast.
- *Apical orbital inflammation:* In this condition, there is typical orbital apex syndrome with painful ophthalmoplegia, mild proptosis, and pain.

Tolosa-Hunt syndrome, a granulomatous inflammation of the orbital apex extending posteriorly up to the cavernous sinus, is now considered in the spectrum of the idiopathic orbital inflammation syndrome. There is also involvement of the cavernous carotid with narrowing of the lumen and thrombosis of the ophthalmic vein. There are recurrent attacks of deep orbital pain with painful paralysis of the third, fourth, and sixth cranial nerves including the ophthalmic and maxillary divisions of the trigeminal nerve. It is usually bilateral but may be unilateral.

ORBITAL CELLULITIS

Sinusitis is the most common cause of the orbital cellulitis. Infection from the sinuses involves the orbit through direct involvement through the disruption of the thin bony medial orbital wall or through the valveless intercommunicating veins. The orbital/periorbital infection can be classified into five stages:

- *Inflammatory edema:* There is swelling and hyperemia of the eyelid.
- *Preseptal cellulitis:* The infection is limited to the skin and subcutaneous tissue anterior to the orbital septum, usually the medial aspect the upper eyelid. There are no signs of orbital involvement.
- *Postseptal cellulitis:* This is infection of the orbit proper. There is diffuse edema of the orbital contents. Usual presentation is pain, restricted extra ocular movement, no/minimal proptosis but usually no visual deficit. There is stranding of the orbital fat in noncontrast CT. In fat-suppressed T2-weighted images, the edema is prominent and there is diffuse enhancement in the fat suppressed T1-weighted images with contrast

- *Subperiosteal abscess*: The edema is more generalized with more severe symptoms. In postcontrast images, there may be infiltration/abscess cavity between the involved sinus and the periorbital region.
- *Orbital abscess*: The abscess occurs within the orbit proper. The symptoms are more severe with visual loss. With progressive involvement there is ophthalmic vein and/or cavernous sinus thrombosis.
- *Cavernous sinus thrombosis*: This occurs either as a late complication of infection of the central face (areas of face that has venous drainage to cavernous sinus) or as extension of epidural infection. *Staphylococcus* is the most common organism. Angioinvasive fungi (such as *Rhizopus*) also cause this, particularly in the setting of diabetic ketoacidosis. The patients usually present with severe headache; dysfunction of the third, fourth, and fifth cranial nerves; and first and second division of trigeminal nerve associated with symptoms and signs related to primary site of infection. In noncontrast CT, there is loss of low density in the cavernous sinus. In contrast-enhanced images, there is enhancing cavernous sinus mass with filling defects. The lateral margin of the cavernous sinus may be convex. The enlarged ophthalmic vein is also seen. MRV can show absent flow in the ophthalmic vein and in the cavernous sinuses.

SARCOIDOSIS

This is a systemic disease with myriad manifestations. Ocular involvement occurs in approximately 25% of patients. Any part of the orbit or orbital contents (including optic nerve) can be involved. The most common orbital presentation is chronic dacryoadenitis, which may present with dry eye. The involved areas are usually isointense and enhance with contrast. Optic nerve involvement presents with progressive loss of vision with or without disc change. Imaging features include enhancement of the optic nerve including the intracranial segment.

OPTIC NEURITIS

The most common cause is multiple sclerosis. Devic disease, clinicopathologically different from multiple sclerosis, involves the optic nerve and spinal cord specifically without/with periventricular brain involvement. This can also occur after viral infection. The intraorbital portion of the optic nerve is the most common location. The optic nerve is focally enlarged. There is focal T2 hyperintensity, best appreciated by coronal STIR sequence. In more than 90%, there is enhancement in T1 + c.

TUMORS

Optic nerve sheath meningioma: Optic nerve sheath is a relatively uncommon site for meningioma. Menin-

gioma circumferentially involves the orbital or canalicular optic nerve. In most of the cases, the optic nerve sheath is secondarily involved from the meningioma arising from the meninges in relation to the optic nerve course. They may be associated with NF2. The peak age of presentation is fourth to fifth decade with significant female preponderance (2–4:1). Usually, they present with exophthalmos and gradually progressive painless unilateral loss of vision. The classic triad of presentation is visual loss, optic atrophy, and opticociliary shunt vessels from the occlusion of the central retinal vein. Histologically, they are similar to intracranial meningioma. There is enlargement of the optic nerve sheath with bright enhancement, which on axial scans appear as “tram track.” Calcification also occurs within the tumor in one-third to one-half of the cases, which often helps to differentiate the condition from optic nerve glioma, perineuritis, sarcoidosis. “Periopic cyst,” dilation of the subarachnoid space between the distal edge of an optic nerve sheath meningioma and the eyeball, is a specific finding but is not commonly seen.

Retinoblastoma: Retinoblastoma is the most common intraocular tumor of the childhood. This can be isolated or familial (autosomal dominant) because of mutation of the Rb1 tumor suppressor gene. The familial tumors are usually bilateral. This tumor is highly malignant, arising from the nuclear layer of the retina. The earliest presentation is leukocoria. Later on, they develop vision loss, proptosis, or strabismus. The average age at presentation is 18 months. Bilateral and familial disease usually present earlier.

Calcification is the most dominant feature and is found in more than 90% of cases. There is homo- or heterogeneous enhancement on the postcontrast scans. On MR, they are moderately hypointense (to vitreous) mass with homo-/heterogeneous enhancement. If bilateral retinoblastoma is associated with midline intracranial neuroblastic tumor (usually pinealoblastoma), the condition is known as trilateral retinoblastoma.

Orbital melanoma: The most common location is choroid, but it can arise from ciliary body or iris. The peak age of incidence is 50 years, with a slight male preference. They usually present with painless vision disturbance. They are small soft-tissue density mass with moderate enhancement. They are very bright in noncontrast T1 and hypointense (to vitreous) in T2. There is diffuse enhancement in the postcontrast scan. The associated retinal/choroid detachment is also well evaluated by MR.

Lymphoma: The most common neoplasm of orbit is lymphoma. B-cell NHL is the most common type. Usually they are primary orbital lymphoma but there may be secondary involvement of the orbit, too. Usual age of presentation is the seventh decade. They usually present with gradually enlarging painless orbital mass. Most commonly they are intraconal well-defined masses with diffuse enhancement.

Optic nerve glioma: Optic nerve gliomas are relatively uncommon and usually occur in children and may be associated with NF1. When associated with NF1, they usually involve the anterior optic nerve; otherwise chiasmatic or retrochiasmatic involvement is more common. Enhancement and signal intensity are variable. They are described in detail in the brain tumor chapter.

Rhabdomyosarcoma: Rhabdomyosarcoma is the most common primary orbital malignancy in the childhood. The peak age at presentation is 2 to 5 years. Orbital rhabdomyosarcoma is almost always unilateral and involves the superior aspect of the orbit. There is usually a short history of progressive proptosis. They usually arise from the mesenchymal tissue, not from the extraocular striated muscles. Depending upon the stage of the disease, the mass can be homo-/heterogeneous, well/ill defined, without/with bone destruction. CT is better for demonstration of bone destruction; however, on fat-saturated T2, there is edema in the bone marrow. They are usually isodense to muscles and frequently show intratumoral hemorrhage. There is usually intense enhancement in the postcontrast scans.

Schwannoma/neurofibroma: Schwannoma is a well-defined benign peripheral nerve sheath tumor growing eccentrically from the nerve. It typically arises from a sensory nerve, most commonly from the V1 division. It is usually extraconal but if it arises from the nasociliary nerve or rarely from the ocular motor nerves, it can be intraconal. Unlike neurofibroma, there may be occasional hemorrhage within the schwannoma best identified in MR.

- Circumscribed neurofibromas also most commonly arise from the V1 division of the trigeminal nerve and usually involve the nerve circumferentially. On T2, they are homogeneously hyperintense or there may be occasional “target sign” with hyperintense periphery and central hypointensity.
- Plexiform neurofibromas usually occur in association with NF1. They are ill-defined masses of the orbit and are usually associated with sphenoid wing dysplasia. They are usually hypointense (to muscles) on T1-weighted images and show hyper-

intense (to muscles) signal on T2-weighted images. They may enhance intensely with contrast.

Metastasis: The most common primary to metastasize in the orbit is the breast cancer. Others may be lung, colon, or prostate. In children, common tumors that metastasize to orbits are neuroblastoma, leukemia, and Ewing sarcoma. In children, the usual location is the orbital wall, and in adults they usually start at highly vascular choroid.

Developmental cysts: Dermoid cysts are most common congenital benign orbital masses. They usually occur in early childhood and present with proptosis and eyelid swelling. They usually result from trapped ectodermal elements within the sutures during orbital development. This explains their frequent location in relation to the sutures and frequent bony erosions. They usually show fat density/intensity in MR.

Epidermoid cysts are less common, well-defined tumors that follow the signal intensity of CSF.

SINONASAL CAVITIES

CONGENITAL

Choanal atresia is a rare congenital anomaly; may be uni-/bilateral. Bilateral choanal atresia is a medical emergency. The choana may be obstructed by fibrous tissue or rarely by a bony ridge.

INFECTION

Rhinosinusitis: This is acute inflammation of the sinonasal mucosa lasting less than 4 weeks of duration. They may occur in both young and adult people usually after upper respiratory tract viral infection. Usual presentations are nasal congestion, thick postnasal discharge, headache, olfactory disturbance. They are most common in ethmoid sinus followed by maxillary sinuses. On imaging, there is thickening of the paranasal sinus mucosa with or without obstruction of the drainage pathway. There may be air-fluid level with bubbly appearance. The inflamed mucosa usually enhances avidly with contrast.

If the inflammation continued beyond 12 consecutive weeks, it is defined as chronic sinusitis. The symptoms of the acute inflammation continue. On imaging, there is mucosal thickening or opacification of sinus without expansion of sinus. There is sclerotic and thickened sinus wall. The secretion may become hypo-, iso- to hyperdense (to the muscles) depending upon the protein

content of the secretion. With chronic obstruction, the water in the secretion is reabsorbed, and there is Goblet cell metaplasia of the mucosa, which further secretes protein-rich secretion. On T2-weighted images, the signal intensity drops as the protein content of the secretion increases. If the protein concentration is greater than 35%, there is signal void on T2 images. Evaluation of the disease with only MRI may underestimate the extent of the disease.

Allergic fungal sinusitis: This is a severe form of the chronic sinusitis, probably resulting from type I hypersensitivity reaction. Multiple sinuses may be involved. There is expansion of the involved sinus. The disease may invade the orbits. They are usually hyperdense on CT and typically hypointense on T2 images. There is enhancement of the mucosa with contrast.

Invasive fungal sinusitis: This is rapid-progressing fungal infection in immunocompromised (including diabetic) patients with spread of the disease from the sinuses to the vessels caused by angioinvasive fungi (*Mucor*, *Aspergillus*, and *Rhizopus*). They most commonly occur in the setting of the uncontrolled diabetes. The most common presentation is acute-onset fever, epistaxis, sinus pain, headache, cough, and nasal mucosal ulceration. Orbital and intracranial extension is the most dreaded complication. In diabetic patients, there is black crusting of the nasal mucosa. There is complete or partial obstruction of the sinus. There is also infiltration of the fat and soft tissue around the sinuses. On contrast-enhanced images, there is enhancement of the mucosa and also the inflamed fat and soft tissue around the sinuses. There can be narrowing of the arterial and venous lumen because of vasculitis. CTA can demonstrate this finding very well. MRI is better for demonstration of disease beyond the sinuses.

Sinonasal polyposis: This is due to nonneoplastic proliferation of the nasal and paranasal mucosa. They may be associated with asthma, cystic fibrosis, aspirin sensitivity, and also allergic fungal sinusitis. They usually present with nasal stuffiness and nasal obstruction. They are usually diseases of adulthood. On CT scan, they appear as multiple polypoid soft tissue within nasal cavity and paranasal sinuses. If associated with allergic sinusitis, there may be bone erosion. On MR they are usually hyperintense on T2 images. If the obstruction is chronic, the signal intensity on T2-weighted images drops.

Mucocele: Mucocele is expansion of the sinus cavity caused by obstruction of the drainage pathway. The frontal sinus is most commonly affected, in approximately 60% of cases. On CT, there is expansion of the

sinus with thinned sinus wall containing hypodense material. Early mucocele are hyperintense on T2 but later, they are hyperintense on T2 images.

TUMORS

Juvenile angiofibroma: This benign but locally aggressive highly vascular tumor occurs almost exclusively in adolescent males. Common presenting symptoms are unilateral nasal obstruction and spontaneous epistaxis. The typical location is at or around the sphenopalatine foramen at the lateral nasopharyngeal wall. The classic imaging findings are widening of the pterygopalatine fossa, anterior displacement of the posterior wall of the maxillary sinus, erosion of the medial pterygoid plate. Thin-section CT scan in axial plane with coronal reformation is required for complete evaluation. On MR, the mass is heterogeneous on T2 images with numerous flow voids. They also enhance brightly. Conventional angiography is required for delineation of vascular anatomy (supplied from the internal maxillary, ascending pharyngeal and palatine arteries) and also for presurgery embolization of the tumor.

Inverted papilloma: Typically, they occur in males between 40 to 70 years. The typical location is lateral nasal wall near the middle turbinate and usually extends into the sinuses (more commonly into the maxillary than ethmoid). Very rarely, they may be purely intrasinus or arise from the nasal septum. Usual presenting symptoms are nasal obstruction and epistaxis. Microscopically, there is hyperplastic squamous epithelium. There is also squamous metaplasia in the surrounding mucosa, explaining frequent recurrence after resection and need for en block resection. Carcinoma may rarely develop from these papillomas. Imaging features are variable from small nasal polyp to an expansile mass. There is no specific CT or MR imaging sign.

Osteoma: This is a benign, expansile proliferation of mature bone. They are almost exclusively found in relation to the membranous bones of the skull and face, most commonly frontal sinuses followed by ethmoid sinus. They are usually incidental but may obstruct the ostium and need early decompression. Multiple osteomas are associated with Gardner syndrome. They arise either from the wall of the sinus or from the septum. They are usually hyperdense well-defined masses on CT and on MR they are hypo- to isointense.

SCC: This is the most common cancer of the nasal cavity and paranasal sinuses. The most common location is the maxillary antrum. Occupational exposure to nickel, chromium, and wood fibers increases the chance of cancer development. There may be metachronous or

synchronous development. They usually occur in the sixth or seventh decade of life. When they are small, they may be misdiagnosed as chronic sinusitis, nasal polyposis. Cancer of the frontal and sphenoid sinuses is rare. They usually present with symptoms of chronic sinusitis. On CT, they are heterogeneous masses with irregular margin with variable enhancement. They are intermediate to hyperintense in T2-weighted images with mild to moderate enhancement.

Approximately 10% of the sinonasal cancers may be adenocarcinoma.

Esthesioneuroblastoma: This is a neural crest–derived highly malignant tumor. They have bimodal age distribution in the second and sixth decades of life. The common locations are superior nasal cavities, superior turbinates, and ethmoid. On CT, they are homogenous hyperenhancing masses with bone destruction/remodeling. They frequently invade the base of the skull and involve the anterior/middle cranial fossa. There are multiple cysts at the interface of normal brain and the tumor. There may be intratumoral calcification. On MR, the signal intensity varies but they enhance brightly.

SNUC: SNUC is a highly malignant tumor with undifferentiated cellular lineage. These are rare tumors occur usually after the fifth decade of life. Most of the SNUCs occur at the same location of the esthesioneuroblastoma and usually present with nasal obstruction, epistaxis, and pain with or without orbital symptoms. The radiologic features are similar to the SCC with destruction of the bones. They are highly cellular tumors; on diffusion-weighted imaging, they may appear hyperintense.

Lymphoma: Lymphoma in head and neck most commonly involves the lymph nodes, 10% being extranodal. Sinonasal lymphoma is most common in Asia. This can be either B-cell or T-cell lymphoma. On imaging, they are bulky soft-tissue masses that enhance to a moderate degree. They tend to remodel bone, but bone erosion is not unknown. Most often the disease involves the nasal fossa and the maxillary sinuses. They are of intermediate signal intensity on all MR sequences.

Plasmacytoma: They are rare extramedullary tumors, which predominantly occur in the head and neck. The most common location is the nasal cavity followed by paranasal sinuses. On CT they are a homogenous hyperenhancing mass of the nasal cavity and paranasal sinuses. They are highly vascular and may have flow voids on MR.

JAW PATHOLOGIES

Odontogenic cyst: Periapical cyst is the most common odontogenic cyst, which can occur at any time of life.

The condition is usually associated with tooth infection. The infection extends to the pulp, and from there ultimately extends outside the apex and causes apical periodontitis, which ultimately becomes a periapical or a radicular cyst. They are well-defined lucent/hypodense periapical masses surrounded by thin cortical rim.

Dentigerous cyst: This is the second most common odontogenic cyst. They develop from the crown of an unerupted tooth. They are most commonly identified in the mandible at the third or fourth decade of life. Dentigerous cyst may also develop from the maxilla. The cyst usually develops between the epithelium or between the enamel and the epithelium. The typical imaging appearance is a lucent/lytic mass in relation to the crown of an unerupted tooth in the mandible surrounded by thin cortical rim.

Cherubism: This is an autosomal dominant disease presented with bilateral painless enlargement of jaw. This is a disease of early childhood. The mandible is involved first followed by the maxilla. On CT there are multiple expansile cystic masses at the mandibular junction.

Other pathologies bone (like ABC, simple cyst) can also involve the jawbones.

Ameloblastoma: They are locally aggressive benign epithelial odontogenic tumors. They are more common in the mandible, mostly at the molar region. The usual time of presentation is from the fourth to sixth decade. They usually present with painless jaw swelling. They are thought to arise from the ameloblast. They may also develop from the dentigerous cyst. They may be uni- or multilocular. The multilocular tumor often has bubbly appearance. There may be focal cortical invasion and involvement of the soft tissue. On MR, these are solid cystic lesions with a thick enhancing wall.

UPPER AERODIGESTIVE TRACT

PHARYNX

Tornwaldt cyst: They are midline, well-circumscribed developmental cysts of the posterior wall of the nasopharynx anterior to the longus colli muscles. They are usually asymptomatic. They may sometime present with pain and halitosis if there is infection. They are low-density lesions in the typical location with minimal thin rim enhancement.

Peritonsillar abscess: Acute tonsillitis is usually a self-limited process. The most common offending agent is *Streptococcus pneumoniae*. Suppurative uncontrolled infection of the tonsil may lead to abscess in the peritonsillar region. The peritonsillar abscess

may spread to the parapharyngeal or lateral retropharyngeal space. Trismus may develop if the medial pterygoid muscle is involved. On CT, there is homogenous swelling of the tonsillar region. There may be stranding of parapharyngeal fat. If there is development of an abscess, it appears as ugly ring-enhancing lesion.

Retropharyngeal infections: Retropharyngeal space infections are rare but may be potentially life threatening. Infection of the retropharyngeal abscess used to be due to lymphatic spread of infections from sinonasal cavities, tonsil, oral cavity, and middle ear. Nowadays, the most common cause of infection in this region is due to penetrating trauma or extension from the cervical osteomyelitis. They are more common in immunocompromised patients. Retropharyngeal space infection may spread to the mediastinum via the danger space, which is located immediately posterior to the retropharyngeal space. Patients usually present with sore throat, fever, pain, odynophagia, chills, neck pain, and stiffness. Both CT and MR are excellent for the evaluation of the retropharyngeal space infection. Though MR has best soft-tissue resolution, CT is most commonly performed for evaluation of retropharyngeal infection. Retropharyngeal abscess is a low-density lesion with enhancing walls and expansion of the retropharyngeal space. Retropharyngeal adenitis appears as low-density lesion with subtle enhancement of the wall.

NPC: Squamous cell cancer is the most common tumor in this location, followed by the lymphoma and adenocarcinoma. The squamous cell variety is much more common in Asia than the Americas. This is more common in males. Unlike squamous cell cancers at other sites of the head and neck, the etiology of NPC is not usually related to tobacco and alcohol use, but is multifactorial with viral, genetic, and environmental factors. Epstein-Barr virus is strongly associated with NPC. Immunoglobulin A antibodies against the capsid antigen of EBV is widely used as a tumor marker with 80% to 90% sensitivity.

NPC occurs most commonly at the fossa of Rosenmuller. It can extend anteriorly into the nasal cavity, anterosuperiorly to the ethmoid sinus and orbits, superiorly into the sphenoid sinus and foramen lacerum, laterally into the parapharyngeal space and pterygoid muscles, and inferiorly into the oral cavity.

CT and MR are complementary to each other for evaluation and staging of NPC. CT is best for determination of cortical involvement. MR is best for determination of tumor spread. The tumors are hyperintense in T2 signal compared to the muscles. They usually enhance brightly with contrast. Imaging of cervical lymph node is essential

as 90% of the cancers go to the lymph node at the time of the initial diagnosis. Retropharyngeal and level II lymph node are most commonly involved.

Oropharyngeal cancer: The most common cancer is the squamous cell cancer followed by lymphoma and minor salivary gland tumor. For a definite description of the tumor, they are described as cancer of anterior tonsillar pillar, posterior tonsillar pillar, tonsillar fossa, soft palate, and base of tongue.

Hypopharyngeal cancer: More than 95% of cancers are SCC. Risk factors include tobacco, alcohol, and previous radiation therapy. Plummer-Vinson syndrome is an independent risk factor for development of cancer at this location. Seventy-five percent of the SCC at this location has lymph node spread at the time of diagnosis. Up to 15% of the tumor has a second primary, which may be synchronous or metachronous.

ORAL CAVITY

VASCULAR MALFORMATION

As there is no cellular proliferation, vascular lesions are not tumors per se. They are developmental anomalies. They may involve the capillary level, the veins, the arteries, and the lymphatic system.

Capillary malformation: These lesions were previously called port wine stain, capillary hemangioma, nevus flammeus. They may be associated with Sturge-Weber syndrome. There is hypertrophy of the involved part.

Venous malformation: They are sometimes called cavernous malformation. They do not involute with age. They may involve the bone too. They are the most common vascular lesions of the oral cavity. They may be enormous in size. They may involve multiple fascial planes and may be purely intramuscular. They are usually muscle density masses, which enhance variably with contrast. There may be phlebolith within these lesions. On MR, there may be vascular flow void from high flow arterial or venous lesions.

Arteriovenous malformation: Arteriovenous malformation or fistula is a high-flow common developmental anomaly of the head and neck area. Angiographically, there is an arterial part and an early draining vein.

Lymphatic malformation: Lymphatic malformation used to be called lymphangioma. As there is no cellular proliferation microscopically, so these lesions are better called lymphatic malformation or venolymphatic malformation, if there is a venous part associated within the lesion. They are usually poorly marginated lesions and may involve multiple fascial

planes. They may contain subacute blood, which is easily picked up in MR.

INFECTION OF THE ORAL CAVITY

Infection of the oral cavity is a very common clinical condition and has numerous causes. The most common is secondary extension of the infection from the teeth. Other causes include bad oral hygiene, infection of the salivary gland, and involvement from osteomyelitis. CT is the preferred modality as it can depict small calculus and clearly delineate osteomyelitis. It typically appears as a low-density uni- or multilocular ring-enhancing lesions with stranding of the adjacent fatty tissue. On MR, the abscess has typical hypointense lesions on T1, which is hyperintense in T2 with rim enhancement of the abscess wall.

LUDWIG ANGINA

Ludwig angina is extensive infection of the floor of the mouth by oral flora. The most common source of this infection is a mandibular molar. This usually presents as extensive transfascial cellulitis often with bilateral involvement from floor of mouth downward. This infection is spread by contiguous involvement rather than lymphatic spread. Any structure in the course of the infection can be involved. The salivary glands are usually spared.

RANULA

These are mucous retention cysts of the floor of the mouth and may be of two types:

Simple ranula is lined by true epithelium in the region of sublingual space above the mylohyoid muscle. Most probably, they arise from the obstruction of the minor salivary glands. Diving/plunging ranula is due to rupture of the simple ranula and is lined by granulation or fibrous tissue. The lesion typically grows posteriorly into the submandibular region. On imaging, they typically appear as cysts. The plunging component usually enters into the submandibular space medially and displaces the submandibular gland laterally. By comparison, the second branchial cleft cyst, which is sometimes confused with the plunging ranula without any sublingual component, arises from the posterior aspect of the gland and displaces the gland medially.

ORAL CAVITY CANCER

Oral cavity cancer is a potentially devastating condition, typically first identified as small painful nonhealing ulcers. It is commonly associated with tobacco and alcohol use. Oral cavity is a large space. Description of the locations of the oral cavity cancers are described separately: lips, buccal mucosa, floor of the mouth, retromolar trigone, oral tongue, hard palate, soft palate, alveolar ridge. The most common cancer is SCC, followed by minor salivary gland cancer, lymphoma, and sarcomas.

Complete radiologic evaluation of the head neck cancer, including PET/CT and MR, should be obtained before biopsy for baseline record of the tumor and lymph node status as biopsy may alter the original uptake pattern. MRI is clearly the imaging modality of choice as it can depict the extension of the tumor very well. Noncontrast T1-weighted scans are very helpful for detection of tumor extension. PET has emerged as a powerful adjunct for the detection of the tumor both for pretreatment staging and also for screening of head and neck metastasis.

ADENOID CYSTIC CARCINOMA

Adenoid cystic carcinomas are cancers of the minor salivary glands. They are present in the entire upper aerodigestive tract but concentrated at the buccal, labial, palatal, and lingual region. They typically occur in middle age. On imaging, it is not possible to differentiate this lesion from SCC. This tumor is notorious for spreading along the nerves. On CT, perineural spread is demonstrated as enlargement of the cranial nerve foramina at the base of the skull, enlarged pterygomaxillary fissure. On MR, the involved nerve is thickened, they are hyperintense in T2, and enhance with contrast.

LARYNX AND TRACHEA

Laryngomalacia: In the nontraumatic setting, laryngomalacia is due to delayed development of laryngeal support system. The inherent supporting structures are weak. Usually the supraglottic larynx is involved.

Vocal cord paralysis: The vocal cord is supplied by the superior laryngeal nerve and recurrent laryngeal nerve. Vocal cord paralysis may be due to paralysis of either of the two nerves. Superior laryngeal nerve palsy causes the arytenoid to rotate toward the paralyzed site. The more common cause is paralysis of recurrent laryngeal nerve, which supplies all of the laryngeal muscles, except the cricothyroid. On cross-sectional imaging, there is enlargement of the ventricle as the thyroarytenoid muscle atrophies.

Laryngocele: The enlarged saccule of the laryngeal ventricle in the paraglottic region of the supraglottic larynx containing air or fluid, or both is known as laryngocele. It can be internal, external, or mixed. An internal laryngocele is within the larynx and presents as a mass in the supraglottic larynx. The mixed one has both internal and external component. The internal mass comes out through the thyrohyoid membrane. Most of these lesions are mixed type. They can be easily identified in CT, MR, and x-rays. The CT density/MR intensity changes with the protein contents. Although laryngocele is benign, it may be associated with malignancy. Careful examination of the ventricle should be done.

Epiglottitis: Epiglottitis is a disease of early childhood; the peak age of presentation is 2 to 4 years. The typical organism is *Haemophilus influenzae*. The classical presentation is sore throat and inability to swallow and the epiglottis appears as cherry red. The epiglottis is thickened in the lateral radiograph. This is a medical emergency and the child should be under strict surveillance.

Rheumatoid and other connective tissue disorders: The cricoarytenoid and cricothyroid joints are synovial joints and therefore may be involved in rheumatoid arthritis. In rheumatoid arthritis, there will be variable mixture of erosion and sclerosis in and around the joint associated with soft tissue. They usually present with hoarseness. In late stage, there may be joint fixation.

SCC: The most common cancer of the larynx is SCC. The most common offending agents are tobacco and alcohol. Laryngeal papilloma may also be turned into malignancy. For complete description, the laryngeal cancers are described as supraglottic, glottic, and subglottic.

- Supraglottic carcinomas usually involve the aryepiglottic fold, epiglottis, and periepiglottic areas. The usual clinical presentation is sore throat with or without hoarseness. The peak age of presentation is the sixth decade with a male predominance. These carcinomas are moderately enhancing infiltrating masses of these regions. In late stage of the disease, the carcinomas can involve the laryngeal cartilage. On MR, there is diffuse enhancement with contrast. One treatment option of this tumor may be supraglottic laryngectomy. However, the contraindications are bilateral arytenoid involvement, involvement of cartilages, invasion of the vocal cord involvement of the pyriform sinus, and involvement of the base of the tongue.
- Glottic cancer arises in the vocal cords. Most common presenting symptom is hoarseness. The demography is the same as that of supraglottic cancers. On imaging, there is thickening of the true vocal cords. They are hyperintense lesions of the vocal cord with homogenous enhancement. As they arise from the vocal cord, they present very early with hoarseness.
- Laryngeal cancer arising from inferior to the true vocal cord down to the cricoid cartilage is considered as subglottic cancer. As they don't produce any symptom in the early stage of the disease, they are usually large at presentation with lymph node involvement.

PAROTID SPACE

INFECTION/INFLAMMATION

Acute parotitis: Acute infection of the gland may be viral or bacterial. Bacterial infections are due to direct

spread from the oral cavity. Obstruction to the flow of secretion is the single most common cause of acute parotitis. The infection of the parotid gland is more common than that of the submandibular gland because of larger orifice and small diameter of the Stensen's duct, and the disadvantageous position makes the distal duct and orifice prone to injury. Acute infection of the salivary gland is very painful. The entire gland swells and is very tender to touch. This usually occurs in dehydrated patients with bad oral hygiene. The common organisms are *Staphylococcus aureus*, *Streptococcus viridans*, and *H. influenzae*. Usually the patient presents acutely. A CT scan shows dilated ductular system with diffuse enhancement of the gland and duct walls. It is also very good to demonstrate small calculus. Sialography is contraindicated in this acute setting. Mumps is the most common virus that infects the parotid gland. The presentation may be acute or chronic.

Sialolithiasis: Eighty to ninety percent of sialolithiasis occurs in the submandibular gland as a result of the orientation (and vertical course) of the duct, thick mucoid secretion, alkaline pH, and narrower orifice. Parotid gland calculus is not uncommon. Smaller stone presents with intermittent pain during increased salivation. Larger stone presents with deep aching pain. The calculus can be identified in x-rays as they are made up of calcium phosphate. On CT, the dilated ductular system obstructed by the calculus could be easily identified.

Benign lymphoepithelial disease: In this condition, there are bilateral benign mixed solid and cystic lesions in the diffusely enlarged parotid glands in the setting of HIV. It is usually associated with lymphadenopathy, fatigue, night sweats, diarrhea, and weight loss. Associated opportunistic infections might not be present in this early stage. The lymph nodes in the parotid glands are known to contain salivary gland acini and ducts. Since lymphoid tissue is vulnerable to HIV infection, intranodal epithelial proliferation can occur, causing cyst formation. Parotid gland lymphoepithelial cysts are painless and slow growing. They can suggest the presence of HIV infection in a patient with cervical lymphadenopathy. These cysts usually involve the superficial parotid lobe bilaterally. Multiple cysts are more common than single cysts. Their size varies from 0.5 to 5 cm in diameter. There may be thin rim enhancement.

Sjögren syndrome: Sjögren syndrome is an autoimmune disorder of the exocrine glands in which there is lymphocyte-induced destruction of the glands resulting in decreased secretion and dryness. It may be primary when it manifests alone or it may be secondary if occurs along with other connective tissue disorders.

The mean age of diagnosis is the sixth decade of life. It occurs more frequently in women. It presents with recurrent acute episodes of tender glandular swelling and chronic glandular enlargement with superimposed acute attacks. There is dry mouth and dry eyes because of involvement of the exocrine glands. There is increased risk of development of non-Hodgkin lymphoma (usually MALT type) in the setting of Sjögren syndrome.

In the early stage of the disease, the gland appears normal in cross-sectional imaging. With time, the gland gradually enlarges in size and becomes increasingly dense. In later stage, there will be development of honeycomb appearance. This is a characteristic finding of Sjögren syndrome but not pathognomonic. Like cross-sectional imaging, the sialograms are usually normal in the early stage of the disease with normal-appearing central ducts. Later on there are multiple globular areas of contrast accumulation close to the dilated central ducts.

TUMORS

Pleomorphic adenoma: This is the most common salivary gland tumor of the major salivary glands and accounts for 70% to 80% of all the benign tumors. Of all, approximately 85% occur in parotid glands and approximately 10% in submandibular gland, approximately 5% in the minor salivary glands (this is the most common tumor in the minor salivary glands), and less than 1% in sublingual glands. Ninety percent of the parotid pleomorphic adenomas arise from the superficial parotid gland.

Typically they present as painless slow-growing tumors. They may be a few millimeters to several centimeters in size. The usual presentation is fifth decade onward with slight female predominance. Microscopically, they contain both glandular and ductular elements. They are well-marginated, high-density spherical tumors with variable enhancement. Smaller tumors tend to be homogeneous in appearance but larger tumors are heterogeneous in both pre- and postcontrast study. Usually the tumors enhance with time, so a delayed postcontrast scan is helpful. On MR they are hypointense in T1 and hyperintense on T2 images, with T2 hypointense periphery.

There is a high recurrence rate of this tumor after resection, so they are typically treated with partial parotidectomy. Part of the tumor may be dedifferentiated to carcinoma expleomorphic adenoma.

Warthins tumor: This is the second most common benign tumor of the parotid gland. This is also a slow-growing benign tumor, which occurs almost

exclusively in the parotid gland. They are commonly cystic. Like pleomorphic adenoma, they occur after the sixth decade of life. They are the most common bilateral parotid tumors (occurs in 5%–14%). They are small oval tumors, usually at the posterior aspect of the superficial lobe of the parotid gland. They are homogeneous iso- to hypodense lesions, if not cystic. There is no dystrophic calcification. The solid tumor is hypointense on T1-weighted images and, hyperintense on T2-weighted images. The cystic tumors may be heterogeneous and demonstrate uptake 99mTc pertechnetate. Oncocytoma is the only other parotid tumor which also uptakes 99mTc pertechnetate.

Mucoepidermoid carcinoma: This is the most common malignant tumor of the minor salivary glands. They present earlier than the benign tumors, usually from the fourth decade and slightly more common in women. Radiation can cause the tumor. The tumors may be of low grade, intermediate grade, and high grade. The imaging appearance varies with tumor grade. The low-grade tumors are homogenous and benign looking; however, the high-grade tumors are aggressive looking with soft-tissue involvement beyond the gland and spread along the nerves. Noncontrast T1 is the best modality because of inherent contrast of intraglandular fatty tissues.

Adenoid cystic carcinoma: Though this more commonly occurs in minor salivary glands, the most common location of the tumor in the major salivary glands is the parotid gland. They usually occur fourth decade onward. They are slow-growing malignant tumors with potential for extensive infiltration of the surrounding tissues. These tumors are notorious for perineural spread along the cranial nerves into the skull base and cranial cavity. Microscopically, there are multiple subtypes of the tumor. On imaging, the tumor may appear benign or malignant looking, depending upon the grade of the tumor. MRI is the best modality for detection of the perineural spread and also to define the extensive soft-tissue involvement. Usually the tumor enhances with contrast as is the involved soft tissue and perineural spread.

Lymphoma: Primary lymphoma of the salivary gland is a rare entity. They most commonly involve the parotid glands. The lymphomas are usually MALT type. However, secondary involvement of the parotid gland from systemic lymphoma may also occur. There is no specific imaging sign of the lymphomas. They may be solitary or multiple, usually homogenous masses. They usually enhance with contrast. There may be cystic degeneration. They may be benign-looking nodular masses or there may rarely be invasive infiltrating tumor of the entire gland. MRI is better modality for the evaluation of the tumor.

CAROTID SPACE

Carotid body paraganglioma (carotid body tumor):

They are tumors arising from the neural crest cell and mesenchymal cell of the third branchial arch. They typically arise from the adventitial layer at the carotid bifurcation. They may be familial; bilateral and multiple tumors are common in familial diseases. They may be associated with pheochromocytoma and other head and neck paragangliomas. These tumors appear as slowly growing, asymptomatic palpable masses in the anterior triangle of the neck. In late stage, they may surround the external and internal carotid arteries characteristically without any significant compression. Large tumors may involve cranial nerve of the carotid sheath, pharyngeal compression and skull base, and intracranial invasion. Uncommonly, the tumor may present with pain, hoarseness, dysphagia, Horner syndrome, tongue paresis, and vertigo. Functional paragangliomas are rare. The peak age of presentation is 40 to 50 years.

On ultrasonography, the demonstration of a solid, well-defined, weakly echogenic mass located within the carotid bifurcation safely differentiates and excludes purely cystic masses. High-frequency high-resolution ultrasonography depicts accurately the location, shape of the disease process and anatomic relationship of the tumor with the vessels of the neck, and demonstrates multiplicity of nodules if any. Doppler analysis of the mass demonstrates low-resistance arterial blood flow within the mass.

CT demonstrates a hypodense solid mass that shows intense homogenous enhancement on intravenous contrast administration. The large tumor vessels may also be visualized.

There is intense tumor-blush in the region of carotid bifurcation. This tumor can be embolized preoperatively to decrease the bleeding from the surgery.

On MR, they are heterogeneous both in T1- and T2-weighted images that is due to flow voids from the prominent tumor vessels.

Schwannoma: Schwannoma in the carotid space is not uncommon. In the nasopharyngeal carotid space, they may arise from ninth to twelfth cranial nerves and from tenth cranial nerve from oropharynx downward. The imaging features are similar to its cranial counterpart.

VISCERAL SPACE

THYROID GLAND

Acute thyroiditis is rare and is usually due to suppurative infection, the most common organism being *Staphylococcus*. The most common associated lesion is pyriform

sinus in children and young men. Necrosis within a thyroid malignancy is usually commonly associated in elderly people. The usual clinical presentation is thyroid pain with referred pain in the throat and ears. CT and ultrasound help to localize the tumor.

GOITER

Goiter is enlarged thyroid gland. The gland can be enlarged because of numerous causes. Goiter is classified as follows:

Diffuse nontoxic goiter: There is diffuse enlargement of the gland with no hyperfunctioning or nodularity.

Nontoxic multinodular goiter: Multinodular goiter is diffuse nodularity of the enlarged gland, which is hormonally inactive.

Toxic multinodular goiter: In this condition there is enlargement of the thyroid gland with nodularity associated with subclinical or mild thyrotoxicosis.

THYROID MALIGNANCY

Malignant thyroid tumors are classified as follicular epithelial cells, C-cell malignancy and lymphomas, metastasis, and sarcomas. Follicular epithelial cell carcinomas are again subdivided into papillary carcinoma, follicular carcinoma, and undifferentiated carcinomas. The most common tumor is papillary cancer, which constitutes approximately 80% to 90% of cancer.

LYMPH NODE DISEASE

There are numerous lymph nodes in the head and neck region. They are systemically classified into seven stages according to the international staging system.

Level I: IA, submental; IB, submandibular

Level II: Jugulodigastric, from the base of the skull to the level of the hyoid bone.

A: Closely related to the carotid vessels

B: Related posterior, away from the carotid vessel

Level III: Jugulodigastric lymph nodes from hyoid bone down to the lower border of cricoid cartilage.

Level IV: Jugulodigastric lymph nodes from the lower border of cricoid cartilage to the supraclavicular region.

Level V: Lymph nodes of the posterior triangle.

A: Above the level of hyoid

B: Below the level of hyoid

Level VI: Level VI lymph nodes are suprasternal lymph nodes between sternomastoid heads.

Level VII: These are superior mediastinal lymph nodes.

PEDIATRIC DISEASES

BRANCHIAL CLEFT ANOMALIES

First branchial cleft cyst: They are derived from the first branchial arch around the ear and can be of two types: periauricular and periparotid. They are well-circumscribed low-density masses with or without enhancement of the wall. They usually present in children as a painless swelling.

Second branchial cleft cyst: They are derived from the second branchial arch, and may be fistula, sinus, or cyst or any combination of the three. They are most commonly located anteromedial to the sternomastoid lateral to the carotid space. They usually present early in childhood. Unless they are treated early, they may get infected.

Third branchial arch cyst: They are thin-walled cystic lesions in the posterior triangle along the border of the sternomastoid.

Fourth branchial anomaly: They are epithelial-lined cysts lateral to the left lobe of thyroid usually attached to the thyroid cartilage. There may be associated sinus or fistula. They usually present in infants.

Thyroglossal duct cyst: They are developmental aberrations of the thyroglossal duct and can occur anywhere from the foramen cecum to the thyroid gland. Most of them are related to the hyoid bone. They are usually midline except in the infrahyoid neck, where they are usually paramedian. On CT, they are hypodense structures with or without enhancement of the wall. If they are infected, there is usually enhancement of the wall. They are usually asymptomatic swellings of early childhood. If infected, they may present with pain. The surgical treatment is a Sistrunk procedure.

Lymphangioma (cystic hygroma): They are trans fascial multicystic soft masses of the posterior triangle. Usual age of presentation is less than 2 years. Large lesions may present with respiratory obstruction. They are ill-defined lesions with multiple fluid-fluid levels, usually with no significant enhancement.

QUESTIONS AND ANSWERS

- Which of the following is most likely to present with symptoms other than pulsatile tinnitus?
 - Dehiscence of jugular foramen
 - Glomus tumor
 - Cholesteatoma
 - Aberrant carotid artery
 - Temporal bone tumor

ANSWER: C. Vascular lesions produce pulsatile tinnitus. Cholesteatoma is not a vascular lesion.

- You identify a new cystic mass in the carotid space in a 55-year-old patient who smokes. Which of the following is the most likely diagnosis?
 - Abscess
 - Branchial cyst
 - Metastasis
 - Paraganglioma

ANSWER: C. New-onset cystic mass in the carotid space in an older patient who smokes is most likely due to a lymph node metastasis with cystic degeneration.

- A patient with head and neck carcinoma presents with a submental node. According to the WHO lymph node classification, at which level is this node located?
 - I
 - II

SUGGESTED READING

Benson MT, Dalen K, Mancuso AA, et al. Congenital anomalies of the branchial apparatus: embryology and pathologic anatomy. *Radiographics*. 1992;12:943-960.

Caldemeyer KS, Mathews VP, Azzarelli B, et al. The jugular foramen: a review of anatomy, masses, and imaging characteristics. *Radiographics*. 1997;17:1123-1139.

- C. III
- D. IV
- E. V

ANSWER: A. Submental lymph nodes are considered as level Ia.

4. Which of the following does *not* present with leukokoria?
- A. Optic glioma
 - B. Retinoblastoma
 - C. Coat disease
 - D. PHPV
 - E. Congenital cataract

ANSWER: A. Optic gliomas do not usually involve the optic disc or retina unless very far advanced. This is retrobulbar pathology not seen in ophthalmoscopy. Other four conditions are known to produce leukokoria.

5. What is the most common cause of facial hemipalsy?
- A. Ramsey Hunt
 - B. MS
 - C. Vertebrobasilar dolichoectasia
 - D. Bell palsy
 - E. Facial nerve schwannoma

ANSWER: D. Bell palsy is the most common cause of facial nerve palsy. Others are rare conditions.

6. Which of the following is the cause of pulsatile exophthalmos in NF1?
- A. Plexiform neurofibroma
 - B. Venous malformation
 - C. Sphenoid wing dysplasia
 - D. Optic nerve glioma

ANSWER: C. Sphenoid wing dysplasia allows for direct transmission of the intracranial carotid pulsation through the absent sphenoid wing. Plexiform neurofibroma, venous malformation, and optic nerve glioma cause exophthalmos but typically not pulsatile.

7. A young woman with a history of sore throat presents with four weeks of irritability and weight loss. A radioactive thyroid iodine uptake tests less than 1% uptake. Which of the following is the most likely diagnosis?
- A. Grave disease
 - B. Acute suppurative thyroiditis
 - C. Subacute nonsuppurative thyroiditis
 - D. Hashimoto thyroiditis
 - E. Thyroid carcinoma

ANSWER: C. This is the classic presentation of early-stage subacute nonsuppurative thyroiditis when there is destruction of the gland that releases the T3 and T4, which decreases the TSH level causing low iodine uptake. In Graves disease, the feature of hyperthyroidism is more prominent. Acute suppurative thyroiditis presents with thyroid pain and swelling.

8. What is the *least* common presentation of juvenile nasopharyngeal angiofibroma?
- A. Origination in the nasal cavity
 - B. Involves pterygopalatine fossa
 - C. Involves sphenoid sinus
 - D. Contains calcifications
 - E. Presents with epistaxis

ANSWER: D. Angiofibromas are highly vascular tumors, but they do not calcify. They typically arise in the pterygopalatine fossa but may involve the nasal cavity and sphenoid bone.

9. Which of the following is the *most* likely diagnosis in a 35 year-old man with bilateral painless parotid enlargement and cervical adenopathy?
- A. Benign lymphoepithelial cysts
 - B. Warthin tumor
 - C. Mumps
 - D. Sjögren syndrome
 - E. Sialoadenitis

ANSWER: A. Warthin tumor is bilateral but rarely associated with adenopathy. Mumps is not common in adult patients. Sjögren syndrome is more common in women and not associated with adenopathy. Benign lymphoepithelial cysts are a common presentation in HIV.

10. Which of the following is the *least* likely presentation of Tolosa-Hunt syndrome?
- A. Bilateral orbital apex involvement
 - B. Granulomatous inflammation in the cavernous sinus
 - C. Narrowing of cavernous carotid artery
 - D. Thrombosis of the ophthalmic vein

ANSWER: A. It is usually a unilateral granulomatous process that can cause these vascular complications.

15 SPINAL CORD PATHOLOGY

Joseph C. Sullivan III

DEVELOPMENTAL LESIONS

Developmental lesions of the cord include a whole host of processes associated with neural tube closure.

In an adult patient, a tethered cord or low-lying conus below the level of L2 is difficult to distinguish from a thickened filum (thickness greater than 2–3 mm). This may be associated with spinal dysraphism, such as spina bifida occulta, an intradural lipoma, or cutaneous presentation such as a sinus tract or hairy patch on the back. The mildest form can be referred to as lipomatous infiltration of the filum terminale.

Cysts that occur within the spinal canal and cord tend to present with mass effect on the cord. Of these, the most common is the arachnoid cyst. It has a smooth contoured displacement of the cord and demonstrates similar signal characteristics to CSF on all sequences. Clinical presentation tends to be secondary to mass effect with myelopathic symptoms. Other cysts commonly seen are Tarlov cysts. These are truly cystic dilatation of the perineural root pouches generally associated with sacral roots. These are caused by a so-called ball-valve effect at the junction of the osseous elements and the nerve root sheath with underlying cause thought to be secondary to CSF pulsation from respiration and/or arterial fluctuations. These tend to have direct connection with the thecal sac. Differentiation from meningocele, traumatic avulsion, arachnoid cyst, and dural ectasia should be considered.

Epidural cysts may be extramedullary or rarely can be intramedullary in location. The congenital type is the result of ectodermal inclusion of trapped ectoderm at time of neural tube closure. The acquired variant is secondary to intervention displacing ectodermal tissue into the spinal canal or possibly into the cord itself. This, along with epidermoids, may reflect complication of lumbar punctures, providing the teaching of leaving the stylet within the spinal needle until one has traversed the thecal sac. These lesions tend to be discreet and have variable signal intensity on MRI. If there is associated peripheral enhancement, it is likely a reactive response.

Cysts and syrinx formations within the cord develop by one of two processes. In the first type, a syrinx can arise centrally because of dilatation of the central canal. This can occur either above or below the cranio-

cervical junction. The former results from an intracranial obstruction distal to the outflow of the fourth ventricle, and the latter is formed below the craniocervical junction secondary to changes in CSF flow from intramedullary or extramedullary effect. This can be seen with dilation of the central canal or cysts thought to be formed from Chiari I malformations, resulting in impingement of the craniocervical junction with effacement of the foramen magnum. It can also occur in the setting of with intra- or extramedullary lesions such as tumor, and arachnoid cyst, which may form in the association of trauma or canal stenosis, or inflammatory process such as arachnoiditis. This central canal dilatation may be focal or more diffuse. It tends to have a smooth dilatation without abrupt changes in morphology and follows CSF signal on all sequences. CSF flow artifacts may be seen on FLAIR imaging. These cysts/syrinxes tend to expand the overall cord's circumference, as there is displacement of the surrounding normal cord. The second type, which is not centrally located and can be more asymmetric, is thought to originate within the parenchyma of the cord itself. It is uncertain if the mass effect creates myelomalacia of the surrounding cord as in some cases edema and swelling of the cord may present prior to true syrinx formation. Eccentric syrinx formation may also be associated with myelomalacia from direct trauma or asymmetric expansion of the central canal and fissures within the ependymal margin allowing for CSF pulsation to form an eccentric cyst. These may also simply represent arachnoid cysts formed from other etiologies or changes in CSF dynamics from inflammatory processes or adhesions, which can occur in the setting of trauma or ischemia. It is a clinical conundrum as to whether the myelomalacia associated with cord injury is cystic or noncystic in nature. A noncystic myelomalacia implies cord parenchyma loss and, therefore, would not benefit from shunt placement. However, there would be a role for shunt placement if it is a true cyst with mass effect.

INFECTIOUS AND INFLAMMATORY DISORDERS

Inflammatory and infectious processes of the spinal cord traditionally present with symptoms of radiculitis, radiculopathy, or paresthesia and paresis. However, pain may be the only complaint. These inflammatory processes, including multiple sclerosis or connective tissue diseases including Sjögren syndrome, lupus, or rheumatoid arthritis, can lead to rapidly progressive neurologic dysfunction. In transverse myelitis, there may be dysfunction of a portion or the entirety of the spinal cord.

Sarcoidosis, vasculitis, or idiopathic processes can also present with radiculitis, as does disseminated encephalomyelitis, although it has a very different etiology.

B₁₂ (cobalamin) deficiency can present as an acute combined degenerative myelitis, including paresthesia of the hands and feet and loss of protopathic and episcritic sensation, leading to ataxia, spasticity, and lower motor neuroweakness. However, it can also present with lesions in the optic tracts, cerebrum, and peripheral nerves. T2 hyperintensity is identified in the nucleus gracilis and cuneatus, primarily within the cervical and thoracic spine, and there may or may not be associated cord swelling. This tends to be a long segment lesion and can be confused with multiple other etiologies such as those seen with folic acid deficiency, tabes dorsalis (syphilis), certain chemotherapeutic agents such as vincristine, and carcinomatous radiculopathy. The causes of B₁₂ insufficiency include autoimmune reaction toward the gastric parietal cells in the gastric fundus and proximal gastric body. These cells produce an intrinsic factor that is used to bind B₁₂ and allow its subsequent absorption from the terminal ileum. This can also be a complication of extended gastrectomy or decreased intake, which can occur in strictly limited diets (vegan). In such settings, changes within the marrow appearance resulting in benign hyperplastic marrow secondary to pernicious anemia may be an indication of its etiology.

Systemic lupus erythematosus can present as a traditional transverse myelitis with paraparesis or quadriplegia, sensory loss, or back pain. This tends to occur over several segments within the cord without predilection for location. Involved segment tends to be slightly longer than in multiple sclerosis and it may enhance. Etiology is believed to be autoimmune-related, vacuolar degeneration, or ischemia.

Multiple sclerosis tends to occur over a shorter segment, usually two to three vertebral body lengths. It can produce myelopathic signs with only spinal signs and symptoms in up to one-fourth of the cases. Multiple sclerosis has a predilection for the cervical spine and although may commonly affect the lateral cord, it does not have a limitation with respect to the gray or white boundaries. There may be enhancement if there is ongoing demyelination. Over time this can lead to parenchymal loss. However, rarely there is mild edema depending on the acuity of the lesion. A large amount of spinal cord edema and swelling should raise suspicion of other etiologies.

Although unusual, sarcoidosis can present within the spinal cord, also with a predilection for the cervical region. Sarcoidosis can imitate multiple diseases: nodules on the surface of the cord (metastatic disease), a plaque on individual nerve roots (infectious or metastatic

disease), or rarely as an intramedullary lesion, which may be diffuse or discreet. Sarcoid lesions have a mixed pattern of enhancement.

Tuberculosis usually affects the lower spine and thoracolumbar region; it can be an indolent process presenting late in its progression with epidural components or soft-tissue involvement with Pott disease. Pott disease leads to vertebral body destruction with sparing of the disk space, giving the impression of malignant processes. The disease may result in severe alignment deformities. Diagnosis, although usually one of exclusion, requires the difficult isolation and growth of the *tuberculum bacillus*.

Epidural abscess can indirectly compress the spinal cord or create an inflammatory response that secondarily affects the cord. Most commonly, epidural abscesses are caused by direct extension from vertebral or paraspinal infection, which are commonly due to the blood-borne spread of infectious source, such as cardiac or urinary tract infection or other cause of septicemia. Immunosuppression or intravenous drug abuse can also serve as an etiology. Rarely, epidural abscess can be associated with trauma to the spine belong with hematoma formation and subsequent superinfection or can be iatrogenic (spinal surgery or instrumentation). Although nuclear scintigraphy may be beneficial to evaluate for infection on inflammatory processes or osseous involvement, MRI remains the mainstay of imaging and diagnosis because of improved morphologic evaluation. This can also allow the surgeons to plan their operative approach and posttherapy reconstruction.

Diskitis and osteomyelitis are usually blood-borne infections, typically seeding at the endplate, which may result in focal back pain or radicular pain. This may impinge or create inflammatory response in the meningeal or neural elements. Most commonly, diskitis and osteomyelitis are caused by skin pathogens that have penetrated into the blood such as staphylococcus, streptococcus, or less likely *Escherichia coli*. Although gallium nuclear scintigraphy can be very sensitive for this inflammatory process, MRI remains a more conclusive diagnostic tool. If there is extension into the epidural space, ischemia at the neural elements from vascular inflammatory response should be entertained. Vertebral osteomyelitis is also well delineated with a three-phase bone scan. These processes are more frequent in the setting of immunodeficiency but they are not limited to the immunocompromised.

Subacute necrotizing myelopathy can present with clinical symptoms similar to transverse myelitis. It can occur with a multitude of infections: herpes zoster, mononucleosis, mumps, rubeola, toxoplasmosis, or TB. However, it can also be seen in vascular malformations, with dural AVM and venous hypertension.

VASCULAR DISORDERS

Cord ischemia or infarction may occur at any level. However, the blood supply at the junctions of upper thoracic spine and the thoracolumbar junction is more tenuous and so these are the areas most likely to be involved. These areas have the greatest demand for blood by the arms, neck, chest; and within the thoracolumbar junction, where the aorta supplies multiple solid and hollow organ systems and has a tenuous vascular supply (artery of Adamkiewicz) to the spinal cord anteriorly. Spinal cord ischemia and infarction tend to be anterior because of its singular supply. The posterior spinal cord has a dual artery supply, precluding it from ischemia except in the setting where multiple vessels may be involved, for example in vasculitis. Ischemia or infarction of the cord may present in a multitude of clinical scenarios, although lower extremity claudication may be the earliest and mildest presentation. Cord swelling in the upper thoracic or thoracolumbar junction may be the earliest imaging presentation. This cord compromise can be the result of a multitude of clinical etiologies (Table 15-1).

Arteriovenous malformations (AVM) of the spinal cord divided into three categories: spinal dural AVF spinal cord AVM either of a predominately intramedullary type or a mixed intra- or extramedullary, and extraspinal type; and spinal cord AVF.

Spinal dural AVF consists of a single nidus associated with the nerve root. This is the most frequent vascular malformation associated with the spine and is seen more commonly in the dorsal lower thoracic cord. Foix-Alajouanine is a specific myelopathy associated with spinal dural AVF. Arterial pressure creates a kink in the normal venous outflow, resulting in venous hypertension, which leads to edema and possibly ischemia from swelling. This eventually restricts arterial inflow within the cord. A large venous varix can be mistaken for a mass on imaging. However, the most

common imaging appearance is a so called peppered or (multiple nodules) along the cord because of the dilated venous plexus. Treatment of a dural AVF, which arises at the same level as an anterior spinal artery, should be performed surgically because endovascular treatment is contraindicated. Treatment is usually aimed at the ligation occlusion of the arterial supply to the fistula, as removal of the venous plexus at surgery can actually be more detrimental to the cord.

Spinal cord AVM is fed by a single or multiple branches of the anterior and posterior spinal arteries, with an intramedullary nidus of arterial flow extending into multiple spinous veins. This is considered a true AVM. Unlike spinal dural AVF, with its insidious onset, spinal cord arterial venous fistula tends to have a more acute onset usually as a presentation of intramedullary hemorrhage. A variant of the spinal cord AVM, the so-called juvenile type, tends to have extensive involvement of intramedullary, extramedullary, and possibly extraspinal components. These AVM tend to occur earlier in life and have a poor prognosis.

The third type of vascular malformation, spinal cord AVF (type 4 spinal AVM) is an intradural, extramedullary AVF without an intervening capillary network. This is located on the pial surface. It can involve the anterior and posterior spinal arteries or can have a single arteriovenous connection. It may present with progressive myelopathy and/or hemorrhage, as a result of increase in venous pressure. This hemorrhage can often present in a similar fashion as intracranial hemorrhage and is a source of nonaneurysmal intracranial subarachnoid hemorrhage.

Cavernous angiomas are also seen within the spinal cord and are of similar appearance as those seen within the cerebral and cerebellar parenchyma. Their presentation is variable depending on their location.

Soft tissues associated with the neural axis can be injured, creating neural symptoms without direct cord injury. Injuries such as a nerve root avulsion may be caused by seemingly mild spinal trauma. An avulsed nerve root can form an empty pseudomeningocele at the site of injury. These injuries can be diagnosed either with MR imaging or myelography. However, particularly later on, the posttraumatic myelomeningocele may no longer connect with the thecal sac. Other secondary injuries may be associated with prior events such as siderosis from hemorrhage associated with spinal AVM or other medullary or leptomeninges processes. Typical imaging appearance is described as a dark line outlining the neural structures as if they were “dipped in oil.” Other injuries associated with the spinal cord may be secondary to injuries to its sleeve, the so-called tears in the dura, a risk for spinal cord herniation, and adhesion, leading to which can present as a tethered type of myelopathy.

NEOPLASMS

Neoplastic lesions of the cord are considered intramedullary, extramedullary–intradural, and extradural. Of those to be considered here are primarily the intramedullary and extramedullary–intradural. Intramedullary type is a small percent roughly 5% to 10% of CNS tumors, and 90% to 95% of these are glial in origin. Ependymomas are the most common (roughly two-thirds) of these glial lesions with astrocytomas predominating in the other one-third. Ependymomas present more likely within the cervical spine and conus as opposed to the astrocytomas, which occur more commonly in the thoracic spine. Ependymomas tend to be more central secondary to the lining of the central canal with ependymal cells as opposed to the astrocytoma, which is eccentric. Ependymomas tend to be more short segment averaging approximately four segments but tending to be less than six; astrocytomas tend to be seven segments or longer. Cysts associated with these lesions tend to be at the polar aspects with ependymomas. Astrocytomas tend to have intratumoral cysts. Ependymomas occur in adults with a slightly lower grade, while astrocytomas present in children with higher grade. Hemorrhage occurs with ependymomas and not with astrocytomas. Enhancement can be variable in both but is more focal and intense with ependymomas. Therefore, astrocytoma has eight letters prior to “oma” and tends to be longer segment. Ependymoma has fewer letters and tends to be of shorter (six or less) segments. The cysts associated with ependymomas tend to be on the “end” as opposed to astrocytomas, which occur more often in the central aspect. Furthermore, the use of the end can be applied to their age of onset. The appearance of being well-defined with ependymomas tends to go along with the lower grade as opposed to poor definition appearance with astrocytomas, which tends to be of the higher grade. Beyond these glial neoplasms, more common lesions are the hemangioblastoma with dilated tortuous vessels and vascular appearance, which can have cysts and associated syrinx formation. These lesions are associated with von Hippel-Lindau. Spinal paragangliomas are neural-independent, encapsulated lesions that are peripheral and located on the extramedullary surface. Spinal cord metastases are difficult to discern from primary neoplasm. Lymphoma tends to affect the epidural space and vertebral bodies as opposed to an intramedullary lesion. Primitive neural ectodermal tumors tend to be long segment and undifferentiated with a poor prognosis.

The extramedullary–intradural lesions create symptoms by cord displacement. These have a sharp border between the mass and CSF or intrathecal contrast in the setting of myelography. They also enlarge the ipsilateral subarachnoid space. Of these, approximately 90% are nerve sheath tumors (schwannomas and meningiomas). Paraganglion,

dermoids, and epidermoid cysts encompass the remaining 10% of these lesions. Approximately three-quarters of the nerve sheath tumors are intradural, although some can present as a dumbbell shape with extradural extension. Meningiomas are the second most common intraspinal tumors with a slight female predilection. These are more commonly solitary but can be multiple in neurofibromatosis type 2 and are more commonly seen within the thoracic spine. Of those lesions that are extradural but can have an indirect effect on the cord, the differential includes disks, blood, bone, tumor, and sometimes puss. There are three more common primary neoplasms that may affect neural elements by compression: chordoma, lymphoma, and sarcoma. Chordoma is a layered but slow growing, locally aggressive tumor arising from notochordal elements, more commonly seen within the sacrum and clivus, but can be seen within the vertebral body secondary to inclusion at time of neural tube closure. Lymphoma can have multiple appearances within the vertebral body and tends to be secondary when it involves the spine. The “ivory vertebra” is one particular manifestation of Hodgkin disease. Metastatic disease to the vertebral elements may have a similar appearance and effect on the neural elements.

QUESTIONS AND ANSWERS

1. MRI of the cord identifies a mass. What finding suggests the tumor is an astrocytoma rather than an ependymoma?
 - A. Polar cyst
 - B. Hemorrhage at the cap

- C. Seven vertebral segments in length
- D. Mixed enhancement
- E. Adult patient

ANSWER: C. Astrocytomas tend to be longer than six vertebral segments. Their cysts tend to be within the lesion and rarely have hemorrhage at the margins. Astrocytomas occur more often in younger patients and both may have a mixed enhancement pattern.

2. Compression of the thecal sac on myelography could indicate all of the following diagnoses *except*
- A. Hematoma
 - B. Abscess
 - C. Disc herniation
 - D. Astrocytoma
 - E. Metastasis

ANSWER: D. Astrocytomas are intramedullary and would expand the thecal sac. The remaining are part of the extradural differential that typically include disc, blood, bone, tumor, and sometimes pus.

3. Which of the following image findings is a contraindication to endovascular therapy of a spinal vascular malformation?
- A. Multiple arterial supplies to the nidus
 - B. Anterior spinal artery supplied at the same level as an AV fistula
 - C. Involvement of the posterior and anterior supply at the same level
 - D. Only one dominant venous outflow noted
 - E. Asymptomatic patient at time of AVM discovery on imaging

ANSWER: B. Embolization of an artery that also supplies the anterior spinal artery could cause cord infarction if the only arterial supply is at the same level and is treated endovascularly.

4. Sarcoidosis has a predilection for which region of the spinal cord?
- A. Cervical
 - B. Thoracic
 - C. Lumbar
 - D. Central cord
 - E. Peripheral cord

ANSWER: A. Sarcoidosis appears more commonly within the cervical region, but may be seen any where in the cord and can imitate most lesions.

5. Which of the following are the *least likely* to be the origin of an epidural abscess?
- A. Hematoma after trauma with subsequent degradation of products
 - B. Instrumentation

- C. IV drug abuse
- D. UTI in an immune competent patient
- E. Psoas abscess

ANSWER: A. Although a degrading hematoma is the perfect place for bacteria to grow, as long as it is sterile, it is less likely to result in infection. The remainder may seed the epidural space by direct or hematogenous spread.

6. Which of the following is more commonly associated with osteomyelitis than discitis?
- A. Tuberculosis
 - B. Streptococcus
 - C. Staphylococcus
 - D. *E. coli*

ANSWER: A. TB is more often seen to spread to the bone and epidural components contiguously. While the remaining choices spread to the disc as well, the disc is fairly resistant to involvement by TB.

7. What is the mildest form of developmental spinal abnormality?
- A. Caudal sac lipoma
 - B. Spina bifida occulta
 - C. Lipomatous infiltration of the filum terminale
 - D. Meningocele
 - E. Myelomeningocele

ANSWER: C. Fatty filum is the mildest form of developmental spinal abnormality with minimal lipomatous replacement. The remaining options are considered more significant developmental abnormalities.

8. What is the most common cause of cord ischemia?
- A. AVM
 - B. Infection
 - C. Hypertension
 - D. Vasculitis
 - E. Thromboembolic

ANSWER: E. Thromboembolic disease (usually from the aorta) can commonly occur in atherosclerosis and/or aneurysms, while the remainder can contribute to cord ischemia, but are not commonly the sole cause.

9. What is the most common spinal location for cord astrocytoma?
- A. Cervical
 - B. Thoracic
 - C. Lumbar
 - D. Sacral

ANSWER: A. Cervical. These tumors develop from astrocytes within the spinal cord. They occur at any age, but are more common during the early

years of life. In children younger than 10 years of age, they account for 90% of all intramedullary tumors. In adolescents, they account for about 60% of all intramedullary tumors. Most astrocytomas are located in the spinal cord near the neck and upper chest.

10. What is the most common spinal location for cord ependymomas?
- A. Cervical
 - B. Thoracic
 - C. Lumbar
 - D. Sacral

ANSWER: C. Ependymomas develop from ependymal cells. They are most often seen in adults aging 20 to 40 years. This is a relatively common and usually slow-growing spinal tumor, accounting for more than

half of adult spinal cord tumors. Ependymoma can develop anywhere along the spinal cord, but up to 40% are found near the tailbone.

11. What is the most common location for chordomas?
- A. Clival
 - B. Cervical spine
 - C. Thoracic spine
 - D. Lumbar spine
 - E. Sacral spine

ANSWER: A. Chordomas arise from notochordal remnants of the axial skeleton and constitute less than 3% of primary malignant bone tumors. Approximately 50% arise in the sacrococcygeal region, the second commonest site is the base of the skull. They are most common in the fifth and sixth decades and have a male preponderance.

Section 2

PULMONARY

16 NORMAL ANATOMY AND VARIANTS

John C. Texada and Satinder P. Singh

LUNGS

DEVELOPMENT

The embryonic stage begins around day 26, when the lung bud forms at the ventral foregut. Over the next 2 to 3 days, it divides into left and right buds, and the tracheobronchial and esophageal guts separate via transverse ingrowths. By days 32 to 34, the lobar bronchi have appeared. In the pseudoglandular stage, the 5th to 16th weeks of development, additional bronchial tree ramifications develop. By week 16, almost all airways are present but are blind tubules. Cartilage appears in the seventh week and develops distally. In the canalicular stage, the 17th through 24th or 25th weeks of development, the peripheral bronchial tree forms canaliculi that will become the transitional airways. Capillaries grow into the mesenchyme and air spaces form. At around 28 weeks, type I and type II pneumocytes begin to differentiate and resulting blood–gas barrier is capable of gas exchange. In the saccular stage, from the 25th week through birth, acini develop. By the 28th week, several generations of respiratory bronchioles are present, and thereafter the saccules continue to proliferate and increase in vascularity. Alveolar development begins early in this stage. The alveolar period is from 36 weeks to term. Alveolar tissues have been found as early as 30 weeks, but by 36 weeks they are always present. The typical acinus at birth has three generations of respiratory bronchioles, one of transitional ducts, and three of saccules. Most alveoli have developed by 2 years of age, but some development continues until 8 years.

FUNCTIONAL ZONES

The conducting zone includes airways without alveoli and no gas exchange: the trachea (with 16–20 incomplete cartilage rings), bronchi (varying cartilage), and membranous bronchioles (no cartilage). There are about 25 generations of conducting airways from the trachea, the smallest about 0.8 mm in diameter. Ciliated cells are more numerous than secretory epithelial cells, increasingly so in the distal airways. Airways in the transitional zone participate in both conduction and respiration: the respiratory bronchioles and alveolar ducts. There are typically six to nine generations of airway and an average of 10 to 20 alveoli per duct. Up to 40% of alveoli may arise directly from the transitional airways. Upon reaching the alveolar ducts, only minimal connective tissue is left. The respiratory zone is composed of alveoli, whose function is to carry out gas exchange. Approximately 87% of lung volume is alveoli: 6% of which is tissue and the remainder is gas.

CELL TYPES AND ALVEOLAR CONNECTIONS

Alveolar pores are small (2–10 μm) alveolar wall discontinuities, more numerous in older tissue and at the apices and subpleural parenchyma; there are 5 to 20 pores per alveolus, probably covered by surfactant. Alveolar fenestrae are larger (20–100 μm), probably pathologic in nature and perhaps a forme-fruste emphysema. The canals of Lambert are proposed collateral pathways, epithelialized tubes connecting alveoli to distal bronchioles, 0 to 30 μm .

Goblet cells secrete mucus and become more numerous in inflammation. Basal cells at the basement membrane populate the epithelium. Brush cells are rare and may serve in secretion–absorption. Clara cells produce lipids and proteins, including surfactant proteins, and possibly are a progenitor for epithelial redevelopment. Neuroendocrine K cells produce neurosecretory granules

and may function in mediation of hypoxia, fetal–neonatal transition, and/or epithelial growth and repair regulation. Dendritic and Langerhans cells process and present antigens.

Type I alveolar cells, membranous pneumocytes, are only 8% of all parenchymal lung cells, but cover 95% of the alveolar surface. Their function is primarily gas exchange, but they may participate in particle uptake. They are thought to be incapable of cell division. Type II alveolar cells, the granular pneumocytes, are the source of alveolar surfactant. They are capable of undergoing mitosis and are the source for replacement of type I cells. They also function in protein synthesis and maintenance, possible immune response, and fluid uptake.

PRIMARY LUNG UNITS

The primary lobule is composed of the parenchyma distal to the last respiratory bronchiole. There may be as many as 20 to 25 million primary lobules, too small to image. The secondary lobule is the smallest portion of the lung surrounded by a septum, typically 5 to 15 mm. The interlobular septa are best developed at the lung periphery, where they are continuous with the pleura. Normal secondary lobules are visible in high-resolution CT (HRCT), the smallest normal structures identifiable; only with interlobular septal thickening do the secondary lobules become radiographically visible. The acinar unit is the tissue distal to the terminal bronchiole: respiratory bronchioles, alveolar ducts and sacs, and alveoli, and their connective tissue. An acinus may be 6 to 10 mm, and a person may have thousands. Radiographically, a filled acinus may appear as a rosette or a sphere, but normal acini are not apparent even in HRCT.

TRACHEA

The normal trachea is 6 to 9 cm long. It is midline, sometimes with slight rightward deviation at the aortic arch, generally about halfway between the sternum and the spine but occasionally more anterior or posterior. The walls are smoothly corrugated by the tracheal cartilages and are parallel except possible left-sided aortic indentation just above the bifurcation. In cross section, the trachea is generally round or oval, though it may have other shapes. Its dimensions range from 13 to 25 mm and 13 to 27 mm (coronal and sagittal) in men and from 10 to 21 mm and 10 to 23 mm in women. The normal intrathoracic trachea does not change dimensions with changes in pleural pressure.

BRONCHI

The right main bronchus is slightly larger than the left at total lung capacity, 15 versus 13 mm, but it is shorter, 2.2 versus 5 cm. The subcarinal interbronchial angle measures about 60 degrees, with range about 40 to 70 degrees. The angle decreases slightly as the chest lengthens.

BRONCHOPULMONARY SEGMENTAL ANATOMY

Subsegmental and even segmental and lobar bronchial branching may vary, generally without clinical significance. The bronchopulmonary segments are relatively constant despite any airway variation.

The right lung has 10 segments. The right upper lobe bronchus arises 2 cm from the carina and divides into apical, anterior, and posterior segmental bronchi; this bronchus or one of its branches may arise directly from the lateral trachea in bronchus suis. The bronchus intermedius continues 3 to 4 cm and then bifurcates into middle and lower lobe bronchi. The right middle lobe bronchus divides into medial and lateral segmental bronchi; the right lower lobe bronchus into superior, medial basal, anterior basal, lateral basal, and posterior basal segmental bronchi.

The left lung has eight segments. The left upper lobe bronchus arises 5 cm from the carina and soon bifurcates or trifurcates into lingular and upper-division (or independent apicoposterior and anterior) bronchi. The lingular bronchus splits into superior and inferior bronchi and the left lower lobe bronchus into superior, anteromedial, lateral basal, and posterior basal bronchi.

PLEURA

The visceral pleura invests the lungs and parietal pleura invests the chest wall, diaphragm, and mediastinum. The two join at the pulmonary hila. Visceral pleural extensions form the fissures.

The visceral pleura has three layers: the superficial endopleura, the chief layer of collagen and elastic tissue, and the vascular or interstitial layer, containing connective tissue with lymphatic and blood vessels and continuous with the interlobular septal interstitium. The visceral pleura is perfused partly by bronchial artery branches; the costal and diaphragmatic portions may be bronchial or pulmonary. Bronchial veins drain the hilar regions; pulmonary veins drain the rest of the visceral pleura. Innervation is by branches of the vagus nerve and sympathetic nerves.

The parietal pleura is adjacent to the fascia of the chest wall. It has two parts, separated by a layer of fibroelastic tissue, with most of the blood vessels in the most external layer. Perfusion is via branches of chest wall arteries. The parietal pleura is innervated by intercostal nerves.

FISSURAL ANATOMY

NORMAL FISSURES

The major fissures begin near the fifth thoracic vertebral body and course anteroinferiorly along the sixth rib. The left lower lobe usually extends slightly higher than the right. Both fissures face slightly laterally and are slightly undulating. The minor fissure separates the right upper and middle lobes; it is variably oriented but roughly horizontal at the level of the anterior fourth rib, commonly lower anteriorly and laterally. Incomplete normal fissures are common: partial right upper and middle lobe fusion is found in up to 88% of patients; right upper and lower lobe fusion, in 70%; and others range 40% to 50%.

ACCESSORY FISSURES

Any segment of lung may be partially or completely separated from adjacent lung. The azygous fissure is formed by downward migration of the azygous vein through the apical right upper lobe, visible in 0.5% of radiographs and in 1% of anatomic specimens. If a patient with an azygous fissure develops a right-sided pneumothorax, the apical pleural surfaces will not separate and sometimes fluid or pneumothorax can get loculated in azygous fissure creating bizarre radiographic appearance. Its presence may also be a potential impediment to thoracotomy and extrapleural approach to surgery for esophageal atresia and endoscopic thoracic sympathectomy done for hyperhidrosis. The inferior accessory fissure (right or left) separates the medial basal segment from the rest of the lower lobe, visible in 30% to 45% of autopsies and 8% of radiographs. The superior accessory fissure (right or left) separates the superior segment from the basal segments of the lower lobe. Less commonly the left upper lobe fissure is similar to the azygous fissure caused by the left superior intercostal vein; and the left minor fissure separates the lingula from the rest of the left upper lobe.

PULMONARY LIGAMENT

The pulmonary ligament is a double layer of pleura connecting the medial lower lobe to the mediastinum and diaphragm, formed by the mediastinal parietal pleura as it reflects over the hilar bronchovascular structures onto

the surface of the lung as the visceral pleura. It is visible in 60% to 70% (left) and 40% to 60% (right) of CT, where it usually appears as a small peak on the mediastinal surface, extending as a thin line inferiorly, usually coursing obliquely posterior.

CHEST WALL

SOFT TISSUES

The pectoral muscles form the anterior axillary fold, which should curve smoothly from the axilla to the ribcage. Congenital absence of the pectoralis muscle is rare and may be associated with multiple abnormalities including Sprengel deformity (pathologically fixed scapular elevation). In this deformity, a cervical rib may articulate with the scapula (an omovertebral bone) but its presence is not required; 60% to 70% of patients with Sprengel deformity lack this bone.

The sternocleidomastoid muscles are sometimes visible paralleling the spine in the medial third of the apices, curving down and laterally to meet the clavicular companion shadow; this measures 2 to 3 mm, parallels the superior clavicle, and is formed by the skin and subcutaneous tissues overlying the bone. Isolated asymmetric absence of the companion shadow suggests supraclavicular mass.

The transversus thoracis courses from the inferior sternum to the second through fifth costal cartilages, visible in CT at the level of the heart as a thin line, internal to the anterior costal cartilage. Other muscles are clearly visible with CT: the pectoralis major and minor; the serratus anterior, immediately superficial to the lateral ribs; and the superficial, middle, and deep muscles of the back.

PRIMARY RESPIRATORY MUSCLES

In inspiration, the diaphragm is the main primary muscle; the others are the parasternal, scalene, and external intercostal muscles. The parasternal and external intercostal muscles are tonically active, preventing inward rib movement with diaphragm contraction. This ceases with anesthesia, REM sleep, or high spinal cord injury, allowing the ribcage to fall inward with diaphragm contraction. Accessory muscles are recruited when ventilatory demand increases: sternocleidomastoid, pectoralis, serratus anterior, trapezius, and latissimus dorsi.

Expiration is passive in normal people, with activity needed when ventilation exceeds 50% of maximum voluntary ventilation or with increased load. The rectus and transversus abdominis, internal and external obliques,

internal intercostals, and triangularis sterni act when needed.

BONES

Twelve thoracic vertebrae are present, and twelve paired ribs are normally present. On lateral chest radiograph, lucency should increase as the spine progresses caudally; any increase should suggest intrathoracic disease ("spine sign"). Hypoplasia of the first rib may be found in 1.2% of patients, and supernumerary C7 ribs may be found in 1.5%, nearly all bilaterally. An intrathoracic rib is a rare asymptomatic congenital accessory rib arising from the anterior surface of a rib or a vertebral body, and usually extending downward and laterally to end near the diaphragm. Inferior rib indentation near the tubercles is normal and not the pathologic rib notching of coarctation and other processes. Rib cartilage calcification is common and not pathologic; the costal cartilages of men tend to calcify further at the margins, whereas costal cartilages of women tend to calcify centrally first.

The clavicle may have an inferomedial indentation called the rhomboid fossa, where costoclavicular (rhomboid) ligaments attach. The sternum should be visible in its entirety in the lateral projection; in the posteroanterior (PA) projection, only the superior and lateral walls of the manubrium are visible. The scapulae sometimes have well-defined lucencies surrounded by cortical bone: sites of incomplete bone formation, not to be reported as fracture or lytic lesion.

NONCARDIAC VASCULAR MEDIASTINUM

PULMONARY ARTERIES

DEVELOPMENT

The pulmonary artery develops from the sixth aortic arch. The proximal sixth arch on each side develops into the proximal right and left arteries; the right side loses its connection with the aortic arch, whereas the left side keeps the connection as the ductus arteriosus. Branches from each side grow toward the lung buds and form the pulmonary hila, then ramify with airway development. Most preacinar branches are present by 16 weeks gestation.

HISTOLOGY

The pulmonary arteries have thinner walls than systemic arteries of the same diameter, and the intima is very thin. The main, lobar, segmental, and subsegmental arteries are elastic but their elastin is more irregular and fragmented

than in systemic elastic arteries. As vessel diameter decreases to 0.5 mm the elastic tissue is lost forming, the muscular arteries. Beginning at around 0.1 mm the smooth muscle starts to disappear forming, the arterioles. By 70 μm , the vessels have only a thin intima and a single elastic lamina; the arterioles continue to divide in the acinus. The capillaries are composed of endothelium with a basement membrane shared with the pulmonary epithelium.

GROSS ANATOMY

The pulmonary trunk extends cranially, posterior, and slightly leftward for 4 to 5 cm from the right ventricle. It divides within the pericardium into left and longer right pulmonary arteries. The main pulmonary artery diameter range is 22 to 26 mm. The left pulmonary artery continues in the same direction to the hilum; it arcs over the left main bronchus and into the vertical left interlobar artery posterolateral to the lower lobe bronchus. The left interlobar artery then typically divides into segmental branches. The right pulmonary artery courses horizontally posterior to the aorta and anterior to the right main bronchus, and divides into the truncus anterior and interlobar artery. The right pulmonary artery diameter range is 12 to 15 mm. The truncus anterior supplies the upper lobe, and the interlobar artery the middle and lower lobes; in 90% of people a part of the upper lobe posterior segment has its own arterial branch from the interlobar artery. The right interlobar artery runs between the superior vena cava (SVC) and the bronchus intermedius, then in the major fissure before dividing into middle- and lower-lobe segmental branches. The upper limit of interlobar artery diameter is 16 mm in men and 15 mm in women, decreased by 1 to 3 mm in expiration. Segmental branching is variable but one pulmonary artery always follows each bronchial division. Supernumerary arteries are common.

PULMONARY VEINS

DEVELOPMENT

Embryonic pulmonary venous blood flows initially to splanchnic plexus. The cranial sinoatrial heart outpouching develops into the common pulmonary vein, which extends to the developing lungs; it eventually becomes incorporated into the left atrial wall, generally leaving the separate pulmonary veins. The splanchnic–pulmonary connections eventually regress.

HISTOLOGY

Small pulmonary venules are identical to arterioles. Veins are clearly recognizable by a diameter of 60 to 100 μm . They have variable numbers of elastic laminae and small irregular smooth muscle and collagen bundles. There is no external elastic lamina. No valves are

present, but there are focal constrictions created by rings of smooth muscle.

GROSS ANATOMY

The veins arise from alveolar and pleural capillaries, not associated with the airways. Their course is variable but they usually end up as two main superior and two main inferior veins. Numerous supernumerary veins are present. The right-sided veins course beneath the pulmonary artery posterior to the SVC. The right superior vein drains upper lobe segmental veins to the superoposterior left atrium. The middle lobe vein generally enters at the base of the superior pulmonary vein but may enter separately. The right inferior vein drains the lower lobe separately into the posterior inferior left atrium. The left-sided veins pass anterior to the descending aorta. The left superior vein arises from the left upper lobe segmental veins. The lingular vein then joins it and it enters the posterosuperior left atrium. The left inferior vein drains the left lower lobe. It may enter the left atrium separately or join the left superior vein within the pericardium.

VASCULAR PEDICLE

The pedicle extends from the thoracic inlet to the top of the heart. Its boundaries are the right brachiocephalic vein and SVC, and the left subclavian artery. Its width is normally 38 to 58 mm, measured from the SVC-right main bronchus intersection to the left subclavian artery origin. A widened pedicle may reflect vascular enlargement or processes such as hemorrhage.

PULMONARY HILA

The hila may be defined as the areas that connect the mediastinum to the lungs, composed of pulmonary arteries and veins, bronchi, nodes, and connective tissue. The proximal left pulmonary artery is almost always higher than the right interlobar artery and never lower. In lateral radiography, the hila are superposed. The carina projects at thoracic vertebral body level T4-T5. The right upper lobe bronchus can be seen end-on in about half of patients; the left upper lobe bronchus is visible more caudally in 75%. The former is not as well-circumscribed by tissue as the latter; if it is clearly visible that suggests surrounding soft-tissue prominence, usually lymphadenopathy.

BRONCHIAL ARTERIES

The bronchial arteries are variable in number, with patients typically having 2 to 4 bronchial arteries. Com-

monly one right bronchial artery arises from the right third intercostal artery and two on the left arise from the anterolateral aorta at the thoracic level T5/T6. They may originate elsewhere along the aorta or from the subclavian, innominate, internal mammary, or coronary arteries. They anastomose with other mediastinal arteries, then encircle the main bronchi. The true bronchial arteries radiate from these rings, course along the bronchi, and branch with the airways. Two or three arteries are generally present along each bronchus, connecting with adventitial and submucosal plexuses.

BRONCHIAL VEINS

The trachea and large bronchi drain via bronchial veins to the azygous and hemiazygous systems. Most intrapulmonary bronchial drainage is via anastomoses into the pulmonary venous system.

LEFT SUBCLAVIAN ARTERY

This is located in the supra-aortic middle mediastinum. It courses superiorly touching the left mediastinal pleura, visible in PA radiographs as a concave edge extending from the arch to the medial clavicle. Aberrant right subclavian artery (approximately 0.5% prevalence) may be visible as an edge ascending from the aortic arch obliquely to the right. The proximal part of this artery is often dilated, called the diverticulum of Kommerell.

LEFT SUPERIOR INTERCOSTAL VEIN

The first left intercostal space drains via the supreme intercostal vein; the second to fourth intercostal veins drain via the left superior intercostal vein. In most patients, this drains into the accessory hemiazygous vein and then into the left brachiocephalic vein. It may be visible as the aortic nipple as it passes anteriorly adjacent to the arch or at its paraspinal and retroaortic portions.

LEFT SUPERIOR VENA CAVA

The normal right-sided SVC develops from the right anterior cardinal vein. If the left anterior cardinal vein persists, it develops into a left-sided SVC, visible as a straight shadow along the left mediastinum overlying the arch and proximal descending aorta. It generally drains into the coronary sinus but may drain into the left atrium and cause a right-to-left shunt. If a left SVC is

present, the right SVC is present in 85% of cases but is often smaller; it is absent in 15% of cases.

BUCKLED RIGHT BRACHIOCEPHALIC ARTERY

The right brachiocephalic artery is about 5 cm long and fixed at its origin and its division. The aorta lengthens with atherosclerosis and allows the artery to buckle. It is normally not contour forming but if it is enlarged by aneurysm or tortuous and buckled, it may become visible as a smooth opacity in the right superior paramedastinal area extending upward from the arch.

AZYGOUS VEIN

The azygous vein originates at the level of the renal veins as continuation of the right subcostal vein or right ascending lumbar vein. It passes through the right side of the aortic hiatus, courses in front or to the right of T4 to T12, and at T8 or T9 the hemiazygous vein joins it. At T4 or T5, it enters the SVC. It drains the right superior and 5th through 11th intercostal veins, right subcostal vein, right bronchial veins, and superior and inferior hemiazygous veins. The superior part of the azygous vein has posterior, middle, and anterior component; the latter may be measured easily. The upper limit of normal diameter is 10 mm, except in pregnant patients, where it is at least 15 mm.

HEMIAZYGOUS VEINS

The superior hemiazygous vein is the continuation of the left fourth posterior intercostal vein and often connects to the left superior intercostal vein. It courses downward along the spine to T8-T9 then crosses retroaortic to the azygous vein. The inferior hemiazygous vein originates from the left renal vein or as a continuation of the left subcostal or ascending lumbar veins and enters the chest via the aortic hiatus behind the descending aorta; at T8 or T9, it crosses to the azygous vein.

NONVASCULAR MEDIASTINUM

THORACIC INLET

This parallels the first rib and is higher anteriorly than posteriorly. Therefore, an opacity effaced superiorly and situated at or below the clavicles must be anterior, and an opacity projecting above the clavicles is retrotracheal, the cervicothoracic sign.

THYMUS

The thymus is derived from the third pharyngeal pouches and resides in the anterosuperior mediastinum. In adults, it extends from above the manubrium to the fourth costal cartilage. It contacts the trachea, aortic arch and branches, and the ascending aortic and main-pulmonary-arterial pericardium. Most are bilobed with lobules of cortical and medullary cells. The thymus may decrease with physical stress or corticosteroid administration, then return to normal or larger size afterward, in a process called rebound. It is radiographically apparent only in infants and young children; it reaches maximum weight at 12 to 19 years of age, but is inapparent after 2 to 3 years because the body grows faster. The sail sign (only present in 5% of infants) is the right- or left-projecting triangular opacity of thymic tissue as seen on a chest radiograph. In CT, the thymus is visible in 100% of patients younger than 30 years and 17% of patients older than 49 years. Only 30% are visually bilobed, and the left lobe is generally larger than the right. In patients younger than 19 years, the thymus is as dense as or denser than muscle; in most patients older than 40 years, it approaches fat density as it regresses.

RADIOGRAPHIC LINES AND SPACES

The intermediate stem line is a vertically oriented linear opacity up to 3 mm wide because of the posterior wall of the right main and intermediate bronchi. The left retrobronchial line is formed by the left main and proximal left lower-lobe bronchial posterior walls, 3 mm thick or less, shorter, and more posterior than the intermediate stem line.

The anteromedial pleurae of both lungs contact the mediastinum in the retrosternal space, at the anterior junction line. It is composed of four pleural layers and any intervening fat, generally 1 to 3 mm thick, and in PA radiographs courses from upper right to lower left behind the sternum. The right and left superior recesses are formed by the contact of lung with retromanubrial mediastinum, forming a V-shaped anterior mediastinal triangle. Shift of the superior recesses indicates atelectasis. The anteromedial surfaces of the lungs are separated by the heart and mediastinal fat. The lung surfaces contacting this fat form the inverted-V-shaped inferior recesses.

The retrosternal stripe is formed when any mediastinal fat forms a vertical retrosternal opacity abutting the bone. The average thickness is about 3 mm, maximally 7 mm. The lung contacts the upper two-thirds of the anterior chest wall, either to the right or to the left of midline, and this contact forms the parasternal stripe. This is

typically lobulated by the ribs, but can be further lobulated because of internal thoracic lymphadenopathy.

The cardiac apex and epicardial fat exclude lung from the left anteroinferior chest; this area is the cardiac incisura. Its interface with the left lung may be straight, round, or angular. The right side may have a similar process.

The aortopulmonary (AP) window is a space between the aortic arch and the left pulmonary artery, normally fat filled. The medial boundary is the ligamentum arteriosum and the lateral boundary is the left pleural surface. The aortopulmonary window interface is normally concave or straight; a convex aortopulmonary window interface suggests abnormality such as lymphadenopathy or sometimes lipomatosis. The aortopulmonary line is visible in 60% of patients as a continuous opacity with a sharp left border, extending from the arch to the left main bronchus, usually as an extension of the left heart border superiorly. If this line becomes displaced laterally, mediastinal pathology is suggested.

The two posterior pleural reflections (paraspinal lines) are about 1 mm wide, visible in thoracic spine radiographs and some chest radiographs. The left paraspinal line runs from the top or middle of the arch to T9 to T12, depending on inflation. If mediastinal fat is prominent, it may course over the arch to the apex and the subclavian artery. It is commonly parallel to the spine, anywhere medial to the lung–aorta interface. The right paraspinal line is visible less frequently, usually extending only a few vertebral levels near T8 to T12 within a few mm of the spine.

The preaortic recess is formed when the left lower lobe intrudes anterior to the descending aorta and medial to the esophagus. It is anatomically similar to the right-sided azygoesophageal recess but is usually much narrower, and may extend from the arch to the hemidiaphragm.

Contact of the supra-azygous right lung with the right lateral tracheal wall forms the right paratracheal stripe. It normally contains the pleural surface, the tracheal wall, and mediastinal fat, and should be no thicker than 4 mm. The sensitivity of paratracheal stripe widening for detection of lymphadenopathy is 30%. A left paratracheal stripe is uncommon.

The posterior tracheal stripe is formed by the posterior wall of the trachea as it abuts the right upper lobe. This can be visible along the entire length of visible trachea in a good lateral projection. It should not be over 5 mm; the most common abnormality to cause tracheoesophageal stripe thickening is esophageal cancer.

The lung apices contact the retroesophageal mediastinum anterior to T1 and T2, forming the posterior mediastinal triangle bordered by the left and right superior recesses. Anterior to T3 to T5 the lungs abut each other,

and the pleural stripe thus formed is the posterior junction line. It generally projects through the trachea, and is generally straight or left convex. The inferior recesses are formed when the lungs are displaced laterally from midline by the superior intercostal veins, the azygous arch, and the aortic arch. The right inferior recess is generally larger than the left because the aortic arch is higher than the azygous arch.

The right superior esophageal stripe is formed by the right side of gas-filled superior esophagus and right upper lobe pleura. It courses obliquely from upper right to lower left, inwardly convex. The left superior esophageal stripe is formed by the left wall of gas-filled esophagus and left upper lobe pleura. It generally is parallel to the contralateral stripe though they may diverge at their ends.

The azygoesophageal recess is formed by the contact of the right lower lobe with esophagus and ascending azygous vein. It is often visible in PA radiographs as an interface extending from the diaphragm to the level of the azygous arch. Focal convexity to the right should suggest a space-occupying process, though this is not sensitive (approximately 23%). If the esophagus is gas filled, the right and (sometimes) left inferior esophago-pleural stripes may be visible.

HEART

The heart shadow is essentially midline in thin people, only slightly to the left; in larger patients, it extends more to the left. The right heart border projects over the spine commonly in pectus excavatum deformity. Normal transverse heart diameter is 11.5 to 15.5 cm. On PA radiographs, a cardiothoracic ratio of 50% is typically considered upper limit of normal, but at least 10% of normal patients have ratios greater than 50%. Heart size typically changes less than 1.0 cm from diastole to systole. Lower diaphragm is associated with narrower heart shadow; elevated intrathoracic pressure decreases heart size and pulmonary vascularity; and recumbent positioning makes the heart shadow broader. Cardiophrenic recess fat pads are common. They produce obtuse angles with the diaphragm at the inferior mediastinum. Occasionally, the denser heart may be visible through them.

DIAPHRAGM

DEVELOPMENT

The diaphragm is embryologically derived from four structures: the central tendon is derived from the septum

transversarium, small midlateral components are derived from pleuroperitoneal membranes, the esophageal mesentery and diaphragmatic crura are derived from body-wall mesenchyme, and the majority of the muscular diaphragm is derived from a peripheral body-wall mesenchyme.

ANATOMY

The central tendon is a broad sheet of crossing fibers, overall shaped like a chevron pointing anteriorly. The costal muscular components attach to the xiphoid process and the 7th through 12th ribs. Its posterior attachment is from the lateral margins of the right first through third and left first and second lumbar vertebrae. This crural component only lowers the diaphragm without moving the ribcage.

The phrenic arteries arise from the caudal thoracic aorta or sometimes the renal arteries to supply the posterior upper diaphragmatic surface. The musculophrenic and pericardiophrenic arteries, distinct branches from the internal thoracic arteries, supply the anterior portion via extensive arcades and anastomoses with the intercostal arteries perfusing the peripheral portion of the diaphragm. Extensive lymphatic vessels drain to the mediastinum. Pores in the peritoneal mesothelial surface of the diaphragm allow abdominal fluid, particles, or cells to enter the pleural and mediastinal spaces directly. The phrenic nerve is the motor innervation. It has contributions from the C3, C4, and C5 spinal levels, mostly C4.

THORACIC LYMPHATIC SYSTEM

PLEURAL DRAINAGE

The pleural and pulmonary lymphatic systems are largely separate but are connected by small anastomoses. Lymphatic valves are oriented toward the pleural surface. Parietal pleural lymphatic drainage is extensive on the costal and diaphragmatic surfaces. The mediastinal pleural vessels follow the blood vessels. Visceral pleural lymphatic channels lie within the vascular layer. They are more numerous inferiorly, and form a network similar to pleural lobular boundaries, with many smaller tributaries over the pleural surface. Flow is to hilar lymph nodes.

PULMONARY PARENCHYMAL DRAINAGE

Two major pathways exist for pulmonary lymphatic drainage. Peribronchovascular lymphatic channels begin

at the distal respiratory bronchioles, and drain along the bronchovascular tree to the hilum. Channels in the interlobular septa also drain eventually to the hilum. Small anastomotic channels connect the two; distension of these channels creates the Kerley A lines.

THORACIC DUCT

The right and left lumbar lymphatic trunks merge anterior to T12 to L2, forming the cisterna chyli, which continues cranially as the thoracic duct. It courses through the aortic hiatus, usually to the right of the aorta. More superiorly it crosses leftward to course posterolateral to the trachea. It continues between the esophagus and the left subclavian artery; it most commonly joins the left internal jugular vein. In most people, the thoracic duct has valves. Diameter may be up to 7 mm.

THORACIC LYMPH NODES

PARIETAL NODES

The parietal nodes comprise three groups: the anterior and posterior parietal nodes and the diaphragmatic nodes. The internal mammary nodes are the anterior parietal nodes, behind the anterior intercostal spaces, draining the upper anterior abdominal wall, anterior chest wall, anterior diaphragm, and medial breast tissue. They communicate with anterior mediastinal and cervical nodes. The posterior parietal nodes are the posterior intercostal nodes and juxtavertebral nodes, draining the intercostal spaces, parietal pleura, and spine. They communicate with posterior mediastinal nodes and drain to the thoracic duct superiorly and the cisterna chyli inferiorly. The diaphragmatic nodes drain the diaphragm and anterosuperior liver: the prepericardiac group is immediately behind the xiphoid lateral to the pericardium; the juxtaphrenic group is near the phrenic nerves; and the retrocrural nodes lie behind the left and right crura.

VISCERAL NODES

The visceral nodes comprise three groups: the prevascular, posterior mediastinal, and tracheobronchial groups. The anterosuperior mediastinal (prevascular) nodes are along the anterior SVC, innominate veins, and ascending aorta. They drain most of the anterior mediastinum, and drain into the thoracic or right lymphatic duct. The posterior mediastinal nodes are periesophageal and periaortic; they drain the posterior diaphragm, pericardium, the esophagus, and the lower lobes and communicate with the tracheobronchial nodes.

The tracheobronchial nodes are the most important group of visceral nodes and have several subgroups. Paratracheal nodes are anterior to and alongside the trachea. The lowermost right-sided member is the azygous node, medial to the azygous vein. These drain bronchopulmonary and tracheal-bifurcation nodes, the trachea, and the esophagus. Carinal nodes are in the pre-carinal and subcarinal fat, and surrounding the main bronchi; AP window nodes are a subgroup in the mediastinal fat between the left pulmonary artery and aortic arch. Carinal nodes drain the bronchopulmonary nodes, anterior and posterior mediastinal nodes, heart, pericardium, esophagus, and lungs, and drain to the paratracheal group. Bronchopulmonary or hilar nodes are located around the main bronchi and vessels and receive drainage from all lobes of the lungs. They drain to carinal and paratracheal nodes.

QUESTIONS AND ANSWERS

- By what gestational week is alveolar tissue always present?
 - 30
 - 34

- 36
- 38

ANSWER: C. By 36 weeks of gestation, alveolar tissue is present. It can appear as early as 30 weeks.

- Regarding the trachea, which of the following is true?
 - Normal intrathoracic trachea changes dimensions with changes in pleural pressure.
 - Normal trachea is generally halfway between the sternum and the spine.
 - Normal trachea has smooth wall contours.
 - Normal trachea is seldom greater than 15 mm wide.

ANSWER: B. The normal intrathoracic trachea does not change dimensions with pleural pressure. It is generally halfway between the sternum and the spine, but is variable. It has corrugated contour because of cartilage rings and is at most 25 mm × 27 mm in men and 21 mm × 23 mm in women.

- In bronchopulmonary anatomy, which of the following characterizes the right upper lobe?
 - Its bronchus arises from the bronchus intermedius.
 - It has apicoposterior and anterior segments.
 - Its blood supply is generally via the truncus anterioris.
 - It is the site of the superior accessory fissure.

ANSWER: C. The right upper lobe bronchus arises from the right main bronchus. It has apical, posterior, and anterior segments. Its blood supply is generally via the truncus anterioris. It is the site of the azygous fissure; the superior accessory fissure separates the lower lobe superior segment from the basal segments.

- What is the smallest lung unit identifiable on HRCT?
 - Primary lobule
 - Secondary lobule
 - Acinus
 - Canals of Lambert

ANSWER: B. Normal secondary lobules are seen with HRCT. They can only be seen with conventional radiography if there is septal thickening.

- Regarding the relationship of pericardium to the pulmonary vessels, which of the following is true?
 - Main pulmonary bifurcation is within the pericardium.
 - Middle lobe vein generally joins the inferior pulmonary vein within the pericardium.

- C. Left inferior vein often joins the superior vein outside the pericardium.
- D. Right interlobar artery is intrapericardial.

ANSWER: A. The main pulmonary artery bifurcation is within the pericardium. The middle lobe vein generally flows into the base of the superior vein, but may enter separately. The left inferior vein and superior vein may enter the atrium separately, or merge within the pericardium to enter as a single vessel. The right interlobar artery is not intrapericardial.

- 6. Regarding lateral radiography, at what level does the carina project?
 - A. T2-T3
 - B. T4-T5
 - C. T6-T7
 - D. T8-T9

ANSWER: B. The carina projects around T4-T5. The left upper lobe is almost never more cranial than the right upper lobe bronchus and is inferior in 75% of cases. The left upper lobe bronchus is not as well-circumscribed by vessels as is the right upper lobe bronchus, so a clearly defined left upper lobe bronchus suggests a soft-tissue mass is abutting that airway. The intermediate stem line is formed by the posterior wall of the right main and intermediate bronchi.

- 7. What comprises the anterior junction line?
 - A. Thymus and ribcage
 - B. Anteromedial pleurae of both lungs
 - C. Pericardium and the pulmonary ligament
 - D. Visceral pleura

ANSWER: B. The anterior junction line is formed by the contact of the anteromedial pleural surfaces with each other, in the retrosternal space. The superior recess often shifts to the side of atelectasis as the other lung overinflates to compensate. The inferior recess is formed by the anteromedial surfaces of the lungs below the anterior junction line.

- 8. A blue dye is injected into the left posterolateral third intercostal vein. What is its most likely course?
 - A. Left supreme intercostal vein, to azygous vein, to left brachiocephalic vein
 - B. Left superior intercostal vein, to azygous vein, to left brachiocephalic vein
 - C. Left supreme intercostal vein, to accessory hemiazygous, to left brachiocephalic vein
 - D. Left superior intercostal vein, to accessory hemiazygous vein, to left brachiocephalic vein

ANSWER: D. The supreme intercostal vein generally drains the left first intercostal space; the 2nd-4th intercostal veins drain via the superior intercostal vein. The accessory hemiazygous vein drains both of these to the left brachiocephalic vein. The azygous vein drains the 5th-11th right intercostal veins and several other veins.

- 9. Regarding the diaphragm, which of the following is true?
 - A. It is embryologically derived from four different structures.
 - B. The septum transversarium forms the lateral muscle components.
 - C. The diaphragm is not very well supplied with lymphatic drainage.
 - D. The arterial supply is derived from two different arterial systems.

ANSWER: A. The diaphragm is derived from septum transversarium, pleuroperitoneal membranes, and two different body wall mesenchymes. The diaphragm is well-drained and even has pores allowing peritoneal fluid to enter the chest. The arterial supply is via the phrenic, intercostal, and internal thoracic arteries.

- 10. Which of the following nodal chains drains the esophagus?
 - A. Internal mammary
 - B. Prepericardiac
 - C. Posterior mediastinal
 - D. Juxtaphrenic

ANSWER: C. The internal mammary nodes are anterior parietal nodes and drain the upper anterior abdominal wall, the anterior chest wall, the anterior diaphragm, and medial breast tissue. The prepericardiac nodes drain the diaphragm and anterosuperior liver. The posterior mediastinal nodes drain the posterior diaphragm, pericardium, esophagus, and pulmonary ligaments. The juxtaphrenic group also drains the diaphragm and anterosuperior liver.

RADIOGRAPHIC INVESTIGATION

CONVENTIONAL RADIOGRAPHY

Conventional radiography is the cornerstone of chest diagnosis and should be the first step in establishing the presence of disease, with other modalities used to complement the radiograph.

PROJECTIONS

Posteroanterior (PA) and lateral projections are included in the most satisfactory routine examination. The patient should be standing.

Anteroposterior (AP) projection may be used if the patient cannot stand erect. It may be obtained seated or supine.

Lordotic projection can be either AP or PA. In lordotic AP projection, the patient may stand erect, and the x-ray tube is angulated 15-degrees cephalad; this is more reproducible than having the patient assume the lordotic position directly. This projection is helpful to improve the visibility of the apices, superior mediastinum, and thoracic inlet; to locate a lesion via parallax; and to identify the right minor fissure in patients who may have right middle lobe atelectasis.

Lateral decubitus projection requires the patient to lie on one side, and the beam is horizontal. The dependent hemithorax is generally the one being evaluated, so a radiolucent foam cushion or mattress should be placed under the patient's side. This projection is helpful for identification of small pleural effusions: a volume less than 100 mL may be visible in a lateral decubitus projection, whereas erect images may need a volume of 300 mL before visualization. It is also useful to demonstrate a change in an air-fluid level or determine whether part of the cavity is actually freely moving (such as a mycetoma).

Oblique projections are sometimes helpful to locate subtle nondisplaced rib fractures.

BASIC TECHNIQUES

The diagnostic accuracy of chest radiographs is partly dependent on the technical quality and reproducibility of the radiographs. Some basics like patient position are consistent across all radiographic systems (conventional, computed, or digital radiography), but others refer only to conventional imaging.

Patient positioning requires the patient to be centered and not rotated, and the scapulae rotated forward enough that they do not project over the lungs. On properly centered radiographs, the medial ends of the clavicles project equidistant from the margins of the vertebral column.

Patient respiration should be at total lung capacity and fully suspended.

Film exposure should allow faint visualization of the thoracic spine and the intervertebral discs in the PA projection and of the retrocardiac lung parenchyma. Exposure should be as short as possible so that motion is limited. Mild overexposure can be overcome with bright illumination but the decreased visibility in underexposed images cannot be compensated. PA chest radiograph skin radiation should not exceed 0.3 mGy and exposure time should not exceed 40 msec. The focal-film (source-image) distance should be at least 180 cm to minimize the effects of magnification.

Kilovoltage (kV) should be high enough to produce high-quality images. The linear-attenuation coefficients of bone and soft tissues are closer to one another at higher kV ranges, so that both bony and soft-tissue structures are both visible, and the opacity of the mediastinum is reduced so that the retrocardiac tissues and mediastinal reflections are visible. Pulmonary vessels and pulmonary nodules are more clearly visible than with low-kVp images. A range of 115 to 150 kVp is suggested for PA and lateral chest radiography.

Grids and filters help to improve image quality and/or reduce unnecessary radiation. The ACR recommends an aluminum 10:1 grid with 103 lines per inch. An air gap of 15 cm between the patient and the film reduces scatter and makes a grid unnecessary; however, a source-image distance of 10 ft should be used for this technique. A tunnel-wedge filter allows adequate exposure of the mediastinum and lung. A wedge filter equalizes the densities of the thin apical regions and the thicker basal regions and helps increase mediastinal exposure. It is constructed of copper foil to a maximum of about 0.3 mm, which also helps to reduce patient radiation exposure by about 30%. If the patient is not perfectly centered, filters may produce artifacts of attenuation.

SPECIAL TECHNIQUES

Inspiratory-expiratory radiography includes images obtained at total lung capacity and residual volume is indicated for evaluation of air trapping, whether focal or diffuse, and for suspected pneumothorax when the visceral-pleural line is not visible or when findings are equivocal.

Valsalva and Müller maneuvers forced expiration or inspiration, respectively against the closed glottis may help to determine whether a nodule is vascular or solid. The lung volumes must be about the same for the technique to be useful, usually around end of quiet inspiration. A change in size is consistent with a vessel; the absence of change does not change the differential considerations.

Bedside radiography is typically AP in positioning. It is inferior to standard radiography for many reasons, some of them uncontrollable. The patient is frequently supine; there is a short source–image distance; and many patients are unable to hold their breath or inspire to total lung capacity. In semierect or supine images, the source–image distance is often 100 to 125 cm and kVp is 80 to 100. A 6:1 or 8:1 grid significantly improves image quality but it is time consuming to properly position the grid to avoid artifact and most hospitals do not use them.

Because the patient is supine and the source–object distance is smaller, the mediastinum and heart are magnified as much as 15% to 20%, compared to the 5% magnification of PA radiographs. Similarly, technique differences alter interpretation of vascular prominence. Supine position increases pulmonary blood volume by 30%, and the normal dependence-gradient is shifted from craniocaudal to anteroposterior. Blood vessels, particularly the ones at the upper lobes, appear larger.

One study of bedside radiographs in intensive care unit patients over 2 months revealed that 65% of studies, even daily routine studies, resulted in new findings or changes affecting patient management, and 40% to 45% had at least one clinically unsuspected finding. However, unsuspected abnormalities leading to management change were present in 57% of pulmonary and unstable cardiac patients but only 3% of uncomplicated cardiac and miscellaneous groups.

DIGITAL RADIOGRAPHY

Digital radiography has several advantages over conventional screen-film systems. The exposure latitude is 10 to 100 times greater than the dynamic range of screen-film systems. The final image is almost independent on exposure levels (this may result in increased radiation dose if not monitored) and can be acquired in a much wider range of conditions. Electronic images are more easily portable and more easily manipulated. Two types are available: photostimulable storage phosphor and selenium-coated receptors.

PHOTOSTIMULABLE STORAGE PHOSPHOR SYSTEMS

These systems are known as computed radiography. The phosphor system replaces the film cassette. It has a wide

dynamic range of about 1:10 000 versus 1:100 for standard films, so bedside repeat studies due to poor penetration are decreased. The phosphor retains incident x-ray energy until it is “read” by a laser and converted to visible or infrared light. This luminescence is then recorded digitally. The overall image quality of photostimulable storage phosphor (PSP) radiographs is slightly less than that of film radiographs, and the decreased quantum efficiency of the phosphor technology requires equal or greater radiation dose for the same image.

SELENIUM DETECTOR SYSTEMS

These systems are known as digital radiography. The detector may be a selenium drum or a flat-plate selenium detector. The selenium detectors have greater quantum efficiency than film screen does, and the smooth selenium detector decreases intrinsic noise.

INDICATIONS FOR CHEST RADIOGRAPHY

The 1997 ACR standards for accepted medical indications (not necessarily billable but medically warranted) for chest radiography include the following: signs and symptoms related to the respiratory and cardiovascular symptoms; follow-up of previously diagnosed thoracic disease for the evaluation of improvement, resolution, or progression; staging of intrathoracic and extrathoracic tumors; preoperative assessment of patient scheduled for intrathoracic surgery; preoperative evaluation of patients with cardiac or respiratory symptoms or patients with a significant potential for thoracic pathology that may compromise the search for the result or lead to increased perioperative morbidity and mortality; and monitoring of patients with life-support devices and patients who have undergone cardiac or thoracic surgery or other interventional procedures.

INAPPROPRIATE

Cost-effectiveness analyses have determined that routine screening radiographs, obtained to satisfy admission requirements or before surgery, without medical indication or risk factor, are not cost-effective in patients younger than 20 years of age. Even in a high-risk VA population, though 36% of routine admission chest radiographs revealed abnormalities, only 4% of these changed patient management.

The 1997 ACR standards state that routine screening is not indicated in the following groups: routine screening of unselected populations, routine prenatal chest radiographs for the detection of unsuspected disease, routine radiographs solely because of hospital admission, mandated radiographs for employment, and repeated radiograph examinations on long-term facility admission.

CONVENTIONAL TOMOGRAPHY

Conventional tomography allows visualization of a particular selected depth and exclusion of structures superficial and deep to it. The x-ray tube and the film or detector moves reciprocally, causing blurring of all the structures not continuously in focus. The thin slice depth is determined by the ratio of the source–object and object–image distance. At most sites, conventional tomography has been replaced by CT.

CT

CT scanning allows planar imaging through the object of interest. The detailed mechanics and physics of CT scanning are beyond the scope of this review.

TECHNICAL PARAMETERS

Although scanner geometry and physical requirements produce some unalterable parameters, several parameters that affect image quality are operator-dependent. Detector thickness, image slice thickness, spacing, field of view, reconstruction algorithm, and window-level settings are selectable, as are pitch, tube current, and voltage potential.

IMAGE THICKNESS

The thicker the detector and/or the image slice, the more parenchyma is summed into a single image. High-resolution CT (HRCT) for evaluation of interstitial lung disease therefore uses very small detector thickness and reconstruction as low as 1 mm. Images obtained at 10-mm intervals exclude most of the lung parenchyma but allow accurate characterization of diffuse interstitial processes; with the advent of high-number multidetector row CT scanning, the entire chest may be scanned at submillimeter detector width and reconstructions obtained at 1- and 5-mm thicknesses.

FIELD OF VIEW

The field of view should be large enough to include the whole patient and the matrix size should be as large as possible. Using a 40-cm field of view with a 512×512 matrix results in a voxel size of 0.78 mm; a 25-cm FOV has voxel size of 0.49 mm.

RECONSTRUCTION ALGORITHM

Soft-tissue reconstruction algorithm smoothes the image and reduces image noise, but a high-spatial-frequency algorithm is required for assessment of the parenchyma; the technique sacrifices higher noise for better detection of interstitial abnormalities. The combination of a high-

spatial-frequency reconstruction algorithm with thin detector width constitutes the HRCT protocol.

WINDOW-WIDTH AND WINDOW-LEVEL SETTINGS

Air has a defined HU of -1000 , and water has a range of -20 to $+20$ HU. Lung evaluation is best at a window level of -600 to -700 HU and a window width of 1000 to 1500 HU. Window levels of 30 to 50 HU and widths of 350 to 500 HU provide good assessment of the mediastinum, hila, and pleura.

RADIATION DOSE

The average natural radiation exposure to a person in North America is around 3 mSv. The effective dose of a PA and lateral chest radiograph evaluation are 0.15 mSv. The effective dose of a chest CT is on the order of 8 mSv.

Technologies are variously in development, in testing, or in practice to limit radiation exposure. Rapidly varying the tube current with linear attenuation allows decreased current when the scanner is oriented more AP, because in most patients the AP dimension of the chest is less than the transverse dimension; similarly current can decrease when the radiation is penetrating mostly low-attenuation lung versus the denser mediastinum. Conventional CT is usually performed at 200 to 400 mAs, but depending on the indication image quality may be acceptable with time–current levels as low as 20 to 40 mAs. The images have increased noise but this may not necessarily reduce diagnostic quality (e.g., evaluation of metastatic lung nodules). Cardiac gating, either prospective or retrospective, significantly decreases radiation exposure without sacrificing image quality in selected studies.

COMMON INDICATIONS FOR CHEST CT

Evaluation of Suspected Mediastinal Abnormalities Identified on Chest Radiograph

CT can differentiate solid from cystic, localizes masses, and can determine the tissue-type and enhancement characteristics of a lesion. CT can distinguish variable vascular anatomy from mediastinal mass.

Search for occult thymic lesions: Thymoma or thymic hyperplasia in patients with myasthenia gravis may be inapparent.

Determination of the Presence and Extent of Neoplastic Disease

Occult lung metastasis can be detected before surgery in cancers with high propensity for metastasis or when chest radiograph reveals a solitary nodule. Primary neoplasms can be detected with greater sensitivity in patients with positive sputum cytology and negative bronchoscopy. Mediastinal, pleural, osseous, muscular, and

subcutaneous involvement can be detected and spinal invasion characterized.

Search for diffuse or central calcification in a pulmonary nodule: The calcification pattern in a pulmonary nodule can suggest benignity, malignancy, or indeterminance.

Diagnosis of Bronchiectasis

CT allows greater anatomic visualization of the type, course, and distribution of bronchiectasis as well as any associated abnormalities including intraluminal lesion, fibrotic parenchyma, or others.

Detection of Parenchymal Lung Disease

Patients with symptoms or pulmonary function abnormalities suggesting lung disease but normal or equivocal chest radiographic findings can be assessed with CT.

Differential Diagnosis of Diffuse Lung Disease

HRCT can assess patients whose clinical radiographic findings do not provide a confident etiologic diagnosis and in whom further radiographic evaluation is warranted. This includes chronic interstitial and airspace disease and immunocompromised patients with acute parenchymal abnormalities.

Evaluation of Acute or Chronic Cardiovascular Abnormality

CT can accurately evaluate the presence or absence of pulmonary embolism, aortic dissection or aneurysm, and in some institutions coronary–arterial disease, as well as stricture, abnormal course, malformation, or other characteristics. In some institutions, CT can serve as an adjunct to sonography or catheter angiography for evaluation of congenital or acquired heart disease.

Many Other Potential Indications Exist

Others include guidance of percutaneous biopsy; localization of loculated collections after radiographic or ultrasonic techniques prove inadequate.

MAGNETIC RESONANCE IMAGING

PHYSICAL PRINCIPLES

In quantum physical terms, an atomic nucleus has a net “spin” when it contains an unpaired proton or neutron. The spin has a magnetic moment, so when the nucleus is exposed to a magnetic field, it experiences a small torque. Its axis of spin will align with the field direction, and it will rotate at a particular resonant frequency determined by the field strength and the gyromagnetic ratio for that atom. If a pulse of radiofrequency (RF) energy is at exactly the same frequency as the resonant frequency (known as the Larmor frequency), an interaction will occur. The RF

pulse changes the nucleus from an equilibrium state to an excited state that will naturally decay back to the equilibrium state with time. As the nucleus relaxes back to equilibrium, it radiates at the Larmor frequency, the energy it acquired during excitation. This energy can be detected with receiver coils. The nucleus currently used most frequently is that of hydrogen: a single proton.

RELAXATION TIMES

T1 RELAXATION

T1 is the time constant corresponding to restoration of magnetization parallel to the external field, also known as spin–lattice or longitudinal relaxation time. In a pure liquid, the recovery is exponential: after three T1 periods 95% of the nuclei will have returned to equilibrium. T1 relaxation time is generally long for fluids and some proteins and shorter in fat.

T2 RELAXATION

T2 is the time constant corresponding to decay of magnetization perpendicular to the external field, also known as the spin–spin relaxation time. Subtle focal field–strength variations cause the nuclei to spin at slightly different rates and become dephased, eventually with a net signal strength of zero. Nuclei are rephased for measurement. As variability of local magnetic field strength is the determinant of dephasing, T2 times are typically long for homogeneous environments like fluid, and shorter for complex tissues.

BASIC PULSE SEQUENCES

SATURATION RECOVERY

This sequence is composed of two 90-degree pulses separated by a short time TR, shorter than T1 but longer than T2. The T1 signal is dependent on the extent of parallel relaxation that has occurred over the time TR.

INVERSION RECOVERY

This sequence uses a 180-degree pulse to invert the net magnetization, after which the nucleus reverts to equilibrium at a rate determined by its T1 constant. The residual net magnetization can be measured after the magnetization is deflected and made coherent by a 90-degree pulse. The amplitude of the signal depends on the inversion time interval (between the 180- and 90-degree pulses) and the nucleus’s T1 constant.

SPIN ECHO

These sequences use a 90-degree pulse to rotate the net magnetization into a plane perpendicular to the external

field. The nuclei are initially phase-coherent, but begin to dephase because of local field inhomogeneities. At time $TE/2$, a 180-degree pulse refocuses the nuclei and generates an echo at time TE . This is used to determine $T2$ without contamination from field inhomogeneity effects.

T1 weighting—In spin-echo sequences, the 90-degree pulses are separated by time TR . Short repetition times allow distinction of tissues with different $T1$ constants, called $T1$ -weighted sequences. A TR for a $T1$ -weighted sequence in a 1.5 T magnet may be 600 to 1000 msec.

T2 weighting—The signal decays at a rate dependent on $T2$ relaxation time. To distinguish tissues with different $T2$ characteristics a long TE typically over 80 msec is used and to maximize $T2$ effects and minimize the effects of $T1$ relaxation, $T2$ -weighted images have long TR intervals, perhaps 2000 to 3000 msec.

Proton density weighting—Often a double-echo sequence is obtained, in which a long TR is used with both a short TE (20 msec or less) and a long TE (80 msec or more). The short TE signal is proton density, dependent primarily on relative water content. This has the best signal-to-noise ratio but limited contrast resolution.

Other pulse sequences allow visualization of flowing blood, three-dimensional imaging, and a variety of techniques to remove signal from fat, water, or silicon. In addition, fast or turbo sequences make use of multiple echo trains per TR to increase the filling of K -space and decrease dramatically the time required per image.

ADVANTAGES OF MRI

There is no ionizing radiation. The magnetic fields may be aligned in any direction, allowing imaging along any axis (though with the advent of isovolumetric CT this advantage is reduced). Flowing blood in vessels has intrinsic contrast. Soft-tissue contrast is greatly increased.

DISADVANTAGES OF MRI FOR CHEST IMAGING

Respiratory and cardiac motion can degrade images, though with respiratory triggering and cardiac gating this is reduced. Lung parenchyma has low signal-to-noise ratio because of low parenchymal proton density. Innumerable air–water interfaces produce susceptibility gradients in inflated lung, so signal is lost by the time conventional $TE = 20$ -msec imaging. Ultrashort TE gradient-echo sequences and short- TE (7 msec or less)

spin-echo sequences can increase the signal: noise ratio in aerated lung by a factor of 3.5.

INDICATIONS

EVALUATION OF THE HEART AND GREAT VESSELS

MR has a well-established role in evaluating congenital cardiovascular anomalies and is superior to echocardiography in evaluation of adult congenital heart disease. It is usually reserved for patients with equivocal or no diagnostic echocardiography, though. It allows excellent evaluation of central pulmonary arteries, cardiac wall motion and blood flow, valvular stenosis or insufficiency, and enhancement characteristics. MR is not as good as CT in evaluating aortic aneurysm and dissection, particularly arch–vessel involvement, though if a patient cannot receive iodinated contrast material, a MR has much higher contrast resolution even without gadolinium than an unenhanced CT.

EVALUATION OF THE MEDIASTINUM AND HILA

MR is a good secondary modality if CT evaluation is equivocal and is superior in evaluation of cancerous invasion of the mediastinum or vessels. It can help to diagnose bronchogenic cysts if the diagnosis is in doubt after CT.

EVALUATION OF THE CHEST WALL

Primary chest wall tumors and chest wall extension of lymphoma can be well evaluated, as can extension of lung cancer. MR also is a good modality for evaluation of neurogenic tumors and paraspinal lesions since it has good tissue-characterization ability and can evaluate the extent of intraforaminal spread.

EVALUATION OF THE LUNG PARENCHYMA

MR has limited role in parenchymal evaluation but can be helpful in evaluation of chronic interstitial and alveolar disease, determination of lung water content, distinguishing of postobstructive atelectasis from nonobstructive atelectasis, and evaluation of mass lesions within opacified hemithorax.

BRONCHOGRAPHY

Bronchography was once used to evaluate the presence and extent of bronchiectasis, but now that CT and HRCT provide excellent information the procedure has been largely abandoned. It carried the risk of allergy to the bronchographic medium, and temporarily impaired ventilation and diffusion. A variation, fiberoptic bronchography using isosmolar nonionic contrast material, may still be useful in evaluating

patients with recurrent hemoptysis in whom CT is normal or equivocal.

CATHETER ANGIOGRAPHY

Many cases that were historically evaluated with angiography of one vascular territory or another now undergo CT angiographic evaluation. However, catheter angiography still has a role to play, as the resolution of CT angiography is far inferior to catheter angiography; in most cases temporal information (such as direction of flow) is not available, and of course no intervention can be performed with CT angiography as is possible with catheter-based procedures.

PULMONARY ANGIOGRAPHY

TECHNIQUE

Pulmonary angiography can be performed via arm venous injection, via catheter injection into the venous system, right heart, or main pulmonary artery, or by selective right and left pulmonary artery or branch injection; the latter is the method of choice because vascular opacification is much better.

COMPLICATIONS

Complications include cardiac perforation, endocardial and myocardial injury, reversible cardiac or respiratory arrest, and cardiac arrhythmia. Incidence is low, less than 1%. Minor complications include treatable arrhythmia, vasovagal syncope, chest pain, and contrast reaction.

INDICATIONS

Indications classically included detection of pulmonary vascular congenital abnormalities or investigation of thromboembolic disease. As mentioned above, CT angiography has replaced many of these cases.

AORTOGRAPHY

TECHNIQUE

Direct catheterization of the thoracic aorta percutaneously via either the femoral or the brachial artery is the method of choice. Venous injection followed by digital-subtraction angiography is possible but not often used.

COMPLICATIONS

Complications include aortic dissection, plaque embolization, and other catheter-related problems.

INDICATIONS

Indications classically included evaluation of mediastinal injury and evaluation of congenital vascular anomalies.

CT and CT angiography have greatly reduced both of those.

BRONCHIAL AND INTERCOSTAL ARTERIOGRAPHY

TECHNIQUE

Only selective catheterization, usually via femoral-arterial access, allows good opacification of the small vessels. The bronchial arteries arise from the posterolateral aortic wall at around T5 or T6 in 80% of patients, so the catheter is brought to this level and selective catheterization proceeds.

COMPLICATIONS

Complications include damage to the artery of Adamkiewicz, which commonly arises from the aorta around T8-T12, but in 5% of cases arises from the right intercostal-bronchial trunk. Such damage can lead to spinal cord ischemia and transverse myelitis.

INDICATIONS

Indications include evaluation of hemoptysis when radiographic and CT evaluation are negative or equivocal and for percutaneous embolization of life-threatening bronchial-artery bleeding.

RADIONUCLIDE IMAGING

VENTILATION-PERFUSION SCANNING

Perfusion imaging should detect over 90% of occlusive clots in vessels over 2-mm diameter. It is sensitive but not specific, as virtually all parenchymal lung disease can cause decreased pulmonary-arterial blood flow; however, PTE causes mismatched defects, whereas many other lung diseases cause matched defects.

TECHNIQUE

The perfusion and ventilation studies require different radiotracers and techniques.

Perfusion images are acquired after Tc-99m labeled human albumin microspheres (HAM) or Tc-99m-labeled macroaggregated albumin (MAA) is infused via a systemic vein over 5 to 10 respiratory cycles with the patient supine. MAA particles are 90% within 10 to 90 μm , and HAM particles are 35 to 60 μm ; these pass through the pulmonary arterial system until they lodge in precapillary arterioles in proportion to the blood flow to that region.

A 2- to 4-mCi radiopharmaceutical, approximately 200 000 to 500 000 particles, is injected, enough to block about 0.1% of a patient's precapillary arterioles. The number injected should be reduced in patients with

pulmonary hypertension, patients with right-to-left intracardiac or intrapulmonary shunts, children, pregnant patients, and in patients with prior pneumonectomy or single-lung transplant, but the number should not be below 60 000 particles.

When performed to evaluate pulmonary perfusion at least six views should be obtained: anterior, posterior, right lateral, left lateral, and right- and left-posterior oblique.

Ventilation images may be acquired using Xe-133 inhalation, Kr-81m, Tc-99m aerosols, or other gaseous radiotracers.

Xe-133 imaging requires that the ventilation image is obtained first, because of the radionuclide's low-energy photons. A volume of 550 to 770 Mbq (15–20 mCi) is inhaled, then a posterior wash-in image is obtained. Subsequently equilibrium images are obtained while the patient recreates the gas over 4 minutes, followed by serial washout images. Regional air trapping is visible as residual activity during washout.

Xe-127 has higher energy than Tc-99m so ventilation imaging may follow perfusion imaging; this is good because if the perfusion study is normal the ventilation study need not be performed, and if the perfusion study is abnormal the patient can be positioned to highlight the region of the abnormality in the ventilation study. It is more expensive and requires medium-energy collimation.

Kr-81m has a physical half-life of 13 seconds so only washing or breath-hold images can be acquired; however, multiple projections can be obtained. It is expensive and produced from a Rb-81 generator, which itself has a useful half-life of only 1 day. Imaging is typically obtained after perfusion imaging.

Tc-99m *aerosols* (DTPA, sulfur colloid, pyrophosphate, ethylene diphosphate, or glucoheptanate) are 0.5 to 3 μm in size. Tc-99m DTPA has a short residence time in smokers so sulfur colloid or pyrophosphate may be more useful. 30 mCi of the tracer is given via nebulizer and the patient typically acquires 1 mCi in the lungs. Images are generally done before perfusion, and multiple projections can be acquired. These agents require little patient cooperation and can be given to intubated patients; the agents may deposit in the central airways in patients with airway obstruction and most of the dose remains in the nebulizer.

Tc-99m technegas and Tc-99m pertechnegas are produced by burning Tc-99m pertechnetate at high temperature in a carbon crucible, leading to 0.02 to 0.2 μm aerosolized particles. Pertechnegas is purged in 95% argon/ 5% oxygen, whereas technegas is purged in 100% argon. Both agents distribute homogeneously according to ventilation distribution with very little central deposition even in patients with COPD. At that point, pertechnegas can easily penetrate the alveolar membrane and biologic

half-life is 6 to 10 minutes; conversely, technegas has little alveolar penetration or mucociliary clearance, and the effective half-life is essentially the same as the physical half-life, about 6 hours. These agents require little patient cooperation, and require only 2 to 3 breaths to get sufficient activity into the lungs. Imaging is obtained before perfusion imaging, and multiple projections can be obtained.

INDICATIONS

Indications classically included diagnosis and follow-up of acute PTE and prediction of pulmonary function after surgery. The former has largely been supplanted by CT angiography except in certain instances, but the latter remains important. An expected postoperative FEV-1 less than 0.8 L or 35% of predicted generally precludes lung resection.

GALLIUM-67 CITRATE LUNG SCANNING

PHYSICAL PROPERTIES

This radiopharmaceutical is the agent of choice for lung inflammation and infection. Gallium is a ferric analogue that rapidly binds to the acute-phase reactant transferrin; the exact mechanism of radiotracer accumulation at sites of inflammation is uncertain, however. Ga-67 has a physical half-life of 78 hours, and the optimum time to image is after 48 to 72 hours after administration. It is taken up by normal reticuloendothelial tissues, inflammatory processes, and, notably, lacrimal glands.

GRADING

The intensity and distribution of radiotracer can be used to quantify inflammation on a 5-point system (grades 0–4): less than soft-tissue activity, equal to soft-tissue activity, more than soft-tissue but less than liver, equal to liver, and greater than liver. Multiplying the grade of uptake by the area of lung involved yields the gallium index.

IMAGING FINDINGS

In general, Ga-67 citrate radiotracer avidity is a sensitive but nonspecific indicator of inflammatory activity. Gallium-67 scan may be “hot” in conditions ranging from pneumonia to ARDS to drug reactions (such as busulfan, cyclophosphamide, amiodarone, lymphangiography contrast); pneumoconiosis; interstitial pulmonary fibrosis (IPF); sarcoidosis, uremic pneumonitis and neoplasms including lymphoma, leukemia, mesothelioma, or metastatic cancer can be radiotracer avid as well.

In sarcoid, the study produces typical findings of bilateral hilar and right paratracheal lymphadenopathy (the lambda sign), but areas of lung involvement may also be avid. This correlates with response to therapy.

In IPF, gallium imaging does not predict activity, prognosis, or response to therapy and is not recommended.

In lymphoma, high-dose Ga-67 scanning can evaluate mediastinal disease, both in Hodgkin and in non-Hodgkin types.

In immunocompromised hosts, Ga-67 is more sensitive to inflammatory processes than chest radiography. In particular, parenchymal radiotracer activity in a patient with HIV and normal chest radiograph suggests *P. carinii* pneumonia; CMV or cryptococcal infection or lymphoma may produce similar findings. Regional radiotracer uptake may be because of PCP, lymphoma, or bacterial pneumonia. Focal activity combined with regional lymph node uptake is suggestive of *M. avium-intracellulare* or *M. tuberculosis* infection. Kaposi sarcoma is not Ga-67 avid but does take up Tl-201 chloride.

POSITRON EMISSION TOMOGRAPHY

PRINCIPLES

PET imaging is based on the principles of matter-antimatter annihilation. Many tracers exist, but the most common is 18-fluoro-deoxyglucose. The tracer is taken up by cells in proportion to their metabolic activity and phosphorylated; the phosphorylated FDG-6-phosphate metabolite cannot be further metabolized and cannot exit the cell. The 18-F atom decays by positron emission, and the created positron travels a short distance (1–2 mm) before it comes to rest and annihilates an electron. This event releases two 511-keV photons at nearly 180 degrees from one another, which can be detected. Images can be reconstructed from this data. Resolution in dedicated PET scanners is about 3 mm at best. Many, if not most, PET scanners are part of combined PET-CT scanners, allowing high-resolution anatomic imaging localization of metabolic activity.

INDICATIONS

Characterization of solitary pulmonary nodule is often possible; FDG-PET is 80% to 100% sensitive and 50% to 97% specific for the distinction of malignant from benign. Active inflammation, such as sarcoid, tuberculosis, or aspergillosis, can present false-positive findings.

Mediastinal staging of non-small cell lung cancer is more accurate than CT in many instances.

Differentiation of scar and recurrent tumor in patients with prior lung cancer is possible based on metabolic imaging: the sensitivity and specificity of FDG-PET for detecting tumor versus scarring are 97% and 100%, respectively.

Other indications including staging and/or restaging of multiple neoplasms that metastasize to the chest are

also possible, and metabolic imaging remains an area of active inquiry.

ULTRASOUND OF THE CHEST

PRINCIPLES

Ultrasonography produces images based on the transmission of high-frequency sound beams through tissue and evaluation of reflection at impedance changes. Sonography is portable, does not use ionizing radiation, and frequently provides useful information. It is most useful in evaluation of congenital and acquired heart disease, particularly valve morphology, chamber volume, wall thickness, and ejection fraction. Pericardial effusion may be easily evaluated. Transesophageal sonography can evaluate the aorta and the left atrium.

Ultrasonography can evaluate the pleura, diaphragm, and infradiaphragmatic processes, but because air and bone do not transmit sound well, parenchymal evaluation is limited to assessment of masses or consolidation abutting mediastinum, chest wall, or diaphragm.

INDICATIONS

Assessment of Pleural Effusions and Distinction of Effusion from Solid Pleural Thickening

Ultrasound is helpful; differentiating solid from liquid is difficult in a radiograph, but easy with sonography. Septations, homogeneous echogenicity, or complexity suggests exudate.

Assessment of the Diaphragm and Peridiaphragmatic Masses

Ultrasound allows evaluation of small effusions, distinction of peridiaphragmatic masses and collections, detection of right-hemidiaphragmatic tears (via transhepatic imaging), and analysis of diaphragm function. The left hemidiaphragm is often obscured by bowel gas, however.

Guidance for Needle Biopsy and Catheter Placement

Ultrasound allows reduced complications and greater positional accuracy for lesions in contact with the chest wall or diaphragm.

in slight Trendelenburg position decreases the volume required for an effusion to be visible, but this is not required. It is useful for evaluating air-fluid levels, effusions, and contents of cavitory lesions; lordotic projection would be useful for apical evaluation. Lateral-decubitus imaging may visualize an effusion as small as 100 mL.

2. What is the benefit of high over low kVp?
 - A. The linear-attenuation coefficients of bone and soft tissue are more widely separated.
 - B. Pulmonary vessels are more visible.
 - C. Opacity of the mediastinum is increased, allowing better imaging of pleural reflections.
 - D. It uses higher mAs.

ANSWER: B. The linear-attenuation coefficients of bone and soft tissue are closer together with high kVp, so they are both visible in a single exposure. Pulmonary vessels and nodules are easier to see. The mediastinum is less opaque, allowing visualization of the retrocardiac tissues and pleural reflections. It results in less total radiation exposure and uses lower mAs.

3. Regarding the mediastinum in radiography, which of the following is *true*?
 - A. AP radiography typically magnifies the heart by 15% to 20%.
 - B. A longer source-object distance results in greater magnification, with all other variables constant.
 - C. PA radiography does not magnify the heart.
 - D. Upper lobe vessels are typically larger in PA studies than in supine AP studies.

ANSWER: A. AP radiography uses a shorter source-object distance and places the heart further from the detector, so the heart is magnified by 15% to 20%. A longer source-object distance results in less magnification if all else is kept the same. PA radiography does magnify the heart, but much less than AP radiography, approximately 5%. Upper lobe vessels are enlarged in AP studies because supine positioning increases venous return and alters the normal gravity-dependent gradient.

QUESTIONS AND ANSWERS

1. Which of the following is *true* regarding lateral decubitus projection?
 - A. The patient is supine and the beam is shot laterally parallel to the floor.
 - B. The patient is in Trendelenburg.
 - C. It is useful for evaluating the lung apices.
 - D. A pleural effusion of 150 mL would generally be visible on an adequate radiograph.

ANSWER: D. The patient is decubitus and the beam is shot parallel to the floor. Placing the patient

4. Which of the following, on its own, is an accepted medical indication for chest radiography?
 - A. Staging of extrathoracic tumors
 - B. Prenatal evaluation of unsuspected disease
 - C. Hospital admission
 - D. Before employment

ANSWER: A. Chest radiography is indicated for a wide variety of medical reasons including tumor staging. The ACR does not consider as medical

indications the routine screening of unselected patient populations, prenatal chest radiographs for the detection of unsuspected disease, radiography solely for hospital admission, preemployment radiography, or repeat radiograph examinations on long-term facility admission.

5. How many PA and lateral chest radiograph evaluations would be required to equal the average North American background radiation exposure?
 - A. 2
 - B. 20
 - C. 200
 - D. 2000

ANSWER: B. The average North American background radiation exposure is 3 mSv. The effective dose of a PA and lateral chest radiograph evaluation is 0.15 mSv.

6. A MR sequence uses a 180-degree pulse followed by a 90-degree pulse. What is this?
 - A. Saturation–recovery
 - B. Inversion–recovery
 - C. Spin-echo T1
 - D. Spin-echo T2

ANSWER: B. Saturation–recovery sequences consist of two 90-degree pulses separated by a short TR. Inversion recovery sequences consist of a 180-degree pulse to invert the net magnetization, followed by a 90-degree pulse to deflect and cohere the magnetization. Spin-echo T1 uses a 90-degree pulse followed by a 180-degree pulse at TE/2, with short TE and short TR. Spin-echo T2 uses the same 90-degree and 180-degree pulses but uses long TE and long TR.

7. Which of the following is *true* regarding nuclear ventilation–perfusion imaging?
 - A. The perfusion agent is typically 100 μ m and blocks 4% of precapillary arterioles.
 - B. Xe-133 imaging is performed before a perfusion study because of its low-energy photons.
 - C. Tc-99m DTPA aerosols are specifically indicated in patients with COPD.
 - D. An expected postoperative FEV-1 less than 1.5 L generally precludes resection.

ANSWER: B. The perfusion agent is typically 10 to 90 μ m (MAA) or 35 to 60 μ m (HAM), and the particles occlude only about 0.1% of the patient's precapillary arterioles. Xe-133 has a low-energy photon so ventilation study with this agent must be done first; if not, down scatter from Tc-99m perfusion agent will obscure the results. Tc-99m DTPA has a short residence time in smokers and may deposit in

the central airways, so sulfur colloid, pyrophosphate, technegas, or pertechnegas would be better.

8. Regarding gallium-67 citrate scintigraphy, which of the following is *true*?
 - A. Imaging in interstitial pulmonary fibrosis predicts activity but not prognosis.
 - B. Imaging in lymphoma is not possible with Hodgkin disease.
 - C. The intensity and distribution can be quantified with the gallium index.
 - D. Chest radiography is more sensitive in immunocompromised patients.

ANSWER: C. Imaging in IPF does not predict activity, prognosis, or response to therapy and is not recommended. Gallium imaging works with both Hodgkin and non-Hodgkin lymphoma. The intensity of uptake can be graded on a five-point scale, and the intensity multiplied by the area of activity to reach the gallium index. In immunocompromised patients, Ga-67 imaging is more sensitive for the detection of inflammatory processes.

9. Regarding chest FDG-PET, which of the following is *true*?
 - A. PET is 80% to 100% sensitive but 25% specific for characterization of pulmonary nodule.
 - B. PET is not as accurate as CT for mediastinal staging of non–small cell lung cancer.
 - C. PET sensitivity and specificity for detection of tumor versus scar are 97% and 100%.
 - D. Lung parenchyma is attenuating to the 511-keV protons produced in the decay.

ANSWER: C. PET is 80% to 100% sensitive and 50% to 97% specific for pulmonary nodule characterization and is more accurate than CT for detection of mediastinal involvement in non–small cell lung cancer. PET sensitivity and specificity for detection of tumor versus scar are 97% and 100%. Lung parenchyma is quite nonattenuating because the volume is mostly air.

10. Which of the following is *not* an indication for chest sonography?
 - A. Assessment of intraparenchymal lung abscess in aerated lung
 - B. Assessment of traumatic right diaphragm injury
 - C. Assessment of loculated pleural effusion
 - D. Guidance for biopsy of a pleural-based mass

ANSWER: A. The sound beam cannot penetrate aerated lung so the abscess would be invisible. If the lung were collapsed or the lesion abutting the pleura it would be accessible for evaluation. The right

diaphragm can be imaged via a transhepatic window. Loculated pleural effusion evaluation is a good indication for sonography: septations, homogeneous echogenicity, or complexity suggests exudates. Pleural-based masses may be imaged sonographically, reducing complications and increasing positional accuracy compared to non-image-guided biopsy.

18 CONGENITAL THORACIC ANOMALIES

John C. Texada and Satinder P. Singh

Developmental anomalies of the airways and lungs are probably caused by interference with the embryonic, pseudoglandular, and canalicular periods of lung development.

PULMONARY AGENESIS, APLASIA, AND HYPOPLASIA

In agenesis, there is no trace of bronchial, vascular, or parenchymal tissue; in aplasia, there is only a rudimentary bronchus ending in a blind pouch, with no parenchyma or vascular tissue; and in hypoplasia, the lung is grossly normal but there are fewer or smaller airways, vessels, and alveoli. The first two are closely related; the last is often associated with or the result of other anomalies. Patients may die in childhood, particularly those with agenesis, though many patients survive to adulthood. The abnormalities predispose to infection and in neonates to pneumothorax.

AGENESIS/APLASIA

Unilateral agenesis occurs in 1:10 000 people; men and women are equally affected, as are the right and left sides. It has been associated with chromosomal anomalies and with malformations of chest wall, skeleton, or ipsilateral face, suggesting genetic or arch-developmental etiologies respectively. Bilateral agenesis can be associated with tracheoesophageal anomalies, suggesting primary lung bud defect.

PRIMARY HYPOPLASIA

Primary hypoplasia (without an additional causative abnormality) occurs in 1 to 2:12 000 people. Its etiology is uncertain. A hypoplastic lung is typically smaller and less developed than a normal lung and often has 50% to 75% the normal number of airway generations, leading to alveolar count one-third normal. It is often associated with anomalies of ipsilateral pulmonary arteries and anomalous pulmonary venous drainage (hypogenetic lung syndrome).

SECONDARY HYPOPLASIA

Secondary hyperplasia may be due to decreased hemithoracic volume, pulmonary vascular hypoperfusion, decreased fetal respiratory movement, and decreased lung fluid. Other miscellaneous associations include Rh isoimmunization; anencephaly/hydranencephaly; multiple congenital syndromes including Down, Klippel-Feil, Wolcott, Rallison, Matthew-Wood, and Fryns; and other abnormalities.

Decreased hemithoracic volume is the most frequent of these. The most common cause is the presence of a space-occupying mass—often congenital diaphragmatic hernia with thoracic abdominal contents, but sometimes neuroblastoma, sequestered lung, accessory diaphragm, or pleural effusion, and occasionally large intra-abdominal masses or collections.

Decreased pulmonary vascular perfusion is proposed as a mechanism to explain unilateral hypoplasia in some patients with tetralogy of Fallot.

Decreased fetal respiratory movement such as from cord injury or phrenic nerve injury can cause hypoplasia in experimental animals and may have similar effects in people.

Decreased lung fluid such as from oligohydramnios produces hypoplasia in one of two ways. First, lung fluid exerts a positive pressure on the developing lungs. Second, Potter syndrome of renal agenesis, abnormal facial and limb development, and pulmonary hypoplasia may be caused by compression by an oligohydramniotic uterus or some other mechanism.

RADIOGRAPHIC FINDINGS

Aplasia and hypoplasia of the lung appear radiographically similar—absence or near-absence of aerated lung on one side or the other. Ipsilateral ribs are closer together, the ipsilateral diaphragm is elevated, and the mediastinum is shifted. The normal lung is

generally hyperinflated and extends into the other hemithorax.

CT FINDINGS

CT can detect the bronchovascular deficiencies associated with aplasia, or conversely in hypoplasia, CT can reveal the patent bronchovascular structures and lung hypoplasia. To differentiate from Swyer-James syndrome, imaging may reveal air trapping in that syndrome but not in hypoplasia.

Main differential is pneumonectomy performed in early childhood, total atelectasis, severe bronchiectasis with collapse, and advanced fibrothorax.

BRONCHOPULMONARY SEQUESTRATION

A portion of lung tissue is detached from the normal lung and receives blood supply from a systemic artery. The abnormality may be due to anomalous systemic artery exerting traction on a bronchial bud, to failure of normal pulmonary–arterial development, to coincidence, to interference with embryonic organization, or, the favored explanation, to persistence and localized development of anomalous separate branch that retains embryonic blood supply.

The abnormality may be intralobar or extralobar, differentiated by the absence or presence, respectively, of its own visceral pleural membrane. Intralobar sequestration is typically contiguous with normal lung (in the same pleura); extralobar sequestration is generally close to normal lung but may be in or below the diaphragm.

INTRALOBAR SEQUESTRATION

Intralobar sequestration is three-fourths of all sequestrations. Arterial supply is generally the descending aorta; though abdominal aorta, branch artery, or coronary artery origins have been reported. Venous drainage is generally normal, that is, via pulmonary veins, so a left-to-left shunt forms. The anomalous artery often enters via the pulmonary ligament and is often bigger than it should be, sometimes aneurysmal; it may supply only the sequestered tissue or some normal tissue as well.

In two-thirds of cases, the sequestered tissue is in the left lower lobe posterior segment, in the paravertebral gutter. In most of the remainder, it is in the same position on the right. In the uncommon event of upper lobe

sequestration, the arterial supply may be from the ascending aorta or arch vessels or their branches and cardiac anomalies are common. Intralobar sequestration is associated with other anomalies in 15% of cases, most commonly diaphragmatic hernia, but also other skeletal and cardiac anomalies.

