This structure–energy duality has contributed confusion to the Levinthal paradox (Section 20.3.1.1) and many related size estimates of the unfolded population because a single energy basin can span multiple conformers. For example, most sterically accessible conformers of short polyalanyl chains in good solvent [66] are quite extended, as expected in the absence of stabilizing intramolecular interactions. The ϕ, ψ values for these conformers are densely distributed over a broad region in the upper left quadrant of the ϕ, ψ map, as shown in Figure 20.5. When energy differences among these structures are calculated using a simple soft-sphere potential, the population partitions largely into two distinct energy basins, one that includes β-strands and another that includes polyproline II helices [65]. All conformers within each basin can interconvert spontaneously at room temperature (i.e., $\Delta A_{i,j} \leq RT$ at 300 K, where $\Delta A_{i,j}$ is the Helmholtz free energy difference between any two conformers, i and j, R is the universal gas constant and T the temperature in Kelvin). Thus, apparent structural diversity is reduced to two thermodynamically homogeneous populations.

20.4.1.3 The "Rediscovery" of Polyproline II Conformation

More than three decades ago, Tiffany and Krimm proposed that disordered peptides are comprised of left-handed polyproline II (P_{II}) helical segments inter-

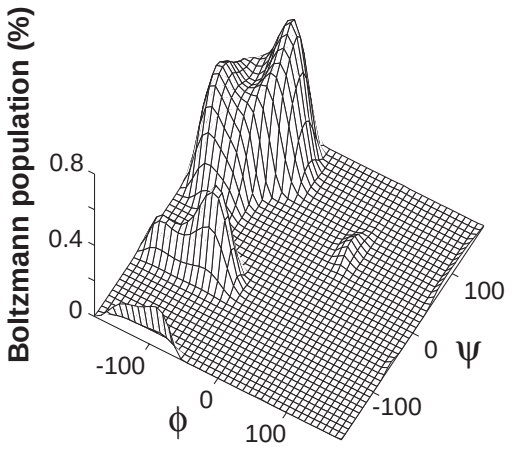

Fig. 20.5. A single energy basin can span multiple conformers. Most sterically accessible conformers of short polyalanyl chains in good solvent are extended. Using a soft-sphere potential, the Boltzmann-weighted population for the alanyl dipeptide is predominantly in the upper left quadrant of ϕ, ψ space and partitions into two distinct energy basins, one that includes polyproline II helices (larger) and another that includes β-strands (smaller) [65]. At 300 K, conformers with each basin interconvert spontaneously.

spersed with bends [95, 96]. They were led to this prescient proposal by the similarity between the optical spectra of P_{II} helices and nonprolyl homopolymers. Even earlier, Schellman and Schellman had already argued that the spectrum of unfolded proteins was unlikely to be that of a true random coil [79]. Following these early studies, the ensuing literature disclosed a noticeable similarity between the spectra of P_{II} and unfolded proteins, but such suggestive hints failed to provoke widespread interest – until recently. See Shi et al. for a thorough review [84].

The designation "polyproline" can be misleading. The circular dichroism (CD) spectrum, characteristic of actual polyproline or collagen peptides, has a pronounced negative band near 200 nm and a positive band near 220 nm. However, similar spectra can be obtained from peptides that are neither "poly" [54] nor proline-containing [96].

The P_{II} conformation is a left-handed helix with three residues per turn ($\phi, \psi \cong -75°, +145°$), resulting in three parallel columns spaced uniformly around the long axis of the helix. This helix has no intrasegment hydrogen bonds, and, in solution, significant fluctuations from the idealized structure are to be expected. The P_{II} conformation is forced by sterics in a polyproline sequence, but it is adopted readily by proline-free sequences as well [21].

Only three repetitive backbone structures are sterically accessible in proteins: α-helix, β-strand and P_{II}-helix [70]. In the folded population, α-helices and β-strands are abundant, whereas P_{II}-helices are rare. More specifically, isolated residues with P_{II} ϕ, ψ values are common in the non-α, non-β regions, accounting for approximately one-third of the remaining residues, but longer runs of consecutive residues with P_{II} ϕ, ψ-values are infrequent [90].

This finding can be rationalized by the fact that P_{II}-helices cannot participate in hydrogen bonds in globular proteins. Hydrogen bonds are eliminated because the spatial orientation of backbone donors and acceptors is incompatible with both intrasegment hydrogen bonding within P_{II}-helices and regular extra-segment hydrogen bonding between P_{II} helices and the three repetitive backbone structures. Upon folding, those backbone polar groups deprived of hydrogen-bonded solvent access can make compensatory hydrogen bonds in α-helices and strands of β-sheet, but not in P_{II}-helices.

Recent work by Creamer and coworkers focused renewed attention on P_{II} [21, 73, 90], raising the question of whether fluctuating P_{II} conformation might contribute substantially to the unfolded population in proteins [96]. Studies performed during the past few years lend support to this idea, as described next.

20.4.1.4 P_{II} in Unfolded Peptides and Proteins

The blocked peptide, *N*-acetylalanine-*N′*-methylamide, is a popular backbone model. Many groups have found P_{II} to be an energetically preferred conformation for this peptide in water [1, 26, 40, 41, 44, 69]. Does this finding hold for longer chains?

Again using alanine as a model, Pappu and Rose analyzed the conformational preferences of longer blocked polyalanyl chains, *N*-acetyl-Ala_n-*N′*-methylamide ($n \leq 7$) [65]. To capture nonspecific solvent effects, they minimized chain:chain interactions, mimicking the chain's expected behavior in good solvent. At physiological temperature, only three energy basins were needed to span ~75% of the population, and within each basin, the population of structures was homogeneous. Notably, the basin corresponding to P_{II} structure was dominant.

Pappu and Rose [65] used soft-sphere repulsion (the repulsive term in a Lennard-Jones potential) to calculate energy. More extensive testing using detailed force fields was performed by Sosnick and coworkers [104].

It is often assumed that the backbone is solvated uniformly in the unfolded state and that the energy of solvent stripping upon folding is not a significant consideration. This assumption follows directly from the random coil model, in which unfolded conformers are readily interconvertible. However, if unfolded state conformers exhibit conformational biases, it becomes important to question this assumption. Is solvation free energy conformation dependent?

A series of papers by Avbelj and Baldwin [4–6] offered a fresh perspective on this issue, motivated by an inconsistency between the measured energy of peptide hydrogen bond formation [81] and the corresponding energy derived from a simple thermodynamic cycle [8]. Specifically, their analysis uncovered a large enthalpy deficit (-7.6 kcal mol^{-1}) upon helix formation that could not be reconciled with data from typical model compounds, such as acetamide derivatives [6]. One or more terms had to be missing.

Avbelj and Baldwin's work prompted a re-examination of peptide solvation in proteins by a number of groups, including themselves [4–6]. Of particular interest are a series of unrelated simulations [4–6, 25, 35, 47, 57, 104], all of which reach a

common conclusion: water interacts preferentially with P_{II} peptides, imparting a previously unsuspected conformational bias.

In sum, both peptide:solvent interactions and peptide:peptide interactions [65] favor P_{II} conformers. In the former case, water is simply a better solvent for P_{II} than for other conformers, e.g., β-strands and α-helices. In the latter case, P_{II} affords the chain greater entropic freedom (i.e., more "wiggle room").

20.4.2 Questions from Experiment

Early NMR studies provided evidence for residual structure in the denatured state of both proteins [36, 61] and peptides excised from proteins [28]. However, the structured regions seen in proteins were not extensive. Furthermore, most isolated peptides lacked structure, and the few exceptions did not always retain the conformation adopted in the native protein [27].

Peptide studies tell a similar story. A prime example involves the assessment of autonomous stability in the α-helix. Early evidence indicated that the cooperative unit for stable helix formation is $\sim$100 residues [105], a length that exceeds the average protein helix ($\sim$12 residues) by almost an order of magnitude. Consequently, the prevailing view in the 1970s was that protein-sized helical peptides would be random coils in isolation. This view was reversed in the 1980s, after Bierzynski et al. [12], expanding upon earlier work by Brown and Klee [15], demonstrated helix formation in water at near-physiological temperature for residues 1–13 of ribonuclease, a cyanogen bromide cleavage product. This finding prompted a re-evaluation of helix propensities in peptides [53, 56, 62, 64] and motivated numerous biophysical studies of peptides [80]. Summarizing this large body of work, there is evidence for structure in some short peptides in aqueous solvent at physiological temperature, but it is marginal at best and, more often, undetectable altogether.

20.4.2.1 Residual Structure in Denatured Proteins and Peptides

The limited success of these early attempts to detect residual structure strengthened the conviction that denaturation abolishes structure and reinforced the notion that the unfolded state is a random coil. Consequently, the field was stunned when Shortle and Ackerman [85] demonstrated the persistence of native-like structure in staphylococcal nuclease under strongly denaturing conditions (8 M urea). Shortle and Ackerman's finding was based on evidence from residual dipolar couplings in oriented gels. However, their interpretation that these data provide evidence of global organization was questioned recently by Annila and coworkers [52]. The ultimate conclusions from such work are still unclear, but the perspective has definitely changed and many recent experiments now find evidence for substantial residual structure in the denatured state (e.g., [22, 34, 46, 76, 88, 102]).

In a similar vein, Shi et al. reanalyzed a blocked peptide containing seven consecutive alanine residues for the presence of residual structure [83]. This peptide

is too short to form a stable α-helix and should therefore be a random coil. Contrary to this expectation, the peptide is largely in P_{II} conformation, in agreement with predictions from theory [65]. While not all residues are expected to favor the P_{II} conformation [73], this result shows that the unfolded state is predominantly a single conformer, at least in the case of polyalanine.

20.4.3 The Reconciliation Problem

The measured radii of gyration, R_G, of denatured proteins have values [58] that are consistent with those expected for a random coil with excluded volume in good solvent (Section 20.3.2.2). Yet, experimental evidence in both proteins [85] and peptides [83] suggests the presence of residual structure in the unfolded population. How are these seemingly contradictory findings to be reconciled? Millett et al. refer to this as the reconciliation problem ([58], see their discussion, p. 257).

Paradox is often a prelude to perception. Equation (6), in its generality, necessarily neglects the chemical details of any particular polymer type. Accordingly, the resultant chain description is insensitive to short-range order, apart from the proportionality constant R_0, which is a function of the persistence length (Section 20.3.1). Sterically induced local order, encapsulated in R_0, is surely present in unfolded proteins [31, 66], but can it rationalize the apparent contradiction between random coil R_G values and global residual structure [85]? One possible explanation is that multiple regions of local structure dominate the ensemble average to such an extent that they are interpreted as global organization [52, 103].

The coil library may provide a useful clue to the resolution of this puzzle. The coil library is the collection of all nonrepetitive elements in proteins of known structure, that fraction of native structure which remains after α-helix and β-sheet are removed. Given that the library is composed of fragments extracted from solved structures, it is surely not "coil" in the polymer sense. However, the term "coil library" is intended to convey the hypothesis that such fragments do, in fact, represent the full collection of accessible chain conformers in unfolded proteins [87]. Taken to its logical conclusion, this hypothesis posits that the coil library is a collection of structured fragments in folded proteins and, at the same time, a collection of unstructured fragments in unfolded proteins. If so, this library, together with α-helix, β-strand, and P_{II} helix, represents an explicit enumeration of accessible conformers from which the unfolded ensemble might be reconstructed [5].

At this writing, the reconciliation problem remains an ongoing question. Regardless of the eventual outcome, this paradox appears to be moving the field in an informative direction.

20.4.4 Organization in the Unfolded State – the Entropic Conjecture

Are there general principles that lead to organization in the unfolded state? If accessible conformational space is vast and undifferentiated, the entropic cost of

populating the native basin exclusively will be large. However, if the unfolded state is largely restricted to a few basins, with nonuniform, sequence-dependent basin preferences, then entropy can function as a chain organizer.

Consider two thermodynamic basins, i and j. The Boltzmann-weighted ratio of their populations, n_i/n_j, is given by $(w_i/w_j)e^{-\beta\Delta U}$, where n_i and n_j designate the number of conformers in i and j, w_i and w_j are the degeneracies of state, β is the Boltzmann factor, and ΔU is the energy difference between the two basins. Both entropy and enthalpy contribute to this ratio. If w_i and w_j are conformational biases (i.e., the number of isoenergetic ways the chain can adopt conformations i and j), and w_i/w_j is the dominant term in the Boltzmann ratio, the entropy difference, $\Delta S_{conf} = R\ln(w_i/w_j)$, would promote organization in the unfolded population.

In particular, if P_{II} is a dominant conformation in polyalanyl peptides, then it is also likely to be favored in unfolded proteins, in which case the unfolded state is not as heterogeneous as previously believed. The usual estimate of about five accessible states per residue in an unfolded protein is based on a familiar argument: the free energy difference between the folded and unfolded populations, ΔG_{conf}, is a small difference between large value of ΔH_{conf} and $T\Delta S_{conf}$ [13, 14]. If $\Delta G_{conf} \cong -10$ kcal mol^{-1} (a typical value) and $\Delta H_{conf} \cong 100$ kcal mol^{-1}, then the counterbalancing $T\Delta S_{conf}$ is also $\sim$100 kcal mol^{-1}. Then $\Delta S_{conf} \cong 3.33$ entropy units per residue for a 100-residue protein at 300 K. Assuming $\Delta S_{conf} = R\ln W$, the number of states per residue, W, is 5.34.

However, instead of a reduction in the number of distinct states, this entropy loss on folding could result from a reduction in the degeneracy of a single state, providing the ϕ, ψ space of occupied regions in the unfolded population is further constricted upon folding. For example, a residue in P_{II} is within a room-temperature fluctuation of any sterically allowed ϕ, ψ value in the upper left quadrant of the dipeptide map ([57], table 1). Consequently, different ϕ, ψ values from these regions would be thermodynamically indistinguishable and therefore not distinct states at all. As a back-of-the-envelope approximation, consider a residue that can visit any allowed region of the upper left quadrant in the unfolded state. Upon folding, let this residue be constrained to lie within $\pm 30^\circ$ of ideal β-sheet ϕ, ψ values. The reduction in ϕ, ψ space would be a factor of 5.58, approximating the value attributed to distinct states. Similar, but less approximate, estimates can be obtained when the unfolded populations are Boltzmann weighted.

What physical factors might underwrite such entropy effects?

20.4.4.1 **Steric Restrictions beyond the Dipeptide**

It has long been believed that local steric restrictions do not extend beyond the dipeptide boundary [70], but, on re-analysis, this conviction requires revision [11, 66, 89] (see Section 20.4.1.1). In fact, systematic steric restrictions operate over chain regions of several adjacent residues, and they serve to promote organization in unfolded protein chains. Two recent lines of investigation focus on identifying the physical basis for longer range, sterically induced ordering.

In a series of remarkable papers, Banavar, Maritan and their colleagues show

that chain thickness alone imposes stringent, previously unrecognized restrictions on conformational space [7, 42, 55]. All the familiar secondary structure motifs emerge automatically when the protein is represented as a self-avoiding tube, coaxial with the main chain, and a single inequality is imposed on all triples of Cα atoms [7, 55]. The further addition of simple hydrogen bond and hydrophobic terms is sufficient to generate the common super-secondary structures [42]. These straightforward geometric considerations demonstrate that sequence-independent steric constraints predispose proteins toward their native repertoire of secondary and super-secondary structural motifs.

Investigating the atomic basis for longer range steric restrictions, Fitzkee and Rose found that a direct transition from an α-helix to a β-strand causes an unavoidable steric collision between backbone atoms [31]. Specifically, a nonnearest neighbor collision occurs between the carbonyl oxygens of an α-residue at position i ($O^{\alpha}{}_{i}$) and a β-residue at position i + 3 ($O^{\beta}{}_{i+3}$). This restriction also holds for the transition from α-helix to P_{II}. These simple steric constraints have pervasive organizational consequences for unfolded proteins because they eliminate all structural hybrids of the form . . . ααββ . . . and . . . αααP_{II} . . . , pushing the unfolded population toward pure segments of α, β, and P_{II} interconnected by irregular regions such as those found in the coil library.

20.5 Future Directions

The early analysis of steric restrictions in the alanyl dipeptide (more precisely, the compound Cα-CO-NH–CαHR–CO-NH-Cα, which has two degrees of backbone freedom like a dipeptide) by Ramachandran et al. [71] has become one of those rare times in biochemistry where theory is deemed sufficient to validate experiment [49]. The fact that the dipeptide map is based only on ''hard sphere'' repulsion alone led some to underestimate the generality of this work, but not Richards, who commented [72]:

> ***For chemically bonded atoms the distribution is not spherically symmetric nor are the properties of such atoms isotropic. In spite of all this, the use of the hard sphere model has a venerable history and an enviable record in explaining a variety of different observable properties. As applied specifically to proteins, the work of G. N. Ramachandran and his colleagues has provided much of our present thinking about permissible peptide chain conformations.***

The notion that repulsive interactions promote macromolecular organization is not limited to the alanyl dipeptide. Space-filling models [48], which represent each atom literally as a hard sphere, were central to Pauling's successful model of the α-helix [67] and have widespread application throughout chemistry. Much of

the theory of liquids is based on the organizing influence of repulsion interactions [19].

Despite such successes, the existence of sterically induced chain organization has had little influence on models of the unfolded state owing to the strongly held conviction that local steric restrictions extend no further than adjacent chain neighbors. Of course, long-range excluded volume effects do affect the population [18, 32], as reflected in the exponent of Eq. (6), but they are not thought to play any role in biasing unfolded proteins toward specific conformations. Given the finding of local steric restrictions beyond the dipeptide (Section 20.4.4.1), it is time to re-analyze the problem.

Re-analysis will involve at least three steps: (1) analysis of local steric restrictions beyond the dipeptide, (2) characterization of elements in the coil library, and (3) combination of the results from these two steps. To the extent that useful insights emerge from this prescription, the folding problem may not be as intractable as previously thought.

Conformation and Dynamics of Nonnative States of Proteins studied by NMR Spectroscopy

Julia Wirmer, Christian Schlörb, and Harald Schwalbe

21.1
Introduction

21.1.1
Structural Diversity of Polypeptide Chains

From a structural point of view, protein folding is one of the most fascinating aspects in structural biology. Protein folding proceeds from the disordered random coil polypeptide chain defined by its primary sequence to intermediates with increasing degree of conformational and dynamic order to the final native state of the protein (Figure 21.1). While the starting point of protein folding, probably best described as a statistical coil, but often called the random coil state of a protein, can be defined as a state in which few if any nonlocal interactions exist, the native state can be described by one predominant conformation around which only local fluctuations of low amplitude occur. Order exists and forms on various levels of the protein structure, the primary structure describing the conformational preferences of the amino acid residues differs from secondary structure elements, which are defined by the conformations adopted by consecutive residues to the final arrangement of secondary structure elements in the three-dimensional fold of the protein.

During folding, the polypeptide chain therefore adopts very different conformations and its interaction with the surrounding solvent changes considerably. This variability in conformational space of a polypeptide chain has become even more interesting with the observation of protein misfolding revealing that proteins can also adopt highly ordered, oligomeric states, so-called fibrillic states of proteins, in which residues adopt repetitive conformations very different to the native fold and in which hydrogen bonding is satisfied in an intermolecular fashion. In addition, the conformational equilibria between the various states of a protein are influenced by interactions with chaperones in the cell. The given sequence of a protein therefore can adopt a continuum of different conformational states and degrees of oligomerization, those states interconvert at different rates and therefore vary widely in persistency (Figure 21.1).

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

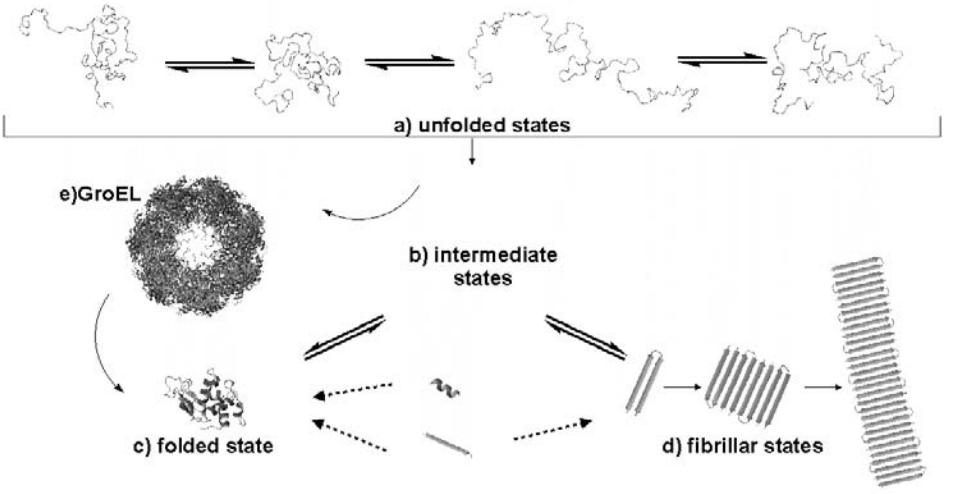

Fig. 21.1. The different conformations adopted by a polypeptide chain can range from the native, often monomeric state (c), in which a single conformation exists and which is build up from secondary structure elements and their specific arrangements, to the ensemble of conformers representing the random coil state of a protein (a). The individual members of this ensemble have widely different compaction, dynamics, local and nonlocal conformations. Protein folding preceeds via formation of folding intermediates (b) whose structure and dynamics may be modulated by protein-protein interactions with molecular chaperones such as GroEL (e) shown in the figure. At the other extreme of conformational states, proteins can aggregate and form oligomeric states called fibrils (d). Liquid and solid state NMR spectroscopy can provide detailed information on structure and dynamics in all of these states.

Spectroscopic techniques to study protein folding are reviewed in Chapter 2. NMR spectroscopy, applied to proteins both in their liquid and solid state, is intrinsically capable of characterizing the variety of conformations and dynamics associated with the polypeptide chain in different states with high precision. In contrast to the native state of proteins, many nonnative states of proteins are ensembles of interconverting conformers. Often, the averaging proceeds locally, e.g., by changes in torsion angles which are rapid (faster than microseconds) on the NMR time scale and lead to sharp NMR signals. In such cases, we will talk in the following of the ''random coil state'' of a protein. However, averaging can also involve the reorganization of preformed secondary structure elements which is considerably slower. In fact, from an NMR point of view, the observation of line broadening and the absence of detectable NMR signals indicative for a persistent tertiary fold serves as the definition of a ''molten globule state'' of a protein. NMR is also capable to study the kinetics of protein folding in real time as discussed in Chapter 16.

For nonnative states of proteins, the NMR observables do not directly define conformation and dynamics in these states. Rather, the experimental observables have to be interpreted in the light of models describing conformational averaging, in which the number of participating conformational states and the rate of their interconversion are the two most important parameters. Such models range from theoretical predictions of the properties of the polypeptide chain to extensive molecular

dynamics simulations. They are being developed to aid the interpretation of NMR parameters such as chemical shifts δ, spin–spin coupling constants J, homonuclear NOE data (NOEs), residual dipolar couplings (RDCs) and heteronuclear relaxation properties such as relaxation rates (^{15}N-R$_1$, ^{15}N-R$_2$) and heteronuclear NOEs ($\{^1$H$\}$-^{15}N-NOE).

21.1.2 Intrinsically Unstructured and Natively Unfolded Proteins

Nonnative states of proteins have also received attention recently because of the observation that an axiomatic linking of the function of a protein to persistent fold might not be general but a number of proteins have been identified that lack intrinsic globular structure in their normal functional form [1–3]. The expression ''intrinsically unstructured'' and ''natively unfolded'' are used synonymously, the latter being coined by Schweers et al. in 1994 in the context of structural studies of the protein tau [4]. Intrinsically unstructured proteins are extremely flexible, noncompact, and reveal little if any secondary structure under physiological conditions. In 2000, the list of natively unfolded protein comprised 100 entries [5] (see Table 21.1b). Natively unfolded proteins are implied in the development of a number of neurodegenerative diseases including Alzheimer's disease (deposition of amyloid-β, tau-protein, a-synuclein), Down's syndrome, and Parkinson disease to name a few (quoted after Ref. [5]). They are predicted to be ubiquituous in the proteome [6, 7] and algorithms available as a web-program (http://dis.embl.de/) have been developed to predict protein disorder [8]. According to the predictions, 35–51% of eukaryotic proteins have at least one long ($>$ 50 residues) disordered region and 11% of proteins in Swiss-Prot and between 6 and 17% of proteins encoded by various genomes are probably fully disordered (quoted from Ref. [6]). Proteins predicted to be intrinsically unstructured show low compositional complexity. These regions sometimes correspond to repetitive structural units in fibrillar proteins. Therefore, it seems likely that the unstructureness of the polypeptide chains in some states of a protein plays an important role in the development of fibrillar states and this further supports the importance for detailed structural and dynamic investigations of nonnative states of proteins. Chapter 8 in Part II is dedicated to the discussion of natively disordered proteins, and Chapter 33 in Part II discusses protein folding diseases.

It has also been noted by Gerstein that the average genomically encoded protein is significantly different in terms of size and amino acid composition from folded proteins in the PDB [9]. This difference would indicate that the structures deposited in the PDB are not random and in turn that they cannot be taken as representative for the entire structural diversity of polypeptide chains.

In this article, we discuss NMR investigations, primarily of nonnative states of proteins based on our investigations in the past using lysozyme and its mutants as well as α-lactalbumin and ubiquitin as model proteins. A number of excellent review articles have been published reporting on the topic of NMR investigations of nonnative states of proteins (see, for example, Refs [10–14]). In order to understand and determine unambiguously those parts of the polypeptide chain in which

residual structural elements are present, it is necessary to have a firm understanding of the NMR data to be expected for a random coil state of a protein that lacks any nonlocal structural elements and/or does not reveal sequence-specific differences in dynamics. Therefore, we interpret our data in the framework of a so-called random coil model (Section 21.4). According to this model, the random coil state is assumed to be a state in which there are no nonlocal interactions along the peptide chain, which is built up from the linear sequence of its repetition units, the amino acids. Different amino residues, embedded in their local sequence context, adopt different local conformations and their specific ϕ, ψ distributions have been extracted from residues in coil regions of native proteins to make theoretical predictions of NMR parameters for a random coil. According to this model, the dynamics of the polypeptide chain can be predicted using simple models treating the polypeptide as a branched or unbranched polypeptide chain. Comparisons of experimental NMR parameters with such predictions reveal regions in which residual conformational preferences and dynamic restrictions exist in the random coil state of a protein.

21.2 Prerequisites: NMR Resonance Assignment

For any detailed investigation of the conformation and dynamics of nonnative states of proteins at atomic resolution, the NMR resonances of the amino acids need to be assigned. For a long time, such investigation were considered impossible due to the very low chemical shift dispersion observed in ^{1}H-NMR experiments for nonnative states of proteins different to the native state (Figure 21.2).

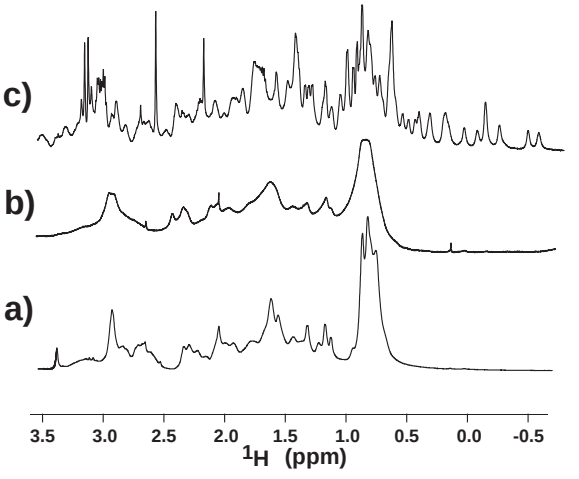

Fig. 21.2. One-dimensional ^{1}H-NMR experiments showing the differences in chemical shift dispersion and linewidth for different states accessible for the protein α-lactalbumin, a protein with 123 amino acid residues and four native disulfide bridges. They range from the random coil state (a) with sharp NMR resonance lines to the molten globule state (b) with extensive line broadening to the native state with well resolved peaks at least for some atomic groups (c).

In addition, while the random coil state of α-lactalbumin obtained by dissolving the protein in high concentrations of denaturant (8 M urea at pH 2) yields very sharp NMR resonances (Figure 21.2a), the molten globule state of α-lactalbumin at pH 2 reveals only an NMR spectra with very broad peaks (Figure 21.2b). The chemical shift dispersion in either of the two states is very limited and the signature of tertiary fold in the native state of the protein, visible in the appearance of upfield shifted methyl groups resonating at ppm values at or below 0.5 ppm is missing (Figure 21.2c).

One approach to overcome the substantial overlap problem observed for nonnative states of proteins was to dissect the protein of interest into smaller peptide fragments (see, for example, Refs [15–17]). These approaches also allowed delineation of those regions of the polypeptide chain that preserves local elements of structure.

Due to introduction of isotope labels and heteronuclear NMR experiments, the low chemical shift dispersion can be overcome in $^{1}H,^{15}N$ heteronuclear correlation experiments [18] and the modern sequential assignment procedures developed for native proteins by Bax and coworkers [19, 20] can be successfully applied also for the random coil state of proteins [21] (Figure 21.3). The addition of ^{13}C isotope labeling does, however, not provide additional resolution (Figure 21.4).

The surprising observation of relative high chemical shift resolution in the $^{1}H,^{15}N$ heteronuclear correlation can be predicted based on the analysis of chemi-

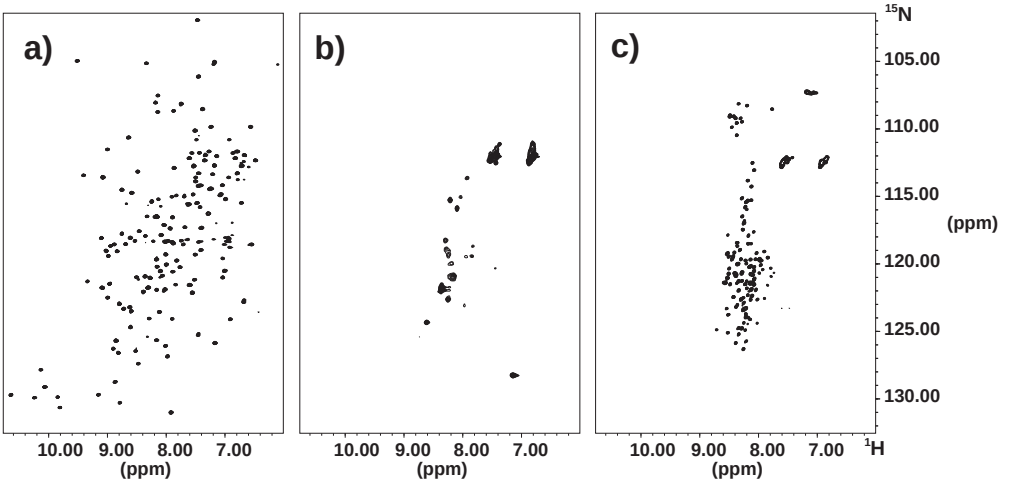

Fig. 21.3. Two-dimensional $^{1}H,^{15}N$-NMR correlation experiments showing the differences in chemical shift dispersion for different states accessible for the protein α-lactalbumin, a protein with 123 amino acid residues and four native disulfide bridges. For the random coil state of the protein (c), the resonances cluster in three regions in the spectra, largely reflecting the characteristic ^{15}N chemical shifts of the different types of amino acids when in unfolded conformations. For comparison, the similar spectrum for the native protein is also shown (a). At pH 2, the protein forms a molten globule state and the spectrum shows only very few peaks, while the other peaks are unobservable due to considerable line broadening (b).

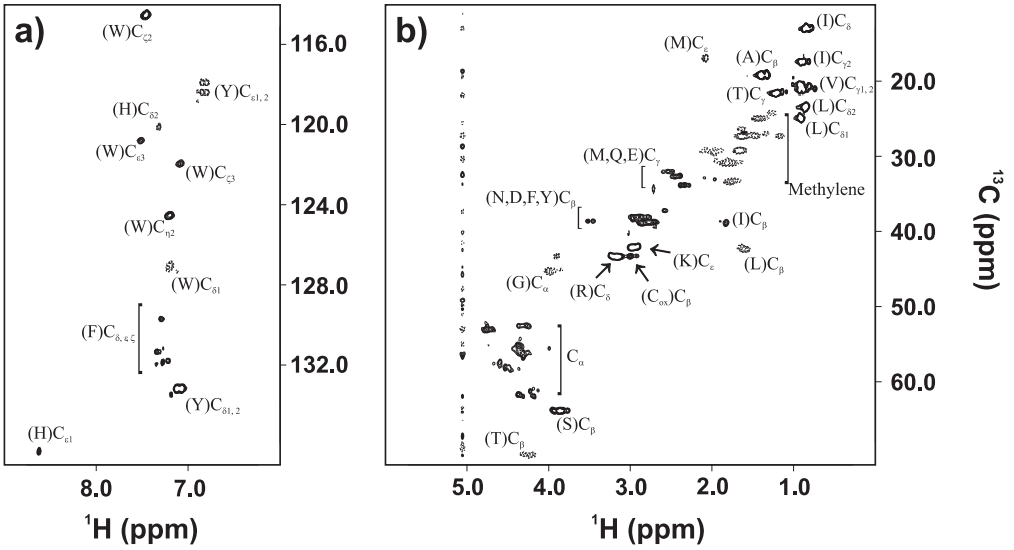

Fig. 21.4. Two-dimensional $^{1}H,^{13}C$-NMR correlation experiment of hen egg white lysozyme denatured in 8 M urea at pH 2. The chemical shift resolution in $^{1}H,^{13}C$ correlation is considerable lower than the $^{1}H,^{15}N$-NMR correlation experiment. a) Aromatic carbon region, and b) aliphatic carbon region. Distinct regions of ^{13}C resonances have been labeled with the one-letter amino acid code. The chemical shifts of the ^{13}C resonances are very similar to literature values for linear denatured hexapeptides [37].

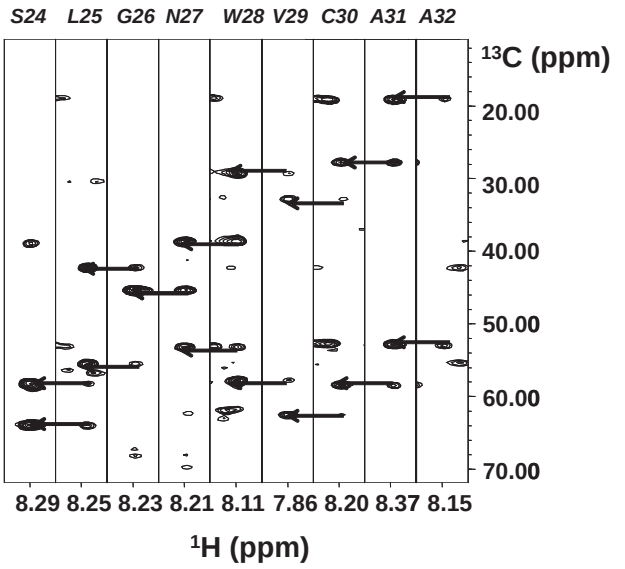

Fig. 21.5. (ω_1, ω_3) strips from the HNCACB experiment of cysteine reduced and methylated lysozyme with the N-terminal additional methionine, a nonnative state of lysozyme in H_2O and at pH 2, taken at the $^1H^N$ (ω_3) and ^{15}N (ω_1) frequencies of Ser24, Leu25, Gly26, Asn27, Trp28, Val29, Cys30, Ala31, and Ala32 (the additional methionine residue is labeled M_{-1} to keep the numbering of lysozyme). Intra- and interresidual correlation peaks are marked and clearly visible.

cal shift in protein structures [22] and from quantum chemical calculations [23]. Resonance assignment following this procedure have been reported for a number of different proteins as summarized in Table 21.1a. Table 21.1b gives an overview of natively unfolded proteins for which lack of structure has been identified by NMR spectroscopy. Table 21.1c summarizes solid state NMR investigations of fibrillar states of peptides.

Figure 21.5 shows the parts of three-dimensional spectra for hen egg white lysozyme for which sequential assignment is shown for a stretch of neighboring residues. The resonance assignment for random coil states of proteins with sharp resonance lines is straightforward provided the amino acid sequence is nonrepetitive.

21.3 NMR Parameters

In Section 21.3, the most important NMR parameters summarized in Table 21.2 will be introduced with an emphasis on the relevant aspects in the context of conformational averaging observed in nonnative states of proteins. It is important to stress here that in contrast to native proteins, the dependence of the measurable

Tab. 21.2. Overview of NMR parameters and their conformational dependence.

NMR parameter	*Conformational dependence*
Chemical shift δ (ppm)	Multiple torsion angles: $\phi, \varphi, \omega, \chi_1$
^{n}J couplings (Hz)	Single torsion angles via Karplus equations
Homonuclear NOEs (a.u.)	Distances, dependence on correlation time and motional properties
Heteronuclear relaxation (Hz)	Motional properties, dependence on τ_c, S^2, τ_e
Residual dipolar couplings (RDC) (Hz)	Overall shape, dynamics, S
H/D	exchangeable H^N
Diffusion	Radius of hydration (R_h)
Photo-CIDNP	Accessible Trp, Tyr, His

NMR parameters on conformation and dynamics for nonnative states of proteins is more complicated and requires additional models to predict the random coil NMR spectra. One successful approach to circumvent this problem is to investigate model peptides that should have no preferred conformation and define their properties such as chemical shifts, coupling constants, hydrogen exchange rates (Table 21.2) and such like as the ''random coil'' value. However, as discussed below, such an approach fails when one predicts NMR observables such as relaxation effects or residual dipolar couplings that show a pronounced dependence on the length of the polypeptide chain. These latter NMR parameters rely on anisotropic interactions and are different for segments of amino acids embedded in a short peptide or in a long polypeptide chain.

A different approach is to predict, using models from polymer theory and distinct torsion angle distributions, for example, the appearance of NMR spectra for the random coil state of a protein. These predictions provide a framework for the interpretation of NMR parameters such as NOEs and J coupling constants [24, 25] or residual dipolar couplings [26] (see Section 21.4).

21.3.1 Chemical Shifts δ

21.3.1.1 Conformational Dependence of Chemical Shifts

Chemical shifts δ depend on the chemical environment of the observed nuclei. Hence, the chemical shifts depend on how and to which degree (parts of) the polypeptide chains are folded. Generally, nonnative states of proteins show a considerably smaller chemical shift dispersion than proteins in their native states (see Figures 21.2a–c and 21.3a–c); NMR active nuclei (^{1}H, ^{13}C, ^{15}N) resonate close to or at their random coil chemical shift because of conformational averaging. For an ideal random coil polypeptide chain, NMR spectra are similar to the spectra of the mixture of the amino acids [27]. supporting the idea of the absence of any nonlocal interactions in the random coil state. The local amino acid sequence particularly affects the random coil chemical shifts of the $^{15}N^H$, $^1H^N$ and ^{13}CO resonances

[28]. Secondary and tertiary structures contribute to the observed chemical shifts and therefore can be investigated by analysis of the chemical shifts [29]. Deviations from random coil chemical shifts are also called secondary chemical shifts and are indicative for the content of residual structures in unfolded or partially folded proteins. An overall averaging over the deviations from random coil chemical shifts gives an impression of the extent of residual structure in denatured states of proteins.

Proper referencing of the chemical shifts to standard substances like DSS (2,2-dimethyl-2-silapentane-5-sulfonic acid) or TSP (3-(trimethylsilyl) propionate) is required for the comparison of experimental spectra to random coil chemical shifts from the literature [30, 31]. In general, the dispersion of the $^{15}N^{H}$, $^{1}H^{N}$, and ^{13}CO resonances in unfolded proteins is much greater than for the $^{13}C\alpha$, $^{13}C\beta$, $^{1}H\alpha$, and $^{1}H\beta$ resonances, reflecting the sensitivity of the former nuclei to the nature of the neighboring amino acids in the primary sequence of the protein [32]. Both $^{13}C\alpha$ and ^{13}CO chemical shifts are shifted downfield when they are in α-helical structures and upfield, when they are located in β-sheets, while $^{13}C\beta$ and $^{1}H\alpha$ resonances experience upfield shifts in α-helices and downfield shifts in β-structures [30, 31, 33].

So-called chemical shift index (CSI) calculations [33] can routinely be used to detect secondary structure elements in proteins. In this method, chemical shift deviations are normalized to 1, 0, and -1, depending on the extent and direction of the deviation, and then plotted against the residues of the protein sequence. The result of this is a topology plot of the protein from which one easily can spot α-helical structures and β-sheet regions, which differ in the direction of the secondary chemical shifts.

21.3.1.2 Interpretation of Chemical Shifts in the Presence of Conformational Averaging

In nonnative states of proteins we observe conformational averaging (e.g., between different rotameric states). Each rotameric state has a characteristic chemical shift which in a dynamic case will be averaged. However, the NMR signal is influenced by the averaging process both in terms of its resonance position and the observed linewidth (Figure 21.6).

In the case of fast conformational averaging (Figure 21.6c), the observed chemical shift is the population weighted average:

$$\delta^{\mathrm{obs}} = \sum_i p_i \delta^i \tag{1}$$

where δ^{obs} is the observed chemical shift, δ^i is the chemical shift in the ith conformation with weights p_i and $\sum_i p_i = 1$. The increase in linewidth at half height $\Delta\Gamma_{1/2}$ due to fast exchange between two site equally populated is given by:

$$\Delta\Gamma_{1/2} = \frac{\pi(\delta\nu)^2}{2k} \tag{2}$$

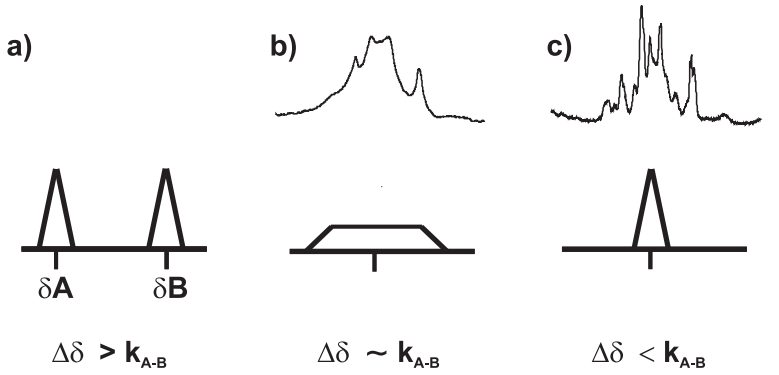

Fig. 21.6. Schematic picture indicating the appearance of NMR spectra for different chemical exchange regimes: a) Slow chemical exchange between conformers, e.g., in the nonnative (A) and native state of a protein (B). The height of the signals indicates the population between the two states, e.g., at a given denaturant concentration. b) Intermediate chemical exchange regime (molten globule state). c) Fast chemical exchange (random coil state).

where $\delta\nu = \nu_A - \nu_B$ and k is the rate of conformational exchange. For fast exchange and small chemical shift differences, a case typically encountered in the random coil conformation of a protein, NMR signals with very narrow linewidths are observed. Under the assumption of two-state fast folding kinetics, in which the unfolded state of a protein is in fast exchange with its folded state, the increase in linewidth (e.g., induced by subsequent addition of increasing amounts of urea starting from the folded state and thereby increasing the population of the unfolded state) can be analyzed to derive microsecond refolding kinetics for two-state folding [34, 35].

However, a detailed description of the random coil state of a protein cannot really be obtained from chemical shift measurement since the prediction of δ^i that is the conformational dependence of chemical shifts is not yet clearly established. It is therefore difficult to predict the chemical shifts for a random coil state of protein from a given distribution of conformations. Rather, reference values for random coil chemical shifts have been determined by measurement of so-called random coil peptides, first of the sequence GGXA [36] and then later of GGYXGG, with Y being either proline or glycine and X any of the 20 amino acids [37, 38].

The NMR spectrum becomes more difficult if the rate of interconversion approaches the differences in chemical shifts $\delta\nu$ (Figure 21.6b). In the case of intermediate conformational averaging between two equally populated sites, called intermediate exchange regime, one very broad line is observed. At the point of coalescance, the exchange rate k is given directly by:

$$k = \frac{|\delta\nu|}{\sqrt{8}} \tag{3}$$

where $\delta\nu = \nu_A - \nu_B$ and is the rate of conformational exchange. For intermediate exchange, a case associated with the molten globule state of a protein, the dramatic line broadening has made resonance assignment for a molten globule protein impossible so far (see Figures 21.2b and 21.3b). In case of unsymmetric exchange between multiple sites, the prediction of the conformations that participate in the chemical exchange is very difficult and always relies on limiting assumptions, such as fixing one or more of the conformations and the rate of exchange between those sites.

Recently, residues in α-lactalbumin have been identified that are involved in formation of a hydrophobic core undergoing slow conformational exchange and therefore forming a molten globule. Redfield et al. [39] started from the random coil state of the protein, stabilized in high concentrations of denaturants at pH 2, and for decreasing amounts of denaturants observed which residues would disappear first due to intermediate chemical exchange. Interestingly, the pattern of disappearance of resonance can be interpreted assuming a preformed core in the α-domain of the protein.

Under favorable conditions, NMR spectra can be recorded in which the folded and the unfolded state of a protein are in slow exchange; two sets of signals arising from either of the two states can be observed (Figure 21.6a). If exchange takes place on a time scale of hundreds of milliseconds, then exchange peaks between the two states can be observed in NOESY experiments [40], magnetization is transferred from one of the states to the other during the mixing time (of the order of 200–500 ms) of the NOESY experiment [41, 42]. These exchange peaks can be used to assign the spectrum of the unfolded state from known assignments in the folded state and exchange kinetics can be derived.

21.3.2 *J* Coupling Constants

21.3.2.1 Conformational Dependence of *J* Coupling Constants

Vicinal (^3J) spin–spin coupling constants can be used for conformational analysis in peptides and proteins. In general, ^3J coupling constants depend on the torsion angles between atoms three bonds apart and the relationship of the dependence of coupling constants on the respective dihedral angles is given by semi-empiric Karplus relations [43] (Table 21.3). Karplus relations are not single-valued, but instead give up to four dihedral angle values for a single coupling constant (Figure 21.7). Karplus parameters have been determined for most of the spin pairs relevant for conformational analysis in the polypeptide backbone and the amino acid side chains (Table 21.3). Coupling constants, especially the coupling constant $^3J(H^N,H_\alpha)$, can be used for the investigation of backbone conformations of partly folded or unfolded states of proteins [36, 44, 45], if the effect of conformational averaging is taken into account.

In addition, ^1J and ^2J coupling constants also contain information about torsion angles, however, their spread in values for different conformations is not as large as for the $^3J(H^N,H_\alpha)$ coupling constant [46–51].

Tab. 21.3. Overview of Karplus parametrization for different ^1J, ^2J, and ^3J coupling constants.

Coupling constant	*Karplus parameterization*	*References*

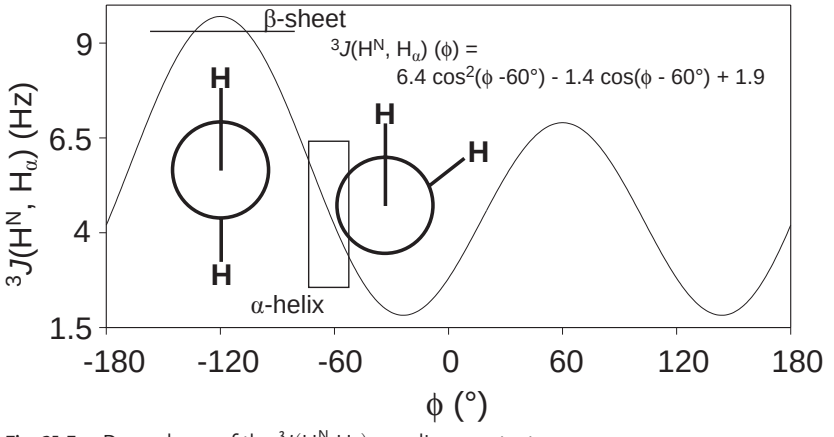

Fig. 21.7. Dependence of the $^3J(\mathrm{H^N},\mathrm{H}_\alpha)$ coupling constants on the backbone torsion angle ϕ using the parametrization by Vuister et al. (see Table 21.3).

Scalar couplings through H-bonds ($^{3h}J(N,C')$) provide information on the state of individual hydrogen bonds and therefore on the formation of α-helix [52]. This information is of particular interest for the investigation of folding states of proteins, because the helicity can be observed at atomic level. Thus, $^{3h}J(N,C')$ are valuable complements to chemical shift deviation data.

21.3.2.2 Interpretation of *J* Coupling Constants in the Presence of Conformational Averaging

In the case of fast conformational averaging, the observed scalar coupling constant is the population weighted average in close analogy to chemical shifts:

$$J^{\mathrm{obs}}(\alpha) = \sum_i p_{\mathrm{i}} J^{\mathrm{i}}(\alpha_{\mathrm{i}}) \tag{4}$$

where J^{obs} is the observed scalar coupling constant, J^{i} is the scalar coupling constant in the *i*th conformation with torsion angle α_{i} and weights p_{i} and $\sum_i p_{\mathrm{i}} = 1$. Two approaches have been developed to interpret the averaged scalar coupling constant. In one approach, random coil scalar coupling constants have been determined for random coil peptides GGXGG in close similarity with the reference chemical shift values [53].

Different to chemical shifts, the dependence of scalar coupling constants on the intervening torsion angle is well established (see Table 21.3) and therefore, coupling constants can be predicted using models for the distribution of torsion angle space in the random coil state of a protein (see Section 21.4).

Table 21.4 shows a comparison of coupling constants predicted from the random coil model and those measured for random coil peptide GGXGG in 6 M GdmCl.

21.3.3 Relaxation: Homonuclear NOEs

21.3.3.1 Distance Dependence of Homonuclear NOEs

NOE interactions between hydrogen atoms form the most important basis for the NMR structure determination (Figure 21.8). Distance information can be obtained through space-mediated transfers in NOESY experiments that reveal cross-peaks between two protons H1 and H2 that are closer than 5 Å together. The cross-relaxation rate between two protons that gives rise to observable cross-peaks in NOESY (ROESY) spectra is defined by the following equation:

$$\begin{aligned} \sigma^{\mathrm{NOE}}_{\mathrm{H1,H2}} &= \frac{d^2\tau_{\mathrm{c}}}{5}\left[-1 + \frac{6}{1+4\omega_0^2\tau_{\mathrm{c}}^2}\right] \\ \sigma^{\mathrm{ROE}}_{\mathrm{H1,H2}} &= \frac{d^2\tau_{\mathrm{c}}}{5}\left[2 + \frac{3}{1+\omega_0^2\tau_{\mathrm{c}}^2}\right] \end{aligned} \tag{5}$$

where ω_{H} is the Lamor frequencies of ^{1}H, $d = \mu_0 h\gamma_{\mathrm{H}}^2/(\sqrt{8}r^3_{\mathrm{H1,H2}}\pi^2)$ describes the

Tab. 21.4. Random coil $^3J(H^N,H_\alpha)$ coupling constants predicted on the basis of the random coil model (see Section 21.4) and measured experimentally. Values for $^3J(H^N,H_\alpha)^{pred.}$ are based on the distribution of ϕ angles in the protein database and represent an average over all the different adjacent amino acids, rather than for residues with adjacent glycines. Experimental coupling constants were measured using a GGXGG peptide in 6 M GdmCl at 20 °C, pH 5.0.

constant for dipolar interaction, μ_o is the permeability of the vacuum, h is Planck's constant, γ_H is the gyromagnetic ratio of nucleus i, and $r_{H1,H2}$ is the distance between H1 and H2.

In the following, we wish to discuss some of the assumptions and complications associated with the use of NOE information to derive structural information for nonnative and random coil states of proteins. In the native state of a protein, a

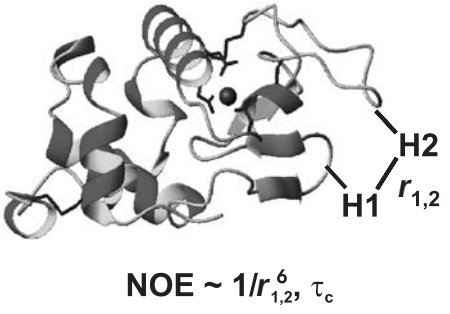

Fig. 21.8. The NOE interaction $\sigma^{NOE}_{H1,H2}$ between two protons H1 and H2 is the most important NMR parameter to determine structures of proteins.

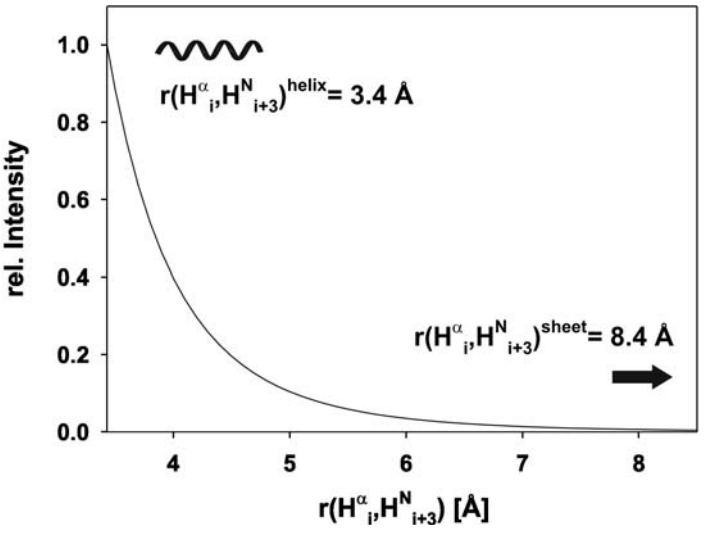

Fig. 21.9. Dependence of the cross-peak intensity $\sigma^{NOE}_{H1,H2}$ in NOESY spectra on the distance between protons H1 and H2. Characteristic secondary structure elements are indicated, the cross-peak for two protons 3.4 Å apart has arbitrarily been scaled to 1.

given cross-peak is interpreted as arising from a single conformation with fixed distance. It is further assumed that the overall rotational tumbling of a molecule is isotropic and can therefore be modeled by a single spectral density function that describes the distribution of motions in a molecule. Furthermore, additional local motions can to good approximation assumed to be absent. These local motions could modulate (decrease) the distance between protons H1 and H2. Under these assumptions, the observed intensity falls off with the inverse sixth power of the distance (Figure 21.9).

Spectral density function The spectral density function $J^{q}(\omega_q)$ is obtained by evaluating the correlation function of the spherical harmonics

$$J^{q}(\omega_q) = \int_0^{\infty} d\tau \overline{F^{(q)}(t)F^{(-q)}(t+\tau)} \exp(-i\omega_q\tau) \tag{6}$$

The bar indicates time average over *t*. *q* can assume values of 0, ±1, ±2. The correlation function describes the probability of a given internuclear vector to stay in a fixed orientation in dependence of the time τ. Due to rotational tumbling, the orientation is lost; for proteins of 15 kDa size, a typical time constant τ_c for this process is of the order of 5 ns. However, depending on the model of rotational reorientation (isotropic, axially symmetric, asymmetric), the spectral density function has

different forms. Different members of ensemble of conformers in the random coil state of a protein will have very different diffusion tensors, and therefore, the spectral density functions will not be identical for compact conformers compared to extended conformers. In the following, we discuss the isotropic case and the case of axial symmetry.

Spherical top molecules The spectral density function for isotropic rotational diffusion has been derived by Hubbard and coworkers [54–57]:

$$J^{q}(\omega_q) = \frac{2}{5}\left[\frac{6D}{(6D)^2 + \omega_q^2}\right] = \frac{1}{5}\left[\frac{2\tau_c}{1 + (\omega_q\tau_c)^2}\right] \tag{7}$$

where D denotes the diffusion constant, with $1/\tau_c = 6D$. The rotational diffusion constant is inversely proportional to the correlation time τ_c. The correlation time for brownian rotational diffusion can be measured by time-resolved fluorescence spectroscopy, light scattering, or NMR relaxation [58] and can be approximated for isotropic reorientation by the Stoke's-Einstein correlation: $\tau_c = \frac{4\pi\eta_w r_H^3}{3k_B T}$ in which η_w is the viscosity, r_H is the effective hydrodynamic radius of the protien, k_B is the Boltzmann constant, and T the temperature.

Axially symmetric top molecules For the case that $D_{xx} = D_{yy} = D_\perp$, one obtains the spectral density function of a symmetric top rotator ($D_{zz} = D_\parallel$) or of an axially symmetric top molecule whose rotational diffusion is defined by a second rank diffusion tensor with polar coordinates θ and ϕ:

$$\begin{aligned} J^{q}(\omega_q) &= \frac{1}{20}\{S_0^2 J^{q,0} + S_1^2 J^{q,1} + S_2^2 J^{q,2}\} \\ S_0^2 &= \langle(3\cos^2\theta - 1)\rangle\langle(3\cos^2\theta - 1)\rangle/4 \\ S_1^2 &= 3\langle(\sin\theta\cos\theta)(\cos\phi)\rangle^2 + \langle(\sin\theta\cos\theta)(\sin\phi)\rangle^2 \\ S_2^2 &= \frac{3}{4}\langle(\sin^2\theta)(\cos 2\phi)\rangle^2 + \langle(\sin^2\theta)(\sin 2\phi)\rangle^2 \end{aligned} \tag{8}$$

in which the reduced spectral density functions ($-2 \le m \le +2$)

$$J^{q,m} = \frac{2\tau_{c,m}}{1 + (\omega_q\tau_{c,m})^2} \tag{9}$$

have been used. The correlation times $\tau_{c,m}$ can be rewritten as diffusion constants $D_\parallel$ and $D_\perp$ according to

$$1/\tau_{c,m} = 6D_{\perp} + m^2(D_{\parallel} - D_{\perp}) \tag{10}$$

The analysis shows that of cross-peak intensities $\sigma^{NOE}_{H1,H2}$ will therefore be very different depending on the overall compactness of the conformer, ranging from nearly isotropic to highly extended and anisotropic shape, in the ensemble in the random coil state of a protein.

21.3.3.2 Interpretation of Homonuclear NOEs in the Presence of Conformational Averaging

In the ensemble of unfolded states, averaging around intervening torsion angles that connect the two protons of interest will lead to averaging of the distances. Local averaging of torsion angles will lead to modulation of the NOE signal in addition to the global reorientation of the molecule and the effect of local and global motions and the ratio of their characteristic time constants τ_e and τ_c, respectively, will influence the cross-peak intensities $\sigma^{NOE}_{H1,H2}$ in NOESY experiments. The formalism to deal with internal motion has been introduced for the analysis of heteronuclear two-spin systems such as C–H or N–H (see Section 21.3.4) and will be introduced for the treatment of a two-spin H–H system.

Internal motion *Derivation of spectral density functions by explicit calculation of the motion:* Internal motion can be incorporated into the spectral density either by the Lipari and Szabo [59, 60] approach or by explicit calculation of the motion from, for example, motional models of molecular dynamics trajectories. In the above given equations, the spectral densities are Fourier transformations of the rotational diffusive motion of the molecule with respect to the external magnetic field [61, 62].

Internal motions analyzed by Lipari-Szabo approach: The model-free or Lipari-Szabo approach for the analysis of relaxation rate aims at the provision of dynamic parameters describing the dynamic behavior of a two-spin system irrespective of any assumed motional model. This is desirable since the relaxation data does not contain any information on the nature of the motions that cause relaxation. The model-free formalism is the most widely applied one for the dynamic interpretation of relaxation data. In the simplest case (Figure 21.10a), these consist of the generalized order parameter S^2, which is a measure for the spatial restriction of the internal motion, and the effective correlation time τ_e defining the time scale of motion. Assuming isotropic diffusion, the spectral density function can then be expressed as follows:

$$J(\omega) = \frac{S^2\tau_c}{1+\omega^2\tau_c^2} + \frac{(1-S^2)\tau}{1+\omega^2\tau^2} \tag{11}$$

In Eq. (11), τ_c is the overall rotational correlation time of the molecule and $1/\tau = 1/\tau_c + 1/\tau_e$. In the absence of internal motion ($S^2 \sim 1$ and $\tau = \tau_c$), $J(\omega)$ simplifies to:

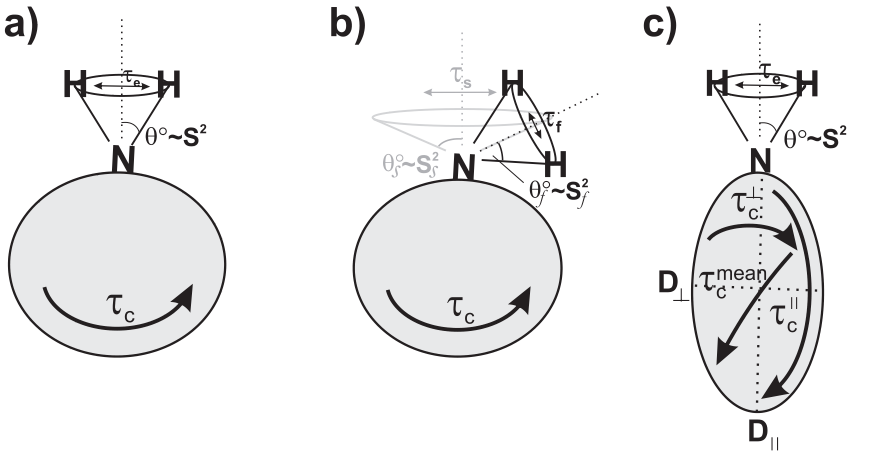

Fig. 21.10. Model-free parameters shown for a N–H spin system within a molecule that tumbles isotropically with the overall rotational correlation time τ_c. A) Simple model with the order parameter S^2 and the effective correlation time τ_e. The overall rotation is assumed to be isotropic. B) Two-time scale extended model with two S^2 parameters, S_S^2 and S_f^2 for slow and fast motions. C) like A but with anistropic overall rotation.

$$J(\omega) = \frac{\tau_c}{1 + \omega^2 \tau_c^2} \tag{12}$$

In cases where different fast motions take place, whose time scales differ by at least one order of magnitude, an extended model-free formalism has been developed with a separate S^2 for each motion, S_S^2 and S_f^2 (Figure 21.10b, Eq. (13)).

$$J(\omega) = \frac{S^2 \tau_c}{1 + \omega^2 \tau_c^2} + \frac{(S_f^2 - S^2)\tau}{1 + \omega^2 \tau^2} \tag{13}$$

In this two-time scale model it is assumed that the contribution of the faster of the two motions can be neglected, therefore, while it contributes to the overall S^2 since $S^2 = S_S^2 * S_f^2$, the term containing the fast effective correlation time τ_f is left out. The time scale of the slower internal motion τ_s is included in τ ($1/\tau = 1/\tau_c + 1/\tau_s$) similar to τ_e of the single-time scale model (it will therefore not be discriminated from τ_e in the following).

Figure 21.11 shows the dependence of the cross-peak intensity $\sigma_{H1,H2}^{NOE}$ in NOESY experiments on the overall correlation τ_c, the internal correlation time τ_e and the order parameter S^2 as defined in the single-time scale model. It can be seen that for global correlation time of 2 ns, an order parameter S^2 of 0.4, and an internal correlation time τ_e of 150 ps, $\sigma_{H1,H2}^{NOE}$ is scaled down from –0.36 in the absence of any internal motion ($S^2 = 1.0$) to -0.12. If one reduces τ_c to 1 ns, $\sigma_{H1,H2}^{NOE}$ is further reduced to -0.04. It is interesting to note that for longer internal correlation times τ_e, $\sigma_{H1,H2}^{NOE}$ increases again. The partition of τ_c and τ_e is difficult to assess by NMR. In the case, in which local and global motions cannot be entirely uncoupled and in

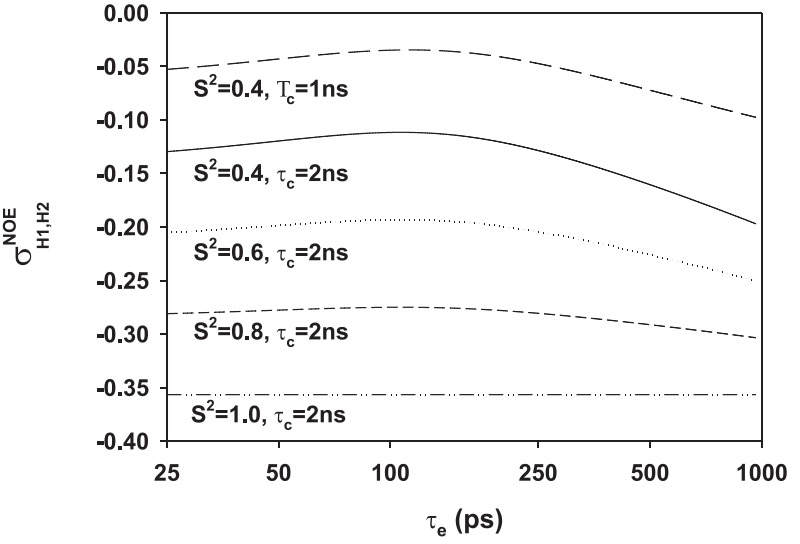

Fig. 21.11. Dependence of the cross-peak intensity $\sigma^{NOE}_{H1,H2}$ in NOESY spectra on the correlation time for local motions τ_e assuming different correlations times τ_2 for the global motion and different order parameters S^2.

which local motions have relative larger amplitudes, interpretation of $\sigma^{NOE}_{H1,H2}$ in terms of arising from an average distance is difficult. In addition, the correlation times for both internal and global motion may be affected in a different manner depending on the specific experimental conditions such as temperature and solvent viscosity; these effects make it difficult to argue that the absence of a specific cross-peak could be taken as evidence for specific conformation sample as is sometimes done in the literature.

Cooperativity in conformational sampling Different to coupling constants J that depend only on a single intervening torsion angle, the distances of atoms further remote is influenced by more than a single torsion and this leads to interesting questions regarding the analysis of cooperativity in sampling different conformations. In this discussion, cooperativity describes the influence of neighbouring residues and their (averaged) conformation on a given torsion angle distribution. Let us assume that the residues of a small peptide can adopt two conformations, α and β, both by 50% (Figure 21.12). Two extreme cases of cooperativity can be distinguished: In the cooperative case of conformational sampling, a residue $i+1$ assumes an $\alpha(\beta)$ conformation if residue i is in $\alpha(\beta)$; in the noncooperative case, a residue $i+1$ assumes either α or β conformation with 50% probability, if residue i is in $\alpha(\beta)$. In the noncooperative case, the eight possible conformations of a tripep-

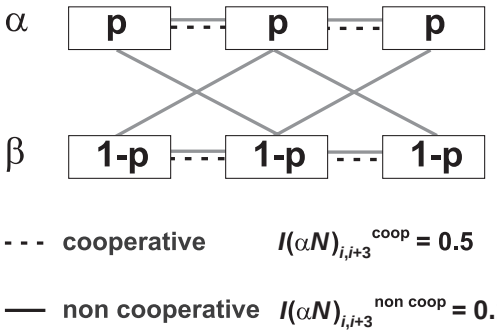

Fig. 21.12. Model of a consecutive stretch of three amino acid residues. For the sake of the argument, it is assumed that the residues can adopt only two different conformations, α and β. In the case of cooperative sampling of conformational space, which is indicated by the dashed lines, the intensity of the NOE cross-peak $I(\alpha, N)_{i,i+3}^{\text{coop}}$ is 50% of the cross-peak observed for a single static conformation. In the case of noncooperative conformational sampling, the intensity $I(\alpha, N)_{i,i+3}^{\text{non coop}}$ decreases to 17%, for which only two out of the eight possible conformation contribute (see Table 21.5).

tide $(\alpha\alpha\alpha, \beta\alpha\alpha, \alpha\beta\alpha, \beta\beta\alpha, \alpha\alpha\beta, \beta\alpha\beta, \alpha\beta\beta, \beta\beta\beta)$ are each sampled by 12.5%. Obviously, the J coupling constant in either of the two cases is the average $(J^{\alpha} + J^{\beta})/2$ and J couplings therefore do not differentiate between different degrees of cooperativity.

This is different for the measurement of an NOE, e.g., between a residue i and $i + 3$. In the cooperative case, there are two populations present $(\alpha\alpha\alpha, \beta\beta\beta)$, each by 50%. Let us assume that the $\alpha\alpha\alpha$ conformer represents a helical fragment and the $\beta\beta\beta$ conformer an extended fragment. Then, Figure 21.9 shows that no cross-peak can be observed for $\beta\beta\beta$ conformer. In the cooperative case, in which 50% of all molecules in the ensemble have an $\alpha\alpha\alpha$ conformation, the cross-peak intensity is 50% of the cross-peak intensity predicted for a helix (Table 21.5). In the noncooperative case, in which all eight conformations are equally populated, the cross-peak intensity drops to 0.17 and only two conformers $(\alpha\alpha\alpha, \beta\alpha\alpha)$ contribute to the cross-peak intensity.

21.3.4 Heteronuclear Relaxation (^{15}N R_1, R_2, hetNOE)

21.3.4.1 Correlation Time Dependence of Heteronuclear Relaxation Parameters

Heteronuclear relaxation rates (^{15}N-R_1, ^{15}N-R_2) and heteronuclear NOEs ($\{^1$H$\}$-^{15}N-NOE) are sensitive both to motions on a subnanosecond time scale and to slow conformational exchange in the millisecond time scale [63]. Motions that influence the NMR parameters are the overall rotational tumbling of a molecule and the local fluctuations (e.g., of an ***NH*** bond vector). The exact formula are given in Eq. (14a–c):

Tab. 21.5. Contribution to NOE cross-peak intensities from different conformations for two models: (i) cooperative sampling of conformational space defined by two different conformations, α and β, or (ii) noncooperative sampling of conformational space (see Figure 21.12).

Conformation of residues i + 1 to i + 3	*Cooperative sampling*		*Noncooperative sampling*	
	Population	*Cross-peak intensity (a.u.)*	*Population*	*Cross-peak intensity (a.u.)*
$\alpha\alpha\alpha$	50%	0.5	12.5%	0.124
$\beta\beta\beta$	50%	0	12.5%	[a]
$\alpha\alpha\beta$	–	–	12.5%	[a]
$\alpha\beta\alpha$	–	–	12.5%	[a]
$\beta\alpha\alpha$	–	–	12.5%	0.037
$\alpha\beta\beta$	–	–	12.5%	[a]
$\beta\alpha\beta$	–	–	12.5%	[a]
$\beta\beta\alpha$	–	–	12.5%	[a]

[a] All other conformations contribute 0.009 [a.u.] to the cross-peak intensity.

$$R_1 = \frac{d^2}{4}[J(\omega_H - \omega_N) + 3J(\omega_N) + 6J(\omega_H + \omega_N)] + c^2 J(\omega_N)$$

$$R_2 = \frac{d^2}{8}[4J(0) + J(\omega_H - \omega_N) + 3J(\omega_N) + 6J(\omega_H) + 6J(\omega_H + \omega_N)] + \frac{c^2}{6}[4J(0) + 3J(\omega_N)] + R_{ex} \qquad (14a\text{–}c)$$

$$\mathrm{NOE} = 1 + (d^2/4R_1)(\gamma_N/\gamma_H)[6J(\omega_H + \omega_N) - J(\omega_H + \omega_N)]$$

In this, ω_H and ω_N are the Lamor frequencies of ^1H and ^{15}N, respectively, $J(\omega)$ is the spectral density function at frequency ω; R_{ex} is the parameter accounting for conformational exchange contributions; $d = \mu_0 h \gamma_N \gamma_H / (8 r_{NH}^3 \pi^2)$ and $c = \omega_N \Delta\sigma_N / \sqrt{3}$ describe the dipolar and the chemical shift anisotropy (CSA) interaction, respectively. μ_o is the permeability of the vacuum; h is Planck's constant; γ_i is the gyromagnetic ratio of nucleus i; r_{NH} is the internuclear distance between N and H; $\Delta\sigma_N$ is the nitrogen CSA.

The dependence of the heteronuclear relaxation parameters on the overall rotational correlation time τ_c in the absence of internal motions and assuming isotropic tumbling is shown in Figure 21.13. While the longitudinal relaxation rate R_1 exhibits a maximum, R_2 increases monotonuously with τ_c. This difference arises from the dependence of R_2 but not of R_1 on a $J(0)$ term (see Eq. (14)), which is negligible at lower τ_c values but becomes more and more relaxation relevant for higher τ_c values. For macromolecules, τ_c usually lies right of the R_1 maximum and consequently small R_1 but large R_2 values are expected.

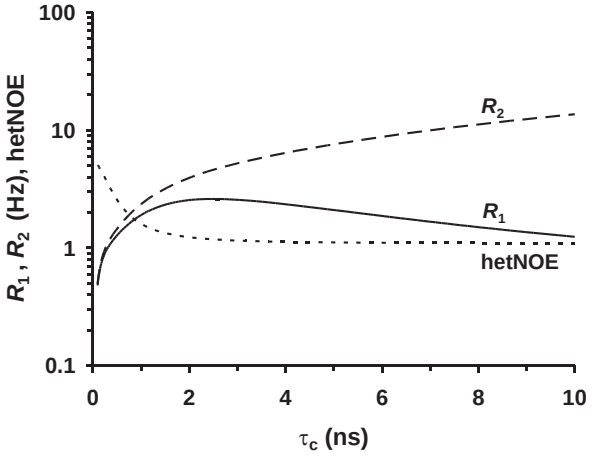

Fig. 21.13. Dependence of R_1, R_2 and the heteronuclear NOE (hetNOE) on τ_c. Calculations are based on the assumption of a rigid molecule tumbling isotropically.

21.3.4.2 **Dependence on Internal Motions of Heteronuclear Relaxation Parameters**

The relaxation rates are influenced by additional internal motions. In order to show the effect of such internal motions on the observed relaxation, Figure 21.14 shows the simulation of the transverse ^{15}N relaxation rates (^{15}N-R_2) as predicted using the Lipari-Szabo approach and a single-time scale model (Eq. (13)). For a given overall correlation time $\tau_c = 1$ ns, the relaxation rate decreases with increasing internal motion and order parameter. However, the use of the Lipari-Szabo

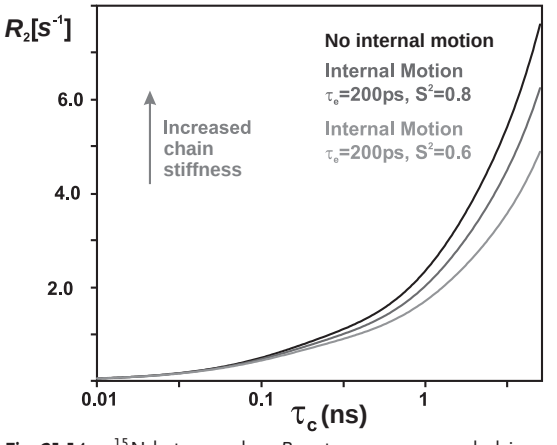

Fig. 21.14. ^{15}N heteronuclear R_2 rates as function of correlation time τ_c for global motions, τ_e for internal motions and the order parameters S^2. The appropriateness of the underlying model-free approach for the description of the dynamics in nonnative states of proteins is discussed in the text.

approach for random coil states of proteins is controversial, for a detailed discussion see, for example, Ref. [64]: the extraction of motional parameters using the Lipari-Szabo approach is based on two (single time scale model) or three (two time scale model) discrete correlation times that can be separated and are uncorrelated to the other motions. In other words, the approach assumes that the time scales of global and local motions can clearly be separated, an assumption questionable in the context of random coil states of proteins.

Alexandrescu and Shortle [65] have used a local model-free approach, according to which one global correlation time is fitted per residue. In the case of extensive averaging over a range of frequency in the nanosecond range, a continuous distribution of correlation times (and subsequently spectral density functions) can be introduced. One of such functions, the Cole-Cole distribution, has been used by Buevich and Baum to describe the relaxation behavior of the unfolded propeptide of subtilisin PPS [66]. An improved treatment of this problem has been proposed by Ochsenbein et al., in which a lorentzian distribution of correlation times (see Eq. (15)) is used to describe the underlying dynamics of the ensemble of conformers.

$$J(\omega) = \int_0^\infty F(\tau) J(\omega, \tau)\, \mathrm{d}\tau$$

$$F(\tau) = K \frac{\Delta}{\Delta^2 + (\tau - \tau_0)^2} \quad \text{for } 0 \le \tau \le \tau_{\max} \tag{15}$$

$$F(\tau) = 0 \quad \text{for } \tau \ge \tau_{\max}$$

In yet another approach, we have fitted the sequence dependence of relaxation rates to a simple two-parameter model, which assumes a common intrinsic relaxation rate for a given residue that depends on the viscosity of the solution, and a length dependence of the influence of neighboring residues on the relaxation properties of any member of the chain. Such simple approach fits the random coil behavior of the polypeptide chain but does not provide a deconvolution of the time scales of motion associated with the apparent relaxation behavior. However, the approach reliably predicts the sequence dependence of the relaxation rates in unbranched and disulfide bridge branched polypeptides based on a small number of parameters and is discussed in detail in Section 21.5.3.

21.3.5 Residual Dipolar Couplings

21.3.5.1 Conformational Dependence of Residual Dipolar Couplings

The measurement of residual dipolar couplings (RDCs), although early recognized as having potential [67], has only recently been reintroduced [68, 69] and is now routinely used as a means to obtain information on the orientation of bond vectors relative to an external alignment tensor, that is, NMR information on long-range orientation of individual bond vectors in a macromolecule. The introduction of residual dipolar couplings has considerably changed NMR structure determination

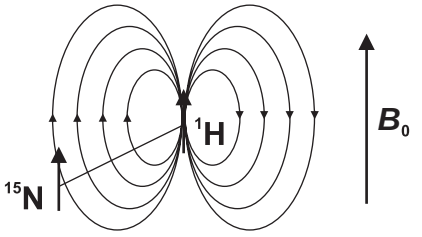

Fig. 21.15. A two-spin system of spin ^{1}H and ^{15}N connected by an internuclear vector r_{NH}. The ^{15}N nucleus exerts a dipolar field, which acts at the side of the ^{1}H nucleus. The magnetic moments of the nuclei are aligned parallel or antiparallel (not shown) relative to the static magnetic field B_o. The dipolar field of the ^{15}N nucleus can increase or decrease the static magnetic field active at the position of the ^{1}H nucleus depending on the orientation of the ***NH*** vector and the spin state of the proton (parallel or antiparallel to B_o).

for native proteins. A number of excellent review articles have been published [70–73]. Only recently have first measurements using RDCs in the case of nonnative states of proteins [74] been published.

In our description of the conformational dependence of RDCs, we follow a recent review article by Bax [73]: Dipolar couplings between NMR-active nuclei such as a spin N–H are caused by the magnetic dipole field exerted by the N nucleus at the site of nucleus H (Figure 21.14). In the following, we keep only the component of the magnetic dipole field that is parallel to the direction (the *z*-direction) of the magnetic field B_o. The dipole field exerted by the N nucleus will change the resonance frequency of the H nucleus. The dipolar coupling D^{NH} depends on the internuclear distance r_{NH} and on the orientation θ of the internuclear vector ***NH*** (bold, italics indicating the vector property) relative to B_o (Eq. (16)). For a fixed orientation of the vector, the dipolar field exerted by N can either increase or decrease the magnetic field of nucleus H, depending on whether the equally populated spin-states α and β of H are parallel or antiparallel relative to B_o.

$$D^{NH} = D^{NH}_{max}\langle(3\cos^2\theta - 1)/2\rangle \tag{16}$$

where θ is the angle between the internuclear vector ***NH*** and the magnetic field B_o, the angle brackets denote averaging over the ensemble of molecules, and

$$D^{NH}_{max} = -\mu_0(h/2\pi)\gamma_H\gamma_N/(4\pi^2 r^3_{NH}) \tag{17}$$

is the splitting observed for $\theta = 0$; the additional constants have the same meaning as explained for Eq. (14a–c).

In the case of isotropic rotational tumbling of a molecule in solution (Figure 21.16a), brownian motions average the magnetic dipole effects to zero, while in the solid state spectrum of a molecule, such dipolar couplings are not averaged and every nucleus couples with a large number of other nuclei, resulting in considerable line broadening.

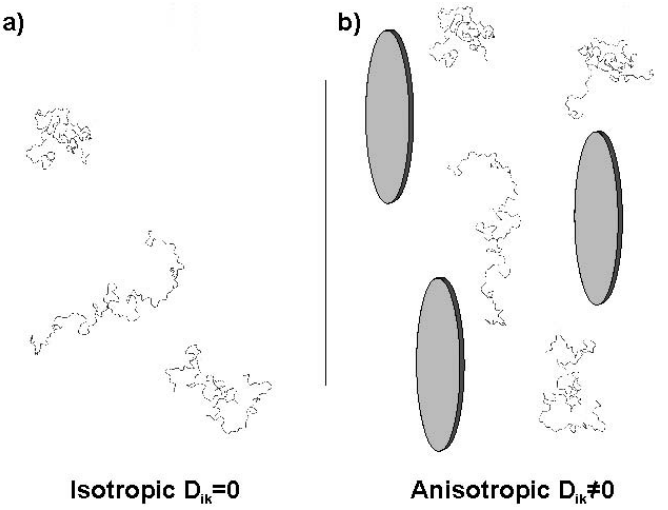

Fig. 21.16. a) Isotropic tumbling of a molecule leads to vanishing dipolar couplings. b) Introduction of non-isotropic medium leads to residual dipolar couplings (RDCs) in solution NMR. RDCs depend on the orientation of a given bond vector relative to an alignment tensor and provide information about the long-range order in high-resolution NMR studies.

However, there are now various methods that impart partial alignment to a dissolved molecule, Many of them are additives to the solution such as liquid crystalline media [75] and partial alignment is induced by steric and/or ionic interaction between the aligned medium and the dissolved macromolecule (Figure 21.16b). In the case of NMR investigations of nonnative states of proteins, the use of polyacrylamide gels that have been compressed in an anisotropic manner have been successful [76, 77].

Yet another different way of inducing alignment of a molecule is to use paramagnetic factors bound to the protein, either by using natural paramagnetic cofactors or metals [78, 79] or specifically designed binding sites for paramagnetic ions [80]. In contrast to external alignment media, alignment is not caused by intermolecular interactions but is rather a property of the molecule itself. This is advantageous in the case of nonnative states of proteins, since different interactions between the members of the ensemble of conformers representing these states and the aligning medium will lead to different extents of alignment for each member of the ensemble.

The aligning of the proteins has the effect that rotational tumbling is not isotropic, and not all orientations are equally likely to occur. The extent of difference in this tumbling can be expressed as an alignment tensor A. Its principal components A_{xx}, A_{yy}, and A_{zz} reflect the probabilities (along the x-, y-, and z-direction) for the diffusional motion relative to the external magnetic field B_o.

The dipolar coupling depends on the polar coordinates of the ***NH*** vector in the frame of the alignment tensor:

$$D^{NH}(\theta,\varphi) = 3/4 D^{NH}_{max}[(3\cos^2\theta - 1)A_{zz} + \sin^2\theta\cos 2\varphi(A_{xx} - A_{yy})] \quad (18)$$

Equation (18) can be rewritten as:

$$D^{NH}(\theta,\varphi) = D_a[(3\cos^2\theta - 1) + 3/2R\sin^2\theta\cos 2\varphi] \quad (19)$$

where $D_a = 3/4 D^{NH}_{max} A_{zz}$ is the magnitude of the dipolar coupling tensor and $R = 2/3(A_{xx} - A_{yy})/A_{zz}$ is the rhombicity.

In the context of the analysis of nonnative states based on residual dipolar couplings, it is of importance to discuss the ability to predict the dipolar couplings from a given conformation. In Eq. (19), the magnitude and rhombicity of the alignment tensor relative to the molecular frame need to be known. For a given conformation, this may be predicted on the basis of the molecular shape [81, 82]. However, best results have been obtained so far if the alignment mechanism is steric and due to the large number of members in the ensemble of structures, such approach is particularily difficult for nonnative states of proteins. A second approach is to obtain a tensor that fits the experimental data best in a linear fitting algorithm [83]. This approach, however, cannot be used to predict RDCs from theoretical models for the torsion angle distributions in nonnative states of proteins.

21.3.5.2 Interpretation of Residual Dipolar Couplings in the Presence of Conformational Averaging

Different NMR parameters are influenced by conformational averaging over different time scales. While relaxation data such as homonuclear NOEs or heteronuclear relaxation rates are sensitive to motions that are faster than the overall rotational correlation time, residual dipolar couplings are sensitive to motions on a considerable longer time scale. This observation has only recently be exploited to access the conformational dynamics of proteins in their native state using a combination of NMR experimental dipolar couplings measured in a number of different alignment media and predictions of dynamics from molecular dynamics calculations [84–86].

Louhivuori et al. [26] have calculated the effect of steric obstruction that an external alignment media can exert on a random coil polypeptide chain (i.e., a random flight chain). Such calculation consists of a model for the spatial distribution funcion for an ensemble of conformers and a treatment of the residual dipolar couplings.

The distribution of conformation of the Gaussian chain is different from the isotropic solution in that the aligning medium introduces a barrier to the free diffusion of the chain (Figure 21.17); the distribution function of the random flight chain in the presence of the aligning medium W^{obs} becomes obstructed and deviates from the distribution function W^{free} in isotropic solution. The effect of the aligning medium is also treated as a distribution function W^{bar}, yielding the equation:

$$W^{obs} = W^{free} - W^{bar} \quad (20)$$

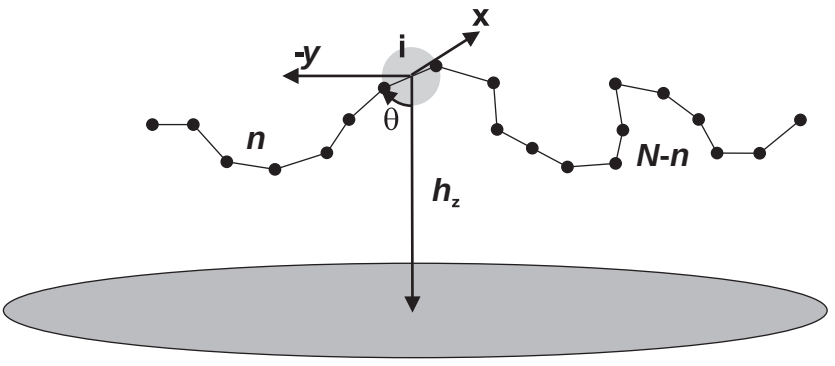

Fig. 21.17. Model for a random flight chain consisting of $N+1$ segment represented by dots and connected by straight lines. The chain tumble at distance h_z from a disk representing the aligning medium. At the locus i, placed at the origin of the molecular frame, the chain is partioned into two half chains containing n and $N-n$ segments. RDCs are functions of the average angle θ of i, the B_o field is parallel to the z-axis.

The random flight chain is composed of $N+1$ segments. For any given element of the chain i, there are n segments before i and $N-n$ segment after i. Therefore, the probability function contains two parts, W_n^{obs}, W_{N-n}^{obs}, and is given by:

$$\begin{aligned} W(z,h_z,c,n,N) &= \frac{1}{N}\{nW_n^{obs}(z,h_z,c,n)+(N-n)W_n^{obs}(z,h_z,c,N-n)\} \\ &= \frac{1}{N}\{n[W_n^{free}(z,c,n)-W_n^{bar}(z,h_z,c,n)] \\ &\quad +(N-n)[W_n^{free}(z,c,N-n)-W_n^{bar}(z,h_z,c,N-n)]\} \\ &= \frac{\sqrt{2n/\pi}}{N}\left\{\exp\left[-\frac{(2+1/2c)^2}{2n}\right]-\exp\left[-\frac{(2h_z-z+1/2c)^2}{2n}\right]\right\} \\ &\quad +\frac{\sqrt{2(N-n)/\pi}}{N}\left\{\exp\left[-\frac{(z-1/2c)^2}{2(N-n)}\right]\right. \\ &\quad \left.-\exp\left[-\frac{(2h_z-z-1/2c)^2}{2(N-n)}\right]\right\} \end{aligned} \tag{21}$$

where $c=\cos\theta$.

For any arbitrary pair of nuclei A and B in the segment i separated by the internuclear vector $\boldsymbol{r}_{AB}$, the vector $\boldsymbol{r}_{AB}$ will be at an angle α_{AB} with respect to the internal coordinate system of the seqment. The segment itself will be oriented at an angle θ with respect to the magnetic field B_o. The distribution W describing the averaging of the ith segment of the chain is a function of the position of each segment, each segment has its own averaged $\langle P_2\rangle$ polynomial. As a consequence, each segment

has its own alignment tensor A, which is axially symmetric due to the distribution functions for a random flight chain. The dipolar coupling D_{AB} is proportional to the axial component of the alignment tensor:

The average of $\cos^2 \theta$ contained in the expression of the dipolar coupling will be obtained by integration over all angles and space weighted by the distribution and normalized. The following observations can be made: For longer chains, $\langle P_2 \rangle$ will become smaller because the distributions of larger number of uncorrelated segments will become more spherical. Only polypeptide chains up to 100–200 residues will give rise to observable dipolar couplings. These observed residual dipolar couplings for a random flight chain are a consequence of the fact that such chain is restrained by the covalent structure of the chain, each segment is coupled and not free. The RDC originates from the individual loci along the chain, not from the whole chain average; each individual segment exhibits a nonvanishing $\langle P_2 \rangle$, it is time and ensemble averaged, but not averaged over all loci.

The treatment of residual dipolar couplings for random coil states of proteins is yet another example in which the prediction of what to expect for such state is of importance before deviations from random coil behavior can be interpreted with any vigor.

21.3.6 Diffusion

The dimensions of spherical proteins can be determined using diffusion NMR measurements since the hydrodynamic radius (R_h) of a protein is inversely proportional to its diffusion constant. Thus knowing the diffusion constant, R_h can be extracted using the Stokes-Einstein equation which requires the knowledge of the exact diffusion constant, temperature and viscosity of the solution. An easier approach for the determination of diffusion constants is by comparison to an internal probe with known hydrodynamic radius such as dioxane ($R_h = 2.12$ Å) [87]. Measurement of diffusion constants is usually done by PFG (pulse field gradient) NMR experiments performed with a PG-SLED (pulse gradient-simulated echo longitudinal encode-decode) sequence using bipolar gradient pulses for diffusion and varying the strength of the diffusion gradients between the experiments [88], the result of such experiments is shown in Figure 21.18: the signals decay with increasing strength of gradients, the decay rate is faster for the small molecule dioxane (b) than for the protein (a).

Empirical equations that relate the length of the polypeptide chain of isotropic native proteins to the hydrodynamic radius of a protein have been identified [87]. Thus, diffusion measurements are used to identify dimers or higher oligomers in native proteins (references 2, 3, 28 and 29 in Ref. [87]).

The situation is somewhat more complicated for nonnative proteins, since the ensemble of conformers in the denatured state can only be described as a distribution of polypeptides that have different hydrodynamic radii, each radius representing a group of conformations; this distribution cannot be determined experimentally, rather the average of the hydrodynamic radii present in a sample is observed.

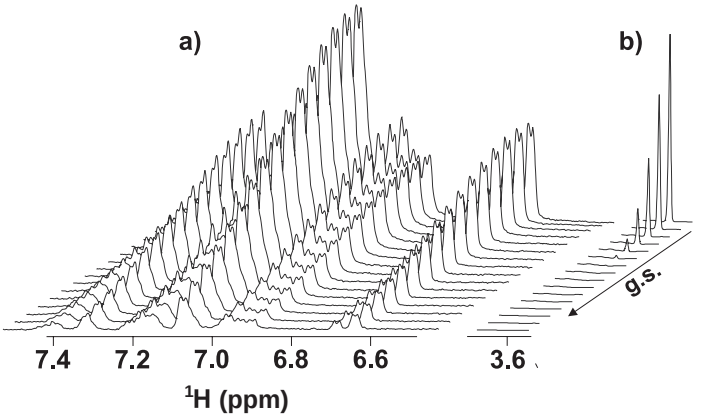

Fig. 21.18. Signal intensity in a ^{1}H 1D NMR spectrum as function of gradient strength (g.s.). a) lysozyme mutant W62G; b) dioxan.

Diffusion measurements have been used to identify urea unfolding of proteins (e.g., of lysozyme [89]) and to characterize different nonnative states of proteins such as BPTI [90] or α-lactalbumin [39]. The R_h of unfolded nondisulfide bridged proteins under highly denaturing conditions (high concentration of urea or GdmCl; extreme pH) can also be correlated to the length of the polypeptide chain [87].

21.3.7 Paramagnetic Spin Labels

Paramagnetic spin labels in proteins can be used to test long-range order or contacts. Spin labels such as nitroxide cause significant enhancement of relaxation rates of resonances that are within a distance of 15 Å away from the label [91, 92]. Spin labels can be attached to a number of residues containing reactive side chains such as Cys [93], His [91], or Lys [92]. Also the N-terminus of the protein can be used to attach a spin label [92]. Solvent-exposed residues especially in folded proteins have to be selected to prevent structure perturbations [94, 95], also paramagnetic metal ions such as Mn^{2+} or Gd^{3+} can be used if specific binding sites exist [96].

In folded proteins, distances can be extracted from the differential line broadening of the diamagnetic protein (reduction of the nitroxide with ascorbate to nitroxylamin) [94] to the paramagnetic protein [91, 92], whereas only a qualitative picture for nonnative states of proteins is gained, since they are composed of fluctuating conformations [97–99]. Using paramagnetic spin labels, long-range interactions were identified (e.g., in highly denatured myglobin) [99], in staphylococcal nuclease [97, 100], and in protein L [98]. Introduction of new binding sites for paramagnetic ions [80] and tagging those to nonnative states of proteins will allow detailed investigations using paramagnetic effects.

21.3.8
H/D Exchange

Hydrogen exchange methods can give insight into protein structure and dynamics by looking at the exchange of amide protons of the protein backbone with solvent protons. In general, protons that are involved in stable hydrogen bonds or are buried within the protein core are protected from exchange with the solvent. If either the buffer contains D_2O or the protein has been deuterated, the exchange of protons for deuterons or vice versa can be monitored by NMR. Hydrogen exchange techniques are valuable for the investigation of protein folding kinetics [101–104], folding intermediates, and unfolded states [105–107], since they can provide information on the degree and dynamics of secondary structure formation, which depends on the formation of stable hydrogen bonds. Hydrogen exchange is slow at low pH and faster at higher pH. In pulse labeling hydrogen exchange experiments [101], the process of folding or refolding could be investigated for some proteins. A typical approach of pulse-labeling hydrogen exchange is to let a deuterated protein initially refold for a short time (ms) (e.g., by diluting into D_2O refolding buffer) and give short pulses of protons at distinct times and high pH. This way, unprotected amide deuterons will exchange for protons and can be detected by 2D-NMR [108]. The reverse approach, namely refolding of nondeuterated protein in H_2O buffer and giving D_2O pulses, is also used [109–111]. The process of protein unfolding has been investigated in pulse-labeling hydrogen exchange NMR studies as well [112]. This topic is further described in Chapter 18.

21.3.9
Photo-CIDNP

Accessible aromatic side chains in proteins can be monitored using the photo-CIDNP (chemically induced dynamic nuclear polarization) NMR technique [113, 114]. The photo-CIDNP NMR technique relies on the temporary interaction of a photoexcited dye – mostly a flavin such as FMN (Figure 21.19) – with an aromatic amino acid side chain (Trp, Tyr, and His). Applying the photo-CIDNP technique to a protein results in signal enhancement as well as a better resolution in the aromatic region of the NMR spectrum (see Figure 21.19). Intensities of photo-CIDNP signals depend on (a) the polarization efficiency of a certain amino acid which is Trp $>$ Tyr $\gg$ His $\ggg$ Met and (b) the accessibility of the amino acid. Emissive photo-CIDNP signals are observed for Tyr residues, whereas the signals of Trp and His are absorptive – the sign of a signal therefore reports on the type of amino acid.

Using photo-CIDNP to achieve polarization enhancement is mostly seen in proton NMR spectroscopy – nevertheless higher enhancements are observed for ^{15}N nuclei [115]. One particular advantage of photo-CIDNP NMR for unfolded states is the better resolution due to the fact that only few residues are polarized. Using unlabeled protein, it is therefore often possible to assign peaks to the respective amino acid side chain and furthermore following changes in accessibility in differ-

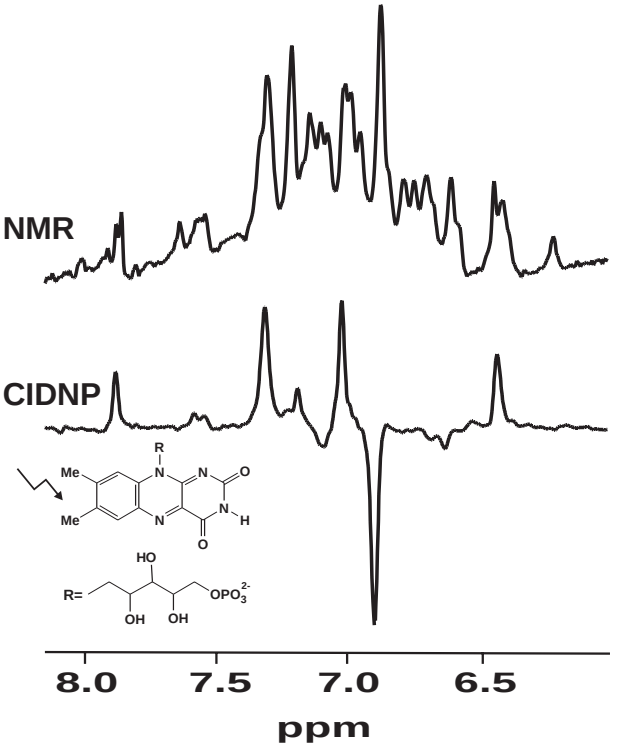

Fig. 21.19. 1D NMR and photo-CIDNP spectra of bovine α-lactalbumin. Photo-CIDNP is induced by irradiation of FMN (structure given at the lower left). Number of scans is 128 for the NMR spectrum and 1 for the CIDNP spectrum.

ent unfolded states [116]. Furthermore, photo-CIDNP NMR is being used in kinetic investigations of protein folding to monitor folding intermediates [117–119] – besides the better resolution since only few amino acids are polarized, better time resolution compared with normal NMR methods can be achieved due to the fact that the interscan delay depends only on the relaxation time of an electron (~10 ms). In addition, CIDNP experiment have been performed that transferred information on accessibilities in nonnative states of proteins onto the native protein using photo-CIDNP by polarizing the protein in the nonnative state, folding it rapidly, and observing polarized spins in the native state [120].

21.4
Model for the Random Coil State of a Protein

In a number of studies investigating nonnative states of lysozyme, α-lactalbumin, and ubiquitin, we have developed a model for the random coil state of a protein. The model assumes that the random coil state of a protein can be described using

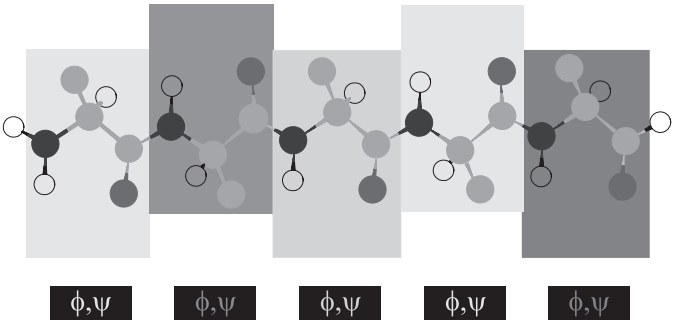

Fig. 21.20. The polypeptide chain consists of a chain of residues. Each residue has an intrinsic conformational preference even in the unfolded chain of protein. For a given distribution, NMR parameters such as *J* coupling constants and NOE can be predicted.

the notion that a polypeptide chain is a polymer consisting of 20 different amino acids. The conformational properties of the amino acids will depend on the nature of the side chain and therefore, amino acids exhibit distinct preferences in their sampling of conformational space described by the torsion angles ϕ, ψ (for the backbone conformation, depicted in Ramachandran plots) and correlated side-chain angles χ_n. Based on a conformational model for the distribution of torsion angle space, NMR parameters such as *J* coupling constants and, using some assumptions, NOEs can be predicted. G. Rose et al. further discuss the conformational properties of unfolded proteins in chapter 20.

Figure 21.21 shows the experimental ${}^3J(H^N H_\alpha)$ coupling constants in reduced and methylated lysozyme recorded in 8 M urea, pH 2. The measured coupling constants all fall in between the values predicted for either α-helical or β-strand secondary structure elements. However, the spread in the mesured values and the uneven distribution also calls for an interpretation of the data. Three models that do not invoke a residue-specific ϕ, ψ distribution could be envisioned to interpret the data: Model I would predict all ϕ-values $(-180^\circ < \phi < 180^\circ)$ to be equally likely, the averaged coupling constants would thus be predicted to be 5.3 Hz. Model II assumes an symmetric average between two conformations, namely 50% α-helical, 50% β-strand conformation. Model III assumes a distribution of ϕ-values as derived from the Ramachandran distribution found in all structure of proteins when averaged over all residues. Neither of the three models predicts the observed coupling constants well, especially the spread in couplings calls for a more detailed model including amino acid-specific sampling of the conformational space.

According to this random coil model, the random coil state of a polypeptide chain is presumed to be one in which there are no specific nonlocal interactions between residues [24, 25, 45, 121]. In such a state, individual residues will, however, have local conformational preferences and will sample the low energy ϕ, ψ conformations in the Ramachandran space. In the model, the ϕ, ψ populations for

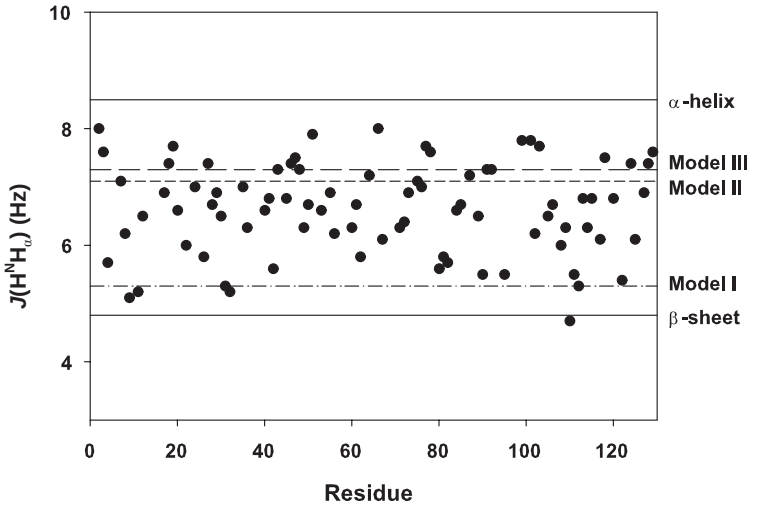

Fig. 21.21. $^3J(H^NH_\alpha)$ coupling constants in unfolded lysozyme (8 M urea, pH 2). Coupling constants expected for an α-helical and a β-sheet conformation are indicated as black lines. Models I–III indicate different averaging models that could be present in a random coil. Model I: all ϕ angles are equally likely (dashed-dotted line); model II: 50% α and 50% β-sheet conformation are populated (small dashed line); model III: populations are equally to the Ramachandran distribution (large dashed line).

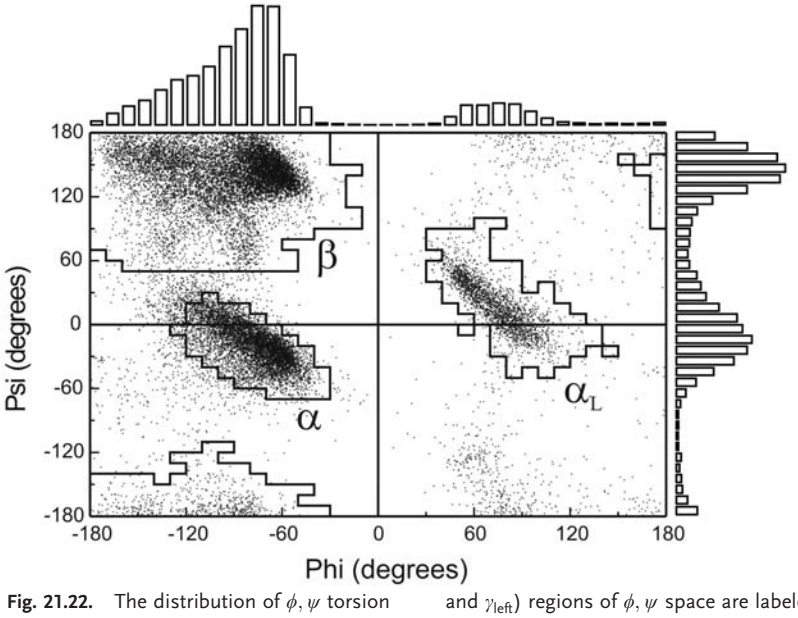

Fig. 21.22. The distribution of ϕ, ψ torsion angles for all amino acids not located in secondary structure elements in a database of 402 high-resolution crystal structures of native folded proteins. The α, β and α_L (combined α_{left} and γ_{left}) regions of ϕ, ψ space are labeled. Similar diagrams can be obtained with sufficient statistic for each amino acid individually.

residues in a random coil are derived from coil regions of 402 proteins from the protein data bank (Figure 21.22). It has been found that the distribution of ϕ, ψ torsion angles in the protein data bank resembles the experimental ϕ, ψ energy surface [24, 45, 122, 123], the effects of specific nonlocal interactions present in individual proteins are thus averaged out over the set of structures.

The amino acid-specific distribution obtained for each amino acid can also be used to calculate residue specific J coupling constants and also to calculate NOE intensities using a Monte-Carlo procedure and a simplified pentapeptide model. The pentapeptide model consists of explicit treatment of the backbone angles ϕ and ψ and a simplistic treatment of the side chains as a pseudoatom. Distributions of interproton distances can then be extracted from the conformational ensembles, and NOE intensities calculated assuming a two-spin approximation and r^{-6} averaging. Predicted values of NOE intensities converged with ensemble sizes of 10^5 conformers.

A different approach is chosen for the interpretation of dynamics in unfolded proteins. Backbone dynamics in proteins can be monitored by ^{15}N amide heteronuclear relaxation measurements. These heteronuclear relaxation measurements are sensitive to motions on a subnanosecond time scale and to slow conformational exchange in the millisecond time scale. Heteronuclear relaxation data unfolded proteins without disulfide bridges show only small variations over the sequence: Values approach a plateau at the middle of the protein while lower values are found at the termini of the sequence (Figure 21.23). This implies that the relaxation properties of a given amide are not influenced by its neighbor, but just by the fact that its part of the polypeptide chain. This relaxation behavior has been found for a number of unfolded proteins [21, 124] and in synthetic polymers [125] (see also Figure 21.35 for random coil state of ubiquitin). It was shown for atactic polystyrene that plateau values of R_1 relaxation rates remain constant for homopolymers between 10 kDa and 860 kDa. Individual segments of the long polymer chain therefore move independently in solutions – the apparent correlation time is therefore largely independent of the overall tumbling rate and only affected by segmental motions.

21.5
Nonnative States of Proteins: Examples from Lysozyme, α-Lactalbumin, and Ubiquitin

After the overview of NMR parameters that can measure aspects of conformation and dynamics of nonnative states of proteins, we wish to show the measurement of these NMR parameters primarily for one particular protein, lysozyme. Many of the experiments have been done together with Chris Dobson and former members of his group.

The native state of lysozyme consists of two domains, the α-domain, which spans from residue 1 to 35 and 85 to 129 and the β-domain that involves residues 36–84. Four disulfides bridges are present in the native structure; two of them in the α-domain of the protein, holding the N- and the C-termini together (C6–C127, C30–C115) one in the β-domain (C64–C80) and one between the domains (C76–C94).

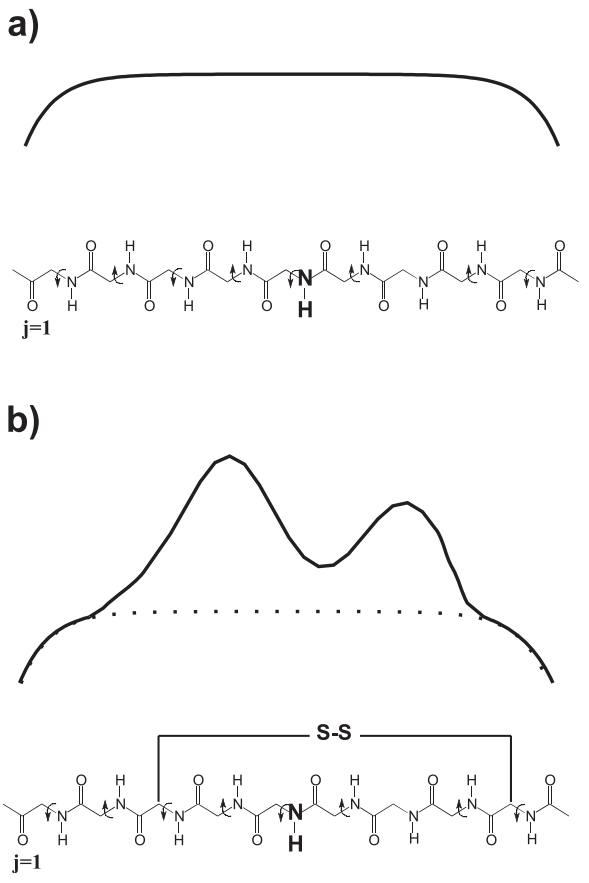

Fig. 21.23. Relaxation dynamics model for the random coil state. The relaxation properties of a given residue is influenced by the number of neighboring residues along the chain. For the interpretation of relaxation rates, one has to distinguish a) the unbranch polymer chain and b) the branched polymer chain, in which disulfide bridges cause additional cross-linking of the polypeptide chain and lead to increased relaxation rates.

Lysozyme has been studied under a range of denaturing conditions by NMR techniques [25, 42, 107, 126–129, 183, 253].

21.5.1 Backbone Conformation

21.5.1.1 Interpretation of Chemical Shifts

The measurement of chemical shifts is the most commonly used method to identify secondary structure in nonnative states of proteins. The most easily available chemical shifts are H^N, H^α, and ^{15}N amide chemical shifts as side products of the assignment of the protein backbone using ^{15}N-labeled protein. In addition, ^{13}C chemical shift assignment can be obtained and the interpretation of the data are

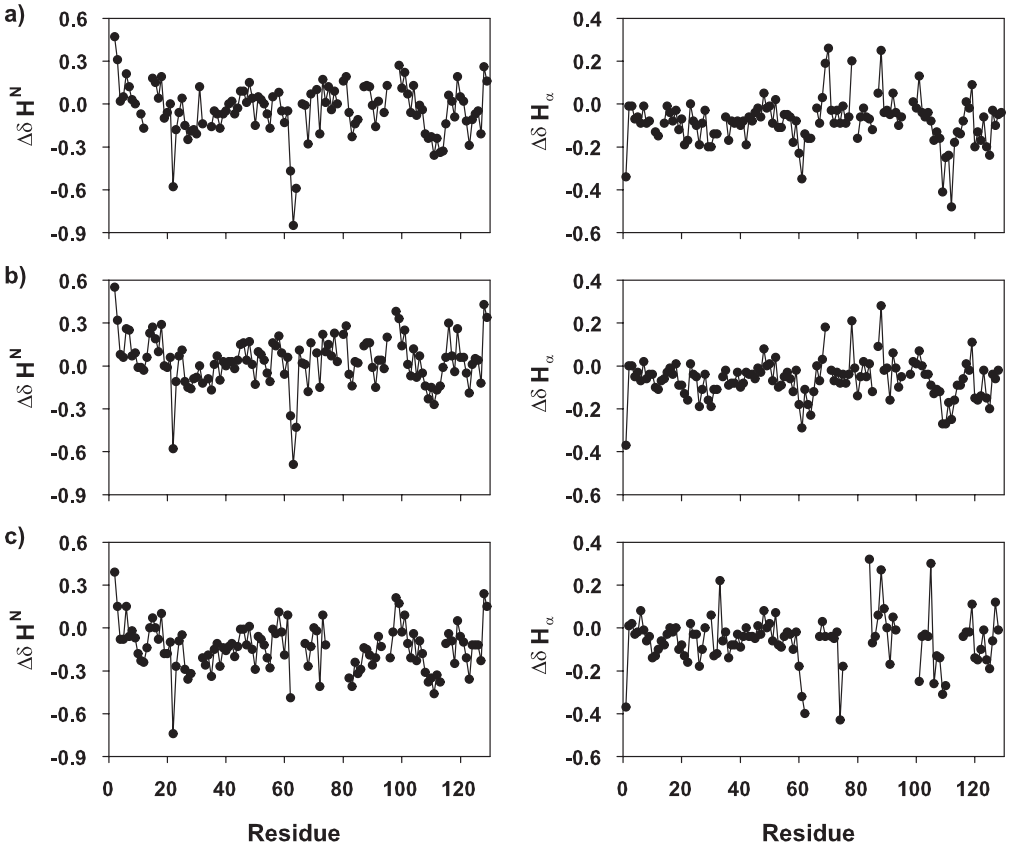

Fig. 21.24. Residual secondary structure in lysozyme as indicated by H^N and H_α chemical shifts pertubations ($\Delta\delta = \delta^{exp} - \delta^{rc}$) from random coil chemical shifts. a) Reduced and methylated hen lysozyme in water, pH 2, b) reduced and methylated hen lysozyme in 8 M urea, pH 2, and c) oxidized hen lysozyme in 8 M urea, pH 2.

shown in Figure 21.25. In the following section, it will be shown how these chemical shifts of random coil proteins can be used to (a) identify residual secondary structure (H^N and H^α) and to (b) investigate mean residue-specific properties of chemical shifts in unfolded states of proteins (^{15}N chemical shift).

H^N and H^α chemical shift perturbations ($\Delta\delta$) in unfolded variants of hen lysozyme from chemical shifts measured in short unstructured peptides are shown in Figure 21.24. The mean chemical shift pertubations are very close to the values measured in small unstructured peptides for all three variants. Figure 21.24a shows perturbations in a lysozyme variant in which all disulfide bridges have been reduced and subsequently methylated. This variant is unfolded at pH 2 in the presence and even in the absence of the denaturant urea. Large downfield deviations are found for Gly22 (H^N), for Val29 and Cys-S^{ME}30 (both H^α) around Trp62/Trp63 (R61 H^α; W62, W63 and C64 H^N), around Trp108/Trp111 (V109, R112 H^α; W111, N113, R114 H^N), and Trp123 indicating residual secondary struc-

ture. All these pertubations are found in aromatic patches of the protein, indicating that aromatic amino acids cluster and hereby form secondary structure elements, presumably to prevent contact with water. The cluster around Gly22 consists of the sequence Tyr-X-Gly-Tyr (where X can be any amino acid) and is also found to form a nonrandom cluster in BPTI [130–132]. Comparison of these chemical shift deviations to deviations of unfolded hen lysozyme in 8 M urea (oxidized and reduced) reveal that the formation of residual secundary structure around aromatic residues is a feature of the protein even detectable in 8 M urea.

Single point mutations of residues involved in patches of residual secondary structure in the unfolded state (A9G, W62G, W62Y, W111G, and W123G) do not change the pattern of chemical shift perturbations observed in methylated protein in water at pH 2 (see Figure 21.26) [253].

For an assessment of residue-specific properties of chemical shifts in random coil states of proteins, a data set of three proteins in 8 M urea at pH 2 was compared: human ubiquitin, reduced and methylated hen egg lysozyme and all-Ala α-lactalbumin [138]. As mentioned in Section 21.2, chemical shift dispersion in nonnative states of proteins is considerably smaller than in folded states of proteins, amide ^{15}N chemical shifts, however, display significant chemical shift dispersion and therefore have been analyzed as discussed below. Aromatic amino acids, cysteine, and methionine residues were excluded from the investigations because of the lack of experimental data and due to the fact that aromatic residues have been found to be involved in nonrandom structures in at least one of the three proteins.

Mean observed chemical shifts in native proteins of the BMRB (as of February 1999) are very close to the mean experimental ^{15}N chemical shifts in the three unfolded proteins ($R = 0.98$, see Figure 21.27). However, the spread of chemical shifts in the native state is very large, while there are only small variations in chemical shifts of the unfolded proteins.

21.5.1.2 Interpretation of NOEs

In contrast to the situation in the folded state of a protein, distances that can be observed by NOE measurements in nonnative states of proteins reflect an average of conformations with various distributions of ϕ, ψ, and χ_1 angles. Using the protein database (PDB), ϕ, ψ distributions of all amino acids can be generated. These distributions can be used as a model for a random coil in which no nonlocal interactions are present due to the fact that specific nonlocal interactions that are present in the individual proteins are averaged out over the ensemble of conformers contributing to the spectroscopic properties of the protein (see Section 21.4). Using this data set, interproton distance distributions can be extracted for the nonnative state of a protein. Table 21.6 shows statistics of interproton distance distributions. Effective interproton distances in the random coil state are given as $\langle r^{-6} \rangle^{-1/6}$ using the ϕ, ψ distributions of all proteins in the PDB.

Two features of the random coil state compared to the folded state of a protein are noticeable: (1) In contrast to the folded state of a protein, the distances αN $(i, i+1)$ and NN $(i, i+1)$ are short in every case, which reflects the averaged population of β and α conformations at the same time. (2) The effective αN $(i, i+2)$ dis-

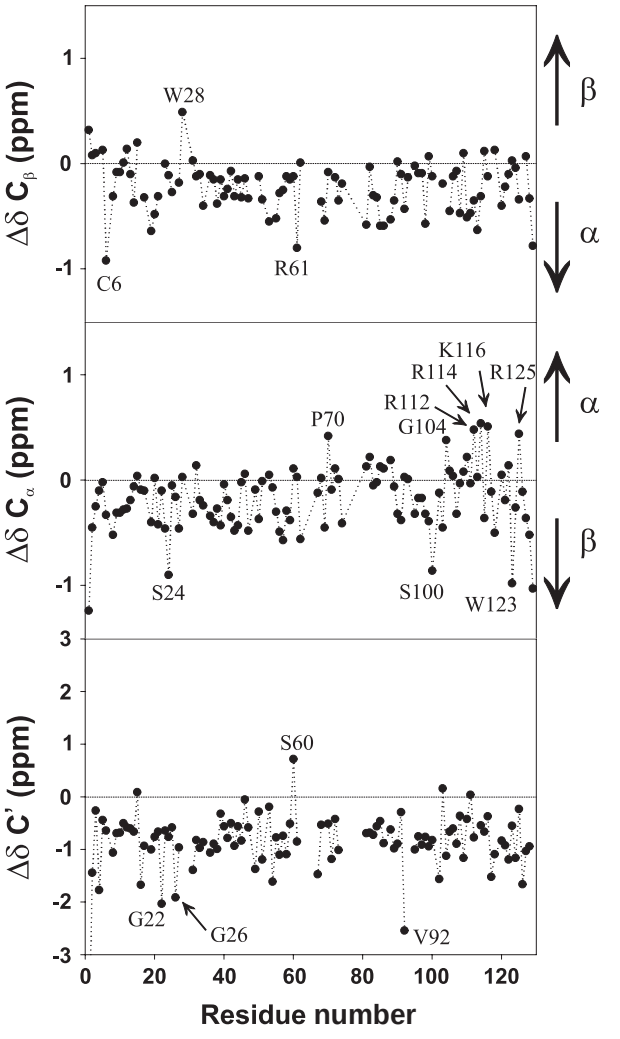

Fig. 21.25. Differences in $^{13}C'$, $^{13}C_\alpha$ and $^{13}C_\beta$ chemical shifts for lysozyme with its four disulfides intact denatured in 8 M urea from empirical values measured in short unstructured peptides ([37] $\Delta\delta = \delta^{exp} - \delta^{emp}$). ^{13}C chemical shifts in the present work are referenced indirectly to the internal standard TSP at pH 2 at 20 °C in 8 M urea. Mean secondary ^{13}C chemical shifts are (with standard deviations given in parentheses): $\langle\Delta\delta C_\alpha\rangle = -0.2$ (0.3) ppm, $\langle\Delta\delta C_\beta\rangle = -0.2$ (0.2) ppm, $\langle\Delta\delta C'\rangle = -0.9$ (0.6) ppm. Residues with $\Delta\delta \geq 0.38$ ppm, $\Delta\delta C_{\alpha,\beta} \leq -0.8$ ppm, and $\Delta\delta C' \leq -1.9$ ppm are labeled by one-letter amino acid code and residue number excluding terminal residues. Appropriate corrections for random coil shifts of Thr69 preceded by Pro70 were employed. Secondary chemical shifts for glutamate and aspartate residues have been omitted as the chemical shifts are affected by the protonation of the amino acid side chains at the low pH value of 2 used in this study. This is reflected by significant average deviations from random coil values for Asp, $\langle\Delta\delta C_\alpha\rangle = -1.6$ ppm, $\langle\Delta\delta C_\beta\rangle = -3.3$ ppm, $\langle\Delta\delta C'\rangle = -1.7$ ppm, and Glu, $\langle\Delta\delta C_\alpha\rangle = -1.3$ ppm, $\langle\Delta\delta C_\beta\rangle = -1.0$ ppm, $\langle\Delta\delta C'\rangle = -1.6$ ppm.

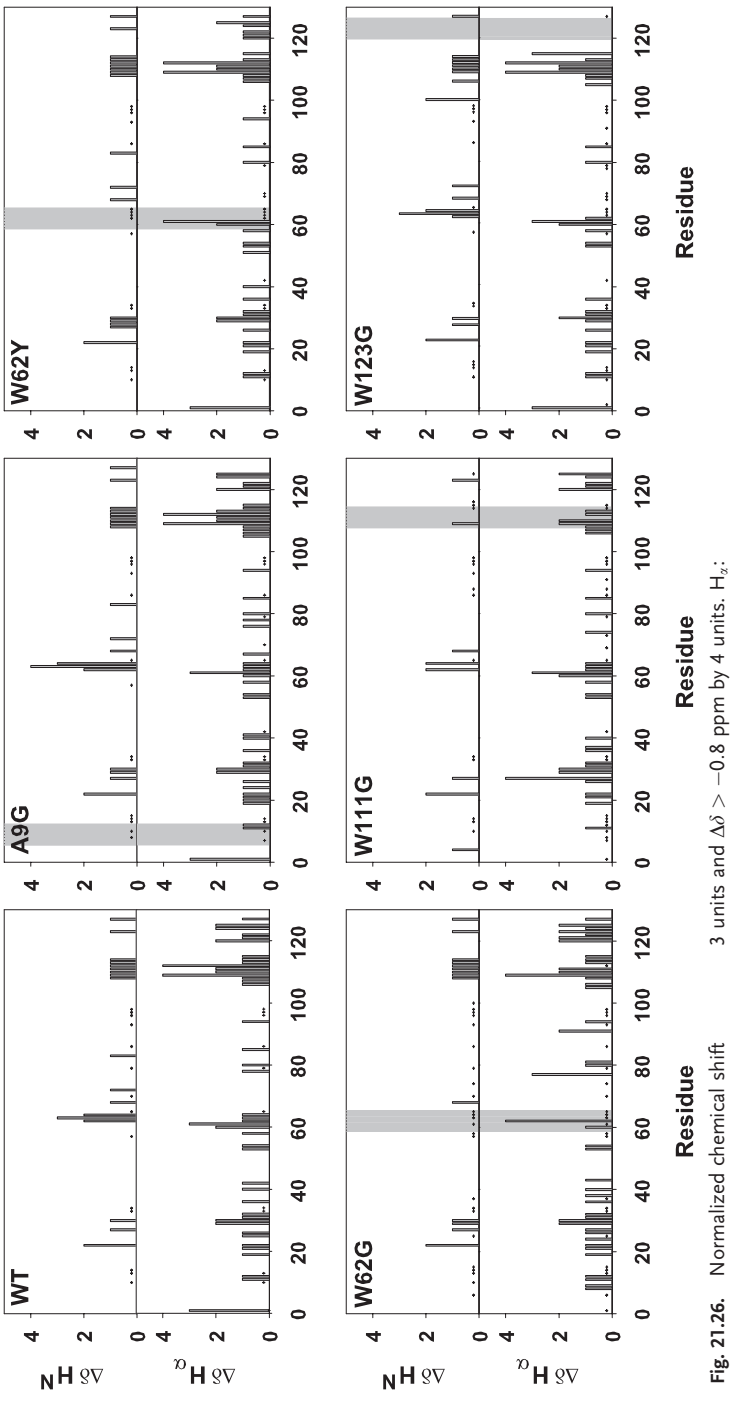

Fig. 21.26. Normalized chemical shift perturbations in methylated lysozyme single point mutants: A9G, W62G, W62Y, W111G and W123G. The following normalization scheme was applied: H^N: $\Delta\delta > -0.2$ ppm by 1 unit, $\Delta\delta > -0.4$ ppm by 2 units, $\Delta\delta > -0.6$ ppm by 3 units and $\Delta\delta > -0.8$ ppm by 4 units. H_α: $\Delta\delta > -0.1$ ppm by 1 unit, $\Delta\delta > -0.2$ ppm by 2 units, $\Delta\delta > -0.3$ ppm by 3 units, and $\Delta\delta > -0.4$ ppm by 4 units. Dots indicate missing assignments.

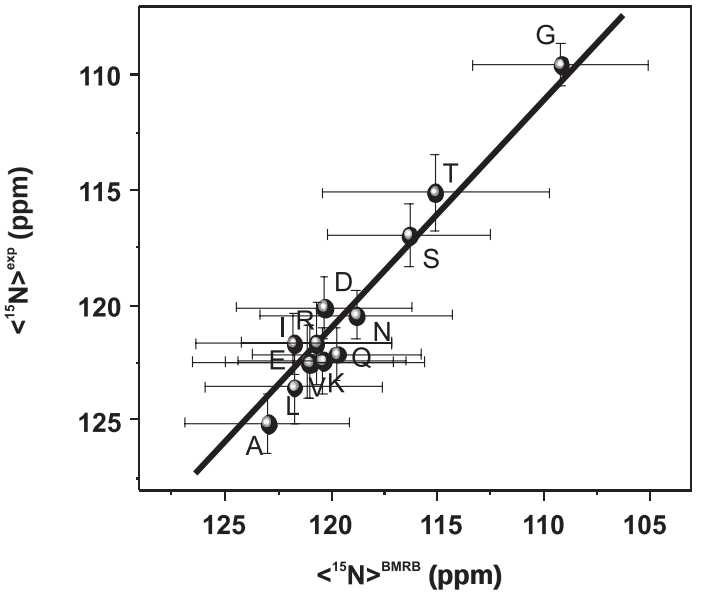

Fig. 21.27. Comparison of experimental ^{15}N chemical shifts in unfolded ubiquitin, hen lysozyme and all-Ala lactalbumin with chemical shifts in native proteins deposited in the databank for biomolecular NMR data (BMRB) (as of February 1999).

tance of 4.2 Å in the random coil state is shorter than in either of the secondary structure types. αN $(i, i+1)$, NN $(i, i+1)$, and αN $(i, i+2)$ as well as NN $(i, i+2)$, αN $(i, i+3)$, and NN $(i, i+3)$ distances have been predicted for hen lysozyme taking into account the amino acid sequence of hen lysozyme and using residue-specific ϕ, ψ distributions extracted from the PDB. The actual observability of NOE cross-peaks in the NOESY-HSQC of hen lysozyme (ox + red) in 8 M urea at pH 2 is dependent on the signal-to-noise ratio in the experiment and the effective correlation time of the protein, which could vary along the protein sequence (for the good signal-to-noise obtainable in the spectra of hen lysozyme, see Figure 21.28) [25].

Tab. 21.6. Comparison of the effective interproton distances in the ensemble of random coil conformers with interproton distances in regions of regular secondary structure. Effective interproton distances $\langle r-6\rangle^{-1/6}$ are given for an ensemble of random coil conformers generated using the ϕ, ψ torsion angle populations of all residues in the protein database.

Distance	*Random coil (Å)*	*α-helix (Å)*	*β-strand (Å)*
αN $(i, i+1)$	2.5	3.5	2.2
NN $(i, i+1)$	2.7	2.8	4.3
αN $(i, i+2)$	4.2	4.4	6.1
NN $(i, i+2)$	4.6	4.2	6.9

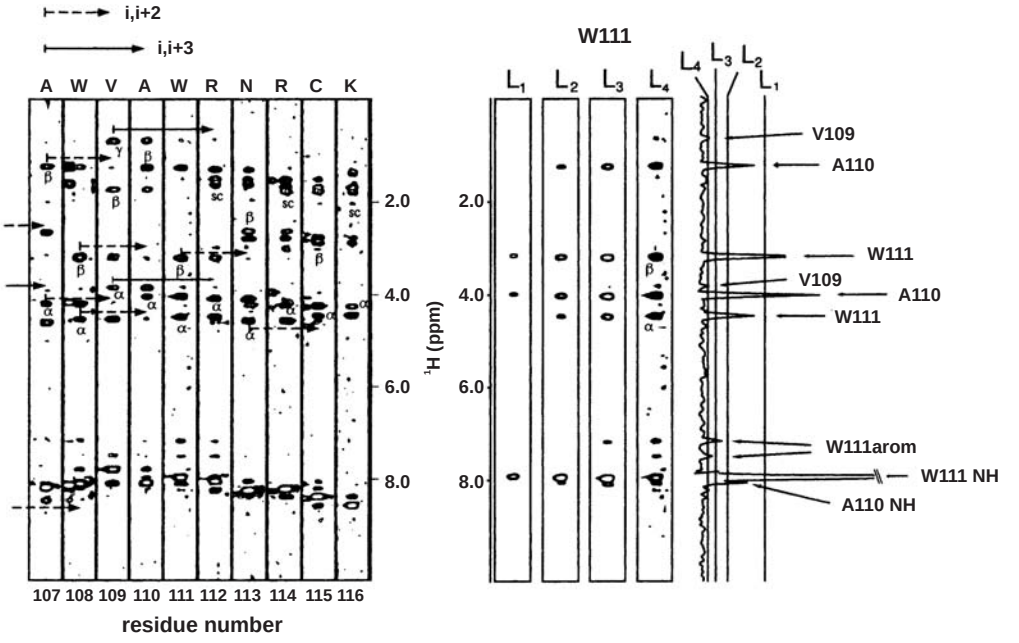

Fig. 21.28. Left: ^{1}H,^{1}H strips of residues 107–116 from a 3D NOESY spectrum of reduced and denatured lysozyme in 8 M urea at pH 2 (mixing time = 200 ms). Arrows indicated $(i, i+2)$ and $(i, i+3)$ cross-peaks as indicated. Right: ^{1}H,^{1}H strip of Trp111 is plotted at four different contour levels (= signal-to-noise levels), and 1D trace of Trp111. The different noise levels are indicated at the 1D trace, cross-peaks and the diagonal peak (Trp111 NH) are indicated.

The overall agreement between the predicted and experimental data from NOESY-HSQC spectra is remarkably good (Figure 21.29). αN $(i, i+1)$ and NN $(i, i+1)$ NOEs are predicted and observed throughout the protein sequence, furthermore 56 out of 82 predicted αN $(i, i+2)$ NOEs are seen while two of the αN $(i, i+2)$ NOEs are observed but not predicted. No correlation is observed between predicted and observed NN $(i, i+2)$ NOEs; while only 11 of the 27 predicted NN $(i, i+2)$ NOEs are observed, 10 NN $(i, i+2)$ cross-peaks are observed that are not predicted. A similarly poor correlation is observed for αN $(i, i+3)$ cross-peaks: two out of eight predicted NOEs are observed and seven NOEs are observed but not predicted. However, it is worth noting, that both the αN $(i, i+3)$ and the NN $(i, i+2)$ crosspeaks are predicted to be weak, and that the observability therefore depends very strongly on the signal-to-noise of the spectrum, which can vary locally. In summary, the considerable amount of predicted and observed NOEs in unfolded hen lysozyme, in particular αN $(i, i+1)$, NN $(i, i+1)$, and αN $(i, i+2)$ NOEs indicate that the averaged backbone conformation predicted from all proteins in the PDB describes the local preferences in lysozyme very well. It is important to note that this presence of NOEs is not a sign of persistent nonrandom structure

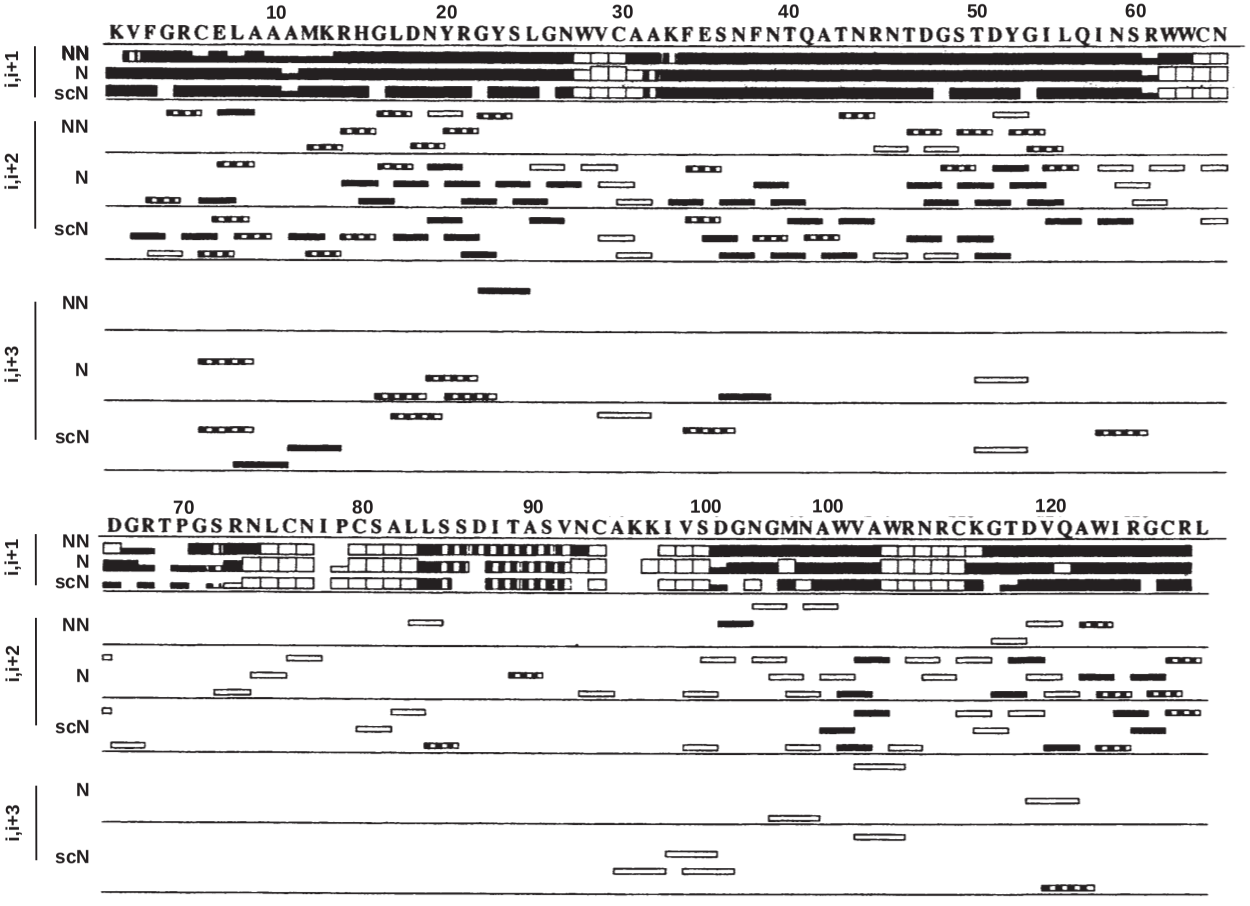

Fig. 21.29. Observed short- and medium-range NOEs in oxidized and reduced lysozyme (8 M urea, pH 2) from 3D NOESY-HSQC spectra (mixing time = 200 ms). Black bars are indicative for NOEs that are present in both states, whereas open bars indicated NOEs observed in the reduced state and dashed bars in the oxidized state only. NOEs to any side chain are summarized as scN NOEs.

in the unfolded state, but arises from statistical averaging of possible conformations in a random coil. This average is dominated by the shorter distances since the NOE is averaged as $\langle r^{-6} \rangle^{-1/6}$.

21.5.1.3 Interpretation of *J* Coupling Constants

A number of ^3J coupling constants (see Table 21.3) report on the torsion angle ϕ. $^3J(H^NH_\alpha)$, $^3J(C'C_\beta)$ and $^3J(C'C')$ have been measured in unfolded lysozyme (oxidized) in 8 M urea, pH 2 [183]. Moreover $^3J(H^NH_\alpha)$ coupling constants in unfolded ubiquitin and all-Ala lactalbumin (both in 8 M urea, pH 2) are available, to allow residue-specific analysis [138]. The experimental $^3J(H^NH_\alpha)$ coupling constants for all three proteins vary substantially along the protein sequence (see Figure 21.21 for reduced and methylated lysozyme in 8 M urea, pH 2, data for other proteins not shown), the values for a given amino acide type, however, typically cluster in small ranges. Figure 21.30 shows a comparison of experimental $^3J(H^NH_\alpha)$ coupling constants of the three proteins and predictions of $^3J(H^NH_\alpha)$ coupling constants using ϕ, ψ distributions from "coil" regions of 402 protein crystal structures and applying the Karplus parameterization shown in Table 21.3.

A fairly good correlation ($R = 0.85$) is observed for a complete data set including aromatic residues (not shown in Figure 21.30). The correlation improves if Glu and Asp residues that are protonated at pH 2 are excluded ($R = 0.89$). The best correlation, however, is observed if aromatics are left out as well ($R = 0.95$). Deviations of the coupling constants from mean values are similar for the predicted

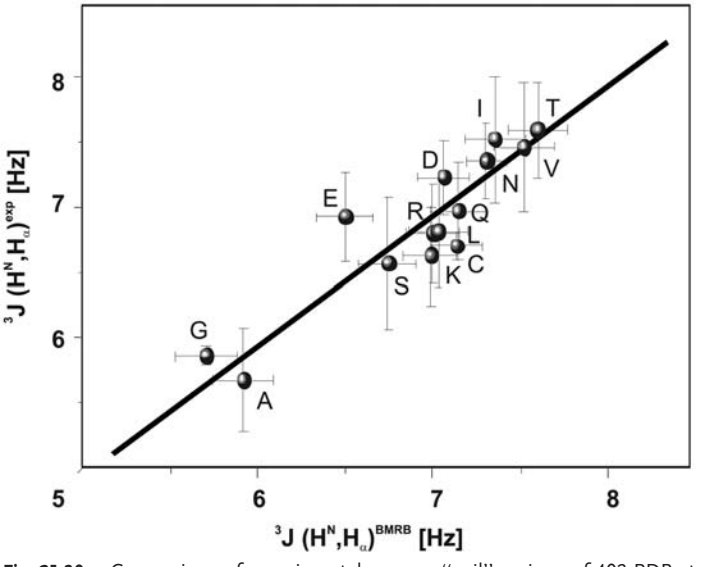

Fig. 21.30. Comparison of experimental $^3J(H^NH_\alpha)$ of unfolded ubiquitin, all-Ala α-lactalbumin, and lysozyme $^3J(H^NH_\alpha)^{exp}$ with $^3J(H^NH_\alpha)$ coupling constants predicted from "coil" regions of 402 PDB structures ($^3J(H^NH_\alpha)^{BMRB}$). Methionine, cysteine, and aromatic residues are left out due to the small amount of available data.

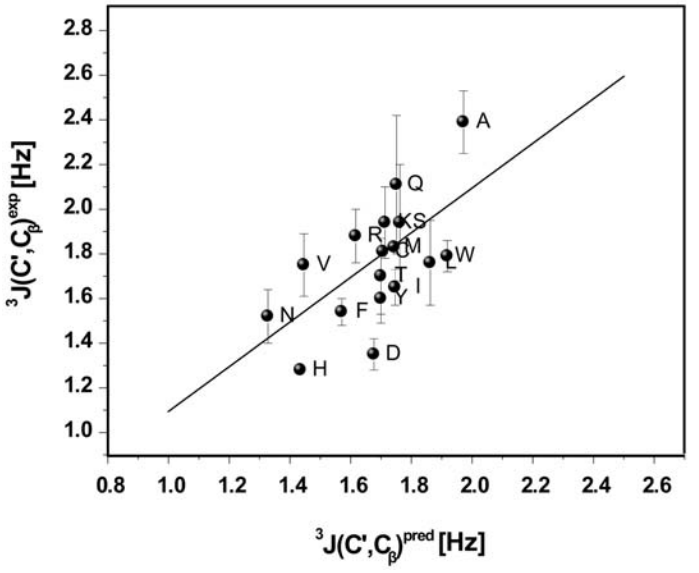

Fig. 21.31. Experimental versus predicted $^3J(C'C\beta)$ coupling constants using the coil model.

and the experimental coupling constants, reflecting the quality of the model used for the predictions. Investigations of the individual data sets (–Glu, –Asp and –aromatics) give rise to similar correlation coefficients ($R = 0.96$ for ubiquitin; $R = 0.94$ for lysozyme and $R = 0.90$ for all-Ala α-lactalbumin). These results indicate the independence of both the primary sequence and the native structure of the protein ubiquitin is composed of mainly β-sheets, while lysozyme and α-lactalbumin contain a significant number of α-helices in the native state.

The variation of $^3J(C'C_\beta)$ and $^3J(C'C')$ coupling constants is smaller than the variation in $^3J(H^NH_\alpha)$ coupling constants (Figure 21.31). The smallest variations are found in the $^3J(C'C')$ values, which range from 0.5 to 1 Hz. Nevertheless clustering of the experimental values is observable: values for eight Gly residues range from 0.5 to 0.7 Hz. A more detailed analysis of residue-specific properties of $^3J(C'C')$ coupling constants is not appropriate due to the small range of measured coupling constants.

Values of $^3J(C'C_\beta)$ in unfolded oxidized lysozyme range from 1.3 to 2.6 Hz. As observed for the $^3J(H^NH_\alpha)$ coupling constants, large variations along the sequence are found. These variations again cluster for different residue types. However a different trend is seen to that for the $^3J(H^NH_\alpha)$ coupling constants: the largest $^3J(C'C')$ are found for alanine residues, which have a high probability of being found in a conformation in the ϕ, ψ Ramachandran space, while the smaller values are found for residues with larger side chains such as histidine, asparagine, and valine residues. Figure 21.31 shows a correlation of experimental coupling constants with predicted coupling constants (Hz) from the coil theory. A correlation coefficient of $R = 0.63$ is observed for the complete data set (axis intercept = 0.07,

slope = 1), $R = 0.69$ (axis intercept = 0.0949, slope = 1) if Asp and Glu residues (that are protonated at pH 2 but not in the data sets used for the predictions) are left out.

The discussion thus far has focused on the determination of coupling constants that report on the backbone angle ϕ. Figure 21.32 shows a comparison of the prediction of $^3J(N^H,H_\alpha)$ coupling constants taking (a) all residues into account or (b)

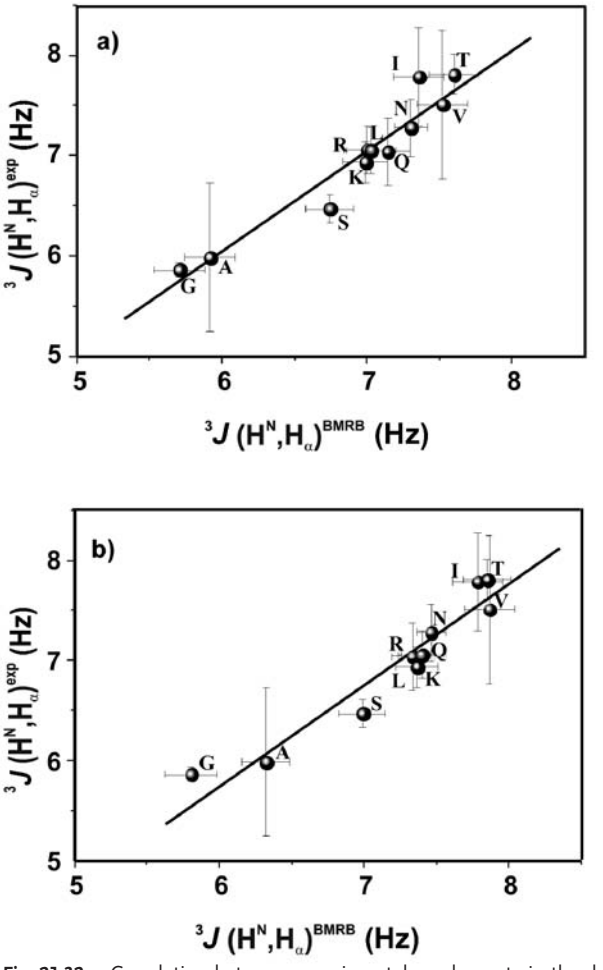

Fig. 21.32. Correlation between experimental $^3J(H^N,H_\alpha)$ averaged for a given residue type, e.g., all alanines in ubiquitin denatured in 8 M urea, pH 2, and $^3J(H^N,H_\alpha)$ coupling constants predicted for amino acids excluding aromatic amino acids and Asp and Glu residues. a) Comparison with predictions for residues that are not located in secondary structure elements in the database of native folded protein structures with ϕ, ψ torsion angles covering all regions of the Ramachandran diagram. b) Comparison with predictions for residues that are not located in secondary structure elements and that have positive ψ torsion angles only.

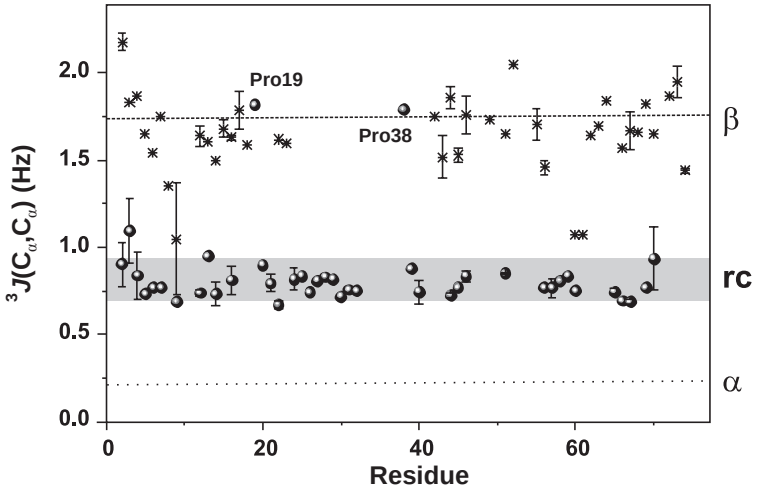

Fig. 21.33. $^3J(C_\alpha,C_\alpha)$ coupling constants in unfolded (dots) and folded (crosses) ubiquitin. Dashed line indicates expected coupling constants in a β-sheet, shaded area indicates expected values in a random coil (rc), and dotted line indicates values of coupling constants in the α-conformation.

only residues with positive ψ angle into account (compare Figure 21.22). A similar correlation ($R = 0.96$ in both cases) is observed showing that $^3J(N^H,H_\alpha)$ coupling constants cannot differentiate between a situation in which only extended conformations are being sampled (positive ψ values) and a situation in which the polypeptide chain samples both α- and β-regions of the Ramachandran space. The presence of experimental NOE contacts H^N_i, H^N_{i+1} and of $H_{\alpha i}$, H^N_{i+1} of similar intensity in nonnative states of proteins indicate that averaging involves sampling of positive and negative ψ torsion angles, which is compatible with predictions of our model. However, a quantitative analysis of populated rotamers from NOE intensities is difficult due to the r^{-6} averaging and complex dynamical properties that are potentially nonuniform along the denatured peptide chain.

$^3J(C_\alpha,C_\alpha)$ coupling constants can probe the conformation around the backbone angle ψ directly and are shown in Figure 21.33 for the random coil state and for the native state of ubiquitin [254]. The dependence of $^3J(C_\alpha,C_\alpha)$ on the angle ψ is unexpected and in contradiction to a simple Karplus-type dependence on the intervening torsion angle ω but was found for data obtained for native ubiquitin. The mean experimental coupling constants $^3J(C_\alpha,C_\alpha)$ for residues in β-sheet regions of native ubiquitin are 1.69 ± 0.1 Hz while coupling constants are too small to be observed in α-helical regions. In the random coil state of ubiquitin, $^3J(C_\alpha,C_\alpha)$ are larger than 0.7 Hz throughout the sequence, including residues 23–34 that are located in the α-helical region in the native state. The mean $^3J(C_\alpha,C_\alpha)$ coupling constant is 0.85 ± 0.2 Hz with a pairwise rmsd of 0.1 Hz for the 41 resonances that are sufficiently resolved to allow coupling constants to be determined. As an exception,

large $^3J(C_\alpha,C_\alpha)$ values are observed for Pro19 and Pro38. This might reflect a strong preference of prolines for ϕ,ψ torsion angles in the polyprolyl region of ϕ,ψ space ($\phi \sim -60°, \psi \sim +150°$) and potentially restricted ψ sampling.

The correlations found here confirm the previous conclusion based on the $^3J(H^N,H_\alpha)$ coupling constants, that the main-chain torsion angle populations in denatured lysozyme predominantly reflect the intrinsic ϕ,ψ preferences of the amino acids involved, and shows that coupling constant measurements can be used successfully to probe main-chain conformations in the nonnative state of a protein.

21.5.2 Side-chain Conformation

21.5.2.1 Interpretation of *J* Coupling Constants

According to the random coil model, the side-chain conformation in nonnative states of proteins has to be correlated with the type of amino acid and at least some degree of nonuniform sampling needs to be present between different amino acids. However, the measurement of such torsion angle distribution based on interpretation of NOE data is difficult due to spectral overlap and chemical shift analysis does not provide a detailed picture of the conformational averaging.

For the random coil state lysozyme, however, the measurement of $^3J(C',C_\gamma)$ and $^3J(N,C_\gamma)$ coupling constants has enabled side-chain χ_1 torsion angle populations to be probed in the random coil polypeptide chain [183]. Analysis of the coupling constant data has allowed the relative populations of the three staggered rotamers about χ_1 to be defined for 51 residues. Amino acids can broadly be divided into five classes which show differing side-chain conformational preferences in the random coil state (Figure 21.34).

The coupling constants were interpreted using a three-site jump model to describe qualitatively the χ_1 angle distributions (Pachler analysis). The analysis assumes, as a first approximation, that only the three staggered rotamers around the side-chain angle $\chi_1 = +60°, 180°, -60°$ have significant populations. It is assumed that there is rapid interconversion between these three rotamers so the observed coupling constants are a population weighted mean of the values expected for each of the three staggered rotamers (see Eqs (22a–c)):

$$
\begin{aligned}
&^3J_{exp}(N,C_\gamma) = p_{180°}\,{}^3J_{trans}(N,C_\gamma) + (1 - p_{180}) \cdot {}^3J_{gauche}(N,C_\gamma)\\
&^3J_{exp}(C',C_\gamma) = p_{-60°}\,{}^3J_{trans}(C',C_\gamma) + (1 - p_{-60}) \cdot {}^3J_{gauche}(C',C_\gamma) \qquad (22)\\
&p_{60} = 1 - p_{180} - p_{-60}
\end{aligned}
$$

Using Eqs (22a–c), the relative populations of the χ_1 conformers of 60°, −60°, and 180° have been calculated for each residue from the experimental $^3J(C',C_\gamma)$ and $^3J(N,C_\gamma)$ coupling constants. Analysis of the populations of the three staggered rotamers derived from the $^3J(C',C_\gamma)$ and $^3J(N,C_\gamma)$ coupling constants has enabled

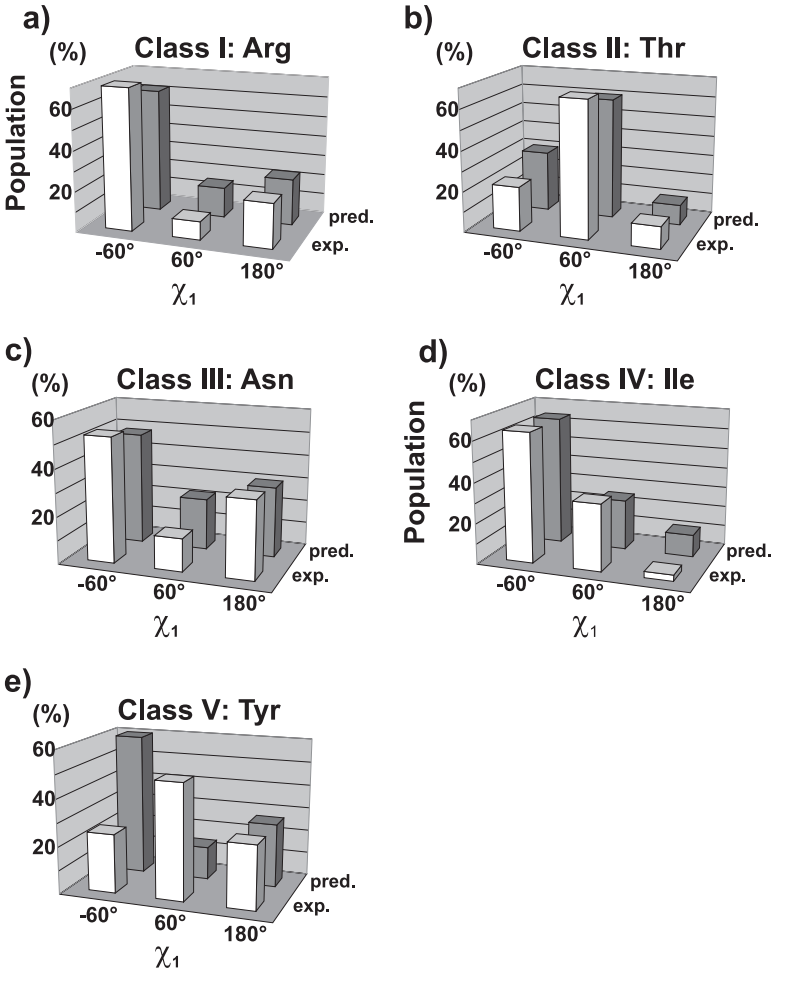

Fig. 21.34. Comparison of the mean percentage populations of the three staggered side chain χ_1 rotamers for different amino acids calculated from the experimental coupling constant data for lysozyme denatured in 8 M urea and predicted from the statistical model for a random coil. The aromatic residues are excluded from this comparison due to their anomalous behavior.

us to recognize several different classes of side-chain behavior (Figure 21.34). For residues with a long aliphatic side chain which is unbranched at C^{β} (Arg, Gln, Glu, Leu, Met; denoted class I), the -60° χ_1 rotamer is significantly favored (70–79% population) with a very low population ($< 10\%$) of the 60° χ_1 rotamer. In contrast for threonine (class II), it is the $+60^{\circ}$ χ_1 rotamer that is most highly populated (67%). For aspartate and asparagine (class III) the populations of the -60° χ_1 (53–55%) and 180° χ_1 rotamers (33–37%) are both significant while for isoleucine

(class IV) the -60° χ_1 rotamer is most populated (64%) with the lowest population for 180° χ_1 (3%). The behavior of the residues with aromatic side chains (class V) varies considerably with a range of populations being seen for a given type of aromatic side chain and different mean populations being observed for the various aromatic residues.

The behavior of the amino acid side chains observed experimentally in the random coil state of lysozyme has been compared with the predictions for a random coil from the statistical model. In particular the χ_1 populations derived from the experimental coupling constants have been compared with the χ_1 distributions in the PDB for residues that are not in recognized regions of secondary structure (COIL parameter set). The choice of this set of residues is important because the steric restraints of regular secondary structure elements can affect the χ_1 distributions significantly [122, 134, 135]. As the Pachler analysis does not consider the population of side-chain conformations other than those of the three staggered rotamers, we compare the relative proportions of χ_1 torsion angles falling within the ranges $\chi_1 = -60^\circ \pm 30^\circ$, $\chi_1 = +60^\circ \pm 30^\circ$ and $\chi_1 = 180^\circ \pm 30^\circ$ in the PDB with the analogous distributions calculated from the coupling constants. In general only a small number of residues in the database have χ_1 torsion angles that do not fall in the three ranges considered (e.g., 87 (5%) of the 1628 aspartate residues in the database). The PDB populations are listed in Table 21.7.

Many of the features of the side-chain populations derived from the experimental coupling constants are also clearly observed in the populations predicted for a random coil from the PDB. Examples of comparisons of the two sets of populations are shown in Figure 21.34. The PDB distributions predict that for all amino acids in a random coil, excluding serine, threonine, valine, isoleucine, cysteine, asparagine, and aspartic acid, the -60° χ_1 rotamer should have the highest population ($> 50\%$) and the $+60^\circ$ χ_1 rotamer the lowest population ($\leq 20\%$). The -60° χ_1 rotamer is most favored as it places the side chain in a position where the steric clash with the main chain is minimized while the $+60^\circ$ χ_1 rotamer is the most sterically restricted and therefore the least populated.

21.5.3 Backbone Dynamics

21.5.3.1 Interpretation of ^{15}N Relaxation Rates

Backbone dynamics in proteins can be monitored by ^{15}N amide heteronuclear relaxation measurements. These heteronuclear relaxation measurements are sensitive to motions on a subnanosecond time scale and to slow conformational exchange in the millisecond time scale. Figure 21.35 shows heteronuclear transverse relaxation rate of the random coil state of ubiquitin in 8 M urea at pH 2. The relaxation rates show only small variations over the sequence: Values approach a plateau at the middle of the protein while lower values are found at the termini of the sequence. This implies that the relaxation properties of a given amide are not influenced by its neighbor, but just by the fact that it is part of the polypeptide chain. The only exception from this behavior is Thr9 with considerable large relax-

Tab. 21.7. Predicted $^3J(C',C_\beta)$ and $^3J(C',C')$ coupling constants and populations of the three staggered side-chain χ_1 rotamers from the statistical model for a random coil. The coupling constant values and were calculated using the residues in all secondary structure elements (ALL) and for residues found neither in α nor β (COIL) in a database of 402 high-resolution crystal structures. The χ_1 populations were calculated using the COIL parameter set considering only the resides whose χ_1 torsion angles fall into 60% ranges centered about the distinct staggered rotamers ($\chi_1 = -60^\circ \pm 30^\circ$; $\chi_1 = 60^\circ \pm 30^\circ$ or $\chi_1 = 180^\circ \pm 30^\circ$). No side-chain populations are given for proline.

	Coupling constants (Hz)				***Relative χ_1 population (%)***		
	$^3J(C',C_\beta)$ ALL	$^3J(C',C_\beta)$ COIL	$^3J(C',C')$ ALL	$^3J(C',C')$ COIL	$\chi_1 - 60^\circ$ COIL	χ_1 60° COIL	χ_1 180° COIL

Val	1.7	1.6	1.0	1.0	26	9	64

ation rates. Besides that, the polypeptide chain of ubiquitin in 8 M urea, pH 2 does not exhibit any amino acid-specific variation of the heteronuclear relaxation rates. This relaxation behavior has also been found for a number of unfolded proteins [21, 124] and in synthetic polymers [125]. It was shown for atactic polystyrene that plateau values of R_1 relaxation rates remain constant for homopolymers between 10 kDa and 860 kDa. Individual segments of the long polymer chain therefore move independently in solutions – the apparent correlation time is therefore largely independent of the overall tumbling rate and only affected by segmental motions.

The relaxation rates for the random coil state of lysozyme are shown in Figure 21.36.

Using a model of segmental motions the relaxation properties can be described, assuming that relaxation contributions due to neighboring residues in a given

Tab. 21.8. Summary of the populations for χ_1 rotamers for denatured lysozyme calculated from the experimental coupling constants for the different classes of amino acids. The experimentally derived populations are mean values for each amino acid, the corresponding standard deviations being given in parentheses. Values for residues where the population of only one of the staggered rotamers could be defined have not been included when calculating the means (except of lysine). For isoleucine the populations listed are a mean of those calculated from coupling constants involving $C_{\gamma 1}$ and $C_{\gamma 2}$.

	Population (%) $\chi_1 = -60^\circ$	***Population (%)*** $\chi_1 = 60^\circ$	***Population (%)*** $\chi_1 = 180^\circ$
Class I: Long aliphatic side chains			
Arg	69.9 (4.1)	8.5 (9.7)	21.6 (11.9)
Gln	70.0 (1.6)	8.1 (1.6)	21.9 (2.7)
Glu	73.3 (0.3)	−1.7 (0.6)	28.5 (1.0)
Lys			35.1 (11.0)

Trp	24.0 (4.5)	20.9 (16.2)	55.1 (11.7)
Tyr	24.7 (6.5)	48.8 (9.1)	26.5 (15.4)

polypeptide chain decay exponentially as the distance from a given residue increases [25].

$$R_2^{\mathrm{rc}}(i) = R_{\mathrm{int}} \sum_{j=1}^{N} \mathrm{e}^{-(|i-j|/\lambda_0)} \tag{23}$$

A description of transverse relaxation rates (R_2 and $R_{1\rho}$) in reduced lysozyme (Figure 21.6d) using the segmental motion model (Eq. (23)) is shown in Figure 21.37 [25, 184]. R_2 relaxation rates and $R_{1\rho}$ relaxation rates are very similar, indicating the absence of significant chemical exchange contributions in the reduced and methylated protein. Deviations from relaxation rates predicted by the segmental motion model for a random coil are observed around Trp62/Trp63 and also near Trp108/Trp111 as well as around Trp123. Positive deviations from the segmental motions model indicate additional stiffness of the polypeptide chain, that is induced by interactions of the bulky side chains. A description of these deviations

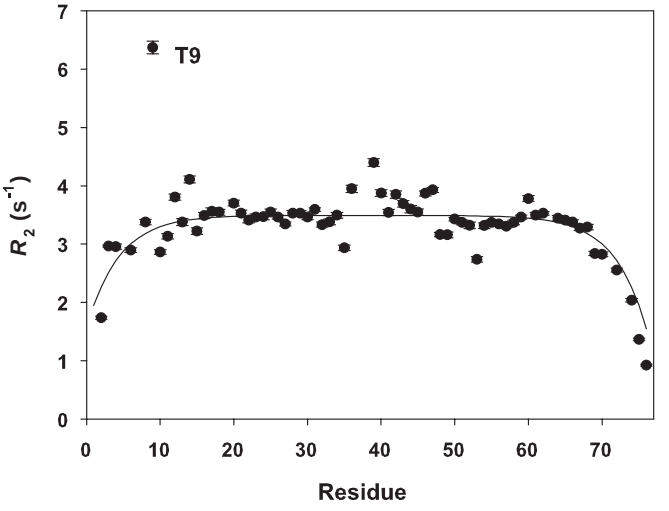

Fig. 21.35. Transverse relaxation rates of the random coil state of ubiquitin (8 M urea, pH 2) at 600 Hz. Fitting parameters for random coil predictions: $R_{int} = 0.4$, $\lambda = 4.35$.

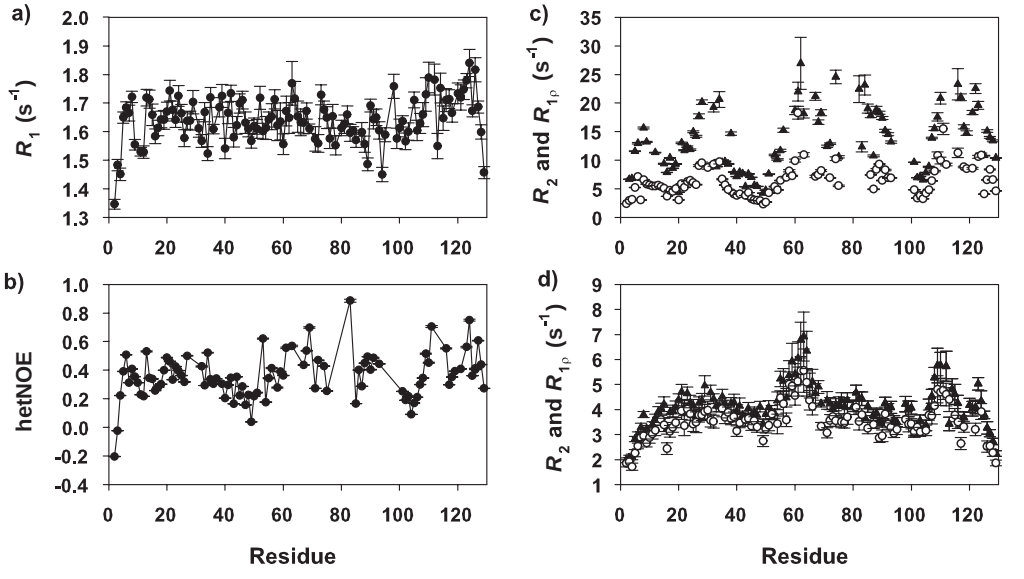

Fig. 21.36. Relaxation data of backbone amides of oxidized and reduced lysozyme in 8 M urea at pH 2. a) R_1 relaxation rates of reduced lysozyme, b) hetNOE of oxidized lysozyme, c) R_2 relaxation rates (filled triangles) and $R_{1\rho}$ relaxation rates (open circles) of oxidized lysozyme, and d) R_2 relaxation rates (filled triangles) and $R_{1\rho}$ relaxation rates (open circles) of reduced lysozyme.

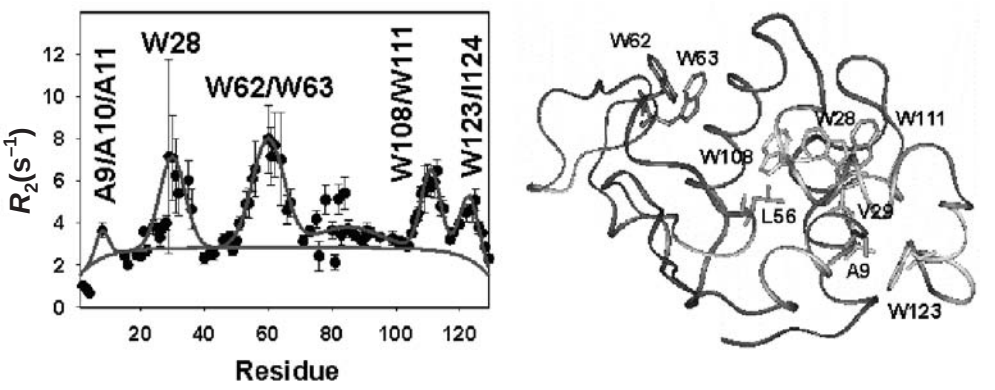

Fig. 21.37. a) ^{15}N R_2 in WT-S^{ME}. The experimental rates are shown as a scatterplot and the rates fitted by a model of segmental motion expected for a random coil with R_2^{rc} ($R_{int} = 0.2\ s^{-1}$ and $\lambda_0 = 7$) are shown as dashed lines. Translation of the relaxation data on the native structure of lysozyme is shown in b).

from the segmental motions model can be done introducing Gaussian clusters to the segmental motion model:

$$R_2^{exp}(i) = R_{int} \sum_{j=1}^{N} e^{-(|i-j|/\lambda_0)} + \sum_{cluster} R_{cluster} e^{-((i-x_{cluster})/2\lambda_{cluster})^2} \quad (24)$$

The clusters of restricted motions observed by relaxation measurements in reduced and methylated lysozyme correspond to the areas of residual secondary structure identified from chemical shift perturbations (see Figure 21.25). The dynamics of the unfolded peptide chain are also investigated in detail in Chapter 22.

The interpretation of R_2 and $R_{1\rho}$ relaxation rates in oxidized and therefore branched unfolded lysozyme is more complicated: not only residues that are near in sequence influence the relaxation properties of a given amide, but also residues that are near via disulfide bridges. A topological distance matrix, $\mathbf{dm}_{ij}$, which counts the shortest path from residue i to residue j, is used in which a disulfide bond counts the same as a peptide bond in connecting two residues (see Eq. (25)). R_2 and R_1 relaxation rates are clearly different, indicating exchange processes taking place around disulfide bridges. For a complete description of R_2 relaxation rates it is therefore necessary to include a term describing these exchange processes as shown in Eq. (25).

$$R_2^{exp}(i) = R_{int} \sum_{j=1}^{N} e^{-(dm_{ij}/\lambda_0)} + R_{exch} \sum_{k=1}^{N_{cys}} e^{-(|i-Cys_k|/\lambda_2)} \quad (25)$$

Due to the complexity of contributions to relaxation rates in branched systems further investigations concerning the nature of deviations from the segmental motion model have been performed using reduced and methylated variants of lysozyme

(i.e., unbranched polypeptide chains). Figure 21.37 shows R_2 relaxation rates measured in reduced and methylated lysozyme in water. Six hydrophobic clusters were identified in WT-S^{ME} using the extended segmental motion model (Eq. (24)). These clusters are centered at residues (1) L8, (2) C30, (3) S60, (4) S85, (5) W111, and (6) W123. The most prominent cluster, cluster 3 is found in the middle of the protein sequence which belongs to the β-domain in folded lysozyme. All other clusters (cluster 1, 2, 4, 5, and 6) are found in what is to be the α-domain in the folded state of the protein. While clusters 3, 5, and 6 are also observed in urea, cluster 2 which is near Trp28 is destroyed by the addition of urea. Furthermore the rather small clusters 1 and 4 cannot be identified in the presence of urea. The importance of weak interactions in protein folding is reviewed in Chapter 6.

Stabilization of these clusters can be tested by single point mutations in conjunction with relaxation measurements [184, 253]: Replacement of Trp62 in cluster 3 by glycine essentially abolishes not only its own cluster 3 but also clusters 1 through 4, and diminishes clusters 5 and 6 (as seen in Figure 21.38). The disruption of the clusters far away in sequence clearly indicates the presence of long-range interactions in WT-S^{ME}. Interestingly, clusters also seem to play an important role in refolding: hydrogen exchange measurements have shown that the α-domain of lysozyme folds a lot faster than the β-domain, with exception of residue W63, which becomes exchange-protected as quickly as the α-domain. An association of the region around W62/W63 with the α-domain as shown by relaxation measurements is therefore not only present in the unfolded state, but seems to be important for the folding nucleus of the protein.