The sequestered tissue is typically well demarcated and contains cysts resembling dilated bronchi that may contain mucus or pus. It may or may not connect to the normal bronchi; if connected, there is often infection both in the sequestration and in the adjacent lung.

RADIOGRAPHIC FINDINGS

The most common finding is a homogeneous density in a posterior basal lower lobe, usually the left, usually contiguous with the diaphragm; it may appear as a cystic mass or prominent vessels. The adjacent normal lung parenchyma's arteries and veins are displaced around the sequestration. If infected there may be air or air-fluid-containing cysts; the adjacent normal tissue is also often infected obscuring the lesion.

OTHER IMAGING FINDINGS

Calcification is rare, but visible in CT. CT may better visualize cysts, venous drainage, and other anomalies than can radiography. Catheter angiography, CT, or MR with or without angiography makes the diagnosis via imaging of the anomalous systemic arterial supply; however CT or MR may miss small vessels. HRCT may image small air-containing cysts.

EXTRALOBAR SEQUESTRATION

Extralobar sequestration, less common, than intralobar sequestration, is left sided in 90% of cases and may be beneath the left lower lobe, in or beneath the diaphragm, or in the mediastinum or retroperitoneum. The tissue will have its own pleura, generally have few airways, and may have cystic spaces. Since it has no connection to other airways, it generally does not become infected unless it communicates with the GI tract, and thus is often incidentally found during evaluation of other anomalies. It is most often discovered in newborns and often is associated with other anomalies; ipsilateral diaphragmatic paralysis or eventration is present in 60% and left diaphragmatic hernia is present in 30%. Pulmonary hypoplasia may be present if the sequestration is large.

Systemic arterial supply is commonly from the abdominal aorta or its branches; often multiple small arteries are present. Venous drainage is usually via systemic veins—vena cava, azygous or hemiazygous veins, or portal veins, resulting in a left-to-right shunt.

RADIOGRAPHIC FINDINGS

A sharply defined triangular opacity or small bump at the posterior costophrenic angle is the most common finding, usually at the left hemidiaphragm. It may appear as a mass elsewhere.

OTHER IMAGING FINDINGS

CT will reveal a homogeneous mass occasionally with cystic spaces, often with hypoattenuation in the surrounding normal lung. Conventional CT is less useful for identifying the sometimes multiple arterial feeding vessels, but CT angiography may be more useful. Aortography may be required.

BRONCHOGENIC CYSTS

There are three types of foregut cysts, based on presumed tissue derivation: paravertebral (enteric) cysts, foregut that has herniated through the notochord, often associated with spinal defects; esophageal cysts, from failure of the esophagus to canalize completely; and bronchogenic cysts, from abnormal tracheobronchial budding.

Bronchogenic cyst probably develop between days 26 and 40 of development; earlier problems lead to mediastinal cysts, while later problems lead to more peripheral lung cysts; 65% to 90% are mediastinal. Bronchogenic cysts are more commonly found in males and in Yemeni Jews. They are typically incidentally detected, though infected cysts can cause hemoptysis or typical infection symptoms, rarely pneumothorax, air embolism, or cancer can develop.

Bronchogenic cysts are generally solitary unilocular thin-walled round lesions filled with mucus or serous fluid. They generally do not connect to the tracheobronchial tree unless they become infected. The presence of cartilage, smooth muscle, and glandular tissue in the walls helps to confirm the diagnosis.

A mediastinal bronchogenic cyst may be classified as paratracheal, carinal, hilar, paraesophageal, or miscellaneous (thymic, pericardial, or vertebral body surface). Paratracheal and carinal origins are the most common. They are almost always solitary. They typically are

asymptomatic but if a mediastinal bronchogenic cyst abuts an important structure, pressure effects may become apparent even if the cyst is small.

RADIOGRAPHIC FINDINGS

Typically, a bronchogenic cyst will appear as a well-circumscribed round or oval mass or nodule, usually in the medial one-third of the lungs, and more commonly in the lower lobes; right and left are affected equally. If followed radiographically, they typically do not change much with time. Since they do not connect to the airways unless infected (the presentation for 75% of cases recognized clinically), they should not contain air. Once infected they may contain air and may be surrounded by inflamed parenchyma. They may enlarge, once air filled, by a check-valve mechanism. The main differential considerations would be postabscess cavity or bulla.

A mediastinal bronchogenic cyst will appear as a clearly defined homogeneous mass, usually at the right paratracheal or right carinal region, overlapping the right hilum. Most are oval or round and some may be large. Wall calcification is uncommon. More than 90% are radiographically visible.

CT FINDINGS

The lesion may be diagnosed if it has smooth thin walls and unenhancing fluid attenuation contents. Half of intraparenchymal cases have greater attenuation contents because of proteinaceous fluid or calcium oxalate. If infected the cyst will be heterogeneous and resemble an abscess.

A mediastinal bronchogenic cyst will almost always be visible and may be diagnosed with confidence as a benign cyst in more than 50% of cases.

MR FINDINGS

T2-weighted images reveal bright homogeneous contents, with intermediate T1 signal intensity; an infected cyst would have intermediate heterogeneous T2 and T1 signal intensities. The more proteinaceous the fluid (and thus more difficult to identify as fluid on CT), the higher its T1 signal intensity will be.

BRONCHIECTASIS

Congenital bronchiectasis is rare and thought to be due to incomplete bronchial branching. Almost all bronchi

in a lobe or lung are dilated, to just below the pleura. Histology reveals cartilage deficiency in the segmental and subsegmental airways. The terminating tissue is also abnormal, with few alveoli, abnormal smooth muscle, and lymphangiectasis. It may have a genetic component. Congenital bronchiectasis typically presents in childhood with cough and repeat infections.

CYSTIC ADENOMATOID MALFORMATION

Cystic adenomatoid malformation refers to a group of pathologically and possibly etiologically distinct lesions characterized by abnormal pulmonary tissue, often with cysts. When cysts are present, they often communicate with normal airways. Most of the time the arterial supply is via pulmonary arteries, but sometimes the supply is systemic. Theories of origin include localized bronchial developmental arrest, hamartoma, or bronchial obstruction. Three types are defined: cystic, intermediate, and solid (Table 18-1).

Most cases are discovered before 5 years of age and more than one-half before 1 month of age. The upper lobes are slightly more commonly involved than the lower and sometimes involvement is multilobar. They may be detected with increasing respiratory distress owing to cyst enlargement, or during evaluation of cough, fever, and recurrent infection.

RADIOGRAPHIC FINDINGS

A homogeneous opacity in a newborn becomes air filled (if type I or II) over the first few days or weeks of life. The lesion is space occupying and may enlarge and shift the mediastinum. Cysts may be visible, containing air, fluid, or air-fluid levels.

CT FINDINGS

CT reveals more fully the cystic and solid components. The lesion may displace and splay bronchovascular structures around it.

TRACHEOBRONCHIAL STENOSIS

Congenital stenosis may be due to cartilage abnormalities of the trachea or of more distal structures. Absence of tracheal cartilage leading to tracheomalacia, which may be focal, and cause expiratory airway obstruction and repeated infection. Incomplete tracheal cartilage segmentation, which may be focal or diffuse, can affect normal posterior tracheal membrane development and turn the trachea into a cartilaginous tube. This may be cylindrical or taper distally. It may cause clinically significant stenosis. It is associated with anomalous left pulmonary artery origin. Other causes include atresia, hypoplasia, and fibrous web formation. These are often associated with other anomalies, including skeletal dysplasias and neonatal lobar hyperinflation.

BRONCHIAL ATRESIA

Bronchial atresia, a rare congenital atresia or stenosis of lobar, segmental, or subsegmental bronchus, is most commonly at the apicoposterior segment of the left upper lobe; the right upper lobe, middle lobe, and lower lobes are affected with descending frequency, and lower lobe involvement is quite rare. It may be due to disconnection but subsequent normal development of a bronchial bud or a localized intrauterine bronchial–arterial disruption leading to wall ischemia and luminal obliteration.

Mucus secreted in the airways distal to the atretic segment builds up into a plug or mucocoele. Air can enter via collateral pathways, leading to regional hyperinflation and expiratory air trapping. It is usually an isolated finding, found over age 15 in half of cases, and most patients are asymptomatic, though some may have repeat infections.

RADIOGRAPHIC FINDINGS

A regional pulmonary lucency is visible in 90% of cases as a result of air trapping and hypoperfusion. Normal lung nearby is compressed and displaced. A hilar mass

TABLE 18-1 Classification of Cystic Adenomatoid Malformations

Type I (50%)	Cystic	Containing large often multiloculated cysts, sometimes with smaller cysts as well; the cyst wall has smooth muscle but no cartilage	Bronchioloalveolar carcinoma may develop in type I CAMs
Type II (40%)	Intermediate	Solid areas and small cysts less than 10 mm diameter	These patients often have other pulmonary abnormalities
Type III (10%)	Solid	Grossly composed of irregular bronchiolar and alveolar tissues similar to the pseudoglandular stage of development	

is visible in 80% of cases, consisting of the branching, ovoid, or cystic dilated mucus-filled blocked distal airways. The presence of both these is found in 70% of cases.

CT FINDINGS

CT allows better visualization of the mucoid impaction and segmental abnormalities and may allow confident diagnosis.

NEONATAL LOBAR HYPERINFLATION

Neonatal lobar hyperinflation, also called congenital lobar emphysema, is defined as variably severe hyperinflation of a pulmonary lobe. It has variable causes, and is often part of a syndrome rather than an isolated process. It may be acquired. It almost always presents as infantile respiratory distress, and often requires urgent surgery; however, in some cases managed medically, the abnormalities appear to regress over time.

Half of cases have no obstructive etiology, but obstructive causes include partial airway obstruction, which may be extrinsic (anomalous vessel is most common), intramural (proposed in two-thirds of obstructive cases, often cartilaginous deficiency causing airway collapse), or intraluminal (developmental mucosal folds or bronchial stenosis, or acquired mucus plugs or bronchiolitis).

About half of patients in one study of this process also had congenital heart defects, though other studies have a lower association. It affects males 3:1; it is most common in the left upper lobe, followed by the right middle lobe and rarely the lower lobes, and is almost always unilateral.

RADIOGRAPHIC FINDINGS

Lobar hyperinflation and air trapping cause increased lobar volume and increased lucency, depressing the hemidiaphragm, and displacing the mediastinum. They may cause atelectasis of other lobes. Sometimes, in cases of impaired fluid drainage, the expanded lobe will be fluid filled and hyperattenuating for up to 2 weeks. Radiography may be diagnostic.

OTHER IMAGING FINDINGS

CT may help to confirm a diagnosis and rule out an obstructing mass. Ventilation-perfusion scan may reveal

abnormalities in the affected lobe and help to evaluate the function of adjacent compressed tissue.

ANOMALOUS TRACHEOBRONCHIAL BRANCHING

Most abnormal branches are asymptomatic and of no consequence, but this may present as recurrent infection. Patients with spontaneous pneumothorax are more likely than control patients to have anomalous branching.

Abnormal number involves the duplication or less likely absence of a lobar or segmental bronchus.

Abnormal origin of a lobar or segmental bronchus may be present. The most common of these is tracheal origin of the right upper lobe, called tracheal bronchus, pig bronchus, or bronchus suis (Latin for pig, because this is a normal anatomic feature of that animal). The abnormal bronchus arises from the rightward trachea less than 2 cm from the carina. Its prevalence is 2% or less. Rarer, the apicoposterior left upper lobe bronchus may arise from the left main bronchus; this often leads to obstructive problems in that segment. A bridging bronchus may supply the right middle or lower lobe via the left main bronchus.

Cardiac bronchus is a supernumerary bronchus arising from the medial wall of the right main or intermediate bronchus opposite the origin of the right upper lobe bronchus. It is lined with bronchial mucosa and has cartilage in its wall distinguishing it from a diverticulum. It usually ends blindly though rarely associated with small abnormal pulmonary parenchyma. Most are asymptomatic. Complications may include hemoptysis caused by infection or cancer.

Isomerism, in which lobar and bronchial development is symmetric in both lungs, is often associated with cardiac defects and with heterotaxy syndromes. In left isomerism, both lungs have a left-lung pattern of two lobes and long main bronchus; in right isomerism, both lungs are three-lobed and have short main bronchi.

ANOMALOUS TRACHEOBRONCHIAL COMMUNICATIONS

TRACHEOBRONCHIAL-ESOPHAGEAL FISTULA

In 85% of cases, the esophagus ends blindly, and the trachea can communicate with either the cranial or the caudal esophageal moiety, or both. About half of patients have other congenital anomalies. Regurgitation of milk leads to aspiration and infection. Less frequently, the fistula may connect the airways to an otherwise normal esophagus. This may go undetected for longer periods,

though there may be aspiration and infection. The esophageal end of the fistula is usually distal to the tracheal end, and there may be one-way valve-like membranes at the esophageal ends, which may reduce the incidence of infection.

RADIOGRAPHIC FINDINGS

Alveolar opacities from aspiration are common. “Esophageal lung” consists of total right lung opacification supplied by a rightward-deviated esophagus, with normal tracheal position; this indicates origin of the right bronchus from the esophagus. In patients without esophageal atresia, bronchiectasis from repeated infection may be visible.

BRONCHOBILIARY FISTULA

Biliary tree fistula to the carina or main bronchus has been reported a few times. Infants present with neonatal pneumonia and greenish sputum.

OTHERS

Accessory or heterotopic lung tissue is a rare finding. Occasionally a lobe or entire lung may be duplicated.

Heterotopic intrapulmonary tissue consisting of skeletal muscle, liver, thyroid, adrenal, or glial tissue may be found occasionally.

Horseshoe lung is diagnosed when a connecting band of lung tissue extends from the right lung base behind the pericardium to join the posterior-basal left lower lobe segment. This is often associated with venolobar syndrome (hypoplastic pulmonary artery, anomalous systemic pulmonary venous return, abnormal systemic arterial supply, and bronchial sequestration), more common on the right but occasionally left-sided.

DEVELOPMENTAL ANOMALIES OF THE PULMONARY VESSELS

PULMONARY ARTERIAL ANOMALIES

ABSENCE OF THE MAIN PULMONARY ARTERY

The main pulmonary artery may be atretic only proximally or over its entire course; in these cases, a residual fibrous cord marks its position, and the left and right pulmonary arteries may remain in normal position, supplied by a patent ductus arteriosus (PDA).

Pulmonary atresia with ventricular septal defect (VSD) is relatively common, manifest as neonatal hypoxemia as the PDA closes. In about half of cases any-

where from one to six collateral arteries arise from the descending aorta.

COMPLETE ABSENCE OF MAIN PULMONARY ARTERY

In persistent truncus arteriosus, a single great artery arises from a common semilunar valve, always with a VSD (see Chap. 102, Table 102-3). Pulmonary blood supply is via branches from the trunk artery.

PROXIMAL INTERRUPTION OF THE PULMONARY ARTERY

Pulmonary arteries are usually large and patent beyond the proximal interruption. Blood supply to the lung beyond the interruption is via a systemic collateral, usually a PDA or bronchial collaterals or from a direct aortic branch. The interrupted vessel often has histologic appearance of ductus arteriosus, so this may be a physiologic response of a persistent right ductus arteriosus.

Right-sided interruption is more common and may be divided into four types: those without pulmonary hypertension, usually asymptomatic; those with PA hypertension, usually discovered in childhood; those with recurrent infection or hemoptysis, often because the lung is abnormal; and those with left PDA or congenital heart disease.

Left-sided interruption is less common and has an association with other cardiovascular anomalies, particularly tetralogy of Fallot.

RADIOGRAPHIC FINDINGS

The right (or left) lung is small and hyperlucent because of hypoperfusion, and the right (or left) hilum is small. Expiratory imaging will not reveal air trapping, which helps differentiate this entity from Swyer-James syndrome. Intercostal artery enlargement may lead to rib notching.

SCINTIGRAPHIC FINDINGS

The affected lung will have no uptake in perfusion imaging (unless there is another shunt elsewhere) because its blood supply is systemic; but ventilation imaging will be normal. In Swyer-James syndrome both ventilation and perfusion are typically abnormal.

CT OR MR FINDINGS

Planar imaging may reveal the absent arterial segment, the patent intrapulmonary arteries, and possibly the systemic collateral arteries.

CONGENITAL PULMONARY ARTERY ANEURYSM

Congenital pulmonary artery aneurysms are rare and usually associated with other anomalies, particularly AVM or bronchopulmonary sequestration. Up to half

are associated with congenital cardiac defects including pulmonary valve stenosis, tetralogy of Fallot, or VSD. They are present at birth and usually the result of turbulent poststenotic flow; as a result of flow dynamics they are much more common in the left pulmonary artery (so the presence of a large left PA and normal right PA should suggest pulmonary valve stenosis). They may uncommonly be isolated, in which case they usually involve the trunk and are usually fusiform.

DIRECT COMMUNICATION OF THE RIGHT PULMONARY ARTERY WITH THE LEFT ATRIUM

In this rare malformation, an anomalous right PA branch connects to the left atrium; the anomalous vessel is often aneurysmal. The right lung may be normal if the anomalous artery exists in addition to normal arteries, or the lower lobe may be aplastic or hypoplastic. Radiography may be normal or may reveal a round nodule adjacent to the left atrium in the right hemithorax.

PULMONARY VENOUS ANOMALIES

CONGENITAL VENOUS OBSTRUCTION

Congenital venous obstruction can result from compression by an intrathoracic mass or from intrinsic venous abnormalities. The intrinsic anomaly is rare, and often associated with other cardiac anomalies. It may be caused by atrial endocardial thickening, by venous muscular hypertrophy or intimal fibrosis, or occlusion by thrombus. Patients present with findings of pulmonary venous hypertension, which may be only regional in radiographs, with or without PA hypertension. Hemoptysis may be the presenting feature. Angiography would reveal small ipsilateral pulmonary artery and contrast material stasis.

PULMONARY VENOUS VARICOSITIES

Pulmonary venous varicosities, a rare abnormality, may either be congenital or acquired. The dilation is immediately preatrial, in the congenital form perhaps an abnormality in the transition from splanchnic to pulmonary-venous drainage. The vessel itself usually is structurally normal. Radiographically a round or oval lobulated opacity will often be visible in the medial third of a lung. Acquired varicosities are due to mitral valve disease, usually regurgitation; they usually are right-sided because the mitral valve plane is directed posterosuperiorly to the right. They are usually asymptomatic but can rupture.

MIXED ARTERIOVENOUS ANOMALIES

HYPOGENETIC LUNG SYNDROME

In this rare defect, with incidence 1 to 3:100 000, the right lung is hypoplastic and right lung pulmonary venous return is via portal or systemic veins. Most commonly it drains below the diaphragm via the inferior vena cava, but may drain to portal, hepatic, or azygous veins or the coronary sinus or right atrium. The right pulmonary artery is hypoplastic, and systemic arteries from the thoracic or abdominal aorta provide part or all of the blood supply of the lung. The abnormal systemic artery does not overlap territories with other pulmonary or bronchial arteries, but is responsible for all the blood flow to the lung parenchyma it supplies. Additional findings include mirror image bronchi (right isomerism), diverticula, or extension of the right lung into the left hemithorax. The syndrome is associated with other cardiovascular anomalies, with ASD present in 25% of patients and others having VSD, tetralogy of Fallot, and other anomalies. A majority of patients have symptoms of left-to-right shunt, repeated infection, or hemoptysis.

RADIOGRAPHIC FINDINGS

The abnormal vein often is visible as a large curved density descending to the diaphragm to the right of the heart. The right lung is small and hypovascular and the hilum is small. The mediastinum is shifted to the right.

CT AND MR FINDINGS

CT and MR can make definitive diagnosis if necessary, and allow identification of other abnormalities that may be present.

PULMONARY ARTERIOVENOUS MALFORMATION

Pulmonary arteriovenous malformations range from microscopic communications to complex aneurysmal dilations of multiple arteries and veins. Etiologic theories include the presence of a capillary defect allowing formation of thin-walled sacs or incomplete degeneration of vascular septa connecting the primitive arterial and venous plexuses.

They are found more commonly in the lower lobes. One-third of patients have multiple lesions in the lungs. Sixty percent of patients have extrapulmonary lesions (called hereditary hemorrhagic telangiectasia or Rendu-Osler-Weber disease; this is inherited in an autosomal

dominant process). Multiple lesions may also be present in patients with Fanconi syndrome and polysplenia syndrome.

They may be asymptomatic, or may result in symptoms of right-to-left shunt. Many patients have symptoms not from their pulmonary malformations but from malformations in other organs, namely, epistaxis, hematemesis, and cerebrovascular hemorrhage. Paradoxical embolization is possible leading to stroke or transient ischemic attack. Patients may have polycythemia, though if they bleed often they may be anemic.

RADIOGRAPHIC FINDINGS

A round homogeneous mass will be well defined, most often in the medial one-third of the lung. Feeding and draining vessels are often apparent. In some cases, a heterogeneous mass representing angiomatous hyperplasia may be visible. Hemorrhage may obscure the lesion. Calcification (phlebolith formation) is sometimes evident.

Additional imaging findings and detailed evaluation are usually necessary after the radiograph, both characterize the known lesions and to find other smaller or undetected lesions. This information is necessary before surgery or embolization and is best acquired with angiography or CT angiography; the latter is much more sensitive. CT will show a homogeneous circumscribed nodule with vascular connections and serial imaging can document diminution of the lesion(s) after therapy.

Perfusion scintigraphy or echocardiography can reveal shunt physiology: in the former, some of the administered radiotracer will pass via the malformation into the systemic circulation without being stopped by the capillary bed and will be deposited in the kidneys; this deposition is detectable and quantifiable with gamma cameras.

LYMPHATIC ANOMALIES

LYMPHANGIOMA

Lymphangioma is likely the result of failure of one part of the lymphatic system to communicate with the rest of the system. Most intrathoracic lymphangiomas are in the mediastinum but they occasionally develop in the lung. Fluid accumulation may result in development of a large mass that can cause respiratory distress.

DIFFUSE PULMONARY LYMPHANGIOMATOSIS

Diffuse pulmonary lymphangiomatosis refers to lesions in which the number of lymphatic vessels is increased,

leading to anastomosing pleural, interlobular-septal, and peribronchovascular lymphatic channels. It is most common in infancy and childhood, in which it accounts for up to 5% of all chronic interstitial disease. Chest radiography will reveal diffuse bilateral interstitial disease, sometimes lower lobe predominant. Chylothorax may be unilateral or bilateral and is common; chylopericardium may also occur. CT reveals interlobular septal and peribronchovascular interstitial thickening, often with pleural effusions or pleural thickening.

CONGENITAL PULMONARY LYMPHANGIECTASIA

Congenital pulmonary lymphangiectasia refers to lesions in which size of lymphatic vessels is increased, not the number or complexity. It is almost invariably fatal. Group I patients have concomitant cardiac anomaly (one-third of cases), often with pulmonary venous obstruction leading to dilated lymphatics. Group II patients do not have concomitant cardiac anomalies; it is believed that their lymphangiectasia is due to a failure of physiologically large embryonic lymph vessels to regress; these patients often have other congenital defects including polycystic kidneys and ichthyoids. Group III patients have both pulmonary lymphangiectasia and other visceral ectasia, often intestinal; pulmonary involvement in these patients is less severe.

SYSTEMIC SUPPLY TO THE LUNG

Systemic arterial supply may be congenital or acquired. Many have been described already. An additional etiology for congenital systemic arterial supply is that of a systemic artery supplying an otherwise normal lung (Pryce I malformation); this has findings similar to intralobar sequestration except that the supplied lung parenchyma is normal and is normally connected to the airways. Systemic-pulmonary fistula may be congenital or acquired after infection, trauma, or surgery.

HEREDITARY ANOMALIES OF PULMONARY CONNECTIVE TISSUE

MARFAN SYNDROME

Five to ten percent of patients may develop spontaneous pneumothorax. Patients may develop apical bullae, diffuse emphysema, bronchiectasis, or upper lobe fibrosis.

Nonpulmonary manifestations include arachnodactyly, ectopic lentis, and cardiovascular disease; cardiovascular disease is most commonly manifest as aortic aneurysm or dissection and as aortic- and mitral-valvular insufficiency and is the cause of death in 90% of patients with Marfan syndrome. The aortic abnormalities often develop in the ascending aorta. Dissection may be more common in pregnancy.

RADIOGRAPHIC FINDINGS

The most common finding in Marfan syndrome is pectus excavatum; long thin chest and scoliosis are also found. Serial radiographs may reveal increasing aortic size and/or cardiomegaly, the latter from aortic valve insufficiency.

OTHER IMAGING FINDINGS

CT of dissection would reveal intimal flap and false lumen. While CT, transesophageal echo, and MR all have 100% sensitivity for detection of dissection, CT is more specific than the other two, 100% versus 94%.

EHLERS-DANLOS SYNDROME

This group of genetic connective tissue disorders has multiple types. Type IV is associated with fragile skin and vessel rupture, caused by a deficiency of type III fibroblast procollagen. Emphysema, often bullous, may develop and pneumothorax may occur. Connective tissue weakness may result in tracheobronchomegaly, called Mounier-Kuhn syndrome. In type IV, pulmonary artery rupture may lead to hemoptysis. Other findings may occur: pulmonary artery stenosis, bronchiectasis, thin-walled cavitory lesions, and fibrous pseudotumors.

CUTIS LAXA

Cutis laxa, also known as generalized elastolysis, is characterized by loose skin and connective tissue. It is usually transmitted in an autosomal recessive manner. In the lungs, panacinar emphysema may develop (alpha-1 antitrypsin levels will be normal) and tracheobronchomegaly (Mounier-Kuhn syndrome), bronchiectasis, and aortic aneurysm may occur.

PSEUDOXANTHOMA ELASTICUM

There is a single case of elastic tissue damage in the pulmonary vessels of a patient with pseudoxanthoma elasticum.

ALKAPTONURIA

This homogentisic acid oxidase deficiency leads to accumulation of homogentisic acid in cartilage and other connective tissues, leading to gray or black discoloration of the tracheobronchial cartilage and fibrous tissue. It has no functional pulmonary effect.

LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis (LAM) is predominantly peribronchovascular smooth muscle proliferation, leading to airway and vascular obstruction and cyst formation. It has pulmonary clinicopathologic manifestations similar to tuberous sclerosis and may be related to that process. Both may be hamartomatous in nature; however, LAM can recur after lung transplant, so some other process must be at work.

Abnormal smooth muscle cells proliferate around bronchioles, blood and lymph vessels, and the pleura, sometimes replacing a large portion of lung parenchyma. Cysts of 2 to 20 mm develop, separated by thickened interstitium, and obstructed small vessels can lead to subclinical hemorrhage. Tiny 1- to 3-mm nodules of benign type II pneumocyte hyperplasia develop in some cases.

LAM is uncommon; it only occurs in women, generally in childbearing years. Shortness of breath is of gradual onset, unless an acute spontaneous pneumothorax develops. Patients may have cough, hemoptysis, or chest pain. Chylothorax is a common occurrence; in addition, thoracoabdominal lymph node involvement may lead to chyloperitoneum or chylopericardium. It has a generally poor prognosis, with most patients dying within 10 years of diagnosis in some studies.

RADIOGRAPHIC FINDINGS

Uncommonly, the chest radiograph may be normal in patients with LAM. The most common finding is bilateral reticular interstitial lung disease, generally diffuse and uniform, but occasionally lower zone predominant. Cysts are visible in 60% of cases, and hyperinflation is often present. Thirty to forty percent of patients will develop pneumothorax and ten to twenty percent will develop effusions.

HRCT FINDINGS

Extent of disease in HRCT correlates better than that in radiographs with disease severity, correlating best with carbon monoxide diffusing capacity (DLCO). Numerous air-filled cysts are diffusely placed and surrounded

by normal parenchyma; the overall size of the cysts is in general indicative of disease severity, with milder disease having smaller cysts. Sometimes there may be mild interstitial or interlobular septal thickening or ground glass attenuation from small hemorrhages. Small nodules may rarely be visible. Pneumothorax and effusion may be visible and mediastinal nodes may be enlarged.

This may be differentiated from pulmonary Langerhans cell histiocytosis in that the latter generally has upper lobe predominant cysts and spares the lower lungs, and nodules are present in most cases.

TUBEROUS SCLEROSIS

Tuberous sclerosis is a disorder of mesoderm development and an autosomal dominant disease affecting males and females equally, sometimes with positive family history. Its classic triad is mental retardation, epilepsy, and adenoma sebaceum; retinal phacomas, renal angiomyolipoma, cardiac rhabdomyoma, osseous sclerotic lesions (which must be differentiated from osteopoikilosis by their different distribution), and subungual fibromas also are common.

The disease uncommonly affects the lungs—less than 2.5% of patients will develop manifestations—and this is most commonly in women. Thin-walled cysts and small nodular foci of type II pneumocyte hyperplasia develop; there may be an increase in clear-cell tumor development.

Patients typically develop dyspnea, with hemoptysis and cough occasionally. Disease progression is variable, from stable findings to progressive dyspnea and eventual death.

IMAGING FINDINGS

Tuberous sclerosis findings are similar to those of lymphangiomyomatosis. Radiograph will reveal diffuse reticular disease with or without thin-walled cysts. HRCT will reveal thin-walled cysts throughout the lungs, sometimes with normal chest radiograph. Pneumothorax may develop in up to half of patients with tuberous sclerosis lung involvement, though chylothorax is rare.

NEUROFIBROMATOSIS

Neurofibromatosis type I is an autosomal recessive neurophacomatosis, with a gene on chromosome 17, with frequency of about 1:3000. Cutaneous café au lait spots and peripheral neurofibromas are the most prominent

findings; patients also develop CNS gliomas, meningiomas, peripheral nerve sarcomas, pheochromocytomas, and angiosarcomas.

In the chest, intercostal nerve tumors may be associated with rib destruction, chest mass, or occasionally hemorrhage from erosion into the adjacent vessels.

Interstitial fibrosis occurs in 5% to 10% of patients; bulla formation is in up to 20% of patients. The fibrosis is pathologically an interstitial pneumonitis with fibrosis and chronic inflammation, most prominent in subpleural tissues. Macrophage aggregation is common.

RADIOGRAPHIC FINDINGS

Symmetric basilar–predominant reticular interstitial lung disease is common; bullae usually are asymmetric and upper lung predominant. Cutaneous neurofibromas may be radiographically apparent. Scoliosis is nonspecific, but an acute-angle lower-thoracic curve involving five or fewer vertebrae is suggestive of neurofibromatosis. Twisted-ribbon rib deformities, scalloping of the posterior vertebral-body cortex, a sequela of dural ectasia, and lateral meningocele formation may be visible.

Intercostal neurofibromas may be visible as paraspinal masses; often these are visible running parallel to and possibly eroding the adjacent rib. As the tumors are generally benign and slow growing, the erosion is generally a remodeling process without cortical destruction. Tumors of vagus, phrenic, or sympathetic chain nerves may appear as mediastinal masses.

CT FINDINGS

CT in the setting of neurofibromatosis will reveal reticular prominence generally in the lower lung zones, if the patient has the related fibrotic lung disease. Apical bullae are often present even if inapparent in radiographs. CT can help to distinguish a cutaneous neurofibroma from an intrathoracic nodule, if this cannot be accomplished via cutaneous marker or chest fluoroscopy, and can characterize any mass visible or suspected radiographically. A neurofibroma typically has lower attenuation than muscle, in the range 15 to 30 HU.

QUESTIONS AND ANSWERS

1. Regarding intralobar bronchopulmonary sequestration, which of the following is *true*?
 - A. Intralobar sequestration has normal venous return but abnormal arterial supply.
 - B. A left-to-right shunt is created.
 - C. Swyer-James syndrome is a form of intralobar sequestration.
 - D. The most common site of intralobar sequestration is right lower lobe superior segment.

ANSWER: A. Intralobar sequestration is invested in the normal pleura and has normal venous return to pulmonary veins, but abnormal systemic arterial supply, thus creating a left-to-left shunt. Swyer-James syndrome is a syndrome of obstructive bronchiolitis. The most common site of intralobar sequestration is the posterior segment of the left lower lobe in two-thirds of cases.

2. Regarding foregut cysts, which of the following is *true*?
 - A. Paratracheal bronchogenic cysts are typically symptomatic.
 - B. Typically multiloculated.
 - C. Esophageal cysts develop from abnormal tracheobronchial budding.
 - D. Enteric cysts are associated with spinal defects.

ANSWER: D. Paratracheal bronchogenic cysts are typically asymptomatic but can sometimes cause pressure effects on adjacent structures. All foregut cysts are typically uniloculated and single. Esophageal cysts develop from a failure of complete esophageal canalization. In enteric cysts, foregut is herniated through the notochord; it is often associated with spinal defects.

3. Regarding cystic adenomatoid malformation, which of the following is *true*?
 - A. Cysts do not communicate with normal airways.
 - B. Arterial supply is via pulmonary arteries.
 - C. Type III is the most common.
 - D. Most cases are asymptomatic.

ANSWER: B. Cysts generally do communicate with normal airways. Most of the time the arterial supply is via pulmonary arteries, though sometimes the supply is systemic. Type I, cystic, is most common at 50% of cases. Type II is mixed solid and small cysts at 40% of cases; type III is grossly solid, but the least common type, approximately 10% of cases. Most cases are discovered before 5 years of age, and over half before 1 month of life caused by

cough, fever, recurrent infection, or respiratory distress because of cyst enlargement.

4. Bronchial atresia is associated with which of the following?
 - A. Atretic segment leads to focal lung collapse
 - B. Most common radiographic finding is a hilar mass
 - C. Apicoposterior segment of the left upper lobe is most commonly affected
 - D. Defect is thought to be caused by intramural obstruction, likely cartilage collapse

ANSWER: C. The atretic segment supplies an otherwise normal lung; hence, the alveoli of that segment are able to fill via collateral pathways. The affected parenchyma is actually generally overinflated. The most common finding is a regional pulmonary lucency, visible in 90% of cases. The presence of a hilar mass is also common, though at 80%. The apicoposterior segment of the left upper lobe is most commonly affected. The defect is thought to be due to either disconnection but subsequent normal development of a bronchial bud, or a localized intrauterine bronchial–arterial disruption leading to wall ischemia and luminal obliteration.

5. Regarding proximal interruption of the pulmonary artery, which of the following is *true*?
 - A. Pulmonary arteries in the lung are generally normal.
 - B. Interrupted vessel is more commonly left sided.
 - C. Right-sided interruption is usually accompanied by serious heart disease.
 - D. Proximal interruption and Swyer-James syndrome are indistinguishable in V-Q imaging.

ANSWER: A. The pulmonary arteries distal to the interruption are generally normal, though their blood supply is via systemic collateral arteries. The interrupted vessel is more commonly right sided, and left-sided interruption is often associated with other heart disease, particularly tetralogy of Fallot. Proximal interruption will result in absent perfusion (because its blood supply is systemic) but normal ventilation; in Swyer-James syndrome both ventilation and perfusion are typically abnormal.

6. Which of the following is *not* a component of the hypogenetic lung syndrome?
 - A. Right isomerism
 - B. Pulmonary artery hypoplasia
 - C. Systemic supply to lung tissue
 - D. Normal venous drainage

ANSWER: D. Hypogenetic lung syndrome is composed of pulmonary hypoplasia, pulmonary arterial hypoplasia with systemic arterial supply to all or part of the lung, right isomerism, diverticula, and other cardiovascular anomalies, most commonly ASD. The venous drainage is distinctly abnormal, with the large draining vein visible as a scimitar-shaped opacity leading below the diaphragm.

7. A patient has ectopia lentis, arachnodactyly, and an aortic aneurysm. Which of the following is the most likely diagnosis?
- A. Ehlers-Danlos syndrome
 - B. Cutis laxa
 - C. Marfan syndrome
 - D. Pseudoxanthoma elasticum

ANSWER: C. Ehlers-Danlos syndrome is a disorder of connective tissues, with type IV caused by a deficiency of type III procollagen resulting in emphysema, tracheobronchomegaly, and pulmonary artery rupture. Cutis laxa is a recessive disorder characterized by loose skin and connective tissue, with panacinar emphysema, tracheobronchomegaly, bronchiectasis, and aortic aneurysm. Marfan syndrome is characterized by arachnodactyly, ectopia lentis, aortic disease, aortic and mitral valve insufficiency, and in the lungs apical bullae, diffuse emphysema, bronchiectasis, upper lobe fibrosis, and spontaneous pneumothorax. Pseudoxanthoma elasticum is reported to have caused pulmonary vascular damage in a single patient.

8. Regarding LAM, which of the following is *true*?
- A. Smooth muscle proliferation leads to airway and vascular obstruction.
 - B. Like tuberous sclerosis, the process has a male predominance.
 - C. HRCT reveals the most common abnormality to be nodules of smooth muscle.
 - D. It is indistinguishable from Langerhans cell histiocytosis.

ANSWER: A. Smooth muscle proliferation in peribronchovascular tissues leads to airway and vascular obstruction and cyst formation. It has several pulmonary manifestations in common with tuberous sclerosis, but it occurs only in women. HRCT reveals the most common abnormality to be thin-walled cysts, with the size of the cysts indicative of disease severity, with nodules only rarely visible. It can be distinguished from Langerhans cell histiocytosis because LAM is a uniform or basilar-predominant disease characterized by cysts but only rare nodules and LCH is an upper lobe predominant disease with frequent nodule formation.

9. Regarding tuberous sclerosis, which of the following is *true*?

- A. Recessive trait
- B. Classic triad of mental retardation, epilepsy, and nodular lung disease
- C. Characterized by abnormal mesoderm development
- D. It usually affects men in contrast to LAM.

ANSWER: C. Tuberous sclerosis is an autosomal dominant trait affecting both men and women, and its classic triad is mental retardation, epilepsy, and adenoma sebaceum. It is characterized by abnormal mesoderm development leading to retinal phacoma, renal angiomyolipoma, cardiac rhabdomyoma, dense bone lesions, and subungual fibromas. Lung disease occurs in less than 2.5% of patients.

10. Regarding neurofibromatosis type I, which of the following is *true*?

- A. Most common fatal inheritable disorder.
- B. Patients develop CNS tumors.
- C. Interstitial fibrosis is a sine qua non of the disease.
- D. Intercostal neurofibromas typically produce geographic bone destruction.

ANSWER: B. Neurofibromatosis type I is common, with a frequency of 1:3000, but cystic fibrosis is slightly more common. Patients develop CNS gliomas, meningiomas, peripheral nerve sarcomas, pheochromocytomas, and angiosarcomas, in addition to the characteristic cutaneous café-au-lait spots and peripheral neurofibromas. Interstitial fibrosis occurs in 5%–10% of patients, caused by an interstitial pneumonitis. Intercostal neurofibromas are benign neoplasms that grow slowly and cause benign-appearing bone remodeling.

19 AIRWAY DISEASES

John C. Texada and Satinder P. Singh

UPPER AIRWAY OBSTRUCTION

ACUTE UPPER AIRWAY OBSTRUCTION

Acute upper airway obstruction occurs most often in infants and children because of small and compliant airways. Acute dyspnea may be accompanied by stridor.

INFECTION

Acute pharyngitis and tonsillitis are most commonly caused by beta-hemolytic streptococci. Rarely this may

cause life-threatening obstruction, particularly with Epstein-Barr virus–related mononucleosis. Acute laryngotracheitis is acute narrowing of the subglottic trachea, caused by parainfluenza or respiratory syncytial virus. Acute bacterial tracheitis is a rare but potentially life-threatening process; if caused by *Corynebacterium pseudodiphtheriticum*, it may become necrotizing. Acute epiglottitis is most often caused by *Haemophilus influenzae*, sometimes by *Staphylococcus aureus* or *Streptococcus pneumoniae*; the epiglottis, aryepiglottic folds, arytenoids, and prevertebral tissues swell. Acute retropharyngeal abscess can obstruct the airway and can extend into the mediastinum. In immunosuppressed patients, a necrotizing pseudomembranous tracheobronchitis can develop from *Aspergillus* infection.

EDEMA

Edema typically affects the larynx. Its causes include trauma, irritant inhalation, and angioneurotic edema. Smoke inhalation may produce enough edema to cause upper airway obstruction, as may scalding by drinking something too hot. Angioneurotic edema may be the most common cause of acute upper airway obstruction. It may be hereditary, as an adverse effect of (ACE) angiotensin converting enzyme-inhibitor therapy, or result from anaphylaxis. It is accompanied by pruritic facial, genital, and extremity swelling and sometimes urticaria. Acute reactions are mast cell reactions; subacute reactions are immune-complex reactions. If caused by ACE-I therapy, angioneurotic edema may be immediate or after prolonged use. The hereditary form is due to absence or abnormal function of C1-esterase inhibitor; resulting C1 increase leads to decreased C2 and C4.

RETROPHARYNGEAL HEMORRHAGE

Retropharyngeal hemorrhage may be caused by neck surgery, trauma, catheter malposition, or infectious erosion. It may be spontaneous in hematologic disorder or coagulopathy patients.

FOREIGN BODY ASPIRATION

Foreign body aspiration is most often in infants and children and more commonly involves the esophagus and bronchi than the upper airway. Peanuts, coins, toys, and screws are common offenders in children; candies are hyperosmolar and can produce severe edema as they melt. Meat and bones are the most common offenders in adults. Preexisting pharyngeal disorders increase the risk of aspiration.

FAULTY INTUBATION

Faulty intubation is more common when performed emergently. The tube should be 3 to 7 cm from the carina with neutral neck positioning. In obstruction,

typically the tube enters the right main stem bronchus, and the cuff occludes the left bronchus; further down the right bronchus, the right upper lobe can be excluded as well. Collapse may take 24 hours if the lung contains air, but only a few minutes if 100% oxygen is present.

CHRONIC UPPER AIRWAY OBSTRUCTION

Dyspnea is a common symptom. Occasionally it is severe enough to result in sleep disturbance or cor pulmonale. Fixed obstruction occurs when the airway cross-sectional area does not change with changing pressures. Variable obstruction occurs when airways respond to changing pressure by changing dimensions. Intrathoracic variable obstruction leads to decreasing cross-sectional area with forced expiration and extrathoracic variable obstruction leads to decreasing cross-sectional area with forced inspiration. The most common causes of chronic upper airway obstruction are tonsillar and adenoidal hypertrophy, goiter, vocal cord paralysis, tracheal stenosis, and neoplastic disruption. Tracheomalacia may play a role in some cases.

LARYNGEAL DYSFUNCTION

In inspiration, the posterior cricoarytenoid muscle dilates the larynx in expiration, sometimes the thyroarytenoid and lateral cricoarytenoid muscles narrow it. Posterior cricoarytenoid muscle paralysis leads to fixed upper airway obstruction and unopposed adductor action leads to laryngospasm. Infants may develop upper airway obstruction from laryngeal hypotonia, laryngeal hypoplasia, cleft larynx, or vocal cord paralysis. Adults may develop unopposed adductor action, sometimes via superior laryngeal nerve disruption at thyroidectomy.

TRACHEAL STENOSIS

The extrathoracic trachea enlarges with Valsalva maneuver and decreases with Mueller maneuver (inspiration against closed upper airway). The intrathoracic trachea does not change with lung pressures but does change in proportion with lung volume. The most common etiology of stenosis is as a complication of intubation or tracheotomy: at the stoma of a tracheostomy; at the cuff; or where the tip of the tube contacts the mucosa.

Tracheal Neoplasm

Tracheal neoplasms are rare; squamous cell is responsible in the majority. Tracheal carcinoma is four times more common in men than women. Adenoid cystic carcinoma has no sex predilection. Rarely, lymphoma, leukemia, soft-tissue neoplasms, or metastasis may occur.

Other Causes of Tracheal Stenosis

A saber-sheath trachea is transversely narrowed and anteroposteriorly expanded. The entire intrathoracic trachea is narrowed, with normal extrathoracic trachea. It is more common in chronic obstructive pulmonary disease (COPD) patients than in those without and may be due to hyperinflation. Relapsing polychondritis is an uncommon autoimmune cartilage disorder affecting airway rings focally, multiply, or diffusely. The airway may become fixed-narrowed or flaccid. Relapsing polychondritis typically does not involve the membranous trachea and is commonly due to degeneration. Small nodules give affected airways a beaded appearance. In the rare disorder tracheobronchopathia osteochondroplastica cartilage and bone develop in tracheal and bronchial submucosa; this is most common in men older than 50 years. Tracheobronchomalacia is a result of cartilage weakness leading to easy collapse, most often caused by tracheal pressure necrosis from a variety of causes but occasionally primary in children. In tracheobronchomegaly, the muscular and elastic tissues are thinned and atrophied, and dilation may extend into peripheral lung tissues. It is most commonly diagnosed in young men. Its etiology is unclear. It may be acquired in patients with pulmonary fibrosis or ankylosing spondylitis.

RADIOGRAPHIC FINDINGS—UPPER AIRWAY OBSTRUCTION

Radiography plays a limited role. Lateral neck imaging excludes epiglottitis, retropharyngeal abscess, or foreign body. The upper airways are often poorly evaluated in the chest radiograph. A tracheal tumor may be visible as intraluminal nodules or as tracheal wall thickening with luminal narrowing. Relapsing polychondritis may be visible as diffuse tracheobronchial narrowing. Tracheobronchopathia osteochondroplastica commonly is seen as speckled calcification of the trachea and bronchi, better appreciated on lateral view. In tracheobronchomalacia and tracheobronchomegaly, radiography will reveal inspiratory airway dilation and premature expiratory collapse. In tracheobronchomegaly, the airways may appear corrugated owing to protruding tissues between the rings. Pulmonary edema rarely develops but indicates the presence of very negative inspiratory pressures. Cardiac enlargement suggests cor pulmonale, the result of chronic pulmonary-arterial hypertension caused by hypoxemia and acidosis.

CT AND MR FINDINGS

Planar imaging defines location and extent of disease, and any mediastinal involvement. Laryngeal paralysis

may be assessed. Goiter may be clearly visible. Benign tracheal tumors such as schwannoma, leiomyoma, or neurofibroma are well-defined sessile or polypoid nodules 2 cm or less, and not extending out of the tracheal wall. Tracheal malignancies cause focal or circumferential narrowing or flat or polypoid mass, sometimes with extratracheal extension, lymphadenopathy, pulmonary nodules, or fistula. Saber-sheath trachea has the expected coronal narrowing and sagittal extension described earlier in the chapter. Relapsing polychondritis will be manifest by mild tracheobronchial circumferential thickening that may be single, multiple, or diffuse. Tracheobronchopathia osteochondroplastica is evident as nodular tracheobronchial thickening resulting in irregular narrowing, with nodular calcification often visible. Tracheobronchomalacia and tracheobronchomegaly will be visible as airways dilate with inspiration and collapse with expiration in dynamic CT. In the latter, the dilation may extend into the peripheral lung parenchyma and the large airways may appear corrugated because of tracheal diverticulosis.

OBSTRUCTIVE SLEEP APNEA

Obstructive apnea is characterized by complete closure of the upper airway for at least 10 seconds per event despite respiratory effort, present in 1% to 10% of the population. Most patients are male. The greatest risk factor for obstructive sleep apnea is obesity, particularly central or visceral obesity. Numerous neurologic, metabolic, musculoskeletal, or other factors are considered risks—anything which may decrease respiratory awareness, muscle strength, or physical ability to breathe. Family history; lower vital capacity; and the use of tobacco, alcohol, sedatives, antihistamines, or certain other drugs increase the risk. Risk also increases with advancing age.

PATHOGENESIS

Obstructive sleep apnea is caused by loss of normal upper airway muscle tone superimposed on underlying upper airway narrowing. It is likely due to a combination of anatomically narrowed airway, collapsible airway, decreased neural drive for pharyngeal abduction, decreased chemoreceptor stimulation, and uncoordinated upper airway muscular activation. Typically the soft palate gets sucked into and obstructs the hypopharynx. Neck adipose tissue is an important factor, and neck circumference is a clinically useful measurement. A structural abnormality may be readily apparent (enlarged adenoids and tonsils, macroglossia, or retro-/micrognathia) or

more subtle, such as small posterior placed mandible, narrow posterior airway, inferiorly placed hyoid bone, or enlarged tongue and soft palate. Patients with obstructive sleep apnea typically have unstable collapsible pharyngeal airways. Once the airway closes, it is more difficult to reopen because of surface adhesion. Sleep deprivation and hypoxia lead to depression of normal phasic respiratory muscle activity in the pharyngeal muscles that work to dilate and stiffen the larynx.

IMAGING FINDINGS

Imaging plays a limited role. Many changes are dynamic. Lateral neck soft-tissue radiography may reveal pharyngeal or craniofacial abnormalities. CT or MR may characterize the bones and soft tissues, including airway dimensions, which is particularly helpful for surgical planning.

ASTHMA

Asthma is characterized by intermittent variable airway narrowing with airway hyperreactivity and inflammation and may lead to permanent fixed obstruction. It may be extrinsic (associated with atopy) or intrinsic. Patients with extrinsic asthma have elevated IgE levels, are more commonly male, and are typically less than 20 years old. Those with intrinsic asthma are older, are more often female, and are at increased risk of autoimmune disease and aspirin sensitivity, and they tend to respond worse to therapy. The prevalence of childhood asthma ranges from 1% to 20% and appears to be increasing. The most important factors are atopy, cigarette smoke exposure, and perhaps childhood bronchiolitis. Asthma has a genetic component, but it does not have a simple inheritance pattern.

PATHOGENESIS

There is airway wall connective tissue deposition and bronchial vascular hyperplasia. The airways and basement membranes are thickened, the soft tissues are edematous and hypervascular, and there is inflammatory cell infiltration. Elastin is degraded and smooth muscle is increased. Inflammatory polyps may form. Cellular and histamine-mediated inflammation play a major role and prostaglandin response is abnormal. Secretions produced in asthma attacks are thicker and more mucoid than normal. In addition, mucociliary clearance is slower than normal even in stable asthma. Nonspecific bronchial responsiveness is increased.

CLINICOPATHOLOGIC FINDINGS

Symptoms in controlled patients include isolated cough, caused by epithelial irritant receptor stimulation, or wheeze. There are early and late (1–8 hours) components to asthma attacks; though the physiology is similar, peripheral airway changes are more prominent late. Beta-adrenergic agonists may block the early response but are less effective for late response; corticosteroids are ineffective in early response but ameliorate the late response. Nighttime symptoms are due to a variety of causes including smaller airway caliber and abnormal inflammatory increases.

Complications are more common in children and include pneumonia, atelectasis, mucoid impaction and mucus plugging, pneumomediastinum, and arterial air embolism. Response to the first 6 hours of therapy can predict recovery time. Severe disease may require intubation; approximately 40% are subsequently extubated within 24 hours and 70% within 72 hours. Mortality for asthmatic patients requiring mechanical ventilation averages 13%.

SEVERITY CATEGORIES

Intermittent asthma means symptoms less than once a week, with brief exacerbations and less than two episodes of nighttime asthma per month. Lung function is normal (greater than 80% of predicted) between exacerbations. Mild persistent asthma means symptoms less than once per day and nighttime symptoms over twice per month, with exacerbations that may affect activity and sleep. Peak expiratory flow (PEF) or forced expiratory volume in 1 second (FEV-1) is normal, but variability is increased (20%–30%). Moderate persistent asthma means daily symptoms and nighttime asthma means symptoms once per week, with exacerbations affecting activity and sleep. Patients require daily short-acting beta-2 agonists. PEF or FEV-1 is 60% to 80% of predicted and variability is greater than 30%. Severe persistent asthma means continuous symptoms with frequent nighttime asthma and frequent exacerbations, with activities limited by symptoms. PEF or FEV-1 is less than 60% of predicted and variability is greater than 30%.

PROVOKING FACTORS

Specific extrinsic triggers include pollen or fungal spores; indoor allergens include animal dander, dust mites, and cockroaches; foods, particularly eggs, fish, shellfish, nuts, spices, and chocolate. Anaphylaxis may

result from drugs, particularly penicillin, stings from *Hymenoptera*, and others including contrast material. Exercise may lead to airway narrowing, the worst usually 5 to 10 minutes after exercise and resolving within an hour. Viral upper respiratory infection and mycoplasma infection exacerbate symptoms in asthmatic patients; bacterial infection does not. Analgesic drugs particularly aspirin can provoke attacks in up to 28% of asthmatic patients. Gastroesophageal reflux may stimulate afferent pharyngoesophageal nerves or may lead to irritant aspiration. Emotional distress can trigger asthma attacks. Environmental factors include outdoor air pollution, indoor wood or gas stove, and fireplace use. Changes in pressure, temperature, and humidity have reportedly led to asthma attacks. A number of miscellaneous factors also are described: food additives; alcohol and drugs including beta-blockers, ACE inhibitors, and radiographic contrast material; perfumes and cigarette smoke; and premenstrual period.

OCCUPATIONAL ASTHMA

Occupational asthma accounts for half of occupational lung diseases. Most offending antigens are high-molecular-weight proteins, polysaccharides, or glycoproteins from living things, though some are small haptens. Cigarette smoking increases the relative risk as much as five times the normal population. The most prominent categories are animal products, grain dust, and latex. Many low-molecular-weight compounds produce symptoms similar to asthma, but may more likely be allergic. The most common of these are isocyanates used in paint, varnish, foam, plastics, adhesives, and molds.

OTHER WORKPLACE AIRWAYS DISEASES

Nonspecific occupational bronchoconstriction is characterized by work-related airway narrowing in patients who already have asthma. Reactive airways dysfunction syndrome is airway injury by acute high-concentration gaseous exposure leading to bronchial hyperresponsiveness.

RADIOGRAPHIC FINDINGS IN ASTHMA

Radiographs are often normal, even during an acute attack. Imaging serves to exclude other etiologies for symptoms and to exclude pneumothorax. The most common positive findings are hyperinflation and bronchial wall thickening. Bronchial wall thickening is

visible as ring shadows or parallel linear opacities, and normally inapparent 3 to 5 mm bronchi may become visible. Radiographs may rarely reveal peripheral oligemia, central increased lung markings, and prominent hila. During an attack, the hyperinflation may be accompanied by areas of expiratory air trapping.

HRCT FINDINGS

HRCT allows quantitative evaluation. Bronchial wall thickening, bronchial luminal narrowing, bronchiectasis, air trapping, and patchy hypoattenuation may be present. The degree of abnormality correlates with disease severity; serial HRCT may document response to therapy.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Clinical chronic bronchitis is characterized by excessive mucus production on most days for at least 3 consecutive months for not less than 2 consecutive years. Morphologic emphysema is abnormal permanent enlargement of airspaces distal to the terminal bronchioles, with wall destruction, without fibrosis. The functional description chronic obstructive pulmonary disease is persistent, largely irreversible obstruction without additional cause.

EPIDEMIOLOGY

Men are more likely to develop COPD even after controlling cigarette smoking. This is more severe in whites than non-whites. Alcoholic patients and patients with CAD have increased risk. Cigarette smoking is the largest risk factor, though only 10% to 20% of heavy smokers will develop COPD. Pipe and cigar smokers are not at as high a risk as cigarette smokers. Infants and children in the houses of smokers are at increased risk of respiratory illness and functional impairment. Air pollution in combination with cigarette smoke has additive effects. Occupational dust or fume exposure decreases lung function, though the effect is one-third to one-half that of cigarette smoking. Infection during childhood may increase the risk of COPD later, and infection in patients already with COPD may lead to more rapid decline in function. Heredity, socioeconomic factors, diet, and nutrition are factors in the development of COPD. Birth weight and weight at 1 year are risk factors for COPD development. Mucus and mucociliary clearance rate appear important. Cigarette smoke leads to delayed

peripheral mucociliary clearance and heterogeneous ventilation. Leukocyte count is inversely proportional to lung function declines in smokers, nonsmokers, and former smokers alike, that is, high white blood cell count leads to greater function decline.

PROGNOSIS AND COURSE

Annual FEV-1 decline for healthy nonsmokers is 10 to 35 mL after age 30 and for smokers is 30 to 70 mL. Patients with preexisting low lung function decline more rapidly than those without. Respiratory muscle fatigue may develop due to pulmonary resistance, mechanical disadvantage, malnourishment, and possible cor pulmonale development. Patients with chronic hypoxemia may develop secondary polycythemia and hypokalemia. Resting left ventricular ejection fraction is normal in COPD patients without cor pulmonale, though exercise-induced dysfunction is common.

Prognosis is related to pulmonary vascular and right ventricular functions. Cor pulmonale may develop from long-standing pulmonary arterial hypertension. With FEV-1 more than 40% of predicted, resting pulmonary artery pressure is generally normal, but exercise leads to elevated pressure; with FEV-1 less than 40% of predicted, resting mean pulmonary artery pressure is generally more than 20 mm Hg and exercise leads to a disproportionate increase. Without therapy pulmonary artery pressure will slowly increase, at a rate correlated with loss of FEV-1. This can be prevented with chronic oxygen therapy, which has been proven to increase survival.

The mortality of acute-on-chronic respiratory failure in severe COPD is 25% per event, 50% over 1 year, and 70% over 2 years. Prognostic factors include age, PA pressure, postbronchodilator FEV-1, and percentage of ideal body weight.

EMPHYSEMA

DEVELOPMENT

There is an abnormal ratio of antielastolytic processes to elastolytic processes. Neutrophil elastase is probably the most important player, and this enzyme is increased in smokers for several reasons. Alpha-1 antitrypsin is the primary antielastolytic enzyme. It has many genetic variants, most of which lead to normal enzyme function. The phenotypes ZZ, SS, or SZ have levels much below normal and phenotypes MS and MZ have levels 60% to 80% of normal.

TABLE 19-1 Emphysema Types

Centrilobular (proximal acinar)	Most common, tobacco use, upper zone
Paraseptal (distal acinar)	Focal, peripheral
Panlobular (panacinar)	Most common nonsmokers, alpha 1- antitrypsin deficiency
Cicatrical (scar)	Most common pathologically, asymptomatic

TYPES (TABLE 19-1)

Centrilobular (proximal acinar) emphysema involves the proximal respiratory bronchioles. It is found in cigarette smokers, and is the most common form. Respiratory bronchioles dilate and alveolar septa disappear; eventually several respiratory bronchioles become confluent into a single space supplied by a terminal bronchiole, leading to relatively normal alveoli. Eventually these spaces become confluent as well. It is upper-zone predominant and heterogeneous.

Paraseptal (distal acinar) emphysema involves alveolar ducts and alveoli. It is usually focal and peripheral, and may be postinflammatory. Bullae may develop from alveolar destruction. It typically has limited extent and is asymptomatic save for occasional spontaneous pneumothorax.

Panlobular (panacinar) emphysema involves the entire acinus. This is the most common form of emphysema in nonsmokers, associated with alpha-1 antitrypsin deficiency. In severe disease the tissue may be composed only of airspaces with traversing strands of tissue and vessels. The process is lower- and anterior-zone predominant.

Cicatrical (scar) emphysema is not localized to a particular acinar site. It is fibrotic and likely postinflammatory. It is the most common form pathologically but is limited in extent and generally asymptomatic.

PATHOLOGIC FINDINGS

Tracheobronchial gland volume is correlated with degree of mucus production. Small-airway resistance increases. Emphysema is present (see the types given earlier). Larger airspaces have lower elasticity and eventually large airspaces contain essentially trapped gas. Increased vascular resistance is a product of simple vessel loss, hypoxic smooth muscle contraction, and vascular mural thickening. With severe COPD and emphysema the bronchial and pulmonary arteries will anastomose extensively.

RADIOGRAPHIC FINDINGS

Chronic bronchitis is not a radiologic diagnosis, but imaging can suggest its presence. Bronchial wall thickening may be visible as ring shadows, parallel densities, or prominent markings. Emphysema bullae and irregular lucency can be visible with very thin walls. In most cases, the findings are of hyperinflation or vascular changes: diaphragmatic flattening or concavity, increased retrosternal airspace, and increased lung height; avascular areas: vessel distortion, increased angle of branching, decreased peripheral vascularity, and hilar arterial prominence.

CT FINDINGS

HRCT detects bronchial wall thickening with greater sensitivity. In emphysema, areas of low attenuation will be present, with walls 1 mm or less thick. Centrilobular emphysema will have multiple small areas of low attenuation, typically diffuse but sometimes upper-zone predominant. Panlobular emphysema will be visible as lower-lobe predominant hypoattenuation with few vessels, sometimes with bronchiectasis. Paraseptal emphysema will be visible as subpleural hypoattenuation with intact interlobular septa. CT findings correlate well with severity of disease.

ALPHA-1 ANTITRYPSIN DEFICIENCY

Alpha-1 antitrypsin is an acute-phase reactant. It is produced mainly by the liver. There are more than 70 genetic variants. The M variant is by far the most common allele. Other variants are far less common, ranging from 0.1% to 6%. The Z variant is an autosomal recessive allele that has deficient antiproteolytic function and aggregates within the cell that produces it. ZZ homozygotes produce levels approximately 20% of normal and heterozygotes approximately 60%. The ZZ genotype is found in 1:1500 to 1:5000 births; approximately 50% to 80% of patients will develop basilar-predominant emphysema. Smoking of course increases the risk, rate, and severity—annual decline in FEV-1 is 80 mL for non-smokers and 317 mL for smokers.

BULLOUS DISEASE

A bulla is a well-defined airspace, 1 cm or larger, with a smooth wall 1-mm thick or less, and with or without internal septa. The walls are composed of pleura, connective tissue septa, or compressed parenchyma. It may be

idiopathic or associated with emphysema or prior infection. Primary disease has a familial tendency, and is increased in patients with connective tissue disorders. It is typically asymptomatic, though spontaneous pneumothorax may occur. Bullectomy may allow a healthy lung to reinflate into the space occupied by the bulla.

Vanishing lung syndrome or giant bullous emphysema is a distinct progressive clinical syndrome, characterized by large bullae in the upper lobes, often unilateral or asymmetric, often seen in young men, and mostly seen in smokers. It is often associated with several types of emphysema. The radiographic criteria for this syndrome include presence of giant bullae in one or both upper lobes, occupying at least one-third of the hemithorax and compressing the normal surrounding lung. Bullae can vary in size from 1 to 20 cm in diameter. Palliative bullectomy is often required and HRCT often is required preoperatively to determine the extent of disease and to determine the presence and severity of associated emphysema.

RADIOGRAPHIC FINDINGS

Bullae are often inapparent but may be visible as thin-walled, well-defined avascular areas. The walls are very thin and may be obscured. Large bullae may create areas of compressive atelectasis. Bullae consistently slowly enlarge with serial radiography. The presence of an air-fluid level within a bulla indicates infection, often with surrounding pneumonitis, but may be due to hemorrhage or cancer formation. Pneumothorax may develop.

CT FINDINGS

Bullae are more easily visible, and CT can define the pulmonary anatomy, lung compression, and extent of emphysema as well as help in volume calculations. CT can help to clarify whether a large airspace is a pneumothorax or a bulla, if there is doubt.

OTHER CAUSES OF EMPHYSEMA

Swyer-James syndrome may lead to emphysema. Intravenous talcosis and hypocomplementemic urticarial vasculitis produce panlobular emphysema. HIV may cause emphysema.

CYSTIC FIBROSIS

EPIDEMIOLOGY AND ASSOCIATED FINDINGS

Cystic fibrosis (CF) is the most common lethal genetic disease among patients of European descent, occurring in 1:2000 to 1:3500 births and usually diagnosed before

age 5. The vas deferens may be absent; cervical mucus abnormalities in affected women also affect fertility. Ten to fifteen percent of patients will have meconium ileus obstruction as neonates, and patients may also have distal obstruction that is due to abnormal gastrointestinal fluid transport. Rectal prolapse occurs in up to one-fifth of untreated patients before age 5. Esophageal dysfunction and gastroesophageal reflux disease (GERD) are common. Hepatic steatosis and biliary cirrhosis may develop, the latter in up to 30% of patients. Gallbladder dysfunction is common. Pancreatic enzyme deficiency occurs in 90% of patients, because of duct obstruction and exocrine atrophy, and they may occasionally have acute pancreatitis.

PULMONARY SYMPTOMS AND SIGNS

Patients have recurrent chest infections and wheeze, dyspnea, productive cough, and hemoptysis. Visceral problems lead to malnutrition and hypoproteinemia. Hemoptysis is generally small but may be massive, because of bronchial-arterial hyperplasia in ectatic airways. Patients are more likely to have atopy or asthma, and often have chronic sinusitis and polyposis but infrequent symptoms. Allergic bronchopulmonary aspergillosis is more common as well.

ETIOLOGY AND PATHOGENESIS

Immune response is normal, but defense is defective because of abnormal mucociliary transport, so the long-term presence of inflammatory mediators contributes to bronchiectasis. It is due to a defect in the cystic fibrosis transmembrane receptor, a cAMP-regulated chloride channel in epithelial cells and tracheobronchial glands. In CF patients, sweat contains elevated sodium, potassium, and chloride. Pancreatic secretions become electrolyte deficient, particularly bicarbonate; major salivary gland output is normal but the products of the minor salivary glands contain elevated electrolytes (these are similar to sweat glands). Mucus contains increased glycoproteins and products of cell breakdown including DNA, and may have a factor that inhibits cilia. Respiratory infection or chronic colonization, particularly by *Pseudomonas aeruginosa* and increasingly by *Burkholderia cepacia*, increases respiratory decline.

RADIOGRAPHIC AND HRCT FINDINGS

The earliest manifestations are small subpleural opacities; thickened bronchi, hyperinflation, and hilar lymphadenopathy are less common. With progression, the

bronchi and bronchial walls become larger, lung volume increases, and the peripheral opacities increase. Bronchiectasis, bronchial thickening, and mucus plugging are present in 90% to 100% of cases; cyst-like spaces visible in 25% to 30% of adults. Bronchiectasis is often diffuse but upper-zone predominant. Hilar enlargement, tracheal dilation, pneumothorax, and pneumomediastinum may develop. HRCT is the method of choice for evaluation of bronchiectasis and is particularly useful for evaluating early peripheral involvement (manifest as tree-in-bud centrilobular nodules). It is more sensitive than radiography especially for mild disease.

BRONCHIOLITIS

Bronchiolitis is inflammation of membranous and respiratory bronchioles. Radiology correlates better with histology than with etiology. It may be classified by the type of inflammation (acute or chronic) and by the type of fibrosis—called obliterative bronchiolitis when narrowing is concentric and epithelium is intact—or bronchiolitis obliterans—organizing pneumonia (BOOP) when granulation or fibroblastic tissue extends from areas of epithelial damage to narrow or obstruct the airway.

RADIOGRAPHIC FINDINGS

Radiographic findings depend on the extent of disease, chronicity, and underlying abnormality, and radiographic severity does not correlate with clinical severity. The radiographic patterns are typically limited to two categories. Hyperinflation and peripheral vascular attenuation are visible with obliterative bronchiolitis, and alveolar consolidation is visible with BOOP. Other findings of peribronchial wall thickening, perihilar linear opacities, and atelectasis are less reproducible.

HRCT FINDINGS

HRCT provides greater anatomic detail, such that this modality can suggest the histology of the process. HRCT may image several patterns of disease.

Centrilobular nodules and branching lines are due to thickening of bronchiolar walls and filling of the bronchioles with pus, mucus, or granulation tissue. This is characteristic of acute infectious bronchiolitis or diffuse panbronchiolitis, and may be accompanied by scattered ground glass or consolidation. The nodules of respiratory bronchiolitis (RB) are poorly defined, whereas the nodules of infectious bronchiolitis and panbronchiolitis are well defined.

Mosaic attenuation is due to airway closure and air trapping, with hypoxemic vasoconstriction. It is present in patients with obliterative bronchiolitis, extrinsic allergic alveolitis, asthma and bronchiectasis, and in patients with primary-vascular processes such as chronic PTE.

Consolidation is visible in BOOP, often patchy and random, because of organizing pneumonia. Centrilobular opacities may be present: granulation tissue or peribronchiolar consolidation.

Ground glass attenuation associated with respiratory bronchiolitis (RB), and RB is associated with interstitial lung disease (ILD), extrinsic allergic alveolitis, and BOOP. In RB, ground glass attenuation is bilateral and patchy or diffuse, and tends to be an upper-lung process. In extrinsic allergic alveolitis, extensive bilateral ground glass attenuation is accompanied by poorly defined centrilobular nodules, often with areas of air trapping.

ACUTE BRONCHIOLITIS

Infectious bronchiolitis is typically due to *Mycoplasma pneumoniae*, *Chlamydia* species, or viruses, most common in young children. Imaging findings include hyperinflation, reticulonodular opacities, and areas of consolidation and atelectasis. HRCT reveals centrilobular nodules or lines and focal consolidation. Noninfectious bronchiolitis may be due to acute exposure to smoke, sulfur dioxide, nitrogen oxides, or other agents. After 2 to 5 weeks, obliterative bronchiolitis develops.

CHRONIC BRONCHIOLITIS

Chronic bronchiolitis may be associated with connective tissue disease, particularly rheumatoid arthritis. Rheumatoid arthritis may lead to obliterative, follicular, lymphocytic, BOOP, or diffuse panbronchiolitis. In Sjögren syndrome, lymphocytic or follicular bronchiolitis is most common. Obliterative bronchiolitis may complicate marrow, lung, and heart-lung transplant. Swyer-James syndrome is characterized radiographically by hyperlucent lobe or lung with reduced inspiratory volume and expiratory air trapping. It is the result of decreased blood flow after bronchiolar obliteration, likely by the progression of acute viral bronchiolitis to fibrous airway obliteration.

BRONCHIOLITIS OBLITERANS—ORGANIZING PNEUMONIA (CRYPTOGENIC-ORGANIZING PNEUMONIA)

BOOP usually is subacute, progressing over several months. The process may completely resolve after corti-

costeroid therapy. BOOP is typically patchy, characterized by loose connective tissue plugs in distal airways and alveoli; chronic inflammation or interstitial fibrosis may be present.

Patchy airspace consolidation is the most common radiographic finding. Opacities are typically pleural based and peripheral, ranging from 3 cm to entire lobes, and can be migratory. They have indistinct margins and may contain air bronchograms. The differential considerations for this presentation include chronic eosinophilic pneumonia, bronchioloalveolar carcinoma, lymphoma, pulmonary alveolar proteinosis, and hemorrhage. Reticular or reticulonodular opacities may be isolated or associated with airspace disease. Unifocal consolidation is unusual; the differential consideration then is lung cancer, and the etiology may be unknown until after resection. Large nodules may simulate metastasis. In HRCT, most patients will have consolidation, small nodules, or both. Peripheral reticulation and ground glass opacities are less often visible.

RESPIRATORY BRONCHIOLITIS

RB is due to cigarette smoking, associated with macrophage deposition in respiratory bronchioles and alveoli, and inflammatory thickening of respiratory bronchial walls. It is called RB with ILD when symptoms are associated with added radiopathologic findings. It responds well to smoking cessation and to corticosteroids.

In simple RB, poorly defined centrilobular nodules or ground glass opacities may be diffuse or may be predominantly upper lobar; with RB-ILD ground glass opacities may be associated with fine reticular or reticulonodular opacities, with normal lung volumes.

FOLLICULAR BRONCHIOLITIS

Lymphoid tissue with prominent germinal centers develops in bronchiolar and bronchial walls, a nonspecific process found in connective tissue diseases (especially Sjögren syndrome and rheumatoid arthritis), immunodeficiency states, hypersensitivities, or infections by *M. pneumoniae* or viruses.

Diffuse reticulonodular disease will be present. Nodular opacities typically ranging from 1 to 3 mm but sometimes as large as 2 cm are mainly peribronchovascular or subpleural. Centrilobular branching opacities, bronchial thickening, and occasionally patchy hypoattenuation are present.

DIFFUSE PANBRONCHIOLITIS

Diffuse panbronchiolitis has unknown etiology but leads to chronic paranasal sinus and respiratory-bronchiolar inflammation. It responds to chronic erythromycin treatment. Most patients are 30 to 60 years old and commonly male. It may have an HLA association with a haplotype most common in Asia.

Diffuse nodules less than 5 mm are present, accompanied by mild-moderate hyperinflation. Small centrilobular nodules and branching lines, bronchiolectasis and bronchiectasis, and mosaic attenuation are present. Large cystic spaces may develop.

BRONCHIAL DISEASES

BRONCHIECTASIS

Bronchiectasis is irreversible bronchial dilation. The common factors are infection, obstruction, and peribronchial fibrosis. Inflammatory factors lead to proteolytic enzyme release. A dilated airway is commonly colonized and chronic inflammation continues the process. Chronic airway obstruction leads to mucus distension, postobstructive infection, or atelectasis, leading to radial traction. Immunologic deficiency states predispose to bronchiectasis by increasing the incidence of bronchial infection or colonization. Other causes include dyskinetic cilia syndrome, Williams-Campbell syndrome of airway cartilage deficiency leading to fourth- through sixth-generation airway bronchiectasis, and Mounier-Kuhn syndrome of tracheobronchomegaly that is due to decreased elastin and smooth muscle. Other causes are variable: measles, pertussis, latent viral infection, congenital abnormality, noxious inhalation, or necrotizing infection.

TYPES OF BRONCHIECTASIS (TABLE 19-2)

- Group I, cylindrical bronchiectasis, is characterized by regular outline and peripherally normal-caliber airways, often plugged by mucus.
- Group II, varicose bronchiectasis, has greater dilation and local constrictions are characterized by irregular outlines. Peripheral bronchi are more obliterated.
- Group III, saccular or cystic bronchiectasis, is characterized by bronchi that continue to dilate peripherally. A mucocele may form when one of these ballooned spaces becomes filled with mucus.

TABLE 19-2 Bronchiectasis

Group I	Cylindrical
Group II	Varicose
Group III	Saccular (cystic)

RADIOGRAPHIC AND HRCT FINDINGS

The radiograph is often normal in milder disease. Parallel line opacities are due to thickened bronchial walls. Tubular opacities represent mucus-filled bronchi. Ring opacities or cystic spaces may be up to 2 cm diameter, and may contain fluid or air-fluid levels. Focal fibrosis and volume loss may occur. Oligemia may result from hypoxic vasoconstriction in severely diseased areas. The uninvolved lung may be hyperinflated.

HRCT is more sensitive and specific than radiography. There will be internal bronchial diameter greater than the adjacent pulmonary artery, lack of bronchial tapering, bronchial visualization within 1 cm of the costal pleura or abutting the mediastinal pleura, or bronchial wall thickening. Other findings such as tracheomegaly or lymphadenopathy may be better appreciated.

BRONCHOLITHIASIS

Irregular calcified or ossified material lies within the tracheobronchial lumen, ranging from submillimeter to large in size. The most common symptom is cough, sometimes hemoptysis. Erosion of calcified lymph node material into the airway is the most common etiology, usually from chronic necrotizing granulomatous lymphadenitis caused by *Mycobacterium tuberculosis*, *Histoplasma capsulatum* (most common in North America), or *Coccidioides immitis*. Broncholithiasis may manifest radiographically as a mobile calcific density or as airway obstruction. CT can generally image the broncholith.

BRONCHIAL FISTULAE

The principal causes of bronchial fistulae are infection and cancer; other causes are trauma, inflammation, or foreign body. The most common form is bronchopleural fistula, which may develop after cancer resection as a result of stump dehiscence. Dehiscence almost always develops within 90 days. Bronchoesophageal fistula may be congenital or acquired. Bronchovascular fistula results in hemoptysis. Bronchoabdominal fistula may develop with subphrenic abscess, colon cancer, or Crohn disease.

TOXIC EPIDERMAL NECROSIS

In toxic epidermal necrosis, a diffuse erythematous rash is followed by bulla formation, usually from staphylococcal infection or drug reaction. In the lungs, bronchial epithelial sloughing can cause obstruction.

PLASTIC BRONCHITIS

Plastic bronchitis results in the coughing up of debris shaped like the airway. It is most common with allergic bronchopulmonary aspergillosis, but may be seen with CF, bronchiectasis, pneumonia, alveolar proteinosis, and airway lymphoid hyperplasia. There is also an idiopathic form of plastic bronchitis.

OBLITERATIVE BRONCHITIS

Obliterative bronchitis is analogous to obliterative bronchiolitis and is often associated with it. When associated with bronchiolitis, the bronchial abnormalities are mild in comparison.

QUESTIONS AND ANSWERS

- Regarding acute laryngotracheitis, which of the following is *true*?
 - Causes narrowing of the supraglottic airway
 - Caused by parainfluenza or respiratory syncytial virus
 - Presence of stridor indicates mild disease.
 - Associated with *H. influenzae*

ANSWER: B. Acute laryngotracheitis causes acute subglottic tracheal narrowing, sometimes with a mucopurulent pseudomembrane requiring endoscopic removal. It is caused by parainfluenza or respiratory syncytial virus in many cases and the presence of stridor indicates immediate laryngeal visualization.

- Regarding upper airway obstruction, which of the following is *true*?
 - Extrathoracic variable obstruction leads to decreased area with forced inspiration.

- Extrathoracic variable obstruction leads to decreased area with forced expiration.
- Intrathoracic variable obstruction leads to decreased area with forced inspiration.
- Intrathoracic variable obstruction leads to increased area with forced expiration.

ANSWER: A. An extrathoracic variable obstruction leads to decreased area with forced inspiration and an intrathoracic variable obstruction leads to decreased area with forced expiration.

- Regarding Mounier-Kuhn syndrome, which of the following is *true*?
 - Disorder of older women
 - Characterized by thickened tracheobronchial muscular tissues
 - Associated with Fanconi syndrome
 - Eponym for tracheobronchomegaly

ANSWER: D. Mounier-Kuhn syndrome is tracheobronchomegaly, found most commonly in young men. Muscular and elastic tissues are thin and atrophied. It is associated with Ehlers-Danlos, Kenny-Caffey, and Brachmann-de Lange syndromes and cutis laxa, but not Fanconi syndrome.

- Which of the following is the greatest risk factor for the development of obstructive sleep apnea?
 - Smoking
 - Obesity
 - Neurologic disorders
 - Elevated circulating estrogens

ANSWER: B. Smoking and some neurologic disorders increase the risk of obstructive sleep apnea, along with many other factors. However, obesity is the greatest risk factor, particularly central or visceral obesity. Some women with obstructive sleep apnea have higher androgen levels than women who do not.

- A 6-year-old boy has wheezing and shortness of breath about once a day and frequently awakes from sleep gasping. His FEV-1 is 64% of predicted. Which of the following is the most likely diagnosis?
 - Mild persistent asthma
 - Moderate persistent asthma
 - Intermittent asthma
 - Severe persistent asthma

ANSWER: B. This boy has moderate persistent asthma, which includes daily symptoms.

- Regarding FEV-1 after age 30, which of the following is *true*?
 - Healthy nonsmokers undergo annual FEV-1 decline of 30 to 70 mL.

- B. Smokers undergo annual FEV-1 decline of 30 to 70 mL.
- C. Smokers with PiZZ genotype undergo annual FEV-1 decline of 30 to 70 mL.
- D. Nonsmokers with PiZZ genotype undergo annual FEV-1 decline of 30 to 70 mL.

ANSWER: B. Healthy nonsmokers undergo annual FEV-1 decline of 10 to 35 mL; healthy smokers, 30 to 70 mL. PiZZ nonsmokers undergo annual FEV-1 decline averages 80 mL; PiZZ smokers, 317 mL.

7. Which of the following is the type of emphysema commonly found in smokers without alpha-1-antitrypsin disorder?
- A. Panlobular emphysema
 - B. Cicatricial emphysema
 - C. Paraseptal emphysema
 - D. Centrilobular emphysema

ANSWER: D. Panlobular emphysema is the most common form of emphysema in nonsmokers, associated with alpha-1 antitrypsin deficiency. Cicatricial emphysema is likely postinflammatory; it is the most common form pathologically but is limited and asymptomatic. Paraseptal emphysema leads to focal peripheral bullae and occasional spontaneous pneumothorax. Centrilobular emphysema is the emphysema of cigarette smokers.

8. Regarding associations of CF, which of the following is most common?
- A. Biliary cirrhosis
 - B. Pancreatic enzyme deficiency
 - C. Meconium ileus
 - D. Rectal prolapse

ANSWER: B. Biliary cirrhosis occurs in up to 30% of patients. Pancreatic enzyme deficiency occurs in 90% of patients. Though meconium ileus is specific for CF, it is nonsensitive; it occurs in only 10%–15% of patients. Rectal prolapse may occur in up to 20% of untreated patients by age 5.

9. Which of the following is the etiology of mosaic attenuation on HRCT of bronchiolitis?
- A. Thickening of bronchiolar walls and bronchiolar filling
 - B. Airway closure and air trapping with resultant arterial vasoconstriction
 - C. Organizing infection
 - D. Lymphoid aggregates

ANSWER: B. Bronchiolar thickening and filling results in centrilobular nodules and lines. Airway closure and air trapping with resultant arterial vasoconstriction leads to mosaic attenuation. Organizing

infection leads to alveolar consolidation. Lymphoid aggregates lead to peribronchovascular and subpleural nodular opacities.

10. Which of the following is a radiographic sign of bronchiectasis?
- A. Ground glass opacities
 - B. Visible right upper lobe bronchus
 - C. Parallel line opacities
 - D. Diffuse hyperinflation

ANSWER: C. Signs of bronchiectasis include parallel lines, tubular or ring opacities, or cystic spaces. Segmental increased size and decreased definition of lung markings can result from fibrosis and retained secretions. Vascular markings may be crowded from volume loss. Oligemia may result from hypoxic vasoconstriction in severely diseased areas. The uninvolved lung may be hyperinflated. The right upper lobe bronchus is visible in normal patients.

20 PULMONARY INFECTION

John C. Texada and Satinder P. Singh

GENERAL FACTS

Inhaled objects greater than 5 μm deposit on the upper airways; objects less than 0.5 μm are exhaled. Objects 1 to 2 μm land in the parenchyma. Typically many bacteria are required to cause disease but in some cases (e.g., TB), a small number is enough. Pneumonia is the number one infectious cause of death in the United States. Up to 18% of surgical patients acquire pneumonia in hospital. Ventilation carries a 1% to 3% daily infection risk. Hospital-acquired pneumonia (HAP) adds 7 to 9 days to hospital stay, with 30% to 70% mortality. Community-acquired pneumonia (CAP) is bacterial in only 2% of patients not requiring hospitalization; the remaining 98% of CAP cases treated on an outpatient basis are caused by atypical agents. Of those patients with CAP serious enough to require hospitalization, 10% have a positive blood culture: *Streptococcus pneumoniae* is isolated in 35% of these; anaerobes, in 20% to 35%; and *Haemophilus influenzae*, in 2% to 8%. *Legionella* causes only 2% of CAP overall, but is more frequently encountered in patients with CAP serious enough to require hospitalization. HAP is defined as pneumonia occurring more than 48 hours after hospital admission; it is often caused by aspiration and is often polymicrobial. HAP acquired early in a hospitalization is often due to gram-positive agents; HAP acquired later in a hospitalization is often due to enteric gram-negative

bacteria. Ventilator-associated pneumonia may be difficult to diagnose radiographically: the air bronchogram is the only helpful sign.

In immunocompromise, agents normally of decreased virulence have high morbidity. Combined immunodeficiency (such as severe CID, ADA deficiency, or purine nucleoside phosphorylase deficiency) causes childhood death without intervention. Antibody deficiency (for example, agammaglobulinemia, IgA or IgG deficiency, or combined-variable immunodeficiency) causes recurrent pyogenic infection. Chronic granulomatous disease predisposes to catalase-positive infection. Patients with Chediak-Higashi syndrome have defective granulocyte oxidative burst, which predisposes to skin and lung disease. Disorders leading to deficient complement predispose to repeated encapsulated organism infection. The X-linked-recessive Wiskott-Aldrich syndrome (comprising thrombocytopenic purpura, eczema, and immunodeficiency) leads to abnormal cell-mediated immunity and thus recurrent infection. The autosomal-recessive syndrome ataxia-telangiectasia (comprising cerebellar ataxia, cancer, oculocutaneous telangiectasia, and sinopulmonary infection) is associated with B- and T-cell dysfunction, with mortality via bronchiectasis and interstitial pneumonitis by the third decade of life. DiGeorge syndrome comprises thymic aplasia or hypoplasia, parathyroid aplasia, and malformations of the third and fourth branchial arches.

ROUTES OF SPREAD

Infection via vessels is usually from extrapulmonary source. Bacteria may be free, within thrombus, or directly invade the vessel wall as in TB. The individual sites of blood-borne infection are nodular: with sepsis, innumerable 1 to 5 mm nodules; with septic emboli, fewer, larger, frequently cavitary nodules. Infection via direct spread occurs with chest wound, mediastinitis, or abdominal abscess. Tracheobronchial spread may be via aspiration, inhalation, or insertion of infected sources.

AIRWAY INFECTION

Mycoplasma and viruses are most common. Bronchiolitis is more dangerous than tracheobronchitis particularly in children; respiratory syncytial virus (RSV) and parainfluenza predominate. Bacterial tracheitis is uncommon, often after viral URI, but can be serious in children. *Staphylococcus aureus* and *H. influenzae* are most common. Acute bronchitis often has normal radiograph but may have bronchial dilation, wall thickening, and peribronchial inflammation. Bacterial bronchitis occurs in patients with airway disease.

AIRSPACE INFECTION

Nonsegmental (lobar) consolidation is by *Streptococcus pneumoniae* and others. Edema develops with little purulence and spreads centrally from the periphery. Radiograph reveals homogeneous demarcated consolidation. Inflammation may expand tissue and bulge fissures. After the infection is resolved, pulmonary parenchymal architecture is typically normal since it remains intact through the infection.

Bronchopneumonia is via *S. aureus*, gram negatives, or some fungi. Exudate forms with little edema, leading to patchy opacity. Ill-defined centrilobular nodules develop and coalesce. Volume loss is common. Abscess, pneumatocele, or pulmonary gangrene may occur. Bronchopneumonia is destructive, so organization or fibrosis is typical. Interstitial pneumonia is by viruses, *Mycoplasma*, and *Pneumocystis carinii*. Interstitial exudate may be lymphocytic or have alveolar damage. Radiograph has reticular-reticulonodular opacities and septal lines. Bronchiolitis causes centrilobular opacities, bronchitis, and peribronchial thickening.

Lung abscess has smooth walls less than 15 mm (cavitated cancer has shaggy thick walls). Air-fluid level is common. Anaerobes, *S. aureus*, and *Pseudomonas aeruginosa* are common. Symptoms may be mild; hemoptysis may be fatal. Pulmonary gangrene is development of necrotic lung fragments. Small lucencies in consolidation coalesce to a cavity. Most are caused by *Klebsiella pneumoniae*. Pneumatocele is a thin-walled airspace formed when check-valve obstruction allows filling of a necrotic region. *Staphylococcus aureus* is a frequent cause with *P. carinii* also in the immunocompromised.

BACTERIAL PNEUMONIA

GRAM-POSITIVE COCCI

Streptococcus pneumoniae is an encapsulated facultative anaerobe in pairs or short chains, the most commonly isolated agent, in at least 40% of cases. Aspiration from colonized nasopharynx produces lobar consolidation. Resolution takes 2 to 4 weeks with adequate therapy; abscess, pneumatocele, or gangrene is rare. Radiograph reveals homogeneous lobar or round opacity with air bronchograms. Acutely volume loss is minimal but atelectasis may develop during resolution.

Streptococcus pyogenes is beta-hemolytic and occurs in chains. Once a common cause of serious bronchopneumonia (hemorrhage and cavitary necrosis caused rapid death), it is rare now, occasionally causing superinfection or occurring in community living sites. Radiograph reveals segmental consolidation and

atelectasis. Abscess and empyema are common; pneumatocele and pyopneumothorax are absent.

Staphylococcus aureus is a clustered coagulase-producing facultative anaerobe, a cause of tracheitis or bronchopneumonia, often after influenza. It causes CAP uncommonly, but 15% of HAP. Infection can be acute hemorrhagic, acute purulent, or chronic organizing. Radiograph reveals multilobar or bilateral segmental consolidation; abscess forms in 25%. Air bronchograms are absent. Pneumatocele and effusion are common, and half the latter are empyema.

GRAM-NEGATIVE COCCI

Moraxella (*Branhamella*, *Neisseria*) *catarrhalis* occurs in pairs, is oxidase positive and catalase positive, and is typically intracellular. It is oral flora and may cause mild pneumonia, particularly with underlying lung disease, but is typically nonbacteremic. Most are beta-lactamase positive.

Neisseria meningitidis occurs in pairs, is oxidase positive and catalase positive, and is typically intracellular. It may cause pneumonia after viral infection often in young adults in military service. It typically forms an easily treatable bronchopneumonia, though sepsis may occur.

GRAM-POSITIVE RODS

Bacillus anthracis is a large encapsulated spore former, typically causing skin or GI infection, often in livestock workers, but may cause pneumonia or sepsis. Its toxin causes edema and hemorrhage: hemorrhagic nodes and tissues and bloody effusion are common. Radiograph reveals mediastinal widening with patchy nonsegmental opacities caused by hemorrhagic edema.

Listeria monocytogenes is a short, motile facultative intracellular organism, found in soil, water, sewage, domestic animals, and human carriers. Infection typically occurs in neonates, pregnant women, immunocompromised patients, and older patients with chronic disease.

Corynebacterium species are club shaped and cause membranous pharyngitis that can extend to the larynx, but not pneumonia. *Rhodococcus equi* is a weakly acid-fast rod or coccus that causes an often cavitary pneumonia in immunocompromised hosts. It is associated with malakoplakia.

GRAM-NEGATIVE RODS

Gram-negative rods are responsible for more than 50% of ventilator-acquired pneumonia and 25% of community-acquired pneumonias (CAP) requiring hospitalization.

The Enterobacteriaceae reduce nitrate, ferment glucose, produce endotoxin, and are oxidase negative. They cause one-third of HAP, and include *Klebsiella*, *Enterobacter*, *Serratia*, *Escherichia coli*, *Salmonella*, *Proteus*, *Morganella*, and *Yersinia*. *Klebsiella pneumoniae* pneumonia occurs typically in alcoholic patients in their fifties and often has bulging fissures; abscess, cavity, gangrene, and empyema are more likely than with pneumococcus. *Serratia marcescens* causes pseudohemoptysis of red sputum. *Proteus* and *Morganella* infect those with chronic suppurative lung disease or tracheostomy. *Yersinia pestis* is the cause of plague: in pneumonia, radiograph reveals homogeneous consolidation simulating edema or ARDS, with lymphadenopathy and occasional effusion.

The fermenting non-Enterobacteriaceae are as follows. *Aeromonas* are found in water, appear in infected wounds or GI disease, and may cause fulminant pneumonia after near drowning. *Chromobacterium violaceum* is nonmotile and catalase positive, and has caused pneumonia in patients with CGD. *Pasteurella multocida* is a nonmotile pathogen typically of animals that causes pneumonia in patients with chronic lung disease. *Vibrio* species are motile aerobic bacteria, the most common bacterium in surface water but almost never a cause of lung disease.

The nonfermenting non-Enterobacteriaceae include *Burkholderia* and *Pseudomonas*. *Burkholderia mallei* causes glanders. Acute pneumonia has abscess, empyema, and lymphadenopathy, and a chronic form similar to TB. *Burkholderia pseudomallei* causes melioidosis. Radiograph reveals consolidation or irregular coalescent cavitary 3 to 15 mm nodules. Chronic disease is similar to TB but spares the apex and rarely calcifies or retracts the hila. *Burkholderia gladioli* colonizes CF patients and can cause pneumonia. *Burkholderia cepacia* presents an opportunistic infection in CF. *Pseudomonas aeruginosa* is a motile obligate aerobe, with a mucoid matrix, a constituent of human flora. It thrives in moisture. *Pseudomonas* is the most common and lethal cause of HAP. Hemorrhagic subpleural nodules form in aspiration-prone areas and along bronchovascular bundles. *Stenotrophomonas* (*Xanthomonas*, *Pseudomonas*) *malophilia*, often drug resistant, colonizes CF patients and infects the immunocompromised. *Acinetobacter*, encapsulated nonmotile aerobes, colonizes hands and catheters and may spread from person to person. Most cases are immunocompromised, severe, and bacteremic.

GRAM-NEGATIVE COCCOBACILLI

Brucella species (*B. melitensis*, *B. abortus*, *B. canis*, and *B. suis*) are small nonmotile nonencapsulated intracellular parasites that can cause human disease via

skin entry; GI absorption, often via unpasteurized contaminated dairy products; or inhalation. In brucellosis, lung disease is uncommon; necrotizing granulomatous disease is similar to chronic TB.

Bordetella species cause whooping cough (*B. pertussis* and *B. parapertussis*) or rarely pneumonia (*B. bronchiseptica*). Pertussis typically occurs in patients younger than 2 years of age. The bacteria produce toxins and filamentous hemagglutinin, responsible for membrane formation.

Francisella tularensis is the nonmotile non-spore-forming cause of tularemia, a small animal disease contacted via skin entry, tick or deer fly bite, ingestion, or culture material inhalation. The disease has multiple forms, with pulmonary infection via hematogenous spread of ulceroglandular and typhoid forms: small necrotic nodules become confluent.

Haemophilus influenzae is pleomorphic non-spore forming and nonmotile, encapsulated or unencapsulated. It is responsible for 5% to 20% of cultured CAP and almost half of chronic infectious pneumonias. Encapsulated types are more virulent; unencapsulated types colonize the throat and may cause bronchitis or pneumonia. Radiograph reveals bronchopneumonia.

Legionella (particularly *L. pneumophila*) lives in water, probably in biofilms or other microbes. They prevent macrophage phagosome-lysosome fusion, preventing killing. *Legionella* causes 2% to 25% of CAP requiring hospitalization, more likely in older men. It infects via moist air drift, sometimes with liver, renal, or CNS abnormalities (Legionnaire disease). Resolution is generally slow even with therapy; radiographic improvement, slower. One-third of patients require ventilation; mortality ranges from 5% with erythromycin therapy to 20% without. Radiograph reveals nonsegmental consolidation that spreads despite appropriate therapy. Disease is often bilateral; abscess or cavitation does not occur. Pontiac fever is a nonpneumonic flu-like illness.

TREPONEMAL INFECTION

Leptospira interrogans lives in host renal convoluted tubules and is shed in urine. Infection occurs via water or soil contact. Leptospirosis is often occupational; pets also can cause it. Infection may have hepatorenal symptoms (Weil disease) or predominant lung disease. Radiograph reveals 1 to 7 mm nodules with or without consolidation, confluent consolidation, or ground glass opacities.

Treponema pallidum causes syphilis. Pulmonary syphilis occurs in congenital syphilis as pneumonia alba, usually associated with stillbirth or early death. In

acquired disease, lung involvement is rare and occurs in the third stage: fibrogummatous disease involves the parenchyma and pulmonary arteritis occurs, associated with aortitis.

ANAEROBIC BACTERIA

Anaerobes cause 20% to 35% of CAP cases requiring hospitalization, often polymicrobial. Important members are gram-negative bacilli *Bacteroides*, *Fusobacterium*, *Porphyromonas*, and *Prevotella*; gram-positive bacilli *Actinomyces*, *Eubacterium*, and *Clostridium*; gram-positive cocci *Peptostreptococcus* and *Peptococcus*; and gram-negative coccus *Veillonella*. Anaerobic pneumonia is associated with poor dentition and decreased mental status, and is male predominant. Anaerobes cause necrosis, leading to abscess, cavitation, and empyema. Radiograph reveals bronchopneumonia coalescing to consolidation often with abscess, gangrene, and lymphadenopathy. Pyopneumothorax may develop with *Bacteroides fragilis* or *Clostridium perfringens*.

MYCOBACTERIAL INFECTION

Mycobacteria are slow-growing nonmotile non-spore-forming aerobes containing up to 25% lipids (helping resist degradation). They are acid-fast, as are some *Nocardia*, *Corynebacteria*, and *Legionella micdadei*. The tuberculosis complex includes *Mycobacterium tuberculosis*; *Mycobacterium bovis*, a once common infection of nodes, GI tract, and bones now uncommon with milk pasteurization; *Mycobacterium africanum*; and *Mycobacterium microti*, not a human pathogen. The nontuberculosis complex includes *Mycobacterium leprae*; photochromogens, including *Mycobacterium kansasii*; scotochromogens, including *Mycobacterium avium-intracellulare* complex; and fast-growing species, including *Mycobacterium fortuitum* and *Mycobacterium chelonae*.

MYCOBACTERIUM TUBERCULOSIS

INFECTION

Up to one-third of the world population has *M. tuberculosis* infection; 3 million die annually. The U.S. rate is approximately 6 to 20:100 000. Infection increases with cough, cavity, upper airway spread, and extent of involvement, as well as ventilation, closeness and duration of contact, and susceptibility. *Mycobacterium tuberculosis* can survive and multiply within macrophages and can live within necrotic tissue for long periods of

time. Virulence is related to a strain's ability to form cords, via cord factor, produce ammonia (these may inhibit lysosome-phagosome fusion), lyse phagosomes, and produce catalase.

DISEASE

Tuberculosis develops in 5% to 15% of infections; the risk is highest in the first 2 years. Disease may be either progressive primary TB or postprimary TB, often reactivation. There are many risk factors: socioeconomic, including malnutrition, homelessness, and population density; exposure via profession or environment; drug and alcohol use; immigration from high prevalence; and coexistent disease (immunosuppression, diabetes, renal failure, gastrectomy or jejunoileal bypass, iron overload, silicosis, and alveolar proteinosis).

Primary Pulmonary Tuberculosis

Droplets incite granuloma formation, necrosis, and coalescence surrounded by fibrous tissue. The initial site, the Ghon focus, may progress or heal and calcify. Lymph node extensions form the Ranke complex. Node enlargement may cause airway compression and atelectasis; extranodal extension may cause edema or airway ulceration; node rupture into a bronchus or vessel results in bronchopneumonia or miliary disease, respectively, or in hemoptysis if it ruptures into both. Bloodstream spread is common but miliary manifestations are not. If the disease is not controlled, it progresses to progressive primary tuberculosis, similar to postprimary disease. Most radiographs are normal. Consolidation is the most common abnormality: unilateral, dense, homogeneous, segmental or lobar, upper lobe predominant. Lymphadenopathy is visible in >90% of children and fewer adults, and may be the only finding, commonly hilar and right-sided. Atelectasis is often lobar, usually caused by nodal airway compression. Effusion is uncommon, more frequent in adults. Cavities and miliary disease occur in less than 10%.

Postprimary Tuberculosis

Postprimary tuberculosis is via reactivation of a primary focus or new acquisition. It tends to be in apical-posterior upper lobe or superior lower lobe. It is similar to primary TB except that necrosis is more rapid and infection tends to progress. Frequent airways communication allows cavitation. Infection causes vasculitis or thrombosis in adjacent vessels. Arteries near a cavity dilate in 4% of cases (Rasmussen aneurysm); death from rupture is common. TB bronchopneumonia is via endobronchial spread of necrotic material. Miliary TB occurs via lymphatic or vascular dissemination: innumerable pulmonary and pleural millet seed–sized nodules. Tracheobronchial TB may occur via luminal, miliary, or lymphatic spread, or direct extension. Cervical or supra-

clavicular lymphadenopathy, pericarditis, or mediastinitis may develop. Mediastinitis may lead to aortic erosion, phrenic nerve palsy, SVC syndrome, esophageal stricture or fistula, or traction diverticula. Contained infection will heal with irregular scars, emphysema, and bronchiectasis.

IMAGING FINDINGS

Consolidation suggests active disease and isolated calcification suggests inactive disease; but this is not absolute. TB localizes in apical and posterior upper lobes or superior lower lobes, often multisegmental. Consolidation often has satellite nodules. Lymphadenopathy is rarely visible; cavitation is often visible. Cavities may be single or multiple, have thick or thin walls or fluid levels, and resolve or become thin-walled cystic spaces with therapy. Hypo- or nonenhancing tuberculomas have small satellite lesions. Tree-in-bud nodules are visible in almost all patients in HRCT, the main or only manifestation in up to 25%. The 2 to 10 mm nodules of endobronchial spread are frequently visible. The 1- to 3-mm nodules of miliary tuberculosis may enlarge and coalesce with inadequate therapy. Bronchiectasis is visible in 30% to 60% of active postprimary disease via HRCT, often bilateral, and generally radiographically inapparent. Approximately 40% have concentric bronchial stenosis on CT.

THE PPD

Protein precipitates are from heat-killed bacteria. The injection is intradermal. Interpretation is on the second or third day, measuring induration. Erythema is unimportant but may suggest subcutaneous injection. Interpretation depends on patient factors. Patients are positive at 5 mm of induration if HIV or risk factors for it; recent close contact with a TB patient; or radiographs consistent with healed TB. Patients are positive at 10 mm of induration if from a high-prevalence part of the world; intravenous drug users; residents of long-term care facility; with TB-associated conditions; or treated with high-dose corticosteroids or immunosuppressive therapy. Everyone else is positive at 15 mm.

NONTUBERCULOUS MYCOBACTERIA

Patients often have COPD or other lung disease. Other risk factors are similar to those for *M. tuberculosis*. Infection by nontuberculous mycobacteria leads to identical pathologic findings and it is difficult radiologically and histologically to differentiate tuberculous from nontuberculous infection, with the possible exception

of *M. avium-intracellulare*. Confident differentiation of any particular case is impossible but trends are present. *Mycobacterium avium-intracellulare* infection is bilateral in more than 60%, with endobronchial spread in more than 80% and bronchiectasis in 80% to 94% of MAI infections versus 27% in *M. tuberculosis*.

Mycobacterium avium-intracellulare bacteria are water and soil organisms. In immunocompromised patients, disease is often disseminated. Up to 50% of AIDS patients will develop it at some point. *Mycobacterium kansasii* is common in the midsouthern United States, Wales, and southern England; it is uncommon elsewhere. *Mycobacterium marinum* is acquired via contaminated water contact, commonly in fish or aquarium workers. Skin defects increase the risk. Commonly skin disease may extend to nodes. *Mycobacterium scrofulaceum* lives in natural water and raw dairy products but is absent in U.S. drinking water. Once a pediatric cervical lymphadenitis, some pneumonias have been reported with underlying lung disease. *Mycobacterium fortuitum-chelonae* complex causes pneumonia and skin disease. It favors lipids and is associated with esophageal obstruction and mineral oil aspiration.

FUNGI

HISTOPLASMOSIS

Histoplasmosis is caused by *Histoplasma capsulatum* and *Histoplasma duboisii*. *Histoplasma capsulatum* is a soil saprophyte, a mycelium in soil, and a yeast in animals. It prefers high nitrogen content, such as bird or bat guano. Most disease is in central and eastern North America, particularly the Ohio, Mississippi, and St. Lawrence river valleys. Inhaled microconidia become yeasts, which are engulfed by macrophages. Inflammation proceeds to granuloma formation, necrosis, and fibrosis, then to calcification. Small sites may coalesce. Lymphadenopathy is constant, more prominent than in TB, and may cause airway compression or broncholithiasis. Frequent and early dissemination leads to small visceral granulomata. Healing is rapid and clinical disease is rare.

Acute histoplasmosis is a flu-like illness, sometimes with hepatosplenomegaly, or erythema nodosum or multiforme. Most radiographs are normal; the most common finding is poorly defined migratory consolidation. Lymphadenopathy is common. With heavy exposure, disseminated nodules may appear. A histoplasma is a 0.5 to 3.0 cm well-defined typically lower lobe nodule often with small satellite nodules. It may be multiple; serial radiographs may reveal slow growth. It may have central or diffuse calcification, and hilar node

calcification is common. Chronic pulmonary histoplasmosis is rare and appears identical to chronic pulmonary TB. Chronic mediastinal histoplasmosis from extracapsular nodal or contiguous pulmonary spread results in ill-defined necrotic tissue in the mediastinum. CT reveals mediastinal-hilar masses with calcifications, pericarditis, SVC or esophageal obstruction, and pulmonary artery and bronchial narrowing. If no calcification is present, the lesion should be biopsied. Disseminated histoplasmosis is rare; acute disseminated histoplasmosis has miliary nodules.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is caused by *Coccidioides immitis*, a soil fungus of the southwestern United States, northern Mexico, and parts of Central and South America. It exists in animals as spherules that divide by cleavage. Infection is common, mostly asymptomatic. "Valley fever" occurs in 5% to 20% of symptomatic patients: erythema nodosum or multiforme, arthralgia, and sometimes eosinophilia.

In primary coccidioidomycosis, arthrospores induce bronchopneumonia. Granulomata form within this inflammation. This center is generally small and resolves into scars; it may progress to nonsegmental cavitory necrosis. Lymphadenopathy is common and nodal erosion causes dissemination. Radiograph is normal or reveals unilateral, lower lobe–predominant, sometimes migratory, consolidation. Thin-walled cavities or small effusion may form. Persistent primary coccidioidomycosis, over 6 weeks, has progressive disease, with peripheral, sometimes cavitory, mid and upper lung–predominant nodules ranging from 0.5 to 5 cm. Calcification is uncommon. Chronic progressive coccidioidomycosis is less common (1%) and is due to either progression of primary disease or reactivation. It develops slowly and may produce symptoms for years. Radiograph is similar to that in chronic TB. Disseminated disease occurs in 1:6000 cases, often the immunocompromised. The CNS is involved in 30% to 50%; osteomyelitis occurs in 10% to 50%, often spinal. Miliary disease is common.

BLASTOMYCOSIS

Blastomyces dermatitidis is a soil fungus found in the central and southeastern United States that in its yeast form buds with wide-necked attachment. Infection is via spore inhalation or reactivation. Blastomycosis is male and middle age predominant and generally subclinical. It involves the urinary tract in up to 20% of cases. Initial bronchopneumonia rapidly is followed by

granuloma formation and coalescence. Airway perforation, cavity formation, and ulcerative bronchitis can occur. Radiograph reveals nonspecific alveolar consolidation that may be of almost any configuration, with masses, air bronchograms, or cavitation. Lymphadenopathy is uncommon and calcification rare. Mediastinal fibrosis may lead to SVC obstruction or nerve impingement.

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis is caused by the dimorphic soil fungus *Paracoccidioides brasiliensis*, which has a characteristic “pilot-wheel” pattern. It is a male-predominant disease of South and Central America. Infections are probably via inhalation. Radiographic findings are nonspecific.

CRYPTOCOCCOSIS

Cryptococcosis is often caused by *Cryptococcus neoformans*, an encapsulated yeast; heavily capsulated forms produce gelatinous disease. The variant *neoformans* is found in pigeon waste. Most patients are immunocompromised. Most cases are via inhalation. Pulmonary infection may lead to well-defined, gelatinous, or cavitary nodules; consolidation sometimes mimicking bronchioloalveolar carcinoma or pneumococcal pneumonia; miliary nodules; or interstitial proliferation without inflammation in the immunocompromised host. Radiograph reveals single or multiple nodules, 0.5 to 4 cm, typically subpleural. Cavitation and lymphadenopathy are uncommon and calcification is rare.

PNEUMOCYSTIS CARINII

Pneumocystis carinii exists as round or crescentic cysts and pleomorphic pseudopodial trophozoites. Infection, presumably via inhalation, is common but generally asymptomatic in normal patients. Trophozoites have no invasive capability, and attach to type I pneumocytes by layering in invaginations. Interstitial alveolitis is common; diffuse alveolar damage may occur. Early radiograph may be normal in 10% but often reveals bilateral perihilar lower lobe–predominant ground glass opacity, progressing to consolidation with peripheral ground glass or reticular opacity. Nodules are uncommon. Cystic spaces develop in AIDS patients. CT reveals diffuse or mosaic ground glass opacity, sometimes with interlobular septal thickening or consolidation.

CANDIDIASIS

Candida is dimorphic fungi existing as yeast in animals, common human saprophytes in normal oral, GI, and skin flora. *Candida* species are responsible for 90% of fungemias, of which 41% are caused by *Candida albicans*. Alterations of normal flora and overgrowth predispose to disease. Most cases are localized mucocutaneous infection, with pulmonary infection uncommon. The most common lung involvement is disseminated miliary disease; aspiration may produce bronchopneumonia. Effusion is uncommon; cavitation and lymphadenopathy are absent. A large acute mycetoma may form. HRCT reveals nodules sometimes with ground glass halos.

ASPERGILLOSIS

Aspergillus is ubiquitous septate uniform hyphae that branches dichotomously at 45-degree angles. The disease has several forms. (a) Saprophytic aspergillosis is noninvasive. Tracheobronchial colonization is common in CF and other lung diseases. Colony formation in a cavity or ectatic bronchus results in aspergilloma. These are often asymptomatic, but particularly mycetoma may cause hemoptysis and serve as an invasive source. (b) Extrinsic allergic alveolitis is a hypersensitivity reaction to inhaled conidia. (c) Allergic bronchopulmonary aspergillosis, a Loeffler-like syndrome, is the most common of these three. Imaging reveals proximal bronchial mucoid impaction, visible as upper lobe and central predominant finger-like opacities. Patients often have asthma or atopy. Disease may be asymptomatic or produce cough, fever, pain, or hemoptysis. Corticosteroids are helpful. The mucus may calcify, and bronchiectasis may result.

Invasive aspergillosis is a disease of the immunocompromised associated with tissue destruction. It may occur in four forms, the first two more common. Acute bronchopneumonia has a nonspecific radiograph. Angioinvasive aspergillosis manifests as sometimes cavitary well-defined nodule with hemorrhagic ground glass rim or wedge-shaped infarct from septic embolism. Hemorrhage can be massive, and chest-wall vascular involvement is possible. Pleural or chest invasion may cause effusion, fistula, or osteomyelitis. Acute tracheobronchitis is found most often in (heart) lung transplant patients. Chronic necrotizing aspergillosis is rare, most commonly occurring with underlying lung disease, characterized by slowly progressive upper lobe disease that may spread to the pleura, mediastinum, chest wall, or contralateral lung.

ZYGOMYCOSIS

Zygomycosis is caused by fungi found in decaying matter with broad, irregular, nonseptated hyphae. *Rhizopus*, *Mucor*, and others cause lung disease via inhalation of sporangiospores or direct invasion. Patients have underlying disease, such as lymphoproliferative-hematopoietic disorders, diabetes, or transplant. The fungi are angioinvasive. Patients have chest pain, fever, and bloody sputum. Pulmonary artery invasion may result in massive hemorrhage. Radiograph reveals homogeneous segmental or round rapidly progressing consolidation, sometimes with nodules of varying size with surrounding ground glass halos reflecting hemorrhage.

ACTINOMYCOSIS AND NOCARDIOSIS

The most important *Actinomyces* species are *Actinomyces israelii* and *Actinomyces bovis*, gram-positive nonmotile branching filamentous anaerobes or microaerophiles, composed of mycelia that fragment into bacterial-shaped forms. Actinomycetaceae are normal oral flora; infection is via aspiration or swallowing. They form sulfur granules in tissue, named for their color. The classic pulmonary disease is empyema with chest-wall sinus tracts, though this advanced form is uncommon. It occurs mostly as cervicofacial infection after tooth extraction, with GI infection second and chest infection third, frequently with other agents. Pulmonary actinomycosis has abscesses with sinus tracts, fibrous tissue, pleural fibrosis, and adhesions. Radiograph reveals lower lobe peripheral consolidation continuing to abscess without appropriate therapy or mass mimicking cancer. Wavy rib periosteal reaction may involve multiple ribs, and true bone destruction may occur.

Nocardiosis is caused commonly by *Nocardia asteroides*, aerobic gram-positive and generally acid-fast nonmotile non-spore-forming soil fungi with delicate filamentous branching hyphae. Sulfur granules are uncommon. It is often an opportunistic infection. Nocardiosis may develop as consolidation or as nodules; the most frequent radiographic finding is homogeneous nonsegmental consolidation without lower lobe predominance. Cavitation is common. Infection may extend to the pleura and cause effusion or empyema, but chest-wall extension is rare.

RNA MYXOVIRUSES

Influenza involves the upper respiratory tract, and in the old and chronically ill may cause a fulminant pneumonia. Group A is classified into hemagglutinin (H),

necessary in binding and membrane penetration, and neuraminidase (N), necessary in particle release. Pneumonia is usually via group A. Disease is characterized by alveolar damage, exudates, and epithelial desquamation. Radiograph reveals coalescent lower lobe segmental opacity, similar to ARDS. Effusion is rare.

Parainfluenza causes croup and bronchiolitis and pneumonitis in infants and children. Adults get pharyngitis or coryza. Radiograph reveals nonspecific lower lobe predominant markings.

Respiratory syncytial virus causes bronchiolitis and pneumonitis in infants and young children (45% of lower airway disease), particularly with underlying disease. Adult disease is generally mild URI. Radiograph is less dramatic than symptoms and may reveal patchy consolidation and hyperinflation, with bronchial wall thickening, peribronchial infiltrates, and perihilar lines.

Measles virus can cause pneumonia; most are via superinfection. Complication risk increases in pregnancy and immunocompromise. Primary pneumonia has reticular interstitial disease and patchy consolidation, with bronchial and perihilar interstitial thickening, small nodules, and peribronchial opacities. Lymphadenopathy is common in children, uncommon in adults.

RNA PICORNAVIRUSES

Group A coxsackieviruses cause soft palate vesicles and ulcers, meningitis, and some colds. Group B viruses cause meningoencephalitis, myocarditis, pericarditis, and orchitis. Echovirus causes rash, fever, diarrhea, and meningitis; type 19 causes infantile pneumonia. Rhinovirus causes more than 50% of coryza and 40% to 50% of colds. Croup, bronchitis, bronchiolitis, and bronchopneumonia may develop. Children with bronchopulmonary dysplasia and adults with COPD have higher risk.

RNA HANTAVIRUSES

Seoul, Hantaan, Puumala, Dobrava, and Prospect Hill viruses cause hemorrhagic fever with renal syndromes, with fever, hypotension, and renal failure. The Sin Nombre, Bayou, and Black Creek Canal viruses cause a pulmonary syndrome. All are rodent borne and transmitted by excreta inhalation. Edema and interstitial lymphocyte infiltration develop; tissue damage is generally mild or absent. Pulmonary syndrome has 50% fatality.

OTHER RNA VIRUSES

Ten to fifteen percent of babies born to mothers infected with the togavirus rubella during the first trimester have teratogenic effects, often pulmonary artery stenosis, and interstitial pneumonitis. The retrovirus HTLV-I causes bronchiolitis or interstitial pneumonitis. HIV causes lymphocytic interstitial and alveolar infiltrates, lymphocytic interstitial pneumonitis, and emphysema.

DNA ADENOVIRUS

Adenovirus causes 7% of respiratory infection in infants and children. It causes hemorrhagic consolidation, atelectasis, overinflation, and necrotizing bronchitis and bronchiolitis. Pneumonia is mild. Radiograph reveals bilateral bronchopneumonia with hyperinflation and atelectasis.

DNA HERPESVIRUSES

HSV-I classically causes oral gingivostomatitis and cold sores. Lower airway infection may be common, typically ulcerating the tracheobronchial mucosa sometimes with necrotizing bronchopneumonia. Radiographs may reveal bilateral alveolar opacities, poorly defined nodular opacities, or ARDS. HSV-II classically causes genital herpes. Neonatal infection may result in hematogenous spread to the lungs. It affects the larger airways less than HSV-I and causes diffuse alveolar damage or interstitial pneumonitis. Herpesvirus 6 causes childhood roseola (exanthem subitum), and can cause interstitial pneumonitis in BMT recipients. Herpesvirus 8 is linked to Kaposi sarcoma, including of the lung, pleural lymphoma, and Castleman disease.

Varicella causes chickenpox and zoster. Pneumonia more typically develops after primary infection. The incidence of pneumonia is 15%, often in patients with preexisting disease or immune deficiency. It causes diffuse alveolar damage and giant cell pneumonia. Airway and pleural vesicles may form. Radiograph reveals 5 to 10 mm nodular opacities, well defined at the periphery but less so elsewhere, rapidly progressing to consolidation. Remote but generally adulthood chickenpox infection may in less than 2% of cases result in diffuse tiny calcified nodules.

CMV may be acquired via transplacental spread; during vaginal delivery, from infected milk or other infected infants; or via contact with secretions. Most infections are subclinical or asymptomatic. CMV pneumonia may cause scattered well-defined hemorrhagic 0.5 to 1.5 cm nodules, or diffuse alveolar damage or in-

terstitial pneumonitis. It often is a coinfecting agent with other agents. Radiograph reveals bilateral reticular, ground glass, and alveolar opacities.

Epstein-Barr virus infects B lymphocytes and pharyngeal and possibly lower respiratory epithelium. It can be dormant for long periods of time, and causes infectious mononucleosis, which uncommonly affects the lungs but may cause lymphadenopathy and/or interstitial pneumonitis. The most common radiographic abnormality is splenomegaly.

OTHER DNA VIRUSES

Patients with history of smallpox may have punctate pulmonary calcifications. Papillomaviruses cause laryngeal and lower respiratory papillomas; these viruses are associated with cancer in papillomatosis, and possibly with squamous cell carcinoma. Simian virus 40 may cause some mesotheliomas. Parvoviruses may cause lung disease in the immunocompromised, as part of systemic infection, and may be associated with acute chest syndrome of sickle-cell disease.

MYCOPLASMAS, CHLAMYDIAE, AND RICKETTSIAE

Mycoplasmas have some features of bacteria but they are less than 1 μm long, lack a cell wall, and have different genetic features. *Mycoplasma pneumoniae* is most important, causing 10% to 15% of all CAP cases and up to 50% of CAP cases in military recruits. Disease is most common in the young. Transmission is via droplet inhalation. Radiographs are indistinguishable from those in viral pneumonia.

Chlamydiae are obligate intracellular microbes unable to synthesize ATP and GTP. *Chlamydia pneumoniae* is a common cause of CAP, associated with lung cancer and asthma. AIDS, CF, and COPD increase risk. Radiograph reveals nonspecific alveolar or interstitial opacities. Neonates born to mothers with *Chlamydia trachomatis* have 50% conjunctivitis risk and 10% to 20% pneumonia risk. Infected patients have paroxysmal cough and tachypnea with little or no fever. Radiograph reveals bilateral diffuse interstitial and alveolar opacity with patchy overinflation and atelectasis. *Chlamydia psittaci* is a bird pathogen, with human infections via excreta. Inflammation begins at respiratory bronchioles and extends to alveoli without necrosis; inflammation resolves over weeks leaving pleural fibrosis. Radiograph reveals ground glass opacity, patchy perihilar- and basilar-predominant reticular opacities, or consolidation. Lymphadenopathy is common.

Coxiella burnetii causes Q fever, described in Queensland, Australia. It is an obligate intracellular bacterium. Its reservoir is ticks. Human infection is primarily via inhalation; it is associated with farmers, slaughterhouse and stockyard workers, and medical veterinary personnel. Radiograph reveals lower lobe–predominant multifocal large round or segmental consolidation. *Rickettsia tsutsugamushi* causes scrub typhus. *Rickettsia rickettsii* causes Rocky Mountain spotted fever; radiograph reveals congestive heart failure caused by myocardial vasculitis, nonspecific opacities, or pleural effusion. *Rickettsia conorii* causes Mediterranean spotted fever.

PROTOZOA

Entamoeba histolytica causes amebiasis. More than 95% of amebic lung abscesses are peridiaphragmatic; 75% arise from liver. Fibrous effusions are often present. Cavitation can occur.

Toxoplasmosis is caused by the obligate intracellular protozoan *Toxoplasma gondii*. Cats are definitive hosts. Infection, rarely clinically evident, is via infected stool or meat, particularly lamb. Disease is rarely pulmonary, but in immunocompromised patients pneumonitis, carditis, and hepatitis occur in addition to CNS infection. Radiograph reveals reticular opacities similar to viral pneumonia, or consolidation. Lymphadenopathy is common. In the immunocompromised, radiographs reveal bilateral reticulonodular or coarse nodules with poorly defined margins.

NEMATODES

Ascariasis is generally due to *Ascaris lumbricoides*. In a complex life cycle, larvae travel in alveoli and airways. Up to 25% of the world's population has been infected. Pulmonary disease occurs with larval passage through the lungs. Patchy consolidation may be transient and perihilar.

Strongyloidiasis is caused by *Strongyloides stercoralis* or other members of the *Strongyloides* genus. Its life cycle includes larval migration through the alveoli and airways. Infection is typically asymptomatic though in hyperinfection, typically in the immunocompromised, severe disease can occur. Larval alveolar migration causes hemorrhage and microabscesses but no residual damage, except in hyperinfection alveolar injury, in which sepsis and ARDS may occur. Radiographic findings are similar to that in ascariasis.

TREMATODES

Paragonimiasis is caused by flukes, usually *Paragonimus westermani*. Humans are infected by eating

raw crabs or crayfish or drinking contaminated water. The life cycle is complex and leads to pulmonary larval maturation and egg deposition. Radiograph may be normal, or reveal varying opacities and thin-walled cystic lesions, with the worm sometimes visible as a crescentic or oval opacity along the cyst wall. Pleural effusion or thickening, or hydropneumothorax is common.

Schistosomiasis is commonly caused by *Schistosoma mansoni*, *Schistosoma japonicum*, and *Schistosoma haematobium*. The intermediate host is the snail. *Schistosoma mansoni* and *S. haematobium* are endemic in the Middle East and Africa. Schistosomes have complex life cycles; humans are infected via contaminated water. Adolescents migrate to the SMV (*S. japonicum*), IMV (*S. mansoni*), or vesical veins (*S. haematobium*). *Schistosoma haematobium* eggs released in the vesical veins embolize to lung arterioles and extrude into perivascular tissues. Inflammation leads to obliterative arteriolitis that may lead to PA hypertension if severe. Radiographs may reveal miliary or reticulonodular opacities, with areas of consolidation around dead worms and occluded arteries.

CESTODES

Echinococcus granulosus hydatid disease requires Canidae hosts. In a complex life cycle, larvae lodge in the lungs and form cysts. Most *E. granulosus* cysts are hepatic; 15% to 30% are pulmonary. The cysts are round and surrounded by inflammatory fibrous pericysts. They contain protective exocysts and germinal endocysts. Daughter cysts have poorly formed endocysts. Radiograph reveals lower lobe–predominant well-circumscribed 1 to 20 cm mass surrounded by normal lung, multiple in 20% to 30%. Rupture may produce a meniscus, air-fluid level, or floating membrane.

Echinococcus multilocularis has Canidae as definitive hosts and rodents as intermediate hosts. The life cycle and disease are similar to that in *E. granulosus*. Cysts are almost exclusively hepatic; the exocyst is poorly formed and the pericyst does not develop. Lesions are gelatinous and spongy, a series of interconnected spaces with intense inflammatory reaction and endarteritis obliterans.

ARTHROPOD INFECTION

Pentastomiasis is often via *Armillifer armillatus* or *Linquatulula serrata*. Ingested eggs hatch and larvae go to the liver, intestine, mesentery, and lung. Living larvae do not cause inflammation, but with death inflammation

leads to numerous 4 to 6 mm calcifications shaped like incomplete rings.

HIRUDINIASIS

Leech infestation is typically a skin disease, but internal hirudiniasis, frequently *Limnatis nilotica* can cause pulmonary disease. The nose, pharynx, larynx, or trachea may be involved. After the leech attaches and feeds on blood, it enlarges and may cause hemoptysis or airway obstruction.

QUESTIONS AND ANSWERS

- Regarding HAP, which of the following is true?
 - Mechanical ventilation is associated with a 1%–3% daily risk of infection.
 - Increases hospital stay by 2–3 days
 - Most frequently a benign condition
 - Infectious agent changes from gram-negative bacteria early in hospitalization to a gram-positive bacteria

ANSWER: A. Ventilation has a 1%–3% daily risk. HAP adds an average of 7–9 days to hospital stay, and mortality is 30%–70%. It is frequently acquired via aspiration and often polymicrobial. Early HAP is often a gram-positive agent and later HAP is often an enteric gram-negative agent.

- Which of the following is the most common cause of nonsegmental consolidation?
 - K. pneumoniae*
 - S. aureus*
 - S. pneumoniae*
 - S. stercoralis*

ANSWER: C. Nonsegmental (lobar) consolidation is frequently caused by pneumococcus, with some cases due to *K. pneumoniae*. *Staphylococcus aureus* typically forms a bronchopneumonia. *Strongyloides stercoralis* typically produces patchy transient perihilar consolidation.

- The radiograph of a male patient with acute-onset cough and fever reveals widened mediastinum, patchy opacities, and large effusions. Which of the following does the chest CT most likely reveal?
 - Small cavities with peripheral densities
 - Hemorrhagic nodes and dense effusion
 - Apical cavitation
 - Tree-in-bud opacities in the middle lobe

ANSWER: B. The patient presents with acute inflammatory–widened mediastinum, suggesting pulmonary anthrax. It causes alveolar and lymph node hemorrhage and bloody effusions. Paragonimiasis causes small cavities with peripheral densities. Most causes of apical cavitation are not acute.

- Which of the following characterizes Enterobacteriaceae?
 - Gram-negative rods that ferment glucose and make endotoxin but are oxidase negative
 - Gram-negative rods that cannot ferment glucose or oxidase but do make endotoxin
 - Gram-negative rods characterized by inability to reduce nitrogen
 - Gram-negative coccobacilli associated with ulceroglandular disease

ANSWER: A. Enterobacteriaceae are gram-negative rods that ferment glucose, reduce nitrogen, and produce endotoxin but are oxidase negative. *Francisella tularensis* is the gram-negative coccobacillus associated with ulceroglandular disease.

5. Which of the following is *true* regarding *Legionella* species?
- Pneumonia caused by these bacteria is segmental.
 - Pneumonia caused by these bacteria is benign.
 - A cause of Pontiac fever
 - Considered normal human flora

ANSWER: C. *Legionella* species live in water. The infection is typically nonsegmental and rapidly progressive, and may be associated with liver, renal, or CNS abnormalities. Resolution is generally prolonged even with therapy; one-third require ventilatory support and 5% die with appropriate therapy. *Legionella* species also cause Pontiac fever, a flu-like illness without pneumonia.

6. Regarding *M. tuberculosis* virulence, which of the following is *true*?
- Produces a toxin against type I pneumocytes
 - Elaborates a compound that inhibits initial phagocytosis
 - Can form cords
 - Can form spores

ANSWER: C. *Mycobacterium tuberculosis* has no toxins and has no effective defense against phagocytosis. Virulence appears related to the ability of strains to form cords, via trehalose-6,6'-mycolate cord factor, and to ammonia production. Virulent strains can lyse phagosomes and produce catalase.

7. A female patient with rheumatoid arthritis controlled with an anti-TNF agent has cough and night sweats. She has no TB exposure risk factors and a normal radiograph. Which of the following would result in a positive PPD test?
- 5-mm indurated wheal
 - 10-mm indurated wheal
 - 15-mm indurated wheal
 - Induration does not matter. It would depend on erythema

ANSWER: B. The patient is on immunosuppression, so it would be considered positive if there is 10 mm of induration, as she is on immunosuppressive therapy (anti-TNF).

8. Which of the following is *true* regarding coccidioidomycosis?
- Affects CNS in acute disease
 - Characteristic form in animal specimens is the conidium.
 - Uncommon in the United States
 - Progressive and disseminated forms

ANSWER: D. Coccidioidomycosis has primary, persistent primary, chronic progressive, and disseminated forms.

The disseminated phase may affect the CNS. Its characteristic form is the spherule. It occurs in the southwestern United States, northern Mexico, and parts of Central and South America.

9. Regarding allergic bronchopulmonary aspergillosis, which of the following is correct?
- Patients improve with corticosteroid therapy.
 - Abnormalities are more often in the lower lobes.
 - Bronchiectasis does not occur.
 - It is the second most common allergic aspergillosis syndrome.

ANSWER: A. Allergic bronchopulmonary aspergillosis is the most common allergic aspergillosis syndrome. Corticosteroid therapy is helpful. Radiographs reveal homogeneous fingerlike opacities in bronchial distribution, usually in the upper lobe. The mucus plug may calcify, and bronchiectasis is often a sequela.

10. An adult asymptomatic patient gets a chest radiograph for a new job. The radiograph reveals innumerable tiny calcified nodules. Which of the following is the patient most likely to experience?
- Pulmonary actinomycosis as a teenager
 - Sore throat treated with ampicillin
 - Remote adulthood varicella pneumonia
 - Cytomegalovirus transplacental infection

ANSWER: C. Actinomycosis develops into pleural and chest wall abscesses and fibrosis. CMV pneumonia can cause nodules but the findings are characteristic of remote varicella pneumonia.

21 NONINFECTIOUS INFLAMMATORY DISEASES

John C. Texada and Satinder P. Singh

CONNECTIVE TISSUE DISEASES

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is characterized by rash, serositis, discoid disease, photosensitivity, oral ulcers, arthritis, and renal, neurologic, hematologic, and immunologic disorders. Patients who meet four criteria may be diagnosed with lupus, others are given overlap or "lupus-like" diagnoses and tend to have good prognosis. Approximately 50% to 60% of SLE patients will have lung or pleural involvement at some point.

Women are more likely to develop lupus; mean age is around 40 years. Heredity likely plays a role: HLA-DR3 and DR2, complement deficiencies, and immunore-sponse genes are associated. Environmental factors include daylight, fluorescent light, and UV light and viral infection. Drugs including hydralazine, procainamide, INH, anticonvulsants, guanidine, methyl-dopa, chlorpromazine, sulfasalazine, and some beta-blockers produce a lupuslike syndrome, usually lacking nephritis or cerebritis. Penicillamine chronic therapy can induce SLE-like syndrome.

Antibodies may be the cause of the syndrome or the result of tissue damage. Serum antinuclear antibodies are the primary screen but may be negative in 5% to 10% of patients. Speckled staining is most common, reflecting antibodies to nucleic ribonucleoprotein and the glycoprotein macromolecule Sm. Rim staining is specific for SLE and reflects antibodies to nuclear DNA. Double-strand DNA antibody levels often track disease status. Nucleolar staining is present in half of patients with scleroderma, rarely with SLE. Homogeneous staining reflects antibodies to nucleoproteins. Cytoplasmic and peripheral antineutrophil cytoplasm antibodies (c-ANCA and p-ANCA) can be positive in SLE but have no bearing on disease status. Antiphospholipid antibodies are associated with thrombocytopenia and thromboembolism.

Pleural fibrosis is the most common lung change, found in 80–100% of patients; effusion or thickening occurs in 70% of patients. In acute lupus pneumonitis (1%–12% of patients), characterized by fever, dyspnea, hypoxemia, and patchy diffuse opacities, there may be diffuse alveolar damage or capillaritis and alveolar hemorrhage. The “shrinking lung” syndrome of hemidiaphragm elevation and decreased vital capacity is because of muscle weakness rather than a direct SLE effect on parenchyma. Upper-airway obstruction rarely occurs with cricoarytenoid or supraglottic inflammation. Focal lung disease is common but diffuse interstitial disease and alveolar hemorrhage are uncommon (less than 5%). Bronchiolitis obliterans and separately BOOP may occur. BOOP may have presentation similar to acute lupus pneumonitis, pneumonia, pulmonary hemorrhage, or pulmonary infarct.

Antiphospholipid antibodies lead to thrombosis, fetal loss, thrombocytopenia, and livedo reticularis. Pulmonary hypertension occurs in as many as 43% of patients, though clinically important disease is rare. Two-year mortality for lupus patients with pulmonary hypertension is 50%.

Many radiographs are normal and frequently underestimate the degree of disease. Effusion is usually bilateral but small. Parenchymal disease is nonspecific; these are generally caused by infection but may be caused by

BOOP. Acute lupus pneumonitis appears as patchy ground glass or alveolar opacities often with pleural effusion. Alveolar hemorrhage also appears as patchy ill-defined basilar-predominant opacities. In interstitial disease, linear opacities may be visible, usually at the bases and sometimes migratory. Nodules are rare. Pericardial effusion may enlarge the cardiac silhouette. Lupus cardiomyopathy may result in congestive failure. HRCT is more sensitive for detection of disease, particularly in patients with normal radiographs. The most common abnormalities are lower lobe predominant and include interlobular septal thickening, intralobular interstitial thickening, small nodular consolidation, and ground glass attenuation. Fibrosis is subpleural and similar to that in other connective tissue diseases.

HYPOCOMPLEMENTEMIC URTICARIAL VASCULITIS

Hypocomplementemic urticarial vasculitis is a syndrome of urticaria and leukocytoclastic vasculitis. Hypocomplementemia is caused by antibodies to C1q and probably is a result of immunocomplex deposition. Hypocomplementemic urticarial vasculitis may be associated in some patients with obstructive disease; pulmonary vasculitis has not been reported.

RHEUMATOID DISEASE

Rheumatoid arthritis (RA) is a well-known chronic inflammatory process primarily affecting joints. Tumor necrosis factor alpha appears to play a prominent role. Serum IgG rheumatoid factor is the most common antibody abnormality but 15% to 30% of patients also have ANAs. Patients with HLA-B40 are 40 times more likely than others to develop RA. RA has extra-articular manifestations in about three-fourths of patients. These are more common in men and in patients with severe articular disease, and include subcutaneous nodules, pulmonary fibrosis, vasculitis, skin ulceration, lymphadenopathy, neuropathy, splenomegaly, episcleritis, and pericarditis. Juvenile RA is a similar process, though by definition occurs in patients younger than 16 years of age. It has an acute systemic type characterized by fever, rash, lymphadenopathy, hepatosplenomegaly, and arthritis in 20% of cases, and polyarticular forms involving four or less joints in about 50% of cases. Pulmonary and pleural disease is uncommon, most commonly pleuritis and effusion.

Approximately 1% to 5% of patients have radiographic evidence of interstitial lung disease, though 40% have reduced DLCO consistent with fibrosis, and

approximately 30% of asymptomatic patients have abnormal HRCT. Interstitial pneumonitis is most common in RF-positive men aged from 50 to 60 years. The appearance is the same as other interstitial pneumonitis causes, except when necrobiotic nodules are present. Serial imaging sometimes reveals decreasing lung volumes. In HRCT, reticular thickening of intralobar and interlobar septa is present, mostly subpleural and lower lung. Honeycombing will be most prominent near the diaphragm at first and spread centrally. Ground glass opacities or pleural thickening or effusion may be present.

Rheumatoid necrobiotic nodules are well-circumscribed masses usually in the subcutaneous tissues but also uncommonly in the lungs. They are typically peripheral and near pleural or interlobular septal surfaces and visible more often in CT. They may be solitary or numerous, may change size with on disease activity, and frequently cavitate with thick smooth walls. Pneumothorax is uncommon but may occur with necrobiotic nodule rupture into the pleura.

Caplan syndrome is the combination of necrobiotic nodules with pneumoconiosis. Uncommon overall, it is common in men with both RA and pneumoconiosis, up to 55%. The nodules are probably a hypersensitivity reaction to dust. A ring of necrotic-pigmented macrophages in the nodule distinguishes it pathologically from standard necrobiotic nodules. They have the same radiographic appearance as other necrobiotic nodules but tend to develop rapidly and in crops.

Pleuritis commonly manifests as chronic inflammation with rare rheumatoid nodules. Pleural fibrosis and adhesions are common autopsy findings. Effusions are typically small and unilateral but may be large or bilateral. They are typically short-lived but may persist for years.

Obliterative bronchiolitis may develop rapidly. It may be associated with penicillamine or gold therapy, though this may be coincidental. A peribronchiolar lymphocytic infiltrate develops and can grow either thickening the wall or extending into the small-airway lumen, producing constrictive or obliterative bronchiolitis, respectively. Chest radiograph is normal or hyperinflated. HRCT may reveal mosaic perfusion, subsegmental bronchiectasis, and air trapping.

BOOP associated with RA is identical to BOOP from other causes. PFT may reveal restriction or mixed restriction–obstruction. It usually improves dramatically with therapy.

Follicular bronchitis and bronchiolitis are uncommon and nonspecific and may appear in other connective tissue and nonrheumatologic conditions. They respond well to therapy. Radiograph reveals diffuse reticulonodular interstitial disease. HRCT reveals centrilobular, subpleural, and peribronchial nodules, bronchial wall thickening, and centrilobular branching opacities.

Bronchiectasis precedes joint disease in almost all cases. It may occur in up to 30% of RA patients. If the laryngeal cartilages become fixed-adducted from inflammation, airway obstruction can follow, especially when exacerbated by viral URI or laryngeal edema. Pulmonary hypertension typically occurs with diffuse interstitial fibrosis, but also with Raynaud phenomenon in which case it may be because of immunocomplex mediated arteritis. Pulmonary vasculitis is rare in RA. Hyperviscosity syndrome is a rare complication in which RF molecules conglomerate into bodies large enough to obstruct small vessels. Purplish palmar erythema, bleeding diathesis, and dyspnea are some of the symptoms.

PROGRESSIVE SYSTEMIC SCLEROSIS

Scleroderma is rare, with incidence 12:1000 000 per year. It is most common in women (3:1) and in patients aged from 30 to 60 years. Pulmonary disease is common, with up to 60% of patients having dyspnea at some point. HRCT may reveal abnormalities in 44% of patients with normal chest radiograph, and bronchoalveolar lavage detects abnormalities in 73% of these patients.

Antinuclear antibodies are common, with antibodies to topoisomerase-1 (called anti-topo-1 or Scl-70) associated with skin changes, pulmonary fibrosis, and poor prognosis. Anti-RNA-polymerase-III is less than 25% sensitive but is specific for progressive systemic sclerosis (PSS). Antihistone antibodies are associated with severe fibrosis. CREST-variant patients have anticentromere antibodies.

Interstitial disease resembles IPF and present in 20% to 65% of radiographs. Progressive radiographs reveal prominent volume loss. HRCT often reveals abnormalities in patients with normal radiographs. In up to 70% of patients, lymphadenopathy increases as disease progresses. Pleural thickening and effusion are less common than in other connective tissue disease. Pulmonary hypertension is of uncertain etiology. Cardiac involvement includes myocarditis or myocardial sclerosis leading to biventricular failure; RV failure because of pulmonary vascular disease, pericardial effusion, and constrictive pericarditis. Esophageal abnormalities (discussed elsewhere) are present in 50% of patients. Rib notching is present in 15% of patients. It is nonspecific, though, as patients with RA, SLE, and Sjogren syndrome may develop this as well.

CREST SYNDROME

CREST syndrome consists of calcinosis cutis, Raynaud phenomenon, sclerodactyly, esophageal involvement, and telangiectasias. Anticentromere antibodies are common,

though only 4% to 16% of patients with these antibodies develop CREST syndrome. It typically has a more indolent course, except when complicated by pulmonary hypertension. Radiographic features are similar to those of PSS. Pulmonary hypertension is present in up to 9% of patients.

RAYNAUD PHENOMENON

Digital–arterial vasospasm leads to cyanosis. It may be idiopathic and isolated (and called Raynaud disease) or appear as an early finding of connective tissue disease.

DERMATOMYOSITIS AND POLYMYOSITIS

These are characterized by neck and proximal limb muscle weakness and pain. Approximately 50% have heliotrope rash, extensor erythema or purpura, or Gottron papules. Overall incidence is 5 to 10:1000 000. It is more common in women (2:1) and peaks in the first decade and again in the forties and fifties. Chest involvement is manifest as hypoventilation and respiratory failure from muscle weakness, interstitial pneumonitis, and aspiration pneumonia.

Anti-aminoacyl-tRNA-synthetases (the most common being Jo-1) are linked to development of interstitial lung disease. HLA-DRw52 is present in almost all patients with these antibodies. Their presence increases the incidence of ILD, arthritis, fever, disease flaring, and of scaly, hyperkeratotic-fissured hands, but they are likely a secondary finding.

The radiograph is generally abnormal. Interstitial fibrosis is identical to IPF but abnormalities may develop acutely as diffuse alveolar damage or BOOP. The appearance improves markedly with adequate therapy. Patients with respiratory–muscle weakness have small lungs with linear atelectasis; pharyngeal muscle weakness may result in aspiration pneumonia.

SJOGREN SYNDROME

This syndrome consists of keratoconjunctivitis sicca, xerostomia, and parotid swelling. It may be isolated, but in up to 59% of cases it is associated with other connective tissue disorders. Chest abnormalities include lymphocytic interstitial pneumonitis, pleuritis, and tracheobronchial gland inflammation.

Primary Sjogren syndrome is characterized by antibodies to small nuclear and cytoplasm particles; SS-A is called anti-Ro; SS-B, anti-La. The antibodies may be elicited by viral salivary damage, perhaps by prior viral infection.

Radiograph sometimes reveals reticulonodular interstitial disease that is usually basilar-predominant. This may be due in different patients to lymphoid interstitial pneumonia, interstitial fibrosis, or lymphoma development. HRCT reveals more disease and is often abnormal when the radiograph is normal. The most common findings are bronchiolectasis, poorly defined centrilobular opacities, and ground glass opacities with occasional honeycombing. A particular pattern consisting of extensive ground glass opacities with scattered thin-walled cysts has been described in the lymphoid interstitial pneumonitis of Sjogren syndrome (but also other instances of lymphoid interstitial pneumonitis); alternatively lymphoid interstitial pneumonitis may present as interlobular septal thickening with nodular bronchovascular thickening indistinguishable from lymphoma.

OVERLAP SYNDROMES AND MIXED CONNECTIVE TISSUE DISEASE

Patients who clearly have connective tissue disease but do not satisfy diagnostic criteria to fit into a particular disease fall into this category of overlap syndromes. They are female-predominant. A particular subgroup with findings of SLE, PSS, and polymyositis is called mixed connective tissue disease and is associated with antibodies to extractable nuclear antigen, anti-nRMP. These patients may develop CNS involvement in 30% to 50% of cases, and membranous glomerulonephritis in some. Pulmonary disease occurs in 20% of cases, sometimes as fatal interstitial lung disease, diffuse alveolar hemorrhage, or pulmonary hypertension. Radiographic findings include those of SLE, PSS, and polymyositis. Interstitial abnormalities are present in 85% of cases, usually basilar-predominant reticular disease that extends superiorly and develops peripheral honeycombing as disease progresses. Pleural effusion is uncommon. Pericardial effusion and myocarditis may occur, and mediastinal lymphadenopathy has been reported.

RHEUMATIC PNEUMONITIS

Patients with rheumatic fever may develop diffuse alveolar damage that can organize into alveolar fibrosis. Small-artery pulmonary vasculitis can occur. The process is usually severe and has extensive cardiac disease.

RELAPSING POLYCHONDritis

This disorder of cartilage inflammatory destruction is uncommon and peaks between 40 and 60 years of age. It

is associated with other autoimmune disorders in up to 25% of cases, and anticarilage and anti-minor-matrix-collagen antibodies have been found in some. Complement appears activated locally. HLA-DR4 is associated with the disease. Cartilage throughout the body is attacked, fragmented, and replaced by fibrous tissue. The most common radiographic finding in the chest is tracheal stenosis, usually a few centimeters long but sometimes diffuse; bronchial stenosis may be visible as well. CT may reveal tracheal or bronchial thickening. Bronchiectasis is sometimes present, possibly because of recurrent infection from airway obstruction.

LUNG INVOLVEMENT IN INFLAMMATORY BOWEL DISEASE

Crohn disease and ulcerative colitis are not autoimmune but are immunologically mediated. Many patients have lymphocytic alveolitis but clinically significant lung disease is rare.

LUNG INVOLVEMENT IN PRIMARY BILIARY CIRRHOSIS

Some patients with primary biliary cirrhosis (PBC), often with Sjogren syndrome, have been reported to have alveolitis, bronchiolitis, BOOP, diffuse alveolar hemorrhage, and interstitial pneumonitis.

DISEASES CHARACTERIZED BY VASCULITIS

WEGENER GRANULOMATOSIS

This multisystem disease has necrotizing granulomatous inflammation of the upper- and lower-respiratory tracts, glomerulonephritis, and necrotizing vasculitis of the lungs and other tissues. Four principal criteria are: nasal or oral inflammation, abnormal chest radiograph, abnormal urinary sediment, and either biopsied granulomatous inflammation or hemoptysis. Presence of two or more is 88% sensitive and 92% specific. Its prevalence is approximately 3:100 000 and is more common in older patients. The cause may be prior respiratory infection or inhalation. It is associated with c-ANCA, specifically anti-proteinase-3, a strong but somewhat nonspecific link.

Leukocyte infiltrates aggregate into small microabscesses that become necrotic and coalesce. Small granulomata may be present. Pulmonary nodules may be 1 to 10 cm and are frequently centrally necrotic or cavitary.

Alveolar hemorrhage, fibrosis, follicular bronchiolitis, and obstructive pneumonitis are usually minor. Airway granulomata are common, sometimes resulting in an obstructing granulation tissue mass. Small-to-medium pulmonary arteries are involved. Paranasal sinus involvement may cause mucosal thickening or even osseocartilaginous destruction. Upper-airway involvement may lead to hoarseness or dyspnea. Cardiac conduction abnormalities, heart failure, or pericarditis may occur but are not common.

The chest radiograph will eventually be abnormal in 85% of patients. Nodules, generally less than 10 and typically diffuse and bilateral, range less than 1 to 10 cm. They often cavitate, leaving irregular thick walls, but rarely calcify. CT reveals more nodules and inapparent cavitation in most nodules over 2 cm. There may occasionally be reticulonodular interstitial thickening. Consolidation and ground glass opacities because of hemorrhage are the second most common finding: random, peripheral wedges simulating infarct, or in peribronchovascular distribution. Bronchial narrowing is seldom radiographically apparent, but may lead to atelectasis. Pleural effusion is variable, and lymphadenopathy is visible in up to 15% of patients.

CHURG-STRAUSS SYNDROME

This syndrome includes asthma, fever, blood eosinophilia, and necrotizing vasculitis with intravascular granulomatous inflammation as well as neuropathy, nonfixed pulmonary infiltrates, paranasal sinus disease, and extravascular eosinophilia. The presence of four or more of these is 85% sensitive and almost 100% specific. It is rare, with incidence perhaps 2 to 3:1000 000. Asthma or rhinitis develops in early adulthood, with vasculitis developing later. The true causative abnormality may be a hypersensitivity reaction to an unknown agent. CSS is associated with p-ANCA, though this antibody may be found in inflammatory bowel disease, RA, SLE, autoimmune liver disease, and some infections; and with atypical ANCA. Circulating immune complexes are sometimes present.

A small-to-medium vessel vasculitis affects arteries and veins, with leukocyte infiltrates evolving into fibrinoid necrosis and granulomata. Nonvascular granulomata are more commonly extrapulmonary but may be found in the lungs; alveolar and interstitial infiltrates are more common, as are changes of chronic asthma. GI and cardiac involvement is common.

The chest radiograph is abnormal in approximately 70% of patients, usually with transient patchy consolidation that may precede systemic problems. They may be symmetric and simulate chronic eosinophilic pneumonia

or may develop into nodular opacities that rarely cavitate. Interstitial thickening and hilar lymphadenopathy are uncommon. Ground glass opacities may be present in 60% of patients, either patchy or peripheral. Small centrilobular nodules, effusions, or septal thickening may occasionally be present.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is a necrotizing vasculitis of the small-to-medium muscular systemic arteries without granulomata. Sites of disease are often at branch points and are aneurismal. Immunocomplex deposition may play a role. Pulmonary arterial involvement almost never occurs, though bronchial artery involvement can develop. It is associated with hepatitis-B virus infection.

MICROSCOPIC POLYANGIITIS

It is similar to PAN (formerly a subcategory of it) except it involves small arterioles, venules, and capillaries; large vessel disease may play a small role. It is associated with p-ANCA (antimyeloperoxidase) and atypical ANCA; RF and ANA may be positive. HBV infection is rare. Pulmonary vessels are affected in 15% to 30% of patients, typically manifest as hemoptysis. Pulmonary findings include alveolar hemorrhage and hemosiderin-laden macrophages. Radiographs reveal patchy opacities because of hemorrhage, occasionally with effusion or edema.

TAKAYASU ARTERITIS

This vasculitis affects the aorta and its major branches, via perivascular/intramural granulomatous inflammation. Pulmonary artery involvement is variable but can involve the main pulmonary arteries or intrapulmonary arteries. It is over 90% female-predominant, and typically develops in the age ranging from 10 to 40 years. Most cases derive from Southeast Asia. In patients from Japan, involvement is typically of the ascending aorta, arch, and arch vessels; whereas, in India, the abdominal aorta and renal arteries are commonly involved. Diagnostic criteria include onset at less than 40 years of age, extremity claudication, decreased brachial artery pulse, blood-pressure difference at least 10 mm Hg between the arms, subclavian or aortic bruit, or arteriographic abnormality. Presence of three or more is 90% sensitive and 98% specific.

Most patients have antiendothelial cell antibodies without ANCA, ANA, ENA, anti-Ro, anticardiolipin, or

anti-DNA; however, it is uncertain whether these cause disease or are a response to vessel damage. Many patients have glomerulonephritis, immune-based skin reactions, or other connective tissue disease. HLA-B52 and -B39.2 are commonly encountered.

Patchy panarteritis involves adventitial fibrosis and mononuclear infiltrate. Vasa-vasorum obliteration is common. Granulomata develop in the media, and intimal fibrosis is frequent.

Contour irregularities of the aorta, including wavy or scalloped descending aortic or arch ectasia are visible in 10% to 75% of patients, and early calcification is visible in 10% to 25% of patients. Cardiomegaly may be present. Pulmonary artery involvement may be visible as focal oligemia. Rib notching may be present if the aorta is occluded. CT or MR findings include dense or calcified vessel wall, mural thickening up to 4 mm, and delayed circumferential enhancement. Descending thoracic aortic stenosis is present in 37% of patients, ascending aortic dilation, in 32% of patients. Pulmonary artery involvement is visible in 70% of patients as abnormal peripheral appearance likely because of occlusion, dilation of the pulmonary trunk is visible in 19%, and central thrombus is visible in 3% of patients.

GIANT CELL ARTERITIS

Giant cell arteritis (GCA) is one of the commonest systemic vasculitides, associated with perivascular granulomatous inflammation. It primarily affects the larger vessels of the head and neck, but the elastic and muscular pulmonary arteries may be affected. It affects patients older than 50 years and is often preceded by infection. Patients present with headache, jaw claudication, polymyalgia rheumatica, vision loss, and often focal tenderness at the involved site. ESR is elevated.

BEHCET DISEASE

This systemic disorder manifests as recurrent aphthous stomatitis, genital ulcers, skin lesions, and uveitis. Men are more frequently affected; age is typically 20 to 30 years. It has unknown etiology, possibly viral or food-induced. HLA-B5 is more common in these patients than in controls. Lung involvement is uncommon. Transmural vascular inflammation may extend into airways and erode bronchial or pulmonary vessels and cause hemoptysis. Thrombi and infarcts may occur. Pulmonary artery aneurysms are usually perihilar and may be up to 3-cm diameter.

The Hughes-Stovin syndrome of pulmonary artery and systemic venous thrombosis with fever, headache,

cough, papilledema, and hemoptysis may be caused by Behcet disease. The interlobar artery is the most common to thrombose. The superior vena cava or brachiocephalic veins may thrombose and lead to mediastinal widening. Pleural effusion may develop as a sequela of pulmonary infarct.

MIXED CRYOGLOBULINEMIA

This uncommon syndrome of purpura, arthralgia, glomerulonephritis, and IgM anti-IgG cryoglobulin is sometimes associated with hepatitis C virus. Immune complex deposition may play a role. It can cause capillaritis and alveolar hemorrhage, visible as diffuse interstitial lung disease.

HENOCH-SCHONLEIN PURPURA

Purpura, abdominal pain, GI hemorrhage, arthritis or arthralgia, and glomerulonephritis constitute the syndrome. It appears most often in childhood; no specific agent is known. Immune complex deposition, typically IgA ANCA, may play a role: IgA activates the alternate complement pathway. Lung involvement is rare, usually as capillaritis and alveolar hemorrhage.

NECROTIZING SARCOID GRANULOMATOSIS

In this uncommon process, typically only detected after resection, confluent granulomata develop with necrosis and destructive vasculitis. It affects middle-aged adults, typically women. The etiology is uncertain, perhaps hypersensitivity. It responds to corticosteroid therapy and may be a variant of classic sarcoid. Radiographs reveal multiple well-defined nodules, usually 5 to 10 mm but occasionally miliary or large, usually peribronchovascular and subpleural.

SARCOIDOSIS–NONNECROTIZING GRANULOMA FORMATION

Most patients are 20-to 40-year-old when diagnosed with sarcoid. Some reports show an increased prevalence in smokers. US prevalence is approximately 10:100 000; prevalence in African American women aged 30 to 39 years is 107:100 000. About half of patients are asymptomatic at diagnosis; half of the remainder have dyspnea and the rest have extrathoracic symptoms. The cause is unknown but pulmonary parenchymal and pulmonary lymphatic involvement suggests inflammatory-immune

response to an inhaled agent. Recurrence after lung transplant and transmission via bone marrow transplant suggest infectious etiology but the agent has not been cultured. There is an association with HLA-A1 and -B8. Patients often have cutaneous anergy, increased CD8:CD4 ratio, and B-cell hyperactivity.

By whatever etiology, pulmonary macrophages are activated with granuloma formation and sometimes fibrosis. The peribronchovascular, interlobular septal, and pleural interstitial tissues are dominantly involved, first as discrete granulomata but eventually coalescing into interstitial thickening. Alveolar involvement is usually minimal but can coalesce into macroscopic nodules. Pulmonary–vascular granuloma formation is common and affects vessels of all sizes. Thrombosis is rare and necrosis does not occur but they can compress the lumen. Serum angiotensin-converting enzyme and lysozyme levels are elevated, though neither of these is specific for sarcoid; and serum alkaline phosphatase is elevated in 30% to 45% of patients.

Staging is helpful for predicting outcome (Table 21-1). More than one-half and approximately one-half of patients in stages 1 and 2, respectively, will have resolution of radiographic abnormalities at follow-up. Only 20% of patients in stage 3 will undergo resolution of radiographic abnormalities. An additional 20% go on to fibrosis.

About one-half of patients will have stage 1 findings of lymphadenopathy, often in the combination of right-paratracheal (70% of cases) and bilateral hilar (95%) disease—the (“1-2-3 sign”). AP-window nodes are enlarged in 50% of cases, and subcarinal nodes are enlarged in 20% of cases. Only 5% of patients have unilateral hilar lymphadenopathy. The distribution is helpful in distinguishing sarcoid from lymphoma and tuberculous infection. Only 5% of patients have calcified nodes at presentation, typically peripheral and eggshell type, though calcification increases with progression up to 20% or more. CT will reveal more stations of lymphadenopathy than are apparent radiographically and may image radiographically occult nodal calcification. Lymphadenopathy may compress a bronchus and lead to lobar atelectasis, most commonly in the middle lobe or may lead to arterial, SVC, or innominate-venous compression.

TABLE 21-1 Staging of Sarcoidosis

STAGE	RADIOGRAPHIC FINDINGS
0 (>10%)	None
1 (50%)	Hilar, mediastinal lymph adenopathy
2 (30%)	Lymph adenopathy and pulmonary abnormalities
3 (10%)	Diffuse pulmonary abnormalities; no lymphadenopathy

Lung involvement is radiographically visible at some point in 50% to 65% of patients. Abnormalities are typically bilateral, symmetric, and mid- and upper lobe predominant. Nodular and reticulonodular disease is most common, with reticular, alveolar, or ground glass opacities less so. Cavitation is distinctly uncommon. Effusion and atelectasis are also uncommon. Nodules are typically irregular, usually less than 3 mm but as large as 1 cm, visible in HRCT as mostly peribronchovascular, peripleural, and along the interlobar and interlobular interstitium, often coalescing to nodular thickening. Reticular disease in HRCT reveals interlobular septal thickening in 20% to 90% of patients and nonseptal lines in 20% to 70%. Traction bronchiectasis is predominantly upper-lung-zone and perihilar. Honeycombing typically involves the subpleural mid-and upper-lung zones. Reticulonodular disease is likely a combination of nodules with interlobular septal or reticular thickening. Alveolar disease in HRCT is often peribronchial or less commonly peripheral. Air bronchograms are generally present, and additional interstitial findings are also generally present. Ground glass opacity is seldom radiographically apparent but visible in 20% to 60% of HRCT scans. In most cases, this is a secondary feature of nodular disease. The heart is frequently involved but the process is not often radiographically apparent. Cardiomegaly may be from cardiomyopathy, valve disease, pericardial effusion, or left-ventricular aneurysm. Pulmonary hypertension and cor pulmonale may develop late.

Approximately 20% of patients will develop pulmonary fibrosis, manifest as architectural distortion and bronchiectasis typically involving the upper lung zones, with upward retraction of the hila, bulla formation, and compensatory lower lobe hyperinflation. In HRCT, peribronchovascular opacity radiates from the hila to the upper lobes, and honeycombing is visible in 40% of cases.

Gallium-67 scan may reveal tracer-avid lymphadenopathy in a “lambda” pattern involving the para-/infrahilar and right paratracheal nodes. The “panda” pattern of elevated bilateral symmetric lacrimal and parotid uptake together with bilateral symmetric hilar lymphadenopathy or pulmonary fibrosis is also specific for the disease. (The “panda” pattern without lung disease may be seen in Sjogren syndrome, HIV, and after head–neck radiation).

LUNG TRANSPLANT-RELATED IMMUNE LUNG DISEASES

In addition to reperfusion edema, which occurs by the first postoperative day in 90% of patients and by the third day in 97% of patients, transplanted lungs are susceptible to immune-mediated disease.

Hyperacute rejection is caused by preformed alloantibodies that bind to the donor organ, and activate complement. Destruction begins within minutes. Diffuse alveolar damage, neutrophil infiltration, and IgG deposition are hallmarks. It is rare in lung transplants, and screening of blood for ABO compatibility and anti-HLA antibodies has made this complication even rarer.

Acute rejection is a T-cell anti-HLA response without B-cell or antibody response. Almost all patients will undergo acute rejection. It may be seen as early as 3 days after transplant but more typically is manifest at 1 to 2 weeks; 60% of all cases occur within 3 months, and after 4 years rejection is uncommon. A patchy mononuclear infiltrate begins in the perivascular interstitium and extends to involve endothelium and alveolar interstitium. Radiographs are abnormal in 50% to 100% of cases; they may reveal fine reticular interstitial disease, interlobular septal thickening, ground glass opacities, alveolar consolidation, and new or enlarging effusions. In the first postoperative month, HRCT findings are nonspecific and do not allow distinction between acute rejection, fluid overload, and reperfusion injury. The most common HRCT finding is ground glass opacity, more likely with higher-grade rejection. Septal lines are less common. Other findings include new or enlarged effusion, basilar consolidation, or peribronchial cuffing.

Chronic rejection may be airways-related or cause an accelerated vascular sclerosis not described here. Up to 70% of patients will develop obliterative bronchiolitis, with mortality up to 55% of affected patients. It appears immune-mediated; the development of infection, particularly CMV, is probably important as well. It may be caused by small vessel-related ischemia. It generally develops within 12 months of transplant. Membranous- and proximal-respiratory bronchiolar subepithelial connective tissues become thickened. Early disease has fibroblasts within loose connective tissue, but increasing severity leads to more fibrosis that may occlude the lumen. It may be active, accompanied by inflammatory infiltrate, or inactive. Luminal tissue deposition should suggest an alternate etiology. Bronchial dilation visible in 80% of patients, mainly segmental and subsegmental lower lobe branches. Expiratory air trapping is common and probably the most accurate indicator of obliterative bronchiolitis. Bronchial wall thickening and mosaic perfusion are less common. In serial, HRCT studies decreased lung volume, decreased peripheral vascularity, and interlobular thickening develop after 7 to 11 months. Bronchial dilation develops at a mean of 12 months; and decreased attenuation and mosaic perfusion develop at mean intervals of 16 and 21 months, respectively.

BONE MARROW TRANSPLANT-RELATED IMMUNE LUNG DISEASES

Patients may acutely develop pulmonary edema or diffuse alveolar hemorrhage, or one of several immune-related lung diseases after bone marrow transplantation (BMT). They are also at increased risk for infection.

Interstitial pneumonitis develops in 10% of patients with BMT and causes 40% of transplant-related deaths. It peaks at 14 to 80 days. Its pathogenesis is unknown; it appears immunologic but not directly related to graft-versus-host disease (GVHD). Chemotherapy and radiation therapy may influence development. Radiographic findings are nonspecific, generally bilateral interstitial thickening with ground glass opacities and small poorly defined nodules.

Obstructive small airway disease (obliterative bronchiolitis) occurs in 5% or less of patients with BMT. It does not develop in the first 3 months, and the median interval is 260 days. Mild bronchiolitis and intramural fibroblastic proliferation develop in the same process as in lung transplant disease. Radiographic findings also are similar.

Graft versus host disease occurs when donor T-cells recognize the recipient as foreign. It may be acute or chronic. Lung findings in acute GVHD are minimal, but the lungs are typically abnormal in chronic GVHD. Whether the abnormality is due directly to the immune process or to secondary causes is uncertain: patients frequently have ongoing pulmonary infection and may develop a sicca syndrome with chronic bronchitis. Some develop a lymphocytic alveolitis and fibrosis that responds well to treatment.

Lymphocytic chronic bronchitis is characterized by epithelial and submucosal lymphocyte infiltrate, with focal epithelial necrosis. It occurs in up to 25% of allogeneic BMT. It is more severe in patients with more severe GVHD and may be because of the same process.

EOSINOPHILIC LUNG DISEASE

Eosinophils contain preformed mediators, importantly major basic protein (MBP), which is toxic to some parasites but also to host cells. Other eosinophil mediators activate and enhance neutrophil response and activate platelets. Eosinophils are thus implicated in several lung diseases. Eosinophilic diseases related to drugs, parasites, and fungal infections are discussed elsewhere.

Simple pulmonary eosinophilia (Loeffler syndrome) is an uncommon disorder characterized by blood eosinophilia and patchy transient alveolar opacities. Patients are typically asymptomatic, though a history of atopy or asthma is common. Interstitial and alveolar edema is

mixed with eosinophils, without immune deposits or destruction. Radiographic findings are typically of migratory and short-lived areas of consolidation, typically peripheral and homogeneous. Differential considerations include drug- and parasite-induced eosinophilic lung disease.

Acute eosinophilic pneumonia is an acute febrile illness of unknown etiology, perhaps hypersensitivity to an unknown antigen. Patients often have allergic tendencies. Radiographs early look like pulmonary edema. It progresses over hours or days to basilar-predominant interstitial and alveolar opacities, generally with small pleural effusions, and can lead to hypoxemic respiratory failure. CT reveals ground glass attenuation, septal thickening, and small effusion, occasionally with consolidation or small nodules. It responds rapidly to corticosteroid therapy, and relapse is not a feature. Patients usually do not have peripheral-blood eosinophilia.

Chronic eosinophilic pneumonia is a relapsing process usually of unknown etiology, though some cases are associated with *Aspergillus* infection, RA, or immune complex vasculitis. It affects women more than men (2:1) and the peak incidence is 30 to 39. It is associated with atopy and asthma, and IgE is elevated during relapses. It is usually insidious and patients may go several months without diagnosis. Peripheral-blood eosinophilia is usually present. It rapidly improves with corticosteroid therapy, but patients may require therapy for months or years, and relapses are common if treatment is reduced or stopped. Alveolar infiltrates containing numerous eosinophils develop and often produce microabscesses. Charcot-Leyden crystals may be visible in the airspaces and in macrophages. Interstitial infiltrates are usually present but less severe. The airways may be ulcerated and obstructive bronchiolitis may develop. The radiograph appears identical to simple pulmonary eosinophilia, except that the opacities in chronic eosinophilic pneumonia persist unchanged until corticosteroid therapy is started.

Hypereosinophilic syndrome is an uncommon multiorgan disease characterized by prolonged blood eosinophilia with eosinophilic tissue infiltrates. Mean age is 33, and there may be a male predominance. Diagnosis requires eosinophil count over 1500 for at least 6 months (unless death intervenes) without other cause and signs and symptoms of organ involvement. Radiographs reveal transient hazy opacities or consolidation that resolves spontaneously. Cardiomegaly, pulmonary edema, and pleural effusion may develop. CT may reveal reticular opacities.

GOODPASTURE SYNDROME AND IDIOPATHIC PULMONARY HEMORRHAGE

These processes have identical chest manifestation: Goodpasture syndrome is essentially idiopathic pulmonary

hemorrhage with renal involvement. Both result in repeated pulmonary hemorrhage, iron deficiency anemia, and acute or chronic pulmonary insufficiency. IPH usually develops in children younger than 10 years, with no sex predominance. Goodpasture syndrome typically affects people older than 16 years, with slight male predominance. HLA-DRw15 and -DR4 are associated with Goodpasture syndrome. Antibodies to type IV collagen of glomerular and alveolar basement membranes develop. IPH may have a heritable basis, and circulating and tissue immune complexes have been found in some patients.

Hemorrhage is confined mostly to the alveoli and small airways. Much blood loss can occur before hemoptysis develops. Hemosiderin laden macrophages and free interstitial iron are present, and there is mild-to-moderate interstitial fibrosis. There may be a mild lymphocytic inflammatory component, and sometimes an acute interstitial capillaritis develops. Immunoglobulins line the basement membrane, usually IgG but sometimes IgA or IgM.

Early in either disease radiographs reveal patchy alveolar opacities, large opacities usually having air bronchograms. The opacities are typically widespread, bilateral, and asymmetric, but may be perihilar or in the mid- and lower-lung zones. Acute pulmonary hemorrhage is visible in CT as mainly dependent areas of ground glass or alveolar opacity. In MRI, the high T1 signal of blood and the low T2 signal of paramagnetic iron can provide diagnostic accuracy. Serial radiographs over the few days after an episode reveal disappearance of the alveolar opacities in 2 to 3 days to be replaced with reticulonodular opacities in the same distribution. CT reveals ill-defined 1- to 3-mm centrilobular nodules in the affected areas, sometimes with ground glass opacity and interlobular septal thickening. The radiograph usually is normal within 10 to 12 days. Repeated episodes deposit more hemosiderin in the interstitium and pulmonary fibrosis increases. A fine reticulonodular pattern in chest radiography indicates the irreversible component, visible in CT as 1- to 3-mm centrilobular nodules throughout the parenchyma.

QUESTIONS AND ANSWERS

- A patient presents with serositis, photosensitivity, thrombocytopenia, and renal insufficiency. Which of these would be most specific and useful for her diagnosis?
 - Anti-Sm
 - Anti-ds-DNA
 - Scl-70
 - c-ANCA
- Regarding rheumatoid arthritis, which of the following is *true*?
 - Extra-articular manifestations are more common in women.
 - Approximately 1% to 5% have radiographic evidence of interstitial lung disease.
 - Incidence of pulmonary rheumatoid nodules is about 1:50.
 - Hyperviscosity syndrome is related to thrombocytopenia.

ANSWER: B. The patient likely has systemic lupus erythematosus. Speckled staining is most common, reflecting antibodies to nucleic ribonucleoprotein and the nonnucleic glycoprotein macromolecule Sm. Rim staining is specific for patients with SLE and reflects antibodies to nuclear DNA. The level of double-strand DNA antibodies reflects disease status in many patients. c-ANCA can be positive in SLE patients but has no bearing on disease status.

ANSWER: B. RA has extra-articular manifestations in about three-fourths of patients, more common in men and in patients with severe articular disease. Approximately 1% to 5% of patients have radiographic evidence of ILD, though 40% have reduced DLCO consistent with fibrosis. Rheumatoid nodules are present in 2:1000 patients. Hyperviscosity syndrome is a rare complication of RA in which RF molecules conglomerate into bodies large enough to obstruct small vessels.

3. A 45 year-old woman with scleroderma is most likely to have which of the following?
- Interstitial pneumonitis
 - Rib notching
 - Anti-RNA-polymerase III antibodies
 - Pleural effusion

ANSWER: A. Interstitial pneumonitis is present in 20% to 65% of radiographs and appears similar to IPF. Rib notching is a nonspecific finding found in 15% of patients. Anti-RNA-polymerase III antibodies are specific for scleroderma but sensitivity is less than 25%. Effusion is less common than in other connective tissue diseases, radiographically apparent in 10% to 15% of patients.

4. Regarding Sjogren syndrome, which of the following is *true*?
- Consists of keratoconjunctivitis sicca, xerostomia, and parotid swelling
 - An isolated syndrome in the majority of cases
 - Associated with bullous changes in the lung apices
 - Antibodies are developed against topoisomerase-1.

ANSWER: A. The Sjogren syndrome consists of keratoconjunctivitis sicca, xerostomia, and parotid swelling. It is associated with other connective tissue disorders in 59% of cases. In the lungs, it is associated with lymphocytic interstitial pneumonitis, pleuritis, and tracheobronchial gland inflammation. Antibodies are developed against small nuclear and cytoplasm particles: SS-A (anti-Ro) and SS-B (anti-La). Anti-topoisomerase-1 (Scl-70) is associated with scleroderma.

5. A 55 year-old man presents with recurrent hemoptysis and renal insufficiency with abnormal urine sediment suggesting glomerulonephritis. What will the chest radiograph most likely reveal?
- Diffuse reticulonodular lung disease
 - Normal study
 - A few nodules, the largest 6 cm and cavitary, with patchy basilar predominant opacities
 - Innumerable subcentimeter nodules with apical-predominant cysts

ANSWER: C. The patient's hemoptysis and glomerulonephritis satisfy diagnostic criteria for Wegener granulomatosis. In such patients, the chest radiograph will eventually be abnormal in 85% of patients. Nodules, generally numbering less than 10 and typically diffuse and bilateral, range from subcentimeter to 10 cm. Consolidation and ground glass opacities because of hemorrhage are the second most common finding and are independent of nodules.

6. A chest CT angiogram obtained to rule out PTE in a 25 year-old man with hemoptysis reveals a 2.5-cm right interlobar artery aneurysm. Which of the following is *true*?

- His disease is associated with blood eosinophilia.
- Biopsy will reveal nonnecrotizing granulomas.
- Antibodies to myeloperoxidase are common.
- His disease may also manifest as aphthous stomatitis and skin lesions.

ANSWER: D. The patient may have Behcet disease. Many inflammatory-allergic processes are associated with eosinophilia, but Behcet disease is not. The disorder is not associated with granuloma formation or with antimyeloperoxidase antibodies. Its manifestations include recurrent aphthous stomatitis, genital ulcers, skin lesions, and uveitis.

7. Chest radiographs obtained for a woman with newly diagnosed sarcoid reveal hilar lymphadenopathy and lung abnormalities. Which of the following is *true* regarding the staging and prognosis?

- Stage 1. Abnormalities are likely to resolve.
- Stage 2. Abnormalities resolve in about one-half of patients.
- Stage 3. Abnormalities resolve in about one-half of patients.
- Stage 3. Abnormalities are unlikely to resolve.

ANSWER: B. The staging is described above. Staging is primarily helpful for predicting outcome.

8. A patient who underwent lung transplant 36 hours ago has developed shortness of breath and hypoxemia. What is the most likely diagnosis?

- Hyperacute rejection
- Acute rejection
- Chronic rejection
- Reperfusion edema

ANSWER: D. Reperfusion edema occurs by the third postoperative day in over 97% of cases. Hyperacute rejection begins within minutes of reperfusion and is owing to preformed antibodies to ABO and HLA antigens. It should never happen with current pretransplant screening. Acute rejection is a T-cell mediated anti-HLA response, seen as soon as 3 days after transplant but more typically manifest at 1 to 2 weeks. Chronic rejection is first visible at 7 months at the earliest.

9. A 30 year-old woman with eczema presents for a prenatal screening radiograph, which reveals patchy peripheral alveolar opacities. She has no symptoms, but a CBC reveals eosinophilia. What is the most likely diagnosis?

- A. Simple pulmonary eosinophilia
- B. Acute eosinophilic pneumonia
- C. Chronic eosinophilic pneumonia
- D. Hypereosinophilic syndrome

ANSWER: A. Simple pulmonary eosinophilia has patchy transient opacities consisting of interstitial and alveolar edema and eosinophilia. Acute eosinophilic pneumonia has acute fever and does not have eosinophilia. Chronic eosinophilic pneumonia and hypereosinophilic pneumonia are associated with eosinophilia but also with long-standing symptoms.

10. Idiopathic pulmonary hemorrhage and Goodpasture syndrome are differentiated by what?
- A. Artery diameter that hemorrhages and associated volume of blood loss
 - B. Presence of free interstitial iron
 - C. Demographic characteristics and sites of involvement
 - D. Presence of alveolar opacities

ANSWER: C. IPH usually affects children aging younger than 10 years and has no sex predominance. Goodpasture syndrome typically affects patients older than 16 years and has a slight male predominance, and it affects the kidneys as well as the lung. In both, hemorrhage is confined mostly to the alveoli and small airways. Much blood loss can occur before hemoptysis develops. Early in either disease, the radiograph may reveal patchy alveolar opacities. The alveolar opacities disappear in 2 to 3 days, replaced with reticulonodular opacities in the same distribution. The radiograph usually is normal within 10 to 12 days. A fine reticulonodular pattern in chest radiography indicates the irreversible component.

Interstitial lung disease (ILD) is a heterogeneous group of disorders with variable interstitial inflammation and fibrosis (Table 22-1). Idiopathic interstitial disease encompasses a group of disorders, which are syndromes rather than diseases. Their classification is determined by not only radiological findings, but also by clinical features and histology. It is impossible to determine a particular type of idiopathic interstitial pneumonia with absolute certainty on HRCT (already defined) alone.

Known causes of ILD should be considered as secondary or nonidiopathic ILD (Table 22-2).

Chest radiography and HRCT of the chest have established roles in the detection, differential diagnosis, and follow-up of patients with ILD. Chest radiograph is often abnormal in 90% of patients with diffuse lung disease although it is insensitive for early ILD. In 10% of biopsy-proven ILD, chest radiographs are normal. Therefore, a normal chest radiograph does not exclude ILD, and extensive ILD on a chest radiograph does not correlate well with physiologic impairment. Evaluation of serial radiographs provides information regarding status of disease progression or regression. By using thin section thickness (1.25 mm) and high spatial frequency reconstruction (bone algorithm), HRCT allows better visualization of fine parenchymal details such as small bronchi, branching vessels, and interlobular septa. HRCT is often performed at full inspiration in supine position. Additional prone imaging is done in patients with suspected basal ILD, which is masked or mimicked by dependent atelectasis in supine imaging. Expiratory HRCT imaging allows detection of air trapping in patients with suspected obstructed airway disease, not visible on inspiratory scans.

IDIOPATHIC PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis (IPF) is the most common form of idiopathic ILD, estimated prevalence is 20 per 100 000 people.

Histology—Histological findings include heterogeneous appearance with acute, subacute, and chronic inflammation, together with fibroblastic foci and honeycombing. No other form of ILD has these heterogeneous features. These are the findings of usual interstitial pneumonitis (UIP). Approximately 70% of cases of UIP are IPF, the remainder are secondary UIP because of known causes.

Clinical—Patients are usually older than 50 years of age and present with nonproductive cough, progressive dyspnea, weight loss, and fatigue. Velcro rales may be heard in the lungs.

22 INTERSTITIAL LUNG DISEASE

Ian Malcolm and Satinder P. Singh

INTRODUCTION

The interstitium of the lung surrounds the central bronchovascular bundles and extends around the smaller airways and alveoli to the subpleural region. Although it is continuous, it is conveniently divided into axial and peripheral, as certain diseases have a tendency to involve either of these regions.

TABLE 22-1 Interstitial Lung Disease Histopathology

Idiopathic pulmonary fibrosis	Subpleural and basal reticulation	Honeycombing	Traction bronchiectasis	Architectural deformity	Irregular pleural, bronchial, and vascular interfaces	Minimal ground glass opacification	Commonly smokers with signs of centrilobular emphysema
Nonspecific interstitial pneumonitis	Ground glass opacities	Reticulation	Patchy consolidation	Traction bronchiectasis	Minimal or absent honeycombing	Subpleural sparing	
Cryptogenic organizing pneumonia	Subpleural and peribronchial distribution	Peripheral wedge, ground glass, or consolidation	Axial interstitial thickening	Axial interstitial nodules	Atoll sign		
Acute interstitial pneumonia	Patchy or diffuse consolidation (geographic distribution)	Patchy or diffuse ground glass opacities	Posterior lower lobe predominance	Later resolution or development of end-stage fibrosis with architectural deformity, bronchiectasis, honeycombing, etc.			
Respiratory bronchiolitis—interstitial lung disease and desquamative interstitial pneumonia							
RB-ILD	Ill-defined centrilobular nodules	Bronchial wall thickening	Air trapping (mosaic attenuation on expiration)	Upper lobe predominance (60%–75%)			
DIP	Acinar opacities (alveolitis)	Diffuse ground glass opacities	Posterior lower lobe predominance (60%–75%)	Small thin-walled cystic lucencies	Centrilobular emphysema		
Lymphocytic interstitial pneumonia	Diffuse or ground glass opacities	Ill-defined centrilobular nodules	Septal thickening (reticulation)	Small cystic lesions	Later, more diffuse cystic disease		

Pulmonary function tests—These are restrictive, with impaired gas transfer and reduced carbon monoxide diffusing capacity.

Radiographs—There are usually symmetrical, peripheral and basilar, linear, or reticular opacities, which progressively spread and coarsen. The lateral view is often more sensitive than the PA view in the detection of early disease. There is ongoing loss of volume and possibly architectural deformity. Decreased lung volumes are radiographically evident at the initial evaluation in over

one-half of cases. Serial radiographs are often used to monitor disease progression and loss of lung volumes. Most patients are smokers, and if there is significant associated emphysema, lung volumes may be normal. A normal chest radiograph cannot be used to exclude UIP as over 10% of these patients have normal radiographs.

HRCT—In 70% to 95% of patients, there is a predominantly peripheral and basal interstitial reticular process because of thickening of the walls of secondary pulmonary lobules (the interlobular septa). Smaller

TABLE 22-2 Interstitial Lung Disease (Decreasing Frequency)

DISEASE	HISTOLOGY
Idiopathic pulmonary fibrosis (IPF)	Usual interstitial pneumonia (UIP)
Idiopathic nonspecific interstitial pneumonitis (NSIP)	NSIP
Cryptogenic organizing pneumonia (COP)	Organizing pneumonia
Acute interstitial pneumonia (AIP)	Acute lung injury with diffuse alveolar damage
Respiratory bronchiolitis (RB) and desquamative interstitial pneumonia (DIP)	Respiratory bronchiolitis and desquamative interstitial pneumonia
Lymphoid interstitial pneumonia (LIP)	LIP

(short) interstitial lines may also be seen because of thickening of intralobular septa, which is the interstitium within the secondary pulmonary lobule surrounding the alveoli and distal small airways. The subpleural margins and bronchial and vascular interfaces may become indistinct because of this diffuse interstitial process. There is associated architectural distortion, traction bronchiectasis, and honeycomb formation. Honeycomb cysts are characteristically similar in size, begin at the periphery, and layer progressively. Predominantly subpleural reticulation and honeycombing are present in majority of patients and fibrosis is most severe in the lower lung zones. In the remainder, all lung zones are similarly involved or mainly upper lung zones are affected. Patients with accelerated-phase disease show focal areas of consolidation, which is histologically shown to be diffuse alveolar damage and organizing pneumonia.

Management—Using clinical data and HRCT, a confident diagnosis of IPF can be made in most patients. A definite diagnosis requires open lung biopsy, but this is generally only performed if clinical management will be determined by this diagnosis. Video-assisted thoracoscopic surgery (VATS) procedure is less traumatic than open lung biopsy.

Lung carcinoma develops in 10% of cases, usually as a nodule but sometimes manifesting as focal consolidation. In the case of smokers, there may be associated emphysema and mosaic perfusion with air trapping. Adenopathy is shown in 70% of cases of IPF, but lymph nodes are unlikely to be greater than 15-mm short axis.

Treatment—Ineffective, as there is usually relentless progression of disease with death in 2 to 4 years. Five-year survival is 20%. Lung transplantation may be required for survival. The most rapid deaths occur with accelerated phase IPF. In the absence of accelerated disease, end-stage patients can also deteriorate with respiratory failure, cor pulmonale heart failure, PTE, or infection.

Secondary UIP may be caused by collagen vascular disease, asbestosis, drug toxicity, chronic hypersensitive pneumonitis (HP), and irradiation injury. These patients will often have additional findings because of the disease process itself. For example, UIP in a patient with scleroderma may also manifest with dilated atonic esophagus and aspiration pneumonia.

IDIOPATHIC NONSPECIFIC INTERSTITIAL PNEUMONITIS

Idiopathic nonspecific interstitial pneumonitis (NSIP) accounts for 14% to 35% of cases of Idiopathic ILD. This disease occurs in a younger age group than IPF (40–50 years of age).

Histology—There are no specific features to suggest UIP, DIP, OP, or AIP. In other words, this is a diagnosis of exclusion. The histology is homogeneous with thickening of alveolar walls with lymphocytes and plasma cells (cellular NSIP) or alternatively fibroblast and collagen (fibrotic NSIP). Patients with cellular disease have an excellent prognosis, whereas patients with fibrotic NSIP have a survival of only 6 to 14 years (Kim).

Clinical—Patients present with dyspnea and dry cough and have widespread basal crackles and finger clubbing (10%–35%). Average age of presentation is from 40 to 50 years.

Radiographs—There is usually bilateral patchy or confluent hazy opacification in the lungs. This predominates in the mid and lower lung zones, sometimes with reticular opacities and consolidation in the lung bases. In 15% of patients, the chest radiograph is normal.

HRCT—There is considerable overlap between the HRCT findings of NSIP and the other interstitial pneumonias. There is commonly symmetrical ground glass opacification and usually superimposed reticulation (crazy paving). Traction bronchiectasis is common. Honeycombing is unusual (10%–30%) and if present is mild, involving less than 10% of the lung parenchyma, unlike UIP and IPF. Peripheral and basal lungs are predominantly involved. In 50% of cases, there is a rim of subpleural sparing. This is also unlike IPF, which is typically most severe in the subpleural region. Patients with fibrotic NSIP have a high incidence of reticulation and traction bronchiectasis.

Honeycombing is not a feature of NSIP. Patients with cellular NSIP have predominant ground glass opacification and are more likely to improve with treatment, with better long-term prognosis. Mild mediastinal adenopathy is present in 80%. Accelerated NSIP can occur with a 1-year frequency of 3%.

Acute deterioration in NSIP can also occur with infection, PTE, pneumothorax, or right heart failure.

Secondary NSIP may occur with collagen vascular disease, chronic HP, drug toxicity, infection, and immunodeficiency. The association with collagen vascular disease is particularly common. Collagen vascular disease with interstitial fibrosis is more likely to be NSIP than UIP.

CRYPTOGENIC ORGANIZING PNEUMONIA

Cryptogenic organizing pneumonia (COP) accounts for 4% to 12% of cases of idiopathic interstitial pulmonary fibrosis. It is more common in nonsmokers and has an average age of presentation of 50 to 60 years.

Clinical—Patients present with cough and dyspnea of short duration (less than 3 months). There may be weight loss, chills, and fever. There are usually widespread lung

crackles on auscultation. Patients are unresponsive to antibiotics, but usually respond well to steroids. However, recurrence is not uncommon.

Histology—Intraluminal polyps of granulation tissue distend the alveolar ducts, alveoli, and sometimes the respiratory bronchioles. There is chronic inflammation of the adjacent lung parenchyma with mononuclear cells, foamy macrophages, and organizing fibrosis. This disease has traditionally been called bronchiolitis obliterans with organizing pneumonia (BOOP), but this description unfortunately emphasizes the bronchial involvement rather than the pneumonia and is no longer favored.

Pulmonary function tests—Mild-to-moderate restrictive function is shown with decreased carbon monoxide diffusing capacity.

Radiographs—There are patchy areas of subpleural consolidation, which vary in size over time and are sometimes migratory. Margins are indistinct and air bronchograms may be seen. Nodules or masses may be seen more centrally in the lungs. There may also be small nodules or reticular markings. Small pleural effusions are seen in 20%. It is unlikely that a diagnosis of COP can be made on chest radiographs.

HRCT—Middle and lower lung zones are predominantly involved. Subpleural areas of wedge-shaped consolidation and ground glass opacification of variable size are shown in 70% of cases. These may change in distribution. Ground glass lesions may have a halo of consolidation, which is referred to as the reversed halo sign. There may be interstitial reticulation superimposed on ground glass opacities (crazy paving). Bronchovascular bundles are characteristically involved with thickening or nodules. These nodules may be of variable size and in 30% to 50% of cases are less than 10 mm. However, they may occur up to 5 cm in size or manifest as larger areas of consolidation. Reversible bronchial dilation sometimes occurs.

Secondary organizing pneumonia may occur with collagen vascular disease, inflammatory bowel disease, inhalational injury, chronic HP, drug reaction, irradiation injury, aspiration, and bronchial obstruction. Areas of organizing pneumonia are a common accompaniment of lung cancer and lung infection.

ACUTE INTERSTITIAL PNEUMONIA

Acute interstitial pneumonia (AIP) should be considered as idiopathic ARDS. It has been previously referred to as the Hamman-Rich syndrome.

Histology—This is acute lung injury with diffuse alveolar damage. In the acute exudative phase, there is sloughing of alveolar cells, intra-alveolar hemorrhage, severe interstitial inflammation, and hyaline membrane formation. The proliferative phase shows type II pneu-

mocyte hyperplasia and early collagen formation in the interstitium. The chronic or reparative phase develops end-stage fibrosis with architectural deformity.

Clinical—Mean age is 50 years with wide age distribution. This disease usually occurs in previously healthy persons. There is often a prodromal infection with fever, chills, and myalgia for less than a week prior to diagnosis. This is followed by progressive dyspnea, hypoxia, and respiratory failure. There is a 50% death rate within 6 months of presentation.

Radiographs—There is bilateral airspace consolidation with prominent air bronchograms. This is initially patchy, but becomes more widespread and diffuse. Distribution involves the lung periphery or full thickness of both lungs, unlike cardiogenic edema, which is perihilar. There may be regional predominance in the upper or lower lung zones.

HRCT—There are geographical areas of ground glass opacification and crazy paving with uninvolved areas of normal lung interspersed with the disease process. Patchy and confluent airspace consolidation is also shown with progression to a more diffuse process over time. Air bronchograms may be very prominent. There is little, if any, pleural effusion. Heart size is usually normal. With progression to the fibroproliferative phase, ground glass opacities become diffuse and there is coalescence of the consolidation. Architectural deformity with honeycomb formation and traction bronchiectasis progressively worsens.

Pulmonary function tests—There is restrictive lung function and impaired gas exchange, with progressive hypoxemia and respiratory failure.

Management—Mechanical ventilation is required which often leads to barotrauma (pulmonary interstitial emphysema, pneumothorax, pneumomediastinum, and subcutaneous emphysema). Approximately 50% of patients die in the acute phase. Of the remainder, some recover with normal lung function and the survivors develop end-stage fibrosis.

Secondary AIP is ARDS. The cause is known. These causes include trauma, sepsis, pancreatitis, shock, aspiration, anaphylaxis, DIC, transfusion reaction, embolic disease (particularly fat embolism and amniotic fluid embolism) therapeutic or nontherapeutic drugs, ketoacidosis, and neurologic disease (head injury and cerebrovascular accident (CVA)).

LYMPHOID INTERSTITIAL PNEUMONIA

Lymphoid interstitial pneumonia (LIP) is part of a spectrum of lymphoproliferative disorders, and idiopathic LIP is extremely rare.

Histology—There is diffuse infiltration of the alveolar septa with lymphocytes and less numerous plasma cells and histiocytes. Lymphoid follicles may be present and if the small airways are predominantly involved rather than the alveoli, the condition is called follicular bronchiolitis. The histological pattern may resemble NSIP or HP.

Clinical—Average presentation is 40 to 50 years. Women are involved two times more than men. There is an insidious cough, dyspnea, and fatigue. Eighty percent of patients have dysproteinemia. Bronchoalveolar lavage shows lymphocytosis. Steroids are helpful, but one-third of patients progress to interstitial fibrosis.

Pulmonary function tests—There is a restrictive defect and reduction of total lung capacity.

Radiographs—A reticular or reticulonodular pattern may be shown in the lungs involving mainly the lower lung zones. Less commonly, there is a nodular pattern with hazy opacities or areas of consolidation.

HRCT—There are four recognized features of LIP on HRCT. Extensive ground glass opacification occurs because of diffuse lymphocytic infiltration in the alveolar walls. Poorly defined centrilobular nodules are produced by peribronchial infiltration of lymphocytes and plasma cells together with histiocytes, similar to the findings in follicular bronchiolitis. There is thickening of the central bronchovascular bundles because of interstitial cellular infiltration. Small cystic airspaces may be seen. These result from obstruction of small airways. Greater than 80% of cases of LIP show thickened peribronchovascular interstitium and septal thickening. More than 70% show cystic airspaces. Lesions have a tendency to resolve, with the exception of the cysts, which are irreversible.

Secondary LIP is much more common than idiopathic LIP. Most cases of LIP occur in patients with underlying autoimmune disease, most commonly Sjögren syndrome and dysproteinemia. Secondary LIP may also occur with AIDS, rheumatoid arthritis, lupus, Hashimoto thyroiditis, autoimmune hemolytic anemia, myasthenia gravis, pernicious anemia, chronic active hepatitis, and drug toxicity.

RESPIRATORY BRONCHIOLITIS AND DESQUAMATIVE INTERSTITIAL PNEUMONITIS

Respiratory bronchiolitis (RB) is a bronchiolitis, but is included because of its association with DIP, which is a true interstitial pneumonitis (fibrosing alveolitis). RB is localized and confined to the small airways.

Histology—Pigment-laden macrophages are shown in alveoli and respiratory bronchioles in RB. They are phagocytosed into the walls of the respiratory bronchioles with consequent inflammation and fibrosis.

Clinical—Patients remain asymptomatic for many years, but eventually develop cough, dyspnea, basal crackles, and a combined restrictive and obstructive lung pattern. At this stage, RB is classified as respiratory bronchiolitis/interstitial lung disease (RB/ILD).

Desquamative interstitial pneumonitis (DIP) may occur in association with or without RB. It is a diffuse process characterized by numerous macrophages within the alveoli, mild inflammation of the alveolar walls, and developing fibrosis. Although DIP is classified as an idiopathic disorder, more than 90% of patients are cigarette smokers.

Radiograph—In RB/ILD, there may be air trapping and peribronchial thickening. There may be linear markings because of thickened small airways peripherally resembling ILD. In DIP, 25% of radiographs are normal. The most common abnormality is ill-defined ground glass opacities in the lower lung zones.

HRCT—Ill-defined centrilobular nodules occur in over 70% because of thickened bronchiolar walls. Patchy ground glass opacities occur in 65% and are caused by alveolitis (DIP). These ground glass opacities tend to have a subpleural and lower lobe predominance. Small cystic lucencies eventually may develop within these areas of ground glass opacity. Mosaic attenuation occurs in over 75% because of air trapping. Honeycombing and septal thickening is rare.

Secondary DIP occurs in association with toxic inhalation, drug reactions, Langerhans cell histiocytosis, leukemia, asbestosis, and hard metal pneumoconiosis.

QUESTIONS AND ANSWERS

- Concerning respiratory bronchiolitis interstitial lung disease, which of the following is *true*?
 - Minority of cases have smoking history.
 - Commonly shows mosaic attenuation on CT
 - Commonly shows tree-in-bud lesions on CT
 - Septal thickening occurs in one-half of patients.

ANSWER: B. Respiratory bronchiolitis commonly shows a mosaic attenuation on CT. The majority of patients with respiratory bronchiolitis have a smoking history. Tree-in-bud and septal thickening are not features of acute cellular bronchiolitis.

- Concerning interstitial lung disease, which of the following is *true*?
 - 20% have a normal chest radiograph on initial presentation.
 - Readily distinguishable from basal atelectasis on portable radiographs
 - 30% show loss of volume on initial chest radiograph.
 - Increased opacification in the lower lung zones is a helpful diagnostic feature on lateral chest radiographs.

ANSWER: D. Lateral chest radiograph is often more sensitive for diagnosis of this disease, particularly in the early stages. Regardless, 10% still present with normal chest radiographs. Over one-half show loss of volume on initial chest radiographs. ILD can be difficult to differentiate from basal atelectasis on portable radiographs.

- What is a prominent feature of idiopathic pulmonary fibrosis on HRCT?
 - Honeycombing
 - Peripheral sparing
 - Ground glass opacification
 - Geographic involvement of lung parenchyma interspersed with normal parenchyma

ANSWER: A. Honeycombing is a prominent feature of IPF on HRCT. Peripheral sparing is a feature of NSIP not UIP (IPF). Ground glass opacification may be present with IPF, but is not a prominent finding. Geographic involvement of lung parenchyma interspersed with normal parenchyma describes acute interstitial pneumonia (AIP) not IPF.

- What is a prominent feature of nonspecific interstitial pneumonitis?
 - Traction bronchiectasis
 - Peripheral reticulation
 - Honeycombing
 - Centrilobular nodules

ANSWER: A. Traction bronchiolitis is a prominent feature of nonspecific interstitial pneumonitis. There is often peripheral sparing, unlike UIP, which has thickened interlobular septae causing reticulation extending to the lung periphery. Honeycombing can occur but is uncommon with NSIP. Centrilobular nodules are not a feature of NSIP. They occur with RB/ILD, HP, and some industrial lung diseases.

- What is a feature of cryptogenic organizing pneumonia with HRCT?
 - Peripheral nodules
 - Peripheral interstitial reticulation
 - Peripheral pleural-based ground glass, wedge-shaped lesions
 - Mosaic attenuation

ANSWER: C. Peripheral pleural-based ground glass, wedge-shaped lesions are a feature of nodules in COP, involve the axial interstitium, and tend to involve the perihilar or central lung regions, not the lung periphery. Reticulation is not a feature. Mosaic attenuation is a feature of a peripheral pulmonary thromboemboli and small airways disease.

- What is a feature of acute interstitial pneumonia on CT?
 - Cardiomegaly
 - Pleural effusions
 - Areas of consolidation and ground glass opacification
 - Rapidly changing parenchymal disease

ANSWER: C. Areas of consolidation and ground glass opacification are features of AIP. The heart size is usually normal unless the patient has an underlying cardiomyopathy. Pleural effusions are small or absent. Unlike aspiration and cardiogenic pulmonary edema, parenchymal disease changes slowly with AIP.

7. Concerning usual interstitial pneumonia, which of the following is *true*?
- Histologically homogenous
 - Most common secondary interstitial lung disease associated with collagen vascular disorders
 - 30% of cases are idiopathic pulmonary fibrosis.
 - Accelerated disease shows areas of organizing pneumonia and diffuse alveolar damage on histology.

ANSWER: D. The histological pattern is characteristically heterogeneous. Nonspecific interstitial pneumonitis is the common pattern associated with collagen vascular disease. Approximately 70% of cases of usual interstitial pneumonia are IPF.

8. Concerning interstitial lung disease, which of the following is *true*?
- Architectural deformity and loss of volume are pathognomonic.
 - Emphysema is commonly associated.
 - Leads to pulmonary hypertension and eventually cor pulmonale heart failure.
 - Expected life span of 10 to 15 years

ANSWER: C. Interstitial lung disease can lead to pulmonary hypertension and eventually cor pulmonale heart failure. Architectural deformity and loss of volume can occur with end-stage lung disease including, but not limited to, IPF. Emphysema is commonly associated with UIP (IPF), not NSIP. Patients with IPF have an expected life span of less than 5 years.

9. Concerning usual interstitial pneumonia, which of the following is *true*?
- Most common interstitial lung disease associated with collagen vascular disease
 - Pathognomonic findings on HRCT
 - Heterogeneous pattern is shown histologically.
 - There is a 40% risk of lung cancer.

ANSWER: C. NSIP is the most common ILD to be found in association with collagen vascular disease. A characteristic case of UIP on HRCT may prove to be some other condition such as NSIP on histology. There is a 10% lung carcinoma incidence in patients with IPF.

10. Concerning nonspecific interstitial pneumonitis (NSIP), which of the following is *true*?
- Patients with IPF have a better steroid response than patients with NSIP.
 - Patients with cellular NSIP respond better than those with fibrotic NSIP.
 - Traction bronchiectasis is uncommon.

- D. Idiopathic NSIP is more common than secondary NSIP.

ANSWER: B. NSIP is steroid responsive, whereas UIP is not. Traction bronchiectasis is a characteristic feature. Secondary NSIP is more common than idiopathic NSIP.

23 PULMONARY NEOPLASMS

*Jonathan Walter, Ian Malcolm,
and Satinder P. Singh*

NOMENCLATURE AND GENERAL CONSIDERATIONS

A pulmonary *nodule* may range in size from 4 mm to 3 cm and a *mass* is greater than 3 cm in size. Nodules seen in patients younger than 35 years, nonsmokers, and patients from typical endemic granulomatous disease regions (i.e., Ohio River valley) are usually felt to be benign in origin. If a pathologic specimen is not obtained, these patients may be followed at 3 to 6 months, 1 year, and 2 years after initial nodule detection. Suspicion for malignant nodules occurs in patients older than 35 years (up to 50% of noncalcified nodules in patients older than 50 years may be malignant), smokers, patients with asbestos exposure, known primary neoplasms, and large lesions. These lesions are typically not followed without obtaining a pathologic specimen unless there is clearly benign calcification, intralesional fat, or lack of growth over at least a 2-year period.

The differential diagnosis for a solitary pulmonary nodule is wide-ranging. The first consideration generally is a neoplasm—primary or metastatic. Next, an infectious process such as round pneumonia, septic embolus, abscess, and granuloma should be considered. Vascular abnormalities such as AVMs and aneurysms comprise the next general class of possibilities. Following, congenital abnormalities such as sequestration, congenital cystic adenomatoid malformation (CCAM), and bronchogenic cyst are included. Finally, and usually least likely, autoimmune disorders such as Wegner's granulomatosis and rheumatoid arthritis with necrotic nodules complete a very brief differential diagnosis.

The radiographic evaluation of a pulmonary nodule or mass may be quite extensive; however, a few general considerations should be followed. First, general radiography is felt to be largely unreliable for lesions less than 1 cm in diameter. Second, the rate of growth is an important factor in determining the nature of a lesion. A sphere has doubled

in size when the diameter has increased by only 25%. Lesions such as bronchogenic carcinoma typically display a doubling time of between 1 month and 2 years; therefore, a regular follow-up schedule is vital. Third, benign lesions typically display a smooth, rounded margin. Malignant lesions are more likely to appear spiculated, notched, angulated, or lobulated. Fourth, there are benign and malignant patterns of calcification. Benign calcification generally may appear complete, central, concentric, laminated, or like popcorn. Malignant calcification may appear punctuate or eccentric. Fifth, fat within a pulmonary nodule is generally indicative of a benign lesion, such as seen with a pulmonary hamartoma. Sixth, most malignant lesions enhance by at least 15 HU (98% sensitive). Finally, PET is generally quite useful for lesions greater than 1 cm (sensitivity as high as 97%, but specificity is only upward of 78%). A lower specificity is generally seen in lesions less than 1 cm, in cases of inflammation, and with hypoactive lesions such as bronchoalveolar carcinoma and carcinoid.

Numerous primary and metastatic pulmonary neoplasms have been described in the literature and several proposed classification schemes have been introduced. Those schemes based upon neoplasm histologic origin provide a rather intuitive means for classification, and this approach will be used in this review (Table 23-1). In addition, for the sake of brevity, we shall consider only the more common primary malignant and benign lesions, followed by a brief overview of more commonly encountered metastatic lesions. More obscure pulmonary neoplasms are beyond the scope of this chapter and are likely of low yield for board examination purposes; however, suggestions for further reading will be provided at the end of this chapter.

MALIGNANT PULMONARY NEOPLASMS

BRONCHOGENIC CARCINOMA

The overwhelming majority (greater than 95%) of primary malignant pulmonary neoplasms fall under the general classification of bronchogenic carcinoma. These neoplasms are epithelial in origin and are derived from either bronchial or alveolar epithelium. Bronchogenic carcinoma is the leading cause of death from malignancy in the US. There are at least four broad histologic subtypes: adenocarcinoma, squamous cell carcinoma, small cell carcinoma, and large cell carcinoma. As a group, general risk factors include smoking (estimates of up to 87% of cases are related to smoking), other exposures such as asbestos (long latency, may be greater than or equal to 20 years) and radon, age greater than 40, male sex, although this association is equalizing, diffuse or localized fibrosis,

and previous mediastinal lymphoma postradiation, and/or chemotherapy. In regard specifically to smoking, small cell carcinoma and squamous cell carcinoma are most closely associated with smoking in men, whereas all subtypes are fairly equally associated with cancer risk in women. The overall 5-year survival rate for patients with bronchogenic carcinoma averages about 10% to 15%.

The radiographic evaluation of the various subtypes of bronchogenic carcinoma will be discussed on an individual basis; however, there are a few general findings, which are fairly unique to this group of cancers as a whole. First, since these neoplasms are epithelial in origin, bronchial obstruction may commonly be seen. This may be observed as incomplete obstruction, analogous to a ball valve mechanism, which results in air trapping or conversely this may be seen as complete obstruction with atelectasis, obstructive pneumonitis, or even mucocoele formation with

mucoid impaction. Next, fairly nonspecific pleural findings may be seen such as pleural effusion or pleural thickening, and evaluation for possible chest wall invasion is critical in the evaluation process. Specifically, one may look for an obtuse angle at the point of contact with any pleural mass, greater than 3 cm of contact between the pleura and mass, pleural thickening immediately adjacent to a mass, infiltration of the extrapleural fat, and finally frank rib erosion or destruction. Other factors such as large size (typically greater than 3 cm) and malignant calcification patterns were mentioned previously. Third, mediastinal invasion must also be considered. Findings such as elevation of a hemidiaphragm may suggest invasion with compromise of the ipsilateral phrenic nerve. In addition, one must look for mediastinal widening, a mediastinal mass, which is contiguous with a pulmonary parenchymal mass, obliteration of vascular fat planes, a mass contacting more than 3 cm of the mediastinum, and a mass contacting greater than 25% of the diameter of the aorta. SVC compression may also be seen with associated SVC syndrome, with lung cancer generally considered to be the most common cause. Finally, lymphangitic carcinomatosis is a final unique consideration seen with bronchogenic carcinomatosis. As tumor invades the pulmonary lymphatics, there are interstitial deposits, interlobular septal thickening, and eventually fibrosis. More specifically, there may be linear or reticulonodular opacities, peribronchial cuffing, subpleural edema, and/or effusion, and often primarily ipsilateral hilar adenopathy.

ADENOCARCINOMA

This is the most common histologic subtype of bronchogenic carcinoma, comprising between 33% and 50% of cases. This is also the most common subtype seen in nonsmokers (weak association with smoking) and in women. Approximately three-fourths of these lesions are seen in the periphery of the lung, while the remaining one-fourth are central. Histologically, these masses demonstrate gland formation and mucin production, and the histochemical stain mucicarmine demonstrates both intra- and extracellular mucosubstance. With time, these lesions then typically proceed to invade the lung parenchyma and there is typically at least a mild/moderate degree of fibrosis. From a radiologic standpoint, these lesions arise from the epithelium and invade into the lung, with the early typical presentation often consisting of a peripheral subpleural nodule or mass. These lesions often become irregular/spiculated in appearance as they enlarge and pleural invasion is common. In addition, these neoplasms may grow around the lung and thus mimic a mesothelioma. These lesions may also contain air bronchograms and can thus mimic infectious processes or even atelectasis. As a group, patients with adenocarcinoma generally demonstrate a 5-year survival of approximately 17%.

Bronchioalveolar cell carcinoma (BAC) is often considered to be a subtype of adenocarcinoma. This neoplasm tends to grow along existing bronchiolar or alveolar walls without invasion or distortion. In essence, true BAC is considered to be a carcinoma in situ since there is no spread beyond the lung parenchyma. On a histologic level, since BAC is a subtype of adenocarcinoma, these lesions also typically demonstrate copious mucous production. Accordingly, with varying degrees of mucous production, these lesions may then appear as solitary pulmonary nodules, nonspecific ground glass opacities, contain air bronchograms or bubbly lucencies, or even mixed solid/ground glass attenuation. When seen diffusely throughout the lungs, BAC may produce apparent airspace opacification, which may mimic pneumonia. These lesions may also demonstrate cavitation and are the second most common type of bronchogenic carcinoma subtype to cavitate after squamous cell carcinoma.

SQUAMOUS CELL CARCINOMA

This is the second most common subtype of bronchogenic carcinoma, comprising between 25% and 33% of cases. Unlike adenocarcinoma, this subtype is strongly associated with smoking and tends to be more central in location (two-thirds of cases). The remaining one-third of cases typically arise in a peripheral location. From a histologic standpoint, this subtype of carcinoma may demonstrate chronic epithelial inflammation/injury, which can then lead to squamous metaplasia. The bronchial wall invasion occurs with nest of malignant cells demonstrating abundant cytoplasm, keratin pearls, and intercellular bridges (fine lines seen extending between cells). Radiologically, these lesions appear as central/hilar polypoid masses, which grow into the bronchial lumen and invade the bronchial wall. As previously discussed, this may then result in either incomplete or complete airway obstruction. When significant obstruction has not yet occurred, this carcinoma subtype is commonly diagnosed from sputum samples (radiographically occult). Central necrosis is a common feature associated with this mass and this is also the most likely lesion to cavitate. If these lesions occur peripherally, they are typically seen as solitary pulmonary nodules or solitary masses. As an aside, squamous cell carcinoma is the first carcinoma subtype in this discussion that is known to produce a paraneoplastic syndrome. Tumors may produce a parathyroidlike substance, which results in hyperparathyroidism, manifesting most classically with hypercalcemia. The overall 5-year survival rate is reported as approximately 15%.

SMALL CELL CARCINOMA

This is the third most common bronchogenic carcinoma subtype, comprising 15% to 25% of cases. There is a

strong association with smoking and lesions are most typically found centrally (90%) arising from main or lobar bronchi. Masses arise from neuroendocrine cells embedded in the epithelium, specifically referred to as type III Kulchitsky cells. Of note, these same Kulchitsky cells (types I and II) give rise to typical and atypical carcinoid tumors, although the type III cells associated with small cell carcinoma are the most malignant. Histologically, lesions demonstrate tightly packed clusters of cells with scant cytoplasm, stippled chromatin within the nuclei, absent nucleoli, mitotic figures, and intracytoplasmic neurosecretory granules. Small cell carcinoma is also the most common bronchogenic carcinoma subtype to cause a neuroendocrine syndrome, two of which are most commonly seen. Cushing syndrome results from ectopic ACTH production and leads to fat redistribution, menstrual irregularity, HTN, DM, and osteoporosis. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) results from the secretion of an ADH-like hormone, which leads to water retention and hyponatremia. Radiologically, small cell carcinoma is a very fast growing malignancy, with early bronchial/peribronchial invasion and invasion of the submucosal/peribronchial lymphatics. These features result in early (often widespread) hematogenous dissemination, which is commonly occurring or has occurred by the time of diagnosis. There is also typically a hilar or mediastinal mass, which may extrinsically compress the airways or even vascular structures. In fact, small cell carcinoma is the most common lung tumor to result in SVC syndrome. Necrosis and hemorrhage are also common features associated with these lesions. The overall prognosis is poor, with an average 5-year survival of only 5%.

LARGE CELL CARCINOMA

This is the least common subtype of bronchogenic carcinoma, occurring in approximately 5% to 15% of cases. There is a strong association with smoking and most masses are found peripherally. Histologically, masses demonstrate large cells (hence the name) with abundant cytoplasm, large nuclei, and prominent nucleoli. Cell clusters tend to grow in uniform sheets. There is also a histologic subtype within this family of neoplasms referred to as giant cell carcinoma. These cells are larger and appear pleomorphic, with multiple unusual shapes instead of uniform sheets. This subtype is particularly aggressive and confers a poorer prognosis. Overall, large cell carcinoma is a histologic diagnosis of exclusion and is typically defined by a non-small cell bronchogenic carcinoma, which lacks characteristics of both adenocarcinoma and squamous cell carcinoma. On radiologic evaluation, lesions arise as solitary peripheral masses, which may be quite large (greater than 3 cm).

Necrosis is common seen, as lesions grow rapidly and metastasize early.

PANCOAST TUMOR

The Pancoast tumor is generally classified as a miscellaneous histologic bronchogenic carcinoma subtype since it may be comprised of any of the bronchogenic carcinoma subtypes, but it is most commonly adenocarcinoma or squamous cell carcinoma in origin. Lesions are seen peripherally and in the lung apices. Symptoms are often related to location, as invasion of local structures is common. Rib destruction and extrathoracic invasion are typically seen. Patients may experience arm pain, muscle atrophy, or even Horner syndrome if the sympathetic chain is invaded. In this scenario, patients may demonstrate ipsilateral ptosis (lid lag), miosis (pupillary constriction), and anhidrosis (decreased facial sweating). As an aside, a patient with metastatic thymoma may also demonstrate an apical pleural-based mass and upper extremity weakness; however, in this case, motor weakness is often secondary to the paraneoplastic effects of the disease with resultant myasthenia gravis.

CARCINOID

Aside from bronchogenic carcinoma, the other major epithelial-derived pulmonary neoplasm is the pulmonary *carcinoid*. This is a relatively uncommon malignancy seen in only 1% to 2% of all lung cancer cases, demonstrates no male/female predilection, occurs commonly in children, and is not thought to be associated with smoking. Most lesions (up to 80%) are found centrally, while peripheral lesions (20%) usually arise as solitary pulmonary nodules. Given central location, bronchoscopy is often performed. The typical appearance is that of a cherry red bronchial lesion owing to the highly vascular nature of these tumors. Biopsy should naturally be avoided secondary to the risk of hemorrhage. Carcinoid metastasizes in about 15% of cases and may be seen in the liver, bone, adrenals, and brain. Classically, patients with liver metastases develop right and often left heart disease as the carcinoid syndrome develops and serotonin levels significantly rise. This results in fibrous deposits along the endocardium, in particular the valve apparatus, with incompetency and stenosis commonly affecting at least the tricuspid and pulmonary valves. As a neuroendocrine tumor, carcinoid tumors may arise from Kulchitsky cells, neuroepithelial bodies, or pluripotential bronchial epithelial stem cells. The classic triad of symptoms includes hemoptysis (secondary to vascular nature of lesions), cough, and pneumonitis. The Carcinoid syndrome, as alluded to above, requires liver metastases. The biochemical conversion of

metabolites within the liver produces flushing, diarrhea, and bronchoconstriction.

Histologically, there are two subtypes of the carcinoid tumor: typical and atypical. The typical carcinoid is more common, with uniform-appearing cells containing abundant cytoplasm arranged in sheets, trabeculae, or glandlike formations. Cells may take many forms, but can be spindle shaped or even palisading. Mitotic figures are not common. Also, since these are vascular tumors, there is a prominent fibrovascular stroma. There may be foci of dystrophic calcification, bone, or amyloid. Finally, neurosecretory granules are present which are larger and more numerous than atypical carcinoids. The other subtype of the carcinoid tumor is the atypical form. This neoplasm is less common, but more aggressive than the typical carcinoid. Histologic features are overall quite similar between the two, except the atypical carcinoid has an increased number of mitotic figures, demonstrates nuclear pleomorphism, disorganized architecture, and often areas of necrosis. On a final note, both typical and atypical carcinoids are capable of synthesizing, storing, and secreting several metabolically active compounds. Serotonin is commonly produced, with patients typically experiencing diarrhea as a consequence of rising serum levels. Cushing syndrome is also associated with carcinoid tumors, with ectopic ACTH producing symptoms as discussed with *small cell carcinoma*. Somatostatin may exert its inhibitory actions on the GI tract, pancreas, anterior pituitary gland, and nervous system. Finally, the potent vasodilator bradykinin may cause flushing.

Carcinoid tumors demonstrate multiple characteristic radiologic findings. The classic description is that of a central mass compressing the bronchus and containing calcifications. In fact, it is the typical carcinoid that is slow growing and centrally located, while the atypical subtype is rapidly growing and more commonly seen peripherally. Central lesions are usually hilar or perihilar, rarely invade the mediastinum, and typically result in external bronchial compression/obstruction. Mucocèles may develop secondary to bronchial obstruction as mucoid material accumulates and impaction occurs. When found peripherally, carcinoid tumors usually appear as rounded or lobulated solitary pulmonary nodules. Overall, carcinoids are endoluminal lesions, which may commonly appear as “iceberg” lesions since the endoluminal component may appear quite small, while the extraluminal component may be very large. Masses are generally large (averaging 2–5 cm) and typically demonstrate avid homogeneous enhancement because of their vascular composition, although some tumors may demonstrate variable or no enhancement if there is little relative vascular stroma. Eccentric calcifications are very commonly seen, but cavitation is rare. Also,

pathologic adenopathy is more typically seen with atypical carcinoids. Aside from radiography, CT, and MRI, nuclear medicine is often utilized in the detection and characterization of carcinoid tumors. Since carcinoid lesions display somatostatin receptors, radionuclide-tagged octreotide may be used for tumor detection. PET is generally not useful since these neoplasms typically have a low metabolism.

Prognosis for patients with carcinoid tumors depends on the histologic subtype. Typical carcinoids usually have an excellent prognosis, often even in the presence of metastatic disease. Five-year survival rates have been reported as high as 85% to 92%. Atypical carcinoids, on the other hand, confer a worse prognosis. Five-year survival in this patient population has been reported in the range of 65% to 70%. Regardless of histologic subtype, the only effective method of treatment is surgical resection.

LYMPHOMA—HODGKIN AND NON-HODGKIN

Both Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL) are primarily mediastinal, hilar, or perihilar in location, although parenchymal involvement does occur and is up to three times more common with HL. Radiologically, mediastinal adenopathy is the typical finding; however, various patterns of parenchymal disease are seen. In HL, parenchymal disease may appear as linear or reticulonodular opacities extending into the lung from hilar nodes, and there is almost always associated hilar adenopathy. The parenchymal findings may produce masslike opacities and airspace consolidation, which may mimic pneumonia. Also, atelectasis is commonly seen secondary to obstructing endobronchial lesions rather than simply from extrinsic airway compression. Finally, subpleural plaques and masses may be present if tumor has invaded the lymphatics. NHL, on the other hand, occurs primarily as mediastinal adenopathy and less commonly involves the lung parenchyma. When there is parenchymal involvement, associated adenopathy may be absent (up to 50% of cases). Also, unlike HL, NHL does not typically produce coarse reticulonodular opacities. Lesions may arise as solitary pulmonary nodules, multiple masses, or as airspace opacities, which again may simulate pneumonia.

PULMONARY BLASTOMA

Pulmonary blastoma is a rare primary pulmonary neoplasm with presentation typically in the fourth and fifth decades, although a significant number of cases are seen in children. These tumors contain both epithelial and

mesenchymal elements and are thought to resemble fetal lung tissue. The epithelial components are glandular, unlike squamous epithelium seen in other mixed lesions such as carcinosarcoma. In addition, pediatric lesions are thought to contain benign rests of epithelial components as opposed to frank carcinomatous elements, although these rests may become inflamed and thus differentiation from carcinoma can be difficult. Mesenchymal components range from relatively undifferentiated embryonic mesenchyma to areas of well-fibrous tissue, smooth muscle, and cartilage. The typical radiologic presentation differs in children and adults. Children may present with opacification of an entire hemithorax caused by a large parenchymal or pleural-based mass and often a large pleural effusion. Adults more commonly present with a peripheral solitary pulmonary nodule or mass. In either population, it should be noted that a clear association with benign pulmonary cysts has been established. On CT, lesions are predominantly low in attenuation and contain whorls of higher attenuation, presumably from mesenchymal components. Surgical resection is rarely curative, and chemoirradiation has been met with mixed success. Overall, prognosis is poor and metastatic disease is commonly found at autopsy.

BENIGN PULMONARY NEOPLASMS

SQUAMOUS CELL PAPILLOMA

Squamous cell papilloma is a benign, painless epithelial growth, which is caused by the human papilloma virus (HPV), typically either the HPV-6 or HPV-11 strain. Lesions are found anywhere along the oral mucosa, larynx, trachea, and bronchi. These lesions generally do not demonstrate significant growth, do not usually spread, and may appear as solitary or multiple endoluminal masses. The course is rather indolent, with regression sometimes seen by adolescence. Although therapy is not necessary since these lesions do not undergo malignant transformation, patients may elect to pursue resection or cryotherapy.

PULMONARY HAMARTOMA

Pulmonary hamartomas are benign lesions, which consist of disorganized epithelial and mesenchymal elements, typically containing cartilage surrounded by fibrous connective tissue and variable amounts of fat, smooth muscle, and mucous glands. Analogous to the pediatric pulmonary blastoma, epithelial components are felt to represent simply reactive tissue, while the mesenchymal components are felt to represent true neo-

plasm. The majority of tumors are found within the lung parenchyma (90%), while the remaining lesions are endobronchial (10%). Parenchymal lesions typically arise as solitary pulmonary nodules, which characteristically contain fat and often calcification/ossification, may appear lobulated, vary in size from 1 to 9 cm, and contain numerous epithelial clefts (unlike endobronchial lesions). Endobronchial lesions demonstrate similar histologic characteristics, but usually contain more fat than parenchymal lesions and may cause varying degrees of airway obstruction. As previously described, incomplete or complete airway obstruction can manifest as atelectasis, minor airway opacification, or frank consolidation. Pulmonary hamartomas are generally slow-growing lesions which can be followed over time; however, large parenchymal lesions or endobronchial lesions resulting in significant airway obstruction may be amenable to surgical resection.

LUNG CANCER STAGING

Radiologic staging is performed by utilizing the tumor, node, and metastasis (TNM) system (Table 23-2). *Clinical staging* is then based upon radiologic staging (Table

TABLE 23-2 Radiologic Staging of Pulmonary Neoplasms

Primary tumor

T_x—malignant sputum cells without identified tumor

T₀—no evidence of tumor

T₁—tumor ≤3 cm, surrounded by parenchyma (lung, pleura), arises distal to main bronchus

T_{1a}—tumor ≤2 cm

T_{1b}—tumor >2 cm

T₂—Tumor >3 cm, any tumor not contained by parenchyma (i.e., invading pleura), resultant atelectasis or obstructive pneumonitis of less than entire lung, greater than 2 cm from carina

T_{2a}—tumor ≤5 cm

T_{2b}—tumor >5 cm

T₃—any tumor with more extensive invasion (chest wall, diaphragm, pericardium, mediastinal pleura) can be <2 cm from carina but cannot involve it

T₄—any tumor with even more extensive invasion (mediastinum including all contained structures, vertebral bodies), separate masses in same lobe, malignant effusion

Nodal metastases

No—No nodal metastases

N₁—Ipsilateral peribronchial or hilar nodes

N₂—Ipsilateral mediastinal or subcarinal nodes

N₃—Ipsilateral supraclavicular/neck nodes or contralateral nodes

Distant metastases

M₀—No metastases

M₁—Distant metastases or separate nodules/masses in different lobes

M_{1a}—Separate tumor nodules in a contralateral lobe or tumor with pleural nodules or malignant pleural or pericardial effusion

M_{1b}—Distant metastases

TABLE 23-3 Clinical Staging of Pulmonary Neoplasms**Generally resectable disease (I-IIIa)**

Ia—T1a or bNoMo

Ib—T2aNoMo

IIa—T1a or 2aN1Mo or T2bN0Mo

IIb—T2bN1Mo or T3N0Mo

IIIa—T1a-3N2Mo or T3N1Mo or T4N0 or 1Mo

Generally unresectable disease (IIIb-IV)

IIIb—T4N2Mo or T1a-4N3Mo

IV—M1 with any other combination

23-3). It should be noted that the “resectable” versus “unresectable” designation within the stage III classification is not clearly defined and careful individual consideration must be given to these cases. For example, a tumor designated T4 would generally fall into the “unresectable” category, yet those lesions with minimal tumor invasion through the mediastinal pleura into fat are generally resectable. As another example, a tumor that has invaded the carina and the distal 3 to 4 cm of trachea (i.e., again radiologic stage T4) can sometimes be resected with pneumonectomy and sleeve bronchoplasty. Finally, small cell carcinoma staging is simplified into limited or extensive disease. *Limited small cell carcinoma* represents disease limited to one hemithorax. *Extensive small cell carcinoma* represents disease involving the contralateral lung or extending outside beyond the lung parenchyma (i.e., extrathoracic spread).

THORACIC METASTASES

Thoracic metastases are common. They develop from extrathoracic primary malignancy and also from primary malignancy arising within the thorax. Metastatic disease commonly occurs by hematogenous and lymphatic spread and also direct spread from adjacent lesions. Less commonly, aerogenic spread can occur in the acini or central airways. Occasionally, malignancies metastasize to endobronchial structures (Table 23-4).

Hematogenous spread of tumor results in deposition of malignant cells in small pulmonary arteries and arterioles. There is invasion of adjacent interstitium with the formation of nodules, which gradually increase in size.

TABLE 23-4 Endobronchial Metastasis

Breast
Colon
Rectum
Kidney
Cervix
Malignant melanoma
Sarcomas

Blockage of affected vessels occurs with prograde and retrograde growth and more peripheral embolization. Hematogenous metastases predominate in the lower lobes where pulmonary blood flow is greatest. Larger tumor deposits affecting more central pulmonary arteries can cause pulmonary thromboembolism, sometimes infarction and regional perfusion defects on CT.

Lymphatic spread may occur when hematogenous metastases invade the lymphatics in the surrounding interstitium. They also occur when blood-borne malignant deposits are carried to mediastinal, hilar, and bronchopulmonary lymph nodes. Malignant cells may reach lymph nodes directly by the thoracic duct also. There is then retrograde spread of tumor from the lymph nodes into the lymphatics of the lung and pleura.

Breast, thyroid, esophagogastric, and liver malignancies may directly spread to the pleura, lung parenchyma, and mediastinum. Chest wall lesions including primary and metastatic bone lesions, cartilaginous malignancies, neurogenic malignancies, and soft-tissue chest wall lesions such as melanoma and fibrosarcoma may also invade the intrathoracic region.

Aerogenic spread occurs within the thorax itself with BAC, where multicentric foci in the alveoli and small airways invade adjacent acinar structures while preserving the normal pulmonary architecture. Extrathoracic and intrathoracic tracheobronchial lesions such as bronchogenic carcinoma and tracheobronchial papillomatosis can also spread by direct invasion.

Primary lesions within the thorax itself, such as lung cancer, will directly invade adjacent mediastinum, pleura, and chest wall as well as spreading into surrounding extrathoracic tissue by hematogenous (arterial and venous) and lymphatic pathways. Neurogenic lesions adjacent to the spine and ribs will invade these bony structures. Mediastinal malignancy such as thymic cancer can also spread directly within the thorax.

PULMONARY NODULES

These are usually well margined and round, although they may be irregular and sometimes have a ground glass peripheral halo. This halo sign occurs with vascular metastases such as angiosarcoma and is because of hemorrhagic necrosis around the lesion or sometimes direct malignant spread. This halo may also occur with nonmalignant nodules such as lymphoma, fungal disease, and vasculitis (Wegener's granulomatosis). Five percent of metastatic pulmonary nodules are cavitory and this is liable to occur with certain malignancies (see Table 23-5). The differential diagnosis of cavitory nodules includes fungal and mycobacterial lesions, septic emboli, and vasculitis. Less commonly, metastatic nodules can be calcific

TABLE 23-5 Cavitory Pulmonary Metastases

5% of metastatic nodules
Squamous cell carcinoma, especially head and neck and cervix lesions
Transitional cell tumors
Adenocarcinoma, especially colon
Sarcoma

(see Table 23-6). The differential diagnosis of these lesions include fungal disease, mycobacterial lesions, and hamartomas. Radiographically, small nodules are easily missed unless they are particularly numerous, which occurs with embolic spread of highly vascular peripheral lesions such as breast carcinoma (see Table 23-7). In such cases, the radiographic appearance may be similar to miliary TB. Lesions 5 mm or greater will usually be shown on good quality radiographs, but may be overlooked in “blind areas” of the radiograph.

CT readily detects nodules 3 mm or greater. The sensitivity is 70% if nodules are less than 5 mm and is 95% with lesions 5 mm or greater. However, because of the common occurrence of benign nodules, specificity is limited. Common benign nodules include granulomas such as mycobacterial disease and sarcoidosis—also, fungal lesions, and intrapulmonary lymph nodes. Many of these benign lesions result from inhalational disease and affect upper lobes predominantly, unlike metastases. Follow-up CT is advisable at 6- or 12-month intervals if the lesions cannot be evaluated by bronchoscopy or percutaneous biopsy, which is usually the case with small lesions. A malignant nodule should grow slowly over several months on follow-up, whereas a benign nodule will remain stable for a 2-year period, or alternatively grow more rapidly than malignancy (weeks or months) in the case of an inflammatory mass. Solitary nodules are metastases in only 5% to 10% of cases overall. However, a solitary nodule in a patient older than 45 years of age with known primary malignancy is metastatic in 85% of cases.

Lymphangitic carcinoma may not be detected radiographically, particularly if localized. Lymphangitic spread from lung carcinoma is usually unilateral. Otherwise, unilateral and bilateral lymphangitic carcinoma occurs equally. There may be mediastinal adenopathy and pleural effusion with lymphangitic carcinoma (see

TABLE 23-6 Calcification in Pulmonary Metastases

Pancreas
Choriocarcinoma
Melanoma
Less commonly with mesothelioma and small cell lung carcinoma

Table 23-8). If lymphangitic spread originates in mediastinal nodes, there may be thickened bronchovascular (axial) interstitium and peribronchial cuffing, but these features may be absent if hematogenous deposits have originated in peripheral lung lymphatics. In most cases, there is thickened interlobular septa, and secondary pulmonary nodules may be outlined, often with a central dot because of thickened interstitium around the centrilobular duct. Associated ground glass opacification is often seen with the crazy paving appearance. Thickened septa may be smooth and resemble interstitial pulmonary edema, but are commonly nodular or beaded in appearance.

Anatomic detail provided by high resolution CT has enabled classification of pulmonary nodules into three types: centrilobular, perilymphatic, and random. Gruden has developed a simple algorithm to distinguish between these three types of nodules.

1. If there are no subpleural nodules, the type is centrilobular. Ill-defined centrilobular nodules occur with subacute hypersensitivity pneumonitis and respiratory bronchiolitis. Cellular bronchiolitis (tree-in-bud) occurs with infectious disease such as bronchitis, TB, MAI, fungal disease, and cystic fibrosis. Bronchioloalveolar carcinoma spread is also centrilobular,
2. If numerous subpleural and interlobar fissural nodules are present, the pattern is either perilymphatic or random.
 - a. In the case of perilymphatic nodules, distribution will be patchy and have a bronchovascular distribution. Lymphangitic carcinoma nodules are perilymphatic. Silicosis also has perilymphatic nodules
 - b. In the case of random nodules, they will either be diffuse and uniform, or predominate in the lower lobes. Hematogenous pulmonary metastases are random nodules. Disseminated fungal nodules are also random (unlike aerogenic fungal nodules)

TABLE 23-8 Key Features of Lymphangitic Carcinoma

5% unilateral and 50% bilateral
Smooth or nodular interstitial reticulation
Often thickened bronchovascular interstitium
Most common with lung, breast, stomach, and pancreatic cancer
Pleural effusion in 40%
Lymphadenopathy in 30%

PLEURAL METASTASES

These usually present as pleural effusions on radiographs and CT. There may be associated loculation, pleural thickening, nodularity, or masses. The pleural thickening may be irregular, show progressively increasing nodularity, and are likely to enhance with contrast. However, this is not specific for malignancy, as empyema will also show peripheral rim enhancement. However, nodularity would not be expected with empyema. Pleural thickening may also be seen with mesothelioma, lymphoma, and leukemia. Lung and breast carcinoma are most commonly associated with malignant pleural effusions. Pleural fluid cytology is positive in 80% to 90% of patients with malignant pleural effusions. This generally indicates unresectable disease. Those patients with lymphangitic carcinoma, which prove to have benign pleural effusions, have exudates because of lymphatic obstruction or pulmonary venous obstruction. Pleural metastatic disease results from hematogenous, lymphatic, or direct spread.

Thoracic metastases and primary malignancy evaluation with PET:

1. With pulmonary nodules greater than 1 cm, PET scanning has a sensitivity and specificity of 97% and 78% for the detection of malignancy.
2. PET scanning is indicated for the detection of metastatic disease from certain primary extrathoracic malignancies, particularly head and neck tumors, breast carcinoma, colorectal carcinoma, and melanoma.
3. Bronchioalveolar carcinoma and small cell carcinoma cannot be reliably evaluated with PET. Primary and metastatic non-small cell carcinoma and esophageal carcinoma can be reliably evaluated. PET is also routinely used in the diagnosis and staging of Hodgkin and non-Hodgkin lymphoma in the thorax.
4. Sensitivity and specificity for staging primary and metastatic non-small cell lung cancer with PET is 93% and 99%, compared with 72% and 94% with chest CT.
5. With non-small cell lung cancer, when CT is equivocal for the detection of metastatic disease, 10% of these patients are found to have metastatic disease on PET.

QUESTIONS AND ANSWERS

1. A patient has multiple pleural-based masses, one of which is apical, and presents with ipsilateral proximal upper extremity weakness. Which of the following is the most likely cause?
 - A. Mesothelioma
 - B. Bronchogenic carcinoma (i.e., Pancoast tumor)
 - C. Thymoma
 - D. Fibrous tumor

ANSWER: C. Given *multiple* masses and the presence of *proximal upper extremity weakness*, thymoma with associated myasthenia gravis is the best single answer. Thymoma may commonly present with metastases to the lungs, pleura, bones, mediastinum, and local lymph nodes, and myasthenia gravis is the most common paraneoplastic disease associated with thymoma. Pancoast tumors are usually single apical lesions and patients typically present with pain and muscular atrophy secondary to brachial plexus invasion.

2. What imaging finding best characterizes lymphangitic spread?
 - A. Centrilobular nodules
 - B. Interlobular septal thickening
 - C. Diffuse ground glass opacity

ANSWER: B. HRCT findings consistent with lymphangitic spread may include smooth or nodular interlobular septal, subpleural interstitial, or peribronchovascular interstitial thickening. In addition, there is preservation of normal lung architecture at the lobular level.

3. A patient has a 4 cm mass in the periphery of the right lung, with ipsilateral mediastinal adenopathy, no distant metastases, and a small malignant pleural effusion. What is the radiologic stage?

A. T1bN1M0
B. T2aN3M1a
C. T2aN2M1a
D. T2bN2M0

ANSWER: C. Refer to Table 23-2. T2a represents a tumor less than or equal to 5 cm. N2 represents ipsilateral mediastinal or subcarinal nodes. M1a represents a malignant pleural effusion, malignant pericardial effusion, separates tumor nodules in a contralateral lobe, or tumor with pleural nodules.

4. An elderly man is found to have facial/upper extremity swelling and a widened mediastinum on chest radiograph. What is the most likely diagnosis?

A. Lymphoma
B. Mediastinitis
C. Bronchogenic carcinoma
D. Teratoma

ANSWER: C. This clinical description fits the SVC syndrome. More than 50% of all cases of SVC syndrome are caused by bronchogenic carcinoma. Lymphoma is the second most common cause.

5. What is the most common presentation of bronchoalveolar cell carcinoma (BAC)?

A. Solitary pulmonary nodule
B. Peripheral focal infiltrate
C. Lower lobe atelectasis
D. Pneumonia

ANSWER: A. The localized form of BAC is more common (60%–90% of cases) and typically presents as a solitary pulmonary nodule. The diffuse form (10%–40% of cases) may mimic any of the remaining choices.

6. Concerning bronchioalveolar cell carcinoma, which of the following is correct:

A. Perilymphatic distribution on high resolution CT

B. Random distribution on high resolution CT
C. Can manifest as “*tree-in-bud*” opacities
D. Commonly presents as interlobular septal thickening

ANSWER: C. BAC spreads by direct spread along the alveolar walls and small airways (bronchioles). This is centrilobular spread, which occurs along the small airways and extends along the alveolar walls. Random distribution occurs with hematogenous spread of malignancy, fungal disease, and TB (miliary). BAC does not involve the interlobular septae (walls of the secondary pulmonary make lobules).

7. Concerning pulmonary nodules, which of the following is correct:

A. Sensitivity of detection is 95% on CT, if nodules are 5 mm or greater.
B. Benign nodules remain stable or grow more slowly than malignant nodules.
C. Stability for 18 months confirms a pulmonary nodule is benign.
D. Nodules are classified into three anatomic types: centrilobular, perivascular, and random.

ANSWER: A. Inflammatory nodules can enlarge much more rapidly than malignant nodules. However, many benign nodules do not change in size. Stability of 2 years indicates a nodule is benign. Three nodules types are centrilobular, perilymphatic, and random.

8. Concerning lymphangitic carcinoma, which of the following is correct:

A. Bronchovascular interstitial thickening is pathognomonic.
B. Survival time is generally less than 6 months.
C. Nodules occur randomly or predominate in the lower lobes.
D. Lymphadenopathy is always present.

ANSWER: B. Bronchovascular (axial) interstitial thickening also occurs with lymphoma, sarcoidosis, and organizing pneumonia (BOOP or COP) and is not pathogenic for lymphangitic carcinomatosis. Random spread or left lower lobe predominance occurs with hematogeneous spread of malignancy and also with miliary TB and hematogeneous fungal disease. Lymphadenopathy is present in 30% of patients with lymphangitic carcinoma. The absence of subpleural nodules indicates the nodule to be centrilobular not perilymphatic.

9. Concerning PET scanning which of the following is correct:
- A. It is comparable with CT scanning in the detection of NSCLC metastases
 - B. It has a sensitivity of 78% in detecting malignancy in pulmonary nodules greater than 1 cm in size
 - C. It is often used to evaluate bronchioloalveolar cell carcinoma
 - D. It is used routinely in lymphoma staging

ANSWER: D. PET is superior to CT for the detection of non-small cell lung cancer metastases. Sensitivity of PET is 97% for malignancy detection in nodules 1cm or greater. Bronchiolar alveolar cell carcinoma cannot be reliably evaluated with PET scanning.

10. Which of the following is true regarding pleural disease?
- A. Nodular pleural thickening is commonly seen in empyema.
 - B. Pleural fluid cytology is seldom positive in malignancy.
 - C. Presence of pleural effusion in lung cancer patients indicates stage III disease.
 - D. Pleural enhancement is specific for empyema,

ANSWER: C. Presence of pleural effusion in a lung cancer patient indicates T4 disease (stage III). Nodular pleural thickening is commonly seen in malignancy rather than empyema. Pleural enhancement can be seen not only in empyema but malignancies as well. Pleural fluid cytology is positive in 85% of patients with malignant effusion.

24 PNEUMOCONIOSES

John C. Texada and Satinder P. Singh

INHALATION OF INORGANIC DUST

Inorganic dust inhalation and the resultant tissue reaction are the inciting events for pneumoconiosis. This may take the form of fibrosis, which can be focal and nodular or diffuse, and is perhaps a toxic effect of the substance on epithelium or inflammatory cells, or of aggregates of particle-laden macrophages, a reaction typically seen with inert dusts. The latter is rarely symptomatic and the former may be quite significant.

SILICA EXPOSURE

Silicon dioxide comes in three forms: crystalline, microcrystalline, and amorphous. Exposure significant enough to become radiographically apparent essentially requires occupational exposure: mining, sandblasting, stonework, foundry work, clay dye and potter's clay, and multiple other miscellaneous occupations. Silicosis is one of the most frequent types of pneumoconiosis affecting up to 3 million U.S. workers. The primary threshold is 5×10^6 particles (less than $10 \mu\text{m}$) per cubic foot; below this exposure will not lead to silicosis. The secondary threshold is 100×10^6 particles per cubic foot: above this all patients exposed will develop silicosis. Thus the development of silicosis is concentration-dependent. The latent period does not require 10 to 20 years of exposure before radiographic abnormalities develop in most cases; in some cases of high exposure, the latent period may be only a few years.

HISTOPATHOLOGY OF SILICOSIS

The two fundamental histologic reactions to silica are silicotic nodule and silicoproteinosis.

SILICOTIC NODULE

Silicotic nodule is a dense concentric deposition of collagen; when severe enough to conglomerate, this becomes progressive massive fibrosis (PMF). Shortly after inhalation, activated macrophages ingest the particles, or if they penetrate the interstitium, tissue macrophages ingest them. The macrophages then interact with other inflammatory cells including neutrophils. The silica itself may be less important in pathogenesis than immune-mediated tissue damage. The earliest lesions of silicosis are typically peribronchiolar, interlobular septal, and pleural, and as they enlarge they become lamellated and more collagenous. Scattered silicate crystals may be seen in polarized microscopy or electron microscopy.

Progressive Massive Fibrosis

PMF is the conglomeration of individual nodules, composed of hyaline collagen and pigmented macrophages, often with focal central necrosis. Fibrotic nodules may be found in hilar and mediastinal lymph nodes, or less commonly in reticuloendothelial tissues.

SILICOPROTEINOSIS

Silicoproteinosis is a result of high exposure, characterized by lipoproteinaceous alveolar filling perhaps by type II alveolar cell hyperplasia as a response to type I

cell damage; this is uncommon. The alveoli become diffusely filled with PAS-positive material similar to alveolar proteinosis, mixed with macrophages, membranous material, and type II cells.

ACCELERATED SILICOSIS

Accelerated silicosis is similar to acute silicosis with exudative alveolar lipoproteinosis and chronic inflammation, and is associated with fibrotic granulomas containing collagen, reticulin, and silica particles. Alveolar walls are lined with hypertrophied and hyperplastic alveolar type II epithelial cells with increased numbers of lamellar bodies.

CAPLAN SYNDROME

Caplan syndrome is characterized by large necrobiotic nodules superposed on simple pneumoconiosis. It is a manifestation of rheumatoid lung disease (more commonly in coal workers' pneumoconiosis than in silicosis). It is significant because the progression of silicosis is faster in these patients than in those without rheumatic disease.

OTHER ASSOCIATIONS

The relative risk for lung cancer is between 3 and 6 for workers with silicosis; for silica exposure without silicosis, the relative risk is 1.3. This risk is not associated with cigarette smoking. Silicosis predisposes a patient to development of tuberculosis. There is a clearly defined association between silica exposure, silicosis, and progressive systemic sclerosis (scleroderma); systemic lupus erythematosus may be linked to acute or accelerated silicosis. Any association with rheumatoid arthritis is uncertain and small if present.

RADIOGRAPHY OF SILICOSIS

SILICOSIS PROPER

Classically silicosis will present as multiple 1- to 10-mm nodules, uniformly dense, and well-circumscribed, with an upper lobe and posterior predominance. This predominance is notable because many pneumoconioses have a basilar predominance. Calcification may occur in 10% to 20%, and reticular patterns may be visible in some cases. Accelerated silicosis has similar radiographic appearance as classic form except for earlier onset and rapid progression.

PROGRESSIVE MASSIVE FIBROSIS

In PMF, large opacities more than 1 cm diameter may develop, usually upper lobe predominant, and their mar-

gins may be irregular and ill defined or smooth. They typically develop bilaterally, though they may be unilateral, at the midlung or periphery and with time shift toward the hila, leaving emphysema in their wake. They may cavitate.

HILAR LYMPHADENOPATHY

Hilar lymphadenopathy may develop with or without lung findings. In up to 5% of cases, these nodes may undergo peripheral "eggshell" calcification, a pattern almost pathognomonic of silicosis.

CT IMAGING OF SILICOSIS

HRCT may detect smaller nodules otherwise inapparent and may allow earlier detection of confluence. PMF is visible as soft-tissue masses often with irregular margins and surrounded by emphysema and often requires evaluation of serial radiographs.

COAL AND CARBONACEOUS DUST EXPOSURE

The manifestations of carbonaceous dust exposure range from the common and insignificant, associated with low exposures, to prominent disease in patients with high exposure.

ANTHRACOSIS

Carbon dust retention is common particularly in smokers, city dwellers, and those residing near industries. Dense black particles 1 to 2 μm diameter are engulfed by macrophages in the terminal or proximal-respiratory bronchioles and in the pleura, and often deposited in bronchopulmonary, hilar, and mediastinal nodes. This exposure typically leads to minimal or no fibrosis or emphysema except when cigarette use is also present.

COAL WORKERS' PNEUMOCONIOSIS

Inhalation of large volumes of coal dust or petroleum dust is a work-exposure disease. It is prominent in coal workers, but may be found in workers involved in graphite, carbon black, and carbon-electrode trades, and may possibly be caused by fly ash inhalation. In 1969, U.S. laws required much decreased exposure, so coal workers' pneumoconiosis is decreasing; however, the current level of dust (2 mg/m^3) can still cause pneumoconiosis. Between 2% and 12% of coal miners will still develop notable disease, and 1% to 7% will develop PMF.

Development of this pneumoconiosis is clearly related to exposure, but the exact pathogenesis is unclear. Coal dust is often mixed with silica, and this may play a role. Coal dust may additionally incite a similar inflammatory response derived from alveolar macrophages. There may also be an immunologic/autoimmune mechanism, though this is unclear (remember Caplan syndrome is more common in coal workers' pneumoconiosis than in silicosis, and was originally reported in this pneumoconiosis).

HISTOPATHOLOGY OF COAL WORKERS' PNEUMOCONIOSIS

The two main manifestations of coal workers' pneumoconiosis are coal macules and PMF. Coal macules are deposits of anthracitic pigment within pigment-laden macrophages at the respiratory bronchiole, without fibrosis; these may be stellate or round, with range 1 to 5 mm. They are typically fairly uniformly distributed but are more numerous at the apices. A larger nodule, still less than 1 cm, may develop, perhaps an intermediate lesion between the coal macules and PMF. PMF in coal workers' pneumoconiosis may be unilateral or bilateral; it tends to be in the posterior upper lobe(s) or the superior lower lobe(s), often with regional emphysema and central necrosis caused by ischemia. Vascular disruption may be severe enough to cause cor pulmonale.

RADIOGRAPHY OF COAL WORKERS' PNEUMOCONIOSIS

Small nodular opacities 1 to 5 mm diameter of coal workers' pneumoconiosis tend to be less well-marginated than those of silicosis and have heterogeneous granular density rather than uniform density; however, these differences are not enough that the two are distinguishable radiographically. Nodules may calcify in 10% to 20% of cases; this begins centrally, with eggshell calcification much less common. PMF is evidenced by development of large opacities, most commonly in the upper half of the lungs, and most commonly superposed on simple pneumoconiosis. PMF may occur in 30% of patients with bilateral disease. Opacities typically start peripherally, with a well-defined lateral border and ill-defined medial border, and thicker in one direction than another (spindle-shaped). Cavitation is occasional, as are central calcifications. The opacity migrates toward the hilum leaving peripheral emphysema.

CT IMAGING OF COAL WORKERS' PNEUMOCONIOSIS

Small nodules may be present diffusely but predominant apically; similarly in silicosis, CT and HRCT are supe-

rior to radiography for detection of small nodules. Subpleural nodules are common, and these may coalesce into small linear pseudoplaques. Calcification within nodules and centrally within nodes may be visible in 30% of cases. PMF may be present.

ASBESTOS-RELATED DISEASE

Asbestos is a family of fibrous materials, in which silicic acid is mixed with magnesium, sodium, iron, and calcium. The family is subdivided into two families by fiber shape: the serpentines are curved (chrysotile is the major entity) and the amphiboles (including amosite, crocidolite, anthophyllite, tremolite, and actinolite) are straight. Of these, chrysotile, tremolite, and crocidolite are responsible for most pulmonary diseases, and crocidolite and amosite are responsible for most carcinogenic diseases. In the United States, up to 9 million people have asbestos exposure. The most common sources of exposure are asbestos mining and processing, industrial and commercial asbestos use (e.g., construction, shipbuilding and repair, boiler making and repair, railroad work, textile and plastic manufacture, gasket and brake lining manufacture, dentistry, and jewelry making), and nonoccupational or paraoccupational exposure from contaminated air or materials (such as the clothes of workers).

PATHOGENESIS OF ASBESTOS-RELATED DISEASE

Longer, thinner, and more durable fibers cause the most disease, and development of disease is dependent upon intensity and duration of exposure. Most fibers are removed by mucociliary processes, but some enter the interstitium and elicit a macrophage inflammatory response. Tissue damage is caused by inflammation and free-radical production.

Tobacco smoke increases evidence of asbestos-related disease; this is caused perhaps by increasing the inflammatory response, by retention of more short fibers, or by increasing the total fiber burden. Patient immune response also influences disease: those who develop a lymphocytic alveolitis are more prone to pleural plaques and less prone to fibrosis, perhaps by gamma-interferon elevation. Autoimmune titers are positive in 25% to 30% of workers with abnormal radiographs, but in low concentrations, raise the possibility of B-cell hyperactivity as an etiologic factor in lung disease.

Pleural manifestations are much more radiographically common than pulmonary manifestations: in one study of asbestos patients, only 11% of cases had solely parenchymal changes, whereas 48% had solely pleural disease and 41% had both. Perhaps two-thirds of asbestos patients have radiographic evidence of pleural disease.

HISTOPATHOLOGIC AND RADIOLOGIC FINDINGS OF ASBESTOS-RELATED DISEASE

Asbestos-related disease may develop in the pleura, parenchyma, lymph nodes, or airways. Manifestations are described in the following sections. Pleural disease must be differentiated from parenchymal disease, both for patient care and for medicolegal clarity.

THE ASBESTOS BODY

A central asbestos fiber is coated with iron and protein, typically 2 to 5 μm wide and 20 to 50 μm long. This is typically intramacrophage, and may be interstitial or alveolar (and because of the latter may be found in sputum); it is rarely visible in pleural plaques but may be found in hilar and mediastinal nodes and in extrapulmonary viscera. Asbestos body number is best arrived at by digestion of tissue, rather than light microscopy, as the bodies are rather rare. Noncoated fibers are between 7 and 5000 times more common than asbestos bodies, and it is likely that the former are responsible for disease. A patient with high exposure may have 20 to 100 times the number of asbestos bodies and fibers compared to that for unexposed persons and a patient with asbestosis or mesothelioma may have 100 to 1000 times more.

ASBESTOS-RELATED PLEURAL DISEASE

Pleural disease is most common, typically as parietal pleural plaques, though visceral pleural fibrosis, diffuse pleural fibrosis, and mesothelioma may develop.

PLEURAL EFFUSION

Effusions related to asbestos exposure are often organizing exudates. Biopsy may show fibrosis, nonspecific chronic inflammation, and/or mesothelial hyperplasia. The etiology is unclear, but development is dose-related. Most are small and asymptomatic. This is the most common abnormality to develop in the first 20 years after exposure.

Benign asbestos-related pleural effusion is uncommonly diagnosed, as it requires exposure history, confirmation of effusion, absence of other cause for the pleural effusion, and no cancer development in 3 years. Most effusions are small, asymptomatic, and nonrecurrent (though they may recur).

PLEURAL PLAQUES

Plaques are generally not associated with other manifestations of asbestos-related disease. They are quite common, visible in 5% to 10% of autopsy patients. They are typically well-defined geographic hard collagenous plaques 2 to 5 mm thick, often with focal calcification and sometimes extensive. They typically develop along

the costal and diaphragmatic parietal pleura, and generally are absent from the apices, costophrenic angles, and anterior chest wall. Plaques may calcify, typically 20 years after exposure.

Pleural plaque formation, pleural thickening, calcification, or effusion may develop. Plaques are more prominent in the caudal chest; they may be smooth or nodular, and while they are typically thin they may be up to 1 cm thick. They are most commonly visible at the dome of the diaphragm, and at the lateral and posterolateral midchest. They are typically bilateral; if unilateral, they are more commonly on the left. Radiographic plaque detection is quite specific for asbestos-related pleural disease, but not a sensitive indicator (8%–40% sensitivity). Fissural thickening, though unrelated to plaques, is found in 85% of patients with plaques and 36% of patients without plaques; it is more frequent in patients with pulmonary fibrosis. It is most frequently visible at the interlobar fissures (in 54% of patients versus 16% of controls).

Visceral Pleural Fibrosis

Discrete fibrosis is most frequently at the lateral lower lobe; in contrast to parietal pleural plaques, these areas are ill-defined and typically 1 mm or less thick. Discrete fibrosis may be associated with round atelectasis, but is otherwise generally radiographically inapparent.

Diffuse Pleural Fibrosis

Some patients develop diffuse fibrosis, typically of both the parietal and visceral pleura and associated with adhesions. This fibrosis can extend into the fissures and septa and into the mediastinum, but does not affect the lung parenchyma.

Diffuse fibrosis is defined as smooth uninterrupted pleural density over 25% or more of the chest wall. Calcification and peripheral lung fibrosis may be present, though the former is not usually prominent. It seldom involves the mediastinal pleura, which helps to differentiate benign fibrothorax from mesothelioma.

Mesothelioma

Asbestos exposure clearly increases the risk of mesothelioma.

Diffuse pleural thickening with associated volume loss is the most common appearance. Pleural effusion is common, though the mediastinum does not shift because it is fixed by malignant tissue. Mesothelioma pleural thickening is more likely than benign pleural thickening to be nodular, to be more than 1 cm thick, to spread circumferentially and/or involve the mediastinum, to involve the fissures, and to have a pleural effusion. Pleural plaques are present in 30% to 70% of patients with mesothelioma.

ASBESTOS-RELATED PULMONARY DISEASE

Lung manifestations beyond the asbestos body include peribronchiolar fibrosis, asbestosis, round atelectasis, and lung cancer.

PERIBRONCHIOLAR FIBROSIS

Some say that fibrosis in the walls of respiratory bronchioles is the first manifestation of disease, with peripheral spreading over time. Others believe that, because similar findings are found in other exposures, this is a nonspecific indicator of airways reaction, and term it mineral dust airway disease rather than asbestosis.

ASBESTOSIS

Asbestosis is diffuse inhalational interstitial fibrosis, usually caused by prolonged occupational exposure. Fibrosis is most prominent in subpleural and lower lobe tissue and ranges from coarse parenchyma to honeycombing.

Radiographically this is visible as irregular small linear opacities, ranging from early fine basilar-predominant reticulation and ground glass, through prominent interstitial reticulation leading to “shaggy heart” obscuration of the heart border, through late midlung and upper lung reticulation. There is rarely radiographically apparent lymphadenopathy. Radiographs may appear normal in 10% to 20% of patients with proven asbestosis. Interestingly, gallium-67 scans are positive in people with asbestosis.

ROUND ATELECTASIS

A portion of lung tissue is collapsed and surrounded by thickened pleura. Typically small and peripheral, but possibly lobar, atelectasis is usually associated with asbestos-related visceral pleural fibrosis. This is not always asbestos related—any chronic pleural inflammatory process may lead to development of round atelectasis. The overlying pleura is fibrotic.

Atelectasis is a round or oval pleural-based opacity with volume loss and with “comet-tail” incurving of adjacent bronchovascular structures. It typically abuts an area of pleural thickening or effusion. It may be anywhere but is most typically in the posterior lower lobe. Like other findings, this is not pathognomonic for asbestos exposure—many chronic pleural diseases (hemothorax, empyema) may produce round atelectasis. They typically grow over months to years. Classically, round atelectasis is not FDG-avid.

LUNG CANCER

Asbestos exposure undoubtedly increases the risk of lung cancer development, particularly in smokers, and has lower lobe predilection.

CT IMAGING OF ASBESTOS-RELATED DISEASE

CT imaging, especially HRCT, has a higher sensitivity for detection of pleural and parenchymal changes (approximately 90% sensitivity for pleural disease v. 50% for radiography, and 70% sensitivity for parenchymal disease v. 35% for radiography).

Plaques may be visible as well-defined areas of pleural thickening separated from the chest wall by a thin layer of fat. Diffuse pleural thickening is defined as thickening more than 3 mm, more than 8 cm craniocaudal, and 5 cm anteroposterior dimensions.

CT may detect asbestosis-related lymphadenopathy, and allow earlier detection and improved sensitivity for reticular changes. HRCT may detect intralobar linear opacities, irregular interlobular septal thickening, subpleural curvilinear band-like opacities parallel to the chest wall, parenchymal bands, and small rounded subpleural opacities—the latter the earliest evidence of asbestosis. Each of these is nonspecific in itself but taken together they increase the likelihood of asbestosis.

Round atelectasis enhances avidly with contrast administration, and the comet-tail bronchovascular structures are more readily apparent.

OTHER MATERIALS

TALC

Talc is magnesium silicate, used in leather, rubber, paper, textiles, ceramic tiles, and roofing, and as an additive in many consumer goods. It has low disease activity. Talc may cause pleural fibrosis, sometimes with calcification and plaque formation, nodular parenchymal fibrosis, diffuse interstitial fibrosis, and peribronchovascular opacities. Ferruginous bodies may be present. Talc plaques may involve the pericardium. Parenchymal disease may be similar to asbestosis.

MICA

Mica is one of several aluminum silicates. It is typically mixed with other compounds so disease may be related to the other agents; however, in some cases, pulmonary fibrosis indistinguishable from asbestosis or talcosis has developed from unmixed mica exposure.

FULLER'S EARTH

In the “fulling” process, clay is used to remove grease from wool. Exposure to clay may cause simple pneumoconiosis or occasionally PMF.

BERYLLIUM

Beryllium oxide is produced during beryllium extraction and alloying. Acute berylliosis is caused by exposure to high levels of dust, often accidental, and is identical to acute chemical pneumonitis: bronchitis, bronchiolitis, and diffuse alveolar damage are present without granuloma formation. Berylliosis may be fulminant or insidious, developing over weeks to months. Chronic berylliosis is more common, and is a systemic granulomatous disease caused by delayed hypersensitivity. It imitates sarcoidosis clinically and pathologically. In the lungs it produces interstitial pneumonitis, producing a finely granular haziness that often spares the apices and bases, sometimes in more severe disease developing ill-defined moderately sized nodules and lymphadenopathy. HRCT may show bronchovascular or interlobular septal well-defined nodules, similar to sarcoids.

WELDING FUMES

Welder pneumoconiosis is caused by exposure to welding fumes, with iron oxide as the principal component of inhaled dust. Welding fumes are also a risk factor for chronic bronchitis and lung cancer. Histologically the main finding is presence of iron dust and dust-laden macrophages and minimal fibrosis. Rounded ferruginous bodies are seen with black core. A ferruginous body is a mineral particle to which macrophages have added an iron-protein coat.

Chest radiograph shows small fine nodules in middle third of lungs in perihilar distribution. These nodules represent radio-opaque collection of iron particles and not fibrosis, and often resolve after the patient is removed from the exposure.

At CT these micron nodules are ill-defined and fine branching linear lines with predominant centrilobular distribution. Emphysema is often seen. The HRCT appearance mimics that of hypersensitivity pneumonitis although mosaic perfusion and GGO are less common in siderosis.

OTHERS

Numerous inorganic dusts have been associated with pulmonary disease: Kaolin, zeolites, silicates, cobalt, tungsten and silicon carbide, and numerous radiopaque dusts (aluminum, iron, silver, tin, barium, antimony, the rare earth elements). Polyvinyl chloride, titanium dioxide, volcanic dust, synthetic mineral fibers, nylon, cement dust, and zirconium also may cause disease (a single case has been identified in the case of zirconium).

QUESTIONS AND ANSWERS

- Which of the following is the primary threshold for silicosis development and what is its significance?
 - 5 million particles per cubic foot. Below this number no one gets silicosis.
 - 5 million particles per cubic foot. Above this number everyone gets silicosis.
 - 100 million particles per cubic foot. Below this number no one gets silicosis.
 - 100 million particles per cubic foot. Above this number everyone gets silicosis.

ANSWER: A. The primary threshold defines the minimum exposure to develop a disease; the secondary threshold defines the level at which every exposed person will develop a disease. The primary and secondary thresholds for silicosis are 5 million particles per cubic foot and 100 million particles per square foot, respectively. This essentially means that to have radiographically apparent disease requires an occupational exposure.

- Which of the following is *true* regarding silicoproteinosis?
 - It is a more common finding in silicosis.
 - It is associated with high levels of exposure.
 - There is type I alveolar cell hyperplasia as a response to type II alveolar cell damage.
 - The abnormal material fills the pulmonary interstitium and collapses the airways.

ANSWER: B. Silicoproteinosis is a result of high exposure and is uncommon. It is characterized by lipoproteinaceous alveolar filling, perhaps by type II alveolar cell hyperplasia as a response to type I cell damage. The alveoli become diffusely filled with PAS-positive material similar to alveolar proteinosis, mixed with macrophages, membranous material, and type II cells.

- Which of the following characterizes PMF?
 - Opacities are lower lobe predominant.
 - It is the result of coalescence of individual silicotic nodules.
 - It is noncavitary.
 - It typically begins as a central process, extending peripherally.

ANSWER: B. PMF is the conglomeration of individual nodules, composed of hyaline collagen and pigmented macrophages, often with focal central necrosis. In PMF, large opacities more than 1 cm diameter may develop, usually upper lobe predominant, and their margins may be irregular and ill defined or smooth. They typically develop bilaterally (though they may be unilateral) at the midlung or periphery and with time shift toward the hila, leaving emphysema in their wake. They may cavitate.

4. Which of the following characterizes the pathologic effect of anthracosis?
- A. Irreversible progressive fibrosis
 - B. Moderate restrictive findings in PFT
 - C. Generally minimal
 - D. It is a synonym for coal workers' pneumoconiosis.

ANSWER: C. Anthracosis is carbon dust retention. It is common particularly in smokers, city dwellers, and those residing near industries. Dense black particles 1 to 2 μm diameter are engulfed by macrophages in the terminal or proximal-respiratory bronchioles and in the pleura, and often deposited in bronchopulmonary, hilar, and mediastinal nodes. This exposure typically leads to minimal or no fibrosis or emphysema except when cigarette use is also present.

5. Coal workers' pneumoconiosis can be differentiated on the basis of which of these findings?
- A. Nodule characteristics
 - B. Fibrosis characteristics
 - C. Calcification characteristics
 - D. Both A and C

ANSWER: D. The small nodular opacities of coal workers' pneumoconiosis tend to be less well marginated than those of silicosis, and have heterogeneous rather than homogeneous density. Nodules may calcify in 10%–20% of cases of both silicosis and coal workers' pneumoconiosis, but when they do in the latter, they begin centrally rather than at the periphery. The same calcification patterns are found in lymph nodes. PMF has similar appearance.

6. Regarding asbestos bodies, which of the following is *true*?
- A. Most asbestos fibers undergo iron and protein coating.
 - B. They make up the majority of the material in pleural plaques.
 - C. They usually are free within the airways.
 - D. They correlate with exposure.

ANSWER: D. An asbestos body is an asbestos fiber coated with iron and protein, typically 2 to 5 μm

wide and 20 to 50 μm long. These are typically intramacrophage. They are rarely visible in pleural plaques but may be found in hilar and mediastinal nodes and in extrapulmonary viscera. Noncoated fibers are between 7 and 5000 times more common than asbestos bodies, and it is likely that the former are responsible for disease. A patient with high exposure may have 20 to 100 times the number of asbestos bodies and fibers compared to unexposed persons and a patient with asbestosis or mesothelioma may have 100 to 1000 times more.

7. Which of the following is the most commonly encountered manifestation of asbestos-related pleural disease?
- A. Pleural effusion
 - B. Pleural plaque
 - C. Pleural thickening
 - D. Round atelectasis

ANSWER: B. Pleural effusion is the most common abnormality to develop in the first 20 years after exposure, and it is uncommonly diagnosed because most are small and asymptomatic. Pleural plaques are typically bilateral, caudal-predominant, well-defined, and geographic. They are visible in 5%–10% of autopsy patients. Pleural thickening is defined as smooth uninterrupted pleural density over 25% or more of the chest wall. Calcification is usually not prominent.

8. Which of the following is the pneumoconiosis most similar to sarcoid?
- A. Acute berylliosis
 - B. Chronic berylliosis
 - C. Fuller earth pneumoconiosis
 - D. Talcosis

ANSWER: B. Acute berylliosis is an acute chemical pneumonitis. Chronic berylliosis is a systemic granulomatous disease caused by delayed hypersensitivity. In the lungs it produces interstitial pneumonitis with bronchovascular and interlobular septal nodules. Fuller's earth may cause a simple pneumoconiosis or occasionally PMF. Talcosis causes parenchymal disease similar to asbestosis.

9. Which of the following characterizes Caplan syndrome?
- A. Large necrobiotic nodules superposed on simple pneumoconiosis
 - B. Proteinaceous alveolar exudates after heavy silica exposure
 - C. Round atelectasis
 - D. Ferruginous bodies with splenomegaly and thrombocytopenia

ANSWER: A. This syndrome is characterized by large necrobiotic nodules superposed on simple pneumoconiosis. It is a manifestation of rheumatoid lung disease, and actually is seen more commonly in coal workers' pneumoconiosis than in silicosis. It is significant because the progression of silicosis is faster in these patients than in those without rheumatic disease. Proteinaceous alveolar exudates after heavy silica exposure are silicoproteinosis. Round atelectasis may develop after any chronic pleural inflammatory process, including asbestos-related pleural disease.

10. A radiograph of a former shipyard worker reveals basilar predominant interstitial reticulation that slightly obscures the heart border. Gallium-67 scan is positive. Which of the following is the most appropriate diagnosis?
- A. Asbestos-related pulmonary disease
 - B. Asbestos exposure
 - C. Asbestosis
 - D. None of these

ANSWER: C. Asbestos-related pulmonary disease is a nonspecific term that includes asbestosis, fibrosis, round atelectasis. Asbestos exposure does not necessarily lead to disease. Asbestosis is a diffuse inhalational interstitial fibrosis caused by asbestos.

John C. Texada and Satinder P. Singh

GENERAL FEATURES

ANATOMY

PULMONARY AND MICROVASCULAR ANATOMY

There is about 70 square meters of alveolar surface available for pulmonary gas and fluid exchange, generally via capillaries but also via pre- and postcapillary vessels. The alveolar septum has a thin side (0.3–0.5 μm) for gas exchange, and a thick side that serves as structural support and a medium for fluid exchange. The thin side is composed only of alveolar epithelium capillary endothelium and their fused basement membranes, whereas the thick side has interstitial tissue with connective tissue elements, myofibroblasts, and inflammatory cells. When excess water or protein develops in the septum, it does so only on the thick side. The alveolar capillaries have large fenestrations, and though they are tightly apposed to one another, there are paracellular

pores through the structural proteins and their junctional complexes are not as well-developed as that of the alveolar cells. Water-soluble compounds cross the endothelium either by pinocytosis or via the paracellular pores, and the latter is probably the predominant mechanism.

A rise in pulmonary microvascular pressure has been theorized to increase the size of the gaps between the capillary cells, which increases the ease at which larger proteins can cross the pores; however, this is controversial and seems not to be correct up to pressures about 30 cm H_2O . Above this value, the high pressures can cause stress failure of the membrane, allowing hemorrhage and increased permeability edema.

BRONCHIAL CIRCULATION

The bronchial arteries supply the airway walls, the peribronchovascular connective tissue, the mediastinal- and diaphragmatic-surface visceral pleura, the mediastinal and hilar lymph nodes, and the vasa vasorum of the large thoracic vessels. In airway walls, there is a submucosal plexus and a peribronchial plexus; at the level of the respiratory bronchioles, bronchial capillaries mesh with the pulmonary capillary and venous system, and most bronchial artery blood (except that supplying the large airways themselves) drains to the left heart. The bronchial capillary bed may have half the surface area of the airway epithelium, allowing a large area for fluid exchange; and bronchial artery capillaries have more fenestrae than pulmonary arterial capillaries, and are more responsive to nitric oxide vasodilation as occurs in inflammation. Despite these findings, it does not appear that bronchial arteries produce much pulmonary edema.

PULMONARY INTERSTITIUM

The pulmonary interstitium is a gel of connective tissues, hydrophilic glycosaminoglycans, and cells and contains 40% of pulmonary extracellular water. This water content can double before fluid spreads into the alveoli. Much of the interstitial water is bound to proteins or glycosaminoglycans and is inaccessible or excluded, though during interstitial swelling some theorize that a portion of this excluded water may be released thereby decreasing osmotic inflow of fluid from elsewhere.

The interstitium may be divided into alveolar wall and peribronchovascular components, the latter contiguous with the pulmonary-venous, pleural, and interlobular-septal interstitium. The alveolar (parenchyma) component is much less compliant to the addition of extra fluid than is the peribronchovascular (axial) component, so interstitial edema tends to collect in the peribronchovascular tissues.

ALVEOLOCAPILLARY MEMBRANE

The alveolar side of the membrane is a continuous epithelium of mostly thin processes from type I alveolar cells with a shared continuous well-defined basement

membrane. As described earlier, the alveolar junctional complexes are tighter than that of the capillary endothelium, and water and small molecules like sucrose, urea, and atomic ions are the only non-lipid-soluble molecules that can cross them. The membrane is lined by a very thin fluid layer that serves to smooth the surface and provide a constant radius (via surface tension effects).

LYMPHATIC SYSTEM

Pulmonary lymphatics have discontinuous or absent basement membranes, thin irregular endothelium, and poorly developed cellular junctions, and this structure offers no flow restriction. They begin as blind vessels at the alveolar ducts and respiratory bronchioles, bound via small filaments to the surrounding tissues so that when this tissue swells the lymphatic vessels expand. Fluid enters the vessels and is pumped centrally both passively, via respiratory motion, and actively, via smooth muscle contractions; one-way valves prevent backflow.

PHYSIOLOGY

THE STARLING EQUATION

The Starling equation relates fluid flux across a membrane to hydrostatic pressure, osmotic pressure, and permeability. In the equation below, Q is the transmembrane flow, K is the filtration coefficient, P is hydrostatic pressure, p is protein osmotic pressure, r is the osmotic reflection coefficient, and the subscripts “mv” and “PMV” refer to microvasculature and perimicrovascular interstitium respectively.

$$Q_f = K_f [P_{mv} - P_{pmv} - r^*(p_{mv} - p_{pmv})]$$

Under normal steady-state conditions, there is continuous net outward flow of fluid and protein from the pulmonary microvasculature to the interstitium, returned to circulation via lymphatics. Disruption of the balance of outflow and lymphatic return lead to pulmonary edema. Increases in microvascular pressure P_{mv} and membrane permeability K_f are the most common causes of edema.

Microvascular hydrostatic pressure is variable. There is normally a gradient in hydrostatic pressure, decreasing from the pulmonary arteries (roughly 20 cm H₂O) to the capillaries then further to the large pulmonary veins and left atrium (roughly 5 cm H₂O), with an additional physical gradient imposed by gravity of about 1 cm H₂O per cm of physical height difference. About 40% of the pressure drop takes place in the capillaries. Most pathologic conditions increase microvascular pressure by increasing outflow pressure and/or outflow resistance; that is, increasing right atrial pressure and/or pulmonary venous resistance.

Perimicrovascular interstitial hydrostatic pressure is generally about -5 to -12 cm H₂O, subpleural interstitial pressure is about -3 cm H₂O, and pericapillary interstitial pressure is even less negative (that is, closer to zero). Like microvascular hydrostatic pressure, there is probably a physical gradient because of gravity, about 0.6 cm H₂O per cm of distance; however, since this gradient is less than that of the microvascular hydrostatic pressure, the increasing pressure differences at the dependent vessels contribute to the dependent predominance of edema.

Plasma protein osmotic pressure is dependent on concentration and membrane protein permeability. It increases linearly with albumin, and nonlinearly with total protein concentration, but is constant throughout the microvasculature.

Interstitial protein osmotic pressure varies, decreasing as fluid filtration increases (i.e., in the more dependent areas, as gravity promotes filtration). Osmotic pressure is related to protein concentration in a nonlinear way, with a 50% decrease in protein concentration creating greater than 50% decrease in interstitial osmotic pressure.

The filtration coefficient is a reflection of endothelial permeability to water (mL per minute per cm H₂O of pressure per unit of lung weight). It is dependent both on endothelial permeability and surface area of membrane per unit weight, so recruiting closed capillaries to open because of increased microvascular pressure will increase the coefficient without directly affecting the permeability of any individual membrane.

The osmotic reflection coefficient reflects the fact that a solute will produce a net osmotic pressure across a membrane if the membrane is less permeable to the solute than the solvent, and if there is a solute concentration gradient across the membrane. It is thus an estimate of the effectiveness of a solute at a given concentration in producing osmotic pressure. A reflection coefficient of 1 that the membrane is completely impermeable to the solute; the values for albumin, globulin, and fibrinogen are about 0.85, 0.9, and 0.98; however, when there is endothelial damage the reflection coefficient approaches zero because the large proteins can travel via the sites of damage. This removes the most effective edema-preventing force from the Starling equation.

ALVEOLAR EPITHELIAL FLUID TRANSPORT

The alveolar epithelium is much less permeable than endothelium to both water and solutes. This means that solutes that exert no osmotic pressure across the endothelium because of low reflection coefficients may produce important effects at the alveolar epithelium. In the normal adult, lung surface tension in the alveolar liquid tends to exert a pressure for fluid to enter the

airspace from the interstitium, about 15 cm H₂O in normal lung because of surfactant but much higher in surfactant deficient states.

BRONCHIAL ENDOTHELIAL FLUID TRANSPORT

Many of the variables in the Starling equation are unknown for transport across the bronchial endothelium. However, the presence of large intracellular gaps, the likely much higher microvascular hydrostatic pressure because of their systemic-circulation origin, and the likely more-negative interstitial fluid pressure because of their presence in the peribronchovascular tissue, all suggest at least the possibility for important levels of fluid exchange at the bronchial endothelium.

SAFETY FACTORS

Lymphatic flow can increase 10-fold or more with acute increases in microvascular pressure or permeability before edema develops. With chronic left ventricular failure, the lymphatic vessels proliferate and enlarge. Some theorize that the limiting factor for pulmonary lymphatic drainage is not the pulmonary lymphatic vessels themselves, but the size of the thoracic and right-lymphatic ducts.

Protein sieving is a safety factor in hydrostatic (but not permeability) edema: as the interstitial fluid increases the interstitial osmotic pressure decreases, lowering the outward pressure on fluid flow.

Interstitial compliance is initially low with increasing pressure, since after the addition of only a small volume of water to the interstitial gel the interstitial pressure increases rapidly. However, at a certain point the gel expands more with only small increases in pressure, followed by a second increase in gel stiffness. It is at this second increase in stiffness (decrease in compliance) that fluid can flow into the alveoli. Notably, this increased interstitial pressure may be responsible for pulmonary vascular redistribution visible in erect chest radiographs: the increased interstitial pressure in more-edematous lung will compress the regional vessels and blood flow will be redistributed to areas with less edema. This decreases V-Q mismatch.

DEVELOPMENT AND CLEARANCE OF EDEMA

The earliest manifestation is expansion of the connective tissue space around the conducting airways and their accompanying vessels, in the interlobular septa, and in the peribronchovascular interstitium. As fluid volume increases, alveolar walls expand as fluid accumulates in the thick side of the alveolocapillary membrane, and just before alveolar edema occurs, small amounts of fluid accumulate in the alveolar corners. Alveolar edema develops

after the pulmonary water content has increased 50%. An individual alveolus can only be air-filled or fluid-filled, with no halfway filling, so edema development is a rapid process for each individual alveolus. The fluid in alveolar edema has the same protein content as the interstitial, so evidently the epithelium loses its ability to sieve and allows flow of pure tissue fluid.

After normal function is restored, pulmonary lymphatics cannot clear edema as rapidly as is clinically apparent. Fluid also reenters the pulmonary microvessels, enters the tracheobronchial tree and is cleared, flows into the mediastinum, and enters the pleural space, where it is returned via pleural lymphatics. Protein clearance is probably mostly via passive diffusion, though albumin and immunoglobulin may be actively transported.

Broadly speaking, pulmonary edema can develop from increased pulmonary microvascular pressure or decreased in plasma oncotic pressure; or an increase in microvascular permeability.

HYDROSTATIC PULMONARY EDEMA

CARDIOGENIC EDEMA

The most common cause for pulmonary edema is increased pulmonary venous pressure caused by left-sided heart disease: Left ventricular failure from a wide variety of causes, mitral valve disease, left atrial myxoma or thrombus, and cor triatriatum are notable examples.

EDEMA ASSOCIATED WITH RENAL DISEASE, HYPERTENSION, OR HYPOPROTEINEMIA

Both acute and chronic renal disease with or without uremia can lead to hydrostatic edema; although, left ventricular failure is likely a large component of this, decreased protein osmotic pressure, hypervolemia, and increased capillary permeability have a role. Uremic patients have constant high cardiac output from anemia and iatrogenic arterio-venous fistula, coronary artery disease, fluid overload, and left ventricular hypertrophy. Patients with renal disease caused by bilateral renal artery stenosis are prone to developing acute edema.

Fluid overload can cause pulmonary edema in otherwise healthy patients, particularly in postoperative settings and in old patients. This is perhaps attributable to temporary high-output heart failure or to decreased colloid osmotic pressure.

Patients with liver disease or prior liver transplant are more likely than others to develop edema. It is unknown whether the etiology is increased capillary pressure or

endothelial permeability, or decreased plasma oncotic pressure. Development of noncardiogenic edema in a patient with end-stage chronic liver failure often is because of sepsis.

EDEMA CAUSED BY PULMONARY VENOUS ABNORMALITIES

Increased pulmonary venous pressure may rarely be caused by pulmonary venous stenosis or increased resistance, such as from congenital heart disease or pulmonary venous atresia; primary veno-occlusive disease or venous thrombosis; mediastinal mass venous invasion or compression; or chronic fibrosing mediastinitis. Type III anomalous pulmonary venous return is often associated with compression or stenosis of the abnormal infracardiac vein.

NEUROGENIC AND POSTICTAL EDEMA

Head trauma, increased intracranial pressure, and postictal state can occasionally, via a poorly understood process probably combining increased permeability and increased microvascular pressure, lead to pulmonary edema.

RADIOGRAPHIC FINDINGS

INTERSTITIAL EDEMA

There is generally a lag between the actual rise in pulmonary venous pressure and the development of radiographic findings. The first manifestation of increased hydrostatic pressure is pulmonary venous hypertension, described earlier, in which pulmonary vascularity is redistributed from the lower to the upper lung zones when pulmonary venous pressure rises above 10 to 14 mm Hg. This may be seen in other processes in addition to edema, including chronic venous hypertension and left-to-right shunts. This can reliably be detected only in erect images with maximal inspiration.

The normal pulmonary arteries in the upper lung zones are the same size or smaller than their companion bronchi, with flow redistribution the artery becomes larger than the accompanying bronchus.

Fluid accumulating within the perivascular interstitial tissue and the interlobular septa produce blurring of the normal sharp pulmonary vascular markings and Kerley-A and Kerley-B lines. The Kerley lines develop at pulmonary venous pressures of 17 to 20 mm Hg or higher. The presence of Kerley lines is a specific indicator of interstitial edema, but not a sensitive one compared to vascular blurring. When edema builds up in the parenchymal interstitial

(the alveolar walls), the radiograph may reveal a faint predominantly lower zone or perihilar haze. Increased perihilar bronchial wall thickness and loss of sharp delimitation can be visible, with similar thickening at the large central airways. However, these findings may also be present in airways diseases such as bronchitis or asthma.

The interlobar fissures may be thickened. This is not true intrafissural fluid but rather fluid buildup in the pleural interstitium itself. Similarly, the costophrenic recesses may be thickened, by pleural interstitial edema or by small true effusions.

In cardiogenic edema, the heart is generally enlarged, though not in all cases (e.g., acute myocardial infarction). In noncardiogenic edema, conversely, the heart is typically normal-sized.

After successful therapy, edema often resolves within a few hours but may persist as long as 22 hours. Persistent interstitial thickening after adequate therapy suggests irreversible fibrosis.

ALVEOLAR EDEMA

Alveolar edema may coexist with interstitial edema. Patchy or confluent bilateral alveolar opacities tend to be symmetric and to be predominantly perihilar and lower zone. Air bronchograms can occasionally be present.

Sparing of the subpleural zone creates a bat-wing pattern of opacity but is not a constant feature of alveolar edema. Several etiologies have been proposed. The peripheral pulmonary arterioles may be uniquely adapted for vasoconstriction and vasodilation, and/or the longer arterial path length to the periphery allows blunting of arterial pressures. The greater volume change of peripheral lung parenchyma with respiration may stimulate increased lymphatic flow.

Unilateral edema may exist for a variety of reasons, the most common of which is prolonged unilateral-dependent positioning. Edema will commonly develop on the same side as the abnormality in systemic-pulmonary shunts in congenital disease, bronchial obstruction, unilateral veno-occlusive disease, unilateral aspiration, pulmonary contusion, and rapid thoracentesis with reexpansion. Right-upper-lobe edema can develop in patients with mitral regurgitation, because of the valve-plane orientation. Edema can develop contralateral to the pathologic process in several processes as well: proximal pulmonary artery interruption or obstruction, Swyer-James syndrome, acute PTE, local emphysema, prior lobotomy, rapid lung reexpansion in a patient who already had left-side heart failure, systemic-pulmonary shunt, pleural disease, and unilateral sympathectomy.

A case of unilateral edema, it may be difficult to distinguish from pneumonia. Shifting the patient's position from supine to lateral decubitus may allow dependent edema to shift position, whereas pneumonia would not be expected

to move. Alternatively, a trial of diuretic medication would decrease the edema but not affect the pneumonia.

Alveolar edema usually clears completely within 3 days after adequate therapy.

CT FINDINGS

Pulmonary venous hypertension is more easily defined, visible as disproportionately enlarged nondependent pulmonary vessels (the arteries by 20%; the veins by 33%). Interstitial edema is more clearly visible: the interlobular septa and the subpleural and peribronchovascular connective tissues are thickened, and ground glass attenuation is present. Pleural and pericardial effusions are more easily visualized. Mediastinal nodes may be enlarged, and the mediastinal fat may be heterogeneous.

Alveolar edema—In addition to the findings of interstitial edema, alveolar consolidation is present (though ground glass opacity is also visible in alveolar edema).

VENTILATION-PERFUSION FINDINGS

With increased pulmonary venous pressure, regional blood flow to the upper lungs rises to almost equal to that of the lower zones. Ventilation is also affected. However, the effects are that heterogeneous and V–Q mismatches occur, producing arterial hypoxemia. This is generally mild with interstitial edema but more severe with alveolar edema. V–Q mismatch and shunt can be improved by positioning the patient prone.

INCREASED-PERMEABILITY PULMONARY EDEMA

EPIDEMIOLOGY

Common causes of increased-permeability pulmonary edema (ARDS) include systemic sepsis, pulmonary infection, trauma, inhalation of noxious fumes or gases, aspiration of noxious fluids, and ingestion or injection of drugs or poisons. ARDS is a specific feature of the systemic inflammatory response syndrome characterized initially by increased microvascular permeability and subsequently by endothelial damage potentially leading to multisystem organ failure.

Mortality is over 50% overall; less if respiratory insufficiency is not accompanied by multiorgan failure, and considerably more (up to 89%) if accompanied by renal failure. Most of those who die do so within 14 days. Patients who gained weight during ARDS treatment were more likely to die than those who lost, likely a re-

flection of ongoing fluid accumulation or of the fact that sicker patients are likely to need more fluid resuscitation.

A wide variety of stress responses is implicated in ARDS. Endothelial and epithelial cell stimulation by endotoxins (in sepsis), by microvascular thrombosis (in hypotensive shock), or other factors lead to evolution of numerous proinflammatory cytokines, including tumor necrosis factor and interleukin-1. Active neutrophils elaborate numerous oxidative factors and also produce elastase, collagenase, and other degradative enzymes. A deficiency of surfactant develops, perhaps due to dilution by exudates, deficiency of production due to epithelial injury, or surfactant deactivation by oxidative processes. The clotting cascade is activated in one-fourth of patients with ARDS, perhaps by collagen exposure after endothelial damage, and disseminated intravascular coagulation (DIC) accompanies ARDS in a similar number of cases. The potent vasoconstrictor endothelin-1 is elevated up to seven times normal levels, and prekallikrein and bradykinin generation have been noted. The complement factor C5a, which can directly increase capillary permeability and causes mast cell histamine release, smooth muscle contraction, and leukocyte chemo taxis, may or may not play a role.

PATHOLOGIC FINDINGS

The exudative phase begins within hours after the initial insult. There is interstitial edema, capillary congestion, and consolidation by exudates and blood, but inflammatory cells are rare in the early phase. By 2 to 7 days, the edema is developing into hyaline membranes composed of cellular debris and fibrin. Type II alveolar cells proliferate. The proliferative phase runs approximately days 7 to 28. Fibroblast and myofibroblast cells proliferate, mostly within alveoli but also in the interstitium, a connective tissue matrix is formed, and lymphocytes enter the tissue. The proximal transitional airways are often spared. Bronchopneumonia development is common. The fibrotic phase occurs in some patients in whom so much collagen is produced that interstitial fibrosis develops. In less severe disease, much of proliferate changes resolve without significant residual fibrosis.

RADIOGRAPHIC FINDINGS

The exudative phase may appear normal up to 12 hours after initial respiratory failure. The earliest findings are patchy ill-defined bilateral opacities, with interstitial edema rare. The heart size is usually normal, and alveolar edema is more peripheral than in cardiogenic edema. Consolidation becomes confluent and affects the entirety of the lungs,

often with air bronchograms (different from cardiogenic edema). Pleural effusions are typically not visible in AP radiographs unless superposed infection, hydrostatic edema, or infarction has developed. The proliferative and fibrotic phases are characterized by development, after about a week, of reticular or bubbly opacities probably representing ongoing fibrosis. In patients who survive, the lungs' appearance improves within the first 2 weeks; failure to improve suggests superposed pneumonia.

CT FINDINGS

Early exudative phase CT or HRCT reveals ground glass or dense consolidation, typically patchy, bilateral, and dependent. Later exudative phase findings include homogeneous and dependent opacities. The proliferative phase is characterized by decreasing overall lung density and development of interstitial reticulation. Interstitial emphysema, pneumomediastinum, pneumothorax, and subpleural air collections may be visible from barotrauma.

DIFFERENTIATING CARDIOGENIC AND PERMEABILITY EDEMA

Pulmonary vascular redistribution is visible in half of patients with cardiogenic edema, no patients with volume overload, and in 10% of patients with permeability pulmonary edema.

Homogeneous pulmonary edema is present in 90% of patients with cardiogenic edema, 30% of patients with renal failure, and 35% of patients with permeability edema.

Perihilar pulmonary edema is present in 10% of patients with cardiogenic edema, 70% of patients with renal failure, and none with permeability edema.

Peripheral-predominant pulmonary edema is present in 45% to 50% of patients with permeability edema and 13% of patients with hydrostatic edema.

Widened vascular pedicle, defined as greater than 53 mm (measured on a PA radiograph, from the crossing of

the SVC and right bronchus to the left subclavian artery origin), was present in one study in 60% of patients with cardiogenic edema, 85% of patients with volume overload, and 20% of patients with permeability edema. Other studies did not find this helpful.

Septal lines are present in 30% to 43% of patients with cardiogenic or volume overload edema and in 0% to 9% of patients with ARDS.

Air bronchograms are present in 70% of patients with permeability edema and 20% to 26% of patients with hydrostatic edema.

Pleural effusion is visible in 40% of patients with cardiogenic edema and 10% of patients with permeability edema, but that number rises to 27% to 29% if decubitus, upright, or CT imaging is performed.

Cardiomegaly is present in 60% to 72% of patients with cardiogenic edema and 32% to 44% of patients with permeability edema (Table 25-1)

SPECIFIC FORMS

HIGH-ALTITUDE PULMONARY EDEMA

This symptom complex is characterized by numerous constitutional symptoms, fever, and dyspnea on exertion, with increased pulse and diastolic blood pressure. It may manifest with acute or (occasionally) chronic exposure to altitudes of 11,500 to 13,000 ft, rarely lower. It typically affects young otherwise healthy patients and appears more common in people who are returning to high altitude after a short stay at low altitude than in people reaching high altitude for the first time. Symptoms generally resolve upon returning to low altitude.

Increased capillary permeability is a factor, but the etiology is uncertain. In one theory, hypoxia causes intense inhomogeneous pulmonary arterial vasoconstriction. The unobstructed regions will experience high pressure and high flow, leading to shear stress, endothelial damage, and subsequently edema.

TABLE 25-1 Comparison of Cardiogenic and Noncardiogenic Pulmonary Edema

FACTOR	CARDIOGENIC (%)	FLUID OVERLOAD (%)	PERMEABILITY (%)
Pulmonary vascular redistribution	50	0	10
Homogeneous edema	90	30	35
Perihilar edema	10	70	0
Peripheral predominant edema	13	13	45–50
Widened vascular pedicle	60	80	20
Septal lines	30–43	30–43	0–9
Air bronchograms	20–26	20–26	70
Pleural effusion	40	—	10 (AP)
Cardiomegaly	60–72	—	44

POSTPNEUMONECTOMY PULMONARY EDEMA

This may develop in 1% of lobectomy patients and 2.5% to 5% of pneumonectomy patients. Risk factors include use of fresh-frozen plasma, high-pressure mechanical ventilation, low preoperative DLCO, and right pneumonectomy. The edema is caused by increased pulmonary permeability, perhaps because of capillary stress failure from suddenly increased arterial flow, similar to high-altitude edema. Postpneumonectomy edema has a mortality rate of over 80%.

REEXPANSION EDEMA

Edema frequently develops after rapid lung expansion, such as after thoracentesis. Typically the effusion being drained is large (over 50% of the hemithorax) and has been present at least several days. Theories for the etiology include sudden increase in negative intrapleural pressure; delay in venolymphatic return caused by stasis, reduced alveolar surfactant after long collapse, or reperfusion injury. Edema usually develops within 2 to 4 hours after lung reexpansion, with consolidation resolving within 5 to 7 days. It typically does not have severe consequences but in some instances can be fatal.

SEVERE UPPER-AIRWAY OBSTRUCTION

This occurs in lesions of the extrathoracic airway, often precipitated by laryngospasm. Edema often develops a few minutes after the obstruction is resolved, such as by reintubation.

TRANSFUSION

Transfusion-related acute lung injury is because of increased capillary permeability caused by HLA incompatibility, leukoagglutinins, or other blood factors. Patients acutely develop chills, fever, tachycardia, cough, and dyspnea, sometimes accompanied by eosinophilia. Radiograph would reveal predominantly perihilar and lower zone opacities without cardiomegaly.

PANCREATITIS

Even in patients without aspiration or sepsis, pulmonary edema can develop. The etiology is uncertain, perhaps because of pancreatic enzymes entering the blood and activating an inflammatory or thrombotic response.

FAT EMBOLISM

Permeability edema often develops with trauma, but many other factors including hypotension, sepsis, or transfusion requirement, are coexistent, so the contribution of fat embolism to ARDS is uncertain.

PHEOCHROMOCYTOMA

Some pheochromocytoma patients develop an acute transient permeability edema. The etiology may be massive sympathetic stimulation resulting in transient pulmonary micro vascular pressure.

DIABETIC KETOACIDOSIS

Noncardiogenic edema may rarely develop without any other cause. One theory is that acidosis activates the complement cascade.

PARENTERAL CONTRAST MATERIAL

Both oil- and water-based contrast materials have caused pulmonary edema. Oil-based contrast material

TABLE 25-2 Other Causes of Pulmonary Edema

Cardiogenic edema	Mitral valve disease Left atrial myxoma Cor triatriatum Left ventricular failure
Edema caused by abnormal volume or protein	Acute or chronic renal disease Hypoproteinemia Hypervolemia Liver failure
Pulmonary venous abnormalities	Venous stenosis Congenital heart or venous disease Primary veno-occlusive disease Venous thrombosis Mediastinal mass/invasion/compression Fibrosing mediastinitis
Neurogenic edema	Head trauma Increased intracranial pressure Postictal state
Increased-permeability edema (ARDS)	Systemic sepsis Pulmonary infection Trauma Inhalation of noxious fumes or gases Ingestion or injection of drugs or poisons

may be metabolized by esterases in the lung, releasing toxic free fatty acids. Water-based intravenous contrast material can produce pulmonary edema during anaphylactic allergic reactions, because of systemic hypotension and complement activation (Table 25-2)

QUESTIONS AND ANSWERS

1. The Starling equation relates transmembrane flow with which of these?
 - A. Permeability-surface area product, protein concentration
 - B. Protein osmotic pressure, hydrostatic pressure, and inflammation
 - C. Protein osmotic pressure, hydrostatic pressure, and permeability

- D. Permeability-surface area product, hydrostatic pressure, blood pressure

ANSWER: C. The Starling equation relates fluid flux across a membrane to hydrostatic pressure, osmotic pressure, and permeability. In the equation below, Q is the transmembrane flow, K is the filtration coefficient, P is hydrostatic pressure, p is protein osmotic pressure, r is the osmotic reflection coefficient, and the subscripts "mv" and "pmv" refer to microvasculature and perimicrovascular interstitium respectively.

$$Q_f = K_f * [P_{mv} - P_{pmv} - r * (p_{mv} - p_{pmv})]$$

Under normal steady-state conditions, there is continuous net outward flow of fluid and protein from the pulmonary microvasculature to the interstitium, returned to circulation via lymphatics. Disruption of the balance of outflow and lymphatic return lead to pulmonary edema. Increases in microvascular pressure P_{mv} and membrane permeability K_f are the most common causes of edema.

2. By what process do most pathologic conditions increase transmembrane flow?
 - A. Increasing outflow microvascular hydrostatic pressure
 - B. Decreasing pulmonary venous resistance
 - C. Increasing perimicrovascular interstitial hydrostatic pressure
 - D. Altering membrane permeability
3. What is the most common cause for pulmonary edema?
 - A. Hypoproteinemia
 - B. Left-sided heart disease
 - C. Uremia
 - D. Altered membrane permeability

ANSWER: B. The most common cause for edema is increased pulmonary venous pressure caused by left-sided heart disease: Left ventricular failure, mitral valve disease, left atrial myxoma or thrombus, and cor triatriatum are notable examples. Both acute and chronic renal disease with or without

uremia can lead to hydrostatic edema; although, left ventricular failure is likely a large component of this.