In order to test whether this property of Trp62 to stabilize the folding nucleus is unique to tryptophan or may be more generally attributable to aromatic amino acids, the effect of replacing Trp62 by tyrosine is shown in Figure 21.38c. The W62Y mutation has a very minor effect on the relaxation properties of WT-S^{ME} compared with W62G-S^{ME}. This result suggests that aromatic residues play an important role in the stabilization of long-range interactions in unfolded states of lysozyme.

A9G-S^{ME} even more so displays WT-S^{ME} properties. There is not even an effect on its own cluster, cluster 1. The hydrophobic clusters remain of virtually identical size and position, indicating that Ala9 is not important for stabilizing the hydrophobic core.

In contrast, results of the replacement of tryptophan residues at positions 111 and 123 are very significant. When Trp111 (cluster 5) is replaced by glycine, the cluster in which the mutation is located disappears entirely, and cluster 6 also decreases significantly in intensity. Loss is also observed in the intensity of cluster 2 (surrounding Trp28) and a very small decrease in the intensity of cluster 3 (surrounding Trp62 and Trp63). Similarly, when Trp123 at the C-terminus (cluster 6) is changed to a glycine, the cluster around the mutation site essentially disappears, and the intensities of clusters 2, 3, and 5 are lessened. The effect of W123G replacement is less significant than that of W111G, as seen by the complete loss of cluster 5 in W111G-S^{ME} but not in W123G-S^{ME}. The largest changes in R_2 distribution as compared to WT-S^{ME} is observed with W62G-S^{ME}. W62G-S^{ME} on one,

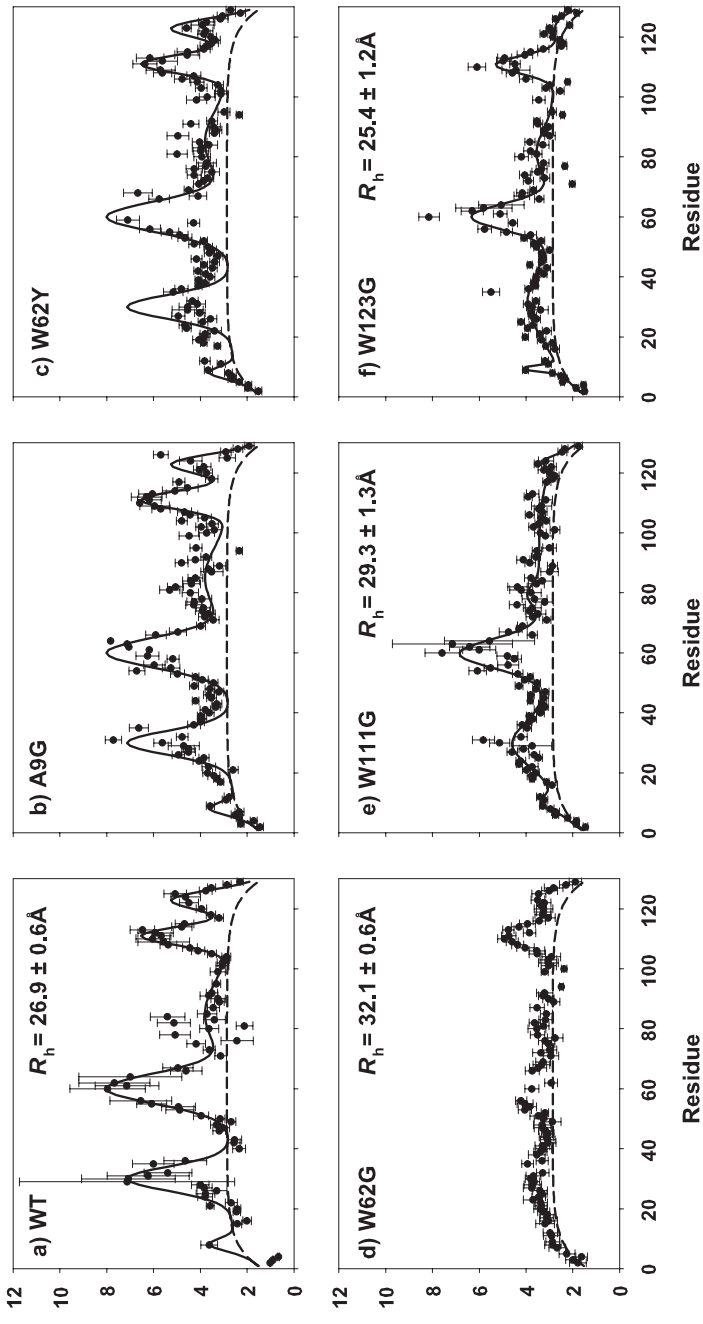

Fig. 21.38. ^{15}N R_2 in WT-S^{ME} and W62G-S^{ME}, W62Y-S^{ME}, A9G-S^{ME}, W111G-S^{ME}, and W123G-S^{ME} are shown in panels a–e, respectively. The experimental rates are shown as a scatter plot and the rates fitted by a model of segmental motion expected for a random coil with R_2^{rc} ($R_{int} = 0.2$ s^{-1} and $\lambda_0 = 7$) are shown as dashed lines; black lines show Gaussian fits for WT-S^{ME} (a,b,c) W111G-S^{ME} (e) and W123G-S^{ME} (f).

W111G-S^{ME} and W123G-S^{ME} on the other side appear complementary to each other: while the W62G mutation causes dramatic disruption of clusters 1–4, and to a lesser extent of clusters 5–6, the W111G and W123G replacements causing more disruption in clusters 2, 5, and 6 and more subtle changes in cluster 3.

21.6 Summary and Outlook

Here we summarize some of the findings from NMR investigations of nonnative states of proteins:

- The investigations show that NMR parameters can be predicted using models for the random coil state of a protein. The applied model treats the polypeptide chain as a (branched or unbranched) homopolymer for the prediction of anisotropic and global parameters such as relaxation rates or RDCs. On the other hand, for the prediction of local parameters, only explicit models such as the random coil model (Section 21.4) with amino acid-specific torsion angle distribution will allow correlation with experimental data such as *J*-couplings and NOEs, since the experiment is sensitive enough to detect small local differences in the conformational sampling. Second-order effects revealing the more detailed dependence on nearest neighbor effect will need a larger statistical database for their firm interpretation.
- Random coil states of proteins sample the ϕ, ψ and χ_1 conformational space according to distribution functions derived from the analysis of structures prevalent in all protein structures [24, 45, 122, 123]. The assumption that the distribution of ϕ, ψ torsion angles in the PDB resembles the experimental ϕ, ψ energy surface and that the effects of specific nonlocal interactions present in individual proteins are averaged out over the set of structures seems to be valid. More sophisticated approaches including molecular dynamics simulations of nonnative states of proteins will be of importance in the future to go beyond the current conformational and dynamic description of these states.
- On the basis of the delineation of the ''random coil'' behaviour, significant deviations identifying nonrandom structures in nonnative states can be found for a number of different proteins. These deviations include both nonrandom conformational preferences and differences from rapid dynamics that would interconvert the ensemble of states. The nonrandom structure can be shown to be stabilized both by local and global interactions and same of the global interactions trap the polypeptide chain into conformations not present in the native structure of the protein. In these investigations, combined mutational and NMR spectroscopic investigations have been particularly powerful tools in showing changes in overall compaction in these states. It is tempting to speculate that mutations do alter the energetics of the ensemble of states representing the unfolded states of a protein.

  Natively unfolded proteins form a significant part of the proteom and reveal

that the polypeptide chain may not necessarily adopt a globular, rigid fold to exert its function. Bioinformatic analysis suggests these states to be more abundant than initially assumed.

- At the same time, misfolded, yet highly regular fibrillar states of proteins are formed in many protein folding diseases. In light of these considerations, heteronuclear NMR spectroscopy seems to be the most versatile and powerful technique to characterize aspects of conformation and dynamics in all of these states of proteins. In all of these investigations, the clear definition of what to expect for a random coil protein will form a firm baseline to predict deviations in a reliable manner.

Acknowledgments

H.S. would like to acknowledge the fruitful and fascinating collaboration and discussions with C. M. Dobson, K. Fiebig, M. Buck, L. Smith, M. Hennig, W. Peti, S. Grimshaw, C. Redfield, J. Jones, S. Glaser, and C. Griesinger in characterizing nonnative states of proteins. The work in the group of H.S. has been carried out by a number of extremely creative and bright students, who we would like to thank: T. Kühn, E. Collins, J. Klein-Seethamaran, E. Duchardt, and K. Schlepckow. We would like to thank the DFG, the European Commission, the Fonds der Chemischen Industrie, the state of Hesse and the University of Frankfurt for financial Support.

22
Dynamics of Unfolded Polypeptide Chains

Beat Fierz and Thomas Kiefhaber

22.1
Introduction

During protein folding the polypeptide chain has to form specific side-chain and backbone interactions on its way to the native state. An important issue in protein folding is the rate at which a folding polypeptide chain can explore conformational space in its search for energetically favorable interactions. Conformational search within a polypeptide chain is limited by intrachain diffusion processes, i.e., by the rate at which two points along the chain can form an interaction. The knowledge of the rates of intrachain contact formation in polypeptide chains and their dependence on amino acid sequence and chain length is therefore essential for an understanding of the dynamics of the earliest steps in protein folding and for the characterization of the free energy barriers for protein folding reactions. In addition, intrachain diffusion provides an upper limit for the speed at which a protein can reach its native state just like free diffusion provides an upper limit for the rate constant of bimolecular reactions. Free diffusion of particles in solution was treated extensively almost 100 years ago by Einstein and von Smoluchowski [1–3] but until recently, only little was known about the absolute time scales of intrachain diffusion in polypeptides. Numerous theoretical studies have been made to investigate the process of intrachain diffusion in polymers [4–10]. These studies derived scaling laws for intrachain diffusion and made predictions on the kinetic behavior of the diffusion process but they were not able to give absolute numbers. This chapter will briefly introduce some theoretical concepts used to treat chain diffusion and then discuss experimental results on intrachain diffusion from different model systems.

22.2
Equilibrium Properties of Chain Molecules

Since chain dynamics strongly depend on the chain conformation we will briefly present some polymer models for chain conformations. This topic is discussed in

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

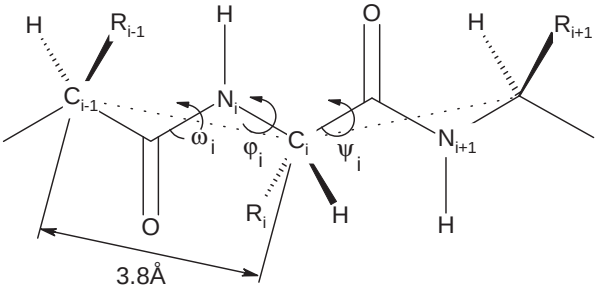

Fig. 22.1. Schematic representation of a polypeptide chain. The R_i denote the different amino acid side chains, the dashed lines denote the virtual chain segment. Adopted from Ref. [12].

more detail in Chapter 20 and in Refs [11–15]. The most simple description on an unfolded state of a protein is the idealized notion of a random coil. In a random coil no specific interactions between residues or more generally chain segments persist and a large conformational space is populated. Polypeptide chains are rather complex polymers as sketched in Figure 22.1. Usually simplified models are applied to calculate general properties of random coils.

22.2.1 The Freely Jointed Chain

The equilibrium properties of an ideal polymer can be described by a three-dimensional random walk. This hypothetical chain, the freely jointed chain, consists of n bonds of length l with equally probable angles at each joint. The chain is described by the $n+1$ position vectors of the joints (chain elements) $\mathbf{R_i}$ or the n bond vectors $\mathbf{r_i}$. The correlation of the bond vectors $\langle \mathbf{r_m} \cdot \mathbf{r_n} \rangle$ is zero for $n \neq m$ because of the independence of the bond vector direction. The average end-to-end distance $\langle r^2 \rangle$ for the freely jointed chain is given by

$$\langle r^2 \rangle = nl^2 \tag{1}$$

For such an ideal chain the end-to-end vectors are normally distributed. The often-used notion of a Gaussian chain, however, refers to a chain model with Gaussian distributed bond lengths. Thus the end-to-end vector distribution is also Gaussian and Eq. (1) holds. This chain model does not describe the local structure of a chain correctly but the global properties of long chains are modeled in a realistic way.

22.2.2 Chain Stiffness

In a chain with restricted angles between two neighboring segments the correlation between segments n, m is no longer zero for $n \neq m$ but asymptotically ap-

proaches zero with increasing distance. The chain is not as flexible as the freely jointed chain because every segment is influenced by its neighbors. This behavior can be described in terms of chain stiffness. The end-to-end distance for such a chain is larger than calculated from Eq. (1). Flory introduced the characteristic ratio (C_n) as a measure for the dimensions of a stiff chain compared to a freely jointed chain [12]

$$\langle r^2 \rangle = C_n n l^2 \tag{2}$$

For short chains C_n increases with chain length due to preferential chain propagation into one direction (see Figure 22.2). For long chains ($n \to \infty$) C_n reaches a constant limiting value (C_∞).

$$\langle r^2 \rangle = C_\infty n l^2 \tag{3}$$

In this limit $\langle r^2 \rangle$ grows proportional to n, like an ideal random-walk chain (see Eq. (1)). However, in a real chain $\langle r^2 \rangle$ increases by a factor of C_∞ more per segment compared with an ideal random-walk chain. The value of C_∞ gives the average number of consecutive chain segments that propagate in the same direction (''statistical segment''). Consequently, for an ideal Gaussian chain where there is no correlation between the bond vectors, the limiting characteristic ratio is 1 (see Eq. (1)). For real chains C_∞ is larger than 1 and larger values of C_∞ indicate stiffer chains.

Kuhn showed that for chains with limited flexibility and n bonds of length l an equivalent to the freely jointed chain can be defined introducing an hypothetical bond length b, the Kuhn length ($b > l$) [16, 17]. The Kuhn length is the length of chain segments that can move freely (i.e., without experiencing chain stiffness). The maximal length of the chain (r_{max}) is the same as for a freely jointed chain and thus $r_{max} = nl = n'b$ with $n' < n$. The Kuhn length b is defined as

$$b = \langle r^2 \rangle / r_{max} = C_\infty n l^2 / r_{max} = C_\infty l \tag{4}$$

Another widely used term is the persistence length l_p. It is a measure for the distance that an infinitely long chain continues in the same direction (i.e., is persistent). The Kuhn and the persistence lengths are connected by the simple relationship

$$b = 2 l_p \tag{5}$$

Both parameters are used as measures for chain stiffness.

22.2.3 Polypeptide Chains

Any real macromolecule like the polypeptide chain has defined segments which are connected by chemical bonds. Bond angles are constrained and the distribution

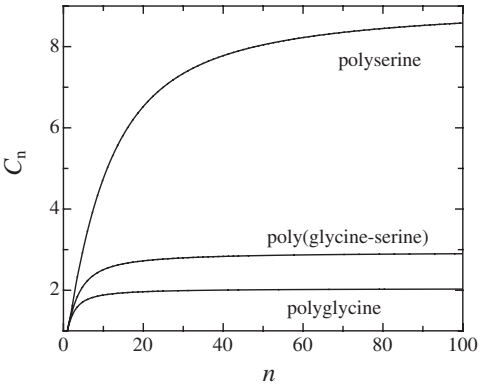

Fig. 22.2. Effect of chain length (n) on the characteristic ratio (C_n) for polyserine, polyglycine and a 50% mixture of serine and glycine. C_n was calculated using average transformation matrices given by Flory [12]. The transformation matrix for alanine was used to calculate the properties of serine.

of torsional angles is given by torsional potentials with several minima. In a peptide chain these torsional potentials are represented in conformational energy plots [18–21] or the Ramachandran map [22]. Flory and coworkers calculated statistical properties of various homopolypeptide chains [12, 18–21] based on the ϕ,ψ-angles from conformational energy plots. An average virtual bond length is defined from $C_{\alpha,i}$ to $C_{\alpha,i+1}$ and taken as 3.8 Å as shown in Figure 22.1 [12]. For polypeptide chains polyglycine represents the most flexible chain with $C_\infty = 2.2$ (see Figure 22.2) [12, 18, 19]. Poly-L-proline gives stiff chains with $C_\infty \approx 100$, due to the formation of a polyproline helix. For all other amino acids, C_∞ is between 8.5 and 9.5 [18]. These values correspond to persistence lengths around 19 Å for chains that do not contain glycine or proline and of 5.7 Å for poly-L-glycine [21]. It should be noted that these values apply for θ conditions, where the attractions between the chain segments (e.g., van der Waals or electrostatic interactions) compensate for the monomer–monomer repulsion due to excluded volume and the chain is apparently unperturbed. For details see Refs [11–15].

22.2.4 Excluded Volume Effects

In real (physical) chains two chain segments cannot occupy the same space. The excluded volume effect was first discussed by Kuhn [16] and leads to a non-ideal behavior of the chain. The chain dimensions increase as a result of the excluded volume, which leads to larger end-to-end distances. Flory obtained an approximate exponent for the chain dimensions including the contributions from the excluded volume effect by simple calculations [11].

$$\sqrt{\langle r^2 \rangle} \propto l \cdot n^{\nu}, \quad \nu = 0.59 \approx \text{or } 3/5 \tag{6}$$

This shows that the excluded volume effect is especially important for long chains. The excluded volume chain has been a subject of much research and is discussed in detail in the literature [13, 23–25] (see also Chapter 20).

For long real chains the end-to-end distribution function, $p(r)$, depends on the solvent conditions and on the temperature of the system if the intrachain interactions have enthalpic contributions. $p(r)$ for real chains can reasonably well be approximated by a skewed Gaussian function [26]

$$p(r) \propto 4\pi r^2 e^{-((r-r_0)/\sigma)^2} \tag{7}$$

where r is the end-to-end distance, σ is the half-width of the distribution and r_0 indicates the shift of the skewed Gaussian from the origin. Polypeptides in solution are complex molecules which may interact strongly with the solvent and with themselves enabling proteins to fold. The unfolded state of natural proteins was shown to contain both native and nonnative short-range and long-range interactions [27–39] (see Chapter 21). But many of the properties of GdmCl-unfolded proteins may be approximated by statistical chain models (see Section 22.4.2.4), although in some proteins specific intrachain interactions have also been found under strongly denaturing conditions [28, 39]. (see Chapter 21).

22.3 Theory of Polymer Dynamics

One of the major interests in polymer chemistry and biology is to elucidate the dynamic behavior of polymers in solution. Usually the dynamics of such molecules are complex and cannot be easily described by classical concepts. This is especially true for protein folding where the polypeptide chain not only moves freely in solution but also undergoes large cooperative structural transitions involving partially folded and native states. In the following we will give a short introduction to the theoretical concepts of polymer dynamics. More detailed information is given in Refs [8, 13, 23, 24].

22.3.1 The Langevin Equation

The energy surface on which a system moves is often complex with sequential and parallel events during the barrier crossing process (see Chapter 12.2). The motions of the system exhibit a diffusional character. The polymer chain in solution is immersed in solvent molecules which supply the energy for the movement by colliding with the polymer chain and at the same time dissipate this energy by exerting a frictional force on the molecule. The system can be described by the Langevin equation for Brownian motion if one assumes that the relaxation time scale for the solvent fluctuations is extremely short compared with the time scale of polymer motion [40]:

$$\ddot{\boldsymbol{x}} = -M^{-1}\frac{\partial U(x)}{\partial \boldsymbol{x}} - \gamma\dot{\boldsymbol{x}} + M^{-1}F_{\text{fluc}}(t) \tag{8}$$

where M is the particle mass, x is the reaction coordinate, $U(x)$ denotes the energy, and γ is a friction coefficient, which is determined by the interactions of the system with its environment and couples the system to the environment. It can be related to solvent viscosity in real solutions. $F_{\text{fluc}}(t)$ is the random force which represents the thermal motion of the environment. The random force is modeled by Gaussian white noise of zero mean and a δ correlation function

$$\langle F_{\text{fluc}}(t)\rangle = 0$$
$$\langle F_{\text{fluc}}(t)\cdot F_{\text{fluc}}(t')\rangle = 2k_{\text{B}}T\gamma M\delta(t-t') \tag{9}$$

22.3.2 Rouse Model and Zimm Model

For long unfolded polypeptide chains, the simplified models used in polymer theory should be applicable. The system, i.e., the peptide immersed in the solvent, encounters no large barriers and undergoes random conformational changes. The dynamic behavior of Gaussian chains can be described analytically using classical polymer theory. Models of a higher complexity are only accessible, however, by solving the equations numerically in computer simulations. Two models have been initially proposed to describe polymer dynamics in dilute solutions: the Rouse model [5] and the Zimm model [6]. In both models the polymer is treated as a set of beads connected by harmonic springs. The Langevin equation (Eq. (8)) is used to describe the brownian motion of the connected beads in the Rouse model. The frictional and activating force from the solvent independently acts on all beads. The movement of the chain is described as a set of n relaxation modes. These modes can be compared to the vibrational modes of a violin string. Each mode p is coupled to a relaxation time τ_{p} and involves the motion of a section of the chain with n/p monomers. The mode with the longest relaxation time describes the overall motion (rotational relaxation) of the polymer chain. All other modes represent internal motions.

Yet, the scaling laws obtained for Rouse chains are not consistent with experimental results [24]. When a chain segment moves through a viscous solvent it has to drag surrounding solvent molecules along. This creates a flow field around the particle. Surrounding monomers are additionally affected by this flow field. As a result, the motion of one chain segment influences the motion of all other segments by hydrodynamic interactions.

The resulting chain model including hydrodynamic interactions was put forward by Zimm [6]. This model also gives internal relaxation modes, but the hydrodynamic interactions lead to significant deviations from the Rouse model. The solvent viscosity influences the system in two ways. First, it affects the random force that delivers the energy and dissipates it at the same time (γ, in the Langevin equa-

tion). Secondly, viscosity changes the strength of the hydrodynamic interactions. Many studies have been performed to compare the predictions of Rouse model, the Zimm model, and more refined models to actual experiments [41]. The overall chain motions including hydrodynamic interactions agree well with experiment [24]. Measurements of dynamics in DNA molecules using time-resolved optical microscopy directly showed internal relaxation modes [42].

22.3.3 Dynamics of Loop Closure and the Szabo-Schulten-Schulten Theory

One particularly intensively treated dynamic event in polymer chains is the loop closure or end-to-end diffusion reaction. Organic chemists are interested in loop closure probabilities for the synthesis of cyclic compounds. Also in nucleic acids end-to-end diffusion is important during formation of cyclic DNA. The kinetics of such cyclization reactions critically depend on the rate of intrachain contact formation. A similar situation is encountered in protein folding, where residues have to come together and form specific non-covalent interactions. Jacobsen and Stockmayer [4] derived a scaling law for end-to-end ring closure probability as a function of the length of the polymer chain. The calculations were based entirely on entropic contributions and yielded

$$p_{\text{ring}} \propto n^{-3/2} \tag{10}$$

where p_{ring} denotes the probability of ring formation and n is the number of monomers in such a ring.

Szabo, Schulten, and Schulten [7] discussed the kinetics that can be expected from a diffusion controlled encounter of two groups attached to the ends of a Gaussian chain (SSS theory). They treated the loop closure reaction as an end-to-end diffusion of a polymer on a potential surface. It was shown that the kinetics of such a process can be approximated by an exponential decay of the probability $\Sigma(t)$ that the system has not reacted (i.e., has not made contact) at time t

$$\Sigma(t) \approx \Sigma_{\text{approx}}(t) = \mathrm{e}^{(-t/\tau)} \tag{11}$$

This approximation holds if the distribution of chain conformations is stationary throughout the reaction, i.e., the interchange of conformations is fast compared with the rate of reaction, and the probability of reaction is small, i.e., the reactive radius is small compared with the chain length. The time constant τ is the mean first passage time of this reaction and depends on the equilibrium end-to-end distribution of the polymer chain $p(x)$, on the diffusion constant D of the chain ends relative to one another and on the reactive boundary r_a, i.e., the distance which leads to contact between the two ends.

$$\tau = \frac{1}{D}\int_{r_a}^{\infty} p(x)^{-1}\left(\int_{x}^{\infty} p(y)\,\mathrm{d}y\right)^2 \mathrm{d}x \Big/ \int_{r_a}^{\infty} p(x)\,\mathrm{d}x \tag{12}$$

The mean first passage time of contact formation can be related to the root mean square end-to-end distance, r, by expanding Eq. (12):

$$\tau^{-1} = k_{\text{contact}} \propto D(\sqrt{\langle r^2 \rangle})^{-3} \tag{13}$$

With Eq. (1) this gives the well-known relationship [4]:

$$k_{\text{contact}} \propto n^{-3/2} \tag{14}$$

for an ideal chain. The effect of viscosity on the rate of reaction is included in the diffusion coefficient D, which is assumed to be inversely proportional to the solvent viscosity. Hydrodynamic interactions, the excluded volume effect and other non-idealities (e.g., a diffusion coefficient dependent on chain conformation) are not considered in these approximations and probably contribute to the dynamics and scaling laws in real systems.

22.4 Experimental Studies on the Dynamics in Unfolded Polypeptide Chains

22.4.1 Experimental Systems for the Study of Intrachain Diffusion

It is now widely accepted that the description of the unfolded state as a complete random coil where the polypeptide chain behaves like an ideal polymer is not accurate. Short stretches along the polypeptide chain behave in a highly non-ideal manner because of chain stiffness, solvent interactions, and excluded volume. In addition, there is evidence for residual short-range and long-range interactions in unfolded proteins in water and even at high concentrations of urea and GdmCl [27, 28, 34, 43, 44]. For the understanding of the dynamic properties of unfolded proteins it is therefore essential to compare scaling laws and absolute rate constants for chain diffusion in homopolymer models with the results from unfolded proteins or protein fragments. Suitable experimental systems to study intrachain diffusion should allow direct measurements of the kinetics of formation of van der Waals contacts between specific groups on a polypeptide chain. To obtain absolute rate constants, the applied method must be faster than chain diffusion and the detection reaction itself should be diffusion controlled (see Appendix).

In the following, we will describe various experimental systems that have been used to study the dynamics of intrachain diffusion. In Section 22.4.2 results from these studies will be discussed in more detail in terms of dynamic properties of unfolded polypeptide chains. A summary of the results is given in Tables 22.1 and 22.2.

22.4.1.1 Early Experimental Studies

Dynamics of synthetic polymers in various organic solvents have been studied for a long time by different means. End-to-end contact formation has been examined

Tab. 22.1. Comparison of end-to-end contact formation rate constants observed in different systems.

k_{app} (s^{-1})	Loop size (n)[a]	Method	Labels[b]	Sequence	Conditions	Reference
$3.3 \cdot 10^8$–$1.1 \cdot 10^8$	4–8, 50[c]	FRET	Dansyl/naphthalene	$(heGln)_n$[d]	Glycerol/TFE	48, 50[c]

[a] Extrapolated from larger loops to 10 amino acids, as the average loop size in proteins. It should be noted that extrapolations used the Jacobsen Stockmeyer or SSS theory scaling law ($k_c \sim n^{-1.5}$), which gives a slightly smaller length dependence than the experimentally determined scaling laws (cf. Figure 22.8). This would result in larger extrapolated values of k_c.

[b] solvent was H_2O unless indicated. The data measured in concentrated GdmCl solutions or EtOH were not corrected for solvent effects. This would lead to a significant increase in k_c (see Figure 22.10).

using phosphorescence quenching of benzophenone in long hydrocarbon polymers [45] and by excimer formation of pyrene groups attached to poly(ethylene glycols) [46]. The dynamics of unfolded polypeptide chains have first been studied using fluorescence resonance energy transfer (FRET) from an energy donor to an energy acceptor group. FRET was shown to be a powerful tool to determine donor–acceptor distances [47], but time-resolved FRET kinetics also contain major contributions from the diffusion of the two FRET probes relative to each other [48, 49]. The number of excited donor molecules ($N^*(r,t)$) with donor–acceptor distance r changes with time in the presence of an acceptor group. This can be described by a second-order partial differential equation for the reduced distance distribution, $\bar{N}(r,t)$, normalized to $N_0(r)$:

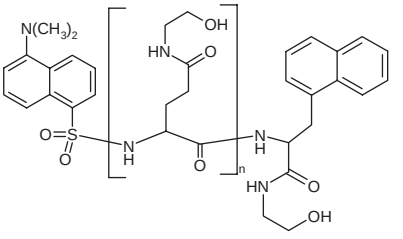
$$\frac{\partial \bar{N}(r,t)}{\partial t} = -\frac{1}{\tau}\left\{\left(1+\left(\frac{R_0}{r}\right)^6\right)\bar{N}(r,t)\right\} + \frac{1}{N_0(r)}\frac{\partial}{\partial r}\left\{N_0(r)D\frac{\partial \bar{N}(r,t)}{\partial r}\right\}$$

$$\text{with } \bar{N}(r,t) = \frac{N^*(r,t)}{N_0(r,t)} \tag{15}$$

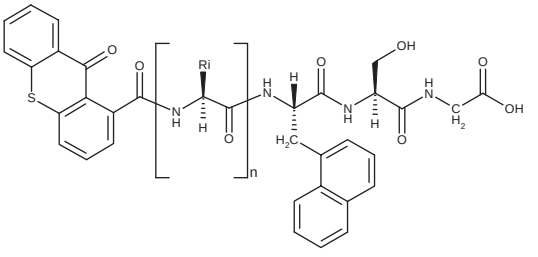
where R_0 is the distance of 50% FRET efficiency, which is a property of the FRET labels, $N_0(r)$ denotes the equilibrium distribution of distances between donor and acceptor, and τ is the fluorescence lifetime of the donor. The first term (equilibrium term) on the right-hand side describes the change of donor excitation with time through spontaneous decay and nonradiative energy transfer. The second term (diffusion term) describes the replenishment of excited labels through brownian motion. This dynamic component of FRET was exploited to determine diffusion coefficients of segmental motion in short homopolypeptide chains (poly-N^5-(2-hydroxyethyl)-L-glutamine) in glycerol and trifluoroethanol mixtures [48, 49] (see Chapter 17). Naphthyl- and dansyl-groups were used as donor and acceptor, respectively (Figure 22.3A).

These studies allowed the first estimates of the time scale of chain diffusion processes in polypeptide chains. Converting the reported average diffusion constants reported by Haas and coworkers [48] into time constants ($\tau = 1/k$) for contact formation at van der Waals distance gives values between 9 and 3 ns for a donor–acceptor separation of between 4 and 8 peptide bonds, respectively [50]. The dynamic component of FRET is sensitive to motions around the Förster distance (R_0), which is around 22 Å for the dansyl–naphthyl pair used in these studies. It therefore remained unclear whether the same diffusion constants represent the dynamics for formation of van der Waals contact between two groups. In addition, analysis of the FRET data critically depends on the shape of the donor–acceptor distribution function, which had to be introduced in the data analysis and thus did not allow model-free analysis of the data. It was found that this distribution can be described most accurately by the skewed Gaussian function mentioned above [51]. It later turned out that the chain dynamics measured by FRET are significantly faster than rate constants for contact formation (see below), which might indicate a distance-dependent diffusion constant in unfolded polypeptide chains.

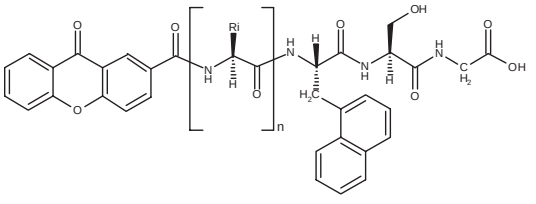
A



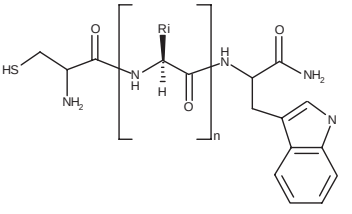
B



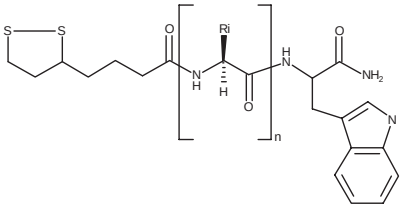
C



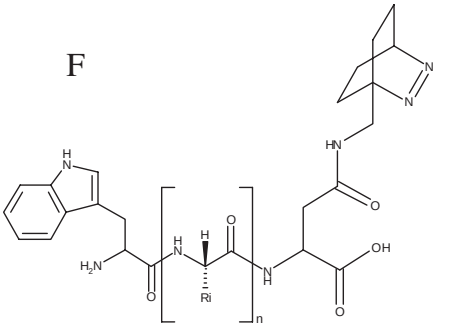
D



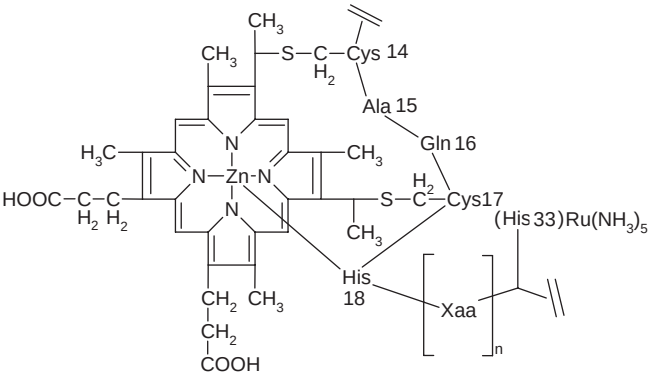
E



F



G



FRET was also used in several proteins to determine donor–acceptor distance distribution functions and diffusion coefficients (see Chapter 17).

Rates of intrachain diffusion have also been estimated from the rate constant for intramolecular bond formation in GdmCl-unfolded cytochrome *c* [52]. The reaction of a methionine with a heme group separated by 50–60 amino acids along the chain gave time constants around 35–40 μs. Extrapolating these data to shorter distances using SSS or Jacobsen-Stockmeyer theory ($k \sim n^{-1.5}$) gave an estimate of 1 μs for the time constant of contact formation at a distance of 10 peptide bonds, which was predicted to be the distance for the maximum rate of contact formation due to chain stiffness slowing down the diffusion process over shorter distances [53]. A problem with this experimental approach is that the recombination reaction of heme with methionine is not diffusion controlled. Thus, the chain dynamics allow a faster breakage of the heme–methionine contact than formation of the methionine–heme bond. Thus, not every contact was productive and the apparent rate constants obtained in these measurements were slower than the absolute rate constants measured with diffusion-controlled systems (see Experimental Protocols, Section 22.7).

22.4.1.2 Triplet Transfer and Triplet Quenching Studies

The early studies on intrachain diffusion did not yield absolute rate constants for contact formation, but they were important to trigger the development of more direct and model-free methods to study chain diffusion. Recently, several experimental systems using fast photochemical methods to directly monitor contact formation in model peptides and protein fragments have been introduced. Bieri et al. [50] and Krieger et al. [54, 55] used triplet–triplet transfer (TTET) between thioxanthone or xanthone derivatives and naphthalene (see Figure 22.3B,C) to directly measure rate constants for intrachain contact formation in synthetic polypeptide chains. A triplet donor and a triplet acceptor group are introduced at specific points in polypeptide chains. The donor is selectively excited by a laserflash and undergoes fast intersystem crossing into the triplet state (see Figure 22.4). Upon intrachain diffusion the triplet donor and triplet acceptor groups meet and the triplet state is transferred to the acceptor. Since TTET is a two electron exchange process (Dexter mechanism) it has a very strong distance dependence and usually requires

Fig. 22.3. Structures of different experimental systems used to measure intrachain contact formation. Results from these systems are summarized in Table 22.1. A) Dansyl and naphthyl-labeled poly-N^5-(2-hydroxyethyl)-L-glutamine used to determine diffusion constants by FRET [48]. B) Thioxanthone and naphthylalanine-labeled poly(Gly-Ser) peptides to measure contact formation by TTET [50]. C) Xanthone and naphthylalanine-labeled peptides to measure contact formation by TTET in various homopolymer chains and natural sequences with up to 57 amino acids between donor and acceptor [54, 55]. D,E) Tryptophan and cysteine or lipoate-labeled peptides to measure contact formation by Trp triplet quenching in various short peptide chains [59, 125, 126]. F) Short peptide chains ($n < 10$) for measuring DBO fluorescence quenching by tryptophan [65]. G) Quenching of Zn-porphyrin triplets by Ru-His complexes in unfolded cytochrome *c* [64].

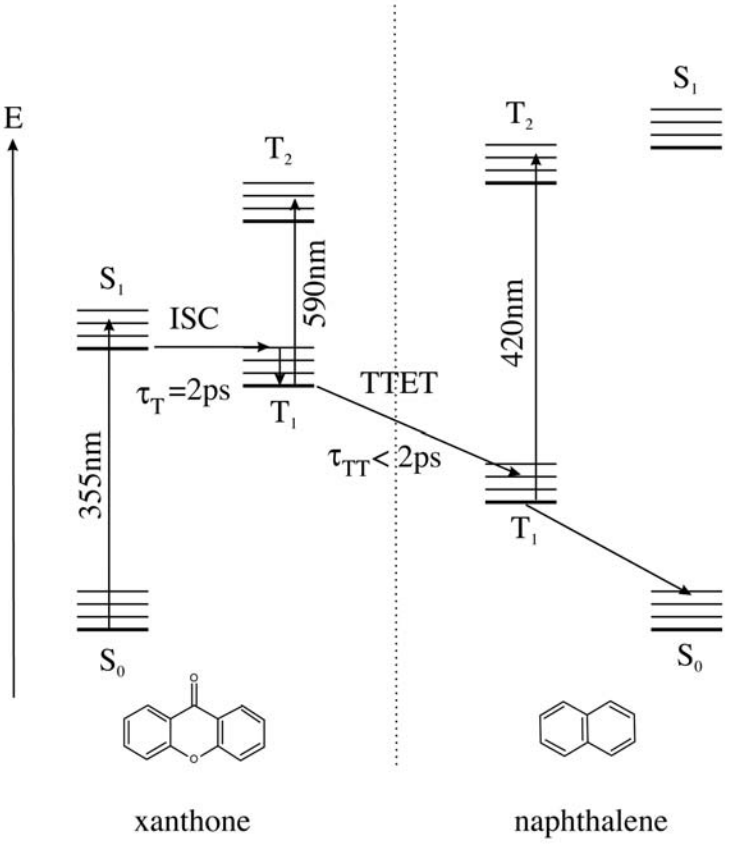


Fig. 22.4. Jablonski diagram for triplet–triplet energy transfer (TTET) from xanthone to naphthalene. Rate constants for triplet formation (k_T) and TTET (k_{TT}) were measured by laserflash photolysis using femtosecond pulses [56].

van der Waals contact to allow for electron transfer. This should be contrasted to FRET, which occurs through dipole–dipole interactions and thus allows energy transfer over larger distances (see above).

The triplet states of the labels have specific absorbance bands, which can easily be monitored to measure the decay of the donor triplet states and the concomitant increase of acceptor triplet states (Figure 22.5). The time constant for formation of xanthone triplet states is around 2 ps [56]. TTET between xanthone and naphthyl acetic acid is faster than 2 ps and has a bimolecular transfer rate constant of $4 \cdot 10^9$ M^{-1} s^{-1} [54, 56], which is the value expected for a diffusion-controlled reaction between small molecules in water (see Experimental Protocols, Section 22.7). Due to this fast photochemistry, TTET between xanthone and naphthalene allows measurements of absolute rate constants for diffusion processes slower than 10–20 ps (Figure 22.6 and Experimental Protocols, Section 22.7). The upper

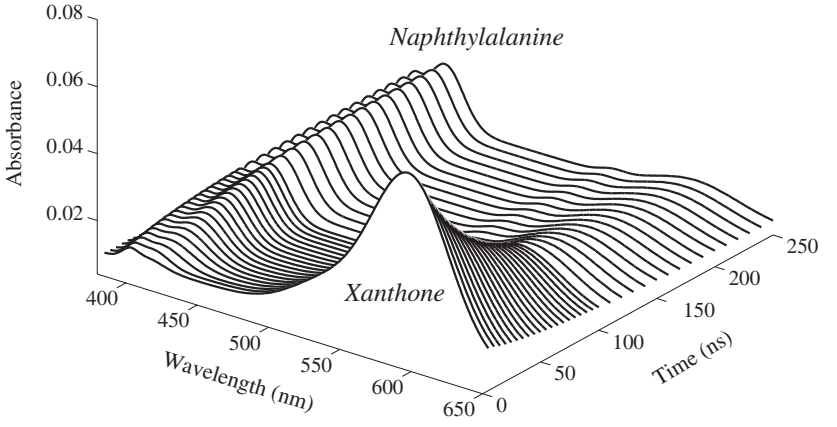

Fig. 22.5. Time-dependent change in the absorbance spectrum of a Xan-(Gly-Ser)$_{14}$-NAla-Ser-Gly peptide after a 4 ns laser flash at 355 nm. The decay in the intensity of the xanthone triplet absorbance band around 590 nm is accompanied by a corresponding increase in the naphthalene triplet absorbance band around 420 nm. Adapted from Ref. [54].

limit of the experimental time window accessible by TTET is set by the intrinsic lifetime of xanthone which is around 20–30 μs in water. Xanthone has a high quantum yield for intersystem crossing ($\phi_{ISC} = 0.99$, $\varepsilon \approx 4000\ M^{-1}\ cm^{-1}$) and the triplet state has a strong absorbance band with a maximum around 590 nm in water ($\varepsilon^{T}_{590} \approx 10\,000\ M^{-1}\ cm^{-1}$). This allows single-pulse measurements at rather low peptide concentrations (10–50 μM).

The low concentrations applied in the experiments also rule out contributions from intermolecular transfer reactions that would have half-times higher than 50 μs in this concentration range [50, 54]. Also contributions from through-bond transfer processes can be neglected, since this cannot occur over distances beyond eight bonds [57, 58] and even the shortest peptides used in TTET studies had donor and acceptor separated by 11 bonds.

Bieri et al. [50] initially used a derivate of thioxanthone as triplet donor and the nonnatural amino acid naphthylalanine (NAla) as triplet acceptor (see Figure 22.3B). Because of the sensitivity of the triplet energy of the donor on solvent polarity the measurements had to be carried out in ethanol. TTET detected single exponential kinetics in all peptides with time constants of 20 ns for the shortest loops in poly(glycine-serine)-based polypeptide chains [50]. The length dependence of contact formation in these peptides did not exhibit a maximum rate constant for transfer at $n = 10$, in contrast to the predicted behavior [53] (see Section 22.4.2.2). Based on these findings, the minimum time constant for intrachain contact formation was shown to be around 20 ns for short and flexible chains. The thioxanthone used in the initial experiments as triplet donor was later replaced by xanthone [54], which has a higher triplet energy than thioxanthone and thus allowed measurements in water (see Figure 22.3C). These results showed two- to threefold faster

rate constants for contact formation compared to the same peptides in ethanol [54], setting the time constant for intrachain diffusion in short flexible chains in water to 5–10 ns. The faster kinetics compared to the thioxanthone/NAla system could be attributed to the effect of ethanol [54] (see below).

A disadvantage of TTET from xanthone to NAla in its application to natural proteins is that Tyr, Trp, and Met interact with the xanthone triplet state either by TTET or by triplet quenching and thus should not be present in the studied polypeptide chains [55].

Lapidus et al. [59] used a related system to measure chain dynamics in short peptides. In this approach contact formation was measured by quenching of tryptophan triplet states by cysteine (see Figure 22.3D). Tryptophan can be selectively excited by a laserflash ($\phi_{ISC} = 0.18$, $\varepsilon_{266} \approx 3500\ M^{-1}\ cm^{-1}$, $\varepsilon^{T}_{460} \approx 5000\ M^{-1}\ cm^{-1}$) and its triplet decay can be monitored by absorbance spectroscopy [60]. The advantage of this system is that donor chromophore and quencher groups are naturally occurring amino acids, which can be introduced at any position in peptides and proteins. As in the case on TTET from xanthone to naphthalene some amino acids interfere with the measurements (e.g., Tyr, Met) since they interact with tryptophan triplets and should thus not be present in the studied polypeptide chains [61].

Major disadvantages of the Trp/Cys system are, (i) that the formation of tryptophan triplets is slow ($\tau = 3$ ns) [62], (ii) that triplet quenching is accompanied by the formation of S·radicals [59], and (iii) that the quenching process is not diffusion controlled [63]. These properties reduce the time window available for the kinetic measurements and do not allow direct and model-free analysis of the quenching time traces (see Experimental Protocols, Section 22.7). In addition, its low quantum yield makes the detection of the triplet states and the data analysis difficult, especially since the kinetics are obscured by radical absorbance bands. In addition to cysteine quenching, two other systems were presented by the same group [59] with cystine or the cyclic disulfide lipoate serving as quencher instead of cysteine (Figure 22.3E). The advantage of using lipoate is that the quenching kinetics are much closer to the diffusion limit. Thus, the rates measured with this system are generally faster. Still, all systems used for quenching of tryptophan triplets gave significantly slower kinetics of intrachain contact formation compared to TTET from xanthone to NAla in the same or in similar sequences (see Tables 22.1 and 22.2). This indicates that tryptophan triplet quenching does not allow measurements of chain dynamics on the absolute time scale [63].

Another recent experimental approach investigated intrachain contact formation in unfolded cytochrome *c* using electron transfer from a triplet excited Zn-porphyrine group to a Ru complex, which was bound to a specific histidine residue (His33; Figure 22.3G). Since electron transfer is fast and close to the diffusion limit these experiments should also yield absolute rate constants for chain diffusion. Contact formation in the 15-amino-acid loop from cytochrome *c* was observed with a time constant of 250 ns [64] in the presence of 5.4 M GdmCl. This is significantly faster than the dynamics in unfolded cytochrome *c* reported by Hagen et al. [52] under similar conditions. However, the dynamics measured by Chang et al. agree well with TTET measurements [50, 54, 55], when the kinetics are extrapolated from 5.4 M GdmCl to water (see below).

22.4.1.3 Fluorescence Quenching

Other approaches to measure contact formation applied quenching of long-lifetime fluorescence probes. Two studies used 2,3-diazabicyclo[2,2,2]oct-2-ene (DBO) as a fluorophore (see Figure 22.3F) [65, 66]. It has a lifetime of up to 1 μs and its excited singlet states can be quenched by tryptophan upon contact. The quenching rate of DBO by tryptophan lies close to the diffusion-controlled limit in water, yet the obtained rates are about a factor of 3 slower than the ones obtained with the xanthone/NAla system in the same peptides [54]. This suggests that the photochemistry of fluorescence quenching may not be faster than breakage of the van der Waals contact between DBO and Trp (see Figure 22.6 and Experimental Protocols, Section 22.7). Another disadvantage of this method is the rather short lifetime of the DBO excited state (< 1 μs), which limits the method to short peptides.

Recently, intrachain diffusion was measured using single molecule fluorescence quenching. Peptides were labeled with a fluorescent dye (MR121) which was quenched by tryptophan [67]. The quenching was reported to only occur efficiently via van der Waals contact. Contact formation between the labels resulted in fluorescence fluctuations, which were recorded by confocal fluorescence microscopy. The rate constants for contact formation were determined using time-correlated single-photon counting. The calculated rates are, however, significantly lower than those determined by more direct methods.

22.4.2 Experimental Results on Dynamic Properties of Unfolded Polypeptide Chains

The different systems presented above were applied to measure intrachain contact formation in a large variety of model peptides. The rates for contact formation have

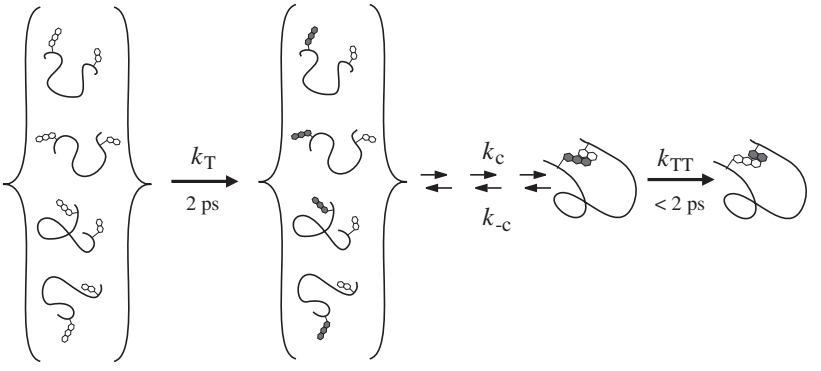

Fig. 22.6. Schematic representation of the triplet–triplet energy transfer (TTET) experiments. Triplet donor and acceptor groups are attached at specific positions on an unstructured polypeptide chain. Triplet states are produced in the donor group by a short laser flash and transferred to the acceptor upon encounter at van der Waals distance in a diffusion-controlled process. The experiments allow determination of the absolute rate constant for contact formation (k_c) in the ensemble of unfolded conformation, if formation of the triplet state (k_T) and the transfer process (k_{TT}) are much faster than chain dynamics ($k_T, k_{TT} \gg k_{-c}, k_c$; see Experimental Protocols, Section 22.7). The rate constants given for k_T and k_{TT} were taken from Ref. [56].

been found to vary depending on the method applied, on the sequence of the peptide and on the peptide length. Results from different groups are compared in Tables 22.1 and 22.2. The results reveal that TTET and electron transfer, which were shown to have fast photochemistry and diffusion-controlled transfer reactions, give virtually identical rate constants and have the fastest contact rates of all applied methods. These methods obviously allow the determination of absolute rate constants for contact formation. In the following, we will discuss results from experiments that used these methods to determine the effect of chain length, amino acid sequence and solvent properties on the rate constants of contact formation.

22.4.2.1 Kinetics of Intrachain Diffusion

All experiments applying TTET [50, 54] and electron transfer [64] to measure dynamics of unfolded polypeptide chains revealed single exponential kinetics on the ns time scale or slower (Figure 22.7). The only exception were short proline-containing peptides, where the kinetics of *cis* and *trans* Xaa-Pro peptide bonds could be resolved [54]. From the observation of single exponential kinetics several conclusions can be drawn. As observed by Szabo, Schulten, and Schulten [7] and pointed out by Zwanzig [68], single exponential kinetics indicate fast interconversion between the different conformations in the ensemble of unfolded states, thus allowing the chain to maintain the equilibrium distribution of the ensemble of conformations that has not made contact. Fast interconversion between individual chain conformations is in agreement with results on conformational relaxation processes in strained peptides, which were shown to occur in the picoseconds time scale [69, 70]. Secondly, the contact radius is small compared to the chain length, which leads to a small probability of contact formation in agreement with the observation that triplet–triplet transfer can only occur when the two labels are in van der Waals contact [7, 68]. A small fraction of chain conformations in equilibrium are predicted to have very short donor–acceptor distances [63] which might allow contact formation on the subnanosecond time scale. From the nanosecond TTET experiments it can be ruled out, however, that a significant fraction (> 5–10%) of chain molecules form donor–acceptor contacts on the subnanosecond time scale, even in the shortest peptides [54]. However, the dynamics of linear peptides in the subnanoseconds time region has not been investigated yet. The fast photochemistry of TTET between xanthone and naphthalene should allow the study of peptide dynamics on the picosecond time scale to detect small fraction of fast transfer processes.

22.4.2.2 Effect of Loop Size on the Dynamics in Flexible Polypeptide Chains

The scaling of the end-to-end diffusion with loop size was measured in TTET experiments by varying the number of amino acids between xanthone and naphthylalanine in two series of homopolypeptides. One series represented flexible polypeptide chains of Xan-$(Gly\text{-}Ser)_x$-NAla-Ser-Gly peptides with x varying from 1 to 28. These peptides allowed measurements of contact formation kinetics between two points on the chain separated by between 3 and 57 peptide bonds, which covers the range of side-chain contacts in small proteins. Figure 22.7 displays three repre-

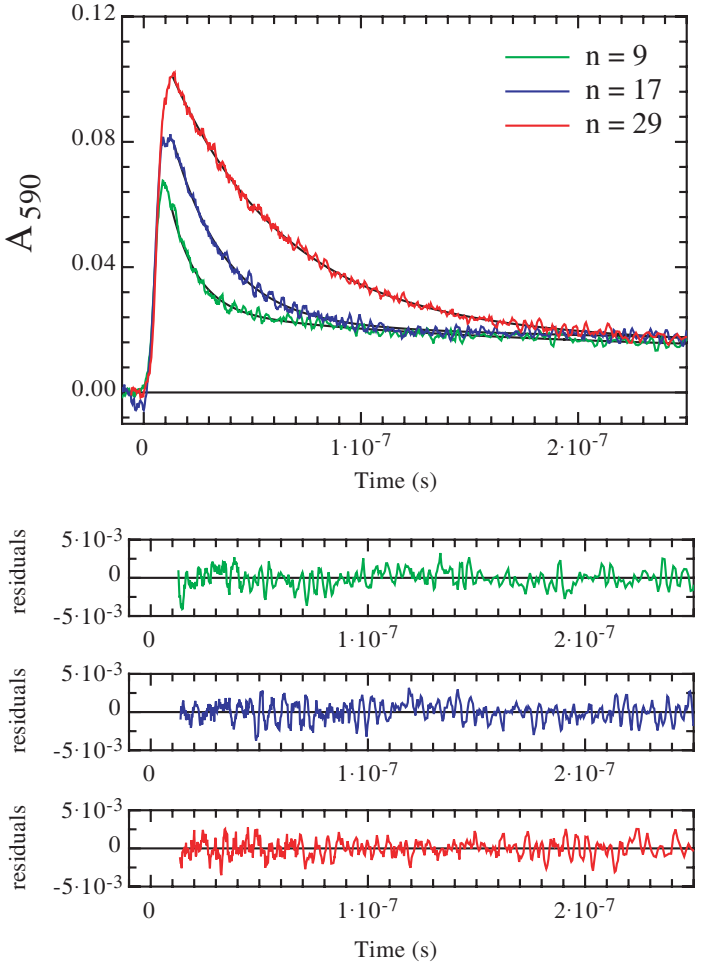

Fig. 22.7. Time course of formation and decay of xanthone triplets in peptides of the form Xan-(Gly-Ser)$_x$-NAla-Ser-Gly after a 4 ns laser flash at $t = 0$ measured by the change in absorbance of the xanthone triplets at 590 nm. Data for different numbers of peptide bonds (n) between donor and acceptor are displayed. Additionally, single exponential fits of the data and the corresponding residuals are shown. The fits gave time constants shown in Figure 22.8. Adapted from Ref. [54].

sentative TTET kinetics for peptides from this series. As mentioned above, single exponential kinetics for contact formation were observed for all peptides.

Figure 22.8 shows the effect of increasing loop size on the rate constant for contact formation. For long loops ($n > 20$) the rate of contact formation decreases with $n^{-1.7\pm0.1}$ (n is the number of peptide bonds between donor and acceptor). This indicates a stronger effect of loop size on the rate of contact formation than expected for purely entropy-controlled intrachain diffusion in ideal freely jointed Gaussian

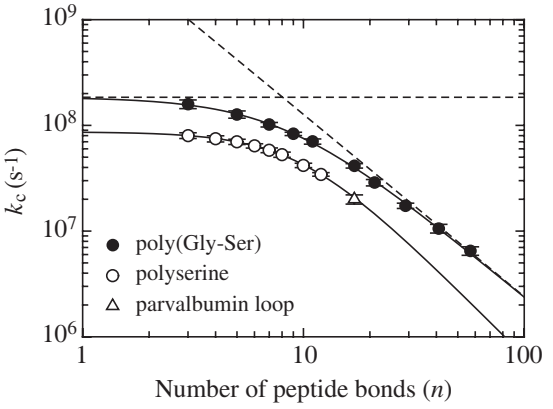

Fig. 22.8. Comparison of the rate constants (k_c) for end-to-end diffusion in poly(glycine-serine) (filled circles), polyserine (open circles) and a parvalbumin loop fragment 85–102 (triangles) measured by TTET between xanthone and naphthylalanine. The data were fitted to Eq. (16) and gave results of $k_a = (1.8 \pm 0.2) \cdot 10^8\ s^{-1}$, $k_b = (6.7 \pm 1.6) \cdot 10^9\ s^{-1}$ and $m = 1.72 \pm 0.08$ for the poly(glycine-serine) series and of $k_a = (8.7 \pm 0.8) \cdot 10^7\ s^{-1}$, $k_b = (1.0 \pm 0.8) \cdot 10^{10}\ s^{-1}$ and $m = 2.1 \pm 0.3$ for polyserine. The dashed lines indicate the limiting cases for dynamics for short chains ($k_c = k_a$) and long chains $k_c = k_b \cdot n^{-m}$). Data were taken from Refs [54, 55].

chains, which should scale with $k \sim n^{-1.5}$ (see above) [4, 7]. However, Flory already pointed out that excluded volume effects should significantly influence the chain dimensions [11]. Accounting for excluded volume effects in the end-to-end diffusion model of Szabo, Schulten, and Schulten [7] gives $k \sim n^{-1.8}$, which is nearly identical to the value found for the long poly(Gly-Ser) chains [54]. This indicates that the dimensions and the dynamics of unfolded polypeptide chains in water are significantly influenced by excluded volume effects, which is in agreement with recent results on conformational properties of polypeptides derived from simplified Ramachandran maps [25]. Additionally, hydrodynamic interactions and the presence of small enthalpic barriers, which were observed in the temperature dependence of intrachain diffusion might contribute to the length dependence (F. Krieger and T. Kiefhaber, unpublished).

The observed simple scaling law breaks down for $n < 20$ and contact formation becomes virtually independent of loop size for very short loops with a limiting value of $k_a = 1.8 \cdot 10^8\ s^{-1}$. As pointed out above, the limiting rate constant for contact formation in short loops is not due to limits of TTET (k_{TT} in Figure 22.6), since this process is faster than 2 ps. Obviously, the intrinsic dynamics of polypeptide chains are limited by different processes for motions over short and over long segments. This is in agreement with polymer theory, which suggests that the properties of short chains are strongly influenced by chain stiffness. This leads to a breakdown of theoretically derived scaling laws for ideal chains [12]. To compare the experimental results with predictions from polymer theory the effect of loop size on the rate constants for contact formation (Figure 22.8) can be compared to

the length dependence of the characteristic ratio (C_n; Figure 22.2). By comparison with polymer theory the limiting value for k_c for formation of short loops might be related to intrinsic chain stiffness, which causes the increase in C_n with chain length for short chains (see Section 22.2).

The 1:1 mixture of glycine and serine used in these experiments is expected to have a C_∞-value of about 3 and C_∞ should be reached for $n > 10$ (Figure 22.2) [21]. Figure 22.8 shows, however, that the poly(glycine-serine) chains behave like random chains only over distances longer than 20–30 amino acids, where $k_c \sim n^{-1.7}$. This indicates increased chain stiffness compared to the predicted value, which could be due to specific intrachain hydrogen bonds or van der Waals interactions and to excluded volume effects that restrict the number of chain conformations. This model is supported by the measurements of activation energies for the peptides of different length. Formation of long loops shows very low activation enthalpies whereas formation of short loops encounter significant energy barriers (F. Krieger and T. Kiefhaber, unpublished).

The complete effect of loop size on intrachain contact formation can be described by a model where length-dependent diffusional processes, which scale with $k = k_b \cdot n^{-m}$, limit the kinetics of formation of long loops. Contact formation reaches a limiting rate constant (k_a) when these diffusional motions become slower than length-independent short-range motions, which are probably governed by chain stiffness and steric effects. Accordingly, the effect of loop size on contact formation can be described by

$$k_c = \frac{1}{1/k_a + 1/(k_b \cdot n^{-m})} \tag{16}$$

The fit of the experimental results to Eq. (16) is shown in Figure 22.8 and gives a value of $k_a = (1.8 \pm 0.2) \cdot 10^8$ s^{-1}, $k_b = (6.7 \pm 1.6) \cdot 10^9$ s^{-1}, and $m = 1.72 \pm 0.08$ for poly(glycineserine), as discussed above.

22.4.2.3 Effect of Amino Acid Sequence on Chain Dynamics

Both theoretical considerations [18, 19, 21] (see Section 22.2) and experimental results from NMR measurements [71] show that polypeptide chains are especially flexible around glycyl residues. All amino acids except proline ($C_\infty > 100$) and glycine ($C_\infty = 2.2$) are predicted to have C_∞-values around 8.5–9.5 and C_∞ should be reached for intrachain distances longer than about 40–50 amino acids [18, 19, 21] (Figure 22.2). This indicates increased chain stiffness and longer root mean square end-to-end distances ($\sqrt{\langle r^2 \rangle_0}$) compared to the poly(glycine-serine) series (Figure 22.2). The effect of chain stiffness on peptide dynamics was tested in TTET experiments in polyserine chains [54]. Figure 22.8 compares the effect of loop size on intrachain diffusion in a series of Xan-$(Ser)_x$-NAla-Ser-Gly peptides with $x = 2$–11 ($n = 3$–12) to the behavior of poly(Gly-Ser) chains. Single exponential kinetics for contact formation were observed in all polyserine peptides. For short loops ($n < 5$) contact formation is virtually independent of loop size with a limiting value of $k_a = 8.7 \cdot 10^7$ s^{-1} (see Eq. (18)). This indicates that the local dynamics in polyser-

ine are about two- to threefold slower than in the poly(glycine-serine) peptides, which seems to be a small effect compared to the largely different properties expected for the stiffer polyserine chains (see Figure 22.2).

The decreased flexibility and the longer donor-acceptor distances in the polyserine chains are probably compensated by the decreased conformational space available for polyserine compared to poly(glycine-serine) peptides. [54] For longer polyserine chains contact formation slows down with increasing loop size. The effect of increasing loop size on the rates of contact formation seems to be slightly larger in polyserine compared to the poly(glycine-serine) series ($m = 2.1 \pm 0.3$; $k_b = (1.0 \pm 0.8) \cdot 10^{10}$ s^{-1}; see Eq. (16)). However, due to limitations in peptide synthesis it was not possible to obtain longer peptides, which would be required to get a more accurate scaling law for the polyserine peptides.

The kinetics of formation of short loops differ only by a factor of 2 for polyserine compared with poly(glycine-serine), arguing for only little effect of amino acid sequence on local chain dynamics (Figure 22.8). The effect of other amino acids on local chain dynamics was measured by performing TTET experiments on short host–guest peptides of the canonical sequence Xan-Ser-Xaa-Ser-NAla-Ser-Gly using the guest amino acids Xaa = Gly, Ser, Ala, Ile, His, Glu, Arg, and Pro [54]. Figure 22.9 shows that the amino acid side chain indeed has only little effect on the rates of contact formation. All amino acids except proline and glycine show very similar dynamics. Interestingly, there is a small but significant difference in rate between short side chains (Ala, Ser) and amino acids with longer side chains (Ile, Glu, Arg, His). Obviously, chains that extend beyond the C_β-atom slightly decrease the rates

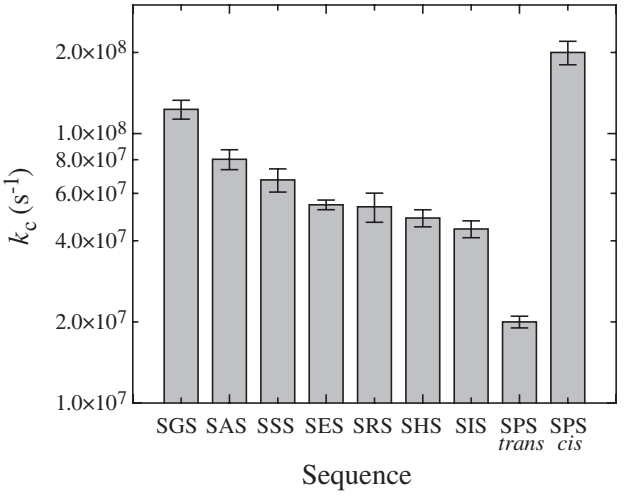

Fig. 22.9. Effect of amino acid sequence on local chain dynamics measured in host–guest peptides with the canonical sequence Xan-Ser-Xaa-Ser-NAla-Ser-Gly. The guest amino acid Xaa was varied and the rate constants for the different guest amino acids are displayed. Data taken from Ref. [54].

of local chain dynamics, whereas charges do not influence the dynamics. Glycyl and prolyl residues show significantly different dynamics compared with all other amino acids, as expected from their largely different conformational properties [19].

As shown before (Figure 22.8) glycine accelerates contact formation about two- to threefold compared with serine. Proline shows slower and more complex kinetics of contact formation with two rate constants of $k_1 = 2.5 \cdot 10^8$ s^{-1} and $k_2 = 2 \cdot 10^7$ s^{-1} and respective amplitudes of $A_1 = 20 \pm 5\%$ and $A_2 = 80 \pm 5\%$. This essentially reflects the *cis–trans* ratio at the Ser-Pro peptide bond in our host–guest peptide, which has a *cis* content of $16 \pm 2\%$ as determined by 1D ^{1}H-NMR spectroscopy using the method described by Reimer et al. [72]. Since the rate of *cis–trans* isomerization is slow ($\tau \sim 20$ s at 22 °C) there is no equilibration between the two isomers on the time scale of the TTET experiments. This allows the measurement of the dynamics of both the *trans* and the *cis* form. The results show that the two isomers significantly differ in their dynamic properties of $i, i+4$ contact formation and that the *cis*-prolyl isomer actually shows the fastest rate of local contact formation of all peptides (Figure 22.9).

22.4.2.4 Effect of the Solvent on Intrachain Diffusion

The dynamics of short poly(glycine-serine) peptides measured with the xanthone–naphthalene TTET pair in water [54] were about 3 times faster than the previously measured rates in the same peptides using the thioxanthone–naphthalene pair in EtOH [50], although both systems were shown to be diffusion-controlled. Figure 22.10 shows that this difference can be attributed to solvent effects [54]. $\ln k_c$ linearly decreases with increasing EtOH concentration in a Xan-(Gly-Ser)$_4$-NAla-Ser-Gly peptide (Figure 22.10A). EtOH is a better solvent for polypeptide chains than water and should thus lead to a more extended ensemble of unfolded states. This model was supported by measuring the effect of GdmCl and urea on the contact rates in aqueous solutions. Both denaturants show similar effects on intrachain diffusion as EtOH, with a linear decrease in $\ln k_c$ with increasing denaturant concentration. Interestingly, the change in $\ln k_c$ with denaturant concentration ($m_c = \partial \ln k_c / \partial$ [Denaturant]) is twofold higher for GdmCl compared with urea, which essentially corresponds to their relative strength in unfolding proteins [73] (see below). Similar m_c-values for EtOH, urea and GdmCl were observed in a Xan-(Ser)$_9$-NAla-Ser-Gly peptides. [54] The observed effect is significantly stronger than expected from the increased solvent viscosity in concentrated GdmCl and urea solutions [50, 74].

The effect of GdmCl and urea on the chain dynamics suggested that these cosolvents may significantly change the chain properties. This was supported by measurements of the effect of GdmCl on the distance dependence of intrachain contact formation. Figure 22.10B compares the effect of loop size on the kinetics of contact formation in the Xan-(Gly-Ser)$_n$-NAla-Ser-Gly series in 8 M GdmCl and water. At high denaturant concentrations the switch from the length-independent dynamics to the length-dependent regime occurs already for formation of shorter loops. This indicates decreased chain stiffness in 8 M GdmCl compared with

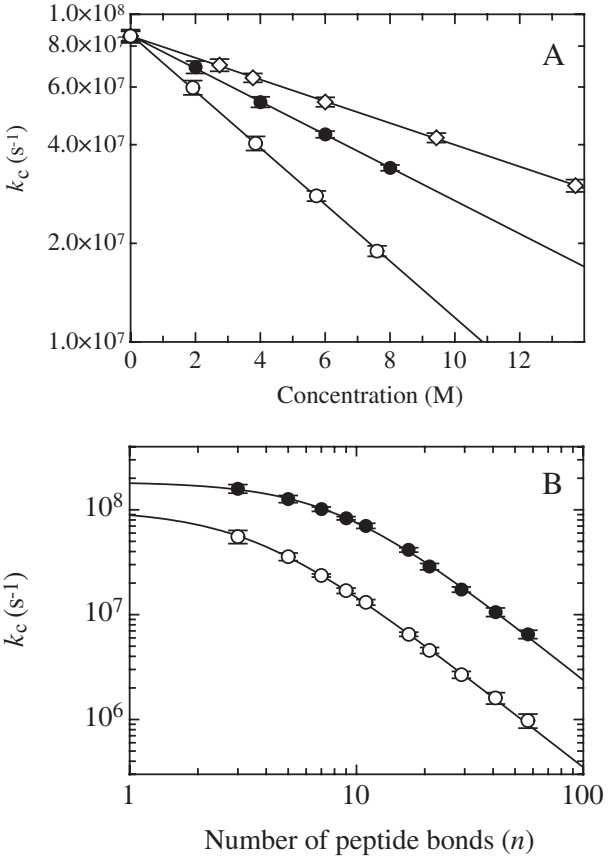

Fig. 22.10. A) Effect of various co-solvents on the dynamics of intrachain contact formation in a Xan-(Gly-Ser)$_4$-NAla-Ser-Gly peptide measured by TTET. Measurements were performed in aqueous solutions in the presence of ethanol (diamonds), urea (filled circles) and GdmCl (open circles). B) Effect of donor–acceptor distance (n) on the rate constant of contact formation in series of poly(Gly-Ser) peptides (cf. Figure 22.8). The rate constants for contact formation in water (filled circles) are compared with the values in 8 M GdmCl (open circles). Data taken from Ref. [54].

water, although the dynamics are significantly slowed down in the presence of GdmCl both for formation of short and long loops (Figure 22.10). For long peptides the effect of chain length on the rates of contact formation is similar in 8 M GdmCl and water with $k_c \sim n^{-1.8\pm0.1}$. These results revealed that denaturants like GdmCl and urea slow down local chain dynamics but lead to more flexible chains that behave like ideal polymers already at shorter donor–acceptor distances (Figure 22.10B). These seemingly contradicting findings can be rationalized based on the effect of denaturants on the conformational properties of polypeptide chains. Unlike water, solutions with high concentrations of denaturants represent good solvents for polypeptide chains. This reduces the strength of intramolecular in-

teractions like hydrogen bonds and van der Waals interactions relative to peptide–solvent interactions, which makes unstructured polypeptide chains more flexible and leads to a behavior expected for an unperturbed chain.

In agreement with this interpretation the effect of loop size on the rates of contact formation in 8 M GdmCl is close to the behavior of an unperturbed polypeptide chain predicted by Flory and coworkers [21] (see Figure 22.2). The decreased rate of contact formation at high denaturant concentrations can only in part be explained by an increased solvent viscosity. Additional effects like increased donor–acceptor distance, which is expected in good solvents compared to water and denaturant binding might also contribute to the decreased rate constants [74].

22.4.2.5 **Effect of Solvent Viscosity on Intrachain Diffusion**

Intrachain contact formation was shown to be strongly viscosity dependent as expected for a diffusional reaction. Viscosity effects on contact formation rates have been measured in TTET experiments on poly(Gly-Ser) peptides [50] (F. Krieger and T. Kiefhaber, unpublished). In all peptides a linear dependency of $\log k_c$ vs. $\log \eta$ was observed and the dependencies could be fitted with the empirical relationship

$$k = \frac{k_0}{\eta^{-\beta}} \tag{17}$$

with $\beta \leq 1$ (Figure 22.11). In the limit for long chains ($n > 15$) the rate of contact formation was found to be inversely proportional to the viscosity ($\beta = 1$) independent of the co-solvent used to alter the viscosity of the solution. In the limit for

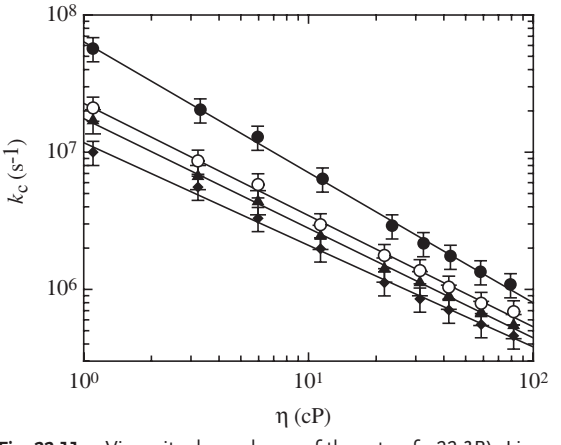

Fig. 22.11. Viscosity dependence of the rate of contact formation for poly(Gly-Ser)$_x$ peptides containing $x = 1$ (filled circles), 2 (open circles), 3 (filled triangles) and 4 (filled diamonds) glycine-serine pairs between thioxanthone and naphthylalanine (cf. Figure 22.3B). Linear fits of the double logarithmic plot of the data give slopes of -0.96 ± 0.05, -0.83 ± 0.05, -0.80 ± 0.05, and -0.81 ± 0.05, respectively. Experiments were carried out in ethanol/glycerol mixtures. Data were taken from Ref. [50].

short chains ($n < 10$), β was smaller than unity (0.8–0.9) [50]. This is not compatible with theoretical consideration which predict $\beta = 1$ as a result from Stokes law relating the solvent viscosity and the diffusion coefficient. β-values < 1 have also been observed for motions of simpler polymers in organic solvents [75–77] and for dynamics of native proteins [78–80].

Several origins have been proposed to explain such behavior like either position-dependent [81] or frequency-dependent [82, 83] friction coefficients. In addition, experiments on myoglobin [80] suggested that deviations from the Stokes law can also be caused by the structure of protein–solvent interfaces, which preferably contain water molecules and have the viscous co-solvent molecules preferentially excluded [84]. This results in a smaller microviscosity around the protein compared with bulk solvent. Additional experiments will be needed to identify the origin of fractional viscosity dependencies of dynamics in short chains.

22.4.2.6 End-to-end Diffusion vs. Intrachain Diffusion

When side-chain contacts are formed within a polypeptide chain during the folding process, the residues are commonly not located near the end of the polypeptide chain. Thus, the end-to-end contact formation experiments represent a rather specific and rare situation during the folding process. Based on the location of the contact sites, three categories of contact formation events in polymers can be distinguished (Figure 22.12). Type I corresponds to end-to-end contact formation. Type II corresponds to end-to-interior contacts and type III contacts are formed between two position remote from the chain ends. Measurements in long hydrocarbon chains yielded trends that cyclization rates are slowed down by additional groups at the ends of the chain [46] without yielding absolute magnitudes of the effects. The xanthone–NAla TTET system has proved to be suitable to perform such experiments in peptides. TTET experiments in type II and III systems have shown that k_c depends on the size of the additional tail (B. Fierz and T. Kiefhaber, unpublished). The strength of the effect is dependent on the nature of the sequence in the observed segment. In long and flexible chains between the labels (i.e., the long chain limit) the dependence on tail length is weaker than for short or stiff chains (the short chain limit).

Such behavior has been predicted by theory [85]. The observed effect should correlate with the surface of the additional amino acids on the ends, if solvent friction limits chain motions as suggested by the viscosity-dependence of the chain diffusion. However the chain movements should only be slowed down to a limiting value. In this limit, the segmental dynamics are independent on further extension of the chain. This limiting rate of innersegmental diffusion corresponds to the maximal rate at which specific side-chain contacts can be formed in the interior of a protein during folding.

22.4.2.7 Chain Diffusion in Natural Protein Sequences

Recently, contact formation rates have been measured in natural protein sequences from cytochrome *c* [64] and carp parvalbumin [55]. The results from these dynam-

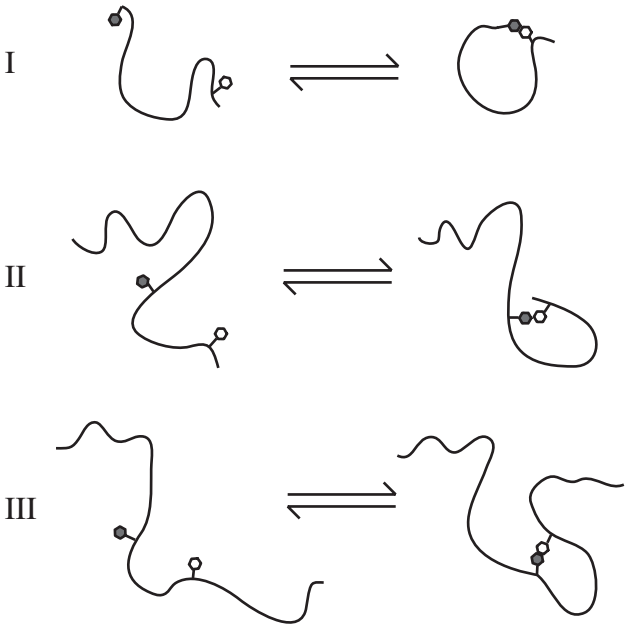

Fig. 22.12. Schematic representation of different types of contact formation in polymer chains. For details see text.

ics are in agreement with dynamics expected from the host–guest studies shown in Figure 22.9. The 18-amino-acid EF-loop of carp parvalbumin connects two α-helices and brings two phenylalanine residues into contact in the native protein, which were replaced by xanthone and naphthylalanine to measure TTET kinetics (Figure 22.13) [55]. The measured kinetics were single exponential (Figure 22.14) and the time constant for contact formation ($\tau = 50$ ns) was comparable to the dynamics for polyserine chains of the same length (Figure 22.8). The EF-loop contains several large amino acids like Ile, Val, and Leu but also four glycyl residues. Obviously, the effects of slower chain dynamics of bulkier side chains and faster dynamics around glycyl residues compensate, which leads to dynamics comparable to polyserine chains. These results indicate that polyserine is a good model to estimate the dynamics of glycine-containing loop sequences in proteins.

The Zn-porphyrine/Ru system was used to measure contact formation in cytochrome *c* unfolded in 5.4 M GdmCl [64]. The donor and quencher groups were separated by 15 amino acids (Figure 22.13) and contact formation was significantly slower ($\tau = 250$ ns) than for polyserine peptide chains of the same length. However, correcting for the effects of denaturant concentration (see Figure 22.10) and end-extensions (Section 22.4.2.6) on chain dynamics gives rate constants for the cytochrome *c* sequence which are comparable to the parvalbumin EF-loop in water.

[55].

22.5 Implications for Protein Folding Kinetics

22.5.1 Rate of Contact Formation during the Earliest Steps in Protein Folding

The results on the time scales of intrachain diffusion in various unfolded polypeptide chains show that the amino acid sequence has only little effect on local dynamics of polypeptide chains. All amino acids show very similar rates of end-to-end diffusion with time constants between 12 and 20 ns for the formation of $i, i+4$

Fig. 22.13. A) Ribbon diagram of the structure of carp muscle β-parvalbumin [127]. Phe85 and Phe102 are shown as space-fill models. The phenylalanine residues have been replaced by the triplet donor and acceptor labels, xanthonic acid and naphthylalanine, respectively. The figure was prepared using the program MolMol [128] and the PDB file 4CPV [127]. B) Sequence of the carp muscle β-parvalbumin EF loop region (residues 85–102) and the synthesized fragment labeled with the two phenylalanine residues at position 85 and 102 replaced by donor (xanthone) and acceptor (naphthylalanine) groups for triplet–triplet energy transfer. C) Sequence from cytochrome *c* between the Zn-pophyrine group (excited triplet group) and the Ru-His complex used in triplet quenching experiments reported by Chang et al. [64].

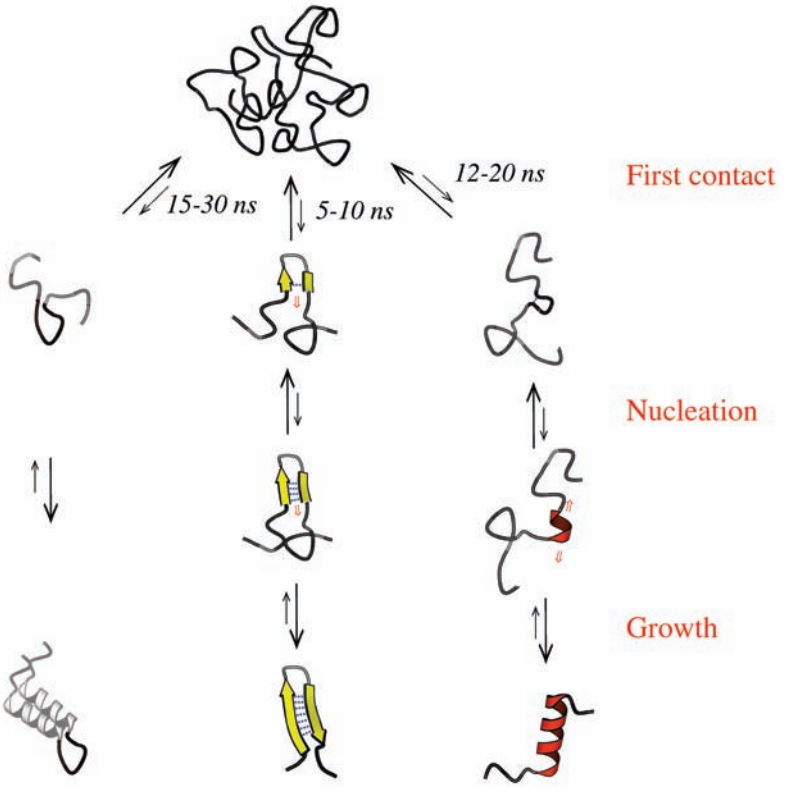

Fig. 22.15. Schematic representation of the time constants for the first steps in formation of loops, β-hairpins and α-helices during protein folding derived from the data measured by TTET in water. Adapted from Ref. [54].

contacts. Polypeptide chains are significantly more flexible around glycine ($\tau = 8$ ns) and stiffer around prolyl residues ($\tau = 50$ ns for the *trans* isomer). Presumably due to the shorter chain dimensions resulting from a *cis* peptide bond the rates of $i, i+4$ contact formation are fastest around the *cis* Ser-Pro bond ($\tau = 4$ ns). These results allow to set an upper limit for the rates of formation of the first productive local contacts during protein folding (Figure 22.15). They can directly be used to estimate the kinetics of loop formation, which are typically of the size of 6–10 amino acids [86]. The results suggest that loops can form with time constants of about 15 ns for glycine-rich loops and 30–40 ns for stiffer loops. β-hairpins, which are the most local structures in proteins, are often rich in glycine and proline [87]. Gly-Ser is actually one of the most frequent sequences found in hairpin loops. The results indicate that the time constants for the first steps in the formation of the tightest turns with $i, i+3$ contacts are around 5 ns for Gly and *cis* Xaa-Pro (Figures 22.8 and 22.9). In glycine- and proline-free turns these rates are slowed down to about 10–20 ns, depending on the amino acid sequence.

Formation of α-helices is most likely initiated by formation of a helical turn,

which involves formation of an $i, i+4$ interaction [88, 89]. Since helices are usually free of glycyl and prolyl residues the initiation cannot occur faster than in about 12–20 ns (Figures 22.8 and 22.9). It should be noted that these values do not represent time constants for nucleation of helices and hairpins (Figure 22.15), which most likely requires formation of more than one specific interaction and most likely encounters additional entropic and enthalpic barriers. The results on the rates of intrachain contact formation rather represent an upper limit for the dynamics of the earliest steps in secondary structure formation (i.e., $<$ for formation of the first contact during helix nucleation). They represent the prefactors (k_0) in the rate equation for secondary structure formation

$$k = k_0 \cdot e^{-\Delta G^{\circ\ddagger}/RT} \tag{18}$$

The measured contact rates thus allow us to calculate the height of the free energy barriers ($\Delta G^{\circ\ddagger}$) when they are compared to measured rate constants (k) for secondary structure formation. However, up to date no direct data on helix or hairpin formation in short model peptides are available. The dynamics of secondary structures were mainly studied by relaxation techniques like dielectric relaxation [90], ultrasonic absorbance [91], or temperature jump [92–94] starting from predominately folded structures (for a review see Ref. [95]). Since helix–coil and hairpin–coil transitions do not represent two-state systems, neither thermodynamically nor kinetically, the time constants for unfolding can not be directly related to rate constants of helix formation [96]. However, the observation of relaxation times around 1 μs for helix unfolding allowed the estimation of time constants for the growth steps of nucleated helices of about 1 to 10 ns, depending on the experimental system [90, 91, 93].

It may be argued that intrachain contacts in a polypeptide chain with a stronger bias towards folded structures can form faster than the observed dynamics in unstructured model polypeptide chains. However, weak interactions like van der Waals contacts between side chains and hydrogen bonds should dominate the early interactions during the folding process and the data on the dynamics of unfolded chains will provide a good model for the earliest events in folding. A stronger energy bias towards the native state will mainly increase the strength or the number of these interactions but not their dynamics of formation.

22.5.2
The Speed Limit of Protein Folding vs. the Pre-exponential Factor

Many small single domain proteins have been found to fold very fast, some of them even on the 10 to 100 μs time scale (for a review see Ref. [97]). These fast folding proteins include α-helical proteins like the monomeric λ-repressor [98, 99] or the engrailed homeodomain [100], β-proteins like cold shock protein of *Bacillus subtilis* or *B. cacodylicus* [101] or the WW-domains [102] and α,β-proteins like the single chain arc repressor [103]. There has been effort to design proteins that fold even faster [104, 105]. A folding time constant of 4.1 μs has been reported for a designed Trp-cage.

These very fast folding proteins sparked interest in finding the speed limit for protein folding, which is closely related to the speed limit of the fundamental steps of protein folding and thus also to the dynamics of the unfolded chain. The results on dynamics of contact formation in short peptides showed that no specific interactions between two points on the polypeptide chain can be formed faster than on the 5–10 ns time scale. Considering that dynamics are slowed down if the two groups are located in the interior of a long chain this time constant increases to about 50 ns. Formation of intrachain interactions represents the elementary step in the conformational search on the free energy landscape. Thus, the dynamics of this process set the absolute speed limit for the folding reaction. However, it will not necessarily represent the prefactor (k_0) for the folding process which represents the maximum rate for protein folding in the absence of free energy barriers ($\Delta G^{\circ\ddagger} = 0$, see Eq. (18)). It was shown that even fast apparent two-state folding proceeds through local minima and maxima on the free energy landscape [106, 107] and up to date it is unclear which processes contribute to the rate-limiting steps in protein folding (see Chapters 12.1, 12.2 and 14).

The transition state for folding seems to be native-like in topology but still partly solvated [108–111], Thus, both protein motions and dynamics of protein–solvent interactions in a native-like topology might contribute to the pre-exponential factor and k_0 will probably depend on the protein and on the location of the transition state along the reaction coordinate, which may change upon change in solvent conditions or mutation (see Section 5.3) [44, 106, 107].

22.5.3
Contributions of Chain Dynamics to Rate- and Equilibrium Constants for Protein Folding Reactions

As discussed above, the pre-exponential factor (k_0) for a protein folding reaction should contain major contributions from the rate of intrachain diffusion in an unfolded or partially folded polypeptide chain [112]. Thus, factors that influence intrachain diffusion, like denaturant concentration (Figure 22.10), will also affect the pre-exponential factor for folding. This will influence the observed folding rate constants and thus also the observed equilibrium constants [112]. A method that allows a quantitative description of reaction rates for processes in solution was developed by Kramers [113]. He considered a particle moving on an energy surface with two metastable states (e.g., native and unfolded protein) separated by a barrier (Figure 22.16). The motion of the particle is diffusional and can be described by the Langevin equation (Eq. (8)). The thermal motion of the solvent is modeled as the random force. Solving the diffusion equations, Kramers observed three different regimes which differ in the strength of interaction between system and environment. In the low friction limit the interactions are only weakly coupled. In this limit the rate of the barrier crossing reaction from the educt to the product state increases with increasing friction γ. In the intermediate friction limit the rate is independent on friction and the results from transition state theory and from Kramers' theory approach each other. In the high friction limit, which should cor-

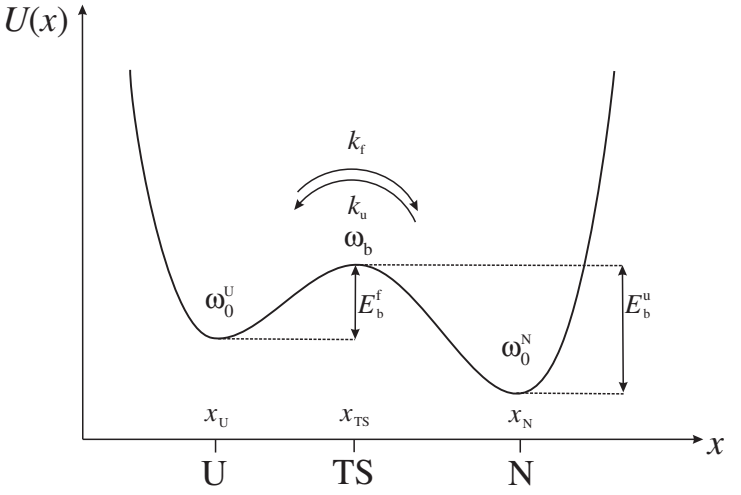

Fig. 22.16. Potential U(x) with two states N and U separated by an energy barriers. Escape from state U to N occurs via the rates k_f and k_u. E_b^f and E_b^u are the activation energies for the forward and back reaction. ω denotes the frequencies of phase point motion at the extremes of the potential. The drawing was adapted from Ref. [114].

respond to most reactions in solution and also to protein folding reactions, the rate of the reaction decreases when the friction is further increased. In this limit the equation for the rate as a function of friction, barrier height and temperature can be written as:

$$k = \frac{\omega_0 \omega_B}{2\pi\gamma} e^{(-E_b/kT)} \tag{19}$$

where ω stands for the frequency of motion of the particle in the starting well (ω_0) and on top of the barrier (ω_B). ω depends on the shape of the barrier and on the nature of the free energy surface [114]. By applying Stokes law this equation can then readily be expressed in terms of thermodynamic parameters and solvent viscosity.

$$k = \frac{C}{\eta(T)} \cdot \exp(-\Delta G^{\circ\ddagger}/RT) = k_0 \cdot \exp(-\Delta G^{\circ\ddagger}/RT) \tag{20}$$

It is not clear whether Kramers' approach in its simple form as described above is directly applicable to protein folding reactions, since it is difficult to measure the viscosity-dependence of folding and unfolding rate constants. The co-solvents used to modify solvent viscosity like glycerol, sucrose, or ethylene glycol generally stabilize the native state [84] and in part also the transition state of folding. This makes a quantification of the effect of solvent viscosity on protein folding rate constants difficult [115, 116].

The results from the viscosity dependence of end-to-end contact formation show that the rate constants in short peptides ($n < 10$) are not proportional to η^{-1} but rather to $\eta^{-0.8}$. This suggests that the presence of barriers in these peptides leads to a more complex behavior than expected from Eq. (20) and indicates that the frictional coefficient from Kramers' theory (γ, see. Eq. (19)) is not only determined by solvent viscosity for protein folding reactions.

Application of Kramers' theory to protein folding reactions shows the problems with quantitatively characterizing the barriers for protein folding. It is very difficult to determine pre-exponential factors for the folding and unfolding reaction, which are most likely different for each protein. Since the pre-exponential factors depend on the shape of the potential and on the dynamics in the individual wells (states), ω_0 will be different for the refolding reaction starting from unfolded protein (ω_0^{U}) and for the unfolding reaction starting from native protein (ω_0^{N}) and hence also the prefactors will be different for the forward and backward reactions. However, under all conditions Eq. (21) must be valid [117]:

$$K_{\mathrm{eq}} = \frac{k_{\mathrm{f}}}{k_{\mathrm{u}}} \tag{21}$$

Thus, the equilibrium constant (K_{eq}) contains contributions from the pre-exponential factors for folding (k_0^{f}) and unfolding (k_0^{u}) and from differences in $\Delta G^{\circ\ddagger}$, according to [112]

$$K_{\mathrm{eq}} = \frac{k_0^{\mathrm{f}} \cdot \mathrm{e}^{-\Delta G_{\mathrm{f}}^{\circ\ddagger}/RT}}{k_0^{\mathrm{u}} \cdot \mathrm{e}^{-\Delta G_{\mathrm{u}}^{\circ\ddagger}/RT}} \tag{22}$$

The contribution of differences in the prefactors for folding and unfolding to $\Delta G^{\circ}(= -RT \ln K_{\mathrm{eq}})$ are consequently [112]

$$\Delta G^{\circ} = \Delta G_{\mathrm{f}}^{\circ\ddagger} - \Delta G_{\mathrm{u}}^{\circ\ddagger} + \Delta G_{\mathrm{pref}}^{\circ}$$

$$\Delta G_{\mathrm{pref}}^{\circ} = RT \ln \frac{k_0^{\mathrm{u}}}{k_0^{\mathrm{f}}} \tag{23}$$

Differences in k_0 for folding and unfolding can thus significantly contribute to apparent protein folding barriers. A fivefold difference in k_0 would contribute 4 kJ mol^{-1} to the experimentally determined barrier height at 25 °C. Consequently, also changes in the dynamics of the unfolded state, which change the pre-exponential factor for the folding reaction by changing ω_0, will influence K_{eq}, even if the heights of the barriers are not changed. For many proteins significant residual structure in the unfolded state has been observed either directly by NMR [27, 28, 34, 43] or from the analysis of the denaturant dependence [44]. It was shown that this residual structure is sensitive to mutation, which can lead to significant changes in the solvent accessibility [44] and in the dynamics [39] of the unfolded state. This will lead to changes in k_0 for the folding reaction (k_0^{f}) by changing ω_0^{U} and will result in a change of the folding rate constant (k_{f}) and consequently also in the apparent free energy of activation, $\Delta G_{\mathrm{f}}^{\circ\ddagger}$(app) even if $\Delta G_{\mathrm{f}}^{\circ\ddagger}$ is

not affected by the mutations [112].

$$\Delta\Delta G_f^{\circ\ddagger}(\text{app}) = \Delta\Delta G_f^{\circ\ddagger} + RT \ln \frac{k_0^f(\text{wt})}{k_0^f(\text{mutant})} \quad (24)$$

As in the example above, a fivefold increase in k_0 of a mutant would apparently decrease $\Delta G_f^{\circ\ddagger}$ by 4 kJ mol^{-1}. This would have large effects on the interpretation of the results in terms of transition state structure (ϕ-value analysis, see Chapters 12.2 and 13), and might contribute to the large uncertainty in ϕ-value from mutants that lead to small changes in ΔG° [111].

Mutants that disrupt residual interactions in the unfolded state will most likely have only little effect on k_0 for unfolding (k_0^u), which should be determined by chain motions in the native state. Most native protein structures and transitions state structures were shown to be rather robust against mutations [44]. Thus, mutations which change the dynamics of unfolded proteins will result in an apparent change in ΔG°, in analogy to the effects discussed above (Eq. (24)).

Figure 22.10 shows that denaturants like urea and GdmCl significantly decrease the rate constants for intrachain diffusion (k_c). According to the considerations discussed above, this will also affect the denaturant dependence of the rate constants for protein folding (m_f-values with $m_f = \partial\Delta G_f^{\circ\ddagger}/\partial[\text{Denaturant}]$). Even if pre-equilibria involving unstable intermediates may dominate the early stages of folding, the observed denaturant dependence of intrachain diffusion will influence these steps by changing the forward rate constants of these equilibria. The m_c-values ($m_c = \partial(-RT \ln k_c)/\partial[\text{Denaturant}]$ for peptide dynamics vary only little with chain length and show values around 0.35 kJ mol^{-1} M^{-1} for urea and 0.50 kJ mol^{-1} M^{-1} for GdmCl [74]. Typical m_f-values for folding of the smallest fast folding proteins with chain length between 40 and 50 amino acids are around 1.0 kJ mol^{-1} M^{-1} for urea, indicating that up to 30% of the measured m_f-values may arise from contributions of chain dynamics. Larger two-state folders consisting of 70–100 amino acids typically show m_f-values around 3 kJ mol^{-1} M^{-1} for urea and 5 kJ mol^{-1} M^{-1} for GdmCl [107, 118], indicating that the denaturant dependence of chain dynamics constitutes up to 10% of the experimental m_f-values.

It is difficult to judge the effect of denaturants on the dynamics of the native state, which will influence the experimental m_u-values. However, it was observed that the effect of denaturants on chain dynamics is mainly based on increased chain dimensions (A. Möglich and T. Kiefhaber, unpublished results). This would argue for only little effects of denaturants on the internal dynamics of the native state and on the transition state structures, which were shown to be structurally robust against changes in denaturant concentration [44, 107, 111]. Thus, the m_u-values should have only little contributions from the effects of denaturants on chain dynamics.

Comparison of kinetic and equilibrium m-values ($m_{eq} = \partial\Delta G^\circ/\partial[\text{Denaturant}]$) is frequently used to characterize protein folding transition states according to the rate-equilibrium free energy relationship [44, 119, 120]:

$$\alpha_D = \frac{m_f}{m_{eq}} \quad (25)$$

α_D is interpreted as a measure for the solvent accessibility of the transition state. The contributions from chain dynamics to the m_f-values of small proteins lead to apparently higher α_D-values and thus to apparently less solvent exposed transition states. This might explain the commonly observed higher α_D-values compared to α_C-values ($\alpha_C = \frac{\Delta C_p^{\circ\ddagger}}{\Delta C_p^{\circ}}$), which are also believed to monitor the solvent accessibility of transition states [44, 120]. Temperature dependence of intrachain diffusion in unstructured peptides showed that this process is not associated with a measurable change in heat capacity (F. Krieger and T. Kiefhaber, unpublished results). This suggests that α_C-values give a more reliable picture of the solvent accessibility of the transition state than α_D-values.

This shows that changes in the dynamics of the unfolded state of a protein lead to changes in the prefactor for the folding reaction which has consequences for both the rate constant and the equilibrium constant of the folding reaction. In general, we cannot expect the pre-exponential factors to be independent of the solvent conditions such as denaturant concentration, temperature, and pressure. This will contribute to the experimentally determined *m*-values and the activation parameters ($\Delta H^{\circ\ddagger}, \Delta S^{\circ\ddagger}, \Delta V^{\circ\ddagger}$, and $\Delta C_p{}^{\ddagger}$) and to the equilibrium properties of the protein.

22.6 Conclusions and Outlook

Several experimental systems have been recently developed to measure rate constants for intrachain diffusion processes. Experimental studies on the dynamics of unfolded proteins have revealed single exponential kinetics for formation of specific intrachain interactions on the nanosecond time scale and have been able to elucidate scaling laws and sequence dependence of chain dynamics. It has further been shown that the results derived from homopolypeptide chains and host-guest studies are in agreement with dynamics of loop formation in short natural sequences. Further studies should aim at the investigation of the dynamics in full length unfolded proteins and in folding intermediates to obtain information on the special equilibrium and dynamic properties of free energy landscapes for protein folding reactions.

22.7 Experimental Protocols and Instrumentation

To measure absolute rate constants for contact formation several requirements have to be met by the experimental method and by the equipment for detection. The methods of choice to study contact formation are electron transfer or excited state quenching reactions. The main advantage of energy transfer systems is that they allow both the donor and the acceptor populations to be quantified during the experiment (see Figure 22.5).

22.7.1

Properties of the Electron Transfer Probes and Treatment of the Transfer Kinetics

The lifetime of excited states of the labels used in a specific system determine the time scale on which experiments can be performed. Triplet states are very long lived compared to fluorescence probes and thus allow studies in long chains and in unfolded proteins. Donor groups which undergo very fast intersystem crossing to the triplet state and which have a high quantum yield for intersystem crossing are well-suited. The xanthone derivatives used by Bieri et al. [50] and Krieger et al. [54, 55] form triplet states with a time constant of 2 ps and a quantum yield of 99% [56]. Tryptophan in contrast, which was used by Lapidus et al., has about 18% quantum yield [60] and forms triplet states with a time constant of 3 ns [62], which sets a limit to the fastest processes that can be monitored using tryptophan as a triplet donor. Triplet states usually have strong absorption bands that are easily observable. It is, however, important that the donor has an UV absorption band in a spectral region where no other part of the protein absorbs (i.e., >300 nm). This allows selective excitation of the donor. The requirements for the triplet acceptor are that the molecule should have lower triplet energy than the donor to enable exothermic TTET and it should not absorb light at the excitation wavelength of the donor. Additionally, no radicals should be formed at any time in the reaction, since they may damage the sample and their strong absorbance bands usually interfere with the measurements.

Further requirements of experimental systems which allow to measure the kinetics of contact formation on an absolute time scale are (i) that the process is very strongly distance dependent to allow transfer only at van der Waals distance between donor and acceptor and (ii) that the transfer reaction is faster than dissociation of the complex so that each van der Waals contact between the labels leads to transfer. The coupling of electron transfer to chain dynamics displayed in Figure 22.6 can be kinetically described by a three-state reaction if the excitation of the donor is fast compared to chain dynamics (k_c, k_{-c}) and electron transfer (k_{TT}).

$$\mathrm{O} \underset{k_{-c}}{\overset{k_c}{\rightleftharpoons}} \mathrm{C} \xrightarrow{k_{TT}} \mathrm{C}^* \tag{26}$$

O and C represent open chain conformations (no contact) and contact conformations of the chain, respectively. k_c and k_{-c} are apparent rate constant for contact formation and breakage, respectively. If the excited state quenching or transfer (k_{TT}) reaction is on the same time scale or slower than breaking of the contact (k_{-c}), the measured rate constants (λ_i) are functions of all microscopic rate constants.

$$\begin{aligned} \lambda_{1,2} &= \frac{B \pm \sqrt{B^2 - 4C}}{2} \\ B &= k_c + k_{-c} + k_{TT} \\ C &= k_c \cdot k_{TT} \end{aligned} \tag{27}$$

If the contact states have a much lower probability than the open conformations ($k_{-c} \gg k_c$) the kinetics will be single exponential and the observed rate constant corresponds to the smaller eigenvalue (λ_1) in Eq. (27). Since this is in agreement with experimental results we will only consider this scenario in the following. We can further simplify Eq. (27) if the time scales of electron transfer and chain dynamics are well separated. In the regime of fast electron transfer compared to chain dynamics ($k_{TT} \gg k_c, k_{-c}$) Eq. (27) can be approximated by

$$\lambda_1 = k_c \tag{28}$$

This is the desired case, since the observed kinetics directly reflect the dynamics of contact formation. In the regime of fast formation and breakage of the contact compared to electron transfer ($k_{TT} \ll k_c, k_{-c}$) Eq. (27) can be approximated by

$$\lambda_1 = \frac{k_c}{k_c + k_{-c}} \cdot k_{TT} \cong \frac{k_c}{k_{-c}} \cdot k_{TT} = K_c \cdot k_{TT} \tag{29}$$

where K_c reflects the ratio of contact conformations (C) over open chain conformations (O). In this limit the chain dynamics can not be measured but the fraction of closed conformations can be determined. It should be kept in mind that these simplifications only hold if the formation of excited states is fast compared to the following reactions. If the excitation is on the nanosecond time scale or slower, the solutions of the linear four-state model have to be used to analyze the kinetics [121, 122].

These considerations show that it is crucial to determine the rate constants for the photochemical processes in the applied system to be able to interpret the kinetic data. The photochemistry of the donor excitation and of the electron transfer process are usually characterized by investigating the isolated labels and the kinetics should be studied on the femtosecond to the nanosecond time scale to gain complete information on all photochemical processes in the system [56] (cf. Figure 22.6). To test whether each donor–acceptor contact leads to transfer it should be tested whether the reaction is diffusion controlled. This can be done by studying the bimolecular transfer process from the donor to acceptor groups and determine its rate constants, its temperature-dependence and its viscosity dependence (F. Krieger and T. Kiefhaber, in preparation). These tests will be described in detail in the following. The results showed, that both the xanthone/NAla system [54–56] and the porphyrin/Ru system [64] fulfill these requirements and thus allow measurements of absolute rate constant for contact formation. The Trp/Cys triplet quenching system, in contrast, is not diffusion controlled and gives significantly slower apparent contact rates than the diffusion-controlled systems [59, 63]. Also the DBO/Trp fluorescence quenching system does not seem to be completely diffusion controlled and might have slow electron transfer kinetics, since it gives significantly slower dynamics [65] compared to the xanthone/NAla system in the same peptides [54].

22.7.2 Test for Diffusion-controlled Reactions

22.7.2.1 Determination of Bimolecular Quenching or Transfer Rate Constants

To test whether an energy transfer or energy quenching pair has diffusion-controlled kinetics, the rate constant of energy transfer (k_q) should be measured using the free labels in solution under pseudo first-order conditions. In these experiments the concentration of the quencher or acceptor [Q] should be at least 10 times higher than the concentration of the donor to be in the pseudo first order regime. Since [Q] is approximately constant during the experiment, the apparent first-order rate constant (k) under pseudo first-order conditions is given by [123]

$$k = k_q \cdot [Q] \tag{30}$$

Thus, the bimolecular transfer constant (k_q) can be obtained by varying the quencher concentration [Q] and analyzing the data according to the Stern-Vollmer equation [124] (see Figure 22.17):

$$k = k_0 + k_q[Q] \tag{31}$$

Here, k_0 denotes the rate constant for triplet decay of the donor in absence of quencher (acceptor) and k the time constant in presence of the acceptor or quencher. For diffusion-controlled reactions of small molecules in water k_q is around $4–6 \cdot 10^9$ s^{-1}.

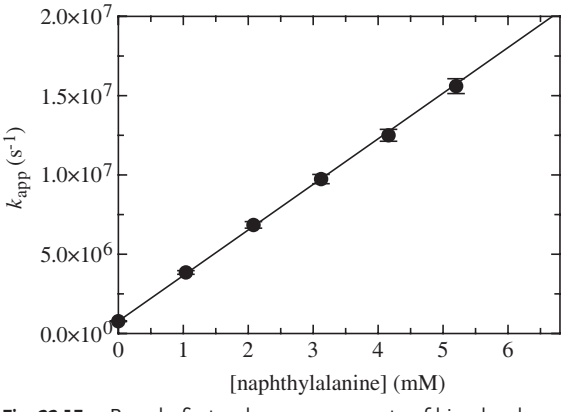

Fig. 22.17. Pseudo first-order measurements of bimolecular TTET from xanthonic acid to naphthylalanine in water. Xanthone concentration was 30 μM. The slope gives a bimolecular transfer constant (k_q) of $3 \cdot 10^9$ M^{-1} s^{-1} (see Eq. (31)). The data were discussed in Ref. [54].

22.7.2.2 Testing the Viscosity Dependence

For a diffusion-controlled reaction, k_q is inversely proportional to solvent viscosity ($k \sim 1/\eta$). The viscosity is usually varied by adding co-solvents like ethylene glycol or glycerol. To determine the final macroscopic viscosity instruments like the falling-ball viscosimeter or the Ubbelohde viscosimeter are used. The molecular size of the co-solvent used in a viscosity study is an important factor. The macroscopic viscosity of a glycerol/water mixture and a solution of polyethylene glycol might be the same, although the microscopic properties of these solutions are very different [80]. In the latter case the dissolved reactant molecules do only feel a fraction of the macroscopic viscosity. Thus it is advisable to use viscous co-solvents of small molecular weight. Glycerol/water mixtures have proven to be most useful because the viscosity can be varied from 1 cP (pure water) over three orders of magnitude by addition of glycerol. It is imperative to control the temperature when working with high concentrations of glycerol because the viscosity is strongly temperature dependent. Note that viscous co-solvents can interfere with the reaction that is studied.

In protein folding studies, the polyols used to vary the viscosity tend to stabilize the native state of proteins [84] making an analysis of the kinetic data difficult. However, for measurements of chain dynamics in unfolded polypeptide chains this effect should not interfere with the measurements as long as the co-solvents do not induce a structure. Specific effects of the polyols on chain conformations/dynamics can be tested by comparing the results from different co-solvents.

22.7.2.3 Determination of Activation Energy

Diffusion-controlled reactions typically have activation energies close to zero. The lack of an activation barrier in a diffusion controlled quenching reaction can be verified by determining the temperature dependence of k_q. The diffusion coefficients of the reactants are, however, temperature dependent, mainly through the effect of temperature on solvent viscosity according to the Stokes-Einstein equation.

$$D = \frac{k_B T}{6\pi r \eta} \tag{32}$$

After correcting for the change in viscosity of the solvent with temperature, the slope in an Arrhenius plot should not be higher than $k_B T$. As any photophysical reaction takes some time, diffusion control is only possible to a certain maximal concentration of quencher molecules. After that the photochemistry of the quenching or transfer process becomes rate limiting. This provides an upper limit of the rate constants that can be measured, even if the system is diffusion controlled at lower quencher concentrations. For the xanthone/naphthalene system TTET has been shown to occur faster than 2 ps and thus this system is suitable to obtain absolute time constants for all processes slower than 10–20 ps [56].

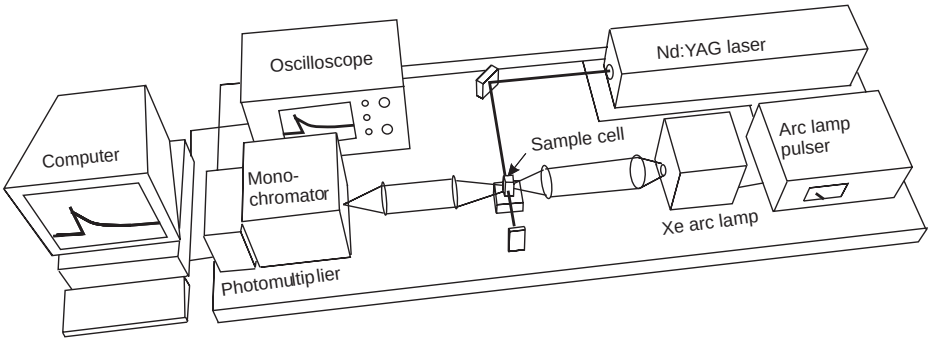

Fig. 22.18. Schematic representation of a laserflash set-up used to measure electron transfer reactions.

22.7.3 Instrumentation

The instrumentation required to perform experiments on contact formation kinetics consists of a high-energy light source to produce excited states and a detection mechanism (Figure 22.18). A pulsed laser is used to produce triplet donor states in TTET or triplet quenching experiments. The duration of the light pulse has to be very short (i.e., shorter than the time scale of the reaction of interest). Additionally, the excitation pulse has to provide enough energy to excite the major portion of the molecules in the sample to order to generate a large signal. A pulsed Nd:YAG laser with a pulse width of <5 ns and a pulse energy of $\sim$100 mJ is well-suited for these purposes. Transient UV absorption is used to detect the triplet states in TTET or triplet quenching experiments. A pulsed flash lamp generates enough light for the absorption measurements. The lamp intensity typically stays at a constant plateau value for several hundred microseconds, which is sufficient for TTET measurements. A monochromator is used to monitor single wavelengths. Transient spectra can be reconstructed from measurements at different wavelengths or by using a CCD camera.

Acknowledgments

We thank Annett Bachmann, Florian Krieger, Robert Kübler and Andreas Möglich for discussion and comments on the manuscript.

Equilibrium and Kinetically Observed Molten Globule States

Kosuke Maki, Kiyoto Kamagata, and Kunihiro Kuwajima

23.1
Introduction

The molten globule state has captured the attention of researchers studying the folding of globular proteins ever since it was proposed that this state is a general intermediate of protein folding [1–4]. Historically, the apparent incompatibility between the efficient folding of a protein into the native structure and the availability of an astronomically large number of different conformations, known as the Levinthal paradox [5], led to the premise that there must be specific pathways of folding, so that by restricting the protein molecule to these pathways, the polypeptide chain can reach its native structure efficiently. According to this view (the ''classical'' view), the folding occurs in a sequential manner with a series of intermediates populated along the specific pathway of folding (the sequential model of protein folding) [6–8]. Therefore, studies on protein folding were focused on detection and characterization of the specific folding intermediates of globular proteins. The discovery that the intermediates were formed during the kinetic folding of many globular proteins convinced the researchers of the significance of the intermediates in elucidating the mechanism of protein folding. The molten globule is the most typical of these folding intermediates, and has been regarded as a general intermediate of protein folding.

Nevertheless, recent theoretical studies of protein folding have shown that what is required for a protein to reach the unique native structure is not the presence of the specific pathway of folding, but just the presence of a small bias of the free-energy surface toward the native state in the multidimensional conformational hyperspace of the protein [9–11]. Therefore, according to this ''new'' view of protein folding, the Levinthal paradox is no longer a real paradox. It is obvious that the attempt to detect the folding intermediate to resolve the Levinthal paradox is now irrelevant, casting a fundamental doubt on the role of the molten globule state as a productive intermediate in protein folding [11, 12]. Apparently in support of this new perspective, kinetic folding of small, single-domain proteins with fewer than typically 100 amino acid residues has been shown to occur simply in a two-state manner without accumulation of the folding intermediates [13, 14]. Because the

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

folding can take place without the intermediates, they are apparently not prerequisites for successful folding of these proteins. The molten globule state might not be obligatory, but rather produced by misfolding events or kinetic traps at local minima on the free-energy surface of the protein folding [3, 4, 15]. Therefore, whether folding intermediates such as the molten globule state are necessary for directing the folding reactions of globular proteins is still an open question, and there has been intense debate on this issue.

However, it is probably more appropriate to address the following question: Is the sequential model of protein folding truly in conflict with the simple two-state folding of small globular proteins, which has been shown to support the new view of protein folding? In spite of the argument in favor of the new perspective of folding, the experimental studies of the folding intermediates of various globular proteins have clearly demonstrated that the molten globule is a real productive folding intermediate in these proteins [16]. Therefore, there must be a more general model that can accommodate both the sequential and the simple two-state folding reactions of real globular proteins.

We have thus previously proposed a two-stage hierarchical model of protein folding [3, 4], in which the folding process of a protein is, in general, divided into at least two stages: stage I, formation of the molten globule state from the unfolded state; and stage II, formation of the native state from the molten globule, as shown in Scheme 23.1.

$$U \xrightarrow{I} I \xrightarrow{II} N$$

Scheme 23.1

The folding intermediates like the molten globule in this model are not to solve the Levinthal paradox, but they are present because the protein folding takes place in a hierarchical manner [17, 18], reflecting the hierarchy of three-dimensional structure of natural proteins. In this model, the interactions that stabilize the molten globule intermediate should be approximately consistent with the interactions that stabilize the native state. Whether or not the observed folding of a protein is a two-state or non-two-state (multistate) transition may depend on the stability of the intermediate (I) and/or the location of the rate-limiting step of folding. A main purpose of this review is thus to test this hypothesis on the basis of recent studies of various globular proteins.

In the present article, we thus first summarize the structural and thermodynamic properties of the molten globules at equilibrium, and then describe how the molten globule state has been identified as a productive intermediate in kinetic refolding reactions of globular proteins. We also describe our recent statistical analysis of the kinetic refolding data of globular proteins taken from the literature, which clearly demonstrates that the molecular mechanisms behind the non-two-state and two-state protein folding are essentially identical. Finally, practical aspects on the experimental study of the molten globule are presented.

23.2
Equilibrium Molten Globule State

23.2.1
Structural Characteristics of the Molten Globule State

The molten globule state was originally an equilibrium unfolding intermediate assumed by many globular proteins under mildly denaturing conditions [1, 19]. It is structurally characterized by (i) the presence of a substantial amount of secondary structure, (ii) the virtual absence of tertiary structure associated with tight packing of side-chains, (iii) the compact size of the protein molecule with a radius only 10–30% larger than that of the native state, (iv) the presence of a loosely packed hydrophobic core that increases the hydrophobic surface exposed to solvent, and (v) dynamic features of the structure that fluctuates in a time-scale longer than nanoseconds. Thus, in short, the molten globule is a compact globule with a "molten" side chain structure [20].

The mildly denaturing conditions in which we can observe the molten globule state at equilibrium include acid pH [1, 21, 22], moderate concentrations of denaturants [23–26], high temperatures [27, 28], low concentrations of alcohol and fluoroalcohol [29, 30], and high pressure [31–33]. It is, however, dependent on protein species whether the molten globule is stably populated under the conditions; the protein may be still in the native state or more extensively unfolded. Certain proteins extensively unfolded at acid pH are known to refold into the molten globule state in the presence of a stabilizing anion [34]. For ligand-binding proteins, the partial unfolding induced by removal of a tightly bound ligand can bring about the molten globule state [27, 35]. Chemical modification, site-directed mutation and covalent bond cleavage of a natural protein often lead to the molten globule-like partially unfolded state [36–40].

In conventional experimental studies, the molten globule state has been characterized by peptide and aromatic circular dichroism (CD) spectra that detect secondary and tertiary structures, respectively [1, 41], by hydrodynamic techniques that determine the molecular size of the protein [2, 42, 43], and by hydrophobic dye (1-anilinonaphthalene-8-sulfonate (ANS))-binding experiments that detect formation of a loose hydrophobic core accessible to solvent [44].

In addition to these conventional techniques, new experimental techniques, such as hydrogen/deuterium exchange NMR spectroscopy, NMR relaxation and heteronuclear secondary chemical shifts and nuclear Overhauser enhancement (NOE) measurements [45–53], solution small-angle X-ray scattering (SAXS) [54–57], and protein engineering techniques [38–40, 58–63], have been used successfully to further characterize the structure of the molten globule state in many globular proteins during the past decade. Use of these techniques has enabled us to describe the structure of the molten globule states more precisely, to at least the amino acid residue level, and to reveal more detailed characteristics of this state.

Studies using these new techniques have shown the structure of the molten globule state to be more heterogeneous than previously thought, that is, one por-

tion of the structure is more organized and native-like while the other portion is less organized [49, 51, 64–66]. The degree of structural organization and the stability of the molten globule state have both been found to be remarkably dependent on the species of protein conformer, there being a range of species possible within the basic molten globule characteristics of secondary structure, compactness and hydrophobic core. Although the classical concept of little or no persistent tertiary structure still often holds, it is not a universal requirement of the molten globule state.

23.2.2 Typical Examples of the Equilibrium Molten Globule State

Representative examples for showing the diversity of the structure of the molten globule state can be found in α-lactalbumin (α-LA) and Ca^{2+}-binding lysozymes from canine and equine milk [67–70] (Figure 23.1), which are homologous (123–130 amino acid residues). These proteins exhibit the equilibrium molten globule state at a moderate concentration of guanidinium chloride (GdmCl) as well as acidic pH [1, 23–26, 71–73]. The overall structures of the molten globule state of these proteins are similar; the α-helical domain (α-domain) composed of the A-, B-, C-, and D-helices, and the C-terminal 3_{10}-helix is more organized with the β-domain less organized as revealed by hydrogen/deuterium exchange and other techniques [22, 38–40, 47, 74–79]. Despite the similarity in overall structure, the lysozymes are substantially more native-like than α-LA. Significant ellipticity in the near-UV CD spectra and incomplete fluorescence quenching by acrylamide indicate the presence of an immobile tryptophan residue buried inside the molecule [22, 24, 25, 71, 80].

Apomyoglobin (apoMb), which is the apo-form of myoglobin, a 153-residue heme protein with eight helices (A–H) (Figure 23.2) [81], illustrates the diversity in the structure of the molten globule state [34, 82–84]. ApoMb forms a molten globule at pH 4 (the pH 4 intermediate or I_1) while the addition of a stabilizing anion (trichloroacetate (TCA), citrate, or sulfate) refolds the protein to form the second molten globule (I_2) [85, 86]. A similar compact molten globule is formed at acidic pH in the presence of chloride ion [34]. The structure of I_1 has been studied by hydrogen/deuterium exchange NMR as well as by other NMR techniques [45, 50, 66]. It has a compact subdomain consisting of the A-, G-, and H-helical regions as well as part of the B-helix region.

Cytochrome *c* (cyt *c*), which is a 104-residue globular protein with a covalently attached heme group surrounded by three α-helices (Figure 23.3) [87], forms a compact intermediate that has the molten globule characteristics [20]. The molten globule state stably populated at acidic pH in the presence of stabilizing anion from salt or acid is more structurally organized and more stable than the molten globule states of α-LA and apoMb [34, 88]. In contrast to the α-LA or apoMb molten globules that correspond to the early folding intermediates, the cyt *c* molten globule corresponds to a late-folding intermediate that is present after the rate-limiting step in the kinetic refolding [89, 90].

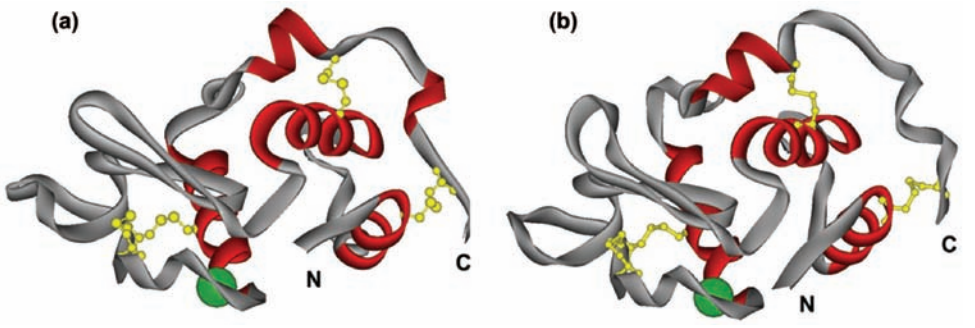

Fig. 23.1. X-ray crystallographic structure of a) human α-lactalbumin (PDB code: 1HML) and b) canine milk lysozyme (PDB code: 1EL1) drawn using DS Modeling. Helices formed in the molten globule state are in red. Four disulfide bonds are shown in yellow in ball-and-stick representation. One Ca^{2+} ion is bound to α-LA and the lysozyme, shown as a green ball.

23.2.3
Thermodynamic Properties of the Molten Globule State

The thermal unfolding of a native globular protein is a highly cooperative, first-order transition. The transition accompanies a large increase in enthalpy, which primarily arises from the disruption of the specific side chain packing interactions, namely, the van der Waals interactions of hydrophobic residues [91]. Because of the disruption of a large fraction of such specific interactions in the molten globule state, thermal unfolding from this state is always less cooperative than the unfold-

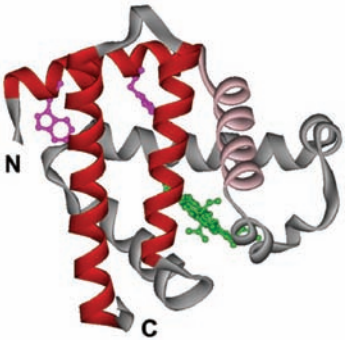

Fig. 23.2. X-ray crystallographic structure of sperm whale myoglobin in the holo form (PDB code: 1MBC) drawn using DS Modeling. The A-, G-, and H-helix regions, which are stably formed in the molten globule state, are in red. The B-helix region, which is partially formed in the structured molten globule state, is in pink. A bound heme and two tryptophan residues (Trp7 and Trp14) are shown in ball-and-stick representation. The heme is in green, and the two tryptophan residues are in purple.

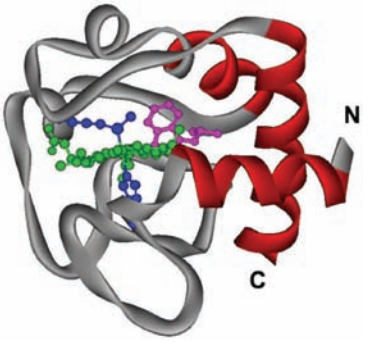

Fig. 23.3. X-ray crystallographic structure of horse cyt *c* (PDB code: 1HRC) drawn using DS Modeling. The N-terminal and C-terminal helices, and the 60s helix, which are stably formed in the molten globule state, are in red. His18, Trp59, Met80, and a bound heme are shown in ball-and-stick representation. His18 and Met80 are in blue, and Trp59 is in purple. Heme is in green.

ing from the native state. The best-characterized molten globules, such as the molten globule state of α-LA and the pH 4 intermediate of apoMb, do not apparently exhibit cooperative thermal transitions [2, 27, 92–94], so that the absence of the thermal transition was thought to be a characteristic of the molten globule state for some time.

However, it is now clear that the molten globules of certain proteins do exhibit a cooperative thermal unfolding transition with a significant increase in enthalpy [24, 28, 73, 95–97]. Thus, the apparent absence of cooperative thermal unfolding observed for the molten globules of α-LA and apoMb is due to their small enthalpy change. The unfolding transitions of the molten globules are apparently noncooperative for some proteins, but highly cooperative for others.

The most notable example of a cooperative thermal unfolding transition of a molten globule is displayed by equine and canine milk lysozymes [24, 28, 73, 97]. Although the overall structure of these molten globule states is very similar to that of the α-LA molten globule, the unfolding from these molten globules shows a cooperative heat absorption peak. The molten globules of cyt *c* and staphylococcal nuclease (SNase) also show cooperative thermal transitions [95, 96]. Therefore, it appears that the cooperative thermal unfolding of the molten globule state is more the rule than the exception.

The degree of cooperativity of the molten globule unfolding transition is, however, not only dependent on the protein species, but also, on the experimental conditions or the nature of amino acid replacements for a given protein [59, 90, 98–101]. The chloride-induced molten globule of apoMb at pH 2 shows a small but distinct heat absorption peak on thermal unfolding, and the TCA-induced molten globule is more stable and shows a still more cooperative unfolding transition [85, 99].

An important aspect concerning the variation in molten globule cooperativity is

the correlation between the intrinsic stability and the degree of cooperativity of the unfolding transition [101, 102]. The order of stability for the well-characterized molten globules for three proteins (α-LA, apoMb, and cyt *c*) is the same as the order of the cooperativity of the molten globule unfolding, that is, α-LA < apoMb < cyt *c* [23, 83, 86, 100, 103]. In apoMb, the molten globule state has been investigated for different mutants in different anion conditions, and there is again a good correlation between stability and cooperativity [101].

The correlation between the intrinsic stability and the degree of cooperativity of the molten globule state may reasonably be interpreted in terms of the two-stage hierarchical model of protein folding (see Scheme 23.1). In this model, the local interactions and nonspecific hydrophobic interactions that stabilize the molten globule state approximate, to a varying degree, the specific tertiary packing interactions that stabilize the native structure. Thus, the presence of specific native interactions further organizes structurally and stabilizes the molten globule state, and makes the unfolding transition more cooperative.

23.3
The Kinetically Observed Molten Globule State

23.3.1
Observation and Identification of the Molten Globule State in Kinetic Refolding

Various experimental techniques, including kinetic CD spectroscopy [41, 104–106], hydrogen/deuterium exchange pulse labeling combined with two-dimensional NMR spectroscopy [46], and stopped-flow SAXS [56, 57, 107], have been used to detect and characterize the kinetic folding intermediates in a number of globular proteins. These studies emphasize the close similarities between the equilibrium molten globule state and kinetic folding intermediates. Kinetic studies have further shown that similar intermediates commonly accumulate during refolding of other proteins whose equilibrium unfolding transitions are represented well by a two-state model. Here we describe how intermediates of protein folding have been identified experimentally as the molten globule states.

Pulsed peptide hydrogen/deuterium exchange combined with two-dimensional NMR and mass spectrometry has been used to characterize transient folding intermediates of several globular proteins, including cyt *c*, ribonuclease A, lysozyme, apoMb, and ribonuclease HI (RNase HI) [46, 74, 108–113]. The transient folding intermediate and the equilibrium molten globule state have both been characterized by hydrogen/deuterium exchange techniques. The two intermediates have been shown to be equivalent by comparison of their hydrogen/deuterium exchange profile in apoMb and RNase HI [109, 111, 113].

The folding intermediate of apoMb formed within 6 ms of refolding has protected protons in the A-, G-, and H-helices as well as in part of the B-helix and appears to be structurally the same as the pH 4 intermediate at equilibrium [109, 113–116]. The hydrogen/deuterium exchange combined with mass spectrometry

indicates that the folding intermediate is obligatory with a significant hydrogen-bonded secondary structure content [112].

The folding intermediate of RNase HI is formed within the dead time (12 ms) of the stopped-flow technique when the refolding starts from the unfolded state, and consists of a structural core region of the protein, namely helices A and D and β-strand 4. This kinetic intermediate resembles both the acid molten globule of the protein and sparsely populated, partially unfolded forms detected under native conditions [111]. Interactions formed in the intermediate persist in the transition and native states, suggesting that RNase HI folds through a hierarchical mechanism [117].

NMR spectroscopy can be applied in real-time to investigating the kinetics of folding and has been used to follow the refolding of bovine α-LA [74, 118, 119]. Although the dead time is approximately 1 s, the kinetics can be monitored directly by a series of one-dimensional NMR spectra and by a single two-dimensional (^{1}H-^{15}N HSQC) experiment, taking advantage of the slow refolding of apo-α-LA. The kinetics monitored by side-chain proton signals in the one-dimensional NMR spectra and by main-chain signals in the two-dmensional experiment are both coincident with those measured by CD and fluorescence [118, 119]. The one-dimensional NMR spectrum observed just after the dead time ($\sim$1 s) was very similar to that of the molten globule state, indicating the folding intermediate of α-LA is identical to the molten globule state [118]. Real-time NMR spectroscopy is a powerful technique, allowing the validity of a specific kinetic scheme to be tested, although it is applicable only for slow-folding proteins that have a rate constant less than $\sim$0.05 s^{-1}. The real-time NMR method is also applied to investigating the unfolding characteristics of interleukin-1β [120].

23.3.2
Kinetics of Formation of the Early Folding Intermediates

The folding intermediates of globular proteins have been observed and characterized as the burst-phase intermediate in most cases because they already accumulated during the dead time of typical stopped-flow instrumentations, which limited the kinetic folding measurements to a time resolution of a few milliseconds. However, recent development of new techniques, which have dead times much shorter than that of conventional stopped-flow instrumentations, allowed us to directly monitor the folding kinetics, including the formation of the molten globule, in submillisecond time region. These techniques include laser photochemically triggering method [121, 122], the temperature-jump method with electrical or laser triggering [123, 124], and the continuous-flow method [125–128].

The folding kinetics of apoMb from the cold-denatured state were monitored by the nanosecond laser temperature-jump method with fluorescence detection, and the subdomain assembly consisting of the A-, G-, and H-helices from the G-H loop and nascent A helix was observed in 5–20 μs after initiation of the folding [129]. CD and SAXS measurements of apoMb using the continuous-flow and stopped-flow techniques have revealed that significant compaction and helix forma-

tion occurs within ~300 μs after initiation of the pH-induced refolding, which is followed by the formation of an intermediate similar to the TCA-induced structured molten globule state of this protein [130].

The continuous-flow fluorescence measurements of cyt *c* revealed the accumulation of a series of intermediates [131]. The earliest intermediate (I_C, see Section 23.3.3) whose Trp fluorescence is fully quenched by the heme is formed with a time constant of ~65 μs, which is much shorter than a typical dead time (a few milliseconds) of the stopped-flow measurement [131]. In fact, this intermediate has been observed as the burst-phase intermediate when the stopped-flow method is used. The continuous-flow CD and SAXS measurements also revealed two intermediates along the sequential folding pathway of cyt *c* [132, 133]. The first intermediate was, however, observed as the burst-phase intermediate because the dead times of the measurements, 160–390 μs, were much longer than the time constant of formation of the first intermediate. The first intermediate is more compact than the unfolded state with ~20% helicity of the native state, and may correspond to the I_C intermediate. The second intermediate formed with a time constant of ~400 μs is further more compact with a radius of gyration ~30% larger than the native state with ~70% helicity of the native state, and hence its size is close to that of the molten globule state of this protein [132, 133]. The second intermediate may be more similar to the α-LA and apoMb molten globules that are known to be less structurally organized and less stable than the salt-induced cyt *c* molten globule (see Section 23.2.2).

23.3.3
Late Folding Intermediates and Structural Diversity

Although the molten globule states are formed in less than a few milliseconds as burst-phase intermediates, in many of the proteins shown above, the equilibrium molten globule states occasionally correspond to late-folding intermediates formed after the burst-phase and other early intermediates have accumulated. The late-folding intermediates, which are usually more structured than the burst-phase intermediates, often correspond to the structured molten globules formed by addition of stabilizing anions at equilibrium.

The best-studied example is the late-folding intermediate of cyt *c* [90, 134, 135]. Cyt *c* at neutral pH folds by a sequential mechanism, which involves three intermediates (I_C, I_{NC}, N*) as shown in Scheme 23.2 [89, 90, 108, 134].

$$U \rightarrow I_C \rightarrow I_{NC} \rightarrow N^* \rightarrow N$$

Scheme 23.2

I_C is the earliest intermediate characterized by the continuous-flow studies (see Section 23.3.2), and it was observed as the burst-phase intermediate by the stopped-flow method. I_{NC} is a more structured intermediate with tightly interacting N- and C-terminal α-helices, and this was characterized by pulsed hydrogen/

deuterium exchange and mutagenesis techniques [89, 108, 136]. The last intermediate, N*, is known to affect the kinetics of unfolding, but does not accumulate during refolding. It is structurally very close to the native state, but lacks the native Met80 heme ligand. Studies on the KCl-induced kinetic refolding of the protein from the acid-unfolded to the compact molten globule state suggest that the acid compact equilibrium molten globule state may correspond to N* [90].

Similarly, apoMb accumulates at least two intermediates, Ia and Ib, in the kinetic refolding, and the late intermediate, Ib, may correspond to the anion-induced, more structured, molten globule state observed at equilibrium [86]. These intermediates of apoMb may also correspond to the two folding intermediates detected by the continuous-flow experiments (see Section 23.3.2).

Apparently, there is a diversity of molten globule states in terms of where they accumulate along the folding pathway, and this is analogous to the diversity of the equilibrium molten globule state that depends on the protein species and the experimental conditions, as described in Section 23.2. When accumulation takes place at a late stage of refolding, it is more structured than the early intermediate and may correspond to the structured molten globule state observed at equilibrium.

23.3.4
Evidence for the On-pathway Folding Intermediate

The folding kinetics of certain globular proteins have been analyzed very carefully, and hence we can address the question of whether the molten globule intermediate formed during kinetic folding is a productive, on-pathway intermediate, or not. If the intermediate is productive, it must be placed between the fully unfolded and the native states along the folding pathway. Observation of a lag phase during the refolding is known to provide firm evidence that the intermediate is productive. Jennings and her coworkers have studied kinetic refolding of interleukin-1β by pulsed hydrogen/deuterium exchange mass spectrometric analysis, stopped-flow CD, and fluorescence. The transient folding intermediate accumulates with a time constant of 126 ms, and there is a lag phase in the production of the native state of at least 400 ms, clearly indicating that the intermediate is a productive on-pathway intermediate [137]. A similar lag phase has also been reported in SNase and dihydrofolate reductase (DHFR) [138–141], the refolding reactions of which have been characterized by tryptophan fluorescence and methotrexate (an inhibitor of DHFR) absorbance, respectively. In apoMb, two transient intermediates, Ia and Ib, accumulate during refolding from the acid-unfolded state, and the kinetics analyzed by interrupted refolding and interrupted unfolding experiments have been shown to be consistent with a linear folding pathway (U $\rightarrow$ Ia $\rightarrow$ Ib $\rightarrow$ N), in which both are productive on-pathway intermediates [86].

A detailed analysis of Im7 folding and unfolding by monitoring the whole fluorescence signal change using the continuous-flow and stopped-flow methods unambiguously revealed that the kinetic folding intermediate of this protein is an on-pathway, obligatory intermediate [142]. Similar quantitative analysis of the fold-

ing and unfolding reactions of several proteins, including the B1 domain of protein G, ubiquitin, cyt *c*, and interleukin-1β, indicates that the experimentally observed folding intermediates are on-pathway and obligatory [16, 143–146].

23.4 Two-stage Hierarchical Folding Funnel

Here, we consider the structural and energetic aspects of protein folding represented by the two-stage hierarchical model, and this together with the funnel representation of protein folding will give us a reasonable picture of the structural diversity of the molten globule state observed experimentally.

Structural changes and their associated energetic properties are different between the two stages in the two-stage hierarchical model of protein folding [3, 4]. In stage I, the protein molecule forms native-like secondary structure, tertiary fold and compact shape, lacking specific side-chain packing, thus acquiring the broad structural architecture of the native molecule. Local interactions that determine preference for secondary structure, and nonspecific hydrophobic interactions that determine the overall backbone topology and the compact shape are important in this stage. On the other hand, in stage II the specific side-chain packing is organized, and specific van der Waals contacts are dominant in this process. Furthermore, the structure formed in stage I may be similar to an expanded version of the structure formed in stage II, and the overall tertiary fold formed in stage I brings the appropriate side chains close in space to enable the specific native packing interaction between them to take place and stabilize the overall native-like tertiary fold.

Taking advantage of the funnel picture of protein folding, it is useful to describe the two-stage hierarchical folding model in terms of the folding funnel. The presence of the two stages indicates the presence of two corresponding folding funnels, I and II (Figure 23.4). The differences in the structural classes and energetics associated with the two stages are reflected in differences in shape between the two folding funnels. The compaction of protein, which occurs in stage I, results in a much larger decrease in the conformational entropy, suggesting that funnel I is much wider at its top than funnel II. The multiple specific tertiary packing interactions occurring in stage II are enthalpic in nature, and, because they are not always native-like, a previously formed interaction must often be broken to form a more stable set of interactions later in stage II. There must, therefore, be a number of enthalpic barriers along funnel II. Because the free-energy barrier is much more entropic in funnel I, the energy landscape must be much more rugged in funnel II.

The two-stage folding funnel provides a nice picture of why the experimentally observed molten globule states are structurally diverse. As described in Section 23.2, some molten globules have no observable tertiary structure, while others often contain native-like side-chain packing in a limited region of the molecule. The degree of structure in the molten globule state depends on where the largest

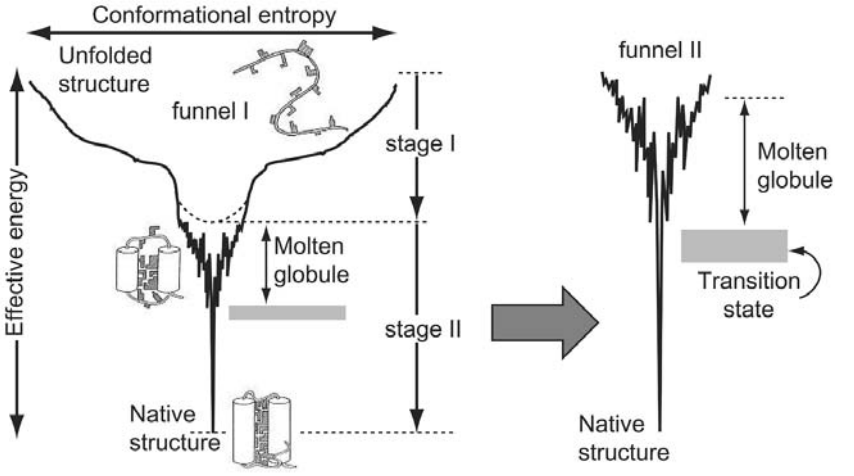

Fig. 23.4. A schematic representation of the hierarchical folding funnel. See the text for details.

energetic barrier is located along funnel II. When it is located at the top of funnel II, there will be no specific side-chain packing in the molten globule, but when close to the bottom, a number of the specific side-chain interactions may already be formed. In cases like apoMb, there may be two large energetic barriers along funnel II, resulting in accumulation of two structurally different molten globules.

23.5 Unification of the Folding Mechanism between Non-two-state and Two-state Proteins

Now we re-address the question raised at the beginning of this chapter, because a number of small globular proteins with fewer than 100 amino acid residues have been found to exhibit two-state folding without any accumulation of the intermediate [14]. These two-state proteins often correspond to a part (domain) of an entire protein molecule, and there are now more than 30 examples of the two-state proteins, including Src homology 3 domain [147–150], E9 colicin-binding immunity domain [151], cold shock protein B [152], N-terminal domain of λ repressor [153], IgG-binding domain of protein L [154], and chymotrypsin inhibitor 2 [155]. Apparently, the accumulation of the folding intermediate is not a prerequisite for the successful folding of these two-state proteins.

Questions thus arise. (i) Is the sequential model of protein folding truly in conflict with the simple two-state folding of small globular proteins? (ii) What is the role of the molten globule intermediate in protein folding if the successful folding takes place for the two-state proteins? (iii) What is a unified view of protein folding? Two possible answers to these questions are: (i) Protein folding is in principle a highly cooperative two-state transition, and any molten globule-like species observed at early stages of folding are not productive, but produced by kinetic trap-

ping and misfolding events; and (ii) non-two-state folding with the molten globule as a productive folding intermediate is more common in globular protein folding, and the two-state folding observed in the small proteins is rather a simplified version of the more common non-two-state folding. Which answer better represents real protein folding is crucial to our understanding of the mechanism of folding.

A recent paper by Kamagata et al. has shed light on this issue, and strongly suggested that the second answer is more appropriate in real globular proteins [156]. They have found that the rate constants for formation of the intermediate and the native state of non-two-state proteins both show essentially the same dependence on the native backbone structure as the rate constant of folding of two-state proteins. This indicates that the folding mechanisms behind the non-two-state and the two-state protein folding are essentially identical.

23.5.1 Statistical Analysis of the Folding Data of Non-two-state and Two-state Proteins

Kamagata et al. have collected the kinetic folding data of globular proteins from the literature, classified the proteins into non-two-state and two-state proteins, and investigated the relationships between the folding kinetics and the native three-dimensional structure of these proteins. Classification of the proteins as two-state folders was based on the criteria: (i) single-exponential refolding kinetics after exclusion of slow isomerization steps such as proline isomerization in the unfolded state, (ii) the absence of rollover behavior in the logarithmic folding rate constant as a function of denaturant concentration, and (iii) the agreement of unfolding parameters between the equilibrium and kinetic experiments. The proteins that did not satisfy these criteria might be non-two-state folders, but they also employed a more rigorous rule to identify non-two-state proteins; namely, the protein that showed the single-exponential refolding kinetics with the rollover behavior was classified as a non-two-state folder only if one of the following criteria was satisfied: (i) the presence of a burst-phase (i.e., missing amplitude) in the folding kinetics, and/or (ii) the accumulation of a well-characterized kinetic folding intermediate. Furthermore, only the proteins for which the kinetic folding mechanism had been determined clearly were used for the analysis, and the proteins with a heme group or disulfide bonds were excluded from the analysis. As a results, there were 16 natural proteins classified as the non-two-state folders; however, if we include proteins that satisfied only the condition of rollover behavior, additional five proteins could be included as well, resulting in 21 non-two-state folders. For 10 proteins among these 21 folders, the folding kinetics were multiphasic, and the rate constant for the formation of the folding intermediate was reported. On the other hand, there were 18 proteins that were classified as two-state folders.

Figure 23.5 shows the relationship between the rate constant (k_I) for formation of the folding intermediate and the parameter (the number of sequence-distant native pairs, Q_D) that represents the backbone topology of the native structure [157], and the relationship between the rate constant (k_N) for formation of the native state and Q_D, in the non-two-state proteins, and these relationships are compared with

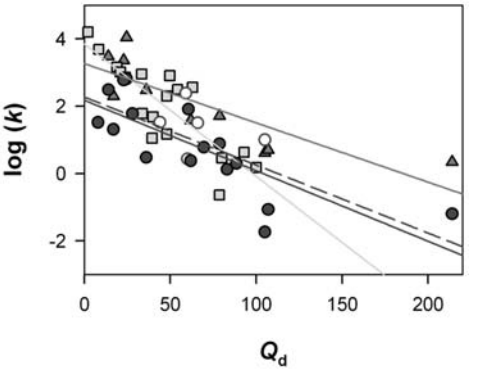

Fig. 23.5. A comparison of the folding rates of non-two-state and two-state folders. The logarithmic rate constants are plotted against the number of sequence-distant native pairs. Filled squares represent the folding of two-state folders. Filled triangles represent the formation of the intermediate of non-two-state folders. Filled circles and open circles represent the formation of the native state for the 16- and 21-protein data set, respectively, of non-two-state folders. The solid lines represent the best linear fit for the formation of the native state for 18 two-state folders, the intermediate for 10 non-two-state folders, and the native state for 16 non-two-state folders, respectively. The dashed line represents the best linear fit for the formation of the native state for 22 non-two-state folders [156].

the relationship between the folding rate constant (k_{UN}) and Q_D in the two-state proteins. It can be seen that all the rate constants (k_I, k_N, and k_{UN}) are significantly correlated with Q_D that is determined by the native backbone topology as given by:

$$Q_D = \sum_{i=2}^{L_p} \sum_{j=1}^{i-1} \Delta_{ij} \tag{1}$$

where i and j are the residues numbers of two contacting residues for which the Cα–Cα distance in space was within 6 Å in the PDB structure, and L_p is the total number of amino acid residues of a protein excluding the disordered terminal regions. $\Delta_{ij} = 1$ if $i - j > 12$, and otherwise $\Delta_{ij} = 0$. Similar correlations of these rate constants were also found with other structure-based parameters, the absolute contact order (ACO) [158] and cliquishness [159], but there were no significant correlations between the rate constants for the non-two-state proteins (k_I and k_N) and the relative contact order (RCO) [160], and this is in contrast with the significant correlation found between k_{UN} and RCO in the two-state proteins. The difference between the non-two-state and the two-state proteins with respect to the correlation with RCO was ascribed to a difference in the chain-length distribution between the two types of proteins. Because RCO is given by ACO/L_p, the correlations of the logarithmic rate constants with ACO and the chain length canceled each other out in the RCO for the non-two-state proteins that had a much wider distribution of L_p.

The significant correlations of both the logarithmic rate constants, $\log k_I$ and $\log k_N$, with Q_D (the correlation coefficient $r = -0.74 \sim -0.83$) in the non-two-state

proteins indicate that both the processes from the unfolded state (U) to the intermediate (I) and from I to the native state (N) are rate-limited by the process of forming a more native-like backbone topology. Protein molecules thus become progressively more native-like during the folding process from U to N via I, clearly demonstrating that the kinetic intermediate of refolding in the case of non-two-state proteins is a real, productive folding intermediate. Furthermore, both the value of log k_{UN} and its dependence on Q_D in the two-state proteins are very similar to those found in the plots of log k_I and log k_N versus Q_D for the non-two-state proteins (Figure 23.5). This clearly demonstrates that the mechanism of folding does not differ between the two classes of proteins. The non-two-state folding, with the accumulation of a productive folding intermediate, may be a more common mechanism of protein folding, and the two-state folding may be apparently a simplified version of the more common non-two-state folding.

23.5.2
A Unified Mechanism of Protein Folding: Hierarchy

The presence of the molten globule-like intermediate at an early stage of kinetic refolding, together with the productive nature of the intermediate, strongly suggests the two-stage hierarchical model shown earlier in this chapter (Scheme 23.1) as a general mechanism of protein folding. At this point, however, at least two questions arise. First, if the two-stage model is more general, why do certain small globular proteins exhibit two-state (i.e., single-stage) folding? Second, if stage II of Scheme 23.1 corresponds to the process of the specific tertiary packing of side chains from the molten globule to the native state, why does the k_N for non-two-state folders show essentially the same dependence on native backbone topology (i.e., Q_d) as k_I does (see Figure 23.5)?

As regards the first question as it relates to the two-state folders, there are two possible explanations. First, this effect could be due to the movement of the rate-limiting step from stage II in non-two-state folders to stage I in two-state folders. When the size of a protein decreases, it becomes easier to determine the specific conformation of side-chain packing due to the decrease in the number of specific interactions, thereby making the first stage, rather than the second stage, rate-limiting. Thus, this process would lead to the two-state kinetic behavior of the protein. On the other hand, a second explanation would ascribe the two-state behavior to the destabilization of the folding intermediate. When the intermediate is less stable than the unfolded state, a protein must undergo simple two-state folding without any accumulation of the intermediate. If the first explanation is applied to the two-state type of folding, the rate constant k_{UN} of the two-state protein may coincide with the rate constant k_I, at which the intermediate forms in the non-two-state protein. On the other hand, if the second explanation is applied, with the rate-limiting step remaining at stage II, then the rate constant k_{UN} of the two-state protein may coincide with the rate constant k_N, at which the native state for the non-two-state protein is formed. Figure 23.5 shows that the k_{UN} values for the two-state proteins coincide with the k_I values for the non-two-state proteins at Q_d

values of less than 25, suggesting the validity of the first explanation. However, when Q_d is larger than 25, the two-state k_{UN} shows variation in either the non-two-state k_I or k_N, or between the k_I and k_N, and hence both mechanisms given by the two explanations may play a role in the folding of two-state proteins.

However, it still remains unclear why the k_N for non-two-state folders shows essentially the same dependence on Q_d as does the k_I (Figure 23.5). This question may be even more difficult to answer than those discussed above; however, the known structural characteristics of the folding intermediates indicate that stage II includes the process of the specific tertiary packing of side chains. It is possible that this packing process is also dominated by the organization of the native backbone topology. Thus, the folding that occurs in stage II would again be correlated with the native backbone topology, but would take place in a concerted manner together with the tertiary packing of side chains and the organization of the backbone topology.

23.5.3
Hidden Folding Intermediates in Two-state Proteins

Although many small globular proteins fold fast and apparently in a two-state manner without detectable intermediates, it is now becoming increasingly clear that hidden meta-stable folding intermediate may exist along the folding pathway, but behind the rate-limiting transition state. Sanchez and Kiefhaber have shown that nonlinear activation free-energy relationships (i.e., nonlinear relationships of the logarithmic rate constant of folding or unfolding versus denaturant concentration) reported for 23 two-state proteins are caused by sequential folding pathways with consecutive distinct barriers and a few obligatory intermediate that are hidden from direct observation by the high free energies of the intermediates [161]. Bai has also suggested from native-state hydrogen/deuterium exchange data of a number of two-state proteins that partially folded intermediates may exist behind the rate-limiting transition state in these proteins and evade detection by conventional kinetic methods [162]. He proposed two types of the hidden intermediates: type I intermediates, more stable than the unfolded state but hidden behind the rate-limiting transition state located between the unfolded state and the intermediate, and type II intermediates that are less stable than the unfolded state. These are fully consistent with our explanation for the observation of the two-state folding proteins (see Section 23.5.2).

It is thus concluded that there is essentially no difference in mechanism between the non-two-state and the two-state protein folding, and the apparent two-state folding is merely a simplified version of more common non-two-state folding that accumulates obligatory folding intermediates. The major difference between the non-two-state and the two-state folding is the relative stability of the folding intermediates. In fact, non-two-state proteins also exhibit apparent two-state folding and unfolding kinetics under a solution condition where the intermediates are destabilized or by introduction of amino acid replacements that destabilize the intermediates [163].

23.6
Practical Aspects of the Experimental Study of Molten Globules

23.6.1
Observation of the Equilibrium Molten Globule State

As described in Section 23.2, certain proteins show equilibrium unfolding intermediates including the molten globule state, while the other proteins unfold without detectable intermediate. Therefore, when we analyze the experimentally observed unfolding transition of a protein, we must be careful about the possible presence or absence of the equilibrium unfolding intermediates. When there is no intermediate observed, we shall use a two-state model of the unfolding transition, and otherwise a model that involves the intermediates (see Section 23.6.1.2).

The unfolding transition curve of a protein can be obtained by measuring a physical parameter, which reflects the conformational states of the protein, as a function of denaturing perturbations such as denaturant (typically GdmCl or urea) concentration, pH and temperature [1, 23, 28]. The physical parameters often used are optical ones, such as absorption, CD and fluorescence. Here, we will describe a procedure widely used in the analysis of the protein unfolding transitions.

23.6.1.1 Two-state Unfolding Transition

Equilibrium unfolding transitions occurring without detectable intermediate states can be well approximated by the transition between only the two states [164], the native (N) and the fully unfolded (U) states as:

$$N \rightleftarrows U$$

This approximation of the unfolding transition is referred to as the two-state model.

When a denaturant-induced unfolding transition follows the two-state model, the observed value of a given physical parameter (optical absorbance, fluorescence, CD, etc.) $A(c)$ at denaturant concentrations c is given by:

$$A(c) = A_N \times f_N(c) + A_U \times f_U(c) = A_N \times f_N(c) + A_U \times (1 - f_N(c)) \quad (2)$$

where $f_N(c)$ and $f_U(c)$ ($f_N + f_U = 1$) are the fraction native and unfolded at denaturant concentration c, A_N and A_U are the ideal values of the parameter in the native and the unfolded states, respectively, and these are often obtained by linear extrapolations of the dependence of the parameter values on c from the pretransition (native) and the posttransition (unfolded) regions as $A_n = a_1 c + a_2$ and $A_U = a_3 c + a_4$, where a_i is constant. Because an equation essentially the same as Eq. (2) is obtained for the pH- and temperature-induced unfolding transitions, the description of the equilibrium unfolding transition shown below also applies to the pH- and temperature-induced unfolding transitions. Equation (2) is rewritten as:

$$f_N(c) = \frac{A(c) - A_U}{A_N - A_U} \quad (3)$$

This shows that a single observation probe can determine the fraction native and unfolded ($f_U = 1 - f_N$) in the two-state model.

Equation (3) indicates that the fraction native and unfolded calculated from the unfolding transition curves monitored by different probes should be superimposable to each other if the two-state approximation holds. This characteristic of the two-state unfolding transition is often used to distinguish between the two- and multistate unfolding transitions. Figure 23.6A shows an example of the two-state unfolding transition of hen egg white lysozyme [23].

The unfolding transitions approximated by the two-state model exhibit a specific point (for example, at a specific wavelength) in the spectra of the native and the

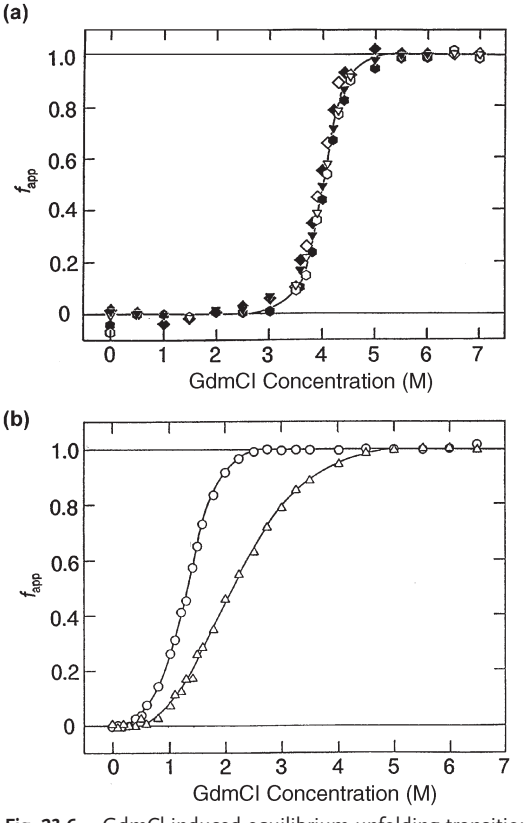

Fig. 23.6. GdmCl-induced equilibrium unfolding transition curves of a) hen egg white lysozyme and (b) α-lactalbumin monitored by CD spectra at a) 222 nm (inverted triangles), 255 nm (hexagons), and 289 nm (diamonds), and b) 222 nm (triangles) and 270 nm (circles) [23].

fully unfolded state, where these two states exhibit the identical value of the parameter used. If there exists such a point(s) in the spectra, all the spectra involved in the unfolding transition at different denaturant concentrations exhibit essentially the same value at that point with the condition that $a_1 \approx a_3 \approx 0$. This is readily evidenced by Eq. (2). Here we take an example of absorbance as an optical probe, and suppose that the absorbance spectra of the native and unfolded states exhibit the same value (A_λ) at a wavelength λ. According to the above assumption ($A_N = A_U = A_\lambda$), the absorbance value ($A(c)$) at λ should be essentially identical (A_λ) at any denaturant concentration [165].

Thus, the existence of these specific points (a single point in many cases), referred to as isosbestic and isodichroic points for absorbance and CD, respectively, lends support to the two-state unfolding transition whereas we have to think about a multistate unfolding transition in the absence of these kinds of points.

23.6.1.2 Multi-state (Three-state) Unfolding Transition

The three-state unfolding transition is a simple extension of the two-state unfolding transition in terms of an additional intermediate state that is stably populated at equilibrium. The unfolding equilibrium of the three-state model is described as:

$$N \rightleftarrows I \rightleftarrows U$$

where I is the equilibrium unfolding intermediate. The observed value of a given physical parameter $A(c)$ at denaturant concentrations c is thus given by

$$A(c) = A_N \times f_N(c) + A_I \times f_I(c) + A_U \times f_U(c) \tag{4}$$

where A_I is the ideal value of the parameter in the intermediate state, $f_I(c)$ is the fraction of the intermediate state at denaturant concentration c, and $f_N + f_I + f_U = 1$. When the intermediate is fully populated at an intermediate concentration of denaturant, we can experimentally determine A_I and extrapolate the values into regions where the intermediate is not stably populated. However, this is not always the case. For the molten globule intermediate, we can often assume that $A_I = A_N$ for the parameters that represent the native secondary structure and that $A_I = A_U$ for the parameters that represent the specific tertiary structure of side chains (see below). Although the two-state unfolding transition in principle requires only a single probe to determine the fraction native or unfolded, the three-state unfolding transition requires two independent probes when the two transitions, $N \rightleftarrows I$ and $I \rightleftarrows U$ are not separated from each other.

As described previously, the molten globule state has a native-like secondary structure with virtually no specific side-chain packing. Taking advantage of these properties of the molten globule state, CD spectroscopy in the far- and near-UV regions, which are sensitive to the backbone secondary structure and the asymmetry of the side chains in aromatic residues, respectively, is extremely useful because they can monitor individually these two properties specific for the molten globule state.

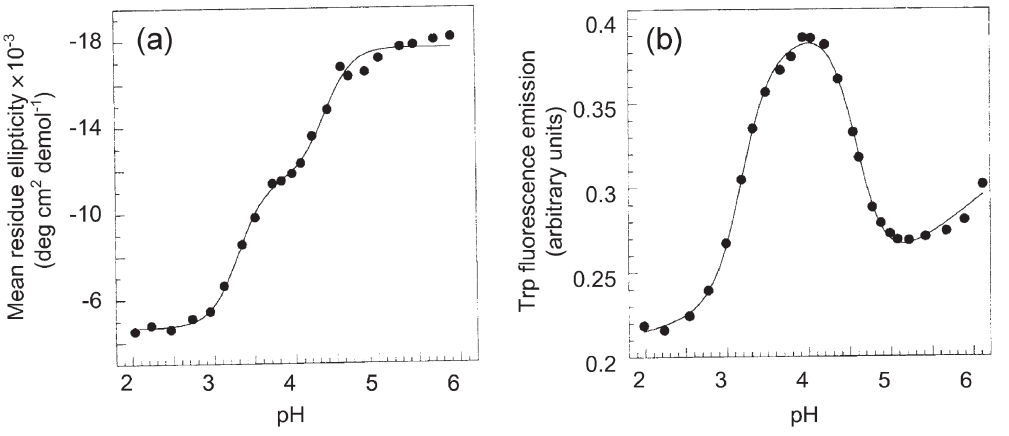

Fig. 23.7. pH-induced unfolding transition curves of apoMb monitored by a) CD at 222 nm and b) tryptophan fluorescence emission. From [84] with permission of Oxford University Press.

The equilibrium unfolding of α-LA monitored using CD spectroscopy in the far- and near-UV regions is an excellent example that clearly demonstrates that the molten globule is stably populated at equilibrium. The transition occurs at a lower denaturant concentration when monitored by the near-UV CD than when monitored by the far-UV CD (Figure 23.6b), and such noncoincidence of the apparent transition curves measured by the different probes is clear evidence that the molten globule intermediate accumulates between the two transition regions [23]. Accumulation of the molten globule state was also observed in the same manner in many other proteins, including canine and equine milk lysozymes [25, 80].

Another example demonstrating the population of the equilibrium unfolding intermediate is the observation of a two-step (or multi-step) unfolding transition measured by a single spectroscopic probe. A good example is the observation of the molten globule intermediate of apoMb at an intermediate pH (pH 4) in the pH-induced unfolding transition. Figure 23.7 shows the pH-induced unfolding transition curve of apoMb monitored by the far-UV CD and the intrinsic tryptophan fluorescence [84]. In contrast to the two-state unfolding transition curves that must have only a single-step transition, apoMb exhibits a two-step transition with a significant enhancement (more intense than the values in the native as well as the unfolded states) in the fluorescence and a plateau region in the far-UV CD at a modest acidic pH region around pH 4. These spectroscopic properties are consistent with population of the molten globule state at the intermediate pH as described in Section 23.2; it contains a portion of the native helical structure with two partially buried tryptophan residues that are located in the A-helix region and give rise to the enhancement of the fluorescence [45, 84].

The apparent difference in the behavior of the unfolding transition curves between α-LA and apoMb is, however, not essential. Because the α-LA molten globule

exhibits a substantial amount of the secondary structure with virtual lacking the specific side-chain packing, there is little change in the far- and the near-UV CD intensities on the N ⇄ I and I ⇄ U transitions, respectively, which results in non-coincident single-step unfolding transitions measured by these probes. On the other hand, the apoMb molten globule is sufficiently stable at the intermediate pH values, and exhibits the properties distinct from those in the native and the unfolded states, so that it emphasizes the population of the molten globule state in the unfolding transition curves.

23.6.2
Burst-phase Intermediate Accumulated during the Dead Time of Refolding Kinetics

For many globular proteins, a kinetic folding intermediate is accumulated at an early stage during the refolding from the fully unfolded state under a strongly native condition, and this accumulation of the intermediate often occurs within the dead time of the measurements. Figure 23.8 shows the kinetic trace of α-LA refolding monitored by CD in the far-UV region at 222 nm [106]. In the kinetic trace, a significant fraction of the CD change occurs within the dead time of the measure-

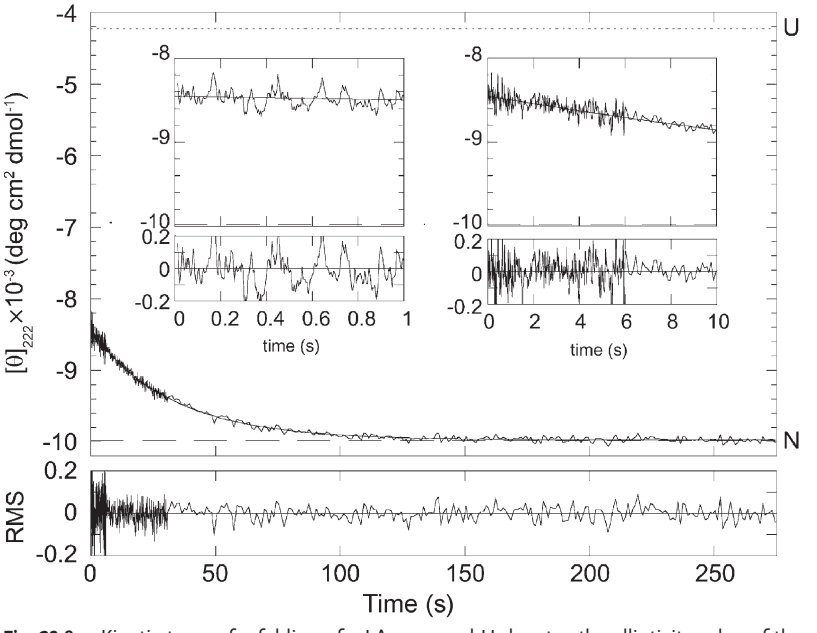

Fig. 23.8. Kinetic trace of refolding of α-LA monitored by CD at 222 nm. The refolding reaction was initiated by a GdmCl concentration jump from 5 M to 1 M. N denotes the ellipticity value of the native state, and U denotes the ellipticity value of the unfolded state at 1 M GdmCl obtained by linear extrapolation of the baseline for the unfolded state. From [106] with permission from Elsevier.

ments, indicating the transient accumulation of an intermediate state that has a substantial amount of the secondary structure.

The unresolved signal change (missing amplitude) occurring within the dead time of measurement in kinetic refolding experiments is referred to as the ''burst-phase'' change, and the corresponding intermediate is referred to as the ''burst-phase intermediate'' of refolding. Kinetic traces for the refolding reactions are fitted to a sum of exponential functions. If the significant structural formation occurs within the dead time during refolding, the value obtained by extrapolating the fitted kinetic refolding curve to zero time must be different from the expected value for the unfolded state that can be obtained by extrapolating the values of the unfolded state in the posttransition region of the equilibrium unfolding transition curve to the refolding condition. A more strict definition of the burst-phase change is, thus, a change from the expected value for the unfolded state to the zero-time extrapolated value of the fitted kinetic refolding curve. The burst-phase change results from at least one very fast phase unresolved in the observed kinetic trace, whose rate constant should be much larger than 1/(dead time).

The burst-phase change can be observed by using a variety of conformational probes, including CD, pulsed hydrogen/deuterium exchange, intrinsic and extrinsic fluorescence, and SAXS [57, 80, 104–106, 113, 166]. Among these, SAXS is useful in estimating the size and the overall shape of the burst-phase intermediate. Our previous SAXS measurements of α-LA have directly demonstrated that the burst-phase intermediate, accumulated within ~10 ms after the initiation of the refolding, has a radius of gyration very close to that of the equilibrium molten globule state (~10% larger than that of the native state) with a globular shape [57], lending support to the idea that the kinetic intermediate of α-LA is identical to the molten globule state.

Whether or not the burst-phase intermediate is observed in the kinetic refolding of a protein depends on the rate of formation of the intermediate and the dead time of measurement. For example, the fluorescence of cyt *c* is quenched by almost 80% of the total change expected on the refolding reaction within the dead time of stopped-flow measurement (a few milliseconds) while kinetic traces monitored by using continuous-flow fluorescence methods with a dead time of ~50 μs provides the total signal change expected [131].

23.6.3
Testing the Identity of the Molten Globule State with the Burst-Phase Intermediate

Measurements of the kinetic progress curves of refolding at various wavelengths will give us the CD spectrum of the intermediate state. Figure 23.9 shows the far- and near-UV CD spectra of α-LA burst-phase intermediate and they are compared with the equilibrium CD spectra of the protein [104]. The CD spectra of the burst-phase intermediate are similar to the equilibrium CD spectra of the molten globule state. These results further support the idea that the folding intermediate of α-LA is identical to the molten globule.

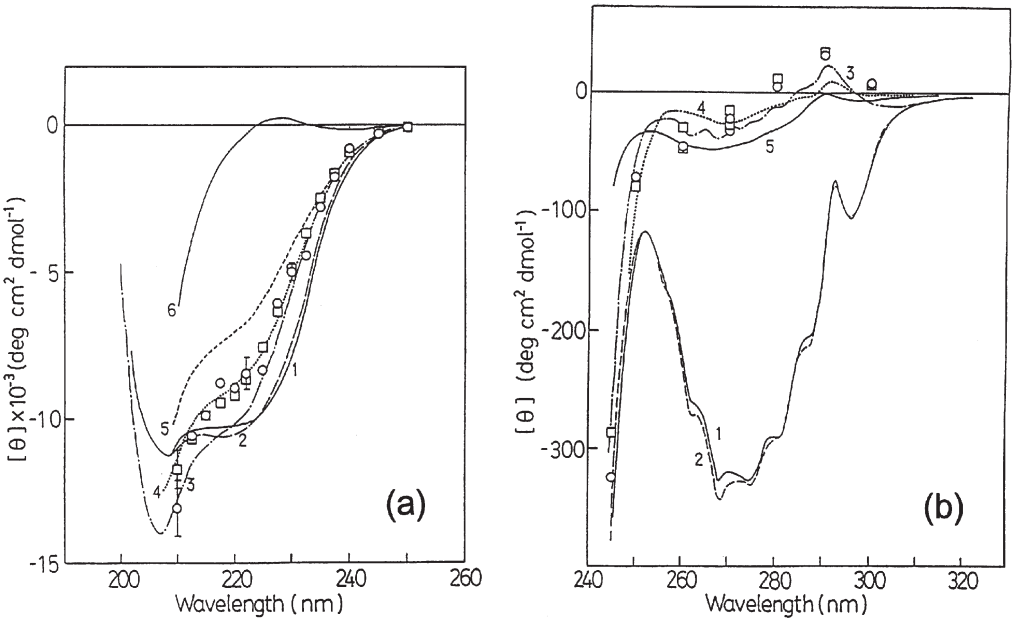

Fig. 23.9. CD spectra of the molten globule state of α-LA at pH 2.0 in the far- and near-UV regions compared with the CD spectra of the native and unfolded states. Open circles and squares show the CD values obtained by extrapolating to zero time of the refolding curves. 1 and 2, the native state of the holo and apo forms, respectively; 3, the molten globule state at pH 2.0; a) 4 and 5, the thermally unfolded states at 41 and 78 °C, respectively; 6, the unfolded state by GdmCl; b) 4, the thermally unfolded state at 62.5 °C; 5, the unfolded state by GdmCl. From [104] with permission from the American Chemical Society.

The formation of secondary structure in the burst-phase of refolding is a very rapid process occurring within a few milliseconds, so that the rapid pre-equilibrium between the unfolded and the intermediate states is established at a very early stage in the refolding reaction. The simplest example of the refolding reactions involving an on-pathway intermediate can be described as follows:

$$U \overset{\text{very rapid}}{\rightleftharpoons} I \xrightarrow{\text{slow}} N$$

where U, I, and N represent the unfolded, the intermediate, and the native states, respectively.

The unfolding transition curve of the intermediate state is obtained by measuring the refolding reactions at varying denaturant concentrations and by investigating the dependence of the burst-phase CD spectrum on the denaturant concentration. Comparison of the unfolding transitions of the molten globule state and the burst-phase provide an additional test for the identity of these two states in terms of stability. Figure 23.10 shows the unfolding transition curves of the burst-phase intermediate and the equilibrium molten globule state of α-LA measured by ellip-

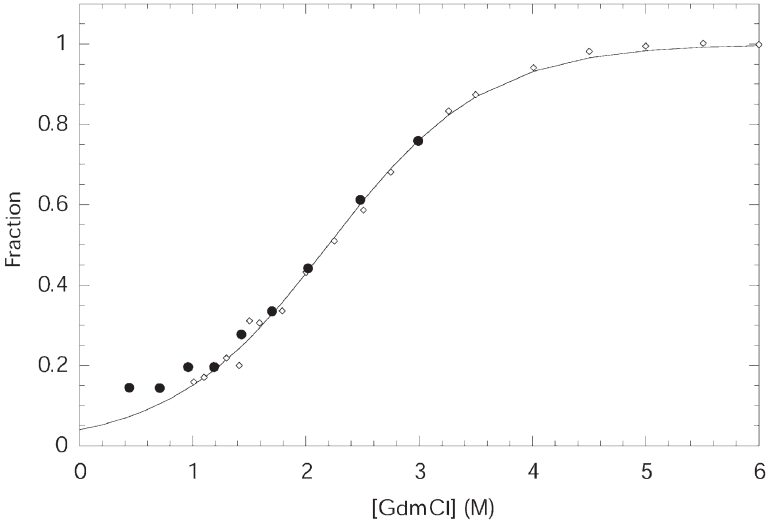

Fig. 23.10. The normalized unfolding transition curves of the burst-phase intermediate of α-LA (filled circles) compared with that of the equilibrium molten globule state at neutral pH (open diamonds). The solid line shows the theoretical curve assuming a two-state transition between the molten globule state and the unfolded state. From [106] with permission from Elsevier.

ticity at 222 nm [106]. The unfolding transition curve of the burst-phase intermediate is superimposable to the unfolding transition of the molten globule state that has been observed at equilibrium, indicating, again, that these two states of α-LA are identical to each other.