4. What is the earliest manifestation of increased hydrostatic pressure?
 - A. Pulmonary venous hypertension
 - B. Kerley lines
 - C. Alveolar filling
 - D. Unilateral edema

ANSWER: A. The first manifestation of increased hydrostatic pressure is pulmonary venous hypertension, in which pulmonary vascularity is redistributed from the lower to the upper lung zones when pulmonary venous pressure rises above 10 to 14 mm Hg. Fluid accumulating within the perivascular interstitial tissue and the interlobular septa produce blurring of the normal sharp pulmonary vascular markings and Kerley-A and Kerley-B lines. The Kerley lines develop at pulmonary venous pressures of 17 to 20 mm Hg or higher. Unilateral edema may exist for a variety of reasons.

5. What is the most common cause of unilateral pulmonary edema?
 - A. Mitral regurgitation
 - B. Unilateral veno-occlusive disease
 - C. Prolonged unilateral dependent positioning
 - D. Reexpansion edema

ANSWER: C. The most common cause of unilateral edema is prolonged dependent positioning. Edema will commonly develop on the same side as the abnormality in systemic-pulmonary shunts in congenital disease, bronchial obstruction, unilateral veno-occlusive disease, unilateral aspiration, pulmonary contusion, and rapid thoracentesis with re-expansion. Right-upper-lobe edema can develop in patients with mitral regurgitation, because of the valve-plane orientation. Edema can develop contralateral to the pathologic process in several processes: proximal pulmonary artery interruption or obstruction, Swyer-James syndrome, acute PTE, local emphysema, prior lobectomy, rapid lung re-expansion in a patient who already had left-side heart failure, systemic-pulmonary shunt, pleural disease, and unilateral sympathectomy.

6. In which of the following phases of ARDS does hyaline membrane formation occur?
 - A. Exudative, days 2–7
 - B. Proliferative, days 7–28
 - C. Fibrotic, days 28 and above
 - D. Proliferative, days 2–7

ANSWER: A. The exudative phase begins within hours after the initial insult. There is interstitial edema, capillary congestion, and consolidation by exudates and blood, but inflammatory cells are rare in the early phase. By 2 to 7 days, the edema is developing into hyaline membranes composed of cellular debris and fibrin. Type II alveolar cells proliferate. The proliferative phase runs approximately days 7 to 28. Fibroblast and myofibroblast cells proliferate, mostly within alveoli but also in the interstitium, a connective tissue matrix is formed, and lymphocytes enter the tissue. The proximal transitional airways are often spared. Bronchopneumonia development is common. The fibrotic phase occurs in some patients in whom so much collagen is produced that interstitial fibrosis develops. In less severe disease, much of the proliferate changes resolve without significant residual fibrosis.

7. Comparing patients with ARDS to patients with cardiogenic edema, which of the following is *true*?
 - A. ARDS patients are more likely to have homogeneous edema and perihilar edema.
 - B. ARDS patients are more likely to have visible septal lines and air bronchograms.
 - C. ARDS patients are more likely to have air bronchograms and narrow vascular pedicle.
 - D. ARDS patients are more likely to have pleural effusion and cardiomegaly.

ANSWER: C. No single finding is diagnostic, but combination of findings allows accurate identification of hydrostatic edema in 80% to 90% of patients and of permeability edema in 60% to 90% of patients. ARDS patients are less likely to have pulmonary vascular redistribution, homogeneous pulmonary edema, perihilar pulmonary edema, widened vascular pedicle, septal lines, effusions, and cardiomegaly. ARDS patients are more likely to have peripheral-predominant pulmonary edema and air bronchograms.

8. Regarding reexpansion pulmonary edema, which of the following is correct?
 - A. More common after removal of acutely-developed collections
 - B. Edema usually develops after 1 to 2 days.
 - C. More common with drainage of large collections
 - D. Probably not clinically significant

ANSWER: C. Edema frequently develops after rapid lung expansion, such as after thoracentesis. Typically, the effusion being drained is large and has been present at least several days. Edema

usually develops within 2 to 4 hours after lung reexpansion, with consolidation resolving within 5 to 7 days. It typically does not have severe consequences, but in some instances can be fatal.

9. Regarding high-altitude pulmonary edema (HAPE), which of the following is *true*?
- Most commonly associated with chronic high-altitude exposure
 - Associated with cardiogenic causes
 - More common in healthy patients
 - Not associated with constitutional symptoms

ANSWER: C. HAPE is characterized by constitutional symptoms, fever, and dyspnea on exertion, with increased pulse and diastolic blood pressure. It may manifest with acute or occasionally chronic exposure to altitudes of 11 500 to 13 000 ft. It typically affects young otherwise healthy patients. Symptoms generally resolve upon returning to low altitude. Increased capillary permeability is a factor, but the etiology is uncertain.

10. Regarding ARDS, which of the following is correct?
- Mortality is over 50%.
 - Associated with surfactant overproduction
 - Associated with decreased endothelin-1 levels
 - Patients who gain weight during therapy are less likely to die.

ANSWER: A. Mortality is over 50% overall; less if respiratory insufficiency is not accompanied by MOSF, and considerably more (up to 89%) if accompanied by renal failure. Patients who gained weight during ARDS were more likely to die than those who lost, likely a reflection of fluid accumulation or of the fact that sicker patients are likely to need more fluid resuscitation. A wide variety of stress responses is implicated in ARDS. Among them, a deficiency of surfactant develops, perhaps due to dilution by exudates, deficiency of production due to epithelial injury, or surfactant deactivation by oxidative processes. The potent vasoconstrictor endothelin-1 is elevated up to seven times normal levels, and prekallikrein and bradykinin generation have been noted.

26 PULMONARY ARTERIAL HYPERTENSION

Ian Malcolm and Satinder P. Singh

PULMONARY HYPERTENSION

Normal pulmonary vascular bed is a high-flow, low-pressure, and low-resistance system with compliant thin-walled vessels and resistance less than one-tenth the resistance of systemic bed. Pulmonary vascular resistance is expressed as a quotient of the difference between pulmonary artery (PA) or inflow pressure minus pulmonary venous (PV) or outflow pressure divided by cardiac output. The normal pulmonary resistance is approximately 1 wood unit. Pulmonary arterial hypertension (PAH) is present when the PA systolic pressure is greater than 35 mm Hg or the mean PA pressure is greater than 25 mm Hg at rest or greater than 30 mm Hg with exercise. Athletes can normally have higher resting PA systolic pressure.

PATHOPHYSIOLOGY

Pulmonary blood flow is regulated by small muscular arterioles less than 1 mm in diameter, proximal to the capillary bed. Pulmonary vascular endothelium responds to changes in oxygen tension, transmural pressure, and blood flow. If these changes are prolonged and severe, endothelial damage produces structural change (Table 26-1). This change occurs earliest in the small vessels of the lung and is initially reversible (intimal proliferation and medial smooth muscle hypertrophy). However, it eventually becomes irreversible (fibrinoid necrosis, luminal thrombosis, dilation, and plexiform lesions). These latter changes are called plexogenic arteriopathy and may occur with advanced pulmonary hypertension, whatever the cause be.

In a normal individual, pulmonary vascular resistance actually decreases with increasing cardiac output, such as with exercise, because the pulmonary vasculature maintains pulmonary artery pressure (PAP) within a narrow range by its ability to fine tune the resistance

TABLE 26-1 Histologic Findings in Pulmonary Arterial Hypertension

- Intimal hypertrophy
- Medial hypertrophy
- Plexiform arteriopathy

offered. The pulmonary microvasculature relaxes further when the cardiac output is increased. However, when the pulmonary vasculature is diseased with medial and smooth muscle hypertrophy, this compliance is lost and in fact vessels may actually decrease in size rather than distend, leading to increased contractile force of the right ventricle (RV) to compensate and maintain flow, which then increases pressure.

NATURAL HISTORY OF PULMONARY ARTERIAL HYPERTENSION

Decreased pulmonary vascular capacitance

Increased pulmonary arteriolar resistance (>3 wood units)

Elevated pulmonary artery pressures

Right ventricular pressure overload

Tricuspid regurgitation

RV failure, reduced cardiac output, hypotension

Myocardial ischemia

PAH is classified according to the underlying etiology (Tables 26-2 and 26-3), including idiopathic, familial, connective tissue disorder, liver disease, and HIV (Table 26-4). Idiopathic PAH is uncommon with incidence of 1 to 2 per million, with median age of 40 years. It is more common in females (female-to-male ratio is 2.5:1).

Multimodality imaging plays an important role in evaluation of common symptoms including dyspnea on exertion, syncope, fatigue, dizziness, and chest pain. Classic auscultatory findings are heard in PAH (Table 26-5) and ensuing right ventricular failure (Table 26-6). It is often misdiagnosed as deconditioning, heart failure, asthma, heart rhythm disorder, coronary artery disease, and psychiatric problems. Diagnosis is often delayed up to 2 to 3 years. Chest radiographic findings include dilatation of main and central PA to pulmonary hypertension greater than 17 mm with rapid tapering, enlarged RV, and PA calcification in severe prolonged cases (Table 26-7).

Echocardiography is used as a screening tool for patients with unexplained dyspnea (Tables 26-8 and 27-9). Pulmonary pressures can be estimated, although

Left-sided heart failure

Mediastinal fibrosis (pulmonary vein occlusion)

Pulmonary veno-occlusive disease

echocardiography cannot reliably detect mild PAH. Tricuspid regurgitation is present in 90% of patients, and a tricuspid regurgitant velocity of 3 m/s corresponds with pulmonary pressures of greater than 30 mm Hg. Limitations of echocardiography include operator dependence, wide variability, under- or overestimation of severity of PAH, and missed left ventricular disease in congenital heart disease.

CT IN PULMONARY ARTERIAL HYPERTENSION

CT is used to exclude other causes of PAH, such as chronic pulmonary thromboendarterectomy (PTE), interstitial lung disease (ILD), etc. CT is more accurate in evaluation of main PA size in comparison to radiograph (Table 26-10). The ratio of transverse main pulmonary artery (MPA) diameter to that of the aortic diameter at the same level should be greater than 1. Main CT findings in pulmonary hypertension are described in Table 26-10.

*As per World Health Organization, 2003.

MR is often used to evaluate the effect of pulmonary hypertension on RV and to establish underlying intracardiac shunt (Table 26-11). Sometimes it is performed to diagnose the presence of pulmonary hypertension when echocardiographic findings are equivocal.

Pulmonary angiography, more frequent in the past, is now done only in special circumstances, especially when other noninvasive imaging findings are equivocal or there is discrepancy in clinical suspicion and imaging results. In addition, it is also done routinely at some institutions for the evaluation of chronic thromboembolic pulmonary hypertension prior to thromboembolism.

Angiographic features of pulmonary hypertension include dilated PAs, abnormal tapering, and in chronic PTE the features are irregularity, webs, areas of narrowing and dilatation in PA branches. PAPs are elevated.

Determine etiology of PAH

In primary PAP, V/Q scan is usually normal or may show mild heterogeneity in pulmonary perfusion. It distinguishes chronic thromboembolic pulmonary hypertension from idiopathic pulmonary hypertension with a sensitivity of 90% to 100% and a specificity of 94% to 100%. However, segmental perfusion defects occur with pulmonary veno-occlusive disease, large vessel arteritis, or encasement, compression, or occlusion of PAs in the mediastinum by fibrosing mediastinitis or invasive carcinoma in the mediastinum.

SELECTED CAUSES OF PULMONARY HYPERTENSION

CONNECTIVE TISSUE DISORDERS AND PAH

Scleroderma is the most common cause of PAH among connective tissue diseases, with one-third of patients with scleroderma and more than 50% of patients with CREST syndrome afflicted. High incidence suggests echocardiographic screening to be reasonable practice in this population. It carries a very poor prognosis. Other connective tissue disorders associated with PAH include mixed connective tissue disorder, rheumatoid arthritis, SLE, and polymyositis.

CONGENITAL HEART DISEASE

PAH can develop in adults with ASD as a result of chronic increased blood flow through its effect on the endothelium. These patients are often evaluated with echocardiography, which can show the right to left shunt on doppler in addition to the ASD itself. A bubble study can be used to differentiate intracardiac from intraparenchymal shunt: intracardiac shunt bubbles are seen within three heart beats in the left circulation while intraparenchymal bubbles are delayed up to five or more heart beats. There is often massive dilatation of PA along with cardiomegaly. PA eccentric calcification may be present and is better seen on CT.

LUNG PARENCHYMA AND CHEST WALL DISORDERS

Factors responsible for PAH include chronic alveolar hypoxia, compression of pulmonary vasculature by high lung volumes in COPD, or destruction in chronic fibrotic states leading to loss of small vessels in vascular beds, increased cardiac output, and increased viscosity from polycythemia. Development of PAH in patients with cystic fibrosis carries a grave prognosis with mean survival as short as 8 months from the time of development.

Pulmonary thromboembolism can occur following deep venous thrombosis in the legs or pelvis, venous catheter thrombus, and emboli from right atrial thrombi or endocarditis of the pulmonary and tricuspid valves. Acute PTE usually causes transient elevation of pulmonary pressures, with subsequent development of chronic thromboembolic pulmonary hypertension in less than 5% of cases. CTA shows eccentric or flattened mural thrombi in central PAs with this chronic disease, which compress or occlude the lumen. Fibrous bands or webs often develop, which also compromise the lumen. Ten percent of thrombi have calcifications. Mosaic perfusion may be present. Bronchial collateral vessels in the mediastinum enable systemic to venous shunting, and enlarged bronchial arteries (greater than 1.5-mm diameter) are a good prognostic factor, prior to thromboembolism. Patients may be asymptomatic for many years before developing cor pulmonale (exercise intolerance, ascites, hepatomegaly, and peripheral edema).

Role of conventional arteriography in chronic PTE is for preoperative planning before thromboendarterectomy to visualize arterial lumens, determine the presence or extent of thrombi, both acute and chronic, and provide pressure measurements. However, it is invasive and often the central embolus is not well visualized.

Thromboembolism is used to decrease the extent of pulmonary vascular obstruction, reduce PAP, and improve cardiac function. Patients are selected if they have

- central chronic PTE (main, lobar, or segmental arteries, more accurately seen on CTA),
- absence of concurrent disease, or
- PVR greater than 5.0 wood units.

Mortality with thromboembolism is 10–20%.

Drug-induced pulmonary hypertension is indistinguishable from idiopathic pulmonary hypertension. It occurs with anorexigenics, cocaine, amphetamine, and some chemotherapeutic agents. There are extensive plexogenic lesions in the pulmonary microvasculature, and parenchymal nodules are shown on high resolution CT.

Pulmonary veno-occlusive disease is a rare condition with fibrous obliteration of PVs and venules. Unlike

left-sided cardiac lesions, right-sided cardiac catheterization in pulmonary veno-occlusive disease will not show elevated pressures in the left atrium. Left ventricle and left atrial size is normal. There is also absence of cephalization pulmonary venous hypertension on erect chest radiographs. Pulmonary veno-occlusive disease has been associated with pregnancy, drugs (bleomycin, carmustine, and oral contraceptives), toxic ingestion, bone marrow transplantation (GVHD), immunological disorders, and viral infection.

The rare condition, capillary hemangiomatosis or microvasculopathy, is difficult to diagnose prospectively. In fact, many patients are misdiagnosed as having heart failure.

Both pulmonary veno-occlusive disease and capillary hemangiomatosis cause similar radiographic changes including interstitial septal thickening with pleural effusion, mimicking edema but without cardiac enlargement. HRCT shows additional centrilobular ground glass opacities. Use of vasodilators in these conditions can cause fatal edema.

HIV-induced PAH affects 0.1% of the HIV population, with higher pulmonary pressures if AIDS is present. Chronic thromboembolic pulmonary hypertension is also present in a low percentage of these patients. Vasculopathy and radiographic findings are indistinguishable from idiopathic pulmonary hypertension.

Mild PAH due to associated hyperdynamic cardiac output is common in liver disease. More severe (portopulmonary) hypertension is caused by associated vasculitis. PAH occurs in up to 16% of patients referred for liver transplant assessment. Mean survival is 6 months and 10% patients have 5-year survival.

PAH secondary to left heart conditions (postcapillary pulmonary hypertension) is perhaps the most common cause of secondary PAH. Diagnosis is often made based on echocardiographic findings.

Left heart decompensation causes increased pulmonary venous pressure. Pulmonary venous hypertension is present when pulmonary venous pressure, usually approximated by capillary wedge pressure, is equal to or exceeding 18 mm Hg. This may occur with mitral stenosis (mitral valve obstruction by thrombus or myxoma), hypertension, aortic stenosis, cardiomyopathy, or constrictive pericarditis. A rise in PAP is required to maintain flow through the capillary bed, resulting in PAH.

Pulmonary veno-occlusion due to encasement of the pulmonary veins by mediastinal fibrosis, mediastinal carcinoma, or sclerotic lymphoma may also prevent forward pulmonary blood flow to the left cardiac chambers.

Treatment includes curing underlying disease (left heart disease, shunts, pulmonary parenchymal, or thrombotic processes). Pharmacotherapy includes diuretics, war-

farin, O₂, digoxin, calcium channel blocker, prostanoids (Epoprostenol), endothelin receptor antagonist (Bosentan), and phosphodiesterase inhibitors.

It is important to distinguish pulmonary veno-occlusive disease from interstitial lung disease, because induced vasodilation, which is used to treat interstitial lung disease, will precipitate pulmonary edema in pulmonary veno-occlusive disease.

Surgical intervention includes atrial septostomy (palliative in precapillary PAH) and pulmonary thromboendarterectomy in chronic PTE. The survival rate in lung transplantation is 1 year for 70% to 75% patients and 5 years for 40% to 45% patients.

QUESTIONS AND ANSWERS

- Regarding chronic thromboembolic pulmonary hypertension, which of the following is *true*?
 - Radionuclide scanning has only limited value in distinguishing chronic thromboembolic pulmonary hypertension from idiopathic pulmonary hypertension.
 - Commonly develops after acute pulmonary thromboembolism
 - Mosaic perfusion is frequently seen with CTA.
 - Mediastinal vascular collateral circulation is a poor prognostic indicator prior to thromboembolism.

ANSWER: C. V/Q scanning is the optimal method of distinguishing chronic thromboembolic pulmonary hypertension from idiopathic pulmonary hypertension. Chronic thromboembolic pulmonary hypertension develops in less than 5% of cases. Bronchial collateral circulation in the mediastinum is a good prognostic factor, prior to thromboembolism.

- Regarding congenital heart disease and pulmonary hypertension, which of the following is *true*?
 - Increased flow with shunt lesions causes pulmonary venous hypertension.
 - Chest radiography in children is useful in the detection of shunt lesions.
 - Lung biopsy can help determine operability and prognosis in cases that are not detected early.

- Patient with Eisenmenger physiology requires urgent correction of intracardiac shunt lesions.

ANSWER: C. Increased flow with shunt lesions causes pulmonary arterial hypertension, not pulmonary venous hypertension. Chest radiographs are not useful in most cases. Echocardiography is diagnostic and also the method of choice. Surgery for cardiac lesions is required before irreversible vasculitis occurs in the lungs with Eisenmenger physiology. Lung biopsy reveals the condition of pulmonary microvasculature.

- Regarding postcapillary hypertension, which of the following is *true*?
 - Parenchymal sarcoidosis may be the cause.
 - Pulmonary venous hypertension is present when pulmonary venous pressure is equal to or exceeding 14 mm Hg.
 - Left atrial and left ventricular pressures are elevated in left ventricular failure.
 - Mediastinal fibrosis and carcinomatous encasement of pulmonary veins can also cause elevated left atrial pressure and consequent pulmonary hypertension.

ANSWER: C. Pulmonary arterial hypertension, secondary to left heart conditions (LA, LV, or chronic MV disease), is perhaps the most common cause of secondary PAH. Parenchymal sarcoid causes precapillary PH as a result of destruction of the capillary bed. Pulmonary venous hypertension is present when pulmonary venous pressure is equal to, or exceeds, 18 mm Hg. These conditions also cause pulmonary hypertension, but there is no elevation of left atrial pressures.

- Regarding restrictive lung parenchymal diseases and pulmonary arterial hypertension, which of the following is *true*?
 - If unilateral lung transplantation is being considered, radionuclide V/Q scanning may be useful to select the lung with most compromised function.
 - CT has limited value in the evaluation of pulmonary hypertension and lung vascularity.
 - Pulmonary hypertension occurs more commonly with collagen vascular disease than with chronic obstructive pulmonary disease (COPD).
 - Pulmonary hypertension is readily identifiable.

ANSWER: A. CT is useful in determining pulmonary hypertension (evaluation of right ventricle, main pulmonary artery and segmental pulmonary arteries) and is also useful for determining lung vascularity (mosaic perfusion in the case of PTE, extent of capillary bed destruction with ILD and COPD).

COPD has a higher incidence of pulmonary hypertension than ILD (including collagen vascular disease). Pulmonary hypertension may be severe yet go unrecognized until cor pulmonale develops.

5. Regarding the pathogenesis of pulmonary hypertension, which of the following is *true*?
- A. Arteriolar vasomotor tone is low in the resting state.
 - B. Vasculitis in pulmonary hypertension varies with the underlying cause.
 - C. Longstanding pulmonary venous hypertension results in increased arteriolar tone to facilitate pulmonary blood flow with consequent pulmonary hypertension.
 - D. Increased vasomotor tone is directly responsible for dilated central pulmonary arteries in pulmonary hypertension.

ANSWER: C. In the resting state, only a fraction of the capillary bed is active. Increased vasomotor tone enables majority of lung capillaries to be collapsed and uninvolved with gas exchange until exercise, when suitable vascular recruitment takes place as needed. The same vasculitis occurs regardless of the cause of pulmonary hypertension. Although initially reversible, it becomes irreversible as pulmonary hypertension worsens. Dilated central pulmonary arteries are a late feature of PAH and result from loss of elastic tissue in the walls following increased pressure in these vessels. This is an indirect response to the small vessel vasculitis.

6. Regarding CT imaging with pulmonary hypertension, which of the following is *true*?
- A. Measuring interlobar pulmonary arteries to evaluate pulmonary hypertension is more accurate if ratios of segmental pulmonary arteries with relation to adjacent bronchi is also performed.
 - B. Ratio of main pulmonary artery diameter to ascending aortic diameter is a reliable measure of pulmonary hypertension.
 - C. Evaluation of anomalous pulmonary venous return detection is unreliable with CTA.
 - D. Right ventricular dilation is always present if there is right ventricular hypertrophy.

ANSWER: A. The ascending aorta is commonly ecstasic because of atherosclerosis, cystic medial necrosis, or sometimes secondary to aortic stenosis. Consequently, the MPA/aortic ratio may be unreliable in such cases. Anomalous pulmonary venous return can reliably be detected with CT angiography. Right ventricular hypertrophy precedes right ventricular dilation and may be present without it.

7. Regarding MR imaging for pulmonary hypertension, which of the following is *true*?
- A. MRI is commonly used to detect PTE.
 - B. Interventricular septal systolic dysfunction is pathognomic of PAH.
 - C. MRI is often the first modality to evaluate patients with unexplained dyspnea.
 - D. MRI can accurately evaluate right heart function.

ANSWER: D. MRI is currently the gold standard for cardiac function evaluation. CTA is currently the modality of choice to evaluate PTE and echocardiography is the procedure of choice in the initial evaluation of a patient's unexplained dyspnea. Interventricular septal motion abnormality is seen in diastole and not systole.

8. Regarding pulmonary veno-occlusive disease–induced postcapillary hypertension, which of the following is *true*?
- A. Differentiation from precapillary vasculopathy is important as vasodilated therapy can lead to pulmonary edema.
 - B. Pulmonary venous occlusive disease is characterized by pulmonary hypertension, radiographic features of pulmonary edema, and elevated left atrial pressure.
 - C. All patients with pulmonary venous hypertension have associated pulmonary hypertension.
 - D. Clinical diagnosis is easy.

ANSWER: A. Pulmonary veno-occlusive disease is characterized by pulmonary hypertension and radiological features of pulmonary edema, but left atrial pressures are not elevated. In the case of postcapillary hypertension, pulmonary venous hypertension precedes pulmonary hypertension (pulmonary arterial hypertension) and may be present without it. In practice, a failing left heart with pulmonary venous hypertension is common, but only a few cases develop PAH. Clinical diagnosis of PVOD is difficult and often requires lung biopsy.

9. Regarding pulmonary hypertension, which of the following is *true*?
- A. In spite of newer targeted medical therapies, prognosis in patients with idiopathic pulmonary hypertension has not significantly improved.
 - B. Pulmonary thromboendarectomy can temporarily improve pulmonary hemodynamics, proximal chronic thromboembolic pulmonary hypertension.
 - C. Transesophageal echocardiography is very reliable in detecting mild PAH.

D. Chronic thromboembolic pulmonary hypertension is characterized by laminated internal thrombus, web stenosis, and mosaic perfusion on CT, often with dilated bronchial arteries.

ANSWER: D. Newer targeted medical therapies improve prognosis in patients with idiopathic pulmonary hypertension. Pulmonary thromboendarterectomy can permanently improve pulmonary function. Transesophageal echocardiography is not very reliable in detecting mild PAH.

10. Regarding pulmonary hypertension, which of the following is *true*?

- A. ASD and anomalous venous return are high pressure shunts, which may eventually cause Eisenmenger syndrome.
- B. Drug-induced PAH is indistinguishable from idiopathic pulmonary hypertension and may occur with anorexigenics, cocaine, amphetamines, and some chemotherapeutic agents.
- C. HIV-induced vasculopathy is commonly associated with chronic thromboembolic pulmonary hypertension.
- D. Severe portopulmonary hypertension results from associated hyperdynamic cardiac output.

ANSWER: B. ASD and anomalous venous return are low-pressure shunts, which may eventually cause Eisenmenger syndrome. HIV-induced vasculitis, in association with chronic thromboembolic pulmonary hypertension, only occurs in a small number of cases. Severe portopulmonary hypertension results from vasculitis in small pulmonary vessels.

27 RADIATION-INDUCED LUNG CHANGES

John C. Texada and Satinder P. Singh

PATHOGENESIS

Patients who develop symptomatic radiation pneumonitis most commonly have undergone irradiation for lung and breast cancer, mesothelioma, or Hodgkin lymphoma. Risk rises with total dose (seldom occurring below 30 Gray (Gy) and almost always present above 60 Gy); with daily radiation greater than 2.67 Gy; with decreasing fractionation of dose, which allows less time for repair;

and with use of once-daily rather than twice-daily radiation. Prior irradiation increases the risk, as does previous or concurrent chemotherapy with actinomycin D, doxorubicin, bleomycin, busulfan, cyclophosphamide, mitomycin C, methotrexate, and vincristine. In addition, the likelihood of lung injury is proportional to the volume of lung being irradiated, thus tangential irradiation of chest wall or breast cancers is important in reducing lung toxicity.

It is believed that ion pairs and free radicals formed by photon interactions go on to damage DNA and proteins. Capillary endothelial and type I epithelial damage that characterizes acute radiation pneumonitis are the result of the accumulation of enough protein damage to impair membrane transport.

The delayed fibrotic component of radiation pneumonitis has uncertain etiology. It may be caused by disruption of the normal endothelial-fibroblast interaction: plasminogen activator secretion by the endothelial cells decreases, allowing buildup of fibrin. It may also be caused by radiation-induced cytokine production and growth factor release thus prompting increased fibroblast activity. Lung tissue outside the radiation field may be involved, perhaps via a delayed hypersensitivity reaction to a radiation-damaged antigen.

Many patients are asymptomatic. Symptoms including dry cough, exertional dyspnea, and weakness generally develop slowly, usually between 2 and 3 months. Fever and tachycardia may occur. Pulmonary function test (PFT) abnormalities are typically mild and reversible. The main abnormality is pulmonary restriction, though carbon monoxide diffusing capacity (DLCO) may decrease if a large volume of lung is involved.

PATHOLOGIC CHARACTERISTICS

Endothelial damage is one of the earliest and most consistent findings of radiation pneumonitis, evidenced by cytoplasmic swelling and vacuolization, followed by necrosis and detachment from the basement membrane. Platelet thrombi develop and can narrow or obstruct small vessels. Type I cells become necrotic soon thereafter.

Acute radiation pneumonitis is characterized by diffuse alveolar damage: proteinaceous alveolar exudates, hyaline membranes, capillary congestion, edema, and fibroblast and connective-tissue prominence without inflammatory infiltrate. Type II alveolar cells are hyperplastic and often have large bizarre nuclei.

Fibrotic radiation damage involves fibrosis of both alveoli and interstitium, with increased number of fragmented elastic fibers. Bronchiolitis obliterans and endobronchial fibrosis may be present, and venous intima may be thickened.

CLINICAL PRESENTATION

Symptoms are proportional to the extent of the radiation-induced lung injury and pretreatment lung function of the patient. Common symptoms include cough, fever, and dyspnea and, rarely, severe respiratory failure. Late pulmonary fibrosis is usually asymptomatic though dyspnea may be present.

Symptomatic radiation-induced pneumonitis does not predict subsequent fibrosis. In acute radiation pneumonitis, patients are often more symptomatic than would be expected from the volume of lung irradiated, which is explained by hypersensitivity reaction in response to localized lung injury resulting in out-of-field radiation pneumonitis.

RADIOLOGIC FINDINGS

Acute radiation pneumonitis becomes radiographically apparent approximately 8 weeks after completion of 40-Gy dose and a week earlier for every 10 Gy higher than that. Abnormalities peak 3 to 4 months after therapy. Findings range from subtle hazy opacity to patchy or diffuse alveolar opacity, often with air bronchograms. The abnormal area often has clear, sharp margins because of the port, but does not follow anatomic or segmental margins. There is usually prominent volume loss and atelectasis. Occasionally, consolidation and ARDS or, rarely, hyperlucent lung may develop.

Chronic radiation damage typically starts after 3 to 4 months, increases gradually, and stabilizes within a year of radiotherapy completion. Findings may be as subtle as hilar elevation or pleural thickening. In more advanced cases, there is severe volume loss and normal architecture is lost. Peripheral parenchyma is often airless, replaced by fibrous tissue, and fibrotic bands extend to the hilum. Patients may develop pneumothorax or bronchopleural fistula.

CT FINDINGS

CT and HRCT reveal similar findings in acute radiation pneumonitis, but do so earlier and with slightly increased sensitivity. Homogeneous ground glass attenuation or patchy-to-diffuse consolidation involves the irradiated region, with well-defined borders because of the radiation port. In chronic radiation fibrosis, CT reveals dense consolidation or stranding with volume loss and traction bronchiectasis; although often radiographically inapparent, small pleural or pericardial effusions may be visible on CT imaging.

Myocardial fibrosis, premature atherosclerosis of the aorta or coronary arteries, arterial stenosis, tracheal or bronchial stricture, and pericardial calcification may develop late. Bone demineralization, lucent areas, avascular necrosis, and fractures of rib or clavicle may undergo nonunion or malunion resembling osteosarcoma.

Recurrent tumor is more clearly visible in CT than in radiographs; development of a mass lesion or of a focal opacity without air bronchograms suggests recurrence.

ADDITIONAL IMAGING FINDINGS

POSITRON EMISSION TOMOGRAPHY (PET)

Acute radiation pneumonitis demonstrates increased fluorodeoxyglucose activity, which can persist for months. PET is usually done to detect local recurrence and distant metastasis and is reported to be more accurate than conventional imaging in the evaluation of recurrence after radiation therapy. Integrated CT/PET imaging with co-registration is useful for detecting local disease and allows directed biopsy, improving accuracy in diagnosis of recurrence or persistent disease.

On MRI, radiation fibrosis has T2 signal intensity lower than that of muscle, whereas recurrence often has T2 signal intensity higher than that of muscle. Persistent inflammation, infection, or hemorrhage increases T2 signal intensity as well.

Ventilation-perfusion scans are often abnormal: up to 95% of perfusion studies and up to 45% of ventilation studies. Most commonly a poorly perfused region is ventilated, sometimes similar in appearance to PTE.

Gallium-67 imaging may reveal the extent of radiation pneumonitis better than chest radiography, often detecting radiographically inapparent regions of pneumonitis.

DIFFERENTIAL DIAGNOSIS

Superimposed infection can be difficult to differentiate from radiation-induced pneumonitis because of similar clinical and radiographic presentation. Correlation with temporal relationship to radiation treatment, dose given, and technique used are helpful. Infection should be suspected if pulmonary opacities appear before completion of RT or outside the radiation port, have abrupt onset, or presence of cavitation in irradiated region.

Local tumor recurrence is often difficult to diagnose with ongoing radiation-related lung changes. After stabilization of radiation-induced disease, any change in contour or density of the fibrosis should raise concern

for recurrence. Endobronchial soft tissue on CT, nodules outside the port, and development of pleural effusion more than 12 months after completion of RT (ipsilateral pleural effusion, within 6 months of completion, is common and a normal phenomenon) should also be causes for concern for recurrence.

BRACHYTHERAPY

Brachytherapy is increasingly used for palliative care of obstructing lung cancer; in this process an intraluminal-endobronchial radiation source, usually iridium-192, is placed in the lesion. Changes are predominantly inflammatory at 16 weeks and predominantly fibrotic at 40 weeks. Complications include mucosal fibrosis, bronchial stenosis, localized radiation pneumonitis, bronchoesophageal fistula, and hemoptysis. In one study, stenosis was found to be developed in 12% of patients and 25% patients were found to have developed fatal hemoptysis. Large cell carcinoma, prior laser photoresection, and concurrent external-beam irradiation increase the risk of complications with brachytherapy.

QUESTIONS AND ANSWERS

- Regarding risk of radiation-induced lung changes, which of the following is *true*?
 - Radiation-induced pulmonary disease seldom occurs below 30 Gy.
 - Risk is independent of radiation fractionation.
 - Risk decreases with once- versus twice-daily radiation.
 - Prior irradiation does not increase the risk.

ANSWER: A. Risk for pulmonary disease from radiation rises with total dose (seldom occurring be-

low 30 Gy and almost always present above 60 Gy), decreasing fractionation, daily radiation greater than 2.67 Gy, and use of once-daily rather than twice-daily radiation. Prior irradiation increases the risk as does previous or concurrent chemotherapy with multiple drugs.

- Regarding pulmonary function tests and radiation-induced lung abnormalities, which is *true*?
 - DLCO typically increases
 - Main abnormality is pulmonary restriction.
 - Abnormalities are usually severe.
 - Abnormalities are usually irreversible.

ANSWER: B. PFT abnormalities are typically mild and reversible; the main abnormality is pulmonary restriction. DLCO may decrease if a large volume of lung is involved.

- Regarding acute radiation pneumonitis, which is *true*?
 - Endothelial damage is not commonly encountered.
 - Thrombosis is a minor component.
 - Type II cells become depleted.
 - It is characterized by diffuse alveolar damage.

ANSWER: D. Endothelial damage is one of the earliest and most consistent findings of radiation pneumonitis. Platelet thrombi develop and can narrow or obstruct small vessels. Acute radiation pneumonitis is characterized by diffuse alveolar damage. Type II alveolar cells are hyperplastic and often have large bizarre nuclei.

- A patient undergoing radiation for Hodgkin lymphoma receives a 60-Gy dose to the chest. Which of the following characterizes the response?
 - Acute pneumonitis will become radiographically apparent 6 days after completion.
 - Acute pneumonitis will become radiographically apparent 6 weeks after completion.
 - Abnormalities will peak 6 weeks after completion.
 - Abnormalities will resolve 6 weeks after completion.

ANSWER: B. Acute radiation pneumonitis becomes radiographically apparent approximately 8 weeks after completion of a 40-Gy dose and a week earlier for every 10 Gy higher than that. Abnormalities peak 3 to 4 months after therapy.

- Regarding chronic radiation change, which of the following is *true*?
 - Usually begins after 3 to 4 months
 - Associated with hypoinflation

- C. Bronchopleural fistula is not a complication.
D. Associated with obstructive bronchiolitis

ANSWER: A. Chronic radiation damage typically starts after 3 to 4 months, increases gradually, and stabilizes within a year of radiotherapy completion. In more advanced cases, there is severe volume loss and normal architecture is lost. Patients may develop pneumothorax or bronchopleural fistula.

6. What are the CT findings in acute radiation pneumonitis?
A. Volume loss and bronchiectasis
B. Dense consolidation
C. Ground glass attenuation
D. Myocardial fibrosis

ANSWER: C. CT and HRCT reveal homogeneous ground glass attenuation or patchy-to-diffuse consolidation involving the radiated region, with well-defined borders due to the radiation port. In chronic radiation fibrosis, CT reveals dense consolidation or stranding with volume loss and traction bronchiectasis. Myocardial fibrosis, premature atherosclerosis of the aorta or coronary arteries, arterial stenosis, tracheal or bronchial stricture, and pericardial calcification may develop late.

7. Regarding ventilation–perfusion imaging, which is *true*?
A. Study is often normal.
B. Ventilation study is more often abnormal than the perfusion study.
C. Can resemble PTE findings
D. Radiation changes do not complicate evaluation of acute onset of dyspnea

ANSWER: C. Ventilation–perfusion scans are often abnormal: up to 95% of perfusion studies and up to 45% of ventilation studies. Most commonly a poorly perfused region is ventilated, sometimes similar in appearance to PTE.

8. Regarding tumor recurrence in MRI, which of the following is *true*?
A. Pleural effusion within 6 months of radiation raises concern for tumor
B. T2 signal intensity is higher than muscle.
C. MRI is more sensitive than PET.
D. Hemorrhage does not confound the appearance

ANSWER: B. In MRI radiation, fibrosis has T2 signal intensity lower than that of muscle, whereas tumor recurrence often has T2 signal intensity higher than that of muscle. Early effusion (within 6 months of treatment) is common and usually benign. Persistent

inflammation, infection, or hemorrhage increases T2 signal intensity as well. PET is more accurate and sensitive than MRI in diagnosing recurrence.

9. Regarding gallium-67 imaging in radiation change, which is *true*?
A. Less sensitive than chest radiography
B. May detect radiographically inapparent areas of pneumonitis
C. Radiation changes are inapparent on gallium-67 imaging.
D. Elevated radiotracer activity is specific for radiation pneumonitis.

ANSWER: B. Gallium-67 imaging may reveal the extent of radiation pneumonitis better than chest radiography, often detecting radiographically inapparent regions of pneumonitis. Gallium-67 imaging results in nonspecific images of inflammation. The clinical history is essential.

10. Regarding brachytherapy, which is *true*?
A. Complications include fatal hemoptysis
B. Large cell carcinoma is associated with lower risk of therapy.
C. Inflammatory changes peak at 40 weeks
D. Bronchiectasis is a common complication.

ANSWER: A. Changes are predominantly inflammatory at 16 weeks and predominantly fibrotic at 40 weeks. Complications include mucosal fibrosis, bronchial stenosis, localized radiation pneumonitis, bronchoesophageal fistula, and hemoptysis. In one study, stenosis was found to be developed in 12% of patients and 25% patients were found to have developed fatal hemoptysis. Large cell carcinoma, prior laser photoresection, and concurrent external-beam irradiation increase the risk of complications with brachytherapy.

28 MEDIASTINAL MASSES

Satinder P. Singh

THYMUS

Normal thymus arises bilaterally from the third and fourth brachial pouches, which contain elements derived from all three germinal layers. Thymic lesions can occur anywhere in the anterior mediastinum and also, since thymus migrates from the third and fourth brachial

TABLE 28-1 Origin of Anterior Mediastinal Masses

Thymus
Lymph node
Thyroid
Cysts
Lymphatic
Neurogenic

pouches to the anterior mediastinum during its development, ectopic thymic tissue, or ectopic thymoma can occur anywhere along this path.

Normal thymic size in healthy infants increases up to 4 to 8 months and then decreases with age due to fatty infiltration of the thymic gland. The maximum normal thickness of the thymus perpendicular to the longest axis is 18 mm in patients younger than 20 years of age, and 13 mm in older patients. The normal thymus on CT is usually seen at the level of the aortic arch and the origin of the great vessels as a bilobed homogeneous soft-tissue attenuation structure. On MRI, in a younger patient (younger than 20 years of age), the normal thymus is homogeneous with slightly low to intermediate signal intensity on T1-weighted images (greater than that of muscle, but less than of fat). The signal intensity is slightly greater than that of muscle, but equal or slightly less than that of fat on T2-weighted images.

Thymoma and thymic carcinoma are included in the differential diagnosis of anterior mediastinal masses (Table 28-1).

THYMOMA

Thymoma is the most common primary thymic tumor of epithelial origin. It is often seen in the fifth or sixth decade of age with no gender predilection. It is often asymptomatic. In one-third of the patients, compression or invasion of surrounding structures causes signs and symptoms of cough, pain, dysphagia, hoarseness, and dyspnea.

Parathymic syndromes include myasthenia gravis, pure red cell achalasia, and hypoglobulinemia. Approximately 40% of patients with thymoma have myasthenia gravis and 10% of the patients with myasthenia gravis have thymoma. Five percent of patients with thymoma have pure red cell achalasia and 10% to 50% of patients with red blood cell achalasia have thymoma. Occasionally, it is associated with stiff person syndrome, characterized by muscle rigidity and superimposed spasm of the trunk and limbs.

Tumors are usually round or oval, encapsulated with lobulated surface. Cyst formation (40%) and focal hemorrhage and necrosis (30%) are seen.

INVASIVE THYMOMA

Invasive thymoma occurs with invasion of adjacent structure. Pleural/pericardial implantation is common; transdiaphragmatic extension and extrathoracic metastasis is often present.

IMAGING FINDINGS

In one-third of patients with thymoma, tumor is suspected incidentally on chest radiograph. As an anterior mediastinal mass, it is better seen on the lateral radiograph. CT is superior to chest radiograph in the diagnosis and determining the extent of the tumor. Thymomas on CT appear as well defined, round, or oval masses with sharp margins or lobulated contours, usually with homogeneous attenuation, though may contain hemorrhage, cysts, or necrosis causing low attenuation areas. Cystic thymomas may manifest as masses containing fluid and soft-tissue components. The CT features are suggestive of capsular invasion and extracapsular extension and include irregular margins, gross invasion of great vascular structures or chest wall, encasement of mediastinal structures, and irregular interface with the lung. Thymoma may involve the pleura or pericardium (drop metastasis). There is nodular diffuse smooth or nodular pleural thickening mimicking mesothelioma. Pericardial involvement may leave pericardial nodules, thickening, and effusion. The tumor may extend to the abdominal cavity through the diaphragmatic foraminae (gravitational metastasis).

MRI

Masses are of low to intermediate signal intensity on T1-weighted images and intermediate to high signal intensity on T2-weighted images. Areas of necrosis and cysts appear as low signal on T1-weighted and high signal intensity on T2-weighted images. Hemorrhage is seen as high signal intensity on T1-weighted and T2-weighted or may demonstrate a hemosiderin ring or fluid level on T2-weighted or gradient echo images. The tumor enhances homogeneously after contrast. MR is usually superior to CT in assessing the invasion of the capsule or extracapsular extension.

TREATMENT AND PROGNOSIS

Encapsulated tumors usually respond to complete surgical excision with 5-year survival after excision at 92%. Invasive thymomas often need adjuvant radiation and chemotherapy, though controversial. If resected completely, their survival is similar to encapsulated tumors.

THYMIC CARCINOMA

The two most common types of thymic carcinomas are squamous cell and neuroendocrine carcinoma. These

account for 15% to 20% for all thymic epithelial tumors. They often lack capsule and demonstrate focal invasion or metastasis to mediastinal lymph nodes. These tumors are often large, lack visible septa or nodular structures, and may contain foci of necrosis and hemorrhage. Cystic changes and calcification are uncommon.

The most common clinical features include chest pain, cough, fatigue, fever, SVC syndrome, and anorexia. Not associated with myasthenia gravis or pure red cell achalasia, though paraneoplastic polymyositis has been reported. These are mostly middle-aged patients with slight female dominance. The tumor invades locally into the lungs, pericardium, and major vessels and may metastasize to lymph nodes or distantly to brain, bone, liver, or lung. These tumors have the worst prognosis in comparison to thymoma, though squamous cell carcinoma has a better prognosis in comparison to other thymic cancers.

In 25% of patients with thymic neuroendocrine tumor, there is a positive family history of multiple endocranial neoplasia (MEN) type 1 (pituitary adenoma, parathyroid adenoma, and pancreatic islet tumor). Eight percent of patients with MEN type 1 have thymic carcinoid tumor, mostly in males.

CLINICAL MANIFESTATIONS

These are mostly local symptoms in two-thirds of the patients from SVC syndrome or compression or invasion of mediastinal structures. Carcinoid syndrome is rare (less than 1%). Cushing syndrome is the most frequent paraneoplastic syndrome; up to 30% of thymic carcinoid tumors in adults and more than 50% of childhood thymic carcinoid are associated with Cushing syndrome.

IMAGING

Radiographs often show a large, poorly defined anterior mediastinal mass, better seen on CT, with areas of necrosis or cystic changes. The mass is often lobulated or irregular in contour with calcification seen in 10% to 40% of patients.

MRI

Neuroendocrine tumors have bright signal intensity on T2-weighted images, a feature that is highly suggestive of neuroendocrine tumor when present. The encasement and direct invasion adjacent mediastinal structures can be shown on MRI.

PET AND THYMIC CANCER

Thymic carcinoid tumors show a high uptake of FDG. Conventional bone scintigraphy and MRI are the most sensitive methods for detecting bone metastasis from carcinoid.

TREATMENT

Patients with thymic masses more than 3 cm should be resected. Twenty-five percent of patients after thymectomy demonstrate remission in myasthenia gravis.

GERM CELL TUMORS

These tumors occur most commonly in the gonads. Extragonadal germ cell tumors are often in midline, most commonly in the mediastinum, probably arising from the multipotential primitive germ cell misplaced along midline structures during embryogenesis (Table 28-2). Most of these are near or within the thymus and constitute 20% of all mediastinal tumor and cysts. The known risk factors for mediastinal nonseminomatous germ cell tumors are Klinefelter syndrome (47 XXY).

Teratoma is a neoplasm composed of several tissue components: with two of three embryonic layers represented. Mediastinal teratomas account for 50% to 70% of all mediastinal germ cell tumors. Teratomas are slightly more common in females, although immature teratomas occur exclusively in males. Mature teratoma is the most common type while immature teratomas are uncommon and constitute 1% of all mediastinal teratomas and are more aggressive in adults.

CLINICAL FEATURES

Usually teratomas are asymptomatic; in 50% of patients, though, large tumor may compress the surrounding structures producing symptoms. Rarely, they can rupture causing trichoptysis or pleural effusion. A rupture into the mediastinum can lead to mediastinitis. Hemorrhage into the tumor can lead to rapid increase in the size with severe retrosternal pain.

Usually, lobulated, encapsulated large tumors contain hair, teeth or bone, white, yellow, brown, oily sebaceous, or gelatinous material. Most tumors are cystic, unilocular, or multilocular with focal areas of solid components.

IMAGING FINDINGS

These are sharply margined, large, lobulated masses in the anterior mediastinum from the thoracic inlet to the diaphragm, anywhere in the mediastinum. There may be calcification in the cyst wall or tumor substance, or presence of teeth or bone. Rarely, a fat fluid level may be seen.

TABLE 28-2 Various Germ Cell Tumors

Teratoma
Seminoma
Embryonal carcinoma
Endodermal sinus tumor (yolk sac tumor)
Choriocarcinoma
Mixed germ cell tumor

CT demonstrates a large cystic mass in the prevascular space containing different variable CT attenuations corresponding to calcium, fat, fluid, and soft tissue. A mediastinal mass containing fat, calcification, and soft tissue with hair ball like opacities on CT is highly suggestive of teratoma.

MRI

The most common MRI finding of mature teratoma is a mass with markedly heterogeneous signal intensity. The masses are isointense to skeletal muscle; serous fluid shows low signal intensity on T1-weighted and high signal intensity on T2-weighted the intratumoral fat has high signal intensity on T1-weighted and relatively high signal intensity on T2-weighted images.

TREATMENT

Complete surgical excision has an excellent prognosis, nearly 100% 5-year survival.

SEMINOMAS (ALSO KNOWN AS GERMINOMA OR DISGERMINOMA)

These are usually seen in males in the third or fourth decade of life. One-third of patients with pure seminoma have moderately elevated serum beta-HCG levels, but normal serum AFP level.

CLINICAL SYMPTOMS

These include pain, dyspnea dysphagia, hoarseness, weight loss, and fever, though the patient can be asymptomatic in one-fourth of the cases.

IMAGING FINDINGS

Large, bulky-lobulated soft-tissue anterior mediastinal masses which can grow on either side of midline. CT shows a homogenous soft-tissue attenuation lobulated mass with minimal enhancement after contrast. Necrosis and calcification are rare.

TREATMENT AND PROGNOSIS

Tumors are radiosensitive and radiation therapy combined with cisplatin-based chemotherapy is the treatment of choice with a survival rate at 5 years of 75% to 100%. Poor prognostic features include higher tumor stage (lymph node metastasis, hepatic metastasis, or mediastinal invasion), older patients, SVC syndrome, and pyrexia.

NONSEMINATOUS MALIGNANT GERM CELL TUMORS

Nonseminatous malignant germ cell tumors include embryonal carcinoma, endodermal sinus tumor, choriocarcinoma, and mixed germ cell tumor. These tumors are

more common in males and are mostly symptomatic in 90% to 100% of patients. Associations include Klinefelters syndrome in 20%, hematologic malignancies, elevated AFP, endodermal sinus tumor or embryonal carcinoma, elevated HCG (choriocarcinoma).

PATHOLOGIC FINDINGS

The embryonal carcinoma is a germ cell tumor composed of large primitive cells of epithelial appearance with abundant clear or granular cytoplasm, resembling embryonal germ disc cells with tubular and acinar patterns.

ENDODERMAL SINUS TUMOR

This tumor is characterized by a pattern similar to that of yolk sac allantois and extraembryonic mesenchym with reticular pattern and multiple communicating spaces.

CHORIOCARCINOMA

This is a highly malignant neoplasm with cytotrophoblast and syncytiotrophoblast and hemorrhage. The mean age of presentation is around 27 years of age and symptoms include thoracic or shoulder pain, shortness of breath, hoarseness, cough, or SVC syndrome. These tumors frequently invade adjacent structures, mediastinal pleura, and lung and 50% have hematogenous metastasis at the lymph nodes as well as distant organs.

IMAGING FINDINGS

Large anterior mediastinal masses with smooth lobular or irregular margins are identified. At CT, there is heterogeneous attenuation of the large masses with central areas of low attenuation, peripheral enhancement. Pleural and pericardial effusions are often present. Direct tumor invasion of adjacent structures can be seen. As with other tumors, MRI is more sensitive in depicting infiltration into adjacent chest wall, mediastinal pleura, pericardium, heart, or great vessels.

TREATMENT AND PROGNOSIS

The treatment and prognosis carries the poorest prognosis among all germ cell tumors. Cisplatin-based chemotherapy is the therapy of choice. Serum tumor markers are helpful in assessing the response to treatment or tumor recurrence.

THYMIC CYSTS

Thymic cysts are uncommon and can be found along the embryologic course of the thymus in the mediastinum or

neck. They are a congenital anomaly of the third pharyngeal pouch. They are usually seen in young patients, asymptomatic and have an excellent prognosis.

IMAGING FINDINGS

Smooth or round and may contain calcification in the cyst wall. Differential diagnosis for thymic cyst includes cystic thymoma, cystic teratoma, cystic degeneration of Hodgkins lymphoma, and other cysts.

THYMOLIPOMA

Usually found in young patients without gender predilection. It is asymptomatic in 50% of cases. A large tumor can be symptomatic.

RADIOGRAPHIC FINDINGS

These lesions can be unilateral or bilateral, often in the anterior inferior mediastinum. They may conform to the shape of the heart, mimicking cardiac enlargement and may drape along a hemidiaphragm mimicking elevation of the diaphragm. They may also change in shape with change in positions. CT and MRI are useful in identification of fat within the mass.

MEDIASTINAL LYMPHOMA

Primary mediastinal lymphoma arises in the mediastinal lymph nodes or in the thymus and is relatively common. The most common type of primary mediastinal lymphomas include large B-cell lymphoma, precursor T-cell lymphoblastic lymphoma/leukemia, and classic Hodgkins lymphoma, especially the nodular sclerosing variety.

PRIMARY MEDIASTINAL LARGE B-CELL LYMPHOMA

Primary mediastinal large B-cell lymphoma accounts for approximately 2% to 3% of non-Hodgkin lymphoma. Usually found in young patients with female predominance.

PRECURSOR T-CELL LYMPHOBLASTIC LYMPHOMA/LEUKEMIA

Precursor T-cell lymphoblastic lymphoma/leukemia occurs frequently in late childhood, adolescent or young adulthood with male predominance. These tumors constitute only 2% of adult non-Hodgkin lymphoma.

HODGKINS LYMPHOMA

This is derived from B-cells in most cases. Two main varieties are nodular lymphocyte predominant Hodgkin lymphoma and classic Hodgkins lymphoma.

The nodular sclerosing Hodgkins lymphoma is a subtype of the classic Hodgkin lymphoma with collagen band surrounding the nodule and lacunar type of Hodgkin and Reed-Sternberg cell. It is especially common in higher socioeconomic groups, urban areas and industrialized countries. There is a slight female predominance and a median age of 28 years.

CLINICAL PRESENTATION

These are usually because of a large bulky mediastinal mass causing superior vena cava syndrome, airway obstruction, and pleural or pericardial effusions. The precursor T-cell lymphoblastic lymphoma usually presents acutely with airway compromise, SVC syndrome, and massive pleural or pericardial effusion causing cardiac tamponade.

The nodular sclerosing Hodgkins lymphoma usually presents with chest discomfort and dyspnea or may be asymptomatic with tumor discovered incidentally on chest radiography.

IMAGING FINDINGS

This usually presents as a large anterior mediastinal mass causing widening of the mediastinum and obliteration of retrosternal space on the lateral radiograph. Bulky anterior mediastinal adenopathy is the hallmark of Hodgkins lymphoma. Pleural effusion may be present, especially in one-third of patients with primary large B-cell lymphoma and is often associated with poor prognosis. In Hodgkins lymphoma, the mediastinal hilar para-aortic or deep cervical lymph nodes may be enlarged and the thymus may also be involved in up to 30% of cases. There may be mass effect on the adjacent mediastinal structures, pleura, pericardium, or chest wall. The vascular involvement is less common with Hodgkins (7%) in comparison to non-Hodgkins lymphoma (40%–60%). The lung involvement rate is higher in Hodgkins (20%) in comparison to non-Hodgkins (less than 10%). SVC syndrome can be nicely seen on contrast-enhanced CT including its collateral circulation and mediastinal edema.

MRI

Hodgkins lymphoma has a relatively homogeneous low signal intensity on T1-weighted images similar to muscle and mixed or relatively high signal intensity on T2-weighted images, equal or slightly higher than fat.

PET

Often performed to evaluate response to therapy and detect early treatment failure, as well as follow up of patients with lymphoma.

LYMPHANGIOMA

Benign, rare mesenchymal lesions in the mediastinum, typically found in children and young adults. Ninety percent are discovered by 2 years of age. The majority involves the neck or axilla and in 10% extends into the superior aspect of the anterior mediastinum.

PATHOGENESIS

Proliferation of lymph vessels sequestered from the lymphatic system in early development. Fluid accumulates in the lumen of the lymph vessels resulting from lack of communication with the lymphatic tree. When these lesions contain large cystic spaces, they are referred to as cystic hygroma. Small cystic spaces are cavernous lymphangioma.

IMAGING FINDINGS

Soft-tissue mass in the anterosuperior mediastinum may extend into the middle and posterior compartments. Cervical and axillary mass is often present. CT shows fluid density content and septations may be seen. In one-third of cases, multilocular cystic masses are present with cysts demonstrating minimal enhancement after contrast.

NEUROGENIC TUMORS

Most mediastinal and paravertebral neurogenic tumors in adults are benign. Neurogenic tumors constitute approximately 20% of all resected primary mediastinal neoplasms in adults. They constitute 75% of primary posterior mediastinal neoplasms.

SCHWANNOMA

This is the most frequent mediastinal neurogenic tumors, usually seen in the third and fourth decades of life without any sex predilection. Most patients are asymptomatic though chest pain or discomfort is most common symptom when present.

IMAGING FINDINGS

This consists of a smooth or oval, round mass. Adjacent bone changes including erosion, splaying of the ribs, or enlargement of the intervertebral foramina may be seen. CT shows a homogeneous attenuation of the large masses with a variable contrast enhancement. The masses are low to intermediate signal intensity on T1-weighted MR and have intermediate to high signal intensity on T2-weighted image with peripheral enhancement after gadolinium injection. MRI is useful in patients with suspected intraspinal tumor extension.

TABLE 28-3 Neurogenic Tumors

Arising from peripheral nerves:

Schwannoma
Neurofibroma

Malignant tumor of nerve sheath origin:

Autonomic ganglia tumors
Ganglioneuroma
Neuroblastoma

Neoplasm of paraganglia:

Paraganglioma

NEUROFIBROMA

This is the second most common neurogenic mediastinal tumor, more frequent in male than in females, usually in their twenties to forties, single or multiple, commonly associated with neurofibromatosis. The affected nerve is circumferentially compressed or diffusely penetrated by the tumor.

IMAGING FINDINGS

Smooth rounded masses of homogeneous attenuation on CT. Tumor may grow through the intervertebral foramina into the spinal canal resulting in dumb-bell or hour-glass configuration.

MRI

Homogeneous low to intermediate signal intensity on T1-weighted. On T1-weighted images, the tumors have high signal intensity in the peripheral zone and a slightly lower intensity area in the center (target sign) (Table 28-3).

MALIGNANT TUMOR OF NERVE SHEATH ORIGIN

Malignant tumor of nerve sheath origin is also known as neurofibrosarcoma, and it may occur in patients with or without neurofibromatosis. Sarcomatous degeneration in neurofibromatosis is around 5%. Usually patients are young, 20 to 40 years of age, with equal sex predilection. Features favoring diagnosis of malignant nerve sheath tumor include a large size (more than 5 cm), large low attenuating areas within the primary tumor, irregular ill-defined margins, compression or destruction of the adjacent structures, pleural nodules, or effusions or presence of metastatic pulmonary nodules.

TUMORS OF SYMPATHETIC GANGLIA

These are predominantly seen in infants and children and more than 50% of malignant and include ganglioneuroma, ganglioneuroblastoma, and neuroblastoma.

GANGLIONEUROMA

These are benign and well differentiated, attached to either sympathetic or intercostal nerve. The majority occurs in patients younger than 20 years of age, in males more than females. Prognosis is excellent after surgical resection.

The most common site of tumors is the paravertebral region followed by retroperitoneum and, least common, cervical region.

IMAGING

Ganglioneuromas are elongated masses oriented in the vertical axis of the sympathetic chain. These are oval lesions with very little mass effect on surrounding soft tissue. They are low attenuating on noncontrast CT and show mild-to-moderate enhancement after intravenous contrast. Foci of calcification may be seen in 20% of patients and these calcifications are usually punctuate and discrete (rather than amorphous and coarse as in neuroblastoma). They demonstrate homogeneous intermediate signal intensity on T1-weighted and T2-weighted sequences. They may have a whorled appearance.

GANGLIONEUROBLASTOMA

These tumors contain components of malignant neuroblastoma as well as benign ganglioneuroma. Calcification is frequent and is commonly seen in younger children and rare after the age of 10. The most common site is in the abdomen, followed by mediastinum, neck, and lower extremity.

IMAGING

Similar to ganglioneuroma, they are well defined, vertically oriented soft-tissue masses with variable cystic areas.

NEUROBLASTOMA

This is the most common malignancy of early childhood. Fifty percent of patients are younger than 2 years and 90% are younger than 5 years. The most common location is the adrenal with the mediastinum the second most common location. These are neural crest origin tumors.

IMAGING

Thoracic neuroblastoma is always paravertebral and may contain calcification in up to 10% and rib or vertebral erosion may also be present.

These tumors lack a capsule and have areas of inhomogeneity due to tumor necrosis. The prognosis is poor,

25% with a 2-year survival. There is a better prognosis of children younger than 1 year of age.

Tumors are paraganglionic in origin (paraganglioma), also known as chemodectoma. Rare neural tumors arise from the paraganglion cell. In the thorax, they arise near the base of the heart and great vessels, adjacent to the pericardium or heart within the interatrial septum or left atrial wall.

IMAGING

They appear as soft-tissue masses in the aortopulmonary window or paravertebral region. They show extensive enhancement after intravenous contrast, with low to intermediate signal intensity on T1-weighted images and intermediate to high signal intensity on T2-weighted images. Surgical excision can be challenging and may not be possible due to extensive collateral vascularity of these masses.

QUESTIONS AND ANSWERS

- Which of the following statement is *false*?
 - Thymus arises from fourth and fifth a brachial pouches.
 - Normal thymic size increases in healthy infants up to 4 to 8 weeks.
 - Normal thymus contains elements derived from all three germinal layers.
 - In younger individuals, normal thymus has low to intermediate signal intensity on T1-weighted images.

ANSWER: A. Normal thymus arises bilaterally from the third and fourth (and not fourth and fifth) brachial pouches, which contain elements derived from all three *germinal* layers. Normal thymic size in healthy infants increases up to 4 to 8 months and then decreases with age due to fatty infiltration of the thymic gland. On MRI, in a younger patient, younger than 20 years of age, the normal thymus is homogeneous with slightly low to intermediate signal intensity on T1-weighted images (greater than

that of muscle, but less than of fat). The signal intensity is slightly greater than that of muscle, but equal or slightly less than that of fat on T2-weighted images.

2. Which of the following is *true* regarding thymoma?
 - A. Most common primary thymic tumor of epithelial origin in young male adults
 - B. Majority of patients are asymptomatic.
 - C. 40% of myasthenia gravis patients have thymoma.
 - D. 15% of thymoma have red cell aplasia.

ANSWER: B. Thymoma is the most common primary thymic tumor of epithelial origin. It is often seen in the fifth or sixth decade of age with no gender predilection. It is typically asymptomatic; however, in one-third of the patients, compression or invasion of surrounding structures causes cough, pain, dysphagia, hoarseness, and dyspnea. Parathymic syndromes include myasthenia gravis, pure red cell aplasia, and hypoglobulinemia. Approximately 40% of patients with thymoma have myasthenia gravis and 10% of the patients with myasthenia gravis have thymoma. Five percent of patients with thymoma have pure red cell aplasia and 10% to 50% of patients with red blood cell achalasia have thymoma.

3. Regarding invasive thymoma, which of the following is *false*?
 - A. Encapsulated tumors usually respond to complete surgical excision with excellent 5-year survival after excision.
 - B. MR is more sensitive than CT in detecting extracapsular extension.
 - C. Drop metastases are common.
 - D. Chest radiography is usually abnormal.

ANSWER: D. Thymomas with invasive of adjacent structures, pleural/pericardial implantation is common, transdiaphragmatic extension and extrathoracic metastasis is present. Only in one-third (not majority) of patients with thymoma, tumor is identified incidentally on chest radiograph. As an anterior mediastinal mass, it is better seen on the lateral radiograph. CT is superior to chest radiograph in the diagnosis and determining the extent of the tumor. Thymoma may involve the pleura or pericardium (drop metastasis). There is nodular diffuse smooth or nodular pleural thickening mimicking mesothelioma. Pericardial involvement may leave pericardial nodules, thickening, and effusion. The tumor may extend to the abdominal cavity through the diaphragmatic foramina (gravitational metastasis). MR is usually superior to CT in assessing the invasion of the cap-

sule or extracapsular extension. Encapsulated tumors usually respond to complete surgical excision with a 5-year survival of 92%. Invasive thymomas often need adjuvant radiation and chemotherapy, though controversial. If resected completely, their survival is similar to encapsulated tumors.

4. Regarding thymic cancer, which of the following is *true*?
 - A. Fifty percent patients with MEN type 1 have thymic carcinoid.
 - B. Cystic changes and calcification are common.
 - C. Tumor is more aggressive in patients with MEN type 1.
 - D. Association with red cell aplasia is common.

ANSWER: C. Thymic carcinoma accounts for 15% to 20% of all thymic epithelial tumors. They often lack capsule and demonstrate focal invasion or metastasis to mediastinal lymph nodes. These tumors are often large, lack visible septa or nodular structures, and may contain foci of necrosis and hemorrhage. Cystic changes and calcification are uncommon. They are not associated with myasthenia gravis or pure red cell aplasia, though paraneoplastic polymyositis has been reported. In 25% of patients with thymic neuroendocrine tumor, there is a positive family history of multiple endocrinal neoplasia (MEN) type 1 (pituitary adenoma, parathyroid adenoma, and pancreatic islet tumor). Eight percent of patients with MEN type 1 have thymic carcinoid tumor, mostly in males.

5. Which of the statements regarding germ cell tumors is *false*?
 - A. Extragonadal germ cell tumors are often in midline, most commonly in the mediastinum.
 - B. The known risk factor for mediastinal nonseminomatous germ cell tumors is 47XXY.
 - C. Seminoma is the most common germ cell tumor.
 - D. Complete surgical excision has an excellent prognosis.

ANSWER: C. Germ cell tumors occur most commonly in the gonads. Extragonadal germ cell tumors are often in midline, most commonly in the mediastinum, probably arising from the multipotential primitive germ cell misplaced along midline structures during embryogenesis. Most of these are near or within the thymus and constitute 20% of all mediastinal tumor and cysts. Klinefelter syndrome (47XXY) is a known risk factor for mediastinal nonseminomatous germ cell tumors. Teratoma and not seminoma is the most common germ cell tumor. Complete surgical excision has an excellent prognosis, nearly 100% 5-year survival.

6. Which of the following is *true* regarding seminomatous germ cell tumors?
- A. Presence of pyrexia is a poor prognostic feature.
 - B. In >80% of patients, serum AFP is elevated.
 - C. Tumors are bulky with necrosis and calcification common.
 - D. Tumors are radioresistant.

ANSWER: A. Seminomas are usually seen in males in the third or fourth decade of life. One-third of patients with pure seminoma have moderately elevated serum beta-HCG levels, but normal serum AFP level (not elevated).

Tumors are large bulky lobulated soft-tissue anterior mediastinal masses, which can grow on either side of midline. Necrosis and calcification are rare and not common. Tumors are radiosensitive, and radiation therapy combined with cisplatin-based chemotherapy is the treatment of choice with a survival rate at 5 years of 75% to 100%. Poor prognostic features include higher tumor stage (lymph node metastasis, hepatic metastasis, or mediastinal invasion), older patients, SVC syndrome, and pyrexia.

7. All of the following are nonseminatous germ cell tumors *except*:
- A. Embryonal cell carcinoma
 - B. Yolk sac carcinoma
 - C. Teratoma
 - D. Endodermal sinus tumor

ANSWER: C. Nonseminatous malignant germ cell tumors include embryonal carcinoma, endodermal sinus tumor, choriocarcinoma, and mixed germ cell tumor. Teratoma is the most common mediastinal germ cell tumor.

8. Which of the following regarding neurogenic tumors is *true*?
- A. Most mediastinal and paravertebral neurogenic tumors in adults are malignant.
 - B. Constitute only 5% of all resected primary mediastinal neoplasms in adults.
 - C. Constitute 75% of primary posterior mediastinal neoplasms.
 - D. Ganglioneuroma is the most common mediastinal neurogenic tumor.

ANSWER: C. Most mediastinal and paravertebral neurogenic tumors in adults are benign. Neurogenic tumors constitute approximately 20% of all resected primary mediastinal neoplasms in adults. They constitute 75% of primary posterior mediastinal neoplasms. Schwannoma is the most frequent mediastinal neurogenic tumors, usually seen in the third and fourth decades of life without any gender predilection.

9. Features favoring sarcomatous degeneration in neurofibroma include all *except*:
- A. Large size >5 cm
 - B. High attenuating areas in tumor
 - C. Irregular margins
 - D. Compression or destruction of adjacent structures

ANSWER: B. Malignant tumor of nerve sheath origin is also known as neurofibrosarcoma. May occur in patients with or without neurofibromatosis. Sarcomatous degeneration in neurofibromatosis patient is around 5%. Usually patients are young, 20 to 40 years of age, with equal gender predilection. Features favoring diagnosis of malignant nerve sheath tumor include a large size (more than 5 cm), large low (not high) attenuating areas within the primary tumor, irregular ill-defined margins, compression or destruction of the adjacent structures, pleural nodules, or effusions or presence of metastatic pulmonary nodules.

10. Which of the following is *true* regarding neurogenic tumors?
- A. Neurofibroma is the most common neurogenic mediastinal tumor.
 - B. Ganglioneuroma arises from parasympathetic nerves.
 - C. Ganglioneuroblastoma is usually seen before age 10.
 - D. Paraganglioma commonly located in the paravertebral location in the thorax.

ANSWER: C. Neurofibroma is the second most common neurogenic mediastinal tumor (Schwannoma is the most common). It is more frequent in males than females, usually in their twenties to forties, single or multiple, commonly associated with neurofibromatosis. Ganglioneuromas are benign and well differentiated, attached to either sympathetic or intercostal nerve (not parasympathetic nerve). The majority occurs in patients younger than 20 years of age, in males more than females. Prognosis is excellent after surgical resection. Ganglioneuroblastoma tumors contain components of malignant neuroblastoma as well as benign ganglioneuroma. Calcification is frequent and is commonly seen in younger children and rare after the age of 10. The most common site is in the abdomen, followed by mediastinum, neck, and lower extremity. Paraganglioma, also known as chemodectoma, are rare neural tumors arising from the paraganglion cell. In the thorax, they arise near the base of the heart and great vessels, adjacent to the pericardium or heart within the interatrial septum or left atrial wall (and not paravertebral location).

29 PLEURAL DISEASES

Satinder P. Singh

NORMAL PLEURAL ANATOMY

The pleura is the serous membrane of continuous surface epithelium of mesothelial cells and underlying connective tissue that covers the lung parenchyma, mediastinum, diaphragm, and the rib cage. The visceral pleura lines the lungs and fissures, and the parietal pleura lines the non-parenchymal surfaces inside of the thoracic cavities. The pleural space is a potential space containing 2 to 10 cm³ of pleural fluid normally. Its fluid production capacity is approximately 100 cm³/h and fluid absorption capacity is approximately 300 cm³/h. The parietal pleura is composed of loose, irregular connective tissue covered by a single layer of mesothelial cells. Within the pleura are blood vessels, capillaries, and lymphatic lacunas. Deep to the parietal pleura is the endothoracic fascia, a band of dense irregular connective tissue composed mainly of collagen and elastin, covering the ribs and intercostal space. The visceral pleura in humans is a thick membrane composed of two layers: mesothelium and connective tissue. The connective tissue layer in the visceral pleura has two important functions: It contributes to the elastic recoil of the lung, which is important in expelling air from the lung, and it restricts the volume to which the lung can be inflated, thereby protecting the lung.

The mesothelial cells range in size from 6 to 12 μm in diameter. Under the electron microscope, the pleural surface is visible as either flattened or bumpy. Microfillae are also noted diffusely over the entire pleural surface. The most important function of microfillae is to enmesh glycoproteins rich in hyaluronic acid, especially in the lower thorax to decrease the friction between the lung and chest wall.

The mesothelial cells are active cells, but are very fragile and sensitive/responsive to various stimuli. Mesothelial cells produce type 1, type 2, type 4 collagens, elastin, fibronectin, and laminin. They also express intermediate filaments typical of both epithelial cells and fibroblasts, express coagulant activity because of a tissue factor that binds factor 7 at the cell surface. These cells also produce nitric oxide and transforming growth factor beta-1. The normal flux of fluid in the pleural space is from parietal capillaries to pleural space to visceral capillaries.

BLOOD SUPPLY OF THE PLEURA

The parietal pleura receives blood supply from systemic capillaries. Small branches of the intercostal arteries

supply the costal pleura, and the pericardial phrenic artery supplies the mediastinal pleura. The diaphragmatic pleura is supplied by the superior phrenic and musculophrenic arteries. The venous drainage of the parietal pleura is primarily via the intercostal veins which drain into the inferior vena cava or brachiocephalic trunk.

The blood supply to the viscera pleura is variable; in animals with thin pleura, the blood supply is from pulmonary circulation, whereas in animals with thick pleura, the blood supply is systemic via the bronchial arteries. The venous drainage of the visceral pleura is through the pulmonary veins.

The lymphatic vessels of the costal pleura drain ventrally toward nodes along the internal thoracic artery and dorsally toward the internal intercostal lymph nodes near the head of ribs. The mediastinal pleural lymphatic vessels pass to the tracheobronchial and mediastinal nodes while the lymphatic vessels of the diaphragmatic pleura pass to the parasternal, middle phrenic, and posterior mediastinal nodes. The visceral pleura lymphatics form a plexus of intercommunicating vessels that run over the surface of the lung toward the hila and also penetrate the lung to join the bronchial lymph vessels passing in the interlobular septa. Normally, fluid from the pleural surface does not enter the lymphatics and visceral pleura in humans. The lymphatic vessels in the parietal pleura have stomas communicating with the pleural space (2–6 μm in diameter). These stomas are found mostly on the mediastinal pleura and intercostal surface. The dilated lymphatic spaces called lacinas are found in the submesothelial layer of the parietal pleura. The stomas, with their associated lacinas and lymphatic vessels, are the main pathway for the elimination of particulate matter from the pleural space. No stomas are found in the visceral pleura and the lymphatic vessels of the visceral pleura are separated from the mesothelial layer by a connective tissue layer.

Kampmeier described small milky spots in the dorsal and caudal portions of the mediastinum. Microscopically, these spots are aggregates of lymphocytes, histiocytes, plasma cells, and other mononuclear cells around the central lymphatic or vascular vessel. The high concentration of asbestosis in these foci leads to the development of pleural plaque and mesothelioma. The black spots in patients with parietal anthracosis correspond to the Kampmeier foci and the distribution of asbestosis fiber in the pleura is also concentrated in these foci.

Sensory nerve endings are present in the costal and diaphragmatic parietal pleura: intercostal nerves supply the costal and the peripheral portion of the diaphragmatic pleura. Stimulation of this area leads to pain referred to the edges and chest wall. The central portion of the diaphragm is innervated by the phrenic nerve; stimulation of this pleura causes pain in the ipsilateral shoulder. The

visceral pleura contains no pain fibers. Therefore presence of pleuritic chest pain indicates inflammation or irritation of the parietal pleura.

PHYSIOLOGY OF THE PLEURAL SPACE

The pressure within the pleural space is important in cardiopulmonary physiology because this pressure plays an important role in determining the volume of three important structures: Outer surface of the lung, heart, and the inner surface of the thoracic cavity. At functional residual capacity, the opposing elastic forces of the chest wall and the lung produce a negative pressure between the visceral and parietal pleura called the pleural pressure. This pressure around the lung is the primary determinate of the volume of the lung. The pleural pressure represents the balance between the outward pull of the thoracic cavity and the inward pull of the lung. The normal pleural pressure ranges between 0.5 to 1 cm H₂O per centimeter vertical height. The pleural pressure can be safely measured indirectly via a balloon or micromanometer positioned in the esophagus. Normally, the pleural pressure is not uniform throughout the pleural space. There is often a gradient in pleural pressure with the pleural pressure being lowest and most negative in the superior aspect and highest or least negative in the inferior portion of the lungs. The factor responsible for this pleural pressure gradient includes gravity, mismatching of the shapes of the chest wall and lung, and weight of the lung and other intrathoracic structures. In an upright position, the difference in the pleural pressure between apex and the base of the lung may be 12 cm or more. Because the alveolar pressure is constant throughout the lungs, gradient in the pleural pressure results in the different parts of the lung have different distending pressures. The pleural pressure gradient causes the alveoli in the superior part of the lung to be larger than those in the inferior part of the lung. Pleural pressure gradient also accounts for the unevenness of the distribution of ventilation. Normally, the pleural pressure is a negative pressure.

Fluid in the pleural space can originate in the pleural capillary, interstitial spaces of the lungs, intrathoracic lymphatics, intrathoracic blood vessels, or the peritoneal cavity. The movement of the fluid in the pleural capillaries and pleural spaces is governed by the Starling's law.

PATHOGENESIS OF PLEURAL EFFUSION

When the rate of pleural fluid formation exceeds the rate of pleural fluid absorption, fluid accumulates in the

TABLE 29-1 Causes of Pleural Effusion

Increased pleural fluid formation
Increased interstitial fluid in the lung; heart failure, pneumonia, or PTE
Increased intravascular pressure in the pleura; right or left ventricular failure, SVC syndrome
Increased permeability of the capillaries in the pleura; pleural inflammation, increased VEGF
Increased pleural fluid protein level
Decreased pleural pressure; lung atelectasis or increased elastic recoil of the lung
Increased fluid in the peritoneal cavity; ascites or peritoneal dialysis
Disruption of the thoracic duct
Disruption of blood vessels in the thorax
Decreased pleural fluid absorption
Obstruction of the lymphatic draining the parietal pleura
Elevation of the systemic vascular pressures; SVC syndrome or right ventricular failure

VEGF: vascular endothelial growth factor

pleural space. Normally, a small amount (0.01 mL/kg/h) of fluid constantly enters the pleural space from capillaries in the parietal pleura. Almost all of the fluid is removed by lymphatics in the parietal pleura, which has a capacity to remove at least 0.20 mL/kg/h (nearly 20 times the inflow). Fluid can accumulate because of either increased pleural fluid formation or decreased pleural fluid absorption (Table 29-1).

Normally there is no air in the pleural space and any movement of gas into the pleural space occurs only if the pleural pressure is less than 6 or 7 mm Hg or less than -54 mm Hg relative to atmospheric pressure. Presence of air in the pleural space indicates one of three things: communication between the alveoli and the pleural space, communication between the atmosphere and the pleural space, or presence of gas-producing organisms in the pleural space. The rate of absorption of air in the pleural space depends upon the difference between sum of the partial pressure in the pleural space and in the capillary blood. Since the sum of the partial pressure in the capillary blood is most dependent on the PO₂, this sum can be decreased by having the patient to breath supplemental oxygen which reduces the PO₂ of the capillary blood without changing the other parietal pressures. Therefore, in patients who have a small pneumothorax, administration of supplemental oxygen facilitates the resorption of the pneumothorax. The most common causes of pleural effusion in the United States is congestive heart failure (Tables 29-2 and 29-3). Pleural fluid can be transudate or exudate (Table 29-4). The number of neutrophils in the pleural fluid is correlated with the ILD-8 levels and empyemas have the highest level of ILD-8. Examination of the pleural fluid neutrophil in patients with parapneumonic effusion is useful. If pleural infection is present, the neutrophils

undergo a characteristic degeneration; nucleus become blurred and no longer is stained purple, cytoplasm shows toxic ventilation initially and later neutrophilic granules become indistinct and are lost. Pleural eosinophilia is present when there are more than 10% of eosinophils in the pleural fluid. The most common cause of pleural fluid eosinophilia is air in the pleural space; the mechanism responsible is unknown, probably related to IL-5. The second most common cause of pleural fluid eosinophilia is blood in the pleural space (Table 29-5). Other causes include parapneumonic effusion, malignancy, tuberculosis, asbestos-related pleural effusion, pleural effusion secondary to drug reaction (dantrolene, brocryptedin, and nitrofurantoin), infections secondary to parasites (paragonimiasis, hydatidosis, amebiasis, or ascariasis) and pleural effusion associated with Churg-Strauss syndrome is eosinophilic. A low

pH of pleural fluid	Higher than the simultaneous blood pH	Usually lower less than 7.2

pleural fluid glucose level (less than 16 mg/dL) indicates parapneumonic effusion, malignant disease, rheumatoid disease, tuberculous effusion or tuberculous pleuritis.

Pleural fluid amylase above the upper normal limit for serum amylase indicates one of three problems: pancreatic disease, malignant tumor, or esophageal rupture. Most patients with high LDH in pleural fluid have exudative effusions and those with normal protein level but high LDH are either parapneumonic or have malignant pleural disease. Pleural fluid LDH is a reliable indicator of the degree of pleural inflammation; the higher the LDH, the more inflamed the pleural surfaces. Pleural fluid from patients with mesothelioma is often abnormally viscous. This increased viscosity is due to the presence of an increased amount of hyaluronic acid (hyaluronate).

As many as 40% of hospitalized patients with bacterial pneumonia have accompanying pleural effusions and morbidity and mortality rates in patients with pneumonia and effusion is higher than that in patients with pneumonia alone. Most effusions associated with pneumonia resolve without any specific therapy directed toward the effusion; only 10% of patients require operative intervention for their resolution (Table 29-6).

Pleural fluid markers for tuberculosis include:

Pleural fluid ADA level: If pleural fluid ADA level is more than 50 U/L and the patient has predominant lymphocytes in the pleural fluid, diagnosis of tuberculosis is certainly made.

Pleural fluid interferon-gamma level: Elevated levels of interferon levels are noted in tuberculous pleuritis. Using a cutoff level of 3.7 U/mL, a sensitivity of 0.99 and specificity of 0.98 has been reported in tuberculous effusions.

RADIOGRAPHIC FINDINGS

In patients with free pleural effusion, a concave upward sloping at costophrenic angle (meniscus appearance) is commonly seen. In the presence of subpulmonic effusion, there is lateral displacement of apex of the diaphragm and flat superior surface with sharp downward slanting. Increased haziness and presence of apical cap on supine radiographs often suggest presence of effusion. Blunt posterior costophrenic angle occurs with fluid more than 75 cm³. Blunt lateral costophrenic angle occurs with more than 200 cm³. Fluid layering on a decubitus radiograph represents more than 5 cm³ of fluid. Ultrasound is much more sensitive in detecting small pleural effusion and presence of echogenic or anechoic fluid with septations suggests exudate.

EMPHYEMA

Empyema by definition is the presence of thick purulent pleural fluid. The differentiation of empyema from parapneumonic effusion is a subject of debate. The evolution of parapneumonic effusion has three stages:

1. Exudative stage—containing sterile pleural fluid in the pleural space with fluid likely originating from the interstitial spaces of the lung. The pleural fluid has a low WBC, low LDH, and a normal glucose level and pH.
2. Fibropurulent stage—characterized by a large effusion with many polymorphonuclear leukocytes, bacteria, and cellular debris. Fibrin is deposited as a continuous sheet with increased tendency toward loculation and formation of limiting membrane. At this stage, the pleural fluid pH and glucose levels are progressively lower and the LDH level progressively higher.
3. Organization stage—where fibroblasts grow into the exudative state producing an elastic membrane called “pleural peel.” This peel encases the lung and renders it virtually functionless. The exudate is thick and if the patient remains untreated, the fluid may drain spontaneously through the chest wall (empyema necessitans) or into the lung producing a bronchopleural fistula.

Incidence of infected pleural effusion is more common in anaerobic bacterial pneumonias.

RADIOGRAPHIC APPEARANCE

In the early stages, empyema appears as a free pleural effusion. In the later fibropurulent stage, more loculation appears, which can be detected on decubitus radiograph, CT, or ultrasound. An air-fluid level in the empyema can mimic lung abscess. Empyemas tend to be lenticular shaped and have different diameters on PA and lateral views, whereas abscesses are spherical and have the same diameters on PA and lateral views.

On CT, a strong enhancement of both visceral and parietal pleura separated by unenhancing fluid is useful in distinguishing empyema from lung abscess and is referred to as the split pleura sign. Development of a new air-fluid level in the empyema indicates the development of a bronchopleural fistula. Air-fluid level of empyema crosses fissures and may extend to chest wall and is longer in one view.

PLEURAL EFFUSIONS RELATED TO METASTATIC MALIGNANCIES

Carcinoma of the lung, breast cancer and lymphoma accounts for 75% of malignant pleural effusions. Metastatic ovarian cancer is the fourth leading cause of malignant effusion. Malignant pleural effusion is usually bloody and exudative in nature (Table 29-5).

CHYLOTHORAX AND PSEUDOCYLOTHORAX

A high level of lipid accumulates in the pleural fluid in two situations: when the thoracic duct is disrupted, chyle enters the pleural space to produce a chylous pleural effusion (chylothorax), and in long-standing pleural effusions, a large amount of cholesterol or lecithin-globulin complexes accumulate in the pleural fluid to produce chyloform-like pleural effusion (pseudochylothorax).

CHYLOTHORAX

Cisternal chyli overlies the anterior surface of the second lumbar vertebra, posterior to and to the right of the aorta. Normally, one major lymphatic vessel, the thoracic duct, leaves the cistern of chyli and passes through the esophageal hiatus of the diaphragm (T-10 level) into the thoracic cavity. The thoracic duct ascends extrapleurally in the posterior mediastinum along the right side of the anterior surface of the vertebral column and lies

between the azygous vein and descending thoracic aorta in close proximity to the esophagus and pericardium. At T4-6 vertebral levels, the duct crosses to the left of the vertebral column and continues cephalad to enter the superior mediastinum between the aortic arch and subclavian artery and the left side of the esophagus. More cephalad, it passes the thoracic inlet, arches 3 to 5 cm above the clavicle and passes anterior to the subclavian artery, vertebral artery, and thyrocervical trunk to terminate in the region of the left jugular and subclavian vein. Wide variation exists in the course of the thoracic duct.

Chyle is the lymph returning from the intestine to the heart drained by the thoracic duct. Chyle is a milky opalescent fluid, and approximately 1500 to 2500 mL of chyle normally empties into the venous system each day. Ingestion of fat increases the flow of lymph in the thoracic duct by 2 to 10 times the resting level. Ingestion of liquid also increases the chyle flow, but ingestion of protein or carbohydrate has little effect on the lymph flow. The protein content of the chyle is usually more than 3 g/dL and the left to right composition is similar to that of serum.

The most common cause for a chylothorax is malignancy, and lymphoma is the most common etiology in 75%. Chylothorax may be the presenting symptom of lymphoma; therefore, a nontraumatic chylothorax is an indication for a diligent search for a lymphoma. The second leading cause of chylothorax is trauma resulting from cardiovascular, pulmonary, or esophageal surgical procedure. A chylothorax is particularly frequent following an operation in which the left subclavian artery is mobilized. Penetrating trauma to the chest or neck such as a gunshot or knife wound can also injure the thoracic duct. With trauma, the spine is hyperextended or a vertebra is fractured and is most likely to cause chylothorax, especially if injury occurs after ingestion of a recent fatty meal. A chylothorax secondary to closed trauma is usually on the right side and site of rupture is most commonly in the region of T9-10 vertebrae (injuries from falls from height, or compression injury to the trunk secondary to heavy blow to the back or stomach or childbirth). Rarely, chylothorax may occur secondary to coughing, vomiting, and weight lifting. The third leading cause of a chylothorax is idiopathic. This includes congenital chylothorax. Chylothorax is the most common form of pleural effusion encountered in the first few days of life. Congenital chylothorax is more common in patients who are hydropic or who have polyhydramnios. There is also association of congenital chylothorax with Turner syndrome, Noonan's syndrome, or Down syndrome. Birth trauma causing disruption of the thoracic duct is another explanation. Other miscellaneous causes include thrombosis of the SVC or subclavian vein, fibrosing mediastinitis, radiation, mediastinal

scarring, and its association with lymphangioleiomyomatosis (LAM), Gilbert syndrome, Kaposi sarcoma in AIDS patients, and Castleman disease.

CLINICAL MANIFESTATIONS

Related to space-occupying fluid in the thoracic cavity and the usual symptom is dyspnea. Pleuritic chest pain and fever are rare, as chyle is not irritating to the pleural surface. With traumatic chylothorax, there is usually a latent period of 2 to 10 days between the trauma and the onset of pleural effusion. Lymph collects extrapleurally in the mediastinum initially after the thoracic duct disruption forming a chyloma mimicking a posterior mediastinal mass, which eventually ruptures into the pleural space. With nontraumatic chylothorax, the onset of symptoms is usually gradual.

The main threat from chylothorax is malnourishment and compromised immunologic status, since the thoracic duct carries 2500 cm³ of fluid daily containing substantial protein, fat, electrolytes, and lymphocytes. The patient can become cachectic rapidly and develop lymphopenia if repeated chyle is removed through the chest.

DIAGNOSIS

The diagnosis of chylothorax is usually not difficult. Chyle usually has a distinctive white, odorless milky appearance. The main differentiation is between empyema and pseudochylothorax. The milkiness of empyema is caused by suspended white blood cells, and if such fluid is centrifuged the supernatant is clear. The cloudiness in chyloform pseudochylothorax is due to high lipid level, and not cholesterol or lecithin globulin complexes. Chylus and chyloform pleural fluid remain opaque after centrifugation. It is to be noted with congenital chylothorax, the pleural fluid is initially serous and only turns chylus when milk feeding is started.

IMAGING

Chylothorax mimics a pleural effusion. In the early stages, a mass may be noted in the posterior mediastinum because of chyloma. At CT, chylothorax may not be low attenuating and cannot differentiate from typical effusion. In the past, lymphangiograms have been obtained to evaluate the integrity of the thoracic duct.

PULMONARY LYMPHANGIOLEIOMYOMATOSIS

Pulmonary lymphangioleiomyomatosis (LAM) is characterized by widespread proliferation of immature smooth muscles throughout the peribronchial, perivascular, and perilymphatic regions of the lung. The perilymphatic

proliferation of smooth muscle results in lymphatic obstruction and high incidence of chylothorax. The lymph nodes and the mediastinal retroperitoneal space may also be infiltrated with immature smooth muscle cells further impairing the lymphatic flow. The thoracic duct may be either dilated or obliterated. The proliferation of smooth muscles in the perivascular space may cause obstruction of the pulmonary venules and may lead to pulmonary hemorrhage, hemoptysis, and pulmonary hemosiderosis. Proliferation of peribronchial smooth muscle can partially or completely obstruct the airway to cause air trapping, cyst and bullae formation, and high incidence of pneumothorax. Approximately one-third of patients have renal angiomyolipoma.

LAM usually or exclusively occurs in women of reproductive age. Most patients have increasing shortness of breath and/or cough and, rarely, hemoptysis pneumothorax or incidentally discovered chylothorax can be the presentation. Incidence of chylothorax is approximately 30%.

GORHAM'S SYNDROME

This is a rare disease, most often found in children or young adults without sexual predilection and no inheritance pattern. Other names include hemangiomatosis, disappearing bone disease, and massive osteolysis. There is intraosseous proliferation of vascular lymphatic channels leading to disappearance of bones. There is propensity for involving maxilla, shorter girdle, and pelvis. There is a high incidence of chylothorax in these patients.

PNEUMOTHORAX

Pneumothorax is air in the pleural space (air between lung and chest wall). This can be a spontaneous pneumothorax (primary and secondary causes) without any trauma or other obvious cause, or can be traumatic, including iatrogenic injuries.

PRIMARY SPONTANEOUS PNEUMOTHORAX

Primary spontaneous pneumothorax usually occurs in an otherwise healthy individual. This can result from rupture of subpleural emphysematous blebs which are usually located in the apices of the lung. Pathogenesis of these blebs is likely related to airway inflammation and is strongly associated with the development of primary spontaneous pneumothorax in cigarette smoking which suddenly produces airway inflammation. There may be

some association with broad swings in the atmospheric pressure. It is postulated that air in the apical bleb is not in free communication with the airway; therefore, when the atmospheric pressure falls, the distending pressure of the bleb may increase and result in its rupture.

Patients with primary spontaneous pneumothorax are usually taller and thinner. Since the gradient in pleural pressure is greater from the lung base to the apex in taller individuals, the alveoli at the lung apex are subjected to a greater mean distending pressure. Over a long period of time, these phenomena could lead to the formation of subpleural blebs in taller individuals.

There seems to be some familiar tendency. There is high incidence of bronchial abnormalities in nonsmoking patients with spontaneous pneumothorax. The most common abnormality is disproportionate bronchial anatomy (smaller than normal dimensions) and deviating anatomic arrangements at various locations; other abnormalities include accessory bronchus or a missing bronchus.

PATHOPHYSIOLOGY

The pressure in the pleural space is negative with reference to atmospheric pressure, and alveolus pressure is always greater than pleural pressure because of the elastic recoil of the lung. Therefore, if a communication develops between the pleural space and the alveoli, air-flow will occur from the alveolus into the pleural space until the pressure gradient is equalized. The main physiologic consequences of a pneumothorax are decreased in the vital capacity and decreased in PaO_2 along with increased alveolar-arterial oxygen difference. The reduction appears to be due to anatomic shunt in the areas of flow ventilation-perfusion ratio in the partially collapsed lung.

Peak age of primary spontaneous pneumothorax is in the early twenties, it rarely occurs after age 40. It usually develops while the patient is at rest with symptoms of chest pain and dyspnea. Approximately 10% to 20% of patients have an associated pleural effusion.

There is a high risk of recurrence in patients with primary spontaneous pneumothorax. Most recurrences occur within the first year.

SECONDARY SPONTANEOUS PNEUMOTHORAX

Secondary spontaneous pneumothorax occurs as a complication of underlying lung disease, most commonly COPD, and also in patients with AIDS, cystic fibrosis, LAM, or tuberculosis. Most patients with AIDS who have a spontaneous pneumothorax have a history of *Pneumocystis carinii* infection, or are on prophylactic pentamidine,

and have a recurrence of their PCP infection. Pneumothorax occurs because of the presence of multiple subpleural lung cavities associated with subpleural necrosis. The bullous and cystic changes develop because of repeated episodes of inflammation and cytotoxic effects of HIV on pulmonary macrophages. Occurrence of spontaneous pneumothorax in patients with AIDS and PCP is ominous prognostically. These patients have a tendency for recurrent pneumothoraces or contralateral pneumothorax. Because of the necrotic lung surrounding the ruptured cavity, these pneumothoraces are difficult to treat.

PNEUMOTHORAX SECONDARY TO CYSTIC FIBROSIS

Sixteen to twenty percent of patients with cystic fibrosis who are older than 18 years of age will develop a pneumothorax at some time in their lives.

CATAMENIAL PNEUMOTHORAX

A catamenial pneumothorax is an unusual entity that occurs in conjunction with menstruation and is usually recurrent. Initial pneumothorax usually does not occur until the patient is in her twenties.

Classical symptoms are chest pain and sometimes dyspnea within 24 to 48 hours of onset of menstrual flow. It is usually right-sided, but left-sided or even bilateral pneumothoraces have been reported. Pathogenesis is not definitely known. Hypothesis includes air that gains access to the peritoneal cavity during menstruation and then enters the pleural cavity through a diaphragmatic defect or leakage of air from the lung into subpleural endometrial implant is a more likely explanation.

NEONATAL PNEUMOTHORAX

Spontaneous pneumothorax occurs more commonly in the newborn period than at any other age. A pneumothorax is present shortly after birth in 1% to 2% of all infants, and asymptomatic pneumothorax is present in 0.5%. Infants are usually full term or post term. The baby has a history of fetal distress requiring resuscitation or a difficult delivery with evidence of aspiration of meconium, blood, or mucous. Incidence of pneumothorax in infants with respiratory distress syndrome is high.

IATROGENIC PNEUMOTHORAX

The leading cause of iatrogenic pneumothorax is transthoracic needle aspiration of lung masses (20%–40%). The second leading cause is insertion of a central line

(0%–12%). The third leading cause is thoracentesis (5%). Mechanical ventilation is next in line as a cause of iatrogenic pneumothorax.

Other procedures associated with pneumothorax include pleural biopsy, transbronchial lung biopsy, laparoscopy, and liver biopsy. Patients who are heart/lung transplant recipients do not have an intact mediastinum and therefore iatrogenic pneumothorax in these patients may lead to life-threatening bilateral pneumothoraces.

TRAUMATIC (NONIATROGENIC) PNEUMOTHORAX

Traumatic (noniatrogenic) pneumothorax results from penetrating or nonpenetrating chest trauma. The mechanism for pneumothorax in patients without penetrating injury is caused by increased alveolar pressure from severe chest compression leading to alveolar rupture. Air then enters the interstitial space, dissects toward the visceral pleura or the mediastinum to produce mediastinal emphysema. A pneumothorax results when either the visceral or mediastinal pleura ruptures.

TRAUMATIC PNEUMOTHORAX SECONDARY TO DRUG ABUSE

There is a high incidence of traumatic pneumothorax in intravenous drug abusers. This is usually accompanied by attempted injection into the subclavian or internal jugular vein.

TENSION PNEUMOTHORAX

Tension pneumothorax is present when the intrapleural pressure exceeds atmospheric pressure throughout expiration and often during inspiration, leading to compromise of the venous return to the heart. The mechanism is related to some type of one-way valve process in which the valve is open during inspiration and closed during expiration.

Radiographs are accurate detectors of pneumothorax, although a tiny pneumothorax, especially in the supine position, may not be seen. CT is more sensitive in detecting the presence and quantifying the size of the pneumothorax. In an upright position, the pneumothorax is always at the apex, unless there are pleural adhesions. In a supine position, pneumothorax is usually more anterior and basal. Deep sulcus sign is present in the supine patient when pneumothorax has a large basilar component making the costophrenic angle steeper, sharper, and more inferior than the contralateral site. An upright expiratory radiograph is more sensitive in

detecting small pneumothoraces. A tension pneumothorax is a clinical diagnosis, and radiographically is suggested as a possibility when there is a large pneumothorax with contralateral mediastinal shift.

TREATMENT

Supplemental oxygen used in the treatment of pneumothorax accelerates the air absorption in small pneumothoraces. Other treatments include aspiration, tube thoracostomy, tube thoracostomy with installation of sclerosing agent especially done in patients with recurrent pneumothorax, autologous blood patch for persistent air leak, intrapleural fibrin glue for persistent air leak, and VATS procedure.

Pleurodesis is done in patients with recurrent pneumothoraces or pleural effusions. The goal is to incite intense inflammatory reaction in the pleural space that would obliterate the pleural space. The commonly used sclerosing agents are talc and tetracycline. Radiographically, after pleurodesis there is diffuse pleural thickening, and on CT high attenuating material is noted along the pleura representing the talc.

PLEURAL THICKENING

Pleural thickening due to fibrosis is the second most common pleural abnormality after pleural effusion. The thickening could be localized (apical cap, pleural plaques [Table 29-7], or rounded atelectasis) or diffuse. Most common causes of diffuse forms are from organization of recurrent effusion following collagen vascular diseases, asbestosis exposure, and drugs.

APICAL CAP

Apical cap is the thickening of the pleural line at the lung apices, occasionally in the interlobar fissure usually less than 5 mm in thickness, often bilaterally and symmetric. The cause is idiopathic or commonly seen with increasing or advancing age. There is no association with tuberculosis, emphysema, or underlying lung fibrosis of any etiology. The main differential is Pancoast (superior sulcus tumor), which is often unilateral asymmetrical increased opacity, and there is often associated bone destruction

from chest wall invasion. Other differentials include tuberculosis, postradiation fibrosis, and hemorrhage secondary to aortic injury or subclavian stick.

DIFFUSE PLEURAL FIBROSIS

Causes of diffuse pleural fibrosis include asbestos exposure, systemic lupus erythematosus, rheumatoid arthritis, tuberculosis, hemothorax, drugs, and CABG.

A more severe form of pleural fibrosis leads to fibrothorax with resulting decreased volume of the hemithorax, decreased intercostal spaces, and circumferential pleural thickening and sometimes calcification.

PLEURAL NEOPLASMS

Secondary pleural neoplasm is more common than primary neoplasm.

PLEURAL METASTASIS

Pleural metastasis is the most common pleural neoplasm (95%), mostly adenocarcinoma (lung, breast, ovary, stomach) or lymphoma. Pleural effusion is the most common manifestation of metastatic disease and is exudative in nature. In patients with bronchogenic carcinoma, 15% of patients have a malignant effusion at initial presentation and 50% of patients with disseminated disease have pleural effusion. Breast cancer is the second most common cause for malignant pleural effusion. Fifty percent of patients with systemic disease have malignant effusion. More common is ipsilateral (60%–80%) or could be contralateral or bilateral. Positive cytology is identified in two-thirds of these patients and carries a poor prognosis.

Etiology of pleural effusion in malignancy is either due to direct involvement of pleura or lymphatic obstruction or endobronchial obstruction/atelectasis or severe hypoproteinemia.

Ninety percent of malignant effusion is diagnosed by a combined pleural cytology and pleural biopsy. Diagnostic yield is increased with multiple thoracentesis and multiple pleural biopsies.

SOLID PLEURAL METASTASES

Solid pleural metastases are most commonly from the peripheral adenocarcinoma of the lung, but can also be from breast, ovarian tumor, invasive thymoma, or lymphoma. There is direct pleural invasion with tumor growth along the interstitium. It can mimic diffuse

Pleural thickening more than 1 cm
Mediastinal pleural involvement

malignant mesothelioma or invasive thymoma. It can be bilateral. CT features suggestive of malignant pleural thickening are summarized in Table 29-8.

PRIMARY PLEURAL NEOPLASMS

Primary pleural neoplasms are less common than metastases and include diffuse malignant mesothelioma, localized fibrous tumor of the pleura, and other tumors.

MALIGNANT MESOTHELIOMA

Pleural mesothelioma is the most common primary malignant neoplasm of the pleura. Mesotheliomas derive from mesothelial cells of the pleura, pericardium, peritoneum, or tunica vaginalis of the testes. Mesothelioma develops in the parietal pleura first and then spreads to the visceral pleura, chest wall, mediastinum, diaphragm, and abdomen. Three microscopic varieties include epithelial, sarcomatous, and mixed. Epithelial type is the most common (50%).

The incidence of malignant neoplasm is higher in individuals exposed to asbestos (10%). The peak incidence is 35 to 40 years after exposure. Amphibole asbestos fibers are most tumorigenic. Incidence is highest in cities in with shipyards and asbestos plants. The male-to-female ratio is 3.6:1, and it usually is found in the sixth to eighth decade of life.

CLINICAL PRESENTATION

Often there is insidious onset of symptoms of dyspnea, chest pain, cough, and weight loss. Rarely, SVC syndrome, dysphagia, vocal chord paralysis, hypertrophic pulmonary osteoarthropathy, clubbing, and Horner syndrome occur.

Radiographic findings include moderate-to-large unilateral pleural effusion, multiple pleural nodules or masses and diffuse circumferential pleural thickening involving mediastinal pleura without significant mediastinal shift (frozen mediastinum). Often the size of the hemithorax is smaller. Asbestos-related pleural disease is found in 20% to 25% of cases. CT imaging reveals nodular and circumferential pleural thickening involving the fissures associated with pleural effusions; volume loss; lung encasement; and extension into the chest wall,

TABLE 29-9 Brigham's Staging System for Malignant Mesothelioma

STAGES	FEATURES
Stage 1	Disease confined to parietal pleura: ipsilateral pleural, lung, and pericardium
Stage 2	Stage 1 with positive intrathoracic (N1 or N2) lymph nodes
Stage 3	Local extension of disease into the chest wall or mediastinum, to the heart, or through the diaphragm into the peritoneum with or without extrathoracic or contralateral (N3) lymph node enlargement.
Stage 4	Distant metastatic disease

diaphragm, or upper abdomen (Table 29-8). MRI shows a minimally increased signal on T1-weighted images and a moderately increased signal on T2-weighted images.

DIAGNOSIS

VATS is the diagnostic procedure of choice with high sensitivity. Pleural fluid cytology, fine needle aspiration and cutting needle pleural biopsy are of limited value.

STAGING OF DIFFUSE MALIGNANT MESOTHELIOMA

The TNM staging system is currently the most widely used staging system. The other most commonly used staging system is Brigham's system based on resectability (Table 29-9).

ROLE OF PET/CT

The localized FDG uptake is significantly higher in malignant than in benign pleural diseases, such as asbestos-related pleural thickening or inflammatory/infectious pleuritis. The correlation of the T stage with PET is not significantly better than with CT or with MRI. The role of PET in nodal metastatic disease detection is also not very sensitive, perhaps because of lack of resolution of PET to distinguish tumor from contiguous mediastinal nodal metastases.

The value of PET appears to be in its ability to detect extrathoracic metastasis. PET is also very useful in the management of mesothelioma; for example, in patients with diffuse pleural thickening and only a focal area of malignancy, PET can provide information and direct biopsy to appropriate site. PET is also useful in predicting prognosis; higher FDG uptake is associated with significantly shorter survival time.

TREATMENT AND PROGNOSIS

The overall prognosis for mesothelioma is extremely poor, with a median survival of approximately 10 months.

The prognosis is related to the extent of local or distant tumor spread. Prognosis is better in tumors with epithelial subtype rather than sarcomatous or mixed variety types.

Often, multimodality therapy is used to improve survival and protocols include combined surgical site reduction with adjuvant radiation, chemotherapy, or both.

Sensitivity of mesothelioma to chemotherapy is only modest with a response rate in the range of 0% to 50%. Various agents which have been used include antimetabolites, platinum-based agents, such as cisplatin and carboplatin, and recent antifolate agent pemetrexed (Alimta).

Three options are available for surgical treatment: thoracoscopy with sclerosing, pleurectomy-decortication, and extrapleural pneumonectomy. Thoracoscopy with sclerosing is a palliative procedure with a success rate of more than 80%. Pleurectomy-decortication involves removal of the pericardium, visceral and parietal pleura from the apex of the lung to the diaphragm. The recurrence rate is higher, although morbidity and mortality are less than that for extrapleural pneumonectomy (1.5%–5%). Extrapleural pneumonectomy is end-block resection of the parietal and visceral pleura along with the contained lung, the pericardium, and the ipsilateral diaphragm. This procedure allows the best site of reduction and allows higher doses of radiotherapy to be delivered to the same thorax because the lung has been removed. There is, however, higher morbidity and mortality in comparison to pleurectomy decortication.

The radiosensitivity of mesothelioma is intermediate between that of non-small cell lung cancer and small cell lung cancer. The problem for radiation therapy is that a large radiation field is required to treat the entire ipsilateral pleura at high doses more than 40 mGy and association or proximity to the adjacent dose limiting structures such as lung, liver, spinal cord, heart, and esophagus. Radiotherapy has been used to prevent malignant seeding along the sites of invasive diagnostic procedures in patients with malignant pleural mesothelioma. It is also useful in palliation of symptoms, especially painful local recurrent sites. Trimodality therapy is now accepted as the only method for improved survival in a selected group of patients with mesothelioma.

LOCALIZED FIBROUS TUMOR OF THE PLEURA

Localized fibrous tumor of the pleura is also known as localized mesothelioma or pleural fibroma. This is a rare mesenchymal tumor accounting for 5% to 10% of primary tumors of the pleura. The etiology is unknown. However, occasionally tumors are recorded after chest wall irradiation. There is no known association with cig-

TABLE 29-10 Radiographic Features Suggestive of Pleural Mass

May cross fissures
Osseous or soft tissue changes denote chest wall involvement

arette smoking. Usually, there is no relation to asbestosis exposure.

CLINICAL PRESENTATION

The majority are asymptomatic. Symptoms, when present, include cough, dyspnea, and chest pain related to tumor size. There is a high incidence of clubbing of the fingers, hypertrophic osteoarthropathy, and episodic hypoglycemia. The peak age of incidence is sixth or seventh decade with equal male-to-female occurrence. It most commonly involves the visceral pleura (80%) than the parietal pleura (20%). They are encapsulated round or ovoid lobulated, pedunculated, or broad-based pleural masses (Table 29-10). Ten to twelve percent of localized fibrous tumors are malignant and range in size from 1 to 25 cm with a mean diameter of 6 cm. The presence of pedicle is associated with a lower risk of malignancy, often hypertrophied vessels are noted.

RADIOGRAPHIC FEATURES

Localized fibrous tumors of the pleura classically appear as a large, round, lobulated solitary peripheral noncalcified mass. When located in the fissure, it can mimic a lung mass. The pedunculated tumor may change in position with respiration or posture. Effusion is present in 5% to 20% of cases. The tumor demonstrates contrast enhancement and calcification is rare. There is often no associated lymphadenopathy in the mediastinum or hila.

MRI

MR may better characterize the fibrous nature of the tumor with predominantly low to intermediate signal intensity on T1- and T2-weighted images. However, heterogeneous signal intensity on T2-weighted images is frequent because of associated necrosis, cystic or myxoid degeneration, and areas of increased cellularity and vascularity. A common finding on T2-weighted images is the presence of septa of low signal intensity. Intense heterogeneous enhancement after gadolinium is typical.

TREATMENT AND PROGNOSIS

Complete excision is the treatment of choice with a 90% cure rate. Symptoms usually resolve after surgery and only recur if there is tumor recurrence, which is seen in 10% of the patients.

MISCELLANEOUS MESENCHYMAL TUMORS

The most common mesenchymal tumor of the pleura is benign lipoma. Generally, this is detected incidentally in asymptomatic patients via pleural-based soft-tissue density which can mimic lung neoplasm. CT is diagnostic by demonstrating a fat density in the mass. Liposarcomas demonstrate a heterogeneous mixture of fat and soft-tissue attenuation and variable enhancement.

PLEURAL LYMPHOMA

Pleural lymphoma usually occurs as part of disseminated disease (secondary lymphoma). Ten percent of malignant pleural effusions are the result of pleural lymphoma. Prevalence of pleural disease in lymphoma is around 25% to 30%. There is associated mediastinal adenopathy in the majority of patients (70%).

A rare type of primary pleural lymphoma in the Japanese population is pyothorax-associated lymphoma. This is a non-Hodgkin lymphoma of large B-cell variety developing in patients with a long history of pyothorax caused by artificially induced pneumothorax done for treatment of pulmonary tuberculosis. There appears to be a link between remote tuberculous pleuritis and Epstein-Barr virus.

Lymphoma typically involves the subpleural lymphatics in both non-Hodgkin and Hodgkin variety. The lymphomatous deposit in the lymphatic channel and lymphoid aggregate in the subpleural connective tissue below the visceral pleura are present.

Clinical presentation is variable, including usually chest pain and fever. In patients with pyothorax-associated lymphoma, chest swelling may be present. If a tumor extends into the spinal cord, there may be paralysis of the lower limbs.

IMAGING FINDINGS

Unilateral or bilateral pleural effusion with or without pleural thickening is the major finding. Effusion is more common in Hodgkin lymphoma. In non-Hodgkin lymphoma, associated lymphadenopathy is more common. CT is more sensitive in describing the extent of pleural involvement. Pleural thickening—focal or diffuse—is often nodular and typically involves the parietal pleura. Pleural effusion is easily seen. Many patients have posterior mediastinal lymphadenopathy because of the lymphatic drainage pattern of parietal pleura and chest wall. Lymphomatous pleural effusion may be chyliform. Pyothorax-associated lymphoma appears as a large inhomogeneous soft tissue masses often extending into the chest wall with associated rib destruction.

QUESTIONS AND ANSWERS

- Which of the following is *false* regarding pleura?
 - Visceral pleura consists of mesothelium and connective tissue.
 - Visceral layer contributes to the elastic recoil of the lung.
 - Parietal pleura is supplied by systemic circulation.
 - Venous drainage of visceral pleura is via intercostal veins.

ANSWER: D. The visceral pleura in humans is a thick membrane composed of two layers: mesothelium and connective tissue. The connective tissue layer in the visceral pleura has two important functions: it contributes to the elastic recoil of the lung, which is important in expelling air from the lung, and it restricts the volume to which the lung can be inflated, thereby protecting the lung. The parietal pleura receives its blood supply from the systemic capillaries. The venous drainage of the parietal pleura is primarily via the intercostal veins which drain into the inferior vena cava or brachiocephalic trunk. The blood supply to the viscera pleura is from pulmonary circulation and the venous drainage is through the pulmonary veins.

- Regarding pleural pressure, which of the following is *false*?
 - Normal pleural pressure is negative.
 - Pleural pressure is lowest and most negative in the lung bases.
 - Alveoli in the lung apices are larger than in the lung bases because of pressure gradient.
 - Primary determinate of the volume of the lung

ANSWER: B. At functional residual capacity, the opposing elastic forces of the chest wall and the lung produce a negative pressure between the visceral and parietal pleura called the pleural pressure.

This pressure around the lung is the primary determinant of the volume of the lung. The pleural pressure represents the balance between the outward pull of the thoracic cavity and the inward pull of the lung. Normally, the pleural pressure is not uniform throughout the pleural space. There is often a gradient in pleural pressure with the pleural pressure being lowest and most negative in the superior aspect and highest or least negative in the inferior portion of the lungs. The normal pleural pressure ranges 0.5 to 1 cm H₂O per centimeter vertical height. The pleural pressure gradient causes the alveoli in the superior part of the lung to be larger than those in the inferior part of the lung. Pleural pressure gradient also accounts for the unevenness of the distribution of ventilation.

3. Regarding pleural effusion, which of the following is *true*?
- A. Most of the fluid produced is removed by lymphatics in the visceral pleura.
 - B. Pleural eosinophilia is present when there are > 25% eosinophils in the pleural fluid.
 - C. Most common cause of pleural effusion in the United States is metastatic disease.
 - D. In the presence of infections, pleural neutrophils undergo degeneration with toxic vacuolation with blurred nucleus.

ANSWER: D. Normally, a small amount (0.01 mL/kg/h) of fluid constantly enters the pleural space from capillaries in the parietal pleura. Almost all of the fluid is removed by lymphatics in the parietal (and not visceral) pleura, which has a capacity to remove at least 0.20 mL/kg/h (nearly 20 times the inflow). The most common cause of pleural effusion in the United States is congestive heart failure (not metastatic disease). Examination of the pleural fluid neutrophil in patients with parapneumonic effusion is useful. If pleural infection is present, the neutrophils undergo a characteristic degeneration, the nucleus become blurred and no longer is stained purple, the cytoplasm shows toxic vacuolation initially, and later neutrophilic granules become indistinct and are lost. Pleural eosinophilia is present when there are more than 10% (and not >25%) of eosinophils in the pleural fluid.

4. Common causes of pleural eosinophilia include all *except*:
- A. Asbestosis
 - B. Drugs
 - C. Parasite infection
 - D. Pyothorax

ANSWER: D. The most common cause of pleural fluid eosinophilia is air in the pleural space. The second most common cause of pleural fluid eosinophilia is blood in the pleural space. Other causes include parapneumonic effusion, malignancy, tuberculosis, asbestos-related pleural effusion, pleural effusion secondary to drug reaction (dantrolene, brocypitin, and nitrofurantoin), infections secondary to parasites (paragonimiasis, hydatidosis, amebiasis, or ascariasis), and pleural effusion associated with Churg-Strauss syndrome is eosinophilic. Pyothorax is associated with increased neutrophil (and not eosinophil) counts and characteristic degeneration of the neutrophils.

5. Low pleural glucose level is seen in all *except*:
- A. TB
 - B. Pneumonia
 - C. Pancreatitis
 - D. Rheumatoid arthritis

ANSWER: C. A low pleural fluid glucose level (less than 16 mg/dL) indicates parapneumonic effusion, malignant disease, rheumatoid disease, tuberculous effusion, or tuberculous pleuritis. In pancreatitis, pleural glucose levels are normal though amylase level is high.

6. Regarding pleural effusions, which of the following statement is *true*?
- A. Pleural fluid LDH is a reliable indicator of the degree of pleural inflammation.
 - B. Pleural fluid from patients with mesothelioma is often abnormally viscid.
 - C. Esophageal rupture leads to elevated pleural amylase level.
 - D. Elevated pleural fluid interferon-gamma levels are seen in rheumatoid arthritis.

ANSWER: D. If pleural fluid ADA level is more than 50 U/L and the patient has predominant lymphocytes in the pleural fluid, diagnosis of tuberculosis is certainly made. Elevated levels of interferon levels are noted in tuberculous pleuritis (and not RA). Using a cutoff level of 3.7 U/mL, a sensitivity of 0.99 and specificity of 0.98 has been reported in tuberculous effusions. Most patients with high LDH in pleural fluid have exudative effusions and those with normal protein level but high LDH are either parapneumonic or malignant pleural disease. Pleural fluid LDH is a reliable indicator of the degree of pleural inflammation; the higher the LDH, the more inflamed the pleural surfaces. Pleural fluid amylase above the upper normal limit for serum amylase indicates one of three problems:

pancreatic disease, malignant tumor, or esophageal rupture.

7. Transudative pleural effusion is seen in all *except*:

A. CHF
B. Cirrhosis
C. PTE
D. Nephrotic syndrome

ANSWER: C. Causes of transudative pleural effusion include congestive heart failure, cirrhosis, nephrotic syndrome, superior vena cava obstruction, peritoneal dialysis, myxedema, and hypoalbuminemia. PTE usually leads to exudative effusion.

8. Which of the following statement is *false* regarding transudative pleural effusion?

A. Pleural fluid protein to serum protein ratio of <0.5
B. Pleural fluid LDH less than two-thirds of normal for serum LDH
C. pH <7.2
D. Pleural fluid LDH divided by serum LDH ratio <0.6

ANSWER: C. pH of pleural fluid <7.2 is seen in exudative effusion and not transudation. All other statements are correct for transudate effusion.

9. Which of the following parameters suggests intervention in a patient with parapneumonic effusion?

A. Negative Gram stain
B. LDH <1000 IU
C. pH <7.0
D. Glucose >60 mg/dL

ANSWER: C. Criteria for intervention in patients with parapneumonic effusion include presence of thick pus, positive (not negative) Gram stain, pH less than 7.0, glucose less (not more) than 60 mg/dL, LDH more (not less) than 1000 IU.

10. The radiographic features suggesting pleural origin of a mass include all of the following *except*:

A. Irregular margin
B. Cross fissure
C. Elliptical shape
D. Margins are not well seen on different views.

ANSWER: A. Radiographic features of a pleural mass include elliptical shape with obtuse margins, smooth (not irregular) margins. Discrepancy in margin visualization on different views may cross fissures and osseous or soft tissue changes denote chest wall involvement.

30 ATELECTASIS

Satinder P. Singh

Atelectasis is defined as incomplete expansion of all or part of the lung with corresponding decreased lung volume. The term “collapse” is usually reserved for complete atelectasis.

MECHANISMS OF ATELECTASIS

There are different mechanisms of atelectasis (Table 30-1). Obstructive atelectasis is secondary to airway obstruction with resorption of oxygen, leading to decreased alveoli volume. The partial pressure of nitrogen and carbon dioxide in the alveoli increases relative to capillary blood, leading to diffusion of both of these gasses into the blood thus further decreasing in alveolar volume. Airway obstruction leads to distal volume loss either at lobar or entire lung, depending on the location of the obstruction. It often takes approximately 24 hours for atelectasis to develop in a normal person with central airway obstruction. A patient on 100% oxygen develops atelectasis within a few hours.

Passive atelectasis is the collapse of the lung because of pneumothorax. Pleural effusion can also cause passive atelectasis, although some consider it as compressive. The proportion of atelectasis of lung is usually proportional to the amount of air in the pleural space without any adhesions.

Compressive atelectasis results from a space-occupying lesion compressing the lung, usually a large pleural effusion, a neoplasm, emphysematous bulla, or cyst.

Adhesive atelectasis occurs in part as a result of deficiency of surfactant, commonly seen in radiation pneumonitis, acute respiratory distress syndrome, pulmonary thromboembolism, as well as hyaline membrane disease in the newborn. The function of the surfactant is to reduce the surface tension of the alveoli as their surface area or volume decreases, and therefore the critical closing pressure of alveoli occurs at a lower volume and distending pressure, thereby effectively protecting against collapse.

Cicatrizational atelectasis results in volume loss, secondary to pulmonary fibrosis, regardless of underlying

TABLE 30-1 Mechanisms of Atelectasis

Obstructive (resorbed)
Passive
Compressive
Adhesive
Cicatrical (scar)

etiology. The fibrotic process undergoes retraction and results in loss of volume of the affected portion of the lung. The fibrosis can be localized as seen in healed granulomatous infection, such as histoplasmosis, tuberculosis, and radiation fibrosis, or could be diffuse as seen in idiopathic pulmonary fibrosis. The bronchi within the affected lungs are usually dilated because of the increased elastic recoil from surrounding pulmonary fibrosis and traction bronchiectasis.

PATTERNS OF ATELECTASIS

Depending on the site of obstruction, atelectasis could be complete lung, lobar, segmental, or subsegmental.

COMPLETE LUNG COLLAPSE

This is usually secondary to main bronchial occlusion: central bronchogenic carcinoma in adult and elderly, carcinoid in young females, mucous plugging in patients with asthma, or foreign body in children.

Radiographic findings include complete opacification of hemithorax with ipsilateral mediastinal shift (Table 30-2). The hemidiaphragm is elevated and apparent on the left side as seen from displaced stomach bubble. In the chronic state, there is crowding of the intercostal spaces. Often, the overexpanded contralateral lung crosses the midline, an unusual lucency projected over the mediastinum. Complete atelectasis may be seen with tension pneumothorax, where the loss of volume may occur with slightly increased radiodensity of the collapsed lung around the hila.

LOBAR ATELECTASIS

RIGHT UPPER LOBE ATELECTASIS

In right upper lobe atelectasis, the minor fissure and the upper major fissure are displaced upward and forward, respectively. In complete atelectasis, there is increased density of the collapsed lung along the right superior mediastinum; on the lateral view, the collapsed lung

may appear as an indistinct triangular shadow with its base contiguous with the pleura, just posterior to the apex of the hemithorax, and its apex at the hila.

The “S” sign of Golden is seen with central obstructing mass. The superior curve is the displaced minor fissure, while the inferior portion is the curved surface of the tumor itself. Juxtaphrenic sign is a triangular, sharply defined opacity that projects upward from the medial half of the diaphragm, at or near the highest point of the dome. It results from upward retraction of the portion of the visceral pleura that protrudes into the recess of the basal segment of the lung near the inferior pulmonary ligament. In majority of the cases, the juxtaphrenic peak is related to an inferior accessory fissure.

LEFT UPPER LOBE ATELECTASIS

The major difference between the right and left upper lobe is due to absence of minor fissure on the left; therefore, all lung tissue anterior to the major fissure is involved. The oblique fissure is more vertical than the major fissure on the right, is displaced forward in a plane parallel to the anterior chest wall, and is better seen on the lateral view. The collapsed lobe obliterates the left cardiac border in the frontal view (silhouette sign). With hyperexpansion of the lower lobe, especially the superior segment of the lower lobe, the aerated lung is interposed between the aortic arch and collapsed left upper lobe, therefore maintaining a sharp interface of the arch (known as air crescent or Luftsichel sign).

RIGHT MIDDLE LOBE ATELECTASIS

This is easily recognized on the lateral view, but is difficult on frontal radiographs. The minor fissure and caudal portion of the major fissure approximate, resulting in a triangular pancake of tissue, which has an apex at the hila and base approximately contiguous with the parietal pleura over the anterolateral thorax, best seen on the lateral view. The right cardiac margin is not well seen on the frontal view (silhouette sign). Because of the obliquity of the atelectatic lobe, the right middle lobe atelectasis may not be well seen on the frontal view but can be detected on a lordotic or lateral view. On CT, a triangular opacity is seen with the apex toward the hila, the minor fissure moves downward, while the major fissure moves upward and forward.

LOWER LOBE ATELECTASIS

Right and left lower lobe atelectasis has a similar appearance with collapse medially toward the mediastinum. Their contact with the hemidiaphragm is maintained, leading to diaphragmatic indistinctness (silhouette sign). On the frontal view, the hila and interlobar arteries are displaced downward and medially and the hemidiaphragm is not well seen. On the lateral view, the

TABLE 30-2 Radiographic Findings of Atelectasis

Direct signs

Displacement of interlobar fissure
Crowding of vessels and bronchi

Indirect signs

Local increase in opacity
Elevation of the ipsilateral hemidiaphragm
Displacement of the mediastinum
Compensatory overinflation of remaining lung and displacement of the hila

oblique fissure is displaced posteriorly and downward. On the frontal view, the collapsed lung is also seen as a triangular opacity with a sharp lateral margin because of displaced oblique fissure.

COMBINED LOBAR ATELECTASIS

Atelectasis of two lobes simultaneously produces a very distinctive radiographic pattern only in the right lung.

COMBINED RIGHT MIDDLE AND LOWER LOBE ATELECTASIS

This is due to obstruction of the bronchus intermedius. On the frontal view, the collapsed lower lobe obscures the right hemidiaphragm and the collapsed middle lobe obscures the right heart margin. Both major and minor fissures are displaced downward and backward so that the opacity occupies the posteroinferior portion of the right hemithorax. CT nicely demarcates the right middle and lower lobe atelectasis, which usually abuts the right cardiac border and right hemidiaphragm.

COMBINED RIGHT UPPER AND MIDDLE LOBE ATELECTASIS

This is uncommon, but may occur usually as a result of lung cancer, carcinoid, inflammatory processes, or mucus plugging. The radiographic findings are similar to that of left upper lobe atelectasis. On the frontal view, an opacity obscures the outline of the mediastinum and indistinctly fades laterally. There is displacement of the hilar vessels along with obscuration of the right cardiac margin. On the lateral view, the major fissure is displaced anteriorly, while the minor fissure may be straight, convex anteriorly, or convex posteriorly.

MIGRATING LOBAR ATELECTASIS

Atelectasis with fluid, pneumonic consolidation, or tumor may migrate within the hemithorax with change in body position. Migrating atelectasis may occupy a dependent position on erect radiograph and lateral view and mimic hilar or mediastinal mass.

SEGMENTAL ATELECTASIS

Segmental atelectasis results from bronchial obstruction and is associated with obstructive pneumonitis. The homogeneous opacity is noted in the distribution of the bronchopulmonary segment; usually no air bronchogram is seen. The radiographic appearance depends

on the original volume of lung parenchyma as well as the volume of inflammatory tissue within the segmental atelectasis.

LINEAR OR DISCOID OR PLATE-LIKE ATELECTASIS

These are linear soft tissue opacities ranging from 1 to 3 mm in thickness and 4 to 10 cm in length, usually in the mid and lower lungs, unilateral or bilateral, single or multiple. It commonly occurs in the setting of restricted inspiratory effort, such as rib fracture or chest pain from any etiology, intra-abdominal surgery, or inflammatory process near the diaphragm.

ROUND ATELECTASIS

This is a distinct form of atelectasis associated with focal pleural thickening. It appears as a homogenous round or oval or wedge-shaped mass in the periphery of the lung, adjacent to the thickened pleura. It is variable in size, ranging from 3 to 6 cm, and is associated with loss of volume of the affected lobe. The bronchi and vessels in the adjacent lung are displaced in a curvilinear fashion (comet tail sign); this finding is best seen on CT. It is most commonly found in the lower lobes. Air bronchograms are seen in approximately 60% of the cases. Subpleural fat may be seen within the mass suggesting its chronicity. The mass may be mistaken for malignancy. MR reveals signal intensity higher than muscle and lower than fat on T1-weighted images and similar to or lower than fat on T2-weighted images. There is uniform enhancement of the atelectatic lung after administration of gadolinium. FDG PET usually shows little or no uptake and is quite helpful in distinguishing round atelectasis from cancer. It is usually seen in patients exposed to asbestosis, but can also be seen in chronic pleural effusion from tuberculosis, malignancies, pulmonary infarct.

QUESTIONS AND ANSWERS

1. How long does it take for atelectasis to develop in a normal person with central airway obstruction?
 - A. 2 hours
 - B. 12 hours
 - C. 24 hours
 - D. 2 days

ANSWER: C. It takes approximately 24 hours to develop, but significantly less time for patients dependent on oxygen.

2. What is the underlying cause of adhesive atelectasis?
 - A. Deficiency of surfactant
 - B. Large bulla
 - C. Pneumothorax
 - D. Mucus plug

ANSWER: A. Adhesive atelectasis is caused by decreased surfactant occurring with radiation pneumonitis, ARDS, PTE, and hyaline membrane disease.

3. Luftsichel sign suggests what diagnosis?
 - A. RUL atelectasis
 - B. RLL atelectasis
 - C. LUL atelectasis
 - D. LLL atelectasis

ANSWER: C. Luftsichel (air crescent) sign is the strip of hyperinflated superior segment of the lower lobe between the aortic arch and the collapsed left upper lobe.

31 DIAPHRAGMATIC DISEASES

John C. Texada and Satinder P. Singh

ABNORMALITIES OF DIAPHRAGMATIC POSITION AND MOTION

Diaphragmatic motion accounts for 60% to 75% of vital capacity, with excursion from expiration to inspiration highly variable but approximately 3 to 7 cm and slightly greater on the right.

Diaphragmatic motion is best visualized fluoroscopically. Imaging should be obtained PA and at multiple obliquities, and should include evaluation during tidal breathing, deep rapid breathing, and sniffing. Sniffing may reveal otherwise inapparent restriction or paradoxical motion; however, in some normal people, sniffing may produce paradoxical motion of one hemidiaphragm and so this should be considered pathologic only if greater than

2 cm and involving the entire hemidiaphragm. Sonography of the diaphragm may reveal additional abnormalities not visible fluoroscopically and may evaluate thickness, configuration, and relationships to other structures.

UNILATERAL DIAPHRAGMATIC PARALYSIS

Patients with unilateral diaphragmatic paralysis are often asymptomatic, though some may have dyspnea on exertion, or orthopnea. Pulmonary function tests show mild restriction.

ETIOLOGY

This is usually caused by phrenic nerve interruption from any of a variety of causes: cancer, injury (section such as during coronary artery bypass surgery, stretching, cooling, venipuncture, birth injury, cervical manipulation), neuritis (brachial neuritis [Parsonage-Turner syndrome], herpes zoster, mononeuritis multiplex), CNS or cord abnormalities (stroke, multiple sclerosis, rhizotomy, amyotrophic), nerve compression (spondylosis, mediastinal lymphadenopathy, goiter), or others including diabetes, carbon monoxide poisoning, or upper abdominal surgery. The latter is a temporary response to inhibitory nerve stimulation in the diaphragm, most severe at 8 hours post-procedure. Malignant invasion is most common, with the most common cancer being lung cancer. “Unknown” is the second most-common etiology; this idiopathic form is encountered almost always on the right side and in males, and may be due to a viral neuritis.

RADIOGRAPHIC FINDINGS

Radiographically, the paralyzed hemidiaphragm is elevated and the dome is accentuated. The costophrenic and costovertebral sulci are deep and narrow. If left-sided, the stomach and colon will rise and the stomach may undergo mesenteroaxial volvulus (in which the stomach rotates along its mesenteric axis such that the greater curve lies superior to the lesser curve). Motion will be diminished, absent, or paradoxical, with paradoxical motion during sniffing; the mediastinum will swing laterally with respiration.

The most reliable test is sniffing evaluation. Normally both hemidiaphragms descend sharply; a paralyzed hemidiaphragm will rise. False positives are 5%, and false negatives may be produced if the patient uses abdominal muscles.

BILATERAL DIAPHRAGMATIC PARALYSIS

EPIDEMIOLOGY

Patients with bilateral diaphragmatic paralysis are severely short of breath; bilateral paresis will produce

milder symptoms. Most patients with paralysis will develop ventilatory failure and hypercapnia; some may develop cor pulmonale. Severe restriction will be found with pulmonary function tests. In addition to the causes listed previously, sympathetic or muscular dystrophy may produce diaphragmatic weakness and a number of CNS and cord abnormalities may be considered.

RADIOGRAPHIC FINDINGS

Both hemidiaphragms will be elevated, and basilar atelectasis may be present. Both hemidiaphragms will rise paradoxically during sniffing; this, accompanied by outward chest motion and inward abdominal motion, is called thoracoabdominal paradox.

EVENTRATION

ETIOLOGY

Eventration is the congenital failure of muscle development, in part or whole of the diaphragm. Partial eventration is most often at the anteromedial right hemidiaphragm. Complete hemidiaphragm eventration is called Petit's eventration; this is almost exclusively left-sided (in contrast to the almost exclusively right-sided idiopathic unilateral paralysis).

RADIOGRAPHIC FINDINGS

Eventration appears radiographically same as paralysis, though on fluoroscopy and ultrasound, the affected area will move with the normal portions of the hemidiaphragm (it may have a slight inspiratory lag).

OTHER ABNORMALITIES OF DIAPHRAGMATIC MOTION

Numerous diseases, not directly affecting the diaphragm, may restrict diaphragmatic motion, for example, Emphysema or severe acute asthma produces hyperinflation and air trapping, which prevents normal motion. Localized infectious inflammatory processes may produce splinting of the hemidiaphragm. Tonic contraction may be due to tetany, tetanus, rabies, strychnine poisoning, and Coxsackie B infection. Respiratory myoclonus may produce diaphragmatic flutter. Hiccups are a notable example as well.

DIAPHRAGMATIC HERNIAS

NORMAL DIAPHRAGMATIC OPENINGS AND WEAK POINTS

The aortic aperture lies behind the left median arcuate ligament at the T12 level; it contains the aorta, the tho-

racic duct, and other lymphatic, azygous, and hemiazygos veins. The esophageal aperture splits the medial fibers of the right diaphragmatic crus usually at T10; it contains the esophagus, the vagal nerves, and the gastric vessels. The inferior vena cava aperture lies at T8 between the central tendon and the costal muscle portion of the right hemidiaphragm. The foramen of Morgagni (the parasternal hiatus) and the foramen of Bochdalek (pleuroperitoneal hiatus) lie inferiorly and posteromedially, respectively.

ESOPHAGEAL HIATAL HERNIA

This is the most common nontraumatic hernia. It is largely acquired, with the most important factors being obesity and pregnancy. In one study, the prevalence of hiatal hernia increased from 5% in patients older than 40 years to 65% in patients aged 60 to 79 years. The stomach is the most common structure to herniate.

Radiographically, a herniated stomach will appear as a retrocardiac mass, often with an air-fluid level; diagnosis may require barium evaluation or CT. If large, the stomach may undergo volvulus in the chest or become incarcerated or strangulated.

PLEUROPERITONEAL HIATAL HERNIA (THROUGH THE FORAMEN OF BOCHDALEK)

This is the most common and most serious hernia in infancy, with an incidence of 1:2200 and 75% to 90% being left-sided. They may be so large that the hemidiaphragm is almost absent and much of the abdomen lies in the chest. Mortality rate for large hernias is 30% even after surgical correction, and this is due to pulmonary hyperplasia and pulmonary artery hypertension. In adults, small pleuroperitoneal hiatal hernias are generally asymptomatic and usually fat-containing; their incidence increases with age. Prevalence may be 6% to 12%, mostly left-sided. Peritoneal lining is generally not present.

Radiographically, a Bochdalek hernia may appear as a focal diaphragmatic bulge or a posteromedial basilar mass; it is often less attenuating than soft tissue because of internal fat. It is easily defined with CT.

PARASTERNAL HIATAL HERNIA (THROUGH THE FORAMEN OF MORGAGNI)

Also called retrosternal hernia, this is mostly a right-sided process, as the left parasternal hiatus abuts the heart. The defect is developmental but the hernia is associated with obesity, severe effort, and increased intra-abdominal pressure. Most patients are obese, middle-aged women. Most are asymptomatic, though epigastric or sternal pressure and discomfort may be described. Peritoneal lining is often retained; the hernia may contain omentum or less likely liver, bowel, or other structures; strangulation and obstruction can occur.

Radiographically, a Morgagni hernia is a well-defined right cardiophrenic angle mass. Other differential diagnoses for a CP angle mass include epicardial fat, pericardial cyst, lymphoma, and thymoma. If bilateral (a rare occurrence), abdominal organs will herniate in the midline. CT or MR can easily image the lesion.

DIAPHRAGMATIC NEOPLASMS

PRIMARY NEOPLASMS

Primary diaphragmatic tumors are rare, more than 50% are benign and mostly from the tendinous or anterior muscular portion. Lipoma is the most common tumor, though angiofibroma, neurofibromatosis, leiomyoma, teratoma, and other tumors may develop. The most common malignant neoplasm is fibrosarcoma, though malignant fibrous histiocytoma, hemangiopericytoma, germ cell tumors, and others may be found. Benign diaphragmatic neoplasms are most often asymptomatic, but patients with a diaphragmatic cancer may complain of chest or abdominal pain, cough, or dyspnea.

Most of these tumors present radiographically as round or lobulated masses extending into the lung base, mimicking unilateral elevation of diaphragm. Malignant tumors often involve much of the hemidiaphragm and often have associated pleural effusions.

SECONDARY NEOPLASMS

The most common secondary neoplasm of the diaphragm is the direct extension of lung cancer or mesothelioma; other hepatic, peritoneal, or lung tumors may spread by extension. Ovarian cancer is a likely site of origin for metastasis of peritoneal origin. Distinct hematogenous or lymphatic nodular metastasis is uncommon.

OTHER DIAPHRAGMATIC ABNORMALITIES

ACCESSORY DIAPHRAGM

In this rare process, the right hemidiaphragm is divided by a musculotendinous membrane; 30 cases had been reported by 1995. The accessory tissue is usually in the oblique fissure and attaches to the pericardium, diaphragm, and chest wall.

DIAPHRAGMATIC DEFECTS

Defects may be too small to allow true herniation, but allow passage of fluid in Meigs syndrome or cirrhotic ascites.

INTRADIAPHRAGMATIC CYSTS

These are rare and are usually formed by extralobar sequestration, and are almost always left-sided. A chronic diaphragmatic hematoma may evolve into a cyst.

QUESTIONS AND ANSWERS

1. Regarding unilateral diaphragmatic paralysis, which of the following is *true*?
 - A. Etiology is typically related to nerve damage.
 - B. Etiology is uncommonly tumor invasion.
 - C. Paralyzed hemidiaphragm is lower than the normal one.
 - D. Most reliable test is Valsalva maneuver.

ANSWER: A. This is usually caused by phrenic nerve interruption from any of a variety of causes: cancer, injury, neuritis, CNS or cord abnormalities, diabetes, carbon monoxide poisoning, or upper abdominal surgery. Malignant invasion is most common, with the most common cancer being lung cancer. Radiographically, the paralyzed hemidiaphragm is elevated and the dome is accentuated. The most reliable test is sniffing evaluation.

2. Regarding diaphragmatic eventration, which of the following is *true*?
 - A. Etiology is unknown.
 - B. Ultrasound may be helpful in diagnosis.
 - C. Petit eventration is usually right-sided.
 - D. Associated with severe restriction in PFT.

ANSWER: B. Eventration is congenital failure of muscle development, in part or whole of the diaphragm. Complete hemidiaphragm eventration is called Petit eventration; this is almost exclusively left-sided, in contrast to the almost exclusively right-sided idiopathic unilateral paralysis. Eventration appears radiographically similar to paralysis, though on fluoroscopy and ultrasound the affected area will move with the normal portions of the hemidiaphragm (it may have a slight inspiratory lag).

3. Strychnine poisoning produces which of the following in the diaphragm?
 - A. Respiratory myoclonus
 - B. Splinting
 - C. Air-trapping
 - D. Tonic contraction

ANSWER: D. Emphysema or severe acute asthma produces hyperinflation and air trapping that prevents

normal motion. Localized infectious inflammatory processes may produce splinting of the hemidiaphragm. Tonic contraction may be due to tetany, tetanus, rabies, strychnine poisoning, and Cox-sackie B infection. Respiratory myoclonus may produce diaphragmatic flutter.

4. What type of hernia contains peritoneum?
 - A. Parasternal hiatus
 - B. Bochdalek
 - C. A congenital diaphragmatic hernia causing pulmonary hypoplasia
 - D. Pleuroperitoneal hiatus

ANSWER: A. The Morgagni hernia of the parasternal hiatus generally retains peritoneal lining. The Bochdalek hernia typically does not.

5. The radiograph of an obese, 50-year-old woman reveals a well-defined right cardiophrenic angle mass. Of these, which is most likely?
 - A. Parasternal hiatal hernia
 - B. Bochdalek hernia
 - C. Diaphragmatic cancer
 - D. Accessory diaphragm

ANSWER: A. Radiographically, a Morgagni hernia is a well-defined right cardiophrenic angle mass. The defect is developmental but the hernia is associated with obesity, severe effort, and increased intra-abdominal pressure. Most patients are obese, middle-aged women. Radiographically, a Bochdalek hernia may appear as a focal diaphragmatic bulge or a posteromedial basilar mass. Primary diaphragmatic tumors are rare. Accessory diaphragm is rare and is not a mass-like entity.

6. What is the most common cause of intradiaphragmatic cyst?
 - A. Hematoma
 - B. Cystic adenomatoid malformation
 - C. Extralobar sequestration
 - D. Degenerated myoma

ANSWER: C. Intradiaphragmatic cysts are rare and are usually formed by extralobar sequestration, and are almost always left-sided. A chronic diaphragmatic hematoma may evolve into a cyst.

7. Regarding diaphragmatic neoplasms in general, which is *true*?
 - A. Primary tumors arise mostly from the posterior muscular portion.
 - B. Primary tumors are more common than secondary tumors.

C. Secondary neoplasms arise by hematogenous seeding.

D. Ovarian cancer is a common etiology.

ANSWER: D. Primary diaphragmatic tumors are rare, mostly from the tendinous or anterior muscular portion. The most common secondary neoplasm of the diaphragm is the direct extension of lung cancer or mesothelioma; other hepatic, peritoneal, or lung tumors may spread by extension. Ovarian cancer is a likely site of origin for metastasis of peritoneal origin. Distinct hematogenous or lymphatic nodular metastasis is uncommon.

8. What is the most common primary tumor of the diaphragm?
 - A. Angiofibroma
 - B. Lipoma
 - C. Leiomyoma
 - D. Fibrosarcoma

ANSWER: B. Lipoma is the most common tumor, though angiofibroma, neurofibromatosis, leiomyoma, teratoma, and other tumors may develop. The most common malignant neoplasm is fibrosarcoma, though malignant fibrous histiocytoma, hemangiopericytoma, germ cell tumors, and others may be found.

9. A 25-year-old man presents after an upper respiratory infection with shortness of breath. If the etiology is related to the diaphragm, which of these is *true*?
 - A. More likely a right-sided process
 - B. Associated with a depressed hemidiaphragm
 - C. Bacterial in origin
 - D. Motion will be normal.

ANSWER: A. Idiopathic hemidiaphragm paralysis is almost always right-sided, and in males, perhaps a viral neuritis. Radiographically, the paralyzed hemidiaphragm is elevated and the dome is accentuated. Motion will be diminished, absent, or paradoxical, with paradoxical motion during sniffing; and the mediastinum will swing laterally with respiration.

10. Regarding bilateral diaphragmatic paralysis, which is *true*?
 - A. Severe obstruction is visible with pulmonary function tests.
 - B. Hypercapnia is an uncommon complication.
 - C. Associated with thoracoabdominal paradox
 - D. Petit eventration

ANSWER: C. Patients with bilateral diaphragmatic paralysis are severely short of breath; bilateral paresis will produce milder symptoms. Most patients with paralysis will develop ventilatory failure

and hypercapnia; some may develop cor pulmonale. Severe restriction will be found with pulmonary function test. Both hemidiaphragms will rise paradoxically during sniffing; this, accompanied by outward chest motion and inward abdominal motion, is called thoracoabdominal paradox. Petit eventration is complete hemidiaphragm eventration.

32 CHEST TRAUMA

Ian Malcolm and Satinder P. Singh

INTRODUCTION

Thoracic trauma is a common cause of significant morbidity and mortality. Most thoracic injuries in developed countries result from motor vehicle crashes (MVC) and other causes are falls or blow from blunt objects. Thoracic injuries account for 25% of trauma-related deaths. Imaging of patients with thoracic trauma must be accurate and timely to avoid preventable death.

Imaging usually starts with conventional radiography, often followed by CT imaging depending on severity of injury. Anteroposterior radiographic technique, poor inspiratory effort, patient rotation, aortic tortuosity, congenital arch anomalies, and mediastinal lipomatosis can simulate mediastinal widening because of traumatic hematoma, and mediastinal trauma is difficult to evaluate in children secondary to normal thymus. Also, 60% of patients with traumatic aortic injury do not have clinical signs on physical examination. Although the negative predictive value of a normal chest radiograph in trauma setting is quite high (98%), it is not specific, and in patients with abnormal chest radiograph, only 10% to 20% have positive angiographic findings.

CT of the chest is the modality of choice for initial evaluation of trauma. It has high sensitivity and negative predictive value and its specificity is good. CT study has false-positive rate of 0% to 39% and very low false-negative rate of 1% to 2%. The use of CT should be determined by the level of trauma, rather than the radiological signs and clinical findings. Trauma CT should be contrast-enhanced and CT angiography is preferable for the evaluation of aortic injury. Reformatted coronal and sagittal images improve diagnostic accuracy. Commonly observed artifacts that are due to aortic or cardiac pulsation may require CT angiography to exclude injury. These artifacts may resemble focal dissection or pseudoaneurysm and often occur on the medial aspect of the ascending aorta and can be overcome by using gated CT study.

TRAUMATIC AORTIC INJURY

Thoracic aortic injury accounts for up to 15% of deaths in MVC in the United States (Table 32-1). Between 85% and 90% of patients die before reaching the hospital, and approximately 50% of those who initially survive may die within 1 week in the absence of appropriate treatment. Rapid deceleration results in an intimal tear of the thoracic aorta, typically at the sites of aortic attachments, including (in descending order of frequency) the proximal descending aorta near the ductus, aortic root, and distal descending aorta at the aortic hiatus. Transection with subsequent rupture results in rapid exsanguination. Sixty percent of aortic tears involve the intima and media, with intact adventitia. Seventy percent of severe aortic injuries cause death at the injury scene. There are three sites of relative aortic fixation where compression and shear forces cause traumatic aortic injury. The predominant site of injury is at the isthmus between the left subclavian artery and the ligamentum arteriosum. The second site is the ascending aorta, which is involved in 5% of clinically observed cases. The incidence of injury at this site, on autopsy series, approximates 20%. In this region, aortic injury may be accompanied by hemopericardium, possible tamponade, and intracardiac valve injury. The final site involves less than 2% of cases and is at the level of the aortic diaphragmatic hiatus. Hemopericardium and mediastinal hematoma are not specific for aortic trauma. Hemopericardium more commonly occurs with cardiac contusion, without aortic injury. Mediastinal hematoma commonly occurs with sternal and costochondral fractures, which injure the internal mammary and intercostal vessels. Mediastinal venous injury and aortic arch branch vessel injury also may cause mediastinal hematoma.

There are often associated severe injuries elsewhere. The patient may be in hemorrhagic shock with upper body hypertension, interscapular pain, rarely paraplegia, and lower body and leg ischemia.

Imaging features of aortic injury are summarized in Tables 32-1 and 32-2. A normal aorta on CT with no

TABLE 32-1 Traumatic Aortic Injury

1%–2% of all blunt trauma
18% of deaths in MVC
Poor prognosis: 80%–90% die before reaching a hospital, 50% of the survivors die in 24 hr, 80% of the treated live
2%–5% of the untreated survive and develop pseudoaneurysm (PSA)
Location (sites of fixation)
Ligamentum arteriosum, isthmus (most common)
Sinus of valsalva within pericardium (5%)
Diaphragmatic hiatus (2%)
Mechanism of injury: shear, torque, pinching, and compression at attachment sites cause intimal rupture. Pressure for rupture: 2500 mm Hg

TABLE 32-2 Types of Traumatic Aortic Injury

Transsection: transverse tear, which may be complete or incomplete (intact adventitia)

Dissection: intimal tear with leakage of contrast into the media; this may remain localized or create a channel in the media, which connects more distally with the lumen via a second intimal tear

Pseudoaneurysm: focal bulge of the weakened aortic wall following a traumatic defect of the intima and media

mediastinal hematoma excludes traumatic aortic injury. A periaortic hematoma typically accompanies thoracic aortic injury and is believed to represent bleeding from small veins in the area or from the vasa vasorum of the aorta itself. A periaortic hematoma may be seen at chest radiography as a mediastinal abnormality such as mediastinal widening, blurring of the aortic contour, or thickening of the paratracheal stripe. The presence of a mediastinal abnormality at chest radiography has a diagnostic sensitivity of 90% to 95% for a thoracic aortic injury but a poor specificity of only 5% to 10% (Table 32-3). Anteroposterior radiographic technique, poor inspiratory effort, patient rotation, aortic tortuosity, congenital arch anomalies, and mediastinal lipomatosis can simulate mediastinal widening as a result of traumatic hematoma.

CT is considered the modality of choice for detecting and characterizing aortic injury especially with its multireformat capabilities. Intramural hematoma in the aortic wall can occur in a trauma setting with no visible flap. Intramural hematoma demonstrates high attenuation soft tissue in thickened aortic wall and appears hypodense on a contrast-enhanced CT (Table 32-4).

Arterial and venous injury may occur not only in the superior mediastinum but also in branch vessels of the axilla, thoracic inlet, and base of the neck. When the aorta is involved, the most common arch branch vessel involved is the brachiocephalic artery. In the absence of aortic injury, all arch branch arteries are equally involved. The injured vessel may be detected on the initial contrast CT, but follow-up angiography or CT

TABLE 32-3 Radiographic Signs of Traumatic Aortic Injury

First rib fracture

Chest radiographs have only a 15% positive predictive factor for mediastinal hematoma.

TABLE 32-4 CT Signs of Aortic Injury

Direct: irregular contour, change in caliber, presence of intimal flap

Indirect: mediastinal hematoma

False positive: thymus, atelectasis, motion, volume averaging, normal adjacent structures

angiogram is often required prior to surgical repair (Table 32-5). CT angiographic detail now approaches that of angiography, which remains the reference standard. Optimal bolus timing is required, and the patient is positioned appropriately to evaluate the injured artery or vein. The venous injection is made in the arm away from the injured vessel to avoid volume-averaging artifact, which results from intense contrast agent in the injected vein.

Transesophageal echocardiography (TEE) is a bedside examination that is very useful in evaluating an unstable patient, especially when other imaging findings are equivocal. However, it is technically inadequate in 15% patients and is minimally invasive with a complication rate of 2% to 3%. Findings suggestive of aortic injury include detection of intimal flap, pseudoaneurysm, or aortic wall hematoma. False-positive results can occur as a result of atherosclerotic disease. MRI has no role in an acute trauma setting, though it can be used to follow traumatic aortic injury and pseudoaneurysm.

Cardiac and pericardial injuries include contusion, chamber rupture, arrhythmia, coronary artery injury, pneumo- and hemopericardium, and tamponade. Electrocardiographic (EKG) changes in trauma setting indicate traumatic cardiac injury. Bedside echocardiography is a commonly used initial modality. Hemopericardium can be missed on echodiography (Table 32-6).

Prehospital deaths because of cardiac injury are common, according to autopsy findings. Hemopericardium often occurs as a result of ruptured pericardial vessels and less commonly because of aortic or myocardial rupture. Pneumopericardium occurs secondary to pneumomediastinum, some cases of which result from tracheobronchial and esophageal injury. Pericardial rupture occurs rarely and may result in herniation of myocardium through the defect with impaired myocardial contractility.

LUNG INJURY

- *Contusion*: common, hemorrhage in alveoli, appears quickly and clears in a few days
- *Laceration*: tear in lung leading to hematoma cyst formation; takes longer to resolve
- Other causes of consolidation in trauma: aspiration, atelectasis from mucous plug or splinting, and cardiac and noncardiac edema

PULMONARY CONTUSION AND LACERATION

Pulmonary contusion and laceration injury occur in up to 70% of cases of chest trauma and have a mortality of 10% to 25%. The patient may be hypoxic and have dyspnea and hemoptysis. Acute respiratory failure or ARDS may develop. There may be signs of aspiration as well as contusion (Table 32-7). Contusion is alveolar distention with blood from injured blood vessels. Air bronchograms are less frequent than with other forms of consolidation (pneumonia, pulmonary edema), likely because the airways are often also distended with blood. Contusion resolves completely with no residual injury. Laceration is a parenchymal tear resulting from shear forces or laceration by an adjacent displaced rib fracture. In the latter case, a pneumothorax and subcutaneous air is usually seen (Tables 32-8 and 32-9). These signs are more difficult to detect radiographically. The distribution of pulmonary contusion and laceration depends on the site and severity of blunt trauma. Aspiration at the time of, or subsequent to, injury may be distinguished from contusion by “tree-in-bud” lesions. If

TABLE 32-7 Radiographic Signs of Pulmonary Contusion

Patchy nonsegmental airspace consolidation
Air bronchograms are usually not present
May take up to 6 hours to develop
Opacification reaches its maximum in 1–3 d
Resolves in 1–2 wk, unless associated laceration is present
Must be distinguished from aspiration, pulmonary edema, pneumonia, or ARDS on subsequent radiographs

TABLE 32-8 CT Signs of Pulmonary Laceration

Focal consolidation without air bronchograms.
Linear or bubbly air collections within the lung parenchyma on CT. These must be distinguished from loculated hydropneumothorax.
Hematomas. These are circumscribed round or oval lung lesions.
Pneumatocoeles. These are round, usually thin-walled air collections, sometimes with air fluid levels. These may or may not develop following contusion and are generally present on follow-up CT examination.
Pneumatocoeles may persist as lung cysts. Hematomas may persist for months or years as pulmonary nodules. These progressively decrease in size and organize into fibrous lesions or parenchymal scars.

more than 20% of the lungs are involved with contusion, there is an 80% chance of developing ARDS. In some patients, consolidation occurring because of pulmonary contusion does not resolve but stabilizes or progressively worsens because of the development of other parenchymal disease.

ASPIRATION

Opacities caused by aspiration develop in the dependent portions of the lungs, variable with patient positioning. In a supine patient, the posterior segments of upper lobes and superior segments of lower lobes tend to be involved. Hospitalized patients frequently develop perihilar opacities because of aspiration in the lower lobe superior segments, which can be mistaken for pulmonary edema. Because of gastric acid, opacities may develop and change more rapidly than pulmonary contusion or pneumonic consolidation. There is likely to be cellular bronchiolitis (tree-in-bud and centrilobular nodules) because of aspiration into terminal and respiratory bronchioles. Aspirated food particles may block large- and medium-sized airways with lobar, segmental, or subsegmental collapse or alternatively air trapping.

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

ARDS is secondary to increased-permeability pulmonary edema caused by alveolar epithelial or capillary endothelial damage. ARDS commonly develops as a result of acute lung injury; however, there are many other causes including shock and sepsis. Patients have refractory hypoxemia with dyspnea, parenchymal consolidation, and no evidence of left heart failure. There is an acute hemorrhagic phase with epithelial cell sloughing, hemorrhagic alveolar filling, hyaline membrane formation, and intense interstitial inflammation. A subsequent fibroproliferative phase results from granulation tissue

TABLE 32-9 Radiographic Signs of Tracheobronchial Injury

Pneumomediastinum
Lower lobe collapse

Overinflated endotracheal cuff
Double wall sign
Occasionally pneumothorax and subcutaneous emphysema

formation in the interstitium and subsequent development of fibrous tissue. Because of intractable hypoxemia and poor lung compliance (stiff lungs), assisted ventilation is required with common development of barotrauma. Approximately 30% to 50% of patients die in the acute phase and the remaining ones recover or develop pulmonary fibrosis and end-stage lung disease. Radiographically, there is patchy consolidation in both lungs, which becomes progressively more diffuse over time. A coarse reticular pattern develops in the fibroproliferative phase with progressive loss of lung volumes. CT abnormalities develop within 12 hours. There are extensive ground glass opacities, with or without airspace consolidation, in a geographical pattern with interspersed areas of normal lung. Interstitial reticulation may be superimposed on the ground glass opacities thus causing the crazy paving pattern. Consolidation worsens and becomes gravitational dependent with prominent air bronchograms. In the fibroproliferative phase, there is coarse reticulation, traction bronchiectasis, and honeycomb cystic change.

AIRWAYS INJURY

Tracheal injury is uncommon because of shear or crush injury (Table 32-10). There is usually pneumomediastinum, but pneumothorax, deep cervical and subcutaneous emphysema, and also retroperitoneal air in the abdomen may occur. Bronchial fracture may cause delayed lower lobe collapse or, rarely, the fallen lung sign. In the latter case, the lung collapses dependently below the hilum, rather than inferomedially. Air may track along the bronchial wall causing the double wall sign. Injuries to the right lower lobe bronchus occur more commonly than left lower lobe bronchial or tracheal injuries. Injuries predominate within 2 cm of the

1.5% of blunt chest trauma
Often not recognized, delayed diagnosis
Associated fractures: 1–3 ribs, scapula, clavicle, sternum in up to 40%
Bronchial fractures within 2.5 cm of carina

carina. The endotracheal cuff may appear hyperinflated and the endotracheal tube itself may be visualized outside the tracheal lumen. Bronchoscopy is used to detect these injuries and also complications such as bronchostenosis, bronchopleural fistula, bronchiectasis, and postobstructive pneumonia. These lesions are treated by direct surgical repair of the airway or by lobectomy or pneumonectomy in severe cases.

PNEUMOTHORAX

CT readily shows extremely small pneumothoraces, but the detection of pneumothoraces is more challenging on radiographs. Displaced rib fractures may tear the parietal pleura. Pneumomediastinum may rupture through the parietal pleura and cause pneumothorax. Direct trauma may force air from the alveolar spaces into the alveolar interstitium. This may subsequently rupture the visceral pleura and cause pneumothorax. Alternatively, air may track medially into the bronchovascular interstitium (pulmonary interstitial emphysema) and subsequently into the mediastinum. Thirty percent of pneumothoraces are missed on supine or semierect radiographs. Rib fractures, together with subcutaneous air, indicate that pneumothorax is present even though it may not be visualized radiographically. The mediastinum may be more sharply defined than normal, with small pneumothoraces. A deep costophrenic sulcus may be seen if the air is situated inferomedially. Contralateral mediastinal shift indicates tension requiring chest tube decompression.

PNEUMOMEDIASTINUM

Small pneumothoraces and small collections of mediastinal air are readily identified with CT. There is direct air leakage if tracheobronchial structures are injured. Pneumomediastinum may also arise from extension of subcutaneous or deep cervical emphysema or direct extension of retroperitoneal air. Direct trauma or assisted ventilation may cause pulmonary interstitial emphysema, with subsequent pneumomediastinum. This commonly occurs with ARDS, where the lungs have loss of compliance and positive pressure is required to improve hypoxemia. On chest radiographs, pneumomediastinum reveals as vertical streaks in the mediastinum, which may extend into the cervical soft tissues. The air may surround vessels (“ring around the artery” and “tubular artery signs”) or around the airway (“double bronchus sign”). A peripheral lucency may be present along one or both sides of the mediastinum with surrounding parietal pleural line. Alternatively, lucency may outline the heart with surrounding pericardium (pneumopericardium).

Air posterior to the pericardium may show the continuous diaphragm sign, where the entire upper margin of the diaphragm is outlined by air. Pneumomediastinum should resolve. If this does not occur, tracheal injury should be ruled out with bronchoscopy.

HEMOTHORAX

Fifty percent of cases with blunt trauma show hemothorax. The blood may arise from pulmonary, intercostal, phrenic, or internal mammary vessels and may also be seen with traumatic aortic injury. Small hemothoraces are readily seen on CT. On radiographs, small- and medium-sized hemothoraces may be missed, particularly on portable examinations taken in erect or semi-erect positions. Supine radiographs may show an apical cap of pleural fluid or mild opacification of the affected side because of blood layering posteriorly in the pleural space. Some 200 to 500 mL of pleural fluid is required to cause blunting of the costophrenic recesses on erect radiographs, but lateral decubitus films may show collections as small as 5 mL. CT detects small collections and can differentiate blood from serous fluid by high attenuation values (35–70 HU). Aortic bleeding can occasionally be detected by contrast extravasation into the pleural space. Loculation is inclined to develop and fibrothorax may result if chest tube drainage of the blood is not carried out.

TRAUMATIC DIAPHRAGMATIC INJURY

Penetrating trauma (10%) is the most common cause of traumatic diaphragmatic injury and is usually small. In 3% to 6% of major blunt trauma, the diaphragm can be injured and this is usually a large-size injury. Majority of diaphragmatic injuries (70%) are initially missed because of associated lung injury, pleural effusion, and mechanical ventilation. Left-sided injury is more common (77%–95%) with liver protecting the diaphragm from right-sided injury. More than three-fourths of patients have other visceral injuries. Radiographic diagnosis is often difficult. Associated pulmonary contusion, hemothorax, and lacerations of the liver and spleen may conceal the area of interest.

The mechanism of injury for diaphragmatic injury is increased intrathoracic pressure and shearing forces. The most common site of injury is the posterolateral portion of the diaphragm at the junction of central tendon and posterior leaves because of congenital weakness of fusion of costal and lumbar muscular attachments.

Chest radiographs are abnormal in 77% patients, though injury is suspected only in 50% patients. The

Intrathoracic viscera. This may be bowel, liver, spleen, or mesenteric fat. The amount of herniated viscera is dependent upon the size of the tear.
Dependent viscera sign: upper third liver abutting posterior ribs, or stomach/bowel lay in contact with posterior ribs, in 90%, may be an early indicator before visceral herniation.
Nasogastric tube tip within the thorax
Contralateral mediastinal shift
Collar sign: waistlike constriction of the displaced intrathoracic; sensitivity 67% for left, and 50% for right, specificity 100%.

most reliable radiographic signs are intrathoracic bowel and enteric tube tip in the thorax. Other signs are elevation of the diaphragm, indistinct diaphragm, or contralateral mediastinal shift. CT has a sensitivity of up to 90% in the detection of tears, and the confidence of interpretation is helped by reformatted coronal and sagittal images (Table 32-11). False-positive diagnosis is often due to splenic injury and peridiaphragmatic hematoma. False-negative diagnosis is due to associated lower lobe consolidation or pleural effusion. Treatment is by direct surgical repair or synthetic graft repair. Mortality from diaphragmatic rupture is 30% and delayed diagnosis results in bowel strangulation.

SKELETAL TRAUMA

Rib fractures without displacement have no serious consequences. Displaced fractures may cause pneumothorax, hemothorax, and subcutaneous emphysema. Individual ribs with multiple fractures may result in flail chest with impaired ventilation (Table 32-12). An unusually large extrapleural hematoma on chest radiographs, in association with rib fractures, should raise the suspicion of flail chest. Elderly patients have osteopenic ribs and vertebrae that fracture more readily. Children have flexible ribs that fracture less readily and consequently, childhood rib fractures are associated with higher mortality. Certain rib fractures have common associated injuries. First through third rib fractures

TABLE 32-12 Flail Chest

Fractures of 4 consecutive ribs in >2 places or >3 segmental rib fractures (multiple rib fractures)
Significant kinetic force injury
Diagnosis: physical examination, paradoxical chest wall motion, chest radiograph findings, physiologic derangement
Usually associated with lung contusion

commonly occur with aortic, great vessel, and tracheobronchial injury. Tenth through twelfth rib fractures are associated with hepatic, splenic, and renal injuries.

Sternal fractures may be associated with bleeding and consequent mediastinal hematoma or hemothorax. They are often associated with cardiac, aortic arch, and great vessel injury. Posterior sternoclavicular dislocations cause penetrating injury, which may involve the trachea, esophagus, and mediastinal great vessels.

Scapula fractures indicate significant trauma also. Patients with scapula fractures commonly have a pneumothorax and there is an 11% chance of ipsilateral subclavian, axillary, or brachial artery injury. Ipsilateral subclavian axillary or brachial artery injury should be searched for when scapula fractures are identified.

QUESTIONS AND ANSWERS

- Concerning CT evaluation of aortic injury, which of the following is *true*?
 - Aortic injury is excluded if the aorta is normal and no mediastinal hematoma is identified.
 - Clinical evaluation of the patient determines whether HRCT is indicated.
 - Hemopericardium indicates ascending aortic injury.
 - Aortic arch branch vessel injury is common.

ANSWER: A. The level of trauma, not the clinical examination, should determine whether CT is indicated. Hemopericardium occurs more commonly with cardiac injury than ascending aortic injury. Aortic branch vessel injury occurs much less commonly than aortic injury.

- Concerning aortic injury, which of the following is *true*?
 - Majority of patients with aortic trauma have clinical signs when examined.
 - Traumatic dissection is most likely to occur in the ascending aorta.
 - Aortic transection usually results in death before surgery can be initiated.
 - Chest radiography has a 25% positive predictive factor for mediastinal hematoma.

ANSWER: C. Sixty percent of patients have no clinical signs on initial examination, when aortic injury is present. Traumatic dissection predominantly occurs at the isthmus. Chest radiography has only a 15% positive predictive factor for mediastinal hematoma.

- Concerning pulmonary contusion, which of the following is *true*?
 - Readily distinguished from pulmonary laceration on initial radiographs
 - May progressively worsen on radiographs for the first 3 days
 - Forty percent of the lungs must be involved before ARDS subsequently develops.
 - Air bronchograms are usually present.

ANSWER: B. Pulmonary contusion and laceration cannot usually be differentiated on initial radiographs. If 20% of the lungs are involved, there is an 80% chance of subsequent ARDS. Air bronchograms are not usually seen.

4. Concerning pulmonary laceration, which of the following is *true*?

- A. Lucent round, oval, or linear areas are shown on initial chest radiographs.
- B. Lacerations must be distinguished from hydropneumothorax on CT.
- C. Penetrating injury is required for pulmonary laceration to develop.
- D. Injuries severe enough to cause pulmonary lacerations are likely to have associated aortic injury.

ANSWER: B. Initially, only consolidation is seen on radiographs. Laceration may also occur due to shear forces associated with blunt chest trauma. Pulmonary laceration occurs more commonly than aortic injury. Aortic injury involves more severe trauma than is required for pulmonary laceration to occur.

5. Concerning tracheobronchial injury, which of the following is *true*?

- A. Left lower lobe bronchus is more readily involved than the trachea or right lower lobe bronchus.
- B. Tracheobronchial injury is the most common cause of traumatic pneumomediastinum.
- C. The endotracheal tube may be identified outside the tracheal lumen.
- D. Tracheobronchial injury is commonly associated with pneumothorax.

ANSWER: C. Right lower lobe bronchus is most commonly involved. Tracheobronchial injury is not common and consequently is not a common cause of pneumomediastinum. Pneumothorax is only occasionally found in association with tracheobronchial injury.

6. Concerning traumatic diaphragmatic injury, which of the following is *true*?

- A. Sensitivity of detection with CT is 50% to 70%.
- B. Diaphragmatic injury may initially be obscured by other injuries.
- C. Common cause of mediastinal shift.
- D. Bronchopleural fistula is a common complication.

ANSWER: B. Sensitivity of detection with CT is 70% to 90%. Mediastinal shift occurs much more commonly than diaphragmatic injury because of a variety of causes such as pneumothorax and hemothorax. Bronchopleural fistula is an unrelated injury.

7. Concerning sternal fractures, which of the following is *true*?

- A. Displaced sternal fractures and mediastinal hematoma indicate traumatic aortic injury.

B. May be associated with cardiac contusion and hemopericardium

C. Anterior sternoclavicular joint dislocations may result in injury to the trachea and esophagus.

D. Pulmonary contusion occurs in less than 10% of cases.

ANSWER: B. Both sternal fractures and mediastinal hematoma are commonly seen in the absence of aortic injury. Posterior sternoclavicular dislocation is liable to cause trauma injury to the trachea and esophagus. Pulmonary contusion occurs in up to 70% of cases of chest trauma.

8. Concerning branch vessel injury, when the aorta remains intact

A. Arch branch vascular injury should be searched for in the case of first rib fractures

B. Brachiocephalic artery is the arch branch usually injured

C. Hematoma is often identified in the pretracheal and AP window regions

D. Angiography is required prior to surgical repair

ANSWER: A. Arch branch vessels are involved equally if there is no aortic injury. Hematoma is usually in the anterior mediastinum. It also occurs less commonly in the posterior mediastinum with injuries of the descending aorta or spinal injury. Pretracheal hematoma may occur with tracheal injury that is much less common. Good quality CT angiography provides adequate information in many cases and avoids the delay caused by angiography if surgery is urgently required.

9. Concerning aspiration with chest trauma, which of the following is *true*?

A. Aspiration is invariable with severe chest trauma.

B. Rib fractures should be expected if aspiration is present.

C. Aspiration can simulate pulmonary edema with rapidly developing and rapidly resolving opacities in the perihilar region.

D. Aspiration is seldom severe enough to precipitate ARDS.

ANSWER: C. Aspiration can occur, but usually does not. No known relationship between rib fracture and aspiration has been described. The level of consciousness and the severity of trauma would be expected to correlate with the severity of aspiration. Severe aspiration may cause ARDS and is more likely to occur with head injury with loss of consciousness in a patient who has recent food or fluid ingestion, prior to the chest trauma.

33 DRUG-INDUCED LUNG TOXICITY

John C. Texada and Satinder P. Singh

INTRODUCTION

Drug reactions are quite common and must always be considered as the etiology for a patient's new symptoms. They may be categorized into one or more of six types: bronchospasm, systemic lupus erythematosus–like syndrome, responses from illicit drug abuse, eosinophilic reactions, interstitial or airspace pneumonitis, or pulmonary edema from increased permeability.

CHEMOTHERAPEUTIC AND IMMUNOSUPPRESSIVE DRUGS

BLEOMYCIN

Bleomycin is an antibiotic isolated from *Streptomyces verticillus*. Although bleomycin does not produce myelosuppression like many other chemotherapeutic agents, many patients will develop dose-related lung toxicity—overall incidence is 3% to 5%, but above 450 units of drug incidence is 13% to 17%. The risk of developing toxicity rises in old people, smokers, and people receiving combined chemotherapy, oxygen, or radiation therapy. Radiographic changes are more common than symptoms, and CT changes are still more common.

HISTOPATHOLOGIC FINDINGS

The compound gets concentrated in lung and skin, and these tissues do not have much of the enzyme necessary to degrade it. Once within cells, it can cleave DNA. Alveolar macrophage recruitment is an early response, followed by inflammatory cell recruitment, tissue injury, and fibrosis. Diffuse alveolar damage (DAD) is characteristic. BOOP, eosinophilic pneumonia and pleuritis, and venoocclusive disease may occur.

RADIOGRAPHIC FINDINGS

Findings develop 6 to 12 weeks after beginning therapy; they may resolve after therapy is stopped, or may persist. Bilateral basilar reticular/reticulonodular/nodular opacities are often peripheral, and often involve or are confined to the costophrenic angles. More severe disease extends upward in the lungs or evolves to airspace consolidation.

CT FINDINGS

CT detects parenchymal abnormalities in 38% of patients as against 15% from the radiography. CT or

HRCT may reveal focal consolidation or dense irregular lines; in mild disease, as in radiography, the findings are subpleural and posterior, with disease spreading with increasing severity.

OTHERS

MITOMYCIN

Mitomycin is an antibiotic derived from *Sporobolus caespitosus*. It may cause lung disease in 3% to 7% of patients, via an uncertain mechanism perhaps related to its alkylating properties. It causes endothelial damage, type I cell damage and type II cell proliferation, and interstitial fibrosis. It may be associated with a hemolytic-uremic syndrome.

BUSULFAN

Busulfan is used in myeloproliferative disorders and in bone-marrow transplant preparation. It produces clinically apparent lung disease in 5% of patients, but 50% of patients have pathologic evidence of damage. The former is associated with long-term use, at least of several months, and symptoms are insidious. Large atypical mononuclear cells (altered type II cells) are present, and fibroblasts and collagen deposition increase leading to fibrosis that may be diffuse or basilar-predominant. Mean survival after fibrosis develops is 5 months.

CYCLOPHOSPHAMIDE

Cyclophosphamide is an alkylating agent. Its pulmonary toxicity is probably less than 1%; fibrosis may develop after a dose of as little as 150 mg, but the risk increases with higher doses. There is DAD and atypical alveolar cells, with chronic pneumonitis, fibrosis, and less commonly BOOP. Basilar reticular opacities, often with consolidation, are visible; pleural thickening also is commonly present. The presentation is often acute or subacute, but may be chronic. Steroids help prevent and reverse toxicity.

CHLORAMBUCIL

Chlorambucil is an alkylating agent useful in blood malignancy. It rarely causes lung toxicity. When chlorambucil does lead to pulmonary toxicity, it usually manifests as interstitial pneumonitis and fibrosis. Bilateral basilar reticular opacities are present. Onset may be delayed. Mortality can be high, though drug cessation and steroid therapy may help.

Others drugs, including melphalan (a phenylalanine derivative of nitrogen mustard gas useful in multiple myeloma), nitrosoureas (alkylating agents that interfere with DNA repair and synthesis), the anti-androgen nilutamide, and the vinca alkaloids, may produce similar toxicity syndromes.

Tamoxifen may increase the risk of thrombotic events. Cyclosporine may cause acute respiratory distress syndrome (ARDS). Procarbazine may cause acute allergic reaction.

ANTIMETABOLIC DRUGS

METHOTREXATE

Methotrexate is a folic acid analogue that creates acute deficiency of intracellular folate coenzymes and thereby inhibits cell reproduction. It is used both in cancers and as disease-modifying therapy in several autoimmune diseases. The incidence of reaction is estimated at 2% to 5% for low-dose therapy as with rheumatoid arthritis. Frequency, dose, and duration are risk factors as is pre-existing lung disease.

PATHOLOGIC FINDINGS

Unlike many other agents, methotrexate-induced lung disease is often reversible; it is generally a hypersensitivity reaction, evidenced by eosinophilia and pulmonary granuloma or eosinophil infiltration. It can, though, induce chronic interstitial fibrosis occasionally. Interstitial pneumonitis or fibrosis are the most common findings, with occasionally DAD or rarely BOOP.

RADIOGRAPHIC FINDINGS

The radiographic appearance is characteristic. Initially a basilar or diffuse reticular or ground glass opacity develops, which in turn rapidly develops into patchy consolidation before reverting to interstitial opacity and then resolves. Nodules or lymphadenopathy may also develop.

OTHERS

Cytosine arabinoside (an inhibitor of DNA synthesis) may cause lung disease in 15% to 30% of patients treated with high IV doses, often in treatment for leukemia; DAD or a proteinaceous acellular alveolar exudates may develop. Gemcitabine is similar to cytosine arabinoside. Azathioprine (an interferon of purine synthesis) has been reported to rarely cause lung disease, in a dose-related manner. Fludarabine may cause interstitial pneumonitis or DAD. L-Asparaginase increases the risk of thrombotic events.

BIOLOGIC RESPONSE MODIFIERS

Interleukin-2 is believed to increase capillary permeability, and thereby may cause a syndrome of car-

diopulmonary failure with edema, hypotension, and weight gain. Radiographic manifestations range from mild-to-severe edema, often with pleural effusions. Tumor necrosis factor may cause asymptomatic noncardiogenic edema, or rarely DAD. Granulocyte-macrophage colony stimulating factor produces a capillary leak syndrome and may produce acute eosinophilic pneumonia, pleural and pericardial effusions, and PTE. Interferon has been shown to produce interstitial pneumonitis and BOOP, and may spur development of antiphospholipid antibody and thus increase risk of thrombosis.

ANTIMICROBIAL DRUGS

NITROFURANTOIN

This drug may rarely cause lung disease, and severe disease is still rarer. Two presentations occur with nitrofurantoin toxicity: (1) an acute reaction, almost certainly due to hypersensitivity, as evidenced by abrupt onset and peripheral eosinophilia and (2) a less common chronic reaction developing after weeks to years of therapy, likely due to oxidant tissue damage.

PATHOLOGIC FINDINGS

Interstitial pneumonitis and fibrosis are indistinguishable from IPF. Rare cases of other findings may occur.

RADIOGRAPHIC FINDINGS

In acute reaction, a diffuse basilar-predominant reticular pattern develops, sometimes with septal lines; the pattern resembles interstitial edema. Pleural effusions often occur, sometimes without other findings. Some patients developed ARDS. In chronic toxicity, a bilateral lower lung predominant reticular interstitial pattern develops; HRCT reveals subpleural and peribronchovascular consolidation and fibrosis. In chronic toxicity, effusions are uncommon.

OTHERS

Sulfasalazine may occasionally produce an acute migratory opacity and peripheral eosinophilia, almost certainly due to hypersensitivity. Biopsy may reveal BOOP or interstitial pneumonitis and fibrosis. Radiographs may reveal poorly defined peripheral and upper-lung (not lower-lung) predominant consolidation.

Tetracycline and minocycline produce pulmonary eosinophilia, likely due to hypersensitivity; sulfonamides, penicillin, *para*-aminosalicylic acid, ethambutol, ampicillin, maloprim, cephalosporins, and other agents may cause pulmonary hypersensitivity reactions.

ANTIARRHYTHMIC DRUGS

AMIODARONE

Amiodarone HCl is an iodinated benzofuran derivative used in arrhythmia therapy. The drug accumulates in various organs but is most concentrated in the lungs—up to seven times more concentrated than in other body tissues. Up to 5% to 7% of patients on amiodarone develop lung toxicity, and of those 5% to 10% will die. Its pathogenicity is uncertain; it is, though, dose related. The drug causes inhibition of phospholipids degradation, so phospholipids accumulate, and this may be one etiology for damage; the drug itself may also directly cause cell damage; or an immune-inflammatory response may cause the damage. Damage onset is generally months after initiation of therapy in patients taking dosages greater than 400 mg/d, although lung injury has been reported with treatment for periods as short as 3 weeks and with dosage as low as 200 mg/d. Treatment with drug removal and steroids is very effective.

PATHOLOGIC FINDINGS

There is often chronic inflammation and septal fibrosis, type II hyperplasia, and foamy macrophage accumulation with characteristic lysosomal inclusions probably containing the drug or a metabolite (though the presence of these inclusions is not diagnostic of drug toxicity). Less commonly, DAD, BOOP, necrotizing bronchiolitis, or necrotizing pneumonia may develop.

CLINICAL PRESENTATION

Chronic interstitial pneumonitis is the most common presentation, characterized by insidious onset of cough, dyspnea, and weight loss.

ARDS is rare but potentially fatal form of lung toxicity, with fulminant course and typically seen in patients who undergo surgery or pulmonary angiography. It is hypothesized that amiodarone may sensitize susceptible individuals to either high concentrations of inspired oxygen or to iodinated contrast media.

RADIOGRAPHIC FINDINGS

Radiographs often show diffuse bilateral reticular or alveolar opacities, often peripheral and often upper-lung predominant, resembling chronic eosinophilic pneumonia. Focal consolidation, nodule development, and pleural thickening have been described.

CT FINDINGS

Because amiodarone contains iodine, dense liver and spleen are common; dense lung lesions are also com-

mon; dense myocardium has been reported but is uncommon. Consolidation, (often wedge shaped and pleural based), reticular interstitial disease, atelectasis, or round consolidation may be present. Effusions are visible in 50% of cases. Gallium-67 imaging will be positive in amiodarone-induced lung disease.

OTHERS

Lidocaine, tocainide, verapamil, procainamide, and sotalol have caused lung toxicity or edema in a few cases.

ANTICONVULSANT DRUGS

DIPHENYLHYDANTOIN

This antiseizure medication acts as a membrane stabilizer. It may produce an acute hypersensitivity reaction with peripheral eosinophilia and diffuse reticulonodular interstitial disease that resolves within 2 weeks of discontinuing therapy. Mediastinal lymphadenopathy may develop, often reactive, though incidence of lymphoma in patients on this drug is increased up to ten times. Rarely airspace consolidation or miliary nodules may develop.

CARBAMAZEPINE

Twelve cases of carbamazepine-induced lung toxicity have been reported, manifested by pneumonia, eosinophilia, and skin rash; radiograph appearance may be of reticular or reticulonodular interstitial disease or alveolar opacity, occasionally with lymphadenopathy. In addition, patients may also develop decreased diffusion capacity of the lung for carbon monoxide (DLCO) but have normal radiographs.

ANALGESIC DRUGS

Aspirin can produce acute pulmonary edema, particularly in middle-age and elderly patients taking large doses. Younger people often do not develop edema in aspirin overdose. The edema is the result of increased capillary permeability, perhaps from increased intracranial pressure causing neurogenic edema, or from inhibition of prostaglandin productions leading to vasodilation and permeability.

Nonsteroidal anti-inflammatory drugs (NSAIDs) may rarely produce lung toxicity; there are scattered reports describing acute development of pulmonary

alveolar opacities and eosinophilia in patients taking naproxen or other NSAIDs.

ANTIRHEUMATIC DRUGS

PENICILLAMINE

This penicillin derivative can chelate metals and is used to treat lead poisoning, Wilson disease (abnormal copper deposition), cystinuria, and connective tissue diseases. It may produce a wide variety of lung diseases, including lupus-like disease, myasthenia-like disease, alveolitis, obliterative bronchiolitis, and DAD. The risk is quite low and is not dose related. The reactions are probably type I and/or type III immune reactions. Acute hypersensitivity has a good prognosis; however, patients who develop pulmonary–renal syndrome or obliterative bronchiolitis often die. Radiographs may reveal one of the following three patterns: (1) reticular/reticulonodular interstitial disease with or without limited alveolar opacity; (2) overinflation, associated with advanced obliterative bronchiolitis; and (3) diffuse alveolar consolidation in patients with DAD. HRCT findings in patients with obliterative bronchiolitis include areas of mosaic attenuation and bronchial dilation.

GOLD

Gold therapy causes lung disease in less than 1% of patients, in a non–dose-dependent manner that may be associated with certain major histocompatibility complex antigens. The reaction is believed to be a hypersensitivity reaction, with perhaps a cell-mediated immune component. Pathology reveals interstitial pneumonitis and fibrosis, or occasionally BOOP or obliterative bronchiolitis. Chest radiograph may reveal interstitial and alveolar opacities.

SYMPATHOMIMETIC DRUGS

Beta-Agonist medicines terbutaline, ritodrine, and isoxsuprine suppress preterm labor; they can rarely produce a hyperpermeability pulmonary edema.

ILLICIT DRUGS

SEDATIVE-NARCOTIC DRUGS

The opiates can produce pulmonary edema, as often as 50% to 75% of cases of heroin overdose and also re-

ported with multiple other sedative-narcotic drugs. The presence of high protein concentrations in the developed fluid indicates a capillary hyperpermeability state, perhaps from endothelial damage caused by hypoventilatory acidosis. Bronchiectasis may be found in patients with opiate-induced edema, but this is likely a sequela of prior infections from aspiration. Pneumothorax may develop from attempts at venous access.

COCAINE

Crack cocaine causes a variety of lung toxicities. Users often report cough, black sputum production, chest pain, shortness of breath, or hemoptysis. Pulmonary edema may develop, perhaps from endothelial damage, or perhaps from cardiac dysfunction. Pulmonary hemorrhage is an important manifestation of “crack lung,” characterized by acute respiratory failure and diffuse consolidation in radiography. Thermal injury may be complicated by tracheal stenosis or reactive airway disease. BOOP, pneumothorax, pneumomediastinum, and pneumoperitoneum have been reported. Chronic use may lead to reduced DLCO by an uncertain mechanism.

MARIJUANA

Marijuana users may develop acute and chronic bronchitis similar to tobacco smokers. Because marijuana often contains *Aspergillus*, its users may develop allergic bronchopulmonary aspergillosis and immunocompromised smokers may develop *Aspergillus* infection. Long-term use may lead to reduced DLCO.

OTHER DRUGS

Antidepressants and antipsychotic drugs have been reported to cause occasional lung toxicity, most often ARDS but occasionally hypersensitivity or BOOP.

Ethiodol used in lymphangiography and hysterosalpingography may produce a subacute ARDS picture similar to fat embolism.

Water-soluble contrast material can cause pulmonary edema if aspirated, likely because it is quite hyperosmolar.

Ionic contrast material produces acute reactions in 5% to 15% of injections, though 0.05% to 0.1% are life threatening. Nonionic contrast material produces fewer reactions, on the order of 3%.

ACE inhibitors cause a chronic nonproductive cough in up to 44% of patients, probably closer to 10%. It often begins after months of therapy, but may happen after the first dose or as late as a year. It disappears within 10 days of drug cessation. These drugs may also cause asthma, angioedema, and peripheral eosinophilia.

Hydrochlorothiazide may rarely cause hyperpermeability edema. Beta-blockers can produce a lupus-like syndrome, and importantly may produce bronchospasm. A large number of other drugs have been reported to cause lung toxicity in rare or individual cases.

POISONS

ORGANOPHOSPHATES

Organophosphate pesticide poisoning occurs commonly in farm workers during or after spraying of crops; it occurs occasionally in industry workers and in accidents and suicide attempts. Parathion and malathion may be absorbed through the skin and are converted in the liver to metabolites that inhibit nerve-ending acetyl cholinesterase. This results in initial hyperstimulation and subsequent inhibition of nerve transmission, and symptoms develop within 5 minutes to 24 hours depending on dose. The nerve action leads to miosis, diaphoresis, salivation, bronchorrhea, bronchoconstriction, bradycardia, and hyperperistalsis. Neurogenic muscle fasciculations lead to paralysis, including of the diaphragm. CNS cholinergic receptor stimulation and subsequent inhibition leads to depression and coma.

PARAQUAT

This bipyridylium herbicide (Gramoxone, Weedol, Orthoparaquat, Orthodualparaquat, and Ortho-spot) may be ingested in accidents or suicide attempts, or absorbed through the skin. It may produce respiratory failure from acute exposure, and prolonged absorption of low concentrations may produce lung damage. Its mechanism is believed to be oxidative damage, and it primarily affects type I alveolar cells and largely spares the endothelium. Pulmonary edema and hemorrhage develop, and may result in rapid death. Those who do not die may go on to develop DAD and fibrosis, which may be progressive.

OTHERS

Carbamate insecticides may cause asthma. Propoxur, a carbamylester agent, binds acetyl cholinesterase and produces symptoms similar to organophosphate toxicity. Toxaphene is a chlorinated camphene agent that is 68% chlorine. Inhalation causes allergic bronchopneumonia.

HYDROCARBONS

Five percent of childhood poisonings are hydrocarbon based, often kerosene. Although fairly common, the

process is generally mild, but can uncommonly have progressive disease. Some believe that the hydrocarbon is absorbed from the GI tract and transported to the pulmonary capillaries; others believe the hydrocarbon arrives via emesis and aspiration. Regardless of its route, once in the lungs hydrocarbon produces hemorrhagic edema, necrosis, and acute inflammation. Radiographs are typically abnormal within an hour of kerosene ingestion but abnormalities may take longer to develop with other hydrocarbons. Patchy alveolar opacities, predominantly basilar, may develop, and the pulmonary hila may become indistinct. Resolution tends to be a slow process that lags clinical improvement; pneumatocele formation is a common sequela.

INHALED SUBSTANCES

Many gases, fumes, and aerosols provoke pulmonary irritation and/or damage. Most of the time capillary damage results in pulmonary edema, but in some cases the bronchi and bronchioles are the site of chemical damage. After the acute insult obliterative bronchiolitis may develop.

OXYGEN, OZONE, AND NITROGEN DIOXIDE

These oxidants produce reactive oxygen species that damage lipids, DNA, and proteins. Hyperoxia (including iatrogenic oxygen administration) provokes intracellular oxygen free radical production, and the cellular damage produces bronchoconstriction, mucus secretion, decreased surfactant function, and increased permeability. Changes may appear within 24 hours: Type I cells may be swell or desquamate, and type II cells proliferate. After prolonged administration macrophage function and intrapulmonary immune defense are impaired.

The oxygen concentration that leads to toxicity is unknown, but FiO_2 of 50% can be tolerated for long periods without irreversible damage.

Ozone does not cause a serious acute response, but chronic exposure to even low levels of ozone (which is a major constituent of smog) produces toxicity: cilia swell and mat; collagen production increases; epithelial hyperplasia and macrophage aggregation occur; and reversible fibroblast and macrophage accumulation occur.

Nitrogen dioxide exposure is responsible for silo-filler disease; fresh material in newly filled silos produces nitric oxide that oxidizes to form nitrogen dioxide. Early injury is characterized by abrupt onset of cough, dyspnea, and a choking feeling; pathologically, there is bronchiolitis and peribronchiolitis, occasionally with alveolar damage. Pulmonary edema can develop

but usually clears without permanent damage if the patient survives. In the subacute phase, which lasts 2 to 5 weeks, constitutional symptoms and shortness of breath may persist, and the chest radiograph is normal. In the late phase, after 5 weeks, obliterative bronchiolitis may develop, characterized by development of multiple nodular opacities of varying size.

SULFUR DIOXIDE

On exposure to moist tissues, sulfur dioxide becomes sulfuric acid, which causes direct mucosal injury. In addition to its presence as an environmental pollutant, high accidental exposures may be found in pulp and paper factories, refrigeration plants, and fruit-preserving factories. Exposure may produce a similar triphasic response to nitrogen dioxide.

HYDROGEN SULFIDE

Sulfide ions act as direct cytotoxins by binding to mitochondrial cytochrome oxidase and inhibiting electron transport. This compound is responsible for a rotten-eggs odor at 0.2 ppm. At 250 ppm the compound produces keratoconjunctivitis, bronchitis, and pulmonary edema, and at higher concentrations it affects the CNS. Several people have died from acute exposures to high concentrations produced by decaying organic matter; if the patient survives pulmonary sequelae are not usual.

AMMONIA

Inhalation of ammonia leads to serosanguineous and purulent secretion production, and inflammation and desquamation of large bronchi. Bronchiectasis and obliterative bronchiolitis may develop after the acute exposure. Even household ammonia is strong enough to cause esophageal necrosis and ARDS if ingested.

CHLORINE

Acute exposure to high concentration causes pulmonary edema, epithelial necrosis, and bronchial inflammation.

PHOSGENE

Carbon oxychloride is a colorless dense gas that when inhaled splits into hydrochloric acid and carbon dioxide. The acid then produces necrosis of the epithelium and pulmonary edema. There is often a delay of several

hours after exposure before dyspnea develops, but pulmonary edema can kill the patient within 24 hours.

FORMALDEHYDE

Formaldehyde compounds are used in wood adhesives and foam housing insulation. Exposure may produce upper-respiratory symptoms, but no acute or chronic respiratory impairment has been found.

METAL FUMES

Fumes of mercury, zinc, manganese, cadmium, nickel, and vanadium can cause acute tracheobronchitis, ARDS, interstitial pneumonitis, and “fume fever” characterized by thirst, metallic taste, substantial tightness, headache, fever, chills, muscle aches, increased BAL TNF, and neutrophilic alveolitis. Symptoms usually appear within 12 hours, and resolve within 24, without sequelae.

BURNS

Pulmonary complication incidence is directly proportional to burn severity. Direct heat trauma may severely damage the upper respiratory mucosa, with symptoms developing particularly in the first 24 hours. Cyanide and hydrochloric acid cause tissue damage. Patients may develop edema after 12 to 48 hour latency; and may develop intravascular fibrin thrombi and intra-alveolar hemorrhage. After 2 to 5 days atelectasis, edema, and pneumonia may develop, and later than that, PTE and ARDS may develop.

QUESTIONS AND ANSWERS

1. Which of the following is *not* a type of pulmonary drug reaction?
 - A. Bronchospasm
 - B. SLE-like syndrome
 - C. Scleroderma-like syndrome
 - D. Interstitial pneumonitis

ANSWER: C. Drug reactions may be categorized into one or more of six types: bronchospasm, SLE-like syndrome, responses from illicit drug abuse, eosinophilic reactions, interstitial or airspace pneumonitis, or pulmonary edema from increased permeability.

2. Regarding bleomycin toxicity, which of the following is *true*?
 - A. It produces myelosuppression.
 - B. It produces a dose-related lung toxicity.
 - C. Radiographic changes are less common than symptoms.
 - D. It produces a dose-unrelated lung toxicity.

ANSWER: B. Although bleomycin does not produce myelosuppression like many other chemotherapeutic agents, many patients will develop dose-related lung toxicity. Overall incidence is 3% to 5%, but above 450 units of drug incidence is 13% to 17%. Radiographic changes are more common than symptoms, and CT changes are more common still.

3. What is the most common form of pulmonary bleomycin toxicity?
 - A. Central and superior ground glass opacity.
 - B. Subpleural and posterior predominant findings.
 - C. Apical-predominant reticulonodular disease.
 - D. It is inapparent.

ANSWER: B. Bilateral basilar reticular/reticulonodular/nodular opacities are often peripheral and often involve or are confined to the costophrenic angles. More severe disease extends upward in the lungs or evolves to airspace consolidation. CT or HRCT may reveal focal consolidation or dense irregular lines; in mild disease, as in radiography, the findings are subpleural and posterior, with disease spreading with increasing severity.

4. Regarding amiodarone toxicity, which of the following is *true*?
 - A. Most concentrated in the liver
 - B. Unrelated to dose
 - C. Associated with chronic inflammation
 - D. Radiograph may reveal dense nodules

ANSWER: C. Amiodarone accumulates in various organs but is most concentrated in the lungs—up to seven times more concentrated than in other body tissues. Up to 5% to 7% of patients taking amiodarone develop lung toxicity, and of those, 5% to 10% will die. Its pathogenicity is uncertain; it is, though, dose related. There is often chronic inflammation and septal fibrosis, type II hyperplasia, and macrophage accumulation. Radiographs often show diffuse bilateral reticular or alveolar opacities, often peripheral and often upper-lung predominant, resembling chronic eosinophilic pneumonia.

5. Regarding organophosphate poisoning, which of the following is *true*?
 - A. Results from acetyl cholinesterase inhibition
 - B. Most commonly occurs as childhood poisoning
 - C. Associated with reactive oxygen species
 - D. Related to direct mucosal injury by a metabolite

ANSWER: A. Organophosphate pesticide poisoning occurs commonly in farm workers during or after spraying of crops; it occurs occasionally in industry workers, and in accidents and suicide attempts. Parathion and malathion may be absorbed through the skin, and are converted in the liver to metabolites that inhibit nerve-ending acetyl cholinesterase. This results in initial hyperstimulation and subsequent inhibition of nerve transmission, and symptoms develop within 5 minutes to 24 hours depending on dose. Neurogenic muscle fasciculations lead to paralysis, including of the diaphragm. CNS cholinergic receptor stimulation and subsequent inhibition leads to depression and coma.

6. Which of the following is responsible for silo-filler disease?
 - A. Nitrogen dioxide
 - B. Sulfur dioxide
 - C. Ozone
 - D. Hydrogen sulfide

ANSWER: A. Nitrogen dioxide exposure is responsible for silo-filler disease: fresh material in newly filled silos produces nitric oxide that oxidizes to form nitrogen dioxide. Sulfur dioxide is an environmental pollutant and may produce accidental exposures in some industries. Ozone does not cause a serious acute response.

7. What is the latency of pulmonary edema in burn patients?
 - A. Immediate
 - B. 2–5 days

- C. 12–48 hours
- D. There is no edema

ANSWER: C. Direct heat trauma may severely damage the upper respiratory mucosa, with symptoms developing particularly in the first 24 hours. Patients may develop edema after 12 to 48 hour latency; and may develop intravascular fibrin thrombi and intra-alveolar hemorrhage. After 2 to 5 days atelectasis, edema, and pneumonia may develop, and later than that, PTE and ARDS may develop.

8. Regarding hydrocarbon poisoning, which of the following is *true*?
- A. Generally a mild process.
 - B. Radiographic resolution is rapid.
 - C. Produces chronic inflammation and fibrosis.
 - D. Radiographic abnormality is more delayed with kerosene than other hydrocarbons.

ANSWER: A. Although fairly common, hydrocarbon poisoning is generally mild. Once in the lungs, hydrocarbon produces hemorrhagic edema, necrosis, and acute inflammation. Radiographs are typically abnormal within an hour of kerosene ingestion but abnormalities may take longer to develop with other hydrocarbons. Patchy alveolar opacities, predominantly basilar, may develop, and the pulmonary hila may become indistinct. Resolution tends to be a slow process that lags clinical improvement; pneumatocele formation is a common sequela.

9. Concerning lung toxicity secondary to diphenylhydantoin, which of the following is the best descriptor?
- A. Pathognomonic radiographic appearance
 - B. Disorder of membrane deposition

- C. Associated with mesothelioma
- D. An acute hypersensitivity reaction

ANSWER: D. Diphenylhydantoin may produce an acute hypersensitivity reaction with peripheral eosinophilia and diffuse reticulonodular interstitial disease that resolves within 2 weeks of stopping therapy. Mediastinal lymphadenopathy may develop; though this is often reactive, the incidence of lymphoma in patients on this drug is increased up to ten times. Rarely airspace consolidation or miliary nodules may develop.

10. Regarding methotrexate therapy, which of the following is *true*?
- A. Incidence of lung toxicity is 2% to 5% for low-dose therapy.
 - B. Duration of therapy is not a risk factor for lung toxicity development.
 - C. Lung toxicity is generally irreversible.
 - D. Radiographic appearance is nonspecific.

ANSWER: A. Methotrexate is used both in cancers and as disease-modifying therapy in several autoimmune diseases. The incidence of reaction is estimated at 2% to 5% for low-dose therapy as with rheumatoid arthritis. Frequency, dose, and duration are risk factors, as is preexisting lung disease. Unlike many other agents, methotrexate-induced lung disease is often reversible; it is generally a hypersensitivity reaction, evidenced by eosinophilia and pulmonary granuloma or eosinophil infiltration. The radiographic appearance is characteristic. Initially a basilar or diffuse reticular or ground glass opacity develops, which develops rapidly into patchy consolidation before reverting to interstitial opacity and then resolves.

CARDIAC

34 CARDIAC MRI TECHNIQUE

Satinder P. Singh

INTRODUCTION

Cardiac MR imaging has evolved over the last decade from traditional spin echo sequences to spoiled gradient echo and balanced steady-state free precession sequences obtained during breath-hold. These developments allow evaluation of ventricle function, perfusion and viability, flow quantification, coronary MR angiography, and better morphologic assessment of the heart. Various cardiac MR sequences are listed in Table 34-1.

TABLE 34-1 Cardiac MR Sequences and Their Use

TECHNIQUE	USES
ECG-gated spin echo	Morphology
Cine GRE	Morphology, cardiac dimensions and volumes, global and regional functions of left and right ventricles
Fast (turbo) GRE	Regional myocardial (relative) perfusion, rapid imaging of great vessels
Segmented fast (turbo) GRE	Morphology (including coronary arteries), cardiac dimensions and volumes, global and regional functions of left and right ventricles
Velocity-encoded cine GRE	Valvular function (quantification of regurgitation, estimation of peak valvular gradient), measurement of stroke volume and cardiac output of both ventricles, quantification of shunts, measurement of differential flow in right and left pulmonary arteries, quantification of gradients of stenosis or coarctation of great arteries
Echoplanar	Global and regional function of left and right ventricles, quantification of regional myocardial blood volume and perfusion

DARK OR BLACK BLOOD TECHNIQUE

Fast flow blood is black or of low-signal intensity in these sequences and provides excellent anatomic delineation of blood vessel lumen and cardiac chambers. Examples of such technique include conventional spin echo, breath-hold turbo, or fast spin echo (TSE, FSE) and half Fourier turbo spin echo sequence with double inversion recovery (IR) pulses to suppress blood signal (HASTE, double-IR TSE-FSE).

BRIGHT BLOOD TECHNIQUE

Flowing blood is white or of high-signal intensity in gradient recalled echo sequence (GRE). Examples of such technique include fast low-angled shot (Turbo FLASH), fast spoiled gradient recalled echo, turbo field echo, and fast field echo. Cine GRE sequences produce a motion picture loop through various phases of the cardiac cycle.

Newer, fast, short TE GRE sequences with completely refocused gradients provide excellent contrast between the myocardium and blood flow. Examples of such sequences include true FISP, balanced fast field echo, or FIESTA. The true FISP type sequences are very useful for segmenting the myocardium from the blood flow and are excellent for the functional assessment of the myocardium. Standard GRE sequence should be used in the assessment of cardiac valves or when attempting to identify intracardiac shunts.

VELOCITY-ENCODED CINE MR IMAGING

Velocity-encoded cine (VEC) MR imaging is used for the quantitative assessment of flow dynamics across valves and in congenital heart disease. This is a phase-contrast sequence, which is used to assess the vessel of interest in a plane perpendicular to the flow vector. Magnitude and phase VEC images are obtained in a plane

perpendicular to the direction of flow in the vessel. To determine flow volume across a vessel lumen, spatial mean velocity of the vessel of interest is multiplied by the cross-sectional area of the vessel. The pressure gradient is estimated with the modified Bernoulli equation: $P = 4v^2$, where v = peak flow velocity in m/s and P = peak pressure gradient in mm Hg.

CARDIAC IMAGING PLANES

The three standard orthogonal planes used for cardiac imaging are axial, sagittal, and coronal. Two additional imaging planes parallel or orthogonal to the cardiac axes are the short and the long axis of the heart.

Examination usually begins with a dark blood anatomic survey examination in one or more planes: axial, sagittal, and coronal.

1. Scout images are done on the axial plane and display normal anatomy of the heart and great vessels, which is especially useful in evaluating congenital heart disease.
2. The coronal and sagittal planes are useful for viewing the aortic valve, the entrance of pulmonary veins into the left atrium, and the extension of pericardium, and so on. Double oblique (oblique sagittal) planes through the pulmonary trunk and aorta are useful for demonstrating pulmonary and aortic valve and their respective outflow tracks.
3. The vertical long-axis plane (two-chamber view) is used to evaluate the left heart structures including mitral valve. This plane is prescribed from an axial image.
4. The horizontal long-axis plane (four-chamber view) displays the relationship of the four cardiac chambers to each other on a single image. A cine GRE image in this plane demonstrates mitral, tricuspid, and aortic valve functions as well as right and left ventricular contraction. This image plane can be prescribed from the left ventricular long-axis or two-chamber view as well as oblique transverse imaging through a short-axis scout.
5. The short-axis plane demonstrates the true cross-sectional dimensions of the cardiac chambers, with the initial chamber viewed through the papillary muscle and subsequent views toward the heart apex and base. Cine GRE images allow quantification of systolic myocardial wall thickening. This plane is also used for quantifying left and right ventricular volume and mass and ventricular ejection fraction.
6. The long-axis view through aortic and mitral valve is usually prescribed from a coronal image. This plane demonstrates both the aortic and mitral valves and

demonstrates or displays portions of the left ventricle, right ventricle, left atrium, right atrium, and ascending aorta. Therefore, it is sometimes known as the five-chamber view or LVOT view.

MYOCARDIAL PERFUSION AND VIABILITY

Imaging to determine myocardial perfusion and viability is performed using first-pass myocardial turbo flash type sequences with rapidly establishing T1 contrast for multiple slices with high-temporal resolution. Depending on the “RR” interval, 3 to 5 slice positions can be obtained over multiple phases. Underperfused myocardium is seen as a low-signal area due to either ischemia or infarction.

Single-slice inversion recovery turbo flash, true FISP, or newer three-dimensional IR prepared sequences are used for delayed imaging, usually 10 to 15 minutes after contrast injection. An infarcted area shows delayed contrast enhancement on T1-weighted images.

With these sequences, selection of the IR pulse is the key to suppress (null) the signal from the normal myocardium. Usually, between 200 and 300 milliseconds, the optimal IR pulse is dependent upon the dose of contrast given and the length of delay after contrast injection.

TAGGED MYOCARDIAL IMAGING FOR WALL MOTION ABNORMALITY OR CONSTRICTIVE PERICARDITIS

Saturated tagged sequences are obtained in short-axis as well as long-axis views. The saturation bands appear as dark lines that deform during ventricular muscle contraction. An area of nondeformation suggests lack of muscle contraction or pericardial adhesions from constrictive pericarditis.

QUESTIONS AND ANSWERS

1. Which of the following is used for quantifying ventricular function?

- A. Vertical long axis
- B. Short axis
- C. Horizontal long axis
- D. Sagittal plane

ANSWER: B. Vertical long-axis plane (two-chamber view) is used to evaluate the left heart structures including the mitral valve. Horizontal long-axis plane (four-chamber view) displays the relationships of four cardiac chambers to each other on a single image. A cine GRE image in this plane demonstrates mitral, tricuspid, and aortic valve functions as well as right and left ventricular contraction. Short-axis plane shows the true cross-sectional dimensions of the cardiac chambers. Cine GRE images allow quantification of systolic myocardial wall thickening, and this plane is also used for quantifying left and right ventricular volume and mass and ventricular ejection fraction. Coronal and sagittal planes are useful for evaluating the aortic valve, the entrance of pulmonary veins into the left atrium, and the extension of pericardium.

2. If the myocardium demonstrates decreased signal on fast turbo first-pass GRE and no enhancement on delayed single-slice inversion recovery turbo flash images, what is the diagnosis?

- A. Ischemia
- B. Infarction
- C. Normal
- D. Myocarditis

ANSWER: A. Underperfused myocardium is seen as a low-signal area because of either ischemia or infarction in the first-pass imaging. Single-slice inversion recovery turbo flash, true FISP, or newer three-dimensional IR prepared sequences are used for delayed imaging, usually 10 to 15 minutes after contrast injection. Infarcted areas show delayed contrast enhancement on T1-weighted images, and the ischemic region will be isointense with the rest of the myocardium. Myocarditis shows regions of patchy hyperenhancement of the myocardium but usually shows no perfusion abnormality in the first-pass images.

3. Which of the following is used to determine the pressure gradient across stenosis?

- A. Fast spin echo
- B. Turbo FLASH
- C. Velocity-encoded cine MR imaging
- D. Tagged myocardial imaging

ANSWER: C. Fast spin echo is an example of a dark blood spin-echo sequence where fast flow blood appears as black or of low-signal intensity. It provides excellent anatomic delineation of blood vessel lumen and cardiac chambers. In the bright blood technique, the flowing blood is “white” or of high-signal intensity. Cine GRE sequences produce a motion picture loop through various phases of the cardiac cycle. Examples include fast low-angled shot (Turbo FLASH), fast spoiled gradient recalled echo, turbo field echo, and fast field echo. For quantitative assessment of flow dynamics across valves and in CHD, velocity-encoded cine MR imaging is used. This is a phase-contrast sequence used to assess the vessel of interest in a plane perpendicular to the flow vector. In tagged myocardial imaging, saturated tagged sequences are obtained in short-axis as well as long-axis views. The saturation bands appear as dark lines that deform during ventricular muscle contraction. An area of nondeformation suggests a lack of muscle contraction or pericardial adhesions from constrictive pericarditis.

35 CYANOTIC CONGENITAL HEART DISEASE

Satinder P. Singh

INTRODUCTION

Cyanotic heart disease is a heart defect, present at birth (congenital), that results in low blood oxygen levels. The defect affects the structure or function of the heart or vessels, and there may be more than one defect (Tables 35-1 and 35-2).

TABLE 35-1 Cyanotic Congenital Heart Disease with Decreased Pulmonary Vascularity

Tetralogy of Fallot
Tricuspid atresia
Pulmonary atresia
Pulmonary stenosis and atrial septic defect
Ebstein anomaly

TABLE 35-2 Cyanotic Congenital Heart Disease with Increased Pulmonary Vascularity

Total anomalous pulmonary venous connection (TAPVC)
Truncus arteriosus
Transposition of great arteries
Single ventricle
Double outlet right ventricle

TETRALOGY OF FALLOT

Tetralogy of Fallot (TOF) is the most common cyanotic congenital heart malformation (beyond *neonatal* period) and accounts for 6% to 10% cases of congenital heart disease (CHD). The most common neonatal cyanotic CHD is transposition of the great arteries. Four anatomic features of TOF include a right ventricular outflow track obstruction, ventricular septal defect (VSD), aorta overriding VSD communicating with left ventricle (LV) and right ventricle (RV), and right ventricular hypertrophy.

A failure of the conal septum to fuse with the septal band leads to anatomic malformation. The infundibular septum deviates anteriorly and cephalad from its normal position. The most common type of VSD in TOF is perimembranous; the next most common is muscular VSD, and the least common VSD is within the ventricular outlet.

The pulmonary trunk is usually smaller than normal, and there is a variable degree of stenosis involving the trunk and the right and left pulmonary arteries. Often hypoplasia of the right and left pulmonary arteries is present. Left pulmonary artery stenosis is more common than right.

Common anomalies associated with TOF include patent ductus arteriosus (PDA), multiple VSDs, atrial septal defect/patent foramina ovale (pentalogy of Fallot), and the presence of left superior vena cava (SVC) and anomalous origin of the left common artery from the right coronary artery. Associated extracardiac anomalies include DiGeorge syndrome, Klippel-Feil syndrome, and VACTERL and CHARGE associations.

Pulmonary atresia with VSD is a variant of TOF in which the communication between the RV and the pulmonary artery is lost; this condition is often called pseudotruncus arteriosus or truncus arteriosus type IV. The VSD is usually juxta-aortic, and the RV is hypertrophied. Although the patients usually appear normal at birth, the infant becomes cyanotic after several hours because of closure of the ductus arteriosus.

CLINICAL PRESENTATION

Patients with TOF present with cyanosis, depending on the degree of pulmonary stenosis present. In the milder form,

cyanosis develops only with exertion, resulting in a delay of symptoms and therefore delayed presentation later in childhood. Patients with severe stenosis or pulmonary atresia are severely cyanotic after the closure of the ductus and are dependent on aortopulmonary collaterals.

On examination there is a moderate systolic ejection murmur, which disappears during a hypoxic spell. Patients with aortopulmonary collaterals have continuous murmurs. Associated polycythemia and clubbing occurs, usually in older children.

RADIOGRAPHY

Depending on the degree of pulmonary stenosis, the heart size may be normal or slightly enlarged with right ventricular enlargement visible on chest radiography. The pulmonary trunk is not obvious, and central pulmonary arteries are usually small. Decreased and asymmetric pulmonary vascularity are common, are often due to system-pulmonary collaterals from peripheral pulmonary artery stenosis, or are due to prior palliative shunt. A right aortic arch is seen in 25% to 50% of the patients. However, the natural history is determined by the severity of the right ventricular outflow track; 25% of untreated infants die in the first year of life.

TREATMENT

Very young infants with a complicated morphology can be managed with a staged shunt (usually modified Blalock-Taussig) procedure. Progressive hypoxemia and recurrent spells are common indications for elective repair. Patients with TOF and pulmonary stenosis without symptoms and uncomplicated morphology usually undergo elective repair between 3 and 24 months of age.

The goal of surgery for TOF with pulmonary atresia is to repair the defect and provide blood flow from the RV to as many pulmonary segments as possible. Surgical options include shunting and second-stage repair to relieve RVOD obstruction and to leave the VSD open. Residual VSD can be closed after further development of pulmonary vasculature. Ligation of the aortopulmonary collateral is required.

Risk factors for early death from TOF include very young age of diagnosis, severity of annular hypoplasia, small size of pulmonary arteries, high peak RV–LV pressure ratios, multiple VSDs, and coexisting cardiac anomalies. Survival rate at the age of 5 years is about 90%. A 25-year survival rate of 90% or better is common with complete correction of TOF. Late complications usually occur from pulmonary valve insufficiency and right ventricular dysfunction.

TRANSPOSITION OF GREAT ARTERIES (D-TGA)

Complete TGA is a combination of concordant atrioventricular and discordant ventriculoarterial connections. This is the most common cyanotic heart disease in the newborn. The aorta is anterior and slightly rightward. The left and right ventricular outflow tracks are parallel. (Normally they cross each other diagonally.) A significant VSD is present in approximately 30% of patients.

The right and left coronary arteries arise from the right and left posterior cusp facing the pulmonary artery. If the VSD is small, or the septum is intact, the newborn is intensely cyanotic and often needs balloon atrial septostomy (Rashkind procedure). If a large VSD is present, cyanosis is usually less intense, but early heart failure occurs.

RADIOGRAPHY

In a newborn with TGA and an intact ventricular septum, the heart size is normal with mild plethora and an egg-shaped cardiac silhouette on a narrow vascular pedicle (Table 35-3). The pedicle is narrowed because of the posterior medial location of the pulmonary trunk.

If a large VSD is present, the heart is often dilated with increased pulmonary shunt vascularity (Table 35-4). In patients with left ventricular outflow tract (LVOT) obstruction, the pulmonary vascularity is decreased.

Two-dimensional echocardiography can provide most of the important information to evaluate cases of TGA. However, coronary arteries may need further evaluation with selective angiography, which is also needed to determine other associated cardiovascular anomalies.

TABLE 35-3 Imaging Signs of Various Congenital Heart Defects

ANOMALIES	INDICATING SIGN
Transposition of great arteries	Egg-on-a-string sign
TAPVR	Snowman sign
Partial anomalous pulmonary venous return	Scimitar sign
Endocardial cushion defect	Gooseneck sign at left ventricular angiography

Ebstein anomaly	Box-shaped heart

TABLE 35-4 Cyanosis with Shunt Vascularity (“T Lesions”)

Transposition of great arteries (most common)
Truncus arteriosus
TAPVC
Tingles (single ventricle or atrium)
Tricuspid atresia without RVOT obstruction

SURGICAL TREATMENT

Palliative procedures for treating TGA include the creation of an atrial septal defect (ASD), to ensure adequate admixture of blood, and pulmonary artery banding in patients with VSD and TGA where surgical correction early in life is not possible. Banding is performed to reduce the pressure in the pulmonary circulation to prevent development of obstructive pulmonary vascular disease.

Complete repair of TGA includes performing Senning-Mustard, Rastelli, and Jantene procedures. The atrial switch operation (Senning-Mustard procedure) involves rerouting of the systemic venous return to the left atrium through a surgically created channel after resection of the atrial septum. The pulmonary venous return is directed to the right atrium. Complications of atrial switch operation include stenosis of the connection of the inferior or superior vena cava to the left atrium or right pulmonary vein to the right atrium. Transventricular rerouting of the left ventricular outflow (Rastelli procedure) is possible in patients with VSD without LVOT obstruction. VSD is closed by a patch so that the LV is joined to the right ventricular outflow and to the aorta. The pulmonary trunk is ligated and divided, and an external conduit is put in place between the RV and the pulmonary trunk.

In the three-stage arterial switch procedure (Jantene procedure), the great arteries are transected above the sinus of Valsalva, the aorta is reconnected to the pulmonary root, and the pulmonary artery is reconnected to the original aortic root. The coronary arteries are then detached from the aortic root with a cuff and translocated to a new arterial trunk.

Late complications of the arterial switch operation include stenosis in the right ventricular outflow track, stenosis in the pulmonary trunk, stenosis in the middle portion of the ascending aorta, and stenosis of the coronary arteries.

CONGENITALLY CORRECTED TRANSPOSITION (L-TGA)

Congenital correction of TGA consists of a discordant ventriculoarterial connection and a discordant atrioventricular connection. The aorta is anterior and to the left of

pulmonary artery. The ventricles are inverted. The LV with its mitral valve lies to the right, posteriorly and inferiorly to the RV. Both ventricular outflow tracks are side by side and do not cross each other. Cardiac apex is mostly on the left. In 25% of cases of L-TGA, there is dextrocardia. Associated anomalies include VSD, which is present in 80% of hearts with perimembranous defects most common, and often the defect is large. The tricuspid left-sided valve is abnormal in the majority of hearts. The most common anomaly is leaflet dysplasia and the least common is Ebstein anomaly. Other important associated conditions include coarctation, interruption of the aortic arch, PDA, and pulmonary outflow track obstruction.

The coronary arteries arise from the posterior cusp. The right-sided coronary artery has morphology of the normal left coronary artery with LAD and circumflex branches, and the left-sided right coronary artery arises from the left cusp and distributes over the RV. Clinical presentation depends on the pulmonary blood flow and the associated intracardiac anomaly. Diagnosis is made by echo and catheterization.

TREATMENT

Treatment includes a double switch procedure: atrial switch (Senning or Mustard) and arterial switch or Rastelli repair.

TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION

All pulmonary veins drain into the right atrium, either directly or via tributaries, in cases of total anomalous pulmonary venous connection (TAPVC). A patent foramen ovale or an ASD is present and necessary for post-natal survival. Four major types of TAPVC include supracardiac (45%) to the SVC or tributaries; cardiac (25%) to the coronary sinus or right atrium; infracardiac (25%) to portal vein, ductus venosus, or a tributary; and mixed (5%) anomalous connection to multiple sites.

The infracardiac TAPVC is frequently associated with pulmonary venous obstruction (Table 35-5), which could be due to high resistance of hepatic parenchymal circulation, physiologic compression at the esophageal hiatus due to diaphragmatic contraction or during swallowing, or area of stenosis within the common vein or its junction with the portal vein.

TABLE 35-5 Pulmonary Edema in Newborn

Total anomalous pulmonary venous return with obstruction
Left hypoplastic heart
Transient tachypnea of the newborn

TABLE 35-6 Atrial Isomerism

FEATURES	RIGHT-SIDEDNESS	LEFT-SIDEDNESS
Spleen	Asplenia	Polysplenia
Systemic venous anomalies	Uncommon	Azygous continuation of IVC interruption, bilateral SVCs
Pulmonary venous anomalies	TAPVC	Rare
Ventriculoarterial connections	Discordant, DORV 30%	DORV 35%
ASD/VSD	AVSD	AVSD
Pulmonary outflow	Obstructed in majority	Less common obstruction

In supracardiac TAPVC, the vertical vein connecting the common pulmonary vein to the left innominate vein can pass anterior to the pulmonary artery or between the left main bronchus and left pulmonary artery or left main pulmonary artery resulting in obstruction to the pulmonary venous flow.

Intracardiac TAPVC is frequently associated with atrial isomerism (polysplenia or asplenia syndrome) (Table 35-6).

RADIOGRAPHIC APPEARANCE

- When there is no pulmonary venous obstruction (usually supracardiac and cardiac variety), the heart is enlarged and there is increased pulmonary shunt vascularity. In supracardiac TAPVC, dilated systemic veins (vertical vein, innominate vein, and dilated right SVC) form part of the head of the snowman configuration, the body being formed by enlarged cardiac mass (Table 35-3). The intracardiac TAPVC mimics left-to-right shunt at the atrial level with cyanosis.
- In patients with pulmonary venous obstruction (usually the infracardiac variety), the heart is of normal size. Pulmonary venous hypertension and pulmonary edema are present. The differential diagnosis for these findings include noncardiac diseases such as aspiration, transient tachypnea of the newborn, and respiratory distress syndrome. In patients with severe obstructions, the infant will be critically ill with tachypnea, hypoxemia, and metabolic acidosis.

Echocardiography can trace all pulmonary venous connections. Chest CTA can also nicely demonstrate the anomalous pulmonary venous connections. However, catheterization will delineate the exact anatomy, evaluate the degree of pulmonary venous obstruction and hypertension, and identify other associated structural intracardiac abnormalities.

TREATMENT

Obstructed TAPVC is a surgical emergency. Nonobstructed TAPVC requires prompt repair to prevent rapid deterioration, sequelae of cyanosis, and volume overload of the heart and lungs. The corrective procedure is reconnection of pulmonary vein to the left atrium. The surgical death rate is greatest for the infradiaphragmatic type.

TRICUSPID ATRESIA

In cases of tricuspid atresia (TA), the right atrioventricular valve is atretic with obligatory admixture in the left atrium. The RV is small and the chamber is incomplete (missing inlet portion). A VSD is present in the majority (60%) of cases and is located in the trabecular septum. Patients with large VSDs have increased pulmonary shunt vascularity.

Patients are usually cyanotic from birth due to atrial right-to-left shunt and decreased pulmonary blood flow due to right ventricular outflow tract (RVOT) obstruction or restrictive VSD. Patients with TA and large VSDs are usually asymptomatic at birth and develop increased shunt vascularity progressing to heart failure in later life.

RADIOGRAPHY

The radiographic appearance of TA is quite variable. It may resemble TOF or occasionally the radiograph is normal. In patients with TA and concordant ventriculoarterial connections, pulmonary vascularity is decreased with hypoplasia of RVOT. In patients with discordant ventriculoarterial connections, pulmonary plethora is present along with cardiomegaly and a narrow pedicle.

Left juxtaposition of the atrial appendages is a common association and appears as a bulge in the left midcardiac silhouette simulating enlarged left atrial appendage. CT and MRI reveal no right atrioventricular connections, hypoplastic RV, large LV, or ASD.

TREATMENT

Surgical repair procedures include the Glenn, bidirectional Glenn, and Fontan-Kreutzer procedures (atriopulmonary connection).

EBSTEIN MALFORMATION

Ebstein malformation is a congenital anomaly of the tricuspid valve leaflet with septal leaflet displacement downward and toward the apex. There is physiologic

atrialization of the right ventricular inlet segment with thinning of the atrialized myocardium. The right AV orifice and right atria are enlarged. Usually, the posterior and septal leaflets are displaced with a variable degree of valvular dysplasia commonly associated with tricuspid insufficiency due to dilatation of the tricuspid annulus and RV. There is dilatation of the right atrium as well as atrialized portion of the RV, which may pulsate paradoxically in ventricular systole. The left atrium and LVs are usually normal.

The most commonly associated anomalies are pulmonary stenosis, atresia, patent foramen ovale or ASD, and Wolff-Parkinson-White syndrome. There is a high incidence of this anomaly in patients with a history of ingesting lithium during early pregnancy.

RADIOGRAPHY

A chest radiograph will reveal a box-shaped heart with a narrow pedicle (Table 35-7). The predominant feature is dilatation of the right atrium and right ventricular outflow track. In a cyanotic patient, pulmonary vascularity is decreased because of atrial right-to-left shunt. Differential diagnosis includes Uhl anomaly, which is a rare, focal, or complete absence of RV myocardium.

TRUNCUS ARTERIOSUS

Truncus arteriosus is a conotruncal anomaly in which a single common trunk arises from the heart through a single arterial valve and can give rise to aortic, pulmonary and coronary arteries. The typical morphologic abnormalities are single truncal valve, juxta-arterial VSD, and partial or complete deficiency of aortopulmonary septum. The truncal semilunar valve has a posterior and inferior location and annulus is usually in continuity with the mitral valve. The valve has three leaflets in the majority of patients; in the remaining patients, there are four cusps. The origin of pulmonary arteries from the truncus is variable. In type 1, a short pulmonary trunk arises from the truncus and then divides into right and left pulmonary artery. In type 2, the pulmonary trunk is absent; therefore, right and left pulmonary arteries arise directly from the truncus from the posterior aspect. In type 3, the right

TABLE 35-7 Massive Cardiac Silhouette Enlargement in Newborn

Ebstein anomaly
Uhl disease (right ventricular myocardial thinning)
Tricuspid atresia
Massive pericardial effusion
Diaphragmatic herniation into the pericardial sac

and left posterior pulmonary arteries arise separately from the lateral wall of the truncus. Type 4 is not considered as truncus but rather TOF with pulmonary atresia and origin of branch pulmonary arteries from collaterals (see Table 102-3).

The VSD of the truncus arteriosus is located in the outlet septum, immediately below the truncal valve. The aortopulmonary septum is absent or deficient. The ventricular mass is usually formed by two ventricles. Right ventricular hypertrophy is present, but the LV is usually normal unless severe truncal valve insufficiency is present. Coronary arteries arise from the sinus of Valsalva above the truncal leaflets.

RADIOGRAPHY

The heart is usually enlarged with right ventricular prominence visible on chest radiography, and pulmonary vascularity is usually increased. The vascular pedicle is narrow. The main pulmonary artery silhouette is usually absent, and the left pulmonary artery projects higher than usual. The aortic arch is right-sided in 30% to 50% of cases, usually with mirror image branching. A chest radiograph demonstrating pulmonary plethora, right aortic arch, and a high position of the left pulmonary artery in a patient with cyanosis is strongly suggestive of truncus arteriosus.

HYPOPLASTIC LEFT HEART SYNDROME

Hypoplastic left heart syndrome is characterized by hypoplasia or atresia of the ascending aorta, aortic valve, LV, and mitral valve. This is usually associated with patent ductus arteriosus and juxtaductal coarctation.

HEMODYNAMICS

Hypoplastic left heart is a ductus-dependent lesion with severe outflow obstruction and systemic hypoperfusion. Cranial and coronary perfusion is via retrograde flow from PDA into hypoplastic arch and ascending aorta. There is left-to-right shunt and admixture in the right atrium leading to severe cyanosis.

CLINICAL PRESENTATION

The clinical presentation of hypoplastic left heart syndrome involves congestive heart failure with severe cyanosis and hypoxia (Table 35-8). Poor systemic perfu-

TABLE 35-8 Differential Diagnosis of Congenital Heart Disease Based on Patient Age at Presentation

AGE	DIAGNOSIS
0–2 days	Hypoplastic left heart, aortic atresia, obstructed total anomalous pulmonary venous return
7–14 days	Aortic stenosis, coarctation
Infants	VSD or PDA
Adults	ASD

sion leads to metabolic acidosis, renal failure, and necrotizing enterocolitis. Death occurs within days or weeks if the patient is not treated.

IMAGING

Chest radiograph will show cardiac enlargement with pulmonary venous hypertension and edema. The mediastinum is narrow due to thymic atrophy. Echocardiogram is useful for prenatal as well as postnatal diagnosis and is sufficient for treatment planning. CTA or MR is occasionally performed after staged Norwood or Stanzel procedures.

TREATMENT

Prostaglandin E-1 is initially administered in order to keep the PDA open. Rashkind balloon atrial septostomy is performed in patients with restricted foramen ovale.

Palliative procedure includes Norwood procedure, which is atrial septectomy and reconstruction of the aorta from the pulmonary artery, and a Blaylock-Taussig shunt is placed for pulmonary perfusion. The Damus-Kaye-Stanzel procedure is a variation of the Norwood procedure with side-to-side anastomosis between the pulmonary artery and the hypoplastic ascending aorta. Conversion to Hemi-Fontan (connection between SVC and right pulmonary artery) is performed at 4 to 6 months. When the patient is approximately 2 years of age, a Fontan procedure is performed to create a fenestrated venous conduit through the right atrium connecting the inferior caval flow to the right pulmonary artery.

QUESTIONS AND ANSWERS

- Regarding tetralogy of Fallot, which of the following is *true*?
 - Most common neonatal cyanotic congenital heart malformation.
 - Embryological basis is anomaly of sinus venosus.
 - Auscultation may reveal continuous murmurs.
 - Symptoms depend upon size of VSD.

ANSWER: C. Tetralogy of Fallot is the most common cyanotic congenital heart malformation beyond the neonatal period. The most common neonatal cyanotic congenital heart disease is transposition. The failure of conal septum fusion with the septal band leads to two anatomic malformations and deviation of infundibular septum anteriorly and cephalad from its normal position. The clinical presentation depends upon the degree of pulmonary stenosis not the size of VSD. Patients with severe stenosis or pulmonary atresia are severely cyanotic after the closure of the ductus. Patients often develop aortopulmonary collaterals, which produce continuous murmur on auscultation.

- Regarding treatment and prognosis of tetralogy of Fallot, which of the following is *incorrect*?
 - Progressive hypoxemia and occurrence of spells are indications for elective repair.
 - Presence of aortopulmonary collaterals is contraindication for surgery.
 - Risk factor for early death include multiple VSDs and coexisting cardiac anomalies.
 - Twenty-five-year survival rate of 90% or more is common after complete correction of tetralogy of Fallot.

ANSWER: B. Patients with tetralogy of Fallot and pulmonary stenosis without symptoms and uncomplicated morphology usually undergo elective repair between 3 and 24 months of age. Many young infants with a complicated morphology are managed with a staged shunt procedure. However, progressive hypoxemia and occurrence of spells are common indication for early elective repair. Risk factors for early death include very young age, severity of annular hypoplasia, small size of pul-

monary arteries, high peak RV–LV pressure ratios, multiple VSDs, and coexisting cardiac anomalies. A 25-year survival rate of 90% or more is quite common after complete correction of tetralogy of Fallot.

- Which of the following is *true* regarding D-TGA?
 - There is atrioventricular concordance and ventriculoarterial discordance.
 - It is considered congenitally corrected transposition.
 - The aorta is anterior and slightly leftward to pulmonary artery.
 - Newborns are asymptomatic if the ventricular septum is intact.

ANSWER: A. D-TGA or complete transposition of great arteries is a combination of concordant atrioventricular and discordant ventriculoarterial connections. The left and right ventricle outflow tracts are parallel with the aorta anterior and slightly rightward of the pulmonary trunk. For survival, an intracardiac defect at the ventricular or atrial septum level is a must. Newborns with intact ventricular septum are intensely cyanotic and often need emergent balloon atrial septostomy to live.

- Regarding L-TGA, which of the following is *true*?
 - Aorta lies to the right and anterior of pulmonary trunk.
 - Coronary arteries arise from anterior cusps.
 - Large muscular VSD is a common association.
 - There is ventriculoarterial and atrioventricular discordance.

ANSWER: D. L-TGA is congenitally corrected transposition and consists of discordant ventriculoarterial and atrioventricular connection. The aorta is anterior and to the left of the pulmonary arteries and ventricles are inverted. VSD is present in 80% of heart diseases with perimembranous defect most common. The coronary arteries arise from the posterior (not anterior) cusps; the right-sided coronary artery has morphology of the normal left coronary artery with LAD and circumflex branches, and the left-sided right coronary artery arises from the left cusp and distributes over the right ventricle.

- What is the most common type of total anomalous pulmonary venous connection?
 - Supracardiac
 - Cardiac
 - Infracardiac
 - Mixed

ANSWER: A. Supracardiac TAPVC is the most common type (45%) draining into SVC or its

tributaries. Cardiac (25%) TAPVC connects to the coronary sinus or right atrium, and intracardiac (25%) TAPVC drains into the portal vein, ductus venosus, or a tributary. Mixed type is the least common (5%).

6. Regarding total anomalous pulmonary venous connection, which of the following is *incorrect*?
- A. Atrial isomerism is frequently associated with infracardiac TAPVC.
 - B. Intracardiac TAPVC is frequently associated with pulmonary venous hypertension and edema.
 - C. In patients with pulmonary venous obstruction, the heart is enlarged.
 - D. Patent foramen ovale or ASD is often present.

ANSWER: C. Patent foramen ovale or ASD is present in TAPVC and is necessary for postnatal survival. The intracardiac TAPVC is frequently associated with pulmonary venous obstruction leading to pulmonary venous hypertension and edema on radiograph. The intracardiac TAPVC is frequently associated with atrial isomerism (polysplenia or asplenia syndrome). When there is no pulmonary venous obstruction, heart is enlarged and there is increased shunt vascularity. A patient with pulmonary venous obstruction has a normal-sized heart with pulmonary venous hypertension and edema.

7. Regarding atrial isomerism, which of the following is *true*?
- A. Asplenia is not commonly associated with systemic venous anomalies.
 - B. Polysplenia is associated midpulmonary venous anomaly.
 - C. Bilateral right-sided bronchial anatomy is seen in polysplenia.
 - D. Bilateral left-sided bronchial anatomy is seen in asplenia.

ANSWER: A. Asplenia is associated with right-sided bronchial anatomy and has common pulmonary venous anomalies such as TAPVC. The systemic venous anomalies such as azygous continuation of IVC interruption is common in polysplenia, which is associated with bilateral left-sided bronchial anatomy.

8. Which of the following is *not* a common cause for pulmonary edema in the newborn?
- A. Obstructed TAPVC
 - B. Hypoplastic left heart syndrome
 - C. Transposition of great arteries
 - D. Transient tachypnea of the newborn

ANSWER: C. Transposition of great artery is the most common cyanotic neonatal CHD and radiographic appearance depends upon the presence of VSD. A patient with large VSD presents with increased pulmonary shunt vascularity and those with intact ventricular septum have normal to mild plethora. Pulmonary edema is not a presentation for transposition but the common presentation for obstructive TAPVC, hypoplastic left heart syndrome, and transient tachypnea of the newborn.

9. Regarding radiographic signs of congenital cardiac anomalies, which of the following is *incorrect*?
- A. Gooseneck sign at left ventricular angiography is seen in endocardial cushion defect.
 - B. Egg-on-a-string sign is seen in Epstein anomaly.
 - C. Snowman sign is seen in supracardiac TAPVR.
 - D. Boot-shaped heart is associated with tetralogy of Fallot.

ANSWER: B. Egg-on-a-string sign is commonly seen in transposition of great arteries due to a narrow vascular pedicle from posterior and medial location of the pulmonary trunk. Boot-shaped heart is due to right ventricular enlargement and shift of apex upward and outward, commonly seen in tetralogy of Fallot. In the supracardiac TAPVC, the vertical vein connecting the common pulmonary vein to the left innominate vein, innominate vein, and dilated right SVC form the head of the snowman configuration, the body being formed by an enlarged cardiac mass. Gooseneck sign on ventriculography is pathognomic of AVSD (endocardial cushion defect) and is due to elongation of the left ventricular outflow track caused by the absence of AV septum and apically displaced atrioventricular valves.

10. Regarding Epstein malformation all of the following are *true*, except:
- A. Right cusp leaflets are dysplastic.
 - B. Posterior and septal leaflet are displaced toward the apex.
 - C. Tricuspid stenosis is present.
 - D. Right atrium dilatation is present.

ANSWER: C. Ebstein malformation is a congenital anomaly of the tricuspid valve leaflet with septal leaflet displacement downward and toward the apex with physiologic atrialization of the right ventricular inlet segment. The right AV orifice and right atria are enlarged and there is associated tricuspid insufficiency (not stenosis) due to dilatation of the tricuspid annulus and right ventricle.

36 ACYANOTIC CONGENITAL HEART DISEASE

Satinder P. Singh

INTRODUCTION

Congenital heart defects are the most common type of birth defect, affecting 6 to 8 of every 1,000 newborns. Each year, more than 35,000 babies in the United States are born with congenital heart defects. Acyanotic congenital lesions account for 70% of all cases of congenital heart disease. Acyanotic heart diseases can be further categorized as those with left-to-right shunt and the resultant increased pulmonary shunt vascularity or those without any shunt and normal pulmonary vascularity (Tables 36-1 and 36-2).

Management of patients with CHD heavily relies on imaging. Echocardiography is often the first line of investigation due to its easy to use, portability, and inexpensiveness. However, echo is limited in evaluating vessels beyond the heart and is user dependent especially in patients with poor acoustic windows. More detailed anatomical and functional information is usually acquired from cardiac catheterization, which however is invasive, and does not provide any three-dimensional information. More recently cardiac MRI and MDCT have evolved as important noninvasive modalities for diagnosis and follow-up of patients with CHD.

PERSISTENT LEFT SUPERIOR VENA CAVA

Persistent left superior vena cava (SVC) is present in 0.3% of the general population and in approximately 4% of hearts with congenital cardiac malformation. In the majority of cases, the left SVC drains through the coronary sinus into the right atrium. Coronary sinuses are invariably larger than normal. In 80% of patients, a right SVC is pres-

TABLE 36-2 Acyanotic Congenital Heart Disease with Normal Pulmonary Vascularity

Coarctation of the aorta
Aortic stenosis
Pulmonary stenosis
Corrected transposition of great arteries (LTGA)

ent. Rarely, the SVC may be connected directly to the right atrium or it may drain into the left atrium through unroofed coronary sinus. Usually it is detected incidentally and is easily recognized on CT or MRI.

ANOMALOUS PULMONARY VENOUS CONNECTION

Anomalous pulmonary venous connection (APVC) can be total or partial. In cases of total anomalous pulmonary venous connection, the entire pulmonary venous drainage is connected to the right atrium or tributary (a cyanotic condition and discussed under cyanotic heart diseases). In partial anomalous pulmonary venous drainage, one or both lungs connect to right atria or its tributary (a non-cyanotic anomaly).

In partial anomalous pulmonary venous connection, the abnormal connection may be to the left SVC, innominate vein, right SVC, inferior vena cava (IVC), right atrium, or the coronary sinus. It is usually associated with an atrial septal defect (ASD).

Right pulmonary vein connection to SVC is associated with sinus venosus ASD. Sometimes, the anomalous vein can be seen on chest radiograph, connected to the SVC, or if drainage is into the azygous vein, chest radiographs will show an enlarged right vascular pedicle and dilated azygous vein.

Right pulmonary vein connection to the IVC usually involves the entire right lung drainage into the IVC. Occasionally, only the middle or lower lobe is involved. The anomalous vein descends to the diaphragm with a crescent shape and then sharply curves to the left, toward the IVC. The anomalous vein is usually anterior to the hilum of the right lung, and the entrance to the IVC is just superior to the hepatic vein orifices. In most instances, this anomaly is part of the scimitar syndrome, which includes right lung hypoplasia with marked mediastinal shift and dextroposition of the heart, hypoplastic right pulmonary artery, and systemic vascular blood supply from descending thoracic and abdominal aorta.

ATRIAL SEPTAL DEFECT

Atrial septal defect (ASD) is the most common type of congenital cardiac malformation. The four anatomic

TABLE 36-1 Acyanotic Congenital Heart Disease with Increased Pulmonary Vascularity

Atrial septal defect
Ventricular septal defect
Patent ductus arteriosus
Endocardial cushion defect
Partial anomalous pulmonary venous collection (PAPVC)
A-P Window
Sinus of Valsalva aneurysm rupturing into RA or RV
Coronary artery fistulas to right circulation

types are as follows: fossa ovalis or ostium secundum (most common), ostium primum, sinus venosus, and coronary sinus.

Ostium primum ASD is due to absence of atrioventricular septum located in the inferior aspect of the atrial septum near the mitral valve, associated with partial or complete AV canal defect. Sinus venosus defect is located immediately below the orifice of the SVC and is often (80%) associated with right upper lobe pulmonary venous anomalous connection to the SVC or azygous vein. The coronary sinus ASD is part of the unroofed coronary sinus syndrome. The association of mitral stenosis and hemodynamically significant ASD is called Lutembacher syndrome.

CLINICAL FEATURES

The clinical features of patients with ASD are largely due to left-to-right shunt. The typical symptoms in an adult patient include exertional dyspnea and recurrent respiratory tract infections. Volume overload leading to atrial dilatation predisposes the patient to arrhythmias, and ASD is also a risk factor for paradoxical thromboembolic stroke. In patients with chronic long-standing ASD, especially those in the third and fourth decades of life, pulmonary arterial hypertension may develop, and it is usually due to thrombosis in the dilated pulmonary arteries with secondary changes in intima and media. Older patients may present with congestive heart failure. Infants may present with large left-to-right shunt across the atrial septal defect, especially in the presence of partial anomalous venous connection, and may also present with congestive heart failure and tachypnea.

RADIOGRAPHIC FINDINGS

Patients with significant left-to-right shunt demonstrate cardiomegaly with right atrial and right ventricular enlargement. The pulmonary trunk is enlarged with dilated central, right and left pulmonary arteries. Increased pulmonary shunt vascularity is noted in both lungs. The left atrium is typically normal in size. The left ventricle is not enlarged, but may be displaced by a dilated right ventricle. The aortic arch is small because of decreased systemic blood flow. If the QP/QS ratio is less than 1.5, the patients are asymptomatic and no radiographic findings are noted on chest radiograph. In patients with associated mitral stenosis, the left atrial dilatation is present.

In the typical evaluation of ASD, the following information is needed: type and location of defect, quantification of the shunt, detection of any intra-atrial thrombus,

assessment of right ventricular function, and detection of any associated pulmonary venous anomaly.

Echocardiography is the main imaging technique to assess ASD. However, it cannot adequately quantify the shunt and is not good at detecting small ostium secundum and sinus venosus defects or associated pulmonary venous anomalies. Cardiovascular MRI is often used in equivocal cases as well as to determine the functional significance of ASD by calculating the shunt (QP/QS ratio).

TREATMENT

Options include closure of ASD via transcatheter ASD mechanical occluding devices or open surgical repair, especially for large defects greater than 40 mm in size.

ATRIOVENTRICULAR SEPTAL DEFECT

Atrioventricular septal defect (AVSD) is a complex cardiac anomaly with deficiency of the atrioventricular septum resulting in ostium primum ASD above the atrioventricular (AV) valve and defect in the inlet portion of the ventricular septum beneath the AV valve. This is also known as endocardial cushion defect, or AV canal defect.

AVSDs are classified as partial or complete, depending on the presence or absence of interventricular communication. In partial defects, there are two AV valves, while in complete defects, only one AV valve is found. The AV septum separates the right atrium from the left ventricle in normal hearts, with concordant atrioventricular connections.

There is a high association of atrioventricular septal defect in patients with Down syndrome (trisomy 21) (Table 36-3). Down syndrome is present in 75% of patients with complete forms of AVSD. Other associated anomalies are noted in 25% of patients with AVSD and include PDA, TOF, and double outlet right ventricle.

CLINICAL FEATURES

Clinical features of AVSD are due to left-to-right shunt. In partial form, features are similar to other types of

TABLE 36-3 Syndromes Associated with Congenital Heart Disease

Down syndrome: hypersegmented manubrium, eleven ribs in one-fourth, AVSD, duodenal atresia (double bubble)
Holt-Oram syndrome: absence of radius, bowing of ulna, hypoplasia of thumb, absence of thumb or triphalangeal thumb, ASD or VSD
Turner syndrome: coarctation of aorta
Noonan syndrome: dysplastic PV stenosis
Cornellia de Lange syndrome: common atrium

ASD. If there is associated AV valve incompetence, the atrial shunt is increased, leading to early heart failure. In cases of complete AVSD, there are large shunts at the atrial and ventricular levels, leading to biventricular failure early in life.

RADIOGRAPHIC FINDINGS

Complete AVSD usually presents in infancy at around 6 to 8 weeks of age; large atrial ventricular shunts are present with dilatation of both ventricles and a globular heart. In patients with Down syndrome, multiple ossification centers for the manubrium are found. Because of the absence of AV septum, the atrioventricular valves are displaced apically, elevating the location of the aortic valve and elongating the left ventricular outflow track, resulting in a characteristic angiographic appearance during left ventriculography. This is known as the “goose-neck deformity,” which is pathognomic of AVSD. Echo, MRI, and CT studies all show defects in the atrial and ventricular septum and abnormal AV valves.

VENTRICULAR SEPTAL DEFECT

Ventricular septal defect (VSD) is the most common congenital heart lesion. It is an isolated anomaly in 20% of cases and associated with other anomalies in 5% of cases.

VSD is classified based on the location in the septum and its borders.

- A. Perimembranous defects (most common, 80%) are located in the confluence of the inlet, trabecular, and outlet portions of the left ventricle and involve the membranous septum. The superior border of such VSD is formed by the junction of the right and non-coronary cusp of the aortic valve.
- B. Muscular defects (10%) are completely surrounded by the muscular septum and can be multiple. When multiple small ventricular septal defects exist they produce a Swiss cheese septum appearance.
- C. Juxta-arterial defects are subpulmonary or supracrystal and are situated in the right ventricular outflow track, higher than the perimembranous defect. The superior rim in these defects is formed by valve tissue of both the aortic and pulmonary valve. The infundibular septum, which separates the aortic valve and the right ventricular outflow track, is hypoplastic or absent and the aortic and pulmonary valves are at about the same level instead of the pulmonary valve being higher. It is more commonly associated with prolapse of the right cusp of the aortic valve through the VSD resulting in

aortic insufficiency and is more common among Japanese and other Asian populations.

CLINICAL FEATURES

The clinical features depend on the magnitude of intracardiac shunt, depending on the size of the defect and pulmonary vascular resistance. As the pulmonary vascular resistance decreases, the left-to-right shunt increases and both ventricles dilate. Patients with a large VSD can develop heart failure as well as hyperinflation of the lungs from compression of the bronchi from distended pulmonary arteries.

On physical examination there is wheezing, precordial pan systolic murmur, hyperactive heart, and apical diastolic murmur from large flow across the mitral valve.

About 80% of patients with large VSD are seen at 1 month of age, 60% at 3 months, 50% at 6 months, and 25% at 12 months close completely.

IMAGING FINDINGS

Echocardiogram is the first modality for evaluation and is quite accurate. Cases of VSD with QP/QS ratio of less than two are often not detected on chest radiograph. There is often left ventricular enlargement in patients with a large defect. Right and left ventricle enlargement, as well as pulmonary hypertension, may develop. The aortic arch is often small at angiography, so the long axial oblique view is most useful in detecting various types of VSD. Fifty percent of patients with VSD have associated additional cardiac anomalies; aortic stenosis and coarctation of the aorta are common associations.

TREATMENT

Indications for surgery include a large VSD, a patient younger than 3 months of age with heart failure, and QP/QS ratio of 2:1 or more. Elective repair is usually done at 6 months of age if the patient's pulmonary vascular resistance is less than 8.0 units, or if there is the presence of endocarditis, aortic insufficiency, or supracrystal VSD of any size.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus connects the descending aorta to the pulmonary artery. After birth, the ductus closure is mediated by the release of vasoactive substance (acetylcholine, bradykinin), variation in pH, oxygen tension, and prostaglandins. Increasing oxygen tension constricts the ductus musculature, while prostaglandin

relaxes it. Complete ductus closure occurs by 8 weeks of age in the majority of people. Associated anomalies include severe pulmonary stenosis or pulmonary atresia, aortic atresia, or interruption of the aortic arch.

In the left aortic arch, ductus arteriosus joins the descending aorta just beyond the origin of the left subclavian artery and the junction of the left pulmonary artery and pulmonary trunk. In patients with a right aortic arch, the ductus usually arises from the origin of the left innominate artery or the aberrant left subclavian artery.

CLINICAL FEATURES

The clinical features depend on the size of the PDA. With a large ductus, there is a large left-to-right shunt, ultimately leading to pulmonary hypertension and congestive heart failure. In a smaller ductus, symptoms are not present, though typically a murmur can be heard.

RADIOGRAPHIC FINDINGS

On chest radiograph, there is shunt vascularity in the lungs and the heart is enlarged with left ventricular and left atrial enlargement. The aortic arch is enlarged as well. In patients with increased pulmonary vascular resistance, the pulmonary trunk is dilated.

TREATMENT

PDA can be closed percutaneously or via left thoracotomy.

COR TRIATRIATUM

Cor triatriatum is an uncommon cardiac anomaly, mostly involving the left atrium, in which pulmonary veins enter a proximal left atrial chamber that is separated from the distal chamber that contains the atrial appendage and the mitral valve. The proximal chamber is often larger. Associated anomalies include persistent left SVC, ASD or partial anomalous pulmonary venous connection, unroofed coronary sinus, VSD, AV septal defect, and coarctation of the aorta.

Clinical features are due to pulmonary venous obstruction (Tables 36-4 and 36-5). The heart size is normal or slightly enlarged with a normal left atrium. The pulmonary vascularity is prominent due to a combination of pulmonary venous hypertension and a variable left-to-right shunt through the fossa ovalis. Diagnosis is often made with two-dimensional echocardiography.

TABLE 36-4 Congenital Heart Disease with Congestive Heart Failure in Neonate

Hypoplastic left heart
Critical aortic stenosis
Coarctation of the aorta
Obstructed total anomalous pulmonary venous connection
Congenital severe mitral stenosis
Cor triatriatum

CT or MR can clearly show the accessory chamber and its connections.

CONGENITAL MITRAL STENOSIS

Congenital mitral stenosis is a rare cardiac anomaly that includes commissural fusion, parachute mitral valve, mitral archade, and supralvalvular stenosing ring of the left atrium. Parachute mitral valve may be associated with Shone syndrome (coexistent supralvalvular stenosing ring of the left atrium, subaortic stenosis, and coarctation of the aorta).

PULMONARY VALVE STENOSIS

This is a critical stenosis of the pulmonary valve with a pin hole opening usually with shortened, thickened rigid leaflet tissue (pulmonary valvar dysplasia). The dysplastic pulmonary valve is often seen with Noonan syndrome. This abnormality usually presents in neonates who are critically ill, irritable, tachypneic, and severely hypoxic. Echocardiography is often diagnostic.

CLINICAL FEATURES

In a milder form of stenosis, only partial commissural fusion and thickening of the free edges of the valve are present. Many patients are asymptomatic. Dyspnea on exertion is the most common symptom, with a harsh systolic murmur ejection click and right ventricular heave. In a neonate with critical pulmonary stenosis, marked tricuspid insufficiency is usually present.

TABLE 36-5 Differential Diagnosis of Acyanotic Neonate with Normal Heart Size and PVH

Cor triatriatum
Pulmonary vein atresia
Congenital MS

RADIOGRAPHY

In the neonate with severe congestive heart failure, the heart is enlarged with marked dilatation of the right atrium and pulmonary oligemia. In adults, the heart size is normal or mildly enlarged, with right ventricular prominence; pulmonary trunk and left pulmonary arteries are dilated (in 70%) and pulmonary vascularity is usually normal. At angiography, the leaflets are moderately thick and fused at the level of the commissures, creating a dome appearance during systole.

TREATMENT

Balloon valvuloplasty is the treatment of choice for isolated pulmonary valvar stenosis.

RIGHT VENTRICULAR INFUNDIBULAR STENOSIS

The ventricular and infundibular fold and the infundibular septum form the crista supraventricularis in normal hearts. The discrete form of infundibular stenosis is most frequently associated with other conditions such as tetralogy of Fallot. Most hearts with right ventricular outflow stenosis also have VSD.

AORTIC STENOSIS

Aortic stenosis obstruction can be at the level of the valve (valvar stenosis), beneath the valve (subaortic stenosis), or above the valve (supravalvar stenosis) (Table 36-6).

VALVULAR AORTIC STENOSIS

This is the most common (75%) type of aortic stenosis. *Severe valvular stenosis* in the neonatal period is from hypoplasia of the annulus or dysplastic, myxomatous thick valve leaflets to commissural fusion. The most common abnormality, however, is bicuspid aortic valve. This is estimated to occur in 2% to 3% of all live births. These valves, however, are not stenotic in infancy, but during adult years become stenotic from early degenerative calcifications.

TABLE 36-6 Types of Aortic Stenosis

Valvular (75%)
Subvalvular (discrete or in association with IHSS)
Supravalvular (associated with William syndrome)

Left coronary arterial dominance is present in 20% to 50% of patients with bicuspid aortic valves. Of all patients with congenital valvular aortic stenosis, 5% to 30% have associated cardiac anomalies such as coarctation of the aorta, congenital mitral stenosis, and PDA.

CLINICAL FEATURES

Infants with aortic stenosis usually develop congestive heart failure (Table 36-7). The bicuspid aortic valve becomes stenotic in adolescent or adult life with presenting symptoms of dyspnea on exertion, angina, or even syncope. Bicuspid aortic valve is a risk factor for aortic dissection.

IMAGING FEATURES

Two-dimensional echo is fairly accurate in diagnosing stenotic aortic valve. Cardiac MR can determine the severity of aortic stenosis as well as the aortic valve area for surgical planning.

SUPRAVALVAR AORTIC STENOSIS

A supravalvar aortic stenosis is due to localized or diffuse narrowing of the aorta above the valve. The localized variety is more common. Abnormality of the aortic valve is uncommon. Coronary artery ostia may be involved. The most commonly associated anomaly is multiple stenoses in the peripheral pulmonary arteries, which when familial are known as Williams syndrome.

SUBVALVAR AORTIC STENOSIS

Subvalvar aortic stenosis is due to obstruction of the left ventricular outflow track below the aortic valve. There may be a thin, fibrous membrane below the valve annulus and often attached to the anterior mitral leaflet, producing mitral regurgitation. Subvalvar stenosis frequently coexists with other congenital cardiac defects such as VSD and Shone syndrome.

TABLE 36-7 Differential Diagnosis of Acyanotic Neonate with Cardiomegaly and PVH/Edema

Coarctation of aorta (most common in second and third week)
Critical AS (4–6 weeks)
Interruption of aortic arch
Cardiomyopathy/myocarditis
Anomalous origin of left coronary from pulmonary artery
Noncardiac causes: hydrops fetalis, peripheral A-V fistula, chorioangioma of placenta

PERIPHERAL PULMONARY ARTERY STENOSIS

Congenital pulmonary artery stenosis is often associated with other congenital cardiac anomalies such as pulmonary atresia TOF or tricuspid atresia. Peripheral pulmonary artery stenosis may be associated with Ehlers-Danlos syndrome, Takayasu disease, congenital rubella syndrome, or part of a genetic disorder such as Bouillaud syndrome.

SINUS OF VALSALVA ANEURYSM

Sinus of Valsalva is a potential space between the semilunar valve cusp and the adjacent lateral wall of the great artery. This aneurysm can be congenital or acquired (from bacterial endocarditis, inflammatory and degenerative diseases of the aortic wall such as syphilis or Marfan syndrome, or may be associated with VSD).

Congenital sinus of Valsalva aneurysms most commonly involves the right sinus followed by noncoronary sinus. Because of congenital weakness in the aortic wall, there is a protrusion of the sinuses into the underlying cardiac chamber. The aneurysm progressively enlarges and eventually ruptures into the chamber. The site of rupture is most commonly into the right ventricle followed by the right atrium.

CORONARY ARTERIOVENOUS FISTULAS

There can be a direct communication between a coronary artery and one of four cardiac chambers, coronary sinus, vena cava, or pulmonary artery. The right coronary artery or its branches are involved in 50% to 55% of cases. The left coronary artery is involved in 45% of cases and more than 90% of fistulas open into the right heart chamber or its connecting vessels. The involved coronary artery is usually dilated and tortuous due to increased flow through the vessel; rarely coronary artery aneurysms are noted.

Clinically, symptoms include exertional dyspnea or angina due to coronary steal. Continuous murmur from the fistula is heard commonly. The diagnosis is confirmed by selective coronary angiography. CT can also demonstrate the dilated coronary arteries and its fistulous communications.

QUESTIONS AND ANSWERS

- Regarding persistent left SVC, which one of the following is *correct*?
 - Commonly associated with congenital cardiac malformation.
 - Directly drains into the right atrium.
 - In less than 50%, a right-sided SVC is present.
 - Incidence is 0.3% in general population.

ANSWER: D. Persistent left SVC is present in 0.3% of the general population and in only 4% of hearts with congenital cardiac malformation. In the majority of cases, the left SVC drains through the coronary sinus into the right atrium. In 80% of cases, right SVC is present.

- Regarding anomalous pulmonary venous connection, which one of the following is *correct*?
 - Total anomalous pulmonary venous connection is an acyanotic condition.
 - Partial anomalous pulmonary venous connection is often associated with ostium primum ASD.
 - Scimitar syndrome includes anomalous right pulmonary venous connection, right lung and pulmonary artery aplasia, and systemic blood supply from the descending thoracic and abdominal aorta.
 - Partial anomalous primary venous connection is an acyanotic condition.

ANSWER: D. Partial anomalous pulmonary venous drainage is an acyanotic congenital anomaly, whereas the total anomalous pulmonary venous connection is a cyanotic condition. The most common association of partial anomalous pulmonary venous connection is sinus venosus type ASD. Scimitar syndrome includes anomalous right pulmonary venous collection to IVC, right lung and pulmonary artery hypoplasia (not aplasia), and systemic blood supply from descending thoracic and abdominal aorta.

- Which of the following is *correct* for ASD?
 - Ostium primum type of ASD is most common.
 - Left atrium is commonly enlarged.
 - Aortic arch is dilated.
 - Patient becomes symptomatic when QP/QS ratio is more than 1.5.

ANSWER: D. Ostium secundum is the most common type of ASD. If the QP/QS ratio is less than

1.5, patients are often asymptomatic and no radiographic findings are noted on chest radiograph. Left atrial enlargement is not present in ASD unless there is associated mitral valve disease. Because of decreased systemic blood flow, the aortic arch is smaller than normal.

4. Which of the following is *correct* regarding atrioventricular septal defects?
- A. Atrioventricular septum separates the left atrium from right ventricle.
 - B. Common association of atrioventricular septal defect is Trisomy 21.
 - C. Clinical features are due to right-to-left shunting.
 - D. Left ventricular outflow tract is shortened.

ANSWER: B. The normal AV ventricle septum separates the right atrium from the left ventricle. Because of the absence of AV septum, the atrioventricular valves are displaced apically, elevate the location of aortic valves, and elongate the left ventricular outflow track, resulting in a characteristic angiographic appearance during left ventriculography, the goose-neck deformity pathognomic of AVSD. The clinical features are due to left to right shunting and the most common association of AVSD is Down syndrome (trisomy 21).

5. Indication for surgery for VSD include all *except*:
- A. Large VSD
 - B. QP/QS ratio of 2 or more
 - C. Severe pulmonary vascular disease
 - D. Patients with supracristal defect

ANSWER: C. Surgical closure of VSD is indicated for patients of any age with large VSD in whom clinical symptoms and failure to thrive cannot be controlled medically and in infants 6 to 12 months of age who have large defects associated with pulmonary hypertension, even if symptoms are controlled by medication. Patients older than 24 months with a QP/QS ratio greater than 2 and patients with supracristal VSD of any size are usually referred for surgery because of the high risk of aortic valve regurgitation. Severe pulmonary vascular disease is a contraindication to surgical closure of a VSD.

6. Which of the following is the most common site for sinus of Valsalva aneurysm rupture?
- A. RA
 - B. RV
 - C. LA
 - D. LV

ANSWER: B. The most common site of rupture of sinus of Valsalva aneurysm is the right ventricle followed by the right atrium.

7. Which of the following statements is *correct*?
- A. Congenital sinus of Valsalva aneurysm most commonly involves left sinus followed by the right and noncoronary sinus.
 - B. Coronary artery fistula involves the left circulation more commonly than right.
 - C. Coronary artery fistulas are most commonly communicated with right cardiac chambers.
 - D. Sinus of Valsalva aneurysm is a common cause of acyanotic congenital heart disease with decreased pulmonary vascularity.

ANSWER: C. Congenital sinus of Valsalva aneurysm is a rare cause of acyanotic congenital heart disease with increased (not decreased) pulmonary vascularity. It most commonly involves the right sinus followed by noncoronary and rarely the left sinus. The direct communication between a coronary artery and cardiac chamber most commonly involves right coronary circulation and more than 90% of fistulas open into the right heart chamber or its connecting vessels.

8. Regarding aortic stenosis, which of the following is *incorrect*?
- A. Valvular stenosis is the most common form of aortic stenosis.
 - B. Diffuse variety of supravalvular stenosis is more common than the localized type
 - C. Common association of valvular aortic stenosis is Williams syndrome.
 - D. Shone syndrome is frequently associated with supravalvar aortic stenosis.

ANSWER: A. Stenosis at the valvular level is the most common form of aortic stenosis resulting from hypoplasia of the annulus or dysplastic myxomatous thick valve leaflets to commissural fusion. Supravalvar aortic stenosis is more commonly localized rather than diffuse and may be associated with multiple peripheral pulmonary artery stenosis, which is commonly known as Williams syndrome. Shone syndrome is frequently associated with subvalvar stenosis, which is due to obstruction of the left ventricle outflow tract below the aortic valve.

9. What is the most common type of ventricular septal defect?
- A. Muscular
 - B. Perimembranous
 - C. Juxta-arterial
 - D. Mixed

ANSWER: B. The classification of ventricular septal defect is based on the location in the septum and its borders. Perimembranous location is the most common form of VSD (80%). It is located in the confluence of the inlet, trabecular, and outlet portions

of the left ventricle, and it involves the membranous septum. The muscular defect (10%) is completely surrounded by muscular septum and can be multiple. The least common variety is juxta-arterial situated in the right ventricle outflow tract higher than the perimembranous defect.

10. Which of the following statements is *true* for ventricular septal defect?
- Majority close spontaneously
 - Chest radiograph may be normal in patients with QP/QS ratio of 3.
 - Associated cardiac anomalies are uncommon.
 - Perimembranous VSD is often associated with aortic insufficiency.

ANSWER: A. The most common natural outcome of the VSD is spontaneous complete closure. QP/QS ratio of more than 2 is often associated with chest radiographic abnormalities, commonly left ventricular enlargement, right ventricle enlargement, and pulmonary hypertension features. Of all cases of VSD, 50% have associated additional cardiac anomalies; coarctation of aorta and aortic stenosis are the most common associations. The juxta-arterial VSD, which is situated higher than the perimembranous defect, is commonly associated with prolapse of the right cusp of the aortic valve through the VSD, leading to aortic insufficiency.

37 VALVULAR HEART DISEASE

Satinder P. Singh

INTRODUCTION

In developed countries, acquired valve heart disease is now most commonly due to degenerative diseases rather than rheumatic and infectious causes. There is an increasing prevalence of mitral regurgitation and aortic stenosis compared to a higher incidence of mitral stenosis and aortic insufficiency. Patients are presenting at advanced age, and many disease processes have few radiographic findings because of early detection with echocardiography.

MITRAL VALVE DISEASE

World-wide rheumatic heart disease still remains a prevalent condition. Nonrheumatic mitral valve disease is now the most common mitral valve (MV) abnormal-

ity in the Western world. Nonrheumatic disease is usually manifested as mitral regurgitation, and mitral stenosis is extremely rare.

A normal MV has two leaflets (bicuspid) with surface area of 4 to 6 cm². The larger anterior leaflet is contiguous with the aortic valve while the posterior smaller, scalloped leaflet extends more than 50% of mitral annulus circumference.

MITRAL REGURGITATION

Mitral regurgitation (MR) can result from either abnormality of the leaflets such as in mitral valve prolapse (MVP), bacterial endocarditis, mitral commissurotomy, prosthetic valve leaks, SLE, and mucopolysaccharidosis or due to abnormality of the supporting structures such as dilatation of MV annulus, chordae tendineae rupture, mitral annulus calcification, papillary muscle rupture as a complication of myocardial infarction and atrial myxoma.

MITRAL VALVE PROLAPSE

MVP most commonly occurs in isolation, but can be associated with atrial septal defect and Marfan syndrome. Myxomatous degeneration of the valve leaflet and elongation of chordae tendineae allows prolapse of MV leaflet back into the left atrium in ventricular systole. Its diagnosis requires more than 2.5 mm prolapse into the left atrium. It may be associated with chest pain and EKG changes suggesting ischemic heart disease.

CHORDAE TENDINEAE RUPTURE

Chordal rupture leading to mitral regurgitation can be seen in bacterial endocarditis and, less frequently, in connective tissue diseases and myocardial infarction. There is improper coaptation of the leaflets in systole, producing severe mitral regurgitation. On auscultation, the murmur is usually mid-to-late systolic in onset. If chordal rupture occurs suddenly, as in myocardial infarction, it can lead to acute pulmonary edema with normal heart size.

Functional mitral regurgitation due to dilatation of left ventricle or mitral annulus dilatation as occurs in dilated cardiomyopathy or ischemic heart failure. The resulting mitral regurgitation is usually mild-to-moderate.

MITRAL ANNULUS CALCIFICATION

It occurs in the angle between the left ventricular wall and MV cusp and is seen as a “C”-shaped ring on chest

radiographs. Calcification occurs more frequently in women and in the elderly. It is usually benign, but may be associated with transient ischemic attacks due to emboli and atrioventricular conduction disturbances. The risk of infective endocarditis also increases in the presence of calcification. Mitral annular calcification is another marker for atherosclerosis and premature calcification is seen in patients with end-stage renal disease.

IMAGING FINDINGS

The chest radiographic appearance depends on the duration and severity of mitral regurgitation and associated heart disease. Acute severe nonrheumatic mitral regurgitation may present with acute edema with normal heart size. In chronic states, the heart usually enlarges with left ventricular dilatation. Left atrium enlargement is variable and left atrial appendage is usually not enlarged. The severity of mitral regurgitation can be estimated with cardiac MR and echocardiography. On cardiac MR, mitral regurgitation is seen as signal loss jet due to turbulent regurgitant flow into the left atrium during systole. Intraoperative transesophageal ultrasound is commonly used to determine the functional status of MV repair by detecting and quantifying regurgitation during the repair.

RHEUMATIC MITRAL VALVE DISEASE

Rheumatic fever is a systemic inflammatory disease occurring in response to group A beta-hemolytic streptococcal infection due to immune response injury to heart. The majority of patients are between 5 and 15 years of age; 30% of patients develop RHD after the first attack of rheumatic fever, 50% have only MV involvement, and 20% to 50% have MV and aortic valve (AV) involvement. Tricuspid valve involvement is less common and PV is rarely affected.

In the early acute rheumatic carditis, mitral regurgitation is present due to myocarditis. This mitral regurgitation is often transient and reversible. Chronic rheumatic MV disease usually results in mitral stenosis due to fusion of the commissures, thickening and shortening of the chordae tendineae, and fibrosis of the papillary muscles. This most commonly results in a mixture of mitral stenosis and regurgitation. Valve replacement or valvuloplasty is indicated for severe stenosis with a valve area of 0.8 to 1.2 cm². There is usually an increased left atrial pressure, which is transmitted back to the pulmonary veins, thus ultimately leading to interstitial and then alveolar pulmonary edema. In chronic MV

disease, lung parenchymal changes of hemosiderosis and intraparenchymal ossification may be seen. The patient can develop secondary pulmonary artery hypertension, leading to right ventricular dysfunction and functional tricuspid regurgitation. Left atrial fibrillation can be complicated by thrombi, which can result in systemic embolization.

IMAGING FEATURES

The classic radiographic feature of rheumatic MV disease is left atrial enlargement and left atrial appendage enlargement. Left atrial enlargement on chest radiograph is seen as double density through the heart. Displacement of the left main bronchus, and occasionally the esophagus posteriorly, is best seen on lateral radiographs. Left ventricular enlargement is seen in significant mitral regurgitation but is not common in pure mitral stenosis. Curvilinear calcification in the wall of the left atrium or the thrombus lining the atrial wall can be seen in long-standing MV disease. MV calcification, if present, strongly suggests rheumatic etiology, and there is a variable degree of pulmonary venous hypertension. Echocardiography is the best method for the assessment of MV disease. Cardiac MR shows restricted opening of the MV and thickening of the leaflets in mitral stenosis.

TRICUSPID VALVE DISEASE

Normal tricuspid valve usually has three leaflets (tricuspid): anterior, septal, and one or two posterior leaflets.

TRICUSPID INSUFFICIENCY

Tricuspid regurgitation can be due to rheumatic diseases, functional from right ventricular dilatation, due to endocarditis (a frequent cause among intravenous drug abusers), and is rarely due to trauma. Tricuspid valve abnormality is also seen in congenital heart disease, corrected transposition of the great arteries, and Ebstein anomaly. Severe tricuspid regurgitation can also occur in endomyocardial fibrosis and carcinoid syndrome.

TRICUSPID STENOSIS

Tricuspid stenosis is usually caused by rheumatic heart disease, and carcinoid syndrome is the second most

common cause. The majority of patients also have MV disease, and common clinical presentation includes long-standing fatigue and edema. Its treatment includes balloon valvuloplasty or surgical replacement.

Clinically, presence of pulsating, enlarged liver and high venous pressure with big *v* wave suggest tricuspid regurgitation. A slow *y* descent in neck vein pulsation indicates presence of tricuspid stenosis

IMAGING FEATURES

There is enlargement of the right atrium which shows bulging to the right with increased curvature of the right heart border. Presence of prominent right atrium in rheumatic heart disease patients always suggests tricuspid valve involvement. Ultrasound is the definitive modality to diagnose tricuspid disease. In severe regurgitation, the pressure drop across the valve is low and may not be recognized immediately on ultrasound or cardiac MR.

AORTIC STENOSIS

The most common cause of aortic stenosis in the Western countries is degenerative calcific disease in middle-aged or elderly patients. Calcium deposition on the aortic cusp causes obstruction to the outflow as well as stiffening of the cusp, leading to stenosis (see Table 36-6). Aortic stenosis in adults is also commonly seen in a congenitally deformed bicuspid valve (Table 37-1). Other causes of aortic stenosis include rheumatic heart disease as well as degeneration of normal tricuspid trileaflet aortic valve.

The clinical presentation includes chest pain, syncope, or shortness of breath. Left ventricular hypertrophy is noted on the ECG. There is systolic ejection murmur on auscultation. Echocardiography easily recognizes the severity of aortic stenosis. Severe aortic stenosis is present when aortic valve area decreases below 0.5 cm^2 (normal aortic area is 2.5 cm^2).

IMAGING FEATURES

Chest radiograph demonstrates left ventricular hypertrophy and, in chronic stages, LV dilatation. Ascending aorta

may be dilated. Aortic valve calcification can be seen on the lateral chest radiograph, although best documented by fluoroscopy or now by MDCT. Cardiac MR can show impaired aortic valve opening, assess stenosis, and determine morphology of the valve. There is systolic flow defacing in the aortic root. Associated regurgitation is seen as diastolic flow defacing in the left ventricular outflow track.

Rheumatic aortic stenosis is usually associated with MV involvement. Clinically, dyspnea is pronounced due to associated mitral disease. On chest radiography, there is often left atrial enlargement due to associated MV disease. Poststenotic dilatation of the aorta is rare in rheumatic aortic stenosis and gross aortic valve calcification is also uncommon. Ultrasound is often required to determine the severity of aortic and MV disease in rheumatic heart disease.

AORTIC REGURGITATION

Aortic regurgitation can be due to disease of the aortic wall or disease of the cusp, such as bacterial endocarditis, trauma, or aortic dissection (Table 37-2). Chronic aortic regurgitation may also been seen from congenital bicuspid aortic valve or subarterial ventricular septal defect. Aneurysm of the ascending aorta causes dilatation of the valve link, leading to aortic regurgitation. The most common cause of acquired chronic aortic regurgitation is the complication of congenital deformity of the valve or rheumatic heart disease.

IMAGING FEATURES

The chest radiograph shows left ventricular dilatation, although the patient may remain asymptomatic until cardiac

failure develops. The entire thoracic aorta may be moderately dilated. When MV disease is present, left atrial enlargement may dominate. Ultrasound is the primary modality for aortic valve disease evaluation. Aortic root diseases such as annuloaortic ectasia or dissection are best evaluated by CT angiography or cardiac MR. Complications of endocarditis with paravalvar abscess are best seen on cardiac MR or contrast-enhanced CT angiography.

Marfan syndrome and syphilis are two conditions that can involve the ascending aorta and cause aortic aneurysm formation. In Marfan syndrome, the aneurysm involves the aortic sinuses and aortic calcification is rarely seen, whereas in patients with syphilitic aortitis, the aortic sinuses are spared and aortic calcification is seen commonly.

QUESTIONS AND ANSWERS

1. What is the most common cause of valvular heart disease in the United States?
 - A. Rheumatic
 - B. Infective endocarditis
 - C. Degenerative
 - D. Congenital
2. Which of the following is *false* regarding mitral valve?
 - A. World-wide rheumatic heart disease is the most common cause of mitral valve disease.
 - B. In the Western world, nonrheumatic mitral stenosis is the most common mitral valve abnormality.
 - C. The anterior leaflet is the largest and is contiguous with the aortic valve.
 - D. Mitral valve prolapse can occur in Marfan syndrome.

ANSWER: B. World-wide rheumatic heart disease still remains a prevalent condition. Nonrheumatic mitral valve disease is now the most common mitral valve abnormality in the Western world. Nonrheumatic disease is usually manifested as mitral regurgitation, mitral stenosis is extremely rare. The mitral valve is bicuspid with larger anterior leaflet which is in fibrous continuity with aortic valve, in comparison to tricuspid valve which is separated from the pulmonary valve by muscular infundibulum. Mitral valve prolapse most commonly occurs alone, but can be associated with atrial septal defect and Marfan syndrome. Myxomatous degeneration of the valve leaflet and elongation of chordae tendineae allows prolapse of mitral valve leaflet back into the left atrium in ventricular systole.

3. Regarding rheumatic heart disease, which of the following is *true*?
 - A. Injury to heart is caused by immune response to group B beta-hemolytic *Streptococcus* infection.
 - B. In the majority, both mitral and aortic valves are involved.
 - C. In early stages of myocarditis, mitral stenosis is common, transient, and reversible.
 - D. Left ventricle enlargement is seen more commonly in mitral regurgitation than in pure mitral stenosis.

ANSWER: B. Rheumatic fever is a systemic inflammatory disease in response to group A beta-hemolytic streptococcal infection with immune response injury to heart. The majority of patients are between 5 and 15 years of age; 30% of patients develop RHD after the first attack of rheumatic fever, 50% have only MV involvement, and 20% to 50% have MV and AV involvement. TV involvement is less common and PV is rarely affected. In the early acute rheumatic carditis, mitral regurgitation is present due to myocarditis. This mitral regurgitation is often transient and reversible. Chronic rheumatic mitral valve disease usually results in mitral stenosis due to effusion of the commissures, thickening and shortening of the chordae tendineae, and

ANSWER: C. In developed countries, acquired valve heart disease is now most commonly due to degenerative diseases rather than rheumatic and infective causes. There is an increasing prevalence of mitral regurgitation and aortic stenosis compared to a higher incidence of mitral stenosis and aortic insufficiency.

fibrosis of the papillary muscles. This most commonly results in a mixture of mitral stenosis and regurgitation.

4. Which of the following is *false* regarding tricuspid valvular disease?

- A. Tricuspid stenosis is most commonly caused by carcinoid syndrome.
- B. Tricuspid insufficiency is commonly due to right heart failure.
- C. Pulsatile large liver suggest tricuspid insufficiency.
- D. Echo is the definitive modality for diagnosing tricuspid valve diseases.

ANSWER: A. Tricuspid stenosis is usually caused by rheumatic heart disease, and carcinoid syndrome is the second most common cause. Pulsating, enlarged liver and high venous pressure with big *v* wave suggest tricuspid regurgitation. A slow *y* descent in neck vein pulsation suggests tricuspid stenosis. TR is most commonly due to right heart failure of any etiology (PS, primary PAH, or MV disease). Other causes include Ebstein anomaly, carcinoid syndrome, rheumatic heart disease, and infective endocarditis.

5. Regarding aortic stenosis, which of the following is *false*?

- A. Most common cause in Western world is degenerative disease.
- B. At CMRI, there is diastolic flow dephasing.
- C. Rheumatic aortic stenosis is often associated with mitral valve disease.
- D. Poststenotic dilatation is not commonly seen in rheumatic aortic stenosis.

ANSWER: B. The most common cause of aortic stenosis in the Western countries is degenerative calcific disease in middle-aged or elderly patients. Calcium deposition on the aortic cusp causes obstruction to the outflow as well as stiffening of the cusp, leading to stenosis. Aortic stenosis in adults is also commonly seen as a congenitally deformed bicuspid valve. Cardiac MR can show impaired aortic valve opening, assess stenosis, and determine morphology of the valve. There is systolic (and not diastolic) flow defacing in the aortic root. Associated regurgitation is seen as diastolic flow defacing in the left ventricular outflow tract. Rheumatic aortic stenosis is usually associated with mitral valve involvement and chest radiography often shows associated mitral left atrial enlargement. Poststenotic dilatation of the aorta is rare in rheumatic aortic stenosis. Gross aortic valve calcification is also uncommon in rheumatic disease.

38 ISCHEMIC HEART DISEASE

Satinder P. Singh

INTRODUCTION

Myocardial ischemia results from an imbalance between myocardial oxygen demand and myocardial blood flow. This imbalance typically occurs due to a decreased blood flow resulting from atherosclerotic disease of the coronary arteries, but can also result from excessive oxygen demand such as that occurring in severe hypertension, severe aortic stenosis, or hyperdynamic states (Table 38-1).

The primary clinical presentation of ischemia is angina and infarction. This may lead to ventricular failure, mitral regurgitation, ventricular aneurysm formation, ventricular rupture, or arrhythmias.

CORONARY ARTERY ANATOMY

Two coronary arteries, the right and the left, originate from the right and left sinuses of Valsalva, respectively. In the majority of people, the left coronary artery (LCA) supplies the majority of the left ventricle (LV) and the right coronary artery (RCA) supplies the inferior portion of the LV as well as the entire right ventricle.

RIGHT CORONARY ARTERY

The RCA arises from the right coronary cusp at a slightly higher location in comparison to the LCA. The first branch of the RCA is usually the conal artery branch, which supplies the right ventricle outflow tract. (In up to 50% of cases, the conus branch may arise from the sinus itself and therefore has been referred to as the third coronary artery.) The RCA courses under the right atrial appendage to the right atrioventricular groove. In

TABLE 38-1 Causes of Myocardial Ischemia

Decreased oxygen supply
Decreased coronary blood flow, which could be due to atherosclerosis, thrombosis, coronary artery spasm, dissection, or malignant anomalous coronary artery compression
Severe anemia
Hypoxemia
Increased oxygen demand from increased after-load
Increased preload
Metabolic disturbances such as hyperthyroidism

more than 50% of patients, a sinoatrial nodal artery arises from the proximal RCA, coursing backward toward the junction of the SVC and right atrium. The free anterior wall of the right ventricle is supplied by acute marginal branches, which are an important source of collateral blood flow to both the distal RCA as well as the left anterior descending (LAD) coronary artery. After the crux, the RCA gives rise to the posterior descending artery (PDA), which runs along the inferior surface of the heart in the posteroinferior interventricular groove supplying the inferoposterior third of the interventricular septum. This vessel is usually accompanied by the middle cardiac vein, which serves as an identifying marker for PDA on cardiac computed tomography (CT). The atrioventricular (AV) nodal branch often originates at the crux and marks the beginning of the posterolateral segmental branch (PLB), which supplies the posterolateral wall of the LV. The PLB courses to a variable distance in the posterior (AV groove, depending on the length of the left circumflex artery (LCX)). In patients with left dominance circulation, both PDA and posterolateral branches arise from the LCX in addition to LAD wrap at the LV apex. In codominant circulation, the PLB branches arise from the circumflex artery, while the PDA comes from the RCA.

LEFT CORONARY ARTERY

The LCA arises from the left coronary sinus and divides into two or sometimes three branches shortly after its origin. The major branches are LAD and LCX. In patients with trifurcation of LCA, the ramus intermedius branch supplies the anterolateral wall of LV.

The LAD runs in the anterior interventricular groove toward the apex and sometimes wraps at the apex extending into the inferior interventricular groove, especially in patients with a small PDA or codominance. It supplies the anterolateral wall of the LV with diagonal branches and supplies the anterior two-thirds of the interventricular septum with multiple septal perforator branches.

The circumflex artery runs in the posterior or left AV groove and gives off branches to the left atrium and lateral LV free wall (known as obtuse marginal branches). In 45% of patients, the SA nodal branch arises from the proximal circumflex artery.

CORONARY ARTERY DISEASE

Coronary artery disease begins as fatty streaks in the coronary arteries and other arterial beds quite early in

life. The development of atherosclerosis appears to follow a complex pathway including endothelial dysfunction (caused by a number of factors such as hypertension, hyperlipidemia, cigarette smoking, etc.) and infiltration of leukocytes, lipids, and macrophages within the intimal layer of the artery followed by inflammation (lipid-rich foam cells form as macrophages ingest LDL particles), leading to proliferation and migration of smooth muscle cells from the medial layer to form a fibrous cap over the lipid-rich lesion (proliferation of vasovasorum provides the blood supply to the lesion). Further plaque progression causes growth and necrosis of lipid core calcifications, hemorrhage in the plaque, and surface erosions leading to formation of nonobstructive clots. Thinning and weakening of the fibrous caps may cause acute plaque rupture. Plaques that are less than 70% obstructed appear to be more likely to undergo rupture due to their higher lipid content, thin fibrous cap and more irregular configuration, and the presence of shear forces at the edges of the plaques.

PREVALENCE AND INCIDENCE OF CORONARY HEART DISEASE

The incidence of coronary heart disease death from myocardial infarction (MI) is approximately 1.2 million cases per year with a prevalence of 13.2 million cases in the United States. The risk factors for coronary heart disease can be differentiated into three types: nonmodifiable factors, which include male sex, age, and family history of premature coronary heart disease; major modifiable risk factors, which include low HDL cholesterol, elevated LDL cholesterol, diabetes, and hypertension; and the minor risk factors, which include lack of regular exercise, psychological stress, and obesity.

The normal coronary artery is a smooth, gently tapering structure. Atheromatous disease leads to irregularity and progresses to stenosis. A greater than 60% decrease in the diameter of the artery can be flow limiting. In the initial stages of atherosclerosis, the atheromatous burden in the wall is eccentric and bulges outward from the artery lumen, which remains unchanged in diameter (known as the Glagov effect or positive remodeling). Therefore, catheter coronary angiography performed at this stage is often normal. However, coronary CT angiography (CTA) has a distinct advantage over catheter angiography since it can provide information about the coronary artery wall in addition to coronary lumen status.

The collateral flow between adjacent coronary arteries is responsible for variable presentation of CAD. Angiographically, collateral pathways are identified as tortuous vessels, which are usually smaller than native

arteries, though, occasionally, these can be quite large. The common collateral pathways between LAD and RCA are conus artery, septal perforators, marginal branches, and PLB to diagonal branches. And those between LAD and circumflex artery include diagonal to obtuse marginal branches, distal LAD to obtuse marginal branches, and septal to left PDA branches. The common collateral pathway between LCX and RCA is PLB to obtuse marginal branches. Anastomosis between the atrial branch of LCX and AV nodal artery is known as the Kugel artery. The collateral flow between the conus artery (arising from RCA) and proximal LAD forms the ring of Vieussens.

CORONARY THROMBOSIS

Coronary thrombosis most frequently occurs in conjunction with atherosclerotic disease in a moderate-grade stenosis from plaque rupture due to activation of platelets. Less common causes include high hematocrit, which occurs in cases of polycythemia vera and tetralogy of Fallot. A clot can also be seen following severe coronary artery spasm.

CORONARY ARTERY SPASM

Coronary artery spasm can occur in both normal and atherosclerotic arteries. The classic description is Prinzmetal angina where chest pain occurs at rest and is accompanied by ST segment elevation. If coronary angiograms are performed, they are usually normal. Spasm is often confirmed by pharmacological provocation with acetylcholine or ergonovine.

CORONARY ARTERY DISSECTION

Coronary artery dissection occurs most frequently during interventional procedures (percutaneous transluminal coronary angioplasty [PTCA]), but occasionally can also be seen in otherwise healthy patients, especially young pregnant women. In patients with type A aortic dissection, the dissecting flap can extend into the coronary artery and in these patients the origin of the RCA is most commonly compromised.

MYOCARDIAL INFARCTION

Following a critical imbalance between oxygen supply and myocardial demand, there is a rapid development of myocardial necrosis. The most common cause of MI is narrowing of the epicardial blood vessels due to athero-

sclerotic plaques. Irreversible myocardial damage occurs if the total occlusion of the vessel persists for more than 4 to 6 hours; therefore, reperfusion within this period can salvage significant myocardium, thereby reducing morbidity and mortality. It is now well known that the infarct-causing lesion is not the most stenosing lesion. In fact, in the majority of patients, MI is caused by plaque rupture from a lesion, which causes less than 50% diameter stenosis.

The nonatherosclerotic causes of MI include coronary vasospasm (Prinzmetal angina), use of cocaine and amphetamine, vasculitis, embolization from infected valve, and rarely trauma.

CLINICAL PRESENTATION OF MI

The clinical manifestations of plaque rupture known as acute coronary syndrome include acute MI, unstable angina, and sudden death due to ventricular fibrillation. Other manifestations include stable angina and ischemic cardiomyopathy. Chest pain (radiating to jaw, neck, and arm), dyspnea, anxiety, diaphoresis, and wheezing are common symptoms. A silent MI can occur in patients who are diabetic, in female patients, in patients with dementia, and in patients with heart failure.

DIAGNOSTIC EVALUATION OF MI

The initial diagnostic evaluation of a suspected MI includes serial cardiac enzymes (troponin, creatinine kinase [CK], and myoglobin) and serial EKGs. Chest radiography is often done to assess the heart size and detect the presence of edema and to exclude other diseases causing chest pain (such as pneumonia, pneumothorax, etc.). Echocardiography is useful to detect regional wall motion abnormality and to detect complications of MI such as acute mitral valve regurgitation from papillary muscle rupture, myocardial rupture, or presence of pericardial effusion. Myocardial perfusion imaging is done to assess the viability and extent of ischemic damage.

Serum troponin levels start increasing within 3 to 12 hours, peak at 24 to 48 hours, and then gradually return to the baseline in 1 to 2 weeks. According to the ACC/AHA consensus statement, troponin levels are now the criterion standard in defining and diagnosing MI. CK levels increase within 3 to 12 hours of chest pain, peak at 24 hours, and return to the baseline in 2 to 3 days. CK levels have high sensitivity and specificity, though less than that of troponin. The three subtypes of CK are CK-MM (found in skeletal muscle), CK-BB (found in the brain), and CK-MB (found mainly in the heart). Myoglobin levels can rise within 1 to 4 hours of chest pain and are highly sensitive in early detection of MI but may not be specific.

Ventricular function can be evaluated with echocardiography, radionuclide imaging, MDCT, CMR, and conventional ventriculography. CMRI is perhaps the most accurate and widely used method to evaluate ventricular function. The ejection fraction is calculated as stroke volume divided by end diastolic volume. Impaired wall motion abnormalities can be designated as reduced motion (hypokinesia), absent wall motion (akinesia), or paradoxical wall motion (dyskinesia). Normal LVEF is greater than 50%. Regional wall motion abnormalities can be seen in patients with ischemia as well as scarring. Reversible wall motion abnormalities can be seen in patients with stress-induced ischemia. Severity of LV dysfunction is an important prognostic factor that plays a role in outcome after MI.

The role of cardiac CT in evaluating acute chest pain is evolving. Because of its high negative predictive value, it is extremely useful in excluding significant coronary artery disease. CT can also help effective and quick triage, thereby reducing health care cost by avoiding unnecessary further expensive testing.

Coronary angiography is often performed in patients with typical chest pain occurring due to atherosclerotic disease or unstable angina. It is performed to guide management by providing anatomic assessment of disease severity. Percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) is indicated for severe coronary artery disease not responding to medical treatment, life-threatening left main coronary artery disease, positive stress test with severe disease in corresponding artery, and acute MI to salvage myocardium.

Myocardial stunning refers to temporary prolonged myocardial dysfunction following an ischemic episode. The myocardium is viable and has contractile reserve. The key elements of a stunned myocardium are (a) short-term total or near total reduction in the coronary blood flow, (b) reestablishment of the coronary blood flow, and (c) subsequent temporary LV dysfunction. Acute, coronary occlusion causes a rapid decline (within seconds) in ventricular performance. If the coronary flow is reestablished, ventricular function will slowly return to normal. The duration of reduced performance (myocardial stunning) depends on the duration of the preceding ischemia. Stunning is completely reversible, and therefore there is no permanent damage to the myocardium. The stunned myocardium, however, is less responsive to inotropic drugs and cardiogenic shock may occur. Stunning may occur following coronary angioplasty, thrombolysis, coronary vasospasm, and cardiopulmonary bypass.

Myocardial hibernation is a term used to describe the condition in which regional cardiac function is depressed due to chronic ischemia. Restoration of the normal coronary flow (e.g., by coronary bypass) will restore normal function in the affected region. Myocardial

hibernation can occur in chronic stable or unstable angina, acute MI, heart failure with and without severe LV dysfunction, and in patients with an anomalous coronary artery. The pathophysiology of myocardial hibernation is characterized by reduced regional contractile function distal to a coronary artery stenosis that recovers after removal of the coronary stenosis. It is estimated that 20% to 50% of patients with ischemic LV dysfunction have a significant viable hibernating myocardium, which has the potential for improvement after revascularization. In summary,

- a transient postischemic LV dysfunction is called “stunned” myocardium.
- a chronic but potentially reversible ischemic dysfunction due to a stenosed coronary artery is called “hibernating” myocardium.

Although the mechanism of stunning and hibernation are not completely known, evidence suggests that impaired calcium handling by the sarcoplasmic reticulum as well as damage by oxygen free radicals may play an important role.

Complications of MI include arrhythmias, cardiac rupture, papillary muscle rupture leading to acute mitral valve regurgitation, left ventricle aneurysm, and thrombus formation.

Post-MI mitral valve regurgitation usually occurs due to posterior papillary muscle rupture after inferior MI. A chest radiograph in this situation may show alveolar consolidation due to atypical acute edema, which is often localized to the right upper lobe because of the direction of regurgitant jet passing into the right upper lobe pulmonary vein mimicking air space pneumonia. Often, the cardiac size is normal unless there is long-standing hypertension. A systolic murmur is heard on examination and echo may show the disrupted mitral apparatus and LV inferior wall motion abnormality.

ISCHEMIC CARDIOMYOPATHY

Ischemic cardiomyopathy is a result of coronary artery disease with impaired left ventricular function and decreased left ventricular ejection fraction (LVEF), usually occurring after a transmural infarct with LV remodeling. Diffuse LV involvement usually due to three-vessel coronary artery disease results in a dilated hypokinetic LV.

IMAGING FINDINGS

A chest radiograph may demonstrate enlarged heart with evidence of failure. PET is considered to be the

gold standard for myocardial viability assessment, although MR is evolving and may even be superior to PET.

MR IMAGING

First-pass MR perfusion may show hypoperfusion (subendocardial or transmural). Delayed contrast enhancement obtained 10 to 15 minutes after bolus of 0.1 mL/kg of gadolinium may reveal the infarct. Scar tissue appears as a bright, hyperenhanced region, and viable myocardium appears black.

DRESSLER SYNDROME

Dressler syndrome occurs 10 to 30 days after MI or cardiac surgery. It may remit and relapse over weeks or months and is characterized by pleuritis, pneumonitis, and pericarditis. Aspirin or steroids provide good symptomatic response.

CARDIAC MDCT

Current indications of cardiac CTA include evaluation for suspected CAD, atypical chest pain, patient with equivocal stress tests or discrepancies between imaging and clinical assessment, graft or coronary stent evaluation, anomalous coronary artery evaluation, and coronary vein and pulmonary venous mapping.

Recent advances in MDCT technology with high temporal and spatial resolution and submillimeter slice collimation allow evaluation of coronary arteries in a single breath-hold. A coronary CTA is highly accurate in excluding significant (greater than 50% luminal narrowing) stenosis with very high negative predictive value of 97% to 100%. MDCT can detect calcified and noncalcified plaques in coronary arteries and has good correlation with intravascular ultrasound. The most important parameter in obtaining a good quality coronary CTA study is a low heart rate of preferably less than 60 bpm.

There are two ways to gate cardiac CT to EKG: prospective and retrospective gating. In prospective gating, the scanning begins at a predetermined time interval from the R wave usually in late diastole, followed by table movement, and then repetition in a “step and shoot” axial scanning protocol. Axial image thickness is greater than 2 mm. This is commonly used for noncontrast coronary calcium scoring. Recently, however, different manufacturers are now offering a prospective gated coronary CTA with contrast images obtained at thin collimation (0.625 mm) with significant reduction in radiation dose (often less than 3 mSv). This prospective

gated CTA is possible only in patients with a heart rate of less than 65 bpm and in some vendors is limited by patient weight (weighing less than 250 lb). Since imaging is performed in one phase of cardiac cycle, no functional information can be obtained from a prospective scan.

Retrospective gating is commonly used for all coronary CTA examinations wherein continuous helical scanning is obtained in a single breath-hold. The data is reconstructed in different phases of cardiac cycle, which is used to obtain ventricular functional information as well as anatomic information.