Although this method is powerful to compare the stability of the burst-phase intermediate with that of the molten globule, thermodynamic parameters of the burst-phase intermediate may not be able to be reliably obtained. As described in Section 23.2.3, the unfolding transitions of the molten globule state may not occur in a cooperative manner [58], which means that the two-state model may not apply to the transition between the unfolded state and the intermediates. Nevertheless, it is worth measuring these unfolding transitions for the purpose of comparing the molten globule and the burst-phase intermediate.

Alcohol- and Salt-induced Partially Folded Intermediates

Daizo Hamada and Yuji Goto

24.1
Introduction

The structures and stabilities of proteins are perturbed by additives such as small organic and inorganic molecules. In this chapter, we discuss the effects of alcohols and salts on inducing partially folded intermediates of proteins. These co-solvents are expected to stabilize otherwise unstable folding intermediates. They can also reveal the conformational preference of the intermediate or unfolded states. This information is valuable for characterizing the structure and stability of the folding intermediates under physiological conditions in the absence of co-solvents. Since this chapter focuses on the effects on the intermediate and unfolded states among various effects on proteins, readers should refer to other reviews on the general effects of alcohols [1, 2] and salts [3–7] on proteins.

In the early 1960s, Tanford and coworkers performed pioneering studies about the effects of organic solvents on the conformational properties of proteins using optical rotatory dispersion (ORD) [3, 4, 8]. For example, the conformational transition of bovine ribonuclease A induced by the addition of 2-chloroethanol into aqueous solvent occurred in two distinct stages involving partial unfolding of the native structure followed by the formation of an α-helical structure. A similar conformational change was also observed for bovine β-lactoglobulin [3, 4] and diisopropylphosphoryl chymotrypsin [9]. Recently, circular dichroism (CD) spectroscopy has become more popular than ORD because of the simplicity in the interpretation of data. However, the results obtained by CD provide essentially the same information as can be obtained by ORD. Further information about the effects of alcohols can be analyzed even to atomic resolution by solution nuclear magnetic resonance (NMR) spectroscopy.

Alcohols are basically categorized as denaturants, as are guanidinium hydrochloride (GdmCl) or urea. Although GdmCl and urea induce random coil structures, alcohols tend to stabilize well-ordered conformations such as α-helical structures. According to the review by Tanford [3], Imahori and Doty first recognized that a high proportion of α-helical proteins form α-helical structures in 2-chloroethanol. Similar effects have been found for many other alcohols. Importantly, Herskovits and Mescanti [10] have reported that α_8-casein, a typical natively

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

unfolded protein [11–14] is also converted into an α-helical structure in the presence of 2-chloroethanol or methanol. Although a significant number of α-helical structures are formed by alcohols, they are certainly not equivalent to the native conformation and are classified as denatured conformations, which lack the native protein's functions.

The properties of alcohols that induce the conformational change in proteins are also widely used for analyzing the intrinsic structural preference of proteins and peptides, particularly to analyze the kinetic intermediates accumulating at the early stages of folding. Although proteins assume significant levels of nonnative α-helical conformations at high concentrations of alcohols, several short peptides form β-turn or β-hairpin conformations according to the structural preference of the amino acid sequence [15–22]. The structures formed in alcohol/water solvent somehow mimic the properties of early intermediates in protein folding, since both structures are stabilized predominantly by local interactions which are formed between residues near each other in amino acid sequence (Figure 24.1) [23, 24]. Moreover, the molten globule state, a compact denatured state with a significant amount of native-like secondary structures but with fluctuating tertiary structures [25–29] (see Chapter 23), is sometimes observed during the alcohol-induced denaturation of several proteins under moderate concentrations of alcohols. Thus, alcohols have the potential to stabilize different types of partially folded structures of polypeptide chains depending on the alcohol species and concentration ranges used (Figure 24.2). It is noted that, in this chapter, our definition of the molten globule state is not as strict as the original proposal and can be also used for the compact denatured state with some native-like secondary structures.

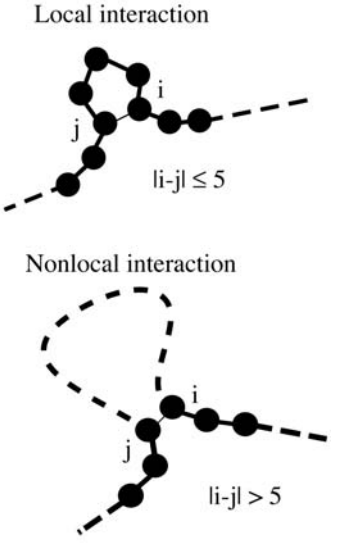

Fig. 24.1. Local (a) and nonlocal (b) interactions [23]. In the figure, circles represent each amino acid. The local interactions are formed between residues near each other in the amino acid sequence, whereas the nonlocal interactions are formed between residues apart each other in the sequence.

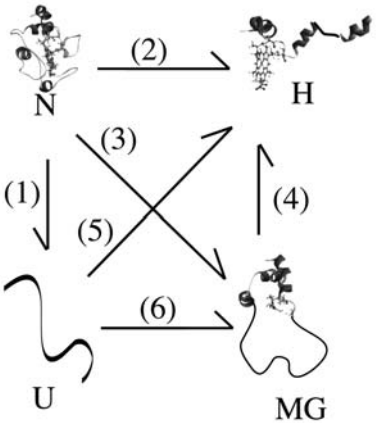

Fig. 24.2. Conformational transitions of proteins. N, native; U, fully unfolded; MG, molten globule; H, alcohol-induced helical states. Transitions by denaturants (GdmCl or urea) or at extreme pH (1), by strong helix inducers such as TFE or HFIP (2), by moderate concentrations of weak helix induces such as methanol or ethanol (3), by high concentrations of weak helix induces (4), by alcohols at extreme pH (5) and by anions at acidic pH (6) are represented schematically.

Salts have been used widely for various purposes in the preparation and characterization of proteins, including salt-induced precipitation (salting out), dissolution of proteins (salting in), and stabilizing or destabilizing protein structures [5–7] (see Chapter 3). Among them, denaturation of proteins by GdmCl is one of the most important applications of salt effects on proteins; we can understand the conformational stability of proteins on the basis of the salt-induced denaturation [1, 3, 4]. However, the findings that horse cytochrome *c* and several proteins form the molten globule intermediate in the presence of salts, as will be described in detail in this chapter, attracted much attention on the salt effects, suggesting that salts might be useful for specifically stabilizing the folding intermediates. Salt-stabilized molten globule states have been the target of extensive studies addressing the conformation and stability of the folding intermediates. In particular, characterization of the salt-dependent conformational changes of acid-denatured proteins have revealed a more clear view of the acid denaturation and effects of ions in modulating the conformations of the intermediate and unfolded states.

24.2
Alcohol-induced Intermediates of Proteins and Peptides

24.2.1
Formation of Secondary Structures by Alcohols

Alcohols promote the formation of ordered secondary structures in disordered polypeptide chains. The effectiveness of alcohols in inducing the conforma-

tional transition varies substantially (see below). Among various alcohols, 2,2,2-trifluoroethanol (TFE) is often used because of its relatively strong effects and low absorbance in the far-UV region, which makes far-UV CD measurements feasible. 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) has a higher potential than TFE to induce the alcohol-dependent effects, although the formation of alcohol clusters might complicate the interpretation of the alcohol effects (see below).

For many disordered peptides, α-helical structures are induced because they are stabilized by the most local interactions, but various peptides assume β-hairpin or β-turn structures in alcohol/water solvents [15–22]. Importantly, these secondary structures are all stabilized by local hydrogen bonds. The formation of β-sheet structures, which need a network of nonlocal hydrogen bonds, is not usually expected for short peptides unless the peptide molecules are associated into oligomeric structures or aggregates. Nevertheless, there are several examples of longer polypeptides or proteins, including tendamistat and leucocin A [30, 31], showing stabilization of β-sheet structures.

Thus, the exact types of secondary structures stabilized in alcohol/water solvent depend on the amino acid sequence. The intrinsic structural preference of each amino acid sequence is an important factor in determining the types of secondary structures in alcohol/water solvent [15–22, 30–39]. The ability of alcohols to induce the particular secondary structures is, therefore, useful to analyze the intrinsic conformational propensity of a short peptide with no appreciable ordered conformation in aqueous solution. The peptide conformation induced in alcohol/water solvent can be readily analyzed by conventional CD or solution NMR methods. These methods are also useful in detecting the structural properties of early intermediate of protein folding [32, 36, 39–42].

The same experimental system has been successfully applied to elucidate the conformational stabilities and properties of less structured de novo designed proteins in water solvent [19–20]. As is the case for short peptides, de novo proteins often fail to assume ordered conformations in water. In such a case, the addition of alcohol induces the formation of otherwise unstable secondary structures. By analyzing the alcohol-dependent transition, one can estimate the stability of the ordered conformation in water. Such an analysis is helpful to optimize the sequence of de novo proteins in order to create a rigid native-like structure even in the absence of alcohols. Furthermore, the structural properties of membrane proteins can be analyzed in alcohol/water solvent by solution NMR spectroscopy [43–46].

Interestingly, a high correlation was found between the α-helical content expected from secondary structure prediction based on amino acid sequence and the α-helical content estimated by CD in the presence of high concentrations of TFE [47, 48]. This observation supports the idea that the local interactions are dominant in the alcohol-induced protein conformations. Conventional secondary structure predictions consider mainly local interactions. A lesser correlation was found between the α-helical content in the native structure and that in the TFE state, indicating the role of nonlocal interactions for stabilizing the native structures. The α-helical content of the alcohol-induced state tends to be larger than that of the native state. Thus, the TFE-induced structures of polypeptide chains should contain a significant amount of nonnative α-helices.

24.2.2 Alcohol-induced Denaturation of Proteins

As described above, alcohols were originally used as denaturants. However, alcohols are not the first choice reagent for the analysis of protein stability since uncertainty exists in the thermodynamic interpretation of alcohol-induced states. Moreover, alcohols tend to induce nonspecific aggregates of proteins at neutral pH, probably because of the reduced electrostatic repulsion between protein molecules. Therefore, studies have often been performed under acidic conditions where the solubility of proteins in alcohol/water solvent increases.

Shiraki et al. [48] analyzed the effects of TFE on protein conformation using various types of proteins with different secondary structures. The transitions induced by TFE were monitored by far-UV CD. The transition curves obtained by plotting the ellipticity at 222 nm as a function of TFE concentration consisted of two phases. The initial transition was relatively cooperative showing an increase in α-helical content at a certain TFE concentration. At neutral pH, the concentration range of this transition was predominantly determined by the stability of native structure. On the other hand, at acidic pH $\sim$ 2, many proteins were unfolded in the absence of TFE. For most of these unfolded proteins at pH 2, the induction of α-helical structure was observed in the TFE concentrations of 10–20% (v/v). For proteins with a relatively low propensity toward α-helices, the α-helical content just after the first transition was low, but, in the second stage, it gradually increased with further increases in the TFE concentration. When the intrinsic α-helical propensity is high, the posttransitional increase in α-helical content was less obvious because the helical content achieved after the first cooperative transition is already high.

The transition curves observed, for example by the far-UV CD, can be simply analyzed by assuming a two-state mechanism between the native and alcohol-induced states (see chapter by Pace and Scholtz for details of two-state analysis). In most cases, this method works well, providing two parameters, namely $\Delta G(H_2O)$ (a free energy change between the native and TFE states) and the *m*-value (a measure of cooperativity of transition). The value of $\Delta G(H_2O)$ provided by a such treatment is often consistent with the value obtained from the analysis of GdmCl or urea unfolding curves [2]. This is rather surprising since the TFE denatured state with highly ordered secondary structures is unlikely to be thermodynamically equivalent to the GdmCl unfolded state. Unlike the native state, the denatured state consists of an ensemble of nonnative conformations. Thus, a conformation similar to the alcohol-induced state possibly pre-exists at a low level in such an ensemble of denatured structures even under the native conditions.

The TFE-induced states of several proteins, for example hen lysozyme and bovine β-lactoglobulin, have been well characterized by high-resolution heteronuclear NMR [49, 50]. The chemical shifts of NMR spectra for the TFE state show less dispersed signals compared to the native structures. Beside this, a number of nuclear Overhauser effects (NOEs) consistent with the presence of α-helices can be observed. Other information on the secondary structure, extracted from a chemical

shift index or coupling constants, also provides the evidence for the presence of α-helices. On the other hand, the backbone amide hydrogens are much less protected against hydrogen/deuterium exchange even though significant parts of the protein molecule are in an α-helical conformation. Thus, the secondary structures formed in the TFE state are mobile, and parts of polypeptide chain are rapidly interconverted to the extended configurations. In accordance with this, small-angle solution X-ray scattering indicated that the TFE-induced state of hen lysozyme possesses a chain-like character as is the case of fully unfolded structures in high concentrations of urea or GdmCl [51]. On the other hand, the radius of gyration of the TFE state was between the fully unfolded state and the compact native state. Taken together, the TFE state is considered to be an "open helical conformation" in which the α-helical rods are exposed to the solvent because of the absence of strong hydrophobic attraction between them, contrasting with the compact molten globule stabilized by salt. Similar results were obtained with the methanol-induced α-helical states of horse cytochrome *c* [52] and horse apomyoglobin [53].

24.2.3
Formation of Compact Molten Globule States

Although the alcohol-induced denaturation of proteins is often approximated by a two-state mechanism between the native and TFE-induced α-helical states, accumulation of the molten globule-like intermediate during the transition is sometimes observed in several proteins (Table 24.1) [52–67]. Generally speaking, the alcohols having less potential to induce α-helical structures seem to have a higher potential to induce a three-state transition with a molten globule intermediate. However, even an effective helix inducer such as TFE sometimes stabilizes the molten globule state, as has been shown for α-lactalbumin [60]. Interestingly, many such proteins are also known to form the molten globule states in the pres-

ence of moderate concentrations of urea or GdmCl or by addition of salts in the acid-denatured state (Table 24.1).

The molten globule state is often found in the presence of moderate concentrations of alcohols. Higher concentrations of alcohols tend to stabilize the extended highly α-helical conformation as described above. The mechanism of how alcohols induce such a three-state transition with the molten globule intermediate is still ambiguous. A significant number of the native tertiary contacts between hydrophobic side chains are disrupted in the alcohol state. At the same time, the nonpolar environment introduced by alcohols forces the polypeptide chains to form nonnative α-helices. In the presence of moderate concentrations of alcohol, it is likely that such effects of alcohols are less obvious, so that some proteins remain in a compact denatured state with native-like secondary structures.

24.2.4 Example: β-Lactoglobulin

Alcohol can induce α-helical conformations even in proteins consisting of predominantly β-sheets. Most all-β proteins tend to show a less significant increase in α-helical content in alcohol/water solvents. An interesting example revealing a dramatic increase of α-helical content is bovine β-lactoglobulin. The native structure of β-lactoglobulin consists of nine antiparallel β-strands and a long α-helix at the C-terminal region (Figure 24.3A). Shiraki et al. [48] demonstrated that bovine β-lactoglobulin exhibits an extremely high α-helical content upon the addition of TFE (Figure 24.3B). Our systematic analysis of peptide fragments derived from the β-sheet regions of β-lactoglobulin demonstrated that the peptide fragments also have a high α-helical preference [36, 39]. As discussed above, the conformational propensity of peptide fragments in TFE/water solvent is thought to reproduce the situation of early intermediates formed during the refolding processes. Therefore, the intermediate with nonnative α-helical structures is assumed to be accumulated at the early folding stage of β-lactoglobulin. This was confirmed later by the study of folding kinetics using stopped-flow CD in the absence and presence of TFE [68–71].

Bovine β-lactoglobulin assumes a monomeric native state at pH 2, while it is dimeric at neutral pH. In addition, the presence of a free thiol group (Cys121) in addition to two disulfide bonds (Cys66-Cys16 and Cys106-Cys119) (Figure 24.3A) complicates the refolding experiments because of possible thiol/disulfide exchange reactions in the unfolded state [72]. Therefore, the refolding of β-lactoglobulin was initiated by diluting the unfolded protein in a high concentration of GdmCl at pH 2.0 into the refolding buffer at the same pH, and the folding kinetics were monitored by ellipticity measurements at 222 nm. Usually, the signal is expected to change from the unfolded baseline to the value of the native state (Figure 24.4). Contrary to expectation, the ellipticity at 222 nm exceeded the value of the native baseline at the burst phase and subsequently it slowly returned toward the native value. This suggested the transient formation of nonnative α-helices. Similar kinetic traces were monitored at various wavelengths to construct the far-UV CD

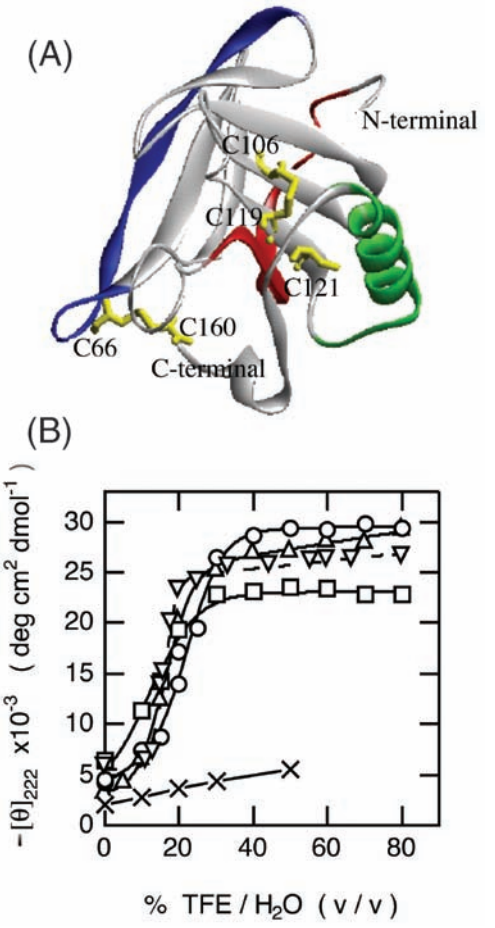

Fig. 24.3. Structure of native β-lactoglobulin (A) and the transitions of its peptide fragments by TFE (B). A) The positions of the fragments are represented by red (fragment 1), blue (fragment 2) and green (fragment 3). The cysteine residues are also shown by yellow. B) The transitions by fragment 1 (circle), fragment 2 (triangle) and fragment 3 (square) are shown. [36] with permission.

spectrum of the burst phase intermediate (Figure 24.4). The spectrum shows a clear minimum around 222 nm, confirming the presence of an increased amount of α-helical structure. The addition of 9.8% (v/v) TFE in the refolding buffer further increased the α-helical content of the burst phase intermediate, supporting the mechanism that the nonnative α-helices are formed at the early stage of the folding reaction of β-lactoglobulin.

A detailed analysis of the early intermediates of β-lactoglobulin was performed using ultra-rapid mixing techniques in conjunction with fluorescence detection

and hydrogen/deuterium exchange labeling probed by heteronuclear NMR [70, 71]. It has been shown that the βA-strand region is involved in the formation of nonnative α-helical structures (Figure 24.5). On the other hand, the data also suggested that, in the early intermediate, the native-like structure is also formed around the βG and βH-strands. This region corresponds to the hydrophobic core in the native structure, and both β-strands are linked by disulfide bonds between Cys106 and Cys119. These properties around the βG and βH strands are likely to

play an important role in the initial stage of the folding reaction of β-lactoglobulin [73]. On the other hand, the role of nonnative α-helices in the early intermediate state is still unknown. Indeed, the formation of such nonnative secondary structures might be less effective in terms of rapid folding since the structure should be disrupted at the later stage of folding. It is probable, however, that the formation of nonnative α-helical segments is useful for preventing intermolecular aggregation since the polypeptide chain becomes relatively compact. The folding mechanism of β-lactoglobulin is still intriguing to understand the interplay between the local and nonlocal interactions during protein folding, and moreover, to understand the α–β transition suggested from several biologically important processes [74, 75].

24.3 Mechanism of Alcohol-induced Conformational Change

Although alcohols are often used to probe the structural preferences of polypeptide chains, the detailed mechanism of how these co-solvents induce the conformational change of polypeptide chains is still debatable. The chemical properties of alcohols are relatively similar to detergents in a sense that the molecules consist of both hydrophobic (hydrocarbon or halogenated hydrocarbon) and hydrophilic (hydroxyl) groups. Possible mechanisms by which alcohols induce conformational changes in polypeptides, therefore, include (1) destabilizing intramolecular hydrophobic interactions and (2) promoting the formation of local backbone hydrogen bonds [23, 24, 76–79]. In alcohol/water solvents with low polarity or low dielectric constant, hydrophobic interactions stabilizing the native structure are weakened and instead the local hydrogen bonds are strengthened, resulting in denaturation and the simultaneous formation of an ''open helical conformation'' or ''open helical coil'', i.e., solvent-exposed helices.

In the case of nonhalogenated alcohols, the efficiency as a helix inducer linearly increases with an increase in the number of carbon atoms in an alcohol molecule [80, 81]. This confirms that the hydrophobic interactions play an important role in the alcohol effects. Although an alcohol is defined by the presence of hydroxyl (OH) group(s), the contribution of the OH group to the alcohol effects is negative. In other words, alcohol effects arise from the dissolved hydrophobic groups, and the OH group is important mainly for dissolving otherwise insoluble hydrocarbon groups into water. In this sense, halogenated alcohols might be expected to be poor alcohols in stabilizing α-helical structures in polypeptide chains, since the halogen atoms have a larger electronegativity than hydrogen atoms. In contrast, halogenated alcohols such as TFE and HFIP have higher potentials to induce the α-helical conformation than nonhalogenated alcohols. Systematic analysis of various halogenated alcohols indicated that the effect of fluoride is the lowest of the various halogens [80, 81]. Nevertheless, the low absorbance of fluoride in the far-UV region makes TFE and HFIP the most useful alcohols to examine the alcohol effects on proteins by CD.

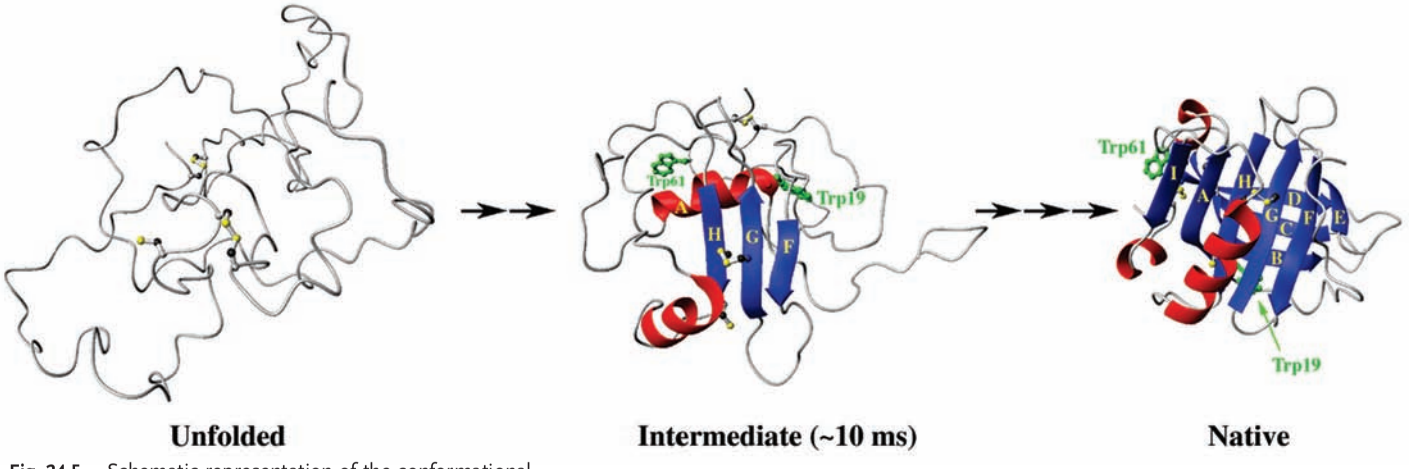

Fig. 24.5. Schematic representation of the conformational states encountered during folding of β-lactoglobulin, including the unfolded ensemble, a partially structured intermediate populated on the millisecond time scale and the native state. Reproduced from Ref. [71] with permission.

Importantly, studies with solution X-ray scattering provided the evidence that water/alcohol mixtures of some halogenated alcohols such as TFE or HFIP assume micelle-like clusters [82]. This suggests that the halogenated alcohols in fact have higher hydrophobicity than nonhalogenated ones, producing dynamically hydrophobic clusters of alcohols, which can interact effectively with protein molecules, thus enhancing the alcohol effects on proteins. In other words, the direct interactions between proteins and alcohol molecules by hydrophobic interactions play an important role in the alcohol effects on proteins.

From a systematic analysis of the alcohol-induced transitions of melittin, a basic and amphiphilic peptide of 26 amino acid residues present in honey bee venom, Hirota et al. [80, 81] indicated that the effects of each alcohol can be rationalized by the additive contribution from the hydrocarbon (CH), hydroxyl (OH), and halogen groups (F, Cl, and Br), providing the following equations for the *m*-value, a measure of the cooperativity for the alcohol-induced transition:

$$m = a\ \mathrm{ASA(CH)} + b\ \mathrm{ASA(OH)} + c\ \mathrm{ASA(F)} + d\ \mathrm{ASA(Cl)} + e\ \mathrm{ASA(Br)} \quad (1)$$

$$m = a\ [\mathrm{ASA(CH)}]^2 + b\ [\mathrm{ASA(OH)}]^2 + c\ [\mathrm{ASA(F)}]^2 + d\ [\mathrm{ASA(Cl)}]^2 + e\ [\mathrm{ASA(Br)}]^2 \quad (2)$$

where ASA(X) corresponds to the accessible surface area of each group X and the value of a, b, c, d, and e are the empirically determined proportionality coefficients which are summarized in Table 24.2. Equation (2) provides a better fit than Eq. (1) when the effects of TFE and HFIP are included. It is noted that the coefficient for the OH group is negative while others are positive. A similar relationship was observed for the alcohol-induced denaturation of β-lactoglobulin [83].

These results indicate the importance of the direct interaction between alcohols and polypeptide molecules. Accordingly, the results from NMR spectroscopy and molecular dynamics simulations suggested that TFE molecules preferentially bind to the backbone carbonyl oxygen group and minimize the solvent exposure of amide hydrogen groups, leading to the stabilization of intramolecular hydrogen bonds in a polypeptide chain [84–88].

These results, moreover, suggest that alcohols will be useful for dissolving protein aggregates stabilized by hydrophobic interactions. In fact, some alcohols such

as TFE or HFIP are useful to dissolve aggregates formed during peptide synthesis. HFIP is often used to dissolve prion and Alzheimer's amyloid β-peptides which tend to form aggregates or amyloid fibrils [89–91]. On the other hand, these alcohols, in particular TFE, are known to induce well-ordered fibrillar architectures similar to the amyloid fibrils [92–95]. These observations are apparently inconsistent with each other and understanding of these contrasting phenomena will be of special importance to clarify the alcohol effects.

24.4 Effects of Alcohols on Folding Kinetics

The studies discussed above are mostly concerned with the behavior of polypeptide chains under equilibrium conditions. During protein folding, many different types of interactions including local hydrogen bonds play important roles. A simple question, therefore, arises: how do proteins behave during kinetic refolding in alcohol/water solvents? Interestingly, Lu et al. [96] first found that the folding kinetics of hen lysozyme is accelerated by the presence of low concentrations of TFE below 5.5% (v/v). In the presence of such a small amount of TFE, the protein is still able to fold into the native structure judging from several spectroscopic data including solution NMR. In addition, pulse-labeling studies suggested that the structural properties of folding intermediates of lysozyme are almost unaffected by the presence of TFE.

An extensive analysis using more than 10 proteins revealed that the acceleration of folding kinetics in the presence of a small amount of TFE is common to all of the proteins examined [97] (Figure 24.6). The logarithm of the refolding rate constant linearly increased with an increase in TFE concentration, but then decreased above a certain concentration of TFE. The concentration range that provides the maximum rate of folding depended on the protein species and other conditions such as pH or temperature. Interestingly, for proteins which fold by a two-state manner without accumulating observable intermediates (two-state proteins), the extent of acceleration by TFE correlates well with the amount of local backbone hydrogen bonds in the native structure (Figure 24.7). This behavior could be rationalized by the fact that TFE stabilizes the local hydrogen bonds in the polypeptide chains, thus forming α-helical or β-turn conformations.

On the other hand, for multi-state proteins which accumulate transient intermediates during the folding process, the acceleration of folding by the presence of TFE was always much less than that anticipated from the correlation found for the two-state proteins (Figure 24.7). The multi-state proteins often assume the molten globule intermediate at the burst phase just after the initiation of folding. According to stopped-flow CD or NMR pulse-labeling analysis, a significant amount of native-like secondary structures is formed in the molten globule intermediates. In such intermediates, the native-like local hydrogen bonds should be already formed. Since the rate-limiting step of folding of the multi-state protein is mainly associated with the rearrangement of partially folded subdomains, the number of local

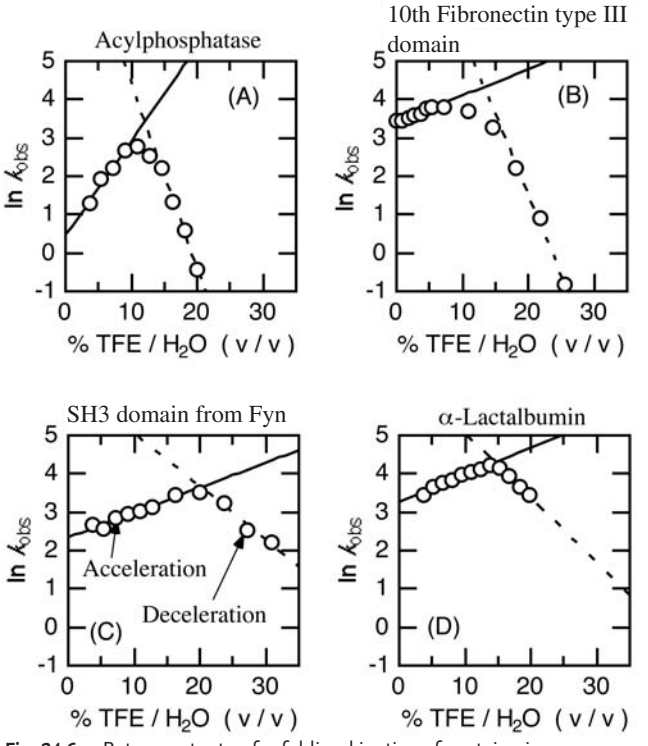

Fig. 24.6. Rate constants of refolding kinetics of proteins in the presence of TFE. Examples are shown for the cases of acylphosphatase (A), 10th type III domain from fibronectin (B), SH3 domain from human Fyn (C), and α-lactalbumin (D). Reproduced from Ref. [97] with permission.

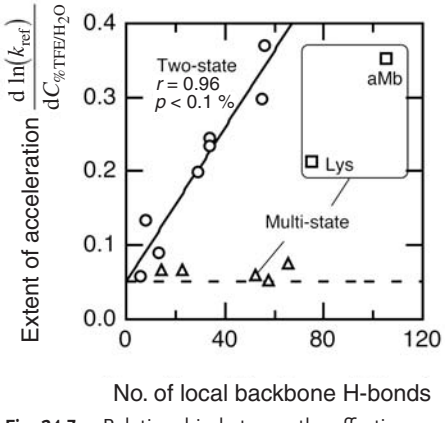

Fig. 24.7. Relationship between the effectiveness of TFE on the acceleration of protein folding and the number of local backbone hydrogen bonds in the native proteins. hydrogen bonds which are formed during the rate-limiting step is less than the number in the native structure. The NMR pulse-labeling studies for several proteins have shown that the number of local hydrogen bonds formed in the intermediate states varies depending on proteins. Consistent with this, the acceleration of folding by TFE for multi-state proteins differs significantly even though the number of local hydrogen bonds in the native structure is similar, as is the case for lysozyme and α-lactalbumin.

In the case of acylphosphatase, a two-state protein, the refolding reaction observed by CD indicated that the absolute intensity at 222 nm for the burst phase intermediate increases upon addition of TFE (Figure 24.8), suggesting the formation of partially folded intermediates which do not accumulate in the absence of TFE [98]. The maximum rate of folding was obtained at the TFE concentration where the ellipticity at 222 nm for the burst phase intermediate is the same as that of the native protein. This observation is consistent with the conclusion drawn

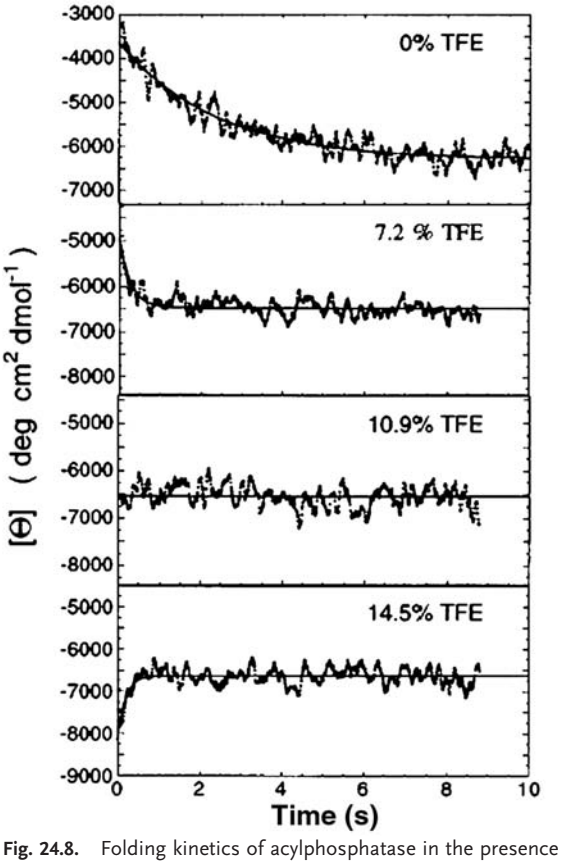

Fig. 24.8. Folding kinetics of acylphosphatase in the presence of TFE monitored by 222 nm far-UV CD. Reproduced from Ref. [98] with permission.

from the analysis of Hammond behavior and nonlinear activation free energy of the folding reaction [99, 100] (see opposing result by Yiu et al. [101]). The analysis indicates that the free energy barriers encountered by a folding polypeptide are generally narrow with robust maxima and that the change in the folding rate by the perturbation of folding landscape, for example, by mutations or changing conditions, is mainly due to the induction of folding intermediates for two-state proteins. Thus, the data suggest that the activation energy is decreased in the presence of TFE because of the decreased stability of the early intermediate relative to the transition state.

24.5 Salt-induced Formation of the Intermediate States

24.5.1 Acid-denatured Proteins

Acid-denatured proteins often assume an intermediate conformation. The most well-known example is the acidic molten globule state of α-lactalbumin [26–29] (see Chapter 23). However, the conformation of acid-denatured proteins depends on the protein species, and the nature of the acid-denatured state was ambiguous in comparison with the unfolded states induced by urea or GdmCl [4, 5] (see Chapter 8). The important results indicating the salt-dependent transition of the acid-denatured state came out with horse cytochrome *c* [25], followed by *Bacillus subtilis* β-lactamase [102] and horse apomyoglobin [103, 104]. These proteins are substantially unfolded at pH 2 in the absence of salt. The addition of a low concentration of salts induced an intermediate state with notable far-UV CD intensity, while the near-UV CD showed disordering (Figure 24.9). The salt-induced state is similar to the acidic molten globule state of α-lactalbumin [26–29]. In fact, the name of molten globule state was first used for the salt-stabilized acidic state of cytochrome *c* [25]. Similar observation with β-lactamase [102], apomyoglobin [103, 104], staphylococcal nuclease [105, 106], and other proteins established that the salt-dependent transition is common to various acid-denatured proteins.

The conformation of the acid-denatured state is determined by a balance of various factors stabilizing or destabilizing the folded state. The most important destabilizing force should be the charge repulsion between positive charges because most of the titratable groups are protonated at pH 2. Consistent with this, proteins with a high p*I* value (for example, cytochrome *c*) tend to be unfolded substantially. On the other hand, the driving forces for folding would be similar to those at neutral pH except that the electrostatic interactions are affected by pH. The addition of salts somehow shields the unfavorable charge repulsion, thus the folding forces come into play, although the distinct ionizations of the titratable groups prevent the formation of native structure.

The participation of hydrophobic interactions, although less than that of the native state, has been established by a series of studies using calorimetric analysis

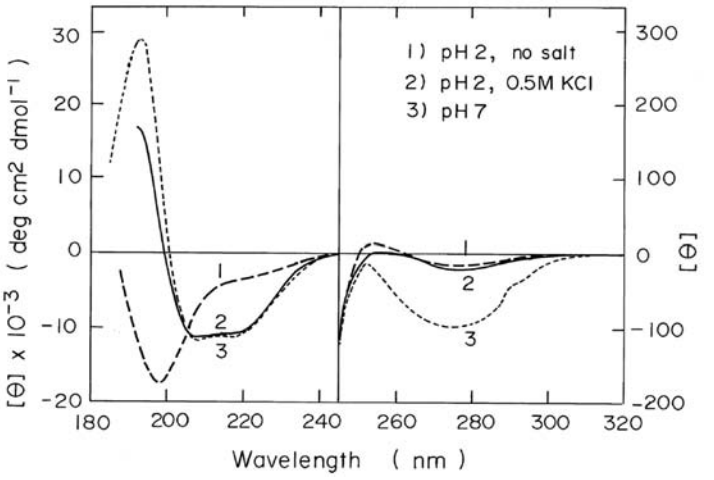

Fig. 24.9. Salt-dependent change of the CD spectrum of the acid-denatured *Bacillus cereus* β-lactamase at 20 °C. 1) The acid-unfolded state at pH 2.0 in the absence of salt; 2) the molten globule state at pH 2.0 in 0.5 M KCl; 3) the native state at pH 7.0. of the salt-stabilized intermediate states [107–111]. Nevertheless, the salt-induced transition itself does not reveal the detailed mechanism of the salt effects.

24.5.2
Acid-induced Unfolding and Refolding Transitions

In an attempt to fully acid-unfold proteins, an intriguing observation was made; increasing the concentration of HCl opposes the unfolding, and rather refolds the protein to the molten globule state [112] (Figure 24.10). The acid-stabilized state was essentially the same intermediate as stabilized by salts. Although the phenomenon was surprising at first, it is straightforward to understand the mechanism once the ionic strength effect is taken into account; decreasing the pH below 2 exponentially increases the concentration of anion as well as of protons by $[Cl^-] = [H^+] = 10^{-pH}$. This suggests that the apparent refolding phenomenon observed by increasing the HCl concentration is caused by the anion effect rather than the pH effects. Consistent with this idea, the acid-induced transition plotted against the concentration of HCl agreed well with that plotted against the concentration of NaCl or KCl [112] (Figure 24.11). By considering the ionic strength effect of HCl, the pH and salt-dependent phase diagram of acid-denatured proteins can be constructed [103, 104, 113] (Figure 24.12). It is important to recognize that decreasing pH increases the chloride concentration, thus producing the prohibited region in the phase. Consequently, decreasing the pH below 2 results in increasing ionic strength, causing the same effects as adding salt at pH 2.

The phase diagram is useful to understand the variation of acid denatured states among proteins. In the cases of horse cytochrome *c* [25, 113] and horse apomyo-

globin [103, 104], a clear boundary between the fully unfolded state and the molten globule state was observed. For the phase diagram of apomyoglobin, moreover, the unfolding intermediate was observed at moderately acidic pH regions. On the other hand, it is expected for a protein with less charge repulsion that the acid denaturation directly produces the molten globule intermediate without maximally unfolding the protein. This is considered to be the case for bovine α-lactalbumin. Cytochrome *c* species with various degrees of charge repulsion were prepared by acetylating lysine amino groups [107, 114]. The phase diagrams of these variously modifed cytochrome *c* species showed that the boundary between the fully unfolded state and the molten globule state depends on the charge repulsion: decreasing the net charge (that is, decreasing pH) decreases the concentration of salt

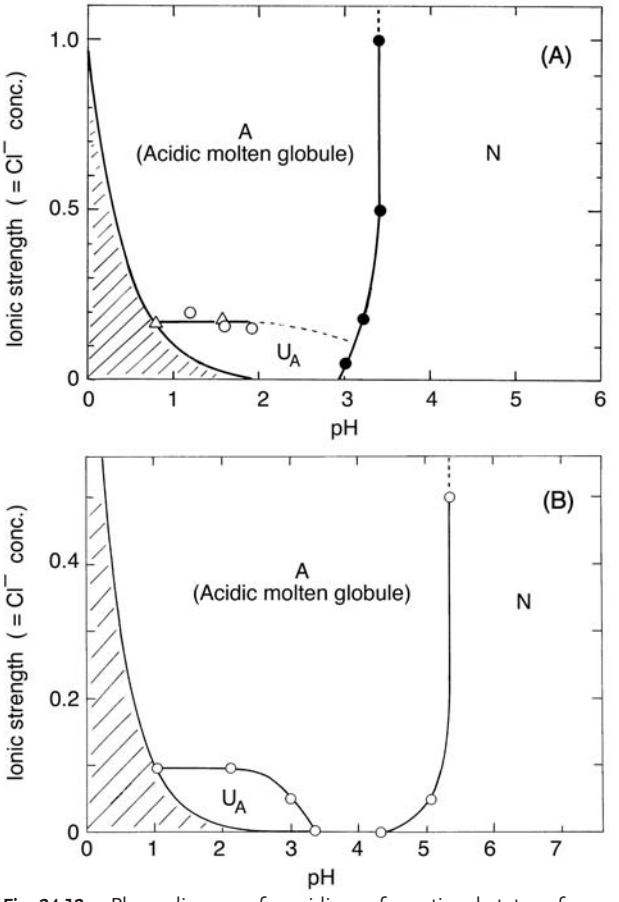

Fig. 24.12. Phase diagrams for acidic conformational states of horse cytochrome *c* (A) and horse apomyoglobin (B). Phase diagram for apomyoglobin reproduced from Ref. [102] with permission.

required to stabilize the molten globule state [113]. Thus, we can understand consistently the variation of acid denaturation among proteins.

An important implication is that to maximally unfold a protein by acid, pH 2 under the low salt conditions will be best. These conditions would also be optimal for dissolving proteins and peptides taking advantage of the net charge repulsion.

The role of charge repulsion and hydrophobic interactions were characterized by analyzing the salt-dependent transition of horse cytochrome *c* [107, 114]. Conformational transitions of variously acetylated cytochrome *c* derivatives, that is, modified cytochrome *c* species with different p*I* values, revealed that the net charge repulsion destabilizes the molten globule state by about 400 cal mol^{-1} per charge at 25 °C. In addition, thermal unfolding of these acytylated cytochrome *c* species verified the contribution of hydrophobic interactions in the stability of the molten glob-

ule state, which is about 30–40% of that of the native state [107]. The enthalpy change upon formation of the molten globule state and its temperature dependence were directly determined by isothermal titration calorimetry measurements of the salt-dependent conformational transition, which is consistent with the value determined by DSC measurements [110]. Similar measurements were performed with horse apomyoglobin [111].

24.6 Mechanism of Salt-induced Conformational Change

Although the importance of anions in shielding the charge repulsive forces is evident, anions can work in various ways [115]. (1) Salts can shield the charge repulsion through Debye-Hückel screening effects. (2) Some anions, such as sulfate, are well known to stabilize the native state, which has been interpreted in terms of the effects on water structure (that is, structure maker) consequently strengthening the hydrophobic interactions of proteins. (3) Anions can directly interact with positive charges on proteins to shield the charge repulsion. These three possibilities can be distinguished by examining the effects of various anion species [115].

Debye-Hückel effects are independent of anion species. It is known that the effects of anions in stabilizing protein structure follow the Hofmeister series [5, 6]. The representative series is:

$$\text{sulfate} > \text{phosphate} > \text{fluoride} > \text{chloride} > \text{bromide} > \text{iodide} > \text{perchlorate} > \text{thiocyanate} \quad (3)$$

Although the exact mechanism of stabilization or destabilization by these anions is unknown, the results are consistent with the idea that these salts affect the water structure. On the other hand, the affinity of a particular anion to an anion-exchange resin is called electroselectivity. The selectivity series of various anions depends critically on the structure of the resin and the solution conditions. However, the general trend of selectivity can be seen from the following examples [116, 117]:

$$\text{sulfite} > \text{sulfate} > \text{perchlorate} > \text{thiocyanate} > \text{iodide} > \text{nitrate} > \text{bromide} > \text{chloride} > \text{acetate} = \text{fluoride} \quad (4)$$

$$\text{perchlorate} > \text{iodide} > \text{trichloroacetate} = \text{thiocyante} > \text{nitrate} > \text{bromide} > \text{trifluoroacetate} > \text{chloride} > \text{acetate} > \text{fluoride} \quad (5)$$

The order of the Hofmeister series is distinct from that of electroselectivity. In particular, the orders of monovalent anions are opposite between the two. Moreover, the concentrations of salts to induce the Hofmeister effects are generally higher than those for anion binding (electroselectivity).

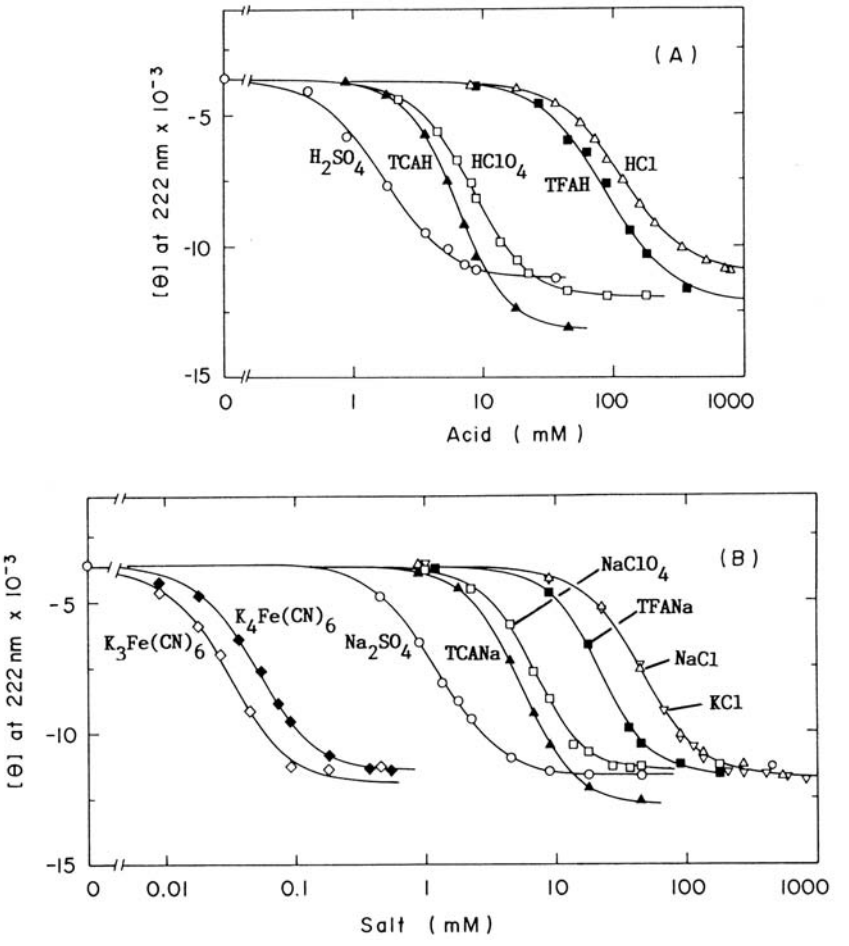

Fig. 24.13. Acid-induced (A) or salt-induced conformational transitions of horse cytochrome *c* in the presence of 18 mM HCl measured by the ellipticity at 222 nm at 20 °C. Reproduced from Ref. [114] with permission.

The effects of various salts on the acid-unfolded cytochrome *c* and apomyoglobin were examined [115] (Figure 24.13). Similar experiments with various acids were also performed, producing essentially the same results with respect to the order of anions:

$$\begin{aligned} &\text{ferricyanide} > \text{ferrocyanide} > \text{sulfate} > \text{trichloroacetate} > \text{thiocyanate} \\ &\quad > \text{perchlorate} > \text{iodide} > \text{nitrate} > \text{trifluoroacetate} \\ &\quad > \text{bromide} > \text{chloride} \end{aligned} \tag{6}$$

The results showed convincingly that the effects depend on anion species, and the order of effectiveness was consistent with the electroselectivity series (Eqs (4) and (5)). Anions with multiple charges show stronger potentials. Among the monovalent anions, chaotropic anions such as iodide or bromide show stronger effects while the effects of chloride are the weakest. These results demonstrate that the electrostatic attraction between the positively charged proteins and negatively charged anions causes the direct interactions between them, thus shielding the charge repulsion.

24.7 Generality of the Salt Effects

Although anion binding-induced stabilization of the intermediate state is often observed at acidic pH, it is likely that a similar interaction plays a role in determining the protein conformation under physiological pH when a protein is highly positively charged. The salt-dependent conformational transition has been known for many years for melittin. The conformational transition of melittin has been shown to be dependent on anion binding [118–120]. Moreover, the similar role of anion binding was also shown for another basic and amphiphilic bee venom peptide, mastoparan [121] and a designed amphiphilic peptide [122]. These results imply that the anion binding can control the conformational transition of some of natively unfolded proteins. Recently, a natively unfolded *Bacillus subtilis* ribonuclease P was shown to exhibit anion-dependent folding, indicating that the anion-dependent folding plays a role in the function of some proteins [123]. On the other hand, the role of cations in determining the conformation of proteins is less clear, although it is conceivable that the opposite situation takes place for negatively charged unfolded proteins and peptides.

Finally, it is useful to consider the effects of GdmCl in relation to the anion effects as described in this chapter. GdmCl is a salt made of a guanidinium cation and chloride. Hagihara et al. [124] observed intriguing GdmCl-dependent conformational transitions with the acid-unfolded horse cytochrome *c* and horse apomyoglobin (Figure 24.14). By the addition of low concentrations of GdmCl, the acid-unfolded proteins at first refolded to the molten globule intermediate before unfolding again at high GdmCl concentrations. Although the observation might be surprising, the interpretation is straightforward, as is the case of the acid-induced refolding. The first refolding by GdmCl is caused by the anion effect while subsequent unfolding is driven by the normal chaotropic effects of GdmCl. The similar refolding and unfolding transitions were observed for a designed amphiphilic peptide at neutral pH [122]. Moreover, the stabilizing effects of low concentrations of GdmCl may be common to several proteins under the physiological conditions [125]. Thus, when GdmCl is used, it is important to interpret the data taking into account the salt effects of GdmCl. It is also recommended to compare the results with the denaturation caused by urea, another popular denaturant.

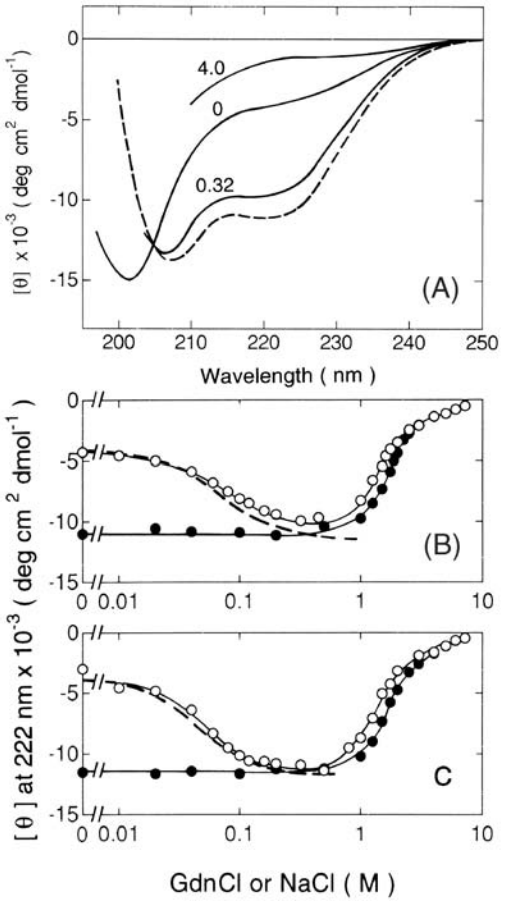

Fig. 24.14. GdmCl-induced refolding and unfolding transitions of acid-unfolded proteins. A) Far-UV CD spectra of horse apomyoglobin as a function of GdmCl concentration in 20 mM HCl (pH 1.8) at 20 °C. The numbers refer to the GdmCl concentration in molar units. The broken line shows the spectrum of the molten globule state stabilized by 0.4 M NaCl in 20 mM HCl. B,C) Conformational transitions of horse apomyoglobin (B) and horse cytochrome *c* (C) measured by the change in ellipticity at 222 nm. Open and filled circles indicate the GdmCl-induced transitions in the absence and presence of 0.4 M NaCl, respectively. Open squares show the reverse transition, in which proteins were initially unfolded in 4 M GdmCl. For comparison, NaCl-induced refolding transitions in the same buffer are shown by broken lines. Reproduced from Ref. [123] with permission.

24.8 Conclusion

Alcohols and salts affect the conformational stability of partially folded intermediate in various ways. The effects of alcohols are basically explained by destabiliza-

tion of intramolecular hydrophobic interactions and stabilization of the local hydrogen bonds, often resulting in the formation of the open helical conformation. The molten globule-like compact intermediate is occasionally observed at moderate concentrations of alcohols and, moreover, β-structures are stabilized for some peptides and proteins. Of particular interest is the formation of fibrillar architechtures similar to the amyloid fibrils in alcohol/water solvents. These results indicate that, although major effects of alcohols on protein and peptides are the same, the resultant conformation varies substantially depending on the balance of various forces, the details of which are still unknown. Salts can also stabilize the intermediates in several ways. Major effects of salts are Debye-Hückel screening effects, effects on water structure, resulting in the modulation of hydrophobic interactions, and counter ion binding. Among them, we discussed that the direct interactions of anions with positive charges on proteins play important roles in determining the structure and stability of partially folded intermediates. Understanding kinetic aspects of these alcohol and salt effects will further clarify the conformation and stability of the partially folded intermediates.

Prolyl Isomerization in Protein Folding

Franz Schmid

25.1
Introduction

Peptide bonds in proteins can occur in two isomeric states: *trans*, when the dihedral angle ω is 180°, and *cis*, when ω is 0°. For the bonds preceding residues other than proline (nonprolyl bonds[1]) the *trans* conformation is strongly favored energetically over *cis*, and therefore *cis* nonprolyl bonds are rare in folded proteins. Peptide bonds preceding proline (prolyl bonds) are frequently in the *cis* conformation. In this case the *trans* form is only slightly favored energetically over *cis*. *Cis* peptide bonds in native proteins complicate the folding process, because the incorrect *trans* forms predominate in the unfolded or nascent protein molecules, and because the *cis* $\rightleftharpoons$ *trans* isomerizations are intrinsically slow reactions. Incorrect prolyl isomers do not block the folding of a protein chain right at the beginning, but they strongly decelerate the overall folding process. This is clearly seen for small single-domain proteins. Many of them refold within milliseconds or even less when they contain correct prolyl isomers, but when incorrect isomers are present (typically *trans* isomers of bonds that are *cis* in the native state) folding is decelerated from milliseconds to the time range of several minutes.

Several strategies are useful for identifying proline-limited steps in a folding reaction. They include interrupted unfolding and refolding in double mixing experiments as well as the use of prolyl isomerases, which are enzymes that catalyze prolyl isomerizations (see Chapter 10 in Part II). The prolyl isomerases are ubiquitous proteins. They are found in all organisms, and in bacteria a prolyl isomerase

1) To facilitate reading I use the terms *cis* proline and *trans* proline for proline residues that are preceded by a *cis* or a *trans* peptide bond, respectively, in the *folded* protein. ''Native-like'' and ''incorrect, nonnative'' denote whether in an unfolded state a particular prolyl peptide bond shows the same conformation as in the native state or not. Further, I use the expression ''isomerization of Xaa'' for the isomerization of the peptide bond preceding Xaa. Peptide bonds preceding proline are referred to as ''prolyl bonds,'' those preceding residues other than proline as ''nonprolyl bonds.'' The folding reactions that involve Xaa-Pro isomerizations as rate-limiting steps are denoted ''proline-limited'' reactions.

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

is associated with the ribosome. This enzyme, the trigger factor, accelerates proline-limited folding reactions particularly well and might in fact also catalyze prolyl isomerizations in the folding of nascent proteins. Prolyl isomerization in protein folding and its catalysis by prolyl isomerases are covered in a number of review articles [1–10].

25.2 Prolyl Peptide Bonds

In a peptide bond the distance between the carbonyl carbon and the nitrogen is 0.15 Å shorter than expected for a C–N single bond and both the C and the N atom show sp^2 hybridization [11], which indicates that the peptide bond has considerable double bond character. Peptide bonds are thus planar, and the flanking Cα atoms can be either in the *trans* or in the *cis* conformation (equivalent to dihedral angles ω of 180° and 0°, respectively). For peptide bonds preceding residues other than proline the *cis* state is strongly disfavored. Fischer and coworkers found *cis* contents between 0.11 and 0.48% for a number of nonprolyl peptide bonds in oligopeptides. The highest propensity to adopt the *cis* conformation was observed for a Tyr-Ala bond in a dipeptide [12].

In native, folded proteins nonprolyl *cis* peptide bonds are very rare [13–16]. Only 43 *cis* nonprolyl peptide bonds were found in a survey of 571 protein structures [16]. Interestingly carboxypeptidase A contains three of them [17].

For Xaa-Pro peptide bonds (''prolyl bonds'') the *cis* and *trans* conformations differ much less in energy because the Cα of Xaa is always arranged in *cis* with a C atom: either with the Cα or the Cδ of the proline (Figure 25.1). The *trans* isomer is thus favored only slightly over the *cis* isomer and in short peptides frequently *cis* contents of 10–30% are observed [18–21]. The *cis*/*trans* ratio depends on the properties of the flanking amino acids and on ionic or van der Waals interactions that are possible in one isomeric state, but not in the other.

In small, well-folded proteins the conformational state of each prolyl bond is usually clearly defined. It is either *cis* or *trans* in every molecule, depending on the structural framework imposed by the folded protein chain. About 5–7% of all prolyl peptide bonds in folded proteins are *cis* [13–16], and 43% of 1435 nonredundant protein structures in the Brookhaven Protein Database contain at least one *cis* proline [20]. Several proteins are heterogeneous and show *cis*/*trans* equilibria at

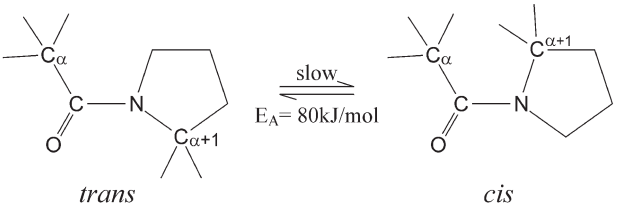

Fig. 25.1. Isomerization between the *cis* and *trans* forms of an Xaa-Pro peptide bond.

one or more prolyl bonds. Most of these heterogeneities were discovered by NMR spectroscopy. They will be discussed later (see Section 25.5).

The energy barrier between the *cis* and the *trans* form is enthalpic in nature. The average activation enthalpy is about 80 kJ mol^{-1} and the activation entropy is close to zero. Because of this high energy barrier prolyl isomerizations are intrinsically slow reactions with time constants that range between 10 and 100 s (at 25 °C). The absence of an activation entropy indicates that the surrounding solvent is not reorganized when the activated state of this intramolecular isomerization reaction is reached.

Secondary amide [22] and prolyl isomerizations are faster in nonpolar solvents than in water. This was traditionally explained by assuming that the transition state for isomerization is less polar than the ground state because the peptide bond is twisted and thus the resonance between the carbonyl group and the nitrogen is lost [23]. Eberhardt et al. [24] found, however, that the rate constant of prolyl isomerization in the dipeptide Ac-Gly-Pro-OCH_3 does not correlate with the dielectric constant of the solvent, but with its ability to donate a hydrogen bond to the carbonyl oxygen of the peptide.

The nitrogen of the amide bond can be protonated by very strong acids. This protonation abolishes the resonance between C=O and N of the prolyl bond. Thus, the partial double bond character is lost and the barrier to rotation is diminished. Prolyl isomerization is in fact well catalyzed by a solution of acetic acid in acetic anhydride [25] or by $\geq$7 M $HClO_4$ [26].

In summary, prolyl isomerization is slow because the resonance energy of the CN partial double bond must be overcome. The reaction is decelerated when the resonance is increased, such as in solvents that donate a hydrogen bond or a proton to the carbonyl oxygen. It is accelerated when the resonance is decreased, in particular by N protonation. The mechanism of nonenzymic prolyl isomerization is thoroughly discussed by Stein [23] and Fischer [21].

25.3
Prolyl Isomerizations as Rate-determining Steps of Protein Folding

25.3.1
The Discovery of Fast and Slow Refolding Species

In seminal work Garel and Baldwin [27] discovered that unfolded ribonuclease A (RNase A) consists of a heterogeneous mixture of molecules. They found fast-folding U_F molecules[2] that refolded in less than a second, and slow-folding U_S molecules that required several minutes to fold to completion. Similar U_F and U_S

2) Abbreviations used: U, I, N, the unfolded, the intermediate, and native state of a protein, respectively; U_F, U_S, fast- and slow-folding unfolded forms, I_N, native-like intermediate; τ and λ, apparent time constant and rate constant, respectively, of a reaction; k, microscopic rate constant.

species were later found in the folding of many other proteins [7, 28, 29]. In 1975, two years after the discovery by Garel and Baldwin, Brandts and coworkers [30] formulated the proline hypothesis and suggested that the U_F and U_S molecules differ in the *cis*/*trans* isomeric state of one or more Xaa-Pro peptide bonds.

In the native protein (N) usually each prolyl peptide bond is in a defined conformation, either *cis* or *trans*, depending on the constraints dictated by the ordered native structure. After unfolding ($N \rightarrow U_F$), however, these bonds become free to isomerize slowly as in short oligopeptides (in the $U_F \rightleftharpoons U_S^i$ reaction), as shown in Scheme 25.1.

$$N \xrightarrow[\text{fast}]{\text{unfolding}} U_F \underset{\text{slow}}{\overset{\text{Pro isomerization}}{\rightleftharpoons}} U_S^i$$

Scheme 25.1. Kinetic model for the coupling betweeen protein unfolding and prolyl isomerization.

The isomerizations thus create a mixture, which consists of a single unfolded species with correct prolyl isomers (U_F) and, depending on the number of prolines, one or more unfolded species with incorrrect prolyl isomers (U_S^i). The U_F molecules with the native-like prolyl isomers can refold directly in a fast reaction to the native conformation. The U_S^i molecules, however, refold slowly, because their refolding involves the re-isomerizations of the incorrect prolyl bonds.

25.3.2
Detection of Proline-limited Folding Processes

Proline-limited reactions in the unfolding and refolding of a protein can be identified and characterized in several ways.

1. *Rates and activation energies of refolding.* Circumstantial evidence for a proline-limited folding reaction is provided when its time constant is in the 10–100 s range (at 25 °C) and when its activation energy is about 80 kJ mol^{-1}. Conformational folding reactions can, however, show very similar kinetic properties, and therefore time constants and activation energies provide weak evidence for a proline-limited process.
2. *Properties of the refolding reactions.* The various U species that are populated at equilibrium in the unfolded protein give rise to parallel direct and proline-limited refolding reactions. The relative amplitudes of these refolding reactions should depend only on the relative populations of these U species. They should be independent of the final folding conditions and independent of the probe that was used to monitor refolding. The amplitudes of refolding should also be independent of the initial unfolding conditions, because the *cis*/*trans* equilibria at prolyl bonds are largely independent of the denaturant concentration, of temperature, and of the pH (unless the prolines are flanked by ionizable groups).

These criteria are valid only when direct folding is much faster than proline-limited folding and when partially folded intermediates with incorrect prolines do not accumulate during folding. U species with several incorrect prolines can enter alternative refolding routes, and the rank order of the re-isomerizations may change with the refolding conditions. Guidelines for the kinetic analysis of folding reactions that are coupled with prolyl isomerizations are given by Kiefhaber et al. [31, 32].

3. *Slow refolding assays (double jumps)*. Prolyl isomerizations in the unfolded form of a protein (after the $N \rightarrow U_F$ unfolding step, Scheme 25.1) can be measured by slow refolding assays. The $U_F \rightleftharpoons U_S$ isomerizations usually cannot be monitored directly by a spectroscopic probe. Rather, the amount of U_S formed after different times of unfolding is determined by slow refolding assays in "double jump" experiments [30, 33]. Samples are withdrawn from the unfolding solution at different time intervals after the initiation of unfolding; these samples are transferred to standard refolding conditions, and the amplitudes of the resulting slow refolding reactions, $U_S \rightarrow N$, are determined. These amplitudes are proportional to the concentrations of the U_S species present at the time when the sample was withdrawn for the assay, and their dependence on the time of unfolding reveals the kinetics of the $U_F \rightleftharpoons U_S$ reactions. An experimental protocol for double-jump experiments is given in Section 25.9 (Experimental Protocols). Slow refolding assays work very well when conditions can be found under which the conformational and the proline-limited events are well separated in both the unfolding step and in the subsequent refolding assay. It cannot be used when conformational folding ($U_F \rightarrow N$) in the second step shows a similar rate as the $U_F \rightleftharpoons U_S$ reactions. In this case the prolyl isomerizations couple with the $U_F \rightarrow N$ reaction in the refolding assay, and the amplitudes of refolding no longer reflect the concentration of the U_S molecules, as present at the time of sample transfer.
4. *Catalysis by prolyl isomerases*. Prolyl isomerases are excellent tools to identify proline-limited folding reactions. Since they catalyze only prolyl isomerizations (see Chapter 10 in Part II), the acceleration of a particular folding reaction by a prolyl isomerase provides compelling evidence that it involves a proline-limited step. Partial folding may render prolyl bonds inaccessible for a prolyl isomerase. Therefore a lack of catalysis does not strictly rule out prolyl isomerization as the rate-limiting step of a particular folding reaction. Several families of prolyl isomerases with different substrate specificities are available and can be used as tools in folding studies [3, 7, 8].
5. *Replacement of prolines by other residues*. Site-directed mutagenesis of proline residues is an apparently simple und straightforward means to detect proline-limited folding reactions and to identify the prolines that are involved in a particular folding reaction. The interpretation of the changes in the folding kinetics is usually straightforward when a *trans* prolyl bond of the wild-type protein is changed to a nonprolyl *trans* bond by the mutation, or when a *cis* prolyl bond is replaced by a "normal" nonprolyl *trans* bond. The protein stability and the rate of the direct folding reaction should not be changed strongly by the proline

substitution. For *cis* prolines such conditions are rarely met. Often, mutations of critical *cis* prolines are strongly destabilizing and the *cis* conformation of the respective bond is maintained even after the mutation to a residue other than proline. *Trans* → *cis* isomerizations at nonprolyl peptide bonds are also slow. An unchanged slow folding reaction after the replacement of a particular proline is therefore not sufficient evidence to exclude its isomerization as a possible rate-limiting reaction. It is necessary to analyze the unfolding and refolding kinetics after a proline replacement in detail, in order not to draw incorrect conclusions.

6. *Analysis of the folding kinetics by NMR spectroscopy.* Perhaps the best approach would be to follow the isomerization of a particular proline during folding directly by real-time NMR spectroscopy. The CαH resonance of the residue preceding the proline and the CδH resonance of proline are sensitive to the isomeric state of the prolyl bond and could be used to follow a prolyl isomerization directly in the course of a protein folding reaction. Unfortunately, these resonances are in a very crowded region of the NMR spectrum of a protein, and therefore, to the best of my knowledge, this approach has not yet been employed.

25.3.3
Proline-limited Folding Reactions

Proline-limited steps were found in the folding kinetics of many small single-domain proteins. The direct folding reactions of these proteins are usually fast (often in the time range of milliseconds) and therefore the proline-limited steps can easily be identified in unfolding and in refolding either directly or by double-mixing experiments, as described in Section 25.3.2 and in Section 25.9 (Experimental Protocols).

As expected, proline-limited reactions with large amplitudes are found for proteins with *cis* prolines, such as the immunoglobulin domains [34], thioredoxin [35], barstar [36], staphylococcal nuclease [37, 38], ubiquitin [39], plastocyanin [40], or pseudo-azurin [41]. In most of these cases partially folded intermediates accumulate in refolding before the final slow prolyl *trans* → *cis* isomerization.

Single-domain proteins with only *trans* prolines also show slow refolding reactions. Their amplitudes are usually small, because the *trans* isomer is favored in the unfolded molecules as well. Often, the amplitude of slow folding is smaller than expected from the number of *trans* prolines. This may originate from the fact that in unfolded polypeptides the *trans* form is more favored over *cis* than in short peptides and that some *trans* prolines are nonessential for folding. In addition, native-like intermediates may accumulate prior to re-isomerization, which also decreases the amplitudes of the slow folding reactions. Proteins with only *trans* prolines include cytochrome *c* [42], barnase [43], the chymotrypsin inhibitor CI2 [44], FKBP12 [45, 46], acylphosphatase [47], MerP [48] the immunity proteins Im7 and Im9 [49], the cell cycle protein p13suc1 [50], and the amylase inhibitor Tendamistat [51].

For large oligodomain or oligomeric proteins it is usually difficult to identify prolyl isomerizations in unfolding and refolding, chiefly because direct folding is often slow and not well separated from the proline-limited steps. As a consequence, the two reactions are strongly coupled, and the isomerizations cannot be followed easily by the double-mixing techniques. Nevertheless there are numerous examples for proline-limited steps in the folding of oligodomain and/or oligomeric proteins [52–55].

The immunoglobulins are heterotetramers that are composed of two light chains (with two domains each) and two heavy chains (with four domains each). The individual domains show a related fold (the "immunoglobulin fold") and typically contain a single *cis* proline. Its *trans* → *cis* isomerization determines the folding of the separate domains [34] and of the intact light chains [56]. In the folding of the F_{ab} fragment (which consists of four domain: two from the light chain and two from the heavy chain) proline isomerization can occur late in folding, after association [57]. In the folding of the isolated C_H3 domain, however, prolyl isomerization occurs before this domain associates to a homodimer [58].

The gene-3-protein in the coat of the phage fd is essential for its infectivity. Early in the infection of an *Escherichia coli* cell, the two N-terminal domains of the gene-3-protein (N2 and N1) interact successively with the F pilus and the TolA receptor. To expose the binding site for TolA the domains must disassemble, otherwise infection would be stopped. In refolding, the domains N1 and N2 fold rapidly, but the final domain assembly is unusually slow and shows a time constant of 6200 s (at 25 °C). It is controlled by the *trans* → *cis* isomerization of the Gln212-Pro213 bond in the hinge between the domains. The kinetic block of domain reassembly caused by this very slow isomerization at Pro213 could ensure that after the initial binding of N2 to the F pilus the domains disassemble and that this open state has a lifetime long enough for the N1 domain to approach and interact with TolA. Pro213 isomerization of the gene-3-protein might thus serve as a slow conformational switch during the infection process [59, 60].

Ure2 is a prion-like yeast protein with an unfolded N-terminal prion domain and a compactly folded C-terminal domain, which harbors a *cis* proline at position 166. Unfolded molecules with the native-like *cis* Pro166 fold and dimerize rapidly, whereas molecules with the incorrect *trans* isomer do not reach the native state within several hours [61]. Apparently, Pro166 isomerization decelerates productive folding so strongly that it can no longer compete with side reactions, such as aggregation.

A few important points should be considered when, in the folding of large proteins, the role of many *trans* prolines or of a mixture of *cis* and *trans* prolines is investigated.

1. Not all prolines are necessarily important for the folding kinetics.
2. The *trans* form is usually favored over the *cis*, and therefore *cis* → *trans* isomerizations show small amplitudes and are about 5–10 times faster than *trans* → *cis* isomerizations.

3. The prolyl isomerizations after unfolding are parallel reactions. As a consequence, the rate of U_S formation should increase with the number of prolines.
4. The rate of refolding, however, decreases with the number of incorrect prolines [62], because only the species with all prolines in the native-like isomeric state can complete folding.
5. For large proteins the direct refolding reaction is often rather slow and not well separated in rate from the proline-limited steps. As a consequence, the analysis by slow refolding assays becomes difficult.

Carbonic anhydrase provides a good example. It contains 15 *trans* and 2 *cis* prolines and after long-term denaturation virtually all molecules are in U_S states, i.e., they have nonnative prolines and refold slowly [63]. More than half of the U_S molecules form rapidly after unfolding in a reaction that is about tenfold faster than expected for a single prolyl isomerization [64]. This increase in rate is probably caused by the additive and independent isomerizations of the many *trans* prolines of this protein. The remainder of the slow-folding molecules is then created very slowly in a reaction that is probably caused by the *cis* $\rightleftharpoons$ *trans* isomerizations of one or both *cis* prolines. Short-term unfolding of carbonic anhydrase yields U_F molecules with correct prolines, but only a fraction of them can in fact refold rapidly, because molecules with incorrect isomers continue to form early in refolding, in competition with the direct refolding reaction, which is only marginally faster than the multiple *cis* $\rightleftharpoons$ *trans* isomerizations. Addition of cyclophilin had a peculiar effect on the refolding of the short-term denatured molecules. At the onset of the experiment this prolyl isomerase catalyzed *cis* $\rightleftharpoons$ *trans* isomerization in the unfolded molecules and thus increased the fraction of molecules that fold on slow proline-limited paths. These molecules, however, refolded more rapidly, because cyclophilin accelerated the proline-limited steps in their refolding [64]. A similar behavior was found for the single-chain Fv fragment of an antibody, which contains four *trans* and two *cis* prolines [65].

25.3.4
Interrelation between Prolyl Isomerization and Conformational Folding

When they initially suggested the proline hypothesis, Brandts and coworkers assumed that the nonnative prolyl isomers can block refolding right at its beginning [30], and that the slow $U_S \rightarrow U_F$ isomerization in the unfolded molecules is the first and rate-limiting step of folding. Since then many proline-limited folding reactions have been investigated (see Section 25.4), and it is clear now that conformational folding can start while some prolines are still in their nonnative states, and that partially folded intermediates can tolerate incorrect prolines. The final folding steps, however, require correct prolines and therefore they are limited in rate by the prolyl isomerizations [7, 29, 66, 67].

The extent of conformational folding that can occur prior to prolyl isomerization depends on the location of the nonnative prolyl bonds in the structure, on the

stability of partially folded intermediates and on the folding conditions. Generally, incorrect prolyl bonds in exposed or flexible chain regions will not interfere strongly with conformational folding, and solvent conditions that strongly stabilize folded proteins will also stabilize partially folded structure with incorrect isomers. Thus there is a close interdependence between conformational folding steps and prolyl isomerization. On the one hand the presence of incorrect isomers in the chain can decelerate its folding, and on the other hand rapid chain folding can affect the equilibrium and the kinetics of prolyl isomerization. The close interrelationship between structure formation and prolyl peptide bond isomerization is a key feature of slow folding steps and is of central importance for understanding the role of prolyl isomerases in these processes.

A simple $U_S \rightarrow U_F \rightarrow N$ refolding path is followed only under conditions where the fully folded protein is only marginally stable, such as at the onset of the equilibrium unfolding transition. Here a single incorrect kink in the protein backbone (as introduced by a nonnative prolyl bond) is sufficient to destabilize partially folded conformations.

25.4 Examples of Proline-limited Folding Reactions

25.4.1 Ribonuclease A

Bovine pancreatic RNase A played a central role in the elucidation of proline-limited folding reactions. This protein contains four prolines: Pro42 and Pro117 are *trans* and Pro93 and Pro114 are *cis* in the native protein. Both the proposal of the proline hypothesis and the first experimental evaluations are linked with RNase A. Garel and Baldwin [27] discovered the coexistence of U_F and U_S in unfolded RNase A, and Brandts and coworkers [30] developed the slow refolding assays to measure the $U_F \rightleftharpoons U_S$ equilibration in this protein. The quantitative analyses of the folding kinetics of RNase A in the thermal unfolding transition at pH 3 [68] and in the guanidinium chloride (GdmCl)-induced transition [69] demonstrated that they are in fact well described by a $U_S \rightleftharpoons U_F \rightleftharpoons N$ three-state mechanism. The $U_F \rightleftharpoons U_S$ reaction in unfolded RNase A was found to be independent of denaturants [70] and catalyzed by a strong acid [26], as expected for a proline-limited process.

The first partially folded intermediate with a nonnative prolyl isomer was also discovered in the refolding of RNase A [66, 67]. Under conditions that strongly favor the folded form, the major U_S species (called U_S^{II}) refolds to a native-like form I_N, an intermediate that is folded, as judged by amide circular dichroism and is already enzymatically active. This indicated for the first time that nonnative prolyl bonds do not necessarily block refolding, but that protein molecules with an incorrect prolyl bond could almost reach the native form. The final slow step of folding

($I_N \rightarrow N$) originates from the *trans* → *cis* isomerization of the Tyr92-Pro93 bond [71, 72]. It could be assigned before the advent of site-directed mutagenesis, because it is accompanied by a change in the fluorescence of Tyr92 [73].

The intermediate I_N is less stable and unfolds much faster than native RNase A. The interconversion between I_N and N could thus be measured by unfolding assays which exploited this strong difference between the unfolding rates of I_N and N. In these experiments refolding was interrupted after various times, samples were transferred to standard unfolding conditions and the amplitudes of the fast and slow unfolding reactions were determined as a function of the duration of refolding. These amplitudes reflected the time courses of I_N and N, respectively during folding [74]. Such interrupted folding experiments are excellent tools for discriminating native-like intermediates from the native protein and for following the time courses of these species in complex folding reactions. The method is so sensitive, because the native molecules are often separated from partially folded ones by a high activation barrier, and thus they differ strongly in the rate of unfolding. Section 25.9 gives a protocol for measuring silent slow prolyl isomerizations in largely folded intermediates by such unfolding assays.

The isomeric states of the four prolines in the various U species remained unclear for a long time. The kinetic analyses of the Baldwin, Brandts, and Schmid groups (for reviews see Refs [28, 75]) had indicated already that U_S is heterogeneous and consists of a minor U_S^{I} species and a major U_S^{II} species, which refolds via the native like intermediate I_N.

The Scheraga group re-evaluated the folding kinetics of RNase A, among others, by making many mutants with alterations at the four prolines (see Ref. [9] for a review). They found that the U_F species is heterogeneous as well [76], being composed of 5% of a very fast folding species U_{vf} and 13% of a fast-folding species U_f. U_{vf} and U_f differ in the isomeric state of Pro114. However, they fold with different rates only at low pH, where the conformational stability of RNase A is low. At neutral pH U_{vf} and U_f fold fast with indistinguishable rates. This is consistent with the original finding of 20% fast-folding U_F molecules [27], and it confirms the suggestion that Pro114 is nonessential for the folding of RNase A [66] under favorable conditions. Under unfavorable conditions, such as at low pH, or when an additional proline is incorrect (such as in the intermediate I_N with incorrect *trans* isomers at both Pro93 and Pro114), a *trans* Pro114 might in fact retard folding. Raines and coworkers replaced Pro114 by 5,5-dimethyl-L-proline, which stays almost exclusively in the native *cis* conformation. This mimic of a *cis* proline slightly accelerated the $U_S^{II} \rightarrow I_N$ reaction. The authors interpreted this to suggest that an incorrect *trans* Pro114 slightly decelerates the folding reaction of the U_S^{II} form of the wild-type protein [77]. Together all this suggests that Pro114 of RNase A is a conditional proline. It is unimportant for folding under favorable conditions, but retards folding slightly under unfavorable conditions.

U_S^{II} contains an incorrect *trans* Pro93. Comparative experiments with homologous RNases from various species [71, 78] and early directed mutagenesis work had already suggested a crucial role of Pro93 for the major folding reaction

$U_S^{II} \rightarrow I_N \rightarrow N$ [79]. The more recent results from the Scheraga group confirm this [9]. They also show that, after the Pro93Ala substitution, Tyr92 and Ala93 form a nonprolyl *cis* peptide bond in the folded form of P93A-RNase A [80].

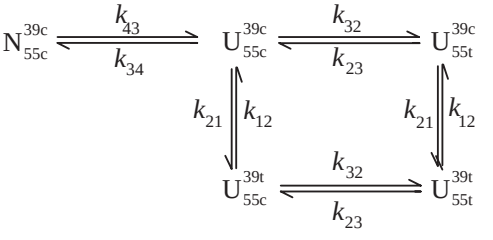
The minor form U_S^I contains one or more incorrect prolines in addition to the incorrect *trans* Pro93 [71]. This destabilizes partially folded structure further and impairs the formation of intermediates such as I_N. Scheraga et al. have now found that U_S^I contains both an incorrect *trans* Pro93 and an incorrect *cis* Pro117 [9, 80–82]. According to their work, Pro42 is unimportant for folding.

25.4.2 Ribonuclease T1

RNase T1 from *Aspergillus oryzae* [83] is a small single-domain protein of 104 amino acids [83–86], which is not related structurally with RNase A. It contains two disulfide bonds (Cys2-Cys10 and Cys6-Cys103, two *trans* (Trp59-Pro60 and Ser72-Pro73) and two *cis* (Tyr38-Pro39 and Ser54-Pro55) prolyl bonds. RNase T1 is most stable near pH 5 and further stabilized when NaCl is added [87–89]. Importantly, in the absence of the disulfide bonds, RNase T1 can still fold to a native-like conformation when $\geq$1 M NaCl are present [87, 88, 90].

The equilibrium unfolding transition of RNase T1 is well described by a simple two-state model [91–94], but the unfolding and refolding kinetics are complex. Almost the entire folding of RNase T1 involves prolyl isomerizations [95, 96] both in the presence and in the absence of the two disulfide bonds [97, 98]. All observable phases in the unfolding and the refolding kinetics could be explained by contributions from the two *cis* prolines only [99–101]. RNase T1 is a good substrate for assaying prolyl isomerases [7, 8, 102].

The mechanism of unfolding is well explained by a model in which conformational unfolding ($N \rightarrow U_{55c}^{39c}$) is followed by the two *cis* $\rightleftharpoons$ *trans* isomerizations at Pro39 and Pro55 (Scheme 25.2). Both are *cis* in N and in U_{55c}^{39c}, but isomerize

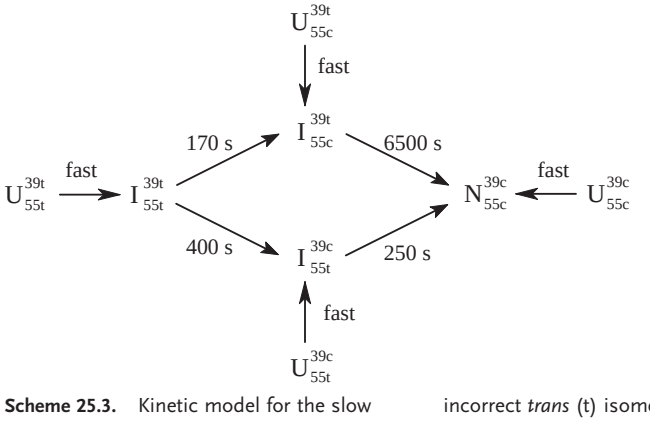


Scheme 25.2. Kinetic model for the unfolding and isomerization of RNase T1. This model is valid for unfolding only. The superscript and the subscript indicate the isomeric states of prolines 39 and 55, respectively, in the correct, native-like *cis* (c) and in the incorrect, nonnative *trans* (t) isomeric states. As an example, U_{55c}^{39t} is an unfolded species with Pro39 in the incorrect *trans* and Pro55 in the correct *cis* state. In the denatured protein the two isomerizations are independent of each other, therefore the scheme is symmetric with identical rate constants in the horizontal and vertical directions, respectively. At 25 °C and 6.0 M GdmCl, pH 1.6 $k_{43} = 0.49\ s^{-1}$, $k_{12} = 2.0 \times 10^{-3}\ s^{-1}$, $k_{21} = 22.6 \times 10^{-3}\ s^{-1}$, $k_{23} = 8.7 \times 10^{-3}\ s^{-1}$, $k_{32} = 50.5 \times 10^{-3}\ s^{-1}$ [103].

largely to the more favorable *trans* state in the unfolded protein. As a consequence, only 2–4% of all unfolded molecules remain in the U^{39c}_{55c} state with Pro39 and Pro55 in the correct *cis* state. U^{39t}_{55t}, the species with two incorrect isomers, predominates at equilibrium, and the two species with single incorrect isomers (U^{39t}_{55c} and U^{39c}_{55t}) are populated to 10–20% each.

Under strongly native conditions refolding is not a reversal of unfolding and cannot be explained solely with Scheme 25.2. Rather, refolding paths via intermediates originate from the different unfolded species (Scheme 25.3). The two slow-folding species with one incorrect prolyl isomer each (U^{39t}_{55c} and U^{39c}_{55t}) and the species with both prolines in the incorrect isomeric state (U^{39t}_{55t}) can regain rapidly most of their secondary structure in the milliseconds range (the $U_i \rightarrow I_i$ steps, Scheme 25.3) [104]. Subsequently, slow folding steps follow that involve the isomerizations of the incorrect prolyl isomers. A peculiar feature of the folding model in Scheme 25.3 is that the major unfolded species with two incorrect isomers (U^{39t}_{55t}) can enter two alternative folding pathways (the upper or the lower pathway in Scheme 25.3), depending upon which isomerization occurs first. The distribution of refolding molecules on these two pathways is determined by the relative rates of the *trans* → *cis* isomerizations of Pro39 and Pro55 at the stage of the intermediate I^{39t}_{55t}. The kinetic models in Schemes 25.2 and 25.3 were supported by experimental data on the slow folding of variants of RNase T1 where the *cis* prolines were replaced by other amino acids [99, 100, 105].

At equilibrium only 2–4% of all unfolded RNase T1 molecules have correct *cis* isomers at Pro39 and Pro55. Their fast direct refolding reaction ($U^{39c}_{55c} \rightarrow N^{39c}_{55c}$) could therefore not be measured initially.



Scheme 25.3. Kinetic model for the slow refolding of RNase T1 under strongly native conditions. U stands for unfolded species, I for intermediates of refolding, and N is the native protein. The superscript and the subscript indicate the isomeric states of prolines 39 and 55, respectively, in the correct *cis* (c) and the incorrect *trans* (t) isomeric states. The rate constants given for the individual steps refer to folding conditions of 0.15 M GdmCl, pH 5.0, 10 °C [106]. The rate constant of the direct $U^{39c}_{55c} \rightarrow N^{39c}_{55c}$ reaction is 5.7 s^{-1} in 1.0 M GdmCl, pH 4.6, 25 °C [103].

Mayr et al. [103] exploited the sequential nature of unfolding ($N \rightarrow U_{55c}^{39c}$) and prolyl isomerizations (cf. Scheme 25.2) to characterize the direct $U_{55c}^{39c} \rightarrow N$ folding reaction. In the first step of a stopped-flow double-mixing experiment they produced U_{55c}^{39c} transiently at a high concentration under conditions, where the $N \rightarrow U_{55c}^{39c}$ unfolding reaction is much faster than the subsequent prolyl isomerizations and then measured its refolding in the second step. In addition, they varied the duration of the unfolding step and monitored the concentrations of all species of the wild-type protein in Scheme 25.2 as a function of time. Thus the rates of the individual prolyl isomerizations in the unfolded protein (cf. Scheme 25.2) could be determined.

The direct refolding reaction of RNase T1 with correct prolyl isomers shows a time constant of 175 ms (at 25 °C, pH 4.6) [103]. This reaction is almost unaffected by the proline substitutions. It depends nonlinearly on temperature with a maximum near 25 °C, which suggests that the activated state for this reaction resembles the native rather than the unfolded state in heat capacity. The folding of the species with single incorrect prolyl isomers ($U_{55c}^{39t} \rightarrow I_{55c}^{39t}$ and $U_{55t}^{39c} \rightarrow I_{55t}^{39c}$) was only about fivefold slower than direct folding and was also accompanied by a strong decrease in the apparent heat capacity.

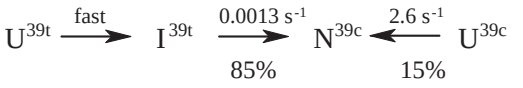
Conformational folding and the re-isomerizations of the prolyl peptide bonds are thus tightly interrelated in the folding of RNase T1. As discussed above, rapid partial folding is possible in the presence of nonnative prolyl isomers [104, 106], but the final events of folding are coupled with the prolyl isomerizations and therefore very slow.

The partially folded structure in the intermediates affects the isomerization kinetics. In particular, the *trans* → *cis* isomerization at Pro39 (in the $I_{55c}^{39t} \rightarrow N$ step) is strongly decelerated by the folded structure in the intermediate I_{55c}^{39t} [106]. In the folding of pancreatic RNase A, however, prolyl isomerization is accelerated in the intermediate I_N [66, 67], and in the folding of dihydrofolate reductase an intramolecular catalysis of a prolyl isomerization was proposed to occur [107].

25.4.3
The Structure of a Folding Intermediate with an Incorrect Prolyl Isomer

In the S54G/P55N variant of RNase T1 [99] the *cis* Ser54-Pro55 prolyl bond is replaced by a *trans* Gly54-Asn55 peptide bond (Hinrichs et al., unpublished results). Thus a *cis* bond is abolished and the branched folding mechanism (Scheme 25.3) is strongly simplified to a sequential mechanism (Scheme 25.4). Only two unfolded species remain: 15% as a fast folding species with the native-like *cis* isomer of Pro39 (U^{39c}), and 85% as a slow folding species with the incorrect *trans* isomer of Pro39 (U^{39t}).

The U^{39t} molecules (Scheme 25.4) refold in two steps. First the intermediate I^{39t} is formed, which then converts to the native protein. This second step is limited in rate by the *trans* → *cis* isomerization of Pro39, which at 10 °C shows a time constant of about 8000 s. The I^{39t} intermediate is thus long-lived enough to obtain highly resolved structure information by kinetic NMR experiments [40, 108–110]



Scheme 25.4. Kinetic model for the slow refolding of S54G/P55N-RNase T1 under strongly native conditions. U stands for unfolded species, I for intermediates of refolding, and N is the native protein. The superscript indicates the isomeric state of proline 39 in the correct *cis* (c) and the incorrect *trans* (t) isomeric states. The rate constants given for the individual steps refer to folding conditions of 1.0 M GdmCl, pH 4.6, 25 °C.

and 2D-NOESY spectroscopy. Balbach et al. determined those protons in I^{39t} that are already surrounded by a native environment and thus show native distances to protons in close vicinity [111]. Surprisingly, amide protons in nonnative environments were found to be located not only close to the incorrect *trans* Tyr38-Pro39 bond in I^{39t}, but were spread throughout the entire protein. The destabilization caused by the incorrect *trans* Pro39 is thus not confined to the local environment of this proline, but involves several regions in the entire molecule.

25.5 Native-state Prolyl Isomerizations

Most prolyl peptide bonds in folded proteins show well defined conformations, being either in the *cis* or in the *trans* conformation. There are, however, a growing number of exceptions to this rule. High-resolution NMR spectroscopy, in particular, identified a series of prolines that are conformationally heterogeneous and exist as a mixture of *cis* and *trans* isomers in the folded state. Examples include staphylococcal nuclease [112], insulin [113], calbindin [114, 115], scorpion venom Lqh-8/6 [116], human interleukin-3 [117] and the TB6 domain of human fibrillin-1 [118, 119]. In folded staphylococcal nuclease *cis*/*trans* equilibria exist at Pro117 as well as at Pro47 [112, 120, 121], and the two equilibria seem to be independent of each other.

There are two strongly diverging, but not mutually exclusive, interpretations of these findings. The first is that conformationally heterogeneous proline residues occur in locally unfolded regions. They lack strong tertiary interactions, which would be necessary to stabilize one isomer over the other. Alternatively, heterogeneity at prolines might point to a functionally important *cis*/*trans* isomerization, which might be used as a slow molecular switch, for example, to regulate the function of the corresponding protein. Such switching functions, possibly modulated by prolyl isomerases, were suggested long time ago [122], but the evidence for proline switches remained circumstantial.

Evidence for a proline-dependent conformational switch was obtained for the SH2 domain of the tyrosine kinase Itk [123, 124]. Unlike other proteins with *cis* and *trans* prolyl conformers in the native state [115, 119, 125–127] the SH2 domain of Itk shows a pronounced change in structure upon *cis*/*trans* isomerization.

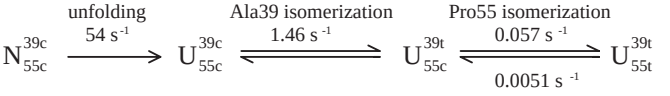
The *cis* and the *trans* forms of Itk-SH2 differ slightly in the affinity for the Itk-SH3 domain and for a phosphopeptide, which represent alternative substrates for the SH2 domain [128]. This conformational switch thus seems to modulate substrate recognition and can be regulated by the prolyl isomerase cyclophilin 18. A review of the proline switch in Itk and in other proteins is found in Ref. [10].

The prolyl isomerase, PIN1, catalyzes the isomerization of phosphoserine-proline bonds, and there is compelling evidence that PIN1 integrates phosphorylation-dependent and prolyl-isomerization-dependent switches for a wide range of signaling reactions [129] (see also Chapter 10 in Part II).

25.6 Nonprolyl Isomerizations in Protein Folding

For nonprolyl bonds the *trans* state is strongly favored over *cis*, and the *cis* content as measured for oligopeptides is far below 1% [12, 130]. A large amount of conformational energy is therefore required to lock such a bond in the *cis* state. A shift in the equilibrium from 0.2% to 99% *cis* requires a Gibbs free energy of 15 kJ mol^{-1}. Nevertheless *cis* nonprolyl bonds are found in folded proteins, but they are very rare, and presumably they are important for the function of a protein. In principle, a nonprolyl *cis* peptide bond would be well suited to construct a molecular switch in a protein that can be actuated only under a very strong load. A tight-binding ligand could, for example, supply a sufficient amount of free energy from its own binding to turn such a strong switch. A compilation of proteins with *cis* peptide bonds is found in Ref. [16]. Because the *trans* isomer is so strongly favored over the *cis*, *trans* → *cis* isomerizations at nonprolyl bonds during refolding must occur for such proteins in virtually all molecules.

The first evidence for a nonprolyl isomerization as a rate-determining step in protein folding was obtained for a variant of RNase T1. The replacement of one of the two *cis* prolines, *cis*-Pro39, of the wild-type protein by an alanine residue led to a variant with a *cis* nonprolyl peptide bond between Tyr38 and Ala39 [131]. This *cis* bond is located adjacent to His40, which is a catalytic residue. The Pro39Ala mutation reduced the stability of RNase T1 by about 20 kJ mol^{-1} and caused a major change in the folding mechanism. As shown in Scheme 25.5, the conformational unfolding of P39A-RNase T1 occurs first (in the $N \rightarrow U^{39c}_{55c}$ reaction) with a time constant of 20 ms. It leads to U^{39c}_{55c}, an unfolded form that has both Ala39 and



Scheme 25.5. Kinetic mechanism for the unfolding and isomerization of P39A-RNase T1. The superscript and the subscript indicate the isomeric states of Ala39 and Pro55, respectively, in the correct, native-like *cis* (c) and in the incorrect, nonnative *trans* (t) isomeric states. The rate constants refer to unfolding in 6.0 M GdmCl (pH 1.6) at 25 °C [96].

Pro55 still in the native-like *cis* conformation. Subsequently, the Tyr38-Ala39 bond isomerizes from *cis* to *trans* (in the $U^{39c}_{55c} \rightleftharpoons U^{39t}_{55c}$ step) in virtually all molecules. This nonprolyl isomerization ($\tau = 730$ ms) is about 60-fold faster than the corresponding prolyl isomerization (of the Tyr38-Pro39 bond) in wild-type RNase T1 [96]. It shows almost the same time constant as the *cis* → *trans* isomerization of the Tyr-Ala bond in the pentapeptide AAYAA ($\tau = 560$ ms [12]). In the unfolding the Tyr-Ala isomerization is then followed by the slow *cis* ⇌ *trans* equilibration at Pro55 ($\tau = 16$ s), which is still present in P39A-RNase T1.

Unfolded molecules in which the Tyr38-Ala39 bond was still in the native-like *cis* conformation (U^{39c}_{55c}) were produced in a stopped-flow double-mixing experiment by a short 100-ms unfolding pulse. They refolded rapidly to the native state with $\tau = 290$ ms (in 1.0 M GdmCl, pH 4.6, 25 °C). After the Ala39 *cis* → *trans* isomerization in the unfolded state, refolding is 1600-fold retarded and shows a time constant of 480 s. This slow refolding is limited in rate by the *trans* → *cis* reisomerization of the Tyr38-Ala39 bond. Under the same refolding conditions the *trans* → *cis* isomerization of the Tyr38-Pro39 bond in the wild-type protein is only twofold slower ($\tau = 1100$ s) [100, 105]. This comparison with the folding kinetics of wild-type RNase T1 indicates that the kinetics of Tyr38-Pro39 and of Tyr38-Ala39 isomerization differ predominantly in the rate of the *cis* → *trans*, rather than of the *trans* → *cis* reaction. The ratio of the rate constants for the *cis* → *trans* and the *trans* → *cis* reactions at the Tyr38-Ala39 bond gives an equilibrium constant of 0.0015, again in good agreement with the equilibrium constant of 0.0011 in the peptide AAYAA [12].

Very similar results were obtained later for the Pro93Ala mutation in RNase A [80, 132]. As in RNase T1, this mutation converted a *cis* Tyr-Pro bond into a *cis* Tyr-Ala bond and abolished the fast-folding reaction. The *cis* → *trans* isomerization of the Tyr-Ala bond in the unfolded protein occurred with $\tau = 1400$ ms at 15 °C [80], which agrees well with $\tau = 730$ ms, as measured for RNase T1 at 25 °C.

TEM-1 β-lactamase from *E. coli* contains a *cis* peptide bond between Glu166 and Pro167, in a large Ω loop near the active site. It is required for the catalytic activity of β-lactamase [133], and its *trans* → *cis* isomerization is a slow step in refolding [134–137]. Similar to Pro39 of RNase T1 the *cis* character of the 166–167 bond is retained when Pro167 of β-lactamase is replaced by a Thr residue, and the *trans* → *cis* isomerization of the Glu166-Thr167 peptide bond becomes rate limiting for the refolding of the P167T variant [135]. *Cis* peptide bonds between the residues equivalent to Glu166 and Pro167 of TEM-1 β-lactamase of *E. coli* are found in many β-lactamases, but interestingly, these *cis* peptide bonds are not always prolyl bonds. The β-lactamase PC1 from *Staphylococcus aureus* shows a *cis* Glu-Ile bond at this position [138].

In summary, the results obtained for RNase T1, RNase A and the β-lactamases show that the *trans* → *cis* isomerizations of nonprolyl peptide bonds are slow reactions (with time constants of several hundred seconds at 25 °C) and control the folding of proteins with nonprolyl *cis* peptide bonds. The *trans* → *cis* isomerizations of prolyl and nonprolyl bonds show similar rates, the reverse *cis* → *trans* isomerizations are 50–100 fold faster, however, for the nonprolyl peptide bonds.

Because the *trans* conformation is so strongly preferred, only one out of 500 or 1000 nonprolyl peptide bonds is in *cis* in an unfolded protein chain. Furthermore, it re-isomerizes to *trans* within less than a second when the protein folds at 25 °C. It is clear that such rare reactions are not easily identified in experimental folding kinetics.

First evidence for nonprolyl *cis* → *trans* isomerization in the refolding of a protein was obtained for a proline-free mutant of the small protein tendamistat [139]. Ninety-five per cent of all molecules of this protein fold rapidly with $\tau = 50$ ms, but 5% refold more slowly with $\tau = 400$ ms (at 25 °C). The slow-refolding molecules are created by isomerizations in the unfolded protein, most likely by the *cis* ⇌ *trans* isomerizations of nonprolyl peptide bonds. The fraction of molecules with incorrect *cis* nonprolyl isomers is small, because the correct *trans* isomer is favored so strongly over the *cis*.

25.7 Catalysis of Protein Folding by Prolyl Isomerases

Prolyl isomerases are ubiquitous enzymes that catalyze the *cis* ↔ *trans* isomerization of prolyl peptide bonds both in oligopeptides and during the folding of proteins. They are described in Chapter 10 in Part II. The first evidence for a catalysis of protein folding by a prolyl isomerase (porcine cytoplasmic cyclophilin 18, Cyp18) was obtained for the immunoglobulin light chain, porcine ribonuclease (RNase) and the S-protein fragment of bovine RNase A [140]. The slow refolding of RNase A could not be catalyzed, probably because the incorrect *trans* Tyr92-Pro93 is shielded from prolyl isomerases in the native-like intermediate I_N (cf. Section 25.5.1).

25.7.1 Prolyl Isomerases as Tools for Identifying Proline-limited Folding Steps

The prolyl isomerases, in particular Cyp18, are valuable tools to examine whether a slow folding reaction is rate-limited by a prolyl isomerization. A catalysis of proline-limited steps was observed in the folding of many proteins, including barnase [141], carbonic anhydrase [142, 143], β-lactamase (A. Lejeune, unpublished results), chymotrypsin inhibitor CI2 [44], yeast iso-2 cytochrome *c* [144, 145], the immunoglobulin light chain [57, 140], staphylococcal nuclease [146], and *trp* aporepressor [147]. *Cis* → *trans* and *trans* → *cis* isomerizations are catalyzed equally well in the folding of these proteins. In the maturation of the collagen triple helix prolyl and hydroxyprolyl isomerizations are rate-limiting steps, and this folding reaction is also accelerated by Cyp18 [148–150].

Proteins with incorrect prolyl isomers can start to fold before prolyl isomerization, and some of them reach a state that is native-like already. This often hinders prolyl isomerases in their access to the incorrect prolines and impairs catalysis of isomerization. The role of the accessibility of the prolines was studied for iso-2 cytochrome *c*. In aqueous buffer the folding of this protein is barely catalyzed by

cyclophilin. When, however, GdmCl is added in increasing, but still nondenaturing concentrations, catalysis is markedly improved, presumably because the denaturant destabilizes folding intermediates and thus improves the accessibility of the prolyl bonds [145].

In native RNase T1 *cis*-Pro55 is solvent exposed in the native protein and presumably also in folding intermediates, and therefore all prolyl isomerases catalyze the isomerization at Pro55 very well. *Cis*-Pro39 is buried in the native protein. Its *trans* → *cis* isomerization is only marginally accelerated, because rapid conformational folding hinders the access of the prolyl isomerases. Cyp18 from *E. coli* at a very high concentration (29 μM) was necessary to obtain a 300-fold acceleration of Pro39 isomerization in the refolding of 2.5 μM RNase T1 [151]. The catalysis at Pro39 is strongly improved when the formation of partially folded intermediates is suppressed by destabilizing mutations, or by breaking of the two disulfide bonds (as in the reduced and carboxymethylated RCM form of RNase T1) [152].

The reduced and carboxymethylated RCM form of the S54G/P55N variant (RCM-(-P55)RNase T1) is a particularly simple model protein for studying catalyzed protein folding, because it involves a single *trans* → *cis* isomerization only (at Pro39; Scheme 25.4) and because the access to this proline is not impaired by premature structure formation, as in the wild-type protein with intact disulfide bonds. The RCM form is unfolded in aqueous buffer but reversible folding to a native-like ordered conformation can be induced by adding 1 M NaCl [152]. Unfolding and refolding in the presence of prolyl isomerases can thus be studied in the absence of denaturants, simply by varying the NaCl concentration [90, 153–155]. This is important because several prolyl isomerases are sensitive to residual concentrations of denaturants, such as guanidinium chloride or urea.

Prolyl isomerases function in protein folding as enzymes. They catalyze *cis* ↔ *trans* isomerization in either direction and carry no information about the isomeric states of the prolyl peptide bonds in the protein substrates. This information is provided by the refolding protein itself. Molecules with native prolyl isomers refold rapidly and are thus no longer substrates for the isomerase. The prolyl isomerases are active in protein *unfolding* as well [152].

25.7.2 Specificity of Prolyl Isomerases

The catalytic function of the prolyl isomerases is restricted to prolyl bonds. They do not catalyze the isomerizations of "normal" nonprolyl peptide bonds. As outlined in Section 25.6, the folded form of the P39A variant of RNase T1 has a *cis* Tyr38-Ala39 bond, and the refolding of virtually all molecules is limited in rate by the very slow *trans* → *cis* re-isomerization of the Tyr38-Ala39 bond. This isomerization is not catalyzed by prolyl isomerases of the cyclophilin, FKBP, and parvulin families. It is also not catalyzed in the peptide Ala-Ala-Tyr-Ala-Ala [156].

Schiene-Fischer et al. discovered that DnaK, a chaperone of the Hsp70 family catalyzes the isomerization of nonprolyl bonds in oligopeptides and in the folding of the P39A variant of RNase T1. This new isomerase is described in Chapter 10 in Part II.

As folding enzymes, the prolyl isomerases can catalyze their own folding. The folding reactions of human cytosolic FKBP12 and of parvulin from *E. coli* are indeed autocatalytic processes [45, 155, 157].

25.7.3 The Trigger Factor

The trigger factor is a ubiquitous bacterial protein, which associates with the large subunit of the ribosome (see Chapter 13 in Part II). Originally it was thought to be involved in the export of secretory proteins [158, 159], but in 1995 Fischer and coworkers [160] discovered that the trigger factor is a prolyl isomerase. This enzymatic activity originates from the central FKBP domain, which encompasses residues 142 to 251. Indeed, a weak sequence homology had been noted between this region of the trigger factor and human FKBP12 [161].

Three domains have been identified in the trigger factor. The central FKBP domain harbors the prolyl isomerase activity of the trigger factor [162, 163] and the N-terminal domain (residues 1–118) mediates the interaction with the ribosome [164–168]. The function of the C-terminal domain is largely unknown. Its presence is required for the high activity of the trigger factor as a catalysts of protein folding [169, 170].

The trigger factor catalyzes the folding of RCM-RNase T1 very efficiently. The addition of as low as 2.5 nM trigger factor led to a doubling of the folding rate of this protein, and in the presence of 20 nM trigger factor this folding reaction is 14-fold accelerated. This remarkable catalytic efficiency of the trigger factor as a folding enzyme is reflected in a specificity constant k_{cat}/K_M of 1.1×10^6 M^{-1} s^{-1}. This is almost 100-fold higher than the respective value for human FKBP12 [170]. The K_M value is 0.7 μM, and the catalytic rate constant k_{cat}. is 1.3 s^{-1} [170]. For Cyp18 the catalysis of the *trans* ↔ *cis* prolyl isomerization in a tetrapeptide is characterized by K_M and k_{cat} values of 220 μM and 620 s^{-1}, respectively [64]. This comparison indicates that the high activity of the trigger factor as a folding catalyst does not originate from a high turnover number, but from a high affinity for the protein substrate.

Permanently unfolded proteins are strong, competitive inhibitors of trigger-factor-catalyzed folding. One of those, reduced and carboxymethylated bovine α-lactalbumin (RCM-La) inhibits the trigger factor of *Mycoplasma genitalium* with a K_I value of 50 nM. This binding of inhibitory proteins is independent of proline residues. Unfolded RCM-tendamistat (an α-amylase inhibitor with 74 residues) binds to the trigger factor with equal affinity in the presence and in the absence of its three proline residues [171]. The catalysis of folding of RCM-(-Pro55)-RNase T1 occurs at Pro39. The good inhibition by a nonfolding variant of RNase T1 that lacks Pro39 showed that this proline is dispensable for substrate binding [171]. The affinity of the trigger factor for short peptides is also independent of prolines [172]. The isolated FKBP domain is fully active as a prolyl isomerase towards a short tetrapeptide [162], but in protein folding its activity is about 800-fold reduced, and, moreover, this low residual activity of the FKBP domain alone is not inhibited by unfolded proteins, such as RCM-La [170]. The high enzymatic activity in protein

folding thus requires the intact trigger factor [169]. Together, these results suggest that the high-affinity binding site for unfolded proteins is probably distinct from the catalytic site of the trigger factor. It extends over several domains of the intact trigger factor or requires the interaction of these domains.

The good binding of the intact trigger factor to unfolded chain segments probably decelerates the dissociation of the protein substrate from the trigger factor, and the low k_{cat} value of 1.3 s^{-1} may reflect a change in the rate-limiting step from bond rotation (in tetrapeptide substrates) towards product dissociation (in protein substrates). In fact, an unfolded protein dissociates from the trigger factor with a rate constant of 5.8 s^{-1} [173], which is only fourfold higher than the k_{cat} for catalyzed folding. Since high-affinity binding to unfolded proteins is independent of prolines, it is likely that many binding events are nonproductive, because the reactive prolyl peptide bonds are not positioned correctly within the prolyl isomerase site. Indeed, a lowering of both K_M and k_{cat}, as observed for the intact trigger factor, points to nonproductive binding of a substrate to an enzyme [174].

The trigger factor thus seems to have properties of a folding enzyme and of a chaperone. The cooperation of both functions is required for its very high catalytic efficiency in protein folding. Indeed, trigger factor can function as a chaperone *in vitro* [175–177] and presumably also *in vivo* [178, 179]. A combination of the functions as a protein export factor and as a prolyl isomerase seems to be required in the secretion and maturation of a protease of the pathogenic bacterium *Streptococcus pyogenes* [180].

25.7.4
Catalysis of Prolyl Isomerization During de novo Protein Folding

The evidence for a catalysis of proline-limited folding steps during de novo protein folding in the cell remains circumstantial. Early evidence for a role of prolyl isomerization and of prolyl isomerases in cellular folding was provided by studies of collagen folding, which is limited in rate by successive prolyl isomerizations both in vitro and in vivo. Collagen maturation in chicken embryo fibroblasts is retarded by cyclosporin A, possibly by the inhibition of the cyclophilin-catalyzed folding in the endoplasmic reticulum [181]. A similar effect was found for the folding of luciferase in rabbit reticulocyte lysate [182].

Proteins that are targeted to the mitochondrial matrix must unfold outside the mitochondria, cross the two mitochondrial membranes and then refold in the matrix. In a synthetic precursor protein the presequence of subunit 9 of the *Neurospora crassa* F_1F_0-ATPase was linked to mouse cytosolic dihydrofolate reductase (Su9-DHFR) and used to investigate the function of cyclophilins as potential catalysts of protein folding in isolated mitochondria [183–185]. When measured by the resistance against proteinase K, the refolding of DHFR inside the mitochondria showed half-times of about 5 min and folding was about fivefold decelerated when the mitochondria had been preincubated with 2.5–5 μM CsA to inhibit the prolyl isomerase activity of mitochondrial cyclophilin. The refolding of DHFR was similarly retarded in mitochondria that were derived from mutants that lacked a functional mitochondrial cyclophilin. This suggests that the mitochondrial

cyclophilins acted as prolyl isomerases and thereby catalyzed protein folding in organello.

25.8 Concluding Remarks

Cis peptide bonds decelerate folding reactions, but nevertheless they occur frequently in folded proteins, mainly before proline and occasionally before other amino acid residues. *Cis* prolines are very well suited to introduce tight turns into proteins, but the structural consequences of *cis* peptide bonds cannot be the sole reason for their widespread occurrence. The coupling with prolyl isomerization is a simple means for increasing the energetic barriers of folding, and thus not only refolding but also unfolding would be decelerated. In such a way a native protein would be protected from sampling the unfolded state too frequently.

Nonprolyl *cis* peptide bonds are strongly destabilizing, because they introduce strain into the protein backbone. They are found preferentially near the active sites of enzymes where strained conformations might be important for the function.

In the overall folding process prolyl isomerizations and conformational steps are linked. Incorrect prolines decrease the stability of partially folded intermediates, and conformational folding can modulate the rate of prolyl isomerization.

Prolyl isomerizations are catalyzed by prolyl isomerases. Their functions reach far beyond the acceleration of de novo protein folding. In addition to the well-understood role in immunosuppression, prolyl isomerases modulate ion channels and transmembrane receptors, participate in hormone receptor complexes, are required for HIV-1 infectivity, and participate in the regulation of mitosis. The PIN1 protein discriminates between phosphorylated and unphosphorylated Ser/Thr-Pro sequences in its target proteins. Two principles of regulation are probably integrated at this point: phosphorylation and prolyl *cis*/*trans* isomerization.

Prolyl isomerization in folded proteins is thus well suited for switching between alternative states of a protein. The positions of the switch (*cis* and *trans*) can be determined by the binding of effectors, the rate of swichting can be modulated by prolyl isomerases. Some isomerases might be effector and isomerase at the same time. For such isomerases the distinction between binding and catalytic function, which has been discussed for a long time, may be inappropriate.

25.9 Experimental Protocols

25.9.1 Slow Refolding Assays ("Double Jumps") to Measure Prolyl Isomerizations in an Unfolded Protein

As shown in Scheme 25.1, the direct $N \rightarrow U_F$ unfolding reaction can be followed by one or more prolyl isomerizations ($U_F \rightleftharpoons U_S$) in the unfolded protein chains.

U_F and U_S are usually equally unfolded species and show similar physical properties. Therefore the kinetics of the $U_F \rightleftharpoons U_S$ equilibration reactions cannot be measured directly. Rather, the amount of U_S formed after different times of unfolding can be determined by slow refolding assays. Samples are withdrawn from the unfolding solution at different time intervals after the initiation of unfolding; these samples are transferred to standard refolding conditions, and the amplitude of the slow refolding reaction, $U_S \rightarrow N$, is determined. Refolding of the U_F species is usually complete within the time of manual mixing. The amplitude of the slow refolding reaction is proportional to the concentration of U_S which was present at the time when the sample was withdrawn for the assay. The dependence of these slow refolding amplitudes on the duration of unfolding yields the kinetics of the $U_F \rightleftharpoons U_S$ reaction. The measured rate constant λ is equal to the sum of the rate constants in the forward (k_{FS}) and the reverse (k_{SF}) directions, $\lambda = k_{FS} + k_{SF}$. When the equilibrium constant $K = [U_S]/[U_F] = k_{FS}/k_{SF}$ is known, the individual rate constants k_{FS} and k_{SF} can be derived.

25.9.1.1 Guidelines for the Design of Double Jump Experiments

Unfolding conditions Any unfolding conditions can be employed; for practical reasons, however, it is of advantage to select conditions (1) where the $N \rightarrow U_F$ unfolding step is rapid and (2) where the $U_F \rightleftharpoons U_S$ equilibration is slow. Under such conditions, $U_F \rightleftharpoons U_S$ can be studied without interference from the preceding unfolding step and manual sampling techniques can be used to perform the slow refolding assays. Usually it is best to perform the unfolding step at a high concentration of a strong denaturant, such as GdmCl, and at low temperature. The rate of conformational unfolding usually increases strongly with the denaturant concentration, and, because of the high activation enthalpy of proline isomerization, the $U_F \rightleftharpoons U_S$ reaction is strongly decelerated by decreasing the temperature. Consequently, the difference in rate between the two processes is highest in concentrated denaturant solutions and at low temperature. Often, the rate of conformational unfolding can be further enhanced by lowering the pH.

Refolding conditions The slow refolding assays are best carried out under conditions where (1) the $U_F \rightarrow N$ refolding reaction is complete within the time of manual mixing, and (2) the slow $U_S \rightarrow N$ reaction occurs in a single phase in a time range that is convenient for manual mixing experiments. This facilitates the accurate determination of the refolding amplitudes. After each refolding assay the actual protein concentration should be determined to correct for variations in the protein concentration in the individual assays. Usually the final absorbance or fluorescence reached after the refolding step is suitable for such a correction. As in the unfolding step, the rate of slow refolding can be fine-tuned by varying the concentration of denaturant, the temperature and the pH.

In cases where more than one U_S species is formed after unfolding, the individual rates of formation of these species can be measured when the refolding assays are carried out under conditions where the refolding of the various U_S species can be separated kinetically.

25.9.1.2 Formation of U_S Species after Unfolding of RNase A

I describe here a protocol that was used to follow the $U_F \rightleftharpoons U_S$ reaction in unfolded RNase A as an example. In these experiments the refolding assays were carried out under conditions where slow refolding is a single, monophasic reaction. Therefore, the refolding assays yielded the kinetics of overall formation of U_S species after unfolding. They did not discriminate between the different U_S species of RNase A (see Section 25.4.1).

Unfolding To initiate unfolding at time zero, 50 µL of native RNase A (1.5 mM in H_2O, 0 °C) is mixed with 250 µL of 6.0 M GdmCl solution in 0.1 M glycine, pH 2.0 at 0 °C. The resulting unfolding conditions are 0.25 mM RNase A in 5.0 M GdmCl, pH 2.0, 0 °C. Under these conditions the $N \rightarrow U_F$ unfolding step of RNase A is very rapid and complete before the onset of the $U_F \rightleftharpoons U_S$ equilibration. Thus the $U_F \rightleftharpoons U_S$ reaction can be measured in a convenient time range without interference from the preceding $N \rightarrow U_F$ unfolding step.

Refolding assays After different time intervals 70-µL samples are withdrawn from the unfolding solution and quickly diluted into 830 µL of the refolding buffer (1.2 M GdmCl in 0.1 M cacodylate, pH 6.2) in the spectrophotometer cell, which is kept at 25 °C. This gives final conditions of 1.5 M GdmCl, pH 6.0 and 25 °C. These conditions are chosen because slow refolding occurs in a single exponential phase in a time range, which is convenient for manual sampling techniques. The slow refolding reaction of U_S is monitored at 287 nm. At the end of each refolding assay the absorbance of the refolded sample is recorded at 277 nm to determine the actual concentration of RNase A in the assay.

Data treatment The refolding kinetics are analyzed. The time constant for refolding in the assay should be independent of the time of sampling, because the final folding conditions are the same in all assays. The amplitudes of refolding are corrected for variations in the protein concentration (if necessary) and plotted as a function of the time of unfolding. The increase in the refolding amplitude with the duration of unfolding yields the kinetics of the formation of the slow-folding species U_S.

25.9.2 Slow Unfolding Assays for Detecting and Measuring Prolyl Isomerizations in Refolding

Often protein molecules with incorrect prolyl isomers can fold to a conformation that appears native-like by spectroscopic properties or even by enzymatic activity. In such cases the re-isomerization of the incorrect prolines in the final step of folding is silent and cannot be followed by spectroscopic probes or by a functional assay.

To follow such silent isomerizations during refolding, a two-step assay is used. It measures the kinetics of the formation of fully folded protein molecules during a refolding reaction [33, 74]. This assay is based on the fact that native protein mole-

cules have passed beyond the highest activation barrier in their refolding and thus are separated from the unfolded state by this energy barrier. They unfold slowly when the conditions are switched to unfolding, because they must cross the high barrier again, now in the reverse direction. Partially folded molecules (such as those with incorrect prolyl isomers) have not yet passed the final transition state and unfold rapidly.

This translates into a double-mixing procedure. First, unfolded protein is mixed with refolding buffer to initiate refolding. Then, after variable time intervals, samples are withdrawn, transferred to standard unfolding conditions, and the amplitude of the subsequent slow unfolding reaction is determined. It is a direct measure for the amount of native molecules with correct prolyl isomers that had been present at the time when refolding was interrupted, and the increase of the amplitude of slow refolding with time gives the kinetics of formation of the native protein.

25.9.2.1 Practical Considerations

The unfolding assays are best carried out under conditions where the N → U unfolding reaction in the assay is monophasic and occurs in a time range that is convenient for manual mixing experiments. Thus the unfolding amplitudes can be determined with a high accuracy. Most proteins unfold in monoexponential reactions under strongly unfolding conditions, i.e., in the presence of a denaturant at high concentration. The rate of unfolding can be varied in a wide range by changes in the pH, the temperature and the denaturant concentration. As in the refolding assays (see above) the actual protein concentration should be determined to correct for variations in the protein concentration in the individual unfolding assays.

25.9.2.2 Kinetics of the Formation of Fully Folded IIHY-G3P* Molecules

Here I describe how this procedure was used to measure the time course of the *trans* → *cis* re-isomerization at Pro213 in the refolding of the gene-3-protein of the phage fd [59, 60]. This isomerization controls the domain docking in the final folding step of this protein. The unfolding assays were performed in 5.0 M GdmCl, pH 7.0 at 25 °C, conditions under which the gene-3-protein unfolds in a monoexponential reaction with a time constant of 25 s.

To follow the formation of native molecules, unfolded protein (50 μM in 5.0 M GdmCl) was first manually 10-fold diluted with buffer (in a test tube) to initiate refolding at 0.5 M GdmCl and then, after times of refolding between 1 and 540 min, samples were withdrawn and unfolded again at 5.0 M GdmCl by a manual 10-fold dilution with a GdmCl solution of 5.5 M in the fluorimeter cell. Unfolding was followed by the change in tyrosine fluorescence at 310 nm after excitation at 280 nm.

Folding and Disulfide Formation

Margherita Ruoppolo, Piero Pucci, and Gennaro Marino

26.1
Chemistry of the Disulfide Bond

The formation of a disulfide bond from two thiol groups is an electron-oxidation reaction that requires an oxidant. Protein thiol oxidation results from a thiol/disulfide exchange process that transfer equivalents from an external disulfide to the protein (Figure 26.1). The reaction occurs via direct attack of a nucleophilic thiolate anion on the most electron-deficient sulfur of the external disulfide bond. The rate constant for the reaction increases as the basicity of the attacking thiolate nucleophile (S_a) increases (pK_a increases) and as the basicity of the leaving thiolate (R_2S^-) decreases (pK_a decreases). The pK_a of the cysteine sulfhydryl group is generally in the range of 8–9; however this may vary considerably from protein to protein due to the effect of the local environment [1].

Protein disulfide formation in a redox buffer (e.g., low-molecular-weight disulfide and its corresponding thiol) is a reversible reaction that involves the formation of a mixed disulfide intermediate followed by an intramolecular attack in which a second cysteine thiol displaces the mixed disulfide to form the protein disulfide bond (Figure 26.1). Glutathione redox buffers are most commonly used in in vitro experiments since glutathione is present at high concentration in the endoplasmic reticulum [2–4]. Dithiothreitol is often used instead of linear reagents because it does not form long-lived mixed disulfides with protein thiols, thereby making oxidative folding studies easier to interpret because of the reduced number of possible intermediates in the experimental system [5]. However, it has to be taken in consideration that dithiothreitol is not physiological. During oxidative folding, the disulfide component of the redox buffer provides oxidizing equivalents for protein disulfide formation. The ability to form a disulfide will depend on the equilibrium and rate constants for the individual steps illustrated in Figure 26.1 and the concentrations and oxidation potential of the redox buffer [6]. A more oxidizing buffer will favor the formation of protein species with more and more disulfide bonds. At the same time, high concentrations of oxidant inhibit folding by formation of nonproductive intermediates which are too oxidized to fold correctly [2, 7].

The relevant intramolecular step for oxidative folding shown in Figure 26.1 heav-

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

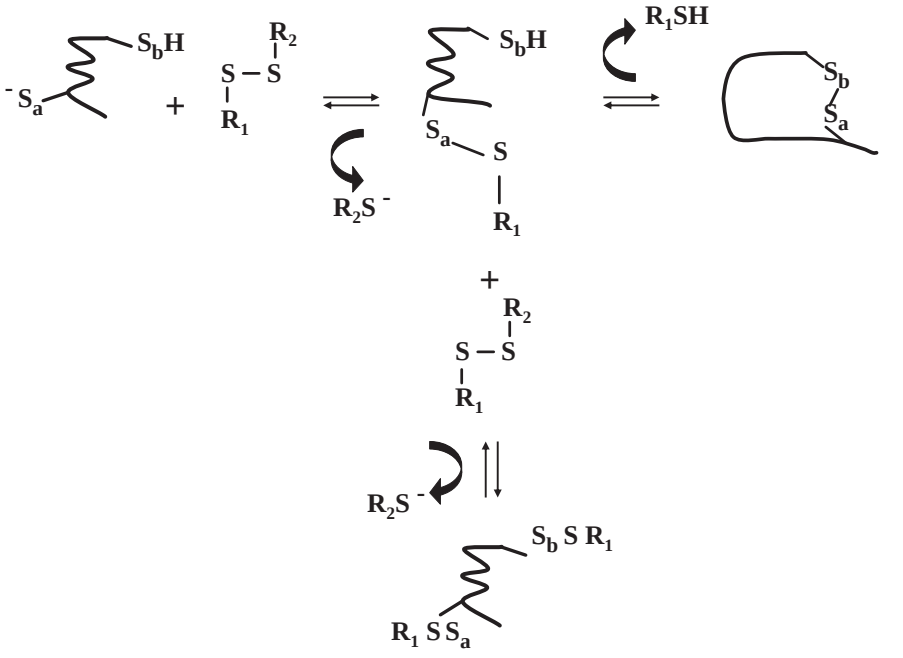

Fig. 26.1. Protein disulfide bond formation.

ily depends on the energetics of the protein conformational changes that bring the two cysteines into proximity to form the disulfide bond [8]. Among intermediates with the same number of intramolecular disulfide bonds, species with the most stable disulfides will have the highest equilibrium concentration regardless the redox buffer composition. The structures of intermediates that result in the formation of the most stable disulfide bond will be present at the highest concentration. Since interconversion among the intermediates with the same number of disulfide bonds constitute a rearrangements that does not involve the net use or production of oxidizing equivalents, the equilibrium distribution of the intermediates with the same number of disulfides will not be affected by the choice of the redox buffer or its composition but it will be an intrinsic property of the protein itself.

26.2 Trapping Protein Disulfides

The strategy of using disulfide bonds as probes to study the folding of disulfide-containing proteins was introduced and developed by Creighton and his group [8]. His pioneering work deserves credit and constitutes a milestone in the field of oxidative folding.

Disulfides present at any instant of time of folding can be trapped in a stable

form by simply blocking, rapidly and irreversibly, all thiol groups in the solution. The quenching reaction should be as rapid as possible to ensure that it faithfully traps the species present at the time of addition of the quenching reagent. Trapping with reagents like iodoacetamide or iodoacetic acid has the advantage of being irreversible, but the reaction has to be carried out in highly controlled experimental conditions to be effective. Once all free thiol groups are irreversibly blocked, the trapped species are indefinitely stable and may be then separated and characterized in details provided that disulfide shuffling is prevented.

Acidification also quenches disulfide bond formation, breakage, and rearrangement. Acidification is very rapid and is not prevented by steric accessibility, but it is reversible. There is then a possibility that separation methods used to separate the acidified species will induce disulfide rearrangements. Finally, acid-trapped species have the advantage that they can be isolated and then returned to the folding conditions, to define their kinetic roles.

The conformations that favor the formation of a particular disulfide bond are stabilized to the same extent by the presence of that specific disulfide bond in trapped intermediate. Because of this close relationship between the stability of disulfide bonds and the protein conformations that favored them, the procedures described above trap not only the disulfide bonds but also the conformations of the protein at that time of folding. Some aspects of the conformation of folding intermediates can then be deduced by identifying the cysteine residues that are involved in the disulfides present in the trapped intermediates.

Although the trapping reaction has the advantage to stabilize the folding intermediates, it has the disadvantage of altering the conformation of the intermediates because of the presence of the blocking groups on the cysteine residues not involved in disulfide bonds. Even intermediates trapped with acid have their free cysteine residues fully protonated, whereas the thiol groups should be at least partially ionized during folding process. Some studies were therefore addressed to prepare the analogs of the folding intermediates replacing the free cysteine residues with Ser or Ala by protein engineering methods [9–12]. These methods have the additional advantage that intermediates that do not accumulate to substantial levels and that they can be prepared in quantities sufficient for structural analysis.

26.3 Mass Spectrometric Analysis of Folding Intermediates

Mass spectrometry is used in protein folding studies to characterize the population of species formed on the folding pathway, and the disulfide bonds present at different times of the process [13, 14]. Figure 26.2 outlines the general strategy. Aliquots withdrawn at different times during the folding process are trapped by alkylation of the free thiol and analyzed by electrospray mass spectrometry (ESMS). The alkylation reaction increases the molecular mass of the intermediates by a fixed amount for each reacted free SH group. Intermediates containing different numbers of disulfide bonds can then be separated by mass, and their relative abundance in the sample can be determined. The nature and quantitative distribution

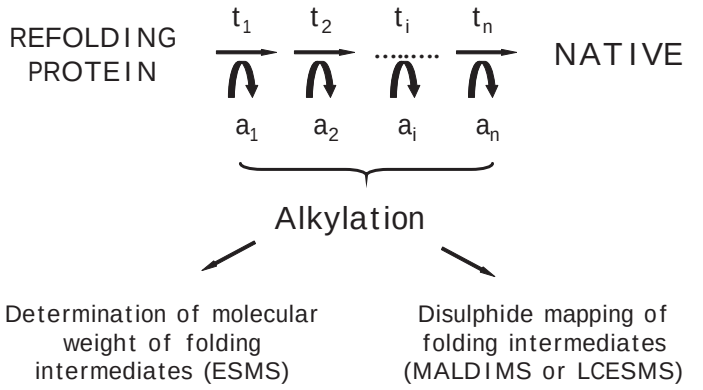

Fig. 26.2. General strategy for mass spectrometry analysis of folding intermediates.

of the disulfide bonded species present at a given time can be used to establish the folding pathway of the protein and to develop a kinetic analysis of the process. The method can also be used to determine the effect of folding catalysts on each step of the folding pathway. Any alteration in the relative distribution of the disulfide bonded species present at a given time due to the catalysts action, in fact, can be identified and quantitated [15].

It should be noted that the intermediates identified by the ESMS analysis are populations of molecular species characterized by the same number of disulfide bonds which may include nearly all possible disulfide bond isomeric species. Once the folding intermediates have been characterized by ESMS in terms of their content of disulfide bonds, a further step would consist in the structural assignment of the various disulfide bonds formed at different times in the entire process by matrix-assisted laser desorption ionization mass spectrometry (MALDIMS) or liquid chromatography ESMS. The experimental approach is based upon determination of the masses of disulfide-linked peptides of unfractionated or partially purified proteolytic digests of folding aliquots in mapping experiments [16, 17]. The folding intermediates should be cleaved at points between the potentially bridged cysteine residues under conditions known to minimize disulfide reduction and reshuffling, using aspecific enzymes or a combination of enzymes, in attempts to isolate any cysteine residue within an individual peptide. The disulfide mapping approach is then used to search for any S–S bonded peptides, which are characterized by their unique masses. The interpretation is then confirmed by performing reduction or EDMAN reactions followed by rerunning the MS spectrum [16].

26.4
Mechanism(s) of Oxidative Folding so Far – Early and Late Folding Steps

During the past three decades, the oxidative folding pathways of various small proteins containing disulfide bonds have been studied by identifying the nature of the intermediates that accumulate during their folding process [18–22]. At present,

no single oxidative folding scenario seems to distinctly emerge from these detailed studies. However some common principles have been highlighted. Disulfide folding pathways are not random: they converge to a limited number of intermediates that are more stables than others. The greater thermodynamic stability of some intermediate conformations can have kinetic consequences, as further folding from the stable conformations is favored. This is most clearly illustrated in the case of bovine pancreatic trypsin inhibitor (BPTI) [8], where early folding intermediates appear to be stabilized by strong native-like interactions. A pre-equilibrium occurs very quickly when the protein is placed under folding conditions; the nature of the pre-equilibrium mixture will only depend upon the final folding conditions. Any favorable conformations present in the pre-equilibrium need not to be present at detectable levels in the denatured state. Conversely, nonrandom conformations that might be present in the denatured state may have no relevance for folding. In the case of BPTI, the most stable partially folded conformations in the pre-equilibrium appear to involve interactions between elements of secondary structure, and there is a considerable evidence for the rapid formation of some elements of secondary structure during the folding of many proteins [8].

The rate-limiting step in disulfide folding occurs very late in the process before the acquisition of the native conformation [8, 15, 23, 24]. The highest free energy barrier separates the native conformation from all other intermediates. At late stages in ''structured'' intermediates, the existing disulfides are sequestered from the thiols of the protein and from the redox reagent, resulting in the slowing of the thiol-disulfide rearrangement reaction by several orders of magnitude (as compared to thiol-disulfide exchange in the ''unstructured'' intermediate at the early stages). As a result, ''structured'' species frequently accumulate during the folding process [23].

The rearrangements that take place in the slow steps of oxidative folding may constitute examples of the conformational rearrangements that take place during the rate-limiting steps in folding transitions not involving disulfide bonds. Such conformational rearrangements are the result of the cooperativiity of protein structure and the similarity of the overall folding transition state to the native conformation.

26.5
Emerging Concepts from Mass Spectrometric Studies

The study of oxidative folding carried out by our group indicated that in quasi-physiological conditions, the process occurs via reiteration of two sequential steps: (i) formation of a mixed disulfide with glutathione, and (ii) internal attack of a free SH group to form an intramolecular disulfide bond. This sequential pathway seems to be a general mechanism for single-domain disulfide-containing proteins as it has been observed in many different experimental conditions.

According to the above concepts, only a limited number of intermediates were detected in the folding mixture and isomerization between species with the same

number of disulfides was found to be only extensive at late stages of the process where slow conformational transitions become significant. Theoretically, the number of all the possible intermediates during the folding process should increase exponentially with the increase in the number of cysteine residues. In contrast, the number of the populations of intermediates increases linearly with the increase in the number of disulfide bonds. Within the frame of this general pathway, differences exist in the amount and accumulation rate of individual intermediates arising from the individual protein under investigation. When the folding pathways of RNase A and toxin α, both containing four disulfide bonds, are compared, some differences can be detected (see below). Species with two disulfide bonds predominate along the RNase A folding [15], while the intermediates containing three disulfides represent the most abundant species in the case of toxin α [15].

Data obtained using different proteins suggests the occurrence of a temporal hierarchy in the formation of disulfide bonds in oxidative folding, in which the sequential order of cysteine couplings greatly affect the rate of the total process. Even the order of formation of native disulfide bonds is in fact important to prevent the accumulation of nonproductive intermediates.

When the folding was carried out in the presence of protein disulfide isomerase (PDI), the folding pathway of reduced proteins was unchanged, but the relative distribution of the various populations of intermediates was altered. All the experiments suggest that PDI catalyzes: (1) formation of mixed disulfides with glutathione, (2) reduction of mixed disulfides, and (3) formation of intramolecular disulfide bonds. These results are not surprising considering the broad range of activities shown by PDI [4].

The oxidative folding pathway of some proteins investigated in our laboratory will be described in detail below.

26.5.1 Three-fingered Toxins

Snake toxins, which are short, all β-proteins, display a complex organization of disulfide bonds. Two S–S bonds connect consecutive cysteine residues (C43-C54, C55-C60) and two bonds intersect when bridging (C3-C24, C17-C41) to form a particular structure classified as ''disulfide β-cross'' [26] because cysteine residues tend to make a cross symbol when viewed along the length of the β-strands. The general organization of the polypeptide chain in snake toxins generates a trefoil structure termed the ''three-fingered fold'' (Figure 26.3). ''Three-fingered'' snake toxins act by blocking ion channels (neurotoxins), or enzymes such as acetylcholinesterase (fascicullin) or Na/K-ATPase and protein kinase C (cardiotoxins), in addition to less-defined targets.

We have shown that three-fingered snake toxins fold according to the general sequential mechanism described above [25, 27]. A single mutation located in an appropriate site of the neurotoxin structure is sufficient to substantially alter the rate of the sequential folding process of the protein and to deeply modify the proportion of intermediates that accumulate during the oxidative folding process. We

Fig. 26.3. Structure of three-fingered toxin. Sequence alignment of neurotoxins and their variants used in our laboratory.

used three variants for which the length of a large turn, turn 2 (Figure 26.3), was increased from three (variant α60, sequence CPG) to four (toxin α, α61, sequence CPGE) and then to five (variant α62, sequence CSPGE) residues. The increase in the length of loop 2 greatly decreased the rate of the folding process. After 2 hours of incubation, about 90% of the variant α60 was folded, whereas no more than 70% of the 61 residues of toxin α and 20% of the variant α62 had reached the native state. Interestingly, three disulfide-containing intermediates were the predominant species in the folding of all variants but this population was markedly more abundant and persistent for the slowest-folding neurotoxin.

Two intermediates containing three disulfides were found to accumulate to detectable levels during early and late stages of neurotoxin α62 folding. Both intermediates consist of chemically homogeneous species containing three of the four native disulfide bonds and lacking the C43-C54 and the C17-C41 coupling, respectively. The des-[43–54] intermediate is the immediate precursor of the native species. Conversely, the des-[17–41] species is unable to form the fourth disulfide bond and has to rearrange into intermediates that can directly reach the native state. These isomerization reactions provide an explanation for the accumulation of three disulfide intermediates along the pathway, which caused the slow oxidative folding observed for neurotoxin α62.

The particular pathway adopted by neurotoxin α62 shares a number of common

features with that followed by BPTI, although the two proteins differ both in the number of disulfides and in their secondary structures. The main similarity is that no scrambled fully oxidized species occur as folding intermediates. In addition, all-but-one-disulfide-containing intermediates (i.e., intermediates containing three and two disulfides) exclusively possess native disulfide bonds [9, 28]. Finally, the native form for both the variant α62 and BPTI results from an intramolecular rearrangement within their respective all-but-one native disulfide populations, with one predominantly productive species, des-[43–54] for the variant α62 and C30-C51 and C5-C55 for BPTI [7]. However, formation of the native form from the productive species seems much faster in BPTI [7] than in neurotoxin α62. It is noteworthy that the folding pathway of variant α62 is much closer to that of BPTI than to those of other all-β disulfide-containing proteins, such as epidermal growth factor (EGF) [29]. In this case disulfide-scrambled isomers accumulate along the pathway and they have to rearrange before forming the native structure.

On more general grounds, the observation that only intermediates with native disulfide bonds accumulate strongly suggests that native disulfide bonds are dominant early in the folding, resulting in funnelling the conformations towards the native state.

26.5.2 RNase A

Bovine pancreatic ribonuclease A has been the model protein for folding studies [30–36] since the landmark discovery by Anfinsen [37] that the amino acid sequence provides all the information required for a protein to fold properly. RNase A contains four disulfide bonds (C26-C84, C40-C95, C65-C72, C58-C110), which are critical both to the function and stability of the native enzyme [38, 39]. The two disulfide bonds C26-C84 and C58-C110 that link a α-helix and a β-sheet in the protein core are the most important to conformational stability. On the other hand, the two disulfide bonds C40-C95 and C65-C72 that link surface loops greatly affect the catalytic activity because of their proximity to active site residues.

The folding of RNase A has been studied in many laboratories, and different mechanisms of folding have been proposed depending on the experimental conditions used. Initial folding studies performed by Creighton and coworkers [40–43] in the presence of reduced and oxidized glutathione suggested that the process proceeds through a single pathway, the rate-determining step being the formation of the C40-C95 disulfide bond.

Parallel studies were performed by Scheraga and coworkers in the presence of reduced and oxidized dithiothreitol [5, 23, 44–46]. These authors suggested that RNase A regenerates through two parallel pathways involving the formation of two native-like species containing three disulfide bonds. The main pathway produces a species lacking C40-C95, in line with former results [40–43], while a species lacking C65-C72 is produced in a minor regeneration pathway.

We showed that the folding of RNase A [15] proceeds throughout the sequential mechanism discussed above. The characterization of the population of one-

disulfide intermediates reveals the presence of only 12 disulfide-bonded species out of the expected 28. These results confirmed previous conclusions, that the formation of the S–S bonds during the folding of RNase A proceeds through a nonrandom mechanism [47] and is coupled to the formation of specific stabilizing structures that are either native or nonnative [8, 12, 23].

Mass spectrometry characterization revealed that in the early stages of the process: (1) the native C26-C84 pairing is absent; (2) disulfide bonds containing C26 are underrepresented; and (3) most of the nonnative disulfide bonds are formed by C110 [48].

The nonrandom coupling of cysteine residues is then biased in three respects: (1) towards the formation of short-range linkages; (2) towards the formation of native disulfides; and (3) towards the formation of disulfides involving cysteines located in the C-terminal rather than N-terminal portion of the molecule. While the first two of these trends are relatively easy to rationalize, the last one is more difficult to interpret. It could reflect more complete collapse of the C-terminal portion of the molecule, allowing easy disulfide interchange within a restricted volume or it could reflect formation of some stable structures around Cys26, which inhibit its interaction with other portions of the polypeptide chain.

The characterization of the population of one-disulfide intermediates produced in the presence of PDI reveals that the PDI-catalyzed refolding generates essentially the same disulfide bonds, and hence the same intermediates identified in the noncatalyzed reoxidation [48]. The similar distribution of isomeric species within the population of one-disulfide intermediates in the uncatalyzed and in the PDI-assisted process indicates that at the early stages of the folding, catalysis of the isomerization of disulfide bonds has no significant effect on the folding pathway. The observation that the population of one-disulfide intermediates is hardly affected by the presence of PDI further proves that thermodynamic control operates at this stage of RNase A refolding. Since nonnative disulfide bonds need to isomerize to produce native RNase A, PDI-dependent catalysis of the rearrangements of disulfide bonds is significant for the overall pathway at later stages of the refolding process. At that stage, the intermediates would already have acquired some tertiary structure and the key function of PDI is to catalyze disulfide rearrangements within kinetically trapped, structured folding intermediates as reported for the PDI-assisted refolding of BPTI [49].

The removal of the C65-C72 disulfide bond has no effect on the kinetics of folding of RNase A. The folding of the C65A/C72A mutant occurs in fact on the same time scale as the folding of wild-type protein [12]. Furthermore the individual native and nonnative disulfides appear at the same times during the folding processes of the mutant and the native protein (with the obvious exception of those involving the two absent cysteine residues). These results suggest that the folding processes of the wild-type and the mutant RNase A are driven by similar interatomic interactions without any great influence of the C65-C72 bond. Interestingly, the C65-C72 disulfide bond is the only disulfide bond that is not conserved throughout the RNase superfamily [50].

The C58A/C110A and C26A/C84A mutants fold much more slowly than the wild-type protein. A steady state is established between two- and three-disulfide

containing species in the folding processes of these two mutants, thus suggesting that the rate-limiting step might be the formation of the third disulfide bond. The assignments of disulfide bonds during the folding of the C58A/C110A and C26A/C84A mutants show that many nonnative disulfide bonds are still present in solution at late stages of the reaction, indicating that many scrambled molecular species have not yet completed the folding process. The formation of C58-C110 or C26-C84 disulfide bonds can function as a lock on the native structure, hampering the three-disulfide-containing species reshuffling in the folding of wild-type RNase A.

Finally, the identification of disulfide bonds formed during the folding of RNase A mutants showed that C110 is the most actively engaged cysteine residue in the formation of disulfide bonds, as occurred in the folding of the wild-type protein. C110 can then function as an internal catalyst able to promote reshuffling of disulfides in order to accelerate isomerization reactions in the regaining of the native state.

26.5.3 Antibody Fragments

Antibodies are multimeric proteins consisting of different domains characterized by two antiparallel β-sheets linked by an intradomain disulfide bond [51–53]. A characteristic feature of antibodies is that the intradomain disulfide bond, which connects residues far apart in the sequence, is completely buried in the core of the protein. Mechanistic studies on oxidative folding of immunoglobulins were previously carried out on antibody fragments and single antibody domains [54–59].

The analysis of immunoglobulin folding by our group was dissected by investigating the folding process of different portions of the antibody molecule. The elucidation of the folding pathway of the noncovalent homodimer formed by the C-terminal domain C_H3 containing a single intramolecular disulfide bond was the first step. We showed that folding, oxidation, and association of the immunoglobulin domain C_H3 requires a fine-tuned and well-coordinated interplay between structure formation to bring the cysteine residues into proximity and to shield the disulfide bond from the solvent and structural flexibility that is required for redox shuffling and rearrangements of structural elements [59].

Analysis of the folding of the Fc fragment constituted by C_H2 and C_H3 domains showed the presence of a kinetic trap during the process that impairs the formation of the second S–S bond from the species containing one intramolecular disulfide. The results indicated that the two domains present in the Fc fragment fold independently. A hierarchy of events exists in the overall process with the disulfide of the C_H3 domain forming faster than the C_H2 S–S bond. During the early stages of folding, the C_H3 domain attains a structure which is able to bring the two cysteines in the right orientation to form the first disulfide bond and to shield it from the solvent as happens for isolated C_H3 [59]. Conversely, the C_H2 domain seems to have a flexible conformation that prevents the formation of the second S–S bond. The rate-limiting step in the overall Fc folding process is then the coupling of

the two cysteines of the C_H2 domain. Consequently, spontaneous folding in the absence of folding helpers only occurs at a very slow rate. The addition of PDI catalyzes the process at various steps, promoting the formation of the C_H2 disulfide.

26.5.4 Human Nerve Growth Factor

Nerve growth factor (NGF), together with brain-derived neurotropic factor (BDNF), neurotrophin-3 (NT-3) and NT-4/5, belongs to the neurotrophin family of protein growth factors. Neurotrophins promote growth, survival, and plasticity of specific neuronal populations during developmental and adult life phases [60, 61]. NGF, BDNF, and other growth factors such as transforming growth factor (TGFβ2), bone morphogenetic protein 2 (BMP-2), and platelet-derived growth factor (PDGF) share characteristic tertiary and quaternary features: the proteins are homodimeric in their native and active conformations and have a typical tertiary fold, the cysteine knot. Our studies showed that the pro-region of recombinant human (rh)-NGF facilitates protein folding. Folding yields and kinetics of rh-pro-NGF were significantly enhanced when compared with the in vitro folding of mature rh-NGF. The characterization of the folding pathway of rh-pro-NGF indicates that structure formation is very efficient since a unique 3S species containing only the native disulfide bonds was detected at early time points of folding. The characterization of intermediates produced in the folding of mature rh-NGF revealed that the process is very slow with the formation of multiple unproductive intermediates containing nonnative cysteine couplings. Two out of the three native disulfide bonds formed after 1 hour, while the formation of the complete set of native disulfide bonds was reached only after 24 hours. Since denatured, mature rh-NGF is known to fold quantitatively as long as the cysteine knot is intact [62], it has been suggested that the pro-sequence assists the oxidative folding by possibly contributing to the formation of the cysteine knot. However, unlike BPTI, the pro-sequence of NGF does not contain a cysteine that could facilitate disulfide bond shuffling during folding of NGF [63].

A possible function of the pro-peptide may be that it acts as a specific scaffold during structure formation of the cysteine knot. Once the native disulfide bonds are formed, the characteristic β-sheet structure is built on and the two monomers can associate to form the rh-pro-NGF dimer. Alternatively, the pro-sequence of NGF could passively confer solubility to aggregation prone folding intermediates by shielding hydrophobic patches and thus enhancing folding yields.

26.6 Unanswered Questions

It is quite clear that many aspects of oxidative folding have been clarified so far. However some questions remain unsolved. An aspect that is still to be clarified

concerns how far the disulfide folding mechanism can be extrapolated to protein folding mechanisms in general. Some common aspects have been highlighted throughout the chapter. However oxidative folding shows peculiar features due to the fact that disulfide-containing proteins constitute a unique class of proteins. In our opinion, the main unanswered questions are related to the observation that some disulfide-containing proteins fold with high efficiency into their native structure while others do not. These aspects are intimately related to the role played in vivo by the multiple redox machineries that cooperate to make folding fast and efficient. These aspects are discussed in Chapters 9 and 19 in Part II.

26.7 Concluding Remarks

Practical considerations drawn from the study of oxidative folding are very important in the production of recombinant proteins with disulfide bonds, many of which are therapeutically useful. A systematic exploration of pH, salt concentration, effectors, cofactors, temperature, and protein concentrations has been made in order to define the best experimental conditions to achieve the highest yield of folded protein. However, fast and high-throughtput methods are still required to investigate optimal folding conditions. There is no doubt that mass spectrometry can be a very useful tool in these kinds of studies. Few solid conclusions have been reached that suggest widely applicable methods for folding denatured and reduced proteins [64]. Guidelines for the optimization of folding methods will be discussed in other chapters.

26.8 Experimental Protocols

26.8.1 How to Prepare Folding Solutions

1. Reduction and denaturation buffer: 0.1 M Tris–HCl, 1 mM EDTA containing 6 M guanidinium chloride, pH 8.5, stable at room temperature for up to 1 month.
2. Folding buffer: 0.1 M Tris–HCl, 1 mM EDTA, pH 7.5; stable at room temperature for up to 1 month.
3. Reduced glutathione stock solution: 50 mM reduced glutathione in folding buffer; prepare fresh daily.
4. Oxidized glutathione stock solution: 50 mM oxidized glutathione in folding buffer; prepare fresh daily.
5. Iodoacetamide (IAM) solution: 2.2 M iodoacetamide solution in folding buffer; prepare fresh daily. IAM is freshly dissolved in folding buffer at 65 °C and cooled to room temperature before use. During preparation of the reagents, the solutions should be protected from light to minimize iodine production, which is a very potent oxidizing agent for thiols.

26.8.2
How to Carry Out Folding Reactions

Preparation of reduced samples

1. Reduce protein with the reduction and denaturation buffer by incubation with reduced DTT (DTT mol/S–S mol = 50/1) for 2 h at 37 °C, under nitrogen atmosphere.
2. Add 0.2 vol of 1 M HCl.
3. Desalt the reaction mixture on a gel-filtration column equilibrated and eluted with 0.01 M HCl.
4. Recover the protein fraction, test for the SH content, lyophilize and store at −20 °C.

Folding reactions

1. Dissolve reduced proteins in 0.01 M HCl and then dilute into the folding buffer to the desired final concentration.
2. Add the desired amounts of GSH and GSSG stock solutions to initiate folding. The choice of the concentrations of reduced and oxidized glutathione depends on the protein under investigation and is based on conditions giving the highest yield of native protein at the end of the folding process. Adjust the pH of the solution to 7.5 with Tris–base and incubate at 25 °C under nitrogen atmosphere. In the case of antibody fragments start folding by diluting 100-fold the reduced and denatured protein in 0.1 M Tris–HCl (pH 8.0), 1 mM EDTA, containing 6 mM GSSG. Carry out the process at 4 °C.
3. Monitor the folding processes by removing 50–100 μL samples of the folding mixture at appropriate intervals.
4. Alkylate the protein samples as described below.
5. Purify from the excess of blocking reagent by rapid HPLC desalting.
6. Recover the protein fraction and lyophilize.
7. Alternatively, quench the folding by adding hydrochloric acid to a final concentration of 3% (experimentally determined pH ∼ 2).

Use of folding catalysts

1. Dissolve folding catalysts in folding buffer.
2. Preincubate for 10 min at 25 °C. Add this mixture to reduced proteins and continue the folding at 25 °C under nitrogen atmosphere, as described.

Alkylation of the folding aliquots

1. Add the folding aliquots (50–100 μL) to an equal volume of a 2.2 M iodoacetamide solution. Perform the alkylation for 30 s, in the dark, at room temperature, under nitrogen atmosphere as described [65].

2. Add 100 μL of 5% trifluoroacetic acid, vortex the aliquots, and store on ice prior loading on the HPLC for the desalting.

26.8.3
How to Choose the Best Mass Spectrometric Equipment for your Study

The determination of the molecular weight of intermediates containing a different numbers of disulfide bonds has to be carried out with a mass spectrometer equipped with an electrospray ion source. The analyzer can easily be a single quadrupole. You do not need very high mass resolution for this kind of analysis.

The assignment of disulfide bonds has to be carried out on the peptide mixtures by using a MALDI time-of-flight mass spectrometer. The instrument has to be a reflectron TOF. You need very high mass resolution for this kind of analysis.

26.8.4
How to Perform Electrospray (ES)MS Analysis

1. Perform mass-scale calibration by means of multiply charged ions from a separate injection of hen egg white lysozyme (average molecular mass 14 305.99 Da) or of horse heart myoglobin (average molecular mass 16 951.5 Da).
2. Dissolve the protein samples in a mixture of H_2O/CH_3CN (50/50) containing 1% acetic acid.
3. Inject the protein samples (10 μL) in concentrations ranging from 10 to 20 pmol μL^{-1} into the ion source via loop injection at a flow rate of 10 μL min^{-1}.
4. Record the spectra by scanning the quadrupole at 10 s per scan. Data are acquired and analyzed by the MassLynx software. Figure 26.4 shows, as an example, the deconvoluted ES spectra of the mixtures of species sampled at 1 min and 4 h from the folding mixture starting from reduced toxin α. The different populations of disulfide intermediates present were identified on the basis of their molecular mass. Each population of trapped intermediates is characterized by a different number of intramolecular disulfide bonds (indicated as *n*S), mixed disulfides with the exogenous glutathione (*n*G) and carboxyamidomethyl (CAM) groups. The number of CAM groups corresponds to the number of free thiols present in the folding intermediates and is therefore indicated as *n*H.

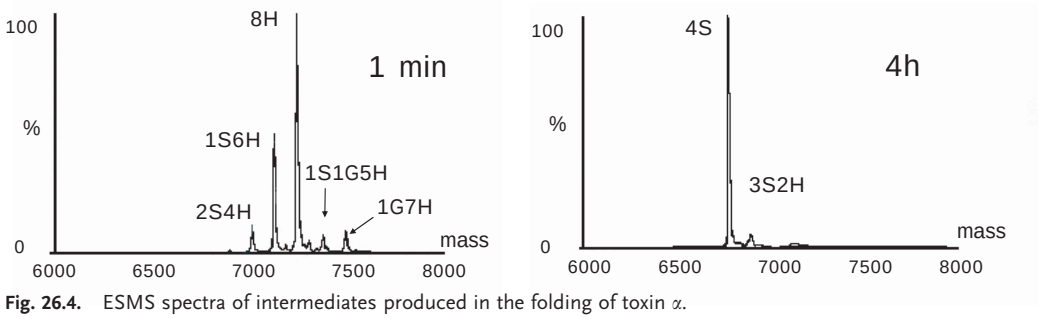

Fig. 26.4. ESMS spectra of intermediates produced in the folding of toxin α.

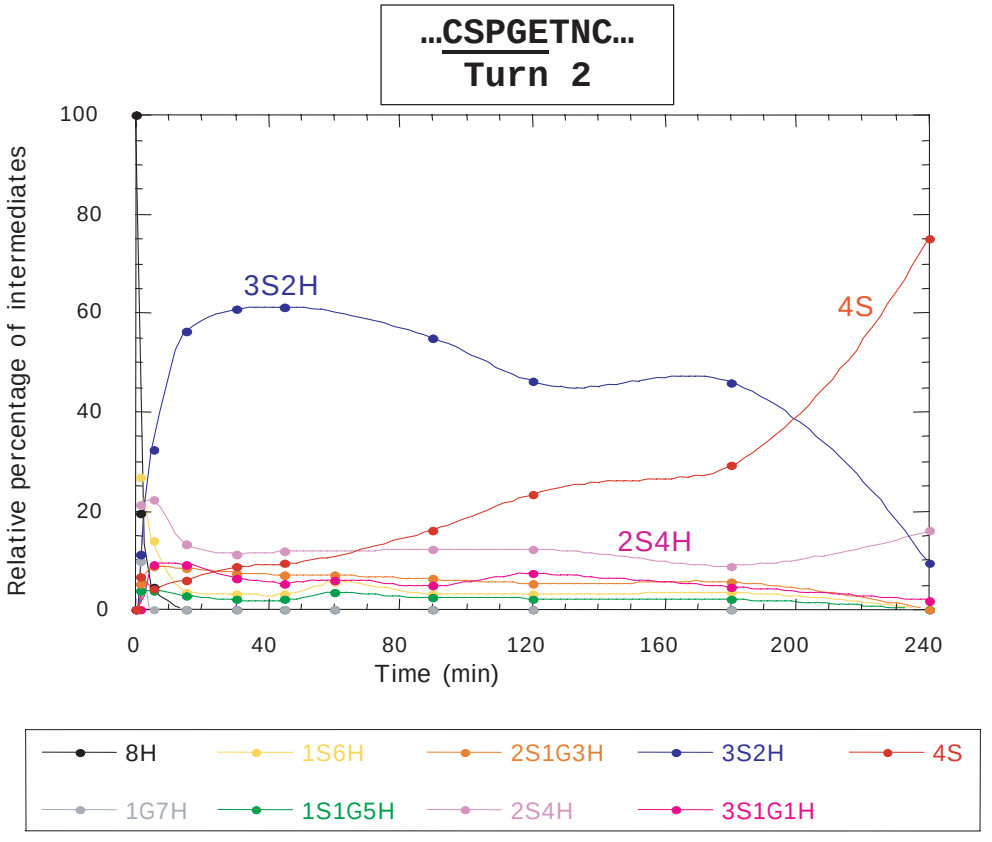

Fig. 26.5. Time course of folding of toxin α62.

Accurately quantify each population of intermediates by measuring the total ion current produced by each species provided that the different components are endowed with comparable ionization capabilities. Each set of folding data should be obtained as the mean of three independent folding experiments. The differences between folding experiments performed completely independently of each other should be about 5%. The time course of folding of toxin α62, plotted in Figure 26.5, shows that intermediates containing three disulfides are predominant from the beginning of the reaction up to about 200 min, when the relative concentration of the species 4S increases.

26.8.5

How to Perform Matrix-assisted Laser Desorption Ionization (MALDI) MS Analysis

1. Hydrolyze the protein samples withdrawn at different incubation times of folding.
2. Dissolve samples in 0.1% trifluoroacetic acid at 10 pmol/μL.
3. Apply 1 μL of sample to a sample slide and allow to air-dry.

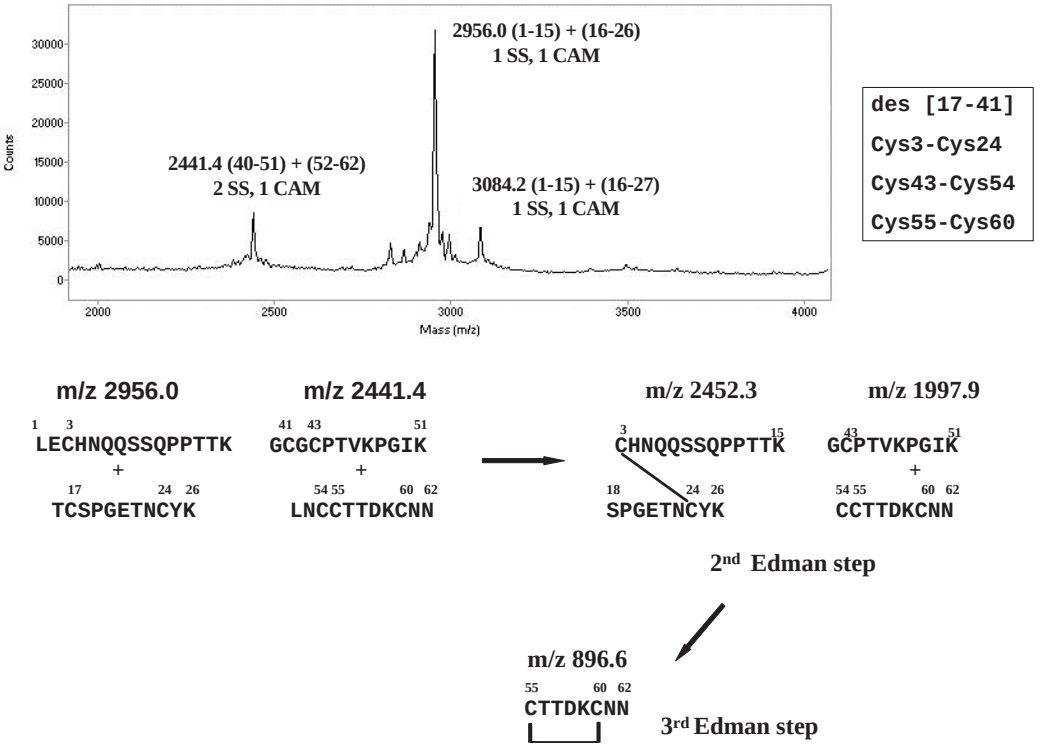

Fig. 26.6. Disulfide mapping of intermediates des-[17–41] accumulating in the folding of toxin α62.

4. Apply 1 μL of bovine insulin to the sample slide and allow to air-dry.
5. Apply 1 μL of α-cyano-4-hydroxycinnamic acid (10 mg mL^{-1}) in ethanol/acetonitrile/0.1% trifluoroacetic acid 1:1:1 (v:v:v) and allow to air-dry.
6. Collect spectra. Mass spectra are generated from the sum of 50 laser shots.
7. Calibrate the mass range using bovine insulin (average molecular mass 5734.6 Da) and a matrix peak (379.1 Da) as internal standards.

Figure 26.6 shows the MALDI mass spectrum of the tryptic mixtures of peptides derived by intermediate des-[17–41] accumulating in the folding of toxin α62. The Edman strategy adopted to assign the disulfide bonds present in the intermediate is also reported.

Concurrent Association and Folding of Small Oligomeric Proteins

Hans Rudolf Bosshard

27.1
Introduction

Our current understanding of protein folding has been mostly obtained through the study of monomeric, globular proteins. However, oligomeric proteins are probably more abundant in nature. There is strong evolutionary pressure for monomeric proteins to associate into oligomers [1]. Many results and conclusions acquired from the study of monomeric proteins can be applied to oligomeric proteins. For example, the stabilities of both monomeric and oligomeric proteins result from a delicate balance between opposing forces, the major contributors to stability being the hydrophobic effect, van der Waals interactions, and hydrogen bonds among polar residues [2–4]. In contrast to monomeric proteins, the stabilizing and destabilizing forces operate not only within single subunits but also between the subunits of an oligomeric protein; that means, both *intra*molecular and *inter*molecular forces contribute to stability. Nevertheless, there are no fundamental differences between the mechanisms of folding of monomeric and oligomeric proteins. For both types of proteins singular as well as multiple folding pathways are observed with no, a few, or many intermediates and sometimes with nonnative, dead-end products.

However, one difference is important: At least one step in the folding of an oligomeric protein must be concentration dependent. This is because the formation of an oligomeric protein includes folding *and* association; and folding and association are concurrent reactions. In some cases, folding and association can be studied as separate and virtually independent reactions, in others they are fully coupled into a single reaction step (''two-state'' mechanism or ''single-step'' mechanism), yet most often they can be distinguished but are not independent of each other. The degree of coupling between folding and association largely depends on the balance between the intra- and intermolecular forces that stabilize the oligomeric structure. If the isolated monomeric subunits are stabilized by strong intramolecular forces and the folded monomeric subunits themselves are thermodynamically stable folded structures, then folding and association are separate steps: formation of the oligomer corresponds to the association of preformed folded monomers. If the iso-

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

lated monomeric subunits are unstable and stability is gained only by intermolecular forces within the oligomeric structure, then folding and association are intimately dependent on each other and are tightly coupled.

The concurrence of intra- and intermolecular reactions and the dependence of folding on concentration adds an extra level of complexity to folding. This is perhaps the main reason why our knowledge of the stability and folding of multisubunit proteins is still rudimentary and often of only a qualitative nature. Indeed, quantitative thermodynamic and kinetic analyses have been restricted to mainly dimeric proteins. Reliable quantitative thermodynamic and kinetic data on trimeric and higher order oligomeric structures are still scarce.

The present chapter focuses on the detailed, quantitative in vitro analysis of the thermodynamics and kinetics of folding of small dimeric proteins and protein motifs, with only brief and passing reference to trimeric and tetrameric structures. The emphasis is on concepts and methods. We do not present a comprehensive review of the assembly of dimeric proteins but select appropriate examples to illustrate experimental methods, concepts and principles. In vitro and in vivo folding and association of oligomeric and multimeric proteins has been reviewed before (see Refs [5–8]). In vivo folding and assembly of large, higher order multisubunit proteins is covered in Chapter 2 in Part II.

27.2 Experimental Methods Used to Follow the Folding of Oligomeric Proteins

In principle, the methods used in the study of monomeric proteins can be used to follow dissociation and unfolding of oligomeric proteins under equilibrium conditions and to measure the kinetics of folding, unfolding, and refolding. The main difference is in data analysis, which has to consider the association step that is lacking in monomeric proteins.

27.2.1 Equilibrium Methods

Chemical unfolding by urea or guanidinium chloride (GdmCl) is the most commonly used method to measure the fraction of folded and unfolded protein, respectively, and to calculate equilibrium constants. Free energies of unfolding at standard conditions, $\Delta G_U(H_2O)$, are obtained by linear extrapolation to zero denaturant as is done for monomeric proteins [9] (see Appendix: Section A2.2 and Chapter 3 for more details). Extrapolation is performed on any suitable signal change paralleling the denaturant-induced change of molecular state; examples are far-UV circular dichroism (CD) to follow secondary structure changes, or tryptophan fluorescence to monitor molecular packing density and polarity. In applying linear extrapolation one tacitly assumes that the effects of the denaturant on both unfolding and dissociation of the oligomeric protein are linear. This assumption is difficult to check. Extrapolating the same value of $\Delta G_U(H_2O)$ from urea and

GdmCl unfolding is a good indication of a linear denaturant dependence of dissociation and unfolding [10, 11].

Another popular equilibrium method is thermal unfolding. If the equilibrium between unfolded subunits and folded oligomer is reversible, the change with temperature of an appropriate spectroscopic signal such as fluorescence emission or CD can be used to determine the fraction of protein in the folded and unfolded states and, occasionally, also the fraction of intermediate states. The immediate result from the thermal melting curve of a protein is its midpoint temperature of unfolding, T_m. If the reversible unfolding of an oligomeric protein follows a two-state mechanism, half of the protein is unfolded and dissociated and half is folded and associated at T_m. (This does not apply to the midpoint T_m of a melting curve obtained by differential scanning calorimetry [12].) The melting curve provides the fraction of unfolded, monomeric protein, f_M, from which the equilibrium unfolding constant K_U and the free energy of unfolding $\Delta G_U = -RT \ln K_U$ is calculated. Note that in using K_U and ΔG_U, the folded, native state is the reference state.

From the temperature dependence of the equilibrium constants of unfolding, the van't Hoff enthalpy of the dissociation–unfolding transition at T_m can be calculated (see Appendix: Sections A2.3 and A2.4). From differential scanning calorimetry experiments the calorimetric enthalpy can be obtained, which is model independent and may differ from the van't Hoff enthalpy if the unfolding reaction is not two-state. Extrapolation of enthalpies and free energies to standard conditions (for example 25 °C) are based on the formalism of equilibrium thermodynamics (see Appendix: Section A2.5). Such extrapolation can be inaccurate if it extends over a large temperature range and the heat capacity change is not accurately known.

The fraction of protein in the oligomeric and monomeric state may also be obtained by following an appropriate signal after simple dilution. This approach is an added benefit of the concentration dependence of the monomer/oligomer equilibrium and can be used under benign buffer conditions, that is, in the absence of denaturant and at ambient temperature. If dissociation and unfolding are fully coupled, the dilution method yields the overall free energy of unfolding plus dissociation. However, if different free energies of unfolding are obtained from the dilution method and from chemical or thermal unfolding, this indicates that folding and association are not, or only partly, coupled. For example, a lower free energy of unfolding from dilution than from chemical unfolding is an indication for a folding intermediate that is populated under benign conditions but not in the presence of chemical denaturant. In other words, the oligomeric protein dissociates into (partly) folded subunits during dilution under benign conditions, yet it dissociates into unfolded subunits in the presence of a denaturant. The difference between $\Delta G_U(H_2O)$ from dilution and $\Delta G_U(H_2O)$ from chemical unfolding can then be ascribed to the unfolding free energy of the subunits.

Other methods to monitor the fraction of folded and unfolded oligomeric proteins under benign buffer conditions are sedimentation equilibrium analysis, gel-filtration chromatography, light-scattering analysis, and isothermal titration calorimetry. In the last method, the heat evolved or taken up when two (or more)

molecules interact with each other is measured and the reaction enthalpy is calculated from the integrated heat change. Isothermal titration calorimetry can only be applied to heterodimeric proteins whose subunits do not form homomeric structures. The procedure yields the change of the enthalpy, the Gibbs free energy and the subunit stoichiometry of the oligomeric structure [12–14].

It should be noted that all the methods based on dissociation under benign buffer conditions work only if the association between the subunits is relatively weak and association/dissociation occurs in the micromolar to nanomolar concentration range. If an oligomeric protein assembles at less than nanomolar concentration, spectroscopic signal changes and calorimetric heat changes may be too weak to monitor by dilution.

27.2.2 Kinetic Methods

The same kinetic methods used for monomeric proteins can be applied to study the time course of folding and association or unfolding and dissociation of oligomeric proteins. Time-resolved methods include conventional stopped-flow and quenched-flow techniques for the time range of milliseconds to seconds, and fast relaxation methods like temperature jump to follow more rapid reactions (see Chapter 14). Variation of the observation signal allows different aspects of the reaction to be investigated. For example, far-UV CD spectroscopy, pulse-labeling NMR and mass spectroscopy are used to follow secondary structure formation and formation of hydrogen bonds; intrinsic and extrinsic fluorescence measurements monitor molecular packing; fluorescence anisotropy and small angle X-ray estimate changes in molecule size; ligand binding reports the gain or loss of biological activity. (See Chapter 2 and Ref. [15] for spectroscopic methods used to study protein folding.)

As for monomeric proteins, unfolding and refolding is often studied by rapid dilution into denaturant and out of denaturant, respectively. This necessitates extrapolation to standard conditions in water. To avoid extrapolation, unfolding under benign buffer conditions may be studied from relaxation after a rapid change of temperature, pH or simply after rapid dilution (see Refs [16] and [17] and Appendix: Section A3). If an oligomeric protein is composed of different subunits, folding can be studied in a very direct way by rapid mixing of the different subunits. This means there is no need to first unfold the heterooligomeric protein and thereafter follow its refolding by returning to folding conditions.

The rates of dissociation of an oligomeric protein can also be measured by subunit exchange. To this end, the protein has to be labeled with a fluorescence tag or another appropriate marker. Folded protein with the marker is rapidly diluted with a large excess of folded protein lacking the marker. The change of the signal of the marker is then proportional to the rate of dissociation of the marked protein provided that reassociation is much more rapid than dissociation, which can be achieved by increasing the protein concentration [17, 18].

27.3
Dimeric Proteins

The simplest folding mechanism of a dimeric protein is a two-state or one-step reaction between two unfolded monomers M_u and the folded dimer D_f as described by Eq. (1).

$$2M_u \underset{k_u}{\overset{k_f}{\rightleftarrows}} D_f$$
$$K_d = \frac{k_u}{k_f} = \frac{[M_u]^2}{[D_f]} \tag{1}$$

Here and elsewhere, we use the notation M for monomer and D for dimer. The subscripts indicate unfolded and folded, respectively. For a monomeric protein both k_f and k_u are monomolecular rate constants (s^{-1}). In the case of a dimeric protein, k_f is a bimolecular rate constant ($M^{-1}\ s^{-1}$) and only k_u is unimolecular (s^{-1}). Square brackets indicate molar concentrations. Also, in contrast to a monomeric protein, the equilibrium dissociation constant K_d has the unit of a concentration. It is related to the thermodynamic parameters of unfolding by the well-known thermodynamic equation:

$$\Delta G_U = \Delta H_U - T\Delta S_U = -RT \ln K_d \tag{2}$$

Equation (1) says that the folding and association reactions are completely linked. In practice, this means that the association of the monomeric subunits and their folding to the native conformation of the final dimer cannot be experimentally separated. However, this does not exclude the fleeting existence of intermediates. Indeed, there are several instances where folding is thermodynamically two-state but kinetics reveal transitory intermediates (see the examples in Table 27.3). Hence, a more physically meaningful mechanism for the formation of a dimeric protein is described by Eq. (3).

$$2M_u \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} 2M_i \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} D_i \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} D_f$$
$$K_{d1} = \frac{[M_u]}{[M_i]} = \frac{k_{-1}}{k_1} \quad K_{d2} = \frac{[M_i]^2}{[D_i]} = \frac{k_{-2}}{k_2} \quad K_{d3} = \frac{[D_i]}{[D]} = \frac{k_{-3}}{k_3} \tag{3}$$

Here, monomeric and dimeric intermediates (subscript i) are at equilibrium with the unfolded monomer M_u and the folded dimer D_f, respectively. Intermediate M_i can be considered as an association-competent subset of conformational forms of the monomer, perhaps a set of partly folded monomers. Only M_i associates to the dimeric intermediate D_i, which then rearranges to the final folded dimer D_f. The first and third equilibria are unimolecular, the middle equilibrium is bimolecular. If the first equilibrium is far on the side of M_u and the last is far on the side of D_f, Eq. (3) simplifies to the one-step Eq. (1). In this case, only M_u and D_f are detected

under equilibrium conditions, but the kinetics of folding and unfolding may exhibit different phases indicative of transitory formation of intermediates.

27.3.1 Two-state Folding of Dimeric Proteins

Several dimeric proteins fold according to Eq. (1), exhibiting two-state transition between two unfolded monomers and a folded dimer. For monomeric proteins it has been shown that a two-state folding model is justified if the protein rapidly equilibrates between many unfolded conformations prior to complete folding [19]. By the same reasoning, two-state folding seems justified if intermediates M_i and D_i of Eq. (3) are ensembles of barely populated conformations at rapid equilibrium with M_u and D_f, respectively. One has to keep in mind that two-state folding is an operational concept: The sole observation of a folded dimer and an unfolded monomer under a given set of experimental conditions does not rule out the existence of folding intermediates. Table 27.1 lists operational criteria that typically apply to two-state folding. At least one of criteria i–iv referring to equilibrium experiments, and one of criteria v–vii referring to kinetic experiments, as well as criterion viii should be met to demonstrate two-state folding. The calorimetric and van't Hoff equality criterion ix is more difficult to test because thermal unfolding has to be over 90% reversible, which is not always the case.

The thermodynamic and kinetic formalism for two-state folding is relatively simple and has often been described (see the Appendix for details). As for monomeric proteins, the equilibrium dissociation constant K_d is obtained from the fraction of monomeric protein f_M, or the fraction of dimeric protein $f_D = 1 - f_M$. For a

Tab. 27.1. Criteria for two-state folding.

(i)	Equilibrium unfolding followed with different physical probes such as light absorption, fluorescence emission, circular dichroism yield superimposable curves
(ii)	Equilibrium measurements are dependent on protein concentration
(iii)	The change of the free energy of unfolding with denaturant concentration is linear
(iv)	The reciprocal midpoint temperature of unfolding ($1/T_m$) is linearly proportional to the logarithm of the total protein concentration
(v)	Refolding kinetics is concentration dependent, unfolding kinetics is concentration independent
(vi)	Kinetics of folding and unfolding exhibit single phases, and these account for the entire amplitude of the signal changes of folding and unfolding, respectively
(vii)	The change of the unfolding and refolding rate constants with denaturant is linear
(viii)	Equilibrium constants determined experimentally are the same within error as those calculated from the ratio of the association and dissociation rate constants
(ix)	The enthalpy change of the dimer to monomer transition obtained by van't Hoff analysis of thermal unfolding curves is the same within error as the calorimetrically measured enthalpy change

monomeric protein the equilibrium constant, defined as $K_d = f_M/(1 - f_M)$, is independent of the protein concentration. In contrast, to determine K_d of a dimeric protein, the protein concentration has to be known. Moreover, the relationship between K_d and concentration is different for homodimeric and heterodimer proteins, as shown by Eqs (4) and (5) (see also Appendix: Section A1).

$$K_d = \frac{2[P_t]f_M{}^2}{1 - f_M} \tag{4}$$

$$K_d = \frac{[P_t]f_M{}^2}{2(1 - f_M)} \tag{5}$$

In the above equations, $[P_t]$ is the total protein concentration expressed as the total monomer concentration: $[P_t] = [M] + 2[D]$. It is important to note that the protein concentration has to be accounted for in analyzing the thermodynamic and kinetic data. For example, the well-known linear extrapolation of chemical unfolding data to zero denaturant concentration has to consider protein concentration because ΔG_U is not zero at the transition midpoint of chemical unfolding (see Appendix: Section A2.2).

27.3.1.1 Examples of Dimeric Proteins Obeying Two-state Folding

Table 27.2 lists five representative examples of small dimeric proteins for which two-state folding has been demonstrated based on several of the criteria listed in Table 27.1. The Arc repressor of bacteriophage P22 is a small homodimeric protein composed of two 53 residue polypeptide chains [10]. Figure 27.1 shows that the fluorescence and CD changes induced by denaturant are superimposable (criterion i of Table 27.1). The position of the unfolding trace is dependent on protein concentration as predicted for a bimolecular reaction (criterion v of Table 27.1). The change of unfolding free energies with denaturant concentration is linear (criterion iii of Table 27.1) and extrapolation to water yields the same free energy of unfolding for both urea and GdmCl unfolding, supporting of the validity of the linear extrapolation approach for both the unfolding reaction and the dissociation of dimers into monomers.

Figure 27.2 shows the urea dependence of unfolding and refolding rates of the dimeric Arc repressor. The rate of refolding increases linearly when the denaturant concentration is lowered; the rate of unfolding increases linearly when the denaturant concentration increases (criterion vii). Refolding is concentration dependent, unfolding is concentration independent, and the single kinetic phases account for the entire amplitude of refolding and unfolding (criterion vi). Finally, the free energy of unfolding and dissociation extrapolated from equilibrium measurements and calculated from the ratio of the refolding and unfolding rate are very similar, as demanded by criterion viii. In the middle range of denaturant concentrations, both unfolding and refolding reactions have to be taken into account when analyzing the unfolding and refolding traces, respectively. The analysis was performed using Eq. (A29) [20]. Note that, unlike in the case of a monomeric protein, the

Mannose-binding lectin (heterodimer)	$\Delta G_U = 55$ kJ mol^{-1}, $\Delta C_P = 13$ kJ M^{-1} K^{-1}, $\Delta H_U(66\ ^\circ C) = 728$ kJ M^{-1} [73]		ΔC_P-values from experiment and calculated from the buried subunit interface agree well

[a] Unless stated, thermodynamic and kinetic parameters refer to ambient temperature (20 to 25 °C).

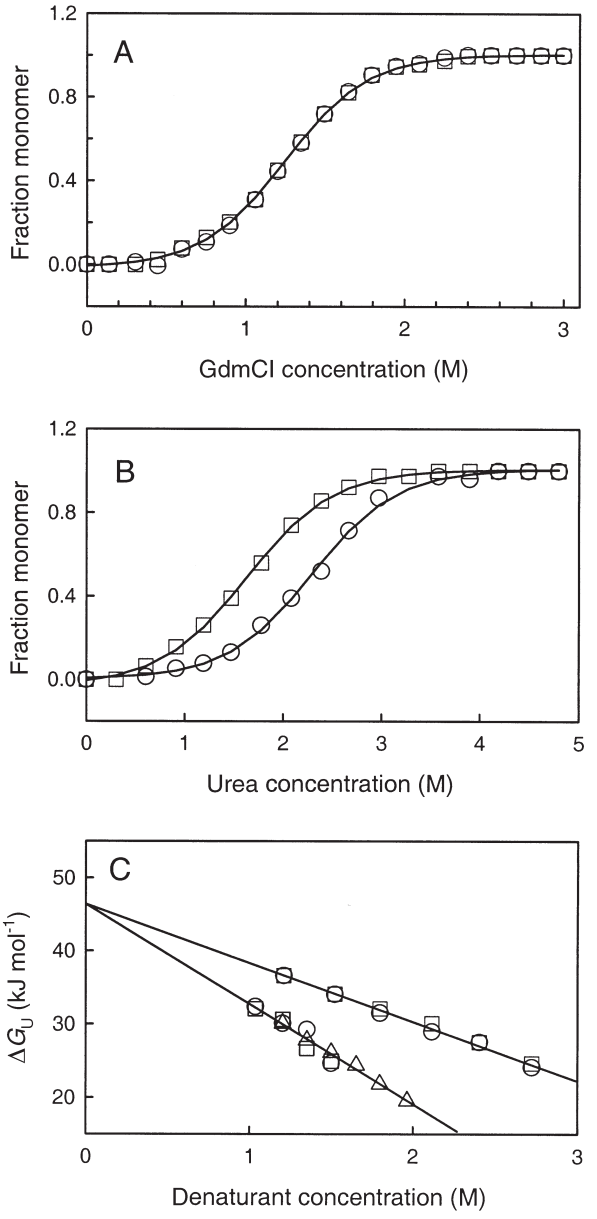

Fig. 27.1. Equilibrium unfolding of dimeric Arc repressor according to a two-state mechanism. A) Guanidinium chloride (GdmCl) denaturation curves monitored by fluorescence (squares) and CD (circles) are superimposable and the solid line is described by Eq. (4) for two-state folding. B) Urea denaturation is concentration dependent as predicted by Eq. (4). Experiments were performed with 1.6 μM (squares) and 16 μM (circles) total protein concentration. C) Free energies of unfolding measured with different total peptide concentrations (different symbols) are linearly dependent on GdmCl concentration (lower data) and urea concentration (upper data). Linear extrapolation of urea and GdmCl according to Eq. (A12) yields the same free energy of unfolding of $\Delta G_U(H_2O) = 46$ kJ mol^{-1}, supporting the validity of the linear extrapolation method. Figure adapted from Ref. [10] with permission.

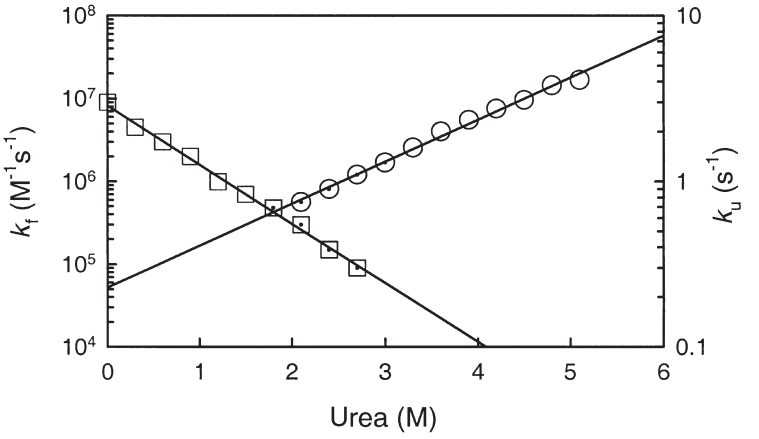

Fig. 27.2. Urea dependence of the rate constants of refolding (squares, left ordinate) and unfolding (circles, right ordinate) of Arc repressor. Empty symbols refer to data analysis neglecting unfolding (Eq. (A22)) or refolding (Eq. (A25)). Dotted symbols refer to data analysis including both unfolding and refolding as described by Eqs (A27) and (A29). Experiments were performed at pH 7.5 and 20 °C. Figure adapted from Ref. [20] with permission.

crossover point of the unfolding and refolding lines in Figure 27.2 do not yield the midpoint concentration of the denaturant at which $[M] = [D]/2$ and $\Delta G_U = 0$. This is because the refolding reaction and hence the midpoint of denaturation depends on the protein concentration.

Extrapolation of the folding rate constant of the Arc repressor to zero denaturant yields k_f of about 9×10^6 M^{-1} s^{-1}, which is about two orders of magnitude below the diffusion limit. Moreover, the folding rate is nearly independent of solvent viscosity. It seems that only a small fraction of collisions of unfolded monomers are productive, otherwise the rate should approach the diffusion limit and depend on solvent viscosity. This is supported by a dimeric transition state of folding exhibiting regions of native-like structure. In particular, there are native-like backbone interactions in the transition state of folding of the Arc repressor [21–23]. Mutating a cluster of buried charged residues forming a complex salt bridge network into hydrophobic residues speeds up folding, makes the folding rate viscosity dependent and brings the structure of the dimeric transition state closer to the unfolded state [24].

The leucine zipper domain of the yeast transcriptional activator protein GCN4 forms a coiled-coil structure in which two α-helices are wound around each other to form a superhelix [25]. This leucine zipper domain of GCN4 folds by a two-state mechanism. However, calorimetric analysis indicates two monomolecular pretransitions at 20 °C and 50 °C before the main concentration-dependent, bimolecular transition takes place [26]. Another coiled coil whose folding has been analyzed in much detail is the heterodimeric leucine zipper AB [27, 28]. This short, designed leucine zipper consists of two different 30 residue peptide chains whose sequences

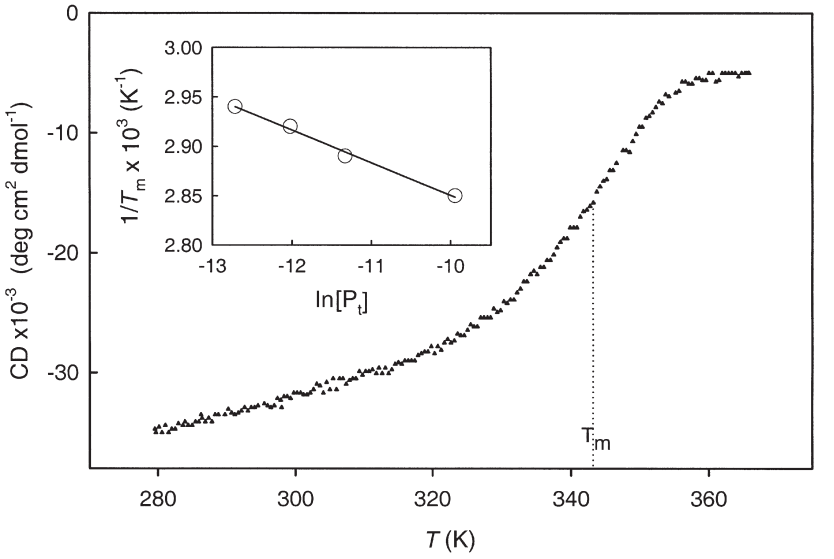

Fig. 27.3. Temperature-induced unfolding of the heterodimeric leucine zipper AB. The unfolding transition was monitored by the change in the CD signal at 222 nm. From $T_m = 343$ K and $[P_t] = 3.9 \times 10^{-5}$ M, the dissociation constant K_d of 1×10^{-5} M at T_m is calculated, corresponding to the free energy of unfolding of $\Delta G_U = 32.9$ kJ mol^{-1}. To calculate K_d at any temperature T, the pre- and post-transition slopes (thin lines) have to be taken into account. Figure adapted from Ref. [27] with permission.

are related to the GCN4 leucine zipper [25]. One chain is acidic (A-chain) and the other is basic (B-chain) so that inter-subunit electrostatic interactions are maximized [27, 29]. Figure 27.3 shows thermal unfolding of leucine zipper AB. The sigmoidal shape is described by Eq. (5) for two-state unfolding of a heterodimeric protein. The midpoint of the thermal transition yields the transition temperature T_m where half of the protein is dimeric and half is monomeric. The enthalpy of unfolding at T_m, $\Delta H_{U,m}$, is obtained from the data in Figure 27.3 by plotting ln K versus T according to the van't Hoff equation (Eq. (A14)). A further test for two-state unfolding is provided by a plot of $1/T_m$ against the logarithm of the total protein concentration, as shown in the inset of Figure 27.3 (Eq. (A18)).

To obtain the unfolding free energy, $\Delta G_U(T)$, at any temperature T, the data from the thermal unfolding curve of Figure 27.3 need to be extrapolated by the Gibbs-Helmholtz equation describing the change of ΔG_U with temperature.

$$\Delta G_U(T) = \Delta H_{U,m}\left(1 - \frac{T}{T_m}\right) + \Delta C_P\left[T - T_m - T\ln\left(\frac{T}{T_m}\right)\right] - RT\ln[K_d(T_m)] \quad (6)$$

The last term of Eq. (6) accounts for the concentration dependence of ΔG_U. This term is missing in the equation used for monomeric proteins. Figure 27.4 shows

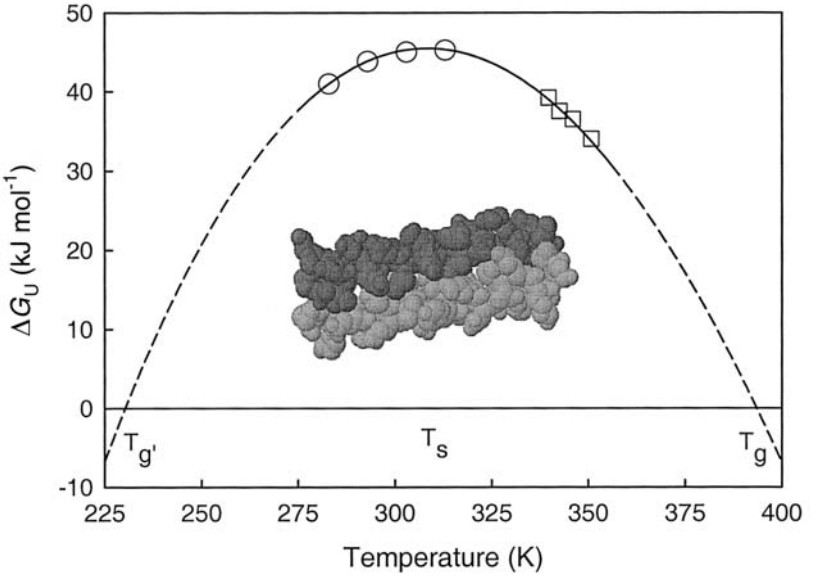

Fig. 27.4. Stability curve of the heterodimeric leucine zipper AB at pH 7.2 and 15 mM ionic strength. The curve was calculated by fitting experimental values of ΔG_U obtained by thermal unfolding (squares) and isothermal titration calorimetry (circles) with the help of Eq. (6). The maximum stability is at T_s = 36 °C, $\Delta G_U = 0$ is at $T_g = 120$ °C and $T_{g'} = -42$ °C. The solid line is a best fit in the range of the experimental data, the dashed line is the extrapolation to T_g and $T_{g'}$. Surface contour model of a leucine zipper is from 2ZTA.pdb. Figure adapted from Ref. [27] with permission.

the thermal stability curve of the heterodimeric leucine zipper AB. The curve was constructed using data sets from thermal unfolding in the range 340–350 K (T_m was varied with protein concentration) and from isothermal titration calorimetry performed between 283 and 313 K. Since neither peptide chain alone associates to a homodimer, the formation of the heterodimeric "AB-zipper" can be followed by titrating one chain to the other by isothermal titration calorimeter. The experiment yields the enthalpy and free energy changes of the coupled association and folding reaction [27]. In this way, the data from thermal unfolding can be complemented with thermodynamic data pertaining to a temperature range in which the folded protein dominates. The stability of the leucine zipper peaks at 309 K (36 °C) and decreases above and below this temperature. This is an example of cold denaturation visible already at ambient temperature. Extrapolation of the stability curve yields the temperatures of heat and cold denaturation, T_g and T'_g, at which $\Delta G_U = 0$.

The shape of the stability curve is governed by the heat capacity change, ΔC_P, of the unfolding reaction. ΔC_P of 4.3 kJ M^{-1} K^{-1} is obtained from a fit of the data in Figure 27.4 using Eq. (6). The positive value of ΔC_P implies that the unfolded monomeric peptide chains can take up more heat per degree K than the folded leucine zipper. The specific ΔC_P normalized per g of protein is 0.6 J g^{-1} K^{-1}. This is

of the same magnitude as the average specific ΔC_P for the unfolding of monomeric globular proteins [30] and points to similar types of inter- and intramolecular forces stabilizing dimeric and monomeric proteins. There have been many attempts to calculate ΔC_P from structural data based on the amount of polar and nonpolar surface buried at the interface of a dimeric protein [31, 32].

The kinetics of folding and unfolding of the leucine zipper AB are presented in Figure 27.5. This dimeric leucine zipper is characterized by several interheli-

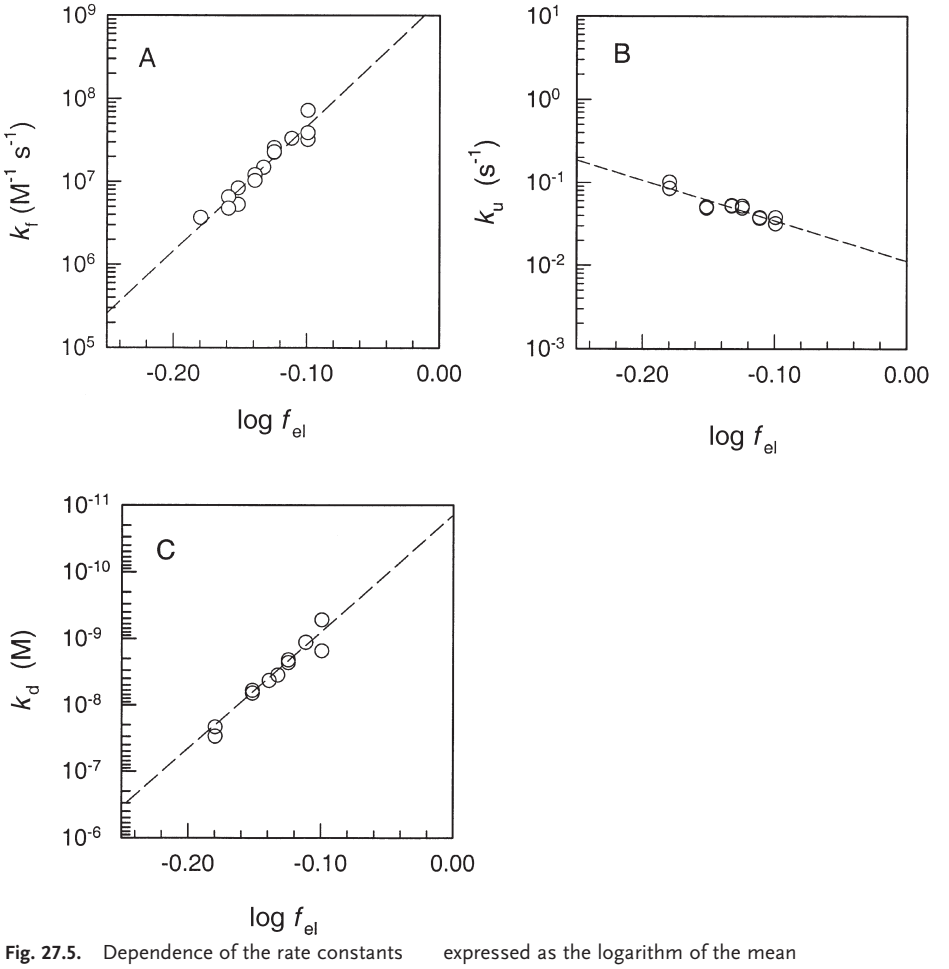

Fig. 27.5. Dependence of the rate constants and equilibrium dissociation constants of folding and association of the leucine zipper AB on ionic strength. A) Rate constant k_f of coupled association and folding. B) Rate constant k_u of coupled dissociation and unfolding. C) Equilibrium dissociation constant calculated as $K_d = k_u/k_f$. The ionic strength is expressed as the logarithm of the mean rational activity coefficient of NaCl [33]. Rate constants were determined under benign buffer conditions by rapid mixing of the unfolded peptide chains. Kinetic traces were analyzed with the help of Eq. (A29). Figure adapted from Ref. [28] with permission.

cal charge–charge interactions (salt bridges). Therefore, the rates of association/folding and dissociation/unfolding depend on ionic strength. The rate of association and folding decreases steeply when the ionic strength is raised (panel A) while dissociation and unfolding is only weakly ionic strength dependent (panel B). Consequently, the equilibrium constant is dominated by the ionic strength effect on the rate of folding (panel C). The strong decrease with ionic strength of the rate of folding could indicate a general effect on the free energy of activation of the folding and association reaction due to long-range electrostatic attraction between the oppositely charged, unfolded polypeptide chains [33]. A small effect of the ionic strength on the rate of unfolding and dissociation has been interpreted by the presence of native-like electrostatic interactions in the transition state of folding [34, 35]. However, in the case of several leucine zippers, interhelical salt bridges contribute negligibly to the stability of the coiled-coil structure, or even destabilize the folded dimer [36–39]. Therefore, the small ionic strength effect on the dissociation rate constant k_u confirms a minor role of electrostatic forces in stabilizing the folded structure [28].

The bimolecular rate constant of association and folding extrapolated to zero ionic strength is very large: $k_f = 9 \times 10^9\ M^{-1}\ s^{-1}$, larger than the rate of about $10^9\ M^{-1}\ s^{-1}$ estimated for the diffusion-limited association of two short, uncharged polypeptide chains [40–42]. The extremely large value of k_f in the absence of salt points to electrostatic acceleration of the association step as reported for other protein association reactions [33, 43]. Such very rapid association may indicate that the interaction is not much geometrically restricted. In other words, the transition state of folding of the leucine zipper is not well structured, which has been supported by kinetic transition state analysis [44].

The folding and association of leucine zipper AB as well as of other leucine zippers [45] are very tightly coupled and very rapid, yet there seems to be a transitory population of association-competent monomers preceding the actual association-folding reaction [$M_u \rightarrow M_i$ in Eq. (3)]. There is indirect evidenced for a small helix content in the association-competent conformation of the peptide chains forming a leucine zipper [46–49]. The impact of preformed helix on the rate of association and folding of a coiled coil has been manipulated by engineering a metal-binding site into the helix sequence to stabilize the helix conformation [50].

27.3.2
Folding of Dimeric Proteins through Intermediate States

As noted above, two-state folding is an operational concept since the lack of observable intermediates (or ensembles of intermediates) may have experimental reasons. Detection of intermediates depends on their stability as well as on the sensitivity and time resolution of thermodynamic and kinetic detection methods. Table 27.3 lists representative examples of dimeric proteins folding by a multistate mechanism, that means through at least one detectable intermediate. A good indication for a thermodynamic intermediate is the disparity between the free energy of unfolding determined by different methods. For example, the dimeric cAMP receptor

Tab. 27.3. Examples of dimeric proteins folding through intermediate states.

Protein	*Mechanism*	*Comments*[a]
cAMP receptor protein (CPR) (homodimer) [51]	$2M_u \rightarrow 2M_i \rightarrow D_f$	Thermodynamically stable monomeric intermediate. $\Delta G_U = 30$ kJ mol^{-1} for $D_f \rightarrow 2M_i$ and 50 kJ mol^{-1} for $2M_i \rightarrow 2M_u$. Equilibrium transition between folded dimer and monomeric intermediate from sedimentation equilibrium, overall unfolding and dissociation from unfolding by denaturant
Disulfoferredoxin (homodimer) [74]	$2M_u \rightarrow 2M_i \rightarrow D_f$	$\Delta G_U = 23$ kJ mol^{-1} for $D_f \rightarrow 2M_i$ and 50 kJ mol^{-1} for $2M_i \rightarrow 2M_u$
LC8, light chain of dynein (homodimer) [75]	$2M_u \rightarrow 2M_i \rightarrow D_f$	$G_U = 35$ kJ mol^{-1} for $D_f \rightarrow 2M_i$ and 62 kJ mol^{-1} for $2M_i \rightarrow 2M_u$
SecA dimeric bacterial ATPase (homodimer) [52]	$2M_u \rightarrow D_i \rightarrow D_f$	Plateau in denaturant unfolding curve indicates intermediate shown to be dimeric by sedimentation equilibrium. $\Delta G_U = 35$ kJ mol^{-1} for $D_f \rightarrow D_i$ and 59 kJ mol^{-1} for $D_i \rightarrow 2M_u$
Ketosteroid isomerase (homodimer) [53]	$2M_u \rightarrow 2M_i \rightarrow D_i \rightarrow D_f$	Two-state folding under equilibrium conditions with $\Delta G_U = 90$ kJ mol^{-1}. Four-state folding in kinetic analysis with $k = 60$ s^{-1} for $M_u \rightarrow M_i$, $k = 5.4 \times 10^4$ M^{-1} s^{-1} for $2M_i \rightarrow D_i$, $k = 0.017$ s^{-1} for $D_i \rightarrow D_f$
Glutathione transferase A1-1 (homodimer) [76, 77]	$2M_u \rightarrow 2M_i \rightarrow D_i \rightarrow D_i' \rightarrow D_f$	Under equilibrium conditions folding is two-state [77]. Folding through a monomeric and two dimeric intermediates; folding pathway complicated by proline *cis* → *trans* isomerization in M_u and M_i [76].
Trp repressor protein (TRP) (homodimer) [54, 58]	$2M_u \rightarrow 2M_i \rightarrow D_i \rightarrow D_f$	Rapid transition to two classes of association-competent monomers which associate in a combinatorial way to three different dimeric intermediates, and these rearrange in the rate-limiting step to the folded dimer [58]. Under equilibrium conditions, folding appears two state [54]
Bacterial luciferase (heterodimer) [59]	$M_{\alpha u} \rightarrow M_{\alpha i}$, $M_{\beta u} \rightarrow M_{\beta i}$ $M_{\alpha i} + M_{\beta i} \rightarrow D_i \rightarrow D_f$	Under equilibrium conditions folding is two state. Folding proceeds through monomeric and dimeric intermediates. The β-subunit can irreversibly form monomeric and dimeric dead-end species

[a] Unless stated, thermodynamic and kinetic parameters refer to ambient temperature (20–25 °C).

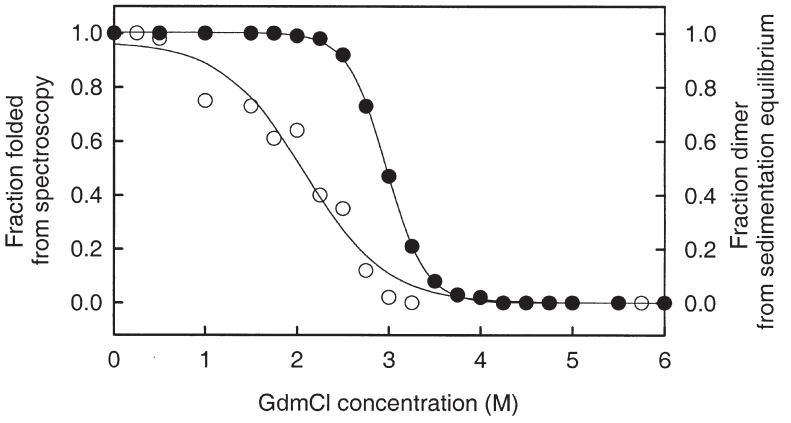

Fig. 27.6. Guanidinium chloride-induced unfolding of the homodimeric cAMP receptor protein (CPR) followed by different spectroscopic methods shows a sharp transition at 3 M GdmCl (filled circles, left ordinate). In contrast, the monomer/dimer ratio followed by sedimentation equilibrium analysis has a transition midpoint at 2 M GdmCl (empty circles, right ordinate). The latter midpoint is assigned to an equilibrium between folded dimer and (partly folded) monomeric intermediate. The midpoint at 3 M GdmCl is assigned to the equilibrium between the fully folded dimer and the fully unfolded monomers. Figure redrawn from Ref. [51] with permission.

protein (CRP) exhibits different unfolding curves depending on whether unfolding is observed by a spectroscopic probe or by sedimentation equilibrium analysis in the ultracentrifuge (Figure 27.6). The midpoint of the denaturant-induced unfolding curve obtained by measuring the monomer/dimer distribution in the ultracentrifuge is at 2 M GdmCl. However, the midpoint shifts to 3 M GdmCl when unfolding and dissociation is followed from the change of the far-UV CD spectrum, from fluorescence emission or from fluorescence anisotropy. The higher midpoint corresponds to unfolding and dissociation, the lower midpoint to dissociation alone, which does not significantly change the CD and fluorescence signals [51]. Thus, CRP folds through a thermodynamically stable monomeric intermediate. The overall free energy of unfolding and dissociation is $\Delta G_U = 80$ kJ mol^{-1}, that for dissociation alone (from ultracentrifugation) is $\Delta G_U = 30$ kJ mol^{-1}. The difference of 50 kJ mol^{-1} is the free energy of unfolding of the stable monomeric intermediate (Table 27.3).

The fourth protein in Table 27.3, dimeric bacterial enzyme SecA, folds through a thermodynamically stable dimeric intermediate, which appears as a plateau in the denaturant unfolding curve [52]. A larger amount of energy is necessary for the unfolding and dissociation reaction $D_i \rightarrow 2M_u$ than for unfolding of D_f into D_i, in accord with a thermodynamically stabilized dimeric intermediate. In the kinetics of folding, the monomolecular transition $D_i \rightarrow D_f$ is rate-determining since even at low protein concentration the bimolecular association $2M_u \rightarrow D_i$ is very rapid [52].

The first four proteins of Table 27.3 fold through thermodynamically stable intermediates. In many cases, however, the equilibrium distribution between folded dimer and unfolded monomer is well described by a two-state mechanism yet transitory intermediates are detectable in the kinetic analysis. Representative examples in Table 27.3 are the ketosteroid isomerase, the glutathione transferase A1-1 and the tryptophan repressor protein (TRP). Equilibrium analysis of all these proteins conforms to two-state folding and fulfills at least one of criteria i–iv but none of criteria v–viii listed in Table 27.1. Thus, dimeric ketosteroid isomerase is stabilized by $\Delta G_U = 90$ kJ mol^{-1} under equilibrium conditions [53]. However, the time course of unfolding exhibits three kinetic phases, a slow monomolecular phase $D_f \rightarrow D_i$, a bimolecular phase $D_i \rightarrow 2M_i$, and a rapid monomolecular phase $M_i \rightarrow M_u$. Thus, two additional states are seen in kinetics. One may say that the simple Eq. (1) applies to the enzyme at equilibrium yet the more realistic Eq. (3) to the time-dependent nonequilibrium situation of folding and unfolding.

Folding of TRP has been studied in much detail [54–58]. Matthews and coworkers have formulated the folding scheme shown in Figure 27.7 based on a large

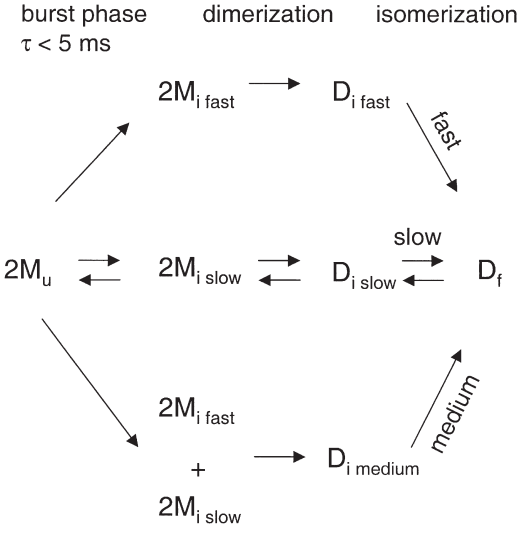

Fig. 27.7. Complex folding scheme for tryptophan repressor protein (TRP) from *Escherichia coli* through three "folding channels." Following the formation of two ensembles of partly folded monomeric intermediates, $M_{i\ fast}$ and $M_{i\ slow}$, folding to the dimer is controlled by three kinetic phases ("channels"). These are due to the association of two molecules of $M_{i\ fast}$ or $M_{i\ slow}$ or of $M_{i\ fast} + M_{i\ slow}$. "Fast," "slow," and "medium" refer to the rate of the final conformational rearrangement from the dimeric intermediate populations $D_{i\ fast}$, $D_{i\ slow}$, and $D_{i\ medium}$ to the unique folded dimer D_f. $D_{i\ slow}$ is a native-like intermediate and $D_{i\ fast}$ and $D_{i\ medium}$ are nonnative intermediates. Only the slow folding reaction through native-like intermediate $D_{i\ slow}$ is reversible. Figure adapted from Ref. [58] with permission.

series of kinetic experiments. In a burst phase following the removal of denaturant, unfolded monomeric TRP rearranges to two different ensembles of partly folded monomers, $M_{i\ fast}$ and $M_{i\ slow}$. These rapidly combine to the three dimeric intermediates $D_{i\ fast}$, $D_{i\ slow}$, and $D_{i\ medium}$. The unique folded dimer is formed in a fast, a medium, and a slow reaction from $D_{i\ fast}$, $D_{i\ medium}$, and $D_{i\ slow}$, respectively. The rate of this final unimolecular reaction exhibits very little dependence on denaturant concentration suggesting an isomerization reaction proceeding with no detectable change in solvent-accessible surface area. The structural basis for the three "folding channels" is the presence of two prefolded monomeric species that randomly associate in different pairwise combinations. The intermediates differ in their compactness. The fast and medium channels access the native structure through the most compact yet least native-like intermediates, $D_{i\ fast}$ and $D_{i\ medium}$, respectively. The slow channel, on the other hand, proceeds through a more "direct" folding route since the dimeric intermediate $D_{i\ slow}$ is native-like. Only this slow route is reversible. The example of TRP shows that the native structure can be accessed through alternative routes, that folding through nonnative states can accelerate folding, and that nonnative states need not lead into kinetic traps [58].

Kinetic traps have been detected in the folding of bacterial luciferase, the last example in Table 27.3. Figure 27.8 shows the complex folding scheme for this heterodimeric enzyme composed of an α- and a β-subunit. The unfolded monomeric subunits $M_{\alpha u}$ and $M_{\beta u}$ are converted to the monomeric intermediates $M_{\alpha i}$ and $M_{\beta i.}$, which associate to the heterodimeric intermediate D_i in a bimolecular reaction followed by the monomolecular rearrangement to the final folded dimer D_f. However, the β-subunit can enter into a dead-end trap as indicated by the irreversible reactions $M_{\beta i} \rightarrow M_{\beta x}$ and $2M_{\beta i} \rightarrow D_{\beta x}$ where $D_{\beta x}$ is a dead-end homodimer of the β-subunit [59].

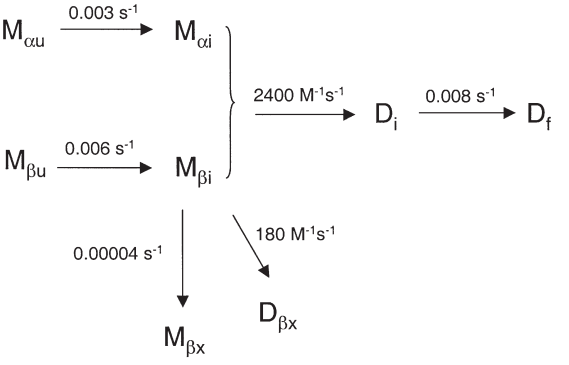

Fig. 27.8. Complex folding scheme for the heterodimeric bacterial luciferase composed of an α-subunit and a β-subunit. Folding proceeds through the monomeric intermediates $M_{\alpha i}$ and $M_{\beta i}$ and the dimeric intermediate D_i. Monomeric ($M_{\beta x}$) and dimeric ($D_{\beta x}$) dead-end species formed from the β-subunit intermediate $M_{\beta i}$ slow the folding and reduce the folding yield. Figure adapted from Ref. [59] with permission.

27.4
Trimeric and Tetrameric Proteins

We only briefly discuss a few examples of small trimeric and tetrameric proteins and refer to Chapter 2 in Part II presenting the folding and assembly in vivo of large, higher order multisubunit proteins. For statistical reasons, any reaction higher than second order is very slow. Therefore, simultaneous association of three polypeptide chains to a trimer is statistically unlikely, and simultaneous association of four chains to a tetramer is impossible. Thus, trimers (Tr) and tetramers (Te) are most likely to form by consecutive bimolecular reactions. For a trimer one can write:

$$3\mathrm{M} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathrm{D} + \mathrm{M} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} \mathrm{Tr}$$

$$K_{\mathrm{d1}} = \frac{[\mathrm{M}]^2}{[\mathrm{D}]} = \frac{k_{-1}}{k_1} \quad K_{\mathrm{d2}} = \frac{[\mathrm{M}][\mathrm{D}]}{[\mathrm{Tr}]} = \frac{k_{-2}}{k_2} \quad \text{two-step folding of trimer} \tag{7}$$

Subscripts u, f, and i have been omitted in Eq. (7) to leave open the conformational state of the three species. Of course, there can be monomeric, dimeric, and trimeric intermediates, making the folding mechanism very complex.

Three-state or two-step folding described by Eq. (7) has been reported for the designed homotrimeric coiled-coil protein LZ16A composed of three 29-residue peptide chains [60]. In the range of 1–100 μM total protein concentration, monomer, dimer, and trimer are populated in a concentration-dependent equilibrium [61]. Figure 27.9 shows the decrease of the CD spectral minimum as a function of total protein concentration. The data are best fit by two equilibria with $K_{\mathrm{d1}} = 7.7 \times 10^{-7}$ M and $K_{\mathrm{d2}} = 2.9 \times 10^{-6}$ M, where K_{d1} refers to the monomer/dimer equilibrium and K_{d2} to the dimer/trimer equilibrium. $K_{\mathrm{d1}} < K_{\mathrm{d2}}$ means that the dimer is a stable intermediate dominating at lower protein concentration. For example, at 10 μM total protein concentration, there is 50% dimer, 35% trimer, and 15% monomer. From kinetic refolding experiments the four rate constants defined by Eq. (7) have been determined and were found to be in agreement with the equilibrium data (see the legend to Figure 27.9).

So it may seem surprising that a trimeric protein can apparently fold in a single-step reaction, which means by a two-state folding mechanism according to Eq. (8).

$$3\mathrm{M_u} \underset{k_{\mathrm{u}}}{\overset{k_{\mathrm{f}}}{\rightleftarrows}} \mathrm{Tr_f}, \quad K_{\mathrm{d}} = \frac{[\mathrm{M_u}]^3}{[\mathrm{Tr_f}]} = \frac{k_{\mathrm{u}}}{k_{\mathrm{f}}} \quad \text{one-step folding of trimer} \tag{8}$$

Here, k_{f} is a trimolecular association rate constant ($\mathrm{M^{-2}\ s^{-1}}$) and k_{u} is a monomolecular dissociation rate constant. One-step folding according to Eq. (8) occurs if the dimer (Eq. (7)) is very unstable and scarcely populated so that the first equilibrium of Eq. (7) is far on the side of the unfolded monomer and the second far on the side of the folded trimer. Under these conditions, trimer formation appears

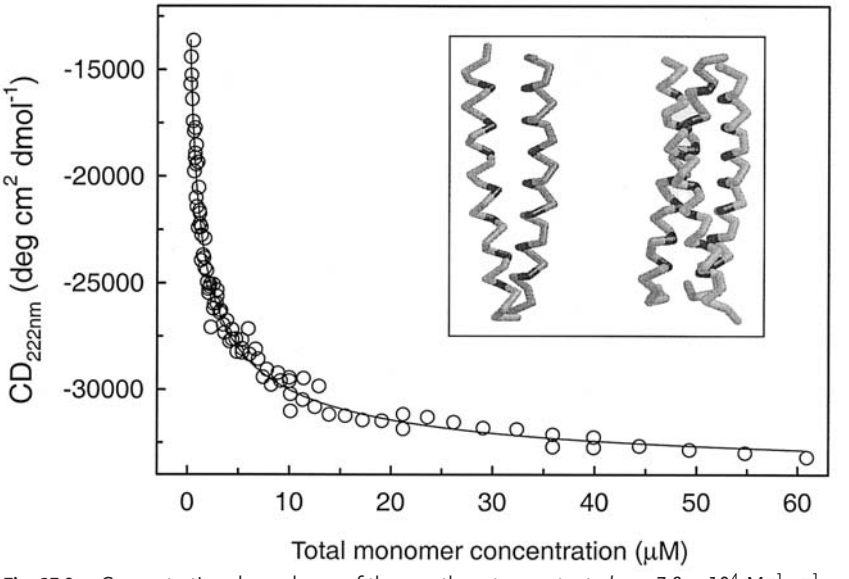

Fig. 27.9. Concentration dependence of the CD signal at 222 nm of the trimeric coiled coil LZ16A. The solid line is a best fit for a monomer–dimer–trimer equilibrium according to Eq. (7) with $K_{d1} = 7.7 \times 10^{-7}$ M and $K_{d2} = 2.9 \times 10^{-6}$ M. These values are in good agreement with the K_1 and K_2 calculated from the rate constants $k_1 = 7.8 \times 10^4$ M^{-1} s^{-1}, $k_{-1} = 1.5 \times 10^{-2}$ s^{-1}, $k_2 = 6.5 \times 10^5$ M^{-1} s^{-1}, and $k_{-2} = 1.1$ s^{-1}. Inset: backbone structure of dimer and trimer; ribbon models are from 2ZTA.pdb (dimer) and 1gcm.pdb (trimer). Figure adapted from Ref. [60] with permission.

two-state. It should be noted that $3M \rightarrow Tr$ can appear two-state despite the presence of a dimeric intermediate if $2M \rightarrow D$ is spectroscopically silent under the chosen detection conditions so that the entire spectral signal change is caused by $M + D \rightarrow Tr$ [60].

An example of a homotrimeric protein folding through only a single reaction step is the six-helix bundle at the core of the gp41 envelope protein of the human and simian immunodeficiency viruses [62]. The structure is shown in Figure 27.10 and is composed of three "hairpins" formed by two α-helices linked through a short peptide loop [63]. The trimer folds from three unfolded monomers in a single step according to Eq. (8). Equilibrium and kinetic data are in excellent agreement: $\Delta G_U(H_2O)$ determined by denaturant unfolding is 116 kJ mol^{-1}, and 114 kJ mol^{-1} when calculated from kinetic rate constants. The transition state of folding seems closer to the unfolded than the folded state. Only 20–40% of the surface buried in the folded trimer is already buried in the transition state of folding [62].

Formation of the catalytic trimer of aspartate transcarbamoylase is at the other extreme of possible folding mechanisms. Here, partly folded monomers are rapidly formed initially and thereafter rearrange in a slow step to association-competent monomers. These monomeric intermediates are thermodynamically stable. They

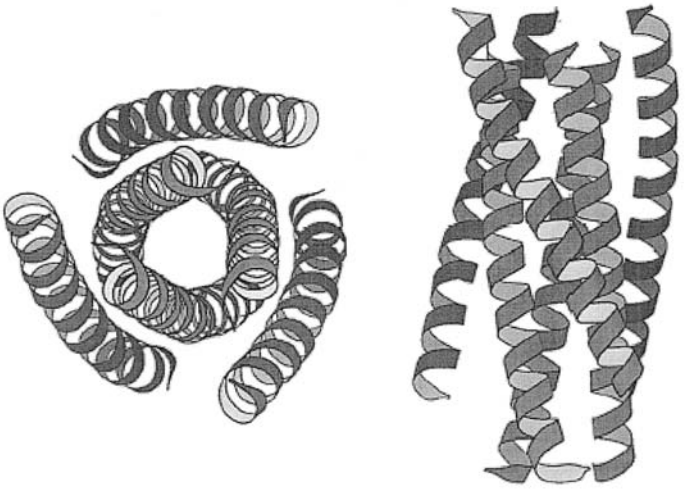

Fig. 27.10. Crystal structure of a six-helix bundle composed of three "hairpins." Each "hairpin" comprises two helices linked by a short loop; the loop is not visible in this crystal structure from Ref. [63]. Left: Axial view looking down the threefold axis of the helix bundle. Right: Lateral view. The trimer folds from unfolded monomers in a single step according to Eq. (8). $\Delta G_U(H_2O)$ determined by denaturant unfolding is 116 kJ mol^{-1}, and 114 kJ mol^{-1} when calculated from kinetic rate constants. The trimolecular rate constant of association is 1.3×10^{15} M^{-2} s^{-1} and the unimolecular rate constant of dissociation is 1.08×10^{-5} s^{-1} [62].

associate through at least two steps to the folded trimeric enzyme [64]. The folding scheme is $3M_u \rightarrow 3M_i \rightarrow\rightarrow Tr_f$.

Finally, we consider two tetrameric proteins: the C-terminal 30-residue domain of the tumor suppressor protein p53 [65] and a small bacterial dihydrofolate reductase composed of four 78-residue polypeptide chains [66]. The C-terminal p53 domain folds into a homotetramer in a thermodynamically fully reversible reaction. Interestingly, under equilibrium conditions, only folded tetramer and unfolded monomer are observed [67]. However, the time course of folding shows two consecutive bimolecular reactions with two kinetic, dimeric intermediates (Figure 27.11) [65]. Folding can be described as an association of dimers, in accord with the crystal structure, which has been likened to a dimer of dimers. The two intermediates shown in Figure 27.11 were deduced from extensive Φ-value analysis [65]. The first bimolecular association reaction is between highly unstructured monomers and can be described by a "nucleation-condensation" mechanism [68]. The first dimeric intermediate $D_{i,1}$ is formed through an early transition state that has little similarity to the native structural organization of the dimer. The second dimeric intermediate $D_{i,2}$ is highly structured and already includes most of the structural features of the native protein. The transition $D_{i,2} \rightarrow Te_f$ is an example of a "framework mechanism" in which stable preformed structural elements "diffuse and collide" [68].

A final example of a tetrameric protein is the bacterial R67 dihydrofolate reduc-

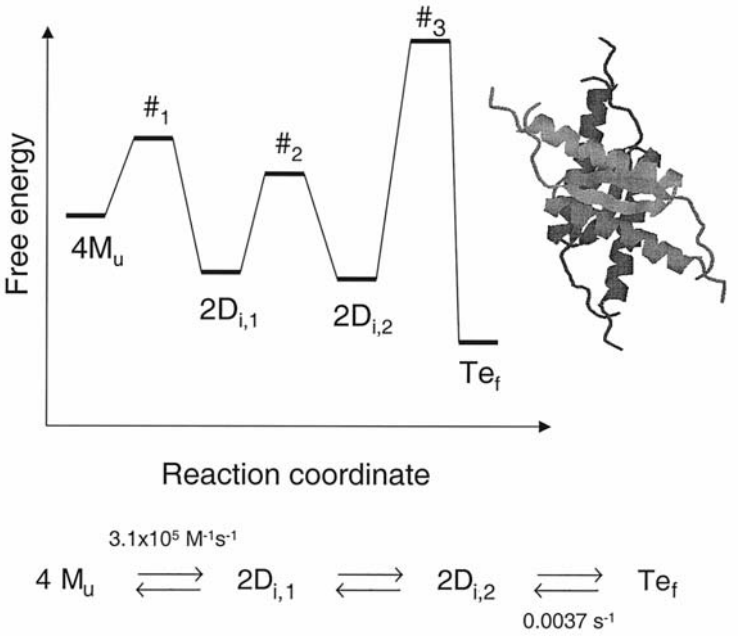

Fig. 27.11. Qualitative reaction coordinate diagram for the folding of the tetrameric protein domain from tumor suppressor p53. Under equilibrium conditions, only a single transition between unfolded monomer (M_u) and folded tetramer (Te_f) is seen [67]. Kinetic refolding and unfolding experiments show a single bimolecular association reaction and a single monomolecular dissociation reaction, which could be assigned as indicated [65]. Ribbon model of tetrameric C-terminal domain of tumor suppressor p53 from sak.pdb. See the text for a more detailed discussion. Figure adapted from Ref. [65] with permission.

tase [66]. Here, two monomeric intermediates (the formation of one being due to slow isomerization of peptidyl-proline bonds) precede dimer formation. Thereafter, two dimers associate to the folded tetramer. The folding reaction can be summarized as $4M_u \rightarrow 4M_{i,1} \rightarrow 4M_{i,2} \rightarrow 2D_i \rightarrow Te$.

27.5 Concluding Remarks

The mechanisms of folding of small oligomeric proteins is highly variable. At one extreme is the fully concerted association of unfolded monomers to folded dimers, trimers and even tetramers. Such folding without a thermodynamically stable intermediate is surprisingly frequent. Even in the case of the tetrameric p53 domain, whose folding proceeds through several kinetic folding intermediates among which the final dimeric intermediate is very native-like, none of the intermediates is sufficiently stable to be noticed at equilibrium. The reason for such scarcity of stable folding intermediates may be due, in part, to destabilizing nonpolar surface

exposed in the transitory intermediates. This surface becomes buried only in the final folded oligomer. Indeed, intermolecular or intersubunit forces dominate the stability of many oligomeric proteins. However, the interface between the subunits of the folded oligomeric proteins is highly variable. Shape complementarity between the contacting interfaces is a common feature and a main contributor to the specificity of intersubunit interactions. In a survey of 136 homodimeric proteins, a mixture of hydrophobic and intersubunit contacts was identified [69]. Small hydrophobic patches, polar interactions and water molecules are scattered over the intersubunit contact area in two-thirds of the proteins studied. Only in one-third of the dimers there was a single, large and contiguous hydrophobic core between the subunits. Though the hydrophobic effect plays an important role in subunit interactions, it seems to be less strong than that observed in the interior of monomeric proteins [70]. Only in a few cases, oligomerization conforms to the association of preformed stable subunits. The case of the trimeric coiled-coil LZ16A at equilibrium with a stable dimeric coiled coil is probably an exception.

From studies addressing the nature of the transition states of folding, it follows that the same principles deduced for monomeric proteins [71] apply also to oligomers. Folding of the subunits and their concurrent association to the oligomeric protein occurs by diffusion and collision of preformed structural frameworks (''framework model'') as well as by simultaneous nucleation and condensation. This is not surprising since the folded structure is always based on an extensive interplay of secondary and tertiary interactions in monomeric proteins and of secondary, tertiary, and quaternary interactions in oligomeric proteins. Because there is no intrinsic difference between tertiary and quaternary interactions there is no principal difference of folding between monomers and oligomers. The main difference is in the association step. Whereas the folding of a monomeric protein can be described by one or several consecutive or parallel monomolecular (single exponential) reactions, the folding of an oligomeric protein exhibits at least one concentration-dependent reaction step. On the one hand this feature complicates the thermodynamic and kinetic analysis. On the other hand the concentration dependence adds a useful variable to assist in the measurement of folding since the monomer/oligomer equilibrium can be studied by simple dilution under benign buffer conditions. Comparison of the data from dilution and from chemical or heat denaturation can give information about the contribution of intermolecular and intramolecular forces to the stability of the oligomeric protein. Also, determination of thermodynamic parameters such as the free energy of unfolding or the heat capacity change of unfolding is facilitated when the protein concentration can be adduced as an additional variable. Finally, in the case of heterooligomeric proteins, folding can be probed by simple mixing of the different subunits.

Appendix – Concurrent Association and Folding of Small Oligomeric Proteins

In this Appendix we have put together a set of equations for the analysis of thermodynamic and kinetic data of two-state folding. Many equations are equivalent to

those for the folding of monomeric proteins except for an additional term accounting for protein concentration. Derivation of equilibrium association constants for two-state folding of oligomeric systems and the relationship between equilibrium constants and the thermodynamic parameters $\Delta G, \Delta H$, and ΔS have been described in more detail by Marky and Breslauer [78]. The folded (native) state is taken as the reference state so that the thermodynamic parameters refer to the unfolding reaction ($\Delta G_U, \Delta H_U$, etc.). A special form of Eq. (A29) describing reversible two-state folding of a homodimer has been published by Milla and Sauer [20]. The method of deducing kinetic rate constants from the shift of a pre-existing equilibrium is briefly summarized (method of Bernasconi [16]).

The kinetic and equilibrium equations presented here are useful for the analysis of simple reaction steps, or steps that are kinetically or thermodynamically well separated. If the reaction steps are linked, numerical integration can be used to analyze kinetic and equilibrium data. There are good computer programs to aid kinetic analysis, some of the programs are freely available on the Web (for example DynaFit [79]). Depending on the scatter of experimental data, numerical fitting of linked reactions may result in large errors and distinguishing between different models can be very difficult.

Numbering of equations Equations appearing only in this Appendix have the prefix A. Other equations are numbered as in the main text.

Abbreviations M, monomer; D, dimer; N, *n*-mer; $[P_t]$, total protein concentration expressed as total concentration of monomer; f_M, fraction of free monomer defined as $[M]/[P_t]$. Subscripts; u, unfolded; i, intermediate; f, folded; m, midpoint; K_d, equilibrium dissociation constant ($= 1/K$).

A1
Equilibrium Constants for Two-state Folding

Association and dissociation of oligomeric proteins results in concentration-dependent equilibria. Expressions for the equilibrium constants of homooligomeric and heterooligomeric proteins are different.

A1.1 Homooligomeric Protein

For a homooligomeric protein, the equilibrium transition between n identical, unfolded monomeric subunits M and the folded n-meric protein N is described by

$$n\mathrm{M} \rightleftarrows \mathrm{N} \tag{A1}$$

The equilibrium dissociation constant K_d is defined as

$$K_d = \frac{[\mathrm{M}]^n}{[\mathrm{N}]} \tag{A2}$$

Defining the fraction of free monomeric subunits as

$$f_M = \frac{[M]}{[P_t]} \quad (0 \le f_M \le 1) \tag{A3}$$

we can write K_d as

$$K_d = \frac{n[P_t]^{n-1} {f_M}^n}{1 - f_M} \tag{A4}$$

where $[P_t] = [M] + n[N]$ is the total protein concentration expressed as total monomer concentration. At $f_M = 0.5$ we have

$$K_{d,f_M=0.5} = n([P_t]/2)^{n-1} \tag{A5}$$

A1.2 Heterooligomeric Protein

For a heterooligomeric protein, the equilibrium transition between n different, unfolded monomeric subunits $M_1, M_2 \ldots M_n$ and the folded n-meric protein N is described by

$$M_1 + M_2 + \cdots + M_n \rightleftarrows N \tag{A6}$$

The equilibrium dissociation constant K_d is defined as

$$K_d = \frac{[M_1][M_2] \ldots [M_n]}{[N]} \tag{A7}$$

The corresponding expression in terms of the fraction f_M of free monomeric subunits is

$$K_d = \frac{[P_t]^{n-1} {f_M}^n}{n^{n-1}(1 - f_M)} \tag{A8}$$

and at $f_M = 0.5$

$$K_{d,f_M=0.5} = \left(\frac{[P_t]}{2n}\right)^{n-1} \tag{A9}$$

In Eqs (A8) and (A9), $[P_t] = [M_1] + [M_2] + \cdots + [M_n] + n[N]$. The difference between Eqs (A4), (A5) and (A8), (A9) reflects the statistical difference between homooligomeric and heterooligomeric equilibria. Equations (4) and (5) of the main text correspond to Eqs (A4) and (A8), respectively.

A2 Calculation of Thermodynamic Parameters from Equilibrium Constants

A2.1 Basic Thermodynamic Relationships

The changes of free energy, enthalpy, and entropy are related by the well-known equation

$$\Delta G_U = \Delta H_U - T\Delta S_U = -RT \ln K_d \tag{2}$$

The superscript ° indicating standard conditions is omitted for simplicity. The van't Hoff enthalpy of unfolding is

$$\Delta H_U^{vH} = RT^2 \left(\frac{d \ln K_d}{dT} \right) \tag{A10}$$

The heat capacity change at constant pressure, ΔC_P, is defined by

$$\Delta C_P = \left(\frac{\partial \Delta H}{dT} \right)_P \tag{A11}$$

The calculation of thermodynamic parameters from equilibrium constants is based on Eqs (2), (A10), and (A11).

A2.2 Linear Extrapolation of Denaturant Unfolding Curves of Two-state Reaction

Linear extrapolation is performed by the same procedure as applied to denaturant unfolding of monomeric proteins, except that the concentration has to be taken into account. The linear extrapolation method is discussed in Chapter 3. Linear extrapolation of the free energy of two-state unfolding of homooligomeric and heterooligomeric proteins is described by

$$-RT \ln \left(\frac{n[P_t]^{n-1} f_M{}^n}{1 - f_M} \right) = \Delta G_U(H_2O) - m[\text{denaturant}] \quad \text{homooligomer} \tag{A12}$$

$$-RT \ln \left(\frac{[P_t]^{n-1} f_M{}^n}{n^{n-1}(1 - f_M)} \right) = \Delta G_U(H_2O) - m[\text{denaturant}] \quad \text{heterooligomer} \tag{A13}$$

The term on the left hand side of Eq. (A12) follows from Eqs (2) and (A4), that on the left hand side of Eq. (A13) from Eqs (2) and (A8). The slope m is the change of ΔG_U with denaturant concentration (J mol^{-1} M^{-1}).

A2.3 Calculation of the van't Hoff Enthalpy Change from Thermal Unfolding Data

From the change of K_d with T, the van't Hoff enthalpy is calculated according to Eq. (A10). In practice, one calculates ΔH_U^{vH} at T_m from a plot of ln K_d against $1/T$. With Eq. (2) one obtains the Arrhenius equation

$$\ln K_d = -\frac{\Delta H_{U,m}}{RT} + \frac{\Delta S_U}{R} \tag{A14}$$

where $\Delta H_{U,m}$ is the van't Hoff enthalpy at T_m. Only data points in a narrow interval around T_m should be used to calculate $\Delta H_{U,m}$ from the slope $\Delta H_{U,m}/R$ since Eq. (A14) neglects the change of the enthalpy with T (heat capacity change assumed to be zero).

A2.4 Calculation of the van't Hoff Enthalpy Change from the Concentration-dependence of T_m

Since association of an oligomeric protein is concentration dependent, T_m changes with concentration. Measuring T_m for varying $[P_t]$ is another way to calculate $\Delta H_{U,m}$. From Eqs (A5) and (A9) it follows that at T_m, K_d is described by

$$K_d(T_m) = n([P_t]/2)^{n-1} \quad \text{homooligomer} \tag{A15}$$

$$K_d(T_m) = ([P_t]/2n)^{n-1} \quad \text{heterooligomer} \tag{A16}$$

From Eqs (2), (A15), and (A16) one obtains after rearranging [78]:

$$\frac{1}{T_m} = \frac{(n-1)R}{\Delta H_m} \ln[P_t] + \frac{\Delta S - (n-1)R \ln 2 + R \ln n}{\Delta H_m} \quad \text{homooligomer} \tag{A17}$$

$$\frac{1}{T_m} = \frac{(n-1)R}{\Delta H_m} \ln[P_t] + \frac{\Delta S - (n-1)R \ln 2n}{\Delta H_m} \quad \text{heterooligomer} \tag{A18}$$

A2.5 Extrapolation of Thermodynamic Parameters to Different Temperatures: Gibbs-Helmholtz Equation

The calculation of the van't Hoff enthalpy described above refers to the transition temperature T_m. To obtain the thermodynamic parameters at any other temperature, the change of ΔH and ΔS with T has to be taken into account according to the Gibbs-Helmholtz equation:

$$\Delta G_U(T) = \Delta H_{U,m}\left(1 - \frac{T}{T_m}\right) + \Delta C_P\left[T - T_m - T \ln\left(\frac{T}{T_m}\right)\right] - RT \ln[K_d(T_m)] \tag{6}$$

The term $-RT \ln[K_d(T_m)]$ on the right hand side is necessary to account for the concentration dependence of ΔG_U. $K_d(T_m)$ corresponds to K_d at $f_M = 0.5$. Depending on the number of subunits and on whether the protein is a homo- or a heterooligomer, the appropriate form of K_d from Eq. (A5) or (A9) is inserted in Eq. (6). For example, the correction term for a homodimeric protein is $-RT \ln([P_t])$. The concentration-independent form of the Gibbs-Helmholtz equation is obtained by using the reference temperature T_g at which $\Delta G_U = 0$

$$\Delta G_U(T) = \Delta H(T_g)\left(1 - \frac{T}{T_g}\right) + \Delta C_P\left[T - T_g - T \ln\left(\frac{T}{T_g}\right)\right] \tag{A19}$$

A3
Kinetics of Reversible Two-state Folding and Unfolding: Integrated Rate Equations

The following integrated rate equations for two-state folding of a dimeric protein are used to calculate the folding rate constant k_f and the unfolding rate constant k_u from kinetic traces. Depending on experimental conditions, only folding (A3.1), only unfolding (A3.2), or both (A3.3) have to be taken into account.

A3.1 Two-state Folding of Dimeric Protein

$$2M \xrightarrow{k_f} D \tag{A20}$$

The time course of folding is given by

$$\frac{d[M]}{dt} = -k_f[M]^2 \tag{A21}$$

After integration, the time course of disappearance of the monomer fraction becomes

$$f_M(t) = \frac{[M_0]}{[P_t](k_f t + 1)} \tag{A22}$$

where $[M_0]$ is the initial monomer concentration at $t = 0$. $[M_0] = [P_t]$ if $[D] = 0$ at the beginning of the folding reaction. Equation (A22) is used to obtain k_f from a folding trace expressed as $f_M(t)$ if the unfolding reaction can be neglected (for example at low denaturant concentration).

A3.2 Two-state Unfolding of Dimeric Protein

$$D \xrightarrow{k_u} 2M \tag{A23}$$

The time course of unfolding is given by

$$\frac{d[D]}{dt} = -k_u[D] \tag{A24}$$

After integration, the time course of disappearance of the dimer fraction $f_D = 1 - f_M$ becomes

$$f_D(t) = \frac{2[D_0]}{[P_t]} \exp(-k_u t) \tag{A25}$$

where $[D_0]$ is the initial dimer concentration at $t = 0$. $[D_0] = [P_t]/2$ if $[M] = 0$ at $t = 0$. Equation (A25) is used to obtain k_u from an unfolding trace expressed as

$f_D(t) = 1 - f_M(t)$ if refolding can be neglected (for example at high denaturant concentration).

A3.3 Reversible Two-state Folding and Unfolding

A3.3.1 Homodimeric protein

$$2M \underset{k_u}{\overset{k_f}{\rightleftarrows}} D \tag{1}$$

The time course of disappearance of the monomer can be written as

$$\frac{d[M]}{dt} = -k_f[M]^2 + 2k_u[D] \tag{A26}$$

which can be recast into

$$\frac{d[M]}{a + b[M] + c[M]^2} = dt \tag{A27}$$

where

$$a = k_u[M_0], \quad b = -k_u, \quad c = -k_f \tag{A28}$$

After integration, the time course of disappearance of the monomer fraction is

$$f_M(t) = \frac{(b+s)(Z-1)}{[P_t]2c(1-Z)}$$
$$\text{where } Z = \left(\frac{2c[M_0] + b - s}{2c[M_0] + b + s}\right)\exp(st) \quad \text{and} \quad s = \sqrt{b^2 - 4ac} \tag{A29}$$

Equation (A29) is used to obtain k_f and k_u from a folding trace expressed as $f_M(t)$ under conditions where both folding and unfolding have to be taken into account (for example at intermediate denaturant concentration).

A3.3.2 Heterodimeric protein

$$M_1 + M_2 \underset{k_u}{\overset{k_f}{\rightleftarrows}} D \tag{A30}$$

The change of $[M_1]$ with time can be written as

$$\frac{d[M_1]}{dt} = -k_f[M_1][M_2] + k_u[D] \tag{A31}$$

The time course of disappearance of the fraction of M_1 or M_2 is again described by

Eq. (A27) except that the constants a, b, and c are different. If $[M_1] = [M_2]$, a, b, and c are

$$a = k_u[M_0]/2, \quad b = -k_u, \quad c = -k_f \tag{A32}$$

If $[M_1] \neq [M_2]$

$$a = k_u[M_{1,0}], \quad b = k_f([M_{1,0}] - [M_{2,0}]) - k_u, \quad c = -k_f \tag{A33}$$

or

$$a = k_u[M_{2,0}], \quad b = k_f([M_{2,0}] - [M_{1,0}]) - k_u, \quad c = -k_f \tag{A34}$$

Equation (A33) is valid for $f_{M1}(t)$ and (A34) for $f_{M2}(t)$; subscript 0 indicates concentration at $t = 0$.

A4

Kinetics of Reversible Two-state Folding: Relaxation after Disturbance of a Pre-existing Equilibrium (Method of Bernasconi)

Rate equations can be simplified if the reaction corresponds to a relaxation after a relatively small disturbance of the equilibrium. The procedure, pioneered by Bernasconi [16], allows rate constants to be obtained in those cases where there is no analytical solution of the differential rate equation. In practise, a pre-existing equi-

Tab. 27.4. Relaxation times for various reversible folding reactions.

Reaction	*Equation for relaxation time*[a]	
$2M \underset{k_u}{\overset{k_f}{\rightleftarrows}} D$	$\frac{1}{\tau} = 4k_f[\bar{M}] + k_u$	(A35)
$nM \underset{k_u}{\overset{k_f}{\rightleftarrows}} N$	$\frac{1}{\tau} = n^2 k_f[\bar{M}]^{n-1} + k_u$	(A36)
$M_1 + M_2 \underset{k_u}{\overset{k_f}{\rightleftarrows}} D$	$\frac{1}{\tau} = k_f([\bar{M}_1] + [\bar{M}_2]) + k_u$	(A37)
$2M \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} D_i \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} D$	$\tau_1 < \tau_2$: bimolecular association is faster than monomolecular rearrangement $\frac{1}{\tau_1} = 4k_1([\bar{M}]) + k_{-1}, \frac{1}{\tau_2} = \frac{4k_1k_2[\bar{M}]}{4k_1([M]) + k_{-1}} + k_{-2}$	(A38)
$2M \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} D_i \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} D$	$\tau_1 > \tau_2$: bimolecular association is slower than monomolecular rearrangement $\frac{1}{\tau_1} = k_1 + k_{-1}, \frac{1}{\tau_2} = 4k_1[\bar{M}] + \frac{k_{-1}k_{-2}}{k_2 + k_{-2}}$	(A39)

[a] Concentrations with overbars are equilibrium concentrations after relaxation to the new equilibrium.

librium between folded and unfolded protein is rapidly disturbed, for example by rapid dilution or rapid increase of temperature (T-jump), and the subsequent relaxation to the new equilibrium is observed. This relaxation is characterized by the relaxation time $\tau = 1/k_{app}$, where k_{app} (s^{-1}) is the apparent rate constant of the exponential decay to the new equilibrium. The number of relaxation times equals the number of reaction steps. Table 27.4 lists a few equations for different reversible folding reactions. They describe the relationship between the experimentally measured relaxation time τ and the individual rate constants of the reversible folding–unfolding reaction. The main difficulty with this procedure is that the equilibrium concentrations of the reactants at the new equilibrium, that is after relaxation, have to be known (concentrations with overbars in Table 27.4). These concentrations can be calculated if the equilibrium constants are known from independent experiments. Alternatively, a fitting procedure can be used in which initial estimates of the equilibrium constants are iteratively adapted until a best fit is obtained.

Acknowledgments

I thank Ilian Jelesarov and Daniel Marti for fruitful discussions and helpful comments on the manuscript. Work from my own laboratory has been supported in part by the Swiss National Science Foundation.

Folding of Membrane Proteins

Lukas K. Tamm and Heedeok Hong

28.1
Introduction

The major forces that govern the folding and thermodynamic stability of water-soluble proteins have been studied in significant detail for over half a century [1, 2]. Even though the reliable prediction of protein structure ab initio from amino acid sequence is still an elusive goal, a huge amount of information on the mechanisms by which soluble proteins fold into well-defined three-dimensional structures has been obtained over this long time period [3]. In marked contrast, our current knowledge on thermodynamic and mechanistic aspects of the folding of membrane proteins is several orders of magnitude less advanced than that of soluble proteins, although integral membrane proteins comprise about 30% of open reading frames in prokaryotic and eukaryotic organisms [4]. There are several reasons why the research on membrane protein folding lags far behind similar research on soluble proteins.

First, the first structure of a soluble protein (myoglobin) was solved in 1958, but the first membrane protein structure (photosynthetic reaction center) was only determined 27 years later in 1985. Even today, of the approximately 25 000 protein structures in the Protein Structure Databank (PDB), only about 140 (i.e., less than 0.6%) are structures of integral membrane proteins.

Second, membrane proteins are more difficult to express, purify, and handle in large batches than soluble proteins. They require the presence of nondenaturing detergents or lipid bilayers to maintain their native structure, which adds an additional layer of complexity to these systems compared with soluble protein systems. The requirement for detergents or membranes also explains why it is more difficult to crystallize membrane proteins or subject them to nuclear magnetic resonance (NMR) for high-resolution structural studies.

Third, it is very difficult to completely denature membrane proteins [5]. Solvent denaturation with urea or guanidinium chloride (GdmCl) is generally not applicable to membrane proteins because secondary structures that are buried in the membrane are often not accessible to these denaturants. Membrane proteins are also quite resistant to heat denaturation, and even if they can be (partially) dena-

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

tured, they are prone to irreversible aggregation. These properties have not helped to make membrane proteins favorable targets for folding studies. However, as will be shown in this chapter, new and different techniques are being developed to study the folding of membrane proteins. If this is done with sufficient care, membrane proteins can be brought back "into the fold" and very useful and much needed information can be gathered on the molecular forces that determine their thermodynamic stability and mechanisms that lead to their native structures. Even though most helical membrane proteins are inserted into biological membranes by means of the translocon [6], knowledge of the energetics and kinetics of membrane protein structure formation are important from a basic science standpoint and for structure prediction and protein engineering of this still neglected class of proteins, which constitutes the largest fraction of all targets of currently available drugs.

To understand the folding of membrane proteins, we first need to understand the dynamic structure of the lipid bilayer (i.e., the "solvent") into which these proteins fold. Fluid lipid bilayers are highly dynamic, yet well-ordered two-dimensional arrays of two layers of lipids with their polar headgroups exposed towards water and their apolar fatty acyl chains shielded from water and facing the center of the bilayer. This structure [7, 8] is maintained almost entirely by the hydrophobic effect [9]. The hydrocarbon chains in the core of the bilayer are quite well ordered, but their order degrades towards the midplane of the bilayer. This region comprises a width of about 30 Å in a "typical" bilayer of dioleoylphosphatidylcholine. The two interfaces of the bilayer are chemically and structurally quite complex and comprise a width of about 15 Å each. These regions contain the phosphate and choline headgroups, the glycerol backbone and about 25 molecules of bound, but disordered water for each phosphatidylcholine (PC) headgroup. The lipids are free to diffuse laterally ($\sim$1 $\mu m^2\ s^{-1}$) and rotationally ($\sim$1 μs^{-1}), but basically do not flip-flop across the membrane.

The molecular packing of lipids in a fluid lipid bilayer is maintained mechanically by a combination of three types of opposing forces: lateral chain repulsions in the core region, headgroup repulsions, and surface tension at the polar–nonpolar interface [10]. These forces create a lateral pressure profile along the membrane normal that cannot be directly measured, but that has been calculated based on the known magnitudes of the relevant forces [11]. This packing and lateral pressure profile has profound consequences on the lipid hydrocarbon chain dynamics [12] and the folding of membrane proteins as will be summarized in later sections of this chapter. Therefore, the mechanical and dynamical properties as well as the chemical properties of membranes change dramatically as the composition of chemical groupings changes along the bilayer.

To dehydrate and bury a single peptide bond in the lipid bilayer is energetically unfavorable and costs 1.15 kcal mol^{-1} [13]. The energetic gain of folding a polypeptide into an internally hydrogen-bonded secondary structure in membranes is much smaller (i.e., of the order of -0.1 to -0.4 kcal per residue) [14–17]. This shows that partitioning of the bare backbone (e.g., polyglycine) into membranes is energetically unfavorable irrespective of whether the peptide is folded or not. Pro-

ductive membrane insertion of a polypeptide segment is only promoted if the segment contains a sufficiently large number of apolar side chains, which by virtue of their favorable partitioning can overcome the energy cost of transferring the peptide backbone into the membrane. As a rule of thumb, the equivalent of a minimum of five leucine substitutions are required to offset the unfavorable energy of trying to insert a 20-residue polyalanine helix (see below).

Forming intramolecular hydrogen bonds is moderately favorable at the interface and presumably quite favorable in the apolar core of the bilayer [18]. The energetic cost of opening a hydrogen bond in a membrane likely depends on the concentration of water or the probability of finding another hydrogen-bonding partner in that location. Since water and other hydrogen-bond acceptors are rare in membranes, one generally finds only fully hydrogen-bonded secondary structures in membrane proteins. Therefore, the predominant building blocks of membrane proteins are transmembrane (TM) helices and closed TM β-barrels. Other fully hydrogen-bonded secondary structures such as 3_{10}-helices and π-bulges are rare, but do occasionally occur in membrane proteins.

Since the α-helix and closed β-sheets are the main building blocks and since these two elementary secondary structures are rarely mixed in membrane proteins, we treat α-helical and β-barrel membrane proteins (for examples of two prototype membrane protein structures, see Figure 28.1) in separate sections of this chapter. These sections are preceded by a general section on the thermodynamics of side-chain partitioning, which applies to both classes of membrane proteins and which also forms the basis of membrane protein topology and structure prediction algorithms.

28.2
Thermodyamics of Residue Partitioning into Lipid Bilayers

The partitioning of apolar amino acid side chains into the membrane provides the major driving force for folding of α-helical and β-barrel membrane proteins. Folding of membrane proteins is always coupled to partitioning of the polypeptide from water into the membrane environment. A large number of hydropathy scales have been developed over the years. The different scales have been derived based on very different physical or statistical principles and, therefore, differ for different residues sometimes quite significantly. It is beyond the scope of this chapter to review the different scales that are in use. The only scales that are based on comprehensive partitioning measurements of peptides into membranes and membrane-mimetic environments are the two Wimley & White (WW) scales, namely the WW interface [19] and the WW octanol scale [13, 20].

The WW interface scale refers to partitioning into the interface region of phosphatidylcholine bilayers and the octanol scale refers to partitioning into octanol, which is thought to be a good mimetic of the core of the lipid bilayer. As has been demonstrated for the hydrophobic core of soluble proteins [21], the dielectric constant in the core of a lipid bilayer may be as high as 10 due to water penetration

(i.e., considerably larger than 2 in pure hydrocarbon and closer to that of wet octanol). Both scales are whole-residue scales, which means that they take into account the thermodynamic penalty of also partitioning the peptide backbone into the respective membrane locations. Based on these partition data, one may group the amino acid residues into three groups, namely those that do not favor membranes (Ala, Ser, Asn, Gly, Glu^-, Asp^-, Asp^0, Lys^+, Arg^+, His^+), those that favor the interface (Trp, Tyr, Cys, Thr, Gln, His^0, Glu^0), and those that favor the hydrocarbon core (Phe, Leu, Ile, Met, Val, Pro). Sliding a 19-residue window of summed WW hydropathy values over the amino acid sequences of membrane proteins and using the thermodynamic $\Delta G = 0$ cutoff predicts TM helices with high accuracy [13]. The residues that fall in the first and third group are not surprising. However, the residues that prefer the interface deserve a few comments. Statistical analyses and model studies of membrane proteins have indicated for quite some time that the aromatic residues Trp and Tyr residues have a strong preference for membrane interfaces [22] (see also Figure 28.1). It has been suggested that their bulkiness, aromaticity and slightly polar character are the major factors that determine their preferred location in the interface [23].

Hydrogen bonding is probably not important for this localization. The moderately polar residues in this group are not surprising. However, the uncharged form of glutamic acid interestingly is apolar enough to localize into the interface. The differential partitioning of glutamate depending on its charge state likely has profound consequences on the pK_a value of this residue at membrane surface because the pK_a is now coupled to partitioning. A manifestation of this shifted pK_a is seen, for example, when the binding and membrane penetration of the fusion peptide of influenza hemagglutinin is examined [16]. This peptide contains two Glu residues in its N-terminal portion. A shift of the pH from 7 to 5 is sufficient to bind the peptide more tightly and more deeply (i.e., deep enough to cause membrane fusion at pH 5, but not at pH 7).

28.3 Stability of β-Barrel Proteins

All β-barrel membrane proteins whose structures are known at high resolution are outer membrane proteins of gram-negative bacteria [24]. However, several mitochondrial and chloroplast outer membrane proteins, namely those that are part of the protein translocation machinery of these membranes also appear to be β-barrel membrane proteins [25, 26]. Bacterial outer membrane proteins are synthesized with an N-terminal signal sequence and their translocation through the inner membrane is mediated by the translocon consisting of the SecY/E/G complex with the assistance of the signal recognition particle and the SecA ATPase, which together constitute the prokaryotic protein export machinery [27]. Helical membrane proteins that reside in the inner membrane have contiguous stretches of about 20 hydrophobic residues that form TM helices, which presumably can exit the translocon laterally into the lipid bilayer [6]. The TM strands of outer mem-

brane proteins on the other hand are composed of alternating hydrophilic and hydrophobic residues [28]. Therefore, they lack the signal for lateral exit from the translocon into the inner membrane and become secreted into the periplasmic space, where they are presumably greeted by periplasmic chaperones such as Skp and SurA [29, 30]. Skp binds unfolded outer membrane proteins, prevents them from aggregation, but does not appear to accelerate their insertion into lipid model membranes (D. Rinehart, A. Arora, and L. Tamm, unpublished results).

The outer membrane proteins of gram-negative bacteria may be grouped into six families according to their functions [31]. Structures of members of each of these families have been solved by X-ray crystallography or NMR spectroscopy. The six families with representative solved structures are: (i) the general porins such as OmpF and PhoE [32, 33], (ii) passive sugar transporters such as LamB and ScrY [34, 35], (iii) active transporters of siderophores such as FepA, FecA, and FhuA [36–39] and of vitamin B_{12} such as BtuB [40], (iv) enzymes such as the phospholipase OmpLA [41], (v) defensive proteins such as OmpX [42], and (vi) structural proteins such OmpA [43]. All outer membrane proteins form β-barrels. The β-barrels of these proteins consist of even numbers of β-strands ranging from 8 to 22. The average length of the TM β-strands is 11 amino acid residues in trimeric porins and 13–14 residues in monomeric β-barrels. Since the strands are usually inclined at about 40° from the membrane normal, they span about 27–35 Å of the outer membrane, respectively.

Most outer membrane proteins have long extracellular loops and short periplamsic turns that alternatingly connect the TM β-strands in a meandering pattern. The loops exhibit the largest sequence variability within each outer membrane protein family [31]. The largest and smallest outer membrane proteins are monomeric, but others such as OmpLA are dimers and the porins are trimers of β-barrels.

Two general approaches have been taken to examine the thermodynamic stability of β-barrel membrane proteins: solvent denaturation by urea and guanidinium chloride and differential scanning calorimetry (DSC). In the following, we will discuss the thermodynamic stability of the simple monomeric β-barrel protein OmpA and then extend the discussion to complexities that arise by the presence of the central plug domain of FepA and FhuA and trimer formation in the case of porins. The most extensive thermodynamic stability studies have been carried out with the outer membrane protein A (OmpA) of *Escherichia coli*. OmpA is an abundant structural protein of the outer membrane of gram-negative bacteria. Its main function is to anchor the outer membrane to the peptidoglycan layer in the periplasmic space and thus to maintain the structural integrity of the outer cell envelope [44]. The 325-residue protein is a two-domain protein whose N-terminal 171 residues constitute an eight-stranded β-barrel membrane-anchoring domain and whose C-terminal 154 residues form the periplasmic domain that interacts with the peptidoglycan. The three-dimensional structure of the TM domain has been solved by X-ray crystallography [43] and, more recently, by solution NMR spectroscopy [45]. The structure resembles a reverse micelle with most polar residues facing the interior, where they form numerous hydrogen bonds and salt bridges, and the apolar residues facing the lipid bilayer [43]. Two girdles of aromatic side chains, trypto-

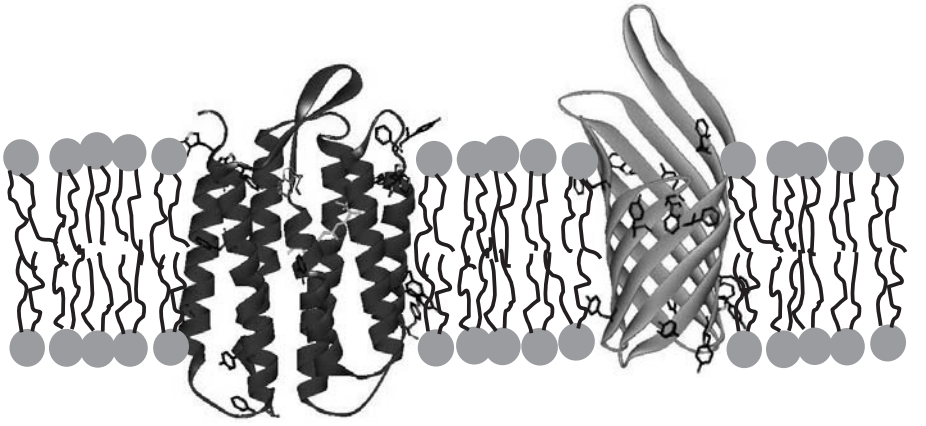

Fig. 28.1. Three-dimensional structures of representative α-helical and β-barrel membrane proteins. Left: Bacteriorhodopsin from *Halobacterium salinarium* (PDB code: 1C3W). phans and tyrosines, delineate the rims of the barrel where they interact with the two membrane interfaces (Figure 28.1).

Extensive mutagenesis studies show that OmpA is quite robust against many mutations especially in the loop, turn, and lipid bilayer-facing regions [46]. OmpA can even be circularly permutated without impairing its assembly and function in outer membranes [47]. Dornmair et al. [48] showed that OmpA could be extracted from the outer membrane and denatured and solubilized in 6–8 M urea and that the protein spontaneously refolded into detergent micelles by rapid dilution of the denaturant. They subsequently showed that urea-unfolded OmpA can also be quantitatively refolded into preformed lipid bilayers by rapid dilution of urea [49].

Recently, we could achieve the complete and reversible refolding of OmpA in lipid bilayers [50]. The reaction was shown to be a coupled two-state membrane partition folding reaction with the unfolded state in urea being completely dissociated from the membrane and the folded state completely integrated into the membrane (Figure 28.2). This represents the first example of an integral membrane protein, for which the thermodynamic stability could be quantitatively accessed. To achieve this goal, a urea-induced equilibrium folding system was developed for OmpA. The system consisted of small unilamellar vesicles composed of 92.5 mol% phosphatidylcholine and 7.5 mol% phosphatidylglycerol in weakly basic (pH 7.0–10) and low ionic strength conditions. These conditions facilitate both the folding and unfolding reactions and dissociation of the unfolded form from the membrane surface. Folding of OmpA is monitored by tryptophan fluorescence or CD spectroscopy, or by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) (Figure 28.3).

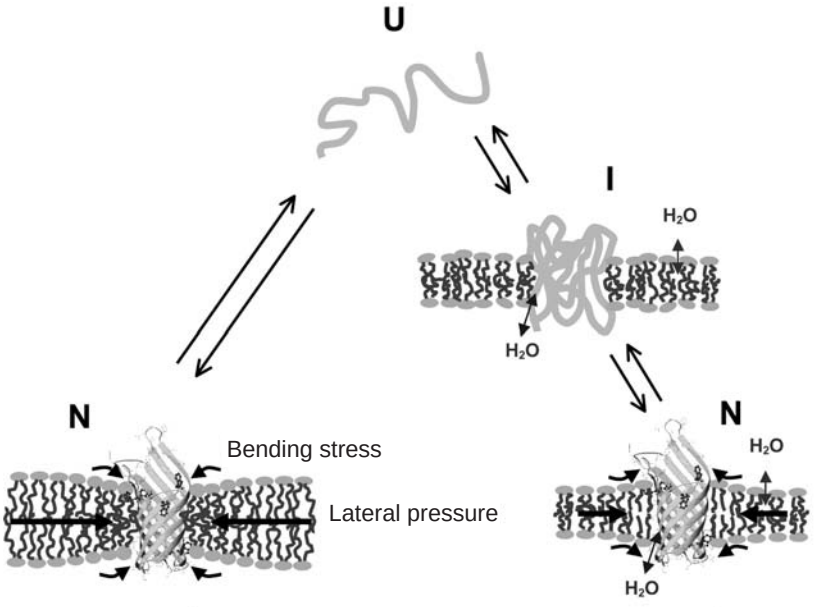

Fig. 28.2. Cartoon depicting the folding of OmpA into lipid bilayers. Left path: Folding into most bilayers is a thermodynamic two-state process. Right path: Folding into thin bilayers is multi-state (i.e., at least one equilibrium intermediate occurs). Bilayer forces acting on OmpA folding are indicated with arrows. The large black arrows indicate lateral bilayer pressure imparted on the lipid/protein interface in the hydrophobic core of the bilayer. Increasing this pressure increases the thermodynamic stability of the protein. The small black arrows indicate lipid deformation forces caused by hydrophobic mismatch between the protein and unstressed bilayers. These forces decrease the thermodynamic stability of the protein. Water molecules penetrate more easily into the hydrophobic core of thin bilayers (blue arrows) and stabilize equilibrium intermediates until, in very thin bilayers, complete unfolding is no longer observed. The unfolded state in urea is dissociated from the membrane. Adapted from Ref. [50].

Each of these techniques monitors a different aspect of the folding reaction. Trp fluorescence reports on the insertion of tryptophans into the lipid bilayer, far-UV CD on the formation secondary structure, and SDS-PAGE on the completion of the tertiary β-barrel structure. If samples are not boiled prior to loading onto the SDS gels, they run at an apparent molecular mass of 30 kDa if the protein is completely folded, but at 35 kDa if it is unfolded or incompletely folded.

This shift on SDS gels has proven to be a very useful assay for tertiary structure formation of OmpA and other outer membrane proteins [51]. Complete refolding as measured by the SDS-PAGE shift correlates with the reacquisition of the ion channel activity of OmpA [52]. Since unfolding/refolding curves as a function of denaturant concentration measured by three techniques that report on vastly different kinetic processes superimpose, it is very likely that folding/unfolding is a ther-

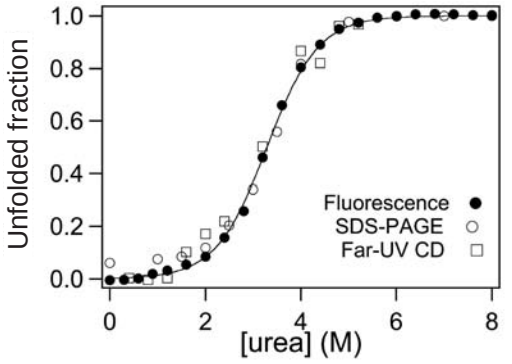

Fig. 28.3. Unfolded fraction of OmpA as a function of urea concentration obtained from the average fluorescence emission wavelength $\langle\lambda\rangle$, far-UV CD spectroscopy, and the SDS-PAGE shift assay. These measures of lipid binding, secondary structure, and tertiary structure, respectively, superimpose in equilibrium measurements although they develop at different times in kinetic experiments. Adapted from Ref. [50].

modynamic two-state process that can be analyzed using a two-state equilibrium folding model.

From such an analysis, Hong and Tamm [50] found a free energy of folding $\Delta G^{\circ}_{H2O} = -3.4$ kcal mol^{-1} and an m-value, which describes the cooperativity parameter of the folding/unfolding reaction, of $m = 1.1$. The rather small ΔG°_{H2O} of OmpA, which is of the same order of magnitude as that of water-soluble proteins, is perhaps surprising in view of the quite extreme heat resistance of this and other β-barrel membrane proteins. However, if one simply calculates the free energy of transfer of all residues that are transferred into the lipid bilayer with the augmented WW hydrophobicity scale, one finds that the net ΔG°_{H2O} amounts to only about -1 kcal mol^{-1}. This value may be further decreased by adding a few (negative) kcal mol^{-1} for folding, which would bring the prediction close to the experimentally determined value. The folding contribution may be the sum of contributions for secondary structure formation, estimated to be about 80×-0.2 kcal mol^{-1}, and on the order of 10 kcal mol^{-1} of entropy and other costs for packing polar residues in the core of the protein.

The take-home message from these measurements and theoretical considerations is that the overall stability of membrane proteins is not as large as one might have anticipated, but rather similar in magnitude to that of soluble proteins of similar size. As is true for soluble proteins, the thermodynamic stability of this and perhaps most membrane proteins is determined by the sum of many relatively large thermodynamic contributions that ultimately cancel to yield a relatively small net free energy of folding.

The study by Hong and Tamm [50] also examined the effect of lipid bilayer forces on the thermodynamic stability of OmpA. The effects of elastic lipid deformation due to a mismatch of the hydrophobic length of the protein compared with the bilayer thickness and due to curvature stress imposed by cone-shaped lipids

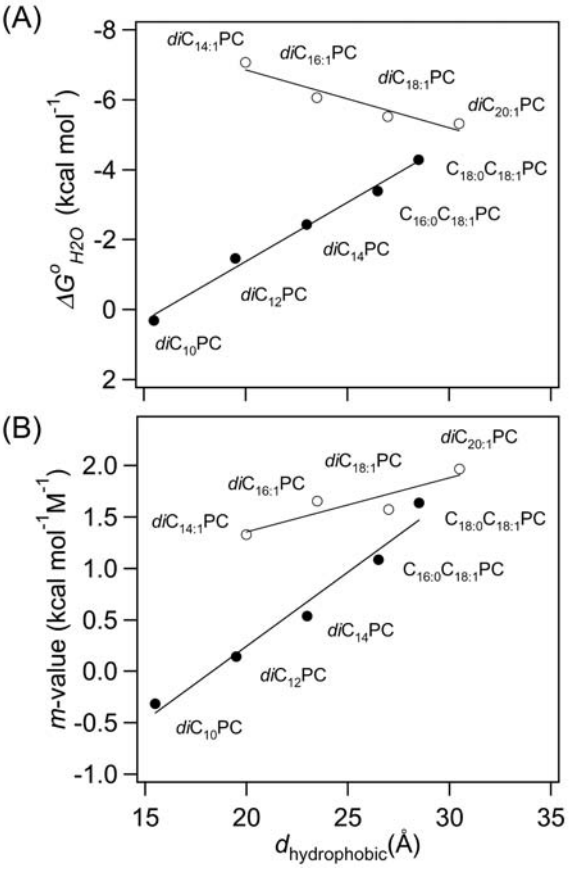

Fig. 28.4. Dependence of A) the free energy of folding ΔG°_{H2O} and B) the *m*-value reflecting the cooperativity of folding on the hydrophobic thickness of phosphatidylcholine bilayers. Filled circles: saturated acyl chain series with small lateral bilayer pressure. Open circles: double-unsaturated acyl chain series with increasing lateral bilayer pressure as hydrophobic thickness decreases. Adapted from Ref. [50].

were investigated. Increasing the thickness of the lipid bilayer increases the stability (i.e., decreases ΔG°_{H2O}) of OmpA. It also increases the cooperativity (*m*-value) of folding (Figure 28.4). The decrease in ΔG°_{H2O} is -0.34 kcal mol^{-1} per Å of increased bilayer thickness, which converts to -4 cal mol^{-1} per Å^2 of increased hydrophobic contact area. This is only about 20% of the standard value for the hydrophobic effect [9]. We conclude that elastic energy due to lipid deformation counteracts the energy gain that would be expected for a full development of the hydrophobic effect.

Including cone-shaped lipids with a smaller cross-sectional headgroup than acyl chain area increases the lateral pressure within lipid bilayers [53]. Increasing the lateral pressure in membranes by including lipids with increasing relative

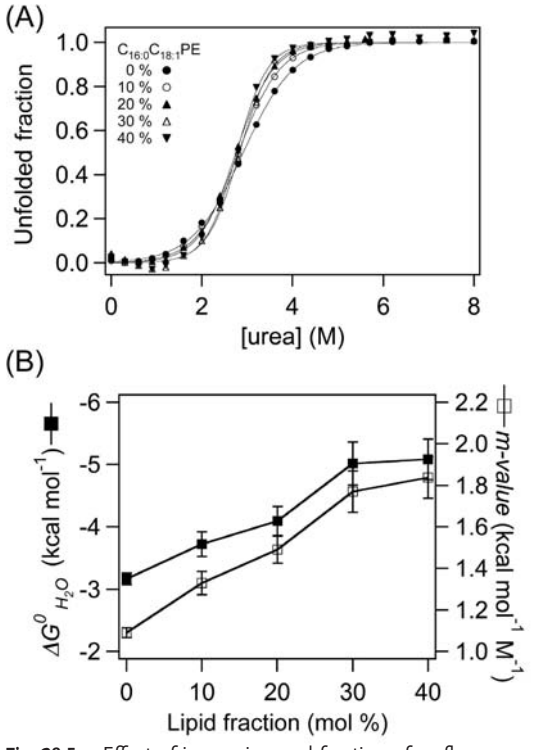

Fig. 28.5. Effect of increasing mol fraction of phosphatidylethanolamine ($C_{16:0}C_{18:1}$PE) in phosphatidylcholine ($C_{16:0}C_{18:1}$PC) bilayers on the thermodynamic stability of OmpA. A) Unfolding curves measured by Trp fluorescence. B) Dependence of ΔG°_{H2O} and *m*-value of OmpA folding on the cone-shaped and lateral pressure-inducing lipid $C_{16:0}C_{18:1}$PE. Adapted from Ref. [50].

amounts of *cis* double bonds in the hydrocarbon region increased the stability (i.e., decreased ΔG°_{H2O}) of OmpA from -3.4 to -7 kcal mol^{-1} and more negative values when phosphatidylethanolamines were included as cone-shape lipids (Figure 28.5). The *m*-value exhibited an increase that was correlated with the ΔG°_{H2O} decrease, in the case of bilayer thickening, but a decrease when the bilayer pressure was increased with *cis* double bonds. The various bilayer forces that act on OmpA and modulate its thermodynamic stability in membranes are illustrated in Figure 28.2.

Gram-negative bacteria possess active transport systems for the uptake of iron–siderophore complexes, vitamin B_{12}, and other essential nutrients. The systems consist of active ATP-requiring transporters in the inner membrane, the TonB linker protein that spans the periplasm, and a family of proteins called TonB-dependent transporters in the outer membrane. The TonB-dependent transporters share common structural features. They are monomeric 22-stranded β-barrels. The lumina of these large-diameter barrels are filled with a N-terminal

"cork" or "plug" domain with a globular mixed α-helix/β-structure. The plug domains are tightly inserted into the barrels and make extensive salt bridge and hydrogen bond contacts with the inner barrel wall. The mechanism of substrate transport through these transporters is presently not well understood.

A thermal denaturation study using DSC of FhuA demonstrated that the plug domain and the surrounding β-barrel are autonomous folding units [54]. In the absence of bound substrate (ferrichrome), a reversible transition centered at 65 °C was well separated from an irreversible transition centered at 74 °C. The binding of the substrate increased the lower transition temperature to 71 °C, while the higher transition temperature was not changed. Since the higher temperature transition was accompanied by a significant change of the CD signal at 198 nm and 215 nm, this transition was assigned to the denaturation of the β-barrel. The lower temperature transition was assigned to the denaturation of the plug domain and neighboring loops emerging from the β-barrel because antibodies targeting unfolded outer loops bound to FhuA only above the lower transition temperature of 65 °C. A deletion mutant (Δ21–128) that lacked the plug domain underwent a thermal denaturation at a lower temperature ($T_m = 62$ °C) than the wild-type protein, implying that the presence of the plug stabilizes the barrel structure.

The stability of FepA in Triton-X100 micelles was probed by solvent-induced denaturation and EPR spectroscopy [55, 56]. In these studies, FepA was functionally refolded from the denatured state by dialysing the denaturant in the presence of TX-100 micelles. When GdmCl- and urea-induced denaturation was monitored by site-directed spin-label EPR spectroscopy at an extracellular loop site, unfolding occurred in a sharp transition at 2.0 M GdmCl or 5.5 M urea, respectively. The free energies of unfolding were approximately 6 kcal mol^{-1} with both denaturants. The rate of unfolding of the substrate-bound protein was significantly smaller than that of the free protein. This confirms that the substrate has a stabilizing effect on FepA as has also been observed by DSC with FhuA. When residues pointing towards the center of the barrel were spin-labeled, their EPR spectra indicated completely mobile residues in 4 M GdmCl. However, residues facing the detergent were still quite immobilized at this GdmCl concentration. The authors argued that denatured FepA retained substantial residual hydrophobic interactions with the detergent micelle. This observation is reminiscent of residual hydrophobic interactions that have been observed in soluble proteins at high denaturant concentrations [57]. However, in these studies with FepA, the degree of denaturation was unfortunately not recorded by a global method such as CD spectroscopy and therefore, it is not clear whether the transition is two-state and whether fully denaturing conditions have been reached in this work.

Porins facilitate the general diffusion of polar solutes (< 400 Da) across the outer membranes of gram-negative bacteria. The porins are composed of 16-stranded β-barrels that assemble into rigid homotrimers whose trimer interfaces are formed by close van der Waals packing of nonpolar residues and aromatic ring stacking interactions [32, 33]. The lumen of each monomer is aqueous and surrounded by hydrophilic residues. An interesting structural and functional feature of the porins is that the long loop L3 folds back into the lumen of the channel where it engages

in a hydrophobic contact with a few residues inside the barrel. The loop forms a constriction in the channel and its acidic residues together with a cluster of basic residues on the opposite channel wall are thought to exert a transverse electric field across the channel opening. The shorter loop L2 forms a "latch" that reaches over from one subunit to a neighboring subunit and thereby further stabilizes inter-subunit interactions. Porins are extremely stable towards heat denaturation, protease digestion, and chemical denaturation with urea and GdmCl [31]. For example, extraction of OmpF from the *E. coli* outer membrane requires the heating of outer membranes in mixtures of isopropanol and 6 M GdmCl at 75 °C for more than 30 min [58]. The trimer structure itself is maintained up to 70 °C in 1% SDS [59].

A mutagenesis study combined with DSC and SDS-PAGE shift assays demonstrates that the inter-subunit salt bridge and hydrogen bonding interactions involving loop L2 contribute significantly to the trimer stability [59]. For example, mutations breaking the salt bridge between Glu71 and Arg100 decrease the trimer–monomer transition temperature from 72 to 47–60 °C and ΔH_{cal} from 430 to 200–350 kcal mol^{-1}. A similar behavior was observed when residues 69–77 of L2 were deleted. The energetic contribution of the nonpolar contact between neighboring barrel walls has not yet been investigated in porins, but would be interesting to examine and compare with lateral associations of interacting TM helices (see below).

28.4 Stability of Helical Membrane Proteins

In 1990, Popot and Engelman proposed a two-stage model for the folding of α-helical membrane proteins [60]. In the framework of this model, TM helices are thought to be independently folded units (stage I) that may laterally associate into TM helix bundles (stage II). The model was inspired by the finding of the same group that the seven-TM-helix protein bacteriorhodopsin (BR) can be split into helical fragments that would still integrate as TM helices and then laterally assemble into a seven-helix protein that was capable of binding to cofactor retinal just as the wild-type protein [61]. Since then, it has been realized that more stages are needed to describe the folding of helical proteins.

The interface is a membrane compartment that may be important in early stages of folding [62]. In addition, cofactors and polypeptide hinges and loops can be additional factors that sometimes play important roles in late stages of helical membrane protein folding [63]. Although the real world of membrane proteins is clearly more complex, the two-stage model has some merits because it is conceptually simple and because it appears to correctly describe the hierarchy of folding of at least a few simple membrane proteins. Therefore, we describe in this section how individual TM helices are established and then proceed in the following section with lateral helix associations and higher order structural principles of membrane protein folding.

As indicated above, open hydrogen bonds are energetically unfavorable in mem-

branes. Sequence segments with a sufficient number of apolar residues are driven into membranes by the hydrophobic effect where they fold into TM or interfacial α-helices. The thermodynamic gain of folding a 20-residue peptide into a TM helix is about -5 kcal mol^{-1}, if we take -0.25 kcal mol^{-1} as the per-residue increment of forming an helix in membranes [16]. Generally and in contrast to soluble protein α-helices, TM helices are quite rich in glycines. Prolines are also not uncommon in TM helices, where they often induce bends, but do not completely break the helix. Finally, serines, threonines, and cysteines are frequently interspersed into otherwise apolar TM sequences. These latter residues often form hydrogen bonds with backbone carbonyls and may therefore have a more apolar character in TM helices than in aqueous environments.

It is generally not possible to obtain interpretable results on the stability of helical integral membrane proteins from thermal denaturation studies because thermal denaturation of these proteins usually leads to irreversibly denatured states [5]. However, the thermodynamic stabilities of a few polytopic helical membrane proteins have been studied by partial denaturation with strong ionic detergents. Early refolding studies by Khorana and coworkers showed that BR could be quantitatively refolded by step-wise transfer from organic solvent to SDS to renaturing detergents or lipids [64, 65]. These protocols were later refined to measure the kinetics of refolding of BR upon transfer from the ionic detergent SDS into mixed lipid/detergent micelles [66, 67]. It should be kept in mind that although tertiary contacts are lost, most secondary structure is retained or perhaps even partially refolded in SDS. Therefore, the reactions observed with these protocols report only on the last stages of membrane protein folding. In 1997, Lau and Bowie developed a system to reversibly unfold native diacylglycerol kinase (DAGK) in *n*-decyl-β-maltoside (DM) micelles by the addition of SDS [68]. In these carefully controlled studies, the ratios of the denaturing and native structure-supporting detergents were systematically varied, so that reversibility of the partial unfolding reaction could be demonstrated. By analyzing their data with the two-state model of protein folding, these authors determined the stability of the three-helix TM domain of DAGK in DM relative to SDS to be -16 kcal mol^{-1}. This large (negative) value is somewhat surprising and indicates an extremely high thermodynamic stability of DAGK. A similar study has been carried out recently with BR [69].

28.5
Helix and Other Lateral Interactions in Membrane Proteins

The packing density and the hydrophobicity of amino acid residues involved in the intramolecular contact of α-helical membrane proteins are similar to those in the hydrophobic cores of water-soluble proteins. The basic principles of the hydrophobic organization of residues in water-soluble proteins appear to hold true also for membrane proteins. However, the energy gain of the hydrophobic effect has already been expended on inserting individual α-helices into membranes and cannot be a driving force for helix association. From comprehensive mutagenesis work

on the TM domain of glycophorin A [70] and later from genome-wide database searches [71], it has become clear that tight van der Waals contacts between complementary helix surfaces provide a strong driving force for lateral helix association in membranes. This force is perhaps best understood if one considers the possibility that lipids even in their fluid liquid-crystalline state do not conform as well to corrugated exposed helix interaction sites as the complementary helix binding partner. Lipids also gain entropy upon release from a helix surface into the bulk liquid-crystalline bilayer (''lipophobic effect''). Since thermodynamic driving forces are always determined by the energetic differences between two states, it is the unfavorable lipid solvation of corrugated helix surfaces that ultimately drives helix association.

Helices of membrane proteins are rarely oriented exactly perpendicular to the plane of the membrane. They are frequently tilted by about 20° from the membrane normal in structurally rugged membrane proteins [72] and by much larger angles in some recently solved structures of ion channels and complex transporters. TM helices interact with each other with left- or right-handed crossing angles [72, 73]. The specificity of helix interactions in membranes is thought to arise from complementary knob-in-the-hole van der Waals interactions. Glycines provide the holes and the β-branched side-chains of valine and isoleucine provide the most frequent knobs on the complementary surfaces. The generality of this interaction is supported by the frequent occurrence of GxxxG motifs in interacting TM segments [71]. The interaction energy of the helix dimer of the glycophorin A TM domain has been measured in C_8E_5 micelles by analytical ultracentrifugation and was found to be -9 kcal mol^{-1} [74]. Although this measurement offers a rare and important glimpse on the thermodynamics of TM helix–helix interactions, the value was determined in detergent micelles and may be different in lipid bilayers. Subsequent alanine scanning experiments indicated that mutation of Gly79 and Gly83 resulted in the largest energy penalty (1.5–3 kcal mol^{-1} relative to wild-type) for dimer formation of glycophorin [75]. The helix interaction ''knobs'' Leu75 and Ile76 also cost more than 1 kcal mol^{-1} in stabilization energy when replaced by alanines.

Another alanine scanning mutagenesis study examined the effect of all side chains of helix B of BR on the thermodynamic stability of helix interactions in this protein [69]. The most destabilizing mutations were Y57A (3.7 kcal mol^{-1} relative to wt) and T46A (2.2 kcal mol^{-1} relative to wt). These were followed by I45A, F42A, and K41A (1.9–1.6 kcal mol^{-1}). Apparently, very different types of side chains (polar, apolar, aromatic, charged) can cause large effects. These studies show that helix packing interactions may be more complex (and less predictable) than previously thought based on extrapolations from the glycophorin paradigm. A remarkable and important result from the Faham et al. [69] study is that each Å^2 of buried surface area yields about 26 cal mol^{-1} of stabilizing energy. This is about the same number as observed for the burying of residues in soluble proteins, which is usually thought to be driven by the hydrophobic effect. Since the hydrophobic effect is already consumed by inserting side chains into a hydrophobic environment (SDS micelle) and since polar residues essentially yield the same

number, the 26 cal mol^{-1} per $Å^2$, packing energy may be more universal than previously thought and may reflect van der Waals, hydrophobic, and lipophobic interactions. Alternatively, water may access helical surfaces in partially denaturing SDS micelles better than in native structure-supporting DMPC/CHAPSO micelles, in which case the result may still conform to the classical hydrophobic effect.

An additional mechanism of helix interaction is thought to arise from inter-helix hydrogen bonds. Side chain-to-side chain (Asn, Gln, Asp, Glu, His) hydrogen bonds have been introduced into engineered TM helical bundles and were found to stabilize homodimers and homotrimers [76–79]. Ser and Thr side chains were also examined in these host–guest model sequences, but were insufficient to support helix association. It has also been suggested that backbone Cα-H to backbone carbonyl hydrogen bonds might stabilize membrane proteins [80]. However, although such hydrogen bonds are observed quite frequently in crystal structures of membrane (and soluble) proteins, they may merely allow close packing and may not make significant energetic contributions to the association of neighboring helices as has been demonstrated for one such bond in BR [81]. Pore loops are found to intercalate into open angled helical membrane protein structures as exemplified by the KcsA potassium channel structure [82]. The loops are generally also fixed to the helical framework of the protein by side chain-to-side chain hydrogen bonds, namely a hydrogen bond from a loop Tyr to a neighboring helix Trp and Thr in the case of KcsA. Finally, many membrane protein structures contain cofactors and pigments that likely contribute significantly to the stability and interaction specificity of these structures. Intersubunit interactions that determine quaternary structures of membrane proteins generally follow the same helix packing rules as those determining their tertiary structures [83]. In case of BR, van der Waals packing between nonpolar surfaces, hydrogen bonding, and aromatic ring stacking of tyrosines in the bilayer interface all contribute to trimer formation.

28.6 The Membrane Interface as an Important Contributor to Membrane Protein Folding

In this and the following sections we turn to pathways and possible intermediates of membrane protein folding. Jacobs and White [84] proposed a three-step thermodynamic model of membrane protein folding based on structural and partitioning data of small hydrophobic peptides. In this model, the first three steps of membrane protein folding are thought include partitioning into the interface, folding in the interface, and translocation across the membrane to establish a TM helix. The model was later extended to a four-step model, which added helix–helix interactions as the fourth step [62]. The model is rather a thermodynamic concept than an actual pathway of folding of constitutive helical membrane proteins because their TM helices are inserted with the assistance of the translocon in biological membranes. However, the concept is relevant for the insertion of helical toxins into membranes, which occurs without the assistance of other proteins, and for the placement of interfacial helices into membranes. Separation of a partition and

folding step in the interface is probably also mostly semantic because in all observable reactions these two processes appear to be coupled. Nevertheless, to think of protein folding as a coupled process of two components is useful for separating the thermodynamic contributions of each component [14–16]. Partition–folding coupling was observed more than 20 years ago for toxic peptides [85], peptide hormones [86], signal peptides [87, 88], and membrane fusion peptides [89]. Beta-sheet forming proteins and peptides may also insert and fold in the membrane interface before they become completely inserted into and translocated across the membrane [90–93]. An example of the respective contributions of $\Delta G, \Delta H$, and ΔS to partitioning and folding of an α-helical fusion peptide in lipid bilayers is shown in Figure 28.6.

28.7 Membrane Toxins as Models for Helical Membrane Protein Insertion

There are several proteins that assume globular structures in solution, but upon interaction with a membrane receptor or at low pH insert into and sometimes translocate across membranes. Among them are several colicins, which are translocated across outer bacterial membranes via porins and subsequently inserted into the inner membrane where they form toxic pores. Other toxins such as diphtheria, tetanus, and botulinum toxins spontaneously insert their translocation domains into mammalian cell membranes and thereby permit the translocation of linked catalytic domains into the cells. Since these proteins form helical structures in solution and in membranes, they are good models to study the refolding of soluble helical proteins into membranes. The channel-forming colicins are perhaps in this regard the best-studied bacterial toxins. The structures of the soluble forms of the channel domains of several colicins are known [94]. They consist of a central hydrophobic helical hairpin that is surrounded by eight amphipathic helices.

Refolding at the membrane interface has been implicated in many models of colicin insertion into lipid bilayers. An early study found a molten globule intermediate at an early stage of colicin A insertion into membranes [95]. The helices were formed, but tertiary contacts were not. Subsequent fluorescence studies indicated that the helices of colicin E were located in the interface, but widely dispersed in this state [96, 97]. The central hydrophobic helical hairpin of colicin A appears to be more deeply inserted, but does not assume a complete TM topology [98]. How the voltage-gated ion channel is opened from this stage is still unclear. Apparently, long stretches of sequence translocate across the membrane upon the application of a membrane potential by a process that is still poorly understood structurally and mechanistically [99, 100].

The process of membrane insertion of the translocation domain of diphtheria toxin likely resembles that of the colicins. The structure of the soluble form features a hydrophobic helical hairpin similar to that of the colicins [101]. It is thought that this hairpin inserts first into the lipid bilayer. The membrane-bound protein can exist in two conformations with an either shallow or deeply inserted

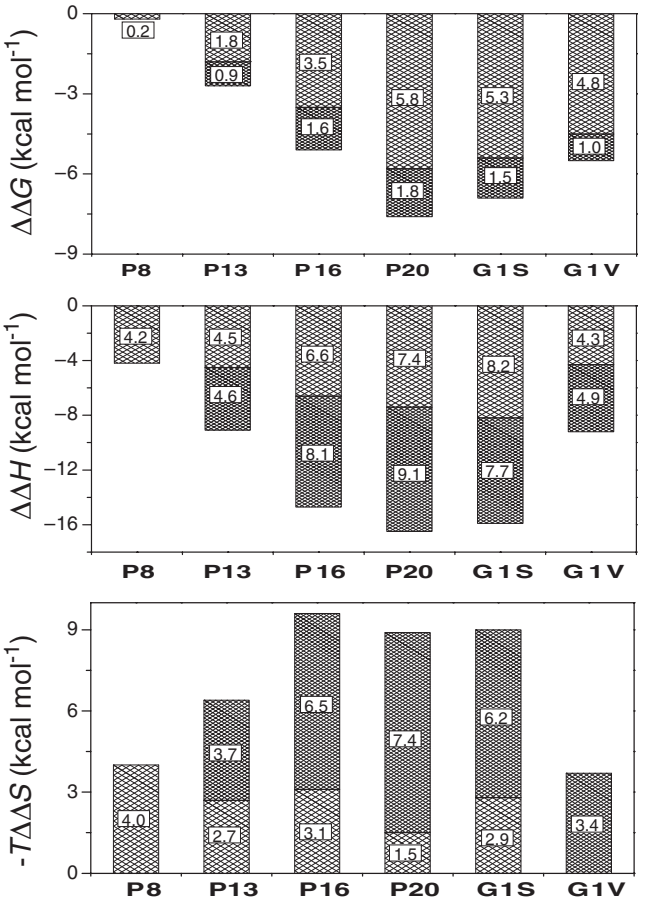

Fig. 28.6. Thermodynamics of partition-folding of the helical fusion peptide from influenza hemagglutinin. The lighter bars represent contributions from partitioning and the darker bars represent contributions from the coil → α-helix transition to ΔG, ΔH, and $T\Delta S$ upon peptide insertion into mixed phosphatidylcholine/phosphatidylglycerol bilayers. P8 through P20 are 8- to 20-residue peptides of the same sequence, and G1S and G1V are single amino acid mutations in position 1 of P20 that cause hemi-fusion or are defective in causing fusion, respectively. The numbers in the bars refer to the respective energies in kcal mol^{-1}. Adapted from Ref. [16].

helical hairpin [102]. Similar to the colicins, diphtheria toxin switches between two very different topologies in membranes and their relative populations depend on the applied membrane potential [103]. Again, the translocation mechanism is only poorly understood at the present time. However, despite many still unexplored details, the bacterial toxins appear to be an interesting class of facultative membrane proteins, from which we expect to learn a great deal about the mechanisms and energetics of refolding helical proteins in lipid bilayers.

28.8
Mechanisms of β-Barrel Membrane Protein Folding

The mechanism of folding and membrane insertion of the eight-stranded β-barrel protein OmpA has been studied by a number of kinetic experiments. The kinetics of folding into lipid bilayers composed of dimyristoylphosphatidylcholine in the fluid phase were found to be rather slow (i.e., on the order of many minutes at 30 °C) [104]. A more detailed kinetic study carried out with dioleoylphosphatidylcholine (DOPC) lipid bilayers in the 2–40 °C temperature range revealed three distinct kinetic phases [105]. The fastest phase detected by tryptophan (Trp) fluorescence changes had a time constant of 6 min and was rather independent of temperature. This phase was attributed to the initial binding of the unfolded protein to the bilayer surface. A second phase was strongly temperature dependent and had time constants in the 15 min to 3 h range (40–2 °C). The activation energy determined from an Arrhenius plot was 11 kcal mol^{-1}. This phase presumably corresponds to a deeper insertion, but not yet complete translocation of the β-strands in the lipid bilayer. The slowest phase was observed by the SDS gel-shift assay, which reports on the completion of the β-barrel. Complete folding in DOPC bilayers was only observed at temperatures greater than 30 °C, had a time constant of about 2 h, and took about 6 h to go to completion at 37 °C.

The translocation process of Trps of OmpA across the lipid bilayer was monitored by time-resolved Trp fluorescence quenching (TDFQ) [106]. In this technique, quenchers of Trp fluorescence are placed at different depths into the membrane and the time course of passage of Trps past these zones of quenchers is followed. When the technique was applied to single Trp mutants that were placed on different membrane-crossing β-hairpins, it was found that all four β-hairpins of OmpA crossed the membrane following the same time course (i.e., using a synchronized concerted mechanism of folding and insertion) [107]. This result is in accordance with the notion that interstrand hydrogen bonds and the barrel itself have to form while the protein translocates across the membrane. Again and very similar to the partition–folding coupling that was discussed in the context of helical membrane protein folding at membrane interfaces, we observe a folding–translocation coupling for this class of membrane proteins.

Thus the mechanism of β-barrel membrane protein folding in lipid bilayers is very different from the two (or more) stage models discussed above for helical membrane protein folding. The requirement that the barrel needs to be completely folded in order to translocate across the membrane probably also explains why the time constants of this process are so slow and the activation energies are so high. Folding and translocation of the barrel requires a large defect to be created in the membrane in order to insert a barrel of the size of OmpA. Moreover, the membrane provides a 100- to 1000-fold more viscous environment than water for folding and inserting membrane proteins.

In another kinetic study, the dependence of the rates of folding and insertion of OmpA on the bilayer thickness was examined [108]. As one might expect from the material properties of lipid bilayers, the folding and insertion rates increased sig-

nificantly as the bilayer thickness decreased. When the bilayers were sufficiently thin, folding of OmpA into large unilamellar vesicles was observed, whereas in average or thick bilayers complete folding and insertion occurs only in small unilamellar vesicles. Small vesicles are more strained and therefore exhibit more defects than large vesicles, which permits the quantitative refolding of OmpA in small, but not in large unilamellar vesicles if the hydrocarbon thickness of the bilayer is more than 20 Å (i.e., that of diC_{12}-phosphatidylcholine). Interestingly, the hydrophobic thickness of outer bacterial membranes is thought to be thinner than that of the inner membranes [109].

28.9 Experimental Protocols

28.9.1 SDS Gel Shift Assay for Heat-modifiable Membrane Proteins

The heat modifiability can be defined as a property of a protein whose electrophoretic mobility depends on the treatment of heat. It is characteristic for many bacterial outer membrane proteins [110]. For example, detergent-solubilized OmpA from *E. coli* migrates on SDS-polyacrylamide gels as a 30-kDa form without boiling, but as a 35-kDa form if boiled in SDS. Likewise, the iron transporter FepA shows an apparent molecular mass of 58 kDa if not boiled, but exhibits its actual molecular mass of 81 kDa after boiling [55]. The correlation between conformational states and electrophoretic mobilities on SDS-PAGE has been studied most extensively for unboiled samples OmpA. The 30-kDa form represents the membrane-inserted native state, which also exhibits a characteristic ion channel activity [45, 49, 52]. The 35-kDa form may represent a completely denatured state in the presence or absence of lipids [49–51], a misfolded state in the absence of lipid [111], a surface-adsorbed partially folded state [49, 90], or a kinetic intermediate at a stage before the complete insertion into membranes [105, 108].

28.9.1.1 Reversible Folding and Unfolding Protocol Using OmpA as an Example

1. Dilute OmpA in 8 M urea more than 100-fold into sonicated small unilamellar vesicles (SUV) composed of the desired lipids to give a final OmpA concentration of 12 μM and lipid-to-protein molar ratio of 800.
2. Incubate for 3 h at 37 °C for refolding.
3. Divide the refolded protein-lipid complex into 10 aliquots.
4. Add appropriate amounts of a freshly made 10 M urea and buffer (10 mM glycine, pH 10, 2 mM EDTA) solutions to the aliquots to reach a 2.5-fold dilution of OmpA and urea concentrations in the range of interest.
5. Incubate reactions overnight at 37 °C.
6. Terminate reactions by mixing the samples with an equal volume of 0.125 M Tris buffer, pH 6.8, 4% SDS, 20% glycerol, and 10% 2-mercaptoethanol at room temperature.

7. Without boiling, load equilibrated samples on 12.5% SDS polyacrylamide gels, run electrophoresis, and stain with Coomassie Blue.
8. Measure fractions folded and unfolded, F and U, by densitometry and fit to two-state equilibrium folding equation:

$$[\mathrm{U}] = \frac{([\mathrm{U}] + [\mathrm{F}])\ \exp(\{m[\mathrm{urea}] - \Delta G^{\circ}_{\mathrm{H2O}}\}/RT)}{1 + \exp(\{m[\mathrm{urea}] - \Delta G^{\circ}_{\mathrm{H2O}}\}/RT)} \quad (1)$$

The fit parameters are the free energy of unfolding, $\Delta G^{\circ}_{\mathrm{H2O}}$, and the *m*-value.

An example of a reversible unfolding/refolding reaction using this protocol is shown in Figure 28.7.

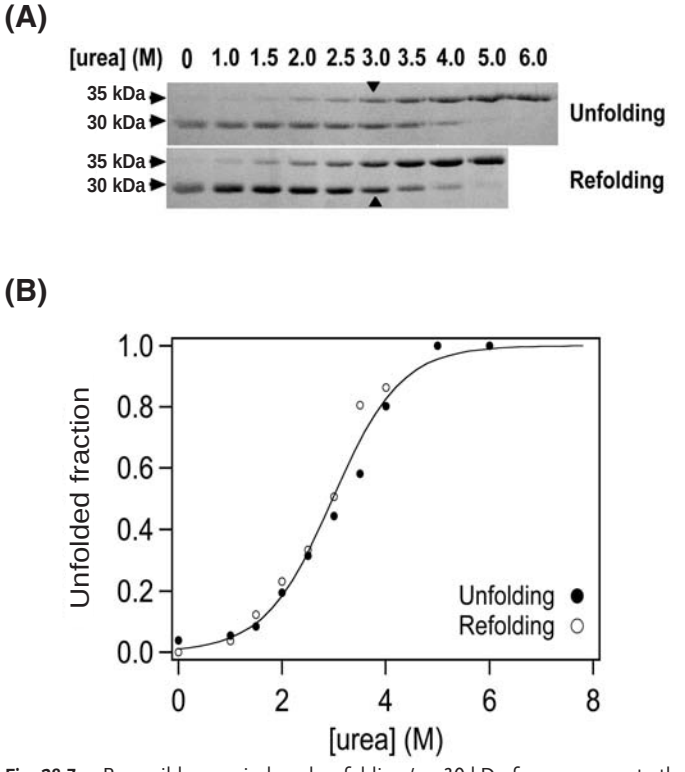

Fig. 28.7. Reversible urea-induced unfolding/refolding of OmpA in lipid bilayers composed of 92.5% phosphatidylcholine ($C_{16:0}C_{18:1}$PC) and 7.5% phosphatidylglycerol ($C_{16:0}C_{18:1}$PG) at pH 10 and 37 °C monitored by the SDS-PAGE shift assay. A) Unfolding (upper panel) and refolding (lower panel) of OmpA. The 30-kDa form represents the native state, and the 35-kDa form represents denatured states. B) Unfolded fractions as a function of urea concentration estimated from A. The data are fitted with the two-state equilibrium folding equation Eq. (1).

28.9.2

Tryptophan Fluorescence and Time-resolved Distance Determination by Tryptophan Fluorescence Quenching

Steady-state and time-resolved Trp fluorescence spectroscopy have been widely used to the study folding and stability of membrane proteins. The relatively large spectral shifts and fluorescence intensity changes of Trps as a result of changing local environments have made Trp fluorescence an excellent tool for such studies. Figure 28.8A shows typical fluorescence spectral changes of OmpA–lipid complexes equilibrated in various urea concentrations. The unfolding transition curves are constructed as a function of urea by parametrizing each spectrum to an average emission wavelength:

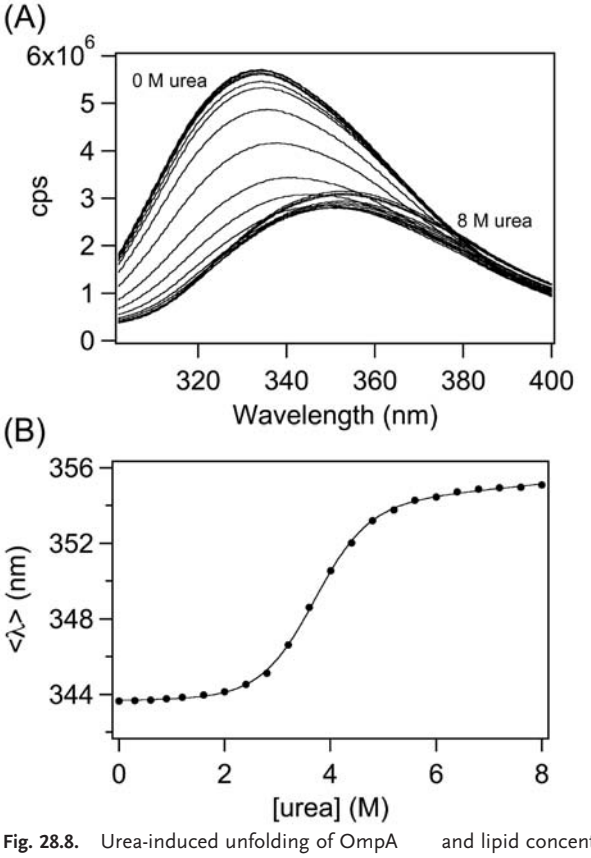

Fig. 28.8. Urea-induced unfolding of OmpA in lipid bilayers composed of 92.5% phosphatidylcholine ($C_{16:0}C_{18:1}$PC) and 7.5% phosphatidylglycerol ($C_{16:0}C_{18:1}$PG) at pH 10 and 37 °C monitored by Trp fluorescence. A) Fluorescence emission spectra of OmpA as a function of urea concentration. The protein and lipid concentrations were 1.2 μM and 10 mM, respectively, and the urea concentration ranged from 0 to 8 M (left to right). B) Unfolding transition monitored by the average emission wavelength $\langle\lambda\rangle$ (Eq. (2)) calculated from the spectra in A and fitted with the two-state equilibrium folding equation Eq. (3).

$$\langle\lambda\rangle = \frac{\sum_i (F_i\lambda_i)}{\sum_i (\lambda_i)} \tag{2}$$

and fitting the data to the two-state equilibrium folding equation:

$$\langle\lambda\rangle = \frac{\langle\lambda\rangle_F + \langle\lambda\rangle_U \frac{1}{Q_R} \exp[m([\text{denaturant}] - C_m)/RT]}{1 + \frac{1}{Q_R} \exp[m([\text{denaturant}] - C_m)/RT]} \tag{3}$$

Inclusion of the weighting factor $Q_R =$ (total fluorescence intensity in native state)/(total fluorescence intensity in denatured state) makes $\langle\lambda\rangle$ proportional to species concentrations and therefore permits $\langle\lambda\rangle$ to be taken as a measure of the fraction of folded protein [112]. The free energy of unfolding is calculated from the fitted denaturant concentration at the mid-point of the transition, C_m, and the m-value using $\Delta G^\circ_{H2O} = mC_m$. Figure 28.8B shows an example of equilibrium unfolding of OmpA measured by Trp fluorescence.

The degree of solvent exposure of Trp residues of membrane proteins and thus their degree of immersion in the lipid bilayer is often determined by the effect of polar (e.g., cesium, iodide, bromide, acrylamide) or nonpolar (e.g., molecular oxygen) quenchers on the fluorescence spectra. A more informative method to determine the depth of Trps in membranes involves the use of spin-labeled or brominated lipids as quenchers. Phospholipids selectively labeled with bromines or spin labels in various positions of the acyl chains are commercially available. Depths in membranes of specific Trps are often measured by using a whole set of these lipids and analyzing the resulting spectra with the ''parallax'' or ''distribution analysis'' methods [113]. These steady-state methods may be extended to measure the time dependence of Trp positions and more specifically the translocation of Trps across lipid bilayers during the folding of membrane proteins [106]. Reliable distances in membranes are obtained by the time-resolved distance determination by fluorescence quenching (TDFQ) technique because the positions and distributions of the bromines in the bilayer are known from X-ray diffraction studies [114].

28.9.2.1 TDFQ Protocol for Monitoring the Translocation of Tryptophans across Membranes

1. Mix solutions of DOPC and one each of DOPC plus 4,5-, 6,7-, 9,10-, and 11,12-diBrPC, respectively, at molar ratios of 7:3 (DOPC:m,n-diBrPC) in chloroform.
2. Dry the mixtures on the bottom of test tubes under a stream of nitrogen and further in a desiccator under a high vacuum overnight.
3. Disperse dried lipids in 1.0 mL buffer (10 mM glycine, pH 8.5, 1 mM EDTA, 150 mM NaCl) to a lipid concentration of 2 mg mL^{-1}.
4. Prepare SUVs by sonication of the lipid dispersions for 50 min using the microtip of a Branson ultrasonifier at 50% duty cycle in an ice/water bath.

5. Remove titanium dust by low-speed centrifugation (e.g., at 6000 rpm for 10 min on a tabletop centrifuge) and store vesicles at 4 °C overnight for equilibration.
6. Measure blank fluorescence emission spectra for each vesicle solution at 1 mM lipid concentration and at the controlled temperature of interest with instrument settings for Trp fluorescence (e.g., excitation at 290 nm with 2-nm slit; emission from 310 to 370 nm with 5-nm slit).
7. Add small volume of concentrated OmpA (stock is typically 20–50 mg mL^{-1}) in 8 M urea to give a final OmpA concentration of 1.4 μM and mix well.
8. Record fluorescence spectra with above settings every 2–5 min. (The first spectrum can be taken 30 s after mixing.) Repeat measurements for each of the five vesicle solutions.
9. Measure fluorescence intensities of smoothed spectra at 330 nm as a function of time and normalize values for each of the quenching vesicles to the corresponding values of vesicles without lipid quencher.
10. Fit normalized fluorescence intensities to the Gaussian distribution equation:

$$\frac{F(d_Q)}{F_0} = \exp\left\{-\frac{S}{\sigma\sqrt{2\pi}}\exp\left\{-\frac{1}{2}\left(\frac{d_Q - d_{Trp}}{\sigma}\right)^2\right\}\right\} \quad (4)$$

F_0 and $F(d_Q)$ are the fluorescence intensities in the absence and presence of a particular m,n-diBrPC quencher. d_Q are the known distances of the quenchers from the bilayer center, and d_{Trp} is the distance of the fluorophor from the center. The dispersion σ is a measure of the width of the distribution of the fluorophor in the membrane, which in turn depends on the sizes and thermal fluctuations of the fluorophors and quenchers. S is a function of the quenching efficiency and quencher concentration in the membrane. The fits yield d_{Trp}, σ, and S.
11. Plot d_{Trp} and σ as a function of time.

The accuracy of the distribution analysis could be improved if more than four membrane-bound quenchers at different depths in the membrane and/or a quencher attached to the polar lipid headgroup were used. Figure 28.9 shows two examples of Trp movements of OmpA into and across lipid bilayers, respectively, measured by TDFQ using four different bromine quenchers in the acyl chain region.

28.9.3 Circular Dichroism Spectroscopy

Circular dichroism (CD) refers to the differential absorption of the right- and left-handed circular polarized lights by a sample that exhibits molecular asymmetry. Far-UV CD spectroscopy has been used to characterize the secondary structures of

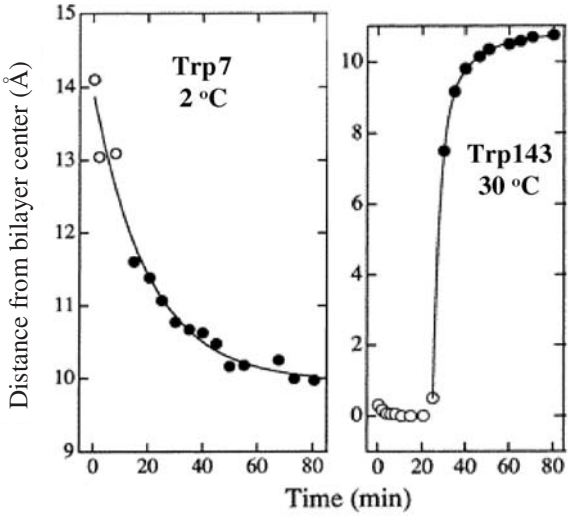

Fig. 28.9. Measurement of the translocation rate of single trypophans of OmpA into and across lipid bilayers composed of phosphatidylcholine ($diC_{18:1}PC$) by time-resolved fluorescence quenching (TDFQ). A) Time course of the movement of Trp7 of OmpA into lipid bilayer at 2 °C. This Trp stays on the *cis* side and does not cross the bilayer. B) Time course of the movement of Trp143 across the lipid bilayer at 30 °C. This Trp translocates across the bilayer with a time constant of 3.3 min at 30 °C. The solid lines are fits of the data to exponential functions. Adapted from Ref. [107].

proteins including membrane proteins because the differential amide absorptions of α-helices, β-sheets, turns, and random coils in the range between 180 and 250 nm yield characteristic CD signals that can be used to determine their secondary structure compositions. The CD spectra of α-helices exhibit minima at 208 and 222 nm. Beta-sheets show a weaker minimum at 216 nm. Both of these structures exhibit maxima just below 200 nm, but the spectra of random coils are negative in the entire accessible far-UV spectral range with a minimum just below 200 nm.

CD spectroscopy of membrane proteins is difficult because the proteo-liposomes, which are necessary for functional reconstitution of membrane proteins, are strong scatterers of UV light resulting in overwhelming spectral noise. Therefore, only SUVs, which are typically obtained by sonication and which are typically 30 nm in diameter, or protein–detergent mixed micelles are recommended for recording CD spectra of membrane proteins. Even with these samples, CD spectra cannot usually be recorded to below 200 nm, which limits the accuracy of secondary structure determinations. Good results can be obtained with 0.05-mm pathlength cells and protein concentrations of 0.5–1.0 mg mL^{-1} in buffers that do not absorb in the far UV. Relatively crude estimates of secondary structure content can be made from the spectral shapes in the 200–240 nm spectral region and using the follow-

ing rule of thumb values for 100% secondary structure: $\theta_{222} = -30\,000$ deg cm^2 dmol^{-1} for α-helix and $\theta_{216} = -15\,000$ deg cm^2 dmol^{-1} for β-sheet.

28.9.4 Fourier Transform Infrared Spectroscopy

Fourier transform infrared (FTIR) spectroscopy is a useful technique for determining the conformation and orientation of membrane proteins and lipids in lipid bilayers. The method has no light scattering artifacts and works well with turbid and even solid samples. Since the absorption bands of liquid water overlap with several bands that are of interest in protein and membrane spectroscopy, it is convenient to work in D_2O solutions. In conventional transmittance spectroscopy, the strong absorbances of residual H_2O and bulk D_2O are minimized by using high protein concentrations and measuring cells of short path lengths.

Another very convenient method for suppressing unwanted water signals is to record attenuated total reflection (ATR) FTIR spectra. In this method, the IR beam is reflected within an IR-transparent internal reflection element such as a germanium plate. An evanescent wave of the same frequency as the incoming IR light builds up at the germanium–water interface. The electric field of the evanescent wave decreases exponentially away from the interface with a characteristic decay length, d_p, which is on the order of a few hundred nanometers in typical applications. This wave probes with high sensitivity samples that are adsorbed at the germanium–water interface such as a reconstituted protein–lipid bilayer. Since absorptions from the bathing buffer solution are greatly suppressed in this surface-sensitive technique, small amounts of H_2O in D_2O are not a problem in ATR-FTIR spectroscopy. An additional advantage is that the orientation of membrane proteins and lipids in the bilayers can be obtained by using polarized light. Microgram quantities of membrane proteins in single supported bilayers are sufficient to record high quality spectra. Finally, buffer conditions can be varied in situ using a perfusable ATR measuring cell. A comprehensive description of ATR-FTIR spectroscopy on supported membranes has appeared [115].

The most widely used conformation-sensitive vibrational mode of proteins is the amide I′ band (1600–1700 cm^{-1}). The secondary structures of proteins are correlated with the amide I′ frequencies, which enables the assignment of the major secondary structure elements of proteins by spectral decomposition of this band (α-helix: 1648–1660 cm^{-1}; parallel and antiparallel β-sheet: 1625–1640 cm^{-1}; antiparallel β-sheet: 1675–1695 cm^{-1}; aggregated strands: 1610–1628 cm^{-1}; turns: 1660–1685 cm^{-1}; unordered structures: 1652–1660 cm^{-1} in H_2O and 1640–1648 cm^{-1} in D_2O). The peak corresponding to the α-helix is often not well resolved from nearby peaks of turns and unordered structures. However, β-sheet can usually be reliably assigned due to its distinctive components at about 1630 cm^{-1} and 1690 cm^{-1}.

The following bands of lipid vibrations are well separated from protein amide bands and are frequently analyzed in studies of protein–lipid interactions: sym-

metric and antisymmetric methylene stretches at 2850 cm^{-1} and 2920 cm^{-1}, respectively, and ester carbonyl stretch at 1730 cm^{-1}.

28.9.4.1 Protocol for Obtaining Conformation and Orientation of Membrane Proteins and Peptides by Polarized ATR-FTIR Spectroscopy

1. Fill liquid ATR cell containing germanium plate with D_2O buffer (e.g., 5 mM HEPES/10 mM MES pH 7.3, 135 mM NaCl) and record FTIR spectra at vertical and horizontal polarizations with a spectral resolution of 2 cm^{-1} to obtain reference spectra.
2. Deposit lipid monolayer on germanium plate by the Langmuir-Blogett technique at 32 mN m^{-1}.
3. Add proteoliposomes (typically about 0.5 mM lipid and 20 μg mL^{-1} protein in same H_2O buffer) to supported monolayer in assembled ATR cell and incubate with gentle shaking for 1 h. The proteoliposomes will fuse with the monolayer during this time and form a complete planar bilayer on the surface of the germanium plate.
4. Flush excess proteoliposomes out of measuring cell with 10 volumes of D_2O buffer. This step also exchanges H_2O for D_2O.
5. Incubate exchanged sample for 1 h at room temperature to equilibrate labile amide protons with deuteriums. This is done in the FTIR spectrometer and the spectrometer compartment is purged with dry air or nitrogen at the same time to remove water vapor.
6. Collect the sample spectra using the same experimental settings as reference spectra at vertical and horizontal polarizations.
7. Ratio sample and reference spectra and calculate absorption spectra.

The following steps describe a recipe to extract secondary structure information from complex (overlapped) amide I′ bands:

8. Calculate second-derivative spectra by differentiation with 11-point Savitsky-Golay smoothing. The minima in the second derivatives indicate possible component peaks.
9. Using only prominent and clearly identified component peaks as starting points, carry out spectral decomposition by least-squares fitting with Gaussian component line shapes. Use as few components as possible to reproduce the experimental line shape. Accept only fits that keep the Gaussian peak components centered close to the component frequencies that were identified in the second derivative spectra.
10. Integrate spectral components, assign to secondary structures, and calculate area fractions to indicate respective secondary structure fractions.

The following steps describe how to obtain orientations of secondary structure elements of proteins and orientations (order parameters) of lipid chemical groups:

11. Calculate ATR dichroic ratio for the amide I′ bands and symmetric or antisymmetric methylene stretching band intensities according to

$$R_{\text{amideI}}^{\text{ATR}} = \frac{\int A_{//}(\nu)\,\mathrm{d}\nu}{\int A_{\perp}(\nu)\,\mathrm{d}\nu} \tag{5}$$

and

$$R_{\text{Lipid}}^{\text{ATR}} = \frac{A_{//}(\nu)}{A_{\perp}(\nu)} \tag{6}$$

12. The order parameter is defined as

$$S_{\theta} = (3\langle\cos^2\theta\rangle - 1)/2 \tag{7}$$

where θ is the angle between the axis of rotational symmetry of an axially symmetric molecule (long axis of the lipid, α-helix, β-barrel, etc.) and the normal to the germanium plate and the angular brackets denote a time and space average over all angles in a given sample.

13. Calculate the order parameter for an amide I′ band component as:

$$S_{\text{amideI}} = \frac{E_{\text{x}}^2 - R_{\text{amideI}}^{\text{ATR}} E_{\text{y}}^2 + E_{\text{z}}^2}{E_{\text{x}}^2 - R_{\text{amideI}}^{\text{ATR}} E_{\text{y}}^2 - 2E_{\text{z}}^2} \tag{8}$$

where E_{x}, E_{y}, and E_{z} are the electric field amplitudes at the germanium–buffer interface. For a 45° germanium plate with a thin attached membrane in D_2O buffer $E_{\text{x}}^2 = 1.9691$, $E_{\text{y}}^2 = 2.2486$, and $E_{\text{z}}^2 = 1.8917$. For α-helices, where the angle between the amide I′ transition dipole moment and the helix axis is 39°, Eq. (8) transforms to

$$S_{\text{H}} = 2.46\frac{E_{\text{x}}^2 - R_{\text{amideI}}^{\text{ATR}} E_{\text{y}}^2 + E_{\text{z}}^2}{E_{\text{x}}^2 - R_{\text{amideI}}^{\text{ATR}} E_{\text{y}}^2 - 2E_{\text{z}}^2} \tag{9}$$

S_{H} is the order parameter that describes the helix orientation relative to the germanium plate and membrane normal. For β-sheets, there is no helical symmetry and Eq. (8) describes the order parameter of the transition dipole moment of the amide I′ band, which roughly coincides with the order parameter of the amide carbonyl bond orientations.

14. Lipid order parameters are obtained from the experimental dichroic ratios of the symmetric and/or antisymmetric methylene stretch vibrations:

$$S_{\text{L}} = -2\frac{E_{\text{x}}^2 - R_{\text{L}}^{\text{ATR}} E_{\text{y}}^2 + E_{\text{z}}^2}{E_{\text{x}}^2 - R_{\text{L}}^{\text{ATR}} E_{\text{y}}^2 - 2E_{\text{z}}^2} \tag{10}$$

Lipid order parameters should always be recorded along with those of embedded proteins because they provide essential controls of the bilayer quality.

Results on protein orientations are only meaningful if lipid orientations (to the germanium plate) are satisfactory.

Lipid-to-protein ratios in supported bilayers:

15. Use the following form of Beer-Lambert's law modified for polarized ATR spectroscopy to calculate the lipid/protein ratio in supported bilayers [116]:

$$L/P = 0.208(n_{\mathrm{res}} - 1)\frac{1 - S_{\mathrm{amideI}}}{1 + S_{\mathrm{L}}/2}\frac{\int_{2800}^{2980} A_{\perp}(\nu_{\mathrm{L}})\,\mathrm{d}\nu}{\int_{1600}^{1690} A_{\perp}(\nu_{\mathrm{amideI}})\,\mathrm{d}\nu} \tag{11}$$

where n_{res} is the number of residues in the polypeptide and ν_{L} and ν_{amideI} are the wavenumbers of the lipid methylene stretch and the protein amide I′ vibrations, respectively.

Acknowledgments

We thank members of the Tamm laboratory, past and present, for their contributions and many discussions. The work from our laboratory was supported by grants from the National Institutes of Health.

Protein Folding Catalysis by Pro-domains

Philip N. Bryan

29.1
Introduction

The activation of secreted proteases is tightly regulated by a variety of maturation mechanisms [1]. The zymogen form of some consists of a domain-sized extension attached to the N-terminus of the mature protease. Biosynthesis of these proteases involves the folding of the pro-protease followed by processing of the pro-domain from the folded protease. The biological imperative for tight regulation of protease activation creates a situation in which the protease domain must coevolve with the pro-domain. In many cases the mature protease does not have the capacity to fold independently of the pro-domain even though the mature protease appears to be a stable globular entity without obvious structural characteristics which would distinguish it from facile-folding proteins.

Some pro-domains will catalyze folding of the mature form of the protease even as a separate polypeptide chain. The bimolecular reaction is an intriguing case of complementation. The folded protease is stable in a practical sense. That is, the native conformation persists under favorable solvent conditions for many months. Yet, once denatured and returned to these same favorable conditions, it remains in an unfolded conformation for many months. When the isolated pro-domain is added to unfolded protein, however, folding of the two components into a stable complex occurs spontaneously. Examples of pro-domain mediated folding have been found in all four mechanistic families of proteases: serine proteases [2–7]; Aspartic proteases [8–10]; metalloproteases [11–15], and cysteine proteases [16].

For most well-studied proteins, sufficient information is contained within the protein sequence itself to guide the folding process without the requirement for additional factors. Thus the amino acid sequence of these proteins has evolved to encode both a stable native state and a folding pathway efficient enough to reach the native conformation on a biological time scale. The existence of high kinetic barriers to folding challenges many widely accepted ideas, namely thermodynamic determination of native structure and the sufficiency of thermodynamic stability to determine a pathway. Thus the evolution of pro-proteins as folding units appears to have created folding mechanisms which are outside the paradigm established from data on facile-folding proteins.

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

This review will focus on what general inferences about protein folding can be made from pro-domain catalyzed folding. General questions include whether native protein conformation is always thermodynamically determined, what causes high kinetic barriers between unfolded and native states, and what do pro-domains do to reduce these kinetic barriers. The proteases that have provided the most mechanistic information on catalyzed folding are subtilisin (SBT) and α-lytic protease (ALP). Both are serine protease secreted from bacteria but are not evolutionarily related [17, 18]. Each has eukaryotic homologs. ALP is a structural homolog of chymotrypsin and trypsin and SBT is homologous in structure to prohormone convertases [19–21].

29.2
Bimolecular Folding Mechanisms

With regard to general questions about protein folding mechanisms, analysis of the bimolecular folding reaction has been particularly informative. Unlike unimolecular folding of pro-protease, which results in a metastable product, the product of bimolecular folding is a stable complex between the native protease and the folded pro-domain. The overall goal of many experiments on SBT and ALP has been to obtain a quantitative understanding of all steps in the bimolecular folding reaction. The mechanism of pro-domain-catalyzed folding is as follows:

$$\mathrm{P} + \mathrm{U} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{P\text{-}I} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{P\text{-}N} \underset{k_{\mathrm{on}}}{\overset{k_{\mathrm{off}}}{\rightleftharpoons}} \mathrm{N} + \mathrm{P}$$

where P is pro-domain, U is unfolded protease, N is native protease, P-I is a collision complex of a partially folded protease and pro-domain, P-N is the complex of native protease and pro-domain. To define mechanistically how the pro-domain participates in folding, it is necessary to measure the rates of all steps in the bimolecular folding reaction. It would also be useful to understand the structure of all populated species in this reaction. The approach has been to characterize the individual steps in the reaction and then use this information to understand the overall reaction.

29.3
Structures of Reactants and Products

29.3.1
Structure of Free SBT

Subtilisin BPN′ is the canonical member of the subtilisin family of proteases [22]. It is a heart-shaped protein consisting of a seven-stranded parallel β-sheet packed between two clusters of α-helices (Figure 29.1). Six α-helices are packed against one face of the central β-sheet and two α-helices are packed against the other [23–

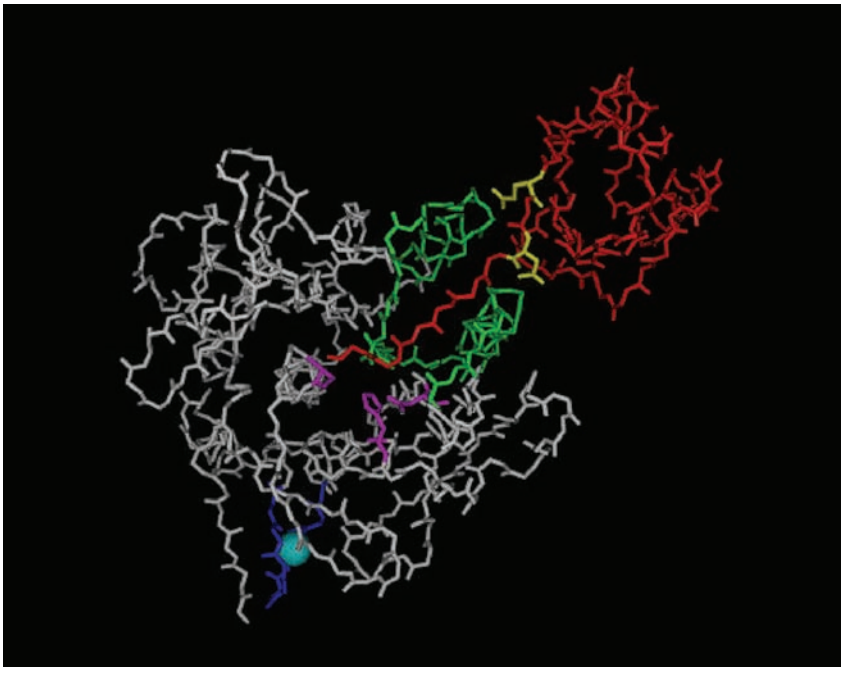

Fig. 29.1. Subtilisin (white) in complex with its pro-domain (red). Active-site triad is shown in violet; α-β-α structure to which pro-domain binds is shown in green; calcium at site A is light blue sphere; calcium-binding loop 75–83 is shown in dark blue. From 1SCJ in the Protein Data Bank [31].

25]. The catalytic triad is distributed as follows: The active-site Ser221 is on the N-terminal end of a long, central helix (helix F); Asp32 is on an interior strand of the β-sheet (β1); His64 is in the N-terminal end of the adjacent helix (helix C). Subtilisin contains a number of notable structural features which are highly conserved across the family. A *cis*-peptide bond occurs between Tyr167 and Pro168 and creates part of the substrate binding pocket. A rare left-handed cross-over occurs between strands β2 and β3. A loop of nine amino acids (75–83) interrupts the last turn of helix C [25]. The loop is part of the left-handed cross-over and forms the central part of a high affinity calcium-binding site (site A). Four carbonyl oxygen ligands to the calcium are provided by the loop (Figure 29.2). The other calcium ligands are a bidentate carboxylate (Asp41) which occurs on an ω-loop (36–45) and the side chain Gln2. Three hydrogen bonds link the N-terminal segment (1–4) to residues 78–82 in parallel-β arrangement. The 75–83 loop also has extensive interactions with a β-hairpin (202–219) so that the calcium ion is buried within the protein structure.

A second ion-binding site (site B) is located 32 Å from site A in a shallow crevice between two segments of polypeptide chain near the surface of the molecule. Evi-

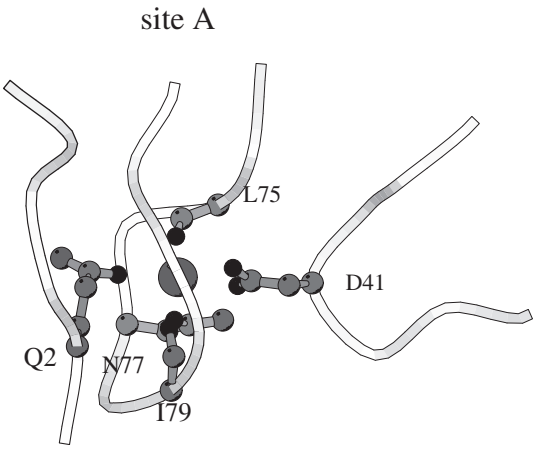

Fig. 29.2. Calcium site A of subtilisin. Ligands to calcium are labeled. From 1SUD in the Protein Data Bank [29].

dence that site B binds calcium comes from determining the occupancy of the site in a series of X-ray structures from crystals grown in 50 mM NaCl with calcium concentrations ranging from 1 to 40 mM [26]. In the absence of excess calcium, this locus was found to bind a sodium ion. The binding of these two ions appears to be mutually exclusive so that as the calcium concentration increases, the sodium ion is displaced, and a water molecule appears in its place directly coordinated to the bound calcium [26]. When calcium is bound, the coordination geometry of this site closely resembles a distorted pentagonal-bipyramid. Three of the ligands are derived from the protein and include the carbonyl oxygen atom of Glu195 and the two side-chain carboxylate oxygens of Asp197. Four water molecules complete the coordination sphere. When sodium is bound, its position is removed by 2.7 Å from that of calcium and the ligation pattern changes. The sodium ligands derived from the protein include a side-chain carboxylate oxygen of Asp197 and the carbonyl oxygen atoms of Gly169, Tyr171, Val174, and Glu195. Two water molecules complete the coordination sphere.

It is not understood how any of these structural features affect folding rate, except for the ion-binding sites. The architecture of site A is the major impediment to folding. Deleting amino acids 75–83 accelerates folding rate by at least 10^7-fold [27–29]. The X-ray structure of the deletion mutant has shown that except for the region of the deleted calcium-binding loop and N-terminal amino acids 1–4, the structure of the mutant and wild-type protein are remarkably similar (Figure 29.3). The structures of SBT with and without the deletion superimpose with an rms difference between 261 Cα positions of 0.17 Å with helix C exhibiting normal helical geometry over its entire length. The deletion also abolishes the calcium binding at site A. As will be discussed below, the formation of calcium site A appears to have a high activation barrier which may contribute to the inability of wild-type SBT to fold.

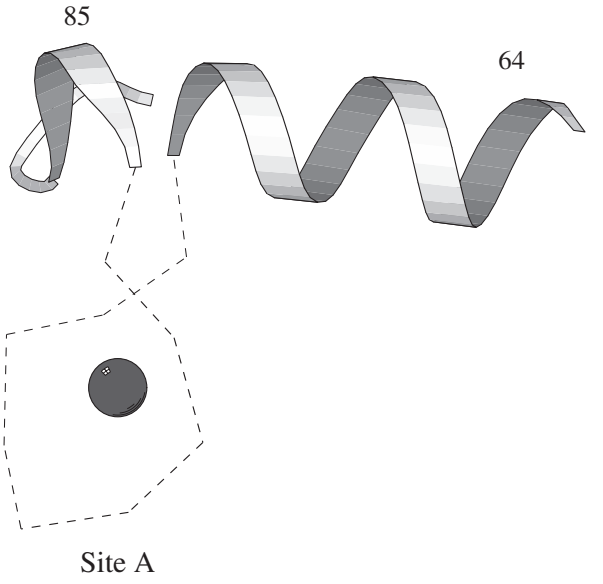

Fig. 29.3. Calcium-binding loop of subtilisin. Region of deletion (75–83) is shown by the dashed line. From 1SUC in the Protein Data Bank [29].

29.3.2 Structure of SBT/Pro-domain Complex

The structure of the native SBT is almost identical in free and complexed states. In the complex, the pro-domain is a single compact domain with an antiparallel four-stranded β-sheet and two three turn α-helices (Figure 29.1) [30, 31]. The β-sheet of the pro-domain packs tightly against the two parallel surface α-helices Asp and Glu (residues 104–116 and 133–144). The pro-domain residues Glu69 and Asp71 form helix caps for the N-termini of the two SBT helices. In another charge-dipole interaction, the carboxylate of Glu112 of SBT accepts H-bonds from the peptide nitrogens of pro residues 42, 43 and 44. The C-terminal residues 72–77 extend out from the central part of the pro-domain and bind in a substrate-like manner along SBT's active-site cleft. Residues Tyr77, Ala76, His75, and Ala74 of the pro-domain occupy subsites S1–S4 of SBT, respectively. If Tyr77 occupies the same position in unprocessed pro-SBT then residues 1–10 of mature SBT would be displaced from their native positions. This hypothetical conformer can be modeled by minor torsional reorganizations involving residues 1–10 with Ala1 and Gln2 of mature SBT occupying the S1′ and S2′ substrate sites. A major consequence for this ''active site'' conformer, is that the calcium site A cannot fully form until after processing because one of the calcium ligands (Gln2) cannot simultaneously bind in the S2′ subsite and bind to calcium in the A-site.

29.3.3
Structure of Free ALP

The overall fold of ALP is of the chymotrypsin type [17]. The fold is typified by the association of two similar domains each consisting of a six-stranded antiparallel β-barrel [32]. The active-site triad occurs in the interface between the domains with His57 and Asp102 in domain 1 and Ser221 in domain 2 (Figure 29.4). Numbering of ALP residues will be given according to the homologous position in chymotrysin. Proteases in this family typically contain multiple intradomain disulfide bonds and ALP contains three. One of these (137–159) is not found in the mammalian enzymes. The structural basis for the inability of ALP to fold independently is not apparent from its basic fold. The activation pathways of trypsin and chymotrypsin do not involve pro-domains but rather small N-terminal activation peptides. In fact active trypsin can be produced in *E. coli* from a gene lacking the hexapeptide activation region [33–35]. Hence the basic fold is not intrinsically problematic for folding. Unique structural features found in ALP and bacterial relatives with pro-domains include a high glycine content (16%) and the extended β-hairpin (167–179). Both features have been suggested as possible impediments to folding [36].

An additional feature which should be noted is a buried salt bridge between Arg138 and Asp194 (Figure 29.4). Asp194 is a key residue in zymogen activation of trypsinogen and chymotrypsinogen. The proteolytic event which creates the mature N-terminus (e.g., Ile16 in chymotrypsin) causes amino acids 189–194 to rearrange into the active conformation [1]. The rearrangement results from a salt bridge formed between the new N-terminus (Ile16) and Asp194. Thus a buried salt bridge occurs in both ALP and mammalian relatives but the burial of the salt bridge in trypsin and chymotrysin follows folding of the zymogen.

29.3.4
Structure of the ALP/Pro-domain Complex

The 166-amino-acid ALP pro-region wraps around the C-terminal half of mature ALP [37]. The contact interface is more than 4000 $Å^2$, almost four-times that of SBT and its pro-domain (Figure 29.4). Most of the contacts to ALP are made with the C-terminal half of the pro-domain (amino acids 65–166) [38], although both N- and C-terminal portions of the pro-domain are required for folding of ALP [39]. Amino acids 160–166 of the pro-domain are inserted like a substrate into the active site, reminiscent of the SBT complex. The edges of a three-stranded β-sheet in the C-terminal part of pro and a β-hairpin (167–179) of ALP abut and form a five-stranded β-sheet in the complex.

As with SBT, the C-terminus of the pro-domain binds tightly in the active site of ALP in the bimolecular complex [37] (Figure 29.4). Thus in the unprocessed molecule, the N-terminus of the active-site conformer would be displaced by 24 Å from

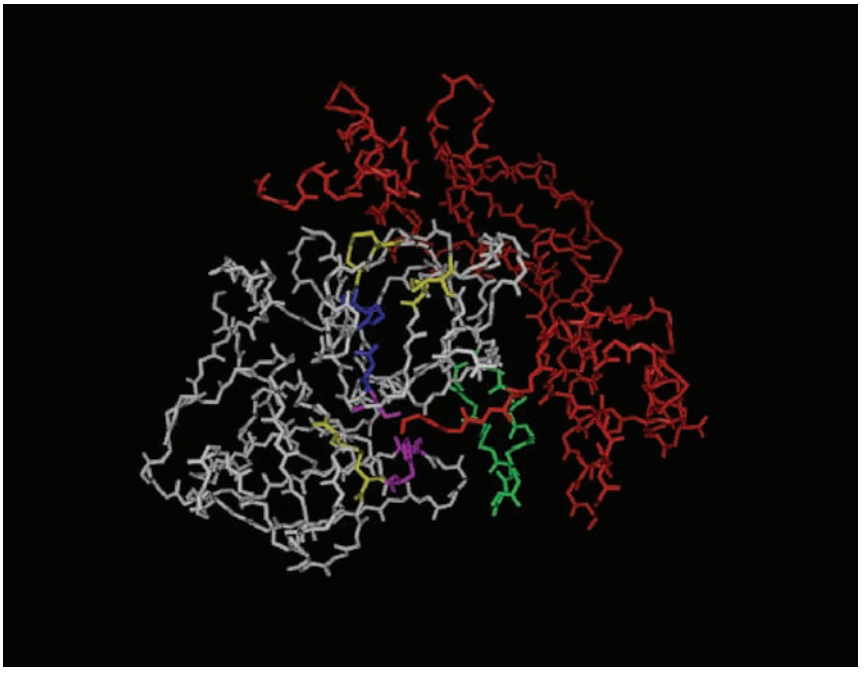

Fig. 29.4. Alpha-lytic protease (white) in complex with its pro-domain (red). Active-site triad is shown in violet; extended β-hairpin 167–179 is shown in green; buried salt bridge Asp194 and Arg138 is shown in dark blue; disulfide bridges are shown in yellow. From 2ALP in the Protein Data Bank [37].

its position in native ALP. Unlike SBT, ALP does not have the complications of metal binding, but it is possible that pro-domain binding organizes Asp194 so that it can form the buried salt bridge with Arg138.

There are some general features of the C-terminal half of the ALP pro-domain that are topologically similar to the SBT pro-domain [38]. Specifically, β-strands 2, 3, 4 and the α-helices connecting strands 1 to 3 and 2 to 4 in the SBT pro-domain have structural counterparts in the ALP pro-domain. Apart from the general similarity of the substrate-binding cleft interactions outlined above, however, there is little similarity in the interactions of pro-SBT and pro-ALP at their binding interfaces with the mature proteases.

ALP pro-domain has no similarity to the small activation peptides of its eukaryotic homologs trypsin and chymotrypsin [1]. The SBT pro-domain on the other hand has high structural homology to the pro-hormone convertase pro-domain, although little sequence similarity [40, 41]. Surprisingly, the SBT pro-domain also has the same basic fold as the pro-domains of eukaryotic carboxypeptidases [42, 43]. This is in spite of the lack of any structural similarity between the mature regions of SBT and the carboxypeptidases.

29.4
Stability of the Mature Protease

29.4.1
Stability of ALP

The most basic folding experiment is determining the free energy of the folding reaction. This is difficult with ALP and SBT because of the problem of establishing equilibrium under conditions in which the ratio of folded and unfolded states can be accurately measured. Denatured ALP diluted into native conditions rapidly collapses into a ensemble of conformations with an average hydrodynamic radius about midway between the native and guanidium chloride (GdmCl)-denatured forms and with almost the same amount of regular secondary structure as native ALP [44]. This collapsed state is stable for weeks at neutral pH without detectable conversion to the native state [44]. The free energy of a two-state reaction can sometimes be determined, however, by (1) measuring a folding rate at a standard state; (2) measuring unfolding rates as a function of denaturant; or (3) extrapolating the unfolding rate to the standard state. From the ratio of the rates of folding and unfolding at the standard state, the free energy of folding is determined. This was the approach taken with ALP [45]. To minimize the influence of autodigestion during the folding reaction, the measurements were made at pH 5.0. As the pH is decreased below the pK_a of the active-site histidine, the proteolytic activity of serine proteases decreases. A pH around 5 is commonly used as a compromise between low activity and preserving some conformational stability [46]. The refolding rate of ALP was determined by incubating denatured protein in native conditions and removing aliquots at intervals. The amount of active ALP was determined by measuring peptidase activity using a synthetic substrate. Over the course of days small but linear increases in activity were detected. Quantitation in the experiment is tricky because the accumulation of active ALP causes digestion of the unfolded protein, but the initial rate of the folding reaction is 6×10^{-12} s^{-1} at 25 °C. This was compared with the unfolding rate which was determined as a function of [GdmCl]. The rate of unfolding without GdmCl was estimated by linear extrapolation to be 1×10^{-7} s^{-1} at 25 °C. Since $\Delta G_{\text{unfolding}} = -RT \ln(k_{\text{unfolding}}/k_{\text{folding}})$ in a two-state system, the simplest interpretation of the unfolding and refolding rates would mean that $\Delta G_{\text{unfolding}}$ is about -6 kcal mol^{-1} at 25 °C.

Even given the uncertainties in determining the folding and unfolding rates, it is convincing that the unfolded state of ALP is more stable than the folded state at pH 5.0. The effect of pH 5.0 on the protonation of Asp194 also may bear consideration. If the formation of the buried salt bridge between Asp194 and Arg138 is involved in the transition state for folding, then partial protonation of Asp194 at pH 5.0 could destabilize its interaction with Arg138 and slow folding significantly.

The stability measurements on ALP were made with the three disulfide bonds intact in all forms, U, I and N. An unstrained disulfide cross-link should stabilize a protein by decreasing the entropic cost of folding. The loss of conformational en-

tropy in a polymer due to a cross-link has been estimated by calculating the probability that the ends of a polymer will simultaneously occur in the same volume element. According to statistical mechanics, the three disulfide bonds in ALP should destabilize the unfolded state by ~10 kcal mol^{-1} at 25 °C [47, 48]. Since the lifespan of a protease depends upon the kinetics rather than the thermodynamics of unfolding, however, disulfide bonds are a surprising feature. The effects of cross-links on the stability of the unfolded state would not generally be manifested in the activation energy of the unfolding reaction, because the transition states for unfolding reactions usually are compact, with a slightly larger heat capacity than the native state. In folding experiments on ALP, the disulfide bonds are present in both the I and N states of the protein and thus do not contribute to the thermodynamic measurements [45, 49].

29.4.2 Stability of Subtilisin

Ion binding has a dominant role in stabilizing SBT. The active-site mutant Ala221 of SBT can be unfolded at 25 °C by incubation in 30 mM Tris-HCl, pH 7.5, 0.1 mM EDTA. The rate of unfolding under these conditions is ~0.5 h [1]. (The S221A mutation reduces proteolytic activity of SBT by about 10^6-fold [50] and eliminates the problem of autoproteolysis during the unfolding process.) Addition of micromolar concentrations of free calcium or millimolar concentrations of sodium will reduce the unfolding rate to $>days^{-1}$. The role of calcium site A in the kinetic stability of SBT is well-documented [51]. SBT with the calcium site A occupied (e.g., 100 mM $CaCl_2$, 100 mM NaCl) unfolds 1000-times slower than the apo-form of SBT (e.g., 1 mM EDTA, 100 mM NaCl) [52] and the activation energy for calcium dissociation from the folded state is 23 kcal mol^{-1}. The binding parameters of calcium at site A have been determined previously by titration calorimetry: $\Delta H_{binding} = -11$ kcal mol^{-1} and $\Delta G_{binding} = -9.3$ kcal mol^{-1} at 25 °C [28]. Thus the binding of calcium is primarily enthalpically driven with only a small net loss in entropy ($\Delta S_{binding} = -6.7$ cal deg^{-1} mol^{-1}). This is surprising since transfer of calcium into water results in a loss of entropy of −60 cal deg^{-1} mol^{-1}. Therefore the freeing of water upon calcium binding to the protein will make a major contribution to the overall ΔS of the process. The gain in solvent entropy upon binding must be compensated for by a loss in entropy of the protein. Loop amino acids 75–83, N-terminal residues 1–5, the ω-loop (36–45) and the β-hairpin (202–219) have increased mobility when calcium is absent from the A-site [27].