ANOMALOUS CORONARY ARTERIES

Coronary arteries anomalies are rare, potentially life-threatening anatomic variants with an incidence of 1%. The anomalous origin and course of coronary artery is categorized as benign (retroaortic or prepulmonic), malignant (between aorta and pulmonary artery), and transseptal (below the interarterial space). The latter is considered less malignant. The most common anomalous coronary artery is LCX originating from RCA with retroaortic course, a benign incidental finding.

MALIGNANT INTERARTERIAL COURSE OF LCA ARISING FROM THE RIGHT SINUS OF VALSALVA OR RCA

This anomaly is found in approximately 1.3% of all coronary anomalies. The most common signs and symptoms in an infant or young patient are due to MI, heart failure or ventricular arrhythmias, or in a young adult compression of the LCA, immediately after exercise, may cause MI and is a well-known cause of sudden death in young athletes.

The anatomical features of symptomatic interarterial course of the LCA arising from RCA or right cusp are the following: vessel lumen is slitlike near its origin, acute angle of origin, intramural course of anomalous vessel, and interarterial path.

Treatment for this condition is reimplantation or unroofing procedure, and prognosis is excellent with early treatment.

BLAND WHITE GARLAND SYNDROME

Bland White Garland syndrome is also known as AL-CAPA (anomalous LCA origin from the pulmonary artery). The majority of patients present in infancy with heart failure. Rarely these patients survive into adulthood and present with angina, MI, or heart failure.

The best noninvasive diagnostic test for ALCAPA is the coronary CTA. Imaging findings show a large LCA arising from the pulmonary artery, multiple collateral vessels, and dilated RCA with left-to-right shunt from right coronary to left coronary to the pulmonary artery. This syndrome is treated by direct reimplantation of the anomalous coronary artery into the aorta.

CORONARY FISTULAS

Coronary-cameral fistulas are abnormal communications between the coronary artery and the cardiac chamber. Vessels are often large and tortuous and may have aneurysmal dilatation. This condition may be associated with coronary steal phenomena via collateral pathways if draining into low-pressure system.

MYOCARDIAL BRIDGE

Myocardial bridge is a congenital variant in which a segment of the epicardial coronary artery has an intramyocardial course. The condition most commonly involves midsegment of the LAD, the LCX, and less likely the RCA. Most patients are asymptomatic, although some may develop ischemia. Myocardial bridge is easily demonstrated on a cardiac CT. There are scattered reports of increased predisposition to atherosclerosis in patients with deep myocardial bridges.

CORONARY ARTERY ANEURYSM

Coronary artery aneurysm is present when the diameter of the coronary artery is more than 1.5 times the normal adjacent segments. There are many causative factors including atherosclerosis, Kawasaki disease, congenital, trauma, iatrogenic, mycotic, and connective tissue disorder (Table 38-2).

Treatment includes anticoagulants/deep platelet therapy, bypass and exclusion of aneurysm, and covered stent graft placement.

KAWASAKI DISEASE (MUCOCUTANEOUS LYMPH NODE SYNDROME)

Kawasaki disease is an idiopathic febrile multisystem disease in children, and its symptoms include fever and cervical lymphadenopathy with accompanying rashes

on palms and soles. Coronary artery aneurysms are present in 25% of patients, often multiple, usually in the proximal segments. Transient gallbladder hydrops can also occur. Treatment for Kawasaki disease includes aspirin and gamma-globulin.

QUESTIONS AND ANSWERS

- Which of the following is *correct* regarding coronary circulation?
 - Obtuse marginal branch arises from the RCA.
 - Acute marginal branch supply left ventricular lateral wall.
 - Majority of the interventricular septum is supplied by LAD.
 - In a codominant circulation, PLB comes from the RCA and PDA branches arise from the circumflex.

ANSWER: C. The obtuse marginal artery is a branch of the circumflex and not the RCA. The acute marginal artery is a branch of the RCA and supplies the right ventricular free wall and not the left ventricle. The LAD supplies anterior two-thirds of the interventricular septum via multiple septal perforators. The posterior one-third of the septum is supplied by the PDA. In a codominant circulation, PDA arises from the RCA and PLB comes from the circumflex.

- Which of the following is *correct* regarding coronary artery disease?
 - Positive remodeling can be easily diagnosed with conventional catheter angiography.

TABLE 38-2 Etiologies of Coronary Artery Aneurysm

Atherosclerosis	Most common in the United States
Kawasaki disease	Most common worldwide
Congenital, trauma, iatrogenic, mycotic, connective tissue disorder	

- B. The ring of Vieussens is a common collateral pathway between RCA and circumflex arteries.
- C. The majority of the culprit lesions in acute coronary syndrome are significant stenotic lesions.
- D. Collateral circulation is difficult to evaluate by coronary CT angiography.

ANSWER: D. Collateral vessels are usually smaller and more tortuous than native vessels and are commonly seen in patients with significant coronary artery disease, and are commonly seen on a catheter angiography in patients with coronary artery disease. These collaterals are difficult to identify by a coronary CTA because of limited spatial resolution and the nondynamic nature of CT. Positive remodeling refers to outward expansion of the vessel wall because of atheromatous plaque deposition without compromising the lumen. Therefore, it is not often seen on conventional catheter angiography. However, CT can nicely demonstrate the wall abnormalities and remodeling. The ring of Vieussens is a common collateral pathway between RCA and LAD (not circumflex). The majority of the culprit lesions in acute coronary syndromes are due to less than 50% diameter stenotic lesions.

3. Which of the following is *incorrect* regarding myocardial infarction?
 - A. Earliest cardiac marker to rise is myoglobin level.
 - B. Troponin levels are the diagnostic defining criteria for myocardial infarction.
 - C. Creatinine kinase levels peak at 24 hours and return to the baseline in 2 to 3 days.
 - D. Coronary CT has high positive predictive value and low negative predictive value in evaluating chest pain.

ANSWER: D. The coronary CTA has a very high negative predictive value and therefore is extremely useful in excluding coronary artery disease in patients with chest pain. The troponin levels are the criterion standard in defining and diagnosing myocardial infarction: they start increasing in 3 to 12 hours, peak at 24 to 48 hours, and then gradually return to the baseline in 1 to 2 weeks. CK levels increase within 3 to 12 hours of chest pain, peak at 24 hours, and return to the baseline in 2 to 3 days. Myoglobin levels can rise within 1 to 4 hours of chest pain and are highly sensitive in the early detection of MI, but are not specific.

4. Which of the following is *correct*?
 - A. Post-myocardial infarction MR is due to anterior papillary muscle rupture.

- B. Myocardium can be salvaged by PCI if performed within 48 hours.
- C. Presence of delayed enhancement on cardiac MRI indicates reversible ischemia.
- D. Dressler syndrome responds well to steroids.

ANSWER: D. Dressler syndrome occurs 10 to 30 days after myocardial infarction or cardiac surgery and responds well to aspirin or steroids. Postmyocardial infarction MR is usually due to posterior papillary muscle rupture from inferior myocardial infarction leading to severe acute MR. Irreversible myocardial damage occurs if the total occlusion of the vessel persists for more than 4 to 6 hours and therefore reperfusion within the period (not within 48 hours) can salvage significant myocardium. The presence of delayed enhancement on cardiac MR indicates scar due to irreversible ischemia/infarction.

5. Which of the following is *correct* regarding cardiac MDCT?
 - A. Cardiac function is routinely evaluated on prospective gated CTA.
 - B. Radiation dose is higher in prospective gating than retrospective gating.
 - C. The most important parameter in obtaining good quality studies is a low heart rate.
 - D. Dose modulation technique is very useful to decrease radiation dose, especially in patients with a high heart rate.

ANSWER: C. In prospective gating, only one phase of the cardiac cycle, usually late diastole, is imaged and therefore cardiac function cannot be evaluated. Retrospective gating, on the other hand, obtains images through the cardiac cycle, and therefore cardiac function is routinely evaluated. Since the x-ray exposure is continuous throughout the helical retrospective imaging, radiation dose is much higher for retrospective gated study and lower for prospective gated imaging. The most important parameter in obtaining a good quality CTA is a low heart rate of less than 60 bpm.

6. Regarding coronary artery anomalies, which is *correct*?
 - A. Most coronary artery anomalies are benign.
 - B. ALCAPA commonly presents in adults.
 - C. Coronary artery aneurysms are commonly congenital in origin.
 - D. Coronary-cameral fistula is a common cause for sudden death.

ANSWER: A. Most coronary artery anomalies of origin and course are benign and are usually detected incidentally on conventional angiography. Anomalous LCA origin from the pulmonary artery

(ALCAPA) is most commonly found in infancy with heart failure as the presenting feature. Rarely, patients surviving into adulthood may present with angina, myocardial infarction, or heart failure. The most common cause of coronary artery aneurysm is atherosclerosis in the United States and Kawasaki disease worldwide. Coronary-cameral fistulas are abnormal communications between the coronary artery and cardiac chambers and may be associated with coronary steal phenomena via collaterals if draining into a low-pressure system. It is not a common cause for sudden death.

7. Which of the following is *incorrect* regarding Kawasaki disease?

- A. Coronary artery aneurysms are commonly in the distal segments.
- B. Treatment includes surgical resection.
- C. Symptoms include fever, lymphadenopathy, and rash on the palms and soles.
- D. Associated with gallbladder hydrops.

ANSWER: D. Transient gallbladder hydrops can occur in Kawasaki disease, an idiopathic febrile multisystem disease in children with typical symptoms of fever, cervical lymphadenopathy, and rashes on palms and soles. Coronary artery aneurysms are present in 25% of patients, are often multiple, and usually occur in the proximal segments (not distal segments). Treatment usually includes aspirin and gamma-globulin and not surgical intervention.

8. Regarding LV aneurysm, which of the following is *correct*?

- A. True LV aneurysm has a narrow neck.
- B. True LV aneurysms are more likely to rupture.
- C. LV pseudoaneurysm has a broad neck.
- D. LV pseudoaneurysms typically occur in the basal, inferior, and lateral LV segments.

ANSWER: D. True LV aneurysms can involve all walls of the myocardium, have a broad neck, usually occur in the LV apex, and are less likely to rupture. Pseudoaneurysms are surrounded by pericardium or organized clot, have a narrow neck, typically occur in the basal, inferior, or lateral LV segment, and are more likely to rupture (Table 38-3).

9. Which of the following is *incorrect*?

- A. Malignant interarterial course of the LCA can cause sudden death in young athletes.
- B. Cardiac CT is the gold standard to evaluate anomalous coronary artery.
- C. Cardiac MDCT has a high temporal resolution in comparison to cardiac MRI.

TABLE 38-3 Left Ventricular Aneurysm

TRUE LEFT VENTRICULAR ANEURYSM	PSEUDOANEURYSM
Usually in the LV apex from LAD disease	Typically basal inferior or lateral LV segment
Involves all walls of the myocardium	Often surrounded by pericardium or organized clot
Broad neck	Narrow neck
Less likely to rupture	Increased risk of rupture

D. Cardiac MR has a better spatial resolution than cardiac CT.

ANSWER: C. Cardiac MDCT has high spatial resolution in comparison to MR, while its temporal resolution is lower than that of cardiac MR. Cardiac MDCT is the gold standard to evaluate anomalous coronary artery origin and course. Common causes of sudden death in a young athlete include malignant interarterial course of the LCA, hypertrophic cardiomyopathy, and ARVD.

10. Which of the following is *correct*?

- A. First branch of the RCA is usually the SA nodal branch.
- B. Conus artery is also known as the third coronary artery.
- C. Right ventricle is supplied by the acute marginal branches.
- D. Circumflex artery supplies the inferior and posterior wall of the left ventricle.

ANSWER: B. In 50% of the patients, conus artery is the first branch of the RCA and in the rest, it arises separately from the right coronary cusp and that is why it is also known as the third coronary artery. The circumflex artery supplies the lateral wall of the left ventricle, whereas the inferior and posterior walls are supplied by the PDA and PLD branches of the RCA.

39 CARDIAC AND PERICARDIAL TUMORS

Satinder P. Singh

CARDIAC TUMORS

Metastatic tumors to the heart and pericardium are 20 to 40 times more common than primary heart tumors. Primary tumors of the heart account for less than 5% of

all cardiac tumors and the remaining 95% are metastatic. Among primary cardiac tumors, benign tumors are more common than malignancies. The most common primary cardiac tumors in adults are myxomas followed by lipomas and fibroelastomas. The most common cardiac tumor in children is rhabdomyoma.

METASTASIS

The heart can be involved by metastasis in three ways: direct mediastinal infiltration by lung cancer, breast cancer, or lymphoma; hematogenous metastasis from malignant melanoma, lymphoma, leukemia, or sarcoma; and transvenous spread from inferior vena cava (renal, hepatic, or adrenal tumors) or via the pulmonary veins or superior vena cava from lung cancer. Pericardial metastasis presenting with pericarditis is the most common symptom of metastatic heart disease (Table 39-1). Less common is asymptomatic pericardial effusion detected incidentally on chest radiograph or echocardiography. Myocardial metastasis may be asymptomatic or may present with arrhythmia, heart block, or myocardial dysfunction. Echocardiography is the most commonly used modality in suspected cardiac metastasis but CT and MR are complementary modalities. Pericardiocentesis allows the diagnosis of pericardial metastasis in 70% to 80% of patients.

CT features that suggest a malignant nature of a cardiac neoplasm are wide attachment to the all of the heart, destruction of the cardiac chamber wall, involvement of more than one cardiac chamber, invasion of the pericardium, extension into the pulmonary artery, pulmonary vein, or vena cava, and involvement beyond the pericardium, lung or mediastinum. CT is not an accurate technique to detect direct invasion of the mediastinum and cardiovascular structures by lung cancer.

PRIMARY CARDIAC TUMORS

Primary cardiac tumors are rare and a great majority are benign (Table 39-2). Myxoma is the most common benign tumor followed by rhabdomyoma and fibroma. The most common malignant tumor is sarcoma.

TABLE 39-1 Causes of Neoplastic Pericarditis

Malignant (25%)
Angiosarcoma
Rhabdomyosarcoma
Fibrosarcoma

PRIMARY BENIGN TUMORS OF THE HEART

CARDIAC MYXOMA

Cardiac myxoma commonly arises in the left atrium (75%) or right atrium (20%) and the rest in either ventricle. Myxomas tend to be solitary, pedunculated, or polypoid masses. These are more common in women and are attached to the interatrial septum near the fossa ovals in the majority of cases. Familial myxomas are uncommon (less than 10% of all myxomas), tend to present at an earlier age, are more likely to have multiple myxomas at atypical locations, and tend to develop recurrent tumors. These are also associated with other dermatological and endocrine abnormalities (*Carney complex*) (Table 39-3).

Clinical Features

Patient may be asymptomatic or may demonstrate peripheral embolic phenomena, signs and symptoms of mitral valve obstruction, and other constitutional symptoms of fever, anemia, elevated ESR, and sometimes clubbing, mimicking infective endocarditis. Systemic symptoms are largely due to the secretion of interleukin-6 by myxomas. Right atrial myxomas may mimic Ebstein anomaly, ASD, or constrictive pericarditis.

TABLE 39-3 Familial Cardiac Tumors (10%)

Carney syndrome:
Cardiac myxoma
Noncardiac myxoma in breast or skin
Pigmentation of skin
Endocrine tumors (pituitary adenomas, adrenocortical disease, or testicular tumors)
NAME syndrome:
Nevi
Atrial myxoma
Myoid neurofibromas
Ephelides
LAMB syndrome:
Lentigines
Atrial myxoma
Blue nevi

Imaging Findings

Heart is commonly enlarged and there is evidence of left atrial enlargement; although rare, the left atrial appendage is also enlarged. Depending on the severity and duration, pulmonary venous hypertension, edema, or even secondary pulmonary artery hypertension may be present. Rarely, these tumors can calcify, which can be detected on CT or fluoroscopy. Myxomas are of intermediate signal intensity on spin-echo MR images, similar to that of myocardium, have low signal intensity on gradient echo images because of partial calcification, and demonstrate higher signal intensity on T2-weighted images. Intratumoral hemorrhage can produce high signal intensity on both T1- and T2-weighted images and contrast enhancement is often seen after gadolinium-enhanced MR. Both cine MRI and echocardiography can show mobility of the tumor often prolapsing through the mitral orifice in ventricular diastole.

Differential for atrial myxoma includes left atrial thrombus and valvular vegetations in endocarditis. The distinguishing features for thrombi are as follows: these usually occur in an enlarged chamber, atrial appendage is the most common site, and atrial fibrillation is often present. Thrombi are usually sessile and do not demonstrate contrast enhancement. Myxomas can be sessile or pedunculated and commonly attach to the interatrial septum. Clinical features help in distinguishing myxomas from endocarditis and vegetations are always related to a cardiac valve.

RHABDOMYXOMAS

Rhabdomyomas is the most common pediatric primary cardiac tumor. It is associated with tubular sclerosis in up to 50% of cases, manifesting in the neonatal period. It usually is intramural and starts in the intraventricular septum; arrhythmia is the main presenting feature. These tumors are often inoperable because of their deep location, poor demarcation, and multiplicity.

FIBROMAS

Fibromas usually involve the left ventricular wall and are resectable. These tumors can calcify, which may suggest the specific diagnosis. Fibromas are more common in children (85%) than in adolescents and adults (15%) and present with heart failure, arrhythmia, or sudden death. Fibromas are reported in associations with Gorlin syndrome. Fibromas are iso- to hyperintense on T1-weighted spin-echo images and low signal intensity relative to myocardium on T1- and T2-weighted spin-echo images due to the short T2 relaxation time of the fibrous tissue.

LIPOMAS

Lipomas can occur in the septa or myocardial free wall. These are best and easily identified on CT as low-

density masses. Lipomatous hypertrophy of the interatrial septum is often found incidentally on routine chest CT and classically spares the fossa ovalis. Lipomas are usually asymptomatic but may be associated with supraventricular arrhythmia. A large right atrial lipoma may present with obstructive symptoms and exertional dyspnea, necessitating surgical resection. Lipoma has high signal intensity on MRI because of its short T1 and long T2 relaxation and loses signal on fat suppression sequences (help differentiating it from melanoma metastasis).

PAPILLARY FIBROELASTOMA

Papillary fibroelastoma is a collection of avascular fronds of dense connective tissue lined by endothelium. Majority of patients with these tumors are asymptomatic, although symptoms can arise due to embolization from thrombi that collect on the tumor. The majority occur on valve surfaces and the most common valve involved is aortic, followed by mitral, and then pulmonary and tricuspid. Fibroelastomas are easily detected at echocardiography as small mobile masses attached to valves by a short pedicle. Because of their small size, they are not well seen at CT or MR imaging. They may appear as elongated strandlike projection or may have a well-defined head. Surgical excision and leaflet repair is curative.

PRIMARY MALIGNANT TUMORS OF THE HEART

SARCOMAS

Angiosarcoma is the most common malignant tumor of the heart, with a male predominance and presentation in early childhood. The right atrium and then the right ventricle are the most commonly affected chambers. Tumors are infiltrating and intramural, usually presenting with intractable arrhythmias, heart failure, caval obstruction, or valvular obstruction. Angiosarcoma often involves the pericardium leading to hemorrhagic pericardial effusion. Echocardiography is the initial primary noninvasive test, which can show the mass as well as the pericardial effusion.

LYMPHOMA

Primary cardiac lymphoma is rare, usually non-Hodgkin, and more common in HIV-positive population. Secondary cardiac lymphoma is more common in patients with known lymphoma. Pericardium is frequently the common site of involvement. Lymphomas may involve myocardium, mimicking hypertrophic cardiomyopathy, or intracavitary masses.

PARAGANGLIOMA

Paraganglioma are tumors that arise from the paraganglia, clusters of neuroendocrine cells in adrenal medulla, carotid, vagal, and para-aortic bodies, and groups of several associated bed sympathetic ganglia. Typical age of presentation is young adults in their thirties and forties, most patients presenting with hypertension and biochemical evidence of catecholamine overproduction. The tumors are easily localized to the heart with nuclear medicine imaging with I-131 or I-123 MIBG. These tumors are highly vascular and tend to involve adjacent structures, including coronary arteries, making surgical resection difficult. The majority of the cardiac paragangliomas are sporadic. The tumors occur in the distribution of the cardiac paraganglia: most arise from the visceral paraganglia in the left atrium, in the posterior wall of the left atrium or left atrial roof. They may also arise from interatrial septum or paraganglia along the coronary arteries. At echocardiography, paraganglia appear as echogenic large left atrial masses. Unlike myxoma, paraganglioma have a broad base of attachment and are firmer than myxoma. At CT, these masses appear as heterogeneous circumscribed low attenuation with extracardiac extension and infiltrative borders and demonstrate intense enhancement after contrast administration. At MR, primary cardiac paraganglioma have markedly increased signal intensity on T2-weighted images and iso- to hypointense signal intensity relative to myocardium on T1-weighted images. Intense contrast enhancement is noted after gadolinium with central nonenhancing areas because of tumor necrosis.

QUESTIONS AND ANSWERS

- Which of the following is *true* regarding cardiac neoplasm?
 - Primary tumors constitute 20% of all cardiac tumors.
 - Among primary neoplasms, benign tumors are more common than malignant tumors.
 - Most common cardiac tumor in children is angiosarcoma.
 - Pericardiocentesis is always diagnostic in cardiac malignancies.

ANSWER: B. Metastatic tumors to the heart and pericardium are 20 to 40 times more common than primary heart tumors. Primary tumors of the heart account for less than 5% of all cardiac tumors and the remaining 95% are metastatic. Among primary cardiac tumors, benign tumors are more common than malignancies. The most common primary cardiac tumors in adults are myxomas, followed by lipomas and fibroelastomas. The most common cardiac tumor in children is rhabdomyoma. Pericardiocentesis allows the diagnosis of pericardial metastasis in 70% to 80% of patients.

- All of the following CT features suggest malignant nature of a cardiac neoplasm *except*:
 - Involvement of multiple cardiac chambers
 - Invasion of pericardium
 - Narrow attachment to the heart
 - Extension into pulmonary artery

ANSWER: C. CT features that suggest a malignant nature of a cardiac neoplasm are wide (not narrow) attachment to the heart, destruction of the cardiac chamber wall, involvement of more than one cardiac chamber, invasion of the pericardium, extension into the pulmonary artery, pulmonary vein, or vena cava, and involvement beyond the pericardium lung or mediastinum.

- Regarding cardiac myxoma, which of the following is *true*?
 - Most common site is right atrium.
 - Majority are multiple.
 - Familial myxomas present at an early age.
 - Demonstrate low signal intensity on T2-weighted images.

ANSWER: C. Cardiac myxoma commonly arises in the left atrium (75%) or right atrium (20%) and the rest in either ventricle. Myxomas tend to be solitary, pedunculated, or polypoid masses. These are more common in women and are attached to the interatrial septum near the fossa ovalis in the majority

of cases. Familial myxomas are uncommon (less than 10% of all myxomas), tend to present at an earlier age, are more likely to have multiple myxomas at atypical locations, and tend to develop recurrent tumors. These are also associated with other dermatological and endocrine abnormalities (Carney complex). Myxomas are of intermediate signal intensity on spin-echo MR images, similar to that of myocardium, have low signal intensity on gradient echo images because of partial calcification, and demonstrate higher signal intensity on T2-weighted images.

4. Which of the following is *true* regarding cardiac thrombus?
- A. Often pedunculated
 - B. Most common site is right ventricle.
 - C. Atrial fibrillation is often present.
 - D. Enhance after contrast injection

ANSWER: C. Cardiac thrombus usually occurs in an enlarged chamber, atrial appendage is the most common site, and atrial fibrillation is often present. Thrombi are usually sessile and do not demonstrate contrast enhancement.

5. Which of the following is *true*?
- A. Primary cardiac lymphoma is common in HIV patients.
 - B. Papillary fibroelastoma most commonly involve mitral valve.
 - C. Angiosarcoma is the most common malignant tumor of heart.
 - D. Fibromas usually involve right ventricle.

ANSWER: C. Fibromas usually involve the left ventricular wall and are resectable. These tumors can calcify, which may suggest the specific diagnosis. Fibromas are most common in children (85%) than in adolescents and adults (15%). Angiosarcoma is the most common malignant tumor of the heart, with male predominance and presentation in early childhood. The right atrium and then the right ventricle are the most commonly affected chambers. Papillary fibroelastoma are mostly asymptomatic, and symptoms can arise due to embolization from thrombi that collect on the tumor. The majority occur on valve surfaces. The most common valve involved is aortic, followed by mitral, and then pulmonary and tricuspid. Primary cardiac lymphoma is rare, usually non-Hodgkin, and more common in HIV-positive population. Secondary cardiac lymphoma is more common in patients with known lymphoma.

40 PERICARDIAL DISEASE

Satinder P. Singh

INTRODUCTION

The pericardium consists of two layers: outer fibrous and inner visceral. The wall thickness of the inner layer is 0.05 to 1 mm, slightly thicker along the right ventricle free wall. The mesothelial cells lining the outer layer produce serous fluid; approximately 20 to 25 cc of serous fluid is present under normal physiologic conditions. The pericardial sac encloses the heart, proximal ascending aorta, pulmonary trunk, and short segments of the pulmonary veins.

The transverse sinuses of the pericardium are seen located between the ascending aorta and the pulmonary trunk as well as between the superior vena cava and the left atrium. Fluid collection in these sinuses may be misinterpreted as lymphadenopathy. The oblique sinus of the pericardium is a blind pouch confined laterally by the pulmonary veins, cranially and anteriorly by the left atrium, and posteriorly by the esophagus. In CT and MR, the normal pericardium is visualized as a pencil-thin line, especially in front and along the right atrioventricular groove and right ventricle separated from the right ventricular myocardium by a connective fat tissue. The normal pericardium thickness on the right side is less than 2 mm. The pericardium line is thinner along the left ventricle and the amount of subepicardial fat is narrower; therefore, the pericardium frequently may not be visualized along the left myocardial wall, although it can be seen in front of the left atrioventricular groove.

Echocardiography is the imaging modality most often used for the initial evaluation of suspected pericardial disease, especially effusion or tamponade. Restricted acoustic window, loculated effusions in unusual locations, and the inability to accurately detect pericardial thickening are the limitations of echocardiography. CT or MR imaging is often used when findings at echocardiography are nondiagnostic or difficult to interpret. CT and MR imaging also help in further characterization of pericardial masses.

PERICARDIAL EFFUSION

The common causes of pericardial effusion include heart failure, renal insufficiency, infection (bacterial, viral, or tuberculous), neoplasm (carcinoma of the lung or breast or lymphoma), and injury (trauma or myocardial infarction). A pericardial effusion with CT attenuation

close to that of water is likely simple effusion. Effusion with CT attenuation greater than that of water suggests exudative effusion from malignancy, infection, and hemopericardium or effusion associated with hypothyroidism. Chylopericardium demonstrates low attenuation with negative CT HU. Nonhemorrhagic fluid has a low signal intensity on T1-weighted spin-echo images and higher intensity on gradient-echo cine images. Hemorrhagic fluid demonstrates high signal intensity on T1-weighted spin-echo images and low intensity on gradient-echo cine images. Nodular, irregular thickening of the pericardium suggests malignancy.

With inflammatory pericarditis, the patient usually has effusion and pericardial thickening. Pericardial effusion originates due to the obstruction of the venous or lymphatic drainage from the heart. MRI is superior to CT in differentiating fluid from thickened pericardium.

PERICARDIAL CYSTS

Pericardial cysts are remnants of defective embryological development of the pericardium. They are most often asymptomatic and discovered incidentally on chest radiographs or CT. The typical location of pericardial cysts is the pericardiophrenic angle, much more common on the right but can be located throughout the mediastinum. On CT, these cysts are seen as nonenhancing well-circumscribed ovoid, fluid density masses adjacent to the pericardium. On T1-weighted MR images, pericardial cysts demonstrate low signal intensity and high and homogeneous intensity on T2-weighted images because of low protein concentration and nonhemorrhagic fluid. On short T1 inversion recovery images, the water content of the cyst shows high signal intensity. If the cystic fluid is proteinogenous, the signal intensity on T1-weighted images is high. The tendency to change in size or shape with respiration or body position is a discriminating feature of pericardial cyst.

PERICARDIAL DEFECTS

The majority of pericardial defects are congenital but can also result from surgery or trauma. Congenital pericardial defect is due to premature atrophy of the left duct of the Cuvier (Cardinal vein) and failure of nourishment of left pleural pericardial membrane, leading to failure of the pericardium to develop. These defects are more common in men and may be detected at any age, usually in the twenties. These may be associated with bronchogenic cysts, diaphragmatic hernia, pulmonary sequestration, VSD, PDA, and mitral stenosis. Clinically, most pericardial defects are asymptomatic and rarely may have tachy-

cardia, palpitation, right bundle branch block, positional discomfort, or chest pain, especially when lying on the left side. The chest radiograph may show a focal bulge in the area of the main pulmonary artery and left atrial appendage. On the lateral radiograph, there is an increased distance between the sternum and the heart because of the absence of the sternal pericardial ligament. On CT or MR, the cardiac axis is rotated to the left and lung interposes between the aorta and pulmonary artery. If these patients develop left pneumothorax, there is an automatic pneumopericardium owing to the absence of the pericardium. Pericardial defect can be partial or complete. Herniation and strangulation of the left atrial appendage can be symptomatic and may require surgical treatment.

CONSTRICTIVE PERICARDITIS

Patients with constrictive pericarditis frequently present with symptoms of heart failure such as dyspnea, orthopnea, and fatigue, and occasionally with liver enlargement and ascites (Table 40-1). The most frequent cause of constrictive pericarditis is cardiac surgery and radiation therapy; other causes include infection (viral or tuberculous or fungal), connective tissue diseases, uremia, neoplasm, or idiopathic.

Difficult to differentiate clinically, both constrictive pericarditis and restrictive cardiomyopathy have similar manifestations and findings at cardiac catheterization and echocardiography. In both conditions, ventricular filling is restricted, leading to increased diastolic pressures in all the four cardiac chambers and equalization of atrial and ventricular pressures. The diagnosis of constrictive pericarditis is aided by CT and MR imaging. Pericardial thickness of 4 mm or more indicates abnormal thickening, and when accompanied by clinical findings of heart failure, it is highly suggestive of constrictive pericarditis. CT is also good at demonstrating

pericardial calcification, although neither pericardial thickening nor calcification is diagnostic of constrictive pericarditis, unless the patient has symptoms of physiologic constriction or restriction. The right ventricle has a reduced volume and narrow tubular configuration. The interventricular septum has an abnormal contour with a prominent leftward convexity and abnormal septal bounce which is quite suggestive of constrictive physiology. Systemic venous dilatation, especially of the vena cava, coronary sinus, hepatomegaly, and ascites are also frequently present.

ACUTE TAMPONADE

Pericardial pressure is normally subatmospheric and becomes more negative during inspiration. Transpericardial pressure is highest at end-diastole when the ventricular volume is greatest. The pressure–volume curve for the pericardium rises steeply after a certain volume is exceeded, so removal of a small amount of fluid will result in a significant reduction in pressure. A rapid increase in intrapericardial fluid can produce acute tamponade with pressure reaching 20 to 30 mm Hg. Systemic venous pressure increases, heart volumes are reduced, and systemic arterial pressures fall (Beck triad). Compression also causes pulsus paradoxus (decrease in the arterial pressure of more than 10 mm Hg during inspiration). The *x* descent is accentuated while the *y* descent is flattened or absent as cardiac filling is severely restricted during diastole (Table 40-2).

CHRONIC CONSTRICTIVE PERICARDITIS

The fibrous envelop reduces end-diastolic volume and causes inadequate preload. The right ventricular pulse wave during diastole demonstrates an early drop followed by a high plateau (square root sign). Mean venous pressure is elevated and *x* and *y* descents are steep and deep. Pulsus paradoxus is infrequent and especially difficult to detect in the setting of atrial fibrillation. Systolic

left ventricular function is preserved, but the heart may still have impaired contractility.

RESTRICTION VERSUS CONSTRICTION

Clinical and hemodynamic profiles are similar in both of these conditions. Both are caused primarily by diastolic filling abnormalities, with preserved global systolic function. The diastolic dysfunction in restrictive cardiomyopathy results from a stiff and noncompliant ventricular myocardium, whereas it is due to a thickened noncompliant pericardium in constrictive pericarditis. Both conditions result in restricted diastolic filling, leading to diastolic heart failure. Pericardium is thickened in constriction but is normal in restriction.

PERICARDIAL HEMATOMA

Acute hematomas show homogeneous high signal intensity; subacute hematomas of 1 to 4 weeks old typically show heterogeneous signal intensity with areas of high signal intensity on both T1- and T2-weighted images. Chronic organized hematomas show peripheral dark rim and low-intensity internal foci because of calcification, fibrosis, or hemosiderin deposition on T1-weighted and gradient-echo images. High-signal-intensity areas on T1- or T2-weighted images often correspond to hemorrhagic fluid.

Coronary or ventricular pseudoaneurysm or neoplasm may resemble hematoma on MR images. Hematomas do not enhance on postcontrast MRI and do not show internal flow on velocity-encoded cine MR images.

PERICARDIAL NEOPLASMS

Pericardial metastases are much more common than primary pericardial tumors. Breast and lung cancer are the most common sources of metastasis in the pericardium followed by lymphoma and melanoma. At CT, there is presence of pericardial effusion and irregular thickening of the pericardium or presence of pericardial masses. Most neoplasms have low signal intensity on T1-weighted images and high signal intensity on T2-weighted images; metastatic melanoma is an exception and has high signal intensity on T1-weighted images because of the paramagnetic metals bound by melanin. There is usually enhancement of the pericardial metastatic masses after contrast administration.

Primary neoplasms of the pericardium are rare. Benign pericardial tumors include lipoma, teratoma, fibroma, and hemangioma; malignant pericardial tumors

TABLE 40-2 Cardiac Tamponade Versus Constrictive Pericarditis

	TAMPONADE	CONSTRICTIVE PERICARDITIS
Pulsus paradoxus	Present	May be present
Kussmaul sign	Absent	May be present
Pericardial knock	Absent	May be present
JVP	Large <i>x</i> descent Small or absent <i>y</i> descent	Normal <i>x</i> descent Large <i>y</i> descent

include mesothelioma, lymphoma, sarcoma, and liposarcoma. Lipoma has a low attenuation on CT images and high signal intensity on T1 spin-echo MR images. Presence of calcium or fat in a pericardial mass at CT suggests teratoma. Pericardial fibroma statistically has low signal intensity on T2-weighted images and often shows either no enhancement or heterogeneous enhancement because of poor vascularization. Primary malignant mesothelioma is rare and manifests as pericardial effusion with or without pericardial nodules or plaques. Lymphoma, sarcoma, and liposarcoma typically appear as large heterogeneous enhancing masses associated with exudative pericardial effusion.

QUESTIONS AND ANSWERS

- Regarding oblique pericardial sinus, which of the following is *false*?
 - Bounded anteriorly by ascending aorta.
 - Left atrium lies superior to the oblique sinus.
 - Esophagus is posterior to the oblique sinus.
 - It is a blind pouch.

ANSWER: A. The oblique sinus of the pericardium is a blind pouch confined laterally by the pulmonary veins, cranially and anteriorly by the left atrium, and posteriorly by the esophagus. Localized fluid collection in this area can sometimes mimic subcarinal adenopathy.

- Regarding pericardial defects, which of the following is not *true*?
 - Mostly asymptomatic and detected incidentally.
 - Result from atrophy of the right duct of the Cuvier (Cardinal vein) and failure of nourishment of right pleural pericardial membrane.
 - On cross-sectional imaging, there is interposition of the lung between aorta and pulmonary artery.
 - Herniation and strangulation of the left atrial appendage may be symptomatic and need surgical intervention.

ANSWER: B. The majority of pericardial defects are congenital but can also result from surgery or trauma. Congenital pericardial defect is due to pre-

mature atrophy of the left (and not right) duct of the Cuvier (Cardinal vein) and failure of nourishment of left pleural pericardial membrane, leading to failure of the pericardium to develop. Clinically, most pericardial defects are asymptomatic and rarely may have tachycardia, palpitation, right bundle branch block, positional discomfort, or chest pain, especially when lying on the left side. The chest radiograph may show a focal bulge in the area of the main pulmonary artery and left atrial appendage. Herniation and strangulation of the left atrial appendage can be symptomatic and may require surgical treatment. On CT or MR, the cardiac axis is rotated to the left and lung interposes between the aorta and pulmonary artery.

- Regarding cardiac tamponade, which of the following is *true*?
 - Tamponade can occur when a small amount of pericardial fluid develops rapidly.
 - Pericardial pressure is normally positive and becomes negative during inspiration.
 - Transpericardial pressure is highest at end-systole.
 - Systemic venous pressure increases, heart volumes are reduced, and systemic arterial pressures rises.

ANSWER: A. Pericardial pressure is normally sub-atmospheric (not positive) and becomes more negative during inspiration. Transpericardial pressure is highest at end-diastole (and not end-systole) when ventricular volume is greatest. The pressure-volume curve for the pericardium rises steeply after a certain volume is exceeded, so removal of a small amount of fluid will result in a significant reduction in pressure. A rapid increase in intrapericardial fluid can produce acute tamponade with pressure reaching 20 to 30 mm Hg. Systemic venous pressure increases, heart volumes are reduced, and systemic arterial pressures fall (not rise), also known as Beck triad.

- Regarding chronic constrictive pericarditis, which of the following is *true*?
 - Caused by a systolic abnormality
 - Pulsus paradoxus is commonly present.
 - Large x and small y descents.
 - Hepatomegaly is commonly present.

ANSWER: D. Patients with constrictive pericarditis frequently present with symptoms of heart failure such as dyspnea, orthopnea, and fatigue, and occasionally with liver enlargement and ascites. Mean venous pressure is elevated and x and y descents are steep and deep (and not large x and small y descent). Pulsus paradoxus is infrequent (not common) and

especially difficult to detect in the setting of atrial fibrillation. Systolic left ventricular function is preserved, but the heart may still have impaired contractility. It is caused primarily by diastolic filling abnormalities (not systolic abnormality), with preserved global systolic function.

5. Which of the following statement is *false*?

- A. Nodular pericardial thickening is suspicious for malignancy.
- B. Pericardium is easily seen along the left ventricle lateral wall.
- C. MR is superior to CT in distinguishing fluid from thickening.
- D. Mesothelial cells lining the outer layer produce the serous fluid.

ANSWER: B. The pericardium consists of two layers: outer fibrous and inner visceral. The wall thickness of the inner layer is 0.05 to 1 mm, slightly thicker along the right ventricle free wall. The mesothelial cells lining the outer layer produce serous fluid; approximately 20 to 25 cc of serous fluid is present under normal physiologic conditions. In CT and MR, the normal pericardium is visualized as a pencil-thin line, especially in front and along the right atrioventricular groove and right ventricle separated from the right ventricular myocardium by a connective fat tissue. CT or MR imaging is often used when findings at echocardiography are nondiagnostic or difficult to interpret. CT and MR imaging also help in further characterization of pericardial masses. The normal pericardium thickness on the right side is less than 2 mm. The pericardium line is thinner along the left ventricle and the amount of subepicardial fat is narrower; therefore, the pericardium frequently may not be visualized along the left myocardial wall. Nodular, irregular thickening of the pericardium suggests malignancy. MRI is superior to CT in differentiating fluid from thickened pericardium.

41 CARDIOMYOPATHY

Satinder P. Singh

INTRODUCTION

Cardiomyopathies are a heterogeneous group of disorders (Tables 41-1, 41-2, and 41-3) with the dominant feature being diseased cardiac muscle itself, ultimately leading to cardiac dysfunction.

TABLE 41-1 WHO Classification of Cardiomyopathies

Dilated cardiomyopathy
Hypertrophic cardiomyopathy
Restrictive cardiomyopathy
Arrhythmogenic right ventricular dysplasia
Unclassified
Specific cardiomyopathy associated with specific diseases or systemic disorders

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy is the most common type with global impairment of contractility and dilatation of all chambers, and is the most common indication for cardiac transplantation (Table 41-4).

CLINICAL FEATURES

Presenting symptoms are usually due to congestive heart failure, and patients can have an acute influenza-like illness. Chest pain is unusual. Differential diagnoses of dilated cardiomyopathy include alcoholic heart disease, diffuse silent ischemic disease, and critical aortic stenosis.

IMAGING FEATURES

Chest radiographs demonstrate enlarged heart due to left ventricular dilatation or enlargement of all chambers, and there is often associated pulmonary venous hypertension with variable degrees of edema. There is often associated mitral regurgitation due to dilatation of the mitral ring. Pericardial effusion may be present, but is without tamponade. Echocardiography, radionuclide ventriculography, and MRI reveal regional or global hypokinesis; regional wall thickening is best seen in short axis views. Gadolinium-enhanced cardiac MR is the best imaging method to categorize various forms of cardiomyopathies and to specifically distinguish the far more common ischemic myocardial disease. In patients with dilated cardiomyopathy secondary to myocarditis, delayed enhancement (DE) may be seen with patchy distribution and

TABLE 41-2 American Heart Association Classification of Cardiomyopathies (Based on Predominant Organ Involved)

Metabolic
Muscular dystrophy
Toxic reactions
Postpartum

normal perfusion imaging. The aortic valve must be examined to exclude end-stage aortic stenosis because both can have similar clinical presentations and aortic stenosis responds favorably to valve replacement.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy is often familial with autosomal dominant inheritance. The majority of mutations involve proteins of cardiac sarcomere, leading to altered sarcomere function and ultimately to hypertrophy and fibrosis. Hypertrophic cardiomyopathy is less common than dilated cardiomyopathy and is characterized by excessive hypertrophy of the left ventricular myocardium. This hypertrophy is symmetrical in the majority of patients, although in approximately 25% of patients; the upper interventricular septum is most affected, resulting in subvalvular obstruction idiopathic hypertrophic subaortic stenosis (IHSS). A rare variant of hypertrophic cardiomyopathy, commonly seen in the Japanese population, affects only the apex of the left ventricle. The complex pathophysiology of hypertrophic cardiomyopathy is due to left ventricular diastolic dysfunction, myocardial ischemia, arrhythmias, left ventricular outflow tract obstruction, mitral regurgitation, and autonomic dysfunction. The left ventricular contractility is often hyperdynamic and leads to small end-systolic left ventricular volume. Systolic anterior motion of the mitral valve (SAM) contributes to left ventricular outflow obstruction.

CLINICAL FEATURES

The clinical presentation of hypertrophic cardiomyopathy is quite variable, ranging from asymptomatic with

diagnosis made based on heart murmur or abnormal screening, EKG, to sudden death. The typical triad in symptomatic patients includes the following:

1. Dyspnea on exertion (due to increased left atrial pressure).
2. Angina (abnormal oxygen supply/demand mismatch due to left ventricular hypertrophy, increased arteriolar compressive wall tension due to diastolic relaxation abnormality, and endothelial dysfunction).
3. Presyncope or syncope (due to arrhythmia or sudden increase in outflow tract obstruction).

IMAGING FEATURES

Chest radiograph may show a normal-sized heart to a variable degree of left ventricular enlargement, and the left atrium may also be enlarged. Echocardiography often is diagnostic and nicely shows the hypertrophy as well as systolic anterior motion of the mitral valve. Cardiac MR can demonstrate the left ventricular wall hypertrophy (greater than 15 mm), assess the left ventricular mass and mitral regurgitation, and often diagnose hypertrophic cardiomyopathy when echocardiography results are negative or equivocal, especially in patients with anterolateral wall hypertrophy.

Serial follow-up evaluation of the left ventricular mass is best done with cardiac MRI. Patchy DE can be seen on delayed postcontrast cardiac MR images and, if present, is associated with increased risk for certain cardiac death. Catheter angiography can be dangerous due to induced arrhythmias. Selective coronary angiography usually shows no arterial disease; coronary arteries are enlarged with prominent septal perforators demonstrating compression during ventricular systole. Left ventriculography reveals a normal size left ventricular cavity in diastole and narrowing of the left ventricular cavity with typical curved shape, like a banana, in patients with severe septal hypertrophy. Ventricular trabeculations are usually coarse.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy may be idiopathic, secondary to infiltrative and storage diseases (such as amyloidosis and sarcoidosis) or associated with myocardial disorders such as hypereosinophilic syndromes. It is characterized by reduced ventricular filling and diastolic volume, leading to atrial dilatation and venous stasis, usually with preserved systolic function.

Cardiac MR is a fundamental diagnostic tool and helps to differentiate between restrictive cardiomyopathy and constrictive pericarditis as both demonstrate reduced

TABLE 41-4 Common Causes of Dilated Cardiomyopathy

Postchemotherapy cardiac toxicity (Doxorubicin)
Peripartum
Alcohol abuse
AIDS

ventricular filling and diastolic volumes. Pericardial thickening of more than 4 mm is typical for constrictive pericarditis, best assessed with morphologic T2-weighted “black blood” images. In restrictive cardiomyopathy, the septal convexity is maintained in all respiratory phases, whereas in constrictive pericarditis, septal flattening and bounce can be observed in early inspiration.

AMYLOID HEART DISEASE

Amyloid heart disease is a classic example of low compliance restrictive cardiomyopathy. There are three general categories. Immunoglobulin light-chain (AL) amyloidosis (previously called primary amyloidosis) is due to light chain immunoglobulin produced by monoclonal plasma cells. It is the most severe form and the most common type encountered in the United States. It can involve the kidneys, liver, heart, and peripheral nerves. Familial amyloidosis (ATTR amyloidosis) is an uncommon autosomal dominant disease resulting from production of unstable variant of the serum protein transthyretin. It can involve the heart and central nervous system. Senile systemic amyloidosis is secondary to deposition of wild-type transthyretin and is exclusively limited to the heart.

Patients with amyloid heart disease present with low output cardiac failure without murmur. EKG is often low voltage. Echocardiography is the noninvasive test of choice, but lacks specificity, especially when other comorbid conditions such as hypertension are present. Gadolinium-enhanced cardiac MRI is more specific and demonstrates decreased T1 of the myocardium and global and/or subendocardial DE.

SARCOIDOSIS

Only 5% of patients with systemic sarcoid have clinical evidence of cardiac involvement, though the incidence is higher (20%–30%) at autopsy. These patients may present with cardiac arrhythmia as well as restrictive cardiomyopathy. Rarely, papillary muscle involvement leads to mitral regurgitation. Cardiac MR can identify sarcoid granulomas as high signal areas on T2-weighted images with fat suppression or areas of hyperenhancement after gadolinium administration. Myocardial biopsy can be falsely negative due to patchy involvement of the myocardium, and cardiac MR can direct endomyocardial biopsy, as well as monitor the results of therapy.

HEMOCHROMATOSIS

Hemochromatosis can be primary, an inherited autosomal recessive disease with iron deposition in liver, heart,

and pancreas or secondary due to repeated blood transfusion and less commonly from long-term hemodialysis and alcohol abuse. It involves both the liver and spleen; however, iron deposition in primary hemochromatosis spares the spleen. Since iron reduces T1 and T2 relaxation rates, hemochromatosis can be diagnosed by cardiac MR. The amount of signal decrease on T2-weighted images correlates well with the iron level in the tissue and therefore cardiac MR can be used to monitor the results of treatment.

ANDERSON-SABRY DISEASE

Anderson-Sabry disease is an X-linked disorder characterized by alpha-galactosidase enzyme deficiency leading to abnormal accumulation of sphingolipids catabolites in various organs including the heart. This abnormal accumulation can lead to arrhythmia, valvulopathy, myocardial infiltration with secondary restrictive cardiomyopathy, and myocardial hypertrophy. MR shows symmetric myocardial wall thickening with increased left ventricle ejection fraction and reduced volume. There is late enhancement due to expression of both intramyocyte accumulation of sphingolipids and interstitial expansion due to fibrosis and collagen deposition. This DE has a specific location (midbasal, lateral left ventricle wall) and distribution pattern (subepicardial and mesocardial) in patients with cardiac symmetric hypertrophy helping in differentiation from hypertrophic cardiomyopathy.

LEFT VENTRICULAR NONCOMPACTION

Left ventricular noncompaction is a rare form of congenital cardiomyopathy resulting from arrest of normal intrauterine developmental progression of loose myocardial fiber network. It can be an isolated finding that is increasingly recognized in adults, or a nonisolated form associated with other congenital heart disease such as hypoplastic left ventricle and ventricular septal defect. The left ventricle is typically involved and has a spongy appearance with increase trabeculations and deep intertrabecular recesses. The clinical presentation ranges from cardiac arrhythmias, embolic events, or premature heart failure at a young age. Diagnosis of left ventricular noncompaction is based on ratio of trabeculations in the ventricular apex and thickness of the left ventricular free wall in end-diastole; all of these features can be seen on echo, CT, and cardiac MRI. A ratio of more than 2.5 to 3.0 is considered abnormal and specific.

TABLE 41-5 Arrhythmogenic Right Ventricular Dysplasia Diagnostic Criteria

Major criteria	Right ventricular dysfunction: severe dilatation and reduction of RV ejection fraction with little or no LV impairment, localized RV aneurysms, severe segmental dilatation of the RV Fibrofatty replacement of myocardium on endomyocardial biopsy Conduction abnormalities: epsilon waves in V1 to V3, localized prolongation (>110 ms) of QRS in V1 to V3 Family history: disease confirmed on autopsy or surgery
Minor criteria	Right ventricular dysfunction: mild global RV dilatation and/or reduced ejection fraction with normal LV, mild segmental dilatation of the RV, regional RV hypokinesia Fibro fatty RV wall replacement Conduction abnormalities: inverted T waves in V2 and V3 in an individual older than 12 years in the absence of a right bundle branch block (RBBB), ventricular tachycardia with a left bundle branch block (LBBB) morphology, frequent PVCs (>1000 PVCs/24 h) Family history of sudden cardiac death before age 35 or family history of ARVD

*Diagnosis depends on two major and two minor criteria or four minor criteria.

ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA

Arrhythmogenic right ventricular dysplasia (ARVD) is characterized by fibrofatty degeneration of the right ventricle leading to arrhythmias and sudden cardiac death. Diagnosis of ARVD is based on strict criteria (Table 41-5) and is present if one of the following is met:

- Two major criteria are present or
- One major and two minor criteria are present or
- Four minor criteria are present

Clinical presentation includes syncope, ventricular arrhythmias (left bundle branch block), or sudden death, especially in young athletes, and heart failure. EKG reveals epsilon waves, small depolarization at the beginning of ST segment. T-wave inversion is present in early leads. MR is the modality of choice for evaluating right ventricular morphology, volume, and intramyocardial fatty infiltration. To optimize demonstration of fat, imaging in systole is preferred.

TAKOTSUBO CARDIOMYOPATHY

Takotsubo cardiomyopathy is also known as transient left ventricular apical balloon syndrome, resulting in

sudden onset of transient akinesia or dyskinesia of the left ventricular apex without significant coronary artery stenosis. It often follows periods of severe emotional or physical stress often in postmenopausal women. Clinical presentation is acute chest pain with reversible ST segment abnormalities and abnormal cardiac biomarkers. It is named because the left ventricle resembles a Japanese octopus pot, which has a narrow mouth and large round base. Akinesia and ballooning are typically seen in the left ventricle apex, and this dysfunctional myocardium distribution does not correspond to perfusion territory of single epicardial coronary vessel. The best imaging tool is cardiac MR, which demonstrates the morphology and left ventricle functional abnormality. In comparison to acute myocardial infarction, there is no evidence of delayed hyperenhancement. The differential diagnosis includes acute myocardial infarction, acute myocarditis, and coronary vasospasm. Rapid and prompt aggressive pharmacologic and hemodynamic support can result in rapid reversal of left ventricle dysfunction.

QUESTIONS AND ANSWERS

1. Which of the following is *not true* regarding dilated cardiomyopathy?
 - A. It is the most common type of cardiomyopathy.
 - B. Chest pain is a common presentation.
 - C. It is the most frequent reason for cardiac transplantation.
 - D. It can mimic severe aortic stenosis.

ANSWER: B. Dilated cardiomyopathy is the most common type of cardiomyopathy and is the most common reason for cardiac transplantation. The presenting symptoms are usually due to congestive heart failure, and sometimes patients may have acute influenzalike illness, but chest pain is unusual. The aortic valve must be examined to exclude end-stage aortic stenosis, which has a similar clinical presentation as dilated cardiomyopathy.

2. The typical clinical presenting triad in hypertrophic cardiomyopathy include all *except*:
- Dyspnea on exertion
 - Syncope
 - Lower extremity swelling
 - Angina

ANSWER: C. The typical triad in symptomatic hypertrophic cardiomyopathy patients include dyspnea on exertion due to increased left atrial pressure, syncope from arrhythmia or sudden increase in outflow tract obstruction and angina due to abnormal oxygen supply/demand mismatch, increased arteriolar compressive wall tension, and endothelial dysfunction.

3. Regarding hypertrophic cardiomyopathy, which of the following is *true*?
- It can cause sudden death.
 - Catheter angiography is often required for diagnosis.
 - Chest radiographs are always abnormal.
 - Ventricular hypertrophy is asymmetric in the majority of patients.

ANSWER: A. Hypertrophic cardiomyopathy is one of the causes for sudden death. The chest radiographs may be normal or may show left atrial enlargement and a variable degree of left ventricular configuration. In the majority of patients, the ventricular hypertrophy is symmetrical, and in approximately 25% of patients only the upper intraventricular septum is most affected. Catheter angiography can be dangerous due to induced arrhythmia and usually is not required for diagnosing hypertrophic cardiomyopathy.

4. Which of the following is *true* for restrictive cardiomyopathy?
- It is characterized by systolic dysfunction and reduced ventricular diastolic volume.
 - Cardiac MR is the diagnostic tool commonly used to differentiate restrictive cardiomyopathy and restrictive pericarditis.
 - Septal bounce is commonly present.
 - HIV infection leads to restrictive cardiomyopathy.

ANSWER: B. Restrictive cardiomyopathy is characterized by reduced ventricular filling and diastolic volume, leading to atrial dilatation and venous stasis, but usually with reserved systolic function. Septal wall motion abnormality and bounce is typically seen in constrictive pericarditis and not in restrictive cardiomyopathy. HIV infection is a common cause for dilated cardiomyopathy and not restrictive cardiomyopathy.

5. Which of the following is *true* regarding cardiomyopathy?
- In 25% of patients with systemic sarcoid, the heart is involved.
 - Most cases of hypertrophic cardiomyopathy are familial.
 - Primary hemochromatosis commonly involves the heart, pancreas, and spleen.
 - Regional wall thickening is best seen in horizontal long-axis view.

ANSWER: B. Only 5% of patients with systemic sarcoid have clinical evidence of cardiac involvement, though the incidence is higher at 20% to 30% at autopsy. Hypertrophic cardiomyopathy is often familial (autosomal dominant) and the majority of mutations involve proteins of cardiac sarcomere causing altered sarcomere function leading to hypertrophy and fibrosis. Secondary hemochromatosis results from repeated blood transfusions, long-term hemodialysis, and alcohol abuse and involves both liver and spleen, whereas primary inherited autosomal recessive hemochromatosis is characterized by island deposition in the liver, heart, pancreas, and spares spleen. Regional wall thickening on echocardiography or cardiac MRI is best evaluated in short-axis views and not horizontal long-axis views.

6. Regarding ARVD, which of the following is *incorrect*?
- It can cause sudden cardiac death.
 - Family history of ARVD diagnosed clinically is a major criterion for ARVD diagnosis.
 - Left bundle branch block is a common arrhythmia.
 - The left ventricle can be involved.

ANSWER: B. ARVD is characterized by fibrofatty degeneration of the right ventricle leading to arrhythmia including sudden cardiac death. Sustained left bundle branch block type of ventricular arrhythmia is considered a major criterion. Family history of ARVD diagnosed clinically is a minor, and not major, criterion. ARVD most commonly involves the right ventricle, though left ventricular involvement has been reported.

7. Which one of the following is the most likely diagnosis in a young postmenopausal female presenting with sudden onset of acute chest pain following severe emotional stress and LV apex dysfunction?
- Left ventricular noncompaction
 - Cardiac amyloid
 - Takotsubo cardiomyopathy
 - Alcohol-induced dilated cardiomyopathy

ANSWER: C. Takotsubo cardiomyopathy typically occurs in postmenopausal females with acute sudden onset chest pain and reversible ST segment

abnormalities following severe emotional or physical stress. The dysfunctional myocardium at the LV apex leads to akinesis and ballooning, which often responds rapidly to aggressive pharmacologic and hemodynamic support (that is why it is also known as transient left ventricular apical balloon syndrome). LV noncompaction is a rare congenital cardiomyopathy with clinical presentation of cardiac arrhythmia, embolic events, or premature heart failure at a younger age. At imaging, the left ventricle is typically involved and has a spongy appearance with increased trabeculations. Cardiac amyloid is an example of low compliance restrictive cardiomyopathy and presents clinically as low output failure without murmur. Alcohol-induced dilated cardiomyopathy presents with features of congestive heart failure, and chest pain is unusual.

8. Regarding ARVD, which of the following is *not* a major diagnostic criteria?
- A. Severe dilatation and reduction in the right ventricular ejection fraction.
 - B. Regional right ventricular hypokinesia
 - C. Localized right ventricular aneurysms
 - D. Familial disease confirmed at surgery

ANSWER: B. Severe dilatation and reduction in the right ventricular ejection fraction and localized right ventricular aneurysm are considered major criteria, whereas regional right ventricular hypokinesia or mild segmental dilatation of the right ventricle, or minor global right ventricular dilatation or ejection fraction reduction are minor criteria. Familial disease confirmed at necropsy or surgery is a major criterion, whereas a family history of premature sudden death caused by ARVD or family history diagnosed clinically based on current criteria are considered minor.

9. Which one of the following is *not* a type of restrictive cardiomyopathy?
- A. Anderson-Sabry disease
 - B. Hypereosinophilic syndrome
 - C. Postchemotherapy cardiac toxicity
 - D. Amyloidosis

ANSWER: C. Postchemotherapy cardiac toxicity (usually from doxorubicin) is a common cause of dilated cardiomyopathy. Restrictive cardiomyopathy may be idiopathic, secondary to infiltrative and storage disorders such as amyloidosis, sarcoidosis, Anderson-Sabry disease, hemochromatosis, or associated with myocardial disorders such as hypereosinophilic syndrome.

10. Which of the following statements is *correct*?
- A. Delayed contrast hyperenhancement is commonly seen in Takotsubo cardiomyopathy.
 - B. Echocardiography is the modality of choice to diagnose ARVD.
 - C. A ratio of more than 3 for LV apex trabeculations and thickness of LV free wall at end-systole is diagnostic for LV noncompaction.
 - D. Hemochromatosis can be diagnosed by cardiac MRI.

ANSWER: D. Since iron reduces T1 and T2 relaxation rates, hemochromatosis can be diagnosed by cardiac MR. The amount of signal decrease in T2-weighted images correlate well with iron level in the tissue. In Takotsubo cardiomyopathy, there is no delayed contrast hyperenhancement on cardiac MRI in comparison to acute myocardial infarction. CMRI is the modality of choice for evaluating ARVD. A ratio of more than 3 for LV apex trabeculations and thickness of LV free wall at end-diastole and not systole is diagnostic for LV noncompaction.

42 CARDIAC SURGERIES

Satinder P. Singh

INTRODUCTION

Congenital heart disease (CHD) affects 1% of newborns. Of these, the majority are minor lesions that do not require surgery. However, some are serious and may result in significant morbidity. CHD remains the largest cause of neonatal mortality second to prematurity. Advances in pediatric heart surgery over the past few decades have led to increasing numbers of long-term survivors from both palliative and corrective surgery. Currently 80% to 85% of patients born with congenital heart disease can expect to reach adulthood. Over the past several years, the indications for and timings of palliative procedures have also changed. Common palliative procedures done for CHD are listed in Table 42.1. See Table 42-2 for a list of surgical approaches for congenital and acquired heart disease repair and Table 42-3 for a list of congenital heart lesions suitable for catheter intervention.

CLASSIC BLAYLOCK-TAUSSIG SHUNT

This shunt is created between the subclavian and the pulmonary artery and is constructed on the opposite side

TABLE 42-1 Common Cardiac Surgical Procedures used for CHD

To increase the pulmonary blood flow (aortopulmonary shunt)
Classic Blalock-Taussig shunt: subclavian to pulmonary artery, constructed on opposite side from arch
Modified Blalock-Taussig shunt: Gortex subclavian to pulmonary artery shunt, constructed on same side as arch
Central shunt: Gortex ascending aorta to main pulmonary artery
Waterson: ascending aorta to right pulmonary artery
Pott procedure: descending aorta to left pulmonary artery
Brock procedure: pulmonary valvotomy closed with or without infundibular dilatation or resection
To decrease the pulmonary blood flow
Pulmonary artery banding; Muller-Dammann procedure
To improve mixing of blood
Blalock-Hanlon septectomy: clamps placed behind right pulmonary veins and across a portion of both atria. The lateral portion of the atrial septum is excised
Rashkind balloon septostomy (palliative treatment for TGA)
Park-Blade septostomy at catheterization: used for thicker septum or when large interatrial communication is desired
Open atrial septectomy: most commonly performed during repair of hypoplastic left heart
To reduce ventricular function
Bidirectional Glenn: SVC to pulmonary artery, end-to-side anastomosis
Classic Glenn: SVC to right pulmonary artery, end-to-end anastomosis

from the arch. The orifice of subclavian artery controls flow. This procedure is technically challenging, often leading to pulmonary artery distortion. Reported complications include arm ischemia and decreased growth,

phrenic nerve injury, Horner syndrome, chylothorax, and endocarditis.

MODIFIED BLALOCK-TAUSSIG SHUNT

This Gore-Tex shunt is created between the subclavian and the pulmonary artery and is constructed on the same side as the arch. This procedure is reproducible, has less pulmonary artery distortion and better pulmonary artery growth, and it can be done left or right or the same side of the aortic arch. However, the modified shunt is less durable than the classic Blalock-Taussig shunt. Complications include shunt stenosis or thrombosis.

PULMONARY ARTERY BANDING

The goal of pulmonary artery banding is to reduce pulmonary artery pressure to one-third of systemic pressure. Selecting the correct band diameter is important for good results.

The most common general indication for banding is congestive heart failure in infancy with anticipated delayed repair. The single ventricle is the most common lesion requiring banding to protect the pulmonary bed for future Fontan conversion.

Mortality from these procedures is 5% to 20% and is increased in younger infants with complex lesions. Complications include pulmonary artery distortion, malpositioned band resulting in supraventricular pulmonary

stenosis, or a more distal band disrupting the pulmonary bifurcation.

CLASSIC GLENN SHUNT

The classic Glenn procedure is done to reduce ventricle work by creating a shunt between the SVC and the right pulmonary artery with end-to-end anastomosis. It divides pulmonary circulation and diverts all venous return to the larger right lung, so that subsequent Fontan procedure can only use the smaller left lung. Arterial venous fistula is a late complication.

BIDIRECTIONAL GLENN SHUNT

The bidirectional Glenn procedure is done by creating an end-to-side anastomosis between the SVC and the pulmonary artery. It reduces the ventricular work, decreases Fontan mortality, allows blood flow to both lungs, and can be done as preparation for future Fontan conversion or in combination with Fontan procedure. This procedure is less likely to cause right heart failure from overcirculation as seen with aortopulmonary shunts. As pulmonary vascular resistance gradually increases, the shunt flow decreases over time.

FONTAN OPERATION

The original Fontan operation consists of classic Glenn anastomosis between the superior vena cava and the right pulmonary artery, closure of the atrial septal defect, insertion of a homograft valve in the inferior vena cava, and placement of a homograft valve conduit between the right atrium and the left pulmonary artery. Various modifications of this procedure were developed because of late morbidity from valve conduits. The operation basically bypasses the right ventricle and, via a surgically constructed atriopulmonary connection and atrial separation, conducts blood into the lung without the benefit of pulsatile ventricular flow.

Late complications after the Fontan procedure include right atriomegaly and hepatic dysfunction, narrowing and/or leak in the Fontan pathway, dilatation of the coronary sinus, myocardial dysfunction and failure, recanalization of ligated main pulmonary trunk, systemic venous collateralization, plastic bronchitis, protein-losing enteropathy, sinus node dysfunction, and pulmonary arteriovenous malformations.

ATRIAL SWITCH REPAIR FOR TRANSPOSITION OF GREAT ARTERIES

The Mustard and Senning operations are the definitive operations for transposition of great arteries to correct the physiologic abnormalities of the transposed great arteries by forming a baffle within the atria in order to switch the flow of blood at in-flow level. This results in a reversion of the normal flow of blood with the heart and lungs being in series, with the left ventricle becoming the pulmonary ventricle and the right ventricle the systemic ventricle. In the Senning operation, the baffle is created from the right atrial wall and atrial septal tissue without the use of extrinsic material, whereas the Mustard operation involves resection of the atrial septum and the creation of a baffle from the pericardium or synthetic material. These operations are performed at varying stages of life, but usually when the patient is between 1 month and 1 year of age.

RASTELLI OPERATION

The Rastelli operation is the most frequently used procedure for patients with transposition of great arteries, pulmonary outflow tract obstruction, and VSD. It involves placement of a baffle within the right ventricle, directing blood from the VSD to the aorta, and utilizes the VSD as part of the left ventricular outflow track. The pulmonary valve or subpulmonic region is oversewn and the conduit is inserted between the right ventricle and pulmonary artery. The main advantage of this operation is that the left ventricle becomes the systemic ventricle. An important limitation in this procedure is that the patient is committed to further operations, as the conduit is likely to be replaced several times during the patient's life.

ARTERIAL SWITCH OPERATION (JATENE PROCEDURE)

The arterial switch operation involves transection of the aorta and pulmonary artery above the valve sinuses; coronary arteries are detached from the aorta with a surrounding button of aortic wall and sutured into place into the neo-aorta. The pulmonary trunk is moved forward into the new position anterior to the aorta, and the switched great arteries are sutured into place. This is a technically challenging operation performed within the first 2 weeks of life and should be undertaken, at the latest, by 4 to 6 weeks of life. Its advantage over the Mustard or Senning procedure is that the left ventricle becomes the systemic ventricle.

NORWOOD PROCEDURE

The Norwood procedure is used for repair of hypoplastic left heart. It is a two-stage procedure: in stage I the aorta origin is widened, the PA is transected and closed, and then followed by a modified right BT shunt and atrial septectomy; in stage II a modified Fontan procedure is performed when cyanosis is increased.

PERCUTANEOUS OCCLUSION OF ASD

Early closure of ASD in asymptomatic adults with enlargement of the right ventricle is performed to reduce the risk of atrial arrhythmias, for symptoms of right ventricular failure, and at onset of pulmonary vascular disease.

Device closure is not appropriate for sinus venosus defects, atrioventricular septal defects, or secundum defects greater than 40 mm in size. Two common devices used are the Amplatzer septal occluder and the CardioSEAL implant. Anatomic consideration for device closure includes detailed anatomic study typically with transesophageal echocardiography, especially to evaluate the pulmonary veins, right upper lobe pulmonary vein, mitral and tricuspid valves, coronary sinus, and vena cava. The presence of anomalous pulmonary venous drainage or close proximity of the defect to these structures preclude the use of device closure.

QUESTIONS AND ANSWERS

- For what congenital cardiac defect is pulmonary banding used?
 - ASD in infants
 - TOF
 - Single ventricle
 - TGA

ANSWER: C. Pulmonary artery banding is done in patients with excessive pulmonary blood flow causing CHF in infants who get definitive repair later in life. The single ventricle is the most common lesion requiring banding in order to protect the pulmonary bed for future Fontan conversion. In ASD usually a definitive repair with a septal patch or percutaneous occlusion is done. TOF patients have decreased blood flow therefore need a shunt procedure to increase blood flow and not banding. In TGA the repair is either done by switching the atria (Senning/Mustard procedure) or arteries (Jatene procedure).

- Regarding percutaneous atrial septal occlusion, which of the following is *false*?

- Early closure in asymptomatic adults is often done to decrease atrial fibrillation.
- The onset of pulmonary vascular disease is decreased.
- It is ideal for sinus venosus defects.
- Defects must be <40 mm.

ANSWER: C. Early closure of ASD in asymptomatic adults with enlargement of the right ventricle is done to reduce the risk of atrial arrhythmias, symptoms of right ventricular failure, and onset of pulmonary vascular disease. Device closure is not appropriate for sinus venosus defects, atrioventricular septal defects, or secundum defects greater than 40 mm in size.

- Regarding the Fontan procedure, which of the following is *false*?
 - It bypasses the right ventricle.
 - It includes Glenn anastomosis between the aorta and pulmonary artery.
 - Blood flow to the lungs is nonpulsatile.
 - Protein losing enteropathy is a known complication.

ANSWER: B. The original Fontan procedure consists of classic Glenn anastomosis between the superior vena cava and the right pulmonary artery (not aorta and PA), closure of the atrial septal defect, insertion of a homograft valve in the inferior vena cava, and placement of a homograft valve conduit between the right atrium and the left pulmonary artery. Various modifications of this procedure were done because of late morbidity from valve conduits. The operation basically bypasses the right ventricle and, via a surgically constructed atriopulmonary connection and atrial separation, conducts blood into the lung without the benefit of pulsatile ventricular flow. Protein losing enteropathy is a known late complication of this procedure.

- The following surgical procedures are done in transposition of great arteries, *except*:
 - The Rastelli procedure
 - The Norwood procedure
 - The Senning procedure
 - The Jatene procedure

ANSWER: B. The Norwood operation is done in cases of hypoplastic left heart syndrome and is a two-stage procedure: in stage I the aorta origin is widened, the PA is transected and closed, and then followed by a modified right BT shunt and atrial septectomy; in stage II a modified Fontan procedure is performed when cyanosis is increased.

The Rastelli procedure involves placement of a baffle within the right ventricle, directing blood from the VSD to the aorta, and utilizes the VSD as part of

the left ventricular outflow track. The pulmonary valve or subpulmonic region is oversewn, and the conduit is inserted between the right ventricle and pulmonary artery. It is most frequently used for patients with TGA, pulmonary outflow track obstruction, and VSD. Jatene or arterial switch operation involves transection of the aorta and pulmonary artery at the level above the valve sinuses, detaching the coronary arteries from the aorta with a surrounding button of aortic wall, and suturing into place into the neo-aorta. The pulmonary trunk is moved forward into the new position anterior to the aorta, and the switched great arteries are sutured into place. The Senning procedure (atrial switch operation) involves forming a baffle within the atria in order to switch the flow of blood at in-flow level. In the Senning operation, the baffle is created from the right atrial wall and atrial septal tissue without the use of extrinsic material, whereas the Mustard operation involves resection of the atrial septum and the creation of a baffle from the pericardium or synthetic material.

5. What is the shunt between the ascending aorta to right pulmonary artery known as?
- The Pott procedure
 - The Blalock-Taussig procedure
 - The Waterson procedure
 - The Brock procedure

ANSWER: C. The Waterson procedure involves a shunt between the ascending aorta to the right pulmonary artery; the Pott procedure involves connecting the descending aorta to the left pulmonary artery; the classic Blalock-Taussig procedure involves a shunt between the subclavian to the pulmonary artery, constructed on the opposite side from the arch; the Brock procedure includes a pulmonary valvotomy closed with or without infundibular dilatation or resection.

43 AORTIC DISEASES

Satinder P. Singh

ACQUIRED AORTIC DISEASES

THORACIC AORTIC ANEURYSM

Thoracic aortic aneurysm is defined as localized or diffuse dilatation of more than 50% of the normal diameter of the thoracic aorta. In the thoracic aorta, more than 4.5 cm is

TABLE 43-1 Etiology of Thoracic Aortic Aneurysm

Atherosclerosis (most common)
Trauma
Infection
Cystic medial necrosis (Marfan, Ehler-Danlos syndrome)
Hypertension
Bicuspid aortic valve
Inflammatory (Takayasu, giant cell arthritis)

considered aneurysmal. More than 6 cm is considered to present a significant risk of rupture. They are mostly fusiform (80%) and less common saccular (20%). Aneurysms of the descending aorta are most common, followed by those of the ascending aorta, and least commonly involve the arch. Thoracic aortic aneurysms are less common than the abdominal aorta aneurysm. Although atherosclerosis is the most common cause of aortic aneurysms, there are numerous other etiologies (Table 43-1), which are dependent on location (Tables 43-2, 43-3, and 43-4). Thoracic aneurysms are often associated with an abdominal aneurysm. They are more common in men (2.5:1).

The lifetime probability of rupture of thoracic and thoracoabdominal aneurysms is 75% to 80%, with 5-year untreated survival rates of 10% to 20%.

CLINICAL FEATURES

Clinical presentation of aortic aneurysms includes the following:

- Asymptomatic (40%), often discovered incidentally on physical examination or chest radiography.
- Chest pain.
- Peripheral embolization (bowel or extremity ischemia, TIA).
- Systemic symptoms in inflammatory or mycotic aneurysms (Table 43-5).

COMPLICATIONS OF THORACIC AORTIC ANEURYSM

Complications of thoracic aneurysm include expansion, rupture, and dissection. Thoracic aortic aneurysms expand at a rate of 0.43 cm/y (faster in aneurysms greater than 5 cm). Rupture of thoracic aortic aneurysms is more frequent than abdominal aortic ruptures. Patients may be asymptomatic, though they are more often symptomatic and these symptomatic patients have poor prognosis. There is dramatic onset of excruciating pain,

TABLE 43-2 Causes of Ascending Aortic Aneurysm

Marfan syndrome
Syphilis
Atherosclerosis (rare)

TABLE 43-3 Etiology of Aortic Arch Aneurysm

Takayasu arteritis
Atherosclerosis

and rupture commonly occurs into the left pleural space. Intrapericardial rupture leads to hypotension or even tamponade.

IMAGING FEATURES

CT is a common and reliable modality performed for initial diagnosis of aneurysm, preoperative assessment, and postoperative surveillance. Transesophageal echocardiogram (TEE) is not accurate for diagnosing thoracic aneurysm though it is quite accurate in diagnosing dissection and can be done bedside if the patient is unstable. TEE is excellent in documenting pericardial effusion and aortic regurgitation. MRI is particularly useful for long-term serial follow-up and in those with coexisting aortic valve disease.

TREATMENT

Treatment for thoracic aneurysm includes surgical or endostent repair or a combined staged approach. Indications for repair of aortic aneurysm include the following:

- Growth rate > 1 cm/y.
- Symptomatic aneurysm.
- Size > 5.5 cm ascending and > 6.5 cm descending aorta. (In familial and Marfan syndrome cases, surgery is performed sooner.)

Prior to endostent repair, preoperative assessment is performed with CTA with multiplanar reformatting. It is important to describe any branch vessel involvement, any angulation of the aorta, diameter and length of the aneurysm, and presence and extent of aortic wall calcification. Typically greater than 1 cm of normal aortic wall is required adjacent to the abnormal aneurysm wall, and there should be 40 to 42 mm or less diameter of proximal and distal aortic necks, 9 mm or larger size of femoral and iliac arteries, and no severe tortuosity. Follow-up after stent placement is also performed with CTA at 3-, 6-, and 12-month intervals and yearly thereafter.

TABLE 43-4 Syphilitic Aneurysm

Typically involves the ascending aorta
Spare the sinuses (sinuses in Marfan)
Calcification is common (tree bark appearance)

TABLE 43-5 Key Features of Mycotic Aneurysm

Etiology
Bacterial aortitis (usually *Salmonella* or *Staphylococcus aureus*)
Syphilitic aortitis (ascending aorta sparing sinuses)
Rapid eccentric saccular aneurysmal growth
Periaortic soft tissue stranding, edema, fluid or gas, lobular outline, enhancement of periaortic soft tissue
Major branching points
Increased risk in
Bacterial endocarditis
Immunocompromised status
Prosthetic vascular devices
Intravenous drug abuser
Treatment
Surgical resection and grafting following antibiotic therapy
In some cases, endovascular stent repair with antibiotic therapy

Complications of endostent treatment include endoleak (see Table 66-1 in Chapter 66), stent migration, pseudoaneurysm formation, dissection, perforation, thrombosis, kinking, coverage of visceral branch, and spinal ischemia. Type I endoleak is the most common in the thoracic aorta, but type II is the most common endoleak in the abdomen. Both types I and III have an increased risk of rupture; type IV endoleak is usually transient.

POSTTRAUMATIC PSEUDOANEURYSM

Posttraumatic pseudoaneurysm is typically located at the isthmus with or without typical eccentric peripheral calcification. A saccular pseudoaneurysm is contained by adventitia and does not contain normal aortic wall. Following initial trauma, 2.5% of patients develop chronic posttraumatic pseudoaneurysm. It is usually asymptomatic with an increased tendency to rupture if larger than 6 cm. It is treated with endovascular stent graft or open surgical repair.

INTRAMURAL HEMATOMA

Intramural hematoma, also known as noncommunicating aortic dissection, is part of the acute aortic syndrome. It is secondary to hemorrhage within the aortic wall due to rupture of the vasa vasorum with typical absence of intimal tear. Classification and treatment are similar to aortic dissection: type A (ascending aorta involved) and type B (descending aorta only) (Table 43-6). Most patients are hypertensive and present with acute chest pain.

TABLE 43-6 Aortic Dissection Classification**Stanford classification**

Type A: Involves ascending aorta, descending aorta may or may not be involved, surgical treatment

Type B: Limited to descending aorta, medical management

DeBakey classification

Type 1: Involves ascending aorta, aortic arch, and descending aorta

Type 2: Ascending aorta

Type 3: Descending aorta distal to the left subclavian artery

Natural history of intramural hematoma includes complete resolution (30%), progression to dissection or aneurysm, and subsequent rupture.

IMAGING FEATURES

CT is the primary modality of choice for diagnosis and reveals crescentic hyperdense aortic wall thickening on noncontrast examination. Hypodense aortic wall with elliptical aortic lumen with well-defined margins, but without intimal flap, is identified on contrast-enhanced CT.

MR reveals high signal in the aortic wall on T1-weighted images. There is low signal on postcontrast T1-weighted images. Postcontrast images show lack of contrast in the intramural hematoma.

PENETRATING AORTIC ULCER

Ulcerated atherosclerotic lesions penetrate the elastic lamina into the media with associated aortic wall hematoma. The most common location is the descending aorta (more than 90%) followed by the ascending aorta. In 10%, multiple ulcers are present.

Pathological findings include focal outpouching of the aortic wall and irregular edges with associated extensive aortic atheroma. The risk of aortic rupture is high. The most common signs and symptoms are similar to those of aortic dissection. Sometimes the patient may be asymptomatic. It is commonly seen in elderly men more than in women. Treatment includes medical therapy to decrease blood pressure or surgical repair, especially if the ascending aorta is involved. Lately, endovascular endostent treatment is used.

AORTIC DISSECTION**ETIOLOGY**

Many diseases predispose to aortic dissection: atherosclerosis, hypertension (most common), collagen disorders, Marfan and Ehlers-Danlos syndrome, collagen

vascular diseases, pregnancy, and congenital disorders (bicuspid aortic valve or aortic coarctation).

Iatrogenic causes include cardiac surgery, valve replacement, coronary artery bypass, or percutaneous catheter placement. Other rare causes include crack cocaine abuse and syphilitic aortitis.

IMAGING FEATURES

Chest radiography may be normal or may show a widened mediastinum of more than 8 cm with an ill-defined large aortic knob with medially displaced intimal calcification when compared with prior radiographs. If there is rupture, hemothorax, left apical cap, tracheal deviation, depression of left main bronchus, esophageal deviation, pericardial effusion, or loss of peritracheal stripe may be visible.

Contrast-enhanced CT will demonstrate the site and extent of dissection, involvement of great vessels in the thorax, and extension and involvement of abdominal aortic branches. Complications such as rupture into the pericardial space or formation of intramural thrombus or rupture of dissecting aneurysm may occur.

CT is recommended for acute presentation. MR is good for follow-up, and transesophageal echo is often obtained in unstable patients at bedside.

TREATMENT

Treatment is surgical for type A and medical for type B dissections. Medical control of hypertension is employed, and surgery is reserved for complicated cases of type B dissection (such as those with mesenteric or extremity ischemia, renal artery involvement or rupture, or aneurysmal enlargement of false lumen). More recently, percutaneous endostent treatment has been used for type B dissection.

TRAUMATIC AORTIC LACERATION

Traumatic aortic laceration is usually secondary to sudden deceleration injury to the thorax (motor vehicle collision or fall from height). Typical location is the aortic isthmus, followed by the aortic arch, descending thoracic aorta, and ascending aorta cranial to the aortic valve.

IMAGING FEATURES

Chest radiography demonstrates mediastinal widening of greater than 8 cm. Other supportive findings include indistinct aortic outline, increased paratracheal soft tissue density, left apical cap, associated first or second rib fractures, and tracheal and downward left mainstem bronchus displacement. Contrast-enhanced CT is the best modality for diagnosis. Laceration must be differ-

entiated from ductus diverticulum and penetrating atherosclerotic ulcer. Ductus diverticulum, which is located at the aortic isthmus, has a smooth contour with obtuse margins and broad-based outpouching. However, no intimal flap or tear is identifiable. Multiplanar reconstruction helps in diagnosis. On the other hand, a penetrating ulcer is located not at the inner aspect of the aortic isthmus, but rather at the descending thoracic aorta and is associated with extensive calcified atherosclerotic plaques.

TREATMENT

The mainstay of treatment is surgical repair with left thoracotomy and placement of interposition graft or anastomosis. Endovascular stent grafting with or without associated open thoracotomy approach is increasingly used.

With surgery, a 60% to 70% survival rate is expected. However, without intervention, 80% of patients die within 1 hour, 85% within 24 hours, and 98% in 10 weeks. Long-term outcome if the patient survives the initial period includes chronic posttraumatic pseudoaneurysm.

TAKAYASU ARTERITIS

Takayasu arteritis is a granulomatous inflammatory vasculitis, affecting medial and large vessel walls, especially the aorta and its branches. It is most common in Asian countries. There is patchy thickening of the large- and medium-sized vessels.

Early in the inflammatory (nonobstructive) phase patients have nonspecific symptoms with elevated ESR. The late (occlusive phase) is also considered the “pulseless phase” because of vascular stenoses. Takayasu arteritis usually presents in younger patients, more commonly in women rather than men.

IMAGING FEATURES

Chest radiograph may show premature calcification of the aorta. CT or MR are the diagnostic modalities most commonly used. There is concentric wall thickening, which may be enhanced with contrast. The left subclavian artery is the most common site of involvement, followed by other main branches and the aorta. Occasionally, the pulmonary artery is involved. Stenosis or ostial arch vessel occlusion is common.

TREATMENT

Treatment includes corticosteroids with angioplasty or surgical bypass for narrowing or occlusion. However, stenting has a high failure rate.

GIANT CELL ARTERITIS

Giant cell arteritis is a rare occurrence in patients younger than 50 years (in comparison with Takayasu arteritis, which is common in younger patients). Otherwise, there is a similar appearance to Takayasu arteritis with mural inflammation, vessel wall thickening, and enhancement. The most common location is the extracranial carotid vessel with a propensity for a superficial temporal artery. It rarely involves the thoracic or abdominal aorta. Like Takayasu arteritis, it is treated with steroids.

CONGENITAL AORTIC DISEASES

COARCTATION OF THE AORTA

Coarctation of the aorta is caused by congenital narrowing of the proximal descending thoracic aorta opposite the origin of the ductus arteriosus (postductal being most common). Less commonly, coarctation occurs proximally between the left subclavian artery and the left common carotid artery, which is more common in infants and neonates. Coarctation accounts for 6.5% of cases of congenital heart disease.

Collateral circulation is present, proximal and distal to the coarctation and usually involves branches of the subclavian artery, especially the internal mammary, vertebral, costocervical, and thyrocervical trunks. The most common anomaly associated with coarctation is the bicuspid aortic valve (27%–46%).

Associated abnormalities of the subclavian artery can significantly alter collateral pathways. Stenosis of the left subclavian artery or anomalous origin of the right subclavian artery (if coexisting with coarctation of the aorta) restricts collateral circulation on the affected side, leading to unilateral rib notching.

CLINICAL FEATURES

The age of presentation depends on the severity of the coarctation and associated anomalies. Severe coarctation usually presents during the first week of life, soon after closure of the ductus arteriosus; patients present with heart failure and acidosis from hyperprofusion of the lower body. Less severe forms usually present in patients at a later age with manifestations of systemic hypertension.

IMAGING FEATURES

In the neonatal period, the heart is invariably enlarged with signs of heart failure. Abnormality of the aortic contour and rib notching is not evident at this age. In older patients, left ventricular hypertrophy is present. Rib notching is more commonly identified after patients

are 8 years of age and is usually due to dilatation of the posterior intercostal arteries and is seen along the medial half of the inferior rib margins of the fourth through eighth posterior ribs. The aortic arch is less prominent due to hypoplasia of the arch with increased prominence of the left subclavian artery. At the site of coarctation, the contour of the descending aorta becomes discontinuous followed by dilatation of the descending aorta (poststenotic dilatation), resembling the number “3.” A reverse “3” sign is seen from the impression on the barium-filled esophagus from coarctation.

Imaging is required to establish the location and degree of stenosis, length of stenotic segment, associated aortic arch abnormalities, and collateral pathways.

Echocardiography is used for diagnosis in the neonatal period, whereas MR and CT are used in later life to establish diagnosis as well as for follow-up evaluation after treatment.

TREATMENT

Surgery is the treatment of choice for most coarctations. Balloon angioplasty also has a high success rate. Recently, endostent treatment following angioplasty has shown excellent results.

PSEUDOCOARCTATION

Pseudocoarctation is an uncommon condition where the aortic arch is unusually high and the descending thoracic aorta buckles at the level of the aortic isthmus. There is no hemodynamic obstruction, and no collateral flow is present. Often radiographic abnormality is detected incidentally, mimicking paramediastinal mass or aortic aneurysm.

VASCULAR RING

Vascular ring is an anomalous configuration of the aortic arch and/or associated vessels creating a complete ring around the trachea or esophagus.

This anomaly, associated with deletion of chromosome region 22q11 occurs early in embryologic development and occurs in many forms. Vascular ring results from incomplete regression of first of the six embryonic brachial arches. Early in development, a dorsal and ventral aortic arch is present. Six embryonic brachial arches connect the two arches. The third, fourth, and sixth arches are crucial in the development of the aortic arch, its major branches, the ductus arteriosus, and the pulmonary artery. In normal development, each arch develops into a vascular structure or involutes in the following manner:

- Right and left first and second arches develop into a portion of the arterial supply of the face.
- The third arch forms the carotid arteries.
- The dorsal aorta between the third and fourth arches involutes.
- The fourth arch is the main contributors to the aortic arch. The proximal right fourth arch develops into the right subclavian artery. The left fourth arch remains as the aortic arch.
- The fifth arch involutes bilaterally.
- The ventral sixth arch develops into the proximal right pulmonary artery. The ventral left sixth arch develops into the left pulmonary artery, while the dorsal portion becomes the ductus arteriosus.
- The seventh segmental arterial branches of the dorsal aorta form the left subclavian artery and the distal right subclavian artery.

DOUBLE AORTIC ARCH

The double aortic arch is due to the persistence of both left and right fourth aortic arches, and it is the most common *symptomatic* vascular ring. The majority of cases are dominant right arch with left descending aorta (75%). In 20% of cases, it is dominant right arch with right descending aorta. The most common symptom is inspiratory stridor worsening with feeding. The trachea is deviated from the dominant arch and right arch and is often larger and more superior than the left arch. As a result, severe tracheal compression may occur.

IMAGING FEATURES

CT or MRI can identify both arches and their branches. Each arch gives rise to a vertebrocarotid and dorsal subclavian artery (“four artery sign”).

Echocardiogram, (suprasternal) notch view, is most helpful in demonstrating two separate arches giving rise to separate carotid and subclavian arteries without brachiocephalic trunks. Echo is inadequate to demonstrate airway compression. On the lateral chest radiograph, the anterior and posterior compression of the trachea may be seen at the level of the arch. (In the left pulmonary sling, there is compression on the anterior aspect of the esophagus and posterior aspect of the trachea.)

TREATMENT

Treatment includes thoracotomy on the side of the smaller aortic arch with division of the smaller of the arch, the atretic segment, and ligamentum arteriosum. Complications of surgery include aortoesophageal fistula, persistent airway compression, and symptoms leading to tracheobronchomalacia.

RIGHT AORTIC ARCH

Right arch with mirror image branching is associated with cyanotic congenital heart disease, whereas right arch with aberrant left subclavian artery is not. There may be dilatation of the origin of the left aberrant subclavian artery (diverticulum of Kommerell). The presence of left ligamentum arteriosum may lead to complete vascular ring and may be associated with airway compression. A right arch is the most common congenital anomaly of the aortic arch in asymptomatic patients. Commonly associated congenital anomalies (10%–15% of cases) include tetralogy of Fallot, pulmonary atresia with VSD (25%), and truncus arteriosus (30%). Tetralogy of Fallot is the most likely diagnosis in the setting of a cyanotic heart lesion with right aortic arch.

PULMONARY SLING

Anomalous origin of the left pulmonary artery from the proximal right pulmonary artery forms a sling around the distal trachea, passing in between the trachea and esophagus. This is the only vascular ring coursing between the trachea and esophagus and, therefore, the only vascular ring associated with asymmetric lung inflation and aeration. The most common clinical presentation is severe stridor, hypoxia, and ventilator dependency. This vascular anomaly is secondary to agenesis or obliteration of the left sixth arch, which normally forms the left pulmonary artery branch.

Lateral chest radiograph reveals soft tissue density between the distal trachea and esophagus with posterior compression of the trachea. On frontal radiographs, the left hilum is lower in position. Barium esophagography reveals anterior indentation on the esophagus. Imaging diagnosis can be made from echo, CT, or MR.

QUESTIONS AND ANSWERS

- Regarding thoracic aortic aneurysms, which of the following is *true*?
 - Thoracic aortic aneurysm is more common than abdominal aneurysm.
 - Thorax aneurysm most frequently involves the aortic arch.
 - Abdominal aortic aneurysm rupture is more frequent than thoracic rupture.
 - In a patient with known aneurysm, sudden onset excruciating pain usually indicates rupture.

ANSWER: D. Abdominal aortic aneurysm is more common than thoracic aneurysm, but thoracic aortic aneurysms rupture more frequently than abdominal aortic aneurysms. Sudden pain in a patient with known aortic aneurysm often indicates rupture, which most commonly occurs into the left pleural cavity. Descending thoracic aorta is the most common site for aneurysm in the chest.

- Which of the following is *not* an indication for repair of thoracic aortic aneurysm?
 - Symptomatic aneurysm
 - Growth rate more than 1 cm/y
 - Involvement of the ascending aorta
 - Size more than 6.5 cm

ANSWER: C. Involvement of the ascending aorta is indication for repair for aortic dissection and not aortic aneurysm. Repair is indicated if the aneurysm increases more than 5.5 cm in size for ascending aorta and >6.5 cm for descending aorta. Most aortic aneurysms grow at rate of 0.43 cm/y; if growth rate is faster (>1 cm/y), then surgery should be considered. The presence of symptoms in patients with aneurysm is also an indication for surgical repair.

3. Regarding endoleak, which of the following is *correct*?
- A. Type II is the most common type of endoleak in the thoracic aorta.
 - B. There is increased risk of rupture for type III endoleak
 - C. Type IV endoleak is related to graft failure.
 - D. Retrograde perfusion of patent aortic branches is the most common cause for endoleak.

ANSWER: B. Type I endoleak is the most common type of endoleak in the thoracic aorta. Type II is secondary to retrograde perfusion of patent aortic branches, but it does not carry an increased risk of rupture. Type I endoleak usually occurs at the proximal or distal stent attachment site, and there is increased risk of rupture for type I and type III endoleak. Type III endoleak is due to graft-related failures, and type IV endoleak is due to graft wall porosity, a transient phenomenon.

4. Concerning mycotic aneurysm, which of the following is *incorrect*?
- A. Show rapid fusiform growth
 - B. Often caused by bacterial infection
 - C. Usually occurs at branching points
 - D. High incidence in intravenous drug abusers

ANSWER: A. Mycotic aneurysms are usually caused by bacterial infections, *Salmonella* or *Staphylococcus aureus*, and occur at branching points with high incidence in patients with immunocompromised status, intravenous drug abuse, bacterial endocarditis, or prosthetic vascular devices. The mycotic aneurysms show rapid eccentric saccular growth, not fusiform growth.

5. Regarding aortic dissection, which is *true*?
- A. The most common site of dissection is the aortic root followed by the proximal descending aorta, and aortic diaphragmatic hiatus.
 - B. Type A dissections are managed medically and type B dissections surgically.
 - C. Iatrogenic cause is common.
 - D. Chest radiograph can be normal.

ANSWER: D. The most common site of aortic dissection is proximal descending thoracic aorta near the ductus ligament attachment, followed by aortic root and aortic diaphragmatic hiatus. Type B dissections involve only descending thoracic aorta and are managed medically. Type A dissections involve ascending aorta and are treated surgically. Chest radiograph may be normal in a patient with aortic dissection, and CT angiography is the modality of choice for diagnosis in an acute setting.

6. Which of the following is *correct* regarding aortic aneurysm?
- A. In Marfan syndrome, ascending aortic aneurysm spares the sinus of Valsalva.
 - B. Tree bark appearance is commonly described for mycotic aneurysm.
 - C. The most common site of rupture for an ascending aorta is the right pleural space.
 - D. Posttraumatic pseudoaneurysm is typically located at the isthmus.

ANSWER: D. Ascending aortic aneurysm can be due to atherosclerosis, Marfan syndrome, or syphilis. The aortic sinus is spared in syphilis but is involved in Marfan syndrome. Tree bark appearance refers to the calcification of the syphilitic ascending aortic aneurysm. The ascending aortic aneurysm usually ruptures into the pericardial space and can lead to tamponade. The descending thoracic aortic rupture is usually into the left pleural space. Posttraumatic aneurysm is commonly located at the isthmus and occurs only in 2.5% of patients following initial trauma.

7. Which of the following is *correct* for acute aortic syndrome?
- A. Penetrating aortic ulcers are common in young women.
 - B. Descending thoracic aorta is the most common site.
 - C. The majority of patients are asymptomatic.
 - D. Intramural hemorrhage is commonly due to blunt trauma.

ANSWER: B. Penetrating aortic ulcers are most commonly seen in the descending aorta in elderly men who have extensive atherosclerotic aortic disease. The most common presentation is chest pain similar to dissection, and only occasionally there are no symptoms. Intramural hemorrhage occurs due to hemorrhage into the aortic wall from rupture of the vasa vasorum. It is often seen in patients with hypertension and is less commonly due to trauma.

8. Regarding aortic arch development, which of the following is *correct*?
- A. The second and third arches are the main contributors to aortic arch.
 - B. Double aortic arch is due to persistence of dorsal and ventral third arches.
 - C. The proximal right fourth arch develops into the right subclavian artery.
 - D. Pulmonary sling is due to obliteration of left fifth aortic arch.

ANSWER: C. Aortic arch is mainly formed from the left fourth arch and double aortic arch forms from persistent right and left fourth arches. Normally, the right fourth arch forms the proximal right subclavian artery. The left pulmonary artery develops from the left ventral sixth arch, and obliteration of the latter leads to formation of pulmonary sling.

9. Regarding coarctation, which of the following is *correct*?
- A. Coarctation of aorta is most commonly located between the left subclavian and left common carotid arteries.
 - B. Patients with postductal coarctation present with upper extremity cyanosis.
 - C. The most common associated anomaly is atrial septal defect.
 - D. There is no hemodynamic gradient in pseudo-coarctation.

ANSWER: D. The most common location of coarctation is postductal beyond the origin of the left subclavian artery. Most patients with postductal coarctation present with systemic hypertension during young adolescence, while those with severe coarctation present in infancy after ductus closure with heart failure, severe acidosis, and lower extremity hypoperfusion. Bicuspid valve is the most

common associated anomaly (27%–43%). Pseudo-coarctation is due to an unusual high arch with buckling of descending aorta detected incidentally on radiograph mimicking aneurysm or coarctation. It is differentiated from coarctation based on the absence of hemodynamic gradient and collateral flow.

10. Regarding aortic dissection, which is *correct*?
- A. The majority of patients survive aortic transection.
 - B. Chest radiographs are often abnormal.
 - C. Surgical repair is done via right thoracotomy.
 - D. In 40% of patients, a chronic pseudoaneurysm develops after initial trauma.

ANSWER: B. The majority of aortic transection patients die before reaching the hospital due to exsanguination. With surgery, a 60% to 70% survival rate is expected; without intervention, 80% die within 1 hour, 85% die within 24 hours, and 98% die within 10 weeks. Chronic posttraumatic pseudoaneurysm can develop but only in a minority of patients (fewer than 5%). Since the most common location of aortic traumatic injury is near the isthmus, a left and not right thoracotomy is required for repair. Chest radiographs are abnormal in the majority of patients who make it to the hospital.

44 GI TRACT CONTRAST AND TECHNIQUE

Cheri L. Canon

There are two general categories of contrast agents used in gastrointestinal (GI) tract fluoroscopy: barium sulfate-based and iodine-based agents. The type of contrast prescribed is determined by the clinical indication for the examination.

Although relatively few, there are risks associated with barium contrast fluoroscopy. Barium sulfate is relatively inert but can incite inflammatory response if spilled into the mediastinum or peritoneal cavity, particularly if spilled with infected bowel contents. For this reason, a water-soluble agent is preferred if perforation is suspected. Some patients may have a hypersensitivity to the additives or the latex in the rectal tube or balloon. Aspiration of small quantities of barium is not a significant danger; however, as with all types of liquids, there is increased risk of respiratory failure with large-volume aspiration, particularly in patients with compromised pulmonary function.

Barium contrast must be used cautiously when performing diagnostic enema examinations in patients suspected of having mechanical obstruction of the colon, because of the danger of barium becoming inspissated above the site of obstruction. In general, if barium flows freely in a retrograde fashion across a strictured region, in all likelihood it will pass without difficulty. Additionally, rectal balloons should be employed with caution and only inflated with fluoroscopic visualization after the rectum has been distended with contrast to ensure normal compliance. Its use is contraindicated in patients with proctitis or with history of prior pelvic radiation, most commonly for prostate cancer in men and cervical cancer in women. Small bowel obstruction is not a contraindication to the oral administration of barium, but CT

is a better method to evaluate this clinical condition. As with all studies that incorporate ionizing radiation, pregnancy status must be determined before beginning any fluoroscopy examination in women of childbearing age.

Barium agents come in various densities. They are measured by weight per volume (total number of grams of barium sulfate present in 100 mL of the barium solution) or weight per weight (total number of grams of barium sulfate in each 100 g of dry product). “Thin-barium” suspensions for the upper GI tract usually range from 35% to 80% w/v. These solutions, usually used in the single-contrast examinations, provide good luminal distension and can be used for assessment of emptying and motility. High-density or “thick-barium” solutions, usually 210% to 250% w/v, are used in the double-contrast portion of the upper GI examination. They provide good mucosal relief when an effervescent agent is used for distension. Small bowel studies typically use 46% to 60% w/v solution with a minimum volume of 500 mL of the barium solution. Double-contrast barium enema examination uses a solution of 60% to 120% w/v, and 12% to 15% w/v is used for single-contrast enema examinations.

Barium swallow and upper GI studies are typically biphasic in nature, containing both elements of single- and double-contrast examinations. Therefore, assessment for stricture, motility, and mucosal pathology is completed with one study. Double-contrast, or air-contrast, examination indicates that both air and high-density barium are used to delineate a mucosal surface. Single-contrast examination incorporates a full column of usually slightly less dense medium to distend the GI tract. Prone, single-contrast views of the stomach and duodenum may incorporate the use of a compression paddle to displace the dense pool of barium, allowing for a more see-through view. Collapsed views of the esophagus are helpful for the diagnosis of varices which tend to fill (distend) in this view and are effaced with esophageal distension.

Diatrizoate meglumine (Gastrografin) and diatrizoate sodium (MD-Gastroview) solutions are iodine-based

water-soluble contrast agents for enteric use. They have high osmolality and can cause severe bronchospasm, flash pulmonary edema, pneumonitis, and even death if aspirated. As a result, they are contraindicated in patients at risk for aspiration or with a tracheoesophageal fistula. Additionally, because of their high osmolality (1940 mOsm/kg H₂O, 2000 mOsm/kg H₂O, respectively. Remember, plasma is approximately 300 mOsm/kg H₂O), they are limited in volume that can be administered orally, ranging from 30 to 120 mL (up to 4 oz). Volumes higher than this can drastically alter fluid balance by drawing fluid into the bowel lumen. This becomes a particular concern with infants and elderly patients, particularly if dehydrated, because of risk of aspiration and large volume shifts using the hyperosmolar enteric contrast agents. There has been a significant shift to use low-osmolar agents (Omnipaque, Isovue) typically administered intravenously for contrast-enhanced CT examinations. The typical enteric dose ranges from 50 to 500 mL.

As with intravenous iodinated agents, there is a small risk for anaphylactoid reactions. Theoretically, small quantities of luminal contrast agent can be absorbed across the mucosa and enter into the bloodstream. Since these types of reactions are not volume dependent, even a small amount may lead to mild reactions of urticaria to life-threatening reactions including laryngospasm, bronchospasm, arrhythmia, hypotension, and death. Therefore, a history of a severe anaphylactoid reaction to iodinated agents is a contraindication to their administration enterally as well as parenterally.

Glucagon is the most common antispasmodic agent used in the United States. It can be given intravenously, submucosally, or intramuscularly (Table 44-1). It increases the concentration of blood glucose and is used in the treatment of hypoglycemia. It also relaxes the smooth muscle of the stomach, duodenum, small bowel, ileocecal valve, and colon. However, its effect on the esophagus is less apparent. Dosages typically range from 0.1 to 1 mg. Smaller dosages can be used in the upper GI tract, but 1 to 2 mg dosages are need to induce colonic hypotonia. It is contraindicated in patients who have known hypersensitivity, usually to one of the additives and not glucagon itself. Additionally, in patients who have an insulinoma or pheochromocytoma, it can result in severe subsequent hypoglycemia because of the release of insulin or catecholamines, respectively.

TABLE 44-1 Glucagon Pharmacokinetics

DOSE	ROUTE	ONSET	DURATION
0.5 mg	IV	1 min	9–17 min
1.0 mg	IV	1 min	22–25 min
	IM	8–10 min	12–27 min

IM, intramuscular; IV, intravenous.

SUGGESTED READING

ACR Contrast Media Manual, Version 6.0. May 2008.

Skucas J. Contrast media. In: Gore RM, Levine MS, Laufer I, eds. *Textbook of Gastrointestinal Radiology*. Vol. 1. Philadelphia, PA: W.B. Saunders; 1994;190: 709-714.

QUESTIONS AND ANSWERS

- Which of the following is the typical density of barium contrast used in the air-contrast portion of biphasic esophagography?
 - 15% w/v
 - 35% w/v
 - 60% w/v
 - 250% w/v

ANSWER: D. Air-contrast views typically use 210%–250% w/v density barium agents (thick barium).

- Which of the following is the dose of glucagon used to induce colonic hypotonia?
 - 0.5 mg
 - 0.75 mg
 - 1.0 mg
 - >5 mg

ANSWER: C. Typical dose range for glucagon for barium enema examination is 1–2 mg, 0.5–1.0 mg for upper GI tract.

45 ESOPHAGUS

Cheri L. Canon and Sanjiv K. Bajaj

NORMAL ANATOMY

PHARYNX

The pharynx is divided into three sections: nasopharynx, oropharynx, and hypopharynx. The soft palate separates the naso- and oropharynx. Radiographically, the boundary between the oro- and hypopharynx is the hyoid bone. The anatomic boundary, not well-visualized on contrast studies, is the pharyngoepiglottic fold overlying the stylopharyngeal muscle.

ESOPHAGUS

The esophagus originates at the cricopharyngeus, the upper esophageal sphincter (UES); courses through the

posterior mediastinum; and terminates after 23 to 25 cm at the lower esophageal sphincter (LES). It has three segments: cervical, thoracic, and abdominal. The wall, 3 mm thick when normally distended, is composed of layers common to the gastrointestinal (GI) tract: mucosa, submucosa, muscularis propria with inner circular and outer longitudinal layers, and adventitia. However, unlike the remainder of the GI tract, there is no serosal layer allowing rapid dissemination of infection and tumor. The mucosa is composed of squamous, not columnar epithelium. The muscularis comprises striated muscle in the upper one-third portion and smooth muscle in the remaining portion. Contrast esophagography visualizes three normal extrinsic compressions: aortic arch, left main stem bronchus, and left atrium.

Identification of normal anatomy at the gastroesophageal junction (GEJ) avoids misdiagnosis of pathology (Fig. 45-1). The phrenic ampulla (or esophageal vestibule) represents normal relaxed LES, and its mild dilation should not be confused with a hiatal hernia. The A ring delineates the superior aspect of the phrenic ampulla, which is a muscular boundary, and the upper component of the LES. The B line, a mucosal boundary that occurs at the squamocolumnar junction (also known as the Z line) and the GEJ, migrates superiorly in the abnormal setting of Barrett metaplasia. The LES (measuring 2–4 cm) lacks mucosal delineation and requires manometric identification. Its normal resting pressure is approximately 15 to 45 mmHg.

A hiatal hernia is diagnosed when the GEJ, identified by the termination of the gastric folds, lies more than 1.5 cm above the diaphragmatic hiatus. The hiatus can be identified as the “pinched” area through which the esoph-

FIG. 45-1 Gastroesophageal junction.

agus or fundus courses. The level of the GEJ is not static; it moves with positioning, respiration, and swallowing.

PATHOLOGY

PHARYNX

DIVERTICULA

Pharyngeal pouches and diverticula occur in areas of anatomic weakness, most commonly at the level of the thyrohyoid membrane, where the superior laryngeal vessels and the accompanying branch of the superior laryngeal nerve perforate the alimentary tract. Less commonly, these protrusions occur from the tonsillar fossa. Pouches are transient, usually bilateral, and almost always asymptomatic. Diverticula occur in the setting of significantly increased pharyngeal pressure, classically in glass blowers, are persistent, and may be symptomatic depending upon their size. Both pharyngeal pouches and diverticula increase with age. A laryngocele is a focal dilatation of the laryngeal ventricle, not the pharynx; therefore, it is not typically identified on esophagography, except as an air-filled sac.

Zenker diverticulum is a posterior, midline diverticulum arising from the hypopharynx at Killian dehiscence (not the cervical esophagus)—an inherent weakness at the junction of the inferior pharyngeal constrictors and oblique and horizontal fibers of the cricopharyngeus. It is associated with both cricopharyngeal achalasia and reflux disease. Patients present with pharyngeal dysphagia, chronic halitosis, and symptoms of aspiration (cough, hoarseness, pneumonia, etc.). Radiographically, Zenker diverticulum appears as a posterior outpouching from the hypopharynx, extending downward to the level of the cervical esophagus where it can cause extrinsic compression. There is an entity called a pseudo-Zenker (or pre-Zenker) diverticulum, which is a small, asymptomatic collection of barium in the same region as a Zenker diverticulum. However, it is significantly smaller, does not extend beyond the normal contour of the posterior pharyngeal wall, and completely disappears after pharyngeal peristalsis discontinues.

Killian-Jamieson diverticulum (or pouch) arises from the Killian-Jamieson space, an area of weakness in the anterolateral cervical esophagus. It is more common than a Zenker diverticulum and is usually asymptomatic. Lateral pharyngeal views best detect a Zenker diverticulum, while frontal views best demonstrate a Killian-Jamieson diverticulum (Table 45-3).

WEBS

Webs in the hypopharynx and cervical esophagus appear as 1 to 2 mm shellflike filling defects. These should

TABLE 45-1 Etiology of Cervical Esophageal Webs

Congenital/idiopathic
Epidermolysis bullosa dystrophica
Benign mucus membrane pemphigoid
Pemphigus vulgaris
GERD
Plummer-Vinson Syndrome

not be confused with the “postcricoid defect”—a region of redundant mucosa along the anterior wall of the hypopharynx at the level of the cricoid cartilage, which at one time was incorrectly thought to represent a venous plexus. A web is likely clinically significant when there is a “jet effect,” proximal ballooning, and proximal retained contrast. It is most commonly congenital/idiopathic and asymptomatic (Table 45-1). Diseases associated with cervical esophageal webs include epidermolysis bullosa dystrophica, benign mucous membrane pemphigoid, pemphigus vulgaris, and reflux disease. Plummer-Vinson (or Paterson-Kelly) syndrome is a cervical esophageal web in the setting of iron deficiency anemia. In some countries, it is considered premalignant for pharyngeal and esophageal carcinoma, although this is not true in the United States.

NEOPLASIA

True benign neoplasms of the pharynx are rare (lipoma, neurofibroma, hamartoma). Retention cysts are the most common benign lesions, but they are not neoplastic. Radiographically, these entities present as smooth, round filling defects, most commonly arising from the valleculae or aryepiglottic folds.

Squamous cell carcinoma, the most common malignant tumor of the pharynx, carries a slightly better prognosis than esophageal cancer. Patients with pharyngeal cancer should have their esophagus screened because of the increased risk of a synchronous or metachronous esophageal cancer. Lymphoma (non-Hodgkin type) accounts for 10% of pharyngeal cancers and usually occurs in the palatine tonsil. Lymphoid hyperplasia of the lingual tonsil must be differentiated from lymphoma. Both present with nodules extending from the tongue base into the vallecula. Lymphomatous nodules tend to be larger, and therefore masslike, and asymmetric.

ESOPHAGUS

NORMAL MOTILITY AND MOTILITY DISORDERS

The swallowing process has three phases: oral, pharyngeal, and esophageal. There are three types of peristalsis in the esophagus: primary, secondary, and tertiary. Primary esophageal peristalsis is initiated by swallowing.

Its initial inhibitory wave, deglutitive inhibition, precedes a continuous wave of contraction that courses through the entire length of the esophagus, cephalad to caudal. LES relaxation quickly follows the UES relaxation. Secondary peristalsis resembles primary in its propagation. It is initiated by distention at the level of a retained bolus and extends downward. Secondary contractions occur only when the initial wave does not clear the esophagus. Tertiary contractions are uncoordinated, nonperistaltic segmental contractions, usually involving the smooth muscle portion of the esophagus, and are always abnormal. Peristaltic evaluation requires horizontal positioning to eliminate effects of gravity. Additionally, single swallows should be observed from UES to LES. Deglutitive inhibition with a second swallow interrupts prior peristalsis.

Achalasia is defined as failure of LES relaxation along with loss of esophageal peristalsis (Table 45-2). The etiology is unknown, but thought to be neurogenic. Barium fluoroscopy demonstrates a dilated esophagus with “bird beak” tapering at the hypertonic LES. The LES intermittently opens, but never to a normal caliber. Primary and secondary peristalsis are absent, although tertiary waves may occur (vigorous achalasia). The LES remains tightly closed, giving a persistent air–fluid level in the upright position. Additionally, the esophagus often contains retained food and saliva. A gastric bubble is usually absent. Longstanding achalasia leads to marked dilatation, referred to as megaesophagus (or sigmoid esophagus when it becomes elongated). It carries an increased risk of esophageal cancer. Chagas disease, caused by destruction of the myenteric plexus after infection with the protozoan *Trypanosoma cruzi*, appears identical to achalasia both radiographically and manometrically. Unlike achalasia, Chagas disease can affect the entire GI tract.

The appearance of the LES helps differentiate achalasia from other dysmotility disorders, including pseudoachalasia and scleroderma. Pseudoachalasia is narrowing of the distal esophagus secondary to carcinoma of the GEJ or gastric cardia. (Often, esophageal or gastric origin of cancer is impossible to determine.) Patients have irregular distal tapering extending into the gastric cardia. Tumor spread occasionally causes smooth

TABLE 45-2 Esophageal Hypomotility

GERD (no tertiary contractions)
Presbyesophagus (tertiary contractions)
Achalasia (bird beak deformity)
Pseudoachalasia (fixed, irregular beaking)
Scleroderma/mixed connective tissue disorders (patulous LES, can be strictured)
Diabetes
Chagas disease (other GI tract abnormalities)

tapering of the LES as seen in achalasia. However, in pseudoachalasia, the LES remains fixed and does not intermittently open.

On the other hand, scleroderma, or progressive systemic sclerosis, presents with a patulous LES and aperistalsis. Severe reflux esophagitis often causes distal stricture that mimics achalasia. Patients may even retain an air–fluid level in the upright position along with a dilated esophagus. However, opening of the LES is absent, and the stricture in scleroderma is fixed. Findings of diffuse interstitial lung disease and asymptomatic esophageal dilatation on cross-sectional imaging strongly suggest the diagnosis. Other collagen vascular diseases present with similar hypomotility: dermatomyositis, polymyositis, systemic lupus erythematosus, and mixed connective tissue disease.

Patients with diffuse esophageal spasm (DES) present with chest pain and dysphagia. Radiographically, severe tertiary contractions give a “corkscrew” appearance. However, there is intermittent normal primary and secondary peristalsis. DES involves the smooth muscle of the distal two-thirds of the esophagus. Radiographically and manometrically, DES and vigorous achalasia appear similar. On CT, DES presents as circumferential thickening of the distal two-thirds of the esophagus and achalasia has a dilated esophagus with a normal wall thickness.

Patients with nutcracker esophagus also present with chest pain and dysphagia. This manometric diagnosis typically has normal radiographic findings with occasional pathologic nonperistaltic contractions. Manometrically, one finds normal peristalsis with distal high-amplitude, prolonged contractions. Some feel that nutcracker esophagus is an early form of DES.

There are many nonspecific dysmotilities. Presbyesophagus occurs in the elderly and radiographically appears as decreased primary and secondary peristalsis with scattered tertiary contractions. Reflux often causes dysmotility with decreased primary and secondary peristalsis that improves with treatment. Unlike presbyesophagus, reflux dysmotility does not have tertiary contractions. Alcoholism and diabetes also cause nonspecific dysmotility similar to presbyesophagus.

CONGENITAL ABNORMALITIES

Although esophageal duplication cysts are rare, they are the second most common duplication of the GI tract after ileal duplications. These cysts occur more commonly in men and are often diagnosed in childhood. These usually occur in the distal right lateral esophagus and do not communicate with the lumen. These cysts are composed of mucosa and muscularis propria and can contain ectopic gastric or pancreatic tissue. In contrast, esophageal retention cysts are acquired (postinflammatory) and are less common. They represent dilated submucosal glands,

TABLE 45-3 Pharyngeal and Esophageal Diverticula

Zenker diverticula	Hypopharynx, pulsion, posterior midline
Killian-Jamieson diverticula	Cervical esophagus, pulsion, anterolateral
Traction	Mid esophagus, granulomatous disease, angular borders
Pulsion	Distal esophagus (epiphrenic), dysmotility or stricture
EIPD	Pseudodiverticula, GERD

occur in the distal esophagus, are usually smaller, and can be multiple.

In the esophagus, ectopic gastric mucosa is most commonly seen in the postcricoid region, at or below the UES. This “inlet patch” is a normally asymptomatic congenital abnormality containing columnar epithelium. It carries the same risk of carcinoma as the stomach. Esophagography demonstrates a flat lesion with a marginal indentation around a raised border, giving an oval ring shadow.

DIVERTICULA

Two types of diverticula, neither of which is congenital, present in the esophagus: traction and pulsion (Table 45-3). Traction diverticula develop in the midthoracic esophagus adjacent to calcified mediastinal lymph nodes. They arise secondary to scarring and retraction from granulomatous disease and tend to be more angular. In contrast, pulsion diverticula are round and occur in the distal esophagus (epiphrenic diverticulum) in the setting of DES, achalasia, or less frequently proximal to a stricture. Zenker diverticula are considered pulsion diverticula.

Esophageal intramural pseudodiverticulosis (EIPD) represents pathologically dilated submucosal mucous glands. It occurs most commonly with gastroesophageal reflux disease (GERD) but is also associated with candidiasis, diabetes, and esophageal cancer. Contrast fluoroscopy detects numerous flask-shaped outpouchings along the course of the esophagus, easily confused with tiny ulcerations seen in infectious esophagitis such as herpes. The pseudodiverticula can appear to “float” outside the lumen of the esophagus when the communicating duct is not filled with barium. Linear intramural tracking between pseudodiverticula arises secondary to acute inflammation and contained rupture with healing and fibrosis, similar to the tracking that occurs in colonic diverticular disease. EIPD is not premalignant or symptomatic.

INFLAMMATION AND INFECTION

Gastroesophageal Reflux Disease (GERD)

GERD is the most common inflammatory condition in the esophagus. Its presentations range from retrosternal burning and dysphagia to asthma, chronic cough, and

hoarseness. Transient inappropriate intermittent relaxation of the LES is the primary pathology in most patients with mild-to-moderate reflux. Those with severe reflux typically have decreased resting LES pressure. The severity of reflux is determined by its frequency, duration of acid contact time with the esophagus, and the acid content of the refluxate. Therefore, patients with scleroderma (without LES pressure and peristalsis to clear acid) and Zollinger-Ellison syndrome have significantly worse esophagitis and stricture.

Double-contrast esophagography findings in reflux esophagitis include granular mucosa (mucosal edema) and linear erosions; severe cases have nodularity, which is difficult to differentiate from candidiasis (Table 45-4). Transient contractions of the muscularis mucosa, feline esophagus, occur in addition to nonspecific dysmotility.

Several types of strictures occur in GERD. Most occur in the distal esophagus, proximal to or at the GEJ. Strictures can be tapered or focal and ringlike. Strictures greater than 20 mm in caliber are usually asymptomatic. Strictures less than 13 mm are almost always symptomatic. Schatzki ring is a focal symptomatic ringlike stricture at the GEJ. Prone positioning facilitates viewing. GERD can also cause longitudinal stricturing thus shortening the esophagus with increasing hiatal hernia. Diagnosis of short esophagus before antireflux surgery is imperative for success because an esophageal lengthening procedure (Collis gastropasty) provides better outcome.

The esophagogastric polyp is not neoplastic; a rugal fold enlarges secondary to chronic inflammation and

granulation from GERD and extends into the distal esophagus. It can appear as a pedunculated polyp, but careful radiographic examination reveals continuity with the rugae in the gastric fundus.

Barrett esophagus occurs secondary to metaplastic esophageal healing in the setting of chronic reflux. It is a premalignant condition occurring in approximately 10% of patients with GERD. Classic findings of Barrett esophagus include a mid-to-high esophageal stricture or ulceration with focal reticular mucosa. However, the reticular pattern is often absent.

The incidence of hiatal hernia increases with aging due to laxity of the phrenoesophageal ligaments anchoring the esophagus to the diaphragmatic hiatus. The hiatal hernia is not the primary cause of GERD (*remember*: abnormal, intermittent relaxation of the LES) but the result of chronic reflux. There are four types of hiatal hernia: Type I, the most common, is a sliding hiatal hernia where the GEJ lies above the level of the diaphragmatic hiatus. Type II is a true paraesophageal hernia, a rare phenomenon where the GEJ retains its normal position below the diaphragmatic hiatus and a portion of the fundus herniates above the diaphragm in a paraesophageal location. Type III hernia combines type I and type II hernia, where the GEJ lies above the hiatus, and there is an associated paraesophageal component. This occurs more commonly than type II hernia. Type IV hernia, the rarest type, presents with a gaping hiatus and intrathoracic stomach with herniation into the chest of other organs, such as colon, omentum, and small bowel. Types II, III, and IV can be large enough to have an intrathoracic stomach, which most commonly rotates in an organoaxial, along the long axis, fashion. Mesoaxial, perpendicular to the long axis, rotation is less common, usually seen in a type II hernia. These gastric rotations are secondary to ligamentous laxity and should not be confused with gastric volvulus, which is an emergency and indicates obstruction with vascular compromise (strangulation).

Esophagitis

Noninfectious: Drug-induced (“pill”) esophagitis (Table 45-4) presents at the level of an extrinsic esophageal compression, most commonly at the aortic arch or left main stem bronchus. Antibiotics (tetracycline and doxycycline) and vitamin C pills most often cause the etiologic contact esophagitis. NSAIDs and aspirin have also been implicated. Radiographically, focal ulcers appear at the level of the aortic arch or left main stem bronchus. There may be focal fold thickening, but the remainder of the esophagus is normal.

Alendronate sodium (Fosamax), a bisphosphonate used to treat osteoporosis and Paget disease, causes a radiologically distinct “pill” esophagitis. It presents as changes of severe GERD with a long segment of distal stricturing and acute ulceration similar to nasogastric

TABLE 45-4 Esophagitis

DISEASE	LOCATION	APPEARANCE
GERD	Distal	Granular mucosa, nodularity, linear erosions, stricture
Pill	Mid (arch or left mainstem bronchus)	Focal erosions
NGT & Alendronate sodium	Distal	Severe, long segment stricture and ulceration; worse than with GERD
Eosinophilic	Proximal & mid	Long segment stricture with multiple rings or diffusely small caliber esophagus; resolves with oral liquid steroids
Radiation	Limited to radiation port	Ulceration (acute), focal stricture (chronic)
<i>Candida</i>	Mid	Linear plaques, ulceration, “shaggy”
<i>Herpes</i>	Diffuse	Multiple small ulcers, rarely large ulcer
CMV & HIV	Mid	Large, solitary or few flat ulcer(s)
TB & Crohn	Diffuse	Severe ulceration and fistula

tube (NGT) esophagitis. Patients must take this medication with plenty of water and remain erect for at least 30 minutes to prevent these complications.

Severe strictures of the esophagus occur in several other conditions. NGT intubation can rapidly cause long strictures of the distal esophagus, secondary to GERD from stenting of the LES by the tube. Caustic esophagitis can present with a long segment stricture, but it is typically more proximal. Lye is the most common etiologic agent and causes severe pharyngeal abnormality with aspiration. Importantly, lye strictures have an increased risk of squamous cell carcinoma.

Eosinophilic esophagitis usually presents in young men with an allergic history, particularly food allergies. In addition to the dysphagia found in most esophagitis, patients present with peripheral eosinophilia. Radiographically, long-segment stricture can appear anywhere in the esophagus. These strictures are unique, with a stacked ring appearance resembling the cartilaginous rings in the trachea. Their length is shorter when they present in the distal esophagus. However in other patients, the only radiographic finding may be a diffusely small caliber esophagus, once thought to be congenital. After satisfactory treatment with swallowed liquid steroids, these strictures typically resolve and the esophagus looks completely normal.

Radiation esophagitis with stricture occurs more focally, predictably within the radiation field. The dose must exceed 5000 rads and is potentiated by Adriamycin. An acute phase of 1 to 4 weeks precedes a chronic phase. The acute phase has mucosal edema and ulceration. The chronic phase demonstrates smooth strictures which can progress for years.

Crohn disease can occur anywhere from the mouth to the anus, including the esophagus. As in the remainder of the GI tract, it can present with aphthous ulcers, strictures, or fistulae. Esophageal involvement is the most uncommon form and does not occur in isolation. Behçet disease, a chronic inflammatory vasculitis characterized by oral and genital ulceration and uveitis, presents with distal esophageal ulceration similar to that found in Crohn disease.

Esophagitis

Infectious: *Candida* is the most common infectious agent in esophagitis. It usually presents in patients who are immunocompromised. However, it also occurs in patients undergoing radiation therapy and even rarely in those with normal immune function. Early *Candida* esophagitis presents with focal mucosal plaques. These plaques are discrete with surrounding normal mucosa and have a similar appearance to glycogenic acanthosis—a benign, degenerative condition seen in older patients in which glycogen accumulates in plaques in the squamous epithelial mucosa. Candidal plaques are linear and less well-defined, whereas

glycogenic acanthotic plaques are round. However, symptomatology provides optimal differentiation between these entities. Glycogenic acanthosis is asymptomatic, whereas candidiasis typically presents with odynophagia. As *Candida* progresses, plaque and pseudomembrane formation increase, and ulceration develops as membranes slough. When barium insinuates around the plaques and pseudomembranes, one visualizes the advanced “shaggy” esophagus (a common finding in AIDS).

Herpes esophagitis, the second most common infectious type, also presents with ulcers, which are small and numerous. As with other infectious esophagitis, patients with herpes esophagitis present with odynophagia. The early stage of vesicle formation does not appear on barium swallow. Once the vesicles rupture, characteristic punctate ulceration suggests the diagnosis. Advanced herpes can mimic candidal plaques and nodularity secondary to reflux esophagitis. In rare occurrences, herpes esophagitis can present with a solitary or a few large ulcers.

Cytomegalovirus (CMV) and human immunodeficiency virus (HIV) esophagitis have radiologically indistinguishable appearances. Typically, one or a few large ulcers occupy the mid esophagus. Endoscopic brush biopsies must evaluate for the Cowdry intranuclear inclusion bodies of CMV. If not present, the patient is treated for HIV esophagitis. The two treatments vary drastically: CMV is treated with antiviral agents, whereas HIV esophagitis is treated with oral steroids.

Tuberculous involvement of the esophagus is typically secondary to spread from regional lymph nodes. There can be ulceration with sinus tracts and fistulous connections to adjacent nodes. The ulceration is deeper than that seen in other infectious esophagitis, and cross-sectional imaging reveals marked mediastinal lymphadenopathy, which may be low in density.

In general, patients with odynophagia should be evaluated with endoscopy, which allows biopsy necessary for therapy. Although barium esophagography can identify these lesions and often suggest an etiology, the diversity of treatments requires microbial confirmation.

NEOPLASIA

Radiographically, one must identify esophageal lesions as mucosal or intramural in origin (Table 45-5). Mucosal lesions tend to form acute angles with the adjacent mucosa; intramural lesions have more obtuse angles and normal overlying mucosa.

Benign Tumors

Benign tumors of the esophagus are rare, representing less than 1% of all esophageal neoplasms. The leiomyoma, an intramural lesion arising from the circular layer of muscularis propria, comprises approximately two-thirds of benign tumors and usually presents distally.

TABLE 45-5 Benign Esophageal Lesions

MUCOSAL	SUBMUCOSAL
Papilloma (most common benign <i>mucosal</i> lesion)	Leiomyoma (most common overall)
Adenoma	Fibrovascular polyp (pedunculated)
Glycogenic acanthosis (degenerative, not neoplastic)	Granular cell tumor
Esophagogastric polyp (inflammatory, not neoplastic)	Duplication cyst (congenital, not neoplastic)

Multiple leiomyomata, a condition referred to leiomyomatosis, is associated with Alport syndrome and visceral leiomyomatosis. Leiomyomata are usually asymptomatic and small. Larger lesions result in dysphagia, ulceration, and bleeding. On esophagography, they present as intramural lesions with normal, smooth overlying mucosa. On CT, they are round, well-circumscribed intramural masses with soft tissue density. Malignant degeneration is exceedingly rare, obviating the need for surgical enucleation. The diffuse proliferation of smooth muscle in leiomyomatosis does not present as a discrete mass but as a long tapered stricture. When occurring at the GEJ, it can mimic achalasia.

Fibrovascular polyps contain both fibrovascular and adipose elements and include tumors previously referred to as fibromas, fibrolipomas, myxofibromas, lipomas, and angioliipomas. They arise in the cervical esophagus but are attached by a long pedicle such that the head of the polyp typically lies in the midthoracic esophagus. Classically, patients present with a mass that has been regurgitated into the oral cavity. More commonly, they have dysphagia. The CT and MR imaging appearances are variable, depending upon the adipose and vascular content of the specific tumor.

Granular cell tumors arise from Schwann cells and radiographically appear like leiomyomata but can be multiple. They are resected only if symptomatic.

Esophageal lipomatosis is fatty deposition in the esophageal wall in patients with a long history of steroid use. Cross-sectional imaging demonstrates a “double-ring” appearance of the esophageal wall from the low-density intramural fat.

The most common benign mucosal lesion of the esophagus is a papilloma, which is composed of hyperplastic squamous epithelium. Multiple lesions are called papillomatosis. Adenomas can occur in the esophagus in the setting of Barrett esophagus but are rare. Like colonic adenomas, these premalignant lesions require resection.

Malignant Tumors

There are two major esophageal mucosal malignancies: squamous cell carcinoma and adenocarcinoma (Table 45-6). Recently, the incidence of adenocarcinoma has

TABLE 45-6 Malignant Esophageal Tumors

Adenocarcinoma (most common in western countries)
Squamous cell carcinoma (most common worldwide)
Spindle cell (carcinosarcoma)
Leiomyosarcoma (GIST rare, unlike remainder of GI tract)
Lymphoma (usually Hodgkin, non-Hodgkin in AIDS)
Small cell
Melanoma (primary tumor more common than metastatic tumor)
Metastases (lung, breast, stomach)

surpassed squamous cell carcinoma in western countries and has the fastest growing incidence rate of all cancers in the United States, and this increase is attributed to GERD. Worldwide, squamous cell carcinoma remains more common.

Esophageal adenocarcinoma occurs with GERD and usually arises in Barrett esophagus. This disease typically presents in middle-aged and older white male patients. Prior research reported that the risk of developing adenocarcinoma in the setting of Barrett esophagus was 125 times greater than the general population; however, more recent studies have suggested a lesser risk.

Etiologic factors for squamous cell carcinoma include alcohol and tobacco use, which have a synergistic effect, environmental toxins including asbestos, petroleum contaminants, thermal injury, and diet. There is also an increased incidence secondary to radiation injury, lye ingestion, achalasia, tylosis, celiac disease, and Plummer-Vinson syndrome. Squamous cell carcinoma most commonly presents in older African American male patients. Unlike adenocarcinoma, it has a predilection for the proximal and mid esophagus.

Several terms describe the pathologic and radiographic findings in esophageal cancer. *Early* esophageal cancer is limited to the mucosa or submucosa and does not involve lymph nodes, whereas *superficial* cancers are also mucosal or submucosal but have positive nodes. *Small* cancers are less than 3.5 cm regardless of nodal status. Advanced carcinomas are described as infiltrating (stricture), ulcerating (flat with ulcer), or varicoid (submucosal spread resembling varices).

Both types of esophageal cancer carry a poor prognosis because of the advanced stage at diagnosis and also because the lack of serosa results in rapid local extension. Both cancers also spread via lymphatic and hematogenous metastases. Lymph node involvement occurs locally in the mediastinum with extension to neck lymphatics for proximal and mid tumors. Spread to the celiac nodal group commonly occurs with more distal cancers. Hematogenous metastases include lung and liver, which have a significantly worse prognosis than with abdominal lymphadenopathy alone. The extent of primary tumor invasion and nodal and distant metastases

determine stage, treatment, and prognosis. Cross-sectional imaging is somewhat handicapped in the staging of esophageal cancer, particularly in nodal staging. The incorporation of PET and endoscopic ultrasound (EUS) with fine needle aspiration (FNA) has improved staging. Except for the absence of serosa in the esophagus, the entire gut has a similar sonographic appearance. Proceeding from the lumen outward, there is a hypoechoic mucosa, hyperechoic submucosa, hypoechoic muscularis propria, and hyperechoic serosa and adventitia.

Leiomyosarcoma is relatively rare in the esophagus but has a better prognosis than other esophageal cancer. It typically presents with a large ulcerating mass. Leiomyosarcomas are more common than gastrointestinal stromal tumors in the esophagus, although the latter are more common in the remainder of the GI tract. Leiomyosarcoma arises *de novo* and not from malignant degeneration of a leiomyoma.

The esophagus is the most uncommon site in the GI tract for primary lymphoma. It is most commonly Hodgkin pathology in young men. Non-Hodgkin type occurs in AIDS. Both types of lymphoma can extend to the esophagus from adjacent mediastinal adenopathy. The radiographic appearance of lymphoma varies, but it commonly presents as a bulky, nonobstructing mass.

Spindle cell carcinoma, previously referred to as carcinosarcoma, is a rare cancer of the esophagus and carries a very poor prognosis. It presents as a large nonobstructing mass. Small cell carcinoma of the esophagus is even rarer with a worse prognosis. On imaging, it appears similar to squamous cell and adenocarcinoma. Unlike the latter, it typically presents with significant mediastinal lymphadenopathy.

Gastric adenocarcinoma is the most common metastatic lesion in the esophagus, secondary to direct extension from cardia tumors. These patients can present with an appearance of pseudoachalasia, but as mentioned before, the thickening of the LES is usually asymmetric and irregular. Breast carcinoma and melanoma demonstrate hematogenous spread to the esophagus, although esophageal melanoma is more commonly seen as a primary tumor than a metastatic lesion. Local extension to the esophagus occurs in lung cancer. Kaposi sarcoma also involves the esophagus.

MISCELLANEOUS CONDITIONS

There are two types of esophageal varices: uphill and downhill. The more common uphill varices, seen in the setting of cirrhosis with portal hypertension (hepatofugal flow, away from the liver), occur secondary to reversal of flow in the coronary vein. The distal esophageal plexus dilates and drains systemically into the azygous vein. Downhill varices occur when there is an obstruction of the superior vena cava. These varices

drain into the azygous system if the obstruction is superior to the azygous vein or into the portal venous system via the coronary vein if the obstruction occludes the azygous vein. Uphill varices occur in the lower esophagus, while downhill varices occur in the upper portion with a patent azygous system or throughout the entire esophagus if the azygous vein is obstructed. On esophagography, varices present as serpentine structures that change in appearance during fluoroscopy. Classically, the collapsed view of the esophagus reveals enlargement of these structures, while the distended air-contrast view effaces the dilated veins. On CT and MR, varices are well seen with contrast enhancement as tubular structures in the paraesophageal region. Differential diagnosis includes varicoid carcinoma, which typically has a fixed appearance during fluoroscopy.

Most commonly, esophageal perforation is secondary to iatrogenic trauma sustained during endoscopy. These types of tears usually occur in the posterior hypopharynx or cervical esophagus. Distal esophageal tears can occur during vomiting (known as Boerhaave syndrome). Perforations in the distal esophagus tend to result in left-sided pleural effusions, while right-sided effusions usually occur in the setting of mid esophageal perforations. Classically, esophageal perforation is a surgical emergency. Cross-sectional imaging evaluates for paraesophageal fluid and mediastinitis, directing clinical care; many perforations are amenable to conservative treatment. Mallory-Weiss tears are limited to the mucosa and have normal radiographic findings in most cases.

Esophageal intramural hematoma occurs secondary to bleeding within the wall. It presents spontaneously in anticoagulation or after a mucosal tear in trauma or sclerotherapy. Cross-sectional imaging reveals an oval intramural mass that does not enhance. On CT, there is increased density, consistent with hemorrhage. Depending on the stage of evolution, MR has a variable appearance.

Esophagogastrectomy with gastric pull-up is commonly performed for primary esophageal cancer. Two surgical approaches are commonly employed. The Ivor-Lewis procedure includes a laparotomy for gastric mobilization and right thoracotomy for esophageal resection and gastric pull-up. The esophagogastric anastomosis lies in the upper thorax or neck. The pylorus sits at the level of the esophageal hiatus, and a pyloromyotomy or pyloroplasty can help gastric emptying, which is poor as a result of denervation of the mobilized stomach. A transhiatal esophagectomy is performed less often. Postoperative recovery is more rapid as there is no thoracotomy, but only a laparotomy and left neck incision. The incidence of postoperative leaks is higher, but

overall morbidity is lower because leaks tend to occur in the neck instead of the more devastating mediastinal location. In this approach, the esophagus is resected transhiatally through the abdominal incision, and the anastomosis is more cranial, near the thoracic inlet. In the immediate postoperative period, contrast fluoroscopy evaluates leak and obstruction. Abscess appears on contrast-enhanced CT. For more remote patients, CT helps identify recurrent and metastatic disease.

Fundoplication is a common treatment for reflux disease. A Nissen fundoplication is a complete 360-degree wrap, while the Toupet fundoplication is a partial 270-degree posterior wrap. For the wrap to be clinically successful, it must encircle the LES for a length of 2 to 3 cm and be situated below the diaphragmatic hiatus. Collis gastroplasty, an esophageal lengthening technique where a segment of neoesophagus is made distal to the GEJ from the gastric cardia, is performed in the setting of short esophagus. Preoperative failure to identify a short esophagus is the most common cause of wrap failure. Contrast fluoroscopy excludes leak postoperatively. CT readily assesses abscess formation.

QUESTIONS AND ANSWERS

- Where is the origin of Zenker diverticula?
 - Vallecula
 - Piriform sinus
 - Hypopharynx
 - Cervical esophagus

ANSWER: C. Zenker diverticulum arises from the inferior hypopharynx, just superior to the cricopharyngeus from an anatomic area of weakness called Killian dehiscence. This occurs at the junction of the oblique and horizontal fibers of the cricopharyngeus. (Not to be confused with Killian-Jamieson diverticulum, which arises from the Killian-Jamieson space.)

- What is the typical finding of HIV esophagitis on esophagography?
 - Shaggy mucosa
 - Giant, shallow ulcer
 - Multiple punctate ulcers
 - Intramural pseudodiverticulosis

ANSWER: B. HIV esophagitis is radiographically indistinguishable from CMV esophagitis. Both present with large, shallow ulcers, which are often solitary. Shaggy mucosa is classically seen in *Candida* esophagitis, although it can be seen in severe *herpes* esophagitis. Intramural pseudodiverticulosis is most commonly associated with reflux disease. However, it was originally described in esophageal candidiasis.

- Regarding secondary esophageal peristalsis, which of the following is true?
 - Occurs directly preceding the primary peristalsis
 - Usually abnormal
 - Begins at the upper esophageal sphincter and spreads distally
 - Initiated by local distension

ANSWER: D. Primary peristalsis begins at the upper esophageal sphincter and spreads in a systematic fashion distally. Secondary peristalsis does not occur with every swallow and is initiated locally by a retained portion of the bolus. It is not abnormal.

- Which of the following is an anterolateral cervical diverticulum?
 - Killian-Jamieson diverticulum
 - Zenker diverticulum
 - Traction diverticulum
 - Congenital diverticulum

ANSWER: A. Killian-Jamieson diverticulum occurs in the cervical esophagus, arising from a region of anatomic weakness, the Killian-Jamieson space. By comparison, a Zenker diverticulum arises in the posterior midline of the hypopharynx above the

cricopharyngeus from another anatomic region of weakness, Killian dehiscence.

5. Regarding esophagitis in an immunocompromised patient, what is the most likely etiology for small punctate ulcers?
 - A. Candida
 - B. CMV
 - C. Herpes
 - D. HIV

ANSWER: C. *Herpes* typically presents with small punctate ulcers, although it rarely can have a giant ulcer. CMV and HIV esophagitis more typically have solitary, large flat ulcers, and candidiasis presents with multiple plaques, often progressing to a shaggy esophagus in an immunocompromised patient. EIPD can mimic small ulcers when seen en face.

6. Which of the following is most helpful in differentiating achalasia from pseudoachalasia?
 - A. Degree of dilatation of the esophagus
 - B. Absent primary peristalsis
 - C. Presence of reflux
 - D. Appearance of the LES

ANSWER: D. Achalasia presents with smooth tapering of the lower esophageal sphincter (“bird beak appearance”). Pseudoachalasia presents with narrowing, but it is more typically irregular with nodular folds extending from the gastric cardia. Additionally, the sphincter is fixed in pseudoachalasia, whereas it may intermittently open during true achalasia.

7. Regarding esophageal varices, which of the following is true?
 - A. On esophagography, carcinoma is included in the differential diagnosis
 - B. Downhill varices are more common
 - C. Systemic drainage for downhill varices is via the brachiocephalic vein
 - D. Air-contrast view of the esophagus is the best method for radiographic diagnosis

ANSWER: A. Varicoid carcinoma is included in the differential diagnosis of varices on esophagography. However, varicoid carcinoma is fixed, while varices tend to fill and empty with peristalsis. Uphill varices are more common than downhill varices, and both can empty into the azygous system; and downhill varices can also empty into the portal system through the coronary vein.

8. Regarding esophageal leiomyosarcoma, which of the following is true?
 - A. Worse prognosis than adenocarcinoma
 - B. Presents with an annular mass

- C. More common in the esophagus than GIST
- D. Arises from malignant degeneration of leiomyoma

ANSWER: C. Leiomyosarcomas have a better prognosis than other esophageal cancers and typically present as a large ulcerating mass. GISTs of the esophagus are very rare, unlike those in the remainder of the GI tract. Leiomyosarcomas typically arise de novo and not from malignant degeneration of their benign counterparts. They are usually solitary.

9. What is the most common benign mucosal tumor of the esophagus?
 - A. Papilloma
 - B. Adenoma
 - C. Fibrovascular polyp
 - D. Leiomyoma

ANSWER: A. Papilloma is the most common benign esophageal mucosal tumor. Adenomas are rare and occur in the setting of Barrett esophagus. Fibrovascular polyps, although intraluminal, are actually submucosal lesions. Leiomyomas are the most common tumor of the esophagus but are not mucosal; they are intramural.

10. Regarding the cricopharyngeus, which of the following is true?
 - A. Also considered upper sphincter
 - B. Not normally identified on barium studies
 - C. Located above a Zenker diverticulum
 - D. Not affected by GERD

ANSWER: A. The cricopharyngeus is the UES and is implicated in the formation of the more superior Zenker diverticulum. It is normally identified on contrast studies, but is more prominent (fails to relax) with cricopharyngeal achalasia. Its dysfunction can also be seen in GERD.

46 STOMACH

Sanjiv K. Bajaj and Cheri L. Canon

NORMAL ANATOMY

The stomach begins at the distal end of the esophagus and extends to the pyloric sphincter. It varies considerably in size. Its unfixed intraperitoneal length contains five parts: cardia, fundus, body, antrum, and the pyloric sphincter. The cardia is a histologically defined region where the esophagus enters the stomach. The fundus projects as a dome immediately adjacent to the cardia

and superior to it, related to the left hemidiaphragm, and extending to the fifth intercostal space in most people. Radiologically, the gastric bubble appears in this region in upright radiographs. The largest portion of the stomach, the body, extends to the incisura angularis on the lesser curvature. The antrum occupies the region between the incisura angularis and the pyloric sphincter. This 1-cm-long distal sphincter composed of circular muscle controls the rate of gastric emptying. The lesser curvature comprises the superior outline of the stomach, and the greater curvature appears as the inferior outline. In the nondistended stomach, one sees rugae, the longitudinal mucosal folds. The anterior gastric wall abuts the diaphragm, the left lobe of the liver, and the anterior abdominal wall. The posterior aspect forms the major portion of the anterior wall of the omental bursa, also referred to as lesser sac, and relates to the pancreas.

Double-contrast examination of the stomach can reveal the *areae gastricae*, the normal polygonal mucosal pattern, representing tiny mucosal crevices. It can be seen throughout the stomach, but most commonly seen in the body and antrum. Increase in the size of the *areae gastricae* can be seen with normal aging or with *Helicobacter pylori* infection. *Areae gastricae* are notably absent in atrophic gastritis.

Lymph from the superior two-thirds of the stomach drains to the gastric nodes, and the superior body and fundus additionally feed the pancreaticosplenic nodes. The right two-thirds and inferior third of the stomach empty into the pyloric nodes, while lymph from the left third of the greater curvature enters the pancreaticoduodenal nodes.

PATHOLOGY

CONGENITAL ABNORMALITIES

Congenital hypertrophic pyloric stenosis arises from hypertrophy of the pylorus's circular muscles with extension to the antrum, creating a tight sphincter and gastric outlet obstruction. The disorder usually presents in the first 2 to 6 weeks of life with nonbilious, projectile vomiting. Physical examination demonstrates an "olive" in the epigastric region representing the hypertrophied pylorus. Ultrasound is the preferred diagnostic imaging modality. It reveals a thickened muscular wall (>4 mm), a pyloric canal greater than 14-mm long, hyperactive gastric peristaltic waves, and absent gastric emptying. Upper GI examination also demonstrates the condition, showing the string sign (contrast in a narrowed, elongated pylorus), Kirklin sign (shouldering by the pylorus in the duodenal bulb), crowded mucosa with multiple ridges, and pyloric channel elongation. This diagnosis

necessitates surgery, most often a pyloromyotomy. Pyloric stenosis can present in the adult population when the process is less severe. Intermittent nausea and vomiting may be the only symptoms, and upper GI examination will demonstrate the abnormality.

Ectopic pancreatic tissue (pancreatic rest) presents most commonly in the stomach after a fragment of the pancreas implants in the gastric wall during embryologic development. Functional tissue can produce local ulceration and subsequent bleeding as enzymes erode the mucosal surface. It appears radiographically as a small filling defect, sometimes with central depression representing a duct, in the distal stomach along the greater curvature. Rarely, this tissue undergoes neoplastic change into malignant pancreatic adenocarcinoma. Lesions causing obstruction or other symptoms usually yield to endoscopic removal.

Gastric diverticula are rare compared to their colonic counterparts. Most of them are true diverticula in that all layers of bowel wall protrude, and they most commonly present in the posterior fundus. Upper GI examination demonstrates a barium filled defect with normal mucosal pattern usually found near the gastroesophageal junction (GEJ). It changes in size and with peristalsis. On CT, these can be confused with a low density left adrenal adenoma, but the presence of an air bubble or gastric contrast excludes this diagnosis. A gastric intramural diverticulum is a pseudodiverticulum occurring along the greater curvature of the antrum secondary to a small invagination of mucosa between the muscular layers. It can mimic an ulcer, although it is not fixed, changes configuration with peristalsis, and has no adjacent fold thickening.