Ion site B also influences stability but to a lesser extent. The K_d of site B for sodium is ~1 mM and 15 μM for calcium [52]. By binding at specific sites in the tertiary structure of subtilisin, cations contribute their binding energy to the stability of the native state and should have predictable effects on thermodynamic stability. If cation binding is exclusively to the native state then the contribution of cation binding to the free energy of unfolding would be:

$$\Delta G_{binding} = -RT \ln(1 + K_a\,[\text{cation}])$$

For example, the free energy of unfolding in 1 mM calcium would be increased by 5.5 kcal mol^{-1} due to the influence of binding at the A-site and an additional 2.5 kcal mol^{-1} due to site B, for a total of 8 kcal mol^{-1} per mM calcium (25 °C).

The distinction between thermodynamic and kinetic effects is blurred, however, by the observations of Eder and Fersht showing that a structured intermediate state of SBT can be induced by high salt (1 M KCl or 0.5 M $(NH_4)_2SO_4$) and calcium (1 mM) [53]. Ala221 SBT was denatured in 6 M HCl pH 1.8 and then either dialysed or diluted into refolding buffer around neutral pH. Upon return to native conditions in high salt (e.g., 1.0 M KCl) mature SBT slowly folds into a state reminiscent of the I-state of ALP: hydrodynamic radius intermediate between native and unfolded and a high percentage of secondary structure. Remarkably, the SBT intermediate state binds a stoichiometric amount of calcium with an affinity ≤ 1 μM. No conversion of the intermediate of the native form was detected in the absence of added pro-domain [54]. This experiment has a detection limit of ~1%, which would mean that uncatalyzed folding of mature Ala221 SBT occurs at a rate of $<10^{-8}$ s^{-1}.

If the salt-induced intermediate is part of the relevant folding landscape, this means that the net contribution of cation binding to the thermodynamics of unfolding would be much less than predicted based on exclusive binding to the native state. If high salt is avoided (e.g., $\leq$0.2 M KCl), however, unfolded SBT remains in a largely unstructured state, indicating the compact state may not be populated under more common folding conditions.

The most straightforward demonstration that mature SBT is thermodynamically stable in high salt was achieved by denaturing and renaturing SBT immobilized on agarose beads to prevent autodigestion [55]. Quantitative renaturation was achieved in 24 h in the presence of 2 M potassium salts, indicating that the folding rate under these conditions must be $>10^{-5}$ s^{-1}. The unfolding rate is not known under these conditions, but the $\Delta G_{unfolding}$ must be greater than 2 kcal mol^{-1} since recovery of native activity approaches 100%. This is surprising since Ala221 SBT in solution could not be renatured in high KCl. It should be noted, however, that SBT might be stabilized by immobilization.

Deleting the calcium A-loop creates a subtilisin that is thermodynamically stable at KCl concentrations above 10 mM. The folding rate of the deletion mutant is strongly ionic dependent [28]. In 30 mM Tris-HCl, pH 7.5 the mutant is not observed to fold. As NaCl or KCl is added, the folding rate increases with the log of the salt concentration. In 0.2 M KCl, pH 7.5, the mutant refolds to the native form in a single exponential process ($k_{fold} = 0.0027$ s^{-1}) [56] (Figure 29.5).

In summary, one can conclude that Ala221 SBT with the wild-type calcium loop is thermodynamically unstable at low ionic strength (e.g., 30 mM Tris-HCl pH 7.5, 0.1 M EDTA). Thermodynamic stability increases as calcium and monovalent salts are added but it is not certain under what ionic conditions the $\Delta G_{unfolding}$ exceeds zero because the folding and unfolding rates are so slow.

In spite of whether ALP or SBT is thermodynamically stable under a given set of conditions, their slow folding reactions are not due simply to instability of the folded state. If this were true folding could be thermodynamically driven by adding

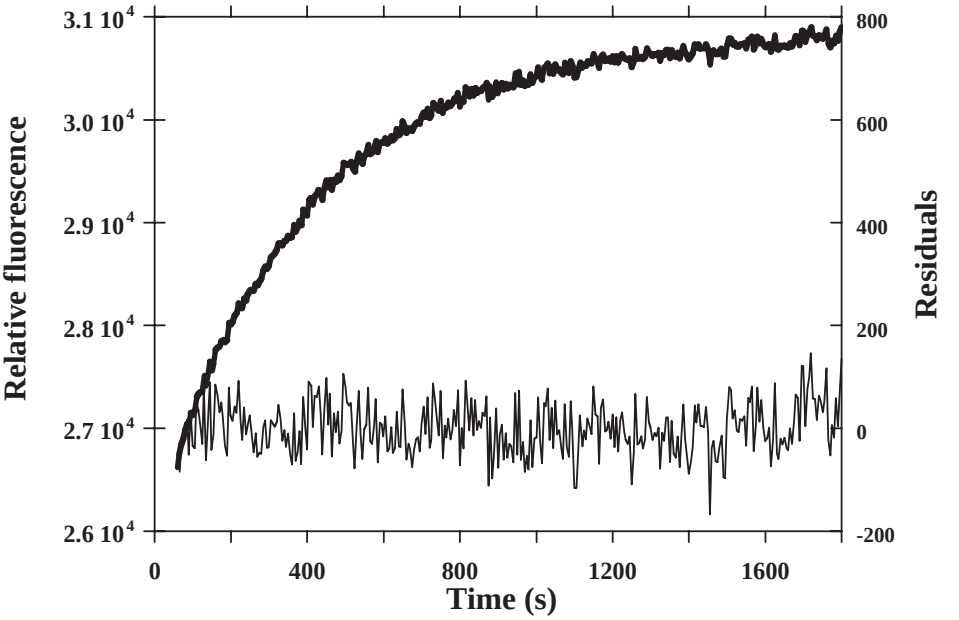

Fig. 29.5. Kinetics of refolding Ala221 Δ75–83 SBT. Refolding in 0.2 M KCl, 30 mM Tris-HCl, pH 7.5, and 25 °C is followed by the increase in tryptophan fluorescence. The curve plotted is the average of three experiments. The residuals after subtracting the data from a single exponential fit ($k = 0.0027\ s^{-1}$) are plotted on a five-times expanded scale.

a ligand which binds tightly and preferentially to the native state. For example, the streptomyces SBT inhibitor protein (SSI) has no detectable influence on the folding rate of SBT even though its binds to SBT more tightly than the pro-domain does [56]. Thus pro-domains must be capable of stablizing some structure in the folding pathway whose formation is limiting in its absence.

29.5
Analysis of Pro-domain Binding to the Folded Protease

$$\mathrm{P} + \mathrm{N} \underset{k_{\mathrm{off}}}{\overset{k_{\mathrm{on}}}{\longleftrightarrow}} \mathrm{P\text{-}N}$$

The SBT pro-domain is a competitive inhibitor of the active enzyme (K_i of 5.4×10^{-7}) [57]. Binding of ALP to its pro-domain is even tighter ($K_i \sim 10^{-10}$) [58]. The high affinity of the pro-domain for the native conformation suggests that its role in folding might be to stabilize native-like structures in the transition state for folding [59]. The details of the complementary interfaces between the respective pro-domains and proteases have been discussed above.

A feature of the isolated pro-domains which influences binding properties is independent stability. The ALP pro-domain is fully folded at 4 °C, independent of binding to ALP [60]. In contrast, the isolated SBT pro-domain is essentially unfolded at all temperatures [56], even though it is a compact globular structured in complex with SBT. This situation suggests that there is thermodynamic linkage between the SBT pro-domain stability and its binding affinity. This linkage can be established by examining the effects of mutations that do not directly affect contacts with the protease but that affect the stability of pro-domain. Although the stability of the isolated pro-domain is low, it has been measured by titration with stabilizing co-solvents and found to have a $\Delta G_{\text{unfolding}} \sim -2$ kcal mol^{-1} at 25 °C [61]. This propensity to fold can be altered by mutations. For example, the mutation I30T in the hydrophobic core of the SBT pro-domain weakens binding to SBT by ~100-fold [62].

A number of mutations have been described that increase the independent stability of the SBT pro-domain with concomitant increases in binding affinity to native SBT [63–67]. Sequentially introducing stabilizing mutations into the pro-domain shifted the equilibrium for independent folding from ~97% unfolded to >98% folded. As the independent stability of the pro-domain increases, the binding affinity for SBT increases concomitantly. The most stable pro-domain mutant bound about ~30-times more tightly than wild-type pro-domain [68]. Since these mutations were introduced in regions of the pro-domain that did not directly contact with SBT, their effects on binding to SBT were linked their to their stabilizing effects on the pro-domain. The linked equilibria for pro-domain folding and binding are:

$$\mathrm{P_u} \overset{K_f}{\leftrightarrow} \mathrm{P} + \mathrm{S} \overset{K_P}{\leftrightarrow} \mathrm{P\text{-}S}$$

where K_f is the equilibrium constant for folding the pro-domain and K_P is the association constant of folded pro-domain for SBT. The observed binding constant is expected to be: $K_{(P+Pu)} = [K_f/(1 + K_f)]K_P$. The data show that as the fraction of folded pro-domain approaches one, the observed association constant approaches its maximum, ~10^{10} M^{-1} [63].

The kinetics of the pro-domain binding to SBT also have been determined by measuring the rate of fluorescence change that occurs upon binding. If the reaction is carried out with a 10-fold or greater excess of P, then one observes a pseudo first-order kinetic process with a rate constant equal to $k_{on}[P] + k_{off}$. The k_{on} for binding the pro-domain to folded SBT is ~10^6 M^{-1} s^{-1} [69]. This value is fairly insensitive to mutations that change the stability of the pro-domain.

29.6 Analysis of Folding Steps

$$\mathrm{P} + \mathrm{U} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathrm{P\text{-}I} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} \mathrm{P\text{-}N}$$

In the kinetic mechanism above, P is pro-domain, P-I is an initial complex between pro-domain and partially folded protease, and P-N is the folded complex of pro-domain and native protease. The reaction has been studied for both SBT and ALP as a function of [P]. Under similar conditions the catalyzed folding of SBT is much slower than that of ALP. For example, adding isolated pro-domain (5 μM) to unfolded Ala221 SBT (5 μM) results in only 50% recovery of the native complex after 8 days at 4 °C [53]. Under similar conditions ALP is expect to fold quantitatively within minutes [44]. At first glance this result suggests that the mechanisms of pro-domain catalyzed folding of ALP and SBT differ in some fundamental way. Closer examination reveals, however, that the mechanisms are more similar than they first appear.

Most of the difference in catalyzed folding rate can be explained by examination of the independent stabilities of the two pro-domains. Recall that the SBT pro-domain is largely unfolded at 25 °C ($\Delta G_{\text{unfolding}} = -2$ kcal mol^{-1}). In comparison, the ALP pro-domain is about 30–40% unfolded at 25 °C ($\Delta G_{\text{unfolding}} \sim 0.3$ kcal mol^{-1}) [60]. Further, the analysis of ALP folding usually is carried out at 4 °C, where its pro-domain is essentially fully folded. The affect of pro-domain stability on catalyzed folding can be seen by examining mutants of the SBT pro-domain which stabilize its independent folding. These mutants were selected based on examination of the X-ray structure of the pro-domain SBT complex and none of the mutations directly contact SBT. Using a fully folded pro-domain mutant (denoted proR9) the kinetics of the conversion of U + P to P-N were determined as a function of [P] ranging from 5 μM to 100 μM [69]. When the concentration of pro-domain is high relative to protease, the kinetics of a single turnover of folding are pseudo first order. The observed rate of folding can be explained by a rapid equilibrium model where k_{-1} is large relative to k_2. In this model, the equilibrium constant K_1 is equal to [P-I]/[U][P]. Since $[\text{P-I}]/[\text{P}_{\text{total}}] = \text{K}_1[\text{P}]/(1 + \text{K}_1[\text{P}])$, the observed rate of formation of P-N would be equal to

$$\{k_2 K_1[\text{P}]/(1 + K_1[\text{P}])\} + k_{-2}$$

At micromolar concentrations of pro-domain, the complex P-I reaches saturation and the reaction is limited by the folding of P-I to P-N. The rate of the isomerization step (k_2) is 0.1 min^{-1} for the folding Ala221 SBT and the stabilized pro-domain proR9 (Ruan and Bryan, unpublished). The kinetics of this reaction are unaffected by either calcium (≤ 100 mM) or EDTA (≤ 10 mM) even though these salts greatly affect the stability of the product.

For ALP folding the concentration dependence of the rate also follows a binding hyperbola, with $K_1 = 23$ μM [60]. The maximum rate of the reaction (k_2) is 0.03 s^{-1}. It appears from the plots that k_{-2} is very small compared with k_2.

Analysis of mutations of the ALP pro-domain indicate that interactions at or near the active site are involved in stabilizing the transition state between the initial complex and the native complex [49, 60]. In contrast these interactions have less effect on the stability of the initial complex (P-I). For example, successive deletions of the last four amino acids of the pro-domain decrease k_2 on average

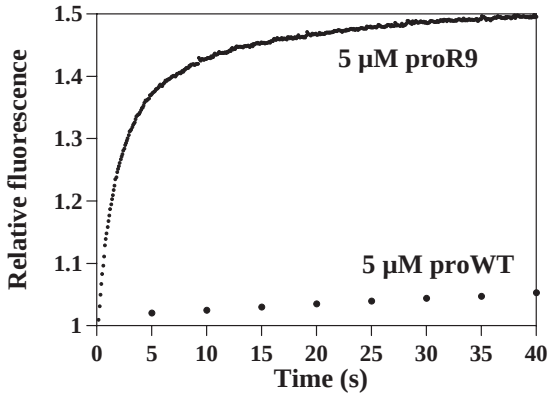

Fig. 29.6. Folding rate of Ala221, Δ75–83 SBT in the presence of the wild-type pro-domain and proR9. Pro-domain (5 μM) and 1 μM denatured SBT mutant were mixed in 5 mM KPO_4, 30 mM Tris pH 7.5 at 25 °C. The reaction was followed by the increase in tryptophan fluorescence which occurs upon folding of SBT into the pro-domain SBT complex.

>10-fold for each lost amino acid. Effects of K_1 are not detectable until three or more amino acids are deleted. Recall that these amino acids bind to ALP in a substrate-like manner (Figure 29.4). It is tempting to speculate that the reduction of k_2 is due to the diminished capacity of the deletion mutants to organize the 189–194 loop.

The catalyzed folding reaction of SBT has also been analyzed using an A221 mutant which lacks the calcium binding loop of site A and which folds more rapidly than wild-type SBT. Using wild-type pro-domain as catalyst, the rate of SBT folding increases linearly as a function of [P] ($[P] \leq 100$ μM) [56]. The absence of curvature in the plot implies that the formation of the initial complex, P-I, is the limiting step in the reaction up to $[P] = 100$ μM. These results indicated that initial association of wild-type pro-domain with Δ75–83 SBT is weak. As the pro-domain is stabilized, the folding reaction becomes faster and distinctly biphasic (Figure 29.6). The fast phase of the reaction corresponds to the second-order binding step (1×10^5 M^{-1} s^{-1}) and the slow phase to the isomerization step (0.15 s^{-1}). With the folded pro-domain proR9 the maximum isomerization rates for SBT and Δ75–83 SBT are similar (~0.1 s^{-1}).

It was possible to demonstrate that proline isomerization is rate limiting in folding Δ75–83 SBT. There are 13 proline residues in SBT. All but one (Pro168) exist as *trans* isomers in the native structure [25]. The peptide bond between proline and its preceding amino acid (Xaa-Pro bonds) exist as a mixture of *cis* and *trans* isomers in solution unless structural constraints, such as in folded proteins, stabilize one of the two isomers. In the absence of ordered structure, the *trans* isomer is favored slightly over the *cis* isomer. The isomerization *trans* ↔ *cis* is an intrinsically slow reaction with rates at 0.1–0.01 s^{-1} at 25 °C. Upon denaturation of SBT, the structural constraints are removed and the *trans* and *cis* isomers of all 13 prolyl peptide

bonds gradually come to equilibrium in the unfolded state, resulting in 2^{13} different proline isomer combinations. To study the catalyzed folding rate of SBT in the absence of prolyl peptide bond isomerization, folding kinetics were measured after a short denaturation time [70]. The Δ75–83 SBT mutant used in these studies can be denatured in acid in <1 s. The rapid denaturation time minimizes the amount of prolyl peptide bond isomerization occurring during the time require to unfold. In the absence of proline isomerization, the observed rate of folding increases as concentration of pro-domain increases, and follows a linear relationship with no intermediate detectable in the course of the reaction. This occurs because the formation of P-N from P-I is faster than the formation of initial collision complex P-I from P and U. The mechanism of folding reaction for denatured Δ75–83 SBT with native proline isomers is as follows:

$$\mathrm{P} + \mathrm{U} \underset{<0.05\ \mathrm{s}^{-1}}{\overset{9\times10^{4}\ \mathrm{M}^{-1}\ \mathrm{s}^{-1}}{\rightleftharpoons}} \mathrm{P\text{-}I} \underset{<0.01\ \mathrm{s}^{-1}}{\overset{>3\ \mathrm{s}^{-1}}{\rightleftharpoons}} \mathrm{P\text{-}N}$$

where U is denatured SBT with all prolyl peptide bond isomers the same as in the native structure. According to the mechanism proposed above, the pseudo first-order rate constant would reach its maximum when [P] is high enough that the value $k_1 \cdot [\mathrm{P}] > (k_2 + k_{-2})$. That point has not been reached at [P] = 20 μM. Thus, in the presence of an independently folded pro-domain mutant, the rate of SBT folding into a complex becomes typical of in vitro folding rates for many small globular proteins. That is, independent of proline isomerization, folding is largely complete within a few seconds [71].

In comparison, the rate of ALP folding plateaus at 0.03 s^{-1}, which is in the range of proline isomerization. ALP has three *trans* and one *cis* proline. It is not known how proline isomerization is involved in the kinetics of the P-I to P-N transition, however.

29.7 Why are Pro-domains Required for Folding?

The question remains as to why folding is so slow without the pro-domain. An efficient folding pathway implies that productive intermediates are significantly more stable than the surrounding landscape of unfolded conformations. Native state H-D exchange experiments for several proteins have shown that partially folded states exist with significantly lower energy than the globally unfolded state [72–74]. Native state H-D exchange experiments for ALP [75] and SBT (Sari et al., unpublished), show highly cooperative exchange behavior. Amides protons in all elements of secondary structure exchange with solvent deuterons at a rate in the range of $year^{-1}$. In ALP, there are 103 amide protons with protection factors $> 10^4$ and 31 amide proton with protection factor $> 10^9$. The most protected protons occur throughout both domains of ALP. In comparison, there are 131 protons in SBT with protection factors $\geq 10^5$. The 49 slowest exchangers have protection factors $\geq 10^9$. These strongly protected residues occur throughout the main structural elements of SBT, except for the short N-terminal α-helices, A and B, and

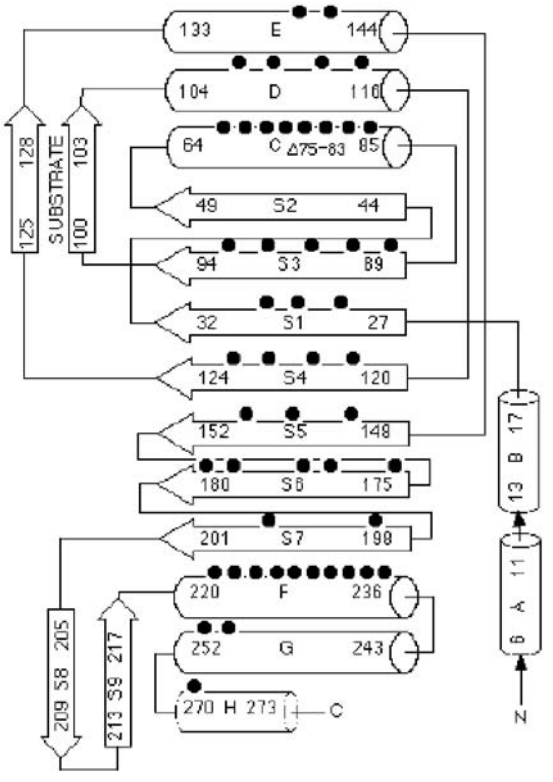

Fig. 29.7. Schematic representation of the subtilisin topology. The positions of the 49 slowest exchanging amide protons in SBT are shown by black dots. The slowest 49 exchanging protons reside throughout the central seven-stranded parallel β-sheet and in all the five major α-helical segments. Adapted from Siezen et al. [85].

strands, β8 and β9 (Figure 29.7). The large cooperative folding core may create a folding problem, because most of the tertiary structure must be acquired before a free energy well is encountered in conformational space. The enormous loss of conformational entropy before that energy well occurs would result in a large transition state barrier to folding [66, 75]. In this model, the transition state of uncatalyzed folding is of high energy because of its low conformational entropy. The prodomain decreases the entropic barrier by pushing the transition state back toward a less folded form of the proteinase. Thus much less conformational entropy is lost in the transition state. Once over the barrier, folding of P-I to P-N is rapid.

29.8
What is the Origin of High Cooperativity?

Formation of the calcium A-site may be responsible for the cooperative folding reaction of SBT. SBT is unstable in the absence of calcium and at low ionic strength.

Addition of calcium increases stability by 8 kcal mol^{-1} per mM but does accelerate the folding reaction to an observable level. The reason that the calcium does not affect folding rate may be that site A is not fully formed until considerable tertiary structure has accrued. The structure elements involved in forming the A-site are the N-terminus, the ω-loop, the 75–83 loop and the 202–219 β-hairpin. Thus calcium binding may not contribute to the stability of intermediately folded states but only to a substantially folded molecule. This situation creates a highly cooperative folding reaction. In addition, the burial of the charged calcium and the requirement for its desolvation prior to burial within the protein creates an additional kinetic barrier to folding. This suggestion is supported by the observation that the Δ75–83 mutant SBT folds $\geq 10^7$-times faster than SBT with the calcium A-site intact.

The origins of high cooperativity in ALP may also be related to a buried ionic interaction: the formation of the buried salt bridge between Arg138 and Asp194. Formation of a structurally homologous ionic interaction is involved in zymogen activation in trypsin and chymotrypsin.

Buried ionic interactions have been implicated previously in raising the activation barrier to folding because of unfavorable protein–solvent rearrangements. For example, replacing a buried salt bridge in ARC repressor dimer with a hydrophobic cluster has little effect on thermodynamic stability but increases the folding rate of the dimer by up to 1000-fold [76, 77]. Desolvating these charged residues in ALP may raise kinetic but not necessarily the thermodynamic barriers to unfolding.

29.9
How Does the Pro-domain Accelerate Folding?

The simplest model of catalyzed folding is one in which the pro-domain accelerates folding by stabilizing a substructure on the folding pathway which does not form frequently in the absence of pro-domain binding. Once the substructure forms, it acts as a folding nucleus with subsequent folding propagating into other regions. The nature of this substructure can be guessed at based on the structures of the folded complexes. In the bimolecular SBT complex, the pro-domain binds to an α–β–α structure (amino acids 100–144) which includes the parallel surface α-helices D and E. It also supplies caps to the N-termini of the two helices (Figure 29.1). In the intermediate P-I, the pro-domain may stabilize the α–β–α structure relative to other unfolded states. Subsequent folding may propagate from this folding nucleus into N- and C-terminal regions of SBT. In the absence of the pro-domain, the α–β–α structure may not have sufficient independent stability to initiate folding very frequently. It should be noted that unimolecular folding of proSBT may circumuvent the problem of calcium A-site formation. The covalent attachment of the pro-domain to SBT prevents the final folding of the calcium A-site region, until after the active site is sufficiently formed to cleave the pro-domain from the mature [30, 78].

In ALP, the pro-domain may stabilize the formation of a long β-hairpin (118–

130) in the C-terminal half of ALP [36, 37] but may also be involved in organizing the 189–194 loop through the interaction of the C-terminus of the pro-domain with the active-site Ser195.

29.10
Are High Kinetic Stability and Facile Folding Mutually Exclusive?

Broad specificity proteinases must be resistant to unfolding. Assuming that partially folded intermediates are good substrates for autolysis, the half-life of active protease would be determined by the equilibrium between the proteinase-resistant native state and the lowest energy, proteinase-labile intermediate [28, 36, 75, 79]. Thus to avoid autolysis, partially folded conformations must be of much higher energy than the native state so that excursions between the two states are rare. Since partially folded states with significant independent stability are important intermediates in the folding pathway of many proteins does resistance to partial unfolding cause proteins to be hard to fold? The answer appears to be not necessarily.

It has been possible artificially to evolved the facile-folding Δ75–83 SBT into a protease which is hyperstable and facile-folding [80, 81]. The initial deletion mutant is unfolds 100-times faster than wild type in 100 mM calcium, but deleting the loop creates the potential to use facile-folding structural solutions for stabilization. Four regions of subtilisin are directly affected by the deletion of the calcium loop: the N-terminal amino acids 1–5; the ω-loop amino acids 36–45; the α-helix amino acids 70–74; the β-ribbon amino acids 202–219. As a result the naturally occurring amino acids in these regions were not optimal for stability in the loop-deleted subtilisin. Residues in these regions were randomized and stabilizing mutations were selected in five iterations [80]. The final result was a mutant which unfolds 1000-times slower than wild-type SBT in 100 mM calcium [81] but, nevertheless, has an uncatalyzed folding rate of 0.02 s^{-1}. This protease can be expressed at high levels through its natural biosynthetic pathway in *Bacillus*, although obviously its long-term evolutionary fitness is unknown. The fact that facile folding and high kinetic stability are not mutually exclusive in the SBT fold suggests that the inability of wild-type SBT and ALP to fold without their pro-domains may be part of the mechanism to regulate the timing of protease activation. It is also possible that when evolution of the folding unit is uncoupled from the sequence of the mature enzyme that the facile folding of the mature enzyme is easily lost.

29.11
Experimental Protocols for Studying SBT Folding

29.11.1
Fermentation and Purification of Active Subtilisin

Subtilisin BPN′ and active mutants were expressed in *B. subtilis* in a 1.5-L New Brunswick fermenter at a level of ~500 mg L^{-1}. After fermentation 16 g of Tris–

base and 22 g of $CaCl_2$ (dihydrate) were added to ~1400 mL of broth. Cells and precipitate were pelleted into 250-mL bottles by centrifugation at 12 000 *g* for 30 min, 4 °C. Acetone (70% final volume) was added to the supernatant. The 70% acetone mixture was then centrifuged in 500-mL bottles at 12 000 *g* for 30 min, 4 °C. The pellet was resuspended in ~150 mL 20 mM HEPES, pH 7.0, 1 mM $CaCl_2$. Resuspended material was centrifuged at 12 000 *g* for 10 min, 4 °C to remove insoluble material. Using a vacuum funnel, the sample was passed over 150 g DE52, equilibrated in 20 mM HEPES, pH 7.0. The DE52 was washed twice with 150 mL 20 mM HEPES, 1 mM $CaCl_2$ buffer and the all washes pooled. Solid NH_4SO_4 was added to the sample to a final concentration of 1.8 M. Final purification was carried out using a 2 × 30 cm Poros HP 20 column on a Biocad Sprint. The sample was loaded and washed in 1.8 M NH_4SO_4, 20 mM HEPES, pH 7.0 and then eluted with a linear gradient (1.8–0 M NH_4SO_4 in 20 mM HEPES, pH 7.0). Subtilisin BPN′ eluted at a conductivity of 108 mS. Assays of peptidase activity were performed by monitoring the hydrolysis of sAAPF-pNA [82]. The [subtilisin] was determined using 1 mg mL^{-1} = 1.17 at 280 nm.

29.11.2
Fermentation and Purification of Facile-folding Ala221 Subtilisin from *E. coli*

Mutagenesis and protein expression of inactive Δ75–83 SBT mutants were performed using a vector called pJ1. Vector pJ1 is identical to pG5 [83] except that the *Cla*I site of pG5 has been removed. The SBT gene was inserted between *Nde*I and *Hin*dIII sites in the polycloning site of pJ1 and transformed into *E. coli* production strain BL21(DE3).

The transformed production strain BL21(DE3) was plated out on selection plates. Ten milliliters of 1LB broth (10 g of tryptone, 5 g of yeast extract, 10 g of NaCl L^{-1} media) supplemented with 100 μg mL^{-1} ampicillin was inoculated with 4–6 ampicillin-resistant colonies in a 250-mL baffled flask. The culture was grown at 37 °C, 300 rpm, until mid-log phase. This culture was used to inoculate 1.5 L of L Broth buffered with 2.3 g of KH_2PO_4, 12.5 g of K_2HPO_4 L^{-1} media supplemented with 100 μg mL^{-1} ampicillin. The culture was grown at 37 °C in a BioFlo Model C30 fermenter (New Brunswick Scientific Co., Edison, NJ, USA) until an A_{600} 1–1.2 was attained, upon which 1 mM IPTG was added to induce the production of T7 RNA polymerase that directs synthesis of target DNA message. Three hours after induction, the cells were harversted by centrifugation for 30 min at 4 °C, 10 000 rpm in a J2–21 centrifuge (Beckman Instruments, Fullerton, CA, USA) with a JA-14 rotor.

E. coli paste from a 1.5-L fermentation (~5 g) was resuspended in 50 mL lysis buffer (50 mM Tris-HCl pH 8.0/100 mM NaCl/1 mM EDTA) and PMSF was added to a final concentration of 1 mM and DNase I (in 40 mM Tris-HCl, 1 M $MgCl_2$) to 20 μg mL^{-1}. The cells were lysed by two passes through a French Press and additional DNase I was added to a final concentration of 25 μg mL^{-1}. Inclusion bodies containing mutant SBT were recovered by centrifugation at 10 000 *g*, 4 °C with a JA-17 rotor for 20 min in a Beckman J2-21 centrifuge. The resulting pellet was

washed three times by repeated resuspension in 60 mL of ice-cold 20 mM HEPES, pH 7.0, and centrifugation for 10 min at the same condition as above. The final pellet was then resuspended in 50 mL of ice-cold 20 mM HEPES, pH 7.0, containing 2 M urea, frozen on dry ice and allowed to thaw at room temperature to clarify the solution. If a precipitate formed, the volume was increased and the freeze/thaw cycle was repeated. The solution then was centrifuged for 10 min and the supernatant applied to a Productive DE cartridge (Metachem Technologies Inc., Torrance, CA, USA) equilibrated with 20 mM HEPES, pH 7.0/2 M urea. The cartridge was washed with 40 mL of cold 20 mM HEPES, pH 7.0/2 M urea. Flow through and wash fractions were combined and dialyzed 36–48 h at room temperature against 3.5 L of 100 mM KPi, pH 7.0 to fold the SBT.

An affinity agarose column was prepared by coupling the tetrapeptide A-L-A-L (Sigma, St. Louis, MO, USA) to Affi-Gel 10 (Bio-Rad, Hercules, CA, USA) following the manufacturer's protocol. The DE cartridge-purified protein was split and each half loaded onto a 4.5-mL column of A-L-A-L-agarose equilibrated with 20 mM HEPES, pH 7.0. The column was washed with 20 mL of 20 mM HEPES, pH 7.0/1 M NaCl followed by 10 mL of 20 mM HEPES, pH 7.0 and the protein was eluted with 50 mM of triethylamine, pH 11.1. Peak fractions (1 mL each) of the protein were immediately neutralized by the addition of 0.1 mL of 1 M KPi, pH 7.0 and pooled together, then dialyzed overnight against 3.5 L of 2 mM ammonium carbonate. Peak fractions were checked on SDS-polyacrymide (SDS-PAGE) gels (Novex Experimental Technoolgy, San Diego, CA, USA). The desired fractions were pooled and dialyzed against 2 mM ammonium bicarbonate, pH 7.0 at 4 °C. After lyophilization, the protein sample was stored at –20 °C.

29.11.3
Mutagenesis and Protein Expression of Pro-domain Mutants

The gene fragment encoding the 77-amino-acid pro-domain was cloned into vector pJ1. When superinfected with helper phage M13K07, the M13 origin enables the DNA replication in single-stranded form for mutagenesis and sequencing. Mutagenesis of the cloned pro-domain gene was performed according to the oligonucleotide-directed in vitro mutagenesis system, version 2, Sculptor system (Amersham International plc., Bucks, UK) or Kunkel dUTP incorporation method [84, 85]. *Escherichia coli* TG1 [K12, Δ(*lac-pro*), *sup*E, *thi*, *hsdD5*/F′traD36, *pro*A + B$^+$, *lacI*^{q}, *lacZ*ΔM15] was obtained from the oligonucleotide-directed in vitro mutagenesis system version 2 (Amersham International plc.). Competent *E. coli* TG1 cells were transformed with mutagenesis product and single-stranded phagemid DNA was then prepared from TG1 cells superinfected with helper phage, while double-stranded phagemid DNA was isolated using Wizard Plus Minipreps DNA Purification System. Phagemid DNA was sequenced as described in Sequenase Protocol (United States Biochemical, Cleveland, OH, USA), using either single-stranded or double-stranded phagemid DNA. Upon confirmation of the mutations, the mutant double-stranded phagemid DNA was used to transform the *E. coli* production strain BL21(DE3)[F$^-$, *hsdS*, *gal*] [86], BL21(DE3) cells contain

the bacteriophage T7 gene 10 which encodes the bacteriophage T7 RNA polymerase. Gene 10 is under the control of *lac* UV5 promoter, inducible by IPTG.

29.11.4 Purification of Pro-domain

Fermentation of of pro-domain was carried out in *E. coli* as described for SBT. Pro-domain was purified using a freeze-thaw method to release soluble protein from the cells [84]. *E. coli* paste from a 1.5-L fermentation (~5 g) was suspended in 10 mL of cold phosphate-buffered saline (PBS) and 20 mL water. PMSF was added to a final concentration of 1 mM, DNase I to 10 μg mL^{-1}, and the oxidized form of glutathione (100 mg in 1 mL total volume of 100 mM KPi, pH 7.0) to 1.6 mg mL^{-1}. The resuspension was frozen by submerging in a dry-ice/ethanol bath until it was completely frozen, and then thawed in a room temperature water bath. This cycle was repeated two additional times, with addition of 100 μL glutathione stock solution before each cycle. The final mixture was centrifuged at 4 °C for 10 min at 10 000 rpm in a J2-21 centrifuge (Beckman Instruments) with a JA-14 rotor. The supernatant containing the soluble protein was diluted four-fold with 20 mM HEPES, pH 7.0, and further purified as described [56]. The concentration of proR9 was determined by UV absorbance using 1 mg $mL^{-1} = A_{275}$ of 0.67.

29.11.5 Kinetics of Pro-domain Binding to Native SBT

The rate of binding of the pro-domain to folded SBT was monitored by fluorescence (excitation $\lambda = 300$ nm, emission λ, 340 nm cutoff filter) using a KinTek Stopped-Flow Model SF2001. The reaction was followed by the 1.2-fold increase in the tryptophan fluorescence of SBT upon its binding of the pro-domain [56]. Pro-domain solutions of 10–160 μM in 30 mM Tris-HCl, pH, 5 mM KPi, pH 7.5 were mixed with an equal volume of 2 μM subtilisin, 30 mM Tris-HCl, pH, 5 mM KPi, pH 7.5 in a single mixing step. Typically 10–15 kinetics traces were collected for each [P]. Final [SBT] was 1 μM and final [P] were 5–80 μM.

29.11.6 Kinetic Analysis of Pro-domain Facilitated Subtilisin Folding

29.11.6.1 Single Mixing

Refolding of subtilisin is accompanied by a 1.5-fold increase in the tryptophan fluorescence of subtilisin upon folding into its complex with the pro-domain. There are three tryptophan residues in the subtilisin mutants and none in pro-domain. Reaction kinetics were measured using a KinTek Stopped-Flow Model SF2001 (excitation $\lambda = 300$ nm, emission: 340 nm cutoff filter) as described [61]. A stock solution of subtilisin at a concentration of 100 μM in 100 mM KPi, pH 7.0 was pre-

pared for refolding studies. Subtilisin was denatured by diluting 20 μL of the stock solution into 1 mL of 50 mM HCl. The samples were neutralized by mixing the subtilisin and HCl solution into an equal volume of 60 mM Tris-base, pH 9.4, KPi and pro-domain in the KinTek Stopped-flow (final buffer concentrations were 30 mM Tris-HCl, pH, 5 mM KPi, pH 7.5). The final concentration of subtilisin was 1 μM, while the pro-domain concentration was varied from 5 to 20 μM. Typically 10–15 kinetics traces were collected for each [P].

29.11.6.2 **Double Jump: Renaturation–Denaturation**

The kinetics of the formation of the folded complex, PS, were determined by a double-jump renaturation-denaturation experiment. The KinTek Stopped Flow in the three syringe configuration was used to perform the two mixing steps. In the first mixing step, 3 μM subtilisin in 50 mM HCl is mixed with a variable concentration of pro-domain in 60 mM Tris-base and KPi. The resulting solution is 30 mM Tris-HCl, 5 mM KPi, pH 7.5. The final concentration of subtilisin was 1.5 μM, while the pro-domain concentration was varied from 5 to 20 μM after the first mixing step. Subtilisin and pro-domain are allowed to fold under native conditions in the delay line of the stopped-flow instrument for aging times ranging from 0.5 to 60 s. After the prescribed aging time the subtilisin/pro-domain solution is mixed 2:1 with 0.1 M H_3PO_4 to bring the pH to 2.3. Fluorescence data for the denaturation of folded complex was collected after the second mixing step. At each renaturation time point, the denaturation curve was fit to a single exponential decay curve. The amplitude of the decay curve was recorded as a function of refolding time to assess the amount of folded complex which had accumulated at each renaturation time. Typically 10–15 kinetics traces were collected for each renaturation time point.

29.11.6.3 **Double Jump: Denaturation–Renaturation**

A double jump denaturation–renaturation experiment was used to study the effect of denaturation time on the rates and amplitudes of the folding reaction. The KinTek Stopped Flow in the three syringe configuration was used to perform the two mixing steps. In the first mixing reaction 3 μM of subtilisin and 30 μM proR9 in 0.05 M KPi, pH 7.2 was denatured by mixing with an equal volume of 0.1 M phosphoric acid. The resulting solution has a pH of 2.15. The denaturation reaction was aged for varied lengths of time and then mixed with one-half volume of 0.15 M KPO_4, pH 12.0. The final conditions were 1 μM of sbt15 and 10 μM of proR9 in 0.1 M KPi, pH 7.2, at 25 °C. The folding process is then followed by fluorescence change.

A second double mixing denaturation–renaturation experiment was used to follow folding kinetics after 0.5 s of denaturation. The two mixing steps were performed using a BioLogic SFM-4 Q/S in the stopped flow mode. In the first step, 2 μM SBT in 10 mM KPi, pH 7.2 is mixed with an equal volume of 100 mM HCl. The resulting solution is 1 μM SBT, 50 mM HCl, 5 mM KPi, pH 2.1. After 0.5 s, the denatured SBT solution is mixed with an equal volume of 60 mM Tris-base, 5 mM KPi and variable amounts of proR9. The resulting solution is 0.5 μM SBT,

5–20 μM proR9, 30 mM Tris-HCl, 5 mM KPi, pH 7.5. The renaturation process is followed by fluorescence change.

29.11.6.4 Triple Jump: Denaturation–Renaturation–Denaturation

A triple mixing denaturation–renaturation–denaturation experiment to measure directly the accumulation of native complex after a denaturation time of 0.5 s. The three mixing steps were performed using a BioLogic SFM-4 Q/S in the stopped flow mode. In the first step, 5 μM SBT in 10 mM KPi, pH 7.2 is mixed with an equal volume of 100 mM HCl. The resulting solution is 2.5 μM SBT, 50 mM HCl, 5 mM KPi, pH 2.1. After 0.5 s, the denatured SBT solution is mixed with an equal volume of 60 mM Tris-base, 5 mM KPi and 10 μM proR9. The resulting solution is 1.25 μM SBT, 5 μM proR9, 30 mM Tris-HCl, 5 mM KPi, pH 7.5. SBT and proR9 are allowed to fold under native conditions in the delay line for aging times ranging from 0.5 to 60 s. After the prescribed aging time the SBT-proR9 solution is mixed 3:1 with 0.132 M H_3PO_4 to bring the pH to 2.3 and denature the folding reaction. At each renaturation time point, the denaturation curve was fit to a single exponential decay curve. The amplitude of the decay curve was recorded as a function of refolding time to assess the amount of folded complex which had accumulated at each renaturation time.

The Thermodynamics and Kinetics of Collagen Folding

Hans Peter Bächinger and Jürgen Engel

30.1
Introduction

30.1.1
The Collagen Family

The human collagen family of proteins now consists of 27 types. The individual members are numbered with roman numerals. The family is subdivided in different classes: The fibrillar collagens (types I*, II, III, V*, XI*, XXIV, and XXVII), basement membrane collagens (type IV*), fibril-associated collagens with interrupted triple helices (FACIT collagens, types IX*, XII, XIV, XVI, XIX, XX and XXII), short chain collagens (types VIII* and X), anchoring fibril collagen (type VII), multiplexins (types XV and XVIII), membrane-associated collagens with interrupted triple helices (MACIT collagens, types XIII, XVII, XXIII, and XXV), and collagen type VI*. The types indicated by an asterisk are heterotrimers, consisting of two or three different polypeptide chains. All others consist of three identical chains or the chain composition is unknown. For type IV collagens six different polypeptide chains are known that form at least three distinct molecules and type V collagens contain three polypeptide chains in probably three molecules. The common feature of all collagens is the occurrence of triple helical domains with the repeated sequence -Gly-Xaa-Yaa- in the primary structure and the high content of proline and hydroxyproline residues. This sequence allows for the formation of a tertiary structure consisting of three polypeptide chains in a left-handed polyproline II helix. The three chains form a right-handed supercoiled triple helix, which is stabilized by hydrogen bonds. The glycine residues in every third position are packed tightly in the center of the triple helix. The residues in the Xaa and Yaa positions are exposed to the solvent and are often proline and hydroxyproline, respectively. All collagens are extracellular matrix proteins responsible for the architecture of connective tissues, such as bone, tendon, cartilage, skin, and basement membranes. Besides their structural roles, collagens interact with numerous other molecules and are crucial for development and homeostasis of connective tissue.

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

30.1.2 Biosynthesis of Collagens

The biosynthesis of procollagens is now fairly well understood at least for the most abundant fibrillar collagens [1, 2]. The current hypothesis of fibrillar procollagen biosynthesis involves the following steps:

1. Translocation of the emerging N-terminal end of the pro-α-chains into the rER.
2. Soon after the synthesis of the N-terminal propeptide, this domain folds and forms intrachain disulfide bonds. HSP47, a collagen-specific heat shock protein, may specifically bind to the N-terminal propeptide, but additionally has binding sites along the helical portion of the molecule.
3. The synthesis continues and some of the proline residues become hydroxylated by prolyl 4-hydroxylase (EC 1.14.11.2) and prolyl 3-hydroxylase (EC 1.14.11.7). During the continued synthesis of the major helical sequences, some interactions with molecular chaperones take place to prevent premature triple helix formation. Some lysine residues are hydroxylated by lysyl hydroxylase (EC 1.14.11.4).
4. After completion of the synthesis of the C-terminal propeptide, this part of the molecule folds, forms intrachain disulfide bonds, and interacts directly or indirectly (with a docking molecule) with the lipid bilayer of the rER.
5. Selection and association of the correct chains occur by diffusion of the C-terminal propeptides attached to the rER membrane.
6. A nucleus for triple helix formation is formed that aligns the chains in the right order. This nucleus initiates triple helix formation and is between propeptides stabilized by interchain disulfide bonds being formed, a reaction probably catalyzed by protein disulfide isomerase (PDI). In mutations of the C-terminal propeptides, an association with GRP78/BiP is found, indicating a potential role for GRP78/BiP in the assembly of procollagen chains.
7. Hydroxylation of proline residues and some lysine residues continues and triple helix formation proceeds from the C-terminal end towards the N-terminal end. The fast propagation of the triple helix formation is followed by a slower folding determined by *cis* peptide bond isomerization at proline residues. These peptide bonds need to be isomerized into *trans* conformation to allow triple helix formation to continue. This step is catalyzed by peptidyl-prolyl *cis-trans* isomerases (PPIases).
8. After completion of the folding of the major helix, the N-terminal propeptides associate and form the small triple helix within this domain. Further modifications occur during the transport through the Golgi stack by cisternal maturation. The long-standing problem of how a 300-nm-long procollagen molecule is transported to the Golgi in 50-nm transport vesicles has recently been investigated [3, 4]. Procollagen traverses the Golgi stack without leaving the lumen of the cisternae, but rather is transported by cisternal maturation. Nothing is known about what proteins direct that process.

The rate of synthesis of procollagen chains was measured for type I and II collagen, and found to be 209 residues per minute [5, 6]. For a fibrillar procollagen mol-

ecule, the synthesis time then is about 7 min. The time for secretion was 30 min when analyzed in bone [7] and biphasic secretion kinetics with half-times of 14 and 115 min were found in fibroblasts [8].

30.1.3 The Triple Helical Domain in Collagens and Other Proteins

The length of the triple helix in fibrillar collagens is about 300 nm and consists of 330–340 Gly-Xaa-Yaa tripeptide units. These molecules can be described as semi-rigid rods, well suited for the formation of fibrils. The fibrils have an axial 67-nm periodicity, which results from electrostatic and hydrophobic sidechain interactions [9]. In other collagens, stretches of tripeptide units are interspersed by interruptions, making these molecules more flexible. A large variation in the length of triple helices can be found in nature, the shortest collagen described is 14 nm long (mini-collagen of hydra) and the longest one 2400 nm (cuticle collagen of annelids) [10]. Gly-Xaa-Yaa repeats that form triple helices are also found in a number of other proteins: complement protein C1q, lung surfactant proteins A and D, mannose-binding protein, macrophage scavenger receptors A (types I, II, and III) and MARCO, ectodysplasin-A, scavenger receptor with C-type lectin (SRCL), the ficolins (L, M and H), the asymmetric form of acetylcholinesterase, adiponectin, and hibernation proteins HP-20, 25, and 27.

30.1.4 N- and C-Propeptide, Telopeptides, Flanking Coiled-Coil Domains

All collagens are synthesized with noncollagenous domains. The fibrillar collagens contain an N-terminal propeptide, an N-terminal telopeptide, the major triple helix, a C-terminal telopeptide and a C-terminal propeptide. The propeptides prevent premature fibril formation within the cell and are cleaved by specific proteases within both the N- and C-terminal telopeptides. The C-terminal propeptide is responsible for chain selection and association. The N-terminal end of the C-terminal propeptide contains three to four heptad repeats indicative of a coiled-coil structure that might facilitate its trimerization and the nucleation of the triple helix [11]. After cleavage, the remaining telopeptides play important roles in the formation of fibrils. The telopeptides also contain the lysine residues for the formation of covalent cross-links between molecules. The N-terminal propeptide consists of a globular domain and a minor triple helix. The globular domain potentially interacts with growth factors. Coiled-coil domains are prevelant in nonfibrillar collagens as well. The transmembrane domain-containing molecules with triple helices show a preference for a coiled-coil domain at the N-terminal end of the ectodomain.

30.1.5 Why is the Folding of the Triple Helix of Interest?

Folding studies of collagens are of interest because of the unusual structure of the collagen triple helix, which is an obligatory trimer. The three chains have to com-

bine to the native state and do not have a defined structure if dissociated. Collagen belongs to the class of filamentous proteins and the mechanism of the folding process is distinctly different from folding pathways in globular proteins. Because of the repeating sequence and the uniform structure, wrong alignments of chains are likely and these are prevented by oligomerization domains.

There are also a number of practical aspects, which render folding studies interesting. Inherited and spontaneous mutations decrease triple helix stability and slow down the folding kinetics. Folding studies of wild-type and mutated collagens are needed for an understanding of theses diseases, which cause severe tissue disorders. The present review surveys the current knowledge of collagen folding. An earlier recent review on collagen folding is by Baum and Brodsky [12] and a useful general chapter on collagens was written by Bateman et al. [13].

30.2 Thermodynamics of Collagen Folding

30.2.1 Stability of the Triple Helix

The collagen molecules undergo a highly cooperative transition from a triple helix to an unfolded state upon heating. The temperature at the midpoint of this transition is termed T_m and is specific for different collagens from different species. Interestingly, the T_m of the collagens is around the body temperature of the organism from which it is isolated [14]. A linear correlation between the T_m and the number of imino acid residues was noticed early on [15]. Later, a better correlation was found between the T_m and the 4(*R*)-hydroxyproline content [16, 17]. Hydroxylation of proline residues is therefore important for the stability of the collagen triple helix and a summary of the posttranslational modifications of collagen molecules is needed. Further stabilization of the collagen molecules is achieved by the formation of supramolecular structures such as fibrils. In this review, we will only deal with individual collagen molecules in solution. The unfolding transition of triple helices occurs in a very narrow temperature interval, indicating a highly cooperative process. The T_m was found to be dependent on the rate of the increase in temperature and a hysteresis or apparent irreversibility is observed for the thermal transition of most extracted collagens. These difficulties in measuring such transition curves have led to the proposal that the collagen molecule is only kinetically stable [18, 19]. True equilibrium transition curves have been measured only recently for such collagens [14, 20]. From these measurements and from transition curves of short fragments of collagen or collagen-like synthetic peptides, it is now established that the collagen triple helix is a thermodynamically stable structure but establishment of equilibrium is slow. Synthetic collagen-like peptides have been extensively used in the characterization of the triple helical structure and its stability.

30.2.2
The Role of Posttranslational Modifications

Collagen molecules undergo extensive posttranslational modifications in the rough endoplasmic reticulum during biosynthesis (for a review see Refs [21, 22]). These enzymatic modifications occur on the nascent chains and require the collagen chains in an unfolded structure. Triple helical molecules are no longer substrates for these enzymes and it is thought that this regulates the stability of the triple helix. Three enzymes are involved in the hydroxylation of proline and lysine residues. Prolyl 4-hydroxylase (EC 1.14.11.2) hydroxylates proline residues in the Yaa position of collagens to form 4(*R*)-hydroxyproline [22]. Prolyl 3-hydroxylase (EC 1.14.11.7) can hydroxylate proline residues in the Xaa position to 3(*S*)-hydroxyproline, if the Yaa position is 4(*R*)-hydroxyproline. This modification occurs much less frequently in vertebrate collagens than the "obligatory" 4-hydroxylation. Certain lysine residues in collagen sequences are hydroxylated by lysine hydroxylase (EC 1.14.11.4) and *O*-linked oligosaccharides are attached. The carbohydrates were identified as 2-*O*-α-D-glucosyl-*O*-β-D-galactosylhydroxylysine and *O*-β-D-galactosylhydroxylysine. Hydroxylysine residues are also used for cross-linking of different collagen molecules in fibrils.

All these modifications affect the thermal stability of the collagen triple helix. When the stability of procollagen is investigated from cells that are incubated with α,α′-dipyridyl, an inhibitor of hydroxylases, the T_m was found to be about 15 °C lower than in the presence of hydroxylation. Such unhydroxylated procollagens are poorly secreted and tend to accumulate in the rough endoplasmic reticulum of the cell.

30.2.3
Energies Involved in the Stability of the Triple Helix

The enthalpy change of the coil ⇄ triple helix transition for collagens was determined to be $\Delta H^\circ - (15\text{–}18)$ kJ mol^{-1} tripeptide units [15]. The enthalpy change increases with increasing imino acid content. On a per residue basis, the change of negative enthalpy for structure formation of triple helices is significantly larger than that of globular proteins. The source of this large change in enthalpy is still controversial.

Another unique feature is the temperature independence of ΔH°. The specific heat of the reaction is zero within the error limits of the measurements [15]. Of the classical energies that determine protein stability, the electrostatic effect is the easiest to deal with in collagen. The stability of the collagen triple helix is only minimally affected by pH and salt concentrations, therefore electrostatic interactions can only play a minor role in the stability of the triple helix. The hydrophobic effect probably plays a role in stabilizing the triple helix, but its effect is not as dominant as in the stability of globular proteins. From the structure of the triple helix, it is evident that an interchain hydrogen bond between the NH group of glycine and the CO group of the amino acid in the Xaa position of a neighboring chain is pres-

ent. Hydrogen exchange studies indicate that two classes of hydrogen bonds exist. The first class consists of 1.0 ± 0.1 very slowly exchanging hydrogens per tripeptide unit and a second class of 0.7 ± 0.1 slowly exchanging hydrogens per tripeptide unit [166]. It is likely that the first class comprises the above-mentioned hydrogen bond. If the Xaa and Yaa positions are not occupied by proline residues, it was suggested that an additional interchain hydrogen bond can form between the carbonyl group of glycine and the amino group of the Xaa residue, probably involving one or two water molecules.

The particular effectiveness of 4(*R*)-hydroxyproline in stabilizing the triple helix has led to suggestions that it may form additional hydrogen bonds through an extended water structure [23]. This notion became weaker, when it was shown that 4(*R*)-fluoroproline formed more stable triple helices than 4(*R*)-hydroxyproline [24, 25]. The replacement of the hydroxyl group by fluorine has several effects. The inductive effect of the fluorine group influences the pucker of the pyrrolidine ring. This is a stereoelectronic effect as it depends on the configuration of the substituent. 4(*R*) substituents stabilize the Cγ-exo pucker, while 4(*S*) substituents stabilize the Cγ-endo pucker. The X-ray structure of $(\text{Pro-Pro-Gly})_{10}$ showed a preference of proline residues in the Xaa position in Cγ-endo pucker, while the Yaa position prolines preferred Cγ-exo puckering [26, 27]. This puckering influences the range of the main chain dihedral angles φ and ψ of proline, which are required for optimal packing in the triple helix. In addition, the trans/cis ratio of the peptide bond is influenced by the substituent [24]. Because all peptide bonds in the triple helix have to be trans, the helix is stabilized, if the amount of trans peptide bonds in the unfolded state is increased. None of these individual effects can fully explain the observed stability of the triple helix and it is difficult to quantitate the contribution of each of them.

A thermodynamic analysis of the triple coil $\rightleftarrows$ triple helix transition of fibrillar collagens shows that the calorimetric enthalpy and the van't Hoff enthalpy are significantly different [15]. The ratio of the van't Hoff enthalpy and the calorimetric enthalpy determines the cooperative length. For fibrillar collagens type I, II, and III a cooperative length of about 80–100 tripeptide units was determined [28]. This corresponds to about one-tenth of the total length of the triple helix. Therefore, the all-or-none model should be a good approximation for the shorter synthetic peptides. The cooperative length is an average parameter that applies to the whole triple helix and does not take into account the sequence variations that occur within a given molecule.

Because the rate of unfolding of the collagen triple helix is very slow in the transition region (see Section 30.3.4.4), great care must be given to the experimental rate of heating. Figures 30.1 and 30.2 show the dependence of the T_m of type III collagen as a function of the rate of heating. The T_m does not vary linearly with the heating rate and true equilibrium curves are only obtained by extrapolation of the heating rate to 0 (Figure 30.2). It should also be noted that most collagens show an irreversible denaturation curve, because the molecules were proteolytically cleaved and lack important domains for folding.

No equilibrium intermediates were observed during the unfolding transition for

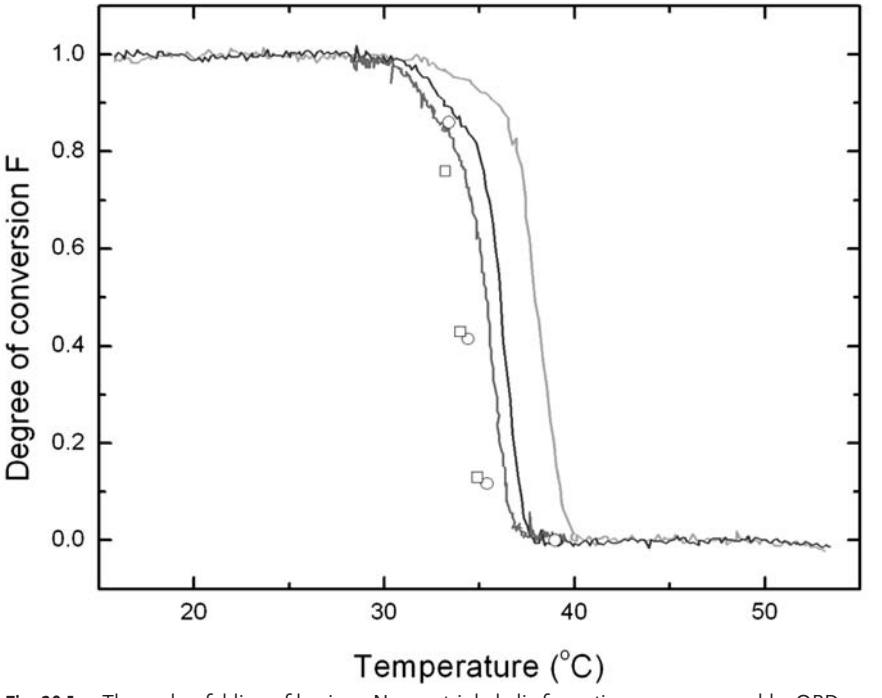

Fig. 30.1. Thermal unfolding of bovine pN type III collagen at different heating rates (thin line = 10 °C h^{-1}, thick line = 2 °C h^{-1}, and dashed line = 0.5 °C h^{-1}). The fraction of triple helix formation was measured by ORD at 365 nm. The endpoints of the unfolding (squares) and refolding (circles) kinetics at the indicated temperature are also shown.

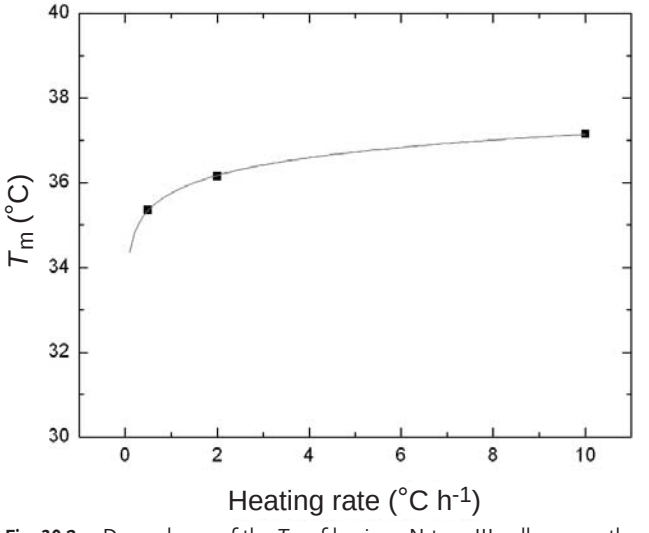

Fig. 30.2. Dependence of the T_m of bovine pN type III collagen on the rate of heating.

the triple helices of type I, II, and III collagen, despite the heterogeneity of the amino acid sequences along the triple helix. Several attempts have been made to calculate differences in stabilities of triple helical regions with the collagen triple helices. Sequence-dependent stabilities were calculated and these can explain the occurrence of unfolding intermediates in the transition of types V and XI collagen [29].

30.2.4 Model Peptides Forming the Collagen Triple Helix

30.2.4.1 Type of Peptides

Synthetic peptides containing Gly-Xaa-Yaa repeats have been used extensively to study the thermal stability and folding of the collagen triple helix. These peptides can be synthesized as either single chains or cross-linked peptides. The first peptides were synthesized by polycondensation of tri- or hexa-peptide units (for a review see Ref. [30]). This procedure resulted in a broad molecular weight distribution that was difficult to fractionate. The introduction of solid-phase methods allowed the synthesis of peptides with a defined chain length. In 1968 Sakakibara synthesized $(\text{Pro-Pro-Gly})_n$ with $n = 5, 10, 15$, and 20 [31]. Later, the oligomers of $(\text{Gly-Pro-Gly})_n$ $n = 1$–8 [32], $(\text{Gly-Pro-Pro})_n$ $n = 3$–7 [33], $(\text{Pro-4}(R)\text{Hyp-Gly})_n$ $n = 5$–10 [34], and $(\text{Pro-Pro-Gly})_n$ $n = 10, 12, 14$, and 15 [35] were synthesized. Sutoh and Noda introduced the concept of block copolymers, where two blocks of $(\text{Pro-Pro-Gly})_n$ $n = 5, 6$, or 7 were separated by a block of $(\text{Ala-Pro-Gly})_m$ $m = 5, 3$, and 1, respectively [35]. This concept was later extended to include all amino acids and called host-guest peptide system. The most studied host-guest system uses the sequence Ac-$(\text{Gly-Pro-4}(R)\text{Hyp})_3$-Gly-Xaa-Yaa-$(\text{Gly-Pro-4}(R)\text{Hyp})_4$-Gly-Gly-$NH_2$ [36], but other variations were also studied [37, 38].

Because the stability of collagen-like peptides is highly concentration dependent, covalently linked peptides were synthesized by various methods. Heidemann used propane tricarboxylate tris(pentachlorophenyl) and *N*-tris(6-amino hexanoyl)-lysyl-lysine as covalent bridging molecules for the three chains [39]. Other covalent linkers include Kemp triacid [40], a modified dilysine system [41], the sequence found at the C-terminal end of type III collagen Gly-Pro-Cys-Cys-Gly [42–46], and tris(2-aminoethyl)amine with succinic acid spacers [47]. Peptides with covalent cross-links at both ends were also synthesized [48]. The noncovalent obligatory trimer foldon [46], peptide amphiphiles [49–51], and the iron (II) complex of bipyridine [52] have also been used to study trimeric peptides.

Initially, all peptides were studied as homotrimers, but strategies were developed to synthesize heterotrimers. Fields proposed the dilysine system to synthesize heterotrimeric peptides of type IV collagen [41] and Moroder used a simplified cysteine bridge to synthesize the collagenase cleavage site of type I collagen [53].

30.2.4.2 The All-or-none Transition of Short Model Peptides

We will start with the triple helix $\rightleftarrows$ coil transition of single chains. The simplest mechanism for this transition can be written as follows [54]:

$$3C \overset{\beta s^x}{\rightleftharpoons} H_x \overset{s}{\rightleftharpoons} \cdots \overset{s}{\rightleftharpoons} H_i \overset{s}{\rightleftharpoons} \cdots \overset{s}{\rightleftharpoons} H_{3n-2} \tag{1}$$

where C is a coiled chain, H_i is a triple helical species with i tripeptide units in a triple helical conformation, β is the cooperativity parameter for the nucleation step, βs^x is the equilibrium constant for the step forming nucleus H_x, c_o is the total concentration of chains and s is the equilibrium constant for the addition of a tripeptide unit after nucleation. Because of the staggering of the chains, only $3n - 2$ tripeptide units can form hydrogen bonds in the triple helix and the complete triple helix is designated as H_{3n-2}. After nucleation, the triple helix is completed in propagation steps, which is the conversion of a coiled tripeptide unit adjacent to a triple helical tripeptide unit into a triple helical tripeptide unit. Since all these steps are essentially identical, the same equilibrium constant is applied to all of them. The process can be simplified if n is relatively small and $\beta {c_o}^2$ is less than 1. Under these conditions, the concentration of H_i becomes small compared with the concentrations of C and H_{3n-2}. The formation of the triple helix can then be approximated by an ''all-or-none'' reaction and the overall reaction can be described by an apparent equilibrium constant K.

$$K = \frac{[H_{3n-2}]}{[C]^3} = \beta s^{3n-2} = \frac{F}{3c_0^2(1-F)^3} \tag{2}$$

where F is the degree of helicity in terms of the fraction of chains or tripeptide units in the triple helical state and c_o the total molar concentration of chains, normally in mol tripeptide units l^{-1}.

$$F = \frac{3[H_{3n-2}]}{c_0} \tag{3}$$

From

$$\Delta G^\circ = -RT \ln K = \Delta H^\circ - T\Delta S^\circ \tag{4}$$

and from Eq. (2) it follows that at the midpoint of the transition ($F = 0.5$ and $T = T_m$),

$$T_m = \frac{\Delta H^\circ}{\Delta S^\circ + R \ln(0.75c_0^2)} \tag{5}$$

where ΔG° is the standard Gibbs free energy, ΔH° is the standard free enthalpy, and ΔS° is the standard entropy. It is important to note that the T_m is concentration dependant and stability values should only be compared at identical molar chain concentrations or concentrations which were corrected for concentration differences with Eq. (5).

ΔH° can be obtained from the slope of the transition curves. A first approximation of ΔH° can be obtained from the van't Hoff equation

$$\Delta H^\circ = 8RT_m^2\left(\frac{dF}{dT}\right)_{F=0.5} \tag{6}$$

It is much more accurate to obtain ΔH° by curve fitting of the entire transition curve with the equation

$$K = \exp\left[\frac{\Delta H^\circ}{RT}\left(\frac{T}{T_m} - 1\right) - \ln 0.75c_0^2\right] \tag{7}$$

which is obtained by solving Eq. (5) for ΔS° and substituting for ΔS° in Eq. (4). In this equation the specific heat c_p is assumed to be zero, as measured for several collagens by Privalov (see Section 30.2.3). In this regard, it is important to calculate F as a function of temperature. In the helical region and especially in the coiled region the circular dichroism (CD) signal shows a linear decrease with increasing temperature.

For a direct fit of F by K and c_o Eq. (2) is rewritten as the cubic equation:

$$F^3 - 3F^2 + bF - 1 = 0 \tag{8}$$

with:

$$b = \frac{9Kc_0^2 + 1}{3Kc_0^2} \tag{9}$$

By the method of Cardano [55] the real solution of this equation was obtained as:

$$F = u + v + 1 \tag{10}$$

with:

$$u = \sqrt[3]{-\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}} \tag{11}$$

and:

$$v = \sqrt[3]{-\frac{q}{2} - \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}} \tag{12}$$

in which $p = q = \dfrac{1}{3Kc_0^2}$.

When measuring CD the molar ellipticity is given by

$$[\Theta] = F([\Theta]_h - [\Theta]_c) + [\Theta]_c$$

where $[\Theta]_h$ and $[\Theta]_c$ are the ellipticities for the peptide in either the completely triple helical conformation or in the unfolded conformation. The linear temperature dependencies of $[\Theta]_h$ and $[\Theta]_c$ can be described by

$$[\Theta]_h = [\Theta]_{h,Tm} + p(T - T_m)$$

$$[\Theta]_c = [\Theta]_{c,Tm} + q(T - T_m)$$

Here the ellipticities at the midpoint temperature T_m are arbitrarily used as reference points. For a best fit of the transition curves, initially the T_m is kept constant and ΔH°, p and q are varied. After an initial fit, the T_m is then also varied.

For peptides that contain a cross-link, the triple helix $\rightleftarrows$ coil transition becomes concentration independent and the equations for the all-or-none model simplify to:

$$K = \frac{F}{1 - F}$$

then F becomes

$$F = \frac{K}{1 + K}$$

and

$$T_m = \frac{\Delta H^\circ}{\Delta S^\circ}.$$

The fitting procedure for the determination of the thermodynamic parameters is otherwise the same as for nonlinked chains. In all fitting procedures the temperature dependence of ΔH° was neglected since the heat capacity c_p was determined to be very small or zero [15].

30.2.4.3 Thermodynamic Parameters for Different Model Systems

The simplest way to study the stability of collagen-like peptides is to measure the thermal transition curve by circular dichroism. The temperature at the midpoint of the transition T_m is normally used as a comparison for the stability between different peptides. However, as shown above this value is dependent on the concentration of the peptide and the rate of heating, and only values either measured or corrected to the same concentration and heating rate should be compared. Heating rates above 10 °C h^{-1} lead to transition curves that are too steep, therefore an enthalpy change that is too large if evaluated by the van't Hoff equation, and to T_m values that are too high. The enthalpy change of the triple helix coil transition can be calculated by fitting of the transition curve with the van't Hoff equation (see Section 30.2.4.2) or measured directly by differential scanning calorimetry (DSC). Van't Hoff enthalpies are usually less accurate than calorimetric values and both methods suffer from uncertainties in baselines. Uncertainties in the thermody-

Tab. 30.1. Thermodynamic data of the triple helix–coil transition of model peptides in aqueous solution determined by circular dichroism ($\Delta H^\circ_{vH}, \Delta S^\circ$) and differential scanning calorimetry (ΔH°_{cal}). The values are expressed per mol of tripeptide units in a triple helix. The number of tripeptide units in the triple helix was calculated as $3n - 2$ for the peptide (Gly-Xaa-Yaa)$_n$.

[a] The EK peptide is (Pro-4(*R*)Hyp-Gly)$_4$-Glu-Lys-Gly-(Pro-4(*R*)Hyp-Gly)$_5$.
[b] Peptide with a parallel chain arrangement.
[c] Peptide with an antiparallel chain arrangement.
[d] Calorimetric data from Ref. [59].
[e] Heterotrimeric type I collagen peptide containing the collagenase cleavage site.
[f] Heterotrimeric type IV collagen peptide containing the $\alpha 1\beta 1$ integrin binding site.
[g] Heterotrimeric (Gly-Pro-4(*R*)Hyp)$_5$ with cysteine bridge.
[h] Dilysine bridged peptide with a collagen type III sequence and a Gly-Pro-4(*R*)Hyp clamp at the N-terminus.
[i] Synthetic α1-CB2.
Flp, fluoroproline.

namic data also arise from the facts that the transition curves monitored by CD are measured at a much lower concentration than the calorimetric measurements and that the concentration dependence is unknown in many studies. All measurements of single-chain peptides include the uncertainty of misaligned chains and errors in the fitting procedures. Data from different sources are summarized in Tables 30.1 and 30.2. In view of the many sources of error it is highly recommended to consult the individual publications in order to gain information on reliability.

For the reasons mentioned above, the published thermodynamic data for the triple helix coil transitions of synthetic peptides vary significantly. The commercially available peptides (Pro-Pro-Gly)$_{10}$ and (Pro-4(*R*)Hyp-Gly)$_{10}$ have been measured in several laboratories. The van't Hoff enthalpy change varies from −7.91 to −18.8 kJ mol^{-1} tripeptide units for (Pro-Pro-Gly)$_{10}$ and from −13.4 to −25.25 kJ mol^{-1} tripeptide units for (Pro-4(*R*)Hyp-Gly)$_{10}$. The published values for the calorimetric enthalpies of these peptides are more consistent.

[a] HG refers to the host–guest peptides with the structure Ac(Pro-4(*R*)Hyp-Gly)$_3$-Gly-Xaa-Yaa-(Pro-4(*R*)Hyp-Gly)$_4$-Gly-Gly-NH$_2$. The tripeptide sequence given after HG corresponds to Gly-Xaa-Yaa. The peptides were measured in PBS, pH 7, unless indicated otherwise. Flp, fluoroproline.

Generally, the triple helix ⇄ coil transitions of short peptides can be described by the all-or-none model discussed in the previous section. Most peptides for which calorimetric data are available show that the ratio of the van't Hoff enthalpy and the calorimetric enthalpy is close to 1, indicating that the all-or-none mechanism is a good approximation, which is expected for peptides smaller than the cooperative length. However, exceptions have been reported, especially in heterotrimeric peptides [56].

Figure 30.3 shows the triple helix coil transition of Ac-(Gly-Pro-4(*R*)Hyp)$_{10}$-NH$_2$ measured by CD in water. The heating/cooling rate was 10 °C h^{-1} and the unfolding and refolding curves are shown for three different concentrations.

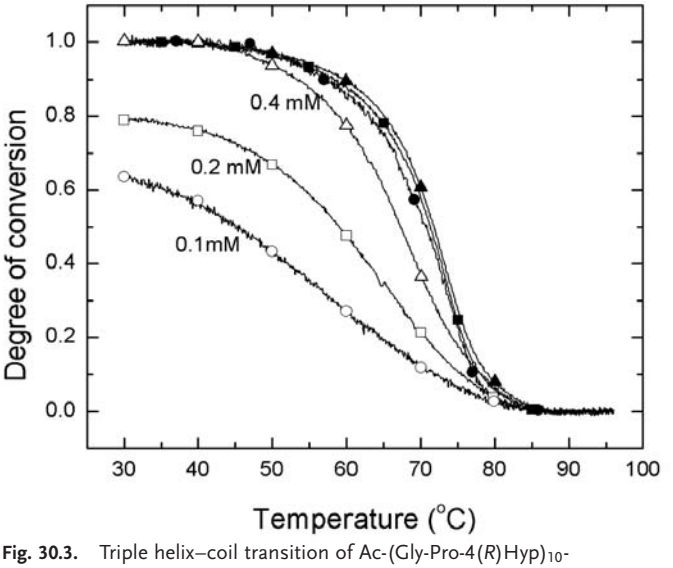

Fig. 30.3. Triple helix–coil transition of Ac-(Gly-Pro-4(*R*)Hyp)$_{10}$-NH$_2$ in water. The transition was monitored by circular dichroism at 225 nm. Closed symbols are for heating and open symbols for cooling, The heating/cooling rate was 10 °C h^{-1}.

The experimental data can be described by the all-or-none model (Mizuno and Bächinger, unpublished). The T_m increases with increasing concentration, but a concentration-dependent hysteresis is observed during refolding (see Section 30.3.4.4).

The studies with synthetic model peptides confirm the stabilizing role of 4(*R*)Hyp in the Yaa position of the triple helix. The influence of 4(*S*)Hyp, 3(*S*)Hyp, 4(*S*)Flp, and 4(*R*)Flp on the stability of the triple helix is entirely based on measurements with synthetic peptides (see Section 30.2.4.7).

The peptides in the host–guest system carry no charges at the ends and the values for the enthalpy and entropy changes are measured over a $(Gly\text{-}Pro\text{-}4(R)Hyp)_7$ background. The stability of $(Pro\text{-}4(R)Hyp\text{-}Gly)_{10}$ was shown to be pH dependent. At acidic and basic pH the peptide carries charges at only one end and is more stable than at neutral pH, where charges are present at both ends [57]. The peptides have the general sequence $Ac\text{-}(Gly\text{-}Pro\text{-}4(R)Hyp)_3\text{-}Gly\text{-}Xaa\text{-}Yaa\text{-}(Gly\text{-}Pro\text{-}4(R)Hyp)_4\text{-}Gly\text{-}Gly\text{-}NH_2$. The thermodynamic data for the guest peptides can be used to predict the stability of triple helices with any sequence [58, 59]. The limitations of this approach are discussed in Section 30.2.4.4. Table 30.2 lists the thermodynamic parameters determined for the host–guest peptides. In contrast to other synthetic peptides and CNBr peptides of type I collagen [60], where the enthalpy change increases with an increasing amount of imino acids, the Gly-Pro-4(*R*)Hyp containing host peptide has one of the lowest enthalpy change observed. The host–guest studies clearly show that hydrophobic residues do not play a major role in the stabilization of the triple helix, rather they perform important tasks in the assembly of collagen molecules into fibrils [36]. Gly-Gly containing peptides show a strong influence in destabilizing the triple helix, which may play an important role in specific functions by modulating the local triple helical stability [61]. These studies also clarify the dependence of the triple helical stability on the identity, position and ionization state of charged residues [62].

30.2.4.4 **Contribution of Different Tripeptide Units to Stability**

The high content of imino acids in collagens suggests a crucial role in the stabilization of the triple helix. Indeed, the most stable natural tripeptide unit is Gly-Pro-4(*R*)Hyp. Heidemann's group used statistical data [63], and published studies of stabilities of synthetic peptides [30, 64, 65] to derive four classes of the most common tripeptide units found in collagens. The first class of tripeptide units, the collagen-typical tripeptides, consists of Gly-Pro-Hyp, Gly-Pro-Ala, Gly-Ala-Hyp, Gly-Glu-Hyp, Gly-Glu-Arg, and Gly-Pro-Lys. The second class consists of tripeptide units often found in clusters with the collagen-typical tripeptides and includes Gly-Leu-Hyp, Gly-Pro-Ser, Gly-Phe-Hyp, Gly-Ala-Ala, Gly-Ala-Arg, Gly-Glu-Hyp, Gly-Asp-Ala, and Gly-Pro-Gln. The third class consists of tripeptide units that do not occur in the collagen-typical clusters and includes Gly-Glu-Ala, Gly-Ala-Lys, Gly-Asp-Arg, Gly-Ala-Asp, Gly-Pro-Ile, Gly-Arg-Hyp, Gly-Glu-Thr, and Gly-Ser-Hyp. The fourth class includes all the rest of the tripeptide units, which do not occur often enough for the statistical analysis.

A sequence-dependent stability profile along the triple helix was generated by assigning numerical values to the classes derived by Heidemann, using a sliding

average to simulate cooperativity [66]. While empirical, this method was able to qualitatively explain the occurrence of unfolding intermediates in the triple helix of type V and XI collagens. In contrast to other fibrillar collagens, collagens type V and XI show unfolding intermediates in the triple helix coil transition [29]. A comparison of the sequence-dependent stability profiles indicates that type V and XI collagens lack a very stable region at the N-terminal end of the triple helix, that is present in other fibrillar collagens. The N-terminal region of the triple helix unfolds at lower temperatures in collagen types V and XI, and this leads to stable unfolding intermediates, that consist of the more C-terminal regions of the triple helix.

Brodsky's group used a host–guest system to quantitate the influence of naturally occurring tripeptide units to the triple helical stability [36, 58, 59, 61, 62, 67, 68, 69, 70]. The host–guest peptide system Ac-(Gly-Pro-Hyp)$_3$-Gly-Xaa-Yaa-(Gly-Pro-Hyp)$_4$-Gly-Gly-NH_2 is used to study the influence of the Xaa and Yaa residues on the thermal stability of the triple helix. While there are over 400 possible combinations of host–guest peptides, only about 80 appear with a significant frequency in known collagen sequences and only 24 tripeptides have a frequency of higher than 1% [71]. These peptides can be divided into three groups: the Gly-Xaa-Hyp group, the Gly-Pro-Yaa group, and the Gly-Xaa-Yaa group. Not surprisingly, the most stable of the 20 peptides of group 1 is Gly-Pro-Hyp, followed by Gly-Glu-Hyp and Gly-Ala-Hyp. The T_m values range from 47.3 °C for Gly-Pro-Hyp to 31.9 °C for Gly-Trp-Hyp. For group 2, the most stable of the 20 peptides is again Gly-Pro-Hyp, followed by Gly-Pro-Arg and Gly-Pro-Met. The T_m values range from 47.3 °C for Gly-Pro-Hyp to 26.1 °C for Gly-Pro-Trp. A reasonable correlation was found between the observed stabilities and the frequencies of occurrence in fibrillar collagen sequences [58]. Forty-one peptides of group 3 that contained no imino acids were synthesized and their stabilities measured [69]. Theoretical calculations, assuming no interaction between the Xaa and Yaa residues, allow the prediction of the stability of all 361 possible peptides. Sixteen of the 41 peptides show a reasonable agreement between the predicted and the measured stability ($\Delta T_m \leq 2$ °C). Seven peptides had a lower T_m than predicted and 18 had a higher T_m, most likely indicating side-chain interactions in the triple helix. These studies should now allow the prediction of the thermal stability of the triple helix in any Gly-Xaa-Yaa sequence. Unfortunately, this is not the case. The tripeptide units Gly-Hyp-Pro and Gly-3Hyp-Hyp show T_m values in the host-guest system that are comparable to Gly-Pro-Hyp, but neither forms a triple helix as a homopolymer [72]. A similar result was also obtained for the guest tripeptide unit Gly-Pro-fluoroproline [59]. The conclusion one has to draw is that these stabilities are dominated by the very stable tripeptide units at either end of the guest tripeptide unit, and that this system has little predictive power for the stability of Gly-Xaa-Yaa in homopolymers.

30.2.4.5 **Crystal and NMR Structures of Triple Helices**

The molecular structure of the triple helix was first derived from diffraction patterns of collagen fibrils [74, 75]. These models and data on the diffraction of tail tendon [76] showed a 10/3 symmetry (3.33 residues per turn). The first structure of

the synthetic model peptide $(Pro\text{-}Pro\text{-}Gly)_{10}$ showed a 7/2 symmetry, giving rise to 3.5 residues per turn [77]. In 1994, a true single crystal was grown from a peptide that consisted of 10 repeats of Pro-Hyp-Gly with a single substitution of a glycine residue by an alanine in the middle [78]. This peptide was a triple helical molecule with a length of 87 Å and a diameter of 10 Å. The structure was solved to 1.9 Å and was consistent with the general parameters derived from the fiber diffraction model, but showed a 7/2 symmetry. It was hypothesized that imino acid-rich peptides have a 7/2 symmetry, but imino acid-poor regions adopt a 10/3 helix [78]. This was later confirmed with a synthetic peptide that contained an imino acid poor region [79, 80]. The structure also confirmed the expected hydrogen bond between the GlyNH and C=O of the proline in the Xaa position. In addition, an extensive water network forms hydrogen bonds with all available carbonyl and hydroxyl groups [23, 81].

The structure of the peptides $(Pro\text{-}Pro\text{-}Gly)_{10}$ [82, 83] and $(Pro\text{-}Hyp\text{-}Gly)_{10}$ [84] was also determined. The structure of $(Pro\text{-}Pro\text{-}Gly)_{10}$ obtained from crystals grown in microgravity, which diffracted up to a resolution of 1.3 Å, showed a preferential distribution of proline backbone and side-chain conformations, depending on the position [85, 26]. Proline residues in the Xaa position exhibit an average main chain torsion angle of -75° and a positive side-chain χ_1 (down puckering), while proline residues in the Yaa position were characterized by a significantly smaller main-chain torsion angle of -60° and a negative χ_1 (up puckering). These results were used to explain the stabilizing effect of hydroxyproline in the Yaa position, because hydroxyproline has a strong preference for up puckering. It also would explain the destabilizing effect of 4(*R*)-hydroxyproline in the Xaa position (see also Section 30.2.4.7).

The structure of $(Gly\text{-}Pro\text{-}Pro)_{10}$ was also solved in the context of the attached oligomerization domain foldon [86].

NMR studies with synthetic model peptides of the triple helix are difficult because of overlapping resonances of the repetitive sequence and by peak broadening from the shape [87–89]. Isotopic labeling was used to observe specific residues using heteronuclear NMR techniques. Hydrogen exchange studies were used to show that the NH groups of glycine exchanged faster in the imino acid-poor region of a synthetic peptide compared with the Gly-Pro-Hyp region [87]. The NH of threonine and the NH of glycine showed a very slow exchange with deuterium in the galactosyl-containing peptide $Ac\text{-}(Gly\text{-}Pro\text{-}Thr(\beta\text{-}Gal))_{10}\text{-}NH_2$ [90]. Heteronuclear NMR was used to monitor the folding kinetics of the triple helix [91, 92]. The hydration of the triple helix was also studied by NMR [93]. The hydration shell was found to be kinetically labile with upper limits for water molecule residence times in the nanosecond to subnanosecond range.

30.2.4.6 Conformation of the Randomly Coiled Chains

Little attention has been paid to the conformation of the unfolded chains in considering the stability of the collagen triple helix. Because the stability is determined by the free energy difference of the unfolded and the folded state, changes in the unfolded state can also contribute to the stability of the triple helix. The triple helix

requires all peptide bonds to be in the trans conformation, so changes in the *cis* to *trans* ratio of peptide bonds in the unfolded state have a direct influence on the stability (see Section 30.2.4.8). Another example comes from studies with synthetic peptides, in which galactosyl threonine was incorporated [94]. The deep-sea hydrothermal vent worm *Riftia pachyptila* has a cuticle collagen that has a very low content of proline and hydroxyproline residues, but a high T_m of 37 °C [95, 42]. The Yaa position of the triple helical sequence in this cuticle collagen is frequently occupied by threonine. Threonines in the Yaa position were frequently galactosylated with one to three galactosyl units. The peptide Ac-(Gly-Pro-Thr)$_{10}$-NH_2 was unable to form a triple helix, whereas the galactosylated version Ac-(Gly-Pro-Thr(β-Gal))$_{10}$-NH_2 showed a T_m of 39 °C [94]. The stabilizing effect of galactosyl threonine has been explained by the occlusion of water molecules and by hydrogen bonding [90]. Additionally, galactosylation of the threonine residues also restricts the available conformations in the unfolded state. The end-to-end distance, determined by fluorescence energy transfer, is increased in the peptide Dabcyl-(Gly-Pro-Thr(β-Gal))$_5$-Gly-EDANS when compared with the peptide Dabcyl-(Gly-Pro-Thr)$_5$-Gly-EDANS (Bächinger, unpublished). However, it is difficult to quantitate the contribution of these different effects to the overall stability of the triple helix.

The importance of the restriction of imino acids in the unfolded state for the efficient folding of the triple helix has recently been described [96].

30.2.4.7 Model Studies with Isomers of Hydroxyproline and Fluoroproline

As mentioned before, it was recognized early on that hydroxproline played a crucial role in the stabilization of the triple helix. Synthetic peptides were used to establish that only 4(*R*)-hydroxyproline stabilized the triple helical structure. 4(*S*)-Hydroxyproline in the peptides (4(*S*)Hyp-Pro-Gly)$_{10}$ and (Pro-4(*S*)Hyp-Gly)$_{10}$ prevented the formation of a triple helix [97]. It was also shown that 4(*R*)-hydroxyproline in the Xaa position prevented triple helix formation in the peptide (4(*R*)Hyp-Pro-Gly)$_{10}$ [70]. Recent studies show that 4(*R*)-hydroxyproline in the Xaa position can lead to an increase in the stability of the triple helix, when the Yaa position is not proline. The peptide Ac-(Gly-Pro-Thr)$_{10}$-NH_2 does not form a triple helix in aqueous solution, but when the proline is hydroxylated the peptide Ac-(Gly-4(*R*)Hyp-Thr)$_{10}$-NH_2 does form a stable triple helix [98]. Further studies of peptides with 4(*R*)-hydroxyproline in the Xaa position showed that valine, but not serine or allo-threonine are able to form stable triple helical peptides, indicating that both the methyl group and the hydroxyl group of threonine, as well as the stereo configuration are important for the stability [73]. It was hypothesized that the methyl group shields the interchain hydrogen bond between the glycine and the Xaa residue from solvent and that the hydroxyl group of threonine and hydroxyproline can form a direct or water-mediated hydrogen bond. In addition, the peptide Ac-(Gly-4(*R*)Hyp-4(*R*)Hyp)$_{10}$-NH_2 has a T_m that is similar to the that of Ac-(Gly-Pro-4(*R*)Hyp)$_{10}$-NH_2 (Mizuno *et al.*, in press).

A small number of 3(*S*)-hydroxyproline residues are present in most collagens in the Xaa position. The occurrence of 3(*S*)Hyp is much less frequent than that of 4(*R*)Hyp in the total amino acid content of collagens. In basement membrane collagens, fractions range from 1 [99] to 15 residues per 1000 residues [100]. 3(*S*)-

Hydroxyproline is also found in other types of collagens, such as type I [100], type V [101, 102], type X [103], and interstitial and cuticle collagens of annelids [105]. The only reported sequences containing 3(*S*)Hyp are in Gly-3(*S*)Hyp-4(*R*)Hyp tripeptide units. Synthetic peptides with 3(*S*)Hyp in a host–guest system decrease the stability of the triple helix in either the Xaa or the Yaa position [38]. A more severe decrease was observed for 3(*S*)Hyp in the Yaa position. It was concluded that the inductive effect of the 3-hydroxyl group of 3(*S*)Hyp decreases the strength of the GlyNH $\cdots$ OC3(*S*)Hyp hydrogen bond, when 3(*S*)Hyp is in the Xaa position, and that, when 3(*S*)Hyp is in the Yaa position, the pyrrolidine ring pucker leads to inappropriate mainchain dihedral angles and steric clashes [38]. When the influence of 3(*S*)Hyp was studied in homopolymers, the peptide Ac-(Gly-Pro-3(*S*)Hyp)$_{10}$-NH_2 did not form a triple helix [104]. Surprisingly, the peptide Ac-(Gly-3(*S*)Hyp-4(*R*)Hyp)$_{10}$-NH_2 was also unable to form a triple helix as a homopolymer. Even when foldon was attached to (Gly-3(*S*)Hyp-4(*R*)Hyp)$_{10}$, no triple helix formation was observed, ruling out a kinetic difficulty for this peptide to form such a structure [104].

While fluoroproline was used in biosynthetic experiments in the sixties [105, 106, 107], its importance to the stability of the triple helix was established by incorporating 4(*R*)-fluoroproline (4(*R*)Flp) into collagen model peptides [25]. Raines and coworkers showed that the substitution of 4(*R*)Hyp by 4(*R*)Flp in the peptide (Gly-Pro-4(*R*)Hyp)$_{10}$ leads to a significant increase in the stability of the triple helix. The authors initially cited an ''unappreciated inductive effect'' as the reason for this increase in stability, but more importantly, this result showed that an electron withdrawing substituent in the 4(*R*) position of proline can stabilize the triple helix without an extended network of water molecules [108]. Since this initial discovery, the inductive effect has been characterized in great detail [109, 110, 111]. The *gauche* effect determines the proline ring puckering (up puckering, Cγ-exo) and therefore predetermines the main-chain dihedral angles. In addition, the *trans* to *cis* ratio of the peptide bond preceeding 4(*R*)Flp increases. Both of these effects increase the stability of the triple helix. Peptides with 4(*R*)Flp in the Xaa position do not form a triple helix [112, 113]. Peptides with 4(*S*)Flp in the Yaa position also do not form a triple helix [44, 110]. In contrast to the peptide (4(*S*)Hyp-Pro-Gly)$_{10}$, which does not form a triple helix, the peptides (4(*S*)Flp-Pro-Gly)$_n$ form a stable triple helix ($n = 7$ [113]; $n = 10$ [112]). This is an unexpected result, because the *trans* to *cis* ratio of the peptide bond is decreased by 4(*S*)Flp. On the other hand, the preorganization of the ring puckering should promote triple helix formation. Why then do peptides with 4(*S*)Hyp in the Xaa position not form a triple helix? It was hypothesized that unfavorable steric interactions occur with 4(*S*)Hyp that are absent with 4(*S*)Flp [113].

The substitution of 4(*R*)Hyp by 4(*R*)-aminoproline in the peptide (Gly-Pro-4(*R*)Hyp)$_6$ also increases the stability of the triple helix. The extent of this increase in stability was strongly pH dependent [114].

30.2.4.8 *Cis* $\rightleftarrows$ *trans* Equilibria of Peptide Bonds

The peptide bond shows partial double bond character, as indicated by a shorter distance between the carbonyl carbon and the nitrogen than expected for a single

C–N bond. Consequently, the peptide bond is planar and the flanking Cα atoms can be either in *trans* ($\omega = 180°$) or *cis* ($\omega = 0°$) conformation. For peptide bonds preceding residues other than proline, only a small fraction (0.11–0.48%) was found to be in the *cis* conformation [115]. Peptide bonds preceding proline are much more frequently in the *cis* conformation, because the energy difference between the two conformations is rather small. *Cis* contents from 10 to 30% were found in short unstructured peptides [116, 117]. The activation energy for the *cis-trans* isomerization is high (80 kJ mol^{-1}) and the rate of isomerization is slow (see Section 30.3.2.4).

The collagen triple helix can accommodate only *trans* peptide bonds, so the ratio of *cis* to *trans* peptide bonds in the unfolded state has a direct influence on the stability of the triple helix. As mentioned above, the stereoelectronic effect of 4-substituents of proline residues influences the *cis*/*trans* ratio of the peptide bond preceding proline. It was proposed that the conformational stability of the triple helix relies on the change in the *cis*/*trans* ratio [110, 118]. These authors measured the $K_{cis/trans}$ for a number of 4-substituted proline residues. Table 30.3 summerizes these results.

There is indeed a good correlation of the observed *cis*/*trans* ratios and the thermal stability of homopolymers containing these residues in the Yaa position. However, a quantitation of this effect can be calculated [119]. The observed stability differences in the homopolymeric peptides $(Pro\text{-}Pro\text{-}Gly)_{10}$ and $(Pro\text{-}4(R)Hyp\text{-}Gly)_{10}$ are too large to be accounted for solely by the change in the *cis*/*trans* ratio of peptide bonds in the unfolded state (Bächinger, unpublished).

30.2.4.9 Interpretations of Stabilities on a Molecular Level

At present it is not possible to derive and quantitate all individual contributions that lead to the stability of the triple helix. It seems likely that a number of small

contributions from the unfolded and folded state lead ultimately to the stable triple helix.

30.3 Kinetics of Triple Helix Formation

30.3.1 Properties of Collagen Triple Helices that Influence Kinetics

The complexity of the kinetics largely depends on the length of the triple helix to be formed. For short collagens and for short model peptides an all-or-none mechanism is a good approximation. The kinetics of systems with up to 45 tripeptide units per molecule (15 units per chain) have been successfully treated using this approximation [35, 120, 121]. Triple helices of most collagens are however much longer (1000–7200 amino acids) and the extent of cooperativity in triple helix formation is not sufficient for all-or-none transitions in systems of this size. The cooperative length of the triple helix in interstitial collagens with about 1000 tripeptide units was estimated to be about 100 tripeptide units from equilibrium studies [28]. This value was determined for the main triple helix of collagens I, II, and III and may apply to other collagens only in a first approximation because of sequence variations. The value is however consistent with the experimentally observed all-or-none nature of transitions with less than 45 tripeptide units. As expected the kinetics of long triple helices are more complex than those of short naturally occurring or designed model systems.

A second feature that largely influences the kinetics is the presence or absence of a cross-link between the three chains in a collagen molecule. As described in the Introduction most collagens contain nucleation domains (also called registration or oligomerization domains), which are located N-terminal or C-terminal of the triple helical domain. As explained in the first part of this review these domains serve to register the three chains at a side at which triple helix formation is nucleated. They are also involved in the selection of different chains in cases in which the collagen is a heterotrimer. The presence of trimerizing noncollagenous domains (designated as NC-domains or N-propeptides and C-propeptides) was found to be essential for proper folding of the triple helical domain. In addition, many collagen triple helical domains contain disulfide cross-links between their chains. The best-studied example is collagen III in which a disulfide knot of six cysteines (two per chain) connects the three chains at the C-terminus. During the physiological folding process, formation of this knot is most likely dependent on earlier noncovalent interactions between the adjacent NC-domains. After its formation it serves as an ideal registration and nucleation site, thus replacing the action of the NC-domain [122].

We shall first deal with the kinetics of folding from noncross-linked single chains and then turn to collagen triple helices, which are trimerized by either the disulfide knot of collagen III or by NC1-domains with strong trimerization poten-

tial. Natural proteins or fragment but also designed collagen-like proteins were employed in these studies.

30.3.2 Folding of Triple Helices from Single Chains

30.3.2.1 Early Work

Historically, all work on collagen folding started with single chains for the simple reason that before about 1980 only collagens from which the NC-domains were removed were available. Key publications of this time are by Piez and Carrillo [123] and Harrington and Rao [124]. In fact, the knowledge about N- and C-terminal NC-domains (frequently named N- and C-propeptides) and their importance developed only at this time and later. Before 1980, some work was also performed with cross-linked collagen chains derived from gelatin [125]. In contrast to the specific links leading to trimers, these chains were more statistically linked by nonreducible cross-links to dimers and higher oligomers.

An intriguing feature of early work in which collagens were refolded from their unfolded denatured chains was the observation that only a small fraction of native trimeric molecules was recovered. This fraction was very small at low temperatures and became higher at refolding temperatures close to the melting temperature [126]. Reaction orders varied between 1 and 2 depending on conditions and the time courses were difficult to interpret by a unique kinetic mechanism. Data indicated formation of products in which collagen triple helices with wrong alignment between the chains were formed. Annealing of these unstable products to native correctly aligned molecules was found to be very slow (for a review see Ref. [127]).

An early breakthrough in the kinetics of collagen triple helix formation from noncross-linked chains was achieved in studies with a short fragment chain of collagen I α1-CB2 [120]. An advantage of this system is its small size (12 tripeptide units per chain, 36 in the triple helix). A reaction order close to 3 was found for α1-CB2 and equilibrium transition curves indicated that the transition was of the all-or-none type with only unfolded chains and triple helices in equilibrium. Because of the relatively low stability of the triple helix formed by α1-CB2 it was difficult to reach a completely folded state at low temperatures. Furthermore, the fragment was isolated from a natural source and was available in small amounts only. Perhaps for these reasons no kinetic constant was derived and measurements of the concentration dependence were performed in a small interval only.

30.3.2.2 Concentration Dependence of the Folding of $(PPG)_{10}$ and $(POG)_{10}$

An extended study on the folding of short chains was performed with the synthetic model peptides $(PPG)_{10}$ and $(POG)_{10}$ [121]. Solutions were first heated to 60 °C ($(PPG)_{10}$) or 70 °C ($(POG)_{10}$) for 5 min to achieve complete unfolding. Time courses of refolding were recorded after fast cooling to 7 °C, at which the triple helix is completely folded according to equilibrium measurements. Kinetics of refolding was found to be extremely concentration dependent as expected for recombination of three chains (Figure 30.4).

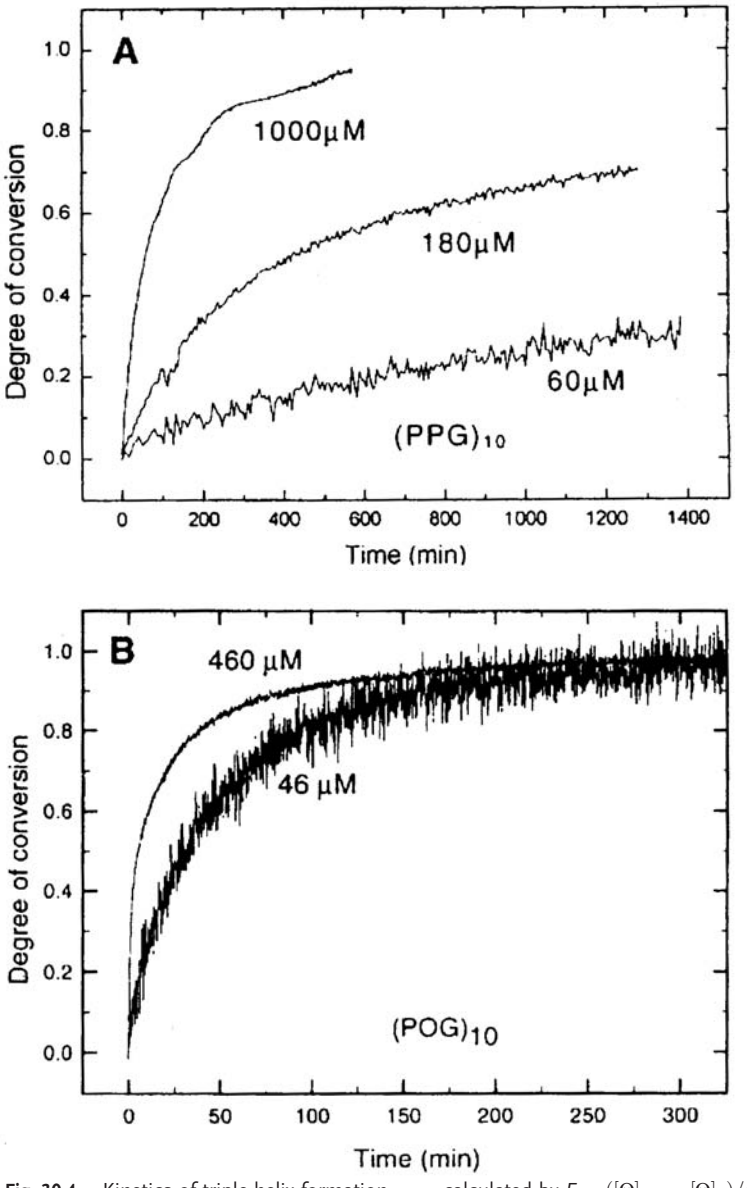

Fig. 30.4. Kinetics of triple helix formation of A) (ProProGly)$_{10}$ ((PPG)$_{10}$)) and B) (ProHypGly)$_{10}$ ((POG)$_{10}$)) at different peptide concentrations. The conversion was monitored at 7 °C after a temperature jump (dead time 2 min) from 60 °C in (A) and 70 °C in (B), temperatures at which the peptides are fully unfolded. The degree of conversion F was calculated by $F = ([\Theta]_{225} - [\Theta]_u)/([\Theta]_f - [\Theta]_u)$, where $[\Theta]_f$ and $[\Theta]_u$ are the ellipticities of the unfolded and folded state. The time courses for 60, 180, and 1000 μM concentrations of (PPG)$_{10}$ demonstrate a high dependence of the folding rate on concentration. For (POG)$_{10}$ the concentration dependence is much smaller and the rates are higher.

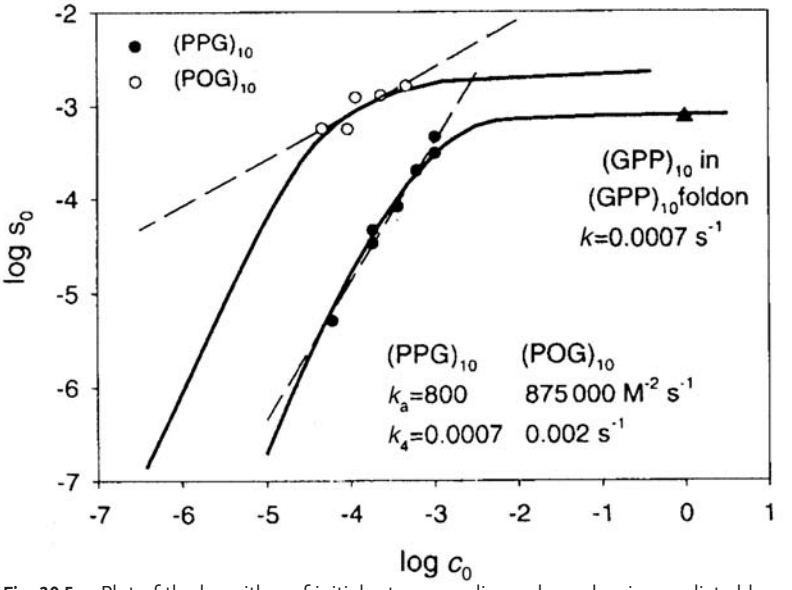

Fig. 30.5. Plot of the logarithm of initial rate of triple helix formation $s_o = (dF/dt)_{t=0}$ as a function of the logarithm of total chain concentration c_o for $(ProProGly)_{10}$ and $(ProHypGly)_{10}$. Broken lines show the best linear fits according to Eq. (2) with the apparent reaction orders of $n = 2.5$ and 1.5 for $(ProProGly)_{10}$ and $(ProHypGly)_{10}$, respectively. Continuous curves show better fits with nonlinear dependencies predicted by mechanism 13. The triangular point indicates the rate constant for $(ProProGly)_{10}$ in $(GlyProPro)_{10}$–foldon. This point was placed at a peptide concentration of 1 M ($\log c_o = 0$), which is the estimated intrinsic chain concentration at the junction of the $(GlyProPro)_{10}$ and foldon domain in $(GlyProPro)_{10}$–foldon.

Satisfactory fits of the time courses with theoretical integrated equations for even reaction orders could not be achieved, but fits with reaction orders of 2 were better than for 1 or 3. In agreement with similar observation with host–guest peptides [128], the data suggested that the reaction order changed with the progress of the kinetics. Therefore, initial slopes s_o were determined by careful extrapolations of the initial phases of the time courses (Figure 30.5).

Plotting $\log s_o$ as a function of $\log c_o$ yielded reaction orders that were 3 at very low concentrations but dropped with increasing concentration. Here c_o is the total concentration of single chains. Interestingly the concentration dependence of s_o for single chains of $(PPG)_{10}$ converged to the value measured for the first-order folding of the peptide cross-linked by foldon or the Cys-knot (see $(GPP)_{10}$–foldon and $(GPP)_{10}$–Cys_2 below).

Activation energies were determined from the temperature dependence of the folding kinetics of $(PPG)_{10}$ and $(POG)_{10}$. Values were much lower than for the cross-linked polypeptides (Table 30.4).

Tab. 30.4. Rate constants and activation energies of triple helix formation from single chains and trimerized chains at 20 °C.

Protein	k_a (M^{-2} s^{-1})	k_4 (s^{-1})	E_a (kJ mol^{-1})
$(ProProGly)_{10}$	900[a]	–	7
$(ProHypGly)_{10}$	about 10^6*	–	8
$(GlyProPro)_{10}$–foldon	0.00197	54.5	
$(GlyProPro)_{10}$–Cys_2	0.00033	52.5	

[a] Experimental values at 7 °C were 800 s^{-1} and 875 000 s^{-1}, respectively.

30.3.2.3 Model Mechanism of the Folding Kinetics

The following mechanism was proposed to explain the high reaction order and its concentration dependence

$$\begin{array}{l} C \\ + \\ 2C \underset{k_2}{\overset{k_1}{\rightleftarrows}} D^* \xrightarrow{k_3} H^* \xrightarrow{k_4} H \end{array} \qquad (13)$$

A schematic view of mechanism 13 is presented in Figure 30.6.

In this mechanism a very unstable dimeric nucleus D^* is in fast pre-equilibrium with monomers. Clearly a simultaneous collision of three particles in solution phase is an extremely infrequent event and a direct formation of a triple helical nu-

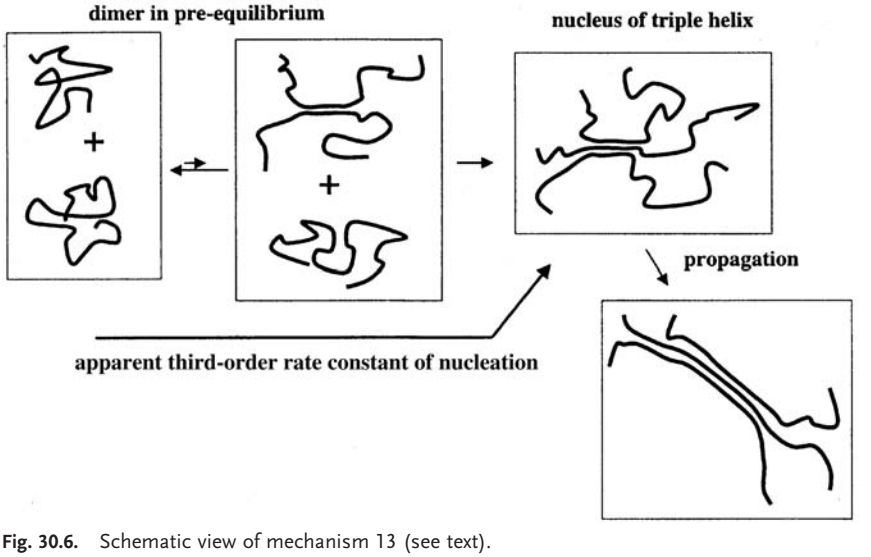

Fig. 30.6. Schematic view of mechanism 13 (see text).

cleus H^* can therefore be excluded. D^* forms in a bimolecular reaction and H^* is formed from it by combination with a third chain.

$$d[D^*]/dt = k_1[C]^2 - k_2[D^*] - k_3[D^*][C] = 0 \quad (14)$$

D^* is present only in very small amounts and therefore a steady state equilibrium ($d[D^*]/dt = 0$) is achieved shortly after the start of the reaction. Furthermore, dissociation into monomers is much faster than formation of H^* ($k_2 \gg k_3$ [C]) and the last term in Eq. (14) can be neglected. It follows that

$$k_1[C]^2 - k_2[D^*] = 0 \quad \text{or} \quad [D^*]/[C]^2 = k_1/k_2 = K \quad (15)$$

The rate of forming H^* (neglecting the decay term $- k_4[H^*]$) is

$$d[H^*]/dt = k_3[D^*][C] = Kk_3[C]^3 = k_a[C]^3 \quad (16)$$

It follows that the apparent third order rate constant k_a is the product of the equilibrium constant K and a true second-order rate constant k_3.

It is safe to assume that the nuclei D^* and H^* do not significantly contribute to the CD signal. This assumption is justified by the high instability and lack of triple helical structure of D^* and a very short segment of H^* (compared with the final length of H), which acts as a nucleus. Mechanism 13 predicts two limiting cases in which either nucleation or propagation is rate limiting.

At very low concentrations formation of H^* is the rate-limiting step and the rate of triple helix formation d[H]/dt equals the rate of nucleus formation as predicted by Eq. (16). In this case, the rate of helix propagation is faster than the rate of nucleation $k_4[H^*] \gg k_a[C]^3$. The experimentally observed degree of conversion F is related to [H] by $F = 3[H]/[C_0]$ in which $[C_0]$ is the total concentration of chains. Consequently the initial rate

$$(dF/dt)_{t=0} = 3k_a[C_0]^2 \quad (17)$$

At sufficiently high concentration nucleation will be faster than propagation and $[H^*] = (1/3)[C_0]$ after an initial phase. Propagation will then be the rate-limiting step of a first-order reaction

$$(dF/dt)_{t=0} = k_4[C_0] \quad (18)$$

Theoretical curves were calculated for mechanism 13 also for intermediate situations by numerical integration [121] and these curves are included in Figure 30.5. The dependencies were calculated with $k_a = 800$ and 875 000 M^{-2} s^{-1} and $k_4 = 0.0007$ s^{-1} and 0.002 s^{-1} for $(PPG)_{10}$ and $(POG)_{10}$, respectively. It can be seen that limiting case 1 is nearly reached for $(PPG)_{10}$, whose reaction order is 2.8–3 in the lowest concentration range. The average reaction order for all data

was 2.5 and as mentioned an extrapolation to high concentration of 1 M is consistent with the rate constant $k_4 = 0.0007\ s^{-1}$ determined for $(GPP)_{10}$ in $(GPP)_{10}$–foldon. Folding of $(POG)_{10}$ has an average reaction order of 1.5 and the initial rate plateaus at higher concentrations. It should be mentioned that experimental determinations of reaction orders are possible only in a rather narrow concentration interval, which is defined by the sensitivity of the CD spectrometer and the solubility of the model peptides.

30.3.2.4 Rate Constants of Nucleation and Propagation

The rate constants derived by mechanism 13 are summarized in Table 30.4. The apparent third-order rate constant k_a reflects the finding of the three chains and the nucleation process. According to the model mechanism 13 this includes formation of a dimeric precursor and the first short trimeric helical nucleus. The model is certainly oversimplified and in reality, chains may meet at many sites. Because of the repetitive sequence of the model peptides, precursors and nuclei will be of comparable stability if nucleated at different sites. The apparent rate constant k_a can therefore not be assigned to a single event. It should be noted that wrong nucleations and mismatching would also happen in natural collagens with their long repetitive sequences. This is probably the reason why special noncollagenous nucleation domains have been invented as registration domains.

Interestingly k_a differs by a factor of 1000 between $(PPG)_{10}$ and $(POG)_{10}$. A faster kinetics is expected in the presence of 4-hydroxyprolines in the Y-position because of its stabilizing action (see Section 30.2.4.3). The large effect of hydroxyprolines on the rate of nucleation may be based in a stabilization of the precursor dimer (increase of K) or in an increase of the rate of addition of the third chain (increase of k_3). Activation energies for k_a are much lower than for the rate constant of propagation (Table 30.4). It should be recalled that k_a is the product of an equilibrium constant with a negative temperature dependence and a true kinetic constant, which always increases with increasing temperature. The small activation energy is therefore most likely caused by a compensation of these opposing effects in a similar way as observed for other kinetics with pre-equilibria [129].

Propagation rate constants of $(PPG)_{10}$ and $(POG)_{10}$ differ only by a factor of 6 and are in fair agreement with the values found for the cross-linked trimerized peptides (Table 30.4). It is a long accepted fact that the rate-limiting events in propagation of collagen triple helices are the *cis–trans* isomerization steps of peptide bond preceding prolines or hydroxyprolines [122, 130, 131]. In unfolded chains, a certain fraction of peptide bonds is in *cis* configuration at equilibrium. In the triple helix, only the *trans* configuration can be accommodated. In other prolines containing proteins, *cis–trans* isomerization is also a slow rate-determining step. In collagens, this effect is particularly prominent because of their unusually high content of prolines and hydroxyprolines. *Cis–trans* isomerization steps process an unusually high activation energy, which originates from the need to uncouple the π-electron system of the semi-double bond during the transition from *cis* to *trans*. Rate constants of *cis–trans* isomerization and their activation energies are dependent on amino acids adjacent to prolines [117], but these changes are in a rather

narrow range and differences of no more than a factor of 10 in rate constants are expected.

An additional feature that may influence the kinetics is the equilibrium ratio of *cis* to *trans*, which again depends to some extent on the amino acid side chains preceding prolines or hydroxyprolines [117]. The approximate value for the equilibrium constant $K_{\text{cis-trans}}$ is 0.2 for the peptide bond between glycine and prolines. A rate constant $k_{\text{cis-trans}} = 0.003\ \text{s}^{-1}$ at 20 °C was determined for the isomerization of this bond in short peptides [116, 117]. Furthermore, variations of the prolines and hydroxyprolines content in the sequence will lead to differences in the number of *cis–trans* isomerization steps required for folding of a collagen segment. The last point does not apply to the comparison of $(\text{PPG})_{10}$ and $(\text{POG})_{10}$, but is relevant for the folding of natural collagens.

30.3.2.5 Host–guest Peptides and an Alternative Kinetics Model

Numerous studies have been performed with collagen-like model peptides of the design $(\text{GPO})_3\text{GXY}(\text{GPO})_4\text{GG}$. Here a guest tripetide is housed between stable hydroxyprolines containing host segments. Peptides of this type were mainly employed for studies of relative stability of guest tripetides with different residues in the X and Y position (see equilibrium part of this review). Kinetic studies were performed comparing guests GPO and GPP [128] in the host. A single GPP interrupting the GPO sequence is not expected to influence the nucleation rate by a large factor. Indeed the rate for the GPP containing peptide was only by a factor of 1.3 slower than that of $(\text{GPO})_8\text{GG}$. Apparently, the kinetic data as well as the equilibrium stabilities are mainly determined by the host regions (see equilibrium part). Time courses of refolding could not be fitted with even reactions orders and measurements of concentration dependencies were restricted to two concentrations. A third-order rate constant about $20\,000\ \text{M}^{-2}\ \text{s}^{-1}$ at 15 °C was derived.

The kinetics of another designed peptide T1-892Y with $(\text{GPO})_4$ at the C-terminus was investigated in greater detail [132]. The N-terminal part of this peptide AcG-PAGPAGPVGPAGARGPA was derived from collagen I. Data were fitted by a mechanism

$$3\text{C}_{cis} \underset{k_{\text{tc}}}{\overset{k_{\text{ct}}}{\rightleftarrows}} 3\quad \text{C}_{trans} \underset{k_{\text{fr}}}{\overset{k_{\text{rf}}}{\rightleftarrows}} \text{H}$$

in which k_{ct} and k_{tc} are the rate constants of *cis–trans* isomerization and k_{rf} and k_{fr} are the rate constants of folding of residues in *trans* conformation. To improve the fits the mechanism was expanded by a branching reaction at C_{trans}. Fitting results supported a nucleation domain composed mainly of the $(\text{GPO})_4$ moiety, which must be in *trans* form before the monomer is competent to initiate triple helix formation. Contrary to the highly positive activation energy of *cis–trans* isomerization, a negative activation energy was found, which was explained by a fast pre-equilibrium. Contrary to mechanism 13 the mechanism does not contain a dimer precursor and assumes a third-order reaction at any concentration in contrast to experimental findings with other model peptides.

Fig. 30.7. Sequences of the short N-terminal and the central triple helix in collagen III. In major parts of the GXY repeats, the residues in the X and Y positions are not indicated. Hydroxyprolines residues (O) were only defined by amino acid sequencing of bovine collagen III. In the other sequences proposed by cDNA sequencing, proline residues in the Y position are probably also hydroxylated, and are indicated by O.

The folding of the designed peptide T1-892 was also investigated by NMR spectroscopy [12, 92]. By this technique *cis–trans* isomerization steps of Gly-Pro and Pro-Hyp bonds were monitored. The study identified individual residues involved in *cis–trans* isomerization as the rate-limiting step in triple helix propagation. Interestingly, the authors were able to define the direction of growth. It started in the $(Gly\text{-}Pro\text{-}Hyp)_4$ part of the peptide, which was defined as a nucleation domain. This finding was incorporated in the above mechanism [132]. Furthermore, a zipper-like folding (see below) was confirmed by the NMR study.

30.3.3
Triple Helix Formation from Linked Chains

Pioneering kinetic work was performed with the short N-terminal and the long central triple helical domains of collagen III, which consists of three identical chains [122, 130, 131]. Both domains are terminated by a disulfide knot. Sequences from three species are compared in Figure 30.7 with the N-terminal parts of the triple helices schematically indicated by GXY repeats [133]. It should be recalled that prolines in Y-positions are hydroxylated to hydroxyproline probably in all chains (Figure 30.7).

Note that the cysteine-containing sequences are different in the two domains. It was however established by molar mass determinations that the three chains are interlinked to trimers in both cases. The three-dimensional structure of the disulfide knots has not been solved yet but two likely models were proposed for the knot terminating the central helix [45, 131].

30.3.3.1 The Short N-terminal Triple Helix of Collagen III in Fragment Col1–3

Fragment Col1–3 consists of the N-terminal propeptide, the short triple helix and a noncollagenous telopeptide. Trimerization by the knot led to an increase in thermal stability and the fragment melts reversibly in an all-or-none type transition

with a midpoint temperature of 53 °C. It refolded in a first-order reaction with a rate constant of 8×10^{-3} s^{-1}, indicating *cis–trans* isomerization to be the rate-determining step. The value matches the later measured values for the propagation rate constants of other systems (Table 30.4). Values are not expected to be identical, because of differences of amino acid composition in the different systems. As a control for the function of the disulfide knot, refolding of Col1–3 was also studied after reductive cleavage. Kinetics was extremely slow and concentration dependent and the transition temperature of the product dropped to 35 °C.

A closer look at the refolding kinetics of Col1–3 trimerized by the disulfide knot revealed that kinetics proceeds in two phases [130]. In experiments with a dead time of 25 s the fast phase remained unresolved. The amplitude of the fast phase was about 50% of the total and rather temperature independent. The amplitude was significantly increased when refolding was started from a nonequilibrium state of the unfolded molecule in which less *cis*-peptide bonds were present than in the equilibrium state. The nonequilibrium state was achieved by refolding from chains, which were unfolded so quickly that most of the *trans* configuration present in the native triple helix was maintained. Experiments closely followed the double jump experiments [134] designed for similar experiments with ribonuclease S. Data are quantitatively analyzed by the zipper model of folding, which will be presented after discussing the kinetic data of the central triple helical domain.

30.3.3.2 Folding of the Central Long Triple Helix of Collagen III

For the central long triple helix the C-terminal propeptide provides a noncovalent link between the chains in the nonprocessed state but even after its removal the chains remain linked by the disulfide knot. The refolding kinetics of this trimerized, purely triple helical domain has been studied in great detail [28, 122]. Contrary to the refolding from noncross-linked chains, the unfolding–refolding process was completely reversible and end-products of refolding at 25 °C were identical to the native molecules as judged by their melting profiles, molecular weights, and sedimentation behavior. Mismatched structures of low stability were formed only at temperatures <15 °C.

The growth of the triple helix was found to proceed from the disulfide knot at the C-terminus at a rather uniform rate in a zipper-like fashion. This was most clearly shown by experiments in which the appearance and disappearance of folding intermediates was monitored directly (Figure 30.8).

The proteolytic assay is based on the ability of the collagen triple helix to resist trypsin digestion whereas the unfolded chains are readily degraded to small fragments [135]. Applying this method it was clearly shown that the folding intermediates all included the disulfide knot. Intermediates with short native triple helices are found at the start of the folding process. They decay and are replaced by longer fragments and finally native molecules with triple helices of full length are formed. In Figure 30.8 this is shown for the chains liberated by disulfide cleavage after digestion by trypsin. Gels were also run under nonreducing conditions [122]. In this

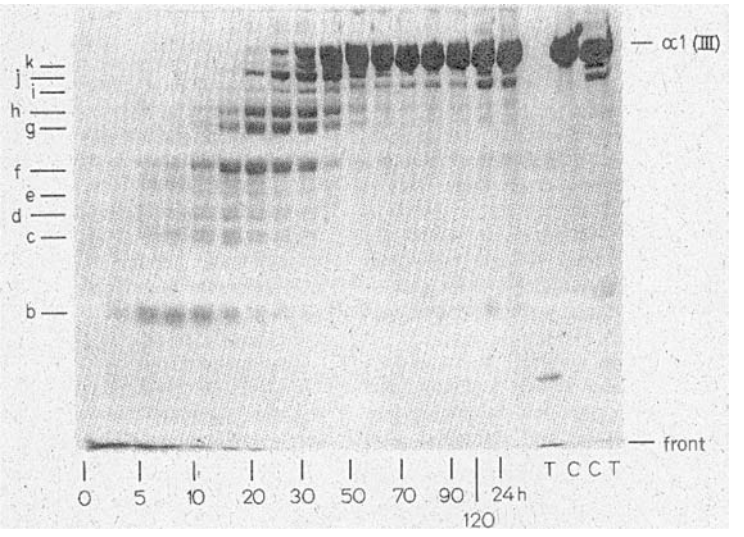

Fig. 30.8. Dodecyl sulfate slab gel electrophoresis of chain fragments which were protected against trypsin digestion by refolding. Type III collagen was denatured at 45 °C for 20 min and renatured at 25 °C for the time interval indicated. After incubation with trypsin at 20 °C for 2 min, sodium dodecyl sulfate was added and the sample was run on 10% polyacrylamide gel under reducing conditions. Eleven trypsin-resistant chain fragments designated by the letters a–k can be clearly distinguished. For comparison, native untreated collagen (C), native trypsin-treated collagen (CT) and trypsin (T) were also run.

case intermediates are not as well resolved because of their three times larger size but the same conclusions can be drawn. Furthermore, identical results were obtained with pN-collagen III, demonstrating that the N-terminal propeptides are not involved in the folding process.

For the zipper-like folding from the C-terminus zero-order kinetics is expected for a large initial fraction of the conversion (see next section). This behavior was experimentally observed for time courses followed by CD (Figure 30.9) [122].

Comparing the kinetics of the long central triple helix with those of the Col1–3 domain and the so-called one-quarter fragment obtained by selective proteolytic cleavage [136], a direct proportionality of the half-times to chain length was observed (Figure 30.9). This observation provides strong additional support to the zipper-like folding.

From the temperature dependence of refolding, activation energies of 85 kJ mol^{-1} were derived for the folding of the central triple helical domains, supporting that the propagation of the zipper is rate limited by *cis–trans* isomerization steps [130]. With the help of a model mechanism, it was concluded that on average, 30 amino acid residues occur in uninterrupted stretches without *cis* peptide bonds. They convert in a fast reaction after each isomerization step. The average rate constant of the isomerization steps was found to be 0.015 s^{-1} at 20 °C.

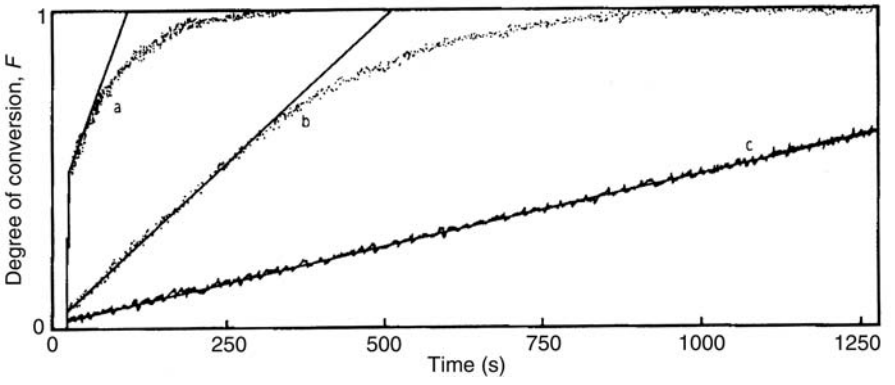

Fig. 30.9. Comparison of the folding kinetics of type III pN-collagen, the quarter fragment of type III collagen, and peptide Col1–3. Refolding of the collagen (c), the quarter fragment (b), and Col1–3 (a) were measured by circular dichroism. The straight lines represent the initial rates.

30.3.3.3 **The Zipper Model**

The model for the zipper-like folding of collagen triple helices is shown in Figure 30.10.

Here the disulfide knot is called h_0 and tripeptide units in correct helical conformation are called h. In the coiled state tripeptide units (v) with all peptide bonds in *trans* configuration are distinguished from units (w) which contain a *cis* peptide

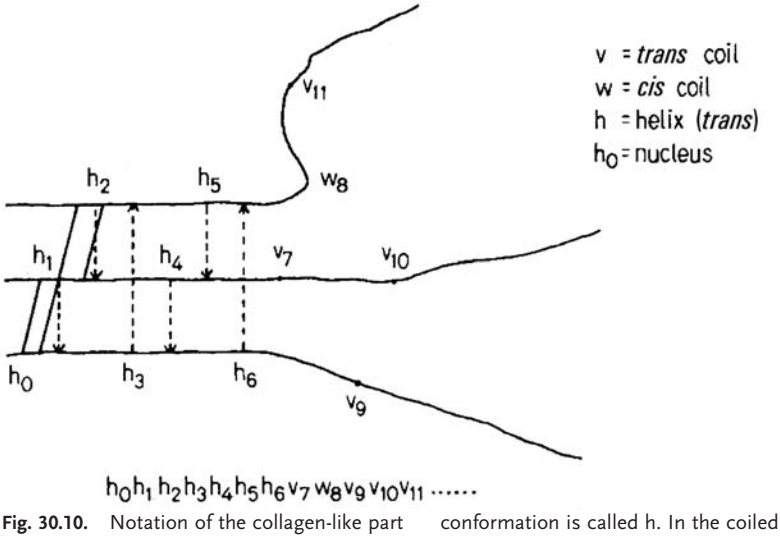

Fig. 30.10. Notation of the collagen-like part of Col1–3 as a linear sequence of letters. The three disulfide bridges are called h_0 and a tripeptide unit while the correct helical conformation is called h. In the coiled state, tripeptide units (v) with all peptide bonds in the *trans* configuration are distinguished from units (w) that contain a *cis* peptide bond.

bond. Tripeptide units are numbered in the way triple helix formation is believed to occur in a sequential way: to an already formed triple helix a tripeptide unit of chain A is added, followed by addition of the closest unit from chain B and then from C. A, B, and C are the designations for the three different chains in collagens. Each addition of a tripeptide unit is defined as a propagation step.

With the above notation, any state during folding can be written as a linear sequence of letters h, v, and w. For example, the partially folded state of Figure 30.10 reads $h_0$hhhhhhvwvvv ..., with h_0 acting as a permanent nucleus. It was shown by designed models for the triple helix (see following sections) that nucleation is mainly achieved by enforcement of a close neighborhood of residues near to the disulfide knot. The local concentration near the disulfide knot is close to 1 M as estimated from the model of the disulfide knot [131] and from the stability of $(GPP)_{10}$–foldon (see equilibrium part). The studies with designed proteins demonstrated that the disulfide knot may be replaced by any other trimerizing agent without affecting the nucleation potential. It should also be recalled that the disulfide knot (or other trimerizing cross-links) serve the important function of keeping the chains in the correct register and preventing misalignments.

Only the stretch of uninterrupted v units, which starts from h_0 and is terminated by the first w, can convert to the triple helix without *cis–trans* isomerization. Under conditions in which back reactions can be neglected, the relative amplitude of the fast phase (δA_f) or slow phase (δA_s) becomes

$$\left(\frac{\delta A_f}{\delta A_0}\right)_{max} = 1 - \left(\frac{\delta A_s}{\delta A_0}\right) = \frac{\langle i_v \rangle}{n} \tag{19}$$

with

$$\langle i_v \rangle = \sum_{i=1}^{n-1} i p_v^i p_w + n p_v^n = \frac{p_v(1 - p_v^n)}{1 - p_v} \tag{20}$$

Here δA_0 is the total change, $\langle i_v \rangle$ is the average length of uninterrupted v units, and n is the total number of tripeptide units in the triple helix. The probabilities of v and w states, p_v and p_w, are related by the equilibrium constant $K = [v]/[w]$ of *trans* to *cis* isomerization.

$$p_v = \frac{K}{1 + K} \tag{21}$$

It can be shown for large n that $\langle i_V \rangle$ may be approximated by K. For peptide Col1–3 with $n = 43$ (Figure 30.9) the relative amplitude of the fast phase was 0.5 and a value of $K = 25$–30 is derived. Note that this equilibrium constant is an average over regions of variable proline and hydroxyproline content and is much larger than the equilibrium constant for the isomerization of a single X-Pro or X-Hyp bond. Assuming that K is identical for the central triple helix ($n = 1026$) and the

quarter fragment ($n = 248$) the relative amplitude is predicted to be inversely proportional to n. This is exactly fulfilled by the experimental data shown in Figure 30.9.

After the initial fast phase, helix propagation will proceed with a rate determined by the rate constant of *cis–trans* isomerization k. Each isomerization step will liberate $(1 + K)$ v segments and the initial rate of the change in degree of helicity F will be

$$\left(\frac{dF}{dt}\right)_{t=0} = k\frac{(1+K)}{n} = k_{app} \tag{22}$$

From kinetic experiments, (Figure 30.9) it was only possible to determine the apparent rate constant k_{app} from the initial rates of the curves. Assuming a rate constant of $k = 0.015\ s^{-1}$ as measured for the isomerization of a Gly-Pro bond [137], other data in [116, 117, 130] follow $K = 30$ in close agreement with the value obtained from the amplitude of the fast phase. This implies that on average about every thirtieth tripeptide unit in the coiled chains of collagen III contains a *cis* peptide bond. This value fits well with qualitative estimates from the distribution of proline and hydroxyproline residues.

It was also possible to derive the time course of the entire slow phase (Figure 30.11).

The probability of finding i w segments in a molecule of n coiled segments is given by a binominal distribution with the probabilities for *trans* and *cis* segments defined in Eq. (14)

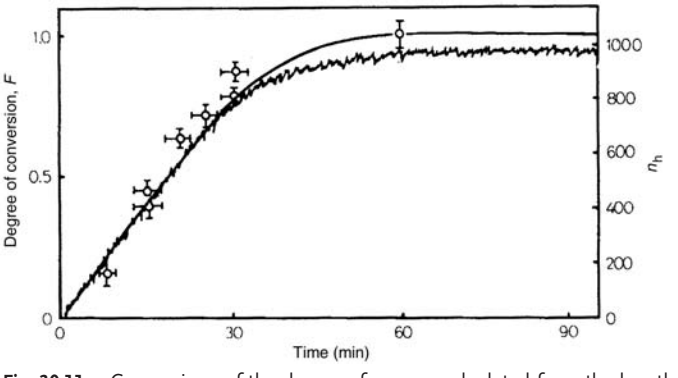

Fig. 30.11. Comparison of the degree of conversion F and length of the chains in triple helical conformation n_h during refolding of type III pN collagen at 25 °C. The experimental curve for the recovery of F with time at 25 °C was taken from Figure 30.9. It is compared with the number of residues in helical conformation n_h (open circles), which was calculated from the length of the trypsin-restistant fragments of Figure 30.8. The experimental time dependencies of n_h and F are compared with theoretical refolding kinetics (drawn-out curve). This was calculated by Eqs (24) and (28) with $k = 0.015\ s^{-1}$ and $K = 30$.

$$\hat{p}_{\mathrm{i}}^{n} = \binom{n}{i} p_{\mathrm{v}}^{n-i} p_{\mathrm{w}}^{i} \tag{23}$$

We consider a species that initially contains i w segments and that converts to a fully helical molecule without w segments. Whenever the growing helix reaches a w segment a *cis* → *trans* isomerization at the h–w junction will lead to a continuation of helix growth and to a species with one w segment less. A *cis* ↔ *trans* isomerization will also occur at other places of the molecule. Since these steps are not coupled to the irreversible helix formation, they are reversible and on average, the same number of w segments will be formed and destroyed. These steps will therefore not contribute to the reaction of interest. As noted above, the rate of helix formation is constant as long as all species contain at least one w segment. This certainly holds true in the beginning of the reaction since $\hat{p}_0^{1018}$ in the binominal distribution (Eq. (23)) is essentially zero. In the later phase of the reaction, however, fully helical species with no h–w junctions will be formed which no longer contribute to the reaction. The approximation $[\mathrm{hw}] \approx c_{\mathrm{P}}$ in Eq. (22) is no longer valid and $f_{\mathrm{hw}} = [\mathrm{hw}]/c_{\mathrm{P}}$ must be calculated as a function of time. Equation (22) becomes

$$\frac{\mathrm{d}F}{\mathrm{d}t} = \frac{k(1+K)}{n} f_{\mathrm{hw}}(t) \tag{24}$$

In order to calculate f_{hw}, the species that initially contains i w segments is designated M_1, the species that is derived from it by disappearance of one w segment M_2, etc. The formation of the final product with no w segments, M_{i+1}, will require i sequential steps which all proceed with the rate constant of *cis* → *trans* isomerization k:

$$\begin{array}{ccccccccc} \mathrm{M}_1 & \xrightarrow{k} & \mathrm{M}_2 & \xrightarrow{k} & \cdots & \xrightarrow{k} & \mathrm{M}_{\mathrm{r}} & \xrightarrow{k} \cdots \xrightarrow{k} & \mathrm{M}_{i+1} \\ i & & i-1 & & i-r+1 & & & & 0 \end{array} \tag{25}$$

$i, i-1, i-r+1$ and 0 indicate the number of w segments in the species.

The rate equations are

$$\frac{\mathrm{d}f_1}{\mathrm{d}t} = -kf_1 \tag{26a}$$

$$\frac{\mathrm{d}f_r}{\mathrm{d}t} = -kf_r + kf_{r-1} \tag{26b}$$

$$\frac{\mathrm{d}f_{r+1}}{\mathrm{d}t} = -kf_{r+1} + kf_r \tag{26c}$$

with $1 < r < i+1$.

Here $f_1, f_2 \ldots f_r, f_{r+1} \ldots f_{i+1}$ are the fractions of species in reaction (25). A fraction is defined by $f_r = c_r/c_1^0$ where c_1^0 is the initial concentration of M_1. To find a solution of this set of first-order linear differential equations we introduce

$$f_r = \Phi(t)e^{-kt} \quad \text{and} \quad f_{r+1} = \Psi(t)e^{-kt}$$

it follows that

$$\frac{df_{r+1}}{dt} = -kf_{r+1} + \frac{d\Psi}{dt}e^{-kt}$$

and with Eq. (26c)

$$\frac{d\Psi}{dt} = k\Phi(t)$$

The initial conditions at $t = 0$ are $f_1^0 = 1$ and all other $f_r = 0$. Integration of the first differential Eq. (26a) with this conditions yields

$$f_1 = e^{-kt} \quad \text{and} \quad \Phi(t) = 1$$

It follows that

$$\Psi(t) = kt \quad \text{and} \quad f_2 = kte^{-kt}$$

Stepwise application of this scheme to $r = 3, 4, \ldots r$ yields the general solution

$$f_r = \frac{(kt)^{r-1}}{(r-1)!}e^{-kt} \tag{27}$$

In order to obtain the fraction of molecules which contain at least one w segment we have to take the sum of f_r from $r = 1$ to $r = i$. Since these are fractions of the species present in the initial distribution we have to multiply each sum over f_r by corresponding $\hat{p}_i^n$ and to take the sum over this distribution in order to obtain the total fraction of species with at least one w segment and with one h–w junction

$$f_{hw} = \sum_{i=0}^{i=n} \hat{p}_i^n \sum_{r=1}^{r=i} \frac{(kt)^{r-1}}{(r-1)!}e^{-kt} \tag{28}$$

The rate of helix formation can now be calculated by Eqs (24) and (28) and the time dependence of F can be obtained by numerical integration of Eq. (24) into which f_{hw} Eq. (28) was substituted. A good fit to the experimental time course was obtained with the parameters $k = 0.015\ s^{-1}$ and $K = 30$ (see Figure 30.11).

30.3.4 Designed Collagen Models with Chains Connected by a Disulfide Knot or by Trimerizing Domains

Natural collagens contain triple helices whose chemical and physical properties are different at different positions of the helix. This property originates from variations of residues in X and Y positions. As described in the equilibrium part stabilities largely depend on the nature of X and Y in short peptides and differences may also result in long triple helices although cooperative influences of neighboring segments may reduce the effect.

Kinetic measurements of designed model proteins with GPP-, GPO-, or other collagen-like repeats, avoid complication caused by sequence heterogeneity. In addition, it is possible to study the influences of cross-linking in a quantitative way. Two methods of cross-linking were applied. In the first one, two Cys residues were added to the ends of the chains either by peptide synthesis or by fusion of the disulfide knot of type III collagen by recombinant technology. The chains were then joined by controlled oxidative coupling. In the second method, noncollagenous domains were fused to either the N- or C-terminus of the model peptide.

30.3.4.1 Disulfide-linked Model Peptides

Cys repeats that differ from those found at the ends of the central helix of collagen III and were different in different chains were placed at the C-termini of model peptides by elaborate peptide chemistry [138]. This strategy was primarily followed to design substrates for matrix metalloproteases (MMPs) and for integrins, which are both structure dependent and recognize triple helices composed of all three chains. The model collagens designed in his way refolded reversibly with first-order kinetics [138]. If reduced they lacked the potential to reform intact triple helices upon reoxidation in the presence of glutathione (L. Moroder, personal communication). Reoxidation was successful, however, when the disulfide sequence GPPGPCCGG of collagen III was used, proving the potential of this sequence for spontaneous formation of a disulfide knot [44–46].

In particular $(GPP)_{10}GPCCGG$ (abbreviated $(GPP)_{10}–Cys_2$) was expressed recombinantly and converted to a trimer in triple helical conformation by reoxidation in the presence of 9 mM oxidized and 0.9 mM reduced glutathione [121]. Data on the stabilization of the $(GPP)_{10}$ triple helix by the cross-link have been reported in the equilibrium part of this review. The kinetics of refolding was monitored after cooling from 70 °C to temperatures between 7 and 35 °C in the presence of 2.5 M GdmCl. The denaturant was added to shift the transition region to a more accessible region, since in plain buffer $(GPP)_{10}–Cys_2$ melts at 90 °C. Kinetics proceeded in a fast, experimentally unresolved phase and a dominant slow phase, which was of first order and concentration independent over a broad range of peptide concentrations. Measurements were performed by CD at the ''collagen CD signal'' at 221 nm. A large temperature dependence of the CD signal pointed to nonconformation-dependent signal change, which was also kinetically unresolved and subtracted from the time course. The measured first-order kinetic

constants are included in Table 30.1 for comparison with the apparent third-order constants for the free uncross-linked chains. For reasons discussed in Ref. [121] activation energies (Table 30.4) were somewhat lower than measured for the *cis–trans* isomerzation of dipeptides [116, 117]. There is no doubt that the slow phase of the refolding reflects the propagation step, whose rate is determined by *cis–trans* isomerization of peptide bonds. The rate constants for the isomerization of individual prolines containing bonds in $(GPP)_{10}$–Cys_2 are unknown and it should be recalled that the overall rate constants are composites of these values.

30.3.4.2 Model Peptides Linked by a Foldon Domain

The foldon domain of T4 phage fibritin consists of three chains with 29 amino acid residues each and forms an obligatory trimer of high stability [46, 86]. Foldon domains were fused to the $(GPP)_{10}$ chains via a GS-linker and the chains were trimerized very efficiently. Care was taken not to unfold the foldon domain in all kinetic measurements performed with $(GPP)_{10}$–foldon. All data therefore correspond to the $(GPP)_{10}$ domains interlinked by an intact foldon trimer.

Results obtained with $(GPP)_{10}$–foldon were very similar to the results obtained with $(GPP)_{10}$–Cys_2 (Table 30.4). The identity of results shows that nucleation of the collagen triple helix is primarily determined by the trimerization at one end and that it does not matter which trimerization domain is applied. It is concluded that a domain like foldon, which was designed to nucleate the folding of fibritin to a trimeric coiled-coil structure, has the same function as the collagen-specific disulfide knot and probably also all other C- or N-terminal propeptide domains of natural collagens. The argument is supported by the observation that propeptide domains differ largely in structure (see Introduction) but do all form trimers.

30.3.4.3 Collagen Triple Helix Formation can be Nucleated at either End

As mentioned earlier, propeptides and disulfide bonds, which are believed to nucleate triple helix folding, are located at the C-terminus of most natural collagens. Exceptions are the membrane-spanning collagens XIII, XVII, XXIII, and XXV, which contain coiled-coil domains at the N-terminal side of the triple helix [139]. Three-stranded coiled-coil domains frequently act as oligomerization domains in extracellular membrane (ECM) proteins [140] and mutation data suggested that the coiled-coil domains nucleate triple helix formation in collagen XIII [141].

In this context, it was of interest to learn whether the kinetics of triple helix formation may be different for nucleation at the N- or C-terminal end. The problem was approached by a comparison of model peptides $(GlyProPro)_{10}$, which were either linked to trimers at the N- or C-terminus [165]. Linkage was either achieved by fusion with a short segment containing the disulfide knot of collagen III or by attachment of the foldon domains. In both cases a stabilization of the triple helix after cross-linking was observed, which was however somewhat less pronounced in the case of N-terminal attachment compared with C-terminal fusion. This difference may be explained by energy differences in the contact regions between the oligomerization domains and the triple helix. In the crystal structure of

$(GlyProPro)_n$–foldon [86] several bad contacts were observed in the contact region between the triple helix and the foldon domain. It was concluded that unfavorable enthalpic interactions may in part counteract the entropic stabilization by cross-linking. The structure of foldon–$(GlyProPro)_n$ was not solved yet but different and probably more unfavorable interactions are anticipated in its contact region. It was also noticed that the insertion of Gly-Ser spacers between the oligomerzation domain and the triple helix is essential. Most importantly, however, the kinetics of triple helix formation was identical for all four model systems $(GlyProPro)_n$–foldon, foldon–$(GlyProPro)_n$, $(GlyProPro)_n$–Cys_2 and Cys_2–$(GlyProPro)_n$. Also, the activation energies of folding were identical for all four peptides. Rate constants of folding were about 10^{-3} s^{-1} at 20 °C and the activation energy was 50 kJ mol^{-1} [165]. In summary, triple helix formation proceeds with closely similar rates in both directions. For the alignment of strands and nucleation of triple helical folding, oligomerization domains are needed but these may be placed at both ends of the triple helix. Their more frequent occurrence at the C-end is not explained by an easier folding from this side.

30.3.4.4 Hysteresis of Triple Helix Formation

As mentioned in Section 30.2.3, thermal unfolding and refolding of the triple helix is highly rate dependent in the transition region. Consequently, transition curves recorded by heating and by cooling form a hysteresis loop (see Figure 30.1). Hysteresis is very prominent for long natural collagens like collagen III and is also observed under isothermal conditions when unfolding is induced by increasing the concentration of guanidine hydrochloride [28]. In the case of collagen III with an intact disulfide knot at the C-terminus, correct and complete refolding of native molecules is achieved at temperatures 10 or more degrees below the transition temperature (or 0.5 M below the GdmCl midpoint concentration) after short incubation times of a few hours. In these cases, true hysteresis, in which equilibrium values are not reached even after very long waiting times, is limited to the range near the transition temperature. As mentioned in Section 30.3.2.1 and other parts of this review, unlinked single chains refold to misaligned structures at low temperatures. In these cases, an apparent hysteresis is observed, when monitoring CD or other parameters. The nature of this apparent hysteresis is very different from the true hysteresis because refolding products differ from the native parent molecules.

It was noticed that hysteresis was less prominent for short collagen triple helices like the one-quarter fragment of collagen III [28]. More recently, it was found that hysteresis loops are clearly observable also for short model peptides as long as the heating and cooling rates are not too slow. The major difference between native long triple helices and short model peptides is apparently the time dependence. For long triple helices the loops persist even at very slow scan rates whereas for short triple helices equilibrium is achieved more quickly.

For the model systems with linked chains, a simple kinetic hysteresis mechanism is proposed (Boudko, Bächinger, and Engel, in preparation). In the transition region the reciprocal apparent rate constant is

$$k_{\mathrm{app}}^{-1} = \frac{1}{k_{\mathrm{f}} + k_{\mathrm{u}}} \tag{29}$$

in which k_{f} and k_{u} are the rate constants of folding and unfolding, respectively. Rate constant k_{f} is dependent on temperature according to the Arrhenius relation with the high activation energy $E_{\mathrm{a,f}}$ of *cis–trans* isomerization (see Section 30.3.3). The temperature dependence of k_{u} is much lower and its activation energy $E_{\mathrm{a,v}}$ can be calculated from $E_{\mathrm{a,f}}$ and the enthalpy of the reaction by $E_{\mathrm{a,v}} = E_{\mathrm{a,f}} - \Delta H^{\circ}$. A satisfactory fit of the experimentally observed change of helicity F during heating or cooling is obtained when the rate law

$$\frac{\mathrm{d}F}{\mathrm{d}t} = k_{\mathrm{f}}(1 - F) - k_{\mathrm{u}}F \tag{30}$$

is integrated with the starting conditions (1) $F = 1$ at $t = 0$ for heating and (2) $F = 0$ at $t = 0$ for cooling. Case 1 yields the time course

$$F = \frac{K}{1 + K} + \frac{1}{1 + K}\mathrm{e}^{-k_{\mathrm{app}}t} \tag{31}$$

and case 2

$$F = \frac{K}{1 + K}(1 - \mathrm{e}^{-k_{\mathrm{app}}t}) \tag{32}$$

with $K = k_{\mathrm{f}}/k_{\mathrm{u}}$. The hysteresis loops can be constructed by calculation of F after different times at different temperatures. Obviously for infinite times t the equilibrium curve $F = K/(1 + K)$ is obtained.

The mechanism of hysteresis for long triple helices of natural collagens is clearly more complicated. They do not fold in an all-or-none reaction like the short proteins as demonstrated by a cooperative length that is about 1/10 of the length of the molecule [28]. A possible mechanism was proposed in Ref. [142].

30.3.5
Influence of *cis–trans* Isomerase and Chaperones

Catalysis of the folding of many proline-containing proteins was discovered shortly after the discovery of the kidney enzyme peptidyl-prolyl *cis-trans* isomerase (PPIase) [143]. Three protein families are now known to have PPIase activities: the cyclophilins, the FK506 binding proteins (FKBP) and the parvulins. In vitro experiments showed that cyclophilin has an accelerating effect on the folding of collagen III [144], but the factor was only close to 2. A similar effect was also found for collagen IV [145]. The action of PPIase on collagen was substantiated by the finding that cyclosporin A [146] and to a lesser extent FK506 [147] slows triple helix forma-

tion in vivo. FKBP65 had only a small effect on the rate of refolding on type III collagen [148]. PPIases are widely distributed and the *Escherichia coli* variant was also investigated with collagen [149]. It was speculated that the relatively small accelerations may originate from the use of enzymes that are not specific for collagen. A PPIase with an acceleration factor of 100 or more as observed for other proteins has not yet been observed. Such an enzyme may, however, be a necessity for animals living in a cold environment at which *cis–trans* isomerization is very slow, because of its high activation energy.

Numerous other helper proteins have been identified in the context of collagens (for reviews see Refs [150, 151, 152]). A collagen-specific chaperone is HSP47, whose physiological importance is manifested by a severe phenotype of transgenic mice lacking HSP47 [153]. Several very different mechanisms of action were discussed for HSP47, but with the exception of a specific binding to collagen, molecular explanations remain to be explored.

30.3.6
Mutations in Collagen Triple Helices Affect Proper Folding

Mutations in collagen genes cause a number of severe inherited diseases [154, 155]. The best-studied collagen-related genetic disease is osteogenesis imperfecta (brittle bone disease). Point mutations at different positions of the triple helix lead to improperly folded and instable triple helices, disturbed fiber formation, and severe pathological changes of the collagen matrix. Mutations near the C-terminus tend to be more severe than similar mutations near the N-terminus. In view of the steric need of small glycine residues in every third position (see Section 30.1.4), mutations of glycines to residues with larger side chains are particularly disturbing and cause large decreases of transition temperatures. In some cases, even kinks were visualized in such mutated collagens [156]. A delayed triple helix formation of mutant collagen from patients with osteogenesis imperfecta was observed [157]. Hydroxylation of prolines only occurs in the unfolded state and consequently the extent of hydroxylation and other posttranlational modifications was much increased in the mutated collagens, apparently at the N-terminal side of the mutation. Recently model peptides were studied with sequence irregularities designed after important natural mutations [158]. With this approach, it is hoped to gain deeper explanations of how a single-point mutation in the triple helix may cause a global pathological condition.

31
Unfolding Induced by Mechanical Force

Jane Clarke and Phil M. Williams

31.1
Introduction

Force spectroscopy has, as yet, been used in very few protein folding laboratories. One has to ask why this is so. There are several possible explanations. First, until relatively recently, only specialized instrumental laboratories had the technical expertise to build instruments. This has been overcome with the advent of commercially available instruments that are relatively simple to use, menu driven, and in one case, where the programming software (Igor) can be adapted for the investigators' convenience – facilitating data collection, collation and analysis. Second, preparing a protein sample is time consuming. With current molecular biology techniques it is possible to clone and express many single domain mutant proteins in the matter of a couple of weeks. But despite the development of versatile cloning systems, the cloning of a polyprotein substrate can take months (and this has to be repeated for each mutant protein you wish to analyze), and after this, a number of simple-to-express, single domain proteins have turned out to be insoluble as polyproteins. Third, the data are complex and time consuming to collect and analyze. Ironically many repeats of the single molecule experiments are required to collect enough data to analyze, and even the very best data can be noisy and are intrinsically unsatisfactory for those of us who are used to collecting many kinetic data points with exquisite accuracy. Worse still, the investigator has to select which data to analyze and which to discard – an anathema to careful experimentalists. Fourth, the data cannot be analyzed by fitting to a simple model, rather a Monte-Carlo or analytical approach has to be used to extract kinetic data.

So, why bother with these experiments? First, there is a biological imperative. It is increasingly apparent that many proteins experience significant force in vivo. In fact, response to mechanical stress has been implicated in a number of signaling pathways. This means that proteins have evolved to resist unfolding when subject to an external force. It has been shown in at least one case that the barrier to unfolding under mechanical stress is not that investigated by traditional unfolding experiments. Only dynamic force experiments can reveal these details of the protein folding landscape. Second, there is an interesting structural biology problem

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

of comparison. Why are certain protein folds stronger than others? How does sequence variation affect mechanical stability? Can the effect of mutation be predicted? How are domains assembled in some of the large multidomain natural load-bearing proteins? Finally, forced unfolding experiments can easily be directly compared with computer simulations. The reaction coordinate (N–C length) is known and measurable.

In this chapter we first describe the experiments and summarize the theoretical background for the analysis of these experiments. We describe how the analysis is performed and what kinetic parameters can be obtained and the confidence limits of these parameters. (We are concentrating on atomic force spectroscopy, as techniques that exploit lower loading rates, such as optical tweezers, have yet to be used on single protein domains and the instrumentation is more complex.) We then show how complementary techniques can be used to help our understanding of the data obtained. We end with a case study of a single protein, illustrating how combination of a number of techniques has enabled the forced unfolding mechanism to be examined in detail.

31.2 Experimental Basics

31.2.1 Instrumentation

A number of commercial instruments are available for use in protein folding laboratories. Figure 31.1 shows the basic components of such instruments. The principle components are a stage, to which is attached the protein substrate, a microfabricated cantilever, and a piezoelectric positioner which adjusts the relative position of the cantilever and stage with subnanometer accuracy.

The protein sample is placed onto the stage. In most experimental studies published to date the protein substrate is a long, multimodular molecule. This may be either a natural multimodular protein, such as a portion of a long extracellular matrix or muscle protein or an engineered construct of multiple repeats of single domains (see Section 31.2.2). Attachment of the protein to the stage may be achieved by specific attachment, for example a gold-sulfur linkage with cysteines at the terminus of the protein, or by nonspecific adsorption onto a glass surface. The protein and cantilever are surrounded by solvent, either as a droplet or in an enclosed cell.

Likewise, attachment to the cantilever is generally through nonspecific adsorption to the surface, although cantilevers can be modified to allow specific attachment. The commercial cantilevers used are usually made of silicon nitride, and are ~20–300 μm in length. The key component is an unsharpened tip (radius ~ 50 nm) to which the protein adsorbs. (Sharper tips are available, but this larger, blunter tip gives a better surface for adsorption of the protein.) Cantilevers used in protein unfolding experiments typically have spring constants in the range 10–

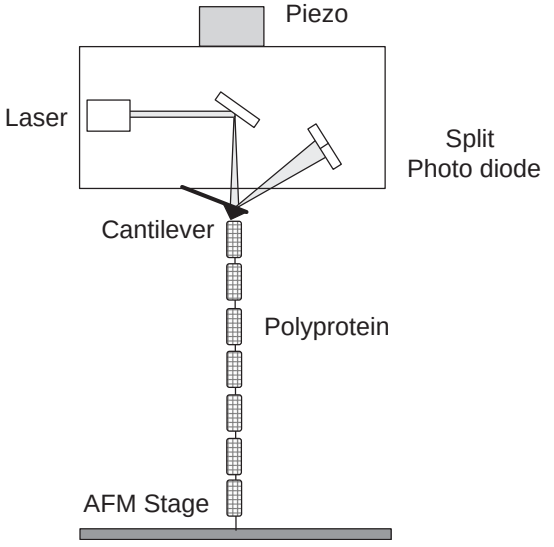

Fig. 31.1. Diagram of an atomic force microscope. The protein molecule is deposited onto the stage and adsorbed to the microfabricated silicon nitride cantilever. The deflection of the cantilever is used to determine the force exerted upon the protein, once the spring constant of the cantilever is known. The separation between stage and cantilever is controlled by the piezo which is capable of repeated cycles of extension and retraction. The photodiode measures the laser light reflected off the back of the cantilever. The deflection of the cantilever is determined from the difference in the output voltages from the two halves.

100 pN nm^{-1}. The actual spring constant has to be measured at the start of each experiment, using methods that are integrated into the software of the commercial instruments. The backs of the cantilevers are reflective and the position of the cantilever is determined by use of a laser reflected onto a split photodiode. Following calibration of the instrument to determine the relationship between photodiode output and bending of the cantilever, the force applied on the protein is determined directly from the deflection of the cantilever. A piezoelectric positioner adjusts the separation of the cantilever tip and the surface.

31.2.2 Sample Preparation

As a tool for protein folding, fragments of large, natural multidomain proteins such as the giant muscle protein titin [1], or the cytoskeleton protein spectrin [2], are of limited use, as they do not report on the unfolding of specific protein domains. Although a few experiments have been reported where a single protein domain has been suspended between tip and stage (see, for example, Ref. [3]), most experiments have used large "polyproteins" which have multiple repeats of a single protein domain cloned in tandem. These large polyproteins have the advantage

of holding the protein at a significant distance from the surface before unfolding occurs, so that tip/surface or protein/surface interactions are minimized.

A number of approaches for constructing such repeats have been reported [4–6], but the most versatile are those that use different restriction enzyme sites at the start and end of each domain. One such system is available on request from our laboratory [6]. The first protein to be multimerized in this way was titin I27. It has a poly-His tag at the N-terminus to facilitate affinity purification, and two cysteines at the C-terminus to attach the protein to an AFM stage by a gold-sulfur linkage. This protein can be produced in large amounts as a soluble polyprotein in *Escherichia coli*. The protein can be used after a one-step purification, but we tend to get better results following a second, size exclusion step. I27 is a very versatile protein – it has proved to be a useful ''handle'' for attaching other proteins, which may not polymerize so easily or where only a single domain of a protein of interest is required [7, 8]. In these circumstances it acts as an internal control.

A few studies have used novel methods to produce multimodular proteins. Yang et al. exploited crystal packing in T4 lysozyme [9]. Cysteines were engineered at contact points and the polyprotein was formed in the crystal. In studies to investigate the effect of attachment point on the effect of force on a protein Fernandez and coworkers used the only known natural polyprotein ubiquitin, linked either via the N- and C-terminus or via specific surface lysine–C-terminus linkages [10]. Brockwell et al. used an elegant, novel lipoic acid–lysine linkage to study the same problem in the protein E2Lip3 [8].

When working with multidomain constructs it is important to know whether the protein is folded in, and how far its properties are changed by, inclusion in a polyprotein. Again, I27 is a ''model'' protein in this respect; it has the same thermodynamic stability and the same kinetic properties in the polyprotein as does an isolated domain [4]. However, the same is not true of all proteins. Some are stabilized and some destabilized by inclusion in the protein. Remarkably, although traditional equilibrium denaturation and stopped flow kinetic experiments can be performed as easily on the polyprotein as on small individual domains these simple controls are very rarely carried out. We have also been able to show that NMR experiments can be easily undertaken on three-module constructs, so structural integrity can also be verified [7].

31.2.3 Collecting Data

Although there are recent reports of constant force experiments (see, for example, Ref. [11]), most experiments reported to date have used a ramp of force induced by retracting the piezo at constant speed. The cantilever is lowered to the surface repeatedly, picking a protein molecule up at random. Since this is a blind ''fishing'' step the experimentalist has little control over whether a protein is picked up and no control over the position on the polyprotein where the protein is attached to the cantilever tip. If the protein is adsorbed at too high a concentration onto the sub-

strate then more than one protein molecule is likely to be attached to the tip. Such traces have to be discarded, as they cannot be interpreted. If the protein is too dilute there will be too few pick-ups. It is estimated that where one approach in 10 picks up a protein we can be confident that most data will be from a single molecule [12]. The concentration of protein that results in such a success rate has to be determined empirically.

The tip is retracted at constant speed and when a protein molecule is picked up a force trace is observed. A large number of such traces have to be collected at a number of pulling speeds. The range of experimentally useful pulling speeds allowed by the commercial instruments currently available is on the order of 10 nm s^{-1} to 10 000 nm s^{-1} but in practice, most useful data are collected in the pulling speed range of ~300 to ~3000 nm s^{-1}. Instrumental drift is a problem at low pulling speeds and at very high pulling speeds, viscous drag and cantilever response time introduce error.

31.2.4
Anatomy of a Force Trace

A ''typical'' force trace is shown and described in Figure 31.2. At the start of the trace there is usually a peak of unpredictable height that reflects tip:surface interactions, deadsorption of the protein from the surface and other nonspecific effects (see arrow on Figure 31.2a). As the cantilever retracts force is applied to the protein. As the force increases unfolded parts of the chain are stretched. At some force one of the protein domains will unfold and this results in a sharp drop in the force trace. The trace does not drop to the baseline, however, as the entropic elasticity of the unfolded protein maintains a force on the cantilever. The force increases again until another domain unfolds, resulting in the signature saw-tooth pattern. The base of subsequent peaks is higher that that of the preceding peak. The spacing between the peaks is regular, reflecting the all-or-none nature of the unfolding events, so that a number of traces can be overlaid. Finally the cantilever is retracted so far that the protein becomes detached. A final ''pull off'' peak is observed, typically much higher than all preceding peaks and the trace returns to the baseline.

31.2.5
Detecting Intermediates in a Force Trace

If the protein domains unfold without populating intermediates the trace should be simple with a single unfolding event per domain, and the unfolded protein should extend as a featureless smooth curve, fitting to a simple model of an elastic polymer (see Section 31.3.4). However, intermediates have been detected in a few forced unfolding experiments by careful examination of forced unfolding data. The intermediates have been detected either by the presence of two consecutive unfolding events per domain (e.g., Ref. [13]), or from the presence of a ''hump'' in the unfolding traces [14] (described in more detail in Section 31.7).

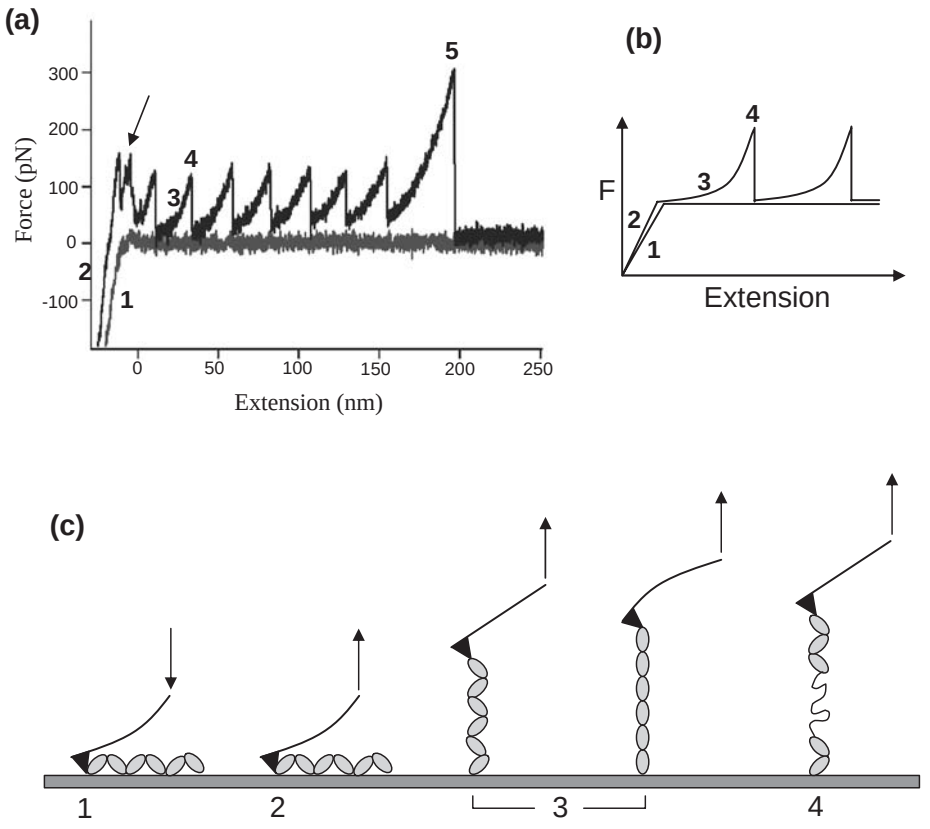

Fig. 31.2. Anatomy of a force trace. Force trace (a) and diagram (b) showing the response of the cantilever during different phases of the AFM approach-retraction cycle. The cartoon in (c) describes the response of the protein and cantilever during the different phases shown in (a). 1) Tip makes contact with surface and is deflected. 2) Protein adsorbs to the cantilever tip. 3) Tip is retracted at a fixed pulling speed from the surface. An entropic restoring force of the protein is generated when it is extended. The cantilever deflects in response to this force. 4) A domain unfolds and extends. The system relaxes. The arrow in (a) shows non-specific adsorption between the tip and/or the protein and the surface.

31.2.6
Analyzing the Force Trace

The unfolding forces can be determined by analysis of the force traces, however, one of the most difficult features of forced protein unfolding experiments is that one has to choose which traces to analyze. As described above, most approach–retract cycles result in no protein being attached to the cantilever at all. Furthermore, a number of the traces where a protein is attached may have large peaks of ''noise'' at the start of the trace, possibly because the protein was attached to other (possibly unfolded) protein molecules on the surface or there may be more than one molecule attached to the cantilever. It is an essential assumption of all the

analysis that the data are collected from a single molecule attached to the tip. It is therefore essential that consistent and rational criteria are applied in choosing which peaks to analyze. This has been discussed elsewhere and a set of criteria have been proposed [15]:

1. Force peaks must be equally spaced and the distance between them must be consistent with the expected contour length of the protein.
2. The trace must include three or more peaks, the last of which is assumed to be the detachment of the protein from the AFM tip.
3. The base of each successive peak should be higher than base of the previous peak.
4. The approach and retraction baselines should overlay, indicating that there was no drift during the course of the pulling experiment.
5. The final baseline should be straight, indicating complete relaxation of the cantilever.

We find that analyzing the trace from the right, at the pull-off peak, towards the left, until the base of the peak touches the baseline, gives us most consistent analysis between investigators and from day to day. Note that all peaks must be counted. The temptation to discard peaks that meet all other criteria on the basis that they are ''too high'' or ''too low'' must be resisted – these will not contribute to analysis of the modal forces.

To determine the height of a peak, the full-length final baseline should be fitted to a line and the height of the peak above this line determined. This allows for drift in the instrument to be accounted for. Once these peak heights have been collected, the modal unfolding force can be determined (see Section 31.3.7).

We have found that it is important to collect data with different cantilevers and on different days to minimize error. We estimate that it is necessary to collect at least three full data sets, where each data set contains at least 40–50 force peaks at each pulling speed [15]. A full range of pulling speeds should be used to minimize errors in analysis. However, for some proteins we have found that we need to collect significantly more data to get reliable estimates of the modal unfolding force.

31.3
Analysis of Force Data

31.3.1
Basic Theory behind Dynamic Force Spectroscopy

In a fluid environment molecular structural transformations, such as those of protein unfolding, are driven by Brownian thermal excitation [16]. It is this agitation by the solvent that ''kicks'' a protein over transition states and provides the activation energy necessary for folding and unfolding. Brownian dynamics therefore sets

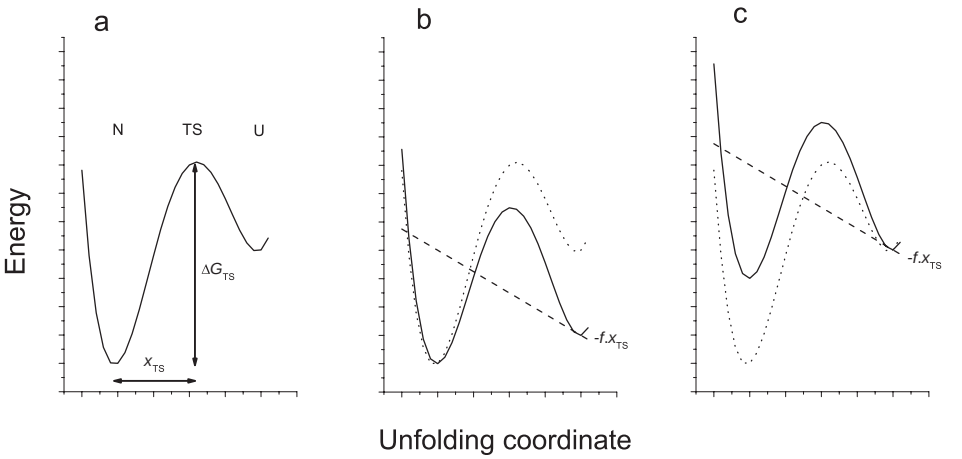

Fig. 31.3. Unfolding energy landscape and the effect of force. a) The rate of unfolding from N is dictated by the magnitude of the free energy relative to the transition state ΔG_{TS} and the shape of the energy potential (encompassed in Eq. (1) as ω_N and ω_{TS}). b) A force f acts on the potential to drop the transition state relative to the native state by the product of the force and the displacement, x_{TS}, of the transition state. Here, force can be considered as having a stabilizing effect on the transition and denatured states. c) Force can be considered as having a destabilizing effect on the native state and unfolding transition states. The effect of force on the unfolding kinetics in (b) and (c) is the same.

the time scale for motions in condensed liquids, which commences at the nanosecond for small ligands and slows with increased molecular size. As shown by Kramers in the 1940s [17], the rate of thermally activated escape from an unfolding potential energy well (Figure 31.3a) can be written as

$$v_o = \left(\frac{(\omega_N \omega_{TS})^{1/2}}{2\pi\zeta}\right) \exp\left(-\frac{\Delta G_{TS}}{k_B T}\right) \quad (1)$$

where ζ is the frictional coefficient of movement (viscous damping), ω_N and ω_{TS} are the curvatures of the energy potential at the native (N) and transition state (TS) respectively and ΔG_{TS} is the relative energy of TS. Although little is known of the exponential prefactor, one does not require its value to measure kinetics. However, conversion from rates to activation energies is not possible without this.

As shown in Figure 31.3b, force has several effects on an energy landscape. Under a persistent force the landscape is "tilted" in the direction at which the force is applied, and this both lowers and shifts the transition state maximum relative to the potential well of the folded, native state. Alternatively, one can consider force as stabilizing the protein's unfolded state and destabilizing the transition state and the folded state more so (Figure 31.3c). Either way, the net effect on the kinetics is the same. Under an external force potential, therefore, the unfolding rate is increased as force (f) lowers the energy of the unfolding transition state relative to

the native state. The amount that the transition state energy has been lowered by is the product of the force applied and the displacement of the state in the direction of force (x_{TS}), and we can re-write Eq. (1) to show this effect:

$$v_u(f) = h\left(\frac{fx_{TS}}{k_B T}\right)\left(\frac{(\omega_N \omega_{TS})^{1/2}}{2\pi\zeta}\right)\exp\left(-\frac{(\Delta G_{TS} - fx_{TS})}{k_B T}\right) \quad (2)$$

where $h(\ )$ describes the movement of the transition state under force [18]. Since the dominant effect of force is the lowering of the transition state, $h(\ )$ can usually be ignored, which gives the rate equation

$$v_u(f) = v_o \exp\left(\frac{fx_{TS}}{k_B T}\right) = v_o \exp\left(\frac{f}{f_\beta}\right) \quad (3)$$

where v_o is the unfolding rate over this TS barrier in the absence of force. Importantly this equation introduces f_β ($= k_B T/x_{TS}$), the *force scale*, commonly used in dynamic force spectroscopy and x_{TS} (or x_u as it is usually referred to in protein unfolding studies) representing the displacement between N and TS. At room temperature, thermal energy $k_B T$ is 4.11×10^{-21} J and over the nanometer length scale of proteins is equal to forces of only a few piconewtons (4.11 pN nm). The catalytic effect of a 100 pN force over this nanometer distance is equivalent to over 14 kcal mol^{-1} (1 kcal mol^{-1} = 6.9 pN nm).

31.3.2 The Ramp of Force Experiment

Virtually all experiments of protein unfolding measured by the atomic force microscope are of the kind where force is increased in time and the maximum force that the protein can withstand recorded. The tip is approached to the surface, protein adheres to the tip, and the tip is then withdrawn from the surface at a constant velocity. The simplest case to consider is where force increases steadily with time and the loading rate on the protein, $r_f = df/dt$, is constant. As we show later, this is usually not true for these experiments but this first approximation provides the introduction to dynamic force spectroscopy. The rate at which force increases is the product of the stiffness of the system (in this first approximation the this is the stiffness of the cantilever alone) and the speed at which the cantilever is withdrawn. Lever stiffness κ_c is of the order of 10–100 pN nm^{-1}, and retract rates v_r can vary from around 10 nm s^{-1} to approaching 10 000 nm s^{-1} (thermal drift and operator patience limiting the low speed and hydrodynamic drag restricting high speeds). AFM loading rates can theoretically range, therefore, between 100 and 1 000 000 pN s^{-1}, although practically achieving more than two to three orders of loading rate is problematic.

As an illustration, we consider the effect of increasing force on a transition state located $x_u = 0.5$ nm along the projection of force. Since at room temperature thermal energy, $k_B T$, is 4.11 pN nm at a loading rate of 1 000 000 pN s^{-1} it takes nearly

10 μs ($k_B T/x_u.r_f = 4.11/0.5/1\,000\,000$) to drop the barrier by 1 $k_B T$. On the time scale of a thermal attempt frequency (see above), therefore, force and the landscape are quasi-static. Experiments of strength adopting a ramp of force can thus normally be considered as a series of many tests under an equally large set of different forces. However, were the rate at which energy is added to the transition state by force ($x_u.r_f/k_B T$) to be comparable to, or exceed, the kinetic prefactor then the dynamics would deviate from that described here.

As unfolding is a kinetic process driven by random fluctuations one must make many measurements to sample the process. In this respect, the measurement of the behavior of a single molecule many times is identical to the measurement of an ensemble of molecules all at once. We can consider each measurement as a sample of this population, the numbers in which follow a simple rate equation. Commencing with all folded proteins, the fraction of the population that are folded under force decays in time as

$$\frac{dS}{dt} = -\nu_u(t)S(t) + \nu_f(t)[1 - S(t)] \tag{4}$$

where $\nu_u(t)$ is the rate at which unfolding occurs at time t, and $\nu_f(t)$ is the rate of refolding. Since time and force are related through the loading rate r_f, Eq. (4) can be written for an increasing force as

$$\frac{dS}{df} = \frac{1}{r_f}\{-\nu_u(f)S(f) + \nu_f(f)[1 - S(f)]\} \tag{5}$$

Until now, we have ignored the refolding term. In fact, since force causes an exponential decrease in folding in the same manner in which it exponentiates unfolding, at forces above a few 10 s of piconewtons refolding can safely be neglected. The master rate equation is simply

$$\frac{dS}{df} = \frac{1}{r_f}\{-\nu_u(f)S(f)\} \tag{6}$$

This can be integrated to reveal the probability distribution of folded states, as

$$S(f) = \frac{1}{r_f}\exp\left(-\int_0^f (\nu_u(g)/r_f)\,dg\right) \tag{7}$$

Equation (7) gives the fraction of the ensemble (the probability) that remain folded as the force increases from 0 to f. The probability that a protein will unfold at this force is the product of this, the survivability to force f, and the unfolding rate at this force. The probability of unfolding at f is therefore the product

$$p(f) = \frac{1}{r_f}\nu_u(f)\exp\left(-\int_0^f (\nu_u(g)/r_f)\,dg\right) \tag{8}$$

substituting for v_u (Eq. (3)) this can be written as

$$p(f) = \left(\frac{1}{r_f} v_o \exp\left(\frac{f}{f_\beta}\right)\right) \exp\left(-\int_0^f \frac{1}{r_f} v_o \exp\left(\frac{g}{f_\beta}\right) dg\right) \tag{9}$$

The integral of an exponential is unchanged, so taking the limits of force the integral can be solved as

$$p(f) = \left(\frac{1}{r_f} v_o \exp\left(\frac{f}{f_\beta}\right)\right) \exp\left(\frac{1}{r_f}\left(f_\beta v_o - f_\beta v_o \exp\left(\frac{f}{f_\beta}\right)\right)\right) \tag{10}$$

A series of tests of strength using a ramp of force at a constant loading rate will form a distribution given by Eqs (8), (9), and (10). There is not a single force at which a protein will unfold. The most probable unfolding force is that where this distribution is at a maximum, and therefore has a zero gradient. This value is found by finding the force where the first derivative is zero. To solve this, we rely on the property that we can scale the distribution and not affect the location of the maximum, and a useful scaling is the natural logarithm. The logarithm of Eq. (10), expanded for clarity, is

$$\ln[p(f)] = \ln[v_o] + \ln\left[\exp\left(\frac{f}{f_\beta}\right)\right] - \ln[r_f] + \ln\left[\exp\left(\frac{1}{r_f}\left(f_\beta v_o - f_\beta v_o \exp\left(\frac{f}{f_\beta}\right)\right)\right)\right] \tag{11}$$

The logarithms of the exponentials cancel, so

$$\ln[p(f)] = \ln[v_o] + \left(\frac{f}{f_\beta}\right) - \ln[r_f] + \frac{1}{r_f}\left(f_\beta v_o - f_\beta v_o \exp\left(\frac{f}{f_\beta}\right)\right) \tag{12}$$

The maximum of this distribution at the most probable unfolding force is found by differentiation with respect to force. The terms that do not depend of force disappear, leaving the maximum as

$$\partial \ln[p(f)] = \left[\frac{1}{f_\beta} - v_o \exp\left(\frac{f}{f_\beta}\right) \Big/ r_f\right]_{f=f^*} = 0 \tag{13}$$

31.3.3 The Golden Equation of DFS

Using Eq. (13) we can find the most probable unfolding force f^* (see Ref. [18])

$$f^* = f_\beta[\ln(r_f) - \ln(f_\beta v_o)] = \frac{k_B T}{x_u} \ln\left[\frac{r_f x_u}{k_B T v_0}\right] \tag{14}$$

Equation (14), the "golden equation" of DFS, has been derived from numerous assumptions (single transition state, stationary in location under force, linear force

loading, $x_u.r_f/k_BT \ll 1/t_D$, etc.) but shows elegantly the features of DFS. A plot of f^* against the logarithm of the loading rate has slope f_β, revealing the location (x_u) of the transition state along the force axis. Similar to the *m*-value of chemical unfolding measurements, f_β is the susceptibility of the unfolding kinetics to force. But here this value has a direct physical relationship to geometric coordinates and structure (x_u). Further, the plot cuts the loading rate axis, where f^* is zero, when $r_f = f_\beta v_o$. Since f_β is known one can determine through this extrapolation the force-free unfolding rate across the transition state (v_o).

Equation 14 is derived for the most probable rupture force; the mode of the distribution. The equation does not hold true for the mean force. In fact, the mean of the force distribution (Eq. (8)) is complex to find, involving exponential integrals with no exact solution. Thus it is important to find the mode of the distribution of forces measured and analyze these, and not their mean. Additionally, the mode of the distribution is less affected by outlying forces from nonspecific tip/sample interactions, multiple unfolding events and instrumental noise. As a rule-of-thumb, however, at high forces the mean unfolding force can be crudely approximated by [12]:

$$\bar{f} \sim f_\beta[\ln(r_f) - \ln(f_\beta v_o) - 0.6] \tag{15}$$

and with force scales f_β for proteins approaching 20 pN, mean forces are 10 pN or so lower than the modes.

31.3.4 Nonlinear Loading

The approximation used above, that the stiffness of the system is dominated by the cantilever, is not valid for most protein unfolding measurements. Typically, tandem repeats of the protein are stressed and multiple copies are unfolded in series revealing the characteristic saw-toothed force extension curve. In this arrangement, the mechanical stiffness of the protein polymer may well be less than the cantilever. The stiffness of the system κ_s, with two springs stressed in series (the cantilever with stiffness κ_c and molecular system κ_m) is

$$\frac{1}{\kappa_s} = \frac{1}{\kappa_c} + \frac{1}{\kappa_m} \tag{16}$$

Clearly the molecule has to be stiffer than the lever ($\kappa_m > \kappa_c$) for the approximation that lever stiffness dominates loading. With soft levers of 10 pN nm^{-1} or so this can be true. However, the saw-tooth pattern measured in the AFM experiments derives from the stretching of the unfolded polypeptide chain after each repeat has unfolded. This means that force loading is not constant during protein unfolding experiments. This has two consequences. First data have to be represented as unfolding force vs. retract velocity (v_r) and second, we need to consider the mechanical stiffness of such random-coil polypeptide chains.

31.3.4.1 The Worm-line Chain (WLC)

The WLC is a convenient description of the mechanical properties of a random coil of amino acids, an unfolded protein. The configurational space accessible to a long polymer is considerable and when free in solution the end-to-end distance fluctuates. When this distance is constrained, such as being tethered between an AFM tip and a sample surface, configurational space has been lost and thus the entropy of the system has been reduced. The force required to maintain an extension is a function of this loss in entropy. The polymer behaves as an entropic spring.

The stiffness of an entropic spring is a function of the contour length of the molecule, L, and a persistence length, b. This is the length corresponding to a bending energy of one $k_B T$. It is generally agreed that a value of ≈ 0.4 nm for the persistence length fit the experimental measurements of proteins well. Under low extensions x (where $x \ll L$), the spring is Hookian and exerts a force of [19]:

$$f_{\mathrm{WLC}}(x) \approx \frac{k_B T}{b}\frac{x}{L} \tag{17}$$

As the extension approaches the contour length (the asymptote as the molecule is inextensible), force increases anharmonically as

$$f_{\mathrm{WLC}}(x) \approx \frac{k_B T}{b}\left(1-\frac{x}{L}\right)^{-2} \tag{18}$$

A convenient equation to show the behaviour of a WLC over all extensions, and one that matches that seen in AFM experiments, is an interpolation between Eqs (17) and (18), as

$$f_{\mathrm{WLC}}(x) \approx \frac{k_B T}{b}\left(\frac{1}{4\left(1-\frac{x}{L}\right)^2}-\frac{1}{4}+\frac{x}{L}\right) \tag{19}$$

A polymer exerts a force of 150 pN (a typical titin I27 unfolding force) when the chain is extended to around 90% of its contour length. The stiffness of the chain $\kappa_{\mathrm{WLC}}(f)$ at this extension is approximately 10 pN nm^{-1}, and for all but the softest of AFM cantilevers it is the polymer that dominates the loading rate (Eq. (16)). So instead of a steady loading rate, r_f depends on the force and increases nonlinearly in time as $r_f = v_r \kappa_{\mathrm{WLC}}(f)$. Substitution of this loading rate term into Eq. (9) and subsequent solving for f^* gives a good approximation of the unfolding kinetics under WLC polymer loading, as [20]:

$$\begin{aligned} f^* &\approx f_\beta\left[\ln\left(\frac{v_r}{v_\beta}\right)+\ln\left(\frac{f^*}{f_\beta}-\frac{3}{2}\right)+\frac{1}{2}\ln\left(\frac{f^*}{f_\beta}\right)\right] \\ v_\beta &= \frac{L v_o}{4}\left(\frac{x_u}{b}\right)^{1/2} \end{aligned} \tag{20}$$

Equation (20) is transcendental (the force term f^* is expressed in terms of f^*) and therefore can be awkward to solve. Methods to fit this equation to data are explained below. A simpler, although less accurate method of fitting to experimental data is to use the each force value to find the stiffness of the system at the point of unfolding, and then multiply this by the retract velocity v_r to give a loading rate (this is only an estimate as the force distributions are no longer described fully by Eqs (8), (9), and (10) since the loading rate increases during cantilever retraction). The stiffness of the protein chain ($b = 0.4$ nm, $k_B T = 4.11$ pN nm) is approximately

$$\kappa_{WLC}(f) \approx 4\frac{k_B T}{bL}\left(\frac{bf}{k_B T}\right)^{3/2} \tag{21}$$

The rate of loading at the point of unfolding can be estimated, therefore, by calculating the stiffness of the unfolded protein at the unfolding force (Eq. (21)), determining the stiffness of the system (Eq. (16)) and multiplying this by the retract velocity v_r. The modal unfolding force can then be plotted against this loading rate estimate and Eq. (14) used to find a reasonable estimate of the force-free unfolding rate and transition state displacement.

31.3.5 Experiments under Constant Force

An attractive method to remove the problems of the nonlinear loading induced by the dynamics of the polymer is to measure the lifetime of the protein under a constant force [11]. Instrumentally, such an experiment requires the incorporation of a feedback system that modulates the cantilever position to maintain a constant deflection, and hence constant force.

The time for which a protein can withstand a constant force is the reciprocal of its unfolding rate

$$t_u(f) = \frac{1}{v_o}\exp\left(-\frac{f}{f_\beta}\right) \tag{22}$$

The constant force experiment has the advantage that it should be independent of the system dynamics, such as the nonlinear loading rate introduced by the polymer stiffness, but suffers from two shortcomings. First, analysis assumes that force is kept constant and that the force-feedback system can respond faster than the unfolding rate of the protein under the force applied. Fortunately, this is often the case. However, a greater limitation of this class of experimentation is that control of force relates to exponential changes in lifetime, as seen in Eq. (22). Therefore, as force is lowered, the experiment lasts for exponentially increasing periods of time. Conversely, at high forces, it becomes increasingly difficult to determine lifetime with the necessary accuracy. The advantage of the ramp of force measurement is

that the force is a direct measurement of lifetime since these are related through the loading rate. However, since the ramp of force measurement is a continuous collection of constant force measurements, these two regimes can be considered identical. The experiment of constant loading rate can be considered as the ideal and relatively simple technological developments are required to realize this methodology. The potential of the constant force experiment is to measure the kinetics of unfolding under high forces. To measure this, however, requires the ability to apply the force instantaneously (through the use of magnetism or electrostatic attraction for instance) and measure the diminishing lifetime with increasing temporal resolution. Current AFM technology, depending on peizo displacement and at best having kilohertz temporal resolution, is incapable of exploiting this potential.

31.3.6
Effect of Tandem Repeats on Kinetics

The use of tandem repeats of proteins in forced unfolding experiments is beneficial for several reasons as previously discussed; including providing a characteristic signature for a single molecule, extension of the unfolding event away from any interactions of the surface, and increased number of data points per trace. But the presence of multiple proteins affects the unfolding kinetics, and this must be accounted for [19].

For a chain of identical tandem repeats there is no specific order in which they will unfold under force as none is more likely to unfold before another. For a chain of N folded proteins, the probability that any one protein will unfold is N-times higher than the probability of failure of the protein on its own. So the unfolding rate of the first event is N-times the unfolding rate of the constituent protein. For the second event, the number of units that may unfold is $N-1$, and the unfolding rate for this is $N-1$ times one, and so on [21]. The effective unfolding rate of the chain decreases for each peak n of N seen in the experiment, as

$$v_{\mathrm{u}}(f,n,N) = (N-n-1)v_{\mathrm{o}} \exp\left(\frac{f}{f_\beta}\right) \tag{23}$$

In addition to the unfolding rate decreasing with the event number, the loading rate also decreases as the length of unfolded protein increases with each event. The drop in unfolding rate leads to an increase in the force, whilst the drop in loading rate causes a competing decrease in force. Between the first and second event the fractional change in rate is small (from Nv_{o} to $(N-1)v_{\mathrm{o}}$) whereas the loading rate changes considerably as the unfolded polymer has increased considerably in length (Eq. (21)). The forces drop over the first events. Conversely, between the second-to-last and last event the unfolding rate halves whereas the fractional change in polymer length is small. The forces increase towards the last events. On average, the net effect is a decrease and then increase in the average rupture force for event number [22].

To analyze accurately the unfolding forces for tandem repeats requires knowledge of the length of repeat being pulled, which can change from test to test, and analysis of individual events based on the each total length, i.e., the 1st, 2nd, and 3rd events of pulls of three repeats, the 1st, 2nd, 3rd, and 4th of pulls of four repeats, etc. A useful observation is that the sixth event in a chain of eight repeats behaves similarly to the mode of all measurements [23]. Fortunately, the effect of changing unfolding rate and polymer length with event number shift the most probable rupture force by only 20 pN or so, and so this effect is usually ignored in all protein folding studies. Titin I27 has been studied in different laboratories using polyproteins with 12, 8, and 5 repeats and the results are essentially the same [4, 5, 24].

31.3.7 Determining the Modal Force

To analyze the kinetics of unfolding using force spectroscopy requires measurement of the full distribution of forces (lifetimes), since unfolding is random. In the inevitable presence of noise, this requires many (several hundred) measurements at each speed. To determine the mode of the distribution (remembering the issues discussed above with the mean) usually requires resorting to a graphics program, binning the data into arbitrary sized bins, and plotting the resulting histogram.

A useful alternative that does not require the use of bins is to estimate a continuous spectrum of forces [25]. Each force measured is assumed to be subject to noise, and assumed to be Gaussian. The largest sources of noise in the force data are from thermal fluctuations of the cantilever, limited sampling rate and hydrodynamic drag. Whilst drag effects are limited by restricting retract velocities to below a few microns per second, and sampling rates are increasing with every new generation of force microscope, thermal noise cannot be easily overcome. The thermal fluctuation of the lever is related to its spring constant κ_c, given as

$$\langle \sigma \rangle = \sqrt{\frac{k_B T}{\kappa_c}} \tag{24}$$

and a cantilever of typical stiffness (30 pN nm^{-1}) fluctuates around 0.3 nm, showing that the standard deviation of the force noise for these soft levers is over 10 pN. The force noise for an AFM is typically between 10 and 20 pN, and we can assume that each force measured is drawn from a Gaussian 10 or 20 pN wide. The sum of all these Gaussians, centered on each force recorded, is calculated and the mode force, where the sum is greatest, found. It is often worthwhile seeing how this estimate of the mode depends on the level of noise chosen, which ideally should be invariant.

The distribution of forces for unfolding over a single transition state has a well-defined form given by Eq. (10). Since the full distribution of forces at a particular rate of loading is given by the two parameters measured, the unfolding rate ν_o and

the transition state location x_u, the distribution serves to validate the experimental measurements. Having found the mode, the histogram of recorded forces (and not the artificial Gaussian sum used above) should be plotted and the distribution predicted using Eq. (10) overlaid.

31.3.8 Comparing Behavior

Dynamic force spectroscopy reveals uniquely the presence of multiple transition states, their locations along a reaction coordinate, and the rate at which they are crossed. As shown in Eq. (1), conversion of these rates to a free energy requires knowledge of the exponential prefactor. However, the ratio of two rates does reveal the difference in free energy between the transition states assuming a constant prefactor, as

$$\begin{aligned} \nu_1 &= \frac{1}{t_D}\exp\left(-\frac{\Delta G_{TS1}}{k_B T}\right) \\ \nu_2 &= \frac{1}{t_D}\exp\left(-\frac{\Delta G_{TS2}}{k_B T}\right) \\ \frac{\nu_1}{\nu_2} &= \exp\left(\frac{\Delta G_{TS2} - \Delta G_{TS1}}{k_B T}\right) \end{aligned} \tag{25}$$

An assumption of the constant prefactor is one of the difficulties in application of Eq. (25). This is a concern when one is comparing mutant proteins with wild-type. Where the transition state being probed is the same, deformed by a point mutation for example, then this assumption is reasonable. But with such a mutation it is still not assured that the same transition state from the same point along the unfolding coordinate is being probed. Good examples are some of the single point mutants of titin I27 studied by AFM [23, 26]. Many proline mutants, and even conservative mutants such as V86A, have been shown to cause a change in the ground state from which unfolding is measured [23]. Whilst it is believed that the same transition state is being studied, the folded state from which the protein unfolds is different (wild type unfolds from an intermediate whereas the mutants unfold from the native state). Therefore, the ratio of unfolding rates extrapolated from these measurements of the mutant behavior to the wild type does not represent the change in kinetic stability caused by the mutation.

31.3.9 Fitting the Data

The data need to be analyzed to extract the two parameters requires, x_u and the unfolding rate at 0 force ν_o. Probably the most obvious method to predict the be-

havior of a system under load is to perform a "Monte-Carlo" simulation [27]. Here, small intervals of time are sampled and the events that could occur within these windows are chosen at random. Commencing at time $t = 0$, the force on the system is determined by the position of the cantilever ($x = v_r t$) and the mechanical properties of the system (Eq. (19)). This force is used to calculate the probability of an unfolding event within the window of time, as the product of the time slice Δt and Eq. (23). This probability is sampled at random by its comparison to a uniform random number. If the event is chosen (i.e., the random number selected is not more than the probability) then the unfolding event has occurred, this domain is deemed to have unfolded and the length of the unfolded polymer increased by the length of the polypeptide chain forming the domain. Next, the cantilever is moved back by a distance equal to the product of the retract velocity and the time-step, the new force calculated and the process of random sampling continued until all the domains have unfolded.

Monte-Carlo simulations such as these provide full force versus extension traces as they represent a reasonably accurate simulation of the experiment (Figure 31.4). However, for this very reason, the simulation must be repeated many times to sample the stochastic nature of unfolding. Furthermore, whilst capable of predicting a distribution of unfolding forces for given values of ν_o and x_u, it is not simple to fit these values to experimental results.

An alternative method of obtaining the full distribution of unfolding forces is to integrate the Master rate equations (for example Eq. (5)) across an increasing force [28]. Unfortunately, the fact that the probability of unfolding increases exponentially in force whilst the probability of surviving to each force decreases exponentially, the equations are so-called stiff, and can be difficult to integrate numerically.

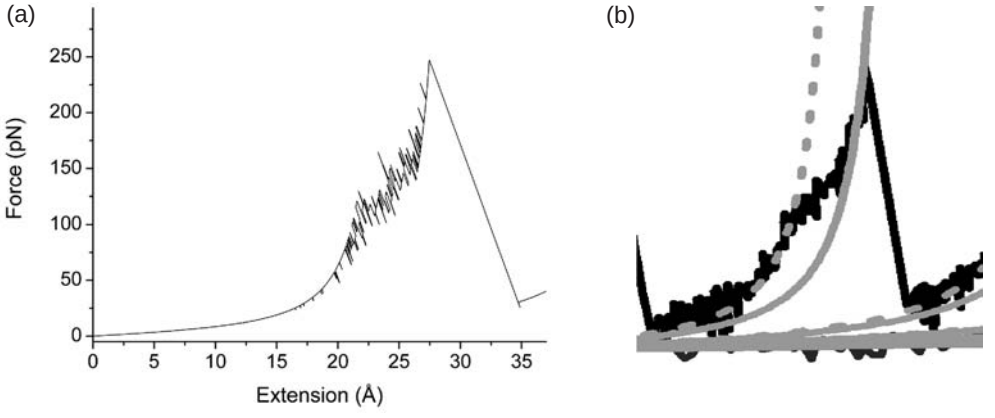

Fig. 31.4. Monte-Carlo simulations. Monte-Carlo simulations (a) of the AFM experiment reveal the full force vs. distance trace of the experiment (b). By incorporating details of refolding and unfolding rate constants and unfolding intermediates fine detail, such as the presence of the force plateau around 100 pN attributed to the population of the force-stabilized unfolding intermediate of I27, can be resolved.

We find the semi-implicit extrapolation method of the Bulirsch-Stoer integration procedure to be the most suitable [23, 29]. Such numerical solutions provide the full unfolding force distribution, an extremely valuable cross-check of the experiment [19]. They do not, however, provide any insight of the individual force vs. extension curve.

Fitting requires predicting the unfolding forces for a set of trial parameters (x_u and ν_o) with each measured value at the rates explored, calculating a difference (commonly as the sum of the squares), and changing the trial parameters until this difference is as small as possible. There are many methods available to perform such minimizations, and a useful method is the simplex minimization procedure. Simplex minimization can be slow, but does not require the use of derivatives that are difficult to compute. A good discussion of simplex minimization is given by Press et al. [29]. Simply, in the n parameter space of the fit ($n = 2$ for a single transition state, x_u and ν_o) the best result is enclosed by a simplex, a shape of $n + 1$ vertices. For example, all possible values of x_u and ν_o can be plotted on a graph, the abscissa representing all the x_u values and the ordinate the ν_o values. The smallest simplex that can be drawn at any point on the graph is a triangle ($n + 1 = 3$). Simplex minimization starts with the simplex occupying an arbitrary region of the parameter space, and then walks the simplex through space depending on a series of rules. The rules can include contracting the shape towards the vertex with the best fit, moving the best fitting vertex away from the worst, etc. Minimization is terminated when all the vertices lie close in space and in value. Again, see Press et al. for a much clearer explanation of this and other minimization and optimization methods [29].

A final note is in the assessment of the goodness of fit and the magnitude of errors. A useful method here, again explained in detail by Press et al. is the bootstrap Monte-Carlo method [29]. Having obtained a fit between the measured and the predicted force data, the goodness of the fit can be estimated by the replacement method. The original data is subsampled and padded with copies. About $1/e$ of the data is removed and these points replaced by remaining values. The total number of forces in the set, therefore, remains the same. The x_u and ν_o parameters are then fitted to this subset of data, and this procedure repeated many times. The variance in the results of these fittings equals the variance in the original fit. Finally, when measuring and reporting variances in ν_o it is important to remember that this value is not linear but exponential, and variances of $\log(\nu_o)$ and not ν_o should be used. For this reason rates are often reported as exponents, as $2 \times 10^{-4 \pm 1.1}$ s^{-1} for example. Since small uncertainties in the experimentally determined x_u lead to large differences in ν_o the errors can be large [15, 30].

31.4 Use of Complementary Techniques

Two complementary techniques have been exploited increasingly in the study of protein folding mechanisms – protein engineering Φ-value analysis and computer

simulation. Both these techniques can also be exploited in the study of forced unfolding mechanisms.

31.4.1 Protein Engineering

One of the best ways to determine the regions of the protein structure involved in the resistance of a protein domain to force is to make site-specific mutants and to investigate the response of these mutants to force. However, unless we combine force spectroscopy with biophysical data, any information gained is purely qualitative. If mutations in two different regions of the protein have different effects on force it is not possible to say that one region is more structured in the transition state than the other unless the effect of the protein on the stability of the native state has been quantified.

Fortunately, the analysis of mutant proteins as a means of investigating protein folding (and unfolding) mechanisms is well established [31]. Essentially, the effect of the mutation on the stability of the protein and on the stability of the transition state for unfolding is compared:

$$\Phi = \frac{\Delta\Delta G_{\mathrm{D-TS}}}{\Delta\Delta G_{\mathrm{D-N}}} = 1 - \frac{\Delta\Delta G_{\mathrm{TS-N}}}{\Delta\Delta G_{\mathrm{D-N}}} \tag{26}$$

where $\Delta\Delta G_{\mathrm{D-N}}$ is the change in free energy on mutation (determined from equilibrium denaturation experiments) and $\Delta\Delta G_{\mathrm{D-TS}}$ and $\Delta\Delta G_{\mathrm{TS-N}}$ are changes in free energy of the transition state (TS), relative to the denatured (D) and native (N) states, respectively, determined from ratios of folding and unfolding rate constants:

$$\Delta\Delta G_{\mathrm{D-TS}} = RT \ln\left(\frac{k_{\mathrm{f}}^{\mathrm{wt}}}{k_{\mathrm{f}}^{\mathrm{mut}}}\right) \quad \text{and} \quad \Delta\Delta G_{\ddagger\mathrm{-N}} = -RT \ln\left(\frac{k_{\mathrm{u}}^{\mathrm{wt}}}{k_{\mathrm{u}}^{\mathrm{mut}}}\right) \tag{27}$$

where k_{f} and k_{u} are the folding and unfolding rate constants, and the superscripts wt and mut refer to the rate constants for wild-type and mutant proteins, respectively.

We have shown that this Φ-value analysis can be applied to force experiments, however, they are somewhat more complex, due to the nature of the data collected [30].

31.4.1.1 Choosing Mutants

The assumptions inherent in Φ-value analysis have been clearly described [32]. The three most important criteria are:

1. The mutations should not alter the structure of the native state significantly: To this end, the mutations should be conservative, nondisruptive mutations. They should not distort the structure or add new interactions. The most suitable mutations are simple deletion mutants such as Ile to Val or Val to Ala.

2. The mutations should not alter the stability of the denatured state significantly, or at least the effect on D should be significantly less than on N. For this reason mutations of or to Pro or Gly should be avoided where possible, as should mutants that change the polar/nonpolar nature of the sidechain.
3. The change in stability ($\Delta\Delta G_{D-N}$) should be significant. Where $\Delta\Delta G_{D-N}$ is small Φ cannot be determined with confidence. In AFM experiments this is particularly important since there is much more error in the experimental data. We do not choose to analyze mutants with a $\Delta\Delta G_{D-N} < 2$ kcal mol^{-1}. Where the effect of mutation is less than this it is unlikely that differences between wild type and mutant can be quantified with any confidence.

31.4.1.2 Determining $\Delta\Delta G_{D-N}$

The effect of the mutation on the stability of the native, starting state, relative to the unfolding state has to be determined from equilibrium denaturation experiments. This can be undertaken on either single domains of the protein, where ΔG_{D-N} has been shown to be unaffected by inclusion in a polyprotein, or by equilibrium investigations of the mutant polyprotein itself. Of course, the denatured state in the forced unfolding experiments is not the same as that measured in the equilibrium unfolding studies. One has to make the reasonable assumption that the effect of the mutation in the compact denatured state ensemble will be the same as the effect of the mutation on the stretched denatured state, or that, at least, the difference is significantly less than the effect on the native state. This is most likely to be true where the mutation is conservative. In some conventional kinetic investigations a ΔG has been determined by the ratio of the folding and unfolding rate constants. This cannot be applied to forced unfolding experiments, however. It has been shown to be possible to determine a folding rate constant for some proteins when the force is (very nearly) reduced to zero, but the protein still held on the tip[4]. However, the principle that $\Delta G_{D-N} = RT \ln\left(\frac{k_f}{k_u}\right)$, applies only where the folding and unfolding reaction are the reverse of each other, i.e., where the same transition state is being explored. Since it is most unlikely that unfolding in the presence of a directional force will be the reverse of folding in the absence of such a force (and it has been shown that this is not the case for at least one protein) measurements of ΔG from the rate constants derived in AFM experiments is not possible. A final important corollary, however, is that if under force the protein adopts an alternative native state, N^F (or unfolding intermediate, I) that is significantly different in structure to N, then this analysis will not hold.

31.4.1.3 Determining $\Delta\Delta G_{TS-N}$

In principle $\Delta\Delta G_{TS-N}$ can be determined from forced unfolding experiments simply by directly comparing the unfolding rate in the absence of force (ν_o, also termed k_f^0) determined from the experimental data. However, as described above, these values are highly sensitive to small changes in the slope of the force vs. log ν_r plot. Again, principles well established in protein folding experiments can be applied. This situation is akin to differences in $\Delta\Delta G_{TS-N}$ determined directly

from experimental measurements and those extrapolated to 0 M denaturant: small changes in the slope can lead to large errors in v_o. We have shown that where the slope is the same within error, i.e., where x_u can be assumed to be the same for wild-type and mutant proteins a number of methods can be used to determine $\Delta\Delta G_{TS-N}$.

1. Analyze the data for wild type and mutant as described above (Section 31.3.9) but assuming a mean, fixed x_u.
2. Fit the force spectra to a fixed mean slope and then compare the pulling speeds (v_r) of wild type (wt) and mutant (mut) at a fixed force in the range of the experimental data:

$$\Delta\Delta G_{TS-N} = -RT \ln\left(\frac{{v_r}^{wt}}{{v_r}^{mut}}\right) \tag{28}$$

3. Fit the force spectra (F vs. ln v_r) to a fixed mean slope (m) and then compare the unfolding force at a fixed pulling speed in the range of the experimental data:

$$\Delta\Delta G_{TS-N} = RT(F^{wt} - F^{mut})/m \tag{29}$$

We have shown that all three methods give the same Φ-value [30].

It is important to note that Φ-value analysis only applies where the unfolding transition that is being measured is the same in wt and mutant proteins. If a mutation changes the folding behaviour so that a different barrier is being explored then this method cannot be used. As an indication of this, the x_u should always be the same for wt and mutant proteins.

31.4.1.4 Interpreting the Φ-values

- $\Phi = 1$: If the mutation is in a region of the protein that is fully structured in the transition state then the mutation will destabilize the transition state to the same extent as the native state. Thus the free energy difference between N and TS will remain the same ($\Delta\Delta G_{TS-N} = 0$) and the force required to unfold the protein will remain the same. In this case $\Phi = 1$.
- $\Phi = 0$: If the mutation is in a region that is fully unstructured in the transition state, then the mutation will have no effect on the stability of TS, while destabilizing N. Thus the difference in free energy between N and TS will be reduced by the same amount as N ($\Delta\Delta G_{TS-N} = \Delta\Delta G_{D-N}$). The unfolding force will be lowered in a manner that can be predicted using Eq. (29).
- $0 < \Phi < 1$: If the mutation is in a region that is partially structured in TS then the unfolding force will be lowered, but not as significantly as might be predicted from $\Delta\Delta G_{D-N}$. Formally, in traditional protein engineering studies, partial Φ-values can be interpreted in a number of ways. A Φ-value of 0.5, for instance, could indicate that half the free energy of the residue was lost in TS, or it could

mean that the protein unfolded by two pathways, one where the Φ-value was 1 and a second where Φ was 0. In these single molecule experiments, however, these two possibilities can be distinguished. If there are two different pathways then the forced unfolding should show a bi-modal distribution of forces. This has not been seen to date, and so the simpler interpretation of partial loss of contacts can be made.

Given the nature of the AFM experiment the error on Φ is larger than that from traditional unfolding experiments. It is probably not possible to say more than that a region is ''fully, or almost fully structured'' (Φ close to 1), ''fully or almost fully unstructured'' (Φ close to 0) or ''partly structured'' (Φ less than 1 but more than 0). This is one reason why mutants being studied should be significantly less stable than wild type, to allow Φ-values to be assigned with confidence. In traditional Φ-value analysis Φ-values are considered to be too prone to error if $\Delta\Delta G_{D-N} < 0.75$ kcal mol^{-1} (it has recently suggested that this limit should be set significantly higher). We suggest that for mechanical Φ-value analysis $\Delta\Delta G_{D-N}$ should be as large as possible and at least >1.5 kcal mol^{-1}.

31.4.2 Computer Simulation

Since even the most detailed protein engineering experiment can only provide ''snapshots'' of the unfolding process, simulations are important to understand the effect of force at the atomistic level. Mechanical unfolding experiments are apparently ideal for comparison with simulation. Unlike addition of temperature or denaturant, the perturbation is directional, suggesting that the reaction coordinate (N–C distance) is comparable in simulation and experiment. Furthermore, it is easy to identify in a forced unfolding trajectory, both metastable unfolding intermediates and the position of the transition state barrier. The problem of time scale is, however, just as difficult in simulations of forced unfolding as it is for other unfolding simulations. To increase the rate of unfolding the system has to be perturbed using conditions that are far from experiment. In simulations of thermal unfolding this requires the use of very high temperatures in a simulation. In forced unfolding simulations the rate of application of force (the loading rate) is significantly higher in simulation than experiment. Since theory suggests that different barriers to unfolding will be exposed at different loading rates, it is not possible to assume that the same barrier will be investigated in theory and experiment. Thus it is important that simulation be bench-marked by experiment.

A number of increasingly computationally expensive techniques have been applied to the study of mechanical unfolding and where these can be directly compared to experiment, the simulations seem to perform well. Lattice and off-lattice simulations have been used to describe the effect of force, and other perturbants (denaturant, temperature) on energy landscapes (e.g., [33–36]). The phase diagrams suggest that interesting data may be obtained if force is applied at higher temperatures and/or in the presence of denaturant. Steered molecular dynamics

simulations, with and without explicit solvent, have been successful in reproducing a number of experimental features. They have also been successful in describing the order of unfolding events in titin I27 (e.g., [37, 38]). The hierarchy of unfolding of different protein domains has been predicted [39]. Simulations have observed unfolding intermediates in experimental systems where they have later been detected in experiment [13, 14, 37, 40, 41]. (But again, a note of caution is required. In only one case has the intermediate been shown to have experimental properties consistent with the intermediate observed in the simulations [14, 24]. In the other cases, the correct experiments have not yet been performed.) Finally, simulations have been successful in predicting the effect of mutation on the unfolding force [42]. Where simulation and experiment agree, the simulations can be used to understand details of the transitions between experimentally observable states.

Recent advances have reduced the unfolding forces observed in simulations to within an order of magnitude of those observed in experiment. Perhaps the most exciting phase is before us. Unlike previous studies in the field of protein folding where simulations have lagged behind experiment, the opposite is true of simulations of mechanical unfolding experiment. There are far more protein unfolding simulations in the literature than detailed experimental analyzes. The good simulation papers suggest experiments to be done.

31.5 Titin I27: A Case Study

31.5.1 The Protein System

Only one protein has, at the time of writing, been investigated in depth. This study shows how a combination of force spectroscopy, biophysical techniques, protein engineering, and simulation can be used to describe the mechanical unfolding of a single protein in detail. Titin I27 was the first protein made into a polyprotein and thus, the first where domain-specific force characteristics were elucidated [4]. It is one of the most mechanically stable proteins yet studied and remains a paradigm for forced unfolding experiments. The studies described here represent the work of a number of different experimental and theoretical groups.

To understand these experiments the structure of the protein has to be considered [43]. Titin I27 has an I-type immunoglobulin (Ig) fold. It has a beta sandwich structure, with the first sheet comprised of antiparallel strands A, B, E, and D and the second of antiparallel strands C, F, and G with, importantly, the A′ strand running parallel to strand G. In the polyprotein, the N and C termini (A and G strands) are connected by two-residue linkers (encoded by the restriction sites used in the cloning process). The N- and C-termini are found at opposite ends of the protein (Figure 31.5).

The first experiments revealed that the v_o was $\sim 10^{-4}$ s^{-1} and the $x_u \sim 3$ Å [4]. Since the unfolding rate was close to that observed in standard stopped-flow experi-

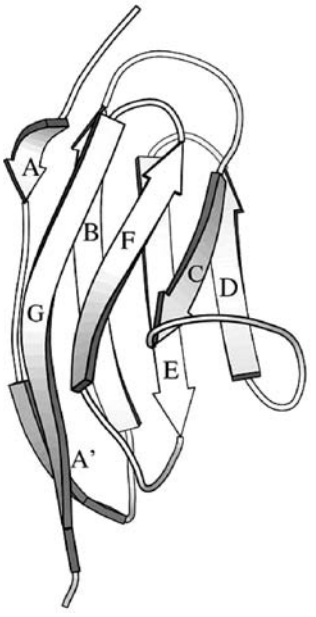

Fig. 31.5. Structure of titin I27. I27 has a beta-sandwich structure with the hydrophobic core enclosed by two antiparallel beta sheets. The strands are labeled A–G. A runs antiparallel to strand B, and A′ runs parallel to strand G.

ments it was suggested that the transition state for unfolding under force was the same as that observed in the absence of force. This idea, however, did not hold for long [5, 24].

31.5.2 The Unfolding Intermediate

The first step observed in the simulations of forced unfolding of I27 was the detachment of the A-strand, to form a metastable unfolding intermediate, which lived longer than the native state in the simulation conditions [37, 40]. Careful examination of the experimental force traces revealed the presence of a ''hump'' in the AFM traces, at around 100 pN, which was attributed to a lengthening due to the detachment of the A-strand in all the domains of the polyprotein [14]. A mutant that disrupted the hydrogen bonding between the A- and B-strands did not show these ''humps.''

Thus, apparently, at forces around 100 pN, the native state becomes less stable than this intermediate, I. If this explanation were correct, then the observed unfolding force reflects the unfolding of this intermediate, and not the denatured state. Studies of an I27 polyprotein with a conservative mutation V4 to A in the A-strand confirmed this explanation [24]. This mutation destabilized the native state

of the protein by ~2.5 kcal mol^{-1}, yet had no effect of the unfolding force, consistent with the intermediate hypothesis, since, if the A-strand is detached in I the V4A mutant would simply lead to I being populated at lower forces as N is destabilized, but I is not. Thus, the experiment and theory agree and the first process, N → I, in the unfolding pathway can be understood, and the unfolding rate constant at 0 force, ν_o, and the unfolding distance, x_u, can be assigned to the unfolding of this intermediate. In a traditional protein folding study of I27, no such folding intermediate is observed [44]. A model of this intermediate (I27 with the A-strand deleted) was purified, shown to be stable and, by NMR spectroscopy, to be structurally very similar to the native state. In MD simulations this intermediate had all the properties of the intermediate induced by force [24].

31.5.3 The Transition State

Possibly the most important state along the unfolding pathway is the transition state, the barrier to forced unfolding. Proteins that can withstand significant force have a free energy barrier to unfolding that remains significant under applied force. In order to probe the nature of this barrier protein engineering Φ-value analysis was undertaken [30]. Mutations were made in the A′, B, C′, E, F, and G strands. Most of these mutations, although strongly destabilizing, had no effect on the unfolding force, i.e., had a Φ-value of 1 (Figure 31.6) [42]. Only mutations in the A′ and G strand lowered the unfolding force. The effect of the mutation in the A′-strand (V13A) was to lower the unfolding force by ~25 pN without changing the x_u giving a Φ-value of ~0.5. The mutation in the G-strand (V86A) changed the slope of the force spectrum (Figure 31.6) so that a Φ-value could not be determined (see Section 31.3.8). Since mechanical Φ-values are much harder to determine than in traditional protein engineering studies (the molecular biology is more laborious, the data are harder to collect, and the $\Delta\Delta G_{D-N}$ of each mutant must be significantly larger than traditionally) only eight mutants were made. This can give only a general picture of the transition state. However, on the contrary, the transition state in MD simulations of forced unfolding experiments is easier to identify than in high temperature simulations of unfolding. The transition state is represented by the structures just at the point where extension proceeds rapidly to a fully unfolded structure. Direct comparison was made between the experimental Φ-values and the Φ-values determined from the simulations. The agreement was very good. This means that the structure of the transition state can be directly inferred from the simulation [42].

The transition state structure is essentially the same as the native structure except in the region of the A, A′, and G strands (Figure 31.7). The A-strand is, of course, completely detached, as it is in I. The hydrogen bonding and side-chain interactions between the A′ and G strands are lost, as are interactions between the A′-strand and the E–F loop and between the G-strand and the A′–B loop. Other interactions of the A′ and G strands with the rest of the protein are, however, maintained in this structure. The mechanical strength of the I27 domain lies in the

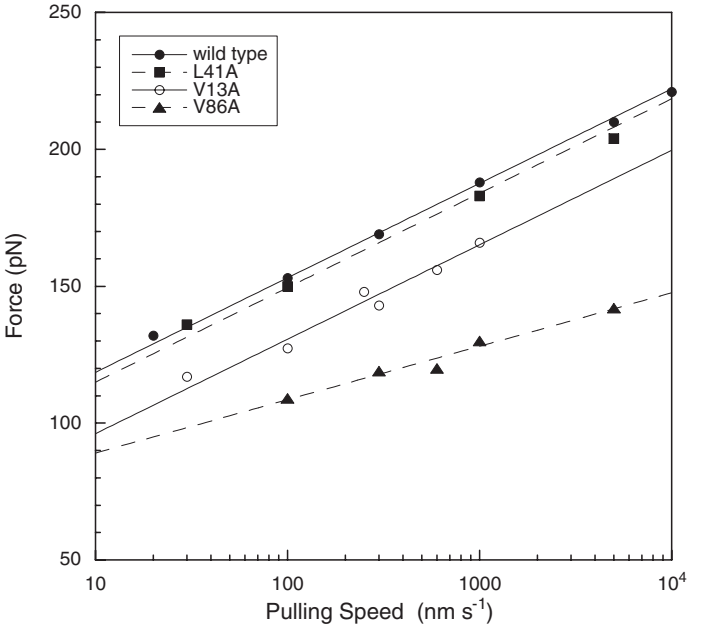

Fig. 31.6. Force spectra of titin I27. Most mutants (such as L41A) have no effect on the unfolding force, nor on the dependence of the unfolding force on the retract speed. V13A lowers the unfolding force but does not affect the pulling speed dependence. V86A both lowers the unfolding force and changes the dependence of the unfolding force on the puling speed. The slope of the force spectrum is $f_\beta \kappa_s = k_B T \kappa_s / x_u$ (i.e., the decrerase in slope for the mutant V86A reflects an increase in x_u).

strength of interactions between the A′ and G strands, and in the strength of interactions of these strands with other regions of the protein. (A mutant I27 studied elsewhere had shown that a substitution that made contacts in the BC loop, also lowered the unfolding force, consistent with these results [5].) Importantly, these experiments show that the interactions of the side chains contribute significantly to mechanical strength, and it is not just the hydrogen bonding pattern that determines mechanical strength, as had been suggested in some theoretical studies [38]. Whether it is simply packing interactions, or a more complex effect of shielding of the hydrogen bonds from attack by solvent has yet to be determined. This side chain dependence does, however, seem to be at the root of the relative mechanical stability of different I-band domains of titin [45, 46].

31.5.4
The Relationship Between the Native and Transition States

Thus far theory and experiment had elucidated the structure of the principle states along the pathway and the relative height of the barrier between I and TS (corresponding to $v_o \sim 10^{-4}$ s^{-1}) and the distance between I and TS ($x_u \approx 3$ Å). However,

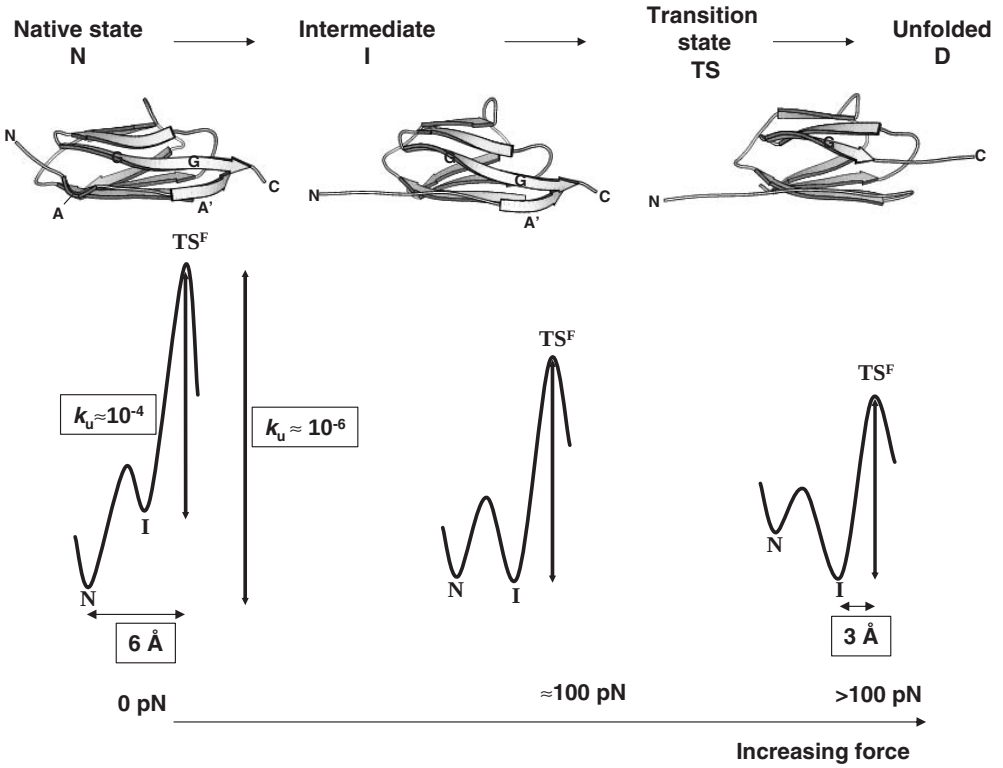

Fig. 31.7. The unfolding of TI I27 in the presence of force. Experiment and simulation combined have allowed the structure of the important states on the forced unfolding pathway to be elucidated. The effect of force on the unfolding landscape and the height and relative position of the energy barriers and the intermediate have been determined. Structures Courtesy of E. Paci.

the relative height of the barrier between N and TS and the distance between these two states was unknown. It is not possible, using AFM, to collect data at pulling speeds low enough to unfold the protein at forces below 100 pN, i.e., when I is not yet populated. However, here again mutant studies were instructive. One of the mutants (V86A) changed the slope of the force spectrum ($x_u \approx 6$ Å) [23]. The same behavior had been seen in a separate study for mutants with prolines inserted into the A′-strand [26]. The anomalous result was that these highly destabilized mutants had, apparently a lower unfolding rate at 0 force (ν_o) than wild type. The simplest explanation is that these mutations lowered the stability of I and/or lowered the TS energy to such an extent that the protein unfolded directly from N before I was populated. In this case, ν_o is the unfolding rate directly from N and x_u is the unfolding distance from N to the transition state. By using this as a model and modeling the data for wild type and mutants it was possible to estimate the rate constant between N and TS at 0 force for wild-type I27 ($\nu_o \approx 10^{-6}$ s^{-1}) [23].

31.5.5
The Energy Landscape under Force

Using all these results a pathway for the forced unfolding of titin I27 could be constructed (Figure 31.7). It is was also possible to compare the transition state in the absence of force (TS^0, as determined by traditional Φ-value analysis) with that observed in the force experiments (TS^F). The height of the energy barrier between N and TS^0 ($\nu_o = 5 \times 10^{-4}$ s^{-1}) is >3 kcal mol^{-1} lower than that between N and TS^F ($\nu_o = 10^{-6}$ s^{-1}). There is also a difference in structure. TS^F is more structured, with higher Φ-values than TS^0. However, the region of the protein that is responsible for mechanical stability (the region that breaks at the transition state) is apparently the same as the region that unfolds early in the denaturant induced unfolding studies, the A′ and G strands. When force is applied to the protein energy landscape, the unfolding pathway changes, and the protein unfolds along a pathway occupied by a high-energy barrier, TS^F, that resists unfolding.

31.6
Conclusions – the Future

Forced unfolding of proteins is in its infancy as a technique for studying proteins. Much of the work that has been done has been to demonstrate the power of atomic force microscopy as a tool. However, now forced unfolding is moving beyond a descriptive science towards analysis of the molecular effect of force on protein structure, stability, and unfolding landscapes. The use in the study of proteins that experience force in vivo is obvious. However, it can also be used, combined with simulation, to test our understanding of the molecular forces responsible for protein folding. How, for example, does a protein molecule respond to force applied in different directions? Can we explain the relationship between protein topology and mechanical strength? Altering the solvent conditions (e.g., temperature, pH, salt) may be used to determine the relative importance of different intramolecular forces. We can also look forward to the development of systems allowing proteins to be attached to the beads of optical tweezers, or the biomolecular force probe so that far lower loading rates, probably closer to those experienced in vivo, can be applied. As yet, the single molecule nature of the unfolding process has yet to be exploited, although rare events (misfolding and cooperative unfolding) have been observed [47, 48]. There are moves to combine single molecule fluorescence with single molecule force measurements. We would expect to see significant advances in the field in the next decade.

Molecular Dynamics Simulations to Study Protein Folding and Unfolding

Amedeo Caflisch and Emanuele Paci

32.1
Introduction

Proteins in solution fold in time scales ranging from microseconds to seconds. A computational approach to folding that should work, in principle, is to use an atom-based model for the potential energy (force field) and to solve the time-discretized Newton equation of motion (molecular dynamics, MD [1]) from a denatured conformer to the native state in the presence of the appropriate solvent. With the available simulation protocols and computing power, such a trajectory would require approximately 10–100 years for a 100-residue protein where the experimental transition to the folded state takes place in about 1 ms. Hence, there is a clear problem related to time scales and sampling (statistical error). On the other hand, we think that current force fields, even in their most detailed and sophisticated versions, i.e., explicit water and accurate treatment of long-range electrostatic effects, are not accurate enough (systematic error) to be able to fold a protein on a computer. In other words, even if one could use a computer 100 times faster than the currently fastest processor to eliminate the time scale problem, most proteins would not fold to the native structure because of the large systematic error and the marginal stability of the folded state typically ranging from 5 to 15 kcal mol^{-1}. Interestingly, only designed peptides of about 20 residues have been folded by MD simulations (see Section 32.2.1) using mainly approximative models of the solvent (see Section 32.3.4). Alternatively, protein unfolding which is a simpler process than folding (e.g., the unfolding rate shows Arrhenius-like temperature dependence whereas folding does not because of the importance of entropy, see Section 32.2.1.2) can be simulated on shorter time scales (1–100 ns) at high temperature or by using a suitable perturbation.

MD simulations can provide the ultimate detail concerning individual atom motion as a function of time. Hence, future improvements in force fields and simulation protocols will allow specific questions about the folding of proteins to be addressed. The understanding at the atomic level of detail is important for a complicated reaction like protein folding and cannot easily be obtained by experiments. Yet, experimental approaches and results are essential in validating the force fields

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

and simulation methods: comparison between simulation and experimental data is *conditio sine qua non* to validate the simulation results and very helpful for improving force fields.

This chapter cannot be comprehensive. Results obtained by using atom-based force fields and MD are presented whereas lattice models [2] as well as off-lattice coarse-grained models (e.g., one interaction center per residue) [3] are not mentioned because of size limitations. It is important to note that the impact of MD simulations of folding and unfolding is increasing thanks to faster computers, more efficient sampling techniques, and more accurate force fields as witnessed by several review articles [1, 4] and books [5–7].

32.2 Molecular Dynamics Simulations of Peptides and Proteins

32.2.1 Folding of Structured Peptides

Several comprehensive review articles on MD simulations of structured peptides have appeared recently [8–10]. Here, we first focus on simulation results obtained in our research group and then discuss the Trp-cage, a model system that has been investigated by others.

32.2.1.1 Reversible Folding and Free Energy Surfaces

***β*-Sheets** The reversible folding of two designed 20-residue sequences, beta3s and ^{D}PG, having the same three-stranded antiparallel *β*-sheet topology was simulated [11, 12] with an implicit model of the solvent based on the accessible surface area [13]. The solution conformation of beta3s (TWIQNGSTKWYQNGSTKIYT) has been studied by NMR [14]. Nuclear Overhauser enhancement spectroscopy (NOE) and chemical shift data indicate that at 10 °C beta3s populates a single structured form, the expected three-stranded antiparallel *β*-sheet conformation with turns at Gly6-Ser7 and Gly14-Ser15, (Figure 32.1) in equilibrium with the denatured state. The *β*-sheet population is 13–31% based on NOE intensities and 30–55% based on the chemical shift data [14]. Furthermore, beta3s was shown to be monomeric in aqueous solution by equilibrium sedimentation and NMR dilution experiments [14].

^{D}PG is a designed amino acid sequence (Ace-VFITS^{D}PGKTYTEV^{D}PG-Orn-KILQ-NH), where ^{D}P are D-prolines and Orn stands for ornithine. Circular dichroism and chemical shift data have provided evidence that ^{D}PG adopts the expected three-stranded antiparallel *β*-sheet conformation at 24 °C in aqueous solution [15]. Moreover, ^{D}PG was shown to be monomeric by equilibrium sedimentation. Although the percentage of *β*-sheet population was not estimated, NOE distance restraints indicate that both hairpins are highly populated at 24 °C.

In the MD simulations at 300 K (started from conformations obtained by spon-

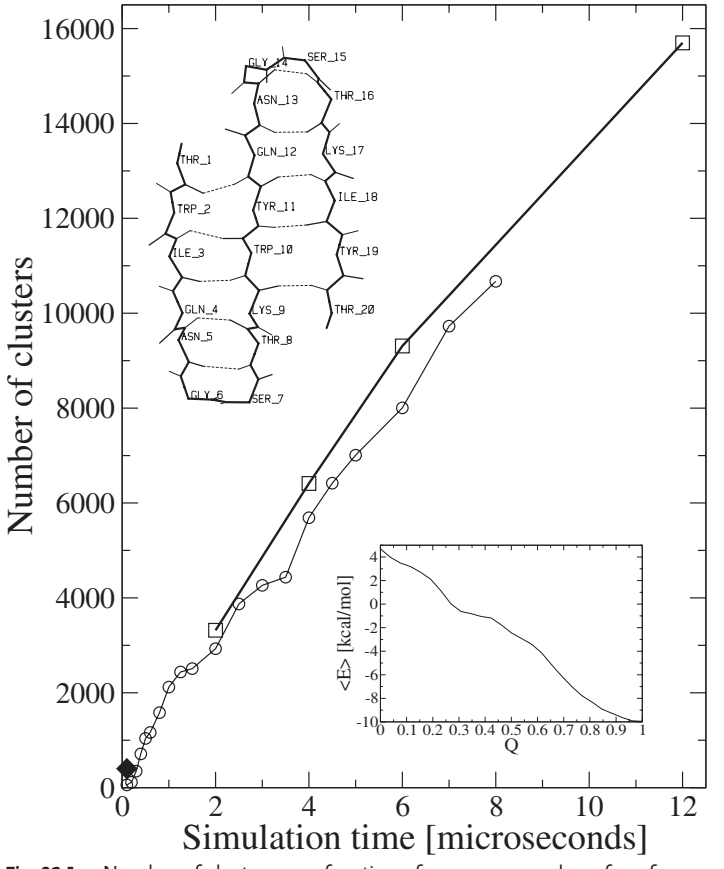

Fig. 32.1. Number of clusters as a function of time. The "leader" clustering procedure was used with a total of 120 000 snapshots saved every 0.1 ns (thick line and square symbols). The clustering algorithm which uses the Cα RMSD values between all pairs of structures was used only for the first 8 μs (80 000 snapshots) because of the computational requirements (thin line and circles). The diamond in the bottom left corner shows the average number of conformers sampled during the folding time which is defined as the average time interval between successive unfolding and refolding events. The insets show a backbone representation of the folded state of beta3s with main chain hydrogen bonds in dashed lines, and the average effective energy as a function of the fraction of native contacts Q which are defined in [11]. Figure from Ref. [33].

taneous folding at 360 K) both peptides satisfy most of the NOE distance restraints (3/26 and 4/44 upper distance violations for beta3s and ^{D}PG, respectively). At a temperature value of 360 K which is above the melting temperature of the model (330 K), a statistically significant sampling of the conformational space was obtained by means of around 50 folding and unfolding events for each peptide [11, 12]. Average effective energy and free energy landscape are similar for both peptides, despite the sequence dissimilarity. Since the average effective energy has a downhill profile at the melting temperature and above it, the free energy barriers

are a consequence of the entropic loss involved in the formation of a β-hairpin which represents two-thirds of the chain. The free energy surface of the β-sheet peptides is completely different from the one of a helical peptide of 31 residues, $Y(MEARA)_6$ (see below). For the helical peptide, the folding free energy barrier corresponds to the helix nucleation step, and is much closer to the fully unfolded state than for the β-sheet peptides. This indicates that the native topology determines to a large extent the free energy surface and folding mechanism. On the other hand, the ^{D}PG peptide has a statistically predominant folding pathway with a sequence of events which is the inverse of the one of the most frequent pathway for the beta3s peptide. Hence, the amino acid sequence and specific interactions between different side chains determine the most probable folding route [12].

It is interesting to compare with experimental results on two-state proteins. Despite a sequence identity of only 15%, the 57-residue IgG-binding domains of protein G and protein L have the same native topology. Their folded state is symmetric and consists mainly of two β-hairpins connected such that the resulting four-stranded β-sheet is antiparallel apart from the two central strands which are parallel [16]. The ϕ value analysis (see Section 32.2.3 for a definition of ϕ value) of protein L and protein G indicates that for proteins with symmetric native structure more than one folding pathway may be consistent with the native state topology and the selected route depends on the sequence [16]. Our MD simulation results for the two antiparallel three-stranded β-sheet peptides (whose sequence identity is also 15%) go beyond the experimental findings for protein G and L. The MD trajectories demonstrate the existence of more than one folding pathway for each peptide sequence [12]. Interestingly, Jane Clarke and collaborators [17] have recently provided experimental evidence for two different unfolding pathways using the anomalous kinetic behavior of the 27th immunoglobulin domain (β-sandwich) of the human cardiac muscle protein titin. They have interpreted the upward curvature in the denaturant-dependent unfolding kinetics as due to changes in the flux between transition states on parallel pathways. In the conclusion of their article [17] they leave open the question "whether what is unusual is not the existence of parallel pathways, but the fact that they can be experimentally detected and resolved."

α-Helices Richardson et al. [18] have analyzed the structure and stability of the synthetic peptide $Y(MEARA)_6$ by circular dichroism (CD) and differential scanning calorimetry (DSC). This repetitive sequence was "extracted" from a 60-amino-acid domain of the human CstF-64 polyadenylation factor which contains 12 nearly identical repeats of the consensus motif MEAR(A/G). The CD and DSC data were insensitive to concentration indicating that $Y(MEARA)_6$ is monomeric in solution at concentrations up to 2 mM. The far-UV CD spectrum indicates that the peptide has a helical content of about 65% at 1 °C. The DSC profiles were used to determine an enthalpy difference for helix formation of 0.8 kcal mol^{-1} per amino acid. The length of $Y(MEARA)_6$ makes it difficult to study helix formation by MD simulations with explicit water molecules. Therefore, multiple MD runs were performed with the same implicit solvation model used for the β-sheet peptides [13].

The simulation results indicate that the synthetic peptide $Y(MEARA)_6$ assumes a mainly α-helical structure with a nonnegligible content of π-helix [149]. This is not inconsistent with the currently available experimental evidence [18]. A significant π-helical content was found previously by explicit solvent molecular dynamics simulations of the peptides $(AAQAA)_3$ and $(AAKAA)_3$ [19], which provides further evidence that the π-helical content of $Y(MEARA)_6$ is not an artifact of the approximations inherent to the solvation model.

An exponential decay of the unfolded population is common to both $Y(MEARA)_6$ [149] and the 20-residue three-stranded antiparallel β-sheet [14] previously investigated by MD at the same temperature (360 K) [11]. The free energy surfaces of $Y(MEARA)_6$ and the antiparallel β-sheet peptide differ mainly in the height and location of the folding barrier, which in $Y(MEARA)_6$ is much lower and closer to the fully unfolded state. The main difference between the two types of secondary structure formation consists of the presence of multiple pathways in the α-helix and only two predominant pathways in the three-stranded β-sheet. The helix can nucleate everywhere, with a preference for the C-terminal third of the sequence in $Y(MEARA)_6$. Furthermore, two concomitant nucleation sites far apart in the sequence are possible. Folding of the three-stranded antiparallel β-sheet peptide beta3s started with the formation of most of the side chain contacts and hydrogen bonds between strands 2 and 3, followed by the 1–2 interstrand contacts. The inverse sequence of events, i.e., first formation of 1–2 and then 2–3 contacts was also observed, but less frequently [11].

The free energy barrier seems to have an important entropic component in both helical peptides and antiparallel β-sheets. In an α-helix, it originates from constraining the backbone conformation of three consecutive amino acids before the first helical hydrogen bond can form, while in the antiparallel β-sheet it is due to the constraining of a β-hairpin onto which a third strand can coalesce [11]. Therefore, the folding of the two most common types of secondary structure seems to have similarities (a mainly entropic nucleation barrier and an exponential folding rate) as well as important differences (location of the barrier and multiple vs. two pathways). The similarities are in accord with a plethora of experimental and theoretical evidence [20] while the differences might be a consequence of the fact that $Y(MEARA)_6$ has about 7–9 helical turns whereas the three-stranded antiparallel β-sheet consists of only two ''minimal blocks'', i.e., two β-hairpins.

32.2.1.2 Non-Arrhenius Temperature Dependence of the Folding Rate

Small molecule reactions show an Arrhenius-like temperature dependence, i.e., faster rates at higher temperatures. Protein folding is a complex reaction involving many degrees of freedom; the folding rate is Arrhenius-like at physiological temperatures, but deviates from Arrhenius behavior at higher temperatures [20].

To quantitatively investigate the kinetics of folding, MD simulations of two model peptides, Ace-$(AAQAA)_3$-$NHCH_3$ (α-helical stable structure) and Ace-$V_5{}^DPGV_5$-NH_2 (β-hairpin), were performed using the same implicit solvation model [13]. Folding and unfolding at different temperature values were studied by 862 simulations for a total of 4 μs [21]. Different starting conformations (folded

and random) were used to obtain a statistically significant sampling of conformational space at each temperature value. An important feature of the folding of both peptides is the negative activation enthalpy at high temperatures. The rate constant for folding initially increases with temperature, goes through a maximum at about T_m, and then decreases [21]. The non-Arrhenius behavior of the folding rate is in accord with experimental data on two mainly alanine α-helical peptides [22, 23], a β-hairpin [24], CI2, and barnase [25], lysozyme [26, 27], and lattice simulation results [28–30]. It has been proposed that the non-Arrhenius profile of the folding rate originates from the temperature dependence of the hydrophobic interaction [31, 32]. The MD simulation results show that a non-Arrhenius behavior can arise at high values of the temperature in a model where all the interactions are temperature independent. This has been found also in lattice simulations [28, 29]. The curvature of the folding rate at high temperature may be a property of a reaction dominated by enthalpy at low temperatures and entropy at high temperatures [30]. The non-Arrhenius behavior for a system where the interactions do not depend on the temperature might be a simple consequence of the temperature dependence of the accessible configuration space. At low temperatures, an increase in temperature makes it easier to jump over the energy barriers, which are rate limiting. However, at very high temperatures, a larger portion of the configuration space becomes accessible, which results in a slowing down of the folding process.

32.2.1.3 Denatured State and Levinthal Paradox

The size of the accessible conformational space and how it depends on the number of residues is not easy to estimate. To investigate the complexity of the denatured state four molecular dynamics runs of beta3s were performed at the melting temperature of the model (330 K) for a total simulation time of 12.6 μs [33]. The simulation length is about two orders of magnitude longer than the average folding or unfolding time (about 85 ns each), which are similar because at the melting temperature the folded and unfolded states are equally populated. The peptide is within 2.5 Å Cα root mean square deviation (RMSD) from the folded conformation about 48% of the time. Figure 32.1 shows the results of a cluster analysis based on Cα RMSD. There are more than 15 000 conformers (cluster centers) and it is evident that a plateau has not been reached within the 12.6 μs of simulation time. However, the number of significantly populated clusters (see Ref. [12] for a detailed description) converges already within 2 μs. Hence, the simulation-length dependence of the total number of clusters is dominated by the small ones. At each simulation interval between an unfolding event and the successive refolding event additional conformations are sampled. More than 90% of the unfolded state conformations are in small clusters (each containing less than 0.1% of the saved snapshots) and the total number of small clusters does not reach a plateau within 12.6 μs. Note that there is also a monotonic growth with simulation time of the number of snapshots in the folded-state cluster. After 12.6 μs (and also within each of the four trajectories) the system has sampled an equilibrium of folded and unfolded states despite a large part of the denatured state ensemble has not yet been explored. In fact, the average folding time converges to a value around 85 ns which

shows that the length of each simulation is much larger than the relaxation time of the slowest conformational change. Interestingly, in the average folding time of about 85 ns beta3s visits less than 400 clusters (diamond in Figure 32.1). This is only a small fraction of the total amount of conformers in the denatured state. It is possible to reconcile the fast folding with the large conformational space by analyzing the effective energy, which includes all of the contributions to the free energy except for the configurational entropy of the protein [11, 34]. Fast folding of beta3s is consistent with the monotonically decreasing profile of the effective energy (inset in Figure 32.1). Despite the large number of conformers in the denatured state ensemble, the protein chain efficiently finds its way to the folded state because native-like interactions are on average more stable than nonnative ones.

In conclusion, the unfolded state ensemble at the melting temperature is a large collection of conformers differing among each other, in agreement with previous high temperature molecular dynamics simulations [8, 35]. The energy "bias" which makes fast folding possible does not imply that the unfolded state ensemble is made up of a small number of statistically relevant conformations. The simulations provide further evidence that the number of denatured state conformations is orders of magnitudes larger than the conformers sampled during a folding event. This result also suggests that measurements which imply an average over the unfolded state do not necessarily provide information on the folding mechanism.

32.2.1.4 **Folding Events of Trp-cage**

Very small proteins are ideal systems to validate force fields and simulation methodology. Neidigh et al. [36] have truncated and mutated a marginally stable 39-residue natural sequence thereby designing a 20-residue peptide, the Trp-cage, that is more than 95% folded in aqueous solution at 280 K. The stability of the Trp-cage is due to the packing of a Trp side chain within three Pro rings and a Tyr side chain. Moreover, the C-terminal half contains four Pro residues which dramatically restrict the conformational space, i.e., entropy, of the unfolded state [36, 37].

Four MD studies have appeared in the 12 months following the publication of the Trp-cage structure [38–41]. All of the simulations were started from the completely extended conformation and used different versions of the AMBER force field and the generalized Born continuum electrostatic solvation model [42]. Two simulations were run with conventional constant temperature MD at 300 K [40] and 325 K [38], a third study used replica exchange MD with a range of temperatures from 250 K to 630 K [41], and in the fourth paper distributed computing simulations at 300 K with full water viscosity were reported [39].

An important problem of the three constant temperature studies is that the Trp-cage seems to fold to a very deep free energy minimum and no unfolding events have been observed [38–40]. Moreover, only one folding event is presented by Simmerling et al. [38] and Chowdhury et al. [40]. The poor statistics does not allow to draw any conclusions on free energy landscapes or on the folding mechanism of the Trp-cage.

Another potential problem is the discrepancy between the most stable state

sampled by MD and the NMR conformers. Only in two of the four MD studies NOE distance restraints were measured along the trajectories and about 20% were found to be violated [40, 41]. Moreover, as explicitly stated by the authors, the native state sampled by distributed computing contains a π-helix (instead of the α-helix) and the Trp is not packed correctly in the core [39]. These discrepancies are significant because the Trp-cage has a very small core and a rather rigid C-terminal segment.

32.2.2 Unfolding Simulations of Proteins

32.2.2.1 High-temperature Simulations

Since the early work of Daggett and Levitt [43] and Caflisch and Karplus [44], several other high-temperature simulation studies have been concerned with exploring protein unfolding pathways. Several comprehensive review articles exist on this simulation protocol [45] which has been widely used since. Recent MD simulations at temperatures of 100 °C and 225 °C of a three-helix bundle 61-residue protein, the engrailed homeodomain (En-HD), by Daggett and coworkers [46, 47] have been used to analyze a folding intermediate at atomic level of detail. The unfolding half-life of the En-HD at 100 °C has been extrapolated to be about 7.5 ns, a time scale that can be accessed by MD simulations with explicit water molecules.

Also, unfolding simulations in the presence of explicit urea molecules have shown that the protein (barnase) remains stable at 300 K but unfolds partially at moderately high temperature (360 K) [48]. The results suggested a mechanism for urea induced unfolding due to the interaction of urea with both polar and nonpolar groups of the protein.

32.2.2.2 Biased Unfolding

Because of the limitations on simulation times and height of the barriers to conformational transitions in proteins, a number of methods, alternative to the use of high, nonphysical temperatures, have been proposed to accelerate such transitions by the introduction of an external time-dependent perturbation [49–54]. The perturbation induce the reaction of interest in a reasonable amount of time (the strength of the perturbation is inversely proportional to the available computer time). These methods have been used for studying not only protein unfolding at native or realistic denaturing conditions, but also large conformational changes between known relevant conformers [51]. Their goal is to generate pathways which are realistic, in spite of the several orders of magnitude reduction in the time required for the conformational change. They are not alternatives to methods to compute free energy profiles along defined pathways. The external perturbation is usually applied to a function of the coordinates which is assumed to vary monotonically as the protein goes from the native to the nonnative state of interest. For certain perturbations the unfolding pathways obtained have been shown to depend on the nature of the perturbation and the choice of the reaction coordinate [52];

this is even more the case when the perturbation is strong and the reaction is induced too quickly for the system to relax along the pathway.

A perturbation which is particularly "gentle" since it exploits the intrinsic thermal fluctuations of the system and produces the acceleration by selecting the fluctuations that correspond to the motion along the reaction coordinate has also been used to unfold proteins [55, 56]. This perturbation has been employed, in particular, to expand α-lactalbumin by increasing its radius of gyration starting from the native state, and generate a large number of low-energy conformers that differ in terms of their root mean square deviation, for a given radius of gyration. The resulting structures were relaxed by unbiased simulations and used as models of the molten globule (see Chapter 23) and more unfolded denatured states of α-lactalbumin based on measured radii of gyration obtained from nuclear magnetic resonance experiments [57]. The ensemble of compact nonnative structures agree in their overall properties with experimental data available for the α-lactalbumin molten globule, showing that the native-like fold of the α-domain is preserved and that a considerable proportion of the antiparallel β-sheet in the β-domain is present. This indicated that the lack of hydrogen exchange protection found experimentally for the β-domain [58] is due to rearrangement of the β-sheet involving transient populations of nonnative β-structures in agreement with more recent infrared spectroscopy measurements [59]. The simulations also provide details concerning the ensemble of structures that contribute as the molten globule unfolds and shows, in accord with experimental data [60], that the unfolding is not cooperative, i.e., the various structural elements do not unfold simultaneously.

32.2.2.3 **Forced Unfolding**

Unfolding by stretching proteins individually has become routinely mainly thanks to the advent of the atomic force microscopy technology [61]. This peculiar way of unfolding proteins opened new perspectives on protein folding studies. Experiments are usually performed on engineered homopolyproteins, and the I27 domain from titin has become the reference system for this type of studies. Experiments measure force-extension profiles, and show typical "saw-tooth" profiles, where peaks are due to the sudden unfolding of individual domains, sequentially in time, causing a drop in the recorded force. These profiles are generally interpreted assuming that the unfolding event is determined by a single barrier which is decreased by the external force. For a detailed description of the experimental techniques and of the most recent results on forced unfolding of single molecules (by atomic force microscopy and optical tweezers) see Chapter 31.

To provide a structural interpretation of the typical saw-tooth-like spectra measured in single molecule stretching experiments, various simulation techniques have been proposed, where detailed all-atom models of proteins are stretched by pulling two atoms apart [62, 63], differing mainly in the way the solvent is treated.

In some cases simulation can effectively explain the force patterns measured (see Ref. [64] for a review). For all the proteins experimentally unfolded by pulling, only a simple saw-tooth pattern has been recorded related to the sudden unfolding

when the protein was pulled beyond a certain length, i.e., a simple two-state behavior. Simulations showed a more complex behavior [63] with possible intermediates on the forced unfolding pathways for certain proteins.[1]

Simulation has been used [65] to compare forced unfolding of two protein classes (all-β-sandwich proteins and all-α-helix bundle proteins). In particular, simulations suggested that different proteins should show a significantly different forced unfolding behavior, both within a protein class and for the different classes and dramatic differences between the unfolding induced by high temperature and by external pulling forces. The result was shown to be correlated to the type of perturbation, the folding topologies, the nature of the secondary and tertiary interactions and the relative stability of the various structural elements [65]. Improvements in the AFM technique combined with protein engineering methods have now confirmed (see Chapter 31) that chemical (or thermal) and forced unfolding occur through different pathways and that forced unfolding is related to crossing of a free energy barrier which might not be unique, but might change with force magnitude or upon specific mutations [66].

It should be borne in mind, however, that the forced unfolding of proteins is a nonequilibrium phenomenon strongly dependent on the pulling speed, and, since time scales in simulations and experiments are very different, the respective pathways need not to be the same. Recently, through a combination of experimental analysis and molecular dynamics simulations it has been shown that, in the case of mechanical unfolding, pathways might effectively be the same in a large range of pulling speeds or forces [67, 68], thus providing another demonstration of the robustness of the energy landscape (i.e., the funnel-like shape of the free energy surface sculpted by evolution is not affected by the application of even strong perturbations [69, 70]). In two recent papers [71, 72] it has been shown that proteins resist differently when pulled in different directions. In both cases the experiments have been complemented with simulations, with either explicit or implicit solvents. In both cases the behavior observed experimentally is qualitatively reproduced. This fact strongly suggests, although does not prove it, that in this particular case the forced unfolding mechanisms explored in the simulations is the same as that which determines the experimentally measured force.

Difference between solvation models is discussed in detail in Section 32.3.4 in the context of forced unfolding simulations, the disadvantage of an explicit solvation model [62, 72, 73] relative to an implicit [63, 65, 67, 68, 71] is not only that of being much slower, but also to provide an environment which relaxes slowly relative to the fast unraveling of the protein under force. Moreover, properly hydrating with explicit water a partially extended protein requires a large quantity of water, thus requiring a very large amount of CPU time for a single simulation. Implicit solvent models, on the other hand, allow unfolding to be performed at much lower

1) The presence of "late" intermediates on the forced unfolding pathway was first observed [63] in the 10th domain of fibronectin type III from fibronectin (FNfn3). A more complex pattern than equally spaced peaks in the force extension profile was predicted to arise from the presence of a kinetically metastable state. Most recent experimental results (J. Fernandez, personal communication) confirm the behavior predicted by the simulation.

forces (or pulling speeds) and multiple simulations to be used to study the dependence of the results on the initial conditions and/or on the applied force.

32.2.3 Determination of the Transition State Ensemble

The understanding of the folding mechanism has crucially advanced since the development of a method which provide information on the transition state [74] (see Chapter 13). The method allows the structure of the transition state at the level of single residue to be probed by measuring the change in folding and unfolding rates upon mutations. The method provides a so-called ϕ-value for each of the mutated residues which is a measure of the formation of native structure around the residue: a ϕ-value of 1 suggests that the residue is in a native environment at the transition state while a ϕ-value of 0 can be interpreted as a loss of the interactions of the residue at the transition state. Fractional ϕ-values are more difficult to interpret, but have been shown to arise from weakened interactions [75] and not from a mixture of species, some with fully formed and some with fully broken interaction.

As we discussed in Section 32.2.2.1, the use of high temperature makes it possible to observe the unfolding of a protein by MD on a time scale which can be simulated on current computers. Valerie Daggett and collaborators [76] first had the idea of performing a very high-temperature simulation and looking for a sudden change in the structure of the protein along the trajectory, indicating the escape from the native minimum of the free energy surface. The collections of structures around the ''jump'' were assumed to constitute a sample of the putative transition state. Assuming that the experimental ϕ-values correspond in microscopic terms to fraction of native contacts, they found a good agreement between calculated and experimental values. This approach was initially applied to the protein CI2, a small two-state proteins which has been probably the most thoroughly studied by experimental ϕ-value analysis; it has been subsequently improved and extended to the study of several proteins for which experimental ϕ-values were available (see Ref. [77] for review and other references).

Another related method has been used recently [78] to unfold a protein by high-temperature simulation (srcSH3 in the specific case) and determine a putative transition state by looking for conformations where the difference between calculated and experimental ϕ-values was smallest.

Both methods presented above have the advantage of providing structures extracted from an unfolding trajectory and thus the fast refolding or complete unfolding from these structures (a property of transition states) has been reported [78, 79]. But both approaches only provide few transition state structures, because a long simulation is required to generate each member of the transition state ensemble, while the transition state can be a quite broad ensemble for some proteins [80].

In a recent development, it has been shown that the amount of information that can be obtained from experimental measurements can be expanded further by

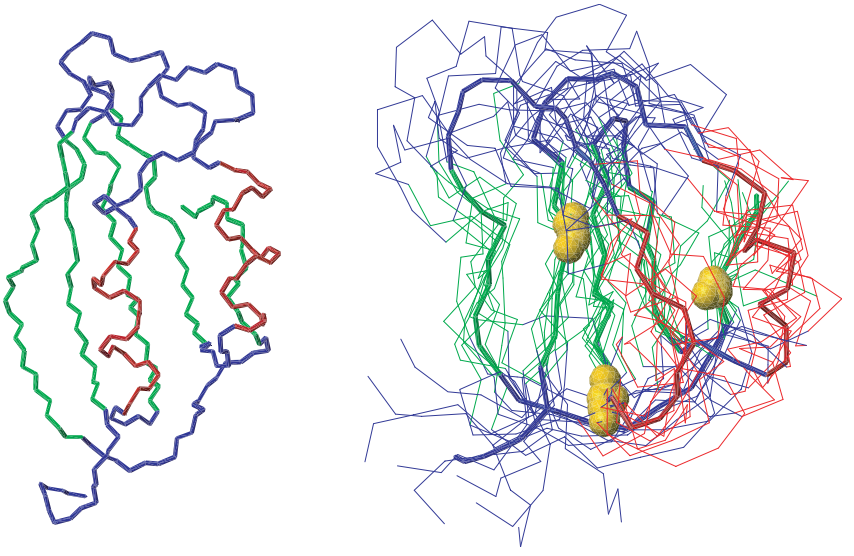

Fig. 32.2. Comparison between the native state structure (left) and the most representative structures of the transition state ensemble of AcP, determined by all-atom molecular dynamics simulations [82]. Native secondary structure elements are show in color (the two α-helices are plotted in red and the β-sheet in green). The three key residues for folding are shown as gold spheres [81, 82]. Figure from Ref. [69].

using the data to build up phenomenological energy functions to bias computer generated trajectories. With this approach (see Section 32.3.2 for a more detailed description of the technique), conformations compatible with experimental data are determined directly during the simulations [81, 82], rather than being obtained from filtering procedures such as those discussed above [78]. The incorporation of experimental data into the energy function creates a minimum in correspondence of the state observed experimentally and therefore allows for a very efficient sampling of conformational space. The transition state for folding of acylphosphatase (see Figure 32.2) was determined in this way [81, 82], showing that the network of interactions that stabilize the transition state is established when a few key residues form their native-like arrangement.

Based on this computational technique, a general approach in which theory and experiments are combined in an iterative manner to provide a detailed description of the transition state ensemble has been recently proposed [83]. In the first iteration, a coarse-grained determination of the transition state ensemble (TSE) is carried out by using a limited set of experimental ϕ-values as constraints in a molecular dynamics simulation. The resulting model of the TSE is used to determine the additional residues whose ϕ-value measurement would provide the most information for refining the TSE. Successive iterations with an increasing number of ϕ-value measurements are carried out until no further changes in the properties of the TSE are detected or there are no additional residues whose ϕ-values can be

measured. The method can be also used to find key residues for folding (i.e., those that are most important for the formation of the TSE).

The study of the transition state represents probably the most interesting example of how experiment and molecular dynamics simulations complement each other in understanding and visualizing the folding mechanisms in terms of relevant structures involved. Simulations are performed with approximate force fields and unfolding induced using artificial means (such as high temperature or other perturbations). At this stage in the development of MD simulations, the experiment provides evidence that what is observed in silico is consistent with what happens in vitro. On the other hand, and particularly in the case in which the full ensemble of conformations compatible with the experimental results is generated [82, 83], the simulation suggests further mutations to increase the resolution of the picture of the transition state, and allows detailed hypothesis of the mechanisms, such as the identity and structure of the residues involved in the folding nucleus [150].

32.3 MD Techniques and Protocols

32.3.1 Techniques to Improve Sampling

A thorough sampling of the relevant conformations is required to accurately describe the thermodynamics and kinetics of protein folding. Since the energetic and entropic barriers are higher than the thermal energy at physiological temperature, standard MD techniques often fail to adequately sample the conformational space. As already mentioned in this chapter, even for a small protein it is currently not yet feasible to simulate reversible folding with a high-resolution approach (e.g., MD simulations with an all-atom model). The practical difficulties in performing such brute force simulations have led to several types of computational approaches and/or approximative models to study protein folding. An interesting approach is to unfold starting from the native structure [84–86] but detailed comparison with experiments [47] is mandatory to make sure that the high-temperature sampling does not introduce artifacts. In addition, a number of approaches to enhance sampling of phase space have been introduced [87, 88]. They are based on adaptive umbrella sampling [89], generalized ensembles (e.g., entropic sampling, multicanonical methods, replica exchange methods) [90], modified Hamiltonians [91–93], multiple time steps [94], or combinations thereof.

32.3.1.1 Replica Exchange Molecular Dynamics

Replica exchange is an efficient way to simulate complex systems at low temperature and is the simplest and most general form of simulated tempering [95]. Sugita and Okamoto have been the first to extend the original formulation of replica exchange into an MD-based version (REMD), testing it on the pentapeptide Met-

enkephalin in vacuo [96]. The basic idea of REMD is to simulate different copies (replicas) of the system at the same time but at different temperatures values.

We recently applied a REMD protocol to implicit solvent simulations of a 20-residue three-stranded antiparallel β-sheet peptide (beta3s) [97]. Each replica evolves independently by MD and every 1000 MD steps (2 ps), states i, j with neighbor temperatures are swapped (by velocity rescaling) with a probability $w_{ij} = \exp(-\Delta)$ [96], where $\Delta \equiv (\beta_i - \beta_j)(E_j - E_i)$, $\beta = 1/kT$ and E is the potential energy. During the 1000 MD steps the Berendsen thermostat [98] is used to keep the temperature close to a given value. This rather tight coupling and the length of each MD segment (2 ps) allow the kinetic and potential energy of the system to relax. High temperature simulation segments facilitate the crossing of the energy barriers while the low-temperature ones explore in detail the conformations present in the minimum energy basins. The result of this swapping between different temperatures is that high-temperature replicas help the low-temperature ones to jump across the energy barriers of the system. In the beta3s study eight replicas were used with temperatures between 275 and 465 K [97].

The higher the number of degrees of freedom in the system the more replicas should be used. It is not clear how many replicas should be used if a peptide or protein is simulated with explicit water. The transition probability between two temperatures depends on the overlap of the energy histograms. The histograms' width depends on $1/\sqrt{N}$ (where N is the size of the system). Hence, the number of replicas required to cover a given temperature range increases with the size. Moreover, in order to have a random walk in temperature space (and then a random walk in energy space which enhances the sampling), all the temperature exchanges should occur with the same probability. This probability should be at least of 20–30%. To optimize the efficiency of the method, one should find the best compromise between the number of replicas to be used, the temperature space to cover and the acceptance ratios for temperature exchanges. In the literature there is no clear indication about the selection of temperatures and empirical methods are usually applied (weak point of the method). The choice of the boundary temperatures depends on the system under study. The highest temperature has to be chosen in order to overcome the highest energy barriers (probably higher in explicit water) separating different basins; the lowest temperature to investigate the details of the different basins.

Sanbonmatsu and Garcia have applied REMD to investigate the structure of Met-enkephalin in explicit water [99] and the α-helical stabilization by the arginine side chain which was found to originate from the shielding of main-chain hydrogen bonds [100]. Furthermore, the energy landscape of the C-terminal β-hairpin of protein G in explicit water has been investigated by REMD [101, 102]. Recently, a multiplexed approach with multiple replicas for each temperature level has been applied to large-scale distributed computing of the folding of a 23-residue miniprotein [103]. Starting from a completely extended chain, conformations close to the NMR structures were reached in about 100 trajectories (out of a total of 4000) but no evidence of reversible folding (i.e., several folding and unfolding events in the same trajectory) was presented [103].

32.3.1.2 Methods Based on Path Sampling

A very promising computational method, called transition path sampling (reviewed in Ref. [104]) has been recently used [105] to study the folding of a β-hairpin in explicit solvent. The method allows in principle the study of rare events (such as protein folding) without requiring knowledge of the mechanisms, reaction coordinates, and transition states. Transition path sampling focuses on the sampling not of conformations but of trajectories linking two conformations or regions (possibly basins of attraction) in the conformational space. Other methods focus on building ensemble of paths connecting states; the stochastic path approach [106] and the reaction path method [107] have been also used to study the folding of peptides and small proteins in explicit solvent. The stochastic path ensemble and the reaction path methods introduce a bias in the computed trajectories but allow the exploration of long time scales. All the methods mentioned above are promising but rely on the choice of a somewhat arbitrary initial unfolded conformation beside the final native one.

32.3.2 MD with Restraints

A method to generate structures belonging to the TSE ensemble discussed in Section 32.2.3 consists in performing molecular dynamics simulations restrained with a pseudo-energy function based on the set of experimental ϕ-values. The ϕ-values are interpreted as the fraction of native contacts present in the structures that contribute to the TSE. With this restraint the TSE becomes the most stable state on the potential energy surface rather than being an unstable region, as it is for the true energy function of the protein. This procedure is conceptually related to that used to generate native state structures compatible with measurements from nuclear magnetic resonance (NMR) experiments, in that pseudo-energy terms involving experimental restraints are added to the protein force field [108, 109]. The main difference is that an approach is required to sample a broad state compatible with some experimental restraints, rather than a method to search for an essentially unique native structure.

The method is based on molecular dynamics simulations using an all-atom model of the protein [110, 111] and an implicit model for the solvent [112] with an additional term in the energy function:

$$\rho = \frac{1}{N_\phi} \sum_{i \in E} (\phi_i - \phi_i^{\exp})^2 \tag{1}$$

where E is the list of the N_ϕ available experimental ϕ-values, $\phi_i^{\exp}$. The ϕ_i-value of amino acid i in the conformation at time t is defined as

$$\phi_i(t) = \frac{N_i(t)}{N_i^{\text{nat}}} \tag{2}$$

where $N_i(t)$ is the number of native contacts of i at time t and N_i^{nat} the number of native contacts of i in the native state.

Molecular dynamics simulations are then performed to sample all the possible structures compatible with the restraints. The structures thus generated are not necessarily at the transition state for folding for the potential used. They provide instead a structural model of the experimental transition state, including all possible structures compatible with the restraints derived from the experiment. The experimental information provided by the ϕ-values might not be enough to restrain the sampling to meaningful structures (e.g., when only few mutations have been performed). In such circumstance, other experimentally measured quantities, such as the m-value, which is related to the solvent accessible surface, must be used to restrain the sampling or to a posteriori select meaningful structures.

This type of computational approach relies on the assumption implicit in Eq. (2). This consists in approximating a ϕ-value, measured as a ratio of free energy variations upon mutation, as a ratio of side-chain contacts. A definition based on side-chains is appropriate since experimental ϕ-values are primarily a measure of the loss of side-chain contacts at the transition state, relative to the native state. Although simply counting contacts, rather than calculating their energies, is a crude approximation [113], it has been shown that there is a good correlation between loss of stability and loss of side-chain contacts within about 6 Å on mutation [114]. Also, Shea et al. [115] have found in their model calculations that this approximation for estimating ϕ-values from structures is a good one under certain conditions. A more detailed relation between experimental ϕ-values and atomic contacts could in principle be established by using the energies of the all-atom contacts made by the side chain of the mutated amino acid.

The same approach can be extended to generate the structures corresponding to other unfolded or intermediate states as the site-specific information provided by the experiment is steadily increasing (see Chapters 20 and 21).

32.3.3 Distributed Computing Approach

As mentioned in the introduction, the problem of simulating the folding process of any sequence from a random conformation is mainly a problem of potentials and computer time. Duan and Kollman [116] have showed that a huge effort in parallelizing (on a medium-scale, 256 processors) an MD code and exploiting for several months a several million dollars computer (a Cray T3E) could lead to the simulation of 1 μs of the small protein villin headpiece. Even approaching the typical experimental folding times (which is, however, larger than 1 ms for most proteins), a statistical characterization of the folding process is still impossible in the foreseeable future.

Developing a large-scale parallelization method seems the most viable approach, as the cost of fast CPUs decreases steadily and their performances approach those of much more expensive mainframes. Time being sequential, MD codes are not massively parallelizable in an efficient way. A good scaling is usually obtained for

large systems with explicit water and a relatively small number of processors (between 2 and 100, depending on the program and the problem studied). One approach has been proposed that allows the scalability of a MD simulation to be pushed to the level of being able to use efficiently a network of heterogeneous and loosely connected computer [117]. The approach (called distributed computing) exploits the stochastic nature of the folding process. In general protein folding involves the crossing of free energy barriers. The approach is most easily understood assuming that the proteins have a single barrier and a single exponential kinetic (which is the case for a large number of small proteins [118]). The probability that a protein is folded after a time t is $P(t) = 1 - \exp(-kt)$, where k is the folding rate. Thus, for short times, and considering M proteins or independent simulations, the probability of observing a folding event is Mkt. So, if M is large, there is a sizable probability of observing a folding event on simulations much shorter than the time constant of the folding process [119]. The folding rate could then in principle be estimated by running M independent simulations (starting from the completely extended conformation with different random velocities) for a time t and counting the number N of simulations which end up in the folded state as $k = N/(Mt)$. Simulations have been reported where the folding rate estimated in this way (assuming that partial refolding counts as folding) is in good agreement with the experimental one (see, for example, Ref. [39]).

However, it has been argued [120] that even for simple two-state proteins, folding has a series of early conformational steps that lead to lag phases at the beginning of the kinetics. Their presence can bias short simulations toward selecting minor pathways that have fewer or faster lag steps and so miss the major folding pathways. This fact has been clearly observed by comparing equilibrium and fast folding trajectories simulations [121] for a 20-residue three-stranded antiparallel β-sheet peptide (beta3s). It was found that the folding rate is estimated correctly by the distributed computing approach when trajectories longer than a fraction of the equilibrium folding time are considered; in the case of the 20-residue peptide studied within the frictionless implicit solvation model used for the simulations, this time is about 1% of the average folding time at equilibrium. However, careful analysis of the folding trajectories showed that the fastest folding events occur through high-energy pathways, which are unlikely under equilibrium conditions (see Section 32.2.1.1). Along these very fast folding pathways the peptide does not relax within the equilibrium denatured state which is stabilized by the transient presence of both native and nonnative interactions. Instead, collapse and formation of native interactions coincides and, unlike at equilibrium, the formation of the two β-hairpins is nearly simultaneous.

These results demonstrate that the ability to predict the folding rate does not imply that the folding mechanisms are correctly characterized: the fast folding events occur through a pathway that is very unlikely at equilibrium. However, extending the time scale of the short simulations to 10% of the equilibrium folding time, the folding mechanism of the fast folding events becomes almost indistinguishable from equilibrium folding events. It must be stressed that this result is not general but concerns the specific peptide studied; the explicit presence of sol-

vent molecule (and the consequent friction), might decrease the differences between equilibrium and shortest folding events. Unfortunately, this kind of validation of the distributed computing approach is not possible for a generic protein in a realistic solvent, as equilibrium simulations are not feasible.

An alternative method to use many processors simultaneously to access time scales relevant in the folding process by MD simulations has recently been proposed by Settanni et al. [122]. The method is based on parallel MD simulations that are started from the denatured state; trajectories are periodically interrupted, and are restarted only if they approach the transition (or some other target) state. In other words, the method choses trajectories along which a cost function decreases. The effectiveness of such an approach was shown by determining the transition state for folding an SH3 domain using as cost function the deviation between experimental and computed ϕ-values (Eq. (1) in Section 32.3.2). The method can efficiently use a large number of computers simultaneously because simulations are loosely coupled (i.e., only the comparison between final conformations, needed periodically to choose which trajectory to restart, involve communications between CPUs). This method can also be extended to complex nondifferentiable cost functions.

32.3.4
Implicit Solvent Models versus Explicit Water

Incorporating solvent effects in MD and Monte-Carlo simulations is of key importance in quantitatively understanding the chemical and physical properties of biomolecular processes. Accurate electrostatic energies of proteins in an aqueous environment are needed in order to discriminate between native and nonnative conformations. An exact evaluation of electrostatic energies considers the interactions among all possible solute–solute, solute–solvent, and solvent–solvent pairs of charges. However, this is computationally expensive for macromolecules. Continuum dielectric approximations offer a more tractable approach [123–127]. The essential concept in continuum models is to represent the solvent by a high dielectric medium, which eliminates the solvent degrees of freedom, and to describe the macromolecule as a region with a low dielectric constant and a spatial charge distribution. The Poisson equation provides an exact description of such a system. The increase in computation speed for a finite difference solution of the Poisson equation [128–131] with respect to an explicit treatment of the solvent is remarkable but still not enough for effective utilization in computer simulations of macromolecules. The generalized Born (GB) model was introduced to facilitate an efficient evaluation of continuum electrostatic energies [42]. It provides accurate energetics and the most efficient implementations are between five and ten times slower than in vacuo simulations [132–134]. The essential element of the GB approach is the calculation of an effective Born radius for each atom in the system which is a measure of how deeply the atom is buried inside the protein. This information is combined in a heuristic way to obtain a correction to the Coulomb law for each atom pair [42]. For the integration of energy density, necessary to obtain the effective Born radii, both numerical [42, 132, 135] and analytical [134, 136, 137]

implementations exist. The former are more accurate but slower than the latter [135]. Moreover, analytical derivatives that are required for MD simulations are not given by numerical implementations.

For efficiency reasons empirical dielectric screening functions are the most common choice in MD simulations with implicit solvent. One kind of solvation model is based on the use of a dielectric function that depends linearly on the distance r between two charges ($\varepsilon(r) = \alpha r$) [138, 139] or has a sigmoidal shape [140, 141]. Although very fast, these options suffer from their inability to discriminate between buried and solvent exposed regions of a macromolecule and are therefore rather inaccurate. A distance and exposure dependent dielectric function has been proposed [142]. Recently, an approach based on the distribution of solute atomic volumes around pairs of charges in a macromolecule has been proposed to calculate the effective dielectric function of proteins in aqueous solution [143].

The simulation results presented in Section 32.2.1 were obtained using an implicit solvent model based on a fast analytical approximation of the solvent accessible surface (SAS) [13] and the CHARMM force field [110]. The former drastically reduces the computational cost with respect to an explicit solvent simulation. The SAS model is based on the approximation proposed by Lazaridis and Karplus [112] for dielectric shielding due to the solvent, and the surface area model for the hydrophobic effect introduced by Eisenberg and McLachlan [144]. Electrostatic screening effects are approximated by a distance-dependent dielectric function and a set of partial charges with neutralized ionic groups [112]. An approximate analytical expression [145] is employed to calculate the SAS because an exact analytical or numerical computation of the SAS is too slow to compete with simulations in explicit solvent. The SAS model is based on the assumptions that most of the solvation energy arises from the first water shell around the protein [144] and that two atomic solvation parameters are sufficient to describe these effects at a qualitative level of accuracy. Within these assumptions, the SAS energy term approximates the solute–solvent interactions (i.e., it should account for the energy of cavity formation, solute–solvent dispersion interactions, and the direct (or Born) solvation of polar groups). The two atomic solvation parameters were optimized by performing 1 ns MD simulations at 300 K on six small proteins [13]. It is important to underline that the structured peptides discussed in Section 32.2.1 were not used for the calibration of the SAS atomic solvation parameters. The SAS model is a good approximation for investigating the folded and denatured state (large ensemble of conformers) of structured peptides. Its limitations, in particular for highly charged peptides and large proteins, have been discussed [13].

The most detailed and physically sound approaches (e.g., explicit solvent and particle mesh Ewald treatment of the long-range electrostatic interactions [146]) are still approximations and might introduces artifacts (see, for example, Ref. [147]). All solvation models, even those computationally most expensive, are approximations and their range of validity is difficult to explore. It is likely that most proteins will unfold fast relative to the experimental time scale if one could afford long (e.g., 100 ns) explicit water MD simulations even at room temperature. Some evidence of this instability has been recently published [148].

32.4 Conclusion

It is a very exciting time for studying protein folding using multidisciplinary approaches rooted in physics, chemistry, and computer science. The time scale gap between folding in vitro and in silico is being continuously reduced and this will bring interesting surprises. We expect an increasing role of MD simulations in the elucidation of protein folding thanks to further improvements in force fields and solvation models.

33
Molecular Dynamics Simulations of Proteins and Peptides: Problems, Achievements, and Perspectives

Paul Tavan, Heiko Carstens, and Gerald Mathias

33.1
Introduction

When viewed from the standpoint of theoretical physics, proteins are extremely complex materials. They are inhomogeneous, non-isotropic, and exhibit dynamic processes covering many spatial and temporal scales (instead of only one or two), that is, they do not offer any of the nice features that make other materials readily accessible to simplified or coarse-grained descriptions. Therefore, theoretical approaches towards protein and peptide dynamics have to be based on microscopic descriptions. Here, atomistic molecular dynamics (MD) simulations, which are based on molecular mechanics (MM) force fields, currently represent the standard [1]. It should be noted, however, that these MM methods represent a first level of coarse graining, because they try to account for the electronic degrees of freedom mediating the interactions between the atoms by simplified parametric descriptions coded into standard MM force fields (for a recent review see Ponder and Case [2]).

In this article we want to address the question, to what extent can MM-MD simulations currently or in the near future contribute to the understanding of protein folding? Although simulations have been published (for a review see Ref. [3]) that allegedly describe folding processes of peptides or small proteins, there are also serious arguments (e.g., in Ref. [2]) that the available MM force fields may not be accurate enough for qualitatively correct descriptions. This would imply that the published simulations, instead of providing a ''virtual reality'' of folding processes, actually represent ''real artifacts.'' Thus, it is worthwhile addressing the issue of accuracy.

Because there are many excellent textbooks and review articles on MD simulation methods for liquids [4] and proteins (Ref. [2] and references therein), there is no point in duplicating this material. Instead, we have chosen to outline our own perspective of the issue, which has been and still is guiding our longstanding efforts to develop and improve the required computational methods. We start with a sketch of the basic physics of protein structure and dynamics. This sketch will

Protein Folding Handbook. Part I. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

serve to identify key challenges that have to be mastered by any attempt aiming at a theoretical description of these complicated processes.

33.2
Basic Physics of Protein Structure and Dynamics

The molecular machinery of life, designed by Darwinian selection in the process of evolution, essentially consists of proteins. Like all machines, these nano-machines are composed of rigid parts that define a specific three-dimensional structure and flexible parts that enable the particular functional dynamics for which the respective protein has been designed. Because proteins are polymer molecules, ''flexibility'' here implies a liquid state, like the one found in polymer melts. Therefore, under physiological thermodynamic conditions, proteins are generally found in a mixed state close to the melting transition between the solid and liquid phases.

The solid ''secondary'' substructures of proteins, for example the α-helices and β-sheets, are shaped by attractive interactions between strong electric dipoles, which are attached to the locally stiff and planar peptide groups within the polypeptide chains (Figure 33.1 illustrates the dipole–dipole interactions within a β-sheet). Here, the specific sequence of amino acid residues selects the respective secondary structures or, alternatively, precludes the formation of such rigid structures by inducing a local melting of the backbone into a flexible loop or random coil. There-

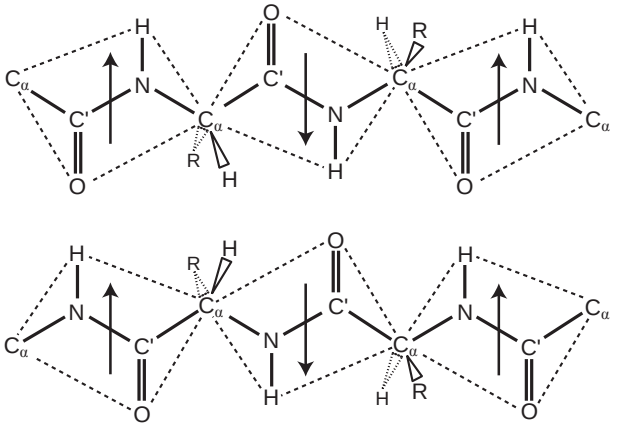

Fig. 33.1. Organization of the dipole–dipole interactions within a β-sheet. As explained by the resonance structures shown in Figure 33.3, the peptide groups form rigid platelets (indicated by the dashed lines) and exhibit strong electric dipole moments (arrows). Such dipoles attract each other, if their arrangement is parallel and axial ($\rightarrow\rightarrow$) or antiparallel and equatorial ($\uparrow\downarrow$). The structural stability of β-sheets is caused by a dipolar organization integrating both arrangements in an optimized fashion. Here, in contrast to α-helices, which exclusively exhibit the ($\rightarrow\rightarrow$)-arrangement, the local dipoles do not add up to a macroscopic dipole.

fore, the specific combination and three-dimensional organization of solid and liquid building blocks into the complex structure and dynamics characteristic for proteins is predetermined by their amino acid sequence.

Considering the thermodynamic state, proteins resemble a mixture of ice and liquid water, which, likewise, is characterized by a competition between enthalpic dipolar binding interactions attempting to generate solid order and temperature-driven entropic unbinding interactions attempting to generate liquid disorder. Nevertheless, there is a distinct difference concerning the complexity of the system: whereas a water–ice mixture homogeneously consists of only one molecular species, proteins are made up of a specific sequence of at least the 20 different residues coded in the genes, not counting all the additional cofactors, which also contribute to the complexity of protein structure and dynamics.

33.2.1 Protein Electrostatics

When attempts are made at a theoretical description, a first difficulty becomes apparent here. The dipole–dipole interactions (commonly called hydrogen bonds), which provide the main contribution to the folding of the polypeptide chains into specific three-dimensional structures, provide binding energies not much larger than the thermal energy $k_B T$ and it is only the combination of many different dipole–dipole interactions that generates the stability of a specific structure. Therefore, the precise description of the many weak electrostatic interactions within a protein is of key importance, since these interactions determine whether particular solid structures are formed or not. This instance is only a specific manifestation of the general fact that electrostatic interactions are dominant in shaping protein structure and dynamics [5]. In contrast, the weaker van der Waals interactions are less important as they are nonspecifically acting between all chemically nonbonded atoms in a similar way.

To obtain a quantitative estimate, consider a hypothetical protein with $N = 100$ residues, whose native conformation lies the typical energy value of $\Delta E = 20$ kJ mol^{-1} below either a compact misfolded conformation or the huge variety of unfolded ones. Then the acceptable error per residue allowing us still to identify the correct conformation is approximately $\Delta E/N^{1/2}$ or 2 kJ mol^{-1} (see Ref. [2] and references therein), where the errors are assumed to be randomly distributed. Systematic errors in the description of the electrostatics will reduce the acceptable error down to $\Delta E/N$ or 0.2 kJ mol^{-1}. Thus, great care has to be taken in the description of intraprotein electrostatics if one wants to generate a ''virtual reality.'' Its quantitatively correct description constitutes the first key problem for theoretical approaches.

33.2.2 Relaxation Times and Spatial Scales

Besides the strong variations of the physicochemical (predominantly electrostatic) properties among the residues, there is a second important difference between a

water–ice equilibrium and a protein, which adds to the indicated complexity. In liquid water the molecules are free to move individually, which confines the relaxation time of water in response to an external perturbation (e.g., to a change of the electric field) to the scale of a few picoseconds. Furthermore, in pure water at room temperature spatially ordered structures are found only up to a distance of about 1.5 nm from a given water molecule; beyond this distance water starts to behave like a dielectric continuum [6]. In contrast, in a protein the motions of the molecular components are strongly constrained by the polymeric connectivity and by solid substructures. These constraints lead to relaxation times that are larger than those in liquid water by up to 12 orders of magnitude or more.

Motions that change the conformation of a protein proceed through thermally activated rotations around the covalent single bonds linking the Cα atoms to the adjacent peptide groups of the backbone. At room temperature such rotations take at least a few 10–100 ps, which is why a protein can start to statistically sample its available conformational space only at time scales above 1 ns. Here, the number of atoms involved in a conformational transition defines a spatial scale and the time required for this transition increases rapidly with the size of the spatial scale. Up to now it is not yet clear whether the resulting time scales of conformational transitions represent a well-ordered hierarchy, within which distinct time scales can be associated to specific processes, or a continuum extending from nanoseconds to seconds. Whereas the former alternative would immediately suggest coarse-grained approaches to protein dynamics, the latter would make them difficult to construct. But whichever of these alternative pictures may be true, the vastly different temporal and spatial scales of molecular motions in proteins generate the second key problem for theoretical descriptions by simulation techniques.

33.2.3 Solvent Environment

Up to this point we have looked at the problem of describing the native structure and dynamics of proteins as if they could be understood as isolated objects. Assuming this hypothesis we have identified two key problems with which any attempt of a realistic description is confronted. The first is posed by the high accuracy required for the modeling of the electrostatics within a protein and the second by the huge span of time scales that have to be covered. But the issue is even more complicated, since proteins cannot be isolated from their surroundings.

Proteins acquire their native structure and functional dynamics solely within their physiological environment, which in the case of soluble proteins is characterized by certain ranges of temperature, pressure, pH, and concentrations of ions and of other molecular components within the aqueous solvent. Although these ranges may vary from protein to protein, there are specific physiological ranges for each of them. Therefore, any attempt to provide a quantitative description for the dynamic processes of protein folding and function has to properly include the environment at its physiological thermodynamic state.

33.2.4 Water

The key component of the environment is liquid water, whose adequate representation in computer simulations represents a challenge on its own (see Ref. [7] for a critical review and Ref. [6] for recent results). A water molecule is nearly spherical and very small (approximately the size of an oxygen atom), it carries large electrical dipole and quadrupole moments, and is strongly polarizable by electric fields generated, for example, by other water molecules, ions, or polar groups in its surroundings.

The large dipole moment causes the unusually large dielectric constant of 78, by which liquid water scales down electrostatic interactions. For proteins and peptides this dielectric mean-field property of water is important, because they are usually polyvalent ions and therefore generate a reaction field by polarization of the aqueous environment, which modifies the electrostatic interactions within the protein. The proper description of these very long-ranged effects thus represents the first problem specifically posed by MD simulations of protein–solvent systems.

The sizable quadrupole moment of the water molecule shapes the detailed structures of the hydration shells of solute molecules and, in particular, also those of proteins. If, as suggested by Brooks [8], water molecules actively support secondary structure formation, for example, by bridging nascent β-sheets, then an accurate modeling of the quadrupole moment is required for the understanding of the detailed folding pathways.

The strong electronic polarizability of the water molecules poses yet another challenge. As illustrated by the computational result in Figure 33.2, due to polar-

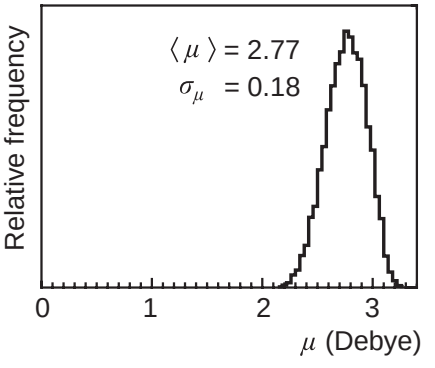

Fig. 33.2. Distribution of the dipole moment of a water molecule dissolved in pure water as obtained from a hybrid MD simulation combining density functional theory (DFT) for the given water molecule with an MM description of the aqueous environment. The DFT description of an isolated water molecule yields a dipole moment of 1.92 D, which is very close to the experimental value of 1.85 D. Thus, the induced dipole moment determined by the calculations is 0.85 D, that is about 40% of the gas-phase value. In liquid water the fluctuations of the dipole moment generated by the electronic polarization are 6.5% as measured by $\sigma_\mu/\langle\mu\rangle$. For technical details and explanations see Ref. [9].

ization the dipole moment increases from a value of 1.85 D for a water molecule isolated in the gas-phase to a value of about 2.6–3.0 D in the liquid phase [7, 9, 10]. Correspondingly the dipole moment of a water molecule will sizably change when it moves from a hydration shell of an ion through bulk water towards a nonpolar surface of a protein.

33.2.5 Polarizability of the Peptide Groups and of Other Protein Components

The polarization-induced changes of the dipole moments of the water molecules sketched above are important in the hydrophobic interactions [11], which are commonly believed to provide a key driving force in protein folding (see Ref. [12] for a discussion). Here, particularly the dipole–induced-dipole interactions, for example, between ordered hydration shells and nonpolar surfaces, are expected to provide large contributions. Therefore, not only the electronic polarizability of the water molecules, but also that of the various protein components has to be included for a quantitative description of the hydrophobic effect.

Furthermore, the electronic polarizability of the components can stabilize local structures in proteins. For instance, about 50% of the binding energy between a positive charge and an aromatic ring is due to polarization (as shown in Ref. [2] for the representative example of potassium bound to benzene). Particularly the polarizability of the peptide groups can be expected to decide about the relative stabilities of the secondary structure motifs in proteins. This claim is proven by the following simple argument:

We have stated further above (and illustrated in Figure 33.1 for the case of a β-sheet) that the dipole–dipole interactions within a protein, particularly those between the peptide groups of the backbone, shape the secondary structures of proteins. The peptide groups, in addition to exhibiting strong dipole moments, are highly polarizable as one can deduce from the resonance structures depicted in Figure 33.3. In response to the electric field generated by the dipole moments of neighboring peptide groups, with which a peptide group interacts in a given secondary structure motif (cf. Figure 33.1), an induced dipole moment will be added to the static dipole moment of the given group, and will correspondingly strengthen or weaken its dipole–dipole interactions (H-bonds). Here, the size and direction of the induced dipole moment will be determined by the spatial distribution and orientation of the neighboring dipoles and partial charges, that is, predominantly by the surrounding secondary structure.

As is also apparent from Figure 33.3, the electronic polarization will concomitantly change the force constants and equilibrium lengths of the chemical bonds (O=C–N–H) within the peptide groups. This effect is apparent in the vibrational spectra of proteins, which are dominated by the normal modes of the peptide groups giving rise to so-called amide bands. The shape of these broad bands is a signature of the differences in polarization experienced by the various peptide groups and, therefore, can be used for an approximate determination of secondary

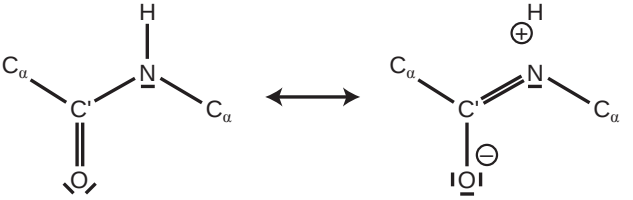

Fig. 33.3. π-electron resonance structures of a peptide group explaining its strong dipole moment and polarizability. An external electric field can modify the relative weights, by which these resonance structures contribute to the electronic wave function. Correspondingly, it will sizably change the dipole moment and the force constants.

structure content (see Ref. [13] for further information). Peaks of the so-called amide-I band, for instance, which belongs to the C=O stretching vibrations of the backbone, are found in the spectral range between 1620 and 1700 cm^{-1}, indicating that the polarization can change the associated C=O force constants by 5%. Conversely, (i) the fact that the large and specific frequency shifts of the amide modes can indicate the secondary structure environment of the corresponding peptide groups, and (ii) the resonance argument in Figure 33.3 uniquely demonstrate that the electronic polarization will entail sizably different strengths ($\geq$5%) of the dipolar interactions (''H-bonds'') within the various secondary structure motifs. This proves our above conjecture that the electronic polarizability provides a differential contribution to the relative stabilities of secondary structure motifs.

As a result, theoretical descriptions of protein dynamics have to include the electronic polarizability. In addition to this general insight, the above considerations have led us also to quantitative estimates as to how much the polarizability contributes to the electrostatics. We found numbers ranging between 50% (charge on top of an aromatic ring) and 5% (peptide groups in different secondary structure motifs). These contributions systematically and differentially change the electrostatic interactions within protein–solvent systems and do not represent random variations. This instance is obvious if one compares the interaction of a dipolar group with a charged and a nonpolar group, respectively. Furthermore, it has been demonstrated above for the dipolar interactions within secondary structure motifs. Below we will refer to the thus established 5% lower bound of the polarizability contribution to protein electrostatics for purposes of accuracy estimates.

Finally, we would like to add that enzymatic catalysis in proteins, which is a prominent feature of these materials, is essentially an effect of polarizability. Here, a substrate is noncovalently attached in a specific orientation to a binding pocket and a highly structured electric field, which is generated by a particular arrangement of charged, polar and nonpolar residues, exerts a polarizing strain on its charge distribution such that a particular chemical bond either breaks or is formed. This example underlines the decisive contribution of the electronic polarizability to protein structure, dynamics and function.

33.3
State of the Art

By considering the basic physics of protein–solvent systems we have identified key challenges that have to be met by MD-based theoretical descriptions of protein and peptide dynamics. The majority of these problems are posed by (i) the complex electrostatics in such systems and comprise (a) the long range of these interactions, (b) their shielding by the surrounding solvent, and (c) their local variability, which is caused by differential electronic polarization in these inhomogeneous and nonisotropic materials. Further challenges derive from the need (ii) to properly account for the thermodynamic conditions and (iii) to cover the relevant time scales.

During the past 25 years, since the first MD simulation of a protein was reported [14], the true complexities of the challenge have become more and more apparent. By now some of the problems have been solved, whereas others are still awaiting a solution. Quite naïvely, the first MD simulation dealt with a protein embedded in vacuum. However, the importance of the aqueous environment and the correct choice of the thermodynamic conditions soon became apparent [15, 16].

33.3.1
Control of Thermodynamic Conditions

In the theory of liquids and long before the history of protein simulations began, MD simulation systems representing a well-defined thermodynamic ensemble had been set up by filling periodic boxes with MM models of the material of interest (cf. the first simulation of liquid water by Rahman and Stillinger [17]). Whereas the temperature (or internal energy) is trivially accessible in any MD approach, up to now the pressure (or volume) can be controlled solely (cf. Mathias et al. [18] for a discussion) through the use of periodic boundary conditions (PBCs). This control can be executed safely and poses no problems.

33.3.2
Long-range Electrostatics

PBCs generate an unbounded simulation system of finite size with the topology of a three-dimensional torus. Therefore, they create the problem of artificial self-interactions whenever the interactions among the simulated particles are long ranged as is the case for electrostatics. To avoid such self-interactions one has to follow the minimum image convention (MIC), which dictates that all interactions beyond the MIC-distance $R_{\mathrm{MIC}} = L/2$ should be neglected, where L is the size of the periodic simulation box [4]. On the other hand, a corresponding truncation of the long-ranged electrostatic interactions in the so-called straight-cutoff (SC) approach leads to serious structural and energetic artifacts, even if the simulated system consists solely of pure water [18–20]. For solutions of polyvalent ions, like proteins or nucleic acids, the SC-artifacts become even worse.

Nevertheless, up to about a decade ago MD simulations of pure water and protein–solvent systems used to apply the SC approach with small cutoff distances $R_C \approx 1$ nm (i.e., $R_C \ll R_{MIC}$) mainly for computational reasons: In an N-particle system the number of long-range interactions scales like N^2 and, therefore, seems to imply an intractable computational effort. However, in the sequel, the unacceptably large errors connected with this crude approximation forced investigators to ignore the MIC and to apply lattice sum (LS) methods [21–23] to the computation of the long-range electrostatics. LS methods take advantage of the periodicity of the simulated system and can evaluate the correspondingly periodic electrostatic potential at a computational effort scaling with $N \log N$. On the other hand, the neglect of the MIC now introduces periodicity artifacts into the description of nonperiodic systems such as liquids and proteins in solution [24]. However, for large simulation systems with $L > 6$ nm in the case of pure water and $L \gg 2d$ in the case of a solvated protein of diameter d, the periodicity artifacts should become negligible or small, respectively [6, 18].

Today, we can even give absolute error bounds for the accuracy of the electrostatics computation in MD simulations. This is due to the recent development of a new algorithmic approach, which avoids the use of a periodic potential and, nevertheless, provides an accurate and computationally efficient alternative to the LS methods [18]. Therefore, it allows us to estimate, for example, the size of the LS artifacts and, in combination with LS results, to actually measure the SC errors. Because a comparably accurate alternative to LS had been lacking before, such accuracy measurements had been impossible. Figure 33.4 sketches the basic concept of this recent multiple-scale approach, which combines toroidal boundary conditions with a reaction field correction (TBC/RF).

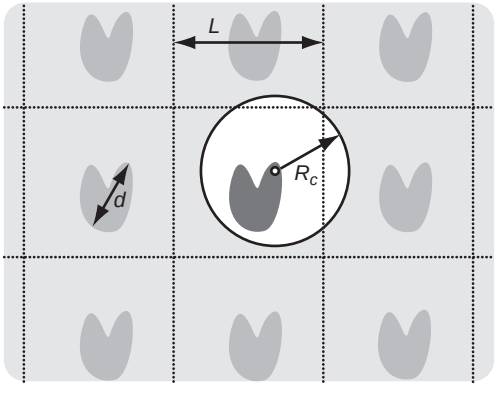

Fig. 33.4. Concept of the TBC/RF approach to the computation of long-range electrostatics in MD simulations of proteins in solution [18]. Each atom of the periodic simulation system of size L containing a protein of diameter d in solution is surrounded by a sphere of radius $R_C = R_{MIC} = L/2$. The polarization of the dielectric outside of that sphere generates a reaction field acting on the central charge, whose interactions with the charges within the sphere are rapidly calculated by fast, hierarchical, and structure-adapted multipole expansions. Here, the applied SAMM algorithm [25, 26] scales linearly with N.

To provide an example for such error bounds, we consider the PBC/LS, TBC/RF, and SC simulations on large water systems ($L = 8$–12 nm, $N = 34\,000$–$120\,000$), which have been executed with two different programs (GROMACS [27], EGOMMII [28]) under otherwise identical conditions (see Refs [6, 18]). The enthalpies of vaporization ΔH per water molecule calculated by PBC/LS and TBC/RF showed relative deviations of at most 3/1000, that is 0.1 kJ mol^{-1}. This deviation is smaller by a factor of 2 than the acceptable systematic error per residue estimated in Section 33.1.1 and by a factor of 20 below the acceptable random error. In contrast, the ΔH value calculated by SC using a cutoff radius $R_C \approx 4$ nm (system size $L = 8$ nm) deviated by 1.2 kJ mol^{-1} from the PBC/LS and TBC/RF values, which is larger by a factor of 6 than the acceptable systematic error introduced in Section 33.1.1.

This example quantitatively proves that SC simulations grossly miss the accuracy required for protein structure prediction in purely dipolar systems, whereas here the two other methods are acceptable. For solutions containing ions and particularly proteins similar comparisons of PBC/LS and TBC/RF treatments will soon provide clues as to which measures can be used to avoid computational artifacts and to achieve the required accuracy in these more complicated cases. As a result, the longstanding problem of how the long-range electrostatics of protein–solvent systems can be treated in MD simulations with sufficient accuracy and manageable computational effort will find a final answer in the near future. Furthermore, we can safely state that the remaining accuracy problems connected with long-range electrostatics computation are much smaller than those associated with the MM force fields to which we will now turn our attention.

33.3.3 Polarizability

As shown in Sections 33.1.4–33.1.5, many components of a protein–solvent system exhibit a significant electronic polarizability and, therefore, their electrostatic signatures, as measured by their multipole moments, will strongly vary with their position within these complex and inhomogeneous systems. In spite of the decisive part played by the electronic polarizability in protein structure, dynamics, and function, all available MM force fields still use static partial charges to model the electrostatic properties of the molecules (see, however, the ongoing development reported by Kaminski et al. [29]). Thus, they try to account for the electronic polarizability in a mean field fashion, which is invalid in inhomogeneous and nonisotropic materials. The examples discussed in Sections 33.1.4–33.1.5 suggest a lower bound of 5% for the size of the relative errors, which the neglect of polarization introduces into the description of the electrostatics.

To convert this relative error into an absolute number, we have conducted a sample TBC/RF simulation for bovine pancreatic trypsin inhibitor (BPTI) [30] in water at a temperature of 300 K and a pressure of 1 bar using the set-up described in Ref. [31]. Here, a periodic simulation box of 8 nm side length, filled with 17 329 rigid TIP3P water molecules [32] (cf. Figure 33.5) and a CHARMM22 model [33] of BPTI ($N_{res} = 58$ amino acid residues), was equilibrated for 1 ns. We took this equi-

librated system as the starting point for a 100 ps simulation and evaluated the average total electrostatic energy $E_{e,tot}$ of the protein atoms. Less than 1% of all electrostatic interactions between the protein charges occur within a given residue. Due to the so-called 1–3 exclusion commonly used in MM force fields [33] they act at comparable distances like the interactions with charges residing at neighboring residues or solvent molecules. Therefore, we estimate the intra-residue contribution to $E_{e,tot}$ to be sizably smaller than at most 20% of $E_{e,tot}$. As a result, the expression

$$E_{e,res} \approx 0.8 \times E_{e,tot}/N_{res}$$

should represent a lower limit for the average electrostatic energy $E_{e,res}$ per residue. Inserting the computed number, we find $E_{e,res} \approx 160$ kJ Mol^{-1}. With the 5% lower bound for the systematic error, which is expected to be caused by the neglect of polarizability, we thus find a lower limit to the ''polarizability error'' of 8 kJ mol^{-1} per residue. This polarizability error is by a factor 4 larger than the acceptable random error and exceeds the acceptable systematic error, which should be more relevant here, by a factor of 40.

Therefore, the neglect of the electronic polarizability is the key drawback of the available MM force fields and, up to now, prevents quantitative MD descriptions of protein structure. Furthermore, it is the reason why the parameterization of such force fields is confronted with insurmountable difficulties. As outlined in Section 33.1.5, the electronic polarizability of the peptide groups provides a differential contribution to the relative stabilities of secondary structure motifs. As a result, the common nonpolarizable MM force fields can either describe the stability of α-helices or that of β-sheets at an acceptable accuracy, but never both. Correspondingly and as illustrated in Ponder and Case [2] by sample simulations, such force fields either favor α-helical structures (e.g., AMBER ff94 [34]) or β-sheets (e.g., OPLS-AA [35]), or else fail concerning intermediate structures (e.g., CHARMM22 [33]).

33.3.4 Higher Multipole Moments of the Molecular Components

For computational reasons, MM force fields apply the partial charge approximation, according to which the charge distribution within the molecular components of a simulation system is modeled by charges located at the positions of the nuclei. Although this approximation should be sufficiently accurate in most instances (if the problem of the missing polarizability is put aside), it will cause problems concerning the description of local structures, whenever ''electron lone pairs'' occur at oxygen atoms [29]. Important examples for this chemical motif are the peptide C=O groups (cf. Figure 33.3) and the water molecule. At the small oxygen atoms the lone pairs cause large higher multipole moments, whose directional signature cannot be properly represented within the partial charge approximation. Although the electric field generated by these multipole moments rapidly decays beyond the

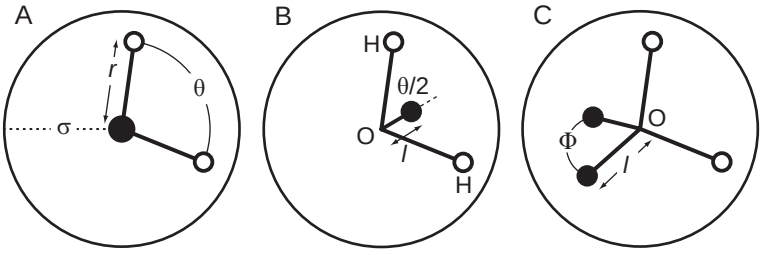

Fig. 33.5. Geometries of three different nonpolarizable MM models for water. Black circles indicate the positions of negative and open circles those of the positive partial charges. The large circle indicates the van der Waals radius. A) TIP3P, B) TIP4P (both Jorgensen et al. [33]), C) TIP5P [36].

first shell of neighboring atoms, it steers the directions of the H-bonds within that shell and, thus, shapes the corresponding local structures. The consequences of this subtle effect are yet to be explored for proteins. For water, however, whose experimental and theoretical characterization has always been and still is at a much higher stage than that of proteins, the importance of this effect is well known.

33.3.5 MM Models of Water

In an excellent review, Guillot [7] has recently given "a reappraisal of what we have learnt during three decades of computer simulations on water." Within the partial charge approximation, MM models of water comprise three charges at the positions of its three atoms ("three point models"). By symmetry and neutrality of the molecule, in this case three parameters (one charge, bond angle, and bond length) suffice to specify the charge distribution (cf. Figure 33.5A). However, these simple three-point models, which are commonly used in MD simulations of protein–water systems, do not correctly account for the higher multipole moments and, therefore, miss essential features of the correlation functions in pure water (see, for example, Ref. [6]). Because of this defect and of the missing polarizability, they cannot be expected to provide an adequate description of the hydration shell structures surrounding proteins.

For an improved description of the higher multipole moments, four- and five-point models have been suggested positioning partial charges away from the positions of the nuclei. Figure 33.5 compares the geometries of correspondingly extended models with that of a simple three-point model. In addition, a series of polarizable models using "fluctuating charges" or inducible dipoles have been proposed. Guillot gives an impressive table listing about 50 different MM models of water and, subsequently, classifies the performance of these models concerning the reproduction of experimentally established properties in simulations. Although Guillot mainly discusses pure water, he also shortly comments on the topic of transferability, which is the unsolved problem of how to construct an MM water

model performing equally well for all kinds of solute molecules. Summarizing his review he arrives at the conclusion that "one has a taste of incompletion, if one considers that not a single water model available in the literature is able to reproduce with a great accuracy all the water properties. Despite many efforts to improve this situation very few significant progress can be asserted." In his view this is due to "the extreme complexity of the water force field in the details, and their influence on the macroscopic properties of the condensed phase." Nevertheless, being a committed scientist he does not suggest that we should quit attempts at an MM description but instead adds several suggestions as to how one should account for the polarizability and for other details in a better way.

33.3.6 Complexity of Protein–Solvent Systems and Consequences for MM-MD

The state of the MM-MD descriptions of pure water sketched above is sobering when one turns to protein–solvent systems, whose complexity exceeds that of pure water by orders of magnitude. This enormous increase of complexity is caused only in part by the much larger spatial and temporal scales characterizing protein dynamics (cf. Section 33.1.2). More important is the combinatorial complexity, which is posed by the fact that one has to parameterize the interactions between a large variety of chemically different components (water, peptide groups, amino acid residues, ions, etc.) into a single effective energy function in a balanced way. If already in the case of a one-component liquid like water subtle details of the MM models determine the macroscopic properties, a difficulty which, up to now, has prevented the construction of a model capable of explaining all known properties, then one may ask whether the MM approach will ever live up to its promises concerning proteins at all. This critical question gains support by our above estimate concerning the size of the errors introduced by the neglect of the electronic polarizability characteristic for the common force fields. Our conservative estimate suggests that nowadays not even a single and most basic property of soluble proteins, namely their structure, can be reliably predicted by extended MM-MD simulations.

33.3.7 What about Successes of MD Methods?

However, this disastrous result on the accuracy of current MM-MD simulations does not imply that their results are always completely wrong. Instead it may sometimes happen that numbers computed by MD for certain observables surprisingly agree with experimental data within a few per cent. Examples are the peptide simulations presented by Daura et al. [37], which have shown a mixture of peptide conformations compatible with NMR data, the simulation of AFM experiments on the rupture force required to pull a biotin substrate out of its binding pocket in streptavidin [38], or the simulation of the light-induced relaxation dynamics in small cyclic peptides [39] (see Section 33.3 for a more detailed discussion of this

example). In such cases, the apparent "success" of an MD simulation may be due (i) to the choice of an observable that happens to be extremely stable with respect to the sizable inaccuracies of the MM force field, or (ii) to the fortunate cancellation of many different errors [40]. Therefore, one cannot readily conclude from such favorable examples that the MD approach towards biomolecular dynamics has "come of age" [41]. Instead, one must expect that observables computed by unrestricted MD simulations differ either quantitatively from experimental data by 10–50% or are qualitatively wrong.

Furthermore, the deficiencies of the MM force fields do not imply that results of MD simulations that are restricted by experimental data are wrong. On the contrary, this type of simulation [42] has led to the greatest success of the MD method and is largely responsible for its widespread application on proteins. In this experimentally restricted MD approach the chemical expertise that is coded into the various parameters of the MM force field (providing standard values for the bond lengths, bond angles, dihedral angles, for the elasticity of these internal coordinates etc.) is combined with a large set of experimental constraints (e.g., from X-ray diffraction or more-dimensional NMR). Shortly after their suggestion in 1987, the corresponding MD-based "annealing simulations" have become the standard tool in the computation of protein and peptide structures from X-ray and NMR data and have acquired a key role in structural biology, because they have enabled the automation of protein structure refinement. In this context, the deficiencies of the MM force fields play a minor role as they are largely corrected by the experimental constraints. Note that the protein electrostatics and its shielding by the solvent are usually ignored in these experimentally restricted simulations, because here one neither wants nor has to deal with the associated complexities.

Finally, another type of restricted MD simulation also does not suffer too much from the deficiencies of the MM force fields. These are the so-called QM/MM hybrid methods, in which a small fragment of a simulation system is treated by quantum mechanics (QM) and the large remainder by MM (the basic concepts of this approach were described in a seminal paper by Warshel and Levitt in 1976 [43]). Here, the attention is restricted to the properties of the QM fragment, which are calculated as exactly as possible by numerical solution of the electronic Schrödinger equation. The electronic polarization of the QM fragment is obtained by importing the electric field generated by the MM environment as an external perturbation into the QM Hamiltonian. If this perturbation changes a certain property of the QM fragment by 10%, then even 10% errors in the external field calculated by MM will entail only errors of 1% in the QM result.

To provide an example we consider the vibrational spectra of molecules. Due to the development [44, 45] and widespread accessibility [46] of density functional theory (DFT) highly accurate computations of intramolecular force fields and of associated gas-phase vibrational spectra have become feasible at a moderate computational effort. On average, the spectral positions of the computed lines deviate by only about 1.5% from the observations, which is sufficient for a safe assignment of observed bands to normal modes [47, 48]. Note that calculated molecular structures are more exact by orders of magnitude than the spectra, because the molecu-

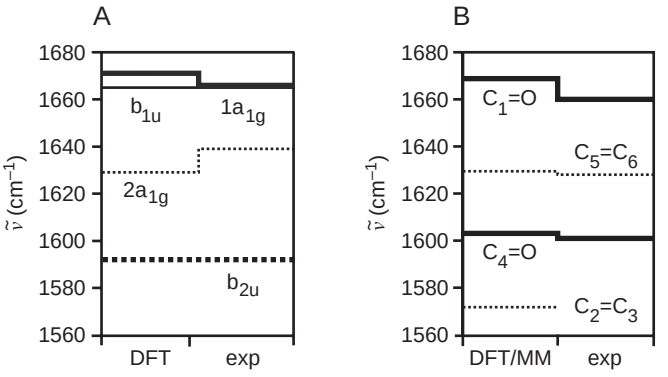

Fig. 33.6. Comparison of DFT (A) and DFT/MM (B) computations with experimental data for the vibrational spectra of the C=O (solid lines) and C=C (dashed lines) modes of quinone molecules in the gas-phase and in a protein, respectively. The DFT results pertain to *p*-benzoquinone [48] and the DFT/MM results to the ubiquinone Q_A in the reaction center of *Rb. sphaeroides* [49]. Both computational results agree very well with the observations. In particular, the DFT/MM treatment correctly predicts the sizable 60 cm^{-1} red shift of one of the C=O modes, which is caused by the protein environment through electrostatic polarization of the quinone.

lar structure is much less sensitive to inaccuracies of the QM treatment than the intramolecular force field.

In condensed phase, the computation of vibrational spectra [49, 50] has recently been enabled by the development of a DFT/MM hybrid method [9]. The perturbation argument given further above entails the expectation that DFT/MM can describe condensed-phase vibrational spectra at an accuracy comparable to the one previously achieved by DFT for the gas-phase spectra. This expectation is confirmed by the results shown in Figure 33.6 and by the infrared spectra of *p*-bezoquinone on water, which have been calculated from a QM/MM hybrid MD trajectory [50]. Thus, although the common nonpolarizable MM force fields are not accurate enough for unrestricted MD simulations of biomolecules, they are valuable in more restricted settings.

33.3.8
Accessible Time Scales and Accuracy Issues

Concerning MM-MD simulations of protein or peptide folding, the insufficient accuracy of MM force fields has the following consequence: If we had computer power enough to simulate the folding dynamics of a small protein or peptide in solution for milliseconds or seconds starting from a random coil conformation, we would have to expect at a high probability that the conformation predicted by the simulation has nothing to do with the native conformation, that is, represents a ''real artifact.''

In this respect it is, in a sense, fortunate that computational limitations have previously restricted MM-MD simulations of protein–solvent systems to the time scale of a few nanoseconds. Because simulations usually start from a structure determined by X-ray crystallography or by more-dimensional NMR, and because in proteins small-scale conformational transitions only begin to occur at this time scale, the actual metastability of a MM-MD protein model is likely to become apparent only in much more extended simulations than in the ones that are currently feasible. At the accessible nanosecond time scale, the large-scale and slow relaxation processes changing a metastable structure are simply "frozen out," and protein simulations are strongly restricted by the accessible time scales. Structural stabilities observed in short-time simulations are due to this restriction and cannot be attributed to the particular quality of the force field. Nevertheless, the apparent stability of protein structures even in grossly erroneous MM-MD simulations (like in those applying the SC truncation to the long-range electrostatics) may have led scientists to believe in the validity of MD results. For the field of MD simulations on protein dynamics this was fortunate, because it has created a certain public acceptance (cf. e.g., Ref. [41]) and has attracted researchers. On the other hand it was also quite unfortunate, because the urgent necessity to improve the MD methods to meet the challenges outlined in Section 33.1 remained an issue of concern only in a small community of methods developers.

However, the speed of computation has been increasing by a factor of 2 each year during the past decades and, according to the plans of the computer industry, will continue to exhibit this type of exponential growth within the coming decade. For the available MM force fields this progress would imply that MD simulations spanning about 0.5 ms become feasible, because the current technology already allows series of MD simulations spanning 10 ns each for protein–solvent systems comprising 10^4–10^5 atoms. Therefore, the deficiencies of the current MM force fields are becoming increasingly apparent in unrestricted long-time simulations through changes of supposedly stable protein or peptide conformations. This experience will drive the efforts to construct better force fields, which must be more accurate by at least one order of magnitude, although such an improvement necessarily will imply a larger computational effort and, therefore, will impede the tractability of large proteins at extended time scales. Here, the accurate and computationally efficient inclusion of the electronic polarizability will be of key importance.

33.3.9
Continuum Solvent Models

The above discussion on the accessible time scales was based on the assumption that a microscopic model of the aqueous environment is employed to account for the important solvent–protein interactions. This approach represents the state of the art and, at the same time, an obstacle in accessing more extended time scales, because in the corresponding simulation systems 90% of the atoms must belong to the solvent (for an explanation see Section 33.2.2 and Mathias et al. [18]). Thus, one simulates mainly a liquid solvent slightly polluted by protein atoms, and most

of the computer time is spent on the calculation of the forces acting on the solvent molecules.

It is tempting to get rid of this enormous computational effort by applying so-called implicit solvent models. Here, one tries to replace the microscopic modeling of the solvent by mean field representations of its interactions with the solute protein, which are mainly the electrostatic free energy of solvation and the hydrophobic effect caused by the solvent. The hydrophobic effect is usually included by an energy term proportional to the surface of the solute. Much more complicated is the computation of the electrostatic free energy of solvation. Here one has to find solutions to the electrostatics problem of an irregularly shaped cavity filled with point charges (the solute) and embedded in a dielectric and possibly ionic continuum (the solvent). Standard numerical methods to solve the corresponding Poisson and Poisson-Boltzmann equations are much too expensive to be used in MD simulations and have many other drawbacks (see Egwolf and Tavan [31] for a discussion).

To circumvent the problem of actually having to solve a partial differential equation (PDE) at each MD time step, the so-called generalized Born methods (GB) have been suggested (for a review see Bashford and Case [51]). GB methods introduce screening functions that are supposed to describe the solvent-induced shielding of the electrostatic interactions within the solute and are empirically parameterized using sets of sample molecules. The required parameters then add to the combinatorial complexity of the force field parameterization.

The GB approximation enables the computation of impressive MD trajectories covering several hundred microseconds [52]. However, not surprisingly, the resulting free energy landscapes drastically differ from those obtained with explicit solvent [53, 54]. Thus, the GB methods apparently oversimplify the complicated electrostatics problem for the sake of computational efficiency and, therefore, fail in structure prediction.

A physically correct method to compute the free energy of solvation and, in particular, the forces on the solute atoms in implicit solvent MD simulations has recently been developed by Egwolf and Tavan [31, 55]. In this analytical ''one-parameter'' approach the reaction field arising from the polarization of the implicit solvent continuum is represented by Gaussian dipole densities localized at the atoms of the solute. These dipole densities are determined by a set of coupled equations, which can be solved numerically by a self-consistent iterative procedure. The required computational effort is comparable to that of introducing the electronic polarizability into MM force fields. This effort is by many orders of magnitude smaller than that of standard numerical methods for the solution of PDEs.

The resulting reaction field forces agree very well with those of explicit solvent simulations, and the solvation free energies match closely those obtained by the standard numerical methods [31]. However, this progress is only a first step towards MD simulations with implicit solvent. For its use in MD, one has to correct the violations of the reaction principle resulting from the reaction field forces. In addition, the surface term covering the hydrophobic forces has to be parameterized in order to match the free energy landscapes found in explicit solvent simulations.

33.3.10
Are there Further Problems beyond Electrostatics and Structure Prediction?

Up to this point, our analysis has been focused on the complex electrostatics in protein–solvent systems and the accuracy problems that are caused by the electrostatics in the construction and numerical solution of MM-MD models. In this discussion we have taken the task of protein structure prediction as our yardstick to judge the accuracy of the available force fields and computational techniques. If MD is supposed to provide a contribution to protein folding or to the related problem of structure-based drug design, this yardstick is certainly relevant. However, there are many more possible fields of application for MD simulation than just these two. Each of them has its own accuracy requirements pertaining to different parts of the force field, as has been illustrated by the various examples of restricted MD-based methods given in Section 33.2.7.

If MD is taken seriously as a method for generating a virtual reality of the conformational dynamics that enables, for instance, energy-driven processes of protein function, then additional aspects of the MM force fields become relevant. Because this conformational dynamics involves torsions around chemical bonds and requires evasive actions to circumvent steric hindrances in these strongly constrained macromolecules, the potential functions mapping the mechanical elasticity and flexibility must be adequately represented for correct descriptions of the kinetics. Here, these so-called ''bonded'' potential functions must be balanced with the van der Waals potentials of the various atoms and with the modeling of the electrostatics. To illustrate the delicate dependence of simulation descriptions on these details of the force field parameterization, we will now return to one of the examples mentioned in Section 33.2.7.

33.4
Conformational Dynamics of a Light-switchable Model Peptide

An important obstacle impeding the improvement of MM force fields is the lack of sufficiently specific and detailed experimental data on the conformational dynamics in proteins and peptides. Structural methods like X-ray or NMR render only information on the equilibrium fluctuations or on the equilibrium conformational ensemble, respectively. In X-ray, a structurally and temporally resolved monitoring of relaxation processes may become accessible through the Laue technique, but this approach is still in its infancy. On the other hand, time-resolved spectroscopic methods for the visible and infrared spectral regions are well-established and, with the recent development of two-dimensional correlation techniques [56], promising perspectives are opening up.

To become useful for the evaluation of MM force fields, these techniques must be applied to small peptide–solvent systems of strongly restricted complexity, because, otherwise, the multitude of the many weak interactions characteristic for large proteins in solution prevents the unique identification of force field deficien-

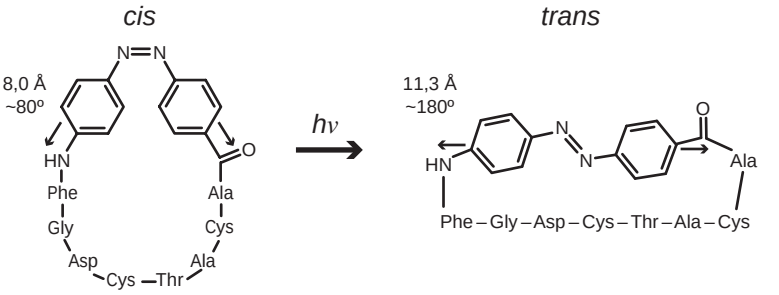

Fig. 33.7. Chemical structures of a small cyclic peptide (cAPB) and scheme of the light-induced photoisomerization, which changes the isomeric state of the azobenzene dye integrated into the backbone of the peptide from *cis* to *trans*. The isomerization widens the angle of the stiff linkage between the chromophore and the peptide from about 80° to 180° and elongates the chromophore by 3.3 Å. The strain exerted by the chromophore after photoisomerization forces the peptide to relax from an ensemble of helical and loop-like conformations into a stretched β-sheet (see Figure 33.9 for structural details).

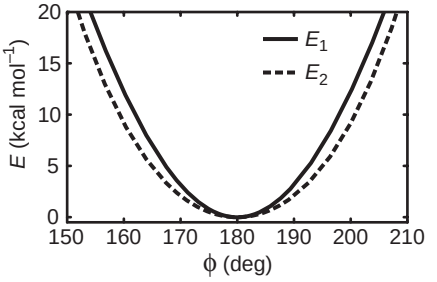
cies. Furthermore, the dynamical processes monitored spectroscopically should proceed rapidly on the time scale of at most nanoseconds, because this time scale is already accessible to MD simulations.

Adopting this view, Spörlein et al. [39] have recently presented an integrated approach towards the understanding of peptide conformational dynamics, in which femtosecond time-resolved spectroscopy on model peptides with built-in light switches has been combined with MD simulation of the light-triggered motions. It has been applied to monitor the light-induced relaxation dynamics occurring on subnanosecond time scales in a peptide that was backbone-cyclized with an azobenzene derivative as optical switch and spectroscopic probe.

Figure 33.7 depicts the chemical structure of this molecule (cAPB) and schematically indicates the changes of geometry that are induced by the photoisomerization of the azobenzene dye. The femtosecond spectra [39] allows us to clearly distinguish and characterize the subpicosecond photoisomerization of the chromophore, the subsequent dissipation of vibrational energy and the subnanosecond conformational relaxation of the peptide. It was interesting to see to what extent these processes can be described by MM-MD simulation.

33.4.1 Computational Methods

To enable the MD simulation of the photochemical *cis–trans* isomerization of the chromophore and of the resulting peptide relaxations, an MM model potential has been constructed (see Refs [39] and [57] for details), which drives the chromophore along an inversion coordinate at one of the central nitrogen atoms from *cis* to *trans* and, concomitantly, deposits the energy of 260 kJ mol^{-1}, which is equal to that of the absorbed photon, into the cAPB molecule. This approach serves to



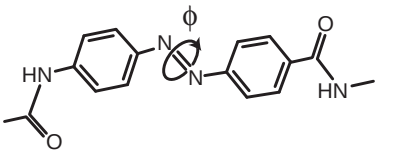


Fig. 33.8. Two different MM potentials obtained from fits to DFT potential curves for the torsion of the chromophore around the central N=N double bond by a dihedral angle Φ [57]. The stiff potential E_1 results from a fit of a cosine to the DFT potential curve in the vicinity of the *trans*-configuration ($\Phi = 180°$) and the softer potential E_2 from a fit of a Fourier expansion aiming at an improved description of the DFT potential curve in a wider range of torsion angles $\Phi \in [70°, 300°]$.

model the photoexcitation of the dye, its relaxation on the excited-state surface, and its ballistic crossing back to the potential energy surface of the electronic ground state through a conical intersection. To describe the subsequent dissipation of the absorbed energy into the solvent and the relaxation of the peptide from the initial *cis*-ensemble of conformations to the target *trans*-conformation, MM parameters for the chromophore, the peptide and the surrounding solvent were required.

Apart from a slight modification [57], the peptide parameters were adopted from the CHARMM22 force field [33]. Like in the experimental set-up, dimethyl-sulfoxid (DMSO) was used as the solvent. For this purpose an all-atom, fully flexible DMSO model was designed by DFT/MM techniques [9], was characterized by TBC/RF-MD simulations, and was compared with other MM models known in the literature [57]. Likewise, the MM parameters of the chromophore were determined by series of DFT calculations. Figure 33.8 illustrates the subtle differences that may result from such a procedure of MM parameter calculation, taking the stiffness of the central N=N bond with respect to torsions as a typical example. The stiffer potential E_1 has been employed in Spörlein et al. [39] and the consequences of choosing the slightly softer potential E_2 will be discussed further below.

A larger number of MD simulations, each spanning 1–10 ns (some even up to 40 ns), have been carried out to characterize the equilibrium conformational ensembles in the *cis* and *trans* states as well as the kinetics and pathways of their photo-induced conversion [57]. The simulation system was periodic, shaped as a rhombic dodecahedron (inner diameter of 54 Å), and was initially filled with 960 DMSO molecules. The best 10 NMR solutions [58] for the structure of the cAPB peptide were taken as starting structures for the simulations of the photoisomerization. They were placed into the simulation system, overlapping DMSO molecules were removed, and the solvent was allowed to adjust in a 100 ps MD simulation at 300 K to the presence of the rigid peptide. Then the geometry restraints initially imposed on the peptide were slowly removed during 50 ps, the system was equilibrated for another 100 ps at 300 K and 1 bar, it was heated to 500 K for

50 ps, and cooled within 200 ps to 300 K. In this way 10 different starting structures were obtained for the 1 ns simulations of the *cis–trans* isomerization, which was initiated by suddenly turning on the model potential driving the inversion reaction. To obtain estimates for the equilibrium conformational ensembles in the *cis* and *trans* states, 10 ns MD simulations were carried out at 500 K starting from the best NMR structures modified by the equilibration procedure outlined above. At this elevated temperature a large number of conformational transitions occur in the peptide during the simulated 10 ns. In all simulations the TBC/RF approach (cf. Section 33.2.2) was used with a dielectric constant of 45.8 modeling the DMSO continuum at large distances (for further details see Ref. [57]).

Due to the lack of space, the methods applied for the statistical analysis of the simulation data cannot be presented in detail here. Instead a few remarks must suffice: The 10 ns trajectories at 500 K have been analyzed by a new clustering tool, which is based on the computation of an analytical model of the configuration space density sampled by the simulation. The model is a Gaussian mixture [59], enables the construction of the free energy landscape and allows the identification of a hierarchy of conformational substates. The associated minima of the free energy are then characterized by prototypical conformations [57]. Concerning the characterization of the photo-induced relaxation dynamics, we will restrict our analysis to the temporal evolution of the total energy left in the cAPB molecule after photoisomerization and will omit structural aspects.

33.4.2 Results and Discussion

Figure 33.9 shows the prototypical conformations of *cis*- and *trans*-cAPB in DMSO at 500 K and 1 bar, which have been obtained from the 10 ns simulations by the procedures sketched in the preceding section. Whereas *cis*-cAPB exhibits a series

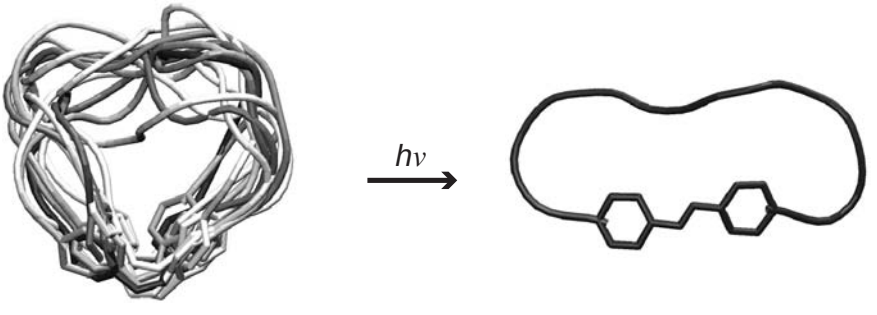

Fig. 33.9. Conformational ensembles in the *cis* and *trans* states of the cAPB peptide as obtained from 10 ns simulations at 500 K. Each backbone structure represents a different local minimum of the free energy landscape. The gray-scale indicates the depth of the respective minimum. Whereas there is only one such minimum in *trans*, there are many in *cis* (see Ref. [57] for details).

of different conformations, which are dynamically related by thermal flips around the dihedral angles at the Cα atoms of the backbone, there is only a single *trans*-cAPB conformer. Although the depicted conformers derive from high-temperature simulations, they are compatible [57] with the NOE-restraints observed by NMR [58]. This agreement may not be taken as a big surprise, because the conformational flexibility of peptide is sizably restricted by the strong covalent linkages within the cyclic structure. Apparently, in the given case these restrictions suffice to compensate those inaccuracies of the force field, which involve weaker dipolar interactions or the neglect of the electronic polarizability.

Figure 33.9 illustrates the process that is driven by the photoisomerization. The photons are absorbed by an ensemble of *cis*-conformers, and the geometry change of the chromophore forces the peptide backbone to relax through flips around the bonds at the Cα atoms towards the *trans*-conformation. In this conformation, the structure of the peptide is that of a β-sheet, up to turns at the covalent linkage with the chromophore. Therefore, the process may be considered as protein folding "en miniature."

As far as the photo-induced relaxation dynamics is concerned, Figure 33.10 illustrates a surprising and, as we will argue below, also somewhat frustrating result, reported previously in Ref. [39]. The kinetics of energy relaxation calculated by MD for the *cis–trans* photoisomerization of cAPB agrees nearly perfectly with that of a corresponding spectroscopic observable! As far as the match within the first picosecond is concerned, this agreement simply reflects the careful design of the MM model potential driving the ballistic photoisomerization and, therefore, is what one should expect, if the assumption of an inversion reaction is correct.

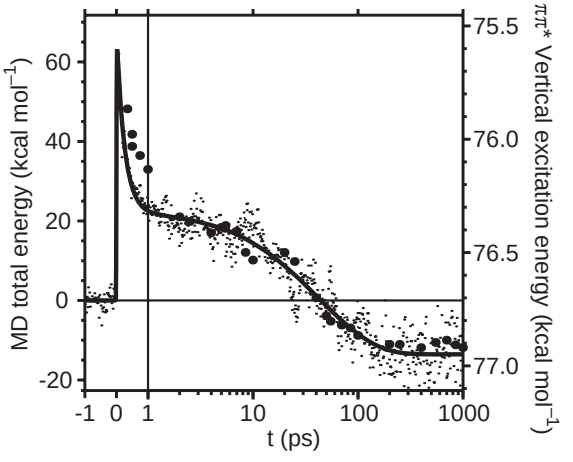

Fig. 33.10. Comparison of the energy relaxation kinetics following *cis–trans* isomerization as observed by femtosecond spectroscopy (black dots, monitoring the spectral position of the main absorption band) and as calculated by MD (black pixels and fit to the MD trajectories, monitoring the total energy of the cAPB molecule) on a linear-logarithmic time scale [39].

From a global fit of all spectroscopic data, covering a wide spectral range, four time constants have been obtained for the relaxation processes, and the analysis of the spectra has allowed to assign elementary processes to these kinetics [39]. Thus, according to spectroscopy, the ballistic isomerization proceeds within 230 fs, a second relaxation channel from the excited state surface to the electronic ground state (not included in the MM model by construction) takes 3 ps, the dissipation of heat from the chromophore into the solvent and the peptide chain proceeds within 15 ps, and a 50 ps kinetics is assigned to conformational transitions in the peptide. As shown in Ref. [60] further conformational transitions in the peptide occur above the time scale of 1 ns until the relaxation process is complete.

The limited statistics of the MD data shown in Figure 33.10 allows us to determine two time constants within the first nanosecond. These time constants are 280 fs for the isomerization of the chromophore and 45 ps for the conformational relaxation of the peptide form the *cis*-ensemble towards the *trans*-conformation. The corresponding two-exponential decay is depicted by the solid fit curve in Figure 33.10. Due to the proximity of the cooling kinetics (15 ps) to that of the conformational dynamics (50 ps) these processes cannot be distinguished in the MD data on cAPB. According to the simulations, after 1 ns the *trans*-conformation has not yet been reached in most trajectories. Thus, within the first nanosecond the relaxation kinetics of the simulated ensemble quantitatively agrees with the observations to the extent, to which the limited MD statistics allows the identification of kinetic constants.

Further above we have stated that this result has been somewhat frustrating for us. Representing the theory group that had been involved in the design of the model system and of its experimental characterization from the very beginning about a decade ago, we had hoped that our integrated approach [39] would provide hints as to how one has to improve the MD methods and MM force fields. This hope had been a key driving force in the original set-up of this interdisciplinary approach. Instead, the results have merely validated our MD methods, raising the question whether (i) the integrated approach is sensitive enough to the details of the MM force field or (ii) our skepticism with respect to the quality of MD descriptions is justified.

To check these questions we have conducted a series of simulations in which certain details of the applied MM force fields were changed one by one [57]. From the huge pile of results collected in this way we have selected a typical example which provides enough evidence to answer both questions. In this example we have changed a single model potential of the MM force field, that is, we have replaced the stiff torsion potential E_1 by the slightly weaker potential E_2 (see Figure 33.8 for plots of these function and Section 33.3.1 for further explanation). One can expect that this potential is important for transmitting the mechanical strain from the chromophore to the peptide after *cis–trans* isomerization. If it is stiff (E_1), then the strain is strong and the relaxation should be fast, and if it is weaker (E_2) the relaxation should become slowed down.

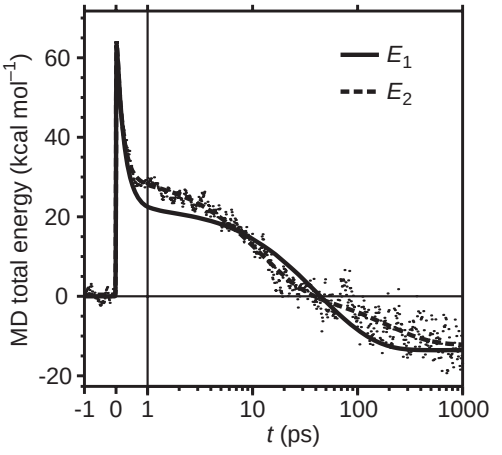

Fig. 33.11. Comparison of the energy relaxation kinetics calculated by MD for two slightly different force fields: The original model potential E_1 is replaced by E_2 (cf. Figure 33.8). The fit curve belonging to E_1 has been taken from Figure 33.10. The dashed fit curve to the 10 MD trajectories (pixels) calculated with E_2 exhibits three kinetic constants. Besides showing a 190 fs ballistic isomerization (exp: 230 fs), it separates an 11 ps heat dissipation (exp: 15 ps) from a 190 ps conformational relaxation (exp: 50 ps).

The above expectation is confirmed by the MD results for the softer potential E_2 shown in Figure 33.11 and by the kinetic data listed in the associated caption. In the case of E_2, the prolonged time scale (190 ps) of the conformational relaxation, which is caused by the slightly softer spring, has enabled us to additionally identify the kinetics of heat dissipation (11 ps) in the data. The results demonstrate that a small change of a single model potential can change the kinetic time constant calculated for the conformational relaxation from 45 ps to 190 ps, that is, by a factor of 4.

This example answers the two questions voiced above, because it provides evidence that (i) our integrated approach is sensitive enough to detect small changes in a force field and (ii) that our skepticism with respect to the quality of MM force fields is well-justified. The latter is apparent from the fact that both fit procedures for obtaining a torsion potential from DFT calculations, the one that has led to E_1, and the one yielding E_2, represent a priori valid choices. It was actually a matter of luck that we happened to choose the right one for the first few simulations published in Ref. [39]. As we now definitely know [57], only a series of further lucky choices in the force field used for our original simulations enabled the surprisingly perfect match. On the other hand, the perfect match obtained in our first attempt to describes the light-induced relaxation in the cAPB peptide also demonstrates that, in principle, MD simulations can give quantitative descriptions. In this sense it gives credit to the method and justifies further efforts aiming at the improvement of the force fields and the extension of time scales.

Summary

As of today, MM force fields are not yet accurate enough to enable a reliable prediction of protein and peptide structures by MD simulation. Here the key deficiency is the neglect of the electronic polarizability in the MM force fields. However, MM-MD is valid in restricted settings, for instance, when complemented by experimental constraints, when applied to systems of reduced complexity, or in the restricted context of QM/MM hybrid calculations. In particular, the development of the DFT/MM methods has generated key tools that are required for the improvement of the MM force fields, because they allow highly accurate computations of intramolecular force fields of molecules polarized by a condensed phase environment. The latter has been demonstrated by computations of IR spectra in condensed phase, whose accurate description critically depends on the quality of the computed force field. For the validation of future MM force fields more specific experimental characterizations of the materials are necessary. Thus, the improvement of the computational methods has to rely on close cooperation between scientists working in experimental and theoretical biophysics, chemistry, biochemistry, and beyond.

1
Paradigm Changes from "Unboiling an Egg" to "Synthesizing a Rabbit"

Rainer Jaenicke

1.1
Protein Structure, Stability, and Self-organization

Max Perutz, in reviewing Anson and Mirsky's discovery [1–3] that hemoglobin fully recovers its functional properties after reversible acid denaturation, felt that "making a protein alive again is as impossible as inventing the *perpetuum mobile*"; this was in 1940 [4]. As we know today from 75 years practice since his first experiments, Anson (Figure 1.1) was right, despite Kailin's protest that "boiling an egg does not denature its protein, it kills it!" [5]: proteins do have the capacity to spontaneously and autonomously organize their three-dimensional structure. At Anson's time this was a model, because the antivitalist creed that the composition of proteins is revealed by analytical chemistry and their behavior, by physical chemistry (which in the last analysis depends on their structure [6]) was no more than a guiding principle for chemists interested in biological material [7]. Svedberg had just published the determination of the molecular weight of the first protein, equine hemoglobin, making use of his newly developed analytical ultracentrifuge [8]. With this data, it became clear that proteins are monodisperse entities with well-defined molecular masses. To determine the detailed 3D structure of hemoglobin at atomic resolution still took more than a generation [9]. Thus, the first folding experiments were based on the assumption that an isolated homogeneous component of mammalian blood, obtained by fractional crystallization, not only had the intrinsic property of self-organization but also allowed one to quantify its physiological activity in vivo in terms of cooperative ligand binding, allostery, Bohr effect etc., following the reductionist's creed and methodology. With this paradigm in mind, the alchemy of protein folding addressed a wide range of fundamental biological problems, tacitly assuming that the results of in vitro studies are biologically relevant. As sometimes happens, a few results of this bold hypothesis turned out to be practicable in various ways, so that, in the long run, the scope switched from pure physical to biological chemistry. After a generation or two, research and development in biotechnology shifted the dimensions of in vitro folding experiments from microliter pipettes and Eppendorf vials to pipelines and 5–10-m^3 tanks, nowadays used in the production of pharmaceutically or technologically im-

Protein Folding Handbook. Part II. Edited by J. Buchner and T. Kiefhaber

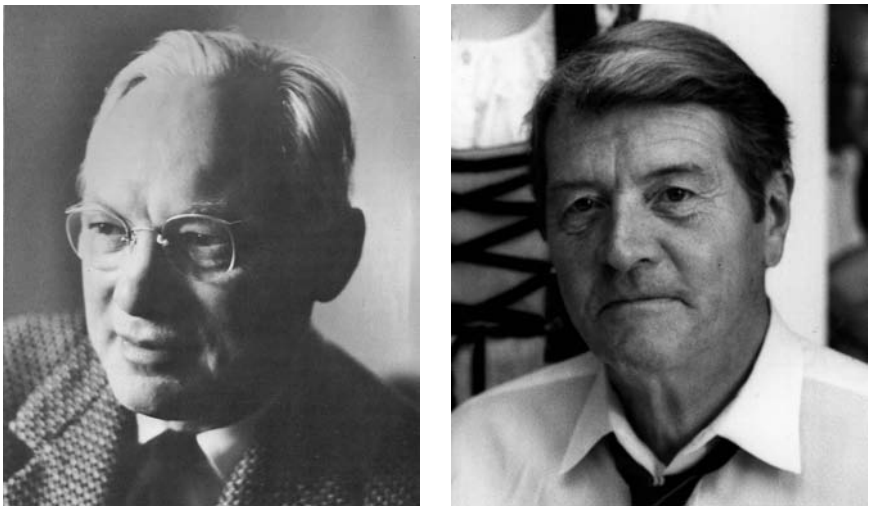

Fig. 1.1. Pioneers in the early days of protein folding: left, M. L. (''Tim'') Anson (1901–1968), right, Chris B. Anfinsen (1916–1995).

portant proteins. Frequently the final products are modified in one way or the other to alter their long-term stability, their specificity, or other properties.

In this context, Anfinsen's (Figure 1.1) classical experiments influenced the philosophy of his followers right from the beginning by the fact that he started from *reduced* ribonuclease A (RNaseA) rather than the natural enzyme with its cystine cross-bridges intact. In spite of the chemical modification, the reshuffling process led to the correctly cross-linked native state, thus proving that all the information required for folding and stabilizing the native three-dimensional conformation of proteins is encoded in their amino acid sequence [10]. Extending this conclusion to the entire structural hierarchy of proteins, it was postulated that the primary structure directs not only the formation of multiple noncovalent (''weak'') and covalent (''strong'') bonds within a single polypeptide chain but also the interactions between the subunits of oligomeric proteins, driving the sequential folding-association reaction and stabilizing the final tertiary and quaternary structure.

In distinguishing between weak and strong interactions, it is important to note that globular proteins in their natural aqueous environment show only marginal Gibbs free energies of stabilization. With numerical data on the order of 50 kJ mol^{-1}, they are the equivalent of a small number of hydrogen bonds or hydrophobic interactions, or perhaps just one or two ion pairs. This holds despite the fact that thousands of atoms may be involved in large numbers of attractive and repulsive interactions, in total adding up to molecular energies a million times larger than the above average value [11]. The reason for this apparent discrepancy is that proteins are *multifunctional*: they need to fold, they serve specific modes of action, and they provide amino acid pools in both catabolic and anabolic processes.

With this in mind, the point is that, given one single device, it is impossible to simultaneously *maximize* the efficiency of all these ''functions''; nature has to compromise, and since stability, biological activity, and turnover all require a certain degree of flexibility, stability (equivalent to rigidity) cannot win.

Recent advances in our understanding of the different types of weak interactions involved in the self-organization and stabilization of proteins were derived from theoretical studies on the one hand ([12–15], cf. R. L. Baldwin, Vol. I/1) and from the analysis of complete genomes of phylogenetically related mesophiles and (hyper-)thermophiles, as well as systematic mutant studies, on the other [16–18]. Apart from the latter ''quasi-Linnaean approach,'' protein engineering provides us with a wealth of alternatives to crosscheck the genomix results [19–23]; in combining and applying these approaches to technologically relevant systems, increases in thermal stability of up to 50 °C have been accomplished [24]. In contrast to such success stories, Kauzmann's catalog of weak intermolecular interactions [25] has not changed since 1959, and a 2004 ''balance sheet of ΔG_{stab} contributions to folding'' would be as tentative or postdictive as J. L. Finney and N. C. Pace's classical attempts to predict ΔG_{stab} for RNase and lysozyme in 1982 and 1996 [26, 27]. What has become clear in recent years is that increases in overall packing density, helicity, and proline content (i.e., destabilization of the unfolded state) and improved formation of networks of H-bonds and ion-pairs are important increments of protein stabilization. In the long-standing controversy regarding the prevalence of the various contributions, evidently all components are significant. In the case of hydrophobic interactions, entropic (water-release) *and* enthalpic (London-van der Waals) effects seem to be equally important [28, 29]. That hydrogen bonding and ion pairs are essential is now generally accepted [27, 30, 31]; surprisingly, recent evidence seems to indicate that polar-group burial also makes a positive contribution to the free energy of stabilization [32].

As has been mentioned, the balance of the attractive and repulsive forces yields only marginal free energies of stabilization. They may be affected by mutations or changes in the solvent, the latter often highly significant due to their effect on the unfolding *kinetics*. The reason is that by adding specific ions or other ligands, the free energy of activation ($\Delta G^{\neq}_{stab}$) of the N → U transition, i.e., the free-energy difference between the native and the transition states, may be drastically increased. The resulting ''kinetic stabilization'' has been shown to be essential for the extrinsic stabilization or longevity of the native state as well as for the folding competence of conjugated and ultrastable proteins [16, 33, 34].

From the thermodynamic point of view, protein folding is a hierarchical process, driven by the accumulation of increments of free energy from local interactions among neighboring residues, secondary structural elements, domains, and subunits (Scheme 1.1). Domains represent independent folding units. Correspondingly, the folding kinetics divide into the collapse of subdomains and domains and their merging to form the compact tertiary fold. Establishing the particular steps allows the folding pathway for a given protein to be elucidated. In proceeding to oligomeric proteins, docking of structured monomers is the final step. In agreement with this mechanism, in vitro experiments have shown that the overall fold-

Structural levels: primary → secondary/supersecondary → tertiary → quaternary structure
Interactions: short-range and long-range (= short-range through-chain and through-space) [11, 12, 42]
Folding pathway: next-neighbor interactions → collapsed unfolded state and/or molten globule state [43, 44] → docking of domains [45, 46] → assembly [47, 48]
Intermediates: kernels/molten globule → folded/unfolded subdomains and domains → native-like structured monomers → stepwise assembly, e.g., nM → n/2 M_2 → n/4 M_4 for a tetramer
Off-pathway reactions: misfolding, domain swapping, misassembly, aggregation [34, 36–40]

Scheme 1.1. Hierarchy of protein folding and association

ing and association reaction can be quantified by a consecutive uni-bimolecular kinetic scheme. In a first folding step, the subunits need to expose specific interfaces to recognize the correct partners; then, after complementary docking sites have been formed, association to well-defined oligomers can occur in a concentration-dependent fashion. Their affinity depends on the same types of weak interactions that participate in the stabilization of the monomeric entities. No wonder that intra- and intermolecular interactions can replace each other, causing misassembly and subsequent aggregation rather than proper quaternary structure formation. At high subunit concentrations, when folding becomes rate-limiting and association becomes diffusion-controlled, aggregation is expected to become predominant. In fact, early refolding studies (focusing on the structure-function relationship of oligomeric proteins) proved that reactivation yielded optimum curves, confirming the consecutive mechanism with aggregation as a competing side reaction [35–37] (Figure 1.2). Later, when "inclusion bodies" were identified as typical byproducts of protein overexpression in vivo, it became clear that the sequential folding/association mechanism (including the kinetic partitioning between the two processes) also holds for the nascent protein when it leaves the ribosome. It took 10 more years to fully appreciate that evolution took care of the problem by providing folding catalysts and heat shock proteins as chaperones [41]. Evidently, they shift the kinetic partitioning between assembly and aggregation toward the native state. So far, the detailed co-translational and post-translational processes *in the cell* have withstood a sound kinetic and structural analysis.