Situs describes the heart and visceral anatomic relationships to the midline. Situs solitus is the normal position. Situs inversus is a rare disorder characterized by abnormal location of the body's organs in mirror image to situs solitus. It occurs more commonly with dextrocardia, in which case it carries a 5% incidence of congenital heart disease, or levocardia, which is rare and almost always complicated by congenital heart disease. Thoracic imaging demonstrates inversion of the lungs, cardiac silhouette, and great vessels. The stomach likewise presents on the right side, with the liver occupying the left. Many patients have Kartagener syndrome, characterized by situs inversus and immotile cilia resulting in pulmonary disease. Some patients present with incomplete situs inversus, known as situs ambiguous. Situs ambiguous can occur with polysplenia, bilateral left sidedness; and asplenia, bilateral right sidedness. Almost all individuals with asplenia have congenital heart disease that is often more severe than in other situs anomalies.

INFLAMMATION AND INFECTION

Peptic ulcer disease most commonly arises secondary to *H. pylori* infection and nonsteroidal anti-inflammatory drugs (NSAIDs). Other contributors include alcohol, autoimmune diseases, sepsis, and severe physiologic compromise. Radiologically, one finds thickened rugal folds, erosions, and frank ulceration. Most gastric ulcers are benign erosions into the submucosa. The majority occur along the lesser curve or posterior wall of the gastric body or antrum. Ulcers in older patients tend to be more proximal, particularly along the lesser curve. Contrast studies reveal a smooth oval rimmed defect through the muscularis mucosa with a swollen lip and gastric folds radiating to its border. These lesions are fixed and, unlike diverticula, do not change with peristalsis. Ulcer extension into the submucosa creates Hampton line, a thin line of barium near the ulcer's most superficial edge. Multiple gastric ulcers or association with enlarged rugae suggests Zollinger-Ellison syndrome (gastrinoma). Ulcers can lead to adhesions, allowing a fistulous tract between the antrum and duodenum that mimics a second pylorus ("double barrel pylorus"). Webs occasionally appear in the gastric antrum, often in association with ulcers. They present as a thin band proximal to the pylorus, sometimes giving the appearance of a second duodenal bulb.

Approximately 95% of gastric ulcers are benign. Double-contrast radiography can demonstrate features suggesting malignancy (Table 46-1). Benign ulcer craters can have various shapes including circular, ovoid, or even linear, but the borders are smooth. Malignant ulcer crater borders are more irregular. Size and multiplicity have no implication regarding malignancy.

Atrophic gastritis is classified based upon etiology. Type A is autoimmune related with mucosal atrophy in the body and fundus. Decreased synthesis of intrinsic factor causes B₁₂ malabsorption and pernicious anemia, and these patients are at an increased risk for gastric adenocarcinoma. Direct mucosal injury to the antrum by alcohol, bile acids, or other caustic agents results in type B atrophic gastritis. Atrophic gastritis on barium examination presents with a smooth tubular stomach that is nondistensible. Rugal folds and areae gastricae are absent.

Chronic alkaline gastritis and esophagitis can result from postsurgical bile reflux through an incompetent pyloric sphincter or anastomotic connection (Billroth I, II). Mucosal protecting agents or further surgery with a Roux limb revision provide amelioration.

There are several etiologies of granulomatous gastritis. Crohn disease can involve any portion of the GI tract, and like elsewhere, presents in the stomach with aphthous ulcers, strictures, and fistulae. The normal pyloric channel becomes patulous, resembling a primary gastroduodenostomy (Billroth I). Tuberculosis, sarcoid, and syphilis sometimes present as gastritis. One generally finds marked architectural distortion with deep ulceration and fistulae, commonly with extraintestinal manifestations such as lymphadenopathy. Gastric tuberculosis is very uncommon and presents with pyloric fibrosis and gastric outlet obstruction. It can be difficult to differentiate from cancer. The stomach is the most common portion of the gut affected by sarcoid, but most patients are asymptomatic. Eosinophilic gastritis presents with eosinophilic infiltrate and gastric outlet obstruction and is associated with food allergy. Steroids resolve the primary process.

CMV also causes a diffuse gastritis with thick gastric folds, especially in immunocompromised patients. There is commonly small bowel and colonic involvement with skip lesions. Ulceration can be superficial but is more often very deep.

Emphysematous gastritis is most commonly secondary to caustic ingestion and alcohol abuse. It can also occur in the setting of trauma and gastric ischemia/infarction, and with superimposed phlegmonous (bacterial) gastritis, especially with *Staphylococcus aureus*, *Escherichia coli*, streptococci, and clostridia. It can lead to stenosis, gastric rupture, and sinus tracts and progresses rapidly to death. Radiologic studies demonstrate gastric pneumatosis with marked fold thickening. CT demonstrates thickening as very low density. This must be distinguished from benign gastric emphysema often seen in the setting of COPD, endoscopy, and violent retching. Fold thickening is notably absent in benign emphysema.

NEOPLASIA

BENIGN TUMORS

Hyperplastic polyps are composed of gastric epithelium and glandular tissue with inflammatory infiltrate. They are usually small (<2 cm) and sessile with a well-demarcated smooth border. They are the most common polyp found in the stomach, can arise anywhere (most commonly in fundus or body), and have no malignant potential, as they are not neoplastic.

TABLE 46-1 Benign Versus Malignant Gastric Ulcer

BENIGN	MALIGNANT
Crater projects beyond lumen	Crater projects within lumen (Carman meniscus sign)
Folds symmetric, smooth, extend to crater edge	Folds asymmetric, nodular, and end proximal to edge
Less common in fundus	More common in fundus
Adjacent areae gastricae may be enlarged	Areae gastricae obliterated

Commonly found in the antrum, gastric adenomas contain cells with nuclear atypia and intestinal metaplasia. They present a true malignant potential, like their colonic counterparts. However, most gastric cancers arise *de novo* and not from adenomas. In the stomach, unlike the colon, adenomas are significantly less common than hyperplastic polyps, except in patients with polyposis syndromes. They are generally broad based and large (>2 cm) with an irregular or lobulated border.

Lipomas are submucosal lesions that are radiographically indistinguishable from other mesenchymal neoplasms. They are benign but can ulcerate and are typically solitary. Identification of fat content on CT is diagnostic. Neurogenic tumors occasionally present in the stomach. Neurofibromas are most often benign, solitary lesions (multiple in neurofibromatosis) that sometimes undergo malignant transformation. Barium studies demonstrate well-demarcated small submucosal masses with occasional central ulceration. CT additionally shows their extragastric portion. Schwannomas, the most common neurogenic tumors in the stomach, present as benign, well-demarcated submucosal tumors covered by normal mucosa with ulceration. Endoscopic biopsy provides a diagnosis of these slow growing neoplasms. Although glomus tumors are rare in the stomach, they are the most common gastric vascular tumor. They are usually solitary, arising in the antrum. Lymphangiomas are even rarer and develop as aberrant lymphatic tissue not possessing normal lymphatic drainage. Unlike glomus tumors, they do not demonstrate arterial enhancement on imaging studies and appear cystic, mimicking duplication cysts.

MALIGNANT TUMORS

Adenocarcinoma (“gastric cancer”) comprises the majority of cases of malignant gastric neoplasms (Table 46-2). It has declined in incidence and mortality in the United States, although it remains the fourth most common cancer worldwide with a death rate exceeded only by lung cancer. It is now the third most common GI malignancy. There are several predisposing conditions associated with gastric adenocarcinoma: *H. pylori* infection, adenomas, polyposis syndromes, pernicious anemia, atrophic gastritis, and partial gastrectomy (Billroth II > I). In fact, *H. pylori* is now classified as a type I carcinogen by the World Health Organization. Diets high in nitrates, nitroso compounds, red meat, and alcohol are also risk factors for development of gastric cancer. It is more common in Asia and twice more common in men than women. Patients present with GI bleeding, weight loss, and often pain. Physical examination sometimes demonstrates a swollen left supraclavicular lymph

node (Virchow node) in metastatic cases. This cancer infiltrates early and commonly ulcerates, with size correlated to prognosis and aggressiveness. Barium studies show an ulcerated filling defect with irregular borders and deranged mucosa. Malignant ulcers more commonly appear on the greater curvature or fundus and differ from their benign counterparts in their irregular borders that do not penetrate into the submucosa, associated irregular mass, and fused surrounding folds. Barium studies can elicit the Carman meniscus sign, the convexity of the crater oriented toward the lumen. This type of ulcer commonly comes to attention with failure to respond to pharmacologic therapy. Diagnosis is confirmed by endoscopic biopsy. CT can demonstrate the primary gastric tumor, metastases (hepatic and peritoneal most commonly), and lymphadenopathy. Mucinous calcification may be present. Metastatic involvement of the ovaries, the Krukenberg tumor, can also be detected by CT.

Linitis plastica is most commonly seen with primary gastric adenocarcinoma, but lymphoma and metastases can produce this morphology (Table 46-3). Breast cancer is the most common metastasis giving rise to this appearance, but local extension from pancreatic and colon carcinoma is also implicated. Infiltrative carcinomas can spread through the wall of the stomach. Upper GI examination demonstrates fixed luminal narrowing and fold effacement, usually with a primary mass. CT shows the thick wall and effacement of rugae. Prognosis is especially poor for this form of malignancy.

The stomach is the most common GI site for primary extranodal lymphoma, almost always non-Hodgkin type. The small bowel is the next most common site, with the esophagus being the least common location in the GI

tract. Multiple risk factors for the development of gastric lymphoma have been implicated (Table 46-4). They often present as filling defects on upper GI studies but can evidence gastric wall thickening (>1 cm) or large, lobulated masses. The wall thickening in lymphoma tends to be greater than that in adenocarcinoma, and it is more homogeneous. Preservation of the perigastric fat plane is more often seen in lymphoma than in gastric adenocarcinoma. Both tend to have nodal disease, but adenopathy in lymphoma often extends below the renal veins. As mentioned above, lymphoma can also present as linitis plastica. Lymphoma is more likely than adenocarcinoma to spread across the pylorus into the duodenum; however, since adenocarcinoma is significantly more common overall, spread from the stomach to the duodenum is usually in the setting of adenocarcinoma.

Most mucosal-associated lymphoid tissue lymphomas (MALTomas or MALT lymphomas) arise in the stomach. B cells comprise these normally indolent non-Hodgkin neoplasms commonly associated with *H. pylori* infection. Upper GI series can demonstrate wall thickening, discrete nodules, or a mass. CT and MRI facilitate determination of tumor extent and extranodal disease, but they cannot assess malignant potential. Endoscopic biopsy allows histologic determination of grade and invasiveness. Treatment of underlying infection with antibiotics and proton pump inhibitors induces remission in the overwhelming majority of cases. Chemotherapy may be necessary for less common nonresponders.

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the GI tract and arise from the pacemaker cell (interstitial cell of Cajal) in the smooth muscle. They are distinctly different from smooth muscle tumors (leiomyoma and leiomyosarcoma), as evidenced by their positive immunohistochemical staining to KIT, a tyrosine kinase growth factor. The stomach is the most common organ involved, but they can arise anywhere in the GI tract, even primarily in the mesentery or omentum. They are considered intramural in origin yet appear as a large exophytic mass. They have a predilection for ulceration, and thus usually present at an earlier stage with bleeding. The majority are benign, with the few malignant ones having a high mitotic index, central necrosis, larger mass, local

invasion, or metastases. Radiographically, it is impossible to differential benign from malignant tumor, but larger lesions have a greater risk of malignancy. Upper GI studies detect filling defects or ulceration. Most intraluminal GISTs present at around 6 cm in diameter while extraluminal ones often grow to 12 cm or more before discovery. CT usually discovers these small, round, or larger lobulated masses. They heterogeneously enhance with intravenous contrast and occasionally calcify.

The stomach is the most common gastrointestinal site for leiomyosarcomas. These lesions frequently come to clinical attention at a large size and with visceral metastases, commonly as incidental findings or after bleeding into the lumen or peritoneum. Barium findings vary from large ulcerated intraluminal mass to extrinsic compression from an extragastric mass. CT shows a heterogeneous mass containing enhancing solid portions alternating with multiple areas of hemorrhage and necrosis. Carney triad involves this neoplasm, pulmonary hamartomas or nodules, and extragastric paraganglioma.

Carcinoid tumors arise from the enterochromaffin cells of Kulchitzky, and there are three classes of gastric carcinoid tumors, all relatively uncommon. Type I, the most common type, develops in the setting of autoimmune-related chronic atrophic gastritis and less commonly pernicious anemia. These tumors are generally benign, arise in the fundus, and can be multiple. Type II tumors are the least common and develop in the setting of Zollinger-Ellison syndrome in patients with multiple endocrine neoplasia type I. Lymph node metastasis is common, but hepatic metastasis with carcinoid syndrome is rare. Type III tumors are sporadic and are large solitary masses. Hepatic metastases can result in carcinoid syndrome, and prognosis is poor.

Gastric small cell carcinoma carries the aggressive characteristics and poor prognosis of its pulmonary counterpart. It presents radiographically as a poorly enhancing large exophytic mass, frequently with metastases at the time of diagnosis.

Kaposi sarcoma of the stomach presents with bleeding and multiple submucosal masses with a bull's eye appearance. Skin lesions are always present. The infiltrating form is rare.

The stomach is a common site for tumor metastases, with melanoma, breast, and lung being frequent offenders. Studies commonly show nodules, either solitary or multiple. Melanoma usually has multiple umbilicated lesions, while breast cancer often causes linitis plastica morphology. Pancreatic cancer sometimes directly spreads to the stomach, creating a filling defect. Additionally, pancreatic pseudocysts can compress the stomach, and surgeons will sometimes drain them into the stomach via direct fistula, cystogastrostomy.

MISCELLANEOUS CONDITIONS

Portal venous hypertension, most commonly from hepatic cirrhosis, results in increased portal pressure leading to increased flow and dilatation of the coronary vein and subsequently the esophageal venous plexus. The systemic shunt is via the azygous vein. Most gastric varices arise from hepatic cirrhosis secondary to alcohol abuse or viral hepatitis. However, one sees isolated gastric varices in splenic vein thrombosis, which can occur in the setting of pancreatitis or pancreatic carcinoma. Short gastric venous dilation creates masslike fundal varices in both situations. In gastric varices secondary to portal venous hypertension, upper GI series demonstrates tortuous and scalloped-appearing filling defects in the esophagus and stomach representing dilated veins. In splenomegaly, one often sees the outline of the enlarged vasculature on the greater curvature of the stomach. Additionally, CT may demonstrate retroperitoneal varices. Portal hypertensive gastropathy has non-specific findings of gastric wall edema that may have transient perfusion defects on arterial imaging.

The stomach contains fixed ends and a mobile length. Significant twisting causes torsion and vascular compromise. Acute onset results in nausea, vomiting, and severe epigastric pain. Organoaxial volvulus involves rotation along the long axis, a line from the pylorus to the GEJ. The greater curve is displaced superior and to the right of the lesser curve. It is the more common pattern and rarely results in significant permanent morbidity. Mesenteroaxial volvulus occurs along the short axis extending between the greater and lesser curves, resulting in superior displacement of the antrum relative to the fundus, with switching of the pylorus and GEJ. It is less common than organoaxial rotation but represents a more serious threat for ischemia. Radiographic studies demonstrate absent filling of part of the stomach with an acute angle transition point or show two portions of the stomach, both with contrast and with air.

Menetrier disease presents with hypoproteinemia and hypochlorhydria secondary to parietal cell loss. Rugae are typically markedly hypertrophied with antral sparing. Patients complain of pain, nausea, vomiting, and weight loss. Many develop a protein losing enteropathy, and endoscopy with biopsy is indicated for diagnosis. After resolution, one carefully monitors patients secondary to the increased risk of gastric adenocarcinoma.

Bezoars represent agglomerated undigested material. They present in the stomach with a mottled appearance and ulceration and sometimes can obstruct the flow of food. The most common types are trichobezoars (hair), which form in the setting of Rapunzel syndrome, and phytobezoars (vegetable matter). Upper GI study shows an unattached filling defect or mass floating in a pool of contrast. Obstruction also clues to the diagnosis.

Amyloidosis results in extracellular deposition of amorphous fibrillar protein and can affect any portion of the gut. It usually occurs in the setting of chronic infection, inflammation, or hemodialysis. Radiographically, it has a protean appearance with fold thickening, mucosal nodules, or even mass.

In the past, antrectomy with vagotomy was commonly performed for the treatment of ulcer disease. There were several methods developed for reconnecting the stomach to the small bowel. Billroth I, a primary gastroduodenostomy, was abandoned because of severe alkaline gastritis and esophagitis. Billroth II (Fig. 46-1), an end-to-side gastrojejunostomy, provided some improvement from alkaline gastritis, although not complete. Additionally, these patients were at an increased risk for gastric carcinoma, greater than the risk seen with Billroth I patients. Patients who have undergone Billroth II procedure may present with afferent obstruction leading to dilation and pain secondary to retained secretions, afferent limb syndrome. They complain of early satiety and pain relieved by bilious vomiting. Distention with rupture is the most severe complication, requiring strict monitoring. Upper GI examination often does not fill the fluid-filled, dilated afferent loop. CT demonstrates biliary obstruction and a fluid-filled

FIG. 46-2 Partial gastrectomy with Roux-en-Y gastrojejunostomy.

afferent limb. Patients with Billroth II anastomosis can also experience severe dumping syndrome.

A Roux-en-y configuration (Fig. 46-2) was developed to address the issues of alkaline reflux, and this is

FIG. 46-3 Roux-en-Y gastric bypass.

FIG. 46-4 Pylorus—preserving pancreaticoduodenectomy (Whipple procedure) with duodenojejunostomy, hepaticojejunostomy, and pancreaticojejunostomy.

the surgery commonly used today. Because of improved medical therapy, surgeries are rarely performed for peptic ulcer disease. Roux limb reconstruction is commonly used gastric bypass (Fig. 46-3) surgery. Laparoscopic gastric bypass is now the most commonly performed bariatric surgery procedure, and these patients are at an increased risk of internal hernia. In the past, congenital paraduodenal hernias were the most common internal hernia. Now, postsurgical mesenteric hernias are most common. Gastric bypass patients are at increased risk because of the loss of their mesenteric fat during weight loss, making obstruction more likely.

The pancreaticoduodenectomy, Whipple procedure (Fig. 46-4), involves resection of the head or all of the pancreas, the adjacent duodenum, and the distal common bile duct. Reconstruction is via Roux-en-y or loop hepaticojejunostomy and pancreaticojejunostomy. There is also a gastrojejunostomy or a duodenojejunostomy if it is pylorus preserving.

QUESTIONS AND ANSWERS

- Which of the following features is most commonly seen with a malignant gastric ulcer?
 - Large crater
 - Ovoid-shaped crater
 - Truncated rugal folds ending before the crater
 - Enlargement of the areae gastricae
 - Multiplicity

ANSWER: C. Malignant ulcers typically present with truncated, nodular folds that are somewhat asymmetric. The crater is irregular, but size or shape does not help differentiate benign from malignant. The crater typically does not extend beyond the gastric lumen, as it does in benign ulcer disease. They are typically solitary.

- In which of the following conditions does one see isolated gastric varices?
 - Portal hypertension
 - Budd-Chiari
 - Pancreatic carcinoma
 - Post-TIPS
 - Splenic infarction

ANSWER: C. Splenic vein thrombosis results in isolated gastric varices. This commonly occurs in the setting of pancreatic cancer or pancreatitis. Portal venous hypertension typically presents with esophageal, gastric, splenic, and other mesenteric varices. Budd-Chiari presents with absent hepatic veins and absent or occluded inferior vena cava.

- Which of the following is associated with enlarged areae gastricae?
 - Peptic ulcer disease
 - Young age
 - Gastric adenocarcinoma
 - Atrophic gastritis
 - Linitus plastica

ANSWER: A. Areae gastricae are commonly enlarged in the elderly and in patients with *H. pylori* infection. Focal enlargement can be seen adjacent to ulcers. Areae gastricae are usually obliterated with gastric carcinoma and completely absent in the setting of atrophic gastritis and linitus plastica.

- What is the most common etiology for multiple small gastric polyps?
 - Hyperplastic polyps
 - Metastatic melanoma
 - Primary adenocarcinoma
 - Lymphoma
 - Adenomas

ANSWER: A. Statistically, multiple small polyps almost always represent benign hyperplasia, as gastric adenomas are much less common. Melanoma typically presents with multiple target mucosal lesions. Adenocarcinoma is usually a primary mucosal mass. Lymphoma can have various appearances, including marked fold nodularity, but focal polyps are atypical.

- What is the most common GI tract location for primary extranodal lymphoma?
 - Esophagus
 - Stomach
 - Small bowel
 - Colon
 - Rectum

ANSWER: B. The most common site for extranodal lymphoma is the stomach, usually non-Hodgkin type.

- Concerning situs anomalies, which of the following presents with more serious congenital heart disease?
 - Situs solitus
 - Situs inversus with dextrocardia
 - Situs inversus with levocardia
 - Situs ambiguous with polysplenia
 - Situs ambiguous with asplenia

ANSWER: E. Congenital heart disease occurs in almost all individuals with a splenia and is more severe than any of the situs anomalies.

7. Concerning gastric carcinoid tumors, which of the following is true?
- A. Associated with Zollinger-Ellison syndrome
 - B. Associated with multiple endocrine neoplasia type II
 - C. Metastasize early
 - D. Typically present with carcinoid syndrome
 - E. Increased risk for adenocarcinoma

ANSWER: A. Carcinoid tumors are associated with multiple endocrine neoplasia type I and Zollinger-Ellison syndrome. They seldom metastasize or produce carcinoid syndrome. There is no increased risk for carcinoma.

8. Concerning gastric leiomyosarcomas, what is the most common cross-sectional imaging appearance?
- A. Ulcerating mucosal plaque
 - B. Mural necrotic mass
 - C. Mucosal nodule
 - D. Multiple target lesions
 - E. Linitus plastica

ANSWER: B. Gastric leiomyosarcoma is typically a large, necrotic mural tumor. It is often exophytic but has ulceration. Radiographically, it cannot be distinguished from GIST. Multiple target lesions are classically seen with metastatic melanoma.

9. Concerning gastric diverticula, which of the following is true?
- A. Most commonly occur in the greater curvature
 - B. Can mimic an adrenal adenoma
 - C. Intramural diverticula are true diverticula.
 - D. Intramural diverticula typically occur in the fundus.
 - E. Cannot be distinguished from an ulcer

ANSWER: B. Gastric diverticula most commonly arise from the posterior fundus and can mimic a left adrenal adenoma on cross-sectional imaging. Intramural pseudodiverticula represent an invagination of the mucosa through the muscular layer along the greater curve in the antrum. They change shape during peristalsis and do not have adjacent fold thickening, differentiating them from ulcers.

10. What is the most common type of internal hernia?
- A. Left paraduodenal
 - B. Right paraduodenal
 - C. Congenital

- D. Transomental
- E. Transmesenteric

ANSWER: E. Postoperative, transmesenteric hernias are now the most common internal hernia.

47 SMALL BOWEL

Sanjiv K. Bajaj and Cheri L. Canon

NORMAL ANATOMY

The small intestine extends from the pylorus to the ileocecal valve in three parts: duodenum, jejunum, and ileum. Its smaller caliber and valvulae conniventes (fine circumferential folds also referred to as plicae circularis) distinguish it from the large bowel. The duodenum is the short initial small bowel segment that forms a C loop encompassing the head of the pancreas. Its segment proximal to the major papilla derives from the foregut, while the remainder arises from the midgut. It lies retroperitoneally except in its first 2 cm (the duodenal cap or bulb of the superior segment). The first (superior) segment of the duodenum courses transversely for 5 cm at the L1 vertebral level. It lies immediately anterior to the portal vein, bile duct, and inferior vena cava. As the first portion turns posterior and downward, a flexural pseudotumor is created on double-contrast duodenography representing the redundant mucosa along the inner angle of the superior flexure. The second (descending) segment of the duodenum encircles the head of the pancreas in its 7 cm inferior course. The main pancreatic duct empties here at the major papilla (ampulla of Vater). The third (inferior) part crosses the L3 vertebral body anterior to the inferior vena cava and aorta during its 6 cm. The superior mesenteric artery's (SMA) passage anterior to it creates a possible sight of compression. The fourth (ascending) part courses superiorly for 5 cm and joins the jejunum at the duodenojejunal junction, an angulated area suspended by the ligament of Treitz. The celiac trunk sends the gastroduodenal artery's superior pancreaticoduodenal branch to the foregut derivatives, while the SMA feeds the midgut portion via the inferior pancreaticoduodenal artery. The veins follow the arteries. The lymphatic channels drain via the pyloric lymph nodes to the superior mesenteric group.

The jejunum and ileum comprise 40% and 60% of the small bowel's 7 m length, respectively. The jejunum primarily occupies the left upper quadrant while the

ileum resides in the right lower quadrant. One distinguishes the two based on appearance; the jejunum grossly possesses deeper color, thicker wall, greater vascularity involving long vasa rectae without complicated arcades, less mesenteric fat, fewer Peyer patches, and many valvulae conniventes. Imaging demonstrates its feathery mucosal pattern. Both segments derive their blood supply from terminal branches of the SMA and drain into the superior mesenteric vein. Lymphatics drain to the superior mesenteric group except in the terminal ileum, where they drain to the ileocolic area.

PATHOLOGY

CONGENITAL ABNORMALITIES

Meckel diverticulum, the most common congenital anomaly of the GI tract, derives from persistence of a portion of the embryonic yolk stalk (the omphalomesenteric duct). It presents as a 2-in long outpouching containing all three bowel layers (including a muscular layer), 2 ft proximal to the ileocecal junction in 2% of people. Half of these lesions contain heterotopic (gastric or pancreatic) mucosa. Bleeding, discomfort, and rare perforation initiate investigation. The invaginated diverticulum serves as a leading edge, causing intussusception in children. Radiographs may demonstrate a focally dilated sentinel loop. Fluoroscopy finds contrast filling the diverticulum with other manifestations of disease, such as intussusception or an ulcer. Meckel diverticulitis is readily identified on CT. Technetium-99 concentrates in gastric mucosa, and nuclear medicine scanning localizes the abnormality when these cells are present.

Small polygonal filling defects can be seen in the duodenal bulb with contrast fluoroscopy. These represent heterotopic gastric mucosa with surrounding normal duodenal mucosa. It is important not to confuse this incidental (clinically insignificant) finding with real pathology. Prolapsing gastric mucosa can protrude into the duodenal bulb, creating a transient, mass-like filling defect. This too is an incidental finding. Like in the stomach, ectopic pancreatic rests can also occur in the duodenal bulb.

Atresia, failure of canalization of the bowel lumen, most commonly occurs in the duodenum secondary to intrauterine insults during bowel development in the first trimester of life. This disorder presents neonatally with obstruction causing bilious emesis and absent stool. Patients have a history of fetal polyhydramnios that is due to inability to swallow amniotic fluid. Many have Down syndrome or associated cardiac or urinary defects. Conventional radiographs demonstrate the “double bubble” sign, representing dilated stomach and duodenum separated by the pylorus. Treatment involves

support with nasogastric tube decompression and (intravenous) fluids followed by surgery to excise the atretic segment and reanastomose the bowel.

Annular pancreas presents similarly to atresia, but its emesis is nonbilious because of more proximal obstruction. The pancreas begins as two separate lobes flanking the duodenum, the ventral and dorsal enlarge. Normally, the left lobe circles the bowel and its remnant atrophies. In this disorder, a ring of pancreatic tissue remains surrounding the descending segment of the duodenum. CT demonstrates the pancreatic ring. Treatment involves supportive stabilization followed by surgery.

Diverticula arise from points of mural weakness in the intestinal tract. Duodenal diverticula commonly appear on upper GI series and CT but are mostly asymptomatic. Duodenal diverticula are usually acquired, containing only mucosa and submucosa, and extend toward the pancreas from the second or third portions of the duodenum; they occasionally cause ampullary obstruction. Because of their close proximity to the pancreas, they can be confused with a cystic pancreatic neoplasm, and care should be taken to identify gas or oral contrast in these collections. Intraluminal duodenal diverticula, usually diagnosed during infancy, give the classic wind-sock deformity on barium studies and CT. Small bowel diverticula other than Meckel diverticula rarely occur; they can cause bleeding, diverticulitis, and perforation. Malabsorption secondary to bacterial overgrowth is seen only in extensive diverticulosis. Jejunal diverticula are larger and more common than their ileal counterparts.

Duodenal and small bowel duplication is rare. Like other locations in the gut, these cystic lesions seldom communicate with the lumen.

Congenital intestinal lymphangiectasia is a rare congenital condition diagnosed in the young. Dilated small bowel lymphatics result in a protein-losing enteropathy. CT findings are nonspecific, with diffuse mural edema.

OBSTRUCTION

Mechanical obstruction presents with waxing and waning crampy abdominal pain, high-pitched bowel sounds, vomiting, constipation, and distention. Patients most commonly have adhesions secondary to surgery, but tumor, hernia, nonsteroidal anti-inflammatory drug (NSAID)-related stricture, foreign body, and intussusception can also cause obstruction (Table 47-1). Upright radiographs show dilated proximal bowel with multiple air-fluid levels and collapsed distal bowel, and supine films depict stacked bowel loops. In cases involving dilated, fluid-filled small bowel and a paucity of small bowel gas, air-fluid levels may be replaced by the appearance of string of pearls representing air bubbles

TABLE 47-1 Small Bowel Obstruction

Adhesions (most common)

Tumor
Intussusception (usually lead point in setting of obstruction)
IBD
NSAID stricture
Foreign body
Gallstone ileus (uncommon)

trapped between the valvulae conniventes. CT shows the transition point by demonstrating dilated proximal loops and collapsed distal ones. It commonly delineates the cause of obstruction as well. Therapy involves bowel rest with nasogastric tube decompression and fluid and electrolyte stabilization. Surgery treats cases failing conservative therapy.

There are several hernia types. External hernias include inguinal hernias, more common in men, femoral hernias, more common in women, and abdominal wall protrusions. Richter hernia is a partial hernia involving only one side of the bowel wall, and Spigelian hernia is a protrusion through the linea semilunaris at the lateral margin of the rectus abdominis, midway between the umbilicus and symphysis pubis. Obturator hernias are rare.

Intussusception involves telescoping of bowel loops, with the proximal intussusceptum telescoping into the distal intussusciptens. It occurs most commonly in children, although adults with mass lesions are also at risk, and presents with intermittent crampy abdominal pain secondary to obstruction. Vomiting and bloody stools with currant jelly appearance classically accompany these symptoms. Radiographs occasionally demonstrate a paucity of gas in the right abdomen. Barium enema examination shows a coiled spring appearance representing contrast between the concentric bowel loops. CT and ultrasound depict telescoped loops as the target sign with mesenteric vessels surrounded by mesenteric fat. Longitudinal section demonstrates a sandwich appearance. On the other hand, small jejunal intussusceptions are typically fleeting and of no consequence in the adult. They commonly occur around intestinal tubes or surgical anastomoses. Multiple, recurrent intussusceptions suggest sprue. However, ileocolonic or colocolonic intussusceptions in the adult are almost always associated with a pathologic lead point, typically adenocarcinoma but also possibly lipomas.

Complicated obstruction can occur in the setting of appendicitis, Crohn disease, diverticulitis, and ischemia to name a few. CT is the imaging modality choice for diagnosis. Strangulation of small bowel most commonly occurs in the setting of closed loop obstruction and is

secondary to the interruption of blood flow. Adhesion and internal hernia are usually implicated in closed loop obstruction. CT remains the modality of choice, although this entity can be difficult to diagnose on this modality. Internal hernias are now most commonly seen in the postoperative patient with transmesenteric obstruction. CT findings included small bowel loops clustered along the anterior abdominal wall, often in a “c” or “u” shape. There may be a swirled appearance to the mesentery.

Volvulus involves torsion of an intestinal segment about its mesenteric stalk. Midgut volvulus most commonly occurs in children congenitally afflicted with malrotation of the intestine. It classically presents in the first month of life with proximal obstruction, bilious emesis, and abdominal pain. Interruption of the vascular supply to the affected area often results in ischemia progressing to infarction, and mortality approaches 20%. Radiographs evidence partial duodenal obstruction or a gasless abdomen. Barium studies show a corkscrew duodenum, an abnormal location of an intestinal segment, and a duodenojejunal junction displaced inferiorly to the right. Emergent surgery minimizes morbidity and mortality.

Adynamic ileus represents a paralytic lack of coordinated intestinal movement with resultant functional obstruction. It presents with abdominal distention and decreased bowel sounds in the setting of surgery, electrolyte imbalance, inflammation, and systemic illness. Radiographs show diffuse small and large bowel dilatation, typically with air-fluid levels on the same level and air in the rectum. It can appear radiographically indistinguishable from obstruction and sometimes evidence a transition point. Real-time fluoroscopy shows absent bowel peristalsis. Treatment involves bowel rest and nasogastric tube decompression. Focal inflammatory lesions such as pancreatitis, appendicitis, diverticulitis, and abscess can cause adynamic ileus in adjacent single loops of small bowel, referred to as sentinel ileus.

VASCULAR ABNORMALITIES

Mesenteric ischemia arises from inadequate blood flow to the intestines, usually secondary to thromboembolic disease or in the setting of closed loop obstruction. The acute form generally follows systemic hypoperfusion or thromboembolic phenomena and presents with pain out of proportion to physical findings. Radiographs are usually unremarkable or demonstrate an ileus. CT demonstrates the ileus, which is often focal mural edema, and sometimes directly visualizes the embolus. Focal enhancement defect in the small bowel wall indicates ischemia or even infarction. Prompt diagnosis improves mortality.

TABLE 47-2 Small Bowel Pneumatosis

MALIGNANT	BENIGN
Ischemia/infarction	Surgery/trauma
Typhlitis	Endoscopy
Obstruction	Enteric tube
	COPD
	Immunosuppression (AIDS, chemotherapy, transplant, steroid use)

Pneumatosis and portal venous gas in the setting of bowel ischemia are ominous. However, there are many other causes of benign pneumatosis (Table 47-2), and clinical correlation with serum lactic acid level is the most important predictor of morbidity and mortality.

Chronic mesenteric ischemia arises from atherosclerosis in two of the three major intestinal vessels (celiac trunk, SMA, IMA) and presents as weight loss with nonspecific intestinal pain shortly after meals. Radiographs may be unremarkable. CT and MR angiography can demonstrate the diseased visceral vessels. Vascular surgery ameliorates symptoms.

Shock bowel results from severe ischemic injury to the intestine after systemic hypoperfusion. It usually arises in cases with significant acute blood loss, as in traumatic bleeding. Hyperenhancement of the mucosa coupled with low density of mural edema give the bowel a cerebriform appearance on CT. Other findings of shock, collapsed inferior vena cava, hyperenhancing adrenal glands, splenic hypoperfusion are typically present. Shock bowel is reversible and seldom progresses to infarction.

Vasculitis results in focal transient ischemia. Like in other causes of ischemia, CT demonstrates mural edema, but it is focal and may be multisegmental. The latter helps distinguish it from thromboembolic ischemia. Systemic lupus erythematosus and polyarteritis nodosa can affect any portion of the GI tract.

Radiation enteritis is another form of vasculitis and causes bowel wall edema in the setting of radiation, leading to smooth fold thickening on imaging. It usually resolves spontaneously. The chronic form presents after history of radiation with nausea, vomiting, diarrhea, and abdominal pain. Microangiopathy causes chronic ischemia resulting in fibrosis, stricture formation, and fistulae in addition to mural edema and fold effacement.

INFLAMMATION AND INFECTION

Duodenitis can be seen in multiple conditions: peptic ulcer disease, Zollinger-Ellison syndrome, uremia in the setting of hemodialysis, Crohn disease, and infection. Findings are nonspecific and include mural edema. Ure-

mic duodenitis tends to present with worse, more nodular fold thickening.

Small intestinal ulceration most commonly occurs in the proximal duodenum secondary to *Helicobacter pylori* infection; smoking and chronic NSAID and steroid consumption confer increased risk. This lesion presents with occult bleeding and epigastric pain improved by meals. It sometimes progresses to perforation into the peritoneum or pancreas. Barium studies show pooled contrast as a discrete radioopaque lesion. Conventional radiographs and CT find complications such as free air and abscess. Treatment involves cessation of the offending agent and triple therapy when applicable with bismuth salt, proton pump inhibitor, and antibiotic active against *H. pylori*.

Multiple ulcers or ulceration in distal duodenum raise suspicion for etiologies such as Zollinger-Ellison syndrome, characterized by gastric acid hypersecretion, secondary to a gastrinoma. The disease presents sporadically or as part of multiple endocrine neoplasia syndromes with ulceration, GI bleed, diarrhea, and abdominal pain. Fluoroscopy demonstrates the ulceration, and conventional radiographs evaluate for perforation. Nuclear medicine studies for somatostatin receptors visualize the etiologic neoplasm, with CT finding larger tumors. Serum gastrin diagnoses the abnormality. Amelioration comes with proton pump inhibitors and H₂ receptor antagonists, and cure comes with surgical resection or total gastrectomy.

Crohn disease involves transmural inflammation with ulceration. It manifests most commonly in the distal ileum but can appear anywhere in the GI tract. It presents bimodally in young and middle-aged patients as colicky lower abdominal pain, diarrhea, obstruction, fever, weight loss, peripheral rash, and arthritis. Fistulae, adhesions, and strictures are common late sequelae. Barium studies demonstrate classic skip lesions with long-strictured segments and deep ulceration in addition to fold thickening and solitary ulcers. CT finds mural edema, mesenteric inflammation, abscesses, and other late manifestations and detects malignancy. Fibrofatty proliferation, secondary to the protective creeping fat, is well seen on CT. Congestion of the mesenteric vasa recta, the “comb” sign, suggests active disease, although there continues to be somewhat poor correlation with radiologic findings and clinical presentation. Colonoscopy allows biopsy of cobblestoned mucosa when it can be visualized. Treatment involves sulfasalazine and vitamin replacement in addition to immunosuppression using steroids, TNF receptor antibodies, methotrexate, and other agents. Surgery treats complications but is largely ineffective in ameliorating the primary process, as the disease tends to recur. Cancer, most commonly adenocarcinoma, occurs at increased rates decades after diagnosis.

Celiac disease (sprue) results from an intestinal hypersensitivity reaction to gluten, a protein found in many grains. It presents with malabsorptive fatty diarrhea, weight loss, bloating, and iron-deficiency anemia. It sometimes regresses after appearance in childhood and reappears later in life. Barium studies demonstrate pooling or flocculation of contrast material in the dilated bowel lumen secondary to secreted fluid, the moulage sign. Folds are decreased in the jejunum and increased in the ileum (jejunitization of the ileum), causing the areas to appear similar. As the process progresses, there may be reversal of the fold pattern. The duodenum may have a bubbly or frankly shaggy appearance. There may be multiple transient intussusceptions. Dermatitis herpetiformis, lymphadenopathy, and hyposplenism are associated with sprue. Antibody tests suggest the disorder, but diagnosis requires small bowel biopsy demonstrating villous atrophy with infiltrating inflammatory cells and crypt hyperplasia. Treatment involves avoidance of gluten. Small bowel adenocarcinoma and lymphoma, esophageal cancer, and melanoma risks are increased. Hypogammaglobulinemia mimics sprue. The lymphoid hyperplasia in this setting results in nodular filling defects along small bowel folds.

Graft-versus-host disease is most common in the setting of bone marrow transplantation and results when the transplanted cells reject the host. It can affect any portion of the gut, most commonly the small bowel. Imaging reveals nonspecific mural thickening with a tubular appearance of the small bowel, nicely depicted on small bowel series.

Infectious enteritides rarely benefit from radiographic imaging. They present with fold thickening, mural edema, and ulceration. Findings are generally nonspecific. *Giardia lamblia* and *Strongyloides stercoralis* involve the duodenum and proximal small bowel, while *Mycobacterium tuberculosis* and *Yersinia enterocolitica* involve the terminal ileum and cecum, mimicking Crohn disease. CMV produces skip lesions with deep ulceration, typically in immunocompromised patients.

Whipple disease is a systemic infectious disorder that is due to a gram-positive bacillus causing watery diarrhea, lymphadenopathy, splenomegaly, arthralgias, and CNS and cardiac pathology. Barium studies demonstrate intestinal fold thickening with small nodules and with flocculation of contrast. CT reveals low density, bulky lymphadenopathy. Diagnosis requires biopsy with PAS stain. A year-long course of ampicillin and tetracycline provides an effective cure.

NEOPLASIA

BENIGN TUMORS

Brunner gland hyperplasia occurs in the setting of an immunologic disorder, such as hypogammaglobuline-

mia, and presents with multiple small, round filling defects in the duodenal bulb. These should not be confused with heterotopic gastric mucosa.

Both hyperplastic and adenomatous polyps are seen in the duodenum. Villous tumors have a predilection for the duodenum, usually near the ampulla, and can be seen in the setting of familial adenomatous polyposis syndrome (FAPS).

Gastrointestinal stromal tumors (GISTs), arising from mesenchymal cells, are the most common benign tumor of the small bowel. These distinctly differ from leiomyoma and leiomyosarcoma and are diagnosed by staining for cKIT. They are rarely malignant, vary greatly in size, and can be either intraluminal or extraluminal. Malignancy is based on histology and metastasis. Tumors mostly spread via local extension, and they commonly recur after resection. Distant spread often involves the liver and peritoneum. Their predisposition to necrosis leads to hemorrhage and perforation, which are common presenting signs in addition to obstruction and abdominal pain. Fluoroscopic and CT studies demonstrate appearance similar to GISTs in the remainder of the GI tract: large, heterogeneous, necrotic tumors.

Other benign tumors of the small bowel include adenomas, lipomas, leiomyomas, and hemangiomas. Hamartomas arise most commonly in Peutz-Jeghers syndrome. Neurofibromas are single except in patients with neurofibromatosis type I, von Recklinghausen disease. Lesions are smooth and well demarcated without extension and rarely hemorrhage. Most patients are asymptomatic, although bleeding, obstruction, and intussusception occur in a minority.

MALIGNANT TUMORS

Adenocarcinoma is the most common duodenal malignancy, but occurs rarely in the remainder of the small bowel. It is more common in the distal duodenum. It usually presents with obstruction and can be annular or polypoid. Malignant small intestinal tumors occur less frequently than in other bowel areas and often present in settings such as Crohn disease and ulcerative colitis. Tumor syndromes such as FAPS and hereditary nonpolyposis colon cancer syndrome (HNPCC) also predispose to these lesions.

Carcinoid tumors, the most prevalent primary small bowel neoplasms, generally arise in the distal ileum from enterochromaffin cells. They are usually malignant when in the small bowel. Most of these tumors are slow growing, asymptomatic neoplasms producing substances including serotonin. Liver metastases lead to carcinoid syndrome, characterized by flushing, diarrhea, bronchoconstriction, and right-sided cardiac valvular disease. Barium studies may demonstrate the primary lesion as a rounded intraluminal filling defect.

Arterial phase CT imaging allows better delineation because of its hypervascular nature. Nodal metastases to the mesentery appear as large stellate calcified masses with adjacent desmoplastic reaction and small bowel thickening secondary to secreted vasoactive amines and lymphatic obstruction. CT allows evaluation of extraluminal masses and metastases. However, the primary tumor is often never identified. The differential diagnosis includes sclerosing mesenteritis, treated lymphoma, and lymphadenopathy secondary to *M. tuberculosis*.

Intestinal lymphoma presents with fevers, diarrhea, and abdominal pain, often with lymphadenopathy and hepatosplenomegaly on physical examination. It generally occurs in the distal ileum and appendix, usually non-Hodgkin type (B cells more common). Burkitt lymphoma arises intestinally in children secondary to Epstein-Barr virus infection and follows an aggressive course. Small bowel follow-through demonstrates fold thickening, diffuse nodular masses, luminal narrowing from intrinsic or extrinsic lesions, filling defects, and ulceration. CT reveals retroperitoneal lymphadenopathy, sometimes with intestinal lymphadenopathy, and can visualize the mass. The pathognomonic finding of aneurysmal dilatation is due to internal ulceration and sloughing of the mucosa. Unlike adenocarcinoma, lymphoma does not usually obstruct. Treatment involves resection with radiotherapy.

Leiomyosarcomas are also seen in the small bowel but less commonly than GISTs. They appear similar to leiomyosarcomas and GISTs in the remainder of the gut.

Metastases to the small bowel arise from nearly any source (Table 47-3), most commonly lung carcinoma and melanoma through hematogenous spread or gastric, pancreatic, and colon cancer through local spread or peritoneal implants. Ovarian and breast cancer can also cause peritoneal carcinomatosis with serosal implants. They are often multiple and appear as filling defects or extraluminal compression along the antimesenteric border. CT demonstrates the lesions and sometimes elucidates the primary.

MISCELLANEOUS CONDITIONS

SMA syndrome is obstruction of the third portion of the duodenum by the SMA as the duodenum crosses midline. It is typically seen in patients after rapid weight loss because of loss of mesenteric fat, decreasing the angle between the aorta and SMA.

Amyloidosis can occur anywhere throughout the GI tract and has a protean appearance. It classically presents with smooth fold thickening throughout the small bowel.

Traumatic injury to the small bowel is best evaluated with CT. The duodenum is particularly susceptible to traumatic compression against the vertebral bodies and may present with intramural hematoma, perforation, or transection. Small bowel hematomas can also occur in the setting of over-anticoagulation and in Henoch-Schönlein purpura. On CT, there is circumferential thickening, which is often high density on noncontrast imaging. Obstruction may occur.

Angioedema occurs secondary to increased capillary permeability and can involve any mucosal surface. It can occur with the use of angiotensin-converting enzyme (ACE) inhibitors. In this case, onset is usually within a week of initiation of medication, but can also be more remote and resolve within 2 days of discontinuation. CT shows nonspecific mural edema which may be focal or multisegmental. It also has been reported secondary to intravenous iodinated contrast.

Scleroderma (progressive systemic sclerosis) is vasculitis that results in fibrosis. Scleroderma results in small bowel dilatation and decreased peristalsis without fold thickening. Fibrosis of the inner circular muscular layer results in shortening of the bowel, a stack-of-coins appearance. Wide-mouth sacculations along the mesenteric border may be present.

Mastocytosis is a mast cell proliferation that presents with multiple small bowel nodules, numerous sclerotic bone lesions, and organomegaly. Waldenström macroglobulinemia also presents with innumerable sand-like small bowel nodules.

Evaluation of the small bowel lumen and fold pattern (Table 47-4) in conjunction with the clinical presentation is helpful in determining the diagnosis. There is significant overlap in the imaging appearance of small bowel disease, so differential diagnoses may be lengthy. Clinical data are imperative.

In general, CT is the imaging modality of choice for the evaluation of the postoperative small bowel. Exceptions include contrast fluoroscopy in the immediate postoperative period to evaluate for leak. Many patients with ulcerative colitis and FAPS undergo prophylactic total proctocolectomy to prevent colon carcinoma. Ileal pouch-anal anastomosis (j-pouch) provides a continent reservoir for these patients, thus eliminating the need for a permanent

ostomy. A j-shaped pouch is created from ileum and anastomosed to the dentate line. After 6 to 8 weeks, patients typically undergo a water-soluble “enema” (pouchogram) to evaluate for leak and obstruction before reversal of the diverting ileostomy. It is imperative that a digital rectal examination is *not* performed and a small rectal tube (red rubber catheter or soft pediatric enema tube) is used to prevent disruption of the anal anastomosis. Leak most commonly occurs from this distal anastomosis along the inner surface of the external anal sphincter. Leak can also occur at the stump or pouch anastomosis.

QUESTIONS AND ANSWERS

- Which of the following is the most common congenital abnormality of the GI tract?
 - Pancreatic rest
 - Duodenal pseudotumor
 - Ectopic gastric mucosa
 - Meckel diverticulum
 - Atresia

ANSWER: D. Meckel diverticulum is the most common GI tract anomaly.

- Which of the following is a true small bowel diverticulum?
 - Meckel diverticulum
 - Duodenal diverticulum
 - Jejunal diverticulum
 - Ileal diverticulum
 - Scleroderma sacculations

ANSWER: A. All of the other diverticula are acquired. Diverticula of the duodenum and small bowel typically do not include the muscular layer of the GI tract.

- Which of the following is the most common cause of small bowel obstruction?
 - NSAID stricture
 - Adhesions
 - Tumor
 - Intussusception
 - Hernia

ANSWER: B. More than 80% of small bowel obstructions are the result of adhesive disease. All other responses can result in small bowel obstruction, although significantly less frequently.

- Which of the following types of hernia involves only one side of the bowel wall?
 - Spigelian
 - Obturator
 - Richter

- Internal
- External

ANSWER: C. Richter hernia is a partial hernia involving only one side of the bowel wall. It can involve colon or small bowel. Spigelian hernia is a herniation through the linea semilunaris along the lateral margin of the rectus abdominus muscle, halfway between the umbilicus and synthesis pubis. Obturator hernias occur through the obturator canal and are extremely rare.

- Which of the following is *not* a cause of complicated small bowel obstruction?
 - Appendicitis
 - Crohn disease
 - Scleroderma
 - Diverticulitis
 - Strangulation

ANSWER: C. Scleroderma can present as pseudoobstruction with dilatation of small bowel and slow transit time. However, there is no frank mechanical obstruction.

- Which of the following is a form of vasculitis?
 - Scleroderma
 - Lymphangiectasia
 - Crohn disease
 - Mastocytosis
 - Whipple disease

ANSWER: A. Scleroderma is the only one that represents a true vasculitis.

- Which of the following is the most common benign tumor of the small bowel?
 - Lipoma
 - Adenoma
 - GISTs
 - Leiomyoma
 - Neurofibroma

ANSWER: C. GISTs are the most common benign tumor of the small bowel. They are rarely malignant.

- Which of the following is the most common malignant tumor of the duodenum?
 - Adenocarcinoma
 - GISTs
 - Lymphoma
 - Carcinoid
 - Small cell

ANSWER: A. Adenocarcinoma is the most common malignancy of the duodenum, but is fairly rare in the remainder of the GI tract.

9. Which of the following is the most common malignant tumor of the small bowel?
- A. Adenocarcinoma
 - B. GISTs
 - C. Lymphoma
 - D. Carcinoid
 - E. Small cell

ANSWER: D. Carcinoid is the most common small bowel neoplasm, typically arises in the distal ileum, and is usually malignant.

10. Which of the following causes nodular fold thickening?
- A. Cirrhosis
 - B. Sprue
 - C. Amyloid
 - D. Radiation enteritis
 - E. Hemorrhage

ANSWER: C. Amyloidosis has a protean in appearance. Classically, it presents with smooth fold thickening, but can also have nodularity or even a focal mass. All other responses demonstrate smooth fold thickening.

48 COLON AND RECTUM

Sanjiv K. Bajaj and Cheri L. Canon

COLON AND RECTUM

NORMAL ANATOMY

The colon begins at the cecum and extends to the anus. It differs from the small intestine in appearance and function. The wall of the colon is less than 4 mm in thickness when normally distended; it contains the four layers seen in the remainder of the gut: mucosa, submucosa, muscularis propria, and serosa. The teniae coli, three thickened bands of the incomplete outer longitudinal muscularis propria, gird it longitudinally from the base of the appendix to the rectosigmoid junction. They fuse in the rectum. The taeniae's restriction of large intestinal length creates the saccular haustra. The colonic caliber greatly exceeds that of the small intestine. While the small intestine largely functions in resorption of nutrients, the large intestine resorbs fluid. In the past, diffuse fatty infiltration of the colonic wall was thought to be secondary to inflammatory bowel disease (IBD). We now know that this can be seen in normal patients, and IBD should only be considered if there are other find-

ings such as wall thickening, stranding changes in the mesentery, abscess, or fistula.

The first colonic division, the ascending colon, rises retroperitoneally from the level of the ileocecal valve to the right lobe of the liver. It is slightly narrower than the cecum and is covered by peritoneum anteriorly and laterally, with the right paracolic gutter at its lateral aspect. The cecum is the portion extending inferiorly from the level of the ileocecal valve. The transverse colon lies intraperitoneally; it begins its horizontal course at the termination of the ascending colon, the hepatic flexure, and extends to the splenic flexure. The descending colon immediately turns caudally at this juncture, taking a retroperitoneal course with the left paracolic gutter abutting it laterally. The S-shaped sigmoid colon follows from the iliac fossa to the third sacral ligament, where it joins the rectum. It has a long mesentery that contributes to its mobility.

The rectum continues inferiorly where the sigmoid terminates at the S3 vertebral level. It transforms to the anal canal at the anorectal flexure, an 80-degree bend maintained by the puborectalis muscle. The terminal dilation of the rectum, the rectal ampulla, holds feces in preparation for defecation. The flexure and ampulla, with their support by the levator ani muscles, are crucial mechanisms enabling fecal continence. Peritoneum covers the anterolateral superior rectum and anterior middle rectum. The male rectum is separated from the bladder by a peritoneal reflection, creating the rectovesical pouch. In females, the vagina lies between the bladder and the rectum, and a similar peritoneal reflection here forms the rectouterine pouch of Douglas, or cul-de-sac. This is the most dependent portion of the peritoneal cavity in upright individuals.

The superior mesenteric artery supplies the ascending colon and proximal two-thirds of the transverse colon through the right and middle colic arteries, respectively. The inferior mesenteric artery supplies the distal third of the transverse colon, the descending colon, and the sigmoid through the left colic artery and superior sigmoid arteries. The junction of these two vessels occurs at the marginal artery of Drummond, an anastomotic vessel located approximately two-thirds across the transverse colon; this area, Griffith point, proves extremely vulnerable to watershed ischemic injury in low-perfusion states. The other watershed region, the point of Sudek, is located at the rectosigmoid colon, at the junction of the inferior mesenteric artery and internal iliac artery. The superior and inferior mesenteric veins drain their respective tributaries into the portal circulation. The lymphatic drainage passes through the paracolic, epicolic, and intermediate colic areas to the right colic area and then to the superior mesenteric group. The intermediate colic nodes drain to the inferior

mesenteric group. The neuronal supply to all parts of the colon includes vagal parasympathetic and lumbar sympathetic innervation via the mesenteric plexi.

The proximal rectum derives its arterial supply from the superior rectal artery, a branch of the inferior mesenteric artery. The middle and inferior rectum derive their supplies from the middle rectal arteries of the inferior vesicle distribution. The inferior rectal artery, arising from the internal pudendal artery, supplies the anal canal. The sympathetic system innervates the rectum via lumbar branches of the sympathetic trunk, and the parasympathetics traverse the pelvic splanchnic nerves.

The superior rectal veins drain the superior rectum into the inferior mesenteric vein of the portal circulation. The middle and inferior rectal veins drain the middle and inferior rectum and anal canal into the systemic circulation. Anastomoses between these drainages in the rectal venous plexus provide a common site for portosystemic shunting. In conditions like cirrhosis, portal hypertension forces retrograde flow through these vessels, dilating these channels.

PATHOLOGY

CONGENITAL ABNORMALITIES

Hirschsprung disease arises from a congenital defect in neural crest cell migration. Dilation of the colon requires these cells' presence; their absence creates a tonically contracted internal anal sphincter and varied length of contracted rectum and sigmoid. This obstruction to fecal flow dilates the normal bowel proximal to the defect. Neonates classically present in the first 48 hours of life with the absence of meconium, although less severe cases can go unrecognized as chronic constipation for weeks or years. Infants evidence refusal to eat, vomiting, constipation, and failure to thrive. Physical examination finds a distended abdomen. Abdominal radiography demonstrates colonic distention and absence of air in the rectum. Barium enema shows the proximal dilation with distal narrowing representing obstruction. Rectal biopsy demonstrates the lack of ganglion cells, confirming the etiology. Treatment involves surgical excision of the affected segment with eventual anastomosis of the colon to the distal normal anorectal segment.

Nonrotation of the bowel is the most common rotational anomaly. The entire colon is located in the left abdomen. There are various degrees of malrotation, resulting from a failure of the fetal bowel's extracorporeal 270-degree rotation during the first trimester of pregnancy. The proximal large intestine thus lies above the level of the duodenum and distal stomach, with Ladd bands in place of a peritoneal cover. These conditions

predispose to volvulus and resultant ischemia secondary to irregular attachments and decreased length of mesenteric base. Intussusception, Hirschsprung disease, and abdominal wall defects also occur with greater frequency in this setting.

Duplication presents as either communicating or noncommunicating cysts in the colon and rectum. Unlike the remainder of the gastrointestinal (GI) tract, colonic duplication cysts usually communicate with the lumen. Colonic duplications warrant removal for fear of complications such as obstruction and volvulus, and rectal cysts are always removed because of malignant potential.

INFLAMMATION AND INFECTION

Two major pathophysiologic patterns comprise IBD: Crohn disease (granulomatous colitis) and ulcerative colitis (UC). UC involves colonic inflammation, worse distally than proximally, especially in the rectum. It presents with microabscesses of the crypts of Lieberkuhn and produces bloody diarrhea, weight loss, fever, and cramping left lower abdominal pain. The pathology involves contiguous distal inflammation limited to the mucosa. Radiologic studies find large ulcerations alongside contiguous shallow lesions that appear as fine serrations. Granular mucosa represents mucosal edema, and pseudopolyps represent normal mucosal islands among erosions. Thumbprinting evidences mural edema secondary to inflammation. UC often associates with other HLA/B27-positive diseases, such as ankylosing spondylitis, and increases the risk of primary sclerosing cholangitis. Acute flares are treated with bowel rest and intravenous fluid. These patients are at significantly increased risk for colonic adenocarcinoma. Total proctocolectomy provides a cure for the primary process and prophylaxes against cancer.

Ulcerative proctitis is a localized form of UC with only rectal involvement. Patients present with diarrhea, tenesmus, and bleeding. Diagnosis and treatment are the same as for UC, but only approximately 20% of cases progress to the diffuse form of the disease. Because carcinoma risk is relatively low, prophylactic bowel resection is rarely indicated.

Crohn disease, on the other hand, most commonly involves chronic granulomatous inflammation of the terminal ileum, although the entire GI tract can be involved. It presents with colicky lower abdominal pain, diarrhea, protein loss, weight loss, malaise, obstruction, and fistulous tracts. Pathology demonstrates noncaseating granulomas with transmural inflammation and mural edema. Lesions classically skip areas of bowel. Ulcerations are deeper than with UC, and patients additionally often have long strictures. Barium enema examination demonstrates bowel wall edema, cobblestoning

representing deep fissures, strictures, stenoses, fistulous tracts, stranding of mesenteric fat, and aphthous ulcers. CT demonstrates fibrofatty proliferation, “creeping fat,” and congested mesenteric vasa recta, the “comb sign.” The latter is thought to be one of the more accurate indicators of acute inflammation. MR is the study of choice for evaluation of perianal disease. The fistulous tracts can be identified relative to the levator muscles, described using the Parks classification and allowing determination of the surgical approach. Severe sequelae include toxic megacolon and adenocarcinoma, although the latter is more common in UC. Surgical intervention is warranted for abscess, severe bleeding, cancer, and severe obstruction secondary to stricture. Disease commonly recurs following surgery. Medical management consists of 5-aminosalicylic acid, immunosuppressants, and steroids.

UC, and to a lesser degree Crohn disease, is the primary cause of toxic megacolon. Other causes included ischemic colitis, pseudomembranous colitis, and amebiasis. This disorder involves extreme acute dilation of the bowel to a diameter of at least 6 cm with loss of tone and function. Patients present with severe abdominal distention, pain, fever, and leukocytosis. Pathology most often occurs in the transverse colon. Radiography demonstrates extreme dilation with mucosal edema and loss of haustral markings. CT shows the thin flimsy bowel wall and massive dilation. Physicians must avoid barium studies in this disorder because of the risk of perforation. Treatment involves conservative medical therapy for 48 to 72 hours. Total colectomy is necessary for failed cases.

Behçet disease occurs in young males, and presents with oral and genital ulceration as well as ulceration of the entire GI tract. Radiographically, it mimics Crohn disease.

Diversion colitis involves bacterial overgrowth in a blind loop through which stool no longer courses. The radiographic appearance often mimics UC, and differentiation of the processes can be difficult, especially when bowel loops are diverted in a patient with IBD. Surgical treatment replaces the loop into continuity with the remainder of the bowel.

Diverticula present in older patients with a history of low-fiber diet as colonic outpouchings of the mucosa and muscularis mucosa where the vasa recta perforate the muscular layer. Most bleed to some degree, although the amount is generally small. Symptomatic left-sided lesions produce bright red blood per rectum, and right-sided pathology presents with dark, tarry stools (melena). The sigmoid colon holds the majority of lesions, with most of the remainder in the ascending segment. Patients can experience significant blood loss. Barium studies demonstrate the outpouchings as barium or air-filled lesions approximately 1 cm in diameter.

Diverticulitis complicates 25% of cases of diverticulosis. It usually manifests as a peridiverticular abscess secondary to microperforation and presents with fever, chills, constipation, and left lower quadrant pain, sometimes greater to rebound than pressure. Barium enema shows the outpouching, abscess, and contrast leakage into the abdomen. CT, the imaging modality of choice, demonstrates the abscess, diverticula, and mesenteric inflammation. Gas within the bladder suggests colovesical fistula; however, secondary signs of inflammation of the bladder (wall thickening) and no history of recent bladder catheterization should be determined before confirming this diagnosis. Differentiating between diverticulitis and colorectal carcinoma can be difficult, particularly with severe thickening. Regional lymphadenopathy suggests a malignancy, while a low-density “halo sign” (mural stratification) suggests benign disease.

Right-sided diverticulitis is less common but has similar imaging findings. The patient population is generally younger and Asian, and the disease process may be difficult to differentiate from appendicitis. CT findings of circumferential thickening and adjacent diverticula versus inflammation centered on the appendix help with this dilemma. Surgical indications include frank perforation, toxicity, and instability from severe bleeding.

The epiploic appendages along the serosal surface of the colon can torse, resulting in epiploic appendagitis. Patients present with severe focal abdominal pain. It is most commonly left-sided, and patients may present with mild elevation of white count, mimicking diverticulitis. On CT, a fat-containing mass with increase density rim and surrounding stranding changes are present. There is often a central dot thought to represent thrombosed vessels. Unlike diverticulitis, there is not typically concentric bowel wall thickening. Omental infarction is typically a larger mass with a more ovoid shape and more internal soft-tissue density. It is more commonly anterior to the transverse colon or right-sided and not as intimately associated with the colon. Both diagnoses are self-limiting.

Ischemic colitis results from thrombotic or embolic occlusion, systemic hypoperfusion, and iatrogenic complications from surgery. It classically presents with pain out of proportion to physical findings in patients at risk. The marginal artery of Drummond is especially vulnerable. Findings include fever, abdominal tenderness, and heme-positive stools. Radiography demonstrates mucosal edema or thumbprinting, classically in the splenic flexure watershed area. CT is the imaging study of choice and demonstrates segmental mural thickening. Pneumatosis in this setting suggests infarction. Flexible sigmoidoscopy shows edematous, friable mucosa with ulceration. Conservative measures optimizing perfusion provide the best outcome; surgery removes obstructing

or necrotic bowel. Healing can result in an annular stricture. Unlike adenocarcinoma, the narrowing is smooth, without shouldering.

Acute radiation colitis presents with mural edema localized to the region of the treatment port. During the chronic phase, there is luminal narrowing and increased pericolic and perirectal fat. The use of a rectal balloon is contraindicated in patients having prior radiation to the rectum, most commonly for prostate and cervical cancer.

Thickening of the entire GI tract can occur in the setting of cirrhosis. It most commonly is seen in the ascending colon secondary to portal hypertension, but can occur anywhere in the GI tract. These patients are also at risk for hypoproteinemia, further increasing diffuse mural edema.

Colitis cystica profunda occurs in young adults. Radiographically, there are multiple mucous-filled cysts in the rectal wall. It is associated with solitary rectal ulcer syndrome and rectal prolapse.

Several infectious diseases target the colon specifically or substantially involve it. The protozoan *Entamoeba histolytica* causes bloody dysentery with frequent bloody mucoid stools, tenesmus, and fever. Patients often have history of foreign travel. Ingested cysts release the organism, which travels to the colon. From there it may spread and cause abscesses in the liver (“anchovy paste–” filled cysts), spleen, and brain, and can lead to toxic megacolon. Diagnosis requires stool studies for the parasite, endoscopic colonic biopsy showing flask-shaped ulcers, or aspiration of cysts with examination of the fluid. Imaging is generally not used. Barium enema reveals ulcerated mucosa representing the flask-shaped invasions and the classic “coned cecum.” CT shows generalized inflammation and abscesses. Metronidazole provides the cure.

Some amoebic infections remain localized to the rectum, especially in homosexual men. These cases tend to present with bloody dysentery, most commonly without the systemic manifestations mentioned earlier. Diagnosis and treatment are as with generalized infection.

Colonic tuberculosis involves the terminal ileum and right colon. There are ulcers and focal areas of stenosis with a coned cecum. Fleischner sign, with enlarged, gaping ileocecal valve, is present; Stierlin sign is seen with narrowing of the terminal ileum.

CMV colitis occurs in patients with immunosuppression, diabetes, and IBD. Cases present with bleeding and abdominal pain; perforation is the most severe complication. Barium enema examination and CT suggest the entity by showing deep ulceration in patients with predisposing history. Diagnosis requires endoscopic biopsy demonstrating Cowdry type A intranuclear inclusion bodies. Ganciclovir effectively controls the infection.

Pseudomembranous colitis arises from infection with the gram-positive bacillus *Clostridium difficile*. Antibiotic use, most commonly clindamycin and beta-lactams, depletes resident colonic flora, predisposing to infection with this agent, which presents 3 to 4 weeks after treatment. *Clostridium difficile* enterotoxin necroses colonic mucosal cells, and their sloughed mass comprises the pseudomembranes. Patients present with watery diarrhea, crampy abdominal pain, fever, and tenderness. Radiography demonstrates increased colonic caliber and mural thickening. Barium enema examination shows thumbprinting, ulceration, and irregularity. CT finds wall thickening, ascites, and the “accordion sign,” representing contrast trapped within edematous mucosal folds. Diagnosis requires stool assay for *C. difficile* toxin, and in some cases, CT may be normal. Metronidazole is the first line of treatment, with vancomycin and bacitracin reserved for resistant cases. Toxic megacolon and perforation are rare but severe sequelae may require colectomy.

Neutropenic colitis, more specifically typhlitis when limited to the cecum, occurs in the setting of severe neutropenia. The neutropenia, via an unclear mechanism, allows the breach of colonic flora across the mucosal barrier. This causes mural thickening and typically more pericolic ascites than seen with other colitides. Graft-versus-host disease can occur throughout the GI tract, resulting in luminal narrowing and typically less thickening than neutropenic colitis. Graft-versus-host disease involves significantly longer segments of bowel, particularly ileum and colon. It occurs after allogeneic bone marrow transplantation and is secondary to rejection of the host by the transplanted cells.

Lymphogranuloma venereum (LGV) is proctitis secondary to *Chlamydia trachomatis* infection. It presents with stricture, sinus tract formation, and fistula, resembling Crohn disease. Gonococcal proctitis can also be seen in HIV-positive and AIDS patients.

NEOPLASIA

BENIGN TUMORS

Polyps are discrete mucosal projections into the bowel lumen. They can be hyperplastic, containing focal cell proliferation with normal nuclear and architectural features, or adenomatous, representing a premalignant state. Hyperplastic polyps are round, well circumscribed, sessile, and usually small. They are more common than adenomas, particularly in the rectum, but are not true neoplasms.

Adenoma is the most common benign tumor of the colon and rectum (Table 48-1). Adenomatous polyps are larger than hyperplastic polyps; can have irregularity; possess a larger base; and can be sessile or pedunculated

TABLE 48-1 Colonic Neoplasms

BENIGN	MALIGNANT
Hyperplastic polyp (most common “polyp”; not true neoplasm)	Adenocarcinoma
Adenoma (most common benign tumor)	Squamous cell carcinoma (anus)
Lipoma (second most common)	Lymphoma
GIST	GIST
Hemangioma	Carcinoid
	Cloacogenic carcinoma

with villous, tubular, or tubulovillous histology. Large, sessile, villous adenomas harbor the greatest risk for malignancy. Endoscopy and barium enema have been the traditional methods to screen and diagnose colonic polyps. CT colonography is the newest modality in the colorectal cancer screening armamentarium and is showing great promise.

Many polyposis syndromes are associated with adenomatous polyps (Table 48-2). Familial polyposis is an autosomal dominant condition involving mutations in the APC gene. It presents with hundreds of adenomatous polyps in the colon, as well as the remainder of the gut, and frequently carcinoma near the ampulla of Vater. Epidermoid cysts, desmoid tumors, and osteomas occur with colonic polyps in the Gardner syndrome variant of this disease. Turcot syndrome is an autosomal recessive polyposis syndrome with central nervous system glioblastoma. Patients with polyposis require subtotal colectomy by age 30 with close monitoring, as the majority will otherwise develop cancer by age 40.

Hamartomatous polyps are normal colonic mucosal cells organized atypically; they represent developmentally abnormal tissue and not a neoplastic process. They may arise anywhere in the GI tract and can lead to bleed-

ing. Peutz-Jeghers syndrome is autosomal dominant and involves mucocutaneous pigmentation and GI tract hamartomas. Negligible malignant potential of the colonic polyps obviates the need for removal except with clinically significant bleeding. However, these patients are at an increased risk of breast, ovarian, and pancreatic carcinoma.

Lipomas are the second most common tumor in the colon. They are submucosal and easily identified by their fat density on CT. GISTs occur throughout the colon but are more common in the anorectum. As in the remainder of the GI tract, they are typically large, exophytic masses and may be ulcerated. They can be benign or malignant, but no imaging findings reliably determine malignant potential.

Cavernous hemangioma usually occurs in the rectum in the setting of congenital anomalies and syndromes, including Klippel-Trenaunay-Weber and blue rubber bleb syndromes and VATER complex. These present as multiple rectal mural nodules or large pelvic masses. They may or may not enhance, depending upon if they are thrombosed. Phleboliths may be identified.

MALIGNANT TUMORS

Adenocarcinoma of the colon causes more deaths than any malignancy, except lung cancer. Risk factors include diets high in animal fat, low in calcium and antioxidants, and advancing age, in addition to IBD, polyposis, and nonpolyposis syndromes. Right-sided lesions (25%) present with iron-deficiency anemia secondary to occult blood loss or with melena. Left-sided pathology includes obstruction and decreased stool caliber. Metastases usually involve the liver, lung, brain, or bone. Barium enema examination demonstrates a mass fungating into the intestinal lumen or a narrowing representing a circumferential, “apple-core” lesion. CT

TABLE 48-2 Polyposis Syndromes

Adenomatous	Inheritance Pattern	
FAPS	AD	Most common; gastric hyperplastic polyps and GI tract and adenomas; ampullary carcinoma
Gardner syndrome	AD	Epidermoid cysts, desmoid, osteoid osteoma
Turcot syndrome	AD	CNS glioblastoma
Hamartomatous		
Peutz-Jeghers syndrome	AD	GI hamartomas, pigmented mucous membrane lesions
Juvenile polyposis	AD	GI hamartomas
Infantile polyposis	AR	Congenital anomalies, ganglioneuroma
Cronkhite-Canada syndrome	Sporadic	Skin hyperpigmentation, alopecia, onychodystrophy, malabsorption, 60% mortality
Cowden disease (multiple hamartoma syndrome)	AD	Only one to involve esophagus

shows lymphadenopathy, distant metastases, and the lesion, often directly extending into pericolonic tissues. Transrectal ultrasound provides staging and allows biopsy of the primary tumor and regional lymph nodes. Colonoscopy provides direct visualization of the lesion with concurrent biopsy. Treatment combines surgery, radiation, and chemotherapy. Stage I and II lesions are limited to the bowel wall while stages III and IV extend to the lymph nodes or possess metastases. Prognosis correlates most closely with stage.

Hereditary nonpolyposis colon cancer (HNPCC) syndrome involves mutations of genes regulating cell growth. HNPCC type I presents in young patients with adenocarcinoma, most commonly in the ascending colon. HNPCC type II presents with cancers of the colon, endometrium, ovary, pancreas, kidney, stomach, and liver. Patients require vigilant monitoring for early treatment of malignancies.

Lymphoma of the colon has a protean appearance. It can have multiple nodules, a large mass, or diffuse thickening. Classically, it is a soft tumor that does not cause obstruction.

Squamous cell carcinoma occasionally arises in the anus and presents much like adenocarcinoma of this region. Digital rectal examination suggests the diagnosis, and CT characterizes the extent of disease to assess resectability. Treatment is with surgery and chemotherapy.

Carcinoid occurs most commonly in the rectum but can occur throughout the remainder of the colon. Patients typically present with a calcified mesenteric metastatic nodal mass, and the primary tumor is often not found.

Cloacogenic carcinomas are tumors arising from the pectinate line. They have variable histologic types and present most commonly with bleeding, decreased caliber of stools, and tenesmus. Barium studies show the narrowed lumen, and CT assesses the extent of the tumor for determination of resectability. Treatment involves surgery and radiation.

The colon serves as a potential site for metastases via the intraperitoneal and occasionally vascular routes. Peritoneal seeding most commonly occurs with ovarian carcinoma. These present with eccentric serosal masses with varying degrees of obstruction. Because of their dependent location, the rectouterine pouch in females, the rectovesical space in males, the rectal shelf, and the ileocolonic junction are common sites for peritoneal spread. Hematogenous metastases usually occur in the setting of lung or breast cancer.

MISCELLANEOUS CONDITIONS

Obstruction complicates many processes, including adhesions, stricture, cancer, intussusception, volvulus,

fecaliths, and incarcerated hernia. Patients present with vomiting, abdominal distention, and cramping abdominal pain. Physical examination includes abdominal distention and high-pitched, tinkling bowel sounds. Radiographs show dilated proximal bowel loops with a distinct transition point and collapsed distal bowel. Air-fluid levels are prominent in upright films. CT shows the transition point and delineates the cause.

Intussusception represents telescoping of a segment of bowel, sometimes secondary to a mass lesion that functions as a lead point. It most often occurs in the distal ileal/cecal area, but also occurs in the colon. It presents most commonly in children with intermittent crampy abdominal pain, bloody stools, and sometimes fever. In this setting, there is typically no lead point. Adults usually have less severe presentations, and there is more commonly a lead point when it involves the colon, either ileocolonic or colocolonic intussusception. Radiography demonstrates the associated mass, small bowel obstruction, and the “crescent sign” representing shouldering on an air-filled segment of bowel. CT visualizes the telescoped bowel loops, demonstrating fat inside the bowel lumen. Ultrasound shows concentric rings, the “target sign.” Barium enema examination evidences the string sign, representing barium contrast passing through the narrowed lumen of the inner loop.

Colonic volvulus involves intestinal twisting about its mesenteric stalk, creating an obstruction and often interrupting the blood supply, leading to ischemia. The sigmoid colon is the most common site for adult volvulus, which usually occurs in debilitated patients after stroke or nursing home placement; younger patients more often present with cecal pathology. Cases not involving the vascular supply present with years of intermittent obstructive attacks. In sigmoid volvulus, radiography demonstrates distention with obstruction, a paucity of haustra, and a coffee bean-shaped bowel loop representing the twisted segment, usually directed toward the right hemidiaphragm and often above the transverse colon. Barium studies show the classic beaking of the twisted segment. Initial conservative therapy with rectal tube placement resolves most cases. Some can be reduced endoscopically. Surgery ameliorates refractory cases or situations with vascular interruption. Cecal volvulus results in small bowel obstruction. There is a large gas collection, the dilated cecum, usually projecting in the left upper quadrant, and the remainder of the colon is collapsed. Cecal volvulus is much less common than sigmoid volvulus.

Angiodysplasia refers to vascular abnormalities, most commonly seen in older patients in the ascending colon and cecum. Patients present with painless lower GI bleeds, often in the setting of cardiac valvular or renal diseases. Angiography or technetium scanning localizes

the lesion. Colonoscopy provides the potential for diagnosis and cure. There is no role for barium studies.

QUESTIONS AND ANSWERS

- Which of the following is a benign colonic neoplasm?
 - Adenocarcinoma
 - GIST
 - Cavernous hemangioma
 - Carcinoid
 - Hyperplastic polyp

ANSWER: C. Hyperplastic polyps are not true neoplastic tumors. Adenocarcinoma and carcinoid are malignant tumors. GIST can be benign or malignant.
- Which of the following disease processes is strictly extracolonic?
 - Crohn disease
 - Diverticulitis

- Behçet disease
- Epiploic appendagitis
- Tuberculosis

ANSWER: D. Epiploic appendagitis occurs secondary to torsion of an epiploic appendage and is not a primary colonic process. All other responses primarily involve the colon and may or may not have extracolonic extension.

- Which of the following polyposis syndromes presents with epidermoid cysts, desmoid tumors, and osteomas?
 - Gardner syndrome
 - Turcot syndrome
 - Familial polyposis
 - HNPCC
 - Cowden disease

ANSWER: A. Turcot syndrome has CNS glioblastomas. Cowden disease is a hamartomatous condition that can involve the esophagus.
- Which of the following groups should begin screening for colorectal carcinoma at age 50?
 - Patients with polyposis syndrome
 - Patients with family history of colon cancer
 - Asymptomatic patients with no known risk factors
 - Patients with prior history of colon cancer
 - Patients with heme-positive stools

ANSWER: C. High-risk patients begin screening at age 40 or when symptomatic.

- Which of the following findings suggests colon cancer rather than diverticulitis?
 - Regional lymphadenopathy
 - Halo sign
 - Pericolonic inflammatory change
 - Ascites
 - Mural thickening

ANSWER: A. Regional lymphadenopathy is more commonly seen with cancer than with diverticulitis. Halo sign is indicative of diverticulitis, and mural thickening and pericolonic inflammatory change can be seen in both cancer and diverticulitis. Ascites is not a discriminator.
- Which is *not* predominantly an ileocolonic disease?
 - Tuberculosis
 - Campylobacter
 - Crohn Disease
 - Giardia
 - Typhlitis

ANSWER: D. Giardia more commonly involves the duodenum and jejunum.

7. What is the most common colonic polyp?
- Hyperplastic polyp
 - Adenoma
 - Lipoma
 - Hemangioma
 - Lymphangioma

ANSWER: A. An adenoma is the most common neoplasm, while hyperplastic polyps are the most common polyps and are not neoplastic.

8. Which of the following is classically seen with sigmoid volvulus?
- U-shaped sigmoid
 - Dilated sigmoid directed toward right hemidiaphragm
 - Twisted appearance of ileo-cecal region
 - Decompressed small bowel
 - Transverse colon cranial to sigmoid colon

ANSWER: B. Sigmoid volvulus typically presents with a markedly dilated sigmoid colon in the shape of an inverted “U” or coffee bean directed toward the right hemidiaphragm and often projecting above the transverse colon. A beaked appearance of the twisted rectosigmoid is often seen with barium enema examination, with proximal obstruction of colon and small bowel. Many cases are treated endoscopically, although surgery may be required for recurrent volvulus.

9. In the United States, what segment of the colon is most commonly involved with diverticulitis?
- Cecum
 - Ascending
 - Transverse
 - Sigmoid
 - Rectum

ANSWER: D. The sigmoid colon is the most common segment involved with diverticulitis. Right-sided diverticulitis (ascending colon and cecum) typically occurs in younger patients, with increased propensity for the Asian population.

10. What is the most common cause of colon obstruction?
- Adhesion
 - Malignancy
 - Hernia
 - Gall stone
 - Volvulus

ANSWER: B. Although all of these can cause colonic obstruction, malignancy is the most common.

49 APPENDIX

Camden L. Hebson and Cheri L. Canon

APPENDIX

NORMAL ANATOMY

The appendix arises at the junction of the taeniae coli, at the posteromedial base of the cecum. It is directed toward the side of the ileocecal valve. There is a wide range of normal locations of the appendix. The ileocolic artery from the superior mesenteric artery provides the blood supply via the appendicular artery branch. The appendix contains the four layers as seen elsewhere in the gastrointestinal tract and is rich with lymphoid tissue.

PATHOLOGY

INFLAMMATION AND INFECTION

Inflammation of the appendix is the most common abdominal surgical emergency and is usually secondary to obstruction (50%–75% of cases) by a fecolith. Other causes include gallstones, lymphoid hyperplasia, stricture, parasite, foreign body, and tumor. Diagnosis is often made based on history, physical examination, and laboratory assessment. Cross-sectional imaging is usually used to confirm the diagnosis. The goal in treatment is surgical resection before appendiceal rupture.

The sequence of events in acute appendicitis is well documented. As mentioned, the inciting event is usually obstruction, with fecolith impaction or reactive hyperplasia of lymphoid tissue. Mucinous fluid continues to be produced in the obstructed lumen, leading to increased intraluminal pressure and collapse of venous drainage. Subsequent ischemia provides a supportive environment for bacterial proliferation, which further increases local inflammation. Inflammation is tied to perception of pain, as the early periumbilical pain is due to increased intraluminal pressure, which stimulates visceral nerve fibers. The classic shift to severe right lower quadrant pain comes after inflamed appendiceal serosa contacts the parietal peritoneum, thus allowing the patient to accurately localize the inflammation. Perforation can result if left untreated, as persistent ischemia leads to transmural infarction.

Appendicitis is most common in adolescents and young adults, but can occur in any age group. Signs and symptoms include tenderness to palpation over the abdomen, fever, leukocytosis, possible nausea and vomiting, and the classic pain pattern: periumbilical pain

shifting to the right lower quadrant. This classic presentation, however, is often absent. Deviations include tenderness in atypical locations, right flank or pelvic pain that is due to a retrocecal appendix, and left upper quadrant pain that is due to malrotation of the colon. These presentations are more common in the very young and old. The differential diagnosis includes epiploic appendicitis, right-sided diverticulitis, mesenteric lymphadenitis, viral infection, inflammatory bowel disease, pelvic inflammatory disease, ectopic pregnancy, cystic fibrosis, and Meckel diverticulitis.

On CT, there is dilatation of the lumen, greater than 6 mm, mural thickening and increased enhancement, and periappendiceal inflammatory change. In early appendicitis, surrounding inflammation may be absent. Appendicoliths may be present, but can be obscured by luminal contrast if bone window settings are not used.

Complicated appendicitis includes perforation, abscess, and small bowel obstruction. CT findings indicating perforation include moderate or severe periappendiceal inflammation, focal defect in enhancing appendiceal wall, extraluminal air, and extraluminal appendicolith.

Chronic appendicitis appears like acute appendicitis on imaging studies, although may have less periappendiceal inflammation. Chronic processes include granulomatous appendicitis, lymphoid hyperplasia, fibrosis, and nonspecific chronic inflammation. Granulomatous appendicitis typically does not progress to Crohn disease in the remainder of the gastrointestinal tract. Chronically inflamed appendices are larger than in simple appendicitis with notable absence of definable wall, and it can be difficult differentiating this entity from neoplasm. Crohn disease of the terminal ileum and cecum can secondarily involve the appendix.

The appendix can contain diverticula and therefore develop diverticulitis. It is not possible to differentiate between acute appendicitis and appendiceal diverticulitis unless the offending diverticulum is identified on CT.

NEOPLASIA

Almost half of patients with appendiceal tumors will present with signs and symptoms of appendicitis. Tumor can mimic appendicitis and should be considered if the diameter is greater than 15 mm. Of all appendiceal tumors, carcinoid is the most common (Table 49-1). Carcinoids arise from neural crest cells of the gastrointestinal tract, which normally function to generate bioactive compounds (peptide hormones) that help coordinate gut function. On gross inspection of the tumors, they are often described as firm, rubbery yellow nodules that often grow through the muscularis mucosa into the mesentery. Histological examination reveals cell structure similar to

TABLE 49-1 Tumors of the Appendix

Carcinoid (most common neoplasm)
Mucocoele (not neoplastic)
Mucinous cystadenoma
Mucinous cystadenocarcinoma
Non-Hodgkin lymphoma
Leiomyoma
Leiomyosarcoma

adenocarcinoma, but without such aggressive metastatic tendency.

Often, carcinoid is an incidental diagnosis at the time of appendectomy for appendicitis. The distal tip of the appendix is the most common location where the tumor will be present as a solitary nodule a few centimeters in diameter. Although transmural extension can occur, appendiceal carcinoids rarely metastasize and follow a benign course as a rule.

Less common than carcinoids in the appendix are mucinous tumors, which range from benign retention mucocoeles to neoplastic cystadenomas and mucin-secreting cystadenocarcinomas. Mucocoeles are often found incidentally: inspection will reveal appendiceal dilation secondary to mucinous secretion (globular enlargement), and eventual atrophy of mucosal cells secondary to distension. Mucocoeles are for the most part asymptomatic. On CT, they appear as dilated tubular structures and may have thin mural calcification.

Mucinous cystadenomas are the most common mucinous tumors of the appendix. Distension can lead to perforation in 15% to 20% of cases, allowing mucus into the peritoneal cavity. Histological examination, however, reveals no malignant cells. This is not the case with mucin-secreting adenocarcinomas, which are less common but more worrisome than the cystadenomas because of propensity to disseminate to the peritoneum. Cystadenocarcinomas produce mucinous dilatation of the appendix identical to cystadenomas, but the invasive cells also spread locally and implant into the peritoneum, which can sometimes lead to mucinous ascites, a condition called pseudomyxoma peritonei. Poorly differentiated adenocarcinoma cells can be found on cytologic examination, distinguishing this more malignant process from other mucin-producing conditions. CT findings include cystic dilatation of the appendix with a nodular enhancing wall. Pseudomyxoma peritonei presents with complicated ascites with areas of attenuation greater than that of water. There is mass effect on adjacent bowel and solid organs, producing a scalloped appearance on the liver and spleen. Repeated debulking procedures have been used to keep this condition in check, but a fatal course is often the rule. There is no way to accurately differentiate benign mucocoeles

from their malignant counterpart, so all should be resected.

Lymphoma, non-Hodgkin type, can involve the appendix and even present with symptoms of acute appendicitis. On CT, lymphomatous appendix is usually larger than one with acute inflammation, typically 2.5 cm or greater. Aneurysmal dilatation seen in small bowel lymphoma can also be seen in the appendix.

Leiomyoma and leiomyosarcoma rarely occur in the appendix, more commonly the benign form.

QUESTIONS AND ANSWERS

- Which of the following is the most common tumor of the appendix?
 - Carcinoid
 - Mucinous cystadenoma
 - Mucinous cystadenocarcinoma
 - Mucocele
 - Leiomyoma

- Carcinoid
- Mucinous cystadenoma
- Mucocele
- Leiomyoma

ANSWER: A. Carcinoid is the most common tumor of the appendix. Mucinous cystadenoma and cystadenocarcinoma are less common. Mucoceles are fairly common, but are not a frank neoplastic process. Leiomyomas are exceedingly rare.

- Which of the following helps differentiate granulomatous appendicitis from acute appendicitis?
 - Appendicolith
 - Extraluminal gas
 - Mural enhancement
 - Small bowel obstruction
 - No definable wall

ANSWER: E. All other responses can be seen in acute appendicitis. Lack of definable wall with large soft-tissue component suggests granulomatous appendicitis.

- Concerning the appendix, which of the following is true?
 - Contains taenia coli
 - Most commonly retrocecal
 - Directed toward the side of the ileocecal valve
 - Supplied by branch of the inferior mesenteric artery
 - Does not contain a serosal layer

ANSWER: C. The appendix arises at the junction of the taenia coli. Although it can be located posterior to the cecum, this is not the most common presentation. Its vascular supply is from the appendicular artery branch of the superior mesenteric artery. It is covered in serosa.

- Which of the following suggests perforated appendicitis?
 - Periappendiceal inflammation
 - Mural thickening
 - Increased mural enhancement
 - Focal defect in enhancing appendiceal wall
 - Appendicolith

ANSWER: D. Focal defect in the enhancing appendiceal wall and severe periappendiceal inflammatory change both suggest perforated appendicitis. All other findings are seen in uncomplicated appendicitis.

- Which of the following suggests malignant mucinous tumor of the appendix?
 - Globular dilatation of the appendix
 - Thin mural calcification

- C. Nodular mural enhancement
- D. Periappendiceal inflammation
- E. Small bowel obstruction

ANSWER: C. Enhancing nodularity indicates mucinous cystadenocarcinoma. All other findings can be seen in mucocoeles as well as mucinous cystadenomas.

50 IMAGING OF THE LIVER

Allen B. Groves and Lincoln L. Berland

INTRODUCTION

The liver's primary functions include detoxification, glycogen storage, plasma protein synthesis, bile production, and decomposition of red blood cells.

EMBRYOLOGY AND ANATOMY

In the fetus, the hepatic diverticulum eventually becomes the biliary tree and the ventral pancreas. Initially, the liver grows in the ventral mesentery, which later involutes leaving behind the falciform ligament and the lesser omentum. Fetal circulation involves the liver in a critical way. The umbilical vein reaches the liver along the inferior aspect of the falciform ligament. At approximately 8 to 12 weeks gestation, the left branch of the umbilical vein becomes the ductus venosus, which bypasses the liver and carries oxygenated blood from the maternal circulation to the heart of the fetus. After birth, the umbilical vein becomes the ligamentum teres in the inferior edge of the falciform ligament, and the ductus venosus becomes the ligamentum venosum.

The liver in the adult is covered by visceral peritoneum except at the porta hepatis, bare area, and the gallbladder fossa. The liver is attached to the posterior abdominal wall and diaphragm by the triangular and coronary ligaments. The liver is connected to the anterior abdominal wall and diaphragm by the falciform ligament. Classically, the liver is divided into five segments, two in each of the right and left hepatic lobes and the fifth being the entire caudate lobe. The falciform ligament divides the medial and lateral segments of the left hepatic lobe, and the right hepatic vein divides the right hepatic lobe into anteroposterior segments. The middle hepatic vein divides the liver into right and left hepatic lobes and defines a plane that ex-

tends from the inferior vena cava to the gallbladder fossa.

Functional division of the liver into multiple individual portions is defined by the Couinaud system (Fig. 50-1). These are functionally independent and defined by individual branches of the hepatic artery, bile duct, and portal vein. These are bound by branches of the hepatic veins. Blood supply to the liver is dominated by the portal vein, which drains the intestines and spleen but is supplemented by systemic arterial blood in the form of the hepatic artery. Outflow of blood from the liver is by hepatic veins, which drain into the inferior vena cava. These eight segments are numbered in a clockwise direction beginning with the caudate lobe. The following is a list describing the position of the Couinaud segments in relation to conventional segmental hepatic anatomy:

- I) Caudate lobe
- II) Left posterolateral segment
- III) Left anterolateral segment
- IVa) Left superomedial segment
- IVb) Left inferomedial segment
- V) Right anteroinferior segment
- VI) Right posteroinferior segment
- VII) Right posterosuperior segment
- VIII) Right anterosuperior segment

The caudate lobe has a direct connection to the inferior vena cava through hepatic veins, which do not communicate with the primary hepatic veins. The caudate lobe may also be supplied by branches of both the right and left portal veins. This is important in many disease

FIG. 50-1 Hepatic (Couinaud) segments.

SOURCE: Courtesy of Anthony F. Zagar, UAB, Department of Radiology, Birmingham, Alabama.

states, which may spare and even hypertrophy the caudate lobe, when there is loss of normal remaining hepatic parenchyma such as in Budd-Chiari. Although rare, there can be congenital absence of one or more hepatic segments.

The vascular anatomy of the liver has many common variations. One of the more frequently encountered vascular variants is the replaced right hepatic artery arising from the superior mesenteric artery, occurring in approximately 11% of patients. The left hepatic artery can also be “replaced” from the normal branching pattern from the proper hepatic artery and arise from the left gastric artery. With regard to portal venous anatomy, the most common variation is a trifurcation at the porta hepatis (rather than a bifurcation) into a left branch and two branches to the right hepatic lobe. Finally, hepatic venous variation is less constant but typically involves small branch vessel drainage directly into the inferior vena cava from the posterior right hepatic lobe rather than passing into either the right, middle, or left hepatic veins which classically drain the liver into the inferior vena cava. Clearly, these vascular variations are important in patients undergoing liver surgery including partial hepatectomy, liver transplant, and so on.

PATHOLOGY

CONGENITAL

Perhaps because of its size and complex operations, the liver is subject to many congenital disorders and mass lesions. Autosomal dominant and recessive polycystic kidney disease can also affect the liver resulting in numerous cysts and fibrosis, respectively. The liver is also subject to hamartomas and congenital mass lesions including hepatoblastomas and infantile hemangioendotheliomas.

Hemangioendothelioma is the most commonly encountered benign liver tumor in the infant. An infant with congestive heart failure should undergo imaging of the liver to exclude this tumor, as it is associated with high-output congestive heart failure. Hemangioendothe-

lioma is also associated with cutaneous hemangiomas approximately 40% of the time. Because of platelet sequestration in these vascular tumors, patients can also present with disseminated intravascular coagulation (DIC) or thrombocytopenia.

Hepatoblastoma is the most common primary hepatic malignancy in children. These typically present as large hepatic masses. There are associations with Beckwith-Wiedeman, hemihypertrophy, and familial adenomatous polyposis syndrome.

Mesenchymal hamartoma is an uncommon benign tumor, most frequently encountered in children. It is typically cystic and solitary and may contain thin septae and intervening nodules (Table 50-1).

INFECTION

Infectious diseases affecting the liver can be subdivided: viral, abscess (pyogenic and amoebic), fungal, parasitic, and granulomatous—with the three former categories representing the most common hepatic infections. Dual blood supply to the liver means that hematogenous dissemination is a cause for hepatic infection. Ascending cholangitis is another common route for spread of infection to the liver. Finally, penetrating trauma can directly inoculate the liver.

Viral infection of the liver can be caused by hepatitis A, B, C, D, and E. In acute hepatitis, the liver is often enlarged. On US, the liver may appear more hypoechoic with relative increased echogenicity of the portal triads resulting in the “starry sky” appearance. Chronic infection may occur with hepatitis B and C and may lead to cirrhosis and increased risk of hepatocellular carcinoma.

Pyogenic abscesses may mimic cysts. Solitary lesions are often caused by *Klebsiella* species, whereas multiple lesions are most commonly associated with *Escherichia coli*. One of the more common appearances on CT is the “double target” sign, consisting of a central hypodense abscess cavity surrounded by an enhancing rim and an outer hypodense zone. Of course, the presence of gas in the lesion is highly suggestive of a pyogenic abscess, but history of percutaneous intervention must be excluded.

TABLE 50-1 Congenital Hepatic Lesions and Associations

INFANTILE HEMANGIOENDOTHELIOMA	HEPATOBLASTOMA	ANGIOMYOLIPOMA	HEPATIC CYSTS OR CYSTLIKE LESIONS
High-output congestive heart failure	Beckwith-Wiedeman, hemihypertrophy	Female > Male	ADPKD
Most common benign tumor in infancy	Familial adenomatous polyposis syndrome	Tuberous sclerosis	Caroli disease
			Biliary hamartomas (von Meyenberg complexes)
			Infection
			Metastases
			Mesenchymal hamartoma

TABLE 50-2 Hepatic Infections and Classic Imaging Findings

VIRAL HEPATITIS	PYOGENIC ABSCESS	CANDIDA INFECTION	AMOEBIC ABSCESS	HYDATID DISEASE	SCHISTOSOMIASIS	TUBERCULOSIS/ HISTOPLASMOSIS
Starry sky appearance (US)	Double target sign (CECT)	Bull's eye appearance (US)	Extrahepatic extension Enhancing wall with peripheral edema (CECT)	Hydatid sand snow storm sign (US) Water-lily sign (US)	Tortoise shell appearance (CECT)	Calcified granulomata

Fungal infection is most commonly caused by *Candida* infection, typically in immunocompromised patients. The lesions are multiple and less than 10 mm in size. Ultrasound (US) may show a “bull’s eye” appearance with an echogenic nidus and hypoechoic rim in the acute phase. Contrast-enhanced CT shows numerous low attenuation lesions, which may have central enhancement.

Finally, secondary inflammation of the liver capsule and diaphragm or perihepatitis related to extrapelvic manifestation of pelvic inflammatory disease (PID) is known as Fitz-Hugh-Curtis syndrome. *Chlamydia* and *Neisseria gonorrhoeae* are the typical causative organisms. One may see an enhancing liver capsule on CT or MRI with this syndrome.

Amoebic abscess accounts for the most common hepatic abscess worldwide and is caused by *Entamoeba histolytica*, although these are rare in the US. Patients are usually younger than those with pyogenic abscess and present acutely ill with fever and right upper quadrant abdominal pain. These typically appear as complex, peripherally enhancing cystic lesions with septae on CT and can be associated with extrahepatic extension.

One of the most common parasitic infections to affect the liver is hydatid disease from the larval stage of the *Echinococcus* tapeworm. Patients are commonly from, or have traveled to, the Mediterranean region, Africa, South America, the Middle East, Australia, or New Zealand. Therefore, patients suspected of having a hydatid cyst should be questioned about foreign travel. The mature hydatid cyst consists of three layers: the outer layer (pericyst), a thick fibrous capsule, the middle membrane (ectocyst), and the germinal layer (endocyst). The middle layer is secreted by the inner layer. Scolices can be present in cyst fluid as a sediment and is known as hydatid sand. This can be appreciated occasionally on US as echogenic foci falling dependently with changes in position during the examination known as the “snowstorm” sign. Floating membranes within the cyst caused by detachment of the endocyst have been termed the “water-lily” sign.

Schistosomiasis may also affect the liver with the three most common species being *Schistosoma japonicum*, *Schistosoma haematobium*, and *Schistosoma mansoni*. Schistosomes live in the bowel and lay eggs in

mesenteric veins that embolize to the portal vein. Subsequent inflammation and even chronic granuloma formation and cirrhosis can occur. Calcification in periportal areas and along the hepatic capsule in the fibrotic liver gives rise to a “tortoise shell” appearance on CT. Left untreated, cirrhosis is common, and there is an increased risk of developing hepatocellular carcinoma.

Tuberculosis (TB) is fairly uncommon, but liver disease is seen in 80% to 90% of autopsy patients with disseminated pulmonary disease. In endemic populations, focal calcifications in the liver are commonly the result of healed granulomas or foci of prior TB, histoplasmosis, or other granulomatous disease (Table 50-2).

BENIGN LIVER TUMORS

Hepatic cysts are the most frequently encountered liver masses in imaging. True cysts are felt to arise from hamartomatous tissue and can be seen with autosomal dominant polycystic kidney disease (ADPKD). Rarely, multiple hepatic cysts can exist as a separate genetic entity isolated to the liver. In both of these conditions, the size and number of cysts generally progresses with time and can occasionally lead to hepatic dysfunction and symptoms requiring intervention and, rarely, transplantation. Some of the above-described infections can also present as predominantly cystic masses. Finally, congenital abnormalities such as Caroli disease or biliary hamartomas (von Meyenberg complexes) can result in numerous cystic masses.

Biliary cystadenoma is a potentially premalignant tumor, which can appear cystlike. It will generally present as a multiloculated cystic mass with septation and nodularity; the locules of fluid will contain varying amounts of debris and be of varying consistency. Contents may include blood products, bile, mucinous substances, or serous fluid. Differentiating biliary cystadenomas from simple cysts may be difficult, but true, simple cysts are typically of water density and have no septations, internal debris, peripheral or central enhancement, perceptible wall, or mural nodularity.

HEMANGIOMA

The most common benign solid liver mass is the cavernous hemangioma. These may be multiple in up to 50% of cases and are rarely associated with calcification. Typical hemangiomas are 2 to 10 cm in size and demonstrate early, peripheral, nodular, discontinuous enhancement with centripetal filling on delayed imaging. Because these lesions reflect vascular filling, they also have virtually identical attenuation to the blood attenuation at all phases. Therefore, a lesion with “washed out” attenuation lower than the hepatic veins does not represent hemangioma.

This tumor is also typically hyperintense on T2-weighted images. On US, hemangiomas are classically well-defined homogeneous echogenic lesions with no significant Color Doppler flow. It occasionally demonstrates acoustic enhancement. In the background of hepatic steatosis, the echogenic texture of hemangioma is difficult to recognize. Tc-99m-labeled RBC scan with SPECT shows a focal defect or less uptake on early dynamic scan and persistent filling over 30 to 50 minutes on delayed scans.

FOCAL NODULAR HYPERPLASIA

Focal nodular hyperplasia (FNH) is also a common benign neoplasm of the liver, reported in 3% to 5% of the population and usually discovered incidentally in young women. Because of its association with other benign vascular neoplasms, many believe that FNH is caused by a “hyperplastic response to a localized vascular abnormality.” On contrast-enhanced imaging, FNH is homogeneously hyperattenuating in the arterial phase and isoattenuating to liver on delayed and unenhanced phases. In lesions larger than 3 cm, 65% will have a fibrous central scar that is initially hypoattenuating and subsequently enhances on 5 to 10 minutes delay series. The central scar is usually hyperintense on T2-weighted images. Because FNH has Kupffer cells, there is normal or increased uptake on Tc-99m-sulfur colloid scanning. There is also prolonged

enhancement in roughly 80% on Tc-99m-HIDA imaging because of the presence of bile ductules. Septations radiating from the central scar to the periphery of the lesion are common and can result in surface nodularity. Multiple lesions have been reported in up to 25% of cases.

HEPATIC ADENOMA

Hepatic adenoma is a fairly uncommon benign liver tumor most often seen in young women with a history of oral contraceptive use. Another group of patients who may have hepatic adenomas are those with type I glycogen storage disease. Anabolic androgenic steroids also increase the risk of adenoma development. The classic clinical manifestation of the tumor is rupture or hemorrhage resulting in acute onset of pain or, rarely, even death because of exsanguination. Unlike FNH, adenomas have only a few, nonfunctioning Kupffer cells and no bile ductules. Therefore, there is often absent or reduced uptake on Tc-99m-sulfur colloid scanning. Adenomas do contain large hepatocytes, glycogen, and lipid. This can manifest as macroscopic fat on occasion. The presence of hemorrhage can complicate imaging diagnosis. Adenomas, particularly small ones, are usually hyperattenuating compared to normal liver on CT and demonstrate rapid homogeneous enhancement. On MR and CT imaging, particularly of larger lesions, there is often heterogeneity. On MRI, heterogeneity may appear on both T1- and T2-weighted images because of the presence of old or new blood products, microscopic or macroscopic fat, cystic spaces, and occasionally calcification. Adenomas have also been reported to undergo malignant transformation to hepatocellular carcinoma.

HEPATIC ANGIOMYOLIPOMA

Hepatic angiomyolipoma is a rare benign lesion with macroscopic fat and is usually seen in patients with tuberous sclerosis. There is a marked female predominance for this lesion (Table 50-3).

TABLE 50-3 Cross-Sectional Imaging Characteristics of Benign Hepatic Lesions

HEPATIC HEMANGIOMA	FOCAL NODULAR HYPERPLASIA	HEPATIC ADENOMA	BILIARY CYSTADENOMA (PREMALIGNANT)	HEPATIC ANGIOMYOLIPOMA
Early, peripheral, nodular, discontinuous enhancement and subsequent centripetal filling	Homogeneous early enhancement	Hemorrhage	Rare	Female > Males
	Delayed enhancement of central scar	Higher attenuation than liver	Multilocular cystic lesion	Rare gross macroscopic fat
	Central scar T2 hyperintense	Occasional fat content		Multiple in patients with tuberous sclerosis
		Rapid homogeneous enhancement		

MALIGNANT LIVER TUMORS

HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) is the most common primary malignant tumor of the liver. Worldwide, it is the eighth most common malignancy. There is an increased incidence in the Far East, Southeast Asia, and sub-Saharan Africa, and it continues to increase in the US. Risk factors include hepatitis B and C, toxins, certain medications, and other chronic liver diseases. The most common sites of metastatic disease include regional lymph nodes, lung, and skeleton. Imaging is important in the detection of HCC because symptoms of the disease are often masked by the chronic conditions leading to the malignancy. Various methods of surveillance are used to monitor patients at risk for HCC, but even the best tests detect only about 70% of cases. HCC can appear as a solitary mass, multiple nodules, or be diffusely infiltrative. The most common appearance on US is that of a hypoechoic mass, but US is not as sensitive as contrast-enhanced MR or CT. On contrast-enhanced, cross-sectional imaging, HCC enhances maximally during the hepatic arterial phase. Classically, in the portal venous phase of imaging, the tumor will be hypoattenuating to normal hepatic parenchyma. Sometimes, lesions are only clearly visible as hypoattenuating lesions on delayed phase. HCC has a broad range of appearances. With MR imaging, the most important sequences for the diagnosis of HCC are the dynamic gadolinium-enhanced images. Usually, the tumors are hypointense on T1 pre-contrast and slightly hyperintense on T2-weighted images. Hepatocellular carcinoma is also well-known to invade the portal venous system with “enhancing” thrombus.

FIBROLAMELLAR HEPATOCELLULAR CARCINOMA

Fibrolamellar hepatocellular carcinoma is an uncommon hepatocellular malignancy different from classic HCC. This is a slow-growing tumor that occurs in an otherwise normal liver in younger patients. It most often presents as large lobulated hepatic mass with a central scar. An important differentiating feature from benign lesions such as FNH is the appearance of the central scar on MR imaging; it is hypointense on T2-weighted sequences. Another feature is lack of enhancement of the central scar on delayed contrast-enhanced series with either CT or MR. Calcifications, necrosis, and a more disorganized appearance than hepatic adenoma or FNH are common.

INTRAHEPATIC CHOLANGIOCARCINOMA

Intrahepatic or peripheral cholangiocarcinoma has a poor prognosis and is most often seen in patients aging from

50 to 60 years. Contributing factors to the development of this tumor include primary sclerosing cholangitis, other forms of chronic or recurrent cholangitis (including parasitic disease), congenital cystic disease of the liver, and prior thorotrast administration. On contrast-enhanced imaging, the classic appearance of cholangiocarcinoma is that of a diffusely infiltrative tumor with associated capsular retraction. However, it may appear as ill-defined hypoattenuating lesion that may cause intrahepatic biliary obstruction. Delayed enhancement 10 to 20 minutes after the administration of intravenous contrast material is associated with cholangiocarcinoma, related to late enhancement of the fibrous component. However, this finding is seen in a minority of cases.

ANGIOSARCOMA, EPITHELIOID HEMANGIOENDOTHELIOMA, AND LYMPHOMA

Primary hepatic angiosarcoma and epithelioid hemangioendothelioma are rare tumors. Angiosarcoma is aggressive and has been linked to environmental and industrial toxins. These tumors contain numerous vascular spaces and may demonstrate peripheral or unusual enhancement patterns that progress with delayed enhanced series.

Epithelioid hemangioendothelioma is a low-grade primary vascular hepatic malignancy. It may demonstrate targetlike enhancement with nonenhancing center, enhancing tissue surrounding the center, and avascular peripheral zone. This should not be confused with infantile hemangioendothelioma. In contradistinction to that disease, epithelioid hemangioendothelioma is a disease of adults (average age 45 years), primarily women.

While primary hepatic lymphoma is rare, secondary lymphoma in the liver is much more common, especially in the setting of HIV disease. Both are typically hypoattenuating on CT without significant enhancement on contrast studies. Both are usually hypointense on T1-weighted images and hyperintense on T2-weighted images. Hepatic involvement with lymphoma typically enlarges the liver because of diffuse infiltration. However, discrete masses may occasionally be seen (Table 50-4).

HEPATIC METASTASES

Metastases to the liver far outnumber primary hepatic malignancies. This may be secondary to the dual blood supply, but is also likely related to the presence of humoral factors, which promote cell growth. Metastases to the liver can originate virtually anywhere in the body but most commonly arise from the colon, stomach, pancreas, breast, and lung. Renal cell carcinoma metastases

TABLE 50-4 Primary Hepatic Malignancies

HEPATOCELLULAR CARCINOMA	FIBROLAMELLAR HEPATOCELLULAR CARCINOMA	INTRAHEPATIC CHOLANGIOCARCINOMA
Early enhancing tumor	No enhancement of central scar	Infiltrative tumor
Portal vein invasion	Low T2 signal in central scar	Occasional delayed enhancement (5–20 min)

and metastatic melanoma are also relatively common in the liver. Some metastases are vascular and have fairly avid enhancement on contrast imaging. These include metastases from breast and renal carcinoma, islet cell tumor, carcinoid, melanoma, choriocarcinoma, thyroid carcinoma, pheochromocytoma, and sarcomas. Many metastatic lesions in the liver are hypovascular on imaging. These are some of the most common metastatic tumors to the liver including lung cancer, gastrointestinal adenocarcinomas, and some ovarian malignancies. However, although these are typical patterns, some commonly hypervascular lesions may be hypoenhancing and vice versa. Other metastatic lesions in the liver may be classified according to features such as calcification or a cystic appearance.

Large metastases tend to outgrow their blood supply and will present with regions of central necrosis. Other metastatic lesions may incite a fibrous or sclerosing reaction around tumor acini leading to scar formation; these include breast and pancreatic metastases. Patients with widespread liver metastases from breast cancer, which respond to treatment, may develop an appearance of “pseudocirrhosis” secondary to the fibrotic reaction. These patients can develop portal venous hypertension and secondary associated findings.

Imaging features of metastases to the liver are often nonspecific. With US, a hypoechoic halo around a well-defined lesion is usually indicative of aggressive behavior. With any modality, the appearance of metastatic lesions will vary depending on the presence or absence of enhancement, cystic regions, calcifications, and necrosis. Posttreatment-related changes are also quite variable. With the advent of some recent chemotherapy

agents, such as Gleevec used for gastrointestinal stromal tumors, some metastatic lesions may necrose quickly and develop a cystic appearance (Table 50-5).

MISCELLANEOUS DISEASES/ CONDITIONS OF THE LIVER

CIRRHOSIS

Cirrhosis is a chronic liver disease resulting from damage to hepatocytes and subsequent regenerative nodule formation, fibrosis, parenchymal necrosis, and often fatty change. Because cirrhosis is the end-stage of chronic hepatocyte injury, its causes are numerous. Exposure to toxic agents including ethanol, chronic viral hepatitis, nonalcoholic steatohepatitis (NASH), other chronic infection, autoimmune disease, and hemochromatosis are some of the causes of hepatic cirrhosis.

Because of the unusual vascular supply of the liver previously described, one of the gross morphologic features of cirrhosis is relative enlargement of the lateral segment of the left hepatic lobe and caudate lobe. This is felt to be on the basis of regenerative change rather than solely on the basis of fibrosis of the right hepatic lobe and medial segment of the left hepatic lobe. The caudate-to-right-lobe ratio is a reasonably sensitive indicator of cirrhosis. A ratio of a horizontal line extending from the medial edge of the caudate lobe to the lateral aspect of the bifurcation of the right portal vein is divided by the distance from the latter point to the lateral extent of the right lobe. A value greater than 0.9 should lead to the suspicion of cirrhosis. Worthy of note,

TABLE 50-5 Classification of Hepatic Metastases

VASCULAR METASTASES	HYPOVASCULAR METASTASES	CALCIFIED METASTASES	CYSTIC METASTASES
Breast	Lung	Mucinous adenocarcinoma	Mucinous adenocarcinoma
Renal	GI adenocarcinoma	Leiomyosarcoma	Serous adenocarcinoma
Islet cell	GI stromal tumor	Carcinoid	<i>Any rapidly growing tumor with cystic degeneration including</i>
Carcinoid	Some ovarian	Endocrine pancreas	Sarcomas
Melanoma	Some pancreas	Medullary thyroid	Neuroendocrine
Choriocarcinoma		Osteosarcoma	Melanoma
Thyroid		Neuroblastoma	Some lung
Pheochromocytoma		Renal cell carcinoma	Some breast
Sarcomas		Testicular	
		Lung	
		Treated carcinoma	

cirrhosis associated with Budd-Chiari or hepatic veno-occlusive disease is associated with a massively enlarged caudate lobe, which is occasionally confused with neoplasm.

On US, CT, and MRI, the contour of the liver is nodular in patients with cirrhosis. As the disease progresses and fibrosis predominates, vascular flow in the liver changes. Portal hypertension develops and is often manifested by a large main portal vein, splanchic collaterals, and enlargement of the spleen. Flow in the portal vein slows and eventually reverses. When there is portal thrombosis, numerous collaterals may form in the porta hepatis and are referred to as cavernous transformation. Hepatic arteries slowly enlarge and become tortuous. Hepatic venous flow, usually triphasic, becomes monophasic as the “stiffness” of the liver increases. Because of the portal hypertension, spontaneous portosystemic shunts may occur. Iatrogenic shunts (TIPS) or surgical portacaval or splenorenal shunts may be created to reduce portal hypertension and help control secondary features such as variceal bleeding and recalcitrant ascites.

Other secondary effects of portal hypertension include increased thickness of the walls of the stomach and bowel and mesenteric edema. This can affect bowel motility and function and result in the so-called portal enteropathy. The progressive loss of liver function can result in a host of abnormalities in the patient including decreased serum protein synthesis, decreased coagulant synthesis, and inability to metabolize and/or catabolize toxins.

Imaging of patients with cirrhosis is often performed to screen for hepatocellular carcinoma for which these patients are at increased risk. Imaging is also used to evaluate the primary and secondary effects of cirrhosis on the liver and mesenteric vasculature. US with Doppler can evaluate intra- and extrahepatic vasculature to monitor disease progression. US, CT, and MR can also define the presence of varices, spontaneous shunts, ascites, portal enteropathy, and other secondary features. Contrast-enhanced series are important to screen for HCC for reasons delineated in the section concerning this malignancy. Pre- and postcontrast series are also useful to help distinguish siderotic regenerative nodules that contain increased amounts of iron and are hyperattenuating on noncontrast CT and hypointense on T1- and T2-weighted MR sequences. Siderotic nodules in the spleen are referred to as Gamna Gandy bodies and are markedly hypointense on MR imaging.

HEPATIC STEATOSIS

Fatty liver is commonly encountered in imaging. It ranges from diffuse to focal and can be associated with a number of disease conditions or represent an isolated

abnormality. Fatty liver or steatosis is characterized by the presence of triglyceride accumulation in the cytoplasm of hepatocytes. Fatty liver is seen in alcoholic liver disease and insulin resistance most commonly. It is also seen with obesity, hyperlipidemia, viral infection, drug use including chemotherapeutic agents, surgery, metabolic disorders including storage disorders, and many other conditions.

On US, fatty liver is manifest by increased echogenicity exceeding that of the spleen and renal cortex. There is decreased penetration of the sound beam and poor definition of intrahepatic architecture. On unenhanced CT, fatty liver can be diagnosed if attenuation of the liver is at least 10 HU less than that of the spleen or if the absolute attenuation is less than 40 HU. With MR imaging, fatty liver is manifest by signal loss on opposed-phase imaging compared with in-phase images. A variant of fatty infiltration of liver is focal or geographic rather than diffuse. Small foci of fatty infiltration are commonly seen adjacent to the falciform ligament, porta hepatis, and in the gallbladder fossa. However, these are secondary to common anomalies of embryologic vascular supply to these areas and do not reflect an abnormal condition. Atypical forms of fatty infiltration can be distinguished from mass lesions by the lack of mass effect on vessels, geographic configuration, and normal enhancement.

BUDD-CHIARI SYNDROME

This syndrome is an unusual condition, representing the result of hepatic venous outflow obstruction at any level, regardless of the cause of obstruction. It is referred to as primary when venous outflow obstruction is the result of an endoluminal venous lesion such as thrombus. It is referred to as secondary when obstruction is either extravascular or related to substance in the lumen of the vessel not originating from the venous system. Budd-Chiari syndrome is more common in women.

Acute, the disease is manifest by decreased enhancement of the hepatic periphery and increased central enhancement (specifically the caudate lobe). Large ascites is common. In the more chronic setting, portosystemic and intrahepatic collaterals are noted. Intrahepatic collaterals have been described as “comma-shaped” on US and MR imaging. On US with Doppler, vascular flow may mimic that seen with cirrhosis; that is, monophasic or no flow in hepatic veins and slow hepatofugal flow in the portal vein. Regenerative nodules in Budd-Chiari are typically large, differentiating themselves from the small nodules associated with alcoholic cirrhosis. Angiographic finding with venacavography is that of a “spiderweb” pattern of collateral vessels, which is pathognomonic.

TABLE 50-6 Diffuse Hepatic Diseases

CIRRHOSIS	STEATOSIS	BUDD-CHIARI	HEMACHROMATOSIS
Nodular contour	10 HU less than the spleen on noncontrast CT	Early decreased peripheral enhancement and increased central and caudate enhancement	Early primary disease manifest by low signal in the liver on MR
Caudate and lateral segment left hepatic lobe enlargement	Absolute HU value less than 40	Intrahepatic comma-shaped collateral vessels	Secondary disease manifest by low signal in the liver and spleen on MR
Right hepatic lobe and medial segment left hepatic lobe fibrosis	Loss of signal on opposed phase MR		Increased attenuation of liver on unenhanced CT (up to 75–135 HU; normal liver is 45–65 HU)
Widening of fissures	Increased echogenicity > spleen or renal cortex on US		

HEMOCHROMATOSIS

Primary hemochromatosis is an autosomal recessive disease of iron metabolism affecting men much more commonly than women. There is increased intestinal absorption of iron and subsequent deposition in the liver, pancreas, myocardium, endocrine glands, joints, and skin. Secondary hemochromatosis is the result of reticuloendothelial deposition of iron in patients who require numerous blood transfusions, have increased iron intake, or have chronic liver disease and/or portacaval shunts. Important imaging characteristics include increased attenuation of the liver on unenhanced CT (up to 75–135 HU, when it is usually 45–65 HU). On MR, with early primary disease, there is signal loss in the liver. With secondary disease, there is signal loss in the liver and spleen. T2*GRE may be the most sensitive MR sequence for the disease (Table 50-6).

QUESTIONS AND ANSWERS

- Which of the following is *true* regarding contrast-enhanced MR imaging of fibrolamellar hepatocellular carcinoma?
 - Central scar is T1 hyperintense and enhances on delayed postgadolinium sequences.
 - Central scar is T2 hypointense and does not enhance.
 - Central scar is T2 hyperintense and enhance.
 - Central scar is T1 hypointense and does not enhance.

ANSWER: B. In fibrolamellar hepatocellular carcinoma, the central scar is hypointense on T2 and does not enhance on delayed postgadolinium sequences. In FNH, if there is a central scar, it will be hyperintense on T2-weighted images and does typically enhance on delayed postgadolinium sequences.

- Which of the following conditions increases risk for hepatic adenomas?
 - von Hippel-Lindau disease
 - Hereditary hemorrhagic telangiectasia syndrome

- C. Type I glycogen storage disease
- D. Multiple endocrine neoplasia IIa

ANSWER: C. Patients with type I glycogen storage disease may have multiple hepatic adenomas.

3. The presence of which of the following imaging features is suggestive of hepatic amoebic abscess in patients with an appropriate clinical history?
 - A. The “water-lily” sign
 - B. Hepatic artery thrombosis
 - C. Capsular retraction
 - D. Extrahepatic extension

ANSWER: D. Extrahepatic extension can be seen with amoebic abscess and can be a helpful distinguishing feature from pyogenic or other abscess. “Water-lily” sign is secondary to floating membranes within the hydatid cysts.

4. Which of the following is an imaging feature suggestive of focal nodular hyperplasia (FNH)?
 - A. Intratumoral hemorrhage
 - B. Delayed activity on Tc-99m-HIDA scan
 - C. “Cold spot” on Tc-99m-sulfur colloid scan
 - D. Hyperintense on T1 because of the presence of fat

ANSWER: B. Delayed activity in a lesion on Tc-99m-HIDA scan is suggestive of FNH because of the presence of bile ductules in the mass.

5. A large infiltrative hepatic mass demonstrating early enhancement and portal vein invasion is most consistent with which of the following?
 - A. Cholangiocarcinoma
 - B. Biliary cystadenoma
 - C. Primary hepatic lymphoma
 - D. Hepatocellular carcinoma

ANSWER: D. While hepatocellular carcinoma can have a varied appearance, it does usually show early (arterial) enhancement and can be associated with portal vein invasion.

6. What portion of the liver is not covered by visceral peritoneum?
 - A. Porta hepatis, caudal right hepatic lobe, and the bare area
 - B. Bare area, porta hepatis, and the gallbladder bed
 - C. Bare area, hepatic dome, and lateral segment
 - D. Porta hepatis, hepatic dome, and gallbladder bed

ANSWER: B. The adult liver is covered by visceral peritoneum except at the bare area, the porta hepatis, and the gallbladder bed.

7. Concerning MR imaging features (with T2-weighting) of primary and secondary hemochromatosis, which of the following is *true*?

- A. Liver and spleen are hypointense in early primary hemochromatosis.
- B. Liver is hyperintense in secondary hemochromatosis.
- C. Liver and spleen are hypointense in secondary hemochromatosis.
- D. Spleen is hypointense in early primary hemochromatosis.

ANSWER: C. In early primary hemochromatosis, the liver is hypointense. In secondary hemochromatosis, both the liver and spleen are hypointense on T2.

8. All of the following are considered vascular metastases on liver imaging, *except*:
 - A. Choriocarcinoma
 - B. Pheochromocytoma
 - C. Renal cell carcinoma
 - D. Lung carcinoma

ANSWER: D. Lung carcinoma is usually associated with hypovascular metastases to the liver.

9. Which of the following is the most common primary hepatic malignancy in children?
 - A. Hepatocellular carcinoma
 - B. Neuroblastoma
 - C. Hepatoblastoma
 - D. Infantile hemangioendothelioma

ANSWER: C. Hepatoblastoma is the most common primary hepatic malignancy in children.

10. A solitary infiltrative hepatic mass demonstrates capsular retraction and delayed enhancement on contrast-enhanced CT. What is the most likely diagnosis.
 - A. Metastatic thyroid carcinoma
 - B. Atypical siderotic nodule
 - C. Hepatocellular adenoma
 - D. Peripheral cholangiocarcinoma

ANSWER: D. Peripheral cholangiocarcinoma.

51 BILIARY SYSTEM

Desiree E. Morgan

NORMAL ANATOMY AND CONGENITAL ABNORMALITIES

The biliary system arises from the hepatic diverticulum on the ventral aspect of the developing gut in the embryo. In general, the intrahepatic bile ducts run parallel

to the portal veins within the liver. The right hepatic duct drains segments 5 through 8 and has two major branches, the posterior duct that drains segments 6 and 7, and the anterior duct that drains segments 5 and 8. The left hepatic duct is formed from segments 2 through 4. The common hepatic duct (CHD) is formed by the confluence of the right and left hepatic ducts, and the cystic duct joins the common hepatic duct (CHD) to form the common bile duct (CBD). Approximately 60% of individuals have this “normal” biliary anatomy. The most common anomalous drainage of the biliary system is drainage of the right posterior duct into the left hepatic duct above its confluence with the right anterior duct. Another common variant is a triple confluence of simultaneous emptying of the right posterior duct, right anterior duct, and left hepatic duct to form the CHD.

The gallbladder is the repository for bile produced in the liver. The gallbladder is composed of the fundus, usually projecting below the inferior border of the liver, the body, and the neck. Typically measuring 2.5 cm in width and 7 to 10 cm in length, normal gallbladder wall thickness is less than 3 mm and the average volume of the gallbladder is 30 to 50 mL. When a patient is fasting, there is concentration of bile in the gallbladder. On MRI, during fasting, the concentration of cholesterol and bile salts increases, leading to shortened T1 relaxation time and brighter signal on T1-weighted images, often with a layered appearance.

Cystic duct insertion into the CHD may also vary, with the most common variants being a low cystic duct insertion (9%), medial cystic duct insertion (10%–17%), or common channel for greater than 2 cm (up to 25%). Small ducts from the hepatic parenchyma (ducts of Luschka) may empty directly into the gallbladder lumen. In general, there may be an increased incidence of bile duct variant configurations in patients who also have portal vein variation.

Anomalous biliary pancreatic duct union occurs when there is fusion of the main pancreatic duct and CBD outside the duodenal wall, with a long common channel (greater than 15 mm) from the papillary orifice to the branch point. In anomalous biliary pancreatic duct union, the bile duct inserts at a 90-degree angle onto the pancreatic duct. This may allow reflux of pancreatic secretions into the biliary system. This anomaly is associated with choledochal web or choledochal cyst (Todani type 1).

Choledochal cysts are rare congenital anomalies of the biliary tree characterized by varying configurations and distribution of duct dilatation. Most choledochal cysts are diagnosed in childhood, however up to 20% of patients will not present until adulthood. The most common clinical presentation of a patient with a choledochal cyst is the constellation of abdominal pain, right upper quadrant mass, and jaundice. The Todani classification is used to discuss the varying types of cysts (Table 51-1).

TABLE 51-1 Todani Classification of Choledochal Cysts

Type I	Extrahepatic bile duct
Type Ia	Diffuse cyst formation along the extrahepatic duct
Type Ib	Focal cyst along the extrahepatic bile duct
Type Ic	Fusiform dilation of the extrahepatic bile duct (80%–90% of cases)
Type II	True diverticulum of the extrahepatic bile duct
Type III	Focal dilation of the common bile within the intramural portion of the duodenum; may be associated with biliary colic or pancreatitis (choledochocele)
Type IV	Multiple cysts
Type IVa	Involving both extra- and intrahepatic bile ducts
Type IVb	Which involves only the extrahepatic bile ducts with multiple sacculations
Type V	Dilatation of the intrahepatic bile ducts (Caroli disease)

Type V (Caroli disease) involves a defect in the embryonic plate that results in varying levels of intrahepatic bile cyst formation versus hepatic fibrosis. When both are present, the condition is known as Caroli syndrome, and it is inherited by an autosomal recessive pathway. One imaging feature of Caroli disease is the “central dot sign,” representing a portal vein branch surrounded by cystic dilation of the intrahepatic bile duct. Patients with Caroli disease may have intraluminal biliary calculi.

STONE DISEASE

Bile may become supersaturated with cholesterol leading to crystal deposition and gallstone formation. Cholesterol stones account for approximately 80% of all gallstones present in the US population. Cholesterol stones are composed of at least 50% cholesterol. Pigment stones on the other hand contain lesser amounts of cholesterol and higher percentages of calcium bilirubinate and glycoproteins. Because of their different makeup, gallstones may be distinguished on MR imaging. Pigmented stones are hypointense on T2-weighted sequences and have increased signal intensity on T1-weighted images, whereas cholesterol stones tend to be hypointense on both T1- and T2-weighted images. Gallstones are found in about 10% of the general population, are twice as common in women as in men, and become more prevalent with increasing age. Risk factors include pregnancy, estrogens, obesity, and rapid weight loss. Most patients with cholelithiasis, however, remain asymptomatic throughout life.

INFLAMMATION

Acute cholecystitis is the most common acute complication of gallstone disease, with clinical presentation

characterized by right upper quadrant abdominal pain, fever, and elevated white cell count. In most cases (90%), the cause of acute cholecystitis is impaction of a gallstone in the gallbladder neck region or cystic duct with obstruction. Ultrasound is the modality of choice for diagnosing acute cholecystitis, with findings described in other chapters. Because sonographic evaluation may be limited in patients with a large body habitus, CT and MRI are being utilized more frequently to evaluate patients with equivocal findings or suboptimal ultrasound examinations. On MRI, the gallbladder wall may show increased signal intensity and thickening, edema of the adjacent liver tissue, and pericholecystic fluid. The signal intensity of bile in the setting of acute cholecystitis is variable because of an inflammation-related increase in bile protein. However, signal within bile is usually markedly hypointense on T1-weighted images because of impairment of gallbladder concentrating ability in the acutely inflamed state. On intravenous, gadolinium-contrast-enhanced, fat-suppressed T1-weighted images, enhancement of the gallbladder wall, adjacent fat, and surrounding hepatic parenchyma may be noted. When there is patchy enhancement of gallbladder mucosa, this is referred to as the “interrupted rim sign” and represents areas of necrosis in gangrenous acute cholecystitis. Other findings of gangrenous cholecystitis on MRI include asymmetric gallbladder wall thickening, intramural hemorrhage, and complex pericholecystic fluid. These latter findings may also be seen on contrast-enhanced CT in patients with acute cholecystitis.

Mirizzi syndrome, defined as impaction of a gallstone within the gallbladder neck or cystic duct leading to extrinsic CHD compression and biliary obstruction, may occur in patients with an intact gallbladder or in patients after cholecystectomy, when there is a stone lodged within the cystic duct remnant. Magnetic resonance cholangiopancreatography (MRCP) is particularly helpful in this condition as it can noninvasively identify the impacted gallstone in the cystic duct or gallbladder neck, the upstream biliary dilation, and the configuration of the cystic duct insertion into the CHD. Patients with low insertion of the cystic duct or long parallel cystic and CHD channels are at increased risk for this condition.

Approximately 10% of patients with acute cholecystitis have no stones. This condition is known as acute acalculus cholecystitis, is usually seen in more acutely ill patients, and carries a higher morbidity and mortality than typical gallstone-induced acute cholecystitis.

Emphysematous cholecystitis is caused by gas-forming bacteria that infect the gallbladder wall, is typically seen in diabetic patients, and is usually not associated with gallstones. Ischemia caused by cystic artery atherosclerosis may also produce emphysematous cholecystitis.

Chronic cholecystitis is invariably associated with gallstones and is the most common form of the symptomatic gallbladder disease. Typically, the gallbladder is small and contracted, with irregular and thickened walls. Presenting symptoms are vague upper abdominal pain. The diagnosis is usually confirmed using a physiologic test such as HIDA scan.

Xanthogranulomatous cholecystitis is an uncommon inflammatory disease of the gallbladder characterized by focal or diffuse inflammation of the gallbladder wall by foamy histiocytes or xanthoma cells admixed with fibrosis. It is hypothesized that this condition results from cystic duct obstruction leading to mucosal injury, macrophage recruitment, and subsequent phagocytosis of insoluble bile lipids and cholesterol which in turn leads to lipogranuloma formation and fibrosis. Most patients have gallstones and many are diabetic. The inflammatory process may extend to the adjacent colon and duodenum with fistula or abscess formation. On imaging, this condition may resemble gallbladder carcinoma with focal or diffuse wall thickening, heterogeneous enhancement, and intramural nodules. On MRI, the intramural nodules have markedly elevated T2 signal intensity. This may help distinguish this condition from gallbladder carcinoma.

Acute cholangitis is a life-threatening complication of incomplete biliary obstruction. Human bile is normally sterile, but may become infected in the presence of gallbladder and/or CBD stones with ascending infection. The triad of jaundice, fever, and right upper quadrant pain, originally described by Charcot, is the classic presentation of cholangitis; however, this constellation of symptoms usually occurs late in the disease. In most patients, biliary sepsis resolves with conservative treatment including fluid resuscitation and administration of broad-spectrum antibiotics (gram-positive and gram-negative organism coverage). The spectrum of bacteria varies between reported series (depending on underlying etiologies and practice profile of the reporting center), but in patients with choledocholithiasis, the most frequent organisms are gram-negative: *Escherichia coli*, *Klebsiella*, *Proteus*, and *Pseudomonas aeruginosa*. Fungal infections are more prevalent in patients who have had previous biliary surgery or nonoperative (endoscopic/radiological) biliary interventions. Those patients with cholangitis who do not respond to conservative therapy require biliary decompression, usually performed endoscopically with endoscopic papillotomy with or without stone extraction, and placement of biliary stents. When patients are extremely ill, stent placement without stone removal is preferred, as excessive manipulation in attempts to remove large stones may result in worsened septicemia. Patients not responding to endoscopic biliary drainage and appropriate antibiotics should be investigated for malfunction

of the biliary drainage system (stent occlusion or migration), associated gallbladder empyema, associated cholangitic abscesses, or additional undrained hepatic segments. When endoscopic drainage fails, or if the cholangitis is because of intrahepatic stones or hilar cholangiocarcinoma, transhepatic biliary drainage is indicated. Whatever method of drainage is used, injection of contrast medium under pressure should be avoided as much as possible, as this may lead to cholangio-venous reflux and exacerbation of septicemia as well. Identification of the underlying cause and level of biliary obstruction with multidetector CT or MRCP is important, with definitive treatment attempted after the patients respond to initial antibiotics or biliary decompression. Choledocholithiasis remains the commonest cause of cholangitis.

Oriental cholangiohepatitis, also known as recurrent pyogenic cholangitis, is most commonly seen among patients from Southeast Asia and is associated with bacterial infection and intrahepatic stones. Endoscopic decompression is less successful in this clinical scenario, and often, surgical drainage is required.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease of unknown etiology that is characterized by progressive inflammation and fibrosis of the bile ducts. It appears to be caused by complex interaction between deregulated immune mechanisms in genetically predisposed individuals, also potentially affected by environmental factors and infectious agents. The disease often results in secondary biliary cirrhosis and is associated with a high risk of cholangiocarcinoma. Most patients are young (mean age 40 years) at the age of diagnosis and there is a male-to-female predominance. Concomitant inflammatory bowel disease may be found in 62% to 72% of patients. Ulcerative colitis is much more common (80%), however there is an association with Crohn disease in up to 14% of all PSC patients. Conversely, up to 4% of patients with inflammatory bowel disease have PSC. Clinically, these patients are often asymptomatic at presentation with isolated biliary enzyme abnormalities; over time, they suffer from recurrent episodes of cholangitis with jaundice, pruritus, and fever, resulting ultimately in end-stage liver disease. The main causes of death in patients with PSC are cholangiocarcinoma and liver failure. Liver transplantation is the only therapeutic option with a cure potential.

PSC is a disease mainly of large bile ducts. On imaging, patients with PSC have characteristic localized or multifocal strictures of the intra- and/or extrahepatic bile ducts, with intervening segments of normal or dilated ducts. Short segment strictures, pseudosacculation, and serrated bile duct margins are best depicted with cholan-

giography. While endoscopic retrograde cholangiography (ERC) is the goal standard for visualization of duct abnormalities in patients with PSC, MRC has a high sensitivity and specificity, with the added advantage of visualizing bile ducts proximal to points of complete bile duct obstruction. Conversely, because of inferior spatial resolution, areas of marked stenoses may be mistaken for complete occlusion with MRC and wall irregularity overestimated.

Patients with small-bile-duct PSC present with similar biochemical and histologic features as typical PSC but have a normal cholangiogram. Formerly, this condition was known as “pericholangitis.” Only 3% to 17% of patients with small duct PSC disease or undergo liver transplantation, compared to 42% to 47% in patients with typical large duct PSC. Histologic findings in PSC include portal fibrosis (onionskin pattern), portal lymphocyte infiltration, and cirrhosis.

Cholangiocarcinoma may arise at any stage of PSC. The frequency of hepato biliary cancer in patients with PSC is 1.5% per year, corresponding to a 161-fold increased risk. Cholangiocarcinomas occur as mass lesions in the liver in 15% of patients, lesions in the distal CBD in 20% of patients, and tumors in the hilar region in 65% of PSC patients. Effective surveillance strategies for PSC patients are challenging. Tumor development may be heralded by elevation of CEA or CA-19-9. ERC alone has a low sensitivity and specificity to discriminate between benign and malignant bile duct stenoses in PSC patients; however, any increase in cholestasis should trigger ERC with brush cytology of suspicious strictures as this yields high specificity despite low sensitivity for cholangiocarcinoma detection.

Selecting the appropriate time for liver transplantation is difficult in patients with PSC, as even those with advanced destructive cholangiopathy may exhibit only mild signs of liver failure, based upon findings of portal hypertension or abnormal coagulation and hypoalbuminemia. The difficulty of screening the high-risk PSC patients for cholangiocarcinoma only compounds the transplant timing conundrum. Compared to patients with nonmalignant diseases, patients with PSC-associated cholangiocarcinoma have a worse prognosis after liver transplantation; thus, it is important to identify these cancers beforehand. In some centers, transplantation following neoadjuvant therapy has shown some benefit, but curative treatment is not possible in the majority of cases.

PRIMARY BILIARY CIRRHOSIS

Primary biliary cirrhosis is an autoimmune disease that results in destruction of small intralobular bile ducts and cholestasis. The cholestasis produces direct liver

injury, causing inflammation and necrosis and ultimately leading to progressive scarring and fibrosis. The condition primarily affects middle-aged women and most patients are asymptomatic at presentation. These asymptomatic patients are identified when routine health examinations reveal elevation of serum alkaline phosphatase (ALP), and gamma-glutamyl transpeptidase (GGT), total serum cholesterol, or positive antimitochondrial antibody (specifically subtype M2 AMA) titers. Occasionally (10%), patients with PBC are AMA negative and must distinguished from patients with other cholestatic liver pathologies (PSC, sarcoidosis, nonalcoholic fatty liver disease). Primary biliary cirrhosis may be associated with other autoimmune conditions as well as complications of cholestasis such as osteoporosis and hypercholesterolemia. Physical examination is generally normal but hepatomegaly may be present in 4% to 31% and splenomegaly in 5% to 25%. If symptomatic, patients most commonly complain of fatigue (11%–81%) and pruritus (18%–41%). The onset of pruritus typically precedes onset of jaundice, a finding that occurs only in the late stages of the disease. Diagnosis is confirmed with liver histology; the characteristic lesion of PBC is destruction of the intralobular bile ducts.

The role of imaging in patients with PBC is not to diagnose the disease, but to distinguish this cholestatic liver disease from others, particularly when the AMA is negative. MRC demonstrates normal bile ducts in early stages of disease helping to distinguish PBC from primary sclerosing cholangitis. In early stages, cross-sectional imaging may show only an enlarged liver with lacelike fibrosis and few regenerative nodules. Adenopathy, ascites, and varices may occasionally be present. In late stages, there is irregular dilation and a truncated appearance of the intrahepatic bile ducts on MRC or ERC, with normal extrahepatic bile ducts. CT and MRI findings in advanced PBC are similar to those seen in other forms of cirrhosis. On T2-weighted MRI, when parenchymal lacelike fibrosis and rounded, low signal intensity lesions surrounding portal vein branches (periportal halo sign) are seen together, the sensitivity for PBC detection is 69%; thus, the imaging findings may support the clinical and laboratory findings of PBC even in the early stages. Patients with PBC are at risk for developing hepatocellular carcinoma when the disease is advanced. In the past, the most common cause of death in patients with primary biliary cirrhosis was liver failure and PBC was a leading indication for liver transplantation, but now there is effective medical therapy using ursodeoxycholic acid. This is particularly effective when the patient is diagnosed with early stage disease and with this therapy, survival for patients with PBC may approach normal life span.

<i>Candida</i>
Other bowel pathogens

AIDS CHOLANGIOPATHY

AIDS cholangiopathy represents one of the hepatobiliary diseases in patients with AIDS. Clinical presentation includes fever, right upper quadrant pain, and marked elevation of serum ALP. Jaundice is usually absent. Many patients are asymptomatic or have only mild elevation of liver serum enzyme tests. As many as 30% of patients with chronic AIDS-related diarrhea have AIDS cholangiopathy. Infection of the biliary epithelium is the cause of ductal disease in most patients. *Cryptosporidium* is the single most common identifiable pathogen (Table 51-2).

These infections cause severe inflammatory changes resulting in an irregularly narrowed duct appearance. The most common imaging findings are intrahepatic and/or extrahepatic changes mimicking sclerosing cholangitis, often associated with papillary stenosis (50%–60% of patients). The left ductal system is disproportionately more severely involved. Focal strictures of the extrahepatic bile duct may be greater than 2 cm in length. This latter feature may help distinguish AIDS cholangiopathy from PSC as the extrahepatic strictures in PSC rarely exceed 4 to 5 mm. Another distinguishing feature is the absence of saccular deformities of the ducts, seen more commonly in PSC compared to AIDS cholangiopathy. Treatment of symptomatic patients with AIDS cholangiopathy consists of endoscopic papillotomy in those with papillary stenosis. While this often results in pain relief, the intrahepatic sclerosing cholangitis tends to progress after papillotomy and is associated with a further rise in serum ALP. If a patient has a dominant extrahepatic stricture, endoscopic stent placement may help, although risk of long-term bacterial infection is not known. Although AIDS cholangiopathy is infectious in etiology, medical therapies are not typically effective. The prognosis in patients with AIDS cholangiopathy is poor (median survival approximately 10 months), not because of the biliary inflammation but because opportunistic infection of the biliary tree occurs only in patients with severe immunodeficiency (CD4 counts less than 50/mm³).

Other diseases of the biliary tract in patients with AIDS include acalculous cholecystitis, lymphoma,

Kaposi sarcoma, and gallstones. The most common manifestation of gallbladder disease in an HIV-infected patient is acalculous cholecystitis. Gallstones may be the cause of cholecystitis in up to 25% of AIDS patients. Treatment for these gallbladder conditions is similar to that in patients with normal immunity.

PARASITIC DISEASE

The most common parasites affecting the biliary tree include *Clonorchis sinensis*, *Opisthorchis viverrini*, *Opisthorchis felinus*, and *Fasciola hepatica*. Patients are often asymptomatic unless they are heavily infected. In addition, *Ascaris lumbricoides* may migrate from the small bowel into the bile duct through the papilla, causing obstructive jaundice and biliary colic. The first three parasites are trematodes that vary in geographic distribution. All are flat, elongated worms ranging from 8 to 15 mm in length and may persist for 20 years or more within the medium-size and small intrahepatic bile ducts. Occasionally, they enter the extrahepatic duct, gallbladder, or pancreatic duct resulting in mechanical obstruction, inflammatory reaction, adenomatous hyperplasia, and periductal fibrosis. Adult flukes within the bile ducts are usually difficult to visualize sonographically or with CT, but are easily identified within the gallbladder. *F. hepatica* is a trematode that infects cattle and sheep but interacts with humans as an accidental host when there is ingestion of contaminated water or aquatic plants. The metacercariae penetrate the intestinal wall and migrate through the peritoneal cavity to the liver where they pass through Glisson's capsule and track through the liver parenchyma to enter the bile ducts and gallbladder. Adult flukes may measure 20 to 40 mm long and appear as clusters of microabscesses in subcapsular portions of the liver. Filling defects that represent the flukes may be identifiable on cholangiogram. *A. lumbricoides* adult worms are 15 to 30 cm long and if present in the biliary tree may produce obstruction, cholangitis, or pancreatitis. Sonographically, these flukes are nonshadowing echogenic tubular structures visible within the bile ducts.

OTHER CHRONIC CONDITIONS

Adenomyomatosis is a very common noninflammatory benign condition that is more often seen in women than men and clinically presents with right upper quadrant pain associated with gallstones. There is proliferation of surface epithelium with invagination through Rokitsky-Aschoff sinuses into the thickened tunica muscularis. When diffuse, the entire gallbladder wall is thickened

with luminal narrowing. Focal circumferential thickening in the midportion of the gallbladder is seen in the segmental form, producing an hourglass configuration. Localized adenomyomatosis is typically found in the fundus and may mimic an early gallbladder cancer. Dysplasia and carcinoma may arise from adenomyomatosis but this is usually related more to gallstones and chronic inflammation than the adenomyomatosis itself.

NEOPLASM

GALLBLADDER CARCINOMA

Gallbladder carcinoma is the most common biliary tree malignancy and is the fifth most common malignancy of the GI tract, with common risk factors being gallstones, chronic cholecystitis, porcelain gallbladder, and primary sclerosing cholangitis. There is a slight female-to-male predominance. Additional risk factors include choledochal cyst, anomalous biliary pancreatic duct union, and gallbladder polyps. Gallbladder cancers may be infiltrative, papillary, or colloid subtypes. Infiltrative forms more strongly associated with gallstones. Most gallbladder cancers originate in the fundus. Three patterns of presentation are seen with imaging: focal or diffuse wall thickening, intraluminal polypoid mass, or subhepatic mass replacing or obliterating gallbladder and invading the adjacent liver (Table 51-3).

The management of gallbladder carcinoma is surgical. Because the extent of surgery is determined by the extent of local tumor spread, accurate staging is important. The overall accuracy for MDCT in T-stage assessment is 83.9%; the addition of multiplanar reformations to the axial CT dataset improves accuracy. The most common imaging presentation of gallbladder cancer is a gallbladder fossa mass that is difficult to separate from the liver. Because there is no serosa at the attachment of the gallbladder to the liver, the connective tissue of the gallbladder is contiguous with that of the liver, providing a ready path of spread. When there is replacement of the gallbladder by tumor, the mass often appears centrally necrotic with

TABLE 51-3 Staging of Gallbladder Cancer

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades lamina propria or muscle layer
T2	Tumor made to a muscular connective tissue does not extend through the serosa or into liver
T3	Tumor perforates serosa, directly invades an adjacent organ, or both (extension into the liver less than 2 cm)
T4	Tumor extends more than 2 cm into the liver, or into to or greater adjacent organs

irregular contrast enhancement. If tumor invades the liver, resection of segments 4, 5, and 6, or the entire right lobe, or right lobe plus segment 4 may be necessary for complete resection. Contraindications to surgical resection include multiple bilobar liver, peritoneal, or distant metastatic disease. Portal vein occlusion or encasement, or involvement of left hepatic artery preclude resection attempt if the right hepatic lobe is involved. Partial colonic and duodenal resections may be employed for complete resection. Prognosis is poor, with less than 5% overall 5-year survival, and overall mean survival of 6 months.