1.2 Autonomous and Assisted Folding and Association

The contributions to the present volume deal with the above side reactions in the self-organization of proteins as well as the helper proteins involved in either avoidance of misfolding or the catalysis of rate-determining steps along the folding pathway. Reading the seminal papers, and having in mind the procedures that were applied in early protein denaturation-renaturation experiments, it becomes clear that the pioneers in the field were aware of the possible role of accessory components long before they were discovered: *templates* assisting the nascent polypeptide chain

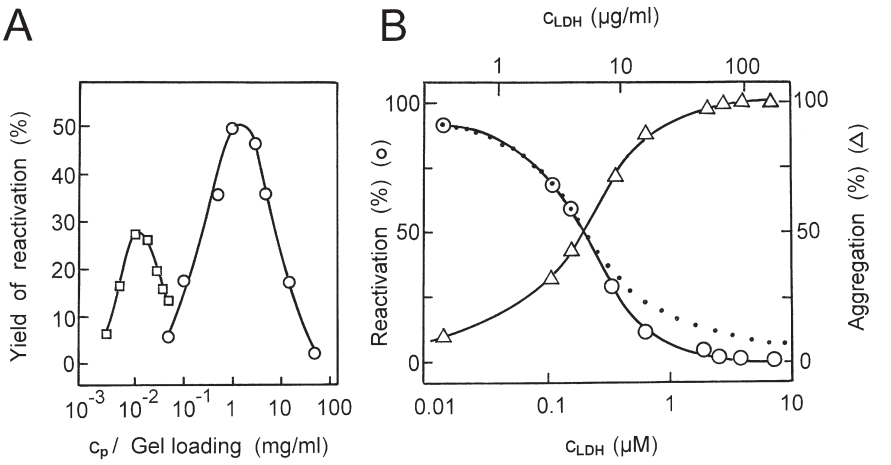

Fig. 1.2. Kinetic competition between folding and aggregation. (A) Effect of protein concentration on the renaturation of α-glucosidase after urea denaturation, illustrating the partitioning between "renativation" and aggregation. Denaturation in 8 M urea, 10 mM K-phosphate pH 7.7, 1 h incubation at 20 °C; reactivation in 10 mM Na-phosphate pH 7.6, 10 °C, 30 mM NaCl, and 8% ethylene glycol, measured after ≥24 h renaturation. (□) refers to wild-type α-glucosidase and (○) to the fusion protein containing a C-terminal hexa-arginine tail, which allows the stabilization of the enzyme on heparin-Sepharose. The yield of reactivation is expressed as a percentage of the activity of the corresponding native enzyme (data from Ref. [38]). (B) With increasing protein concentration, the yield of reactivation of lactate dehydrogenase after acid denaturation in 0.1 M H_3PO_4, pH 2, and subsequent renaturation in phosphate buffer pH 7.0 decreases (○) and aggregation increases (△) in a complementary way [37]. As indicated by the dotted line, to a first approximation, the kinetic competition can be modeled by Eq. (5), i.e., by sequential unimolecular folding ($k_1 = 0.01\ s^{-1}$) and (diffusion-controlled) bimolecular aggregation ($k_2 = 10^5\ M^{-1}\ s^{-1}$), with molar concentrations based on a subunit molecular mass of 35 kDa [39].

on its pathway toward the native conformation, or *shuffling enzymes* and *foldases* as catalysts were postulated or even isolated early in the game [49, 50]. However, they were ignored for the simple reason that there seemed to be no real need for helpers, because the spontaneous reaction was autonomous and fast enough to proceed without accessory components. It took more than two decades to change the paradigm from Cohn and Edsall's purely physicochemical approach [7] to considerations comparing optimal in vitro conditions with the situation in the cell [51, 52]. That catalysts or chaperones might be biologically significant was suggested by three observations (Figure 1.3). First, experiments with mouse microsomes depleted of Anfinsen's "shuffling enzyme" proved *protein disulfide isomerase* (PDI) to be essential for protein folding in the endoplasmic reticulum (ER) [55]. Second, the unexpected bimodal N ↔ I ↔ U kinetics of the two-state N ↔ U equilibrium transition of ribonuclease (RNaseA) and its physicochemical characteristics suggested proline isomerization to be involved in protein folding [56, 57]; in fact, the enzyme *peptidyl-prolyl cis-trans isomerase* (PPI) was found to catalyze rate-limiting steps on the folding pathway of proteins [58–60]. Third, increasing numbers of

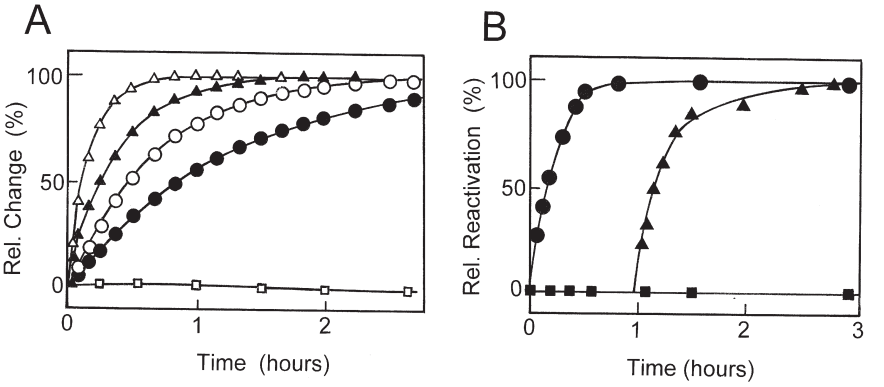

Fig. 1.3. Folding catalysts and chaperones. (A) Acceleration of the oxidative refolding of ribonuclease T1 by PPI and PDI, monitored by tryptophan fluorescence at 320 nm: 2.5 μM RNaseT1 in 0.1 M Tris-HCl pH 7.8, 0.2 M guanidinium chloride, 4 mM reduced/0.4 mM oxidized glutathione, 25 °C. Re-oxidation in the absence of PPI and PDI (●), in the presence of 1.4 μM PPI (○), in the presence of 1.6 μM PDI (▲), in the presence of 1.4 μM PPI plus 1.6 μM PDI (△), and in the presence of 10 mM dithioerythritol (to block disulfide bond formation) (□); the slight decrease in the latter signal is caused by aggregation of the reduced and unfolded protein. Curves calculated for single first-order reactions with time constants $\tau = 4300$ s (●), 2270 s (○), 1500 s (▲), and 650 s (△) [53]. (B) Reactivation of citrate synthase (CS) after preceding denaturation in 6 M guanidinium chloride in the presence of GroEL without GroES and ATP (■), with GroES and ATP (●), and with GroES and ATP added after 55 min (▲). Parallel light-scattering measurements show that in the absence of the components of the GroE system, CS forms inactive aggregates [54].

stress-response proteins (Hsps) were found to be ubiquitous and by no means restricted to heat stress; evidently, they played a role as *molecular chaperones*, i.e., they mediated or promoted correct protein folding by transiently interacting with the nascent polypeptide or with the protein at an early stage of the folding process, without becoming components of its final functional state [61] (see the respective chapters 4, 5, 14–16, 20–24, 31, 32). Evidently, this definition also holds for helper or scaffold proteins that are known to aid the genetically determined *morphopoiesis* of complex assembly systems such as phage [34].

The given examples stand for the end of an era that might be called the heroic age of protein chemistry, with names such as M. Calvin, E. J. Cohn, J. T. Edsall, G. Embden, H. A. Krebs, K. U. Linderstrøm-Lang, F. Lipmann, F. Lynen, O. Meyerhoff, A. Szent-Györgyi, H. Theorell, and O. Warburg, to mention just a few. They developed the methodology to purify proteins by fractionation and to systematically search for their respective biological activities. In proceeding from the inventory of the relevant molecules and the elucidation of their structures, they identified the molecular partners, measuring the rate and equilibrium constants for each reaction. As the next steps, the molecules were localized in the various compartments of live cells, physiological tests for the participation in specific cellular processes

were developed, and mathematical models for understanding the system's behavior were formulated. Crowning the reductionist approach, the data were finally put together, ending up with the sequences and cycles of reactions that constitute the awesome networks of metabolic pathways and information transfer, including their regulation and energetics.

Faced with these Herculean efforts on the one hand, and the pressure in present-day paper production on the other, we reach the latest paradigm change: from the reductionist detail to the simplistic concept that by replacing the atomic complexity of molecules with the information pool encoded in genomes, proteomes and their corollaries at the metabolic, regulatory, and developmental levels might help to solve the riddle of life just by simplifying proteins and their interactions to spheres, squares, triangles, and arrows (as symbols for interactions).[1]

In the minds of some of the above "heroes," this change started long before the *-omix* age: in 1948, at the end of his lectures on *The Nature of Life*, the alternative to mere speculation or getting your hands dirty with experiments led Albert Szent-Györgyi to ironically promise his audience that next time he would pull a synthetic rabbit out of his pocket [64].

In the present context of protein folding vs. protein misfolding, it seems appropriate to start with a critical discussion of the physicochemical principles of self-organization, with special emphasis on the kinetic competition of folding and aggregation that led nature to evolve folding catalysts and chaperones. Combining the structural hierarchy of proteins with the processes involved in folding and association (cf. Scheme 1.1), it has been shown that commonly small (single-domain) proteins can fold without helpers, in many cases undergoing fully reversible equilibrium transitions without significant amounts of intermediates. In contrast, large (multi-domain) proteins and subunit assemblies, owing to the above-mentioned kinetic competition of intra- and intermolecular interactions in the processes of folding and association, require careful optimization to reach high yields; at high protein levels and in the absence of accessory proteins, off-pathway reactions take over (cf. Figure 1.2B) [46–48, 61].

To the uninitiated, the above hierarchical scheme might suggest that the self-organization of proteins necessarily occurs along a compulsory pathway with well-separated consecutive steps, in contrast to the alternative random-search hypothesis, which favors the idea that a jigsaw puzzle might be a more appropriate way to model protein folding [65]. When inspecting available kinetic data, it becomes clear that there is a wide variance of mechanisms that suggest "energy landscapes" rather than simple two-dimensional energy profiles as adequate pictographs to illustrate folding paths [13, 66–68] (Figure 1.4). Relevant experimental facts include

1 For a critical discussion of the dominating role of the "pictorial molecular paradigm" in the biosciences and its philosophical implications, including the question as to whether chemical formulae and graphical representations of biopolymers such as proteins are objective representations of reality, see Refs. [62, 63].

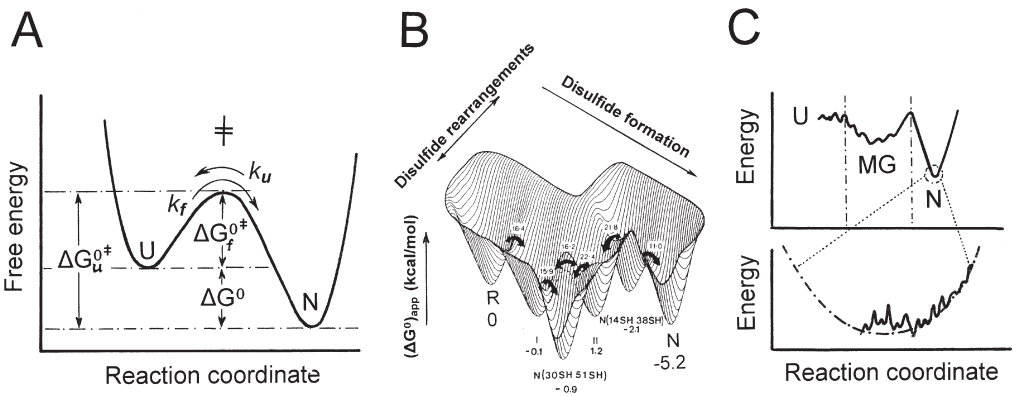

Fig. 1.4. Free-energy profiles and energy landscapes for protein folding and unfolding. (A) Relationships between the free energies of activation for folding ($\Delta G^{0\ddagger}{}_f$), and unfolding ($\Delta G^{0\ddagger}{}_u$) and of the equilibrium free energy (ΔG^0), using conventional transition-state theory. (B) "Energy-landscape" presentation describing the oxidative in vitro folding pathway of basic pancreatic trypsin inhibitor (BPTI) according to Creighton [68, 69]. The apparent free energies (in kcal mol^{-1}) are given for the fully reduced (R), intermediate (I and II), and folded (N) forms of the protein and for the transition states of the *SH* → *SS* reshuffling reaction. The reaction coordinate is represented by the three-dimensional downhill sequence of arrows. The species *I* and *II* include the one- and two-disulfide intermediates; $N_{(14SH,38SH)}$ and $N_{(30SH\text{-}51SH)}$ are native-like intermediates [34]. (C) Hypothetical conformational energy plot illustrating local energy minima and barriers along a possible protein-folding pathway. The lower "rugged potential" depicts the vicinity of the native state [13].

the following. (1) Folding as a cooperative process rarely allows true intermediates to be accumulated to a level suitable for a detailed characterization; this finding does not exclude ordered pathways but just requires a proper choice of conditions to optimize the population of intermediates. (2) For methodological reasons, the analysis of next-neighbor interactions in the folding process is prone to "in vitro artifacts," because anomalous intermediates may be populated (see the classical studies devoted to the folding pathway of basic pancreatic trypsin inhibitor [69] and to the early events in the flash-induced folding of cytochrome *c* [70, 71]). (3) For lysozyme, it has been shown that folding in fact follows multiple pathways [72]. (4) Finally, in the case of bacterial luciferase, it appears that the kinetic competition of folding and association of the $\alpha\beta$-heterodimer constitute a trap on the folding path that guides the individual subunits to the energy minimum of the active dimer [73]. Taken together, these and other examples seem to indicate that individual proteins show individual folding characteristics, an observation that also holds for the stability and stabilization of proteins. Evidently, any generalization in the world of proteins has its limitations, so that firm statements regarding "the in vitro/in vivo issue" or the wealth of expressions for "different types of molten globules" or the distinction between "short-range and long-range intermolecular forces" should either be ignored or at least taken with a grain of salt.

1.3
Native, Intermediate, and Denatured States

Before entering today's jungle of protein folding, with its roots deep in the solid ground of topology, thermodynamics, molecular dynamics, and kinetics from the microsecond to the minutes, hours, or days time range [74] (cf. Vol. I) and its youngest branches in present-day mainstream biotechnology and molecular medicine, it seems appropriate to briefly remind the reader what the starting points look like and what kind of problems motivated the aborigines to settle in the woods before the age of genomics, protein design, and folding diseases. The challenging questions were as follows. Is there a correlation between the 1D information at the level of the gene and the 3D structure of the correspondding protein? What does denaturation of proteins mean? What do the native and denatured states imply with respect to the folding mechanism of proteins? What are the best denaturation-renaturation conditions with minimal side reactions, and which criteria are best suited to characterize the authentic (native) state? What are the limits of in vitro protein folding and reconstitution, with respect to size, compartmentation, and structural complexity? Here are just a few short answers that might help in setting the frame for the crucial questions concerning the ''folding pathology'' in vitro and in vivo.

Owing to the large size of protein molecules and the unresolved problem of how to summarize the weak attractive and repulsive interatomic forces in a unique potential function, theorists have been unsuccessful in the a priori solution of the protein-folding code that would allow one to translate amino acid sequences into their corresponding three-dimensional structures. Considering the present-day output of solved X-ray and NMR structures *per anno* and the promise of developing high-throughput techniques, ''cracking the protein folding code'' has evidently lost its former challenging priority. The reason for this is simply that in order to understand the physical and functional properties of a protein at the atomic level or to acquire insight into the mechanistic details of enzyme catalysis, a resolution of <2 Å is required. This level of accuracy cannot be accomplished by any predictive approach [75].

The question of whether the physical state of a protein obtained either from the crystalline state or at high protein concentration in dilute buffer is related to or indistinguishable from its functional state in vivo has been extensively discussed since Kendrew, Perutz, and Phillips came up with their first 3D structures. Hardly any scientific result has ever been challenged to this extent; the final answer has been fundamentally positive [76], with one important limitation. Owing to their marginal stability in solution, any protein undergoes steady $N \leftrightarrow U$ transitions between the native and unfolded states. Under physiological conditions, the less-structured state is unstable and the protein reassumes its native configuration. Thus, proteins in their native functional state are dynamic systems exhibiting a high degree of local flexibility; ligand binding, allosteric transitions, and catalytic mechanisms depend on the interconversion of multiple states. The detailed quantitative understanding must necessarily take into account the structures of these

alternative states and the energetics of their interconversion. The structural fluctuations are on the order of 2 Å on a picosecond timescale. In the case of myoglobin, they allow the funneling of O_2 to the heme group in terms of "functionally important motions" [77, 78]. Whether structural heterogeneity is determined by thermal fluctuations or represents well-populated conformational substates (defined by high activation barriers beyond the thermal energy) is still under debate (Figure 1.4C). Attempts to characterize the physical and chemical properties of single molecules seem to support the second alternative [79, 80].

The term protein denaturation is essentially vague, because proteins do not unfold to a simple reference state [47, 81]. Instead, various modes of denaturation lead to different denatured states, each of them consisting of an astronomically large ensemble of different conformations but closely similar energy. Their common denominator is that they are solvated to a higher extent than the native state. Considering the amount of hydrophobic residues present in most soluble proteins, water is a poor solvent. Structure formation in the cytosol or in aqueous buffers is driven by this very fact. Making use of heteropolymers with approximately equal amounts of polar and nonpolar residues, nature allows solvation to balance by exposing hydrophilic groups to the aqueous solvent, while at the same time minimizing the hydrophobic surface. Solubilization of the inner core by denaturants leads to unfolding; however, it is obvious from the above balance of hydrophobic and hydrophilic amino acids that complete solvation cannot be accomplished. For this reason it is doubtful whether a polypeptide chain will ever be "fully randomized." Evidence from Tanford's observation that the intrinsic viscosity of denatured proteins obeyed Einstein's equation for spherical particles was weak from the beginning [82]. Even for the nascent protein in the process of translation, the conformational space is expected to be limited, because of the space-filling properties of the nascent polypeptide and its side chains, which do not allow all φ/ψ angles in the Ramachandran plot to be occupied [83]. From the practical point of view, it is important to keep in mind that the extent of unfolding of globular proteins depends not only on the denaturant but also on the physical conditions of the solvent. For the chaotrope, concentration and environmental parameters such as pH and temperature are trivial; however, specific stabilizing ligands or kinetic barriers may be essential as well [34, 84–86]. When analyzing the mechanisms of evolutionary adaptation to the wide variety of extreme physical conditions in nature, it becomes clear that extremophiles took advantage of the specific differences in protein stability [16, 33].

The fact that U is conformationally heterogeneous gives rise to multiple folding reactions in going from the unfolded to the native state. Partially folded intermediates (I) are to be expected as transients in the individual folding reactions. To find out whether intermediates are populated and what their physical properties are, it is mandatory to use different probes to follow folding and to vary the conditions for comparison. The above-mentioned bimodal $N \leftrightarrow I \leftrightarrow U$ folding kinetics of RNaseA [57–60] exemplified a well-established three-state system, with populated *cis-trans* proline isomers as structural intermediates; Figure 1.5 shows stopped-flow NMR spectra of dihydrofolate reductase from *E. coli* to illustrate the structural de-

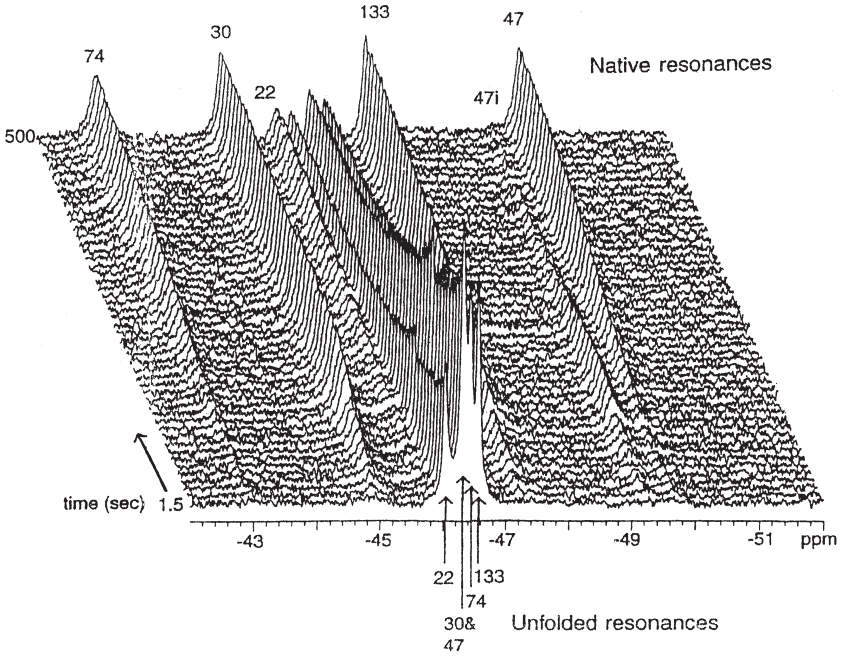

Fig. 1.5. Protein-folding kinetics studied by NMR spectroscopy. Stopped-flow ^{19}F NMR of the refolding of 6-^{19}F-tryptophan-labeled dihydrofolate reductase following dilution from 5.5 M to 2.75 M urea at 5 °C in the presence of 4 mM $NADP^+$. Each spectrum represents the sum of 41 separate rapid dilution experiments. The kinetics and chemical shifts suggest the formation of an intermediate that is unable to bind NAD^+ strongly, having a native-like side chain environment in the regions around Trp 30, 47, and 133 and little if any native side chain environment around Trp 22 and 74. The resonance labeled 47i is that of Trp47 in the intermediate [87].

tail and the time resolution for a specific system [87]. For further details, see Refs. [88, 89].

1.4 Folding and Merging of Domains – Association of Subunits

Domains as compact substructures within protein molecules show the typical characteristics of small globular proteins. There have been many definitions using either the visual inspection of crystal structures or surface area calculations, topological distance considerations, sequence homology at the protein level, or the intron-exon organization at the level of the gene. Among all these definitions [90], the one that is most relevant in connection with the folding and assembly of large proteins refers to the observation that domain proteins "fold by parts," i.e., their constituent parts fold and unfold independently as individual entities in a stepwise fashion [91] (Figure 1.6). This holds not only in vitro but also in the cell, where the

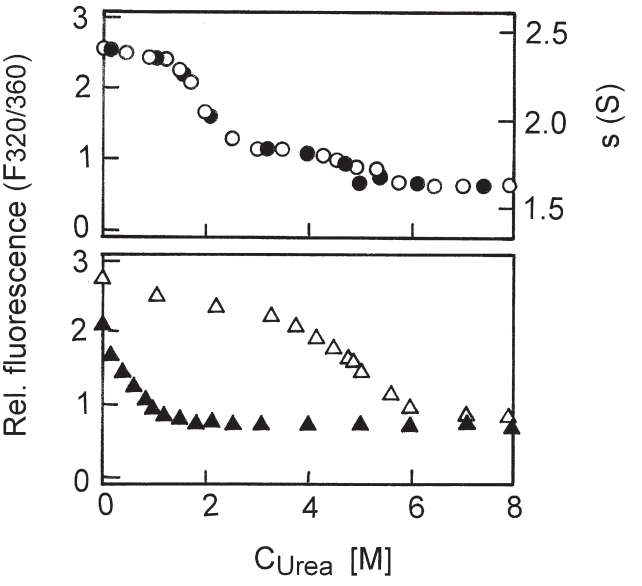

Fig. 1.6. "Folding-by-parts" of γB-crystallin, a prototype two-domain protein. Urea-dependent denaturation-renaturation of γB in 0.1 M NaCl/HCl, pH 2, 20 °C, monitored by intrinsic fluorescence (○) and sedimentation analysis (●). Upper frame: Denaturation equilibrium transition of the natural two-domain protein. Lower frame: Denaturation profiles of the recombinant isolated N-terminal (△) and C-terminal (▲) domains. The difference in ΔG^0_{stab} originates from the difference in net charge z between the two domains: at pH 2, z for the N- and C-terminal domains amounts to 13 and 16, respectively. Approaching the isoelectric point, the difference vanishes [90, 91].

sequential formation of cystine bridges within the single domains of antibody chains has been shown to occur as a co-translational process [51]. Oligomeric proteins share essential properties with domain proteins: in both cases, evolution allowed proteins to acquire the capacity (1) to create new functions by the cooperation of two or more entities, e.g., by forming shared active centers or by allowing allosteric regulation; (2) to become multifunctional, as in the case of multi-enzyme complexes; (3) to improve the intrinsic stability by increasing the state of association [16, 92]; and (4) to enhance the rate of self-organization by synchronous folding and association of medium-sized subunits instead of covalently linked giant proteins. At this point, considering the in vivo situation, the rate enhancement by synchronous nucleation at multiple sites protects the nascent polypeptide chain from proteases; additional advantages are the elimination of misfolded chains from the assembly process on the one hand and the swapping of domains on the other [34, 46].[2]

2 Keeping in mind that many "typical domain proteins" have non-contiguous domains, such evolutionary "advantages" have to be taken with a grain of salt.

Evidently, for some large substrates, domains are the only way to tackle the problem of binding, activating, and releasing the substrate. The classical example to illustrate this combinatorial playground of evolution is the NAD-dependent dehydrogenases, with the Rossmann fold as coenzyme-binding domain and the wide variety of different substrate-binding domains determining the redox specificity of the various enzymes [93]. The key to our understanding of multi-domain proteins is multifunctionality as the common denominator of regulated networks such as the basal membrane, the blood-clotting system, and the non-ribosomal synthesis of peptide and polyketide antibiotics [90]. It is obvious that evolution has gained an enormous combinatorial potential by domain shuffling.

Regarding their folding and association mechanism, multi-domain and multi-subunit systems have been modeled as the sum of their constituent parts plus contributions attributable to their mutual interactions. This approach sounds trivial and easily accomplishable, but it is not, for the simple reason that both folding and assembly may involve multiple-intermediate species differing in either their local conformation or their state of association. Thus, in most cases the two-state model does not hold. Only under "strongly native conditions," i.e., far away from the denaturation transition, can the denaturation-renaturation reaction be approximated by the two-state equation,

$$N \Leftrightarrow U \tag{1}$$

leaving first-order folding as the only significant process. For modular proteins, this may be attributed to the last folding step connected with the docking of the domains; for multimeric proteins, it represents the formation of the "structured monomers" with the correct complementary interfaces required for the specific recognition of subunits. In proceeding from structured monomers to the native quaternary structure, *subunit association* represents a bimolecular reaction that adds concentration-dependent steps to the first-order folding processes. If biological function (as the criterion of the native state) requires the cooperation of domains, domain pairing is expected to be essential in acquiring catalytic activity. Taking NAD-dependent monomeric octopine dehydrogenase as an example, it has been shown that at high solvent viscosity, *domain pairing* becomes rate-limiting; as one would predict from the Stokes-Einstein model of rotational and translational diffusion of rigid bodies, at high viscosity (in the presence of glycerol, sucrose, or polyethylene glycol) reactivation of the enzyme after preceding denaturation is slowed down [34, 89, 90, 94]. Thus, the overall folding kinetics for a two-domain protein may be determined by the folding and pairing of the domains according to,

$$U \xrightarrow{k_{D1}} I \xrightarrow{k_{D2}} N' \xrightarrow{k_{pairing}} N \tag{2}$$

with k_{D1}, k_{D2}, and $k_{pairing}$ as rate constants for the folding of the individual domains and their pairing. In cases in which proline isomerization or other slow reactions participate in the overall mechanism, these steps will lead to kinetic schemes of even higher complexity [94].

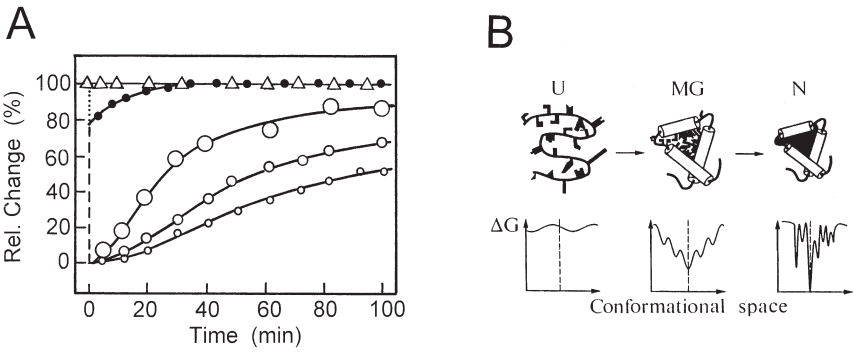

Fig. 1.7. Hierarchical folding of proteins as a multi-step reaction involving the collapse of the unstructured polypeptide and subsequent shuffling (and eventual assembly) of a "molten globule" intermediate. (A) Folding-association pathway of invertase from *Saccharomyces cerevisiae*: changes in circular dichroism (△), fluorescence (●), and enzymatic activity (open circles) allow us to monitor the sequential formation of (1) α-helices, (2) the correct environment of aromatic side chains, and (3) the correct, "native" tertiary (and quaternary) structure. In the case of yeast invertase, catalytic activity requires the dimeric quaternary structure; thus, reactivation is concentration-dependent: ◯, ○, and ○ refer to decreasing subunit concentrations (68, 17, and 8.5 nM) during reactivation. The co-translational glycosylation of the enzyme does not affect the folding/association mechanism [48, 95]. (B) Two-step model for sequential protein folding. The hypothetical structures of a protein in the unfolded (U), molten globule (MG), and native states (N) are shown with the free-energy landscapes at different stages of structure formation [96].

If intermediates on the folding pathway still expose significant hydrophobic surface area, interchain and intrachain interactions may compete, leading to either association (quaternary structure formation) or irregular aggregation. Since association requires complementary surfaces in the periphery of the subunits, folding and association must be consecutive reactions obeying a uni-bimolecular kinetic scheme [34]. In oligomeric systems, the steps preceding subunit assembly are the same as in domain proteins. The overall mechanism consists again of three stages (Figure 1.7): (1) the formation of elements of secondary and super-secondary structure, (2) their collapse to subdomains and domains, ending up with "structured monomers," and (3) association to form the correct stoichiometry and geometry of the native quaternary structure (cf. Scheme 1.1). Evidently, the collision complex of the structured monomers may still undergo intramolecular rearrangements before reaching the state of maximum packing density and minimum hydrophobic surface area; on the other hand, it may be trapped in side reactions of misfolding and/or misassembly, resulting in aggregates or inclusion bodies [47]. Thus, the uni-bimolecular folding-association mechanism may involve further rate-limiting, first-order steps belonging to slow shuffling processes at the level of the native-like assembly or higher-order reactions, attributable to the kinetic competition between correct reconstitution and misassembly. The latter has been observed (and neglected) from the very beginning of protein chemistry. It was considered an irk-

some, unavoidable annoyance that you just had to live with. When I started my own projects in physical biochemistry 40 years ago, my primary interests were the intermolecular forces involved in heat aggregation and the question of how protein denaturation and aggregation are correlated [97]. In asking these basic questions, I was in good company [98, 99]; however, in contrast to protein aggregates, the *interpretation of protein denaturation* and the question *which factors are responsible for protein stability* have turned out to be insoluble to this day. The formal kinetic treatment is obvious: in the simplest case of a dimer, the overall sequential reaction obeys either uni-bi-molecular or uni-bi-uni-molecular kinetics according to:

$$2\ M_u \xrightarrow{k_1} 2\ M_i \xrightarrow{k_2} N \quad \text{or} \quad 2\ M_u \xrightarrow{k_1} 2\ M_i \xrightarrow{k_2} (M_i)_2 \xrightarrow{k_1'} N \tag{3}$$

In the case of aggregation competing with reconstitution, ''kinetic partitioning'' between the sequential folding-association reaction and (higher than second-order) misassembly will occur (see section 1.5):

$$\begin{array}{ccccccc} (m+n+2)M_u & \xrightarrow{k_1} & (n+2)M_i & \xrightarrow{k_1'} & 2M' & \xrightarrow{k_2} & M'_2 \xrightarrow{k_1''} N \\ \downarrow{\scriptstyle k_{>2}} & & \downarrow{\scriptstyle k_{>2}} & & & & \\ (M_u)_m & & (M_i)_n & & & & \end{array} \tag{4}$$

In Eqs. (3) and (4), k_1 and $k_2, k_{>2}$ are first- and second or higher-order rate constants; M_u, M_i, and M' are the monomers in the unfolded, intermediate, and ''structured'' states, respectively, and N is the native dimer. Higher oligomers have been shown to obey the same kinetic scheme because commonly there is only one rate-limiting assembly step in going from the structured monomer to the native oligomer (Figure 1.8).

An enormous repertoire of methods has been devised to analyze the single steps along the paths of folding, association, and aggregation. By applying intrinsic and extrinsic spectral characteristics, flash photolysis, H-D exchange, chemical cross-linking, light-scattering and other kinetic techniques, sequential folding steps have been resolved on the timescale down to microseconds and below. In all these approaches, possible artifacts due to the interference of intra- and intermolecular interactions have to be carefully excluded. Considering these precautions, different methods have been shown to be in excellent agreement, corroborating the above sequential folding-association mechanisms. In the case of combined folding-association reactions, obviously, the alternative of which of the consecutive or competing reactions is rate-limiting depends not only on protein concentration but also on the specific properties of the system. For example, in the case of tetrameric lactate dehydrogenase, the reactivation kinetics after acid denaturation and maximum randomization in 6 M guanidinium chloride differ drastically: acid denaturation starts from a partially active ''structured monomer,'' leaving the association reaction as the rate-determining step, whereas reactivation from the inactive unfolded polypeptide chain follows the sequential uni-bimolecular folding-association mechanism [34, 101]. As expected from the above ''kinetic partitioning'' between proper

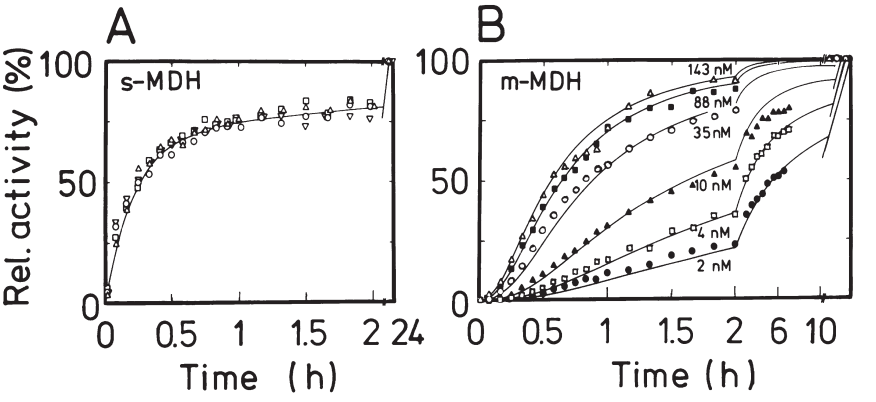

Fig. 1.8. Alternative mechanisms of the sequential folding and association of a dimeric protein: a case study on cytoplasmic (s-MDH) and mitochondrial malate dehydrogenase (m-MDH). (A) Reconstitution kinetics of s-MDH in 0.2 M phosphate buffer pH 7.6 after denaturation in 6 M guanidinium chloride in the concentration range between 1 and 13 μg mL^{-1}. The process is governed by rate-determining folding, yielding structured monomers that (in a subsequent diffusion-controlled step) form the active dimer [34]. (B) Reconstitution kinetics of m-MDH after denaturation in 1 M glycine/H_3PO_4, pH 2.3; renaturation as in (A), at 0.07 (●), 0.14 (□), 0.35 (▲), 1.2 (○), 3.1 (■), and 5.0 (△) μg mL^{-1}. Curves calculated according to Eq. (3), with $k_1 = 6.5 \times 10^{-4}$ s^{-1} and $k_2 = 3 \times 10^4$ M^{-1} s^{-1} (20 °C) [97]. Varying the mode of denaturation (low pH, high guanidinium chloride, urea) or adding the coenzyme (NAD^+) has no effect on the renaturation mechanism [100].

folding and misassembly (cf. "aggregation" in Figure 1.2), association generally contributes as a rate-determining step only below the concentration limit at which the production of structured monomers becomes rate-limiting. If a slow folding reaction at the level of the monomer determines the overall reaction, and association is diffusion-controlled, no concentration dependence can be detected in spite of the bimolecular step; the same holds if an assembly undergoes slow intramolecular rearrangements to finally reach the native state after slow reshuffling [51].

Coming back to the "kinetic partitioning," three questions are of interest: (1) what is the committed step in aggregate formation, (2) when is the "structured monomer" committed to end up as the native protein, and (3) what is known about the structure of aggregates and their constituent polypeptide chains? Regarding the first two points, commitment to aggregation was shown to be a fast reaction, whereas the kinetics of the commitment to renaturation follows precisely the slow kinetics of overall reactivation. This means that early collapsed conformers are much more sensitive to aggregation than later species; after a certain intermediate state has been formed, slow shuffling leads "one way" to the native state. Only the native state is fully protected from misassembly [47, 102]. Concerning the structure of aggregates, electron microscopy and circular dichroism showed that wrong subunit interactions give rise to irregular networks with a broad distribution of highly structured particles at least 10 times the size of the native proteins. At high concentrations, (e.g., at the cellular levels of recombinant pro-

teins giving rise to inclusion bodies), they may form gel-like phases, which in the early days of protein downstream processing were appropriately named "refractile bodies." They resemble the native protein in certain spectral properties, as far as turbidity allows such conclusions [37, 103].

1.5 Limits of Reconstitution

The assumption that "unboiling the egg," after preceding deactivation, randomization, and coagulation (or whatever Max Perutz might have associated with "boiling"), leads to the unrestrained recovery of proteins to their "initial native state" has been accepted as a working hypothesis since Anson and Mirsky's days [1]. In 1944, when the first review on protein denaturation was published, the authors came to the conclusion that "... certain proteins are capable of reverting from the denatured insoluble state to a soluble form which resembles the parent native protein in one or more properties [while] other proteins appear to be incapable of this conversion" [104]. Thirty years later, when the author used this argument, Harold Scheraga's reply was "you didn't try long enough."[3] In the meanwhile, the situation had shifted from the playground of two lonely researchers at the Princeton Institute for Animal and Plant Pathology to a topologically and functionally important hot issue, called the protein-folding problem [105]. To give an example, the question at which state of association on the folding-association pathway an oligomeric enzyme gains enzymatic or regulatory properties required optimal reversibility of both dissociation-reassociation and deactivation-reactivation. Optimization was pure alchemy, blended with some insight into standard denaturation mechanisms and the physicochemical basis of protein stability. There were at least five variables, and the initial and final products had to be carefully compared using all available physical and biochemical characteristics [106]. Proving the native state the proper way, i.e., by X-ray analysis, was the only thing we were unable to do; later we found out that the commercial "crystallized enzyme" we had started out with had been purified using a routine denaturation-renaturation cycle.

As mentioned earlier (cf. section 1.3), different denaturants yield different denatured states. Commonly, maximum yields of renaturation are obtained after "complete randomization" (e.g., at high guanidinium chloride concentration), under essentially irreversible conditions. Exceedingly low protein levels are necessary to minimize aggregation. To escape this highly uneconomical requirement, i.e., to increase the steady-state concentration of the refolding protein at low levels of aggregation-competent intermediates, recycling, pulse dilution, and immobilization techniques were devised [84]. False intermediates, trapped under strongly native

3 Twenty years later, his suggestion might have been "try molecular chaperones or any other accessory protein," because there *are* proteins that have resisted renaturation to this day.

conditions, may be destabilized at optimally chosen residual denaturant conditions or in the presence of 0.5–1.0 M arginine; the rationale behind these unexpectedly efficient recipes is that under strongly native conditions, weakly destabilizing agents help the kinetically trapped aggregation-competent intermediates and aggregates to overcome the activation barrier between the aggregated state and the global energy minimum of the renatured protein [47, 84].

There is no doubt that in general proteins do undergo reversible unfolding and that under optimal conditions the product of renaturation is indistinguishable from the native starting material [34]. As has been shown, side reactions may compete with full recovery. They can be minimized by carefully optimizing the denaturation-renaturation conditions: oxidation by properly adjusting the pH and the redox state of the solvent, proteolysis by adding inhibitors, misassembly by reducing the protein level below the critical concentration of aggregate formation, etc. In asking what the limits of in vitro protein folding and reconstitution are regarding size, structural complexity, and compartmentation in the cell, evolution may teach us how the observed high efficiency of protein self-organization is correlated with the basic architecture of proteins and their genes. In this context, the following questions have been addressed. (1) How is the domain structure of large polypeptide chains correlated with the codon usage and the organization of their corresponding genes? (2) Is there a correlation between the occurrence of domains and the state of association of polypeptides that would clearly support the domain-swapping hypothesis? (3) Does intrinsic form determination of the subunits govern the self-assembly of multimeric proteins? (4) At which level of complexity are assembly structures such as ribosomes or phage and virus particles determined by extrinsic morphopoietic factors or vectorial transcriptional programs? (5) Subunit exchange in oligomeric proteins requires highly homologous subunit interfaces; here the question arises, how can the reciprocity be analyzed to understand the occurrence of homo- and hetero-oligomeric quaternary structures? (6) Finally, is the specific compartmentation of isoenzymes within the cell correlated with specific folding-association mechanisms? The results have been summarized in a number of reviews [33, 34, 46, 51, 90, 106].

In the present context, a few comments may suffice. Domains have been shown to fold as independent entities that, in certain cases, may give rise to large assemblies [34, 47]. Intrinsic form determination holds not only for high-molecular-weight assemblies of a single macromolecular species (e.g., apoferritin, TMV protein, and coats of other viruses) but also for heteromultimeric systems (such as multi-enzyme complexes) [34, 107, 108]. In the case of highly complex multicomponent systems, nature either provides *scaffold proteins* or "aids assembly" by the sequential co-transcriptional supply of protein components. Mimicking this *genetically determined morphopoiesis*, successful in vitro reconstitution was accomplished by sequentially adding "primary," "secondary," "tertiary," etc., components on the one hand and by optimizing the solvent conditions on the other [34, 108, 109]. That nature makes use of the limited specificity of subunit contacts became clear when the five isoenzymes of lactate dehydrogenase were discovered in the 1960s. The general question of how specific the recognition of complementary protein

surfaces is in oligomeric proteins is highly significant because, in the cell, nascent polypeptide chains fold in the presence of high levels of other proteins, including chains coded by the same gene but not synchronized in their translation. Thus, the problem arises whether and to what extent chimeric assemblies of structurally related proteins might occur, either as intermediates or final products. In using two dimeric NAD-dependent dehydrogenases (lactate dehydrogenase from *Limulus* and malate dehydrogenase from pig mitochondria), the result of careful denaturation-renaturation experiments was negative: both the time course and concentration dependence, as well as the yield of reactivation in the absence and in the presence of the prospective hybridization partner, remained unaltered. Similarly, equilibrium experiments did not indicate any exchange of subunits [110]. Similar experiments, using mitochondrial and cytoplasmic malate dehydrogenase, showed that the two isoenzymes could be easily synchronized with respect to their folding and reactivation kinetics; however, their dimerization mechanism differs widely, so that hybrid formation again does not occur [100, 111, R. Jaenicke, unpublished results]. The conclusion that no hybrids are formed is by no means trivial from the perspective of the present-day results of protein engineering, with circular permutants of domains, fragmentation of polypeptides into their (hypothetical) functional modules, and similar acrobatics in our daily routine.

1.6
In Vitro Denaturation-Renaturation vs. Folding in Vivo

In the last chapter I tried to summarize certain limits where the physicochemist's optimism that biological morphogenesis is just a variant of abiotic self-organization might be wrong. At this point it is amusing to meet respectable biologists who, faced with the "in vitro/in vivo issue," happily welcome Aristotle again, assuming that in the crowded cell the vitalistic doctrine is better than Descartes' radicalism. Having in mind that in vivo folding is part of the cellular process of protein biosynthesis and subsequent compartmentation, undoubtedly, there are significant differences between the co- and post-translational structure formation on the one hand, and optimally controlled reconstitution processes involving mature proteins in vitro on the other. There are two questions: are these differences relevant, and can we combine available fragmentary evidence from in vitro translation data with in vivo data on other cell-biological events related to self-organization, growth, and differentiation? In his excellent review on protein folding in the cell, Freedman [112] related the paradigm change from Anfinsen's dogma "one sequence → one 3D structure" to the "Anfinsen-cage" concept in chaperon research to two experimental observations: (1) the formation of misfolded recombinant proteins in microbial host cells and (2) the fate of translation products and their ultimate functional intra- or extracellular location. The wish to understand protein folding in the context of the wide variety of co- and posttranslational processes clearly emphasized that in vitro refolding studies on isolated unfolded proteins provide an incomplete model for describing protein folding in the

cell. In the context of the above observations, two examples may be taken to prove that the model studies do provide essential background against which the cellular events can be understood. One deals with the attempt to gain direct insight into the detailed kinetic mechanism of the folding and assembly of the tailspike endorhamnosidase from *Salmonella* bacteriophage P22 in vitro and in the cell. Making use of temperature-sensitive mutants, spectral and pulse-labeling experiments showed that in both sets of experiments the rate-limiting folding intermediates are formed at identical rates [47] (Figure 1.9). In the other example, it was shown that misfolding and subsequent inclusion-body formation at high levels of recombinant

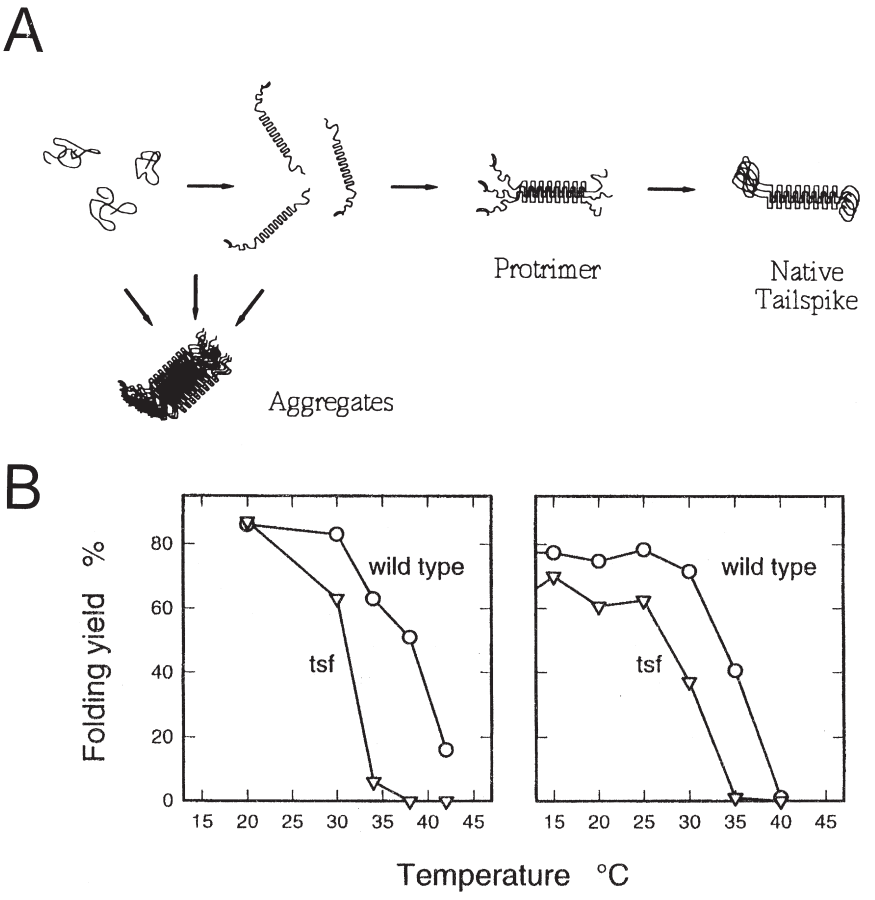

Fig. 1.9. In vitro and in vivo folding and assembly of the trimeric tailspike endorhamnosidase (Tsp) of *Salmonella* bacteriophage P22, making use of the temperature-sensitive folding and aggregation of folding intermediates. (A) Schematic representation of the folding/assembly/aggregation pathways. (B) Folding yields of wild-type and mutant Tsp upon biosynthesis in vivo on the one hand (left), and dilution from denaturant in vitro (right) on the other. The similarity of the data shows that the in vitro reconstitution applies to the situation in the living cell [113, 114].

proteins can be quantitatively described by kinetic partitioning between one rate-determining folding step (k_1) and parallel diffusion-controlled aggregation (k_2), in accordance with Eq. (4) in the simplified form

$$N \overset{k_1}{\leftarrow} U/M_u \overset{k_2}{\rightarrow} A \tag{5}$$

(cf. Figure 1.2B) [39].

The observation that overexpression often leads to the deposition of recombinant proteins in the host cell may favor the idea that under normal physiological conditions in vivo, structure formation yields exclusively native protein. This assumption is incorrect because, in the eukaryotic cell, trafficking through the ER and the Golgi and subsequent quality control may reduce the yield considerably [115]. Thus, in mechanistic terms, refolding does not differ significantly from in vivo folding. The same holds for the directionality of translation in the cell, which, on first sight, seems to be fundamentally different from the integral folding of the complete polypeptide chain in renaturation experiments. Here, due to the involvement of chaperone proteins in the initial folding events, structure formation in vivo does not necessarily occur co-translationally in a vectorial fashion. Furthermore, circular permuted proteins and protein fragments have been shown to fold into stable, functional conformers, indicating that multiple folding pathways exist (altogether leading to the same 3D structure) and that the original N-terminus is not required for the folding process. In this context, inverting the direction of either protein biosynthesis (by Merrifield synthesis) or protein folding (by immobilization) has been shown to end up with the native functional protein: with Merrifield synthesis, one may argue that the synthesis from the C- to the N-terminal end includes coupling-uncoupling and protection-deprotection reactions under nonnative conditions, but the final product is still in its native state [116]. In order to promote the direction of folding in either the natural (N → C) or the inverse (C → N) direction, immobilization of standard proteins at their N- or C-termini (by histidine or arginine tags, combined with ion-exchange chromatography) was applied. In both cases, denaturation-renaturation cycles have shown that the products were the same, independent of the free end of the polypeptide chain [38].[4]

In the present context, the above *one sequence → one 3D structure* dogma is incomplete without stressing the importance of the solvent environment. In contrast to the alchemy of solvent variations that have been worked out in order to optimize the downstream processing of recombinant proteins, evolutionary adaptation has fixed the protein inventory of mesophiles and extremophiles to specific cellular solvent conditions. Making use of the expression of recombinant extremophile proteins in mesophilic hosts, limits can be defined about how far physical variables may be varied without interfering with the ''foldability'' of guest proteins. It is evident that early intermediates on the folding path are most accessible toward delete-

4 An additional spin-off of this approach was that immobilization allowed the kinetic partitioning to be shifted from *A* to *N* (cf. Eq. (5)): the tagged proteins showed not only significantly increased yields of reactivation but also enhanced intrinsic stabilities.

rious solvent effects. Thus, if the native structure can be reached either after recombinant expression or after refolding in vitro, intermediates and subunits must be stable under the respective conditions. Considering temperature, it turns out that alterations in the folding conditions often have surprisingly little effect. A drastic example is the expression of active enzymes from hyperthermophilic bacteria in *Escherichia coli*, in which the temperature difference ΔT_{opt} between the host and the guest may amount to >60 °C. Here, it has been shown that denaturation-renaturation experiments at up to 100 °C yield the fully active protein, indistinguishable from its initial native state, proving that all folding-association intermediates must be stable over the whole temperature range [16]. When comparing homologous proteins from mesophiles and thermophiles, it is interesting to note that thermophilic proteins are often kinetically stabilized, showing drastically decreased unfolding rates but unchanged folding kinetics [18], no doubt highly advantageous considering short-term exposure to lethal temperatures in hydrothermal vents on the one hand, and kinetic competition of protein folding and proteolytic degradation on the other.

Little is known about the effects of the other extreme physical parameters on protein folding. Because the cytosolic pH is close to neutrality, even in the case of extreme acidophiles and alkalophiles, standard in vitro conditions are close to those in the cell. Halophilic proteins seem to require salt, not only as stabilizing agent but also for folding and assembly [117]. For non-halophilic proteins, the ionic strength is not as critical, apart from general Hofmeister effects that may be used to optimize the in vitro folding conditions. Regarding possible effects of high hydrostatic pressure on cellular processes, it is obvious that the adaptive effort to cope with the biologically relevant extremes of pressure (<120 MPa) can be ignored in comparison to the adaptation to low temperature prevailing in the deep sea [118]. Finally, viscosity should be considered because of macromolecular crowding in the cytosol. As has been mentioned, glycerol, sucrose, and other carbohydrates have been used to simulate frictional effects on domain pairing. In connection with protein folding, information is scarce, especially because polyols not only increase the viscosity of the solvent but also enhance the stability of the solute owing to excluded-volume effects and preferential solvation; there is no way to alter viscosity alone.

1.7 Perspectives

As we have witnessed, interest in the protein-folding problem started from the sensational resurrection of denatured proteins in Tim Anson's hands, long before the first 3D structure of a globular protein was elucidated. After self-organization had become an accepted fact, experimental studies were centered mainly on the investigation of the mechanisms of folding and association of model proteins in terms of the complete description of the unfolded (nascent) and final (native) states, including all accessible intermediates along the U → N transition. The main obstacle

in reaching this goal was the elusive nature of the folding protein, especially the question of whether folding is in fact a sequential reaction with well-populated intermediates or a multiple-pathway process, as in the case of a jigsaw puzzle [119]. What was important at this point was the observation that model peptides as well as separate protein fragments and domains were able to form ordered structures, supporting the idea that local structures and modules may serve as ''seeds'' in the folding process. That such nuclei did not necessarily adopt the same conformation in unrelated protein structures was no argument against their significance as intermediates. Specific ligands such as metal ions were found to be essential as guides along the folding path; interestingly, in cases like these, estimated cellular levels were found to be close to the optimum concentration in in vitro refolding experiments [34].

Regarding folding in the cell, in the early days it was tacitly assumed that the in vitro mechanism could be directly transferred to describe the folding and association of the nascent polypeptide as the final step of translation. Obvious discrepancies were clear from the beginning; for example, ''unscrambling'' of ribonuclease took unreasonably long, in vitro reactivation at standard cellular protein levels ended up with aggregates rather than active material, certain proteins were found to be inaccessible to ''renativation,'' etc. The discovery of a whole spectrum of folding catalysts and molecular chaperones resolved most of these challenges because they were clearly correlated with the three established rate-limiting steps in the overall folding reaction: PDI with disulfide shuffling, PPI with proline isomerization, and molecular chaperones with the kinetic partitioning between folding and aggregation. Based on mutant studies and on the fact that under normal physiological conditions several percent of the cellular proteins are molecular chaperones, there could hardly be any doubt that all three classes of proteins were physiologically essential. As a matter of fact, complementing the in vitro experiments with the accessory components allowed the in vitro results to mimic the reality in the cell.

No new biophysical principles emerged from all these studies; on the contrary, the better the mechanisms of folding catalysts and molecular chaperones were understood, the more it became clear that the basic principles of catalysis, allosteric regulation, and compartmentation hold also in the cellular environment. In spite of that, attempts at quantifying protein folding in vivo in physicochemical terms failed because the cytosol represents a *complex macromolecular multicomponent system under crowding conditions*, the full description of which still goes beyond the presently available repertoire of experimental methods. As in other ''real systems'' such as the real gas or concentrated simple electrolytes, the quantitative treatment of the non-ideality of highly charged polyelectrolytes in aqueous multicomponent systems is still beyond the reach of a sound theoretical treatment.

Twenty-five years ago, at the end of the first International Conference on Protein Folding in Regensburg, Cyrus Chothia quoted Johannes Kepler's treatise *On the Six-cornered Snowflake* as the first ''theory of biological structures.'' In his essay Kepler argued that a material's structure arises from its intrinsic properties and that in biological structures it is important to consider the structure-function rela-

tionship [120]. In this context, focusing on protein folding, at the 1979 conference attempts were made to combine the intrinsic physical and chemical properties of proteins and the laws of kinetics and thermodynamics in order to predict how they determine the structure and activity. At that time, ''simple protein molecules'' such as basic pancreatic trypsin inhibitor, ribonuclease, and lactate dehydrogenase were discussed as adequate models, the argument being that the central problem at all levels of biological structure is to understand how the intrinsic entropy of its various constituents is overcome to form particular stable structures in a finite time and how the physical and chemical properties of the materials determine the way in which they function. Cyrus, the theoretician, ended by vaguely announcing that ''the next time we meet in Regensburg we shall talk about more biological systems such as the red cell membrane or coated vesicles'' [121]. I do not have to explain why this second conference never materialized. Now, after a quarter of a century, two former Regensburg graduate students are keeping Cyrus' promise, figuring as editors of the present volume. In fact, this volume covers the state of the art, from the principles, dynamics, and mechanisms of protein stability, protein design, and structure prediction to the function and regulation of chaperones and research and development in the fields of engineering protein folding and stability and refolding technology, an amazing horizon having in mind the first steps in protein folding in the dark age of biocolloidology, when the chemical establishment still considered proteins to be loose aggregates of smaller entities, unflinchingly opposing the term *macromolecule*.

2
Folding and Association of Multi-domain and Oligomeric Proteins

Hauke Lilie and Robert Seckler

2.1
Introduction

Folding and association of nascent or refolding polypeptide chains are spontaneous and autonomous processes. All information required for the formation of the native three-dimensional structure of a given protein or protein complex is encoded in the amino acid sequence. The structure of a protein is the result of an optimum partitioning of the nonpolar and polar parts of the polypeptide chain between regions of high and low dielectric constant in the solvent environment [1]. In aqueous solution this leads to a minimization of hydrophobic surface area. This basic principle governs both structure formation of monomeric proteins and association of subunits of oligomeric proteins.

In many cases the biological activity of proteins depends on their association state. The association can result in homo- or hetero-oligomers that may be either stable or only transiently formed during their specific functional cycle. The Protein Data Bank (pdb) of protein structures contains more than 2000 oligomeric structures, the largest of which comprise virus shells, and homomeric or heteromeric protein complexes containing more than 20 subunits, such as ferritin (24 identical subunits, [2]), the chaperonin complex GroEL/ES (21 subunits $\alpha 14\beta 7$, [3]), and dihydrolipoyl acetyltransferase (60 subunits, [4]).

For quite a number of multi-domain and even oligomeric proteins, folding and assembly pathways as well as their thermodynamic stabilities and dissociation constants have been determined. This chapter deals with the general principles of structure formation and stabilization of multi-domain and oligomeric proteins and the experimental approaches to analyze these reactions. Some closely related topics, which are not part of this chapter, are summarized in other chapters of this book. These comprise virus assembly (Chapter 5), collagen folding in vitro (Chapter 21 in Part I) and in vivo (Chapter 26), formation of protein fibrils (Chapters 31–36), and the catalysis of rate-limiting steps of folding such as peptide bond isomerization (Chapter 27) or disulfide bond formation (Chapter 29).

Protein Folding Handbook. Part II. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

2.2
Folding of Multi-domain Proteins

2.2.1
Domain Architecture

Domains are compact substructures within protein molecules. There are different definitions of "domain" based on analysis of the three-dimensional structure of the respective protein, the autonomous folding units of a protein, and functions such as cofactor binding or resistance to proteolysis. Interestingly, in a number of cases the boundaries of protein domains correlate with intron-exon boundaries on the genetic level [5, 6]. This suggests that exon shuffling (and thus domain shuffling) is an important mechanism in generating functional diversity during evolution of multi-domain proteins [1].

A hierarchical classification of domain structures (CATH) has been proposed, using as parameters the *secondary structure composition* (C for class), the *gross arrangement of secondary structure* (A for architecture), the *sequential connectivities* (T for topology), and the *structural and functional similarity* (H for homology) [7–9]. By this procedure 27 000 known domain structures can be grouped into 1800 sequence families, 700 fold groups, 245 superfamilies, and about 30 different architectures (Figure 2.1, see p. 36/37) of a total of three major classes (all-α, α/β, all-β).

Based on the three-dimensional structure and structure acquisition of proteins, domains are considered as cooperative units in the folding process. In this concept, the individual domains of a multi-domain protein can be considered simply as small, one-domain proteins that fold to a native-like structure independently of the remaining part of the protein. This holds for both in vitro folding and co-translational folding. The latter has been shown for the folding and assembly of nascent antibody chains [10]. Based on this kind of vectorial mechanism with well-defined assembly modules, large polypeptide chains speed up folding by many orders of magnitude. At the same time, possible wrong long-range interactions that would lead to an incorrectly folded protein are minimized.

Methods used to investigate the structure formation process of multi-domain proteins are the same as for simple model proteins and will not be discussed here. The most important techniques are listed in Table 2.1. A detailed description of some of these methods can be found in several chapters of Volume I of this handbook.

Detailed analyses on the structure, thermodynamic stability, and folding of multi-domain proteins have been performed, e.g., for γB-crystallin, lysozyme, α-lactalbumin, the light chain of antibodies, and many other proteins [11, 12]. From these studies it can be concluded that in most cases the domains fold independently kinetically and that they are thermodynamically stable entities. The complete refolding, however, often requires an additional kinetic phase involving intramolecular domain association. If the interaction sites of the domains are very

Tab. 2.1. Experimental approaches to study folding of domain proteins.

Assay	*Methods*	*Information*
Spectroscopy	Circular dichroism (CD)	
	In the far UV region	secondary structure information

Function	Enzymatic activity and/or ligand binding	monitoring the native state (sometimes can be active as well)
Stability	Limited proteolysis or denaturant	only folded domains or the native state might be resistant to proteolytic degradation or increased denaturant concentration

large, then domain-domain interactions may contribute significantly to the stability of the respective domains, and thus the isolated domains are thermodynamically unstable on their own. In such cases the folding and structure of the partner domain represent an essential template for structure formation of the other domain [13, 14].

One might suggest that proteins with very similar structure should show similar folding characteristics. This, however, is not the case. An intriguing example is the comparison of hen egg white lysozyme (HEWL) and α-lactalbumin. Both proteins with a molecular mass of approximately $Mr = 14\,400$ are structurally almost identical, containing an α-helical and a β-sheet domain. However, both their denaturant-induced equilibrium transitions and their folding characteristics are quite different. HEWL shows an equilibrium transition according to a classical two-state model (cf. Chapter 3 in Part I), i.e., only the native and the completely denatured state of the protein are populated in the transition region. In contrast, α-lactalbumin shows a three-state unfolding transition (in the absence of Ca^{2+} ions) according to the model $N \leftrightarrow I \leftrightarrow U$, where N is the native state, I is a partially structured folding intermediate, and U is the completely denatured protein [15]. The equilibrium intermediate I retains the α-helical domain, whereas the β-sheet domain is denatured. This same kind of intermediate can also be observed during the refolding kinetics of α-lactalbumin. It has been used as a model structure for the definition of the molten globule, a type of intermediate often observed in the folding of proteins (cf. Chapter 13 in Part I). Under strong refolding conditions (low residual concentration of denaturant), HEWL also folds via intermediates, which, however, do not resemble a classical molten globule [16]. Furthermore, in the case of HEWL, the intermediate is not obligatory; the protein can fold directly from the denatured to the native state. Due to kinetic competition, a fraction of the denatured molecules folds to an intermediate state, which subsequently undergoes a structural conversion to the native state [17].

2.2.2 γ-Crystallin as a Model for a Two-domain Protein

γ-Crystallin as an eye-lens protein of vertebrates belongs to a superfamily of β-sheeted proteins with a Greek key topology. It is a two-domain protein of a molecular mass of 21 kDa. The two domains, connected by a short peptide linker, are highly homologous (cf. Figure 2.5). γ-Crystallin is extremely stable, retaining its native structure at pH 1–10 or in 7 M urea at neutral pH [18]. The denaturant-induced equilibrium transition at neutral pH yields a broad transition and a partially irreversible denaturation. At acidic pH, however, the overall denaturation process splits into two transitions, both of which are fully reversible [18–20]. Making use of sedimentation analysis, intrinsic protein fluorescence, and circular dichroism, the urea-dependent equilibrium unfolding at pH 2 can be quantitatively described by a three-state transition $N \leftrightarrow I \leftrightarrow U$, with the intermediate populated at 2–4 M urea (Figure 2.2).

The kinetic data on folding and unfolding of γ-crystallin fit well to the biphasic equilibrium transition. Below 3 M urea, the denaturation kinetic is monophasic, representing the reaction N → I. At higher urea concentrations, the unfolding reaction becomes biphasic, the faster reaction corresponding to the structural conversion N → I and the slower one to I → U. Similar effects are observed for the refolding: at 3 M urea, the folding reaction is monophasic (U → I), while under strongly native conditions both reactions U → I and I → N can be observed. On the other hand, when starting either denaturation or refolding from the intermediate state, the respective kinetics are monophasic. Summarizing the dependence of the rate constants (or relaxation times) of folding and unfolding on the urea concentration, two separate V-shaped profiles (chevron plot) are obtained (Figure 2.2). The respective reactions correspond to structural transition of N → I, I → N, U → I, and I → U.

Structural interpretation of these data, however, is difficult. It is not possible to assign any of the equilibrium transitions and kinetic reactions to a certain domain of this two-domain protein. In order to correlate the mechanism with the specific structural properties of γ-crystallin, the recombinantly produced, isolated domains were investigated [19]. Both the C-terminal and the N-terminal domains have been shown to be monomeric in their isolated states as well as if simultaneously incubated even at very high protein concentrations. The thermodynamic stability and folding and unfolding reactions of the isolated N-terminal domain of γ-crystallin resemble those of the intermediate I of the full-length protein [18, 19], indicating that the intermediate I consists of a native-like structured N-terminal and a completely unfolded C-terminal domain. The isolated C-terminal domain, however, is much less stable than it is in the context of the whole protein (Figure 2.3). In fact, even in denaturant-free buffer, a significant fraction of the isolated C-terminal domain is unfolded.

The difference in the stability of the C-terminal domain in its isolated form and in the context of the full-length protein implies a significant contribution of the do-

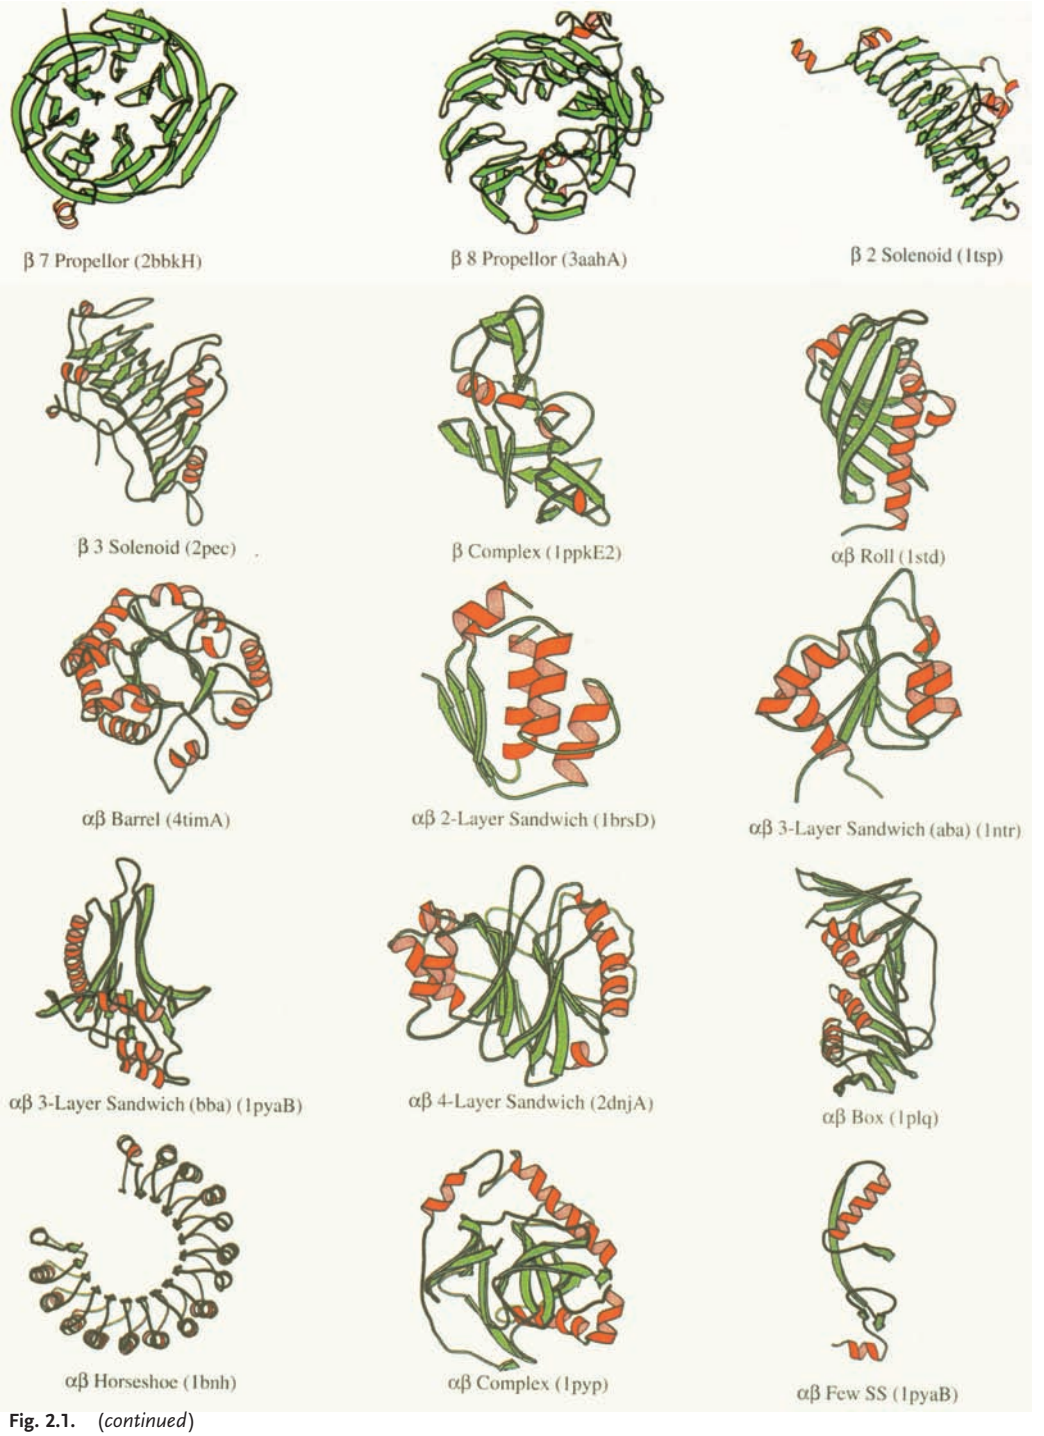

Fig. 2.1. (*continued*)

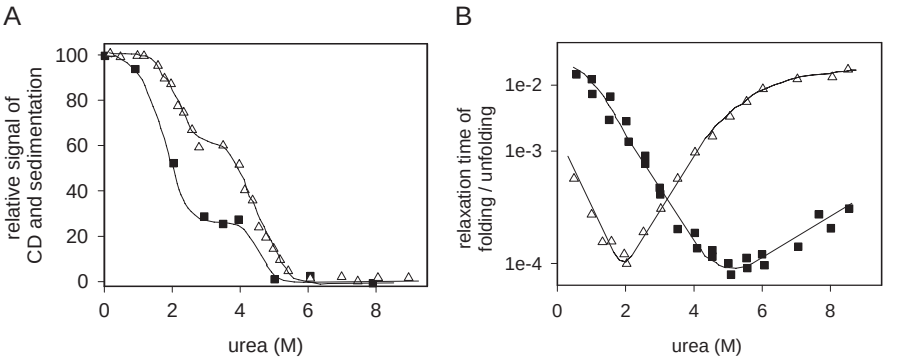

Fig. 2.2. Stability and folding of γ-crystallin (adapted from Ref. [18]). (A) Urea-induced equilibrium transition of γ-crystallin. The protein at a concentration of 0.2 mg mL^{-1} in 10 mM HCl (pH 2), 0.1 M NaCl was incubated at different urea concentrations. Subsequently, the samples were analyzed using CD (△) and sedimentation (s20,w: ■). (B) Kinetics of folding/unfolding of γ-crystallin (△,■) measured by fluorescence and HPLC gel filtration. The relaxation times of the kinetics are plotted against the urea concentration used for folding/unfolding.

main interactions (ΔG_{int}) to the overall free energy of stabilization (ΔG_{γ}), in addition to the sum of the intrinsic stabilities of the isolated domains ($\Delta G_{\mathrm{N}}, \Delta G_{\mathrm{C}}$):

$$\Delta G_{\gamma} = \Delta G_{\mathrm{N}} + \Delta G_{\mathrm{C}} + \Delta G_{\mathrm{int}}$$

Under the given conditions (pH 2) the stability ΔG_{C} amounts to only -4.7 kJ mol^{-1}, whereas the ΔG_{int} is -16 kJ mol^{-1}. Thus, at low pH the C-terminal do-

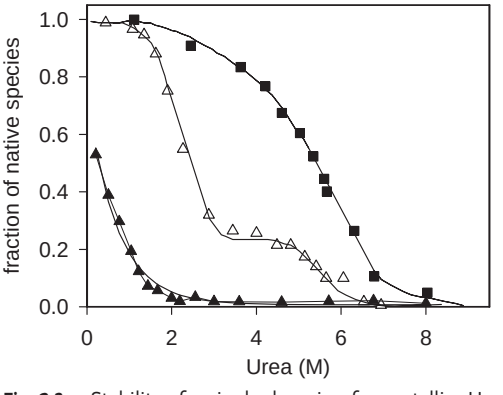

Fig. 2.3. Stability of a single domain of γ-crystallin. Urea-induced equilibrium transition of γ-crystallin and its single domains measured in 10 mM HCl pH 2, 0.1 M NaCl. Complete γ-crystallin (△), the isolated N-terminal domain (■), and the isolated C-terminal domain (▲).

main of γ-crystallin is mainly stabilized by an intramolecular association with the N-terminal domain. This intramolecular interface is characterized by a well-defined hydrophobic core of Phe 56, Val 132, Leu 145, and Val 170. If Phe 56 of the N-terminal domain is replaced by either Ala, thus creating a cavity in the hydrophobic core, or Asp, placing a non-saturated charge in the contact site, the C-terminal domain is considerably destabilized, again emphasizing the importance of the interaction free energy of stabilization (ΔG_{int}) in stabilizing the structure of the C-terminal domain of γ-crystallin.

2.2.3 The Giant Protein Titin

Titin is a protein located in the sarcomere of vertebrate striated muscle cells. A single molecule of titin spans half the sarcomere from the Z-disc to the M-line, extending about 1 μm in length (Figure 2.4). The protein consists mostly of several hundred copies of β-sheet domains of the immunoglobulin type and of fibronectin type III (Fn3); the molecular mass ranges from 3 MDa to 4 MDa, depending on the source of titin. The function of titin varies along the sarcomere. In the M-line it forms an integral part of the protein meshwork, while in the A-band it probably regulates the assembly of the thick filaments and might be involved in the inter-filament interaction of myosin and the actin/nebulin thin filament [21, 22]. In the I-band, titin serves as an elastic connection between the Z-disc and the thick filaments. It is hypothesized that these elastic properties depend on partial unfolding/refolding of titin during muscle tension.

In order to obtain insight into the molecular properties of this giant protein, single immunoglobulin and Fn3 domains as well as tandem repeats of these two domains have been cloned and biophysically analyzed. The individual domains vary considerably in sequence. Using fluorescence and circular dichroism as probes in equilibrium unfolding experiments, the thermodynamic stability of a variety of these domains was determined to be in the range of 8.6–42 kJ mol^{-1} [23]. Similarly, the rates of chemical unfolding of individual domains vary by almost six orders of magnitude [23]. It has been speculated that this dramatic variation in folding behavior is important in ensuring independent folding of domains in the multi-domain protein titin.

Site-directed mutagenesis of each position in a protein together with a detailed analysis of the folding and unfolding kinetics of these mutants permit the structural mapping of the transition state of folding (θ-value analysis, cf. Chapter 2 in Part I). Such an analysis for the titin domain I27 reveals that the transition state of folding is highly structured and remarkably native-like regarding its solvent accessibility. Only a small region close to the N-terminal region of the domain remains completely unfolded.

How do the molecular properties of the single domains of titin correlate with the function of the whole molecule? Titin is involved in muscle tension and elasticity and thus is subjected to mechanical forces. The elasticity of a protein can be measured by atomic force microscopy (AFM) [22]. To this end, the protein is fixed at

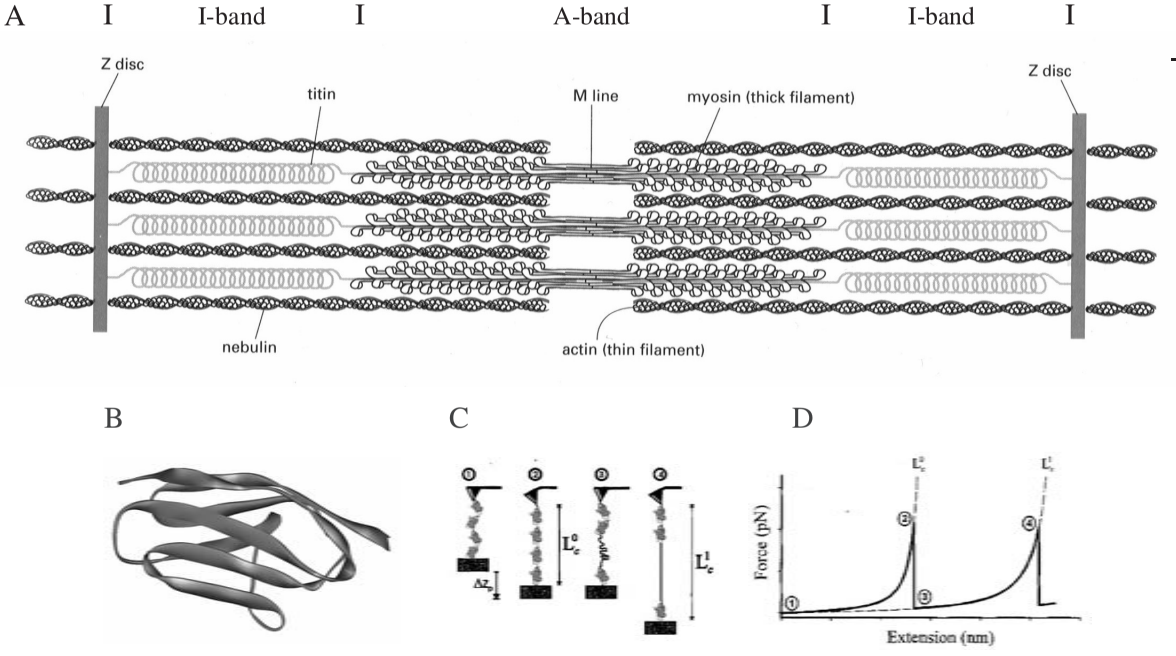

Fig. 2.4. (A) Schematic representation of a sarcomere of striated muscle. (B–D) Single-molecule AFM measurements of an engineered polyprotein of the titin domain I27. (B) Structure of the I27 Ig-like domain. (C, D) Schematic representation of the sequence of events during the stretching of I27 multi-domain protein. Stretching the ends of the polyprotein with an atomic force microscope sequentially unfolds the protein modules, generating a saw-tooth pattern in the force-extension relationship that reveals the mechanical characteristics of the protein. (1) An anchored multi-domain protein composed of four I27 domains. The protein is relaxed. (2) Stretching this protein requires a force that is measured as a deflection of the cantilever. (3) The applied force triggers unfolding of a domain, increasing the contour length of the protein and relaxing the cantilever back to its resting position. (4) Further stretching removes the slack and brings the protein to its new contour length Lc 1.

one end on a surface and at the other end on the tip of a so-called cantilever (Figure 2.4). Moving the cantilever slowly and on an Angstrom scale from the surface and thus continuously increasing the mechanical force leads to a stretching of the fixed protein. The resistance of the protein to this stretching results in a bending of the cantilever that is optically detected. At some point a protein domain unfolds, the resistance is partially released, and the cantilever returns to its starting position. This procedure is repeated as often as domains are located between the static surface and the cantilever. The experimental result is a sawtooth-shaped curve, in which the width of a single sawtooth reflects the difference in length of the folded and unfolded domains (28 nm for the titin domain I27) and the height of the peak corresponds to the mechanical force necessary for domain unfolding (Figure 2.4). The immunoglobulin domain I27 of titin unfolds at 210 pN, and the Fn3 domain I28 unfolds at ca. 260 pN. However, the hetero-oligomer $(I27–I28)_4$ is slightly stabilized, hence the mechanical force to denature the domain I28 in this construct increases to 306 pN [24]. Such a stabilization of the Fn3 domain I28 in the context of the neighboring I27 domain was also observed using chemical denaturation methods [25]. Comparison of the chemically induced unfolding and the mechanically induced unfolding reveals similar mechanisms of denaturation. The forced unfolding starts with the detachment of the N-terminal β-strand from the otherwise stable β-sheet. This N-terminal β-strand is not structured in the transition state of chemical denaturation. Site-directed mutagenesis studies show that the region important for kinetic stability is very similar in both cases, although there are also significant differences in the forced and chemically induced unfolding transition states [26, 27].

Presently, it seems that chemical and mechanical denaturation processes are related, at least for proteins evolved to respond to mechanical stress. However, in the case of barnase, a globular two-domain protein, mechanically and chemically induced unfolding seem to proceed quite differently on the structural level [28].

2.3
Folding and Association of Oligomeric Proteins

2.3.1
Why Oligomers?

Oligomers consist of noncovalently associated subunits of identical origin (homo-oligomers) or different origin (hetero-oligomers). Two or more monomers form dimers, trimers, tetramers, etc. Higher oligomers may possess topological units (e.g., the dodecameric aspartate transcarbamylase (ATCase) from *E. coli* consists of two catalytic trimers and three regulatory dimers). Tetramers of glyceraldehyde-3-phosphate dehydrogenase and yeast pyruvate decarboxylase are formed as dimers of dimers. Compared to other tetramerization pathways such as the addition of monomers to dimers or trimers, the specific topology of a tetramer as a dimer of

dimers leads to kinetics of association that seem to be less prone to competition with off-pathway reactions of nonnative assemblies or accumulation of association intermediates [29].

The advantage of oligomeric proteins compared to their non-associated monomeric counterparts may be found on the functional, structural, and genetic levels. Oligomerization permits an allosteric regulation of enzyme activity. In multienzyme complexes, the catalytic efficiency of the overall process may be significantly increased. This would especially be the case if labile intermediates were channeled from one active site to the other. These functional advantages, however, can be conferred not only by oligomeric structures but also by large multi-domain proteins. Indeed, a few such very large multi-domain proteins consisting of more than 10 000 amino acids are known [30]. There is no fundamental structural or functional distinction between domains and subunits. The eukaryotic fatty acid synthase contains the whole assembly line of fatty acid synthesis [31, 32]; similarly, many non-ribosomal peptides are synthesized by very large proteins (e.g., the cyclosporin synthetase, in which all the different enzyme functions are located in one polypeptide chain) [33]. However, these very large multi-domain proteins are rare: most large protein structures are formed by association of subunits. Oligomerization of small gene products is by far more economical; this is quite obvious in the case of viruses, where a small protein, and thus a small gene, is sufficient for building up a large virus capsid of the size of several megadaltons. Furthermore, errors occurring during protein synthesis can be eliminated more easily in the case of oligomeric structures. Another possible advantage of oligomeric protein complexes versus large multi-domain proteins may result from differences in folding. It has been shown that domains in the context of a larger polypeptide chain fold more slowly than the same domain in its isolated state [34–36]. This difference may result from nonnative long-range interactions with other parts of the polypeptide chain and/or diffusional limitations of a long polypeptide during folding. In the case of the central domain of bacteriophage P22 tail spike protein, the folding of this β-helix domain is accelerated about twofold upon removal of the N-terminal, structurally unrelated domain. This slightly accelerated folding increases the yield of folding significantly both in vitro and in vivo [36, 37].

2.3.2 Inter-subunit Interfaces

The increasing number of high-resolution crystal structures of oligomeric proteins and protein complexes available in the Protein Data Bank allows a statistical analysis of the properties of interfaces of subunits and domains [38–41]. The majority of the subunit interfaces have a surface of 1000–3000 $Å^2$. The major part of this surface is usually hydrophobic, conveying the stability of interaction; polar interactions, including hydrogen bonding and ionic interactions, as well as surface complementarity serve as specificity factors of interaction [43, 44]. In fact, the molecular properties of the interface of stably associated subunits regarding the distribution of hydrophobic versus polar residues are very similar to that of the

hydrophobic core of proteins and, conversely, very different from that of the solvent-accessible surface. In contrast to the interfaces responsible for stable subunit association, the contact sites of proteins that interact only transiently with other proteins are less hydrophobic [41].

A qualitative analysis of 136 subunit interfaces of homodimeric proteins [45] showed that about 30% are characterized by a well-defined hydrophobic core, surrounded by polar interactions [45, 46]. However, the majority of interfaces consist of multiple small, hydrophobic patches interspersed by hydrogen bonds and polar interactions [45].

Such large differences in interface structure might correspond to differences in interface stability and in folding and assembly mechanisms, as proposed by Nussinov and coworkers [40, 47]. This is illustrated by the tetrameric yeast pyruvate decarboxylase (PDC). The topology of PDC is reminiscent of a dimer of dimers. The interface between the dimers that form the tetramer is largely polar, and the tetramer spontaneously dissociates to dimers upon dilution. The dissociation constant of this dimer-tetramer equilibrium is 8.1 μM [48]. The interface between the monomers, however, is strongly hydrophobic; the dimer does not dissociate into monomers just by dilution of the protein. Only in the presence of 2–3 M urea can folded monomers be populated [48]. Unfortunately, there are only very few cases where thermodynamic, kinetic, and crystallographic data of a certain protein can be combined in order to assess these questions. Recent studies suggest that, in a given interface, a few amino acids may play a dominant role in determining the free energy of stabilization of the interaction. These residues are called hot spots of the binding surface [46].

Whereas in most cases the association of proteins is mediated by globular, native-like structured domains, a growing number of protein-protein interactions have been discovered in which one of the partners is unstructured in its isolated state. These natively unstructured proteins can be grouped into two classes, one with random coil structures and the other with a pre-molten globule structure [13]. Only upon association with their targets do these proteins develop an ordered and biologically active structure. Examples are several ribosomal proteins that transform to a rigid well-folded conformation only in the presence of the ribosomal RNA [49, 50]. In the case of cyclin-dependent kinase inhibitor p21, the N-terminal fragment lacks stable secondary and tertiary structure in the free solution state. However, when bound to its target, Cdk 2, it adopts a well-ordered conformation [51].

Besides the usual subunit interaction via globular domains, there is also another major type of protein-protein interaction mediated by special helical structures: the so-called coiled coils [52]. A detailed description of this interaction that may lead to dimers, trimers, or tetramers, depending on the sequence of the coiled coils, can be found in Chapter 18 in part I.

Furthermore, completely artificially designed peptides have been described, conferring heterodimerization of proteins fused to them. These peptides are based on only a stretch of eight charged amino acids and an additional cysteine. Two of these peptides containing complementary charged side chains associate with each

other due to their polyionic interaction; subsequently, the cysteines can form a disulfide bond, thus stabilizing the heterodimerization [53–55].

2.3.3 Domain Swapping

As pointed out by Bennett et al. [56–58], the gradual accumulation of random mutations on the surface of a monomeric protein that are required to create a suitable subunit interface and stabilize a dimer cannot be accomplished within a biologically feasible time. At least in some cases the evolution of domains offers a key to understanding the mechanism to proceed from monomers to dimers. Starting from a two-domain monomer, domain swapping permits the transition from monomers to dimers (or any other association state) simply by switching from an inter-domain to an inter-subunit interaction. In this scheme, the interface that is almost impossible to create by random mutagenesis in evolution is available a priori. Based on the already-existing interaction site, additional mutations might then stabilize the domain-swapped dimer compared to the monomer (Figure 2.5).

The concept of domain swapping may be illustrated by $\beta\gamma$-crystallins. $\beta\gamma$-crystallins are members of the superfamily of β-sheeted proteins containing the Greek key motif. γ-crystallin is monomeric even at extremely high protein concentrations, whereas β-crystallin forms dimers or higher oligomers. Both show highly homologous two-domain structures. Comparison of the structures of γ- and β-crystallins suggests that the β dimers are the product of domain swapping and association of a γ ancestor (Figure 2.5). This hypothesis is supported by the fact that 60% of the interface residues of the N- and C-terminal domains of γ-crystallin are identical or highly conserved compared to those of the N- and C-terminal domains of the two subunits of β-crystallin [59].

Domain swapping does not correlate necessarily with structural domains. Instead, the swapped portion can vary from a large globular domain, as described for $\beta\gamma$-crystallins, to a structural element as short as a single helix or β-strand. In fact, of the ca. 40 structurally characterized cases of domain-swapped proteins, most swapped domains are either at the N- or C-terminus and are diverse in their primary and secondary structure [60]. Hsp33, for example, forms a dimer in which a C-terminal arm of one monomer consisting of two α-helices wraps around a second monomer [61, 62]. This C-terminal arm is connected to the remaining part of the protein by a putatively flexible hinge region. The chaperone-active dimer is in equilibrium with a less active or even inactive monomer ($K_D = 0.6$ μM, [63]). A detailed structural and functional analysis of Hsp33 is presented in Chapter 21. Unfortunately, the structure of the Hsp33 monomer is not known. Thus, at present it is only speculation that in the monomeric structure the C-terminal arm folds back on the monomer.

Higher association states of domain-swapped proteins are found in several virus capsids, in which capsomers swap β-strands, or pathologic aggregates in the case of α1-antitrypsin [64].

Although domain swapping is an intriguing concept in understanding evolution

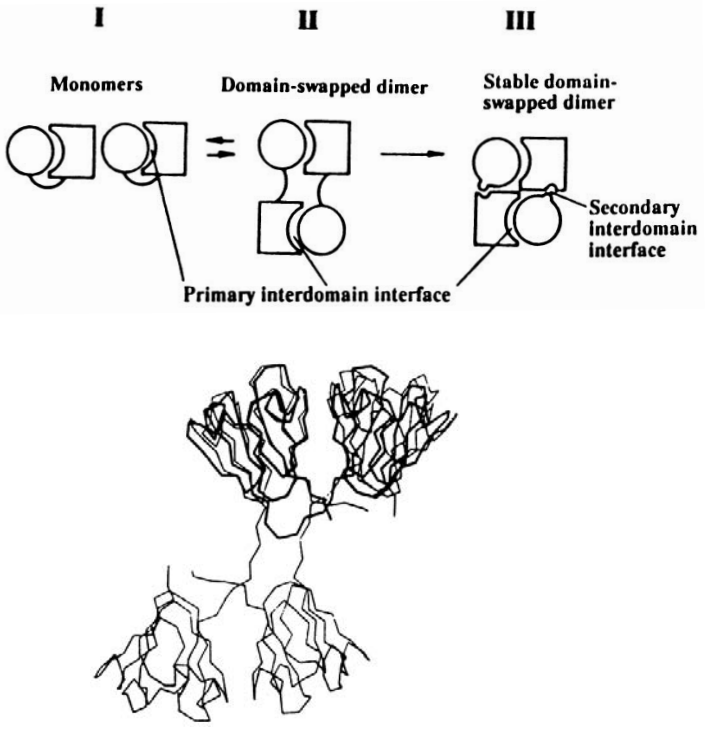

Fig. 2.5. Domain swapping. (A) The monomer (I) with its primary inter-domain interface may participate in interchain interactions, generating domain-swapped dimmers (II). Stabilizing mutations in the linker region allow stable dimers (III) to be formed [56]. (B) β-crystallin dimer (thin line) as potential product of swapped domains of γ-crystallin (thick line) (adapted from Ref. [11]).

of protein dimerization and oligomerization, it can be applied only in a limited number of cases. It cannot explain hetero-oligomerization of subunits encoded by widely differing genes as these subunits do not share a common inter-domain interface or different parallel routes of dimerization, as shown for bovine seminal ribonuclease, which exists in both a domain-swapped and a non-swapped dimeric form [65, 66].

2.3.4 Stability of Oligomeric Proteins

The laws of thermodynamics require that association equilibria be shifted towards the dissociated state at low protein concentrations. Indeed, for several oligomers it has been shown that the dissociation constants of dimerization are in the nanomolar to micromolar range, and thus the dissociation can be achieved directly by dilu-

tion experiments. Examples are phosphofructokinase [67], dimeric Arc repressor [68], Hsp33 [63], and yeast hexokinase [69, 70]. In some cases this association equilibrium is functionally and physiologically relevant. Dimeric Hsp33 is active as a molecular chaperone, whereas the monomeric form is less active or non-active [63, 71]. The K_D describing the monomer-dimer equilibrium is in the range of the physiological concentration of Hsp33 in *E. coli* [63]. In the case of yeast hexokinase, the monomeric state of the protein is less active than the dimeric form. Interestingly, the dimerization is favored in the presence of the substrate glucose [69].

Most oligomeric proteins, however, dissociate only at concentrations too low to observe dissociation by mere dilution [1]. This finding suggests that subunit interactions account for a large fraction of the conformational stability of oligomeric proteins; sub-nanomolar dissociation equilibrium constants for dimerization correspond to standard free energy changes of >50 kJ mol^{-1}. In such cases, dissociation is achievable only by denaturation. Whereas the denaturant-induced equilibrium transition of denaturation of monomeric proteins is independent of the protein concentration, the midpoint of transition of oligomeric proteins varies with protein concentration. In the simplest case of a reversibly denaturing dimeric protein, this transition can be ascribed to the reaction $N_2 \leftrightarrow 2U$. The linear extrapolation method, used for analysis of the transition (cf. Chapter 3 in Part I), yields a straight line with a slope depending on the protein concentration used (Figure 2.6). These lines describing the denaturation transition at different protein concentrations will

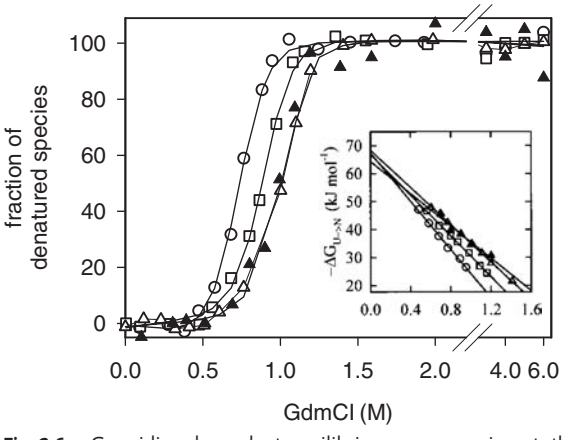

Fig. 2.6. Guanidine-dependent equilibrium transitions of the dimeric antibody domain CH3. Samples were incubated for six days at 20 °C in 0.1 M Tris-HCl (pH 8.0) and varying GdmCl concentrations. For the fluorescence measurements the excitation wavelength was set to 280 nm and emission was analyzed at 355 nm. The CH3 dimer concentrations were 0.2 μM (open circles), 1.6 μM (open squares), and 4.1 μM (open triangles). For the CD experiment, the ellipticity was recorded at 213 nm (filled triangles) at a protein concentration of 4.1 μM. All measurements were carried out at 20 °C. Inset: From the transitions, the stability ΔG could be calculated at the respective GdmCl concentrations. These ΔG values were plotted against the respective GdmCl concentration and linear extrapolated to 0 M GdmCl [42].

intersect the y-axis at the same value that corresponds to the stability of the dimeric native state in the absence of denaturant [72].

Oligomeric states often are not only thermodynamically stable but also kinetically stabilized, i.e., the activation energy of dissociation under native conditions is very high. Dissociation rates in denaturant-free buffer have been estimated by extrapolation to be as low as 10^{-14} s^{-1} [73].

2.3.5 Methods Probing Folding/Association

The reconstitution of oligomeric proteins comprises folding of subunits and their association. Therefore, all methods suited to analyze folding of proteins and domains can be applied to oligomeric proteins as well (cf. Table 2.1). In the following section, only methods that detect association reactions are discussed. In using these methods, one should be very careful, because these techniques do not always distinguish between specific association and unspecific aggregation. The latter, however, will often be found to compete with proper refolding and association.

2.3.5.1 Chemical Cross-linking

Highly reactive bifunctional chemicals can be used to covalently cross-link subunits of an oligomeric structure with each other. In the case that cross-linking proceeds much faster than oligomerization, it is possible to get time-resolved information of the association reaction by cross-linking aliquots of the reaction at different time points. The amount of cross-linked oligomers can subsequently be analyzed on SDS-PAGE. Glutaraldehyde has been shown to be ideally suited as a cross-linker for several reasons. It forms a Schiff base with lysine side chains, which are usually located on the surface of a folded subunit. The reaction is very fast and efficient. It is not dependent on a specific distance between two lysine residues because glutaraldehyde exists in differently polymerized forms in aqueous solutions; therefore, the distance between the two reactive aldehyde groups of glutaraldehyde varies with its polymerization state. For a given protein, the glutaraldehyde concentration, reaction time, temperature, and protein concentration need to be optimized in order to guarantee that non-associated subunits are not cross-linked artificially. A protocol for glutaraldehyde cross-linking is given in the Appendix.

2.3.5.2 Analytical Gel Filtration Chromatography

Gel filtration is a standard technique to determine the molecular mass of proteins. Using it for kinetic analyses of association, however, poses problems. Gel filtration is a comparatively slow method; the time resolution of kinetic measurement will therefore be low. The protein analyzed will be diluted on the column, thus shifting a possible association equilibrium towards the dissociated species. Only if the dissociation of the oligomer is much slower than the time it takes to carry out the gel-filtration chromatography will significant results be obtained (the rate of dissociation might be slowed down by cooling the column). Gel-filtration chromatography

has been used successfully to characterize, among others, the reconstitution of β-galactosidase [74], P22 tail spike protein [75], and an antibody Fab fragment [76].

2.3.5.3 Scattering Methods

Light scattering, small-angle X-ray scattering, and neutron scattering provide information on particle size and shape. They can be used online without the necessity of taking aliquots during reconstitution for analysis. However, scattering methods need high protein concentrations (small-angle X-ray and neutron scattering, several milligrams per milliliter; light scattering, depending on the size of the oligomer, not less than 0.1 mg mL^{-1}). At these high protein concentrations, unspecific aggregation is often favored over correct reconstitution. Light scattering has been used predominantly to monitor formation of large assemblies such as viruses or protein filaments. More often it is used as a method to follow aggregation [77, 78].

2.3.5.4 Fluorescence Resonance Energy Transfer

Fluorescence resonance energy transfer (FRET) can be measured if the emission spectrum of a fluorophore overlaps with the absorption spectrum of another fluorophore. Then the energy of the excited donor fluorophore will not be emitted as fluorescence but will be transferred to the acceptor fluorophore. In this setup, the donor fluorophore will be excited and the fluorescence of the acceptor is measured. The transfer efficiency is inversely proportional to the sixth power of the distance between the two fluorophores, thus permitting measurement of distances within proteins [79] and monitoring of protein complex formation [80]. FRET measurements have to be carefully controlled. The fluorescence dyes that are coupled to the respective subunits are bulky hydrophobic chromophores and might induce association or aggregation of the coupled proteins artificially.

The FRET technique has become increasingly important to study protein-protein interaction in the cellular context. To this end, the proteins in question are fused to different variants of the green fluorescent protein, e.g., BFP and GFP. If these fusion proteins associate in vivo, FRET can be observed and quantified by fluorescence microscopy.

2.3.5.5 Hybrid Formation

The concentration of unassembled subunits can be measured by their ability to form hybrid oligomers. Originally, the technique used a large excess of chemically modified or isoenzyme subunits added after varied reconstitution time to trap unassembled subunits [81–84]. Problems such as slow folding of added subunits and preferential formation of homo-oligomers are associated with this approach. More-reliable data may be obtained with naturally occurring or site-directed mutant proteins with altered net charge but unaffected folding and association kinetics [37, 75, 85]. The technique may be illustrated using the trimeric tail spike protein from phage P22. Wild-type and mutant tail spikes with altered charge were separately denatured by urea at pH 3. Subsequently, both proteins were diluted separately into neutral buffer to remove the denaturants and start refolding. After dif-

ferent times, aliquots from both solutions were mixed, reconstitution of native trimers was allowed to reach completion, and the differently charged hybrids and homo-oligomers were separated by electrophoresis [75]. In samples mixed early during renaturation, wild-type homotrimers, hybrids, and mutant homotrimers formed at the statistically expected ratio of 1:2:2:1, whereas in samples mixed late, only homo-oligomers were detected. The half-time of assembly can be estimated from the amount of hybrid present in samples mixed at intermediate renaturation times.

It should be noted that hybrid formation measures only stably associated protomers; those in rapid exchange between loosely associated oligomers will be equivalent to free subunits.

2.3.6 Kinetics of Folding and Association

2.3.6.1 General Considerations

The reconstitution of oligomeric proteins from the denatured state generally constitutes a series of uni- and bimolecular steps. For a dimeric protein, reconstitution involves the following steps (neglecting possible off-pathway side reactions):

$$2U \rightarrow 2M \rightarrow M_2 \rightarrow N_2$$

where U is the denatured state. M represents a folded monomer, M_2 a nonnative dimer, and N_2 the native dimer. The folding reactions preceding subunit assembly are identical to those of single-domain or multi-domain proteins. They consist of a hydrophobic collapse, formation of secondary structure, and the merging of domains, leading to association-competent monomers. As in the case of monomeric proteins, these reactions may occur as sequential or parallel reactions on multiple pathways [86, 87]. All these reactions follow first-order kinetics and do not depend on protein concentration. In contrast, the association of subunits ($2M \rightarrow M_2$) is a bimolecular and therefore probably a second-order reaction. Subsequently, the dimer may need to undergo further unimolecular rearrangements to reach the final native state ($M_2 \rightarrow N_2$).

The assembly of larger oligomers can be described accordingly as a series of multiple uni- and bimolecular steps. The assembly of a homotrimer is expected to proceed via a dimeric intermediate:

$$3M \leftrightarrow M_2 + M \rightarrow M_3$$

In this reaction scheme, the first association resulting in a dimer, in which only one of two interfaces is buried, is considered a fast equilibrium. This first association step is unfavorable and the dimeric intermediate is not populated in equilibrium. The second association step will pull this equilibrium towards the native trimeric state. In this concept, the overall process follows apparent third-order kinetics [84].

A tetramer may be envisioned as a dimer of dimers. Thus, the scheme for this reaction is just an extension of that shown for a dimeric protein [1, 88]:

$$4U \rightarrow 4M \rightarrow 2M'_2 \rightarrow 2M_2 \rightarrow M_4 \rightarrow N_4$$

In the case of multimers such as fibrillary proteins or virus capsids, the simplest model comprises a stepwise addition of monomers to the growing chain:

$$2A \leftrightarrow A_2, A_2 + A \leftrightarrow A_3, A_3 + A \leftrightarrow A_4, \ldots$$

In this scheme the equilibrium constants of association may be all identical. However, the first steps of multimerization are often thermodynamically disfavored, i.e., the equilibrium is on the side of the non-associated species. Only after reaching a certain size of the oligomer structure does further addition of monomers to this nucleus become thermodynamically favorable. This would lead to an overall assembly process characterized by a nucleation/polymerization reaction.

2.3.6.2 **Reconstitution Intermediates**

Because the half-time of association is concentration-dependent, the nature of the rate-limiting step of reconstitution of oligomeric proteins may change with protein concentration [1]. At high protein concentrations, the formation of association-competent subunits is rate-limiting; at low protein concentrations, dimerization is rate-limiting, and the overall reaction follows second-order kinetics. Under these conditions, highly structured, association-competent subunits often are populated kinetically during refolding/assembly.

Such intermediates can be observed spectroscopically. In general, secondary structure as monitored by far-UV circular dichroism is formed quickly upon folding/association. Furthermore, the secondary structural content of the folded subunits does not change significantly upon subsequent association. Thus, the change in CD signal follows first-order kinetics, reaching the signal of the native protein as subunit folding is completed. In contrast, if reconstitution is analyzed by reactivation, i.e., regain of enzyme activity, no reactivation is observed during subunit folding provided that the non-associated subunits do not possess enzyme activity by themselves. The folding of the subunits results in a lag-phase in regain of activity; reactivation occurs upon association. Thus, the overall reactivation is described by a uni-bimolecular process that follows a sigmoidal time course, with the lag-phase determined by first-order subunit folding (Figure 2.7) [89].

Another method often used to analyze protein folding is fluorescence. However, whereas circular dichroism monitors secondary structure formation almost exclusively on the subunit level and, in most cases, enzymatic activity corresponds to the native state after assembly, fluorescence may detect both subunit folding and association, depending on the localization of the fluorophores in the quaternary structure. Therefore, the interpretation of fluorescence data might be more difficult. On the other hand it allows the detection of the association process even if the protein is enzymatically inactive.

In some cases the folded but non-associated subunit already shows ligand bind-

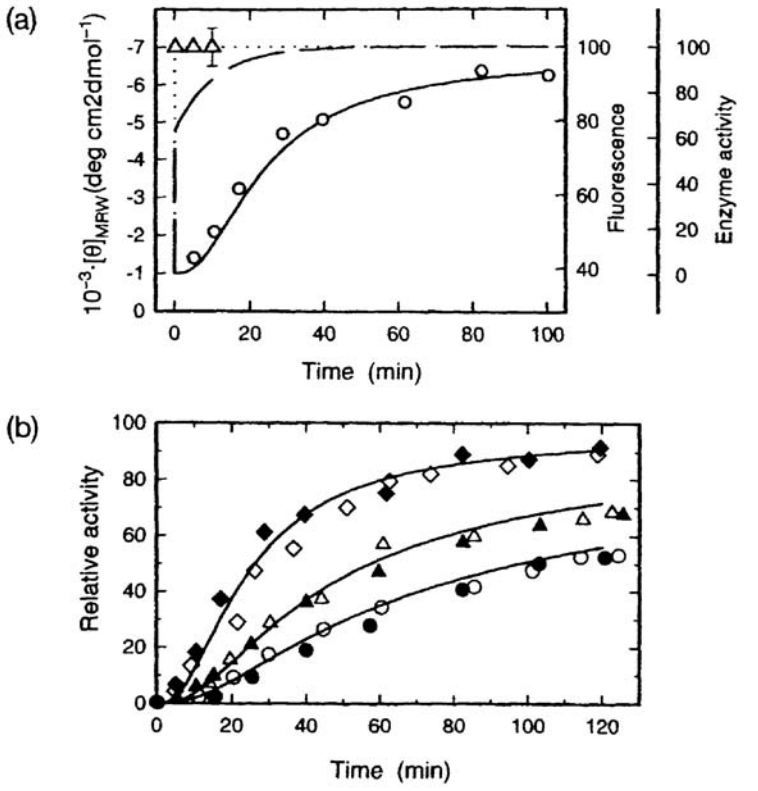

Fig. 2.7. Folding and association pathway of yeast invertase. (a) Changes in circular dichroism (open triangles), fluorescence emission (broken line), and enzymatic activity (open circles) occur with very different kinetics during the reconstitution of homodimeric yeast invertase. (b) The first-order folding rate obtained from the fluorescence change can be used to fit a sequential uni-bimolecular mode to the reactivation data obtained at different protein concentrations (full lines). Subunit concentrations were 8.5 nM (circles), 17 nM (triangles), and 68 nM (diamonds) [89].

ing or partial enzyme activity. Examples are mammalian aldolases [90], lactate dehydrogenase [91], the P22 tail spike protein [92], and yeast hexokinases [69, 70].

Monomeric folding intermediates of oligomeric proteins often possess large interfaces for subunit association. This subunit interaction is quite similar to the domain-domain interactions in multi-domain proteins. As shown before for γ-crystallin, the association can contribute substantially to the overall stability of the subunits. Thus, it is not surprising that folded subunits usually are not detectable as equilibrium unfolding intermediates if the native protein is subjected to high temperature or chemical denaturants [1, 88]. Structured monomers of lactate dehydrogenase have been obtained at low pH in the presence of the stabilizing salt sodium sulfate [93–95]. Another possibility to obtain stably folded monomeric subunits is based on protein engineering, as has been demonstrated for triose phos-

phate isomerase [96, 97], tetrameric human aldolase [98], and P22 tail spike protein [92]. In all these cases the engineered monomeric form retained some enzyme activity, but, as expected, the variants were strongly destabilized compared to the oligomeric wild-type form.

2.3.6.3 Rates of Association

The maximum rate of association of two molecules is determined by their random diffusional collision. For a common protein domain, this limit is about 10^9 M^{-1} s^{-1} [99]. Indeed, this limit is reached in the binding of chaperones to their substrate proteins. Chaperones recognize a wide variety of substrate proteins mainly by hydrophobic interactions. Since these interactions do not need a pre-orientation of chaperone and substrate, most of the diffusional collisions result in complex formation. However, this is quite different for the specific association of folded subunits. Here, the pre-formed interfaces require an exact rotational alignment for association, and this reduces the diffusion-controlled rate by several orders of magnitude. Brownian dynamics simulations estimate the rate of association of model proteins to be 10^6 M^{-1} s^{-1} [100]. Most second-order rate constants determined experimentally are even smaller (Table 2.2). There are, however, two examples published—the core domain of trp repressor and the arc repressor—that show faster dimerization than expected (Table 2.2) [101, 102]. In both cases folding is tightly coupled to association; the association-competent monomers are only partially structured.

2.3.6.4 Homo- Versus Heterodimerization

The molecular interaction of subunits in oligomers can be considered as specific as the formation of the hydrophobic core of a protein. The structure of a protein or subunit determines the kinetic and thermodynamic characteristics of its interaction with other molecules. Therefore, a competition between homo- and heterodimerization is expected only if the different subunits of the oligomer are highly homologous.

Tab. 2.2. Rates of association of some oligomeric proteins.

Protein	*Subunit mass (kDa)*	*Reaction*	*k (M^{-1} s^{-1})*	*Reference*
Triosephosphate isomerase	27	2M → D	3×10^5	1
Malate dehydrogenase (mitochondrial)	33	2M → D	3×10^4	1
Invertase	76	2M → D	1×10^4	89
β-Galactosidase	116	2M → D	4×10^3	74
Alcohol dehydrogenase (liver)	40	2M → D	2×10^3	1
Phosphoglycerate mutase	27	2M → D	6×10^3	103
		2D → T	3×0^4	103
Lactate dehydrogenase	36	2D → T	2×10^4	1
Arc repressor	62	2M → D	1×10^7	102
Trp aporepressor	12	2M → D	3×10^8	101

The most prominent example of such a competition is the reconstitution of heterodimeric bacterial luciferase from *Vibrio harveyi*. The two subunits consisting of a $(\beta\alpha)_8$ barrel are structurally homologous and probably result from gene duplication [104]. The association is mediated by two helices from each subunit forming a four-helix bundle at the contact site [105, 106]. The reconstitution of luciferase from the urea-denatured state is fully reversible. It comprises as rate-limiting steps the folding of the subunits on the monomeric level, the association of the subunits to an inactive heterodimer (at low protein concentrations), and a conformational rearrangement on the dimeric level leading to the native state [107–110]. As shown by far-UV circular dichroism, the inactive dimer seems to be incompletely folded.

Whereas the reconstitution of luciferase is quantitative if the subunits are refolded together, refolding of the subunits separately with a subsequent assembly does not lead to active heterodimer [107, 111]. In a detailed study, it could be shown that active heterodimeric luciferase can be assembled upon folding of the β-subunit in the presence of the pre-folded α-subunit, but not vice versa [73]. In the absence of the α-subunit, the β-subunit forms a homodimer that is almost as stable thermodynamically as the heterodimer. Furthermore, the β_2 homodimer is kinetically very stable, and under native conditions the dissociation does not occur on a biological or experimental timescale [73].

Upon reconstitution, the association of the β_2 homodimer and the $\alpha\beta$ heterodimer compete with each other. The almost exclusive formation of the heterodimer is due to the kinetics of association: the rate of heterodimerization is more than tenfold higher than that of the β_2 homodimerization. The structures of the homo- and heterodimer are almost identical regarding the contacts within the interfaces; most of the inter-subunit hydrogen bonds and water-mediated contacts are conserved between the two dimers [105, 106]. Thus, from the structural point of view, there is no obvious explanation for the different association kinetics of homo- and heterodimeric luciferase.

Mammalian lactate dehydrogenase (LDH) may serve as another example of the competition of homo- and hetero-oligomerization. LDH is a tetrameric protein that exists in two homomeric variants: in skeletal muscle (LDH-M_4) and in the heart (LDH-H_4). If these two isoforms are reconstituted together from the denatured monomers, the product is not only the two homomeric tetramers M_4 and H_4 but also all types of hybrids. Even more surprising, the distribution of all the variants fits to a statistical process, e.g., the ratio of M_4, M_3H_1, M_2H_2, M_1H_3, and H_4 is 1:4:6:4:1 [1, 94]. The beauty of this system is that it can be used to analyze the two different association steps upon reconstitution; at different time points of the reconstitution of LDH-M_4, an excess of LDH-H subunits can be added to the reaction. From the ratios of the hybrids reconstituted after addition of LDH-H subunits to the refolding LDH-M, the amount of monomeric, dimeric, and tetrameric M-subunits can be calculated [94].

Distinguishing homo- from hetero-oligomers is not always a simple matter, because in order to obtain competition of homo- and hetero-oligomerization, the subunits have to be highly homologous. The different hybrids of LDH could be separated by native electrophoresis, and in the case of luciferase the two subunits show

different pI values, allowing a separation of the different subunits by ion-exchange chromatography [109]. Furthermore, enzymatic activity or varying stability of the different species may be used to distinguish between homo- and hetero-oligomers.

2.4 Renaturation versus Aggregation

Folding and association of multi-domain and oligomeric proteins are complex processes involving partially structured folding intermediates. These processes can be accompanied by nonspecific side reactions leading to aggregation. The molecular basis for aggregation is that intermediates in refolding/reassembly may engage in wrong intermolecular rather than in correct intramolecular or assembly interactions. Thus, aggregation is at least a second-order or even higher-order reaction, depending strongly on the concentration of folding intermediates [112, 113]. Therefore, the kinetic partitioning between folding and aggregation favors aggregation at high protein concentrations. In contrast, at low protein concentrations, folding dominates over aggregation (Figure 2.8).

Using reduced lysozyme as a model system, it could be shown that commitment to aggregation is a fast reaction preceding the commitment to renaturation; early folding intermediates were especially prone to aggregation [114]. After a certain intermediate state is reached, slow conformational changes lead exclusively to the native state (Scheme 2.1 [114]).

As shown by circular dichroism and Fourier transform infrared spectroscopy (FTIR), aggregated proteins possess a high content of secondary structure and probably of native-like structured protein domains [115, 116].

Aggregation is not an artifact of in vitro refolding; the same phenomenon occurs in vivo. It is especially obvious in the case of inclusion body formation upon high-level expression of recombinant proteins in microorganisms and the accumulation of fibrillary aggregates in human diseases [115–118]. Cells have developed a set of chaperones and folding catalysts to deal with aggregation. These two protein classes are discussed in detail in several chapters of this book.

2.5 Case Studies on Protein Folding and Association

2.5.1 Antibody Fragments

Antibodies are hetero-oligomeric proteins consisting of two light chains and two heavy chains. These four polypeptides are covalently linked by several disulfide bonds. The light chain consists of two domains and the heavy chain of four domains, with each domain adopting a typical immunoglobulin-like topology of a two-sheeted β structure. Folding of these domains has been shown to be a highly

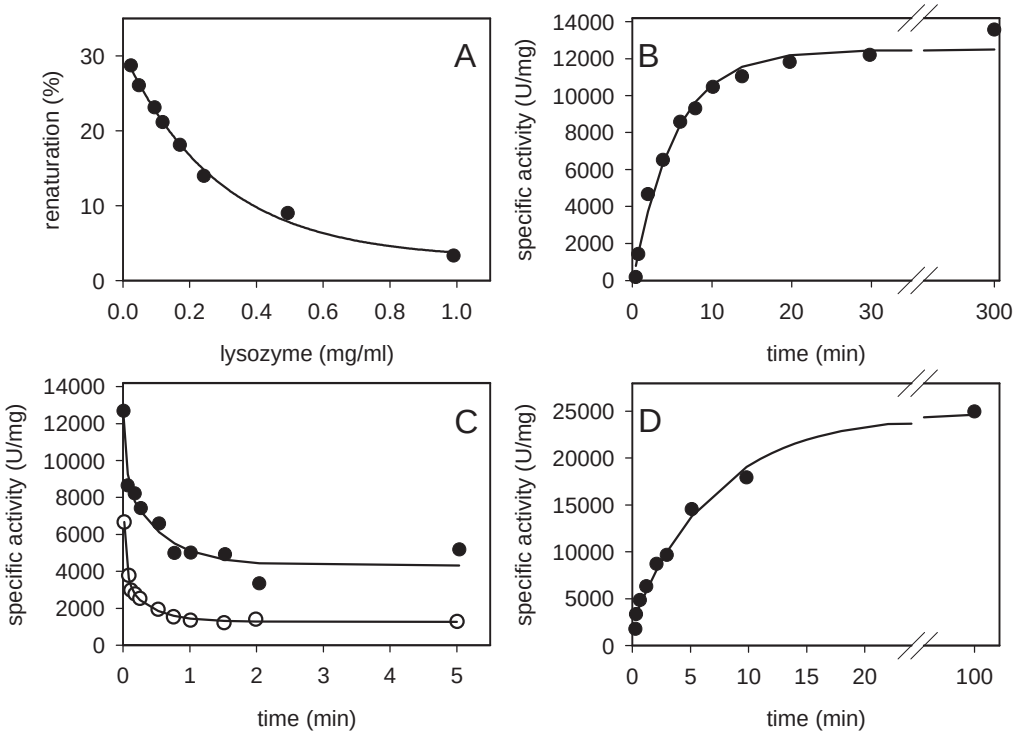

Fig. 2.8. Folding and aggregation of reduced lysozyme. (A) Yield of enzymatic activity as a function of turkey lysozyme concentration during oxidative refolding. (B) Kinetics of reactivation of turkey lysozyme. (C) Kinetics of commitment of aggregation of denatured and reduced lysozyme. Starting protein concentration for renaturation was 0.185 mg mL^{-1} (●) and 0.74 mg mL^{-1} (○). At different time points of renaturation, the samples were further diluted 10-fold and incubated overnight. (D) Kinetics of commitment of renaturation. Renaturation was performed with denatured and reduced turkey lysozyme. At different time points, a high concentration of denatured and reduced hen lysozyme was added. After completion of renaturation, the activity of turkey lysozyme was determined (adapted from Ref. [114]).

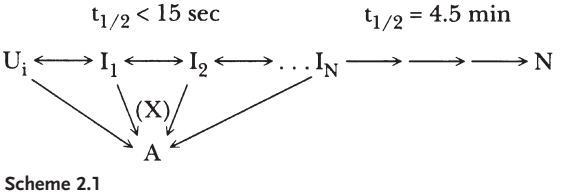
cooperative and reversible process involving an intermediate with already native-like secondary structure [119, 120].

The two antibody domains of the light chain (κ-type) and the C_H1 and C_H3 domain of the heavy chain (γ1-type) contain conserved *cis*-prolines. In the denatured



Scheme 2.1

state (depending on the denaturation time) equilibration between the *cis* and *trans* configuration occurs. Since the two configurations are separated by a high-energy barrier, re-isomerization is a slow process. This is reflected by an additional slow folding phase observed during refolding [119] that can be accelerated by prolyl isomerases [121, 122]. As soon as immunoglobulin domains are covalently linked, as in the case of the immunoglobulin light chain, which is composed of two domains, an additional slow folding phase is detected that may be due to interactions of the individual domains [120]. An additional level of complexity is observed in the case of the antibody Fab fragment, which consists of the light chain and the two N-terminal domains of the heavy chains, the Fd fragment (Figure 2.9). The two polypeptide chains associate noncovalently via contact sites between both the variable domains and the constant domains of each chain. Precise assembly of the two

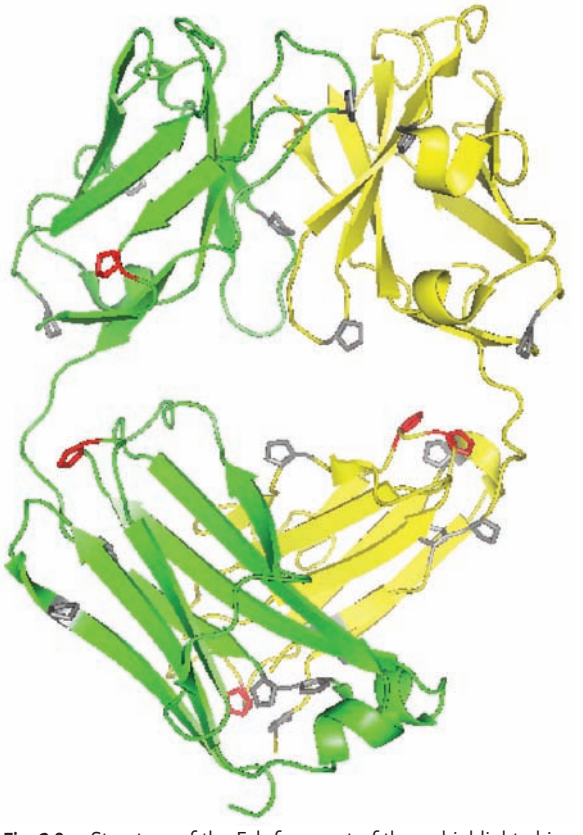


Fig. 2.9. Structure of the Fab fragment of the monoclonal antibody MAK33 (κ/IgG1) (pdb: 1FHE5, [123]). The light chain and the Fd chain are colored in green and yellow, respectively. Proline residues in *trans* configuration are highlighted in gray, those in *cis* configuration in red. The intermolecular disulfide bond connecting the C-terminus of the two chains is not resolved in the structure.

chains is required for antigen-binding activity [124, 125]. Furthermore, a disulfide bond connects the C-terminal domains of both chains covalently.

Despite this molecular complexity, the regain of antigen-binding activity of a Fab fragment, measured by ELISA, follows simple first-order kinetics [76, 122]. Spectroscopic analyses, however, reveal a complex folding behavior, which is expected for a multi-domain protein. The Fab fragment contains 22 prolyl residues, five of them in the *cis* configuration in the native state. Hence, upon refolding all these prolines need to isomerize to their native peptide bond configuration; this reaction dominates the overall folding process. Consequently, as described for the single-antibody domains, the folding of the Fab fragment can be catalyzed by peptidyl-prolyl-*cis*/*trans* isomerases [122]. A detailed description of peptidyl-prolyl-*cis*/*trans* isomerases and their effect on protein folding is given in Chapter 27 of this book.

If the disulfide between the two chains of the Fab fragment is deleted (with the remaining intra-domain disulfides still intact), then the reconstitution comprises both folding of the four domains and association of the two subunits. In this case, the regain of antigen-binding activity follows a sigmoidal time course (Figure 2.10). The kinetics of reconstitution does not depend on protein concentration, indicating that the association of the subunits is not rate-limiting [76]. Instead, the reconstitution process can be described by a serial first-order reaction with one of the phases identical to the proline-determined refolding of the disulfide-bonded Fab described before ($k = 0.04$ min^{-1}, Scheme 2.2). The other phase describes the slow formation of an association-competent state of the light chain.

It is known that structure formation of the two domains of the light chain is a fast process compared to the overall folding/reconstitution of the whole Fab frag-

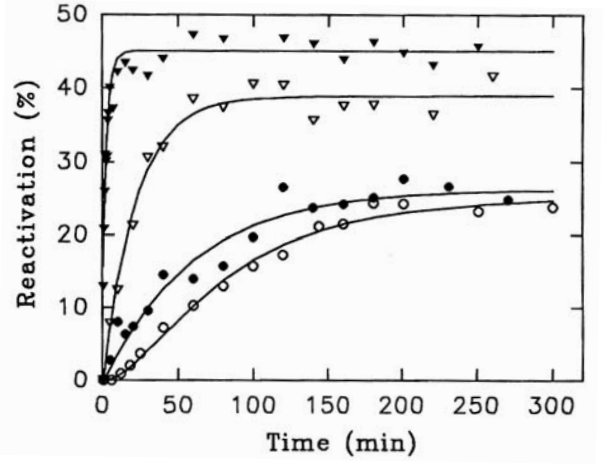

Fig. 2.10. Folding of Fab, not containing the C-terminal disulfide bond between the two chains. Refolding was achieved by diluting the denatured protein into 0.1 M Tris, pH 8, either starting from a long-term denatured protein in the absence (○) or presence (▽) of a fivefold molar excess of native light chain or starting from short-term denatured protein in the absence (●) or presence (▼) of a fivefold molar excess of native light chain. The data were fitted to a single first-order or a serial first-order reaction [76].

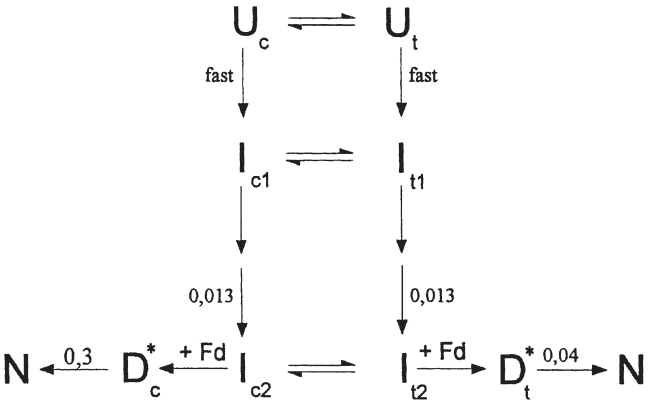

Scheme 2.2. Folding/reconstitution of the non-disulfide-bonded Fab fragment. *U* and *N* donate the denatured and the native state of the Fab fragment. *Fd* marks the position at which the association of light chain and Fd along the reconstitution pathway takes place. *D* describes an intermediate of associated light chain and Fd fragment, and *I* represents non-associated folding intermediates. The subscribed *c* and *t* reflect the *cis* and *trans* configuration of the rate-limiting proline peptide bond, respectively. The values given at two of the arrows indicate the rate constants (min^{-1}) of the respective reactions (adapted from Ref. [76]).

ment, even though folding of the light chain itself is limited by prolyl isomerization [121]. If the prolyl isomerization is catalyzed (or excluded from the folding/assembly reaction by short-term denaturation), the time course of reconstitution of the Fab fragment switches from a sigmoidal to a monophasic first-order kinetic; prolyl isomerization is not rate-limiting anymore. The yield of reconstitution does not change. The yield is determined by aggregation of the Fd fragment. Because peptidyl-prolyl-*cis*/*trans* isomerases catalyze the rate-limiting step occurring after subunit association of the Fab fragment, they do not effect the kinetic competition of off-pathway aggregation and productive reconstitution.

The situation changes if the Fab reconstitution is performed in the presence of an excess of native light chain. Under these conditions, the rate-limiting step before subunit association vanishes, and the regain of Fab activity becomes identical to the prolyl isomerization-determined folding of the Fab fragment, in which the two chains are disulfide-linked. This shows that (1) the rate-limiting step of reconstitution on the monomeric level is the folding of the light chain, presumably corresponding to a specific intramolecular pairing of the two folded domains [120], and (2) the rate-limiting prolyl isomerization on the level of the already associated subunits occurs in the Fd part of the Fab fragment (Scheme 2.2).

The folding/reconstitution of the disulfide-bonded and the non-disulfide-bonded Fab fragment comprise domain folding and domain interactions that are identical on the molecular level; however, in one case the domain pairing occurs intramolecularly, in the other case intermolecularly. The rate-limiting folding of the light chain can be observed only for the non-disulfide-bonded Fab fragment, clearly in-

dicating that in the disulfide-bonded form the folding of the light chain is intramolecularly chaperoned by the nearby Fd part of the Fab fragment. On the other hand, the reconstitution of the non-disulfide-bonded Fab shows that the isomerization of at least one prolyl residue of the Fd part obligatorily occurs only after subunit association. Thus, only the association with the folded light chain provides the structural information for the isomerization state of the respective proline in the Fd part. This is an intriguing example of how folding and association of subunits are interrelated.

Whereas in the case of the Fab fragment the association of the two polypeptides precedes prolyl isomerization, it is different for the antibody domain C_H3. The isolated C_H3 domain forms a dimer. Under conditions where prolyl isomerization does not contribute to the folding kinetics, formation of the β-sandwich structure is a slow process, even compared to other antibody domains, while the subsequent association of the folded monomers is fast. After long-term denaturation, the majority of the unfolded C_H3 molecules reach the native state in two serial reactions involving the re-isomerization of one proline bond to the *cis*-configuration. The folded species with the wrong isomer accumulates as a monomeric intermediate; the proline isomerization is a prerequisite for dimerization of the C_H3 domain [42].

2.5.2 Trimeric Tail spike Protein of Bacteriophage P22

The tail spike protein (TSP) of bacteriophage P22 from *Salmonella typhimurium* has been a paradigm in studying protein folding and association in vivo since Jonathan King's early attempts to solve the problem of phage morphogenesis by genetic methods [126–130]. The beauty of both the system and the approach is that it has provided insight not only into the principles of protein self-organization in the cytoplasm but also into the mechanisms of misfolding, aggregation, and inclusion body formation [85, 115, 131–134]. It has been shown that in vitro reconstitution is clearly related to the situation in the living cell [115, 132].

The tail spike is a multifunctional trimeric protein composed of identical 72-kDa polypeptide chains, attached to the viral capsid by their 108-residue N-terminal domain. Six of these trimers assemble onto the virus head to form the tail, completing the infectious phase of the phage. In the absence of heads, tail spikes accumulate as soluble protein in the bacterial cytosol. Their assembly and the competing formation of inclusion bodies at high temperature have been studied in detail using temperature-sensitive (*ts*) mutants. In this connection, the assembly of viable phage was used as an in vitro assay for proper folding. Other means to follow the folding and assembly pathway of TSP, in addition to spectroscopic and hydrodynamic techniques, are its endorhamnosidase activity (directed toward the *O*-antigen of the host), its reactivity with monoclonal antibodies, and the thermal stability and detergent-resistance of the mature protein.

Crystal structures of wild-type TSP and mutant variants of the protein have been determined at high resolution [135, 136]. The major part of the trimer represents a

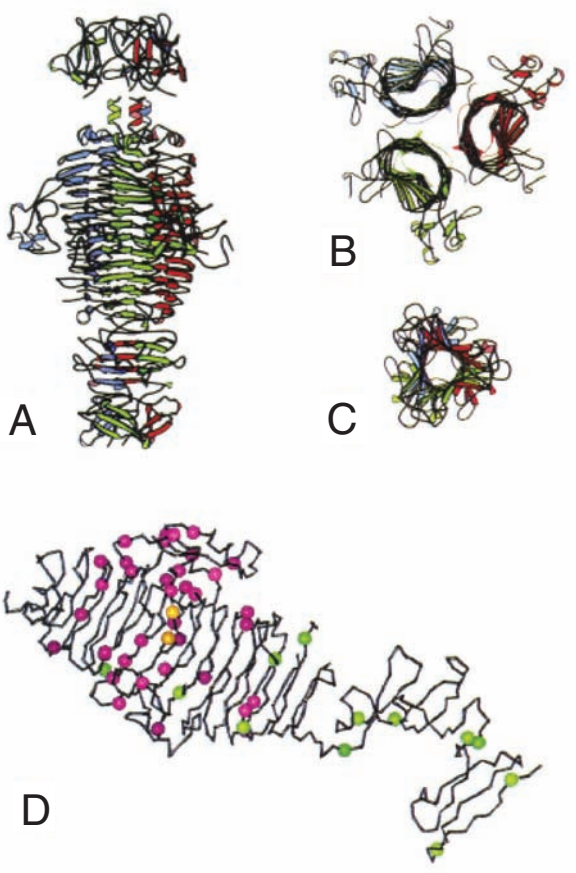

Fig. 2.11. Structure of the tail spike protein (TSP) from *Salmonella* bacteriophage P22. (A) TSP trimer assembled from the structures of the N-terminal (above) and C-terminal (below) fragments [136]. (B) Section through the parallel β-helix in the central domain of the trimer. (C) Section through the C-terminal domain where the subunits form mixed β-sheets. (D) Single TSP subunit with sites of *tsf* mutations in the main body and in the "dorsal fin" (red), sites of global suppressors of the *tsf* phenotype in the central part of the β-helix (yellow), and sites of lethal mutations (green) [134, 135].

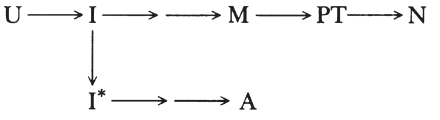
perfect right-handed parallel beta-helix; the side-by-side association of the single polypeptide chains is illustrated in Figure 2.11. Evidently, this part of the molecule can fold separately in the subunits, whereas the interdigitated C-terminal part (Figure 2.11) can be formed only after subunit association.

The native TSP trimer in the absence of denaturants is stable up to temperatures well above 80 °C. However, there are numerous point mutations that prevent phage proliferation at the much lower temperature of 40 °C. Interestingly, the *ts* mutations do not affect protein synthesis, and the mutant proteins are perfectly

stable and biologically active at 40 °C, once synthesized and assembled at lower temperature. However, after expression at the restrictive temperature, they are inactive and react with antibodies specific for the denatured protein. Thus, they have been coined "temperature-sensitive for folding" mutants (*tsf*). A second class of mutants represents global intragenic suppressors (*su*) of the *tsf* phenotype, showing an increase in the yield of correctly folded and assembled TSP at high temperature at the expense of ligand-binding affinity or thermal stability of the native state [131, 132, 137]. Figure 2.11 shows that all these mutations are located in the parallel beta-helix domain and the associated "dorsal fin domain" of the fishlike structure. From the point of view of the folding mechanism, this means that these parts of the polypeptide chain must acquire a native-like conformation at an early stage of the folding pathway [133, 135, 138].

The mechanism shown in Scheme 2.3 describes the folding and association of TSP, starting from the unfolded (or nascent) polypeptide chains (U):



Scheme 2.3

I represents a loosely folded conformation exhibiting native-like secondary and tertiary structure, but it is still quite thermolabile and susceptible to misfolding ($I \rightarrow I^*$) and subsequent irreversible aggregation ($I^* \rightarrow A$); this pathway is preferred at high temperature. At low temperature, polypeptide chains end up in the native trimer (*N*) via the "structured monomer" (*M*). Folding mutations affect the thermal stability of the intermediate (*tsf* mutations destabilizing and *tsf* suppressor mutations stabilizing *I*), thus altering the partitioning between the two pathways. In *M*, the β-helix is preformed in a native-like conformation [92, 133, 138]. Subunit assembly then leads to the incompletely folded, metastable "protrimer" (PT) in which the polypeptides are stably associated but still incompletely folded (i.e., prone to proteolysis and SDS denaturation) [139]. Because PT formation is independent of protein concentration, a unimolecular isomerization reaction must be rate-limiting [85]. The "maturation" of the trimer, in which the protein acquires the high thermal stability and SDS resistance of the native protein, is associated with a high activation energy and occurs with identical rates both in vitro and in vivo [37, 139]. Thus, the reconstitution from unfolded polypeptide chains may be considered a valid model for the self-assembly of the tail spike part of the phage in its host, supporting the conclusion that neither codon frequencies nor co-translational reactions can play a significant role in this part of the phage morphogenesis.

The folding and assembly of TSP confirm the general observation that misfolding and irreversible aggregation are intimately related in the sense that at high pro-

tein concentrations, kinetic competition of folding and association occurs. In the case of TSP, decreasing the stability of an on-pathway intermediate by mutation or high temperature leads to accumulation of less-structured or misfolded conformations that aggregate at a faster rate.

As TSP has been the paradigm for folding studies in vitro and in vivo, this might be the right place to consider briefly the significance of chaperones on the above reconstitution reactions. Incompletely folded TSP chains can be trapped on the *E. coli* chaperonin GroEL in the absence of ATP. However, even an excess of GroEL/GroES increases the yield of TSP reconstitution only marginally at temperatures higher than 30 °C [140]. Overexpression of the chaperone system in *Salmonella* does not suppress *tsf* mutations [141, 142]. On recombinant expression in *E. coli*, TSP mutants impaired in folding or assembly are proteolyzed more rapidly when GroE is simultaneously overexpressed, thereby preventing aggregation of TSP in inclusion bodies [134]. The irreversible aggregation reaction itself has been studied by initiating refolding at intermediate denaturant concentrations at which a large fraction of refolding proteins can be induced to aggregate at low temperature [93, 115, 132, 143, 144]. The misassembly process can be described as a nucleated linear polymerization reaction involving partially folded or misfolded rather than fully unfolded polypeptide chains. It is specific so that TSP does not form mixed aggregates with other proteins (e.g., P22 coat protein), in agreement with the observation that overexpression or heterologous expression of proteins in bacteria commonly leads to inclusion bodies consisting of a single or very few polypeptide species [145].

2.6 Experimental Protocols

Protocol 1: Monitoring Aggregation by Light Scattering

1. Place a stirrable cuvette with the appropriate renaturation buffer in a fluorometer or photometer and adjust the temperature.
2. Set the excitation and emission wavelength to 500 nm. At this wavelength neither protein nor buffer shows any spectroscopic signal. Therefore, any signal observed results from scattering of the light by particles such as aggregates. Start a time-dependent measurement of the light-scattering signal until a stable base line is reached.
3. Dilute the denatured protein to an appropriate protein concentration (e.g., 10–100 μg mL^{-1}) into the renaturation buffer under vigorous stirring and follow the kinetics of aggregation by light scattering. Depending on the folding kinetics of the respective protein, the aggregation can occur on a minute or hour time range.
4. Aggregation can be minimized by variation of the protein concentration, temperature, buffer components and pH, and addition of solubilizing chemicals such as molar concentrations of arginine [113].

Protocol 2: Cross-linking by Glutaraldehyde

1. Dialyze the native protein against a suitable buffer, which should not contain reactive amino groups (e.g., Tris is not suitable).
2. Incubate the protein at concentrations between 5 and 100 μg mL^{-1} with 100 mM glutaraldehyde at room temperature for 2 min. Depending on the amount of cross-linking, the concentration of glutaraldehyde, the temperature, and the time can be varied.
3. Further cross-linking is blocked by addition of 200 mM $NaBH_4$ in 0.1 M NaOH.
4. The cross-linking product is analyzed by SDS-PAGE. The samples at low protein concentration have to be precipitated before. Add 0.01 volume 10% Na-desoxycholate (dissolved in slightly alkaline buffer). Subsequently, add 0.01 volume of 85% phosphoric acid. Incubate for 15 min at room temperature. Harvest the precipitate by centrifugation and resolubilize the pellet in Laemmli buffer.
5. For reconstitution experiments, choose the protein concentration at which the cross-linking is quantitative without formation of any higher molecular mass products (unspecific cross-linking).
6. Initiate reconstitution by diluting the denatured protein into the refolding buffer at the respective protein concentration.
7. Take aliquots at different time points of reconstitution and cross-link the protein as described before.
8. The bands of monomeric and oligomeric species can be quantified by densitometry of Coomassie-stained gels. (Band intensities of silver-stained gels are proportional to the amount of loaded protein only over a very narrow range and are only rarely suited for quantitative analysis.)

Protocol 3: Determination of the Dissociation Constant of a Homodimer by Analytical Ultracentrifugation

1. Dialyze the protein extensively against an appropriate buffer. If the analytical ultracentrifuge is equipped with an absorbance unit, the buffer should not absorb strongly at the detection wavelengths (230 nm and 280 nm). The buffer should contain at least 50 mM salt.
2. Dilute the protein with dialysis buffer to concentrations between 10 and 1000 μg mL^{-1}. Using an eight-hole rotor and six-channel center pieces, 21 samples (150 μL each) can be measured simultaneously.
3. Choose an appropriate rotor speed. Sedimentation equilibrium is reached when the radial distribution of the protein no longer changes over time (identical scans over a time span of 5 h). Depending on the sample volume and the size of the protein, this may take 24–72 h. Ideally, at equilibrium the protein should be completely depleted from the meniscus of the solution. The sedimentation equilibrium can be run at temperatures between 4 °C and 40 °C.
4. Measure the radial distribution of the protein at different wavelength (usually 280 nm and 230 nm).

5. Calculate the apparent molecular mass *Mr* from the equilibrium profile. This can be done using the standard software provided with the ultracentrifuge. A manual method would be the analysis of the slope of a plot of ln *A* versus r^2 according to Eq. (1)

$$Mr = (\mathrm{d} \ln A/\mathrm{d}r^2) \times 2RT/(1 - v\rho)\omega^2 \quad (1)$$

with *A* being the absorbance, *r* the distance to the center of the rotor, *v* the partial specific volume of the protein, ρ the density of the solvent, and ω the angular velocity. The partial specific volume of the protein can be calculated from its amino acid composition [146].

6. If a monomer-dimer equilibrium exits in the respective concentration range, the apparent molecular mass *Mr* will vary with the protein concentration. A semilogarithmic plot of log cp (in molar units) against *Mr* results in a sigmoidal curve. The dissociation constant K_D can be calculated by fitting the data to the following equations:

$$Mr(\mathrm{app}) = ((c_M{}^*M) + c_D{}^*D))/(c_M + c_D) \quad (2)$$

where c_M and c_D are the concentrations of the monomeric and dimeric forms, respectively. *M* and *D* represent the molecular mass of the monomer and dimer. c_D can be expressed as a function of c_M and the dissociation constant, K_D (Eq. (3)):

$$c_D = {c_M}^2/K_D \quad (3)$$

c_M is a function of the total protein concentration c_{total} according to Eq. (4):

$$c_M = -0.5^*K_D/2 + [(0.5^*K_D/2)^2 + 0.5^*K_D{}^*c_{total}]^{0.5} \quad (4)$$

Protocol 4: Thermodynamic Stability of Dimers

The interaction of subunits often contributes significantly to the overall stability of a protein. In some cases, dissociation of the subunits leads to complete denaturation of the protein. Under these conditions, the stability of the oligomeric protein can be inferred from a denaturant-induced transition curve (cf. Chapter 3 in Part I). The analysis of such data, however, is slightly different from that of monomeric proteins.

1. Prepare stock solutions of the native protein, the denatured protein (e.g., in 6 M GdmCl or 10 M urea), and the denaturation buffer (either GdmCl or urea; for preparation of denaturation buffer, compare Chapter 3 in Part I).
2. Dilute the protein into different concentrations of denaturant and allow the solutions to equilibrate. Depending on the protein, this may take only a few hours or several days. Usually a transition curve should consist of 20–30 different denaturant concentrations. To assay the reversibility of the process, the tran-

sition has to be set up starting from both the native and the denatured protein, respectively.

3. Measure the transition at different protein concentrations (e.g., 10–100 μg mL^{-1}) and using different methods (e.g., enzyme activity, fluorescence, CD). Only if the transition is reversible and the different methods yield the same transition curve (at a given protein concentration) can the data be analyzed according to a two-state model. (A reversible transition with different transition curves measured by different methods can be analyzed by a three-state model [15].) The higher the protein concentration, the more the transition midpoint is shifted to higher denaturant concentrations.
4. Calculate the equilibrium constant K_U for each data point within the transitions. K_U is defined as:

$$K_U = [D^2]/[N] = 2P_t[f^2{}_d/(1 - f_d)] \quad (5)$$

In this equation, P_t corresponds to the total monomer concentration of the protein and f_d to the fraction of denatured protein.

5. Calculate the free energy of stabilization ΔG at the different denaturant concentrations from the equilibrium constants using the equation

$$\Delta G = -RT \ln K_U \quad (6)$$

6. Obtain $\Delta G_{U\rightarrow N}$ in the absence of denaturant by linear extrapolation of the data to 0 M denaturant. If the two-state analysis is valid, the linear extrapolation of the ΔG values of transitions measured at different protein concentrations should intersect the y-axis at the same point (compare Figure 2.6).

3
Studying Protein Folding in Vivo

I. Marije Liscaljet, Bertrand Kleizen, and Ineke Braakman

3.1
Introduction

To be biologically active, proteins must fold into their three-dimensional, native structure. Christian Anfinsen and others showed decades ago that all information required for a protein to attain this three-dimensional structure resides in its primary sequence [1]. Irrespective of whether a protein folds in an intact cell, in vivo, or in a test tube, in vitro, essentially the same end product is obtained. Yet, many differences exist between the two. While in vivo folding starts co-translationally [2, 3], in vitro (re)folding starts from the complete protein molecule. The folding environment is different as well: in vivo proteins are folded in an extremely crowded environment [4–6], containing hundreds of milligrams of protein per milliliter, in contrast to in vitro folding where the protein is purified and folds in a diluted system. In vitro, folding often is inefficient under biological conditions such as physiological temperatures, with a large fraction of the protein misfolding and precipitating. In vivo, proteins are assisted during folding, and because of chaperones and folding enzymes [7–9], the folding process is more efficient and results in less aggregation than in vitro [10]. In vitro folding can take place in milliseconds, proteins can be studied directly at the molecular level, and there are no barriers such as membranes between experimenter and the folding proteins. Success rate is highest with relatively small, single-domain proteins, whereas especially mammalian proteins usually are large, consisting of more than one domain. Although in vitro folding experiments provide information on molecular details of the folding process, in vivo studies are essential for a complete view on protein folding. This chapter will discuss how protein folding in a cell can be studied and manipulated, with a slight focus on the endoplasmic reticulum.

3.2
General Features in Folding Proteins Amenable to in Vivo Study

In contrast to in vitro protein folding, protein folding in vivo can be studied only via indirect methods. Instead of direct measurements on the protein itself, the fold-

Protein Folding Handbook. Part II. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

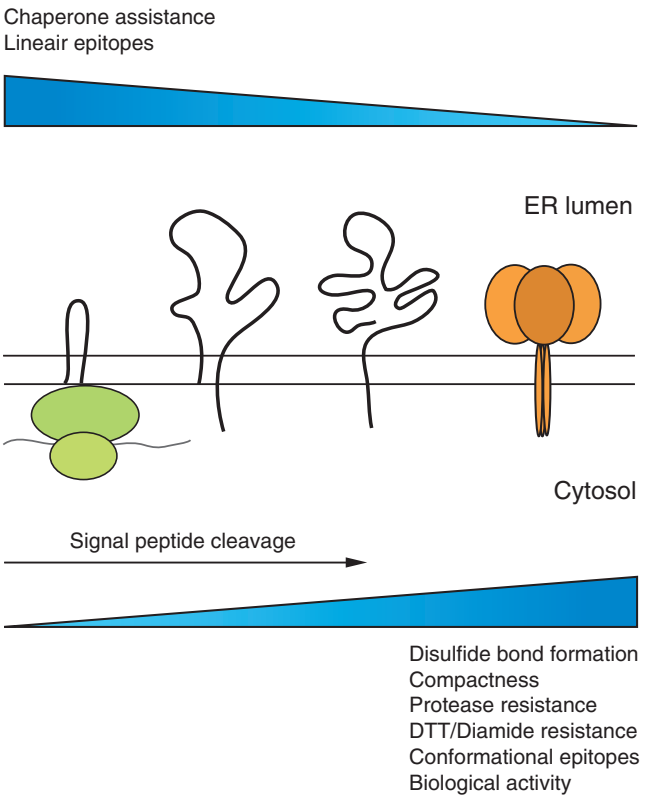

Fig. 3.1. Studying protein folding in the ER. Newly synthesized proteins that are folding in the ER lose and gain various features, which can be used to determine their folding status; examples are given in this figure. Folding starts on the nascent chain and continues after chain termination, during or after which the protein may oligomerize.

ing status of a protein can be followed through changes in shape, associations with other proteins, co- and posttranslational modifications, and its compartmental location (Figure 3.1). During in vivo folding, proteins are not purified but are part of the cell "soup." So far the best way to follow folding of a small population of newly synthesized proteins in a cell is by labeling them with ^{35}S-labeled cysteine and/or -methionine. In this way, changes in a small, synchronized protein population can be followed with time.

A pulse-chase experiment (Figure 3.2) in intact cells is an assay in which kinetics and characteristics of sequential steps are determined in vivo. Newly synthesized proteins are labeled with radioactive amino acids for a very short pulse time, because folding starts during synthesis and one would ideally follow folding from the very first folding intermediates. Labeled proteins are "chased" by incubation with unlabeled amino acids. After different times of chase, cells and supernatants can be collected and cooled on ice, and free cysteines are blocked with an alkylating

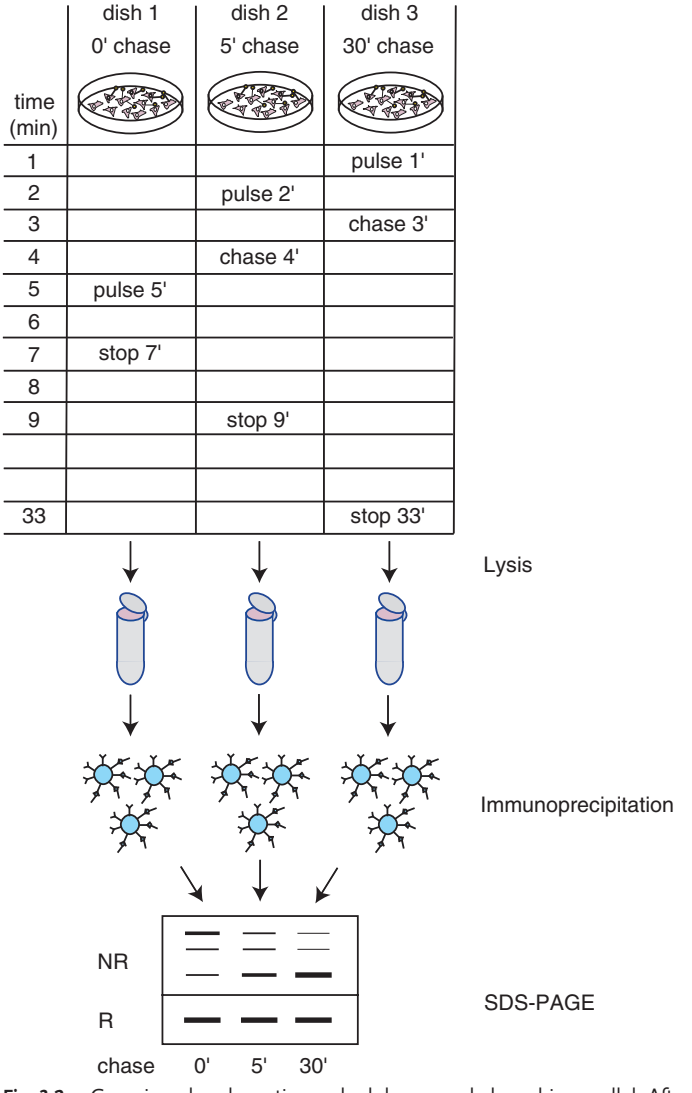

Fig. 3.2. Generic pulse-chase time schedule. To study folding and disulfide bond formation of a newly synthesized protein in the ER, adherent cells expressing the protein of interest are pulse labeled for a short period and chased with unlabeled amino acids; one dish is needed per time point. The experimental design is such that dishes can be pulse labeled and chased in parallel. After different times of chase, free cysteines are blocked with an alkylating agent and cells are lysed in a detergent-containing buffer. The protein is isolated using immunoprecipitation, and samples are analyzed using non-reducing (NR) and reducing (R) SDS-PAGE to visualize disulfide bond formation and changes in molecular weight.

agent. Cells are lysed in a detergent-containing buffer and the protein under study is isolated by immunoprecipitation. Samples can be analyzed by various types of gel electrophoresis, including native gels suitable for detection of complexes, and reducing and non-reducing SDS-PAGE to detect folding intermediates with a variable set of disulfide bonds (see the Appendix and [11]). Other changing features of folding proteins, such as their compactness or resistance to proteolytic digestion, can be determined with this pulse-chase assay as well.

Other labeling assays that can be used to study protein folding include the pulse-chase assay in suspension cells, microsomes, or semi-permeabilized cell systems [12] in which mRNA is translated in vitro in the presence of a source of ER membranes (see Chapter 18) and the recently developed in vitro chase assay in which a protein is translated in vivo and chased in a detergent lysate (Maggioni et al., manuscript submitted). These assays will be discussed in the Appendix.

3.2.1 Increasing Compactness

One of the general features of a protein during folding is its increasing compactness. During the folding process of a soluble protein, all hydrophobic side chains will strive to be buried inside the molecule and all hydrophilic ones to be exposed on the outside; hydrogen bonds are formed within the protein and between exposed residues and water. Electrostatic, van der Waals, and hydrophobic interactions play a major role during the folding process, and disulfide bridges will form within the protein when conformation and environmental conditions allow. The end product of the folding process will be the native conformation of the protein, which is assumed to be the most compact, energy-favorable form. To study the increase in compactness of proteins, non-denaturing gel electrophoresis can be used. The formation of oligomers, protein complexes, and transient protein-protein interactions can be detected on a native gel as well as by sucrose velocity gradient centrifugation. To monitor disulfide bond formation within or between polypeptide chains, non-reducing denaturing gel electrophoresis (SDS-PAGE) [13] is an effective technique. In the assays described in this chapter, the folding process of a (disulfide bond containing glyco)protein can be followed kinetically.

3.2.2 Decreasing Accessibility to Different Reagents

Due to the increasing compactness of a protein on its folding pathway, it will become less accessible to various reagents including proteases. Changes in protein conformation usually result in decreased sensitivity to protease digestion, since potential cleavage sites are buried inside the protein during the folding process. To limit the appearance of protease-specific bands, a range of proteases should be used optimally, some of which cleave frequently in a protein. Examples of the latter are proteinase K, TPCK-trypsin, and TLCK-chymotrypsin. Limited proteolysis was first used to identify domains in immunoglobulin [14] and is a very powerful tool.

The target protein is exposed to a protease, and in a time course the generation of stable products, i.e. protected inaccessible domains, can be monitored. To identify these domains, the digestion pattern of full-length protein can be compared to that of expressed isolated fragments of the protein, or domain-specific antibodies can be used to identify protease-resistant fragments.

Other reagents that can be used to obtain more information about the folding status of a protein include diazenedicarboxylic acid *bis*(*N*,*N*-dimethylamide) (diamide) and 4,4′-dithiodipyridine (4-DPS) [15, 16]. Diamide is an oxidant that, when added to the chase medium, will over-oxidize all compartments in the cell, resulting in oxidation of all cellular thiols, including those in proteins and glutathione. Since only proteins with free sulfhydryl groups are sensitive to diamide treatment, in the secretory pathway, only folding intermediates will oxidize, as most mature folded proteins have disulfide bonds. If treated and non-treated proteins are analyzed by non-reducing SDS-PAGE, folding intermediates and the native protein can be discriminated [17–19] (Braakman and Helenius, in preparation).

Like diamide, reducing agents such as dithiothreitol (DTT) or 2-mercaptoethanol (2ME) can be used in a pulse-chase assay to determine the folding status of a protein. The influenza virus hemagglutinin (HA) [20, 21] and other proteins with disulfide bonds [22, 23] undergo a conversion from DTT sensitivity to DTT resistance during their conformational maturation in the ER. In combination with conformation-sensitive and epitope-specific antibodies, DTT sensitivity is very useful in determining the folding hierarchy in a protein.

3.2.3
Changes in Conformation

During folding, domains are formed within a protein, coinciding with changes in conformation. Antigenic epitopes become exposed, are masked, or form because distant parts of the polypeptide chain start to interact. Conformational changes can be followed by probing the folding protein with conformation-sensitive antibodies. Contrary to general belief, completely conformation-sensitive antibodies are rare. Polyclonal as well as monoclonal antibodies generally recognize a limited conformation range of a protein, depending on how the antigen used to produce the antibody was obtained. Protein bands cut out of SDS-PA gels, when injected into rabbits, yield antibodies that work well in Western blotting (against SDS-denatured antigen) but that often fail to work in immunofluorescence, EM, or immunoprecipitation, which are conditions that allow proteins to remain more or less native. Antibodies generated against native, properly folded and assembled antigens often fail to interact with folding intermediates or SDS-denatured protein. Antibodies against peptides often fail to bind protein, because the peptide is not representative of the protein conformation or the peptide is not exposed in the complete protein. Therefore, an antibody needs to be characterized before it becomes a powerful tool in protein-folding studies.

Another assay that can be used concerns biological function of the folding pro-

tein: this includes binding to ligands and other proteins or an increase in enzymatic activity. To test, for instance, whether the protein can bind its receptor, the receptor may be coupled to Sepharose beads, which can be used in a precipitation assay to isolate the desired protein, or, alternatively, interaction can be tested in an ELISA-like assay.

3.2.4 Assistance During Folding

All information required for a protein to attain its final three-dimensional structure resides in its primary sequence [1]. However, complex proteins need the assistance of molecular chaperones and folding enzymes to reach their native structure efficiently without formation of (large) aggregates. Molecular chaperones interact with nonnative states of proteins; they are important during folding of newly synthesized polypeptides where they facilitate rate-limiting steps, stabilize unfolded proteins, and prevent unwanted intra- and interchain interactions, which could lead to aggregation [24–26]. Classical chaperones in the ER, such as BiP [27], recognize exposed hydrophobic patches [28, 29], while calnexin and calreticulin recognize monoglucosylated glycan chains on proteins in the ER [30]. BiP is a member of the Hsp70 family; ATP binding and hydrolysis are crucial for the cycle of binding and release of substrate [31, 32]. The preference for binding of either BiP or calnexin/calreticulin is thought to depend on the position of the first N-linked glycan in the polypeptide chain [33]. When *N*-glycans are present in the first ~50 amino acids, a protein in general will associate with calnexin and calreticulin first, whereas proteins with *N*-glycans downstream in the sequence may bind BiP or other chaperones first. Other observations, however, suggest that calnexin/calreticulin may interact with non-glycosylated proteins as well [34, 35]. As a rule, a protein's association with molecular chaperones will decrease its folding rate but increase folding efficiency and thereby yield.

The ER in addition possesses a wealth of enzymes that assist proteins during folding. Protein disulfide isomerase (PDI) (56 kDa) [36] is a member of the thioredoxin superfamily that acts catalytically in both the formation and reduction of disulfide bonds, and hence in disulfide bond rearrangements. Another PDI family member is ERp57, which facilitates disulfide bond formation in newly synthesized proteins [37] and works in a complex with either calnexin or calreticulin [38]. A different class of enzymes comprises the peptidyl-prolyl isomerases (PPIases) [39], which catalyze *cis*/*trans* isomerization of peptide bonds N-terminally to proline residues [40] and thereby increase folding rates [41]. The ribosome attaches amino acids in the *trans* conformation, which requires an isomerization step for all *cis* prolines in the final folded structure. PPIases belong to three structurally diverse families: the cyclophilins (inhibited by cyclosporin A [CsA]), the FK506-binding proteins (inhibited by FK506 and rapamycin), and the parvulins. They reside in the cytoplasm as well as in various eukaryotic organelles including the ER. In 1991 Steinmann et al. [42] and Lodish and Kong [43] showed that the folding of procollagen I and transferrin is slowed down by CsA due to inhibition of cyclophilin.

Folding proteins can be assisted by chaperones and folding enzymes from differ-

ent compartments. If a protein is soluble, only the chaperones and folding enzymes that are located in the same compartment as the protein will assist folding. Membrane-bound or membrane-spanning proteins, however, will have domains in different compartments. For example, both P-glycoprotein and the cystic fibrosis transmembrane conductance regulator (CFTR) are multiple-membrane-spanning proteins that are members of the ABC transporter family. For both P-glycoprotein and CFTR, approximately 10–15% of the protein is located in the ER lumen and ER membrane, whereas the bulk is located in the cytosol. The only ER chaperone that interacts with these membrane proteins is calnexin [44, 45]. On the cytosolic side, the most abundant chaperone Hsp70 assists in folding these proteins [46, 47]. Interestingly, when folding attempts fail, Hsp70 also promotes proteasomal degradation of misfolded CFTR by targeting the E3 ubiquitin ligase CHIP to this protein [48]. Cytosolic Hsp90 also has been demonstrated to be involved in degrading CFTR [49]. Since both ER and cytosolic chaperones impose a quality control on this type of membrane protein, it will be of great interest to investigate how events at the two sides of a membrane are communicated and coordinated.

To study a possible interaction of a substrate protein with folding enzymes and chaperones, co-immunoprecipitations (see protocols) can be done using antibodies against folding factors; if interactions are too weak or too transient, chemical cross-linkers may stabilize the complex during analysis. To examine the role of a particular chaperone on the folding of a substrate protein, one may examine the effect of its increased or decreased expression in the cell or its presence or absence in a folding assay. To test whether an ATP-dependent chaperone is involved, ATP can be depleted from cells. Section 3.4 will address these and other conditions that may affect the folding process.

3.3
Location-specific Features in Protein Folding

3.3.1
Translocation and Signal Peptide Cleavage

One location-specific feature of protein folding is its potential coupling to translocation into an organelle and subsequent signal peptide cleavage. Proteins that are targeted to mitochondria, chloroplasts, and the ER normally carry a signal peptide at their N-terminus.

Mitochondria have two membranes: the inner membrane, which encloses the matrix space, and the outer membrane, which is in contact with the cytosol. The majority of mitochondrial proteins are encoded in the cell nucleus and need to be imported from the cytosol via the macromolecular Tim/Tom complex into the mitochondrial matrix, the mitochondrial inner membrane, or the intermembrane space [50].

Chloroplasts are chlorophyll-containing, double membrane-bounded organelles that are present in all higher plants. They possess the same compartments and membranes as mitochondria but have an extra subcompartment, the thylakoid

space, which is surrounded by the thylakoid membrane. Like mitochondria, proteins are posttranslationally imported via the Tic/Toc complex [51].

Proteins that need to be imported into the ER lumen of eukaryotes are translocated from the cytosol through the translocon. Co-translational translocation is signal recognition particle (SRP)-dependent [52]. SRP binds to the signal sequence on the nascent chain, the ribosome/nascent polypeptide/SRP complex docks onto the SRP receptor at the ER membrane, and via multiple steps, the protein is translocated into the ER lumen. Oligosaccharyl transferase (OST) attaches glycans to the nascent chains, and in most proteins the signal peptide is cleaved off co-translationally by the signal peptidase present in the membrane with its active site in the lumen of the ER. Up to now, only few exceptions have been reported in which signal peptide removal is (at least partially) posttranslational, all of them viral glycoproteins [53, 54]. Posttranslational translocation is SRP-independent; this type of translocation needs additional factors to associate with the translocon complex.

Proteolytic cleavage events in mitochondria, chloroplasts, and the ER can be followed by mobility changes of the protein in reducing SDS-PAGE. If the signal peptide of a certain protein is cleaved off, the protein will have an increased electrophoretic mobility. Signal peptide cleavage in nascent chains is not detectable in a one-dimension gel, but it can be followed in two-dimensional SDS-PAGE, where the protein sample is digested with an SDS-resistant protease between the first and second dimension [55].

To test which population of full-length folding intermediates has lost its signal sequence in the ER (when cleavage is posttranslational), the process can be correlated to disulfide bond formation by using another two-dimensional SDS-PAGE system [56]. Samples are run non-reduced in the first dimension (horizontal) and subsequently are reduced in the second dimension (vertical). In this gel all proteins lacking disulfides will run on the diagonal. If a protein has intrachain disulfide bonds, it will run faster in the first (nonreducing) dimension than in the second (reducing) dimension and thus will end up above the diagonal. Proteins that form interchain disulfide-linked complexes will run below the diagonal. Antibodies against the signal peptide itself or antibodies that recognize the N-terminus of the protein after, but not before, cleavage can be used to monitor the process of signal peptide cleavage more directly [57]. Translocation of proteins in a cell-free translation organellar system can be demonstrated by protease-resistance. A newly synthesized protein that is not translocated yet will be degraded by (membrane-impermeable) proteases added to the membranes but will be protected from digestion once translocated.

3.3.2 Glycosylation

Glycan moieties on proteins are essential for folding, sorting, and targeting of glycoproteins through the secretory pathway to various cellular compartments. N-linked glycans affect local conformation of the polypeptide chain they are attached to; increase local solubility of proteins, thereby preventing aggregation; are impor-

tant for the interaction with the two lectin chaperones in the ER, calnexin and calreticulin; and are important for targeting misfolded proteins for degradation. Hence, for most glycoproteins, their N-linked glycans are indispensable for proper folding.

The glycosylation process starts at the cytosolic side of the ER, where monosaccharides are added to the lipid intermediate dolichol phosphate up to $Man_5GlcNac_2$-PP-Dol. This precursor is translocated to the lumenal side, where it is elongated to $Glc_3Man_9GlcNAc_2$-PP-Dol. The oligosaccharyl transferase then transfers the 14-mer to an asparagine residue in the consensus sequence N-X-S/T of a nascent polypeptide chain, wherein X is any amino acid except proline [58]. Glucosidase I (GI, a membrane-bound enzyme) removes the first glucose and glucosidase II (GII, a soluble enzyme), the second and third. Monoglucosylated oligosaccharides associate with the ER-resident lectins calnexin (membrane-bound) and calreticulin (soluble), which are in a complex with ERp57 [38]. When GII cleaves the last glucose, the protein is released from calnexin/calreticulin and, if correctly folded, can leave the ER. UDP-Glc:glycoprotein glucosyltransferase (GT), a soluble ER protein of 160 kDa, is a sensor of glycoprotein conformation and reglucosylates glycans close to un- or misfolded amino acid stretches [59–61]. By reglucosylating the protein, it becomes a ligand again for calnexin/calreticulin and therefore a substrate for this quality-control cycle [9]. Two ER mannosidases can remove one or two mannoses in the ER before the protein is transported to the Golgi, where further oligosaccharide processing proceeds and proteins can be *O*-linked glycosylated. Alternatively, a permanently misfolded protein may be targeted for degradation from the ER through glycan recognition (see Section 3.3.4).

The enzyme endoglycosidase H (Endo H) often is used to monitor the movement of newly synthesized glycoproteins from the ER to the Golgi complex. Glycans on proteins remain sensitive to digestion by Endo H as long as they are in the ER and in early regions of the Golgi, but they become resistant beyond. Endo H digestion after the immunoprecipitation of a glycoprotein allows conclusions to be made on the protein's location. If a protein is highly heterogeneously glycosylated, e.g., HIV envelope, which has ~30 N-linked glycans, Endo H can also be used after the immunoprecipitation to increase mobility of folding intermediates in the ER and to bring about a collapse of smeary bands into one sharp band in a gel, which enables identification and quantitation. The enzyme PNGase F in principle removes all glycans, irrespective of composition, and theoretically is the better deglycosylation enzyme. Its activity changes the glycosylated asparagine into an aspartic acid, however, which in some proteins decreases mobility, increases fuzziness of bands, and may confuse the pattern. The enzyme of choice needs to be determined for every protein one studies. To gather more information on how glycosylation affects protein folding, glycosylation site mutants and enzymes involved in glycosylation can be used (see Section 3.4).

3.3.3
Disulfide Bond Formation in the ER

The lumen of the ER supports a relatively oxidizing environment that facilitates the formation of disulfide bonds in folding proteins. Disulfide bonds are thought

to stabilize proteins during and after folding, but this is an oversimplification of their role. In the cytosol the ratio between reduced glutathione (GSH) and oxidized glutathione (GSSG) is ~60:1, while in the ER this ratio is 3:1 [62]. Glutathione is the major redox buffer in the ER. Therefore, glutathione was thought for a long time to be responsible for generating and maintaining the redox potential in the ER. This view changed with the identification of the FAD-binding [63] ER oxidoreductase 1 (Ero1p) in *Saccharomyces cerevisiae* [64, 65] and its homologues Ero1α and Ero1β in more complex eukaryotes [66, 67]. Disulfide-linked complexes between Ero1p and PDI have been captured in yeast as well as mammalian cells. In addition, disulfide-linked complexes were found between PDI and a newly synthesized secretory protein [68]. Ero1 transfers disulfides to (or rather, electrons from) substrate proteins via protein disulfide isomerase (PDI). Other oxidoreductases, such as Erv proteins [69] and PDI homologues, play a role as well [70].

Formation of disulfide bonds in a folding protein can be followed through a pulse-chase assay. In combination with an immunoprecipitation and reducing and non-reducing SDS-PAGE, the formation of disulfides can be monitored (see the Appendix and [11]). To study which enzymes are involved during disulfide bond formation and isomerization, co-immunoprecipitations can be performed with different antibodies against folding enzymes with or without prior cross-linking. Furthermore, the folding enzyme concentration can be changed, as is described below.

If the studied protein contains disulfide bonds, an alkylating agent must always be added to the stop solution and lysis buffer of the pulse-chase assay to block free sulfhydryl groups [71, 72]. This will prevent formation of (additional) disulfide bonds in the protein after cell lysis. Three commonly used blocking agents are iodoacetamide (IAM), iodoacetic acid (IAC), and *N*-ethyl maleimide (NEM). IAM and IAC bind relatively slowly, but irreversibly. IAC is negatively charged, which decreases mobility of proteins it is attached to. NEM is smaller than IAM and IAC; it binds fast but is under certain conditions partially reversible. It is therefore less suitable when prolonged incubation periods at 37 °C are required. Since all alkylating agents have different characteristics, the alkylation protocol may be optimized for each individual protein.

3.3.4 Degradation

In the ER, a stringent quality-control system operates that discriminates between correctly folded proteins, misfolded proteins, and unassembled protein subunits. This prevents misfolded proteins from leaving the ER, where they can cause harm to the cell or even to the complete organism. The ER-associated degradation (ERAD) pathway ensures ubiquitin-mediated degradation of ER-associated misfolded proteins [73]. Trimming of the α1,2-linked mannose of the middle branch by mannosidase I to $Man_8GlcNac_2$ uncovers a degradation signal [74, 75]. EDEM (ER degradation-enhancing α-mannosidase-like protein) functions in the ERAD pathway by accepting terminally misfolded glycoproteins from calnexin [76, 77]. The substrate is retro-translocated into the cytosol, where proteins are deglycosylated, ubiquiti-

nated, and then degraded by the 26S proteasome [73]. Post-ER quality-control systems exist as well: proteins can be transported to the Golgi or the plasma membrane before they are degraded, most often by vacuolar/lysosomal proteases.