CHOLANGIOCARCINOMA

The majority of cholangiocarcinomas arise from the epithelium of the bile ducts. The tumors may be located within the intrahepatic ducts, the perihilar region (Klatskin tumor), or the distal extrahepatic bile duct. Anatomically, the upper third of the extrahepatic biliary tree extends from the confluence of the hepatic ducts to the level of the cystic duct, the middle third extends from the cystic duct to the upper part of the duodenum, and the lower third extends from that level to the papilla. The reported distribution of bile duct tumors is approximately 55% in the upper third, 15% in the middle third, and 10% in the lower third. Of these tumors, 10% are diffuse. There is a slight male-to-female predominance (1.3–1) with patients presenting between 50 and 70 years of age. Risk factors include sclerosing cholangitis, choledochal cyst, Caroli disease, familial polyposis, congenital hepatic fibrosis, ulcerative colitis, parasitic infection, and biliary-enteric anastomosis.

The most common presenting symptoms in patients with hilar or extrahepatic cholangiocarcinoma are abdominal pain, jaundice, weight loss, and anorexia. There are three types of cholangiocarcinomas: mass forming, periductal infiltrating/sclerosing, and papillary intraductal. Mass-forming tumors typically involve the intrahepatic ducts, have central necrosis and fibrosis, and contain satellite nodules. In the periductal infiltrating/sclerosing type, the tumor tracks along the bile duct wall and produces mural thickening and stricturing, with a dense fibroblast reaction. Intraductal papillary cholangiocarcinomas presents as an intraluminal tumor with partial duct obstruction and upstream dilation. These may track along the mucosal surface, however, and affect several segmental ducts. One very unusual type of lesion is a papillary neoplasm that produces large amounts of mucin, which may obstruct biliary flow proximally and dilate the main duct down to the papilla (distal to the lesion).

On imaging, staging of cholangiocarcinomas is difficult and depends in part on the specific morphology

or lesion type. An intrahepatic cholangiocarcinoma is a poorly margined mass that has more prominent enhancement within viable portions of the tumor typically located in the periphery of the lesion, accompanied by central necrosis. Because of the presence of fibrous tissue, the central portions of the tumor enhance during images obtained at 10 minutes or greater delay on both CT and MRI. The dense fibrosis also causes hepatic capsular retraction, seen in up to 20% of cases. Hilar cholangiocarcinomas may present as a focal area of duct thickening, an intraductal mass, or an infiltrating mass. When they arise from the right or left intrahepatic duct, by the time of diagnosis, they tend to be large and have infiltrated the hepatic parenchyma. When located in the common hepatic or common bile duct, patients present earlier because of painless jaundice. Lobar atrophy and crowding of dilated intrahepatic ducts may be seen with cross-sectional imaging in approximately one-fourth of patients presenting with hilar lesions. Lymphatic metastases are most often to the portacaval and peripancreatic lymph nodes. The extent of tumor in the bile duct determines resectability and is categorized according to the Bismuth classification (Table 51-4).

Cholangiocarcinomas involving the distal CBD tend to have a better prognosis than more central tumors. With this type of lesion, MRC or ERC may demonstrate a short stricture and/or polypoid mass that mimics a pancreatic cancer and produces biliary obstruction.

Mimics of cholangiocarcinoma are protean, include those resembling a sclerosing cholangitis pattern such as AIDS cholangiopathy, autoimmune pancreatitis, PSC, chemotherapy-induced sclerosis, and recurrent pyogenic cholangitis and those that may present with focal disease such as xanthogranulomatous cholangitis, Mirizzi syndrome, sarcoidosis, hepatocellular carcinoma, metastases, lymphoma/leukemia, and primary carcinoid tumors. In patients with sclerosing cholangitis, accurate identification of cholangiocarcinoma is difficult. Differentiating benign from developing malignant strictures in PSC patients may be aided by the following observations that tend to occur in patients with malignant lesions: clinical deterioration, acute elevation of CA 19-9, increased bile duct dilation above a dominant stricture, or a polypoid ductal mass that measures 1 cm or greater.

TABLE 51-4 Bismuth Classification of Cholangiocarcinomas

Type I	Involvement of the common hepatic duct
Type II	Involvement of the bifurcation without involvement of the secondary intrahepatic ducts
Type IIIa	Extends into the right secondary intrahepatic duct
Type IIIb	Extends into the left secondary intrahepatic duct
Type IV	Involvement of the secondary intrahepatic ducts on both sides

OTHER NEOPLASMS

Biliary cystadenomas and cystadenocarcinomas are rare tumors of the biliary tree, which usually arise in the liver rather than the extrahepatic ducts. They are much more common in women and tend to occur in patients older than 30 years of age. Presenting symptoms are nonspecific, despite the tumors being large at presentation (most greater than 10 cm, range 3–25 cm). Like their counterpart in the pancreas, the mucinous cystic neoplasm, these lesions are most often multiloculated cystic masses containing internal septations and enhancing nodules. Unilocular lesions do occur and more frequently indicate a malignant cystadenocarcinoma rather than the benign cystadenoma. Both lesions should be resected, as cystadenocarcinomas are thought to arise from cystadenomas and the lesions cannot be reliably differentiated with imaging, biopsy, or even examination of the macroscopic specimens. Surgical resection is curative in most cases.

Periampullary tumors are described as those that arise within 2 cm of the papilla of Vater. These include ampullary, pancreatic, bile duct, and duodenal cancers; it may be difficult with imaging to determine the exact origin. Most patients with periampullary lesions present with biliary dilation extending to the ampulla, and identification of masses may be difficult to detect on CT. The most favorable resectability rates and survival occur in patients with distal cholangiocarcinomas (5-year overall survival 15%–28%) and periampullary tumors (5-year overall survival 50%–60%).

Biliary papillomatosis is a rare condition characterized by multiple papillary adenomas that may involve the intra- or extrahepatic biliary tree. These multifocal lesions are considered benign but have a high potential for malignant transformation. There are associations with Caroli's disease, choledochal cyst, familial polyposis coli, ulcerative colitis, and cirrhosis caused by hepatitis B and C. The condition is more common in men (2:1 male-to-female ratio) with clinical symptoms of jaundice, abdominal pain, and acute cholangitis. It may be difficult to distinguish biliary papillomatosis from other inflammatory conditions. On CT, dilation of both intra- and extrahepatic bile ducts may be seen along with hypoattenuating, intraductal soft-tissue masses. As opposed to cholangiocarcinomas, on MRI, the papillomas may remain hypointense relative to the adjacent parenchyma after intravenous contrast administration; however, enhancement patterns are diverse. On ERC, multiple filling defects, dilated biliary tree, and serration of the bile duct wall may be present. The disease may be confined to intra- or extrahepatic bile ducts.

Biliary intraductal papillary mucinous neoplasm (IPMN) arise from stem cells of the bile duct cells, biliary

epithelium, or peribiliary gland epithelium and are characterized by papillary growth or mucosal spread along the bile duct. Hypersecretion is a frequent manifestation, and this produces marked dilation of the affected ducts. Occasionally, portions of the biliary system not affected by the neoplasm are also dilated due to mucin production. The gross and microscopic appearance of biliary IPMN depends on epithelial proliferation versus the amount of mucin secretion. When the former predominates, intraductal papillary mass formation is evident, and when the latter predominates, the ducts are grossly dilated and filled with mucin. When there is recognizable lobar or segmental bile duct dilation without a mass, accompanied by severe hepatic peripheral atrophy of the affected segment, the possibility of a biliary IPMN should be considered. Treatment is surgical, and if successful, long-term survival is good.

Gallbladder lymphoma is rare and may be secondary to systemic disease or represent a primary non-Hodgkin lymphoma arising from mucosal associated lymph tissue (MALT). In addition to lymphoma, other rare primary tumors of the biliary tree include carcinoid, extrahepatic biliary cystadenoma and cystadenocarcinoma (much more commonly seen in the liver rather than in the extrahepatic bile duct), and embryonal rhabdomyosarcoma (sarcoma botryoides). Biliary metastases are not uncommon. The bile ducts may be directly invaded by adjacent gallbladder carcinoma, hepatocellular carcinoma, and colorectal cancer metastases. The extrahepatic bile duct is affected by metastases to periportal lymph nodes, which may arise from a variety of tumors, most commonly colorectal carcinoma, but also seen in breast, lung, prostate, and other common cancers. Rare, hematogenous metastases to the biliary system may be seen in patients with melanoma; when isolated, these are surgically resected.

TRANSPLANTATION

Preoperative imaging is important in the evaluation of potential living hepatic donors. Parenchymal (focal or diffuse) disease as well as biliary or vascular abnormalities or variations that may alter the surgical methodology and/or morbidity for partial hepatectomy can be detected preoperatively with imaging. Comprehensive MRI examination includes assessment of the biliary tree, but the examination may be limited for the detection and definition of intrahepatic biliary anatomic anomalies because the donor systems are usually nondilated. Ductal anomalies such as aberrant drainage of right posterior segmental branch into the left hepatic duct or into the bifurcation (producing a biliary “trifurcation”) preclude a single duct-to-duct biliary anastomosis

and require additional biliary anastomosis to be performed, possibly increasing morbidity. In general, three-dimensional, heavily T2-weighted “fluid-sensitive” MRC images provide superior biliary visualization compared to 2D T2-weighted MRC images caused by increased signal to noise in these nondilated systems. Potential off-label use of gadolinium products that are excreted through the biliary pathway may aid in visualization of the bile ducts, but their role in preoperative assessment is not yet established.

After transplantation, the most common and clinically significant complications include arterial venous thromboses and stenoses, fluid collections, rejection, and biliary disorders. Biliary complications occur in an estimated 25% of liver transplant recipients typically within the first 3 months following transplantation. Complications include stenosis/obstruction, bile leaks, stone formation, sphincter of Oddi dysfunction, and recurrent biliary disease. In transplant recipients, the usual biliary anastomosis is a choledochocholedochostomy, with a T tube left in place across the anastomosis for 3 to 6 months. A Roux-en-Y choledochojejunostomy may be performed when there is a discrepancy in donor and recipient duct size, or when there is an existing disease affecting the recipient duct such as biliary atresia, sclerosing cholangitis, or primary biliary cirrhosis. Evaluation of the ducts is usually carried out with ultrasound and T-tube cholangiography during the initial months after transplantation, however, after removal of the biliary catheters, MRC, ERC, or percutaneous transhepatic cholangiography may be employed.

Obstruction is the most common postliver transplant biliary complication, is usually caused by stenosis at the anastomotic site, and results from fibrotic proliferation and narrowing of the bile duct lumen. Occasionally, ischemia related to hepatic arterial thrombosis or stenosis may lead to bile duct stricturing. Strictures located elsewhere along the duct may be related to pretransplant biliary diseases such as sclerosing cholangitis. Diffuse ductal dilation may result from papillary dyskinesia brought on by devascularization or denervation of the papilla of Vater during surgery. The incidence of bile leaks in liver transplant recipients is approximately 5%. These usually present early, with 70% occurring in the first month after surgery. Leaks are generally from the T-tube site and treatment includes stent placement, plus drainage of any focal collections. Ductal ischemia results from stenosis or thrombosis of the hepatic artery, upon which the bile ducts depend entirely for the blood supply. Ductal ischemia may lead to necrosis resulting in bile leak, biloma, and duct scarring with fibrosis.

Following laparoscopic cholecystectomy, a spectrum of biliary complications may occur. Early recog-

nition and diagnosis of these complications helps to minimize morbidity. Biliary complications include retained stones in the cystic duct or common duct, bile leak, iatrogenic bile duct obstruction or injury, and delayed biliary obstruction with stricture. MRC is an effective method for depicting remnant stones, which may produce biliary obstruction after laparoscopic cholecystectomy. Bile leakage is the most common complication, with most leaks occurring from the cystic duct stump. Other causes of bile leak in the postlaparoscopic cholecystectomy patient include unintentional laceration, duct transection, or thermal injury. Bile leaks are often diagnosed with a hepatoscintigraphy or ERC, the latter also providing a mechanism for therapy. Acute bile duct obstruction is twice as common with a laparoscopic approach compared to open cholecystectomy. Classically, the surgeon mistakes the CHD for a cystic duct and places a clip on the CHD resulting in acute biliary obstruction. Failure of recognition of anomalous bile ducts may lead to clipping of these structures as well, producing segmental biliary obstruction. In the past, percutaneous transhepatic cholangiography was used to identify the upstream-obstructed duct and ERC the location of the obstruction and “missing” upstream duct from below. Both may be visualized with MRC nowadays. Injuries to the main bile ducts are grouped according to the Bismuth classification, which designates types I through IV from the lowest part of the CHD to progressively higher levels. When a ligation or excision injury is present, the length of the intact common duct distal to the biliary confluence determines whether a choledochojejunostomy or hepaticojejunostomy is performed. Late strictures of the extrahepatic ducts are probably caused by thermal injury with mild (nontransmural) effects on the bile duct that result in stricturing from fibrosis. Abscess and retention of peritoneal gallstones that are spilled during the laparoscopic cholecystectomy may be observed readily with CT.

Other surgeries resulting in alterations of the biliary tract such as hepatic resection and biliary-enteric anastomosis may be evaluated with imaging. In particular, biliary-enteric anastomosis may preclude the option for ERC, and the use of MRC is most advantageous in these cases. Biliary-enteric anastomosis may be associated with anastomotic structuring as well as stone formation, even when the anastomosis is fully patent.

TRAUMA

Biliary tract injuries may result from blunt abdominal trauma. The most common location of biliary injury is

the gallbladder, occurring in approximately 3% of blunt trauma patients undergoing laparotomy. There is a high association with additional injuries, including hepatic (up to 91%), splenic (up to 54%) and duodenal (up to 54%). Injuries to the gallbladder may be classified into three categories: contusion, laceration/perforation, or complete avulsion. Contusions, or intramural hematomas, are the mildest form of gallbladder injury and are generally treated conservatively. Lacerations and perforations are full-thickness wall injuries and require cholecystectomy. Avulsion of gallbladder may involve all or portions of the gallbladder as well as the cystic duct and cystic artery, the latter leading to major blood loss. CT signs of gallbladder injuries caused by blunt trauma include collapsed gallbladder in a fasting patient, ill-defined or thickened wall, pericholecystic fluid, and active extravasation caused by transection of the cystic artery.

Injuries to the extrahepatic bile duct are the second most common type of biliary injury and typically occur at sites of anatomic fixation after blunt trauma or deceleration mechanism. Delayed complications may result from biliary leakage; symptoms tend to be present when the leaking bile is infected and may include vague abdominal pain, nausea and vomiting, and occasionally jaundice. Intrahepatic bile duct injury occurs rarely and is seen only in patients with severe liver lacerations. While MRCP is commonly used to evaluate iatrogenic injuries, its use in the setting of acute trauma is not established. ERCP is often most helpful for identifying the level of bile extravasation, with the added potential for stenting in appropriate cases.

QUESTIONS AND ANSWERS

- What is the most common type of choledochal cyst?
 - Type I
 - Type II
 - Type III
 - Type IV

ANSWER: A. A type I choledochal cyst involves the extrahepatic bile duct; type Ic, fusiform dilation of the extrahepatic bile duct, represents 80% to 90% of all choledochal cysts.

- What is the most common anomalous drainage of the biliary system?
 - Trifurcation of the confluence
 - Right posterior duct insertion into left hepatic duct above the confluence
 - Drainage through ducts of Luschka
 - Cystic duct insertion into left hepatic duct

ANSWER: B. The most common anomalous drainage of the biliary system is drainage of the right posterior duct into the left hepatic duct above the confluence. Although triple confluence is also common, it is not as common as the correct response. The other answers are much less common.

- Which of the following conditions are represented by the "interrupted rim sign" on CT or MR imaging of the gallbladder in a patient with right upper quadrant pain?
 - Adenomyomatosis
 - Pericholecystic varices in portal hypertension

- C. Acalculous cholecystitis
- D. Gangrenous cholecystitis

ANSWER: D. Gangrenous acute cholecystitis is characterized by focal areas of necrosis in the wall, which are represented by patchy enhancement of the gallbladder mucosa on contrast-enhanced CT or MRI in patients with acute cholecystitis. Adenomyomatosis would give rise to a thickened but enhancing wall, pericholecystic varices would be brighter than the wall but the mucosal enhancement would not be patchy, and acalculous cholecystitis could be severe enough to developed gangrene, but is not as correct as the key.

4. Impaction of a stone in the gallbladder neck producing inflammation of the adjacent common hepatic duct and intrahepatic bile duct dilation describes which of the following conditions?
- A. Choledocholithiasis
 - B. Charcot triad
 - C. Mirizzi syndrome
 - D. Carcinoid syndrome

ANSWER: C. This syndrome was described as impaction of gallstone within the gallbladder neck or cystic duct leading to extrinsic common hepatic duct compression and biliary obstruction in a patient with or without gallbladder. Choledocholithiasis refers to stones located within the biliary tree that may produce obstruction; Charcot triad is the constellation of jaundice, fever, and right upper quadrant pain that described the classic presentation of patients with cholangitis. Carcinoid syndrome describes symptomatic abnormalities present when there are carcinoid metastases in the liver.

5. What percentage of patients with acute cholecystitis have no gallstones?
- A. 10%
 - B. 20%
 - C. 30%
 - D. 40%

ANSWER: A. Approximately 10% of all patients presenting with acute cholecystitis have no gallstones.

6. What percentage of patients with primary sclerosing cholangitis have associated inflammatory bowel disease?
- A. 15%
 - B. 25%
 - C. 40%
 - D. 65%

ANSWER: D. Approximately 62% to 72% of patients with PSC have concomitant inflammatory bowel disease. Ulcerative colitis is much more common (80%) than Crohn disease in patients with both PSC and inflammatory bowel disease.

7. Which location in the biliary tree is most commonly affected by cholangiocarcinoma?
- A. Intrahepatic ducts
 - B. Hilar/upper third of extrahepatic bile duct
 - C. Middle third of extrahepatic bile duct
 - D. Lower third of extrahepatic bile duct (peripapillary)

ANSWER: B. The majority of cholangiocarcinomas arise from the epithelium of the bile duct in the upper third or perihilar region (Klatskin tumors). Although cholangiocarcinomas may arise within intrahepatic ducts and other locations along the course of the biliary tree, they are not as common as lesions in and around the confluence.

8. What is the most common biliary complication encountered in patients after liver transplantation?
- A. Bile duct leak from the cystic duct stump
 - B. Obstruction/stenosis at the anastomosis
 - C. Recurrent stone formation
 - D. Sphincter of Oddi dysfunction

ANSWER: B. Obstruction is the most common postliver transplant biliary complication and is usually caused by stenosis at the anastomotic site. The other answers are all potential complications after liver transplant surgery, but are not as common.

9. What is the most common biliary complication encountered in patients after laparoscopic cholecystectomy?
- A. Bile duct leak from the cystic duct stump
 - B. Acute bile duct obstruction
 - C. Retained stones
 - D. Delayed biliary obstruction with stricture

ANSWER: A. This typically occurs from the cystic duct stump. Acute bile duct obstruction caused by incorrect clip placement is twice as common during laparoscopic compared to open cholecystectomy, but is not the most common complication overall. Retained stones and delayed biliary obstruction are possible but less common.

10. Which location is the most common site of biliary tract injury caused by blunt abdominal trauma?
- A. Intrahepatic ducts
 - B. Gallbladder

- C. Extrahepatic bile duct
- D. Intrapancreatic bile duct

ANSWER: B. The most common location of biliary injury is the gallbladder, occurring in approximately 3% to blunt trauma patients who undergo laparotomy. The extrahepatic bile duct is the second most common location. The portions of the bile duct within the liver and within the pancreas are relatively more protected and less commonly injured.

52 SPLEEN

*Andrew S. Ferrell, Katherine P. Lursen,
and Robert E. Koehler*

THE NORMAL SPLEEN

ANATOMY

The spleen is located in the peritoneal cavity of the left upper abdomen, posterior and lateral to the stomach. By the age of 15, it normally reaches approximately 12 cm in length, 7 cm in width, and 3 cm in thickness. The splenic artery usually arises from the celiac artery, the most common alternate origins being the aorta and superior mesenteric artery. The splenic artery and vein course behind the pancreas to the splenic hilum, where each of them divides into multiple branches before entering the spleen. The splenic artery is essentially an end vessel with relatively little collateral flow, although there is some communication with small arteries in the pancreas and with short gastric arteries extending from the greater curvature of the stomach. Occlusion of the splenic artery therefore often results in splenic infarction.

The spleen is nearly entirely covered by peritoneum and is suspended by several supporting peritoneal ligaments. The gastrosplenic ligament passes from the splenic hilum to the greater curvature of the stomach and is formed by fusion of the lesser and greater peritoneal sacs. It contains the short gastric and left gastroepiploic vessels. The splenorenal ligament passes from the spleen to the left kidney and contains the splenic artery and vein and a portion of the tail of the pancreas. The phrenicocolic ligament connects the lower pole of the spleen to the splenic flexure of the colon and to the diaphragm.

HISTOLOGY AND FUNCTION

The splenic parenchyma consists of “red pulp” and “white pulp,” the red pulp being the predominant tissue in the normal spleen. The white pulp is made up of lymphoid tissue arranged in sheaths around the arterioles that deliver blood to the spleen. This is where splenic T and B lymphocytes interact immunologically with the plasma.

From the white pulp, blood flows on through an array of splenic cords and venous sinuses, which together comprise the red pulp. The cords and blood-filled sinuses of the red pulp are lined with macrophages, which phagocytize abnormal erythrocytes and those at the end of their 100-to 120-day life, aging white blood cells and platelets, and circulating bacteria.

The spleen also serves as a reservoir for blood. Its capsule contains smooth muscle that enables it to function as an expandable and contractible sac, changing in size in response to variations in the body’s blood volume. Although the spleen serves as a site of red blood cell production in the fetus, it does not normally exhibit hematopoietic activity after infancy.

IMAGING APPEARANCE

The spleen has a lobular contour and may have prominent clefts, which should not be mistaken for lacerations. It is normally less dense than the liver on both unenhanced and contrast-enhanced CT images. The spleen is normally at least 15 HU less dense than the liver on noncontrast CT images. If it is not, then either the liver is fatty or the spleen contains excess iron. On contrast-enhanced CT images, if the spleen is more than 25 HU denser than the liver, then hepatic steatosis is usually present. On MRI T1-weighted images, the spleen is hypointense to the liver, while it appears hyperintense to the liver on T2-weighted images.

The normal splenic parenchyma has a diffusely homogeneous appearance on CT and MR images. An exception to this is seen on images obtained by either method a few seconds after administration of intravenous contrast material. These arterial-phase images show marked heterogeneity in parenchymal enhancement because of the variable rate at which the contrast agent reaches different regions within the spleen. The resulting appearance is sometimes referred to as showing multiple “pseudomasses.” On ultrasound images, the spleen has a homogeneous echotexture with midlevel echoes, slightly more echogenic than the liver, and equal to or greater than the adjacent left kidney.

Splenic clefts are commonly seen on imaging studies. They are thought to be due to the fact that the spleen forms by coalescence of multiple cellular aggregates,

sometimes leaving spaces between incompletely fused embryologic tissues. Clefts are most commonly seen along the lateral or superior borders and are of no clinical significance other than occasionally being mistaken for lacerations in the setting of trauma.

CONGENITAL ABNORMALITIES

ACCESSORY SPLEENS

One or more accessory spleens, also known as splenules, are present in 10% to 20% of individuals. They are derived from embryological splenic tissue that fails to fuse with the remainder of the spleen. Accessory spleens are usually spherical, smoothly margined, and 2 cm or less in size. Most lie near the splenic hilum or in one of the suspensory peritoneal ligaments of the spleen, often the gastrosplenic ligament.

The CT attenuation value and MR signal characteristics of accessory splenic tissue mimic those of normal splenic parenchyma. This is also true of the uptake and clearance of a variety of intravenously administered CT and MRI contrast agents. Uptake and retention of Tc-99m-sulfur colloid by reticuloendothelial tissue in an accessory spleen is similar to that of normal splenic tissue, so radionuclide imaging with this agent can be used to distinguish an accessory spleen from a lymph node enlarged by lymphoma.

After splenectomy for treatment of a variety of hematologic conditions, such as autoimmune hemolytic anemia and idiopathic thrombocytopenic purpura, an accessory spleen that was not removed at the time of splenectomy may later hypertrophy and present as an abdominal mass. Hypertrophy of an accessory spleen can also lead to recurrence of the original hematologic disease.

SITUS AND HETEROTAXIA SYNDROMES (POLYSPLENIA/ASPLENIA)

The term situs solitus is derived from the Latin words *situs*, meaning position, and *solitus*, meaning customary. Situs solitus is the normal anatomic arrangement in which the cardiac apex, stomach, spleen, and abdominal aorta lie on the left of the midsagittal plane, and the liver and inferior vena cava lie on the right.

Abdominal situs inversus is said to exist when there is a mirror image location of the abdominal viscera, opposite to that in persons with situs solitus. There are two subtypes, one associated with levocardia and the other with dextrocardia. Situs inversus with dextrocardia is more common with the cardiac apex, spleen, stomach, and aorta, all located on the right and the liver and inferior vena cava on the left. Congenital heart disease is present in only 3% to 5% of such cases. Situs inversus with levocardia is extremely rare and is characterized by

mirror image location of the abdominal viscera and a left-sided cardiac apex. Nearly, all affected individuals have congenital heart disease, which usually leads to diagnosis in early infancy.

Situs ambiguous, also known as heterotaxia, is an abnormal arrangement of viscera and great vessels that is variable and does not fit the pattern of either situs solitus or situs inversus. Congenital heart disease coexists in 50% to 100% of cases according to Fulcher, and there may also be malrotation of the gut, biliary atresia, immunodeficiency, and other serious conditions. Situs ambiguous typically occurs in association with either polysplenia or asplenia and this feature can be used to classify the condition into these two subtypes.

Situs ambiguous with asplenia (Ivemark syndrome), also referred to as right isomerism or bilateral right-sidedness, is characterized by ambiguous location of the abdominal organs and congenital absence of most or all normal splenic tissue. A rudimentary amount of splenic tissue may be present. Approximately two-thirds of reported cases are in males. Congenital heart disease is present in most or all cases. Affected individuals often die within the first year of life because of the associated severe congenital heart disease and immunodeficiency related to the absence of the spleen.

Situs ambiguous with polysplenia, also referred to as left isomerism or bilateral left-sidedness, is characterized by midline or ambiguous location of multiple abdominal organs and the presence of multiple spleens. Associated congenital heart disease, when present, tends to be less severe than in persons with situs ambiguous with asplenia. Absence of the hepatic portion of the inferior vena cava is characteristic, with an enlarged azygous vein carrying venous blood from the abdomen to the right atrium (azygous continuation).

WANDERING SPLEEN

The term wandering spleen is applied when there is a normally formed and functioning spleen that lies out of its expected left upper abdominal location. This is because of laxity of the spleen's supporting peritoneal ligaments in association with abnormalities of intestinal rotation. A wandering spleen may be found anywhere in the abdomen and may present as a palpable abdominal mass. If the lax splenic ligaments become twisted, the resulting torsion of the splenic pedicle can cause ischemia and acute or chronic abdominal pain. Chronic torsion may lead to splenomegaly or gastric varices. If this prevents arterial blood from reaching the spleen, the spleen will not enhance with intravenously administered radiologic contrast agents.

SPLENOMEGALY

Splenomegaly is the most common radiologically demonstrable abnormality of the spleen. It has many

TABLE 52-1 Causes of Splenomegaly

Venous obstruction, e.g., cirrhosis, portal vein thrombosis, congestive heart failure
Lymphoma, leukemia
Metastasis
Primary splenic cysts and tumors
Posttraumatic pseudocyst following subcapsular hematoma
Extramedullary hematopoiesis, e.g., myelofibrosis, osteopetrosis, congenital hemolytic anemias
Splenic hyperplasia caused by infection
Chronic viral infections, e.g., Epstein-Barr, cytomegalovirus
Bacterial, fungal, and protozoal infections, e.g., schistosomiasis
Collagen vascular diseases
Entities mainly seen in children
Acute viral infections
Juvenile rheumatoid arthritis
Histiocytic disorders, e.g., Langerhans cell histiocytosis
Storage diseases, e.g., Gaucher, Niemann-Pick (accumulation of abnormal lipids in splenic macrophages)

causes (Table 52-1), most related to diseases originating in other organs. There are vascular, hematologic, infectious, neoplastic, immunologic, and metabolic causes of splenomegaly. The most common cause of splenomegaly in adults is portal hypertension.

TRAUMA

The spleen is the most commonly injured solid thoracoabdominal organ representing approximately 25% of all significant injuries to the abdominal viscera because of blunt trauma. Combine this with the fact that the spleen contains approximately 1 unit of blood at a given time, and splenic injury poses a potentially life-threatening situation. Splenic trauma may have a surprisingly subtle clinical presentation. Abdominal tenderness and distention are seen in approximately 50% of patients, while hypotension is a presenting sign in only 25% to 30% of patients. In the modern setting, contrast-enhanced CT is the diagnostic method of choice with a sensitivity and specificity of nearly 100%. The limitations of CT in this context are related to motion artifact, misinterpretation of the normal heterogeneous perfusion seen on early arterial phase images, and mistaking a normal splenic cleft for a laceration. The use of intravenous contrast material is important because acute splenic hematomas frequently exhibit similar CT attenuation to that of normal splenic parenchyma on CT images without contrast enhancement. CT is also useful for demonstrating extravasation of intravascular contrast material in patients who are actively bleeding at the time of the scan.

Blunt splenic trauma can cause subcapsular hematoma, intraparenchymal hematoma, laceration, or massive fragmentation resulting in autosplenectomy.

TABLE 52-2 AAST Grading System for Splenic Injury

Grade I
Subcapsular hematoma of less than 10% of surface area
Capsular tear of less than 1 cm in depth
Grade II
Subcapsular hematoma of 10%–50% of surface area
Intraparenchymal hematoma of less than 5 cm in diameter
Laceration of 1–3 cm in depth and not involving trabecular vessels
Grade III
Subcapsular hematoma of greater than 50% of surface area or expanding and ruptured subcapsular or parenchymal hematoma
Intraparenchymal hematoma of greater than 5 cm or expanding
Laceration of greater than 3 cm in depth or involving trabecular vessels
Grade IV
Laceration involving segmental or hilar vessels with devascularization of more than 25% of the spleen
Grade V
Shattered spleen or hilar vascular injury

The Organ Injury Scaling Committee of the American Association for the Surgery of Trauma revised its splenic injury grading system in 1994. This system (Table 52-2) can be used as a guide to classifying the severity of CT findings of splenic injury; however, it has not been proven to correlate closely with clinical prognosis.

SPLENOSIS

Splerosis refers to implants of viable splenic tissue that are disseminated at the time of splenic trauma or splenectomy. The implants are usually multiple and grow into spherical nodules varying from a few mm to 3 cm in size. They typically lie in the peritoneal cavity of the upper abdomen, but can develop in the thorax if the original splenic injury was associated with diaphragmatic rupture. Splerosis is reported to occur in 40% to 60% of splenic injuries. The splenic nature of the nodules can be confirmed with Tc-99m-sulfur colloid imaging since they retain their original reticuloendothelial activity.

SPLENIC MASSES

CYSTS

Posttraumatic cysts, or pseudocysts, are the most common cystic lesions of the spleen. They occur as a result of previous splenic hemorrhage, infarction, or infection. Pseudocysts have no epithelial lining. They may have a thick wall, septations, or prominent curvilinear calcifications. They typically display sonographic findings similar to those of simple cysts in the kidneys or other organs, that is, hypoechoic contents and acoustic

enhancement behind the lesion. Alternatively, the fluid within a posttraumatic splenic pseudocyst may contain echoes related to blood products, cholesterol crystals, or cellular debris.

Epidermoid cysts are congenital in origin. They result from infolding or entrapment of peritoneum within the spleen during its formation. They are therefore lined with epithelium, unlike pseudocysts, which lack an epithelial lining and cystic lymphangiomas and hemangiomas, which are lined with endothelium. Epidermoid cysts grow slowly and are usually asymptomatic. They have an average size of 10 cm at the time of discovery, typically in persons aged 10 to 30 years. Eighty percent are unilocular and solitary. Curvilinear wall calcification occurs in up to one quarter of these lesions, and they often have internal septations and a trabeculated wall. Traumatic rupture and infection are very rare but have been described. Epidermoid cysts are often difficult to distinguish from posttraumatic pseudocysts on imaging studies.

Hydatid or echinococcal cysts are caused by infection with *Echinococcus granulosus*. They usually are seen in association with similar lesions in the liver or lung. While *E. granulosus* infection is the most common cause of calcified splenic cysts worldwide, this organism is rare outside its usual geographic range and hydatid cysts are rarely seen in North America. Hydatid cysts consist of a spherical mother cyst that usually contains smaller daughter cysts that may be seen within it. There can also be internal septations and debris, referred to as hydatid sand. Thick ringlike wall calcification may be seen.

Pancreatic pseudocysts may extend from the pancreatic tail into the splenic hilum. From there, they may erode into the splenic parenchyma or subcapsular space. Associated imaging features of pancreatitis and the presence of other peripancreatic fluid collections usually make the imaging diagnosis straightforward. A variety of splenic neoplasms can also appear cystic as can resolving splenic infarction (Table 52-3).

LYMPHOMA

Lymphoma is the most common malignant tumor of the spleen. It is usually seen as a manifestation of systemic disease. Lymphadenopathy is usually detectable on imag-

ing studies. The most frequent finding is splenomegaly, and this may be the only finding in patients with low-grade lymphomas. Hodgkins lymphoma and higher-grade lymphomas usually show discrete nodules of tumor.

On ultrasound images, lymphomatous deposits typically appear as focal, ill-defined, heterogeneous, and hypoechoic lesions. On contrast-enhanced CT, they are typically lower in density than the surrounding parenchyma, while on MRI they are low on T1-weighted images and varied in signal intensity on T2-weighted images. Lymphomatous nodules usually enhance with intravenous contrast agents. The reported accuracy of contrast-enhanced CT for detecting splenic involvement varies from 37% to 91%. Fortunately the foci of lymphoma within the spleen show increased radionuclide uptake on FDG PET, which has a reported sensitivity approaching 100%.

METASTASIS

Splenic metastases are commonly found at autopsy but often go undetected on radiologic studies. When they are seen, they may be visible only on arterial-phase contrast-enhanced images. According to Rabushka et al., the most common primary tumor to metastasize to the spleen is carcinoma of the breast. Malignant melanoma and carcinoma of the lung, ovary, stomach, and prostate are also relatively common (Table 52-4). On CT, metastases appear as low attenuating cystic or solid lesions. Contrast enhancement can be heterogeneous or homogenous. Necrosis is common while calcification is rare. Sonographically, splenic metastases are usually hypoechoic.

PRIMARY MALIGNANT TUMORS

Other than lymphoma, the spleen is rarely the site of primary malignant tumors. Of those that do occur, Abbott reports angiosarcoma to be the most common tumor. It is an aggressive tumor with a poor prognosis. CT shows a poorly defined area of heterogeneous or low attenuation in an enlarged spleen. These tumors may contain areas of necrosis and be associated subcapsular hematoma. The spleen can rupture spontaneously in patients with splenic hemangiosarcoma. Contrast enhancement is usually poor. On ultrasound, one sees an enlarged spleen with one or more solid heterogeneous echogenic masses. MR findings are varied and not specific.

TUMOR TYPE	PERCENT OF SPLENIC METASTASES (%)
Breast carcinoma	21
Bronchogenic carcinoma	18
Ovarian carcinoma	8
Gastric carcinoma	7
Melanoma	6
Prostatic carcinoma	6

BENIGN TUMORS

While a variety of benign neoplasms can affect the spleen, hemangioma is the most common. It consists of vascular channels lined by endothelium. On CT, a hemangioma may appear as a smooth, well-marginated nodule, which demonstrates marked homogenous enhancement with delayed washout. The peripheral nodular contrast enhancement and centripetal fill-in typically seen with hepatic hemangiomas is often lacking, especially if the tumor is smaller than 2 cm. Small splenic hemangiomas may show no contrast enhancement at all. There may be punctate central or peripheral curvilinear calcification. Ultrasound demonstrates a well-defined echogenic solid or complex cystic mass. On MRI, the lesion is low in intensity on T1 and high intensity on T2, with a variable contrast enhancement pattern. The imaging appearance of splenic hemangiomas is sufficiently variable that differentiation from angiosarcoma is usually not possible on radiologic grounds.

Lymphangiomas are very rare in the spleen. They are often indistinguishable from cysts on ultrasound, CT, and MR and can contain peripheral rim calcifications.

Splenic hamartomas are also rare benign neoplasms and are usually detected incidentally. They are usually less than 3 cm in diameter. Larger lesions can present with splenomegaly, palpable mass, or rupture. Sequestration of hematopoietic cells in large hamartomas can cause thrombocytopenia or anemia. Splenic hamartomas sometimes occur in association with tuberous sclerosis.

Most splenic hamartomas appear hypodense or isodense on unenhanced CT and show moderate heterogeneous enhancement when intravenous contrast material is administered. They can, however, appear hyperdense on unenhanced CT because of hemosiderin deposition. Sonographically, they appear as solid masses with mixed echogenicity, with or without small cystic and hyperechoic areas. On MR imaging, hamartomas appear isointense on T1 and hyperintense on T2.

The radiologic characterization of other splenic neoplasms of vascular origin is further complicated by the fact that some have variable biologic behavior that makes their benign or malignant nature difficult to predict. These include littoral cell angioma, hemangioendothelioma, and hemangiopericytoma.

INFECTION

GRANULOMATOUS INFECTION

The most common radiologically detected splenic infection is histoplasmosis. Radiographs, CT, MRI, and ultrasonography all show multiple, punctate, round calcifications in the splenic parenchyma that are less than 1 cm in size. These lesions represent calcified granulo-

mas that are no longer active. Granulomas in longstanding inactive splenic tuberculosis can have a similar radiologic appearance, but tuberculosis is a less common cause of small-calcified splenic granulomas than histoplasmosis. If more than five small-calcified splenic granulomas are seen, histoplasmosis is the likely diagnosis.

Rarely brucellosis can also cause calcified granulomas of the spleen. The granulomas are usually solitary and 2 cm or larger in size. They may have a low-density center encircled by a calcified outer layer, giving the lesion a bull's-eye appearance.

ABSCESS

Bacterial abscesses, although rare in the spleen, carry a high mortality rate unless diagnosed and treated early. They are typically caused by hematogenous seeding. On CT, they usually appear as well-defined, low attenuating lesions, sometimes with rim enhancement. Unfortunately, their imaging appearance is not specific, although the occasional finding of gas within the abscess is a rare but fairly specific finding.

Fungal abscesses in the spleen, usually because of *Candida albicans*, have a different appearance. They occur in immunocompromised individuals and, like bacterial abscesses, are usually a sequela of blood-borne infection. The typical CT appearance is one of multiple, round, low-density lesions that are usually 5 to 20 mm in size. On ultrasound images, they are hypo- or anechoic and ill-defined. MRI shows multiple small lesions with low signal intensity on T1-weighted images and high signal intensity on T2-weighted images.

On rare occasions, patients with severely immunocompromised function can develop disseminated infection with *Pneumocystis carinii*. In the spleen, this takes the form of multiple small abscesses. CT shows multiple, round, well-circumscribed, low attenuation lesions that may be associated with calcification.

VASCULAR ABNORMALITIES

SPLENIC ARTERY ANEURYSM

Splenic artery aneurysm is the most common visceral arterial aneurysm. These can be caused by atherosclerosis, pancreatitis, or trauma. The incidence is higher in females than males and in women of child-bearing age who have had two or more pregnancies. Although usually asymptomatic, left upper quadrant pain or fullness is sometimes a complaint. The aneurysm is usually saccular in the mid-to-distal artery. Calcification of the aneurysm wall is usually more irregular than that seen in splenic cysts. Diffuse

calcification of the splenic artery should suggest atherosclerosis as the cause. Rupture of a splenic artery aneurysm is rare but can be fatal when it does occur and for this reason, aneurysms over 2 to 3 cm and those in younger patients are sometimes treated by transcatheter embolization or surgery.

SPLENIC VEIN THROMBOSIS

Splenic vein thrombosis is a relatively common sequela of pancreatitis. It can also be related to other inflammatory conditions such as diverticulitis or Crohn enteritis. Splenic vein occlusion leads to the development of varices of the gastric cardia and proximal stomach (short gastric veins).

INFARCTION

Splenic infarction is a consideration in patients who present with acute left upper abdominal pain. A number of conditions predispose patients to the development of splenic infarction (Table 52-5). These include arterial embolization for various reasons, for example, embolization of left atrial thrombus in patients with atrial fibrillation. Sludging of abnormal erythrocytes in the spleen in patients with sickle cell anemia can also be a cause. Any condition that significantly enlarges the spleen can cause it to outstrip its blood supply. Splenic infarcts typically appear as peripheral, irregular, or wedge-shaped, low attenuating defects in contrast enhancement on contrast-enhanced CT or MRI after injection of gadolinium-based contrast agents. Splenic infarction may rarely lead to rupture and perisplenic hematoma.

TABLE 52-5 Conditions That Predispose to Splenic Infarction

Infiltrative diseases

Trauma

MISCELLANEOUS CONDITIONS

SARCOIDOSIS

Sarcoidosis is a disease of unknown etiology in which noncaseating granulomas form in various tissues and organs of the body. It has a predilection for the lymphatic system. The spleen is involved in 50% to 80% of patients with sarcoidosis but usually is asymptomatic. Severe cases can lead to hypersplenism and spontaneous rupture. The spleen is enlarged in approximately one-third of patients and frequently there is associated lymphadenopathy. Splenomegaly is usually the only radiologically detected splenic abnormality. However, aggregates of granulomatous splenic tissue in some patients may appear on CT as numerous, discrete 1 to 2 cm hypoattenuating nodules that usually have irregular borders.

GAMMA GANDY BODIES

Gamma Gandy bodies represent small foci of hemorrhage in the splenic parenchyma that are usually associated with portal venous hypertension. These can be seen as low signal intensity on T2-weighted MR images.

SICKLE CELL DISEASE

Homozygous sickle cell disease affects approximately 1 in 500 African American infants at birth, whereas heterozygous sickle cell trait is found in 8% to 10% of the African American population in the US. Splenic crisis with the resultant sickling and trapping of red blood cells within the splenic sinusoids may lead to loss of splenic function as early as 5 months of age in homozygous patients. Patients with heterozygous sickle cell trait, however, typically retain partial splenic function with splenomegaly persisting into adulthood. Ultimately, sometimes even in patients with sickle cell trait, multiple bouts of spontaneous splenic infarction caused by sickled red blood cells render patients functionally asplenic (autosplenectomy). CT typically demonstrates a shrunken and partially calcified spleen. MRI reveals a small spleen with lower than normal signal intensity on both T1- and T2-weighted images because of hemosiderin deposits.

PELIOSIS

Peliosis is a rare condition, characterized by multiple blood-filled cystlike spaces within a solid organ, usually the liver (peliosis hepatis). When it occurs, splenic peliosis is usually seen in conjunction with hepatic peliosis; isolated splenic peliosis is exceedingly rare. No definite etiology is known, but there are multiple associations, including anabolic steroid use, oral contraceptives, ethanol abuse, Hodgkin lymphoma and other malignant neoplasms, and chronic renal disease. Although most

patients remain asymptomatic, spontaneous splenic rupture can occur.

QUESTIONS AND ANSWERS

- Which one of the following primary neoplasms most commonly metastasizes to the spleen?
 - Renal cell carcinoma
 - Small cell lung cancer
 - Malignant melanoma
 - Breast carcinoma

ANSWER: D. Breast carcinoma (see Table 53-4).

- A contrast-enhanced abdominal CT shows focal areas of high CT attenuation within an epidermoid splenic cyst. What do the high attenuation areas most likely represent?
 - Daughter cysts caused by infection with *Echinococcus granulosus*
 - Proteinaceous material
 - Internal septations
 - Resolving areas of hemorrhage that occurred at the time of cyst formation

ANSWER: D. Epidermoid cysts of the spleen are caused by infolding of peritoneal and mesothelial tissue trapped in splenic sulci during development. They frequently contain internal septations.

- Regarding epidermoid cysts of the spleen, which one of the following is *true*?
 - They are a sequela of previous traumatic hematoma.
 - They are usually over 4 cm in size at the time of detection.
 - Calcification of the cyst wall is useful in differentiating the lesion from hydatid cysts.
 - Occurrence as a single splenic lesion makes this diagnosis unlikely.

ANSWER: B. Epidermoid cysts typically grow quite large before being discovered incidentally on radiologic studies. They are congenital in origin and are usually solitary. The cyst wall commonly calcifies, but this is also true of hydatid (echinococcal) cysts and posttraumatic splenic pseudocysts.

- Concerning splenic involvement in sarcoidosis, which one of the following is *true*?
 - It occurs in less than 20% of patients with sarcoidosis.
 - The spleen is rarely enlarged.
 - Abdominal lymph node enlargement is common.
 - Multifocal low-density splenic lesions are the most common radiologic abnormality.

ANSWER: C. Most patients with sarcoidosis involving the spleen have splenomegaly and lymphadenopathy. Radiologically detectable, focal, low-density lesions can occur in the spleen in a minority of patients.

- What is the most likely cause of multiple, small, round lesions in the spleen on contrast-enhanced CT in an immunocompromised patient?
 - Lymphoma
 - Pneumocystis carinii* infection
 - Fungal abscesses
 - Multiple infarcts

ANSWER: C. Splenic microabscess caused by fungal infection are the most likely cause for this appearance in immunocompromised patients. They represent approximately 25% of splenic abscesses.

6. Which of the following conditions is most frequently associated with severe congenital heart disease?
- A. Situs inversus with dextrocardia
 - B. Situs ambiguous with polysplenia
 - C. Situs solitus
 - D. Situs ambiguous with asplenia

ANSWER: D. Situs ambiguous with asplenia is strongly associated with severe congenital heart disease, which is often fatal in infancy.

7. Which one of the following is the most common benign tumor of the spleen?
- A. Hamartoma
 - B. Hemangioma
 - C. Lymphangioma
 - D. Littoral cell angioma

ANSWER: B. While a variety of benign neoplasms can affect the spleen, hemangioma is the most common one. The CT appearance is typically that of a smooth, well-margined nodule. Contrast enhancement is variable and not as characteristic as that of hepatic hemangiomias.

8. Isolated gastric varices are most often caused by which of the following?
- A. Splenic vein thrombosis
 - B. Cirrhosis
 - C. Congestive heart failure
 - D. Occlusion of the inferior vena cava

ANSWER: A. Gastric varices associated with esophageal varices are usually caused by portal hypertension. The presence of isolated gastric varices without accompanying esophageal varices should suggest splenic vein occlusion, often caused by pancreatitis or pancreatic carcinoma.

9. Concerning peliosis, which one of the following is *false*?
- A. It is more common in the spleen than in the liver.
 - B. It is usually asymptomatic.
 - C. Splenic rupture occurs in some cases.
 - D. It is associated with the use of anabolic steroids.

ANSWER: A. Peliosis is more common in the liver than in the spleen. Cases of splenic rupture have been reported. A number of drugs and toxins have been implicated in its causation.

10. What is the most significant complication of wandering spleen?

- A. Compression of the inferior vena cava by the spleen
- B. Splenic torsion
- C. Splenic contusion
- D. Diaphragmatic herniation

ANSWER: B. Torsion of the spleen around its lax, elongated pedicle leading to splenic ischemia.

53 PANCREAS

Desiree E. Morgan

PANCREAS

CONGENITAL MALFORMATIONS

Pancreas divisum is the most common anatomic variant of the human pancreas, reported in 5% to 10% of autopsy series and 5% to 8% of endoscopic retrograde cholangiopancreatography (ERCP) series. This condition results from lack of fusion of the dorsal and ventral pancreatic anlagen in the developing embryo at approximately 7 weeks. The main portion of the pancreas, including the anterior part of the head, body, and tail, is drained by the dorsal pancreatic duct through the minor (accessory) duodenal papilla, and the posterior portion of the pancreatic head drains through the major papilla (ampulla of Vater). Because the ventral pancreas arises along with the bile duct from the hepatic bud on the ventral aspect of the embryonic gut, the duct of Wirsung always empties into the major papilla along with the common bile duct. The dorsal pancreas arises in the dorsal mesogastrium and when not fused with the ventral duct, the main pancreatic duct supplying this portion of the pancreas empties separately via the duct of Santorini through the minor papilla. Clinical relevance includes an increased incidence of recurrent acute pancreatitis in patients with pancreas divisum.

Other congenital anomalies of the pancreas include annular pancreas, absence of either the dorsal or ventral anlagen, or an anomalous pancreaticobiliary ductal union. Annular pancreas is a rare congenital anomaly and may be one of two types: extramural or intramural. In the extramural type, the ventral pancreatic duct encircles the duodenum to join the main pancreatic duct. In the intramural type, pancreatic tissue is located in the wall of the duodenum (intermingled with muscle fibers) and is drained via small ducts into the duodenal lumen.

In general, annular pancreas produces obstruction of the duodenum in approximately 10% of cases, and about half of symptomatic cases present in infancy. Pancreatic agenesis is extremely rare and incompatible with life. When there is absence of the dorsal or ventral anlagen, the condition is referred to as pancreatic hypoplasia or partial agenesis. Partial agenesis of the dorsal pancreas is more common than agenesis of the ventral pancreas; complete dorsal agenesis is very rare. On cross-sectional imaging, dorsal pancreatic hypoplasia is present when there is varying degree of truncation of pancreatic tissue beyond the head region. In adults, it is important to exclude a pancreatic carcinoma that has resulted in severe upstream glandular atrophy before diagnosing the defect as congenital. An anomalous pancreatobiliary duct union occurs when the fusion of the pancreatic duct and common bile duct is outside the duodenal wall, proximal (upstream) to the sphincter of Oddi. This condition is present when there is more than 1.5 cm of conjoined pancreatic and bile duct (also known as the common channel) and may allow reflux of pancreatic juice into the biliary tree. There is an association with choledochal cyst or, rarely choledochal web formation. Conversely, when bile can reflux into the pancreatic duct, pancreatitis may occur.

PANCREATIC INFLAMMATION

ACUTE PANCREATITIS

Patients with acute pancreatitis present clinically with either mild (80%) or severe (20%) disease. In western countries, acute pancreatitis is most commonly caused by gallstones or ethanol use, with less common etiologies including tumor, trauma, hyperlipidemia, medications, and iatrogenic causes (ERCP, surgery). Symptoms of nausea, vomiting, and abdominal pain are often present, but are relatively nonspecific. More specific signs of acute pancreatitis include Cullen sign (periumbilical ecchymosis) or Gray-Turner sign (flank ecchymosis), both generally indicative of hemorrhagic pancreatitis. Typical laboratory abnormalities indicating the presence of acute pancreatitis include serum amylase and lipase elevation. According to the 2007 Acute Pancreatitis Classification Working Group revision of the Atlanta Classification, the clinical definition of acute pancreatitis now requires two of the three following features: abdominal pain suggestive of pancreatic origin, serum amylase or lipase greater than or equal to three times normal, and characteristic findings on intravenous contrast-enhanced CT (CECT). Onset of pancreatitis has now been defined by the working group as the beginning of abdominal pain.

CECT is the mainstay of imaging patients with acute pancreatitis; however, unenhanced CT may be utilized

for patients with renal insufficiency, or MRI using three-dimensional T1-weighted fat-suppressed spoiled gradient-echo sequences may also be employed. The differentiation between severe and nonsevere (mild) acute pancreatitis depends on clinical findings in the first week and morphologic findings depicted on CECT or MRI thereafter. Various clinical scoring systems have been used to characterize disease severity. Marshall score is the recommended clinical tool for assessing disease severity in the first week. Radiologically, the CT severity index has been used for years as a prognosticator for morbidity and mortality in patients with acute pancreatitis, especially in research settings where comparison of disease severity among populations is important. This index is based on the grade of pancreatic inflammation plus the degree of glandular necrosis. The presence of necrosis is critical for the radiologist to recognize both in research and in everyday clinical operations, because the complications of pancreatic necrosis account for 70% to 86% of deaths caused by acute pancreatitis.

The new morphologic classification system in patients with acute pancreatitis is based on CT or MR findings after 1 week, and has been proposed to better identify patients at risk for developing complications. Acute pancreatitis is divided into either acute interstitial edematous pancreatitis or acute necrotizing pancreatitis. The necrosis may be isolated to the pancreatic gland, isolated to the peripancreatic fat, or may involve both. On CECT, pancreatic glandular necrosis is generally depicted as one or more focal or geographic areas of nonenhancing pancreatic parenchyma. Pancreatic gland necrosis is typically accompanied by varying degrees of peripancreatic fat necrosis. Isolated peripancreatic retroperitoneal fat necrosis is more difficult to identify, but may be suggested when there is incorporation of retroperitoneal fat into a complex but predominately low-attenuation (often fluid density) collection surrounding the pancreas. Potential imaging pitfalls resulting in overestimation of pancreatic glandular necrosis on CT include apparent diminished enhancement in patients with normal fatty infiltration of the pancreas, diffuse parenchymal edema in patients with severe interstitial pancreatitis, and intrapancreatic focal fluid collections. Furthermore, once a large complex collection is present, there may be compression of normal enhancing pancreatic tissue, resulting in overestimation of necrosis, especially in the central gland. Typical CT features of pancreatic necrosis may occasionally not be evident up to 48 hours after onset of symptoms hence the recommendation to characterize the morphologic changes with CT after 1 week of acute pancreatitis symptoms being present.

Infection of pancreatic necrosis is defined as culture positivity of pancreatic and/or peripancreatic necrotic

tissue. This typically is polymicrobial, occurs in the second to third week following onset of symptoms, and occurs in 36% to 71% of all patients with glandular necrosis. With imaging, infected necrosis may be suggested by the presence of gas within a complex retroperitoneal collection; however, proof is achieved by fine needle aspirate and culture. Other explanations for gas being present in retroperitoneal collections associated with acute pancreatitis include spontaneous fistulization to bowel, or introduction of air through drainage catheters. Once drainage is attempted, either percutaneous, endoscopic, or surgical, there may be colonization and/or secondary infection of the residual solid necrotic debris. This debris can be successfully evacuated over time if

measures to irrigate the retroperitoneal cavity and large drainage tracts are employed.

Definition of Retroperitoneal Collections Associated with Acute Pancreatitis

Recent revision of the nomenclature for imaging findings in patients with acute pancreatitis has been proposed. Figure 53-1 compares prior definitions of the 1992 Atlanta Classification to the terms recommended by the 2007 Acute Pancreatitis Working Group. *Acute peripancreatic fluid collection* refers to enzyme-rich pancreatic juice that is located predominantly adjacent to the pancreas, lacks a wall, arises early (within 48 hours) in up to 50% of patients with acute pancreatitis, typically

FIG. 53-1 Acute pancreatitis collection nomenclature.

remains sterile, and resolves spontaneously within 2 to 4 weeks. *Postnecrotic pancreatic collection* is the new term for enzyme-rich pancreatic fluid combined with necrotic pancreatic parenchyma and/or peripancreatic fat. These postnecrotic collections are present up to 4 weeks following onset, and may remain sterile or become infected. The intrapancreatic versus extrapancreatic nature of these collections should be distinguished, as those containing glandular necrosis are more likely to have complications related to duct disruption. If allowed to evolve, eventually postnecrotic pancreatic collections become walled-off necrosis. *Walled-off necrosis* is the new term that describes postnecrotic pancreatic collections that are present more than 4 weeks following onset of symptoms. Prior terms for this condition included organized pancreatic necrosis, pseudocyst associated with necrosis, and central cavitory necrosis, but these should now be avoided. As with postnecrotic collections, it is critical to recognize that in patients with walled-off necrosis, CECT and MRI demonstrate replacement of pancreatic tissue by the collection. This feature helps differentiate walled-off necrosis from a pseudocyst arising from acute pancreatitis on CT. Surgical, percutaneous, and endoscopic procedures have been successfully performed on patients with walled-off necrotic collections, so long as measures are undertaken to remove the necrotic debris during drainage. Both postnecrotic pancreatic collections and walled-off necrosis may remain sterile or become infected, and the presence of gas within one of these types of collection should be treated as an urgent finding by the imager, as prompt drainage is mandated. *Pancreatic pseudocyst* is defined as a collection of pancreatic juice contained by granulation tissue that requires 4 weeks or greater to form and contains little or no necrosis. These collections may resolve spontaneously when small, and are generally not intervened upon unless symptomatic. On CT, pseudocysts are well-defined, homogeneous, low-attenuation, thin-walled collections that are typically adjacent to an otherwise normal-appearing pancreas. If drainage is clinically necessary, identification of potential ductal communication is important. Patients whose upstream main pancreatic ducts fill the pseudocyst but are disconnected from the downstream duct that empties through the papilla are at risk for pancreaticocutaneous or pancreaticoenteric fistula formation. According to the new working group definition, pancreatic pseudocyst should be classified as noninfected or infected (suppurative). Infected pseudocyst is the new name to replace the term pancreatic abscess. An infected pseudocyst is a circumscribed collection of pus located near the pancreas that requires at least 4 weeks to form and has little or no necrosis. On CT or MRI, the wall of an infected pseudocyst is slightly thicker and more irregular than that of a sterile pseudocyst.

Systemic complications arising from acute pancreatitis may also be depicted on CT, and include signs of multisystem organ failure, such as pulmonary edema, pleural effusions, or infiltrates caused by adult respiratory distress syndrome, for example, in the respiratory system. Other intraabdominal findings including gastric outlet obstruction, colonic inflammation, retroperitoneal hemorrhage, pseudoaneurysm formation, ileus, pancreatic ascites, and renal obstruction may be seen in patients with acute pancreatitis; some of these abnormalities are due to mechanical compression by the retroperitoneal collections and others may arise from release of pancreatic enzymes and systemic inflammatory response syndrome.

CHRONIC PANCREATITIS

Chronic pancreatitis is characterized by prolonged pancreatic inflammation and fibrosis with irreversible morphologic and/or functional abnormalities.

There is a strong association of alcohol abuse and chronic pancreatitis; other etiologies include familial hyperlipidemia, hyperparathyroidism, cystic fibrosis (CF), cholelithiasis, and hereditary pancreatitis that is thought to be inherited in an autosomal dominant fashion with variable penetrance. The pathognomonic features on CT in patients with chronic pancreatitis are scattered glandular and ductal calcifications, and ductal dilatation. In addition, parenchymal atrophy, fluid collections, focal pancreatic enlargement that may mimic neoplasm and biliary ductal dilatation may also be present.

As stated previously, smooth or beaded dilatation of the main pancreatic duct is most commonly associated with carcinoma, and irregular dilatation is more frequently seen in chronic pancreatitis. On CT, a ratio of duct width to total gland width less than 0.5 favors the diagnosis of chronic pancreatitis. Chronic pancreatitis severity has been traditionally characterized by the Cambridge classification (Table 53-1), originally described for ERCP. However, similar ductal abnormalities may be well seen with magnetic resonance cholangiopancreatography (MRCP). Secretin stimulation during MRCP thick-slab technique can result in better visualization of the main and side branch pancreatic duct to assess for changes of chronic pancreatitis. Also, the efflux of pancreatic juice can be observed, giving functional information about the gland. The use of diffusion-weighted MRI to help distinguish between focal, mass-like pancreatitis and pancreatic adenocarcinoma is a current area of investigation, but remains problematic. One of the strengths of endoscopic ultrasound (EUS) is to sample indeterminate focal masses in patients that have other EUS evidence of chronic pancreatitis.

Chronic pancreatitis also can be associated with obstruction of the bile duct. In most instances, the lumen of

TABLE 53-1 Cambridge Classification of Chronic Pancreatitis

GRADE	ENDOSCOPIC RETROGRADE PANCREATOGRAM FINDINGS	
	Main pancreatic duct	Side branch pancreatic ducts
Normal	Normal caliber	Normal
Equivocal ducts	Normal caliber	Three or fewer dilated
Mild	Normal caliber	> Three dilated ducts
Moderate	Abnormal dilation	> Three dilated ducts
Severe	Abnormal dilation with calculi, obstruction, extravasation, or cavity formation	> Three dilated ducts

the obstructed bile duct tapers gradually through the inflamed region versus an abrupt transition commonly associated with neoplasm. Chronic pancreatitis may be associated with splenic and portal venous obstruction. Pseudocysts associated with chronic pancreatitis are different than those arising from acute pancreatitis. In general, there is side branch disruption, likely related to obstructive disease of the main pancreatic duct, with extravasation of pancreatic enzymes that may track throughout the abdomen or into the chest; it is not uncommon to see pseudocysts arising from chronic pancreatitis tracking into the gastric wall or along the splenic capsule.

AUTOIMMUNE PANCREATITIS

Autoimmune pancreatitis (lymphoplasmacytic sclerosing pancreatitis) is a chronic inflammatory process of the pancreas that is caused by an autoimmune mechanism, with morphologic hallmarks being periductal infiltration by lymphocytes and plasma cells together with granulocytic epithelial lesions and destruction of the duct epithelium. Serum IgG or gamma globulin elevations are associated in some patients, and there is usually a response to steroid therapy. Typical CT findings include diffuse or focal enlargement of the pancreas without dilation of the main pancreatic duct. Multiple pancreatic masses may be present. The enlarged portion/mass may be isoattenuating or hypoattenuating relative to the pancreatic parenchyma. Although not present in all patients, a rim of low-attenuation tissue surrounding the gland is characteristic and has been reported in 12% to 80% of cases. This is a specific sign, but the sensitivity varies widely (12%–80%

of reported cases). On MRI, the affected portion is generally hypointense on T1-weighted images, and the capsule-like rim may be hypointense on T2-weighted images and show delayed enhancement (suggesting fibrosis) on postgadolinium T1-weighted sequences. Other features include mural thickening and enhancement of the bile duct (obstructive jaundice seen in 63%–75%), rare peripancreatic stranding, venous occlusion, and peripancreatic lymph node enlargement. The incidence of associated extrapancreatic manifestations of autoimmune pancreatitis is reported from 19% to 50% and consists of sclerosing changes of the intrahepatic bile ducts (appearance similar to primary sclerosing cholangitis), retroperitoneal fibrosis, renal involvement (low-attenuation parenchymal masses), mediastinal adenopathy, and lung disease. When focal, distinguishing autoimmune pancreatitis from pancreatic adenocarcinoma may be difficult. Features that might help include absence of main pancreatic duct enlargement, absence of glandular atrophy, and absence of involvement of the major peripancreatic vessels in patients with autoimmune pancreatitis. Also, notably absent are parenchymal calcifications and duct dilation, features that help distinguish autoimmune pancreatitis from other forms of chronic pancreatitis.

OTHER CHRONIC CONDITIONS

Cystic Fibrosis (CF) results from dysfunction of exocrine glands and is an inherited disease characterized by chronic bronchopulmonary infections and malabsorption secondary to pancreatic insufficiency. Pancreatic manifestations include acute pancreatitis, fatty replacement, calcifications, cysts, duct abnormalities, and carcinomas. Complete fatty replacement of the pancreatic parenchyma is the most common imaging finding in adult CF patients, with mean age of this finding being 17 years. The amount of fatty replacement correlates with the degree of pancreatic exocrine, but not endocrine dysfunction. Exocrine gland insufficiency affects 85% to 90% of patients, and endocrine gland dysfunction has been reported in 30% to 50%. CF patients with lesser exocrine dysfunction are at risk for pancreatitis. Other disease patterns include one or more macroscopic fluid-density cysts scattered through the fatty replaced gland, or rarely complete replacement of the gland by true epithelium-lined cysts, pancreatic cystosis.

Primary hemochromatosis is a hereditary disease in which iron is deposited in the parenchyma of various organs. Liver, pancreas, and heart are primarily affected. Deposition of iron in the pancreas tends to occur later in the disease course, after liver damage is irreversible, and may be best seen on T2-weighted MRI.

NEOPLASM

PANCREATIC ADENOCARCINOMA

The clinical presentation of patients with pancreatic neoplasm varies according to the type of tumor. The most common pancreatic neoplasm is pancreatic adenocarcinoma; it is the ninth most common malignancy overall, but represents the fourth most common cause of cancer-related death. Peak incidence occurs in the seventh and eighth decade. These patients present with weight loss, abdominal pain, and jaundice if the tumor is located in the pancreatic head region and obstructs the bile duct. Imaging studies play a critical role in the diagnosis and management of patients with pancreatic neoplasms. Pancreatic adenocarcinoma is the tumor most likely to be spread beyond the organ of origin at diagnosis. At presentation, approximately 45% of patients have distant metastatic disease; 40% have locally advanced tumors that have invaded the peripancreatic vessels; and up to 15% have resectable lesions. Surgical therapy is the only option for cure at present, although patients may receive neoadjuvant or adjuvant therapy that has been shown to have a modest effect on survival. State-of-the-art multiphasic multidetector CECT consists of isometric data sets acquired through the upper abdomen/pancreas prior to contrast and during the pancreatic parenchymal phase, and throughout the abdomen and pelvis in the portal venous phase. With this technique, the overall sensitivity of CT for detection and diagnosis of pancreatic adenocarcinoma is high (89%–97%), and the positive predictive value for determining unresectability is very high (89%–100%). Accurate prediction of resectability is lower because of false-negative errors resulting from lack of detection of small hepatic and peritoneal metastases as well as underestimation of vascular invasion. At present, the criteria for diagnosing vascular invasion by tumor favor specificity over sensitivity, as it is important to avoid errors that result in denying a patient potential curative resection.

During the pancreatic parenchymal phase, typically hypovascular pancreatic adenocarcinoma appears as a low-attenuation, poorly demarcated mass within the more brightly enhancing pancreatic parenchyma. The sensitivity of CT for detection of pancreatic adenocarcinoma is high (89%–97% for larger lesions); however, identification of smaller tumors remains problematic. One recent study reported only 67% detection sensitivity for tumors that were less than or equal to 15 mm diameter, and another study reported 77% sensitivity for detection of pancreatic tumors less than or equal to 2 cm in size. It is this lesion size for which accurate detection with imaging may have the largest impact on patient survival. In addition, approximately 11% of pancreatic adenocarcinomas are isoattenuating to the remainder of the pancreas on

multiphasic CECT. Dilation of the bile duct and pancreatic duct may be present because of obstruction by tumor. Pancreatic adenocarcinomas are most commonly located in the pancreatic head region (approximately 60%). If located elsewhere in the pancreas, upstream main pancreatic duct dilation and glandular atrophy may be present. The duct interruption sign, where there is abrupt termination rather than tapering through a focal low-attenuation mass in the pancreatic parenchyma, favors pancreatic adenocarcinoma over focal mass-like chronic pancreatitis. Local pancreatitis induced by obstruction of the main pancreatic duct may obscure tumor boundaries. On portal venous phase images, the pancreatic primary tumor may be less distinct; however this phase is important for assessment of the peripancreatic veins (superior mesenteric vein and portal vein) as well as for the detection of hepatic metastases. With the volumetric data acquired on multidetector CT, postprocessing may aid in assessing vascular involvement and local extension. Curved multiplanar reformations along the main pancreatic duct or vessels have also been explored and may be helpful in the case of an isoattenuating pancreatic mass.

The American Joint Commission on Cancer recently revised the TNM staging for pancreatic adenocarcinoma (Table 53-2). Tumor staging, or T staging, is as follows: TX, tumor cannot be assessed; T0, no evidence of primary tumor; Tis, carcinoma in situ; T1, tumor confined to pancreas and smaller than 2 cm; T2, tumor confined to pancreas and larger than 2 cm; T3, tumor extension beyond the pancreas but no invasion of major peripancreatic vessels or nerves; T4, tumor invasion of major peripancreatic vessels or nerves. Criteria for resectability of pancreatic lesions currently includes absence of distant metastatic disease, no evidence of tumor involvement of major peripancreatic arteries (superior mesenteric artery, hepatic artery, or celiac axis), and either uninvolved major peripancreatic vein (superior mesenteric vein and portal vein) or suitable limited venous involvement to allow for venous reconstruction. When assessing vascular invasion, degree of contact between the vessel and tumor estimated at greater than 50% represents an “optimal” threshold for predicting vascular invasion, with sensitivity of 84% and specificity of 98%. To avoid denying surgery to patients with potentially resectable disease, it may be preferable to increase the threshold to 75% contact with the circumference of an affected vessel. The shape of the vessel should be commented on as well, as narrowing or teardrop configuration of the superior mesenteric vein for example may indicate tethering caused by tumor infiltration. In addition, it has been proposed that criteria for diagnosing vascular invasion by tumor should differ between arteries and veins—areas of continued investigation. While peripancreatic lymph nodes may be detected on CT, the finding of an enlarged lymph node should not preclude

TABLE 53-2 TNM Staging of Pancreatic Adenocarcinoma

STAGE	TNM	DESCRIPTION	5-YEAR RELATIVE SURVIVAL
0	Tis, N0, M0	Tumor confined to superficial pancreatic duct epithelium (pancreatic carcinoma in situ or pancreatic intraepithelial neoplasia III (PanIn III))	
IA	T1, N0, M0	Tumor confined to pancreas, less than 2 cm; no LN or distant metastases	37
IB	T2, N0, M0	Tumor confined to pancreas, larger than 2 cm; no LN or distant metastases	21
IIA	T3, N0, M0	Tumor extends beyond pancreas but no vascular, LN, or distant metastases	12
IIB	T1-3, N1, M0	Tumor confined to pancreas or peripancreatic extension; no vascular involvement regional LN metastases, but no distant metastases	6
III	T4; any N, M0	Tumor invasion of vessels or major nerves $\pm$ lymph nodes, no distant metastases	2
IV	Any T; any N, M1	Distant metastases	1

attempted resection, as the lymph nodes are resected en bloc with the primary lesion.

Other imaging studies utilized in the evaluation of pancreatic adenocarcinoma include MRI and EUS. On MRI, pancreatic adenocarcinomas are typically hypointense on precontrast T1-weighted fat-suppressed three-dimensional spoiled gradient-echo images, and are relatively hypovascular on pancreatic parenchymal and portal venous phase. The sensitivity of MRI for detection of pancreatic adenocarcinoma is slightly less than helical CT; however, the two modalities are equivalent for determining resectability. Positron emission tomography may be used in patients with pancreatic cancer, with the largest impact being on detection of distant metastases. However, sensitivity for accurate depiction of small hepatic metastases is lower. Combining positron emission tomography and CT as an adjunct to multiphasic pancreatic contrast-enhanced multidetector CT resulted in 88% sensitivity for staging.

CYSTIC PANCREATIC NEOPLASMS

When a cystic lesion is present in the pancreas, the diagnosis of an inflammatory pseudocyst arising from acute pancreatitis, an acute pancreatitis episode superimposed on chronic pancreatitis, or from chronic pancreatitis should first be excluded. Occasionally, history is unrevealing. Aspiration of cysts contents (Table 53-3), typically via EUS fine needle aspirate, may be performed to differentiate between potential etiologies of pancreatic cystic lesions, especially when the imaging appearance is not definitive. However, sampling errors are not uncommon, and interpretation of cyst aspirate results must be performed in conjunction with careful patient history and interpretation of radiologic findings; if the nature of the cystic lesion cannot be definitively established by these combined measures, surgical resection may be warranted.

SIMPLE CYSTS

Epithelial line cysts of the pancreas are rare. They occur in patients with von Hippel-Lindau (VHL) disease, polycystic kidney disease with hepatic and pancreatic involvement, and CF.

Serous Cystadenoma

Serous cystadenoma (former names, microcystic adenoma and glycogen rich adenoma) is a benign cystic neoplasm of the pancreas, more common in females (2:1 ratio) than males, occurs in the seventh decade, and often is not associated with symptoms unless large. On CT, serous cystadenomas have classically been described as heterogeneous mixed-density lesions made up of multiple small cysts (0.2–2.0 cm) that resemble the cut surface of a natural sponge. A minority of patients will have lesions that demonstrate a characteristic central stellate scar with calcification. Individual cysts may be larger than 2 cm, and rarely serous cystadenomas may be unilocular. When the individual cysts are large, this lesion may be mistaken for mucinous cystic neoplasm. In general, combined features of location in the pancreatic head (rather than tail), lobular contour, and the presence of a thin capsule without enhancement or projections/nodules may help to distinguish a serous

TABLE 53-3 Cyst Aspirate Assessment

IPMN	++++		+++	
Inflammatory pseudocyst	+++++			

cystadenoma from a mucinous cystic neoplasm. At ultrasound, these lesions may appear as a solid echogenic mass because of the many interfaces produced by the numerous cysts. Occasionally smaller lesions may appear solid on CT and MRI, depending on the size of individual cysts and amount of fibrous tissue. Aspiration of cyst contents (obtained during EUS with fine needle aspirate) may be helpful in differentiating between the two, as the serous cystadenomas contain epithelial cells that are rich in cytoplasmic glycogen.

Mucinous Cystic Neoplasm

Mucinous cystic neoplasms (MCN; older terms, macrocystic adenoma and macrocystic adenocarcinoma) are more common in females than males (9:1 ratio), occur in the fifth to sixth decade of life, and are usually located in the body or tail of pancreas. At diagnosis, the tumor histology may be benign, atypical, or frankly malignant. All are considered premalignant and require surgical resection. The mucinous cystic neoplasm cavity is lined by tall mucin-producing columnar cells. The cavity is filled with low-attenuation mucinous material and may have papillary projections and nodules that demonstrate progressive enhancement on CT. On MRI, high T2-weighted signal fills the cystic spaces, and enhancement of the wall, septations, and excrescences is apparent after gadolinium administration on T1 fat-suppressed spoiled gradient-recalled echo imaging. While the presence of enhancing nodules and septations correlates with malignancy, absence of these findings does not preclude malignancy. There is generally no communication of MCN with the pancreatic ductal system. Curvilinear calcifications may be noted in the tumor periphery/capsule in 10% to 25% of cases. When multilocular, individual cystic spaces in MCN tend to have diameter greater than 2 cm. In general, the greater the degree of complexity, the more likely the tumor will be malignant at time of diagnosis.

Intraductal Papillary Mucinous Neoplasm

Intraductal papillary mucinous neoplasm (IPMN; older term, duct/ectatic mucinous tumor) is a mucin-producing tumor that arises from the pancreatic duct epithelium. As with MCN, at diagnosis these lesions may be benign, atypical, or frankly malignant. Unlike MCN, IPMNs lack an associated ovarian-type stroma. There is a 2:1 male-to-female predominance, with patients typically presenting in the seventh to ninth decade. Symptoms, malignant potential, prognosis, and imaging features vary according to whether the lesion arises from a side branch duct or from the main pancreatic duct, or both (mixed or combined type). On CT, a side branch-type IPMN typically appears as a small cystic mass, often within the uncinate portion of head of pancreas. The mass is unilocular or may resemble a group of small clustered cysts. Lesions less than 3 cm are usually,

but not always, benign. Communication of this cystic lesion with the main pancreatic duct may be identified on thin-section CT and even more readily on MRCP. If copious amounts of mucin are produced in the side branch IPMN, this may result in main pancreatic duct enlargement downstream from the site of ductal communication. Main duct-type IPMN produces diffuse dilation of the main pancreatic duct. Atrophy of the gland and dysmorphic calcifications may be present, mimicking findings of chronic pancreatitis. However, patients with main duct-type IPMN present at a later age than patients with chronic pancreatitis and may have a bulging papilla because of mucin production. Main duct-type tumors are more likely than side branch IPMNs to be malignant. Approximately 7% to 34% of IPMNs treated with surgical resection will contain carcinoma in situ; more importantly 25% to 44% of IPMNs will contain invasive carcinoma. Imaging features associated with malignancy or invasive carcinoma include main duct diameter greater than 1.5 cm, diffuse or multifocal involvement, enhancing nodules or excrescences within the duct, or the presence of a focal hypovascular soft tissue mass, and bile duct obstruction. If the lesion is a side branch- or combined-type IPMN, large size of the mass suggests malignancy. MR imaging with MRCP demonstrates in the full extent of ductal involvement, and when combined with standard T2- and contrast-enhanced T1-weighted images can be utilized for determination of resectability. The presence of a communication between the cystic lesion and the main pancreatic duct is one of the most reliable findings for the diagnosis of IPMN. The communicating track of malignant IPMNs is typically larger than in benign lesions. All main duct lesions are considered to be malignant, if not frankly malignant at the time of diagnosis, and should be considered for surgical resection. The surgical method may be altered (more radical resection or lymph node dissection) if invasive carcinoma is predicted with imaging.

Follow-up of suspected IPMNs in patients with asymptomatic side branch IPMNs is controversial; in general, if there is no evidence of malignancy these may be closely followed with imaging. Although there is no consensus, one strategy is to follow patients with small (less than 3 cm), unilocular, asymptomatic cystic lesions at 6-month intervals for the first year, at yearly intervals for 3 years, and if stable, consider discontinuing surveillance at that time.

Solid Pseudopapillary Tumor of the Pancreas

Solid pseudopapillary tumor (SPT; former terms, solid and papillary epithelial neoplasm, papillary and cystic tumor) is an uncommon, low-grade malignant tumor that occurs in young women (third decade), is generally large at presentation, and is typically located in the pancreatic tail region. With CECT and MR imaging, SPTs

may demonstrate progressive fill-in of the solid portions of the mass over time, and may contain hemorrhage or fluid/debris levels of blood products in areas of cystic degeneration or necrosis. The absence of high T1 (hemorrhagic) signal within the lesion does not exclude the diagnosis however. When the lesions are small, distinguishing them from other solid pancreatic neoplasms is more problematic.

Pancreatic Neuroendocrine Tumors

Pancreatic neuroendocrine tumors (NETs) are uncommon neoplasms that arise from neural crest cells or well-differentiated neuroendocrine cells of the pancreas, and are classified as functioning (syndromic) or nonhyperfunctioning (nonsyndromic); all produce and secrete hormones to varying degrees. Although most NETs occur sporadically, an increased prevalence of these tumors is seen in patients with VHL syndrome, multiple endocrine neoplasia type I (MEN I), neurofibromatosis type 1, and tuberous sclerosis. Despite their rarity, these tumors are important because they have a high rate of malignancy, ranging from 60% to 92%. Functioning NETs are generally named for the predominant hormone produced and are associated with specific clinical symptoms related to the hormone production (Table 53-4). Hormonally active tumors are typically diagnosed when small. The most common functioning NETs are insulinomas and gastrinomas, with glucagonomas, VIPomas, and somatostatinomas much less common. NETs may also be multiple, especially gastrinomas. Risk of malignancy varies with histology. In general, 5% to 10% of insulinomas are malignant, but 50% to 90% of the other NETs are malignant. Insulinomas are the most common syndromic NET and produce the classic Whipple triad: fasting serum glucose less than 50 mg/dL, hypoglycemia symptoms, and response to glucose administration. Gastrinomas are the second most common syndromic NET and produce symptoms related to excessive gastrin production, Zollinger-Ellison syndrome: epigastric pain related to intractable peptic

ulcer disease, diarrhea related to excess acid delivery to the small bowel. These tumors are often multiple and extrapancreatic, located in either the pancreatic wall or an area termed the “gastrinoma triangle,” an area bounded by the junction of the cystic and common hepatic duct superiorly, the second and third portions of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially. Glucagonomas are rare syndromic NETs and are associated with a characteristic rash—necrolytic migratory erythema. In addition to the dermatosis, these patients may also have diarrhea, depression, and deep vein thrombosis, hence the term 4D syndrome. VIPomas secrete a variety of hormones, most notably vasoactive intestinal peptide that is responsible for fluid and electrolyte secretion into the small bowel and the characteristic watery diarrhea suffered by these patients. Gastrin production is also inhibited; therefore the syndrome is referred to as watery diarrhea, hypokalemia, achlorhydria (WDHA), or sometimes Verner-Morrison syndrome after the men who first described it in 1958. Somatostatinomas are exceedingly rare lesions; the excess somatostatin results in a syndrome of diarrhea, cholelithiasis, indigestion, and hypochlorhydria.

Nonhyperfunctioning tumors represent approximately 20% to 50% of lesions reported in case series of NETs. In general, they are clinically silent unless they produce symptoms caused by metastatic disease or size. These tend to be larger than the syndromic variety; 30% of these lesions are greater than 10 cm at presentation. In addition, when NETs are cystic or necrotic, they are usually nonhyperfunctioning. These lesions are malignant in up to 80% of cases.

On CECT, functioning NETs are generally hypervascular lesions compared to normal pancreatic parenchyma. Because of the brisk enhancement during the arterial or pancreatic parenchymal phase, in the past these lesions were sometimes mistaken for vessels on thicker section axial images alone, but with state-of-the-art multiphasic CT, especially with coronal reformatted

TABLE 53-4 Syndromic Pancreatic Neuroendocrine Tumors

	HORMONE	SYNDROME	LOCATION	CELL ORIGIN	MALIGNANT
Insulinoma	Insulin	Whipple triad	Pancreas	Beta	10%
Gastrinoma	Gastrin	Zollinger-Ellison	Gastrinoma triangle		30%
Glucagonoma	Glucagon	“4D” (dermatosis, diarrhea, depression, deep vein thrombosis)	Body or tail	Alpha	60%
VIPoma	Vasoactive intestinal peptide	WDHA (watery diarrhea, hypokalemia, achlorhydria)	Tail	D1	75%
Somatostatinoma	Somatostatin	Diarrhea, cholelithiasis, indigestion, hypochlorhydria	Pancreas or duodenal wall	Delta	50%

images, this is now not as common. Some lesions, despite the propensity for being hypervascular, are hypoenhancing on early phases and are best seen on portal venous phase. Location of the lesion depicted on CT may alter surgical approaches for smaller lesions; if near the surface, enucleation is often employed. CT features that aid in distinguishing between nonfunctioning NET and other solid lesions such as adenocarcinoma include the presence of coarse calcifications, lack of vascular encasement or invasion despite large size, and cystic degeneration when large. Rarely, nonfunctioning and functioning NETs may appear completely cystic on CT. MR imaging using T1-weighted fat-suppressed three-dimensional spoiled gradient-echo images readily identify pancreatic NETs and have been shown to be at least as effective as CT. Other MR imaging features that help distinguish NETs from ductal adenocarcinomas include higher signal intensity on T2 fat-suppressed images and homogeneous enhancement on immediate post-gadolinium T1-weighted images. In addition, liver metastases are typically hypervascular and well depicted with MR.

OTHER NEOPLASMS

Pancreatic lymphoma may be caused by primary (intrapancreatic) lymphoma or by invasion of the pancreas from peripancreatic nodal involvement. In general, when the pancreas is involved by lymphoma, the lesion is larger than that typically seen with adenocarcinoma, and there is no pancreatic duct dilation despite the large size of the tumor.

Pancreatic metastases most commonly arise from breast, lung, kidney, prostate primaries, or melanoma. In general, there is imaging evidence of other metastatic disease except in the case of renal carcinoma metastases, which may occur many years after the primary tumor is diagnosed and may be an isolated pancreatic finding. The enhancement pattern of pancreatic metastases varies depending on the primary tumor, with renal and melanoma metastases being hypervascular on pancreatic parenchymal phase.

Other rare pancreatic lesions include pleomorphic carcinoma, acinar cell carcinoma, giant cell tumor, sarcoma, and small cell carcinoma. Pancreatic tumors are rare in infants and children, the commonest being pancreatoblastoma, a rare tumor of acinar cell origin in children between ages of 1 and 8.

Periampullary tumors are defined as those arising within 2 cm of the major papilla. These may be difficult to differentiate from pancreatic adenocarcinomas as they commonly obstruct the bile duct and produce a focal mass in the head of pancreas. They are often treated with Whipple procedure, and in general have a better prognosis than pancreatic adenocarcinoma. Lesions include ampullary villous adenoma, ampullary adenocar-

cinoma, distal cholangiocarcinoma, and duodenal adenocarcinoma.

Other focal masses that may mimic pancreatic pathology include intrapancreatic accessory spleen and duodenal diverticulum. Intrapancreatic accessory spleen follows the enhancement of the spleen on all phases of contrast on all modalities; heterogeneous enhancement during arterial or pancreatic parenchymal phases may be a diagnostic clue on CT or MRI. In addition, on MRI with super-paramagnetic iron oxide enhancement, the "mass" will demonstrate signal drop on T2- or T2*-weighted images similar to the spleen. A second portion medial duodenal diverticulum may mimic a cystic neoplasm when fluid filled and a negative oral contrast agent has been used; careful review of prior CTs may demonstrate air in the lesion or obtaining follow-up CT using a positive oral contrast medium may be of help.

SYNDROMES

VHL disease is an autosomal dominant multisystem disorder characterized by development of a variety of benign and malignant tumors. Pancreatic lesions are important to recognize because they may precede other abdominal manifestation by years. Pancreatic involvement includes simple pancreatic cysts in 50% to 91%, serous cystadenomas in 12%, pancreatic NETs in 5% to 17%, and rarely adenocarcinomas. It is uncommon for neuroendocrine lesions and cystic lesions to be present together. NETs occur more frequently in VHL patients who have pheochromocytomas; both lesions are derived from neural crest cells. The frequency of malignancy and metastatic disease in NET associated with VHL is low (less than 10%), whereas sporadic pancreatic NET metastasize in 60% to 92% of cases. Owing to the low malignant potential, these lesions may be followed in VHL patients, and when surgery is indicated pancreas-sparing procedures are employed.

Patients with MEN I have an increased prevalence of pancreatic NETs, usually of the syndromic (functioning) variety. Approximately 10% of patients with insulinomas have MEN I; however, the most common NET in patients with MEN I is gastrinoma.

TRAUMA

Pancreatic injuries occur in 2% to 12% of patients with blunt abdominal trauma. Either blunt or penetrating abdominal trauma may cause pancreatic ductal disruption, with development of the entire spectrum of acute pancreatitis. Most commonly, pancreatic injuries are caused by crushing injury due to impact against the vertebral

column; two-thirds of pancreatic injuries occur in the pancreatic body. Associated injuries to the liver, stomach, duodenum, and spleen occur in more than 90% of cases; isolated pancreatic injury is extremely uncommon. Early recognition of disruption of the main pancreatic duct is important because disruption is the principal cause of delayed complications such as pseudocyst, abscess, or fistula. CT can readily demonstrate pancreatic parenchymal injuries such as lacerations and contusion in the acute setting, and although duct disruption cannot be directly imaged with CT, the extent of parenchymal laceration can help suggest its presence. Direct CT findings of pancreatic injury include pancreatic enlargement, focal laceration with linear nonenhancement coursing a variable distance through the parenchyma, or heterogeneous enhancement. Secondary findings of pancreatic injury are peripancreatic stranding, peripancreatic fluid collections that may communicate with a laceration, fluid between the splenic vein and pancreas, hemorrhage, or fluid tracking/thickening along the left anterior pararenal fascial planes. The most accepted scoring system for pancreatic injury is the American Association for the Surgery of Trauma (AAST) system, which assesses variable of location (proximal vs. distal), type of injury (hematoma, laceration, or transection) and main pancreatic duct integrity (Table 53-5).

Although CT is the standard for evaluation of post-traumatic abnormalities, ductal integrity can be evaluated with MRI and specifically MR pancreatography. Fluid-sensitive MRCP images focused on the main pancreatic duct may help delineate ductal integrity and demonstrate fluid collections upstream to the site of duct transection. ERCP remains important in the assessment of ductal disruption in traumatic pancreatitis as it can be

used for primary therapy with stent placement or serve as a guide for surgical repair. When CT or MRI are suggestive of main pancreatic duct disruption, it is imperative that the imager notify the primary service; delay in therapy longer than 72 hours after the initial trauma may result in a higher complication rate and prolonged hospitalization in patients with traumatic pancreatitis.

TRANSPLANTATION

The majority of pancreatic transplants are combined with renal transplants in patients with end-stage renal disease because of severe type 1 diabetes mellitus. Two methods of pancreatic transplantation may be utilized. The traditional procedure places the graft in an intraperitoneal location of the iliac fossa opposite the renal transplant, with the vascular pedicle (donor splenic artery and superior mesenteric artery) anastomosed to the common or external iliac arteries by way of a vascular Y graft, and the pancreatic venous outflow emptying into the common or external iliac vein; the accompanying cuff of duodenum may be anastomosed to the bladder or small bowel. Alternatively, for portoenteric venous drainage, the graft may be placed in an intraperitoneal location within the upper abdomen, with the vascular pedicle anastomosed to the common or external iliac arteries by way of a longer vascular Y graft, and the pancreatic venous outflow emptying into the superior mesenteric or splenic vein; the accompanying cuff of duodenum is anastomosed to small bowel. The graft may be lost in the immediate perioperative period, most commonly because of vascular thrombosis (arterial or venous), reported from 2% to 19%, and less commonly because of infection, pancreatitis, bleeding, and anastomotic leaks. CT is helpful in evaluating postoperative complications such as anastomotic leaks, hemorrhage or other peripancreatic fluid collections, or graft pancreatitis, and with CTA techniques has the potential to identify vascular thrombosis. In particular, CT may aid in differentiating between acute rejection and pancreatitis, which may appear similar on ultrasound and can readily identify gas in patients with emphysematous pancreatitis of the graft, because of either infection or major vascular thrombosis. Vascular thrombosis is detectable with Doppler ultrasound and MRI. MRI is particularly useful when there is renal allograft dysfunction precluding administration of iodinated contrast medium, and with high-resolution three-dimensional or four-dimensional time of flight MRA and three-dimensional T1-weighted fast-spoiled gradient-echo sequences, investigation of vascular anatomy and abnormalities in addition to evaluation of the graft for reject and infarction.

TABLE 53-5 AAST Scoring System for Pancreatic Trauma

GRADE	INJURY	DESCRIPTION
I	Hematoma	Minor contusion without duct injury
	Laceration	Superficial laceration without duct injury
II	Hematoma	Major contusion without duct injury
	Laceration	Major laceration without duct injury
III	Laceration	Distal transection or parenchymal injury with duct injury
IV	Laceration	Proximal transection or parenchymal injury involving the ampulla or bile duct
V	Disruption	Massive disruption of the pancreatic head

QUESTIONS AND ANSWERS

- Concerning blunt pancreatic trauma, which of the following is the most important determinant of pancreas-related complications?
 - Pancreatic hematoma
 - Pancreatitis
 - Main pancreatic duct disruption
 - Pancreatic necrosis

ANSWER: C. Pancreatic hematoma is possible but generally would be more self-limited than duct disruption. Pancreatitis may develop after trauma, but does not lead to the severe and prolonged complications that disruption of the main pancreatic duct would produce. Pancreatic necrosis could conceivably occur as a complication of posttraumatic pancreatitis and may lead to severe complications, but in the setting of acute trauma main pancreatic duct disruption is the determining factor for disease severity.

- Which of the following is the most common pancreatic abnormality in adult patients with CF?
 - Pancreatic cystosis
 - Complete fatty replacement
 - Partial agenesis of the dorsal duct
 - Pancreatic adenocarcinoma

ANSWER: B. Pancreatic cystosis is a rare manifestation of CF, while partial agenesis of the dorsal duct is not associated with CF. Pancreatic adenocarcinoma may occur in patients with CF, but is not nearly as common as fatty replacement.

- What is the most appropriate term for an enzyme-rich collection of peripancreatic fluid accompanied by focal (<30%) gland necrosis in a patient hospitalized for 10 days with acute pancreatitis?
 - Pancreatic necrosis
 - Postnecrotic pancreatic collection
 - Pancreatic pseudocyst
 - Acute fluid collection

ANSWER: B. Pancreatic necrosis describes diminished perfusion of the pancreatic parenchyma. Pancreatic pseudocyst requires 4 weeks to form and by definition has no necrosis. Acute fluid collection is the older term for enzyme-rich pancreatic juice that is not contained and is released acutely into the retroperitoneum in acute pancreatitis.

- Which of the following is the correct T stage for a pancreatic adenocarcinoma that measures 3.5 cm longest diameter, extends beyond the margins of the pancreas, but does not clearly encase the peripancreatic vessels?
 - T1
 - T2
 - T3
 - T4

ANSWER: C. T1 stage refers to smaller lesions confined to the pancreas (less than 2 cm). T2 stage refers to larger lesions confined to the pancreas (greater than 2 cm). T4 stage refers to locally advanced

tumors that involve the adjacent peripancreatic vessels or nerves.

5. An EUS with fine needle aspirate of primary pancreatic lesion in addition to a nearby lymph node confirms moderately differentiated pancreatic adenocarcinoma. There are no distant metastases detected on contrast-enhanced multiphasic MDCT. Which of the following is the correct TNM stage?
 - A. IIa
 - B. IIb
 - C. III
 - D. IV

ANSWER: B. Stage IIa is node negative. Stage III is incorrect, as T4 lesion (local invasion of vessels) is part of this definition. Stage IV disease refers to pancreatic adenocarcinoma with distant metastatic disease, absent in the above-described case.

6. Which of the following is the most common anatomical variant of the pancreas?
 - A. Pancreas divisum
 - B. Partial dorsal agenesis
 - C. Anomalous pancreatobiliary duct union
 - D. Annular pancreas

ANSWER: A. Pancreas divisum is found in 5% to 10% of the population in autopsy series. Others are much less common anatomic variants.

7. What percentage of non-hyperfunctioning (nonsyndromic) pancreatic NETs are malignant?
 - A. 10%
 - B. 30%
 - C. 50%
 - D. 80%

ANSWER: D. The majority of non-hyperfunctioning or endocrine tumors are malignant.

8. In a patient with a hyperfunctioning pancreatic neuroendocrine tumor, which of the following syndromes corresponds to the symptom complex of fasting serum glucose < 50 mg/dL, hypoglycemia symptoms, and response to glucose administration?
 - A. Verner-Morrison syndrome
 - B. Zollinger-Ellison syndrome
 - C. Whipple triad
 - D. WDHA syndrome

ANSWER: C. The symptom complex (fasting serum glucose < 50 mg/dL, hypoglycemia symptoms, and response to glucose administration) describes the classic Whipple triad. Verner-Morrison syndrome describes clinical findings associated with VIPoma. Zollinger-Ellison syndrome de-

scribes clinical symptoms associated with a gastrinoma. WDHA syndrome is another term to describe the syndrome associated with VIPoma.

9. Which of the following tumors does the patient described in question 8 have?
 - A. Glucagonoma
 - B. VIPoma
 - C. Gastrinoma
 - D. Insulinoma

ANSWER: D. Whipple triad describes the syndrome seen in patients with insulinomas.

10. A 72-year-old woman had an abdominopelvic CT scan to evaluate left lower quadrant pain, suspected diverticulitis. A 4-cm unilocular cystic pancreatic head mass was incidentally discovered. EUS confirmed the unilocular nature, and fine needle aspirate revealed mucin, elevated CEA, and no amylase. Which of the following is the most likely diagnosis?
 - A. Oligocystic serous cystadenoma
 - B. Side branch-type IPMN
 - C. Inflammatory pseudocyst
 - D. Mucinous cystic neoplasm

ANSWER: D. Elevated mucin within a cystic pancreatic mass that appears unilocular is classic for mucinous cystic neoplasm. Oligocystic serous cystadenoma is possible given the imaging findings, but less likely as an oligocystic serous cystadenomas would contain glycogen-rich cells rather than mucin in the aspirate. Although side branch IPMN may appear cystic and reach a size of 4 cm, elevated CEA level is not characteristic. Inflammatory pseudocysts typically demonstrate elevated amylase levels.

54 PERITONEAL CAVITY AND ABDOMINAL WALL

Bhavik N. Patel, Sanjiv K. Bajaj, and Cheri L. Canon

NORMAL ANATOMY

PERITONEUM

The peritoneum forms the lining of the abdominal cavity. It consists of two layers of pleura, the parietal pleura (lining the abdominal wall) and visceral pleura (lining

the organs), which appose to form a double layer that transmits vessels, nerves, and lymphatics. This double layer forms infoldings that divide the abdomen into compartments and support the abdominal organs. The intraperitoneal organs include the liver, spleen, gallbladder, stomach, first portion of the duodenum, small bowel, and transverse and sigmoid colons. The retroperitoneal organs include the adrenal glands, kidneys, ureters, urinary bladder, inferior vena cava, aorta, pancreas, esophagus, second and third portions of the duodenum, ascending and descending colons, and rectum. The dome of the liver (“bare area”) is not covered by peritoneum. It is surrounded by peritoneal reflections in a rounded configuration (“coronary ligament”).

The two major divisions of the abdominal cavity are the greater and lesser sacs. The lesser sac is a normally collapsed space posterior to the stomach that communicates with the greater sac, the remainder of the abdominal cavity, via the foramen of Winslow (epiploic foramen). Its anterior boundaries include the stomach and lesser omentum, a layer of peritoneum hanging from the stomach, and its posterior boundary is the retroperitoneum, including the pancreas. Its inferior margin is formed by the transverse colon and greater omentum and its superior margin by the liver and diaphragm (Fig. 54-1). The spleen bounds it on the left, and the epiploic foramen allows inflow and outflow from the right.

Within the greater sac, peritoneal reflections separate the cavity into distinct zones. The falciform ligament separates the right and left subphrenic spaces. The right subphrenic space communicates easily with Morrison pouch, the hepatorenal space, the most dependant portion of the abdomen in supine individuals. The pouch of Douglas, the rectouterine pouch, is the most dependent portion of the abdomen and pelvis in upright women. The left subhepatic and left subphrenic spaces communicate with each other, but they do not communicate with the left paracolic gutter because of the phrenicocolic ligament.

MESENTERY AND OMENTUM

Developing from the mesenchyme, the mesentery attaches the foregut, midgut, and hindgut to the posterior abdominal wall and later gives rise to the dorsal mesentery during embryonic development. The dorsal mesentery then becomes the respective structures based on its location. For example, the dorsal mesentery near the stomach becomes the greater omentum (Table 54-1). During embryonic development, the mesentery segments of the duodenum, ascending colon, and descending colon becomes fixed to the retroperitoneum. The jejunum, ileum, transverse colon, and sigmoid mesenteries remain mobile. The mesentery serves as an avenue

for the vascular, lymphatic, and neural channels to and from the bowel.

The greater omentum is an apronlike double sheet of peritoneum that hangs inferiorly from the stomach and proximal duodenum and drapes over the small bowel. On CT, it appears as a simple fatty layer between the abdominal wall and is anterior to the stomach, small bowel, and transverse colon. The descending portions of the greater omentum fuse to form the gastrocolic ligament that connects to the transverse colon. Similarly, the gastrosplenic and gastrophrenic ligaments attach to the spleen and thoracic diaphragm, respectively. The greater omentum serves as a visceral fixation and a shield limiting pathologic spread. However, because it is bathed in peritoneal fluid, it is a common site of neoplastic and infectious seeding. The hepatoduodenal and gastrohepatic ligaments, collectively known as the lesser omentum, connect the lesser curvature of the stomach and proximal duodenum with the liver. The gastrohepatic ligament contains the left gastric vessels and lymph nodes and can be identified on CT as a triangular fat-containing region between the stomach and the liver. The hepatoduodenal ligament contains the common bile duct, portal vein, and hepatic artery, and its inferolateral margin forms the anterior margin of the epiploic foramen or the foramen of Winslow. It is through the epiploic foramen that the lesser sac, a peritoneal space between the stomach and the pancreas, communicates with the peritoneal cavity.

ABDOMINAL WALL

The abdominal wall is defined superiorly by the xiphoid process, inferiorly by the pubic symphysis, and posteriorly by the vertebral column and is composed of multiple layers (Table 54-2). The subcutaneous tissue consists of a fatty, superficial layer of fascia known as Camper fascia and a deeper, fibrous connective tissue layer known as Scarpa fascia. The external oblique, internal oblique, and transversus abdominis are the three muscles making up the anterolateral wall and enclose a large portion of the torso. Their fibers run oblique to one another and their aponeuroses fuse anteriorly to form the rectus sheath that encases the rectus abdominis muscles. The external oblique arises from the lower seven to eight ribs and courses inferomedially with its inferior portion of the aponeurosis rolled up on itself posteriorly and superiorly forming the Poupart or inguinal ligament. This portion of the external oblique extends from the anterior iliac spine to the pubic tubercle and forms a groove in which the spermatic cord lies. The iliacus, psoas, and pectineus muscles, and the femoral artery, nerve, and vein run underneath the inguinal ligament. A femoral hernia traverses posterior to the inguinal

FIG. 54-1 Drawing of the anatomy of the greater and lesser omenta (A) and axial (B), coronal (C), and sagittal (D) diagrams of the upper abdomen. The greater omentum (GO) is composed of a double layer of peritoneum that extends from the greater curvature of the stomach (S) inferiorly. Its descending and ascending portions usually fuse to form a four-layer vascular fatty apron; the resulting space is contiguous with the lesser sac (LS). The lesser omentum (LO) connects the lesser curvature of the stomach and proximal duodenum with the liver (L) and contains blood vessels, nerves, and lymph nodes. The lesser sac is empty and collapsed so that only parts of its boundaries, such as the posterior gastric wall and pancreatic body, are observed on axial CT scans. Ao, aorta; C, colon; K, kidney; P, pancreas; Sp, spleen; 1, = falciform ligament; 2, = gastrohepatic ligament; 3, = gastrosplenic ligament.

ligament, while an inguinal hernia passes anterior and superior to it. The internal oblique muscle fibers run in the opposite direction of and lie immediately below the external oblique muscle. Its inferior most fibers run along the spermatic cord and form the cremasteric mus-

cle in the inguinal canal. The transversus abdominis muscle is the deepest of the three muscles and courses transversely from the lower six costal cartilages, lumbar vertebral spinous processes, and the iliac crest to the rectus abdominis muscle.

TABLE 54-1 Dorsal Mesentery Derivatives Based on Location

REGION	STRUCTURE
Stomach	Greater omentum
Colon	Mesocolon
Jejunum and ileum	Mesentery proper

Lying between the transversus abdominis and the extraperitoneal fat, the thin aponeurotic membrane of the transversalis fascia forms the fascial layer that lines the abdominal cavity giving it its structural integrity. A hernia results when there is a defect in this layer. The transversalis fascia forms the floor of Hesselbach triangle (Table 54-3) through which a direct inguinal hernia passes. The preperitoneal space contains adipose tissue through which the inferior epigastric artery and vein course before their entry into the rectus sheath. In addition, three fetal structures also lie within this space: the median umbilical ligament representing the remnant urachus, the medial umbilical ligament representing the vestigial umbilical artery, and the ligamentum teres representing the obliterated umbilical vein. The rectus abdominis muscles are paired midline muscles that are encased within the rectus sheath and extend from the xiphoid to the pubic symphysis. Along the paired muscles, there are approximately three to five tendinous interruptions of the muscle providing a site of attachment for the anterior rectus sheath. The anteroposterior layers of the rectus sheath come together at the midline to form the linea alba. Thinning of the linea alba, or diastasis recti, can lead to protrusion of the anterior abdominal wall. However, as long as the transversalis fascia is intact, there is no true hernia.

PATHOLOGY

PERITONEUM

CARCINOMATOSIS/METASTATIC DEPOSITS

Metastatic cancers frequently involve the peritoneum. Intraperitoneal tumors commonly spread by direct im-

Medial	Lateral border of rectus sheath

plantation, when their cells become mobile in ascitic fluid. Gastric, colonic, and ovarian cancers frequently spread by this route, often to dependant areas, such as Morison pouch, ileocecal region, and the pouch of Douglas. These metastases distort the architecture of the surrounding abdominal organs, leading to fixed, retracted segments of bowel on barium examinations. Nodular, enhancing implants are seen on CT, often with associated ascites. Ultrasound demonstrates frequently hypoechoic nodules or masses, often with internal Color Doppler flow, in the setting of ascites. Treatment targets the primary neoplasm.

PERITONEAL LYMPHOMA

Peritoneal involvement by lymphoma is rare and is nearly always of the Non-Hodgkin type. It classically occurs in patients with HIV. The disease presents similarly to peritoneal carcinomatosis, with peritoneal soft-tissue density nodularity and ascites. Treatment is with chemotherapy.

PSEUDOMYXOMA PERITONEI

Pseudomyxoma peritonei most commonly arises when appendiceal adenocarcinoma gives rise to a thick, mucinous material that spreads throughout the abdomen on appendiceal rupture. Other mucinous cancers, especially ovarian, more rarely give rise to this entity. Patients present with abdominal fullness, pain, and weight loss and many progress to bowel obstruction as the bowel becomes compressed by mucinous masses. Pseudomyxoma peritonei appears on CT as low attenuation ascites that causes nodular impressions upon the visceral organs. The liver surface characteristically has a “scalloped” appearance. The fluid may contain calcifications and appear complex. Ultrasound demonstrates echogenic ascites without mobile reflectors with fixed, displaced bowel loops and scalloping of the liver surface. The prognosis from this entity is extremely poor. Surgical therapy aims to ameliorate symptoms rather than provide a cure.

MALIGNANT MESOTHELIOMA

Primary peritoneal mesothelioma arises from neoplasia of peritoneal mesothelial cells in patients with asbestos exposure. It carries a similarly dismal prognosis to its thoracic counterpart, but is rare, occurring in approximately

one-third of thoracic cases. CT detects enhancing nodular masses on the peritoneum and mesentery that spread by direct extension and can invade abdominal organs. Ultrasound demonstrates nodules that aggregate in layers or plaques with a small amount of associated ascites.

PERITONITIS

Peritonitis represents inflammation of the peritoneum and may arise from many different etiologies. Patients commonly present with signs of an acute abdomen, abdominal pain, guarding, and rebound tenderness. Many acute causes of peritonitis require emergent surgery.

Localized peritonitis can develop from inflammatory processes in adjacent organs, such as appendicitis and diverticulitis. The findings and treatment are of the primary process.

Intraperitoneal abscesses can arise from multiple etiologies, including perforated appendicitis or diverticulitis. Patients typically present with abdominal pain and fever in the relevant setting. Radiographs can demonstrate ileus and displacement of bowel loops when abscesses are large. CT demonstrates loculated fluid collections, classically with enhancing walls after the administration of intravenous contrast. Their density may be higher than simple fluid, and they may contain septations or gas. Ultrasound can show loculated fluid collections with internal reflectors and gas, sometimes with a thickened wall. Treatment involves antibiotics and drainage.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis presents with ascites, fevers, rigors, and abdominal pain and occurs when intraperitoneal fluid becomes infected after translocation of bacteria from the gut. Radiographs reveal ascites and sometimes ileus. CT can demonstrate enhancement and thickening of the peritoneum in the setting of ascites. Ultrasound can show the complicated, loculated ascites with floating debris and often thickened peritoneum. However, the diagnosis requires aspiration of fluid and culture. Untreated spontaneous bacterial peritonitis can lead to intraperitoneal abscess and carries high morbidity and mortality, although timely treatment with antibiotics provides effective cure.

Tuberculous Peritonitis

Tuberculous peritonitis likely develops after hematogenous seeding of acid-fast bacilli, most commonly in the HIV-afflicted population in the United States. Three patterns are described: wet, fibrotic, and dry. The wet type of tuberculous peritonitis presents as loculated or free high attenuation ascites. The fibrotic type can appear like peritoneal carcinomatosis, with soft-tissue density enhancing nodules and sometimes omental caking. The

dry type presents with mesenteric soft-tissue replacement, nodules, and adhesions. All patterns are associated with lymphadenopathy, sometimes low in attenuation. Treatment targets the primary tuberculous infection. Peritoneal sarcoid involvement can mimic tuberculous infection.

Chemical Peritonitis

Chemical peritonitis arises from noninfectious causes, most typically gastric, biliary, or pancreatic rupture with inflammation caused by the relevant fluid. Barium sulfate contrast spillage into the peritoneum, ruptured teratoma, and meconium peritonitis in children are other etiologies. Patients are typically postoperative from biliary or pancreatic procedures or have risk factors for bowel perforation, such as nonsteroidal anti-inflammatory drug use, ulcer disease, or history of trauma. They present with sudden onset of severe abdominal pain, hypotension, and sometimes shock. Imaging studies can show ascites, peritoneal enhancement, and free gas or fluid/fluid levels in certain etiologies. Treatment is aimed at the inciting pathology and at stabilization and support.

Sclerosing Peritonitis

Sclerosing peritonitis arises in the setting of peritoneal dialysis and exposure to certain drugs. Patients present with failure of effective dialysis; they later develop abdominal pain and bowel obstructions. Pathology shows fibrotic soft-tissue thickening of the peritoneum, progressing to encasement of bowel loops. The precise etiology is unclear. Imaging studies demonstrate increased peristalsis, dilated bowel loops, calcifications, and septated, loculated ascites with fibrous soft-tissue thickening that eventually encases bowel loops. Prognosis remains poor despite surgical treatment for the amelioration of symptoms.

MESENTERY

SCLEROSING MESENTERITIS (PANNICULITIS)

Sclerosing mesenteritis is an idiopathic, inflammatory disease of the mesentery adipose tissue. Also known as mesenteric panniculitis, mesenteric lipodystrophy, retroperitoneal xanthogranuloma, sclerosing lipogranulomatosis, lipogranuloma of the mesentery, retractile mesenteritis, and primary mesenteric liposclerosis, sclerosing mesenteritis most commonly involves the small bowel mesentery and to a lesser degree the mesocolon. The disease is characterized by thickened, nodular, and fibrotic mesentery with fat necrosis and nonneoplastic mass like lesions. Ultimately, this leads to a short, thickened, and scarred mesentery that may distort the bowel. Sclerosing mesenteritis commonly presents in males in

their fifth to sixth decade of life with abdominal pain and, on occasion, a palpable abdominal mass. Often, distortion of the bowel may lead to signs and symptoms of small bowel obstruction. Sclerosing mesenteritis does not display the typical infiltrative histological appearance that is commonly seen in mesenteric desmoid. On CT, sclerosing mesenteritis may appear as a spiculated, soft-tissue mass with calcification that may surround the mesenteric vessels without involving the perivascular fat, giving an appearance that has been termed the “fat ring sign.” MRI will reveal low T1 and T2 signal images. Although metastatic carcinoid may appear radiologically similar to mesenteric panniculitis, a somatostatin receptor scintigraphy scan will allow distinction. Prognosis is usually favorable with treatment ranging from observation to surgical intervention. Surgery is usually performed to establish the diagnosis by biopsy or in cases of small bowel obstruction.

MESENTERIC CYSTS

Mesenteric cysts are benign lesions that commonly occur in the small bowel mesentery or the mesocolon. The cause is unknown and typically occurs more commonly in middle-aged women. They may be completely asymptomatic or present with symptoms of mass effect. The cysts usually contain a clear serous fluid and can be diagnosed on ultrasonography or CT. Symptomatic treatment includes surgical excision rather than aspiration, which carries a high risk of recurrence.

MESENTERIC ADENITIS

Mesenteric adenitis is a self-limited disorder characterized by inflammation of the mesenteric lymph nodes usually presenting in the pediatric patient population. Because the nodes in right lower quadrant are most commonly involved, the presentation and diagnosis is often confused for acute appendicitis. Etiology is most commonly viral; however, bacterial pathogens, most commonly *Yersinia enterocolitica*, parasites, and fungi have also been implicated. Often times, patients undergo surgery for presumed appendicitis only to find a normal-appearing appendix. In addition, a number of cases may involve the adjacent small bowel mucosa, giving rise to cecitis and ileocolitis. Ultrasonography is the preferred diagnostic modality and reveals enlarged lymph nodes with increased blood flow. CT may be employed and used to exclude mesenteric adenitis in the case of acute appendicitis. In addition, CT findings of clustered, large lymph nodes in the right lower quadrant with a normal appearing appendix further support the diagnosis.

MESENTERIC CARCINOID

Carcinoid tumors are a type of neuroendocrine tumors that arise from the enterochromaffin cells and produce

vasoactive substances such as serotonin. The gastrointestinal and bronchopulmonary tracts are the most common sites for these tumors. They are slow growing and many patients present with metastatic disease. They are the most common small bowel tumors and can involve the mesentery via direct extension or lymphatogenous spread. Serotonin produced by these tumors elicits a desmoplastic reaction in the mesentery, leading to fibrosis and ischemia. CT may reveal mesenteric fibrosis, mesenteric lymphadenopathy, and nodular deposits that may contain calcifications. In addition, octreotide scintigraphy scan demonstrates positive uptake of the radiotracer by the mesenteric nodules.

MESENTERIC DESMOID

Mesenteric desmoid, also known as intra-abdominal or mesenteric fibromatosis, is part of a group of diseases known benign fibroproliferative processes. It occurs in a wide patient age range and has no race predilection. It is particularly common in patients with familial adenomatous polyposis and has even a stronger association with the subset of patients with Gardner syndrome. Prior abdominal surgery, most commonly a total colectomy, has been associated with an increased risk of developing mesenteric desmoid in patients with familial adenomatous polyposis. This correlation is significantly weaker in sporadic cases. Patients with mesenteric desmoid present with small bowel signs and symptoms, such as abdominal pain, obstruction, perforation, and fistula formation. A hallmark histological finding of these tumors is infiltration into the muscularis propria of the bowel wall that some authors have termed “tentacular or melting insinuation.” Mesenteric desmoid can be often be radiologically and histologically mistaken for gastrointestinal stromal tumor (GIST). However, special immunohistochemical staining allows for differentiation between these two entities.

Radiological features of mesenteric desmoid includes mass effect with displaced bowel segments, partial or complete small bowel obstruction, perforation, or fistula formation. Ultimately, the histological characteristics (especially the degree of infiltration) determine radiological appearance. CT and MRI are the preferred imaging modalities. The degree of collagenous and myxoid stroma components of mesenteric desmoid determines its CT and MRI characteristics. It has minimal contrast enhancement on CT and typically has low to intermediate signal intensity on T1-weighted images and intermediate to high signal on T2-weighted images. Treatment of mesenteric fibromatosis varies. Although complete resection with free margins is commonly preferred, there is a high recurrence rate. In addition, many cases may be complicated by sequelae of the infiltrative nature of the tumor, such as obstruction and fistula

formation. Because of a high recurrence rate, some authors recommend medical management in advanced cases. Sporadic cases typically carry lower disease morbidity and mortality associated compared to those patients with familial adenomatous polyposis.

ABDOMINAL WALL

HERNIAS

An abdominal hernia occurs when there is a protrusion of abdominal contents through a defect in the abdominal wall. Hernias are electively repaired surgically to prevent complications that arise when a hernia becomes irreducible or incarcerated and strangulated. A hernia is incarcerated when it cannot be reduced and can lead to bowel obstruction. A strangulated hernia is one in which there is compromise of the vascular supply (arterial or venous) leading to bowel ischemia and necrosis. CT is the preferred diagnostic imaging modality as it will detect the location and contents of the hernia sac as well as early signs of the aforementioned hernia complications. However, hernias may also be detected on other imaging modalities such as conventional radiographs, contrast fluoroscopy studies, and ultrasonography.

Ventral Hernias

Ventral or anterior abdominal wall hernias occur as a result of a congenital or an acquired defect through the abdominal wall musculature and fascia. The protruding peritoneal sac may contain fat, omentum, and/or bowel loops. Patients can present with abdominal pain, signs and symptoms of bowel obstruction in complicated hernias, and an anterior abdominal bulge that increases with Valsava. However, some patients may be asymptomatic or difficult to examine because of body habitus thus making imaging of greater utility in diagnosis and early detection of complications. CT imaging may detect ventral hernias either by direct visualization of the hernia sac content or through identification of the fascial defect (Table 54-4).

Groin and Pelvic Hernias

Groin and pelvic hernias typically present with vague groin pain and, like ventral hernias, carry an associated risk of strangulation and incarceration. Thus, surgical repair is indicated. CT and contrast fluoroscopy are commonly used to identify these hernias. While inguinal hernias are more common in men, femoral and obturator hernias are more prevalent in women (Table 54-5).

Internal Hernias

Internal hernias are rare and occur when the small bowel protrudes through the mesentery into another cavity. These hernias occur as a result of congenital developmental defects, such as abnormal mesentery fixation and enlarged foramen, and iatrogenic mesenteric defects (i.e., surgically created). With the increase in laparoscopic (minimally invasive) surgical procedures, post-surgical internal hernias are now the most common etiologic type. The most common clinical manifestation is that of small bowel obstruction. CT is the preferred imaging modalities (Table 54-6).

OTHER ABDOMINAL WALL ABNORMALITIES

Abdominal Wall Desmoid Tumor

Unlike mesenteric desmoids, which commonly occur in patients with familial adenomatous polyposis, abdominal wall desmoid tumors occur sporadically. Abdominal wall desmoids are common in young women and have

TABLE 54-4 Ventral Hernias

TYPE	LOCATION	FEATURES
Umbilical/paraumbilical	Midline, at the umbilical ring	Most common ventral hernia Congenital in infants, usually close spontaneously by 4 y of age In adults, it is a result of chronic increased intra-abdominal pressure. Common in obese and multiparous women Repair indicated in large and symptomatic hernias and in children older than 5 y with persistent congenital hernia caused by risk of incarceration
Epigastric & hypogastric	Midline, through linea alba above and below the umbilicus, respectively	Same acquired risk factors as in umbilical hernia
Richter	Midline	Only one side of bowel wall within hernia sac Bowel wall remains patent and thus there is no risk of obstruction. Risk of incarceration still present
Spigelian	Lateral, at the junction of the semicircular and semilunar lines	Occurs below the arcuate line where there is an absence of posterior rectus sheath Results in an interparietal hernia making detection difficult
Incisional	Prior surgical incision site	Increased risk factors include obesity, immunosuppression, postoperative wound infection, and malnutrition

TABLE 54-5 Groin and Pelvic Hernias

TYPE	LOCATION	FEATURES
Direct inguinal	Medial to the epigastric vessels and through Hesselbach triangle	Because of an acquired defect of the transversalis fascia
Indirect inguinal	Lateral to the epigastric vessels	Most common abdominal hernia Occurs because of patent processus vaginalis leading to entry of the hernia contents through the internal ring, into the inguinal canal, and exiting the external ring May extend into the scrotum or labia
Pantaloon	Hernia on both sides of the epigastric vessels	Combined direct and indirect inguinal hernia
Femoral	Femoral canal, below the inguinal ligament and medial to the femoral vein	Occurs because of a defect in the transversalis fascia attachment at the pubis Carries a high risk of incarceration
Obturator	Obturator canal	Occurs because of a defect in the obturator membrane Hernia contents frequently involve bowel accounting for high incidence of obstruction and incarceration Howship-Romberg sign: impingement of the obturator nerve causing medial thigh pain

been associated with increased estrogen states. Just as in mesenteric desmoid, there is some association between prior abdominal surgery and the development of abdominal wall desmoid tumors. They arise either from the abdominal musculature fascia or their aponeurosis. The tumors arising from the superficial fascia are slow growing as oppose to those arising from the aponeurosis. Patients typically present with a painless abdominal wall mass. The histological, CT, and MRI findings are similar to those of mesenteric desmoid tumors and biopsy will provide definitive diagnosis and exclude

other neoplasms such as lipomas or sarcomas. Treatment includes complete resection; however, high recurrence rates are common.

Abdominal Wall Hematomas

The rectus sheath contains a collateral network of vessels including the penetrating epigastric vessels. Damage to these vessels can lead to formation of a rectus sheath hematoma. The extent of the hematoma depends on whether the bleeding occurs below or above the semicircular line. Above this line, the hematomas are

TABLE 54-6 Internal Hernias

TYPE	CHARACTERISTICS	RADIOLOGICAL FEATURES (CT)
Paraduodenal (mesocolic)	Most common type of nonsurgical internal hernia, left more common than right Left—small bowel herniates behind the mesocolon into the fossa of Landzert Right—small bowel herniates into the fossa of Waldeyer	Left paraduodenal hernia will demonstrate crowded loops of dilates small bowel within in a sac located between the pancreas and stomach. The mesenteric vessels supplying the herniated loops will be engorged and part of the hernia sac
Pericecal	Occurs as a result of absent or enlarged ileocecal recesses allowing small bowel to herniation	Cluster of dilated loops of small bowel in the right lower abdomen, lateral to the ascending colon
Transmesenteric/Transomental	Small bowel herniates through defects in the mesentery or omentum resulting in small bowel segments lying anterior to and displacing large bowel	Signs of volvulus and clustered loops of small bowel overlying large bowel and without omental fat. Involved mesenteric vessels may be crowded and engorged
Foramen of Winslow	Small bowel herniates through an enlarged foramen of Winslow	Mesentery will be present between the inferior vena cava and portal vein, dilated loops of small bowel in the foramen of Winslow, and absence of the right colon in the right lower quadrant
Intersigmoid	Small bowel herniation into the intersigmoid fossa	Dilated loops of small bowel will be seen in the intersigmoid fossa, left of the sigmoid mesocolon
Supra-/perivesical and pelvic	Herniation into the supravescical fossa, perirectal fossa, or through a defect in the broad ligament	Dilated loops of small bowel within the respective cavities

well confined and can be controlled by tamponade from the rectus sheath. However, below this line, there is no such confinement and the hematoma can rapidly expand. Bleeding into the rectus sheath can occur as a result of trauma, iatrogenic causes (injections), sudden contraction or stretching of the rectus muscles, or spontaneously in patients on anticoagulation therapy. Patients typically present with abdominal pain and an abdominal wall mass or bulge. CT and ultrasonography can be used to confirm the diagnosis. Treatment depends on the extent of the hematoma and may range from observation to resuscitation to surgical evacuation and vessel ligation.

MISCELLANEOUS DISORDERS

WHIPPLE DISEASE

Whipple disease arises after infection with *Tropheryma whippelii*, which leads to infiltration of lymph nodes by “foamy” macrophages on pathology. Patients present with protean symptoms from multiple body systems, including abdominal pain, diarrhea, arthritis, and ocular and neurologic symptoms. CT demonstrates small bowel wall thickening and intestinal lipodystrophy and low attenuation lymphadenopathy secondary to fatty accumulation in the lymph nodes of the small bowel mesentery. Treatment aims at curing the underlying infection.

CASTLEMAN DISEASE

Castleman disease, or angiofollicular lymph node hyperplasia, presents similarly to lymphoma, with fevers of unknown origin, weight loss, and abdominal masses, often in the setting of HIV infection. CT demonstrates brightly enhancing lymph node masses. The plasma cell type presents more commonly in the abdomen, while the hyaline type is more common in the mediastinum. Both variants carry an increased risk of lymphomatous transformation, although the primary process is nonneoplastic. The prognosis is poor.

QUESTIONS AND ANSWERS

- What is the most dependent space of the abdomen in the supine patient?
 - Morison pouch
 - Pouch of Douglas
 - Left paracolic gutter
 - Right paracolic gutter
 - Lesser sac

ANSWER: A. Morison pouch, the hepatorenal fossa, is the most dependant portion of the abdomen in supine patients. The pouch of Douglas is the most dependent portion of the abdomen in upright women. The right and left paracolic gutters are dependent areas in supine patients, but Morison pouch is more dependent. The lesser sac is an enclosed intraperitoneal space separated from the remainder of the abdominal cavity.
- Hyperenhancing retroperitoneal lymph nodes are identified on CT. What is the most likely diagnosis?
 - Tuberculous peritonitis
 - Peritoneal lymphoma
 - Whipple disease
 - Castleman disease
 - Pseudomyxoma peritonei

ANSWER: D. Castleman disease (angiofollicular lymph node hyperplasia) gives enhancing lymph nodes. The lymph nodes in tuberculous peritonitis and Whipple disease are low attenuation. Peritoneal lymphoma gives soft-tissue density lymphadenopathy. Pseudomyxoma peritonei is characterized by

low attenuation mucinous material that exerts mass effect upon the adjacent organs.

3. Which of the following is *true* of pseudomyxoma peritonei?
 - A. Excellent prognosis
 - B. Fluid is typically high in attenuation.
 - C. Fluid exerts mass effect on adjacent organs.
 - D. Primary process is usually infectious.
 - E. Ovarian carcinoma is the most common etiology.

ANSWER: C. The mucinous fluid from pseudomyxoma peritonei classically exerts mass effect upon the abdominal organs, causing a scalloped appearance. The prognosis is dismal, and the fluid is classically low in attenuation. The primary process is neoplastic, usually secondary to appendiceal or ovarian mucinous adenocarcinoma. Appendiceal carcinoma is a more common cause than ovarian.

4. Which of the following is *true* regarding tuberculous peritonitis?
 - A. Typically results from primary peritoneal infection
 - B. Only occurs in the third world
 - C. Can mimic peritoneal carcinomatosis on CT
 - D. Lymph nodes are usually normal in size.
 - E. No ascites is seen.

ANSWER: C. Tuberculous peritonitis can mimic peritoneal carcinomatosis, with nodular, enhancing soft-tissue thickening and adhesions. The infection is usually secondary to hematogenous spread and can occur in any location. In the US, it most commonly occurs in patients with HIV. There is usually lymphadenopathy, often low in attenuation. There is typically ascites, sometimes loculated.

5. Where is the anatomic defect in a Spigelian hernia?
 - A. Diastasis recti
 - B. Semicircular and semilunar lines
 - C. Linea alba
 - D. Umbilical ring

ANSWER: B. Spigelian hernias are lateral, occurring at the junction of the semicircular and semilunar lines. Diastasis recti is a ventral eventration (not a true hernia) typically seen in patients with increased abdominal pressure (multiparous women, obesity). Epigastric and hypogastric hernias occur in the midline through the linea alba. Umbilical hernias are defects in the umbilical ring.

6. What is the most common etiology of mesenteric adenitis?
 - A. *Yersinia enterocolitica*
 - B. Viral

- C. Parasitic
- D. Fungal
- E. Bacterial

ANSWER: B. Mesenteric adenitis is a self-limited inflammatory condition most commonly caused by a viral pathogen. *Yersinia enterocolitica* has been implicated the most common bacterial cause. Bacterial, parasitic, and fungal can all cause mesenteric adenitis but are not as common as viral.

7. What is the anatomic opening between the greater and lesser sacs?
 - A. Epiploic foramen
 - B. Gastrohepatic ligament
 - C. Coronary ligament
 - D. Fossa of Waldeyer

ANSWER: A. The epiploic foramen (Foramen of Winslow) connects the greater and lesser sacs. The coronary ligament defines the bare area at the dome of the liver. The fossa of Waldeyer is the location of small bowel herniation in a right paraduodenal hernia.

8. Which of the following is the most common type of nonidiopathic internal hernia?
 - A. Left paraduodenal hernia
 - B. Right paraduodenal hernia
 - C. Foramen of Winslow hernia
 - D. Intersigmoid hernia

ANSWER: A. Overall, most internal hernias are postsurgical, usually transmesenteric Paraduodenal hernias are the most common type of congenital internal hernia. The left paraduodenal hernias are more common than the right with the small bowel herniating behind the mesocolon into the fossa of Landzert.

9. Concerning umbilical hernias, which of the following is *true*?
 - A. Most common type of abdominal hernias
 - B. Low risk of incarceration and rarely require repair
 - C. Common in patients with chronically increased intra-abdominal pressure
 - D. Children in which the hernia has not closed by 2 years of age require repair.

ANSWER: C. Umbilical hernias are the most common ventral hernia and occur in patients with increased intra-abdominal pressure, particularly obese patients. They carry a high risk of incarceration and are repaired. Children with umbilical hernias should have spontaneous closure by the age of 4.

10. In distinguishing mesenteric desmoid and abdominal wall desmoid tumors, which of the following is *true*?
- A. Abdominal wall desmoid tumors are more commonly associated with FAP as opposed to mesenteric desmoid.
 - B. They have different histological findings.
 - C. Abdominal wall desmoids have no association with prior abdominal surgery as do mesenteric desmoids.

- D. Most cases of abdominal wall desmoid are sporadic as oppose to mesenteric desmoid.

ANSWER: D. Abdominal wall and mesenteric desmoid are both fibroproliferative diseases that have similar histological findings and an association with prior abdominal surgery or trauma. Abdominal wall desmoid cases are usually sporadic, whereas mesenteric desmoid commonly occur in patients with FAP.

55 INTRAVENOUS CONTRAST AGENTS AND REACTIONS

Philip J. Kenney

INTRODUCTION: UTILITY OF CONTRAST

Shortly after the discovery of x-rays and their potential for diagnostic imaging, researchers began looking for materials that would enhance the detection of disease by introducing differential radiographic density of anatomic structures. In the 1920s, Moses Swick had the first reasonable success in developing an intravenously administered agent that aided visualization of the urinary tract, Uroselectan. For many years, the intravenous urogram was a standard method for initial evaluation of urologic disorders. By injecting an agent that could not cross cell membranes, was excreted by glomerular filtration and incorporated the k-edge properties of iodine, the kidneys, ureters, and bladder could be reasonably well visualized using conventional radiography. The quality was eventually improved by addition of x-ray tomography. With the development of CT, the uses of iodinated intravenous contrast agents exponentially increased and the detection of enhancing lesions in the brain, liver, and extremities became possible. This led to much broader use of these agents. Iodinated contrast also was a necessary factor in development of angiography, initially performed with direct catheter injection into arteries with radiographic imaging, now largely replaced by CT angiography.

Iodinated contrast is successfully used in many noninvasive procedures. Contrast is necessary and useful for visualization of the bladder, urethra, ureters, uterus, and fallopian tubes by direct installation. These procedures include cystography, voiding cystourethrography, retrograde urethrography, antegrade and retrograde direct pyelo/ureterography, and hysterosalpingography (HSG).

Iodinated contrast has also been useful in various gastrointestinal and other nonvascular routes of administration.

The advantage and utility of iodinated contrast is in its ability to aid accurate diagnosis by introducing a differential in radiographic density (whether on radiographic images or CT) between anatomic structures or pathology and background, thus the term contrast. The term “dye” should not be used, as these agents are all colorless. Except for differences in concentration of different formulations, and major differences in osmolality, strikingly little difference in performance has been noted between different specific agents in the same class.

However, despite the great utility, iodinated contrast agents have always had risks of adverse events. Over time, agents with less toxicity have been developed, but adverse events still occur and knowledge of the risk factors, methods for avoidance, and treatments of such events are critical parts of the skill set for the practitioners of radiology.

MRI was a great advance, initially thought to provide inherent contrast such that no injected agents would be necessary. However with further experience, limitations in the inherent tissue contrast and diagnostic capabilities of differences from T1, T2, and proton density factors became recognized. The introduction of gadolinium-based intravenous contrast agents was rapidly adopted. Gadolinium diethylenetriamine penta-acetic acid (DTPA) was the initial agent, still used. Limited to extracellular space and excreted solely by glomerular filtration, this agent mimicked the physiology of iodinated contrast, although the mechanism of action (increasing T1 relaxation time) was very different. Initial research revealed this agent to be remarkably well tolerated, with much lower rates of adverse events compared to iodinated contrast. Additional agents using gadolinium as the active heavy metal with different chelating agents were soon introduced, also well tolerated in studies, with similar low incidence of adverse events.

Only relatively recently has a previously unrecognized serious adverse outcome from exposure to gadolinium contrast agents come to light. Some 10 years after initial release of gadolinium contrast agents, reports of a new

potentially fatal systemic illness, now defined as nephrogenic systemic fibrosis (NSF) appeared in the literature, stimulating the U.S. Food and Drug Administration (FDA) to place a “black-box” warning on all such agents approved for use. It is now also critical for radiologists to understand current recommendations for screening for risk factors and avoidance of this iatrogenic illness.

GENERAL PRINCIPLES

Current iodinated contrast agents are designed to increase differences in attenuation utilizing the properties of iodine for absorption of x-rays. All are based on a tri-iodinated benzoic acid ring. All are stable, not metabolized, with 99% excretion by glomerular filtration from the kidney, and with no significant tubular secretion or reabsorption. Approximately 1% is excreted in bile, tears, sweat, saliva, or breast milk if renal function is normal. The agents all have low lipid solubility, poor protein or membrane binding and are hydrophilic. Upon injection, they initially mix in the vascular pool, then spread through the extracellular space, but do not cross cell walls. With normal renal function, more than 90% is excreted within 24 hours. Thus the mechanism of action of various agents is quite similar. Some agents have higher concentration, which can affect selection of volume of administration. Some have greater or lesser viscosity, which is a consideration when injecting through small catheters.

There are three general classes of iodinated contrast agents. The older class are ratio 1.5 agents, ionic monomers with two soluble particles for every three iodine atoms, since the agents dissociate into the iodinated benzoic acid anion and the cation such as sodium or methylglucamine. These have the highest osmolality, up to five times that of plasma. Newer ratio 3 agents, three iodine atoms for every soluble particle, may be nonionic monomers such as iopamidol or ionic dimers such as ioxaglate. The newest and lowest osmolality ratio 6 agents, six iodine atoms for each soluble particle, are nonionic dimers, such as iodixanol. Because of the large molecular size, these agents also have the highest viscosity.

Utility of iodinated contrast agents is very similar in studies comparing image quality or diagnosis. One major difference affecting the incidence of adverse events is osmolality; however, comparative studies have usually shown equivalence in diagnostic capability of the high osmolar ionic agents when compared to lower osmolar nonionic agents.

A number of physiologic effects have been reported from intravascular administration of iodinated contrast agents. These physiologic effects are seen to a significantly lesser degree with low osmolar iodinated agents. Such effects include inotropic depression.

ADVERSE EVENTS

Certain physiologic effects of the injection of iodinated contrast may cause patient discomfort. These are accentuated with high osmolar contrast. Such effects include pain at the injection site, flushing sensation, warmth, altered taste, nausea, and vomiting (much more likely with a full stomach and high osmolar contrast media [HOCM]). These are not true “reactions” or toxicity, and therefore, do not require therapy.

Cardiovascular events can be stimulated by iodinated contrast injection: inotropic depression, stimulation of arrhythmias, and decreased perfusion. These effects are greater with higher osmolar contrast, intra-arterial injection, and affect the organ closest to injection site. For example, injection of contrast, especially high osmolar, directly into a coronary vessel causes significant inotropic depression; injection directly into a renal artery causes decrease in renal perfusion; injection into aorta or intravenous administration causes much less effect.

Of most concern are allergic-like reactions. Research has shown such adverse events are not true allergies, although the term is often incorrectly used. This is because many of the symptoms and physiologic actions are similar to true allergic reactions, but the exact mechanism of contrast reactions remains unclear. Antibodies to contrast have not been demonstrated and cell-mediated immunity does not play a role.

Because of the potential for harm, whenever a patient is evaluated for a contrast-enhanced examination, three goals must be met: administer appropriate contrast given the indication, minimize the chance for a reaction, and treat a reaction should it occur.

AVOIDANCE OF ADVERSE EVENTS

The most important factor in avoidance of significant adverse events is accurate and consistent screening for risk factors. The most significant factor is history of a prior allergic-like reaction to iodinated contrast. If the patient gives such a history, investigating the details of that reaction and what treatment if any was needed is important. Any history of allergy, especially if severe, increases the risk of contrast reaction. Shellfish allergies are now *not* considered of greater significance than allergies to other substances. Patients with asthma, especially if requiring treatment, have elevated risk as do patients with cardiovascular disease, congestive heart failure, and recent myocardial infarction.

If a patient has moderate risk factors, in particular a prior but not life-threatening reaction, pretreatment may be used if there is a strong indication for a contrast study. HOCM should not be used in such instances. No

data indicate a significant difference in reaction rates of low osmolar contrast media (LOCM) versus isosmolar contrast media (IOCM). There is some published data and much experience suggesting pretreatment reduces the likelihood of a repeat reaction, although the likelihood is not completely eliminated. Pretreatment regimens usually combine a histamine (H1 or H2) antagonist with steroids. Steroids must be administered for at least 12 hours prior to exposure to contrast in order to adequately reduce contrast reaction. One regimen that has been shown to reduce reactions combines oral methylprednisolone 32 mg, 12 and 2 hours prior to contrast. Another recommended regimen includes three doses of 50 mg oral prednisone every 6 hours prior to contrast with 50 mg oral or intramuscular injection diphenhydramine 1 hour before contrast administration. However, there are few if any publications comparing different regimens.

If a patient has had a prior life-threatening reaction, it may be best to avoid iodinated contrast altogether and alternates such as MRI may be used. There does not appear to be strong correlation of reactions to iodinated contrast with reactions to gadolinium, so that this alternative can be used without premedication.

COMMON REACTIONS AND TREATMENTS (Table 55-1)

A variety of distinct types of reactions have been described, all of which vary in severity. Most reactions are mild, self-limited, and resolve without treatment. Moderate reactions are defined as those somewhat more severe but not life threatening; these usually require some treatment. Severe reactions are uncommon, may be life threatening, and require treatment, sometimes vigorous. It has been shown that all reactions occur less commonly with LOCM than HOCM; however, reactions do occur with LOCM. There has not been convincing evidence that fatal reactions are significantly less common with LOCM, but are quite rare. With LOCM, overall incidence of reactions has been reported as 0.2% with severe reactions 0.05%. Luckily, the vast majority of contrast reactions (98%) occur within a short time after contrast injection while the patient is still in the radiology department. Fatal reactions almost always begin immediately or within the first 20 minutes after injection.

Some general principles must be recognized. Since reactions occur and are unpredictable, appropriate items including drugs useful for treating reactions must be kept stocked wherever contrast is administered. Personnel should be trained as to the location and use of these items, and a physician should be in attendance whenever and wherever contrast is administered. There also must be access to a rapid response code team. Oxygen should

TABLE 55-1 Management of Acute Reactions in Adults

Hives (urticaria)

- Stop injection
- Most cases require no treatment, careful monitoring until resolved
- H1 antihistamine: diphenhydramine (Benadryl) po or IM, 25–50 mg
- If severe, widespread, and nonresponding: epinephrine SC (1:1000), 0.1–0.3 mL (0.01–0.3 mg)

Laryngeal edema

- Oxygen 6–10 L/min via mask
- Epinephrine SC or IM (1:1000) 0.1–0.3 mL (0.1–0.3 mg)
- If hypotensive, epinephrine IV (1:10 000) 1–3 mL (0.1–0.3 mg); repeat as needed to maximum 1 mg

Bronchospasm

- Oxygen 6–10 L/min via mask, monitor: ECG, pulse oximeter, blood pressure
- Beta-agonist inhaler 2–3 puffs repeat as needed
Metaproterenol (Alupent), terbutaline (Brethaire) albuterol (Proventil or Ventolin)
- If not responding, epinephrine SC or IM (1:1000) 0.1–0.3 mL (0.1–0.3 mg)
- If hypotension developing, epinephrine IV (1:10 000) 1–3 mL (0.1–0.3 mg), repeat as needed to maximum 1 mg.

Pulmonary edema

- Oxygen 6–10 L/min via mask
- Elevate torso
- Furosemide (Lasix) 20–40 mg slow IV push
- Consider morphine 1–3 mg IV
- Transfer to ED or ICU if needed

Hypotension with bradycardia (vasovagal reaction)

- Monitor vital signs
- Elevate legs 60 degrees or Trendelenburg
- Assure airway open, oxygen 6–10 L/min via mask
- Secure intravenous access administer normal saline or Ringer's lactate 500–700 mL in 20–30 min, continue as needed
- Atropine 0.6–1 mg slow IV
- If not responding repeat atropine to total dose 0.04 mg/kg (2–3 mg adults)
- Do not discharge until hypotension and bradycardia completely resolved

Hypotension with tachycardia

- Elevate legs 60 degrees or Trendelenburg
- Monitor ECG, pulse oximeter, blood pressure
- Oxygen 6–10 L/min via mask
- Intravenous normal saline or Ringer's lactate, 500–700 mL/20 min, continue as needed
- If not responding, epinephrine IV (1:10 000) 1–3 mL (0.1–0.3 mg), repeat as needed to maximum 1 mg.

Severe hypertension

- Oxygen 6–10 L/min via mask
- Monitor ECG, pulse oximeter, blood pressure
- Nitroglycerine 0.4 mg SL may repeat $\times 3$
- If no response, consider labetalol 20 mg intravenous, 20–80 mg intravenous every 10 min to maximum 300 mg.
- If patient with pheochromocytoma, phentolamine 5 mg IV, may use labetalol

Seizures

- Oxygen 6–10 L/min via mask
- Monitor vital signs including pulse oximeter, due to concern of respiratory depression from benzodiazepine
- Consider diazepam (Valium) 5 mg IV, repeat if needed (alternate midazolam (Versed) 0.501 mg IV)
- If longer treatment needed, obtain consultation, consider phenytoin (dilantin) IV 15–18 mg/kg at 50 mg/min

be available. Knowledge of the drugs and dosages is important: particularly regarding epinephrine. This is supplied in two concentrations: 1:1000 (1 mg epinephrine in 1 mL) for subcutaneous or intramuscular administration; 1:10 000 (1 mg in 10 mL) for intravenous administration. Physicians must recognize the difference in these by sight and know appropriate use. Epinephrine can cause serious adverse effects itself even in young and healthy individuals, for example, hypertensive crisis and myocardial ischemia. In general, practitioners must know specific treatments for particular reactions, but must also avoid overtreatment particularly of mild reactions. In addition to the side effects of the treatment, this can cause confusion at times of future evaluation for contrast administration.

Should a reaction occur, a physician must assess the patient, including state of consciousness, vital signs, symptoms, and objective findings. Examination of the skin and respiratory system as well as pulse and blood pressure are key. Careful monitoring for any improvement or progression whether treated or not is important. Some reactions affect a single system, such as respiratory, but some can cascade with increasing severity. Although radiologists should be trained to recognize and treat reactions, especially with very severe reactions such as an unresponsive pulseless patient, there should be no hesitation to “call a code.”

CUTANEOUS REACTIONS

Cutaneous reactions are fairly common. Most often urticaria (hives) occur, more often in upper body, face, neck, chest, and arms. They may be single or multiple. Although usually associated with pruritis, if they are few in number and symptoms not disturbing, treatment is not necessary. If more severe, treatment with H1 antihistamine diphenhydramine (Benadryl), 50 mg oral or intramuscular, is recommended. Benadryl causes drowsiness, so care must be taken if the patient is alone so that they do not leave while still obtunded. In severe cases, H1 blockers (cimetidine or ranitidine, 50 mg in 20 mL fluid slow intravenous push) may also be needed.

Erythema or edema can occur either localized (usually around the face) or generalized. Often this does not need treatment, but if severe, can be treated with H2 antihistamines, H1 blockers, and if very severe, epinephrine.

RESPIRATORY REACTIONS

Upper airway and laryngeal edema is characterized by a feeling of throat tightness, difficulty breathing, alteration of voice due to vocal cord edema, and inspiratory stridor. This can be a very serious event and is best treated with

oxygen and epinephrine and aggressively retreated if not initially responding. H2 receptor blockers are second-line drugs. If laryngeal edema persists, early intubation may be performed, as it may become impossible later if swelling becomes severe enough, necessitating tracheotomy.

Bronchospasm may be more likely in patients with history of asthma, and these patients may be refractory to lower doses of beta-agonist inhalers. Patients with bronchospasm usually have normal speaking voice but have difficulty breathing and audible wheezing. They may complain of chest tightness. If mild, two or three treatments with beta-agonist inhaler may be sufficient. This can be repeated. Oxygen should be administered. If not responding treatment, epinephrine should be given.

While patients having severe anxiety may complain of chest tightness and feeling of difficulty breathing, this is a diagnosis of exclusion. Overtreatment should be avoided. Decision should be based not only on described symptoms but also objective finding such as vital signs and breath sounds.

Contrast can uncommonly stimulate pulmonary edema. This is more common with history of heart disease and congestive heart failure. Treatment includes elevation of upper body, oxygen, diuretics (20–40 mg furosemide), and intravenous morphine (1–3 mg, repeat every 5–10 minutes if needed). Pulmonary edema management will likely require the code team or transfer to emergency department or intensive care unit.

HYPOTENSIVE AND HYPERTENSIVE REACTIONS

Hypotensive reactions may occur as isolated events or in association with (sometimes following) cutaneous or other types of reactions. Systolic blood pressure less than 90 mm Hg, diminished tissue perfusion, and altered mental status are defining features. If responsive, patients sense light headedness and weakness but may become unresponsive. Oxygen should be administered even while obtaining blood pressure. Large volumes of intravenous fluid can be administered (normal saline or lactated Ringer's solution, 500–700 mL in 20 minutes).

Vasovagal reactions are typified by hypotension in association with bradycardia (pulse rate less than 60 beats per minute). If the patient does not quickly respond to leg elevation, oxygen, and fluid, administration of atropine 0.6 to 1 mg slow intravenous push can be given and repeated every 3 to 5 minutes if needed to total dose of 0.04 mg/kg (2–3 mg in adults).

Patients who are tachycardic and hypotensive have a form of anaphylactoid reaction. In addition to the general measures of leg elevation, oxygen, and intravenous

fluids, administration of intravenous epinephrine (1:10,000) slowly repeatable up to total dose of 1 mg.

Hypertensive reactions are less common than hypotensive ones. These can be difficult to treat and may require transfer to the emergency department or intensive care unit. In addition to oxygen and close monitoring, administration of sublingual nitroglycerine, which can be repeated up to three times, may be advanced to labetalol 20 mg, intravenous if needed. In patients who have a known pheochromocytoma and develop a hypertensive reaction, administration of phentolamine 5 mg intravenous (or labetalol) is recommended. However, LOCM, IOCM, and gadolinium contrast are not known to stimulate a hypertensive crisis in these patients.

CENTRAL NERVOUS SYSTEM REACTIONS