Proteins can be degraded after synthesis as well as during their translation, which is undetectable in a pulse-chase assay. The net result is a lower amount of labeled protein, which can be visualized only through the use of a proteasome inhibitor during the pulse labeling. If the total signal of labeled protein at the end of the pulse is higher in the presence than in the absence of the inhibitor, cotranslational degradation apparently does happen in the control situation. Degradation *after* translation can be followed on gel, because the total protein signal will decrease during the chase. Proteasome inhibitors and lysosomal enzyme inhibitors can be added to prove degradation and identify the site of breakdown. A useful system to study protein folding without degradation is an in vitro translation system in the absence or presence of a membrane source, the latter ranging from enriched organelles to digitonin-permeabilized cells. The hemin present in the reticulocyte lysate inhibits proteasomal activity.

3.3.5
Transport from ER to Golgi and Plasma Membrane

Different methods can be used to monitor transport of a protein out of the ER to the Golgi complex or the plasma membrane. Endo H resistance is a good tool to monitor the movement of newly synthesized glycoproteins from ER (sensitive to digestion by Endo H) to Golgi (resistant to Endo H). Resistance of newly synthesized proteins to reduction by DTT (or oxidation by diamide) can be used to determine the folding status of a protein. If a protein is transported very rapidly from ER to Golgi, which then coincides with rapid and massive changes in electrophoretic mobility, such as *O*-glycosylation [78] or *N*-glycan modification [79], and one wants to trap the protein in the ER, in vitro translation in the presence of microsomes or semi-intact cells [12] can be used, since these systems lack ER-to-Golgi transport.

Cell surface arrival of proteins can be shown using protease digestion on intact cells, biotinylation of intact cells, or indirect immunofluorescence on fixed cells. Indirect immunofluorescence allows detection of possible locations of a protein in the cell, but this steady-state method does not allow any conclusion on precursor-product status, or on kinetics of processes. To follow a traveling protein with time throughout a living cell, it may be fused to a fluorescent marker protein such as GFP. For this purpose, the protein population needs to be synchronized by for example release from a protein synthesis block (cycloheximide incubation and removal) [80], a disulfide-bond formation block (DTT incubation and removal) [20], or use of a conditional mutant of either the protein under study or a transport protein such as the Sec mutants often used in *S. cerevisiae* [81]. Receptor or ligand binding can be tested biochemically, either in the cell lysate or on intact cells, after the protein's arrival on the plasma membrane, and when the studies concern a soluble protein, protein secretion can be measured by collecting the chase medium.

3.4 How to Manipulate Protein Folding

3.4.1 Pharmacological Intervention (Low-molecular-weight Reagents)

To study the role of folding factors in vivo, their activity needs to be manipulated. Drugs act fast and do not allow time for genetic adaptation of cells, but they may not inhibit to 100% and may exhibit pleiotropic effects. Genetic changes of cells circumvent this lack of specificity. One particular folding factor can be changed, but compensatory regulation processes may completely change the protein composition of the cell. With these limitations in mind, both high- and low-molecular-weight manipulations can increase our understanding of protein folding in cells.

3.4.1.1 Reducing and Oxidizing Agents

Reducing and oxidizing agents not only are useful to determine the conformation of a folding protein (as discussed in Section 3.2), but also they can be used as a tool to manipulate protein folding. If separation of protein translation and protein folding is desired, for example, to study protein folding in the absence of ATP or to determine whether co-translational disulfide bond formation is needed for a certain protein to fold, a reducing agent such as DTT can be added to the pulse medium to prevent disulfide bond formation during protein synthesis. Furthermore, reducing and oxidizing agents can be added to the chase medium to determine the effect of reduction/oxidation on protein folding and (posttranslational) signal peptide cleavage.

3.4.1.2 Calcium Depletion

In addition to its role in protein folding, the ER has an important role in calcium signaling and in sequestering calcium from the cytosol. The ER contains many calcium-binding proteins, which have a large capacity for calcium and help keep the cellular internal calcium concentration constant. The first identified calcium-binding protein was calsequestrin in the sarcoplasmic reticulum of striated muscle [82]. Its C-terminal domain binds calcium with low affinity but with high capacity. The calcium level in the ER is important not only for signaling but also for proteins traveling through the ER. During folding they are assisted by calcium-binding molecular chaperones such as BiP (Grp78), Grp94 (endoplasmin), and the lectins calnexin and calreticulin. When the level of calcium in the ER drops, some of the newly synthesized proteins misfold and aggregate [83]. To study the effect of calcium on protein folding, calcium in the cell can be depleted using various chemicals. A23187 is a divalent cation ionophore [84] that can be added to calcium-free starvation, pulse, and chase media. Thapsigargin is a potent cell permeable, IP3-independent, intracellular calcium releaser, as it efficiently inhibits all members of the Ca-ATPase family of calcium pumps, which pump calcium into the ER [85, 86]. Calcium chelators such as BAPTA, EDTA, and EGTA can be used as well to study the effect of calcium (and calcium-binding chaperones) on protein folding.

3.4.1.3 ATP Depletion

ATP is a common currency of energy in all cells, and its presence is needed for various reactions and processes, including protein folding [87]. The ER contains many chaperones such as BiP, the lumenal Hsp70 of the ER, which has an N-terminal ATP-binding domain and a C-terminal peptide-binding domain and whose activities are tightly coupled. In the Hsp70 family of chaperones, association and dissociation with the substrate protein are controlled by ATP binding and hydrolysis. To test the effect of ATP(-dependent chaperones) on protein folding, ATP generation can be blocked. 2-Deoxy-glucose inhibits glycolysis and, thereby, anaerobic ATP generation. It can be added to glucose-free cell culture medium and has been shown to be effective in pulse chase experiments [87]. Because 2-deoxy-glucose in some studies was shown to inhibit glycosylation [88], the incubation time and concentration need to be determined carefully. Sodium azide and the uncoupling protonophore carbonyl cyanide 3-chlorophenylhydrazone (CCCP) [89] poison mitochondria, and thus inhibit aerobic ATP generation. Inhibition of both glycolysis and oxidative phosphorylation by combination treatment usually depletes ATP effectively from living cells [87]. After depletion, ATP levels in the cell lysates can be measured, e.g., with a luciferase-luciferin assay in a scintillation counter or luminometer [21, 90].

3.4.1.4 Cross-linking

Chemical cross-linkers are useful for multiple purposes in protein science, such as the stabilization of protein-chaperone complexes. There are two prominent groups of cross-linkers: homobifunctional cross-linking reagents, which have two identical reactive groups, and heterobifunctional cross-linking reagents, in which the reactive groups are chemically distinct. Further variation is present in spacer arm length, cleavability, or membrane permeability, and cross-linkers may react chemically or photochemically upon UV illumination. Whereas membrane-permeable cross-linkers are suitable for cross-linking in the cell, membrane-impermeable reagents are useful for cross-linking at the cell surface and in cell lysates. Cross-linkers with shorter spacer arms (4–8 Å) often are used for intramolecular cross-linking, and reagents with longer spacers are favored for intermolecular cross-linking. The most frequently used cross-linkers at the moment are DSP (dithio-*bis*-succinimidylpropionate), a water-insoluble, homobifunctional *N*-hydroxysuccimide ester with a spacer arm length of 12 Å, which is thiol-cleavable and primary amine reactive and is used in many applications [91], and BMH (*bis*-maleimidohexane), a water insoluble, homobifunctional, non-cleavable cross-linker with a spacer arm length of 16 Å, which is reactive towards sulfhydryl groups and is also used in many applications [92, 93]. Since there is a wide variety in characteristics and potential applications of cross-linkers, it is desirable to compare different cross-linkers before protein-folding studies are performed.

3.4.1.5 Glycosylation Inhibitors

Inhibitors that prevent glycan synthesis or modify the carbohydrate portion of the glycoprotein are useful to determine function of the glycan or change fate of a pro-

tein. A wide variety in glycosylation inhibitors exists (see also chapter 17), each blocking a specific step in glycosylation. Tunicamycin, for instance, was isolated from *Streptomyces lysosuperificus* in the early 1970s [94]; it inhibits transfer of *N*-acetylglucosamine to dolichol phosphate, thereby completely blocking N-linked glycosylation, which most often causes misfolding of glycoproteins. The misfolding of many proteins in the ER can lead to upregulation of classical chaperones and folding-facilitating proteins through a so-called unfolded protein response (UPR) [95].

Other than complete inhibition by tunicamycin, which can trigger the UPR, more subtle inhibitors can be used, e.g., castanospermine. This is a plant alkaloid that was isolated from the seeds of the Australian tree *Castanospermum australe*, which inhibits glucosidase I and II. An example of a glucosidase I-specific inhibitor is australine, whereas deoxynojirimycin inhibits glucosidase II better than glucosidase I. Glucosidase I and II inhibitors can be useful in preventing association of the folding protein with the molecular chaperones calnexin and calreticulin, which bind only to monoglucosylated proteins. If a prolonged association with calnexin or calreticulin is desired, a glucosidase II inhibitor can be added during the chase period in a pulse-chase assay. This prevents cleavage of the last glucose, such that the glycoprotein will remain bound to the lectins calnexin and calreticulin. If a mannosidase I inhibitor such as kifunensine is added during the pulse chase, degradation of misfolded glycoproteins can be prevented.

Glycosylation inhibitors are useful reagents in determining the role of oligosaccharides during protein folding, but because they often do not inhibit 100% and because some inhibitors can have an effect on protein synthesis, it is very important to always include the proper controls when they are used in experiments.

3.4.2 Genetic Modifications (High-molecular-weight Manipulations)

3.4.2.1 Substrate Protein Mutants

To study the effect of certain amino acids or modifications on the folding pattern of a protein, various mutations can be made in the cDNA encoding the protein. To investigate the effect of glycosylation on a protein, *N*-glycosylation consensus sequences can be removed or created by site-directed mutagenesis. Mutations of choice are the exchange of Asn for Gln or the downstream Ser or Thr for Ala; to exclude the effect of an amino acid change rather than of a lacking glycan, both strategies can be used and compared. This allows study of the role of every individual glycosylation site for proper folding, alone or in combination. Additional glycosylation sites can be generated to study the effect of hyperglycosylation. The addition of glycosylation consensus sequences is also used to determine the topology of a protein [96]; interpretation of such data needs care, however, because a glycan may change the topology or fate of a protein.

The role of a specific disulfide bond for protein folding can be studied by changing the cysteines into another residue using site-directed mutagenesis. By creating single-cysteine and double (-cystine) mutations, the effect of removal of a complete

disulfide bond on protein folding can be compared to the removal of a single cysteine, hence the presence of an odd number of cysteines. Cysteines are best changed into alanines, because they leave "only" a small gap in the protein structure, i.e., where the thiol atom resided. Although serines are thought to resemble cysteines more closely than alanines, their higher hydrophilicity and their hydrogen atoms may cause problems when incorporated into the tightly packed core of a protein. Methionines and valines in some instances are better replacements for cysteines, but they may be too large in other sites. To be certain that the result reflects the removal of a disulfide bond rather than the change of an amino acid in the sequence, it is wise to substitute cysteine for more than one other amino acid and compare the effects.

Many other mutants can be thought of. The signal peptide of a protein can be modified to determine which residues are responsible for signal peptide cleavage, and the cleavage site can be changed to determine the effect of timing and cleavage on folding. In addition, the original signal sequence can be replaced completely by the signal sequence of another protein, and folding kinetics and secretion can be studied, as was done for HIV envelope [53]. To determine sequence and hierarchy of domain folding within a protein, and to determine whether domains fold independently of each other, single domains can be expressed, and C-terminal and N-terminal truncation mutants can be studied.

When protein mutations result in clinical phenotypes, as in many inherited diseases, it is interesting to focus on those mutations that result in folding defects.

3.4.2.2 **Changing the Concentration or Activity of Folding Enzymes and Chaperones**

To determine the effect of molecular chaperones and folding enzymes on the folding of a protein, the protein can be overexpressed by infection/transfection. Cells can be transiently transfected using a plasmid encoding the protein of interest behind an appropriate promoter. High expression can be achieved using virus-based expression systems; one example is the recombinant vaccinia virus expressing T7 polymerase in combination with a plasmid containing the protein of interest behind the T7 promoter. Stable, overexpressing cell lines can be used as well; one example is the Dorner cell lines [97], which overexpress a particular ER chaperone, such as PDI, BiP, or Grp94.

Because of the redundancy of many chaperones and folding enzymes, overexpression of a folding factor may not lead to a desired effect. Lowering expression or activity may be more successful. In cases where molecular details of the activity of a folding factor are known, dominant-negative mutants have been generated: the "trap" mutants of chaperones such as GroEL [98] and BiP [99] and active-site mutants of enzymes such as Ero [66]. Many cell lines exist in which a particular folding factor is absent or incapacitated. Examples are the CHO-derived Lec cell lines [100], which include the glucosidase I-negative Lec23 cells [101]. Other examples are the BW 5147 mouse lymphoma-derived PhaR2.7 cell line, which is glucosidase II-deficient (because of which the lectins calnexin and calreticulin cannot bind to their substrates anymore) [102], and the human T lymphoblastoid cell

line CEM.NKR [103], which is resistant to natural killer cells (NK cells) and has no calnexin.

The most dramatic effect can be expected when a folding factor is completely absent. In various organisms such as yeast, genes can be deleted. In mammalian cell lines, this is still a procedure with little success. Alternatives are cell lines derived from knockout animals, which are becoming increasingly available. In other organisms or cell lines, depletion of a gene is the maximum reachable. Gene expression can be suppressed by siRNA, which was first discovered in the nematode worm *C. elegans*; this animal is capable of sequence-specific gene silencing in response to double-stranded RNA (dsRNA) [104]. The technology has been adapted for use in mammalian cells, and an increasing number of siRNA constructs and libraries are becoming available, which makes siRNA a powerful tool to study how chaperones and folding enzymes influence protein folding.

3.5 Experimental Protocols

3.5.1 Protein-labeling Protocols

3.5.1.1 Basic Protocol Pulse Chase: Adherent Cells

In vivo, conformational changes during folding, disulfide bond formation, signal peptide cleavage, other proteolytic processing steps, glycosylation and glycan modifications, transport to other compartments, and some aspects of biological activity all can be studied in intact suspension cells or in adherent cells growing in monolayers in tissue culture dishes [11]. The adherent cells are easiest to use because they allow multiple wash steps in a short period of time, which are needed for short pulse and chase times or for studies requiring frequent changes of media with very different composition. When cells do not adhere or when low volumes of media are desirable (e.g., when expensive additives are needed), most of the analyses can be done in suspension, as described in the alternate protocol. Prepare the cells expressing the protein of choice in 35- or 60-mm dishes. For each time point, at least one dish is needed; the protocol is written for 60-mm dishes. On the day of the pulse chase, the cell monolayer needs to be almost confluent (80–90%).

Prepare all solutions needed. Also prepare a pulse-chase scheme on which all steps in the procedure (pulse, chase, stop) are noted. We use a 1-min scheme, meaning that every minute one action (pulse, chase, or stop) is performed. If aspiration is fast (which depends on the vacuum system used) and the experimenter is experienced, 30-s intervals become possible.

1. Prepare the pulse-chase setup, which includes a water bath at the desired temperature, with tube racks and 1–2 mm water above them, which can be maintained at this temperature. *Make sure the water level is just above the racks, such*

that the bottom of a tissue culture dish is completely in contact with the water but dishes are not floating when they are without cover.

2. Wash the cells with 2 mL wash buffer and add 2 mL starvation medium. Incubate for 15–40 min. at 37 °C in the presence of 5% CO_2.
3. Place the dishes on the rack in the water bath. *Make sure there are no air bubbles below the dishes.*
4. After 15 min pre-incubation with starvation medium, start the first pulse labeling. The staggering schedule (Figure 3.2) should allow labeling of the last dish within ~40 min of the start of starvation. Pulse label the cells one dish at a time: aspirate depletion medium, add 400 µL labeling medium at time 0 s. to the center of the dish, swirl gently, and incubate for the desired labeling time on the water bath. For pulse times longer than 15 min, a larger volume and incubation (on a rocker) in a 37 °C incubator in the presence of 5% CO_2 is recommended. *The pulse time optimally is equal to or shorter than the synthesis time of the protein under study (an average of 4–5 amino acid residues per second). Labeling time should be long enough to detect the protein.*
5. Add 2 mL chase medium at precisely the end of the pulse (i.e., at time 2′0″ if a 2-min pulse is aimed for). Swirl gently to mix; the labeling stops immediately upon addition of chase medium. Aspirate this mix of labeling and chase medium and add another 2 mL of chase medium. For short chases: incubate on the water bath. For chases longer than 30 min, incubate dishes in the incubator. For 0′ chase: add 2 mL chase medium at precisely the end of the pulse. Swirl gently to mix. Aspirate chase medium, place the dish immediately on ice, and add 2 mL of ice-cold stop buffer. *This is best achieved by putting an aluminum plate on top of an ice pan full of ice, with a wet paper towel on top to allow optimal contact between the plastic of the cell culture dish and the ice-cold surface.*
6. Stop the chase: aspirate chase medium at precisely the endpoint of the chase time, place the dish on the aluminum plate on ice, and immediately add 2 mL of ice-cold stop buffer. *If the studied protein will be secreted, collect the chase medium and use it for immunoprecipitation.*
7. Just before lysis: wash the cells again with 2 mL ice-cold stop buffer.
8. Aspirate the dish as dry as possible without letting cells warm up and add 600 µL ice-cold lysis buffer.
9. Scrape the cell lysate and nuclei off the dish with a cell scraper and transfer the lysate to a microcentrifuge tube.
10. Centrifuge lysates at 16 000 *g* at 4 °C for 10 min to spin down the nuclei. Use the supernatant directly for immunoprecipitations or transfer the supernatant to a new microcentrifuge tube, snap freeze, and store at −80 °C.

Buffers for the Pulse Chase

Wash buffer: Hank's Balanced Salt Solution (Invitrogen) or PBS with calcium and magnesium. Keep at 37 °C.

Starvation medium: cysteine- and methionine-free tissue culture medium (ICN) supplemented with 10 mM Na-HEPES (pH 7.4). Keep at 37 °C.

Pulse medium: cysteine- and methionine-free medium containing 10 mM Na-HEPES (pH 7.4), 125 μCi ^{35}S-cysteine/methionine per milliliter. Keep at 37 °C. *To manipulate protein folding, chemicals such as glycosylation inhibitors, proteasome inhibitors, and DTT can be added to the pulse medium.*

Chase medium: complete tissue culture medium for the appropriate cell line (also a 1/1 mix with serum-free medium is possible) supplemented with 10 mM Na-HEPES (pH 7.4), 5 mM cysteine, and 5 mM methionine. Keep at 37 °C. *If protein-folding kinetics is to be studied, 1 mM cycloheximide needs to be added to the chase medium to stop elongation of unfinished nascent chains; without it, the amount of labeled full-length protein may increase during the chase, even though incorporation of ^{35}S label is stopped completely. To manipulate protein folding, chemicals such as glycosylation inhibitors, proteasome inhibitors, DTT, diamide, or cross-linkers can be added to the chase medium, or ATP can be depleted.*

Stop buffer: Hank's Balanced Salt Solution (Invitrogen) or PBS with calcium and magnesium, supplemented with 20 mM alkylating agent (IAC, IAM, or NEM). Keep at 0 °C. *See Section 3.3.3.*

Lysis buffer: PBS (pH 7.4) or similar salt-containing buffer, containing 0.5% Triton X-100, 1 mM EDTA, 20 mM alkylating agent, 1 mM PMSF, and 10 μg μL^{-1} each of chymostatin, leupeptin, antipain, and pepstatin. Keep at 0 °C. *Add PMSF to the lysis buffer just before lysis. PMSF is highly unstable in water and has a half-life of only a few hours on ice. Different proteins may need the use of different protease inhibitors. The combination in the protocol is an empirically determined one that works well for proteins used in our lab. Salt concentration should be isotonic to prevent nuclei from disrupting. When noncovalent interactions are studied, other detergents may work better. Examples include CHAPS, octyl glucoside, or digitonin. When the protein associates with detergent-resistant membranes, the use of Triton X-100 and CHAPS should be avoided. Octyl glucoside is one of the detergents that will solubilize all membranes.*

Postponed Posttranslational Folding To separate translation from the folding process, e.g., to study the effect of factors that would affect translation, such as ATP depletion, oxidative folding can be postponed until after synthesis by addition of a reducing agent to the pulse medium [20]. This will prevent disulfide bond formation during the pulse. When the reducing agent is removed after the pulse, disulfide bond formation and folding can proceed. For various proteins, oxidative folding can be postponed until after synthesis without it creating a problem for folding.

1. Add DTT to the pulse medium to a concentration of 5–10 mM and pre-incubate for 5 min with DTT before the pulse. *The DTT concentration needs to be titrated for each protein, but usually 5 mM should be sufficient. Since labeling efficiency might decrease in DTT, labeling time may need to be increased. DTT may affect cellular ATP levels during long incubations, depending on the cell line. Therefore, a comparison with co-translational folding always needs to be made and ATP levels need to be measured.*

DTT Resistance When proteins fold and become more compact, this is usually reflected by resistance to reduction by DTT in vivo. Influenza hemagglutinin, for example, acquires DTT resistance when it is a completely oxidized monomer that is trimerization-competent but not yet a trimer [21].

1. Label the protein (see pulse-chase protocol) and chase for different times.
2. After the chase: perform in a parallel dish with the same chase time an additional chase of 5 min with 5 mM DTT. Compare this sample with the sample in which the protein is chased without DTT.

Diamide Resistance

1. Label the protein (see pulse-chase protocol) and chase for different times.
2. After the chase: perform in a parallel dish with the same chase time an additional chase of 5 min with 5 mM diamide. Compare this sample with the sample in which the protein is chased without diamide.

3.5.1.2 Pulse Chase in Suspension Cells

When cells do not adhere properly or when small volumes are desired, cells can be pulse labeled in solution. In this assay the different chase samples can be collected from one tube. Wash steps after the pulse and chase are not included, because the centrifugation steps would take too much time. Prior to starting the experiment it is necessary to determine:

- the minimum volume for incubating the cells during the pulse (x µL), (*This is cell line dependent.*)
- the number of chase points (y), and
- the desired sample volume (z). We used, for example, $x = 300$ µL, $y = 3$, and $z = 500$ µL.

1. Transfer suspension cells to a sterile 50-mL tube with cap. We used, for example, $\sim 10^6$ cells per time point.
2. Pellet cells at 500 g for 4 min at RT. Resuspend cells in $2y$ mL depletion medium and pellet cells again. Resuspend cells in $2y$ mL depletion medium. Incubate cells for 15 min at 37 °C in a CO_2 incubator.
3. Pellet cells at 500 g for 4 min at RT. Resuspend cells in x µL depletion medium, change to appropriate tube if necessary, and place in a water bath at 37 °C or the desired temperature for the experiment.
4. Add 50–100 µCi ^{35}S-labeled methionine and cysteine per time point and mix gently to start the pulse. Incubate for the pulse period.
5. Add $\geq yz$ µL chase medium. The total volume should be slightly more than $y \times z$ µL to allow for fluid loss due to evaporation during the experiment. Mix by gently pipetting up and down.
6. Immediately take the first sample (z µL). Transfer to microcentrifuge tube with pre-prepared z µL 2× concentrated lysis buffer on ice, mix well, and keep on ice.

7. After every chase interval, collect a sample and add to 2× concentrated lysis buffer on ice, mix well, and keep on ice.
8. Spin the lysates at 16 000 *g* for 10 min at 4 °C to pellet the nuclei. The post-nuclear lysate can be directly used for immunoprecipitations or transferred to a new microcentrifuge tube, snap frozen, and stored at −80 °C.

Semi-permeabilized Cell System (see Chapter 18) In vitro translation in the presence of semi-permeabilized cells [12] is a method with a complexity between the pulse-chase assay and the in vitro chase assay, since there is only one membrane between the protein and the experimenter, whereas there are two in the pulse-chase assay and none during the second part of the in vitro chase assay.

In the semi-permeabilized cell system, cells are treated with the detergent digitonin, which selectively permeabilizes the plasma membrane, leaving cellular organelles such as ER and Golgi complex intact. These semi-permeabilized cells (SP cells) are added to an in vitro translation system, where they act as a source of ER membranes. Only the mRNA of the protein of interest is present, which precludes the need for immunoprecipitations. This assay is especially useful when there are no antibodies available against the protein under study, for protease resistance studies, or when only the ER form of a protein is under study and ER-to-Golgi transport is undesirable.

In Vitro Chase Assay In the in vitro chase assay (Maggioni et al., manuscript submitted), a protein is pulse labeled/translated in vivo and chased in a detergent lysate. Since there are no membranes during the chase period, the direct environment of the folding protein can be manipulated. For example, ATP levels in the detergent lysate can be depleted, and chaperones and organellar cell fractions can be added.

After point 4 of the basic pulse-chase protocol (now using 10-cm dishes):

For the in vitro assay 10-cm dishes are used instead of 6-cm dishes. Therefore, all buffer volumes used in steps 1–4 of the basic pulse-chase protocol need to be multiplied by 2–2.5.

1. Wash cells twice with 4 mL ice-cold HBSS wash buffer, aspirate the buffer, and immediately lyse with 1.8 mL ice-cold lysis buffer without alkylating agent.
2. Scrape the cell lysate and nuclei off the dish with a cell scraper, transfer lysates to a microcentrifuge tube, and immediately take out 1/6 of the lysate and add NEM to this sample to a concentration of 20 mM (0 min sample in the in vitro chase assay).
3. Spin cell lysates for 10 min at 16 000 *g* at 4 °C to pellet nuclei. Transfer post-nuclear cell lysate to a new tube. The supernatant of the lysate without NEM is used in the rest of the in vitro chase assay.

After transfer to a new tube, add 5 mM GSSG and transfer the tube immediately to a water bath at 30 °C.

4. After different times of in vitro chase, take 300 μL of the lysate and transfer it

into a new tube that contains NEM to a final concentration of 20 mM and immediately incubate on ice.
5. Use the supernatant directly for immunoprecipitations or snap freeze and store at −80 °C.

3.5.2 (Co)-immunoprecipitation and Accessory Protocols

3.5.2.1 Immunoprecipitation

1. Mix 50 µL of washed protein A-Sepharose beads and the optimal amount of antibody and shake in a shaker for 60 min at 4 °C. *Optimize the incubation time for each antibody. The optimal amount of antibody is the amount that precipitates all, or at least the maximum amount, of antigen from the solution. This needs to be tested for each antibody-antigen combination by re-incubation of the supernatant from the beads-antibody-antigen incubation (see step 3 below) with antibody and beads. If the antibody has a low affinity for protein A, protein G-Sepharose beads or a bridging antibody between the primary antibody and the protein A beads, such as a goat or rabbit anti-mouse Ig, can be used. Instead of Sepharose beads, heat-killed and fixed* S. aureus *cells can be used to immobilize the antibody. Because these cells are more difficult to resuspend than Sepharose beads, spin conditions should be 5 min at 1500* g *rather than 1 min at max speed. Resuspension time will be longer and should be added to the wash time.*
2. Add 100 µL to 600 µL post-nuclear cell lysate and couple in the head-over-head rotator for at least 30 min (depending on the antibody) at 4 °C. *Test for each antibody the minimum incubation time needed (between 30 min and overnight). With one lysate, different immunoprecipitations (such as one with an antibody that recognizes all forms of the protein, a conformation-sensitive antibody, or a co-immunoprecipitation) can be done to obtain as much information as possible on the folding protein.*
3. Pellet beads by spinning 1 min at RT max, aspirate the supernatant, and use it for re-precipitation to test whether the antibody precipitated all antigen molecules in the solution (see step 1 above). Add 1 mL washing buffer and shake for at least 5 min in a shaker at RT. Repeat this washing procedure once. *Test different wash buffers with different concentrations of SDS, other detergents, combinations thereof, and salt. Also test different wash times and wash temperatures. It is not necessary to wash more than twice. Rather than increase the number of washes, conditions of the two washes should be changed. If this does not give the desired result, pre-clearing of the detergent cell lysate is the method of choice (see calnexin protocol).*
4. Pellet beads and aspirate supernatant. Add 20 µL TE to the beads, vortex to resuspend the beads, and add 20 µL 2× concentrated sample buffer and vortex again. *If an Endo H digestion is performed, add here the Endo H buffer instead of the TE. It is important to resuspend in TE before adding SDS, because addition of SDS to a pellet may induce or increase aggregation.*

5. Heat samples for 5 min at 95 °C, vortex when still hot, and pellet the beads. The supernatant is the non-reduced sample.
6. To make a reduced sample, transfer 18 µL supernatant to a new tube to which a defined drop of DTT solution has been added (final DTT concentration should be 20 mM) and vortex. Heat samples for 5 min at 95 °C. Centrifuge shortly to spin down the condensation fluid. The samples are now ready to be loaded onto an SDS-PA gel. *Addition of DTT to the bottom of the tube allows one to check whether DTT actually has been added to the sample. Re-oxidation during electrophoresis, which happens if proteins have many cysteines, is prevented by adding an excess alkylating agent, such as 100 mM NEM, to all samples before loading.*

Buffers for Immunoprecipitation

Protein A-Sepharose beads: 10% protein A-Sepharose beads in PBS or the same buffer in which the cells were lysed in, supplemented with 1/10 of the concentration of the same detergent used in the lysis buffer and 0.25% BSA. *The beads are washed twice in this solution to remove the buffer in which the Sepharose was stored. When using* S. aureus *cells, washing should be done twice as well, in the same centrifuge that will be used for the immunoprecipitation, to ensure that the same-sized particles will be pelleted during all washes.*

Wash buffer: PBS, pH 7.4, containing 0.5% Triton X-100 or 150 mM NaCl (representing some of the mildest conditions) or another buffer (such as a harsher one with SDS).

TE buffer: 10 mM Tris-HCl, pH 6.8, 1 mM EDTA.

2× concentrated sample buffer: 400 mM Tris-HCl, pH 6.8, 6% (w/v) SDS, 20% glycerol, 2 mM EDTA, 0.04% (w/v) bromophenol blue.

5× concentrated sample buffer: 1 M Tris-HCl, pH 6.8, 7.5% (w/v) SDS, 50% glycerol, 5 mM EDTA, 0.08% (w/v) bromophenol blue.

3.5.2.2 Co-precipitation with Calnexin ([30]; adapted from Ou et al. [105])

After step 7 from the pulse chase:

1. Aspirate the dish as dry as possible and add 600 µL ice-cold lysis buffer (2% CHAPS in 50 mM Na-HEPES pH 7.6 and 200 mM NaCl. *Do not add EDTA to the lysis buffer, since calcium is needed for the interaction.*
2. Scrape the cell lysate and nuclei from the dish and transfer into a microcentrifuge tube.
3. Use around 200 µL of the lysate for the co-immunoprecipitation and use a parallel amount for an immunoprecipitation using an antibody that recognizes all antigen that is present.
4. Add 0.1 mL of a 10% suspension of heat-killed and fixed *S. aureus* cells to the lysate to reduce background and rotate or shake for 30–60 min at 4 °C.

5. Pellet the fixed *S. aureus* and nuclei at max speed to remove the smallest particles and use the supernatant for the immunoprecipitation.
6. Couple the antibody to the protein A-Sepharose beads for 30 min at 4 °C in a shaker.
7. Add the pre-cleared lysate.
8. Couple at 4 °C for 1–16 h, depending on the antibody.
9. Pellet the beads by centrifugating for 2 min at 8000 *g*.
10. Wash twice with 0.5% CHAPS in 50 mM Na-HEPES pH 7.6, containing 200 mM NaCl.
11. After the last wash: continue the immunoprecipitation protocol at step 4.

3.5.2.3 **Co-immunoprecipitation with Other Chaperones**

The calnexin co-immunoprecipitation protocol can be used as a basic protocol when the interaction of a protein with another chaperone is to be studied. Since each protein-chaperone interaction is different, protocols should be optimized for each new co-immunoprecipitation. To stabilize the interaction of the molecular chaperone BiP with its substrate, adding an ATP-depleting agent to the lysis buffer is recommended, to lock the ATP cycle of the chaperone. When interactions with calcium-binding chaperones are studied, calcium chelators such as EDTA should be omitted from the lysis buffer.

3.5.2.4 **Protease Resistance**

Limited proteolysis can be used to investigate the conformation of proteins. However, most investigators often perform limited proteolysis on purified protein, which will represent only the steady-state conformation. To obtain more dynamic information on how proteins acquire their conformation during the folding process, one can combine in vivo pulse-chase analysis and immunoprecipitation, as described earlier in this chapter, with limited proteolysis. Important considerations should be made before using this technique. First, methionines and cysteines within the protein should be evenly distributed. Second, a highly specific antibody is needed to immunoprecipitate the protein of interest. Third, a mild denaturing buffer should be used for cell lysis and immunoprecipitation to prevent large conformational changes of the protein. For most proteins in our lab, we use MNT (20 mM MES, 100 mM NaCl, 30 mM Tris-HCl, pH 7.4) containing 0.5% Triton X-100 as a mild lysis buffer. It is important to omit protease inhibitors and EDTA during cell lysis. Therefore, perform the immunoprecipitation as shortly as possible to prevent protein degradation.

After the last wash of the immunoprecipitation protocol (step 3):

(Note: one protease concentration tested in a proteolysis experiment is one immunoprecipitation.)

1. Pellet the antigen-antibody-bead complexes and aspirate all wash buffer.

2. Add 10 μL MNT + 0.5% Triton X-100 to the beads and resuspend gently.
3. Add 1 μL protease from a 10× stock. Resuspend by vortexing and incubate for *exactly* 15 min on ice. Use a protease titration range (for example, 0.25, 1, 5, 25, 100, or 500 μg mL^{-1} final concentration) to investigate protease susceptibility of each protein. TPCK-trypsin, TLCK-chymotrypsin, proteinase K, and endoproteinase Glu-C V8 are suitable proteases (Sigma) for these studies.
4. After incubation, inhibit the protease by first adding 1 μL PMSF (phenylmethylsulfonyl fluoride) from a 10× stock before adding 10 μL 2× sample buffer. TPCK-trypsin is specifically inhibited by adding a fivefold excess of soybean trypsin inhibitor.
5. Heating the sample for 5 min at 95 °C will completely inactivate the protease.
6. Analyze the radio-labeled proteolytic pattern on a 12–15% SDS-PA gel and expose to film or phosphor screen.

3.5.2.5 **Endo H Resistance**

After the last wash of the immunoprecipitation protocol (step 3):

1. Pellet beads and aspirate all wash buffer from the protein A-Sepharose beads.
2. Add 15 μL 0.2% SDS in 100 mM sodium acetate, pH 5.5, and heat for 5 min at 95 °C to denature the protein.
3. Cool and add 15 μL 100-mM sodium acetate, pH 5.5, containing 2% Triton X-100 and protease inhibitors: 10 μg μL^{-1} each of chymostatin, leupeptin, antipain, and pepstatin and 1 mM PMSF. Add 0.0025 U Endo H (Roche).
4. Mix and incubate for 1.5–2 h at 37 °C. *Optimize incubation time for each protein.*
5. Spin down the fluid and add 7.5 μL 5× sample buffer and mix.
6. Heat for 5 min to 95 °C.
7. Spin down. At this moment a reducing sample can be prepared (see immunoprecipitation protocol).

3.5.2.6 **Cell Surface Expression Tested by Protease**

Arrival of a protein that followed the secretory pathway at the plasma membrane can be biochemically monitored. At the cell surface, the protein is accessible to various reagents, such as antibodies, proteases, and biotinylation agents. Below is a typical protocol for cell surface detection by proteases.

1. Wash the cells twice with 2 mL stop buffer.
2. Add 0.5 mL PBS containing 100 μg mL^{-1} trypsin or another protease and 2 mM $CaCl_2$ (if the protease needs calcium) at 4 °C to the cells.
3. Incubate for 30 min on ice. *At this step surface accessible protein either will be completely digested, or it will be cleaved specifically into a limited number of fragments.*
4. Collect fluid from cells and add 100 μg mL^{-1} soybean trypsin inhibitor, 1 mM PMSF, and 10 μg mL^{-1} each of chymostatin, leupeptin, antipain, and pepstatin (final concentrations).
5. Add to the cells 0.5 mL of 100 μg mL^{-1} soybean trypsin inhibitor, 1 mM PMSF,

and 10 μg mL^{-1} each of chymostatin, leupeptin, antipain, and pepstatin (final concentrations). Incubate on ice and repeat the incubation. *It is essential to properly inhibit the protease, because it will otherwise digest internal protein upon lysis.*

6. Lyse the cells in 600 μL lysis buffer and continue with the pulse-chase protocol at step 9. *The comparison between untreated and treated cells will show how much of the protein of interest disappeared because of the proteolysis, or the treated sample will contain a mixture of undigested (internal) and digested protein (cell surface–localized).*

3.5.3 SDS-PAGE [13]

1. Prepare 0.75-mm thick polyacrylamide separating and stacking gels. *The acrylamide percentage depends on the molecular weight of the studied protein and should position the protein just below the middle of the gel to allow maximal separation of different forms of the protein.*
2. Load 8 μL of each sample (and 3 μL of the total lysates on a separate gel to check labeling efficiency). Not using the outer lanes of the gel, load 1× sample buffer in the outside as well as empty lanes to prevent "smiling" of the bands. *When reduced and non-reduced samples are loaded in adjacent lanes in SDS-PAGE, DTT can diffuse into the non-reduced lanes. Either one or two lanes should be left open between the two samples, or an excess quencher should be added to all samples (including the non-reduced ones) just before loading. We frequently use 100 mM N-ethylmaleimide (final concentration in the sample) for this purpose.*
3. Run each gel at max speed at constant current (25 mA per gel for Hoefer minigels) until the dye front is at the bottom of the gel. *Maximum speed without overheating limits lateral diffusion and guarantees sharper bands.*
4. Stain the gel with Coomassie brilliant blue for 5 min and destain to visualize antibody bands.
5. Neutralize gels for 1–3 × 5 min. *If incubated too long in the absence of acid, bands will become diffuse. A minimum time of neutralization is needed to prevent precipitation of salicylic acid, if gels are too acidic.*
6. Treat gels with enhancer solution for 15 min. *Do not incubate longer than 15 min to prevent non-specific signal.*
7. Dry gels at 80 °C on 0.4-mm Schleicher & Schuell filter paper.
8. Expose to film at −80 °C or to a phosphor-imaging screen.

Solutions for SDS-PAGE

Coomassie stain: 0.25% (w/v) Coomassie brilliant blue in destain

Destain: 30% (v/v) methanol and 10% (v/v) acetic acid in H_2O

Neutralizer: 30% (v/v) methanol in PBS

Enhancer: 1.5 M sodium salicylate in 30% (v/v) methanol in H_2O

Various types of native gels can be used to study the conformation of proteins, oligomerization, aggregation, and the interactions between different proteins. The mobility depends on both the protein's charge and its hydrodynamic size. Blue native gels [106] are often are used for membrane proteins.

Two-dimensional SDS-PAGE

1. Load samples on a tube gel and run, or run on a slab gel with pre-stained markers on either side of the lane. *The first dimension can be a native gel or a non-reducing SDS-PA gel, an IEF gel, or virtually any other kind.*
2. Extract tube gel from capillary, or cut the lane of interest out of the first dimension slab gel.
3. Boil the tube or strip for 10 min in reducing sample buffer.
4. Place the tube or strip on an SDS-polyacrylamide slab gel.
5. A reduced sample can be run in a separate lane close to the edge of the slab gel.
6. Run in the second dimension as a regular slab gel.

Acknowledgements

We thank Claudia Maggioni for sharing the in vitro chase assay protocol and for assistance with the figures, and we thank other members of the Braakman lab, especially Ari Ora, Aafke Land, and Nicole Hafkemeijer, for critical reading of the manuscript.

Characterization of ATPase Cycles of Molecular Chaperones by Fluorescence and Transient Kinetic Methods

Sandra Schlee and Jochen Reinstein

4.1
Introduction

4.1.1
Characterization of ATPase Cycles of Energy-transducing Systems

ATP has long been known to be involved in many important cellular processes such as energy transduction in molecular motors, ion transport and signal transmission, topological processing of nucleic acids and the fidelity of protein synthesis. In spite of the diverse functions of ATPases, their mechanism includes some universal steps: the specific recognition and binding of the nucleotide, a conformational change induced by nucleotide binding, phosphoryl transfer (chemical reaction), adjustment of the conformation to the product state, and the release of products, which is accompanied by the regeneration of the initial state of the enzyme.

Although ATPases in principle employ the same reaction steps, they have to cope with entirely different tasks. Therefore, the consequence of a single reaction step on a molecular level depends on the respective system. The ATP state of DnaK, for example, represents a form that rapidly traps and releases potential substrate proteins [1, 2]. In the context of molecular motor proteins, ATP binding causes the forward movement of conventional kinesin (power stroke), but ATP binding to myosin, on the other hand, leads to dissociation of myosin from actin and is accompanied by the recovery stroke of its lever arm [3].

With some exceptions, an exact definition of the coupling between ATP hydrolysis and enzymatic action is still missing for many of the systems. History has revealed repeatedly that mechanisms remain a matter of speculation until equilibrium constants and reaction rates of all relevant intermediates (functional states) have been identified. In addition, the stability of enzyme-bound nucleotide as well as the velocity of product release represent molecular timers that are carefully regulated by accessory proteins in many ATPases. Determination of kinetics and measurements of force and motion of single molecules are therefore essential for a comprehensive understanding of the respective enzymatic mechanism.

Protein Folding Handbook. Part II. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

This review summarizes various aspects of fluorescent nucleotide analogues that were used to determine the ATPase cycles of the molecular chaperones DnaK, Hsp90, and ClpB and their regulation by accessory co-chaperones. Experimental protocols and conceptual considerations regarding nucleotide-binding and ATPase reactions of these chaperone systems can be found in the Section 4.3 of this review. The particular details of roles and properties of DnaK/Hsc70 or Hsp90 are not described here since they are well covered by other chapters in this volume.

4.1.2 The Use of Fluorescent Nucleotide Analogues

4.1.2.1 Fluorescent Modifications of Nucleotides

Numerous ATP analogues have been synthesized to report on the action of ATP in biosystems by means of a spectroscopic signal (absorption, fluorescence, and EPR and NMR probes) [4, 5]. Since a comprehensive intrinsic tryptophan fluorescence signal for nucleotide binding is rarely available, the use of fluorescent nucleotide analogues to study nucleotide-binding proteins prevails. Fluorescent nucleotide analogues combine the localization to a defined position with the inherent high sensitivity of the method: fluorophores with high quantum yields (i.e., >0.1) can be readily detected at submicromolar concentrations. Fluorescence can provide information about the size of proteins and structural features of the nucleotide-binding site and allows quantification of the kinetic and equilibrium constants describing the system. The intrinsic fluorescence of the common nucleotides, at ambient temperatures and neutral pH, is far too low (quantum yields on the order of 10^{-4}) to be of general use in the investigation of nucleotide-binding proteins, especially since the furthest reaching absorption maxima of nucleotides are near 260 nm, which overlaps with intrinsic protein absorption. To improve the utility of nucleotides as fluorescent probes, modifications have been introduced to different positions of the nucleotide moiety: the adenosine ring, the ribose groups, and the phosphate moiety [4].

Among the most conservative changes is the substitution of an adenosine with a fluorescent formycin or aminopurine ring (Figure 4.1). These analogues have been used to study the ATPase kinetics of $(Na^+ + K^+)$-ATPase and myosin [6–8]. It was shown that C8-MABA-ADP, with a substitution in the 8 position of adenine, was a useful probe for the nucleotide-binding site of the molecular chaperone DnaK [9–11]. However, one limitation is that the substitutions tend to stabilize the base in the unusual *syn* conformation rather than in the extended *anti* conformation of unmodified nucleotides. As a consequence, binding parameters, specifically kinetic constants, may be altered.

Another fluorescent analogue, etheno-ATP (ε-ATP), includes the addition of an aromatic ring to the adenine moiety [12]. This modification and the addition of different aromatic rings result in bulky fluorophores that are not readily tolerated by many nucleotide-binding sites.

Modifications that do not alter the purine ring systems offer an alternative approach to fluorescent nucleotide analogues. For example, an ATP analogue with

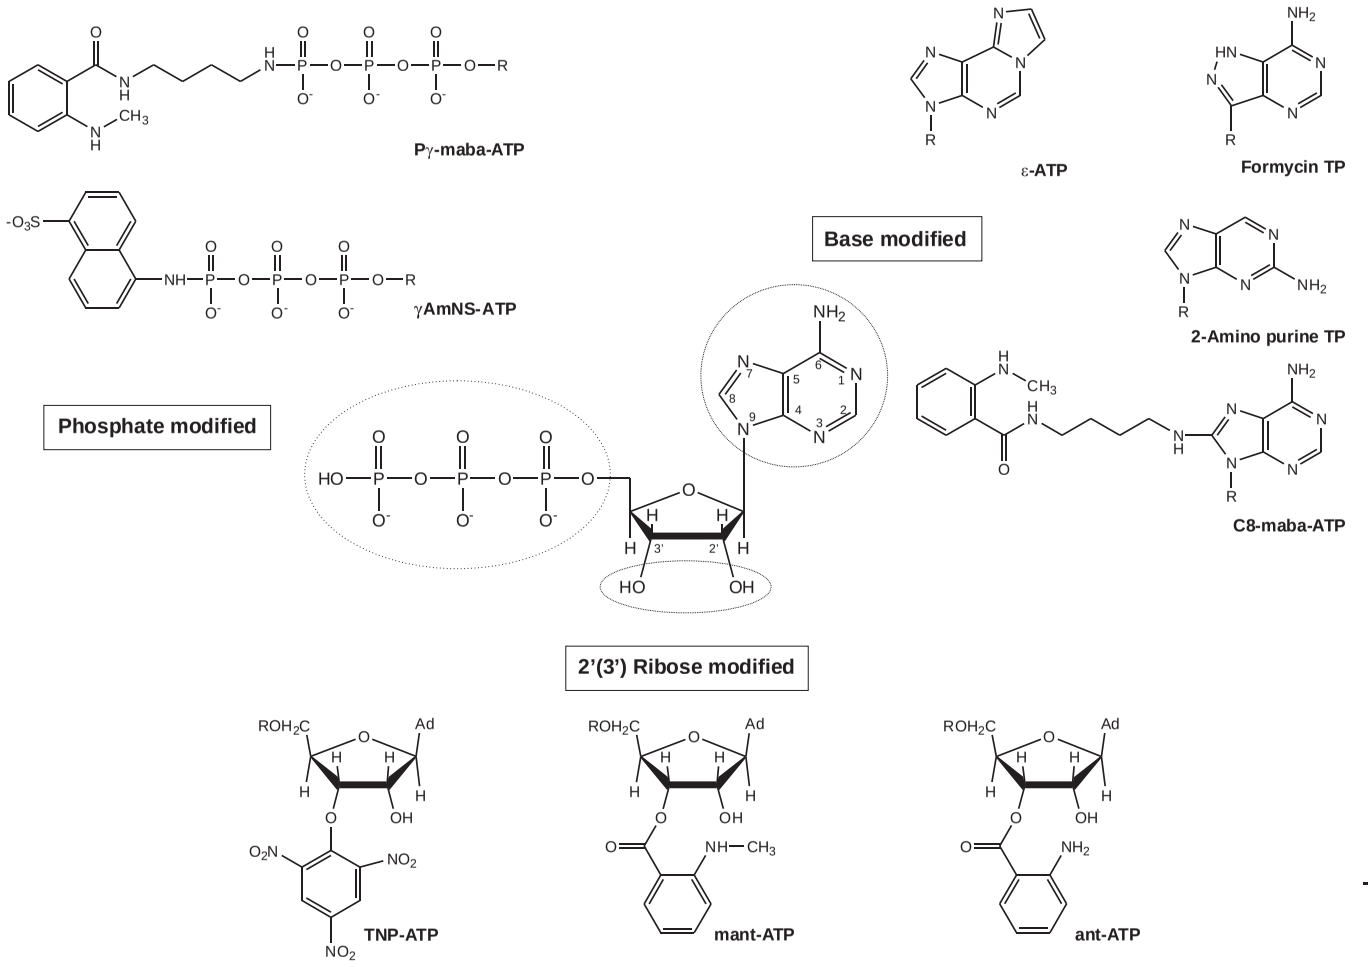

Fig. 4.1. Fluorescent nucleotide analogues. The structures of fluorescent nucleotide derivatives mentioned in the text are shown and derivatives are grouped according to the position of modifications.

altered phosphoryl structure, namely, adenosine-5′-triphospho-γ-1-(5-sulfonicacid)-naphtylamine (γAmNS-ATP), which is a good substrate for *E.coli* RNA polymerase, has been described [13]. By coupling a fluorescent *N*-methylanthraniloyl-group to the phosphate moiety of nucleotides via a butyl linker, nucleotide analogues were obtained that allow the direct determination of binding constants. (P_γ)MABA-ATP (adenosine-5′-triphospho-γ-(*N*′-methylanthraniloyl-aminobutyl)-phosphoamidate) was used for the kinetic characterization of the ATPase cycle of the molecular chaperone Hsp90 [14]. The fluorescent CDP analogue (P_β)MABA-CDP proved to be a specific probe for the NMP-binding site of UMP/CMP kinase [15].

In many cases modification of the ribose moiety of nucleotides offers a satisfactory approach in that the resultant analogues closely mimic the behavior of their parent nucleotides. The advantage of such ribose modification can be understood by examination of the structures of nucleoside 5′-triphosphatases such as p21ras [16], in which case the 2′,3′-hydroxyl groups of the nucleotide project out of the binding domain.

Among the first ribose-modified nucleotides was 2′,3′-O-(2,4,6-trinitrocyclohexadienylidene) adenosine 5′-triphosphate (TNP-ATP), introduced by Hiratsuka and Uchida [17]. Ribose-modified analogues used extensively in studies of nucleoside 5′-triphosphatases are the 2′(3′)-*O*-anthraniloyl (Ant) and 2′(3′)-*O*-methylanthraniloyl (MANT) derivatives of adenine [18–20]. The motivations for this choice of fluorophores were their relatively small size, which implies that perturbation of binding properties would be minimal, and the fact that the fluorescence properties of these probes are environmentally sensitive. MANT-ADP has been applied, among others, to investigate the ATPase cycle of ClpB [21, 22].

It has to be kept in mind that one complication of derivatizing the ribose hydroxyls is that a mixture of 2′ and 3′ isomers will be generated, which may differ in their fluorescent and binding capacities. One way to avoid the complication of mixed isomers is to use nucleotide derivatives based on 2′ deoxyribose.

4.1.2.2 How to Find a Suitable Analogue for a Specific Protein

ATP-utilizing systems vary enormously in their specificity, with the consequence that what acts as a good analogue in one case may be a very poor probe in another case. Without structural information about the nucleotide-protein complex, it is very difficult to accurately predict the effectiveness of a fluorescent nucleotide analogue in a novel biological system. To facilitate the screening of potential candidates, use can be made of the binding of ATPases to ATP-agarose. ATP- and ADP-agaroses are available with their ATP moiety coupled chemically to the N6 or C8 position of the adenine ring or the ribose hydroxyls via linkers of variable length (Table 4.1). If binding of an ATPase to a specific kind of ATP-agarose is observed, chances are high that fluorescent nucleotide analogues, modified at the according position, represent specific probes for the respective protein.

A good indicator for the suitability of a fluorescent derivative as substrate for a specific system is the accordance of the binding parameters (K_d, k_{on}, k_{off}) [23] and kinetic parameters (e.g., K_m, V_{max}) of the ATPase reaction of the fluorescent derivative and the unmodified nucleotide. In addition, the modified nucleotide should support the enzymatic activity of a protein equally to the unmodified nucleotide.

4.2 Characterization of ATPase Cycles of Molecular Chaperones

4.2.1 Biased View

The following description of the ATPase cycles of DnaK, Hsp90, and ClpB systems certainly does not claim to give a comprehensive overview of the many roles and aspects of these chaperones. For this purpose, other excellent reviews in this book and outside, as mentioned in the individual chapters, should be referred to. We are also aware that the selection of results and methods here is highly biased towards fluorescence, nucleotide analogues, and related methods, but we feel that the reader may benefit more from a description of the various aspects of these techniques than from a (bound-to-fail) attempt to cover all conceivable approaches.

4.2.2 The ATPase Cycle of DnaK

The ATPase cycles of DnaK and its eukaryotic ortholog Hsc70 are well characterized from a variety of methods at this point. Comprehensive overviews may be found in this volume and in other reviews (e.g., Refs. [24–27]).

Where applicable, references to particular aspects concerning ATPase activity or nucleotide binding are covered in Section 4.3.

4.2.3 The ATPase Cycle of the Chaperone Hsp90

Hsp90 has a central role in communicating numerous folding as well as other processes in the cell [28–32]. Despite great interest in its molecular mechanism, the involvement of ATP in its function remained a matter of debate for an extended time period. It was reported by Csermely and co-workers that Hsp90 has an ATP-

binding site and autophosphorylation activity that is dependent on catalytic Mg^{2+} and stimulated by Ca^{2+} [33]. ATP-binding studies showed similar dependencies on these cations and were based on affinity labeling with azido-ATP and the ability of Hsp90 to bind to ATP-agarose.

Apparent ATPase activity of Hsp90 was also reported by other groups [34, 35], but considering the low enzymatic activity involved, it was questionable whether the activities observed were not the consequences of minor impurities, e.g., protein kinases that constitute one of the substrates for Hsp90 and may be dragged along the purification process.

Further studies observed the dependence of circular dichroism and Fourier infrared spectra of Hsp90 as a function of ATP concentration. Here ATP was shown to increase the content of β-plated sheet structures and increased interchain interactions. Also, a decrease in intrinsic tryptophan fluorescence and susceptibility to tryptic digestion were seen in the presence of ATP [36]. The conditions necessary to achieve these observed effects, however, still raised some concerns about specific binding of ATP to Hsp90. In a comparative study of highly purified Hsp90 with Hsc70 [37], Hsp90 failed to show any significant binding to immobilized ATP (ATP-agarose) or three different fluorescent nucleotide analogues, namely, 2′(3′)-*O*-(*N*-methylanthraniloyl)-adenosine 5′-diphosphate (MANT-ADP), N^8-(4-*N*′-methylanthraniloylaminobutyl)-8-aminoadenosine 5′-diphosphate (MABA-ADP), or 1,N^6-ethenoadenosine diphosphate (see also Figure 4.1). A subsequent reinvestigation with electron paramagnetic resonance (EPR) spectroscopy and spin-labeled nucleotide analogues, however, detected weak binding of ATP ($K_d = 400$ μM) [38]. This weak binding of ATP remained enigmatic, however, since even BSA is capable of binding ATP with this affinity, again as determined by EPR [39]. This should not mean that weak binding of substrates in general has to be regarded with distrust, but usually weak binding goes hand in hand with high activity, whereas the ATPase activity of Hsp90 was not identified to be particularly high.

A major breakthrough concerning this question arrived with the X-ray structure of the N-terminal domain of Hsp90 in complex with ADP and Mg^{2+} [40]. This important structure showed that ADP and ATP bind in the same binding pocket as the antitumor drug geldanamycin [41], suggesting that geldanamycin acts by blocking nucleotide binding and not in direct competition with protein substrates.

The nucleotide binds to Hsp90 in a peculiar mode with a kinked phosphate chain. The ribose and base are not readily accessible, explaining why fluorescent nucleotide analogues with modifications at the ribose or base could not bind [42]. Based on previous experience with modifications at the terminal phosphate groups [15], fluorescent analogues of ADP and ATP were synthesized. Binding of these new compounds, namely, adenosinediphospho-β-(*N*′-methylanthraniloylaminobutyl)-phosphoramidate and adenosinetriphospho-γ-(*N*′-methylanthraniloylaminobutyl)-phosphoramidate (see also Table 4.1), to Hsp90 results in enhancement of MANT fluorescence. Although it is usually desirable that modified fluorescent nucleotide analogues behave as closely to their ''native'' siblings as possible, with Hsp90 it turned out that this is fortunately not the case. Here the fluorescent analogues bind much more tightly (K_d of 20 μM for Hsp90) than the unmodified nu-

cleotide, with K_d around 500 μM [14]. This fortunate fact allowed us to determine many individual steps of the ATPase cycle of Hsp90 with stopped-flow and other methods. Once the basic properties of P(γ)-MABA-ATP binding were determined, they served as a diagnostic tool to help clarify the role of individual residues or domains [43, 44] and, similarly to studies concerning DnaK and its nucleotide-exchange factor GrpE, the effect of regulating co-chaperones such as Sti1 on the catalytic cycle [45, 46].

4.2.4 The ATPase Cycle of the Chaperone ClpB

4.2.4.1 ClpB, an Oligomeric ATPase With Two AAA Modules Per Protomer

The molecular chaperone ClpB belongs to the AAA superfamily of proteins that couple ATP binding and hydrolysis to the disruption of protein-protein interaction and the remodeling of protein complexes in an extraordinary variety of biological circumstances (for reviews, see Refs. [47, 48]). AAA proteins contain at least one ATPase module consisting of two physical domains with conserved sequence motifs (Walker A, Walker B, sensor-1) [49] and form ring-shaped oligomers. The conformation of the oligomer and in some cases oligomerization itself are controlled by the bound nucleotide [50, 51].

In contrast to the related proteins ClpA and ClpX, which unfold soluble protein substrates for proteolysis, ClpB and its *S. cerevisiae* homologue Hsp104 act directly on protein aggregates to return them to the soluble state [52–54]. Recovery of active proteins from the aggregated state by ClpB requires the assistance of the DnaK-DnaJ chaperone system [52, 55–57].

The molecular details of the mechanism linking ATP binding and hydrolysis to the disruption of interactions in protein aggregates remain largely undefined. In the case of ClpB, which comprises two nucleotide-binding domains (NBD), clarification of this mechanism is a particularly difficult problem. On the one hand, one has to obtain site-specific information regarding the contribution of each NBD to the activity (catalysis and binding), but, on the other hand, one has to consider that these properties are regulated by the activity of the other site. In addition, the accumulation of ATP-binding sites within the ClpB oligomer is suggestive of complex allosteric behavior, in which inter-ring communications might contribute to complexity.

4.2.4.2 Nucleotide-binding Properties of NBD1 and NBD2

To provide an initial, general sense of the nucleotide-binding properties of the two NBDs, the fluorescent nucleotide analogue MANT-ADP was titrated with increasing amounts of ClpB from *T. thermophilus* [21, 22]. The same experiment was executed with ClpB mutants (ClpB(K204Q), ClpB(K601Q)), which were selectively inactivated at one NBD by substituting a conserved lysine residue within the Walker A consensus sequence. As these conserved lysine residues interact directly with the β- and γ-phosphates of bound nucleotides, the introduction of an uncharged amino acid at this position impairs nucleotide binding. The fluorescence of MANT-ADP

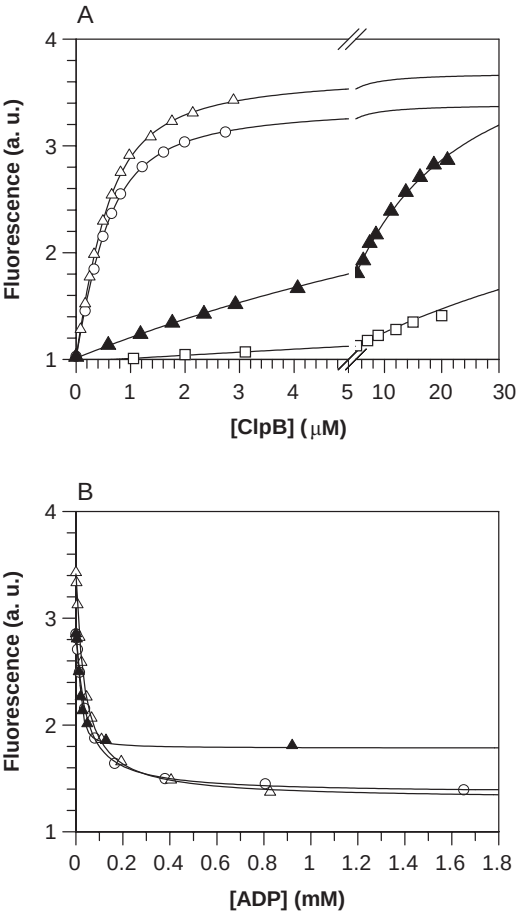

Fig. 4.2. Equilibrium titration experiments with $ClpB_{Tth}$ and MANT-ADP. (A) 0.5 μM MANT-ADP was titrated with $ClpB_{Tth}$(wt) (○), $ClpB_{Tth}$(K204Q) (△), $ClpB_{Tth}$(K601Q) (▲), and the double mutant $ClpB_{Tth}$(K204Q/K601Q) (□) at 25 °C. The excitation wavelength was 360 nm and emission was detected at 440 nm. Data were fitted according to the quadratic equation assuming a 1:1 binding stoichiometry. A K_d of 0.2 μM (±0.02) was observed for $ClpB_{Tth}$(wt) and $ClpB_{Tth}$(K204Q) and a K_d of 15.9 μM (±1.0) was observed for $ClpB_{Tth}$(K601Q). (B) Displacement titration. A preformed $ClpB_{Tth}$*MANT-ADP complex was titrated with ADP ($T = 25$ °C, $\lambda_{ex} = 360$ nm, $\lambda_{em} = 440$ nm). Fitting the curves to a cubic equation yields K_d values of 1.5 μM (±0.08) for $ClpB_{Tth}$(wt) (○), of 2.8 μM (±0.09) for $ClpB_{Tth}$(K204Q) (△), and of 2.3 μM (±0.8) for $ClpB_{Tth}$(K601Q) (▲).

changes in response to binding at both NBDs, and for both ClpB(wt) and the NBD mutants, a saturable increase in fluorescence was observed (Figure 4.2A). Fitting the data to the quadratic binding equation (see Section 4.3) yielded a K_d of 0.2 μM for ClpB(K204Q) and of 16 μM for ClpB(K601Q), indicating that the NBD2 represents a high-affinity and the NBD1 a low-affinity binding site. As the binding affinities differ by two orders of magnitude, MANT-ADP binding to the high-affinity

site of ClpB(wt) masks binding to the low-affinity site. Active site titrations with MANT-ADP and ClpB(K204Q) showed that data are best described by a stoichiometry of 1:2 (one molecule of MANT-ADP binds to a dimer of ClpB), whereas binding to the low-affinity binding site NBD1 follows a 1:1 stoichiometry.

Determination of the affinities for ADP and ATP was based on displacement titrations with a preformed MANT-ADP–ClpB complex and the corresponding nonfluorescent nucleotides (Figure 4.2B). According to the K_d values obtained by fitting this data to the cubic equation (see Section 4.3), ATP binds with a ca. 10-fold lower affinity compared to ADP. (ATP hydrolysis might tamper with the apparent K_d calculated from displacement titrations with ATP. As ATPase activity especially of the NBD mutants is very low, this effect could be neglected.) Surprisingly, the displacement titrations did not confirm the assignment of the NBDs as low- and high-affinity binding sites. With regard to the displacement titrations, both NBDs bind nucleotides with approximately the same affinity (K_d (ADP) ≈ 2 μM; K_d (ATP) ≈ 30 μM).

In contrast to ClpB from *E.coli*, which is capable of hexamerization only in the presence of ATP [51, 58], $ClpB_{Tth}$ forms a hexamer in the absence of nucleotides and in the presence of ATP. ADP binding to $ClpB_{Tth}$ triggers dissociation of high-order oligomers and formation of dimers. Gel-filtration studies with $ClpB_{Tth}$(wt) and the NBD mutants indicated that ADP binding to the NBD1 is responsible for ClpB dissociation [21]. As the bound nucleotide determines the oligomeric state of ClpB, according to the rules of thermodynamics, the oligomeric state should influence nucleotide affinity. To investigate this, the ClpB concentration was kept constant during the fluorescence equilibrium titration with increasing amounts of MANT-ADP (Figure 4.3A). This experiment was repeated with ClpB concentrations ranging from 0.5 μM to 50 μM, thereby covering different distributions of oligomers. Analysis of the obtained data showed that the affinity of the NBD2 to MANT-ADP indeed depends on the oligomeric state of $ClpB_{Tth}$ (Figure 4.3B). The ClpB dimer represents the high-affinity state, while high-order oligomers bind with decreased affinity.

In the case of the chaperone ClpB, application of the fluorescent MANT nucleotide in combination with mutants partially deficient in nucleotide binding has some drawbacks. In the first place MANT-ATP does not meet the requirements of an ATP analogue. The rate of hydrolysis is 100-fold slower compared to ATP, and binding of MANT-ATP triggers oligomer dissociation in contrast to ATP, which stabilizes high-order oligomers. In addition, affinities for MANT-ADP and the unmodified nucleotide differ by a factor of 10, indicating altered kinetic parameters of the modified nucleotide. Notably, these effects are distinct from another technical problem: that of mutations in one active site, such as the K204Q mutation in the Walker A motif of $ClpB_{Tth}$ NBD1, which affects properties of the second site by altering the oligomeric state of the protein.

Because of such problems, we suggest that the site-specific modification of ClpB to introduce fluorescent reporter groups into the NBDs is more suitable to obtain information regarding the properties of each module. A single tryptophan substitution (Y819W) in the C-terminal domain of NBD2 of Hsp104, which has no other

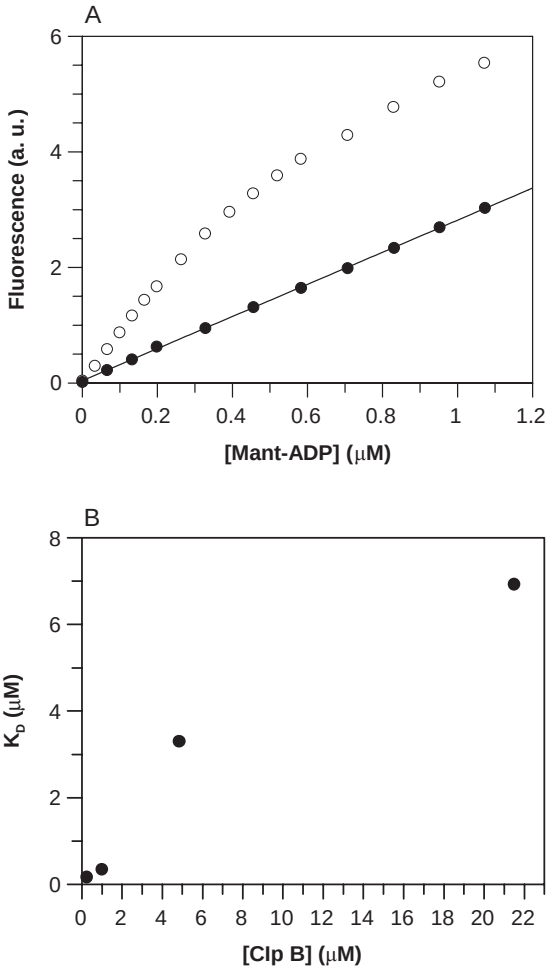

Fig. 4.3. Reverse equilibrium titration of $ClpB_{Tth}$. (A) 0.5 μM $ClpB_{Tth}$(wt) (○) or buffer (●) was titrated with MANT-ADP at 25 °C (λ_{ex} = 360 nm, λ_{em} = 440 nm). The titration curve was corrected for the contribution of the free fluorophore and fitted to a quadratic equation. (B) The plot shows the observed K_d dependent on the ClpB concentration applied in the titra-tion experiment.

tryptophan residues, could be used as an intrinsic fluorescent probe of binding to this site [59]. Site-specific labeling with IANBD of ClpB mutants, carrying Cys substitutions within the NBDs, also proved to be a practical method (S. Schlee and J. Reinstein, unpuplished data).

4.2.4.3 Cooperativity of ATP Hydrolysis and Interdomain Communication

Since ClpB is a hexamer with two binding sites per monomer, the ATP hydrolysis reaction is likely to be regulated at both the homotypic (between identical sites on

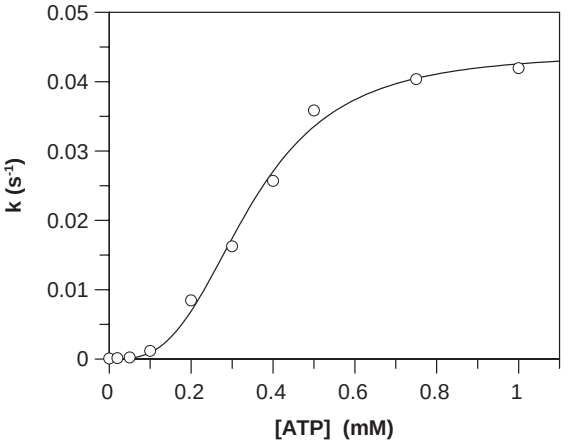

Fig. 4.4. Steady-state kinetic analysis of ATP hydrolysis by $ClpB_{Tth}$. The turnover rate k was determined in a coupled colorimetric assay by incubating 5 μM $ClpB_{Tth}$ with various amounts of Mg-ATP at 25 °C. A fit of the sigmoidal curve with the Hill equation (see "Coupled Enzymatic Assay") yields $n = 3.0$, $k_{cat} = 0.044$ s^{-1}, and $K_m = 0.34$ mM.

different subunits) and heterotypic (between NBD1 and NBD2) levels. Quantitative understanding of the catalytic properties of both ATPase domains is complicated by the fact that effects of mutations on the ATPase activity studied to date are not consistent for different ClpB/Hsp104 proteins [58, 60, 61]. Indeed, measurements of ATP hydrolysis, determined in a coupled colorimetric assay with $ClpB_{Tth}$ [21] or by quantifying released P_i in the case of Hsp104/Hsp78 [61, 62], identified positive cooperativity (Figure 4.4). Mutations in both Walker A motifs of $ClpB_{Tth}$ caused a complete loss of cooperativity and a 100-fold reduction of the ATPase activity. However single-turnover experiments show that both NBDs retain a basal ATPase activity [21]. Remarkably, formation of mixed oligomers, consisting of subunits from ClpB(wt) and the Walker A mutants, leads to a decrease in the ATPase activity, indicating that cooperative effects are based on inter-ring interactions.

A very detailed characterization of the properties of the two AAA modules of Hsp104 could be attained by using [γ-^{32}P]ATP in combination with quantification of a molybdate–inorganic phosphate complex [59]. Analysis of the kinetics of ATP hydrolysis of NBD1 and NBD2 shows that one site (NBD1) is a low-affinity site with a relatively high turnover ($K_m1 = 170$ μM, $k_{cat}1 = 76$ min^{-1}) and that the second site is characterized by a much higher affinity and a 300-fold slower turnover ($K_m2 = 4.7$ μM, $k_{cat}2 = 0.27$ min^{-1}). Both sites show positive cooperativity, with Hill coefficients of 2.3 and 1.6 for the low- and high-affinity sites, respectively. Using mutations in the AAA sensor-1 motif of NBD1 and NBD2 that reduce the rate of ATP hydrolysis without affecting nucleotide binding, Lindquist and coworkers probed the communication between both sites [63]. Impairing ATP hydrolysis of the NBD2 significantly alters the steady-state kinetic behavior of NBD1. Thus, Hsp104 exhibits allosteric communication between the two sites in addition to homotypic cooperativity at both NBD1 and NBD2.

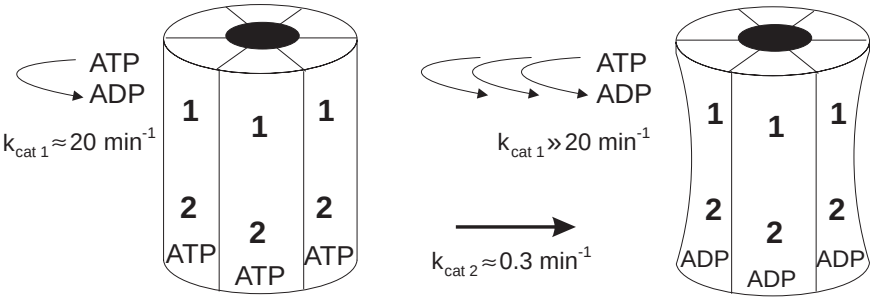

Fig. 4.5. Model for regulation of ATP hydrolysis at Hsp104 NBD1 by the hydrolysis cycle at NBD2 (adapted from Hattendorf et al. [63]). When ATP is bound to NBD2, hydrolysis at NBD1 is relatively slow. Upon ATP hydrolysis at NBD2, a presumed conformational change occurs, resulting in a state in which the rate at NBD1 is elevated.

Interpretation of this data led up to a model predicting that ATP hydrolysis at Hsp104 NBD1 is regulated by the nucleotide-bound state of NBD2 (Figure 4.5). Verification of this model will require transient kinetic measurement of the rate constants associated with ATP binding, ATP hydrolysis, and ADP release at NBD2. Because the oligomeric state stabilized by the bound nucleotide and the effect of mutations within the NBDs were not consistent for ClpB analogues from different organisms, it remains to be clarified whether this model can be generalized or is valid only for Hsp104. In addition, to gain a comprehension of the mechanism linking ATP binding and hydrolysis to the chaperone function of ClpB, the influence of substrates and chaperone cofactors on the ATPase cycle of ClpB has to be defined.

4.3 Experimental Protocols

4.3.1 Synthesis of Fluorescent Nucleotide Analogues

4.3.1.1 Synthesis and Characterization of (P_β)MABA-ADP and (P_γ)MABA-ATP

Synthesis of *N*-(4′-aminobutyl)-2-(methylamino)-benzoylamide *N*-(4′-aminobutyl)-2-(methylamino)-benzoylamide (referred to as tetralinker) was synthesized as follows. To 16.5 g (188 mmol) of 1,4-diaminobutane, 1.66 g (9.38 mmol) of *N*-methylisatoic anhydride was added in small portions. After 4 h of boiling under reflux, the diamine was distilled under vacuum, and the residual (1.86 g, 90%) was dissolved in CH_2Cl_2/MeOH/Et_3N (49:49:2). Chromatography over silica gel 60 (70–230 mesh; Merck, Germany) in the above solvent yielded 1.30 g (63% relative to *N*-methylisatoic acid) of tetralinker with $R_f = 0.14$ (silica gel; CH_2Cl_2/MeOH/Et_3N [49:49:2]) and a melting point of 90–91 °C.

^{1}H-NMR (DMSO-d_6, 500 MHz): $\delta = 1.57$ (m; 4H, $(CH_2)_2$), $\delta = 2.68$ (m; 4H, $(NCH_2)_2$), $\delta = 2.88$ (d; 3H, aryl-NCH_3), $\delta = 3.33$ (t; 2H, alkyl-NH_2), $\delta = 6.73$ (d; 1H, aryl-3-H), $\delta = 6.66$ (m; 1H, aryl-4-H), $\delta = 7.39$ (m; 1H, aryl-5-H), $\delta = 7.65$ (d; 1H, aryl-6-H), $\delta = 7.78$ (t; 1H, OCNH), $\delta = 8.45$ (q; 1H, aryl-NH).

Synthesis of (P_β)MABA-ADP [15] The water-soluble *N*-ethyl-*N*′-(3-dimethylaminopropyl)-carbodiimide (EDC) was used to condense the synthesized tetralinker with the β-phosphate of ADP to give adeninediphospho-β-(*N*′-methylanthraniloylaminobutyl)-phosphoramidate (referred to as (P_β)MABA-ADP) (Figure 4.6). 100 mg (450 μmol) of tetralinker, 19.1 mg (100 μmol) of EDC, and 100 mg (234 μmol) of ADP were dissolved in 1.0 mL 100-mM MES/NaOH pH 6.7 and heated to 50 °C for 35 min. The crude product was purified by HPLC (Waters, Massachusetts, USA) on a semi-preparative reversed-phase C_{18} column (ODS Hypersil Reversed Phase C-18, 5 μm, 120 Å, 250 × 8 mm; Bischoff, Germany) in 0.1 M TEA/HOAc, 25% MeCN with absorption at 260 nm and 350 nm and fluorescence at 430 nm after excitation at 350 nm to identify the product that elutes between ADP and free tetralinker. (P_β)MABA-ADP–containing fractions were pooled, the solvent was distilled under vacuum, and the pure product was lyophilized. The final yield was 31% (relative to ADP) of (P_β)MABA-ADP; the integrity of (P_β)MABA-ADP was proved by ESI-MS and NMR.

^{1}H-NMR (D_2O, 500 MHz; TSP): $\delta = 1.29$ (t; 18H; CH_3; $(CH_3CH_2)_3NH^+$-counter-ion); 1.93 (m; 4H; $(CH_2)_2$); 2.78 (s; 3H; aryl-NCH_3); 2.91 (m; 4H; $N(CH)_2$); 3.21 (q; 12H; CH_2; $(CH_3CH_2)_3NH^+$-counter-ion); 3.74 (m; 1H; 4′-H); 4.23 (m; 2H; 5′-H); 4.37 (m; 1H; 3′-H); 4.49 (m; 1H; 2′-H); 6.08 (d; 1H; 1′-H); 6.72 (m; 1H; aryl-4-H); 6.79 (d; 1H; aryl-6-H); 7.30 (d; 1H; aryl-3-H); 7.37 (m; 1H; aryl-5-H); 8.16 (s; 1H; H-2); 8.47 (s; 1H; H-8).

^{31}P-NMR (D_2O; 500 MHz, PO_4^{3-}): $\delta = -1.24$ (d; α-phosphate); -11.29 (d; β-phosphate).

ESI-MS (negative ion mode): 629.1 g·mol^{-1}, 629.4 g·mol^{-1} were expected.

The extinction coefficient of (P_β)MABA-ADP was determined by comparison of the absorption at 325 nm of (P_β)MABA-ADP and that of the cleaved material. At this wavelength, only the tetralinker contributes to the absorption spectrum. The extinction coefficient of the tetralinker was determined to be 2700 M^{-1} cm^{-1} from a solution of known concentration. Cleavage of (P_β)MABA-ADP is complete after heating the compound for 15 min to 60 °C in 0.1 M HCl according to HPLC analysis. After neutralization, the absorption at 325 nm was unchanged, and the extinction coefficient of (P_β)MABA-ADP is therefore $\varepsilon_{325} = 2700$ M^{-1} cm^{-1}.

Synthesis of (P_γ)MABA-ATP EDC was used to condense the tetralinker with the γ-phosphate of ATP to give adenine triphospho-γ-(*N*′-methylanthraniloylaminobutyl)-phosphoramidate (referred to as (P_γ)MABA-ATP). The synthesis was carried out as described for (P_β)MABA-ADP with 100 mg ATP instead of ADP.

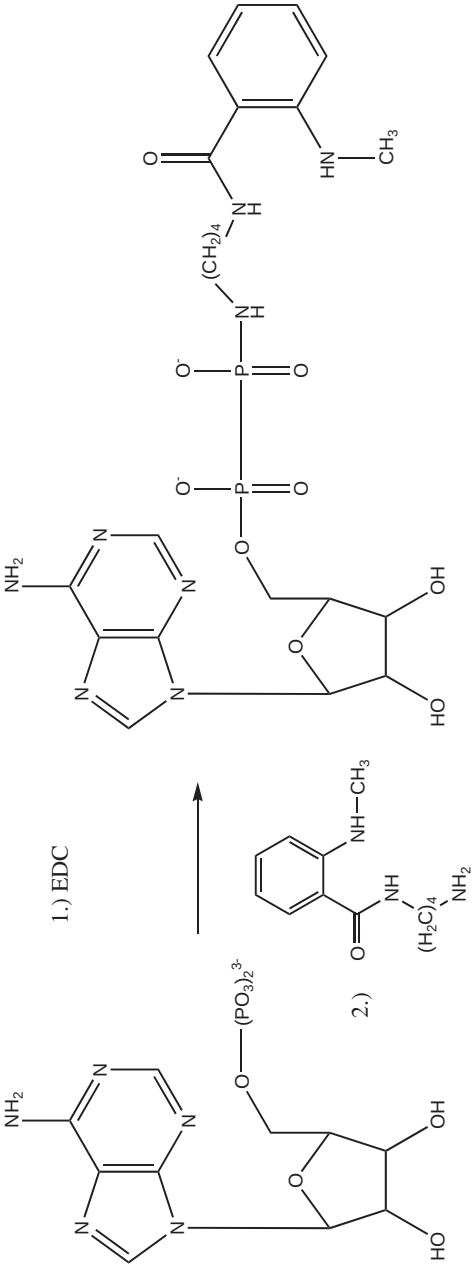

Fig. 4.6. Synthesis of P(β)MABA-ADP. Condensation of ADP with *N*-(4'-aminobutyl)-2-(methylamino)benzoylamide.

^{1}H-NMR (D_2O, 500 MHz; TSP): $\delta = 1.29$ (t; 27H; CH_3; $(CH_3CH_2)_3NH^+$-gegenion); 1.92 (m; 4H; $(CH_2)_2$); 2.78 (s; 3H; aryl-NCH_3); 2.91 (m; 4H; $N(CH)_2$); 3.21 (q; 18H; CH_2; $(CH_3CH_2)_3NH^+$-gegenion); 3.78 (m; 1H; 4′-H); 4.26 (m; 2H; 5′-H); 4.38 (m; 1H; 3′-H); 4.53 (m; 1H; 2′-H); 6.08 (d; 1H; 1′-H); 6.71 (m; 1H; aryl-4-H); 6.78 (d; 1H; aryl-6-H); 7.31 (d; 1H; aryl-3-H); 7.35 (m; 1H; aryl-5-H); 8.16 (s; 1H; H-2); 8.45 (s; 1H; H-8).

^{31}P-NMR (D_2O; 500 MHz, PO_4^{3-}): $\delta = -2.83$ (d; α-phosphate); -13.35 (d; γ-phosphate); -24.73 (t; β-phosphate).

ESI-MS (negative ion mode): 709.1 g·mol^{-1}, 708.4 g·mol^{-1} were expected.

4.3.1.2 Synthesis and Characterization of N8-MABA Nucleotides

Synthesis of MABA-AMP [11] The fluorophores N^8-(4-N'-methylanthraniloyl-aminobutyl)-8-aminoadenosine 5′-tri- and diphosphate (MABA-ATP and MABA-ADP) were synthesized in a four-step reaction. The starting material was AMP that was converted to N8-(4-aminobutyl)-8-aminoadenosine 5′-phosphate (ABA-AMP) [64]. ABA-AMP (50 µmol) was dissolved in 1 mL 0.5-M sodium carbonate (pH 9–10), and 600 µL of 200-mM succinimidyl-*N*-methylanthranylate (SMANT, Molecular Probes) in DMF was added. The mixture was agitated vigorously and left at 50 °C for about 4 h. To quench unreacted SMANT, 1.3 mL of concentrated ammonia (final concentration 8 M) was added, and after 30 min the reaction mixture was diluted with 60 mL water at 4 °C. To remove byproducts, the solution was applied to the quaternary anion-exchange resin QAE Sephadex A 25 (2.2 × 13 cm, Pharmacia). After a wash with water, the column was eluted with a linear gradient to 0.3 M triethyl ammonium bicarbonate (TEAB), pH 7.5. The effluent was monitored by UV absorbance at 260 nm; the product elutes between 0.2 M and 0.25 M TEAB in a single peak. The fractions estimated to contain pure MABA-AMP were pooled and lyophilized three times from water.

Purity of the product was analyzed by reverse phase HPLC with a C_{18} column (ODS-Hypersil, 5 µM, 250 × 4.6 mm) and detection at 280 nm. The sample was eluted with 20% (v/v) acetonitrile in 50 mM potassium phosphate, pH 7.0, over 20 min at 2 mL min^{-1}. A single major peak was observed after 12 min.

The final concentration was determined by UV absorbance with $\varepsilon_{280} = 18\,000$ M^{-1} cm^{-1} at pH 7.5. The molar extinction coefficient was obtained from MABA-ATP by enzymatic ATP determination with hexokinase and glucose-6-phosphate-dehydrogenase [65]. The yield of MABA-AMP from ABA-AMP was ca. 50%.

Synthesis of MABA-ATP MABA-AMP (31 µmol) was dissolved in 0.6 mL water, and 0.23 mL (1 mol) tributylamine was added. The solution was concentrated under reduced pressure and the viscous residue was dried by repeated addition and evaporation of anhydrous pyridine (5 × 0.5 mL) followed by anhydrous DMF (3 × 0.3 mL). The anhydrous tributyl ammonium salt of MABA-AMP was dissolved in 0.5 mL DMF, and 24 mg (0.15 mmol) N,N'-carbonyldiimidazole (CDI) was added. The mixture was agitated vigorously for 20 min and left overnight at

room temperature in a desiccator. In order to hydrolyze excess CDI, 7.5 μL methanol was added, and after 30 min the mixture was concentrated to dryness at 40 °C under reduced pressure. The imidazolide was dissolved in 0.3 mL DMF and stored under anhydrous conditions.

Pyrophosphoric acid (26.7 mg; 0.3 mmol) and 142 μL (0.6 mmol) tributylamine were dissolved in methanol, evaporated, and then evaporated three times with 0.5 mL pyridine and an additional 10 μL tributylamine (0.04 mmol). The precipitate was dissolved in 0.3 mL dry dimethyl formamide (DMF) and added to the imidazolide solution; after shaking vigorously for 30 min, the reaction mixture was left in a desiccator at room temperature for 1–2 days. The precipitate of imidazolium phosphate that formed during the reaction was removed by centrifugation and extracted three times with 0.5 mL DMF. The combined extracts were added to an equal volume of methanol, and the resulting solution was concentrated at 40 °C. The residue was dissolved in 50% (v/v) aqueous ethanol (20 mL) and applied to a QAE Sephadex A25 column (see above).

After washing with 100 mL of 50% (v/v) aqueous ethanol, the sample was eluted with a linear gradient to 1 M TEAB, pH 7.5. The eluent was monitored by UV absorbance at 260 nm. Three major peaks were observed: the first peak at about 0.25 M TEAB was unreacted MABA-AMP, the second at 0.4 M TEAB was MABA-ADP (presumably from phosphoric acid in the pyrophosphoric acid), and the last at 0.6 M TEAB contained MABA-ATP. These fractions were pooled and lyophilized three times from water. Purity was determined by reverse-phase HPLC as described for MABA-AMP. A single major peak was observed at 5 min. The final concentration was determined by enzymatic ATP determination [65]. The UV absorption properties are the same as for MABA-AMP. The yield of MABA-ATP was ca. 27%.

MABA-ADP can be prepared with tributyl-ammonium phosphate instead of the tributyl-ammonium pyrophosphate in the reaction sequence described above.

^{1}H-NMR of MABA-ATP (D_2O, 360 MHz) pH 7.0, 24 °C. The chemical shifts are relative to an external tetramethylsilane standard.

$\delta = 7.98$ (s; 1H; H-2); 7.27 (t; 1H; CH3″) ^3J (7.63 Hz); 7.15 (d; 1H; CH5″) ^3J (7.83 Hz); 6.68 (d; 1H; CH2″) ^3J (8.41 Hz); 6.50 (t; 1H; CH4″) ^3J (7.46 Hz); 5.96 (d; 1H; 1′-H) $^3J1'2'$ (7.8 Hz); 4.65 (t; 1H; 2′-H) $^3J2'3'$ (6.74 Hz); 4.44 (m; 1H; 3′-H); 4.35 (s; 1H; 4′-H); 4.18 (m; 2H; 5′5″-H); 3.55 (m; 2H, $(CH_2)_4$); 3.38 (m; 2H; $(CH_2)_1$); 2.72 (s; 3H; Ph-N-CH_3); 1.79 (m, 2H, $(CH_2)_2$); 1.72 (m; 2H; $(CH_2)_3$); plus counterion (triethylammonium) peaks.

4.3.1.3 Synthesis of MANT Nucleotides

Synthesis of MANT-ADP and MANT-ATP [18] The nucleotide (0.5 mmol ADP, ATP) was dissolved in 7 mL water at 38 °C. The pH was adjusted to 9.6 with NaOH. To this solution a crystalline preparation of methylisatoic anhydride (2.5 mmol) was added in small portions with continuous stirring. The pH was maintained at 9.6 by titration with 2 N NaOH for 2 h. The reaction mixture was cooled and washed three times with 10 mL chloroform; the derivative remains in the

aqueous phase. The reaction products can be monitored by TLC on silica gel. On a silica gel plate developed in 1-propanol/NH_4OH/water (6:3:1, v/v, containing 0.5 g L^{-1} of EDTA), the R_f values behave as follows: unmodified nucleotides < fluorescent nucleotides (R_f (MANT-ADP): 0.44, R_f (MANT-ATP): 0.21) < *N*-methylanthranilic acid. The fluorescent analogue can be identified under an ultraviolet lamp (366 nm) by its brilliant blue fluorescence, while *N*-methylanthranilic acid shows violet fluorescence.

The reaction mixture was then diluted to a volume of 100 mL and the pH adjusted to 7.5 with 1 M acetic acid. To remove byproducts, the solution was applied to the anion-exchange resin Q-Sepharose FF (3.0 × 25 cm, Pharmacia). After a wash with 50 mM triethyl ammonium bicarbonate (TEAB), pH 7.5 at a flow rate of 5 mL min^{-1}, the column was eluted with a linear gradient to 0.7 M TEAB. The effluent was monitored by UV absorbance at 260 nm and 366 nm; the fluorescent nucleotide analogues elute after the unreacted nucleotide and the fluorescent byproduct between 0.6 and 0.7 M TEAB in a single peak. MANT nucleotide-containing fractions were identified by TLC and the absorption profiles. Fractions were pooled, the solvent was distilled under vacuum, the residual was dissolved in methanol, and the pure product was lyophilized.

Purity of the product was analyzed by reverse-phase HPLC with a C_{18} column (ODS-Hypersil, 5 μM 250 × 4.6 mm, Bischoff). The column was developed with a linear gradient to 50% (v/v) acetonitrile in 50 mM potassium phosphate, pH 6.5, over 20 min at 1.5 mL min^{-1} and elution products were monitored by absorption at 280 nm and fluorescence (excitation, 360 nm; emission, 440 nm). MANT-ADP elutes as a single peak after 12.5 min, while MANT-ATP elutes after 11.7 min.

The final concentration of MANT nucleotides was determined by UV absorbance with $\varepsilon_{255} = 23\,300\ M^{-1}\ cm^{-1}$ at pH 8.0. The yield of MANT nucleotide amounts to ~50%. MANT nucleotides exist in solution as an equilibrium mixture of both the 2′ and 3′ isomers (60% 3′ isomer), which are in slow base-catalyzed exchange ($t_{1/2} \sim 10$ min, pH 7.5, 25 °C).

4.3.2
Preparation of Nucleotides and Proteins

4.3.2.1 Assessment of Quality of Nucleotide Stock Solution

It is important that fluorescent nucleotide analogues be fully characterized in terms of structure and purity. The latter should demonstrate the absence of unmodified nucleotides or non-nucleotide fluorescent species that could seriously affect binding studies. Checks on purity are most easily achieved by high-performance liquid chromatography (HPLC).

Unmodified Nucleotides In our experience, commercially available ATP contains a background level of ADP (typically 1–4%). Impurities in nucleotide stock solutions give rise to artifacts when determining rate constants of the ATPase cycle. Therefore, we advise controlling the purity of nucleotide stock solutions by HPLC analysis. The purity of ATP and ADP solutions can be analyzed by reverse-phase HPLC

Tab. 4.2. HPLC program for purity control of P-MABA nucleotides.

Time (min)	*Flow rate (mL min^{-1})*	*A (%)*	*B (%)*
Start	2	70	30
7	2	70	30
7.1	2	0	100
12	2	0	100
12.1	2	70	30
20	2	70	30

with a C_{18} column (ODS-Hypersil, 5 μM, 250 × 4.6 mm, Bischoff) and detection at 254 nm. The sample (usually 20 μL of a 10-μM solution) was eluted with 50 mM potassium phosphate (pH 6.8) over 10 min at 1.5 mL min^{-1}. Nucleotides elute as single peaks with retention times of 3.5 min (ATP), 4.1 min (ADP), and 5.0 min (AMP) at room temperature.

P(β)MABA-ADP and P(γ)MABA-ATP Purity of the phosphate-modified nucleotide analogues P(β)MABA-ADP and P(γ)MABA-ATP was determined by reverse-phase HPLC with a C_{18} column (ODS-Hypersil, 5 μM 250 × 8 mm, Bischoff) and monitoring UV absorption at 254 nm and 325 nm and fluorescence (excitation, 335 nm; emission, 440 nm). The sample was eluted with a step gradient at 2 mL min^{-1} (see Table 4.2) (buffer A: 100 mM triethylammonium acetate pH 7.0; buffer B: 100 mM triethylammonium acetate pH 7.0, 70% acetonitrile). Peaks were observed after 3.8 min (ADP, ATP), 5.7 min (P(γ)MABA-ATP), and 7.6 min (P(β)MABA-ADP).

N8-MABA-ADP and N8-MABA-ATP Purity of nucleotides modified at the N8 position was analyzed by reverse-phase HPLC with a C_{18} column (ODS-Hypersil, 5 μM, 250 × 4.6 mm) and detection at 280 nm [11]. The sample was eluted with 20% (v/v) acetonitrile in 50 mM potassium phosphate, pH 7.0, over 20 min at 2 mL min^{-1}. Peaks were observed after 5.3 min (N8-MABA-ATP), 9.1 min (N8-MABA-ADP), and 12.0 min (N8-MABA-AMP).

MANT-ADP and MANT-ATP The purity of MANT nucleotides can be examined by reverse-phase HPLC with a C_{18} column (ODS-Hypersil, 5 μM, 250 × 4.6 mm), and the effluent is monitored by measuring UV absorbance at 254 nm as well as fluorescence (excitation, 360; emission 440). The column was eluted with a linear gradient to 50% acetonitrile in 50 mM potassium phosphate (pH 6.5) at 1.5 mL min^{-1} (see Table 4.3). MANT-nucleotides elute as double peaks (2′ and 3′ derivatives) with retention times of 13.7 min (MANT-ATP) and 14.5 min (MANT-ADP).

4.3.2.2 Determination of the Nucleotide Content of Proteins

For the investigation of nucleotide-binding capacities of chaperones, the proteins had to be prepared in a nucleotide-free state. To determine the nucleotide content of a protein preparation, 16 μL of a 100-μM protein solution was mixed with 4 μL

Tab. 4.3. HPLC program for purity control of MANT nucleotides.

Time (min)	*Flow rate (mL min^{-1})*	*A (%)*	*B (%)*
0	1.5	100	0
2.0	1.5	100	0
22.0	1.5	0	100
23.0	1.5	100	0
30.0	1.5	100	0

50% (w/v) trichloroacetic acid and incubated for 10 min on ice. The precipitated protein was removed by centrifugation. 10 µL of the supernatant was neutralized with 20 µL of a 2-M solution of potassium acetate. The sample was diluted 1:10 in 50 mM potassium phosphate (pH 6.8) and 20 µL of this solution was analyzed by HPLC (see "Assessment of Quality of Nucleotide Stock Solution" for HPLC conditions). By comparing the integrated peaks with calibration peaks corresponding to nucleotide stock solutions of known concentrations, the nucleotide content of the probe can be calculated.

4.3.2.3 Nucleotide Depletion Methods

Preparation of nucleotide-free chaperones is crucial for the determination of nucleotide-binding kinetics. The nucleotide depletion method applied to a specific chaperone depends on the nucleotide affinity. To prepare ClpB, whose nucleotide affinity is comparatively low (micromolar range), in a nucleotide-free form, it is sufficient to remove Mg^{2+} before a gel-filtration step and thus weaken the binding of nucleotides [21]. Nucleotide depletion of DnaK, which binds nucleotides with dissociation constants in the nanomolar range [66], requires more thorough procedures, which are listed below.

K^+ and Mg^{2+} Depletion As two K^+ and one Mg^{2+} coordinate the bound nucleotide in the ATPase site of DnaK [67], removal of these ions should decrease nucleotide affinity. Therefore, the nucleotide depletion procedure included extensive dialysis over 2–3 days against a buffer containing 1 mM EDTA in the absence of K^+ and Mg^{2+} ions followed by size-exclusion chromatography [68]. A shortcoming of this method is that at high protein concentrations the dissociation of a very small percentage of the bound nucleotide provides enough free nucleotide to prevent further dissociation. When reducing the enzyme concentration to facilitate the dialysis of the bound nucleotide, protein denaturation occurs easily [69].

Exchange Against Low-affinity Nucleotide Analogues Nucleotide removal from DnaK preparations was accomplished by competing off bound nucleotide with excess AMP-PNP or AMP, followed by dialysis to remove less tightly bound AMP-PNP or AMP [68–70]. Nucleotide exchange can be accelerated by addition of catalytic amounts of GrpE to the sample. As for the K^+ and Mg^{2+} depletion procedure, extensive dialysis (72 h) is indispensable. Therefore, the procedure is not suitable

with regard to aggregation-prone proteins. The final purification step is again a size-exclusion chromatography.

Incubation With Alkaline Phosphatase Entirely nucleotide-free $DnaK_{Tth}$ was obtained after treatment with 3–4 U alkaline phosphatase (Boehringer, Mannheim) for 4–6 h in a buffer without K^+ and Mg^{2+} and simultaneous removal of AMP by dialysis. Alkaline phosphatase was removed by a further gel-filtration step [9].

4.3.3 Steady-state ATPase Assays

Observing the ATPase reaction under steady-state conditions implies that the rate of reaction is constant for a relatively long period of time and that multiple turnovers take place. This is the case when the ATP concentration exceeds the chaperone concentration substantially and, ideally, the ATP concentration does not change during the experiment. This could be achieved by using an ATP-regenerating system. Steady-state ATPase assays allow determination of the enzymatic parameters K_m and V_{max}; however, it is not possible to define individual steps and rate constants of the ATPase mechanism. Procedures for determining the steady-state ATPase activity of chaperones are listed below.

4.3.3.1 Coupled Enzymatic Assay

In a colorimetric assay, the hydrolysis of ATP is coupled to the oxidation of NADH by using the enzymes pyruvate kinase and lactate dehydrogenase (Figure 4.7). Because NADH but not NAD^+ absorbs at 340 nm, ATP hydrolysis can be monitored by a decrease in A_{340} [71]. The steady-state ATPase rate of $ClpB_{Tth}$ has been investigated by the coupled enzymatic assay [21].

The assay is carried out in microtiter plates or plastic cuvettes. Measurements are initiated by the addition of an appropriate amount of chaperones (5 μM ClpB) to various concentrations of Mg*ATP and 20 μg mL^{-1} lactate dehydrogenase, 50 μg mL^{-1} pyruvate kinase in 50 mM Tris/HCl (pH 7.5), 100 mM KCl, 5 mM $MgCl_2$, 2 mM EDTA, 2 mM DTE, 0.4 mM PEP, 0.4 mM NADH. The ATP turnover rate in the presence of various ATP concentrations is calculated as follows:

$$k = \Delta A_{340}/(\varepsilon_{NADH} \cdot d \cdot c_p) \quad (1)$$

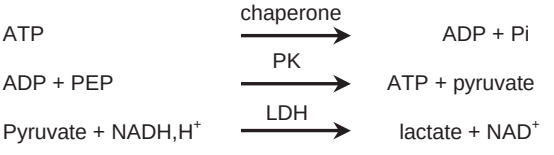

Fig. 4.7. The coupled colorimetric assay. ADP produced by the hydrolysis of ATP reacts with PEP (phosphoenolpyruvate) to form pyruvate in a reaction catalyzed by the PK (pyruvate kinase), whereby ATP is regenerated. Pyruvate is reduced to lactate by the LDH (lactate dehydrogenase), while NADH is oxidized. The decrease of the NADH absorption at 340 nm is a measure for hydrolytic activity.

k: ATP turnover rate in s^{-1}
ΔA_{340}: change of A_{340} in absorption units per s
ε_{NADH}: extinction coefficient of NADH $\varepsilon_{340} = 6220\ M^{-1}\ cm^{-1}$
d: path length in cm
c_p: protein concentration (M)

The k_{cat} and K_m of the ATPase reaction can be determined by plotting the ATP turnover rate k against the ATP concentration and by fitting the obtained curve to the Michaelis-Menten equation (Eq. (2)). If allosteric effects play a role in ATP hydrolysis, the Michaelis-Menten equation should be expanded by introducing the Hill coefficient n (Eq. (3)) (Figure 4.4).

$$k = k_{cat} \cdot S/(K_M + S) \quad (2)$$

$$k = k_{cat} \cdot S^n/(K_M{}' + S^n) \quad (3)$$

k: ATP turnover rate (s^{-1}) at specific ATP concentration
k_{cat}: maximal ATP turnover rate (s^{-1})
S: ATP concentration (M)
K_M: Michaelis-Menten constant (M)
n: Hill coefficient

4.3.3.2 Assays Based on [α-^{32}P]-ATP and TLC

The use of radioactive-labeled ATP facilitates quantification of hydrolytic products. Assays of this kind have been used extensively to characterize the ATPase activity of $DnaK_{Eco}$ [70, 72–75]. Exemplary reaction mixtures (75 µL) contained 50 µg mL^{-1} BSA, 1 nM DnaK, 3 µCi mL^{-1} of [α-^{32}P]ATP or [γ-^{32}P]ATP (1 nM), and 2–80 nM unlabeled ATP in buffer (40 mM HEPES/KOH, pH 7.6, 11 mM magnesium acetate, 200 mM potassium glutamate) [70]. DnaK was pre-incubated at the indicated reaction temperature for 5 min, and hydrolysis reactions were initiated with the addition of ATP. Samples from the reaction mixture (≥ 6 per reaction) were quenched at various times by adding 8 µL of the reaction mixture to 2 µL of 1-N HCl and placing the samples on ice. Each sample (2 µL) was spotted on polyethylenimine cellulase TLC sheets, which were developed in 1 M formic acid, 0.5 M LiCl. The fraction of nucleotide present as ADP could be determined using a phosphorimager system, or spots were cut out and the radioactivity was quantified by liquid scintillation counting. Hydrolysis of ATP should not exceed ~15%, as formed ADP competes with ATP and decreases the hydrolytic rate.

At each concentration of ATP, v_0 was determined from a linear regression analysis. K_M and k_{cat} were determined by fitting a plot of (v_0/[DnaK]) against the concentration of ATP to the Michaelis-Menten equation.

4.3.3.3 Assays Based on Released P_i

Quantification of the P_i released during ATP hydrolysis represents a sensitive measure [76]. A modified method allowed the evaluation of cooperative effects in the

ATPase reaction of Hsp104 [63]. All measurements were performed in 20 mM HEPES pH 7.5, 20 mM NaCl, and 10 mM $MgCl_2$. Hydrolysis reactions were initiated by mixing 12.5 μL of an Hsp104 solution (final concentration 200 nM) and 12.5 μL of an ATP solution containing 10 μCi of [γ-^{32}P]ATP and 1–1000 μM ATP. At varying times reactions were stopped by addition of 175 μL of 1 M $HClO_4$ and 1 mM Na_3PO_4. Ammonium molybdate was added (400 μL of 20 mM) and the molybdate–inorganic phosphate complex was extracted by addition of 400 μL of isopropyl acetate followed by vortexing. The cold P_i is present as carrier and facilitates extraction of the molybdate-phosphate complex into the organic phase.

The amounts of radioactivity in the organic phase and in the aqueous phase were determined by scintillation counting and used to determine the percentage of ATP hydrolysis. After subtraction of free phosphate in a blank reaction, the initial reaction rate was calculated. Plots of the initial reaction rates versus ATP concentration were fitted to a sum of two independent cooperative kinetic transitions [63].

Another possible way to monitor P_i release in real time is the application of the fluorescent reporter PBP-MDCC (A197C mutant of phosphate-binding protein from *E. coli* with attached *N*-[2-(1-maleimidyl)ethyl]-7-(diethylamino)coumarin-3-carboxamide) [77].

4.3.4 Single-turnover ATPase Assays

For measurements of single-turnover ATPase activity, the chaperone has to be present in excess over ATP, so that saturation of the chaperone is achieved (depends on K_d!) and only one turnover of ATP takes place. Conversion of ATP to ADP as a function of time is described by a first-order exponential equation ($y = A \cdot e^{-kt}$).

Typically, ATP and the chaperone are mixed, the reaction is stopped at various times by addition of a quencher, and the fraction of nucleotide present as ADP is determined. As a rule of thumb, the reaction can be analyzed by ''hand mixing'' procedures if $t_{1/2}$ (ATP) > 10 s; faster ATPase rates have to be determined by quenched-flow procedures. If product release (ADP or P_i) is rate-limiting in the ATPase cycle, the rate constant determined under single-turnover conditions exceeds the one observed under steady-state conditions.

4.3.4.1 Manual Mixing Procedures

Reaction mixtures and reactions are essentially identical to those described for measurement of steady-state ATPase activity, except that the protein concentration exceeds ATP concentration and ATP hydrolysis is followed to completion. A protocol used for determining the single-turnover ATPase activity of $ClpB_{Tth}$ is given in ref. [21].

The reaction was started by adding 150 μM ClpB to 75 μM ATP in 50 mM Tris/HCl (pH 7.5), 5 mM $MgCl_2$, 2 mM EDTA, 2 mM DTE, 100 mM KCl. After incubation for appropriate periods (0, 10, 20, 30, . . . , 120 min), 4 μL samples were drawn and the protein was precipitated by addition of 2 μL of 1-M $HClO_4$. After vortexing,

the mixture was incubated for 5 min on ice, and 40 μL of 2-M potassium acetate was added for neutralization. After centrifugation, 20 μL of the supernatant was analyzed with reverse-phase HPLC on a C_{18} column (ODS-Hypersil, 5 μM 250 × 4.6 mm, Bischoff) and detection at 254 nm (for conditions, see 4.3.2.1 "Unmodified Nucleotides"). The relative amounts of ATP and ADP present in each sample were calculated by integrating peaks corresponding to ADP and ATP from the elution profile.

The single-turnover ATPase activity of DnaK has been characterized with radioactive [α-^{32}P]ATP [70, 78] and [γ-^{32}P]ATP [9] using procedures similar to those described for steady-state measurements.

4.3.4.2 Quenched Flow

$DnaJ_{Eco}$ is capable of stimulating the single-turnover ATPase activity of $DnaK_{Eco}$ ≥ 200-fold [78]. As the stimulated ATP-hydrolysis occurred too rapidly to measure by hand, it was monitored using a rapid quench-flow apparatus [79, 80]. Proteins and [α-^{32}P]ATP were loaded into separate 1-mL syringes that were used to fill the 15-μL sample loops. The drive syringes were pushed at a constant velocity, mixing the sample solutions in a 1:1 ratio. The reactions were automatically quenched after a defined reaction time (0.05–120 s) with 80 μL of a 0.3 N HCl solution present in a separate drive syringe [80]. To evaluate the influence of DnaJ on the ATPase activity of DnaK, equal volumes of ATP (8 μM) and nucleotide-free DnaK (9.6 μM) were pre-incubated for 10 s before 1:1 mixing with various concentrations of DnaJ in a quenched-flow apparatus. The reaction was quenched after 0.5 s with perchloric acid [79]. The ATP/ADP ratio in every sample is determined as described for steady-state measurements by HPLC analysis or, in the case of radioactive ATP, with TLC.

4.3.5 Nucleotide-binding Measurements

Techniques used to obtain equilibrium-binding constants (K_a and K_d) are manifold, and methods range from analytical ultracentrifugation to surface plasmon resonance and fluorescence titrations. Hereafter, the methods frequently used to characterize binding equilibria of nucleotides and chaperones are described.

4.3.5.1 Isothermal Titration Calorimetry

In isothermal titration calorimetry (ITC), the heat of interaction between two molecules is used to define the binding process. A syringe containing a "ligand", e.g., the nucleotide, is titrated into a cell containing a solution of the "macromolecule", mostly a protein. As the two elements interact, heat is released or absorbed in direct proportion to the amount of binding that occurs. When the macromolecule in the cell becomes saturated with added ligand, the heat signal diminishes until only the background heat of dilution is observed. The area underneath each injection peak is equal to the total heat released for that injection. When this is plotted against the molar ratio of ligand added to macromolecule in the cell, a complete

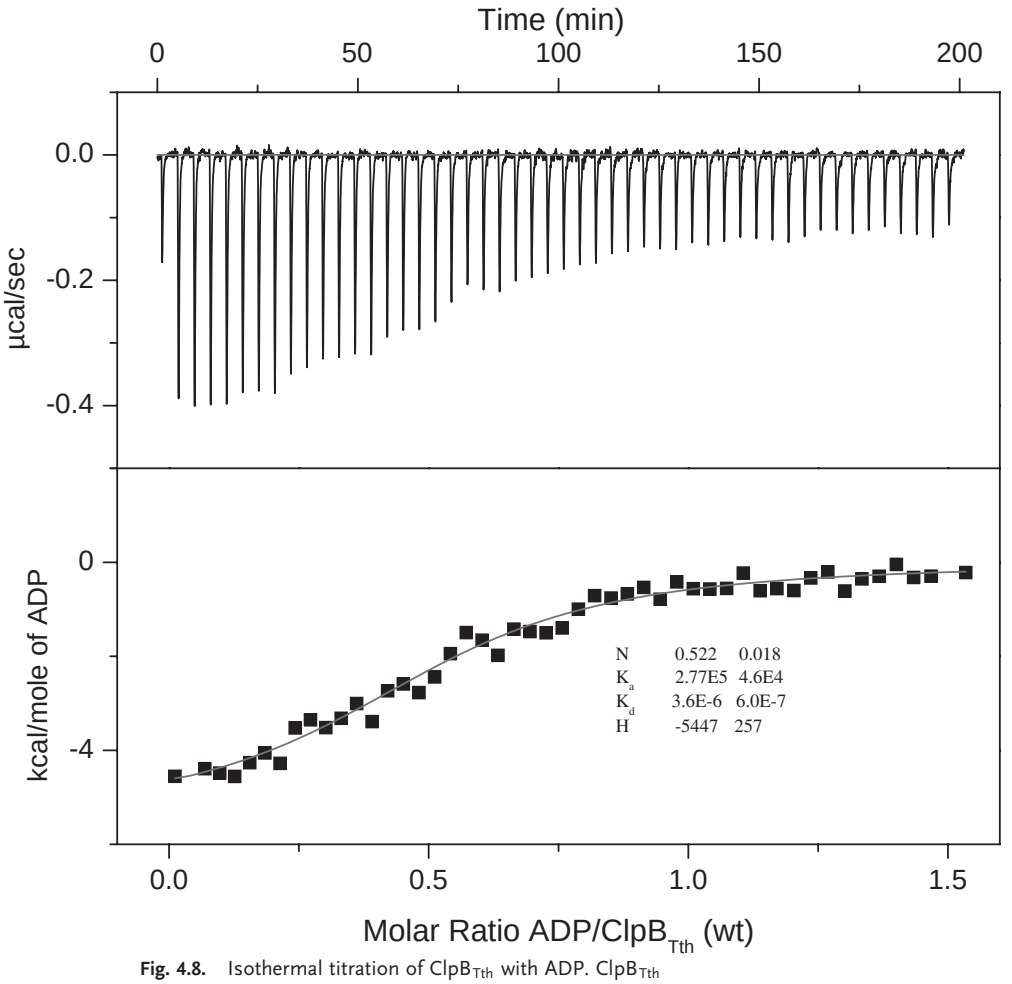

Fig. 4.8. Isothermal titration of $ClpB_{Tth}$ with ADP. $ClpB_{Tth}$ (40 µM) was titrated with 300 µM ADP at 25 °C in an isothermal titration calorimeter in 7-µL steps until saturation was achieved.

binding isotherm for the interaction is obtained (Figure 4.8). ITC measurements yield an entire set of experimental parameters for the binding process, including binding affinity (K_a or K_d), binding stoichiometry (n), heat (ΔH), and heat capacity (ΔCp). ITC measurements were used to identify the ATP-binding site of Hsp90 [81]. The protocol cited below was used for equilibrium studies of the DnaK-GrpE-ADP system from *T. thermophilus* [82].

A solution of 10 µM $DnaK_{Tth}$ in the presence or absence of 42 µM $GrpE_{Tth}$ in 25 mM HEPES-NaOH (pH 7.5), 100 mM KCl, 5 mM $MgCl_2$ (cell volume 1.3 mL), was titrated with 142 µM MABA-ADP in 6-µL steps until saturation was achieved. In the same way, a solution of 11 µM $DnaK_{Tth}$ or $DnaK_{Tth}$ pre-incubated with 20 µM

MABA-ADP was titrated with a solution of 162 μM $GrpE_{Tth}$ in 7-μL steps until saturation. Solutions were incubated for 5 h before measurements to allow for completion of the binary $DnaK_{Tth}$-$GrpE_{Tth}$ or $DnaK_{Tth}$–MABA-ADP complex formation. Data were analyzed by Eq. (4) using the program Microcal Origin for ITC to give the enthalpy, stoichiometry of binding, and association constant.

$$Q = \frac{n \cdot [E] \cdot \Delta H_B \cdot V}{2} \cdot \left(1 + \frac{[L]}{n \cdot [E]} + \frac{1}{n \cdot K_A \cdot [E]} - \sqrt{\left(1 + \frac{[L]}{n \cdot [E]} + \frac{1}{n \cdot K_A \cdot [E]} \right)^2 - \frac{4 \cdot [L]}{n \cdot [E]}} \right) \quad (4)$$

Q: heat in J
$[E]$: total concentration of the protein in M
$[L]$: total concentration of the ligand in M
V: volume of cell in liters
ΔH_B: molar enthalpy of the binding reaction in J mol^{-1}
n: number of active binding sites on the protein
K_A: association equilibrium constant in M^{-1}

4.3.5.2 Equilibrium Dialysis

Nucleotide-binding properties of Hsp70s have been studied extensively by equilibrium dialysis [66, 69]. In any mixture of the ligand and macromolecule, it is difficult to distinguish between bound and free ligand. If, however, the free ligand can be dialyzed through a membrane, until its concentration across the membrane is at equilibrium, free ligand concentration can be measured.

A typical experiment proceeds as follows [66]: [^{14}C]ATP or [^{14}C]ADP together with a regenerating system (creatine kinase/creatine phosphate for ATP, glucose/hexokinase for ADP) were added to both sides of the membrane, while nucleotide-free Hsp70 was added to only one side of the membrane at the beginning of the experiment. Then the dialysis chambers were put in a 4 °C cold room for 24 h with gentle agitation. The nucleotide contents on each side of the membrane were quantified by scintillation counting at the end of the dialysis and yielded the concentration of the free-nucleotide and total nucleotide concentration. Data obtained from several experiments and with varying initial concentrations of ligand can provide the association constant and stoichiometry of the binding reaction.

4.3.5.3 Filter Binding

Apparent rates of association and dissociation of nucleotides with Hsc70 as well as equilibrium dissociation constants were established by filter-binding experiments [83]. To determine the equilibrium-binding constant for MgADP-protein complexes, protein at concentrations from 20 nM to 2.56 μM was incubated with 1 nM [α-^{32}P]ADP at 25 °C. The solution was then filtered and the K_d and the filter efficiency E were determined by a least-squares fit of the equation

$$\theta = \frac{[\text{protein}]}{[\text{protein}] + K_D} E \tag{5}$$

to the data on the fraction of background-corrected counts retained on the filter ($\theta = (C - C_B)/(C_T - C_B)$, where C is the total counts retained on the filter, C_B is the background counts retained when ATP is filtered without protein, and C_T is the total input counts) as a function of protein concentration.

4.3.5.4 Equilibrium Fluorescence Titration

There are two possible situations that can be exploited to study protein-ligand interaction by fluorescence [84]. Either the fluorescence of the protein changes on binding, or the fluorescence of the nucleotide ligand is altered. In general control of temperature and solution conditions is important in binding studies. The fluorescence of most fluorophores, as well as association constants, is sensitive to temperature. Also, care should be taken to control pH during a titration (check pH of nucleotide stock solution!). Dust particles should be removed from both ligand and protein solutions by Millipore filtration or by centrifugation, and buffers should be degassed thoroughly. It is necessary to have accurate values for the total concentrations of ligand ($[L]_0$) and enzyme ($[E]_0$), which may be the greatest limitation for the determination of accurate values of K_d.

Intrinsic Tryptophan Fluorescence When changes in the fluorescence of a protein are observed, the fluorophore may be one or more of the intrinsic tryptophan residues, because emission from this amino acid usually dominates the fluorescence of proteins. The λ_{max} of tryptophan emission ranges from 308 nm for deeply buried tryptophans, to 350 nm for solvent-exposed residues in unfolded proteins. Therefore, not only changes of the amplitude but also shifts of the emission maximum can be exploited as signal. Another advantage of using tryptophan fluorescence is that no chemical modification of either protein or ligand is needed.

The binding of a ligand to a protein may directly affect the fluorescence of a tryptophan residue by acting as a quencher (i.e., by a collisional or energy-transfer mechanism), as seen for ATP quenching the tryptophan fluorescence in human Hsp90 [81, 85], or by physically interacting with the fluorophore and thereby changing the polarity of its environment and/or its accessibility to solvent. Alternatively, a ligand may bind at a site that is remote from the tryptophan residue and may induce a change in conformation of the protein that alters the microenvironment of the tryptophan. These changes in microenvironment may result either in enhancement or quenching of fluorescence or in shifts in the spectrum to the red or blue. Such a fluorescent probe was reported for the NBD2 of Hsp104 [59], where a single tryptophan substitution (Y819W) in the C-terminal domain of NBD2 served as a probe for nucleotide binding.

Tryptophan fluorescence is measured with λ_{ex} between 290 nm and 295 nm and λ_{em} between 310 nm and 350 nm. For equilibrium fluorescence titrations, the applied concentration of the protein should be far below the K_d of the interaction. Nucleotide is added in sequential increments from highly concentrated stock solu-

tion (1–50 mM) until saturation of fluorescence emission is obtained. Fluorescence is corrected for dilution from nucleotide addition, and fluorescence is plotted as a function of nucleotide concentration. Data are usually fit to the quadratic equation (see 4.3.6.1 "Quadratic Equation" below).

Fluorescent Nucleotide Analogues The choice of the fluorescent probe depends on its ability to replace the native nucleotide (Is the modified nucleotide hydrolyzed? Does it bind like the unmodified nucleotide?) and its environmental sensitivity and thus the amplitude of the signal [5]. In addition, binding specificity should be probed before application. The presence of hydrophobic groups in the fluorescent nucleotide analogues presents the possibility that they may bind to proteins at sites other than the nucleotide-binding site. The occurrence of such nonspecific binding can be determined by carrying out the relevant experiment in the presence of a large excess of the physiological nucleotide, which should not give rise to changes in the fluorescent signal. Usually MANT nucleotides show little or no nonspecific binding to ATPases.

With regard to chaperones, examples for equilibrium fluorescence titrations with fluorescent nucleotide analogues are found in Ref. [21] (MANT-ADP and $ClpB_{Tth}$), Ref. [11] (N8-MABA-ADP and $DnaK_{Eco}$), and Ref. [14] (($P\gamma$)-MABA-ATP and yeast Hsp90). In a standard procedure, the fluorescent nucleotide is placed in a cuvette (0.5 μM in standard fluorescence buffer: 50 mM Tris/HCl (pH 7.5), 100 mM KCl, 5 mM $MgCl_2$, 2 mM EDTA, 2 mM DTE), aliquots of the chaperone solution are added (with mixing), and the signal after a brief period of time is measured (correcting the signal for dilution of the fluorescent species and for the inner-filter effect). Curves are fitted according to the quadratic equation (see below). MANT fluorescence is measured with λ_{ex} at 360 nm and λ_{em} at 440 nm. For a tightly binding system, one must be concerned that equilibrium is reached after each addition of reactant. Association is often limited only by diffusion, but dissociation rate constants are much smaller. In such a case, measurements can also be made with a series of prepared solutions, covering various ratios of protein and nucleotide. An example of a fluorescence-binding study is presented in Figure 4.2A.

Active Site Titration In order to perform proper analyses of ligand-binding data and to evaluate enzymatic mechanisms, it is desirable to know with which stoichiometry binding partners interact. For this purpose, a straightforward approach exists that can be performed with various methods; it is described here for the case of fluorescent nucleotide–protein interaction [86]. It is important to note that some constraints apply for successful application of this technique. Firstly, the initial concentration of the signaling ligand, in this case the fluorescent nucleotide, should be well above the estimated K_d (say 5-fold or, even better, 10-fold) such that addition of protein results in nearly complete binding until all nucleotide is bound (saturated). Secondly, the concentrations of the binding partners should be determined accurately, which is straightforward in the case of nucleotides since they are usually pure and have a well-defined extinction coefficient. In the case of protein, this could be more problematic since most common methods to deter-

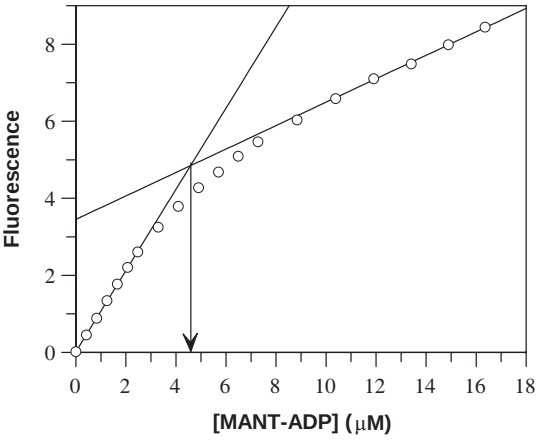

Fig. 4.9. Active site titration of $ClpB_{Tth}$(trunc) with MANT-ADP. Concentration of ClpB(trunc), a shortened ClpB variant lacking the NBD1, at start was 10 μM (measured according to Ref. [106]), and initial volume was 600 μL. Interpolation of the two phases gives an intersection at [MANT-ADP] = 4.8 μM. The volume-corrected concentration of ClpB(trunc) at this point is 9.8 μM. This indicates that one ClpB-dimer is able to bind one molecule of MANT-ADP.

mine protein concentration can deviate for certain proteins. Once these two prerequisites are met, the actual experiment/analysis is quite simple. Protein is added to the ligand in small steps, usually corresponding to concentration increases that amount to 1/20th of the initial ligand concentration until an appreciable saturation of the fluorescence signal is obtained. Now the protein may be added in larger steps until (after volume correction) no further change of signal is observed. The two resulting phases of this titration, initial nearly linear increase and saturation, are extrapolated by hand with linear slopes. The point of intersection then determines at which concentration of added protein the ligand is saturated and as such the stoichiometry of the binding isotherm.

An example for such an experiment is given in Figure 4.9, where MANT-ADP was titrated to $ClpB_{Tth}$(trunc), a shortened ClpB variant lacking a functional NBD1. Interpolation of the two phases gives an intersection at [MANT-ADP] = 4.8 μM, while the volume-corrected concentration of ClpB(trunc) at this point is 9.8 μM. This indicates that one molecule of MANT-ADP is bound per ClpB dimer. Adding $ClpB_{Tth}$(trunc) to MANT-ADP under similar conditions also results in a biphasic curve, where the slope of the second phase is close to zero. The intersection also points to a 2:1 stoichiometry (ClpB(trunc):MANT-ADP).

4.3.5.5 **Competition Experiments**

The affinities of the unmodified nucleotides ADP or ATP for DnaK or ClpB were determined by competition experiments [11, 21, 87]. Therefore, a preformed complex out of the chaperone and the fluorescent nucleotide was titrated with the unmodified nucleotide, and the decrease of the fluorescence signal caused by the displacement of the fluorophore by the non-fluorescent nucleotide was used together

with the known K_d for the fluorescent nucleotide to obtain the affinity (see Figure 4.2B). The general mathematical description of this system is the solution of a cubic equation (see "Cubic Equation" below) [88]. This complete analysis is specifically required if the affinities of the two ligands are very high such that the corresponding K_d values are much lower than the initial concentration of the substance to be titrated.

4.3.6 Analytical Solutions of Equilibrium Systems

4.3.6.1 Quadratic Equation

$[A]$, $[B]$, and $[C]$ are the free concentrations of the compounds A, B, and C.
$[A_o]$, $[B_o]$, and $[C_o]$ are the total concentrations of the compounds A, B, and C.
$[AB]$ and $[AC]$ are complex concentrations of the complexes of A and B or A and C, respectively (e.g., with A being the protein and B a binding ligand).

$$A + B \underset{Kd_{AB}}{\rightleftharpoons} AB$$

Scheme 4.1

Many kinetic experiments require that the concentration of a ligand-protein complex be calculated as a function of any defined concentration of the two substances and a given dissociation constant Kd_{AB}. For a 1:1 stoichiometry (one ligand binds to one binding site of a protein), the dissociation constant is defined as:

$$Kd_{AB} = \frac{[A][B]}{[AB]} \tag{6}$$

Equations of mass conservation:

$$[A_o] = [A] + [AB] \qquad [B_o] = [B] + [AB] \tag{7), (8}$$

Inserting Eqs. (7) and (8) into Eq. (6) gives

$$\begin{aligned} Kd_{AB} &= \frac{[A][B]}{[AB]} \\ &= \frac{([A_o] - [AB])([B_o] - [AB])}{[AB]} \\ &= \frac{[A_o][B_o] - [AB][B_o] - [AB][A_o] + [AB]^2}{[AB]} \\ &\equiv [AB]^2 - [AB]([A_o] + [B_o] + Kd_{AB}) + [A_o][B_o] = 0 \end{aligned} \tag{9}$$

A quadratic equation usually gives two solutions, but here only one is biochemically meaningful, and the final solution to calculate the concentration of the complex AB as a function of the total concentrations of A and B and a given dissociation constant Kd_{AB} therefore is:

$$[AB] = \frac{[A_o] + [B_o] + Kd_{AB}}{2} - \sqrt{\left(\frac{[A_o] + [B_o] + Kd_{AB}}{2}\right)^2 - [A_o][B_o]} \tag{10}$$

The measured quantity is usually the increase/decrease of the fluorescence emission ΔF in every titration step. This quantity is proportional to the binding ratio $[AB]/[B_0]$ and ΔF_{max}, the maximal emission change observed when all the ligand B is bound to the protein (saturation conditions).

$$\Delta F = \Delta F_{max} \cdot \frac{[AB]}{[B_0]} \tag{11}$$

The observed total fluorescence F in every titration step is composed out of the fluorescence of the free ligand F_0 and the change in fluorescence ΔF. Substituting $[AB]$ with Eq. (10) yields an equation for the observed total fluorescence:

$$F = F_0 + \Delta F_{max} \cdot \frac{\frac{[A_0] + [B_0] + Kd_{AB}}{2} - \sqrt{\left(\frac{[A_0] + [B_0] + Kd_{AB}}{2}\right)^2 - [A_0][B_0]}}{B_0} \tag{12}$$

4.3.6.2 Cubic Equation

If two ligands compete for one binding site, as it is the case for displacement titrations with a fluorescent and a non-fluorescent nucleotide, and a 1:1 binding stoichiometry holds, the cubic equation may be applied.

A kinetic system where the ligands B and C compete for binding to A is described in Scheme 4.2.

$$\mathrm{A} + \mathrm{B} \underset{Kd_{AB}}{\rightleftharpoons} \mathrm{AB} \qquad \mathrm{A} + \mathrm{C} \underset{Kd_{AC}}{\rightleftharpoons} \mathrm{AC}$$

Scheme 4.2

The dissociation constants Kd_{AB} and Kd_{AC} are defined as follows:

$$Kd_{AB} = \frac{[A][B]}{[AB]}; \quad Kd_{AC} = \frac{[A][C]}{[AC]} \tag{13), (14}$$

The corresponding mass conservation gives:

$$[A_o] = [A] + [AB] + [AC]$$
$$[B_o] = [B] + [AB] \qquad (15), (16), (17)$$
$$[C_o] = [C] + [AC]$$

If the total concentrations of B and C are much higher than that of A, then the observed dissociation constant of the AC complex, $Kd_{AC}(\text{obs})$, is defined by the simple relationship:

$$Kd_{AC}(obs) = Kd_{AC}\left(1 + \frac{[B]}{Kd_{AB}}\right) \approx Kd_{AC}\left(1 + \frac{B_o}{Kd_{AB}}\right)$$

If the total concentrations of B and C are close to that of A, however, the assumption that $[C] \approx [C_o]$ and $[B] \approx [B_o]$ no longer holds. The deviation from a simple hyperbolic binding is most evident if $[A_o] \gg Kd_{AB}$ and Kd_{AC}.

The general solution of the system in Scheme 4.2 is the solution of a cubic equation. This solution is not based on any assumptions with respect to the relationship of $[A_0]$, $[B_0]$, and $[C_0]$ to Kd_{AB} and Kd_{AC}.

Insert Eqs. (16) and (17) into Eq. (15):

$$[A_o] = [A] + ([B_o] - [B]) + ([C_o] - [C]) \qquad (18)$$

Insert Eq. (13) into Eq. (16) and solve for $[B]$

$$[B] = \frac{[B_o]}{1 + \frac{[A]}{Kd_{AB}}} \qquad (19)$$

Insert Eq. (14) into Eq. (17) and solve for $[C]$.

$$[C] = \frac{[C_o]}{1 + \frac{[A]}{Kd_{AC}}} \qquad (20)$$

Now insert Eqs. (19) and (20) into Eq. (18)

$$[A_o] = [A] + \left([B_o] - \frac{[B_o]}{1 + \frac{[A]}{Kd_{AB}}}\right) + \left([C_o] - \frac{[C_o]}{1 + \frac{[A]}{Kd_{AC}}}\right) \qquad (21)$$

$[A]$ has to be replaced by $[AB]$ since we want to calculate the concentration of the complex $[AB]$. Insert Eq. (19) into Eq. (18) and solve for $[A]$:

$$[AB] = \frac{[A]\dfrac{[B_o]}{1+\dfrac{[A]}{Kd_{AB}}}}{Kd_{AB}}$$

rearrange,

$$[A] = [AB]\frac{Kd_{AB}}{\left(\dfrac{[B_o]}{1+\dfrac{[A]}{Kd_{AB}}}\right)}$$

and finally

$$[A] = -\frac{[AB]Kd_{AB}}{[AB]-[B_o]} \tag{22}$$

Now insert Eq. (22) into Eq. (21)

$$[A_o] = -\frac{[AB]Kd_{AB}}{[AB]-[B_o]} + \left([B_o] - \frac{[B_o]}{1+\dfrac{-\dfrac{[AB]Kd_{AB}}{[AB]-[B_o]}}{Kd_{AB}}}\right) + \left([C_o] - \frac{[C_o]}{1+\dfrac{-\dfrac{[AB]Kd_{AB}}{[AB]-[B_o]}}{Kd_{AC}}}\right) \tag{23}$$

This equation now implicitly expresses $[AB]$ as a function of total concentrations of the three compounds and the two dissociation constants. Now we have to rearrange (factorize for $[AB]$) all terms to get the following cubic equation.

The general form of a cubic equation is:

$$[AB]^3 + a_1[AB]^2 + a_2[AB] + a_3 = 0 \tag{24}$$

and we find the corresponding coefficients to be

$$a_o = Kd_{AB} - Kd_{AC} \tag{25}$$

$$a_1 = \frac{[A_o](Kd_{AC} - Kd_{AB}) + [B_o](2Kd_{AC} - Kd_{AB}) + [C_o]Kd_{AB} - Kd_{AB}{}^2 + Kd_{AB}Kd_{AC}}{a_o} \tag{26}$$

$$a_2 = \frac{[A_o][B_o](Kd_{AB} - 2Kd_{AC}) - [B_o]^2 Kd_{AC} - [B_o]Kd_{AB}([C_o] + Kd_{AC})}{a_o} \tag{27}$$

$$a_3 = \frac{[A_o][B_o]^2 Kd_{AC}}{a_o} \tag{28}$$

The general solution of the cubic equation Eq. (24) may be obtained as described [89].

$$Q \equiv \frac{{a_1}^2 - 3a_2}{9}; \quad R \equiv \frac{2{a_1}^3 - 9a_1a_2 + 27a_3}{54} \tag{29}$$

if $Q^3 - R^2 \geq 0$, then there are three solutions to the cubic equation:

$$\Theta = \arccos\left(\frac{R}{\sqrt{Q}^3}\right)$$

$$[AB]_1 = -2\sqrt{Q}\cos\left(\frac{\Theta}{3}\right) - \frac{a_1}{3}$$

$$[AB]_2 = -2\sqrt{Q}\cos\left(\frac{\Theta + 2\pi}{3}\right) - \frac{a_1}{3}$$

$$[AB]_3 = -2\sqrt{Q}\cos\left(\frac{\Theta + 4\pi}{3}\right) - \frac{a_1}{3}$$

However, only one out of the three solutions given above is meaningful and has to be selected.

The automatic selection is a bit tricky, but once it is implemented it works pretty well. Imagine there is no substance C present; then a quadratic solution would be sufficient to calculate the concentration of the complex $[AB]$. We can still apply the cubic solution since it is valid for any arbitrary situation. If we now compare the solutions from the quadratic equation with the three solutions of the cubic equation, we realize that only one of those three solutions is correct. Now we know which of the three solutions to use. It turns out that this will still hold even if $[C_0]$ is not zero.

A more comprehensive treatment of this problem revealed that it is always the first solution $[AB]_1$ that represents the physically meaningful solution [90].

If $R^2 - Q^3 > 0$, then there is only one solution:

$$[AB] = -sign(R)\left[\sqrt[3]{\sqrt{R^2 - Q^3} + |R|} + \frac{Q}{\sqrt[3]{\sqrt{R^2 - Q^3} + |R|}}\right] - \frac{a_1}{3}$$

This case rarely occurs with the usual values of concentrations and dissociation constants all being positive.

This approach to analyzing competition experiments is complicated and often unnecessary, but experimental constraints do not always allow choosing conditions such that a simple analysis is possible. The choice of appropriate experimental conditions, in conjunction with the complete analysis as described above, also allows gathering information about binding stoichiometries in a competition experiment.

4.3.6.3 Iterative Solutions

Four-component System as an Example: Newton-Raphson Root Search

$A + C \rightleftharpoons AC;\ A + D \rightleftharpoons AD;\ B + C \rightleftharpoons BC;\ B + D \rightleftharpoons BD$

Scheme 4.3

In the examples given above, we searched for analytical solutions that allowed us to define the desired complex concentrations as a function of total concentrations and K_d values. The order of the corresponding equation was directly related to the number of different ligands present. It was a quadratic equation (order 2) for two compounds and a cubic equation (order 3) for three compounds. In principle we could also obtain an analytical solution for a four-component system since the resulting quadric equation would still be solvable. We will avoid this hassle and instead use an iterative method that searches for the roots of a coupled equilibrium system. This method is known as the Newton-Raphson algorithm to find roots in systems of nonlinear equations and is also used by most commercial software packages (e.g., Scientist). It should be noted that these computer programs solve implicit equilibrium systems with this numerical method even with simple two-component systems.

An early practical example of a four-component system was the competition of Mg^{2+} and Ca^{2+} for the metal chelators ATP and EDTA or EGTA in muscle research [91]. Solutions for multi-species equilibria are also regaining attention in chaperone research due to the multi-enzyme–multi-ligand complexes involved. The effects of the DnaK nucleotide-exchange factor GrpE as measured with fluorescent nucleotide in competition with its unlabeled form, e.g., constitute a quaternary system [10, 82, 92], with

$$A \equiv Ca^{2+};\quad B \equiv Mg^{2+};\quad C \equiv EGTA;\quad D \equiv ATP \tag{30}$$

Definition of equilibrium constants:

$$Kd_{AC} = \frac{[A][C]}{[AC]};\quad Kd_{AD} = \frac{[A][D]}{[AD]} \tag{31), (32}$$

$$Kd_{BC} = \frac{[B][C]}{[BC]};\quad Kd_{BD} = \frac{[B][D]}{[BD]} \tag{33), (34}$$

Conservation equations:

$$\begin{aligned}[A_o] &= [A] + [AC] + [AD]\\ [B_o] &= [B] + [BC] + [BD]\\ [C_o] &= [C] + [AC] + [BC]\\ [D_o] &= [D] + [AD] + [BD]\end{aligned} \tag{35)–(38}$$

Rearrangement of Eqs. (35)–(38) and insertion into Eqs. (31)–(34) gives:

$$
\begin{aligned}
&[A] + \frac{[A][C]}{Kd_{AC}} + \frac{[A][D]}{Kd_{AD}} - [A_o] = 0\\
&[B] + \frac{[B][C]}{Kd_{BC}} + \frac{[B][D]}{Kd_{BD}} - [B_o] = 0\\
&[C] + \frac{[B][C]}{Kd_{BC}} + \frac{[A][C]}{Kd_{AC}} - [C_o] = 0\\
&[D] + \frac{[A][D]}{Kd_{AD}} + \frac{[B][D]}{Kd_{BD}} - [D_o] = 0
\end{aligned}
\qquad (39)–(42)
$$

Eqs. (39)–(42) describe the system of equations that has to be solved. One step that is necessary to get the Newton-Raphson (NR) algorithm to work is to generate a matrix of partial derivatives where the species that are iterated (x) are freely selectable. For example:

- If the total concentrations are given, calculate free concentrations and concentrations of complexes.
- If free concentrations are fixed, calculate total concentrations and concentration of complexes.
- If complex concentrations are given, calculate free and total concentrations.

General case:

$$
\begin{bmatrix}
\frac{\partial y_1}{\partial x_1} & \cdots & \cdots & \frac{\partial y_1}{\partial x_4}\\
\cdot & \cdots & \cdots & \cdot\\
\cdot & \cdots & \cdots & \cdot\\
\frac{\partial y_4}{\partial x_1} & \cdots & \cdots & \frac{\partial y_4}{\partial x_4}
\end{bmatrix}
$$

Let us assume that we define the total concentrations and want to calculate the free concentrations; then the matrix of partial derivatives would read:

$$
\begin{bmatrix}
\frac{\partial\left([A] + \frac{[A][C]}{Kd_{AC}} + \frac{[A][D]}{Kd_{AD}} - [A_o]\right)}{\partial[A]} & \cdots & \cdots & \frac{\partial\left([A] + \frac{[A][C]}{Kd_{AC}} + \frac{[A][D]}{Kd_{AD}} - [A_o]\right)}{\partial[D]}\\
\frac{\partial\left([B] + \frac{[B][C]}{Kd_{BC}} + \frac{[B][D]}{Kd_{BD}} - [B_o]\right)}{\partial[A]} & \cdots & \cdots & \frac{\partial\left([B] + \frac{[B][C]}{Kd_{BC}} + \frac{[B][D]}{Kd_{BD}} - [B_o]\right)}{\partial[D]}\\
\frac{\partial\left([C] + \frac{[B][C]}{Kd_{BC}} + \frac{[A][C]}{Kd_{AC}} - [C_o]\right)}{\partial[A]} & \cdots & \cdots & \frac{\partial\left([C] + \frac{[B][C]}{Kd_{BC}} + \frac{[A][C]}{Kd_{AC}} - [C_o]\right)}{\partial[D]}\\
\frac{\partial\left([D] + \frac{[A][D]}{Kd_{AD}} + \frac{[B][D]}{Kd_{BD}} - [D_o]\right)}{\partial[A]} & \cdots & \cdots & \frac{\partial\left([D] + \frac{[A][D]}{Kd_{AD}} + \frac{[B][D]}{Kd_{BD}} - [D_o]\right)}{\partial[D]}
\end{bmatrix}
\qquad (43)
$$

The result is the following matrix:

$$\begin{bmatrix} 1+\frac{[C]}{Kd_{AC}}+\frac{[D]}{Kd_{AD}} & 0 & \frac{[A]}{Kd_{AC}} & \frac{[A]}{Kd_{AD}} \\ 0 & 1+\frac{[C]}{Kd_{BC}}+\frac{[D]}{Kd_{BD}} & \frac{[B]}{Kd_{BC}} & \frac{[B]}{Kd_{BD}} \\ \frac{[C]}{Kd_{AC}} & \frac{[C]}{Kd_{BC}} & 1+\frac{[B]}{Kd_{BC}}+\frac{[A]}{Kd_{AC}} & 0 \\ \frac{[D]}{Kd_{AD}} & \frac{[D]}{Kd_{BD}} & 0 & 1+\frac{[A]}{Kd_{AD}}+\frac{[B]}{Kd_{BD}} \end{bmatrix} \tag{44}$$

Why do we need this matrix of partial derivatives (see Ref. [89] p. 306)?

If $\vec{x}$ is the vector of all x_i, then each function f_i may be extended in a Taylor series around $\vec{x}$.

$$f_i(\vec{x}+\delta\vec{x}) = f_i(\vec{x}) + \sum_{j=1}^{N} \frac{\partial f_i}{\partial x_j}\delta x_j + O(\delta\vec{x}^2) \tag{45}$$

A system of linear equations for the correction factors $\delta\vec{x}$ is obtained if $\delta\vec{x}^2$ and all higher-order terms are neglected. All equations could thus be optimized simultaneously:

$$\sum_{j=1}^{N} \alpha_{ij}\delta x_j = \beta_i \quad \text{where } \alpha_{ij} \equiv \frac{\partial f_i}{\partial x_j} \text{ and } \beta_i = -f_i \tag{46}$$

α thus represents the matrix of partial derivatives. Since we reduced our problem to a system of linear equations, it may be solved by any standard numerical technique like partial pivoting or lower/upper triangular (LU) decomposition. This proceeds iteratively and usually needs some 2 to 10 iterations to converge; the computer simulates the approach to equilibrium!

Trial runs indicated that the numerical calculations became very unstable when the matrix of partial derivatives was generated by the approximation of finite differences, e.g.,

$$\frac{\partial f_i}{\partial x_j} \cong \frac{f_i(x+\Delta x_j)}{f_i(x)} \tag{47}$$

The partial derivatives thus have to be generated analytically.

If the free concentrations of the complexes are defined and the corresponding total concentrations should be calculated, then the matrix of partial derivatives is:

$$\begin{bmatrix} \frac{\partial\left([A]+\frac{[A][C]}{Kd_{AC}}+\frac{[A][D]}{Kd_{AD}}-[A_o]\right)}{\partial[A_o]} & \cdots & \cdots & \frac{\partial\left([A]+\frac{[A][C]}{Kd_{AC}}+\frac{[A][D]}{Kd_{AD}}-[A_o]\right)}{\partial[D_o]} \\ \frac{\partial\left([B]+\frac{[B][C]}{Kd_{BC}}+\frac{[B][D]}{Kd_{BD}}-[B_o]\right)}{\partial[A_o]} & \cdots & \cdots & \frac{\partial\left([B]+\frac{[B][C]}{Kd_{BC}}+\frac{[B][D]}{Kd_{BD}}-[B_o]\right)}{\partial[D_o]} \\ \frac{\partial\left([C]+\frac{[B][C]}{Kd_{BC}}+\frac{[A][C]}{Kd_{AC}}-[C_o]\right)}{\partial[A_o]} & \cdots & \cdots & \frac{\partial\left([C]+\frac{[B][C]}{Kd_{BC}}+\frac{[A][C]}{Kd_{AC}}-[C_o]\right)}{\partial[D_o]} \\ \frac{\partial\left([D]+\frac{[A][D]}{Kd_{AD}}+\frac{[B][D]}{Kd_{BD}}-[D_o]\right)}{\partial[A_o]} & \cdots & \cdots & \frac{\partial\left([D]+\frac{[A][D]}{Kd_{AD}}+\frac{[B][D]}{Kd_{BD}}-[D_o]\right)}{\partial[D_o]} \end{bmatrix}$$

which is as simple as:

$$\begin{bmatrix} -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}$$

All the examples presented above concern calculations of the same type: free concentrations, total concentrations, or complex concentrations. The question is now whether there is a way to calculate mixed species. It is obvious that the choice of species that may be defined or calculated is limited to a certain extent. For example, if the total amount of A_o and the complex concentration is specified, then the concentration of A_f cannot be specified since it has to be varied to give the AC desired. In this case, the system would be overdetermined. There could also be cases where the system is underdetermined; then the solution will not be unique or the system will not converge.

4.3.7 Time-resolved Binding Measurements

4.3.7.1 Introduction

Mechanistic questions and kinetic models are closely related, since a kinetic model is usually derived from hypotheses of the enzyme's mechanism. The model is then scrutinized by other appropriate kinetic measurements that should ideally be designed to falsify – not "prove" – the model. The link between the model and experimental data is provided by the equations that are obtained by solving the differential system determined by the model. Although it is becoming more popular to use computer programs that avoid the hassle of analytical solutions (through numerical integration), it is often still more instructive to use these solutions, and some examples of the most often needed types are shown below.

Differential equations systems could be solved in principle by three major methods: Laplace transformation, matrix method, and substitution method. Because a proper introduction to these mathematical approaches, as well as experimental methods to obtain relevant transient kinetic data, would go far beyond the scope of this chapter, the reader is kindly asked to refer to the following major references that provide fundamental and thorough introductions and overviews.

1) Laplace transformation: Refs. [93, 94]
2) Substitution: Ref. [94]
3) Matrix method: Ref. [95]

A ''cookbook'' that provides solutions to many systems [96] is unfortunately no longer commercially available but could be found in some libraries.

4.3.7.2 One-step Irreversible Process

A well-known example for one-step irreversible processes is radioactive decay of isotopes.

The according kinetic model represents the simplest scheme available:

$$A \xrightarrow{k} B$$

Under certain boundary conditions, this scheme can also be applied to enzymatic reactions, e.g., single-step hydrolysis of ATP where either ATP binding is not rate-limiting and saturating or the reaction is initiated with pre-bound ATP (e.g., by addition of catalytic Mg^{2+}). Another example is the displacement of fluorescently labeled, pre-bound nucleotide by an excess of unlabeled ligand (usually also nucleotide) to measure directly the rate constant for dissociation [10, 11, 97].

If the initial concentration of B at $t = 0$ (B_o) is 0, then the differential equations for that system read:

$$\frac{d[A]}{dt} = -k[A] \qquad \text{(D1)}$$

$$\frac{d[B]}{dt} = k[A] \qquad \text{(D2)}$$

Converted to Laplace space (please refer to literature above for information on how to set up equations)

$$sa = -ka + a_0 \qquad \text{(L1)}$$

$$sb = ka \qquad \text{(L2)}$$

and solved for a and b, respectively:

$$a = \frac{a_0}{s+k}$$

$$b = \frac{ka}{s} = \frac{ka_0}{s(s+k)} \qquad \text{(S1), (S2)}$$

Looking in the table for the back transformation and setting k equal to α gives

$$\mathrm{L}^{-1}\left(\frac{const}{s(s+\alpha)}\right) = \frac{const}{\alpha}(1 - e^{-\alpha t})$$

and

$$\mathrm{L}^{-1}\left(\frac{const}{s+\alpha}\right) = e^{-\alpha t}.$$

Therefore, $[A](t) = [A_0] \cdot e^{-kt}$ and $[B](t) = [A_0](1 - e^{-kt})$.

4.3.7.3 One-step Reversible Process

First-order reversible processes are routinely encountered in protein folding and are discussed here in great detail. Related to that are structural changes that may be induced by ligands or other factors, e.g., light, pH, or temperature among others.

Model:

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B$$

$$\frac{d[A]}{dt} = -k_1[A] + k_{-1}[B]$$

$$\frac{d[B]}{dt} = k_1[A] - k_{-1}[B] \qquad \text{(D1), (D2)}$$

$$sa - a_0 = -k_1 a + k_{-1} b$$

$$sb = k_1 a + k_{-1} b \qquad \text{(L1), (L2)}$$

$$\Rightarrow a = \frac{a_0 + k_{-1} b}{s + k_1} \qquad \text{(S1)}$$

Inserting S1 into L2 and factorizing for b gives

$$b = \frac{k_1 a_o}{(s+k_1)\left(s + k_{-1} - \dfrac{k_1 k_{-1}}{s+k_1}\right)} = \frac{k_1 a_o}{s(s + k_1 + k_{-1})}$$

with $k_1 + k_{-1} \equiv \alpha$.

The transform table gives as the back transformation of

$$\mathrm{L}^{-1}\frac{const}{s(s+\alpha)} = \frac{const}{\alpha}(1-e^{-\alpha t}) \tag{S2}$$

and hence $B(t) = \dfrac{k_1[A_0]}{k_1+k_{-1}}(1-e^{-(k_1+k_{-1})\cdot t})$.

4.3.7.4 Reversible Second Order Reduced to Pseudo-first Order

Reversible second-order processes are mostly observed in simple ligand-binding processes where the binding of ligand does not induce further structural changes.

The corresponding model reads

$$\mathrm{A} + \mathrm{B} \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} \mathrm{C}$$

with an according set of differential equations

$$\begin{aligned}
\frac{d[A]}{dt} &= -k_{+1}[A][B] + k_{-1}[C] \\
\frac{d[B]}{dt} &= -k_{+1}[A][B] + k_{-1}[C] \qquad \text{(D1)–(D3)} \\
\frac{d[C]}{dt} &= k_{+1}[A][B] - k_{-1}[C]
\end{aligned}$$

If the boundary conditions are such that $B_o \gg A_o$ (that is, the species B at $t = 0$ is in excess) and $C_o = 0$, then the reaction becomes pseudo-first order since the concentration of B does not change significantly over time, $B(t) \approx B_o$. The set of (approximated) differential equations then is:

$$\begin{aligned}
\frac{d[A]}{dt} &\cong -k_{+1}[A][B_o] + k_{-1}[C] \\
\frac{d[B]}{dt} &\cong 0 \qquad \text{(D4)–(D6)} \\
\frac{d[C]}{dt} &\cong k_{+1}[A][B_o] - k_{-1}[C]
\end{aligned}$$

The equations in Laplace space are:

$$\begin{aligned}
sa - a_o &\cong -k_{+1}ab_o + k_{-1}c \\
sc &\cong k_{+1}ab_o - k_{-1}c
\end{aligned} \qquad \text{(L1), (L3)}$$

Solve for a

$$a \cong \frac{a_o + k_{-1}c}{s + k_{+1}b_0} \tag{S1}$$

Insert S1 into L3 and solve for c:

$$c \cong \frac{a_o b_o k_{+1}}{s(s + b_o k_{+1} + k_{-1})} \tag{S2}$$

In the tables we find the transformation back to real space

$$\mathrm{L}^{-1}\left(\frac{1}{s(s+\alpha)}\right) = \frac{1}{\alpha}(1 - e^{-\alpha t}) \quad \text{with } \alpha = b_0 k_{+1} + k_{-1}$$

and therefore the solution is:

$$[C](t) \cong \frac{A_o B_o k_{+1}}{B_o k_{+1} + k_{-1}}(1 - e^{-(B_o k_{+1} + k_{-1})t})$$

Note that the amplitude is also an approximation, but in practice a three- to four-fold excess of B_o should be sufficient. To answer how close this approximation is to the real solution, we perform an exemplary calculation.

Assume: $\mathrm{A}_0 = 1\ \mu\mathrm{M}$; $\mathrm{B}_0 = 10\ \mu\mathrm{M}$; $k_{+1} = 1\ \mu\mathrm{M}^{-1}\cdot\mathrm{s}^{-1}$; $k_{-1} = 1\ \mathrm{s}^{-1} \Rightarrow K_\mathrm{d} = 1\ \mu\mathrm{M}$

The approximation according to the kinetic solution is:

$$[C](t = \text{infinity}) = \frac{1 \cdot 10 \cdot 1}{10 \cdot 1 + 1} = \frac{10}{11} = 0.909\ \mu\mathrm{M}$$

The exact solution as calculated with the quadratic binding equation is:

$$\frac{1 + 1 + 10}{2} - \sqrt{\left(-\frac{1 + 1 + 10}{2}\right)^2 - 10 \cdot 1} = 0.90098\ \mu\mathrm{M}$$

We can conclude that the approximation of the amplitude is sufficiently good under these conditions.

If $B_0 = 2\ \mu\mathrm{M}$, i.e., if the excess of ligand is just twofold over A_0, then the kinetic "solution" gives an amplitude of $\frac{1 \cdot 2 \cdot 1}{2 \cdot 1 + 1} = \frac{2}{3} = 0.666$ in comparison to the exact quadratic equation, which gives $2 - \sqrt{4 - 2} = 0.5857$ as a value for the final complex concentration after equilibration. This shows that, even being far from pseudo-first-order conditions, the amplitude derived under these conditions is still

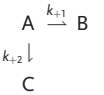
a fair approximation. We should be aware, however, that the shape of the time trace will be substantially different and thus large errors will be introduced for the resulting rate constant after a fitting procedure, including large visible systematic deviations that are clearly visible with a residual plot [95].

One should also note here that in general, without the assumption that one ligand is in excess, binding systems are rarely solvable – as are many other nonlinear systems.

4.3.7.5 Two Simultaneous Irreversible Pathways – Partitioning

Partitioning experiments are very useful and often are the only accessible way to obtain information about particular kinetic systems. One example where this technique was used successfully is in the case of Hsp90. Here a complex of radioactive ATP with Hsp90 was chased off with an excess of unlabeled ATP, and the yield of hydrolyzed, radioactive ADP compared to the yield without chase showed commitment to hydrolysis since the enzyme goes through a complete round of hydrolysis before the chase takes affect [14].

A complete treatment of this method follows the model in Scheme 4.4:



Scheme 4.4

Again, the differential equation system (DES) is generated by summing up all steps that lead away from a certain species with the steps that lead to it.

$$\frac{d[A]}{dt} = -(k_1 + k_2)[A]$$

$$\frac{d[B]}{dt} = k_1[A] \qquad \text{(D1)–(D3)}$$

$$\frac{d[C]}{dt} = k_2[A]$$

Again, in Laplace space, we replace d/dt with the symbol s. Any species N that is not initially zero (at time 0, start of the reaction) gets the additional integration term n_o.

$$sa - a_o = -(k_1 + k_2)a$$

$$sb = k_1 a \qquad \text{(L1)–(L3)}$$

$$sc = k_2 a$$

Solving the resulting linear system in Laplace space:

Solve L1 for a to give S1

$$a = \frac{a_o}{s + k_1 + k_2} \tag{S1}$$

Now insert S1 into L2 and solve for b

$$sb = k_1 \frac{a_o}{s + k_1 + k_2} \Rightarrow b = \frac{k_1 a_o}{s(s + k_1 + k_2)} \tag{S2}$$

The table of Laplace back transformations tells us that the back transformation to real space (L^{-1}) of our system is:

$$L^{-1} \frac{1}{s(s + \alpha)} = \frac{1}{\alpha}(1 - e^{-\alpha t})$$

so that:

$$[B](t) = [A_o] \frac{k_1}{k_1 + k_2}(1 - e^{-(k_1 + k_2)t}) \tag{S3}$$

and accordingly:

$$\begin{aligned} [A](t) &= [A_o]\left(1 - \frac{k_1}{k_1 + k_2}(1 - e^{-(k_1 + k_2)t})\right) \\ [C](t) &= [A_o] \frac{k_2}{k_1 + k_2}(1 - e^{-(k_1 + k_2)t}) \end{aligned} \tag{S3), (S4}$$

The observed rate constant of $k_1 + k_2$ as well as the observed amplitude of $k_1/(k_1 + k_2)$ for the formation of B gives independent information about the rate constants and may be used to obtain k_1 and k_2 from one simple time trace. The example shown in Figure 4.10 demonstrates that for the same $k_{obs} = k_1 + k_2 = 10 + 1 = 11\ s^{-1}$, the different amplitudes allow us to unequivocally assign the individual rate constants. The same holds for equal amplitudes: now the observed rate constants allow us to assign the individual rate constants.

Some useful relationships are

$$k_{obs} = k_1 + k_2$$

$$B_{obs} = A_o \frac{k_1}{k_1 + k_2}$$

$$k_1 = \frac{A_{obs}}{A_o} k_{obs}$$

$$k_2 = k_{obs} - k_1$$

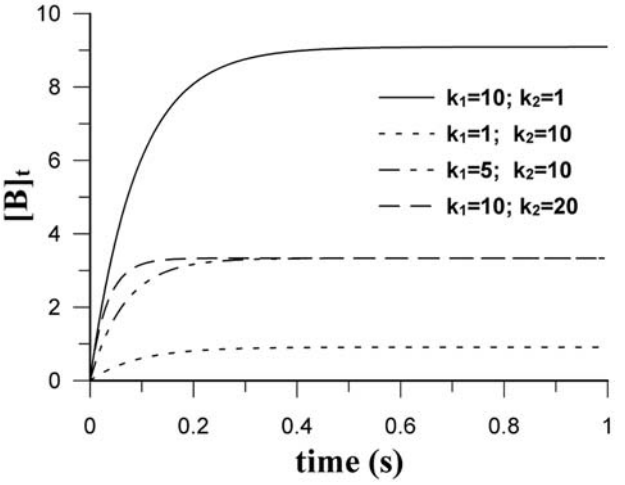


Fig. 4.10. Simulation for time traces according to partitioning scheme.

4.3.7.6 **Two-step Consecutive (Sequential) Reaction**

The following model

$$A \overset{k_1}{\rightarrow} B \overset{k_2}{\rightarrow} C$$

provides a simplified version of two-step irreversible mechanisms that can be applied under certain conditions e.g., binding of ATP (treated as a single step since a conformational change following initial encounter [to give complex A] is rate-limiting) followed by irreversible hydrolysis [79, 80]. In these literature examples, it was important to first generate a hydrolysis-competent DnaK-ATP state that could then be ''chased'' by ATPase-stimulating DnaJ in a second mixing reaction. The experiments therefore had to be designed to allow for complete ATP binding, including the conformational change it induces, without appreciable hydrolysis occurring before the DnaJ ''chase''. The amount of the ''reaction'' intermediate B (DnaK-ATP complex in the closed and DnaJ stimulation-competent conformation) thus had to be maximized prior to addition of DnaJ.

The **differential equation system** that describes this kinetic system is:

$$\frac{d[A]}{dt} = -k_1[A]$$

$$\frac{d[B]}{dt} = k_1[A] - k_2[B] \qquad \text{(D1)–(D3)}$$

$$\frac{d[C]}{dt} = k_2[B]$$

This system is transformed forward into Laplace space to give the following **linear equation system**: boundary conditions: $A(t = 0, A_0)$ and $B_0, C_0 = 0$

$$\begin{aligned} sa - a_o &= -k_1 a \\ sb &= -k_1 a - k_2 b \\ sc &= k_2 b \end{aligned} \qquad \text{(L1)–(L3)}$$

To solve for c, we first solve for a to give:

$$a = \frac{a_o}{s + k_1} \qquad \text{(S1)}$$

Then insert this expression into L2 and solve for b:

$$b = \frac{k_1 a_o}{s + k_1} \cdot \frac{1}{s + k_2} \qquad \text{(S2)}$$

Finally, insert this expression into L3 and solve for c:

$$c = \frac{k_2}{s} \cdot \frac{k_1 a_o}{s + k_1} \cdot \frac{1}{s + k_2} \qquad \text{(S3)}$$

Looking in the table of Laplace back transformations gives us:

$$\mathrm{L}^{-1}\left(\frac{1}{s(s + \alpha_1)(s + \alpha_2)}\right) = \frac{1}{\alpha_1 \alpha_2}\left(1 + \frac{1}{\alpha_1 - \alpha_2}(\alpha_2 e^{-\alpha_1 t} - \alpha_1 e^{-\alpha_2 t})\right)$$

so that transforming back to real space gives:

$$[C](t) = [A_o]\left(1 + \frac{1}{k_1 - k_2}(k_2 e^{-k_1 t} - k_1 e^{-k_2 t})\right)$$

In summary, if the boundary conditions are chosen such that $A_0 \neq 0$, $B_0, C_0 = 0$, then the solutions are:

$$[A](t) = [A_o] e^{-k_1 t}$$

$$[B](t) = [A_o] \frac{k_1}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t})$$

$$[C](t) = [A_o]\left(1 + \frac{1}{k_1 - k_2}(k_2 e^{-k_1 t} - k_1 e^{-k_2 t})\right)$$

Common questions that appear (e.g., in double-mixing or time-resolved structural

measurements) are what the maximum of $[B]$ is that can be obtained and at which time this is reached.

$$\frac{d[B]}{dt} = 0 = \frac{d\left([A_o]\frac{k_1}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t})\right)}{dt}$$

$$= [A_o]\frac{k_1}{k_2 - k_1}(-k_1 e^{-k_1 t_{B\max}} + k_2 e^{-k_2 t_{B\max}})$$

$$t_{B\max} = \frac{\ln \frac{k_2}{k_1}}{k_2 - k_1}$$

Accordingly, the maximal amount of the intermediate B formed is:

$$[B](t_{B\max}) = [A_o]\frac{k_1}{k_2 - k_1}(e^{-k_1 t_{B\max}} - e^{-k_2 t_{B\max}})$$

A plot of the maximal relative yield of the intermediate B as a function of the individual rate constants is simulated and shown in Figure 4.11. Additionally, a similar plot for the time when this maximum is reached is shown in Figure 4.12.

4.3.7.7 Two-step Binding Reactions

The following system represents a reversible two-step binding process that already results in substantial complexity of the according equations. This description was kindly provided by Roger S. Goody and was only slightly adjusted in minor parts.

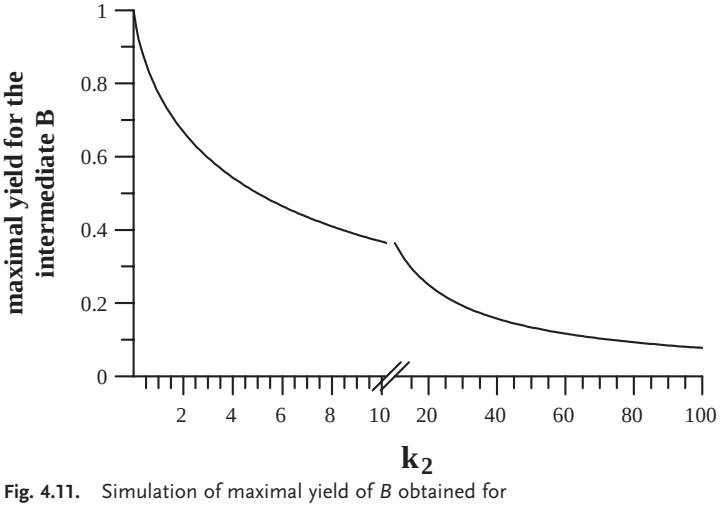

Fig. 4.11. Simulation of maximal yield of *B* obtained for different ratios of k_1 (10) and k_2 of a consecutive reaction ($A \xrightarrow{k_1} B \xrightarrow{k_2} C$).

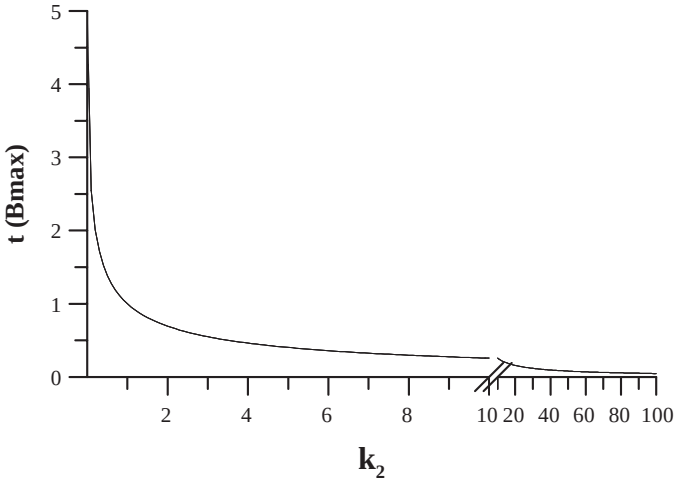

Fig. 4.12. Plot of time point where maximal yield of *B* is reached in consecutive reaction ($k_1 = 10$, k_2 as indicated on x-axis).

For an even advanced treatment, which is necessary for two-step binding mechanisms including competition, the reader is referred to Refs. [98, 99] and to some related "classics" that are concerned mostly with muscle research [100–104].

These mechanisms occur when, e.g., a fluorescent nucleotide serves as an established monitor for a two-step binding process, but of interest are the properties of the unmodified analogue that may also bind in two steps. An approach that uses numerical integration was also described for binding/competition of N^8-(4-*N'*-methylanthraniloylaminobutyl)-8-aminoadenosine 5'-diphosphate and ADP to DnaK from *Thermus thermophilus* [9].

Many binding interactions occur in two or more steps. How do we recognize this and what are the consequences? Two types of mechanism have often been observed. In principle, two different mechanisms are possible: initial "weak" binding followed by an isomerization reaction

$$E + L \rightleftharpoons EL \rightleftharpoons E^*L \qquad \text{(Case 1)}$$

or pre-binding isomerization of one of the components

$$E \rightleftharpoons E^* + L \rightleftharpoons E^*L \qquad \text{(Case 2)}$$

with the asterisk indicating a conformational change.

This problem was also discussed comprehensively for possible two-state binding mechanisms when ATP binding to Hsc70 was analyzed for the first time with stopped-flow measurements using the intrinsic single-tryptophan signal [105].

To derive the according kinetic equations in the most general fashion, we use the following model:

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B \underset{k_{-2}}{\overset{k_{+2}}{\rightleftharpoons}} C$$

$$\frac{dc}{dt} = k_{+2}b - k_{-2}c = k_{+2}(a_0 - a - c) - k_{-2}c$$

$$\frac{da}{dt} = -k_{+1}a + k_{-1}b = -k_{+1}(a_0 - b - c) + k_{-1}b$$

$$b = \frac{dc}{dt} \cdot \frac{1}{k_{+2}} + \frac{k_{-2}c}{k_{+2}}$$

$$\frac{da}{dt} = -\left(a_0 - \frac{dc}{dt} \cdot \frac{1}{k_{+2}} - \frac{k_{-2}c}{k_{+2}} - c\right)k_{+1} + \frac{dc}{dt} \cdot \frac{k_{-1}}{k_{+2}} + \frac{k_{-1}k_{-2}c}{k_{+2}}$$

$$\frac{d^2c}{dt^2} = -k_{+2}\frac{da}{dt} - k_{+2}\frac{dc}{dt} - k_{-2}\frac{dc}{dt}$$

$$= -k_{+2}\left[-a_o k_{+1} + \frac{dc}{dt} \cdot \frac{k_{+1}}{k_{+2}} + k_{+1}c\frac{k_{-2}}{k_{+2}} - ck_{+1} + \frac{dc}{dt} \cdot \frac{k_{-1}}{k_{+2}} + \frac{k_{-1}k_{-2}c}{k_{+2}}\right]$$

$$- k_{+2}\frac{dc}{dt} - k_{-2}\frac{dc}{dt}$$

$$\frac{d^2c}{dt} + \frac{dc}{dt}[k_{+1} + k_{-1} + k_{+2} + k_{-2}] + c[k_{+1}k_{-1} + k_{+2}k_{+1} + k_{-1}k_{-2}] = k_{+2}k_{+1}a_0$$

$$\lambda_1, \lambda_2 = \frac{-[k_{+1} + k_{-1} + k_{+2} + k_{-2}] \pm \sqrt{[k_{+1} + k_{-1} + k_{+2} + k_{-2}]^2 - 4[k_{+1}k_{-2} + k_{+2}k_{+1} + k_{-1}k_{-2}]}}{2}$$

For the case $1(E + L \rightleftharpoons EL \rightleftharpoons E^*L)$ and assuming that $l_0 \gg e_0$, the expression k_{+1} is replaced by $k_{+1}l_o$, or briefly $k_{+1}{}'$, to indicate that the product of k_{+1} and l_o is virtually constant under these conditions:

$$\lambda_1\lambda_2 = \frac{-[k_{+1}{}' + k_{-1} + k_{+2} + k_{-2}] \pm \sqrt{[k_{+1}{}' + k_{-1} + k_{+2}]^2 - 4[k_{+1}{}'k_{-2} + k_{+2}k_{+1}{}' + k_{-1}k_{-2}]}}{2}$$

In the general case, this means complex kinetic behavior, with both solutions (λ_1 and λ_2) of the differential equation contributing to the transient observed. However, under certain conditions, simpler behavior is seen.

Examples are:

1. If k_{-1} is much larger than k_{+2} and k_{-2}, the second term under the square root bracket will always be much smaller than the first, and we can use the first two terms of the binomial expansion as a good approximation.

We can also simplify the first term by removing k_{+2} and k_{-2}.

[Binomial expansion of $a(a-b)^n = a^n - \frac{na^{n-1}b}{1}\ldots$]
Thus,

$$\lambda_1, \lambda_2 = -\frac{[k_{+1}{}' + k_{-1}] \pm \left[[k_{+1}{}' + k_{-1}] - \frac{1}{2}\cdot 4\frac{[k_{+1}{}'k_{-2} + k_{+2}k_{+1}{}' + k_{-1}k_{-2}]}{[k_{+1}{}' + k_{-1}]}\right]}{2}$$

$$\approx [k_{+1}{}' + k_{-1}] \tag{48}$$

or

$$\frac{k_{+1}{}'k_{-2} + k_2k_{+1}{}' + k_{-1}k_{-2}}{k_{+1}{}' + k_{-1}}$$

Note: The solutions of the equation are actually all negative, but the sign will be dropped at this point (terms in the solution are of the form $Ae^{-\lambda t}$).

$$k_{\text{obs}} = \frac{k_{-2}(k_{+1}{}' + k_{-1}) + k_2k_{+1}{}'}{k_{+1}{}' + k_{-1}}$$

$$= k_{-2} + \frac{k_2k_{+1}{}'}{k_{+1}{}' + k_{-1}}$$

$$= k_{-2} + \frac{k_2}{1 + \frac{k_{-1}}{k_{+1}{}'}} = k_{-2} + \frac{k_2}{1 + \frac{K_d{}'}{l_o}}$$

where K_d' is the dissociation constant for the first step. This behavior is shown in Figure 4.13 and was, e.g., observed for the binding of ATP to DnaK [11].

2. If k_{-1} is much smaller than k_{+2} and k_{-2}, we have the following situation when $k_{+1}{}'$ is also small (i.e., at low $l = l_o$):

$$\lambda_{1,2} = \frac{-[k_{+2} + k_{-2}] \pm \sqrt{[k_{+2} + k_{-2}]^2 - 4[k_{+1}lk_{-2} + k_{+2}k_{+1}l + k_{-1}k_{+2}]}}{2} \tag{49}$$

Again, under the conditions chosen, the second term under the square root sign is small compared to the first and to a first approximation

$$\lambda_{1,2} = [k_{+2} + k_{-2}] \quad \text{or} \quad \frac{k_{+1}lk_{-2} + k_{+2}k_{+1}l + k_{-1}k_{+2}}{k_{+2} + k_{-2}} \tag{50}$$

large and of small amplitude if E^*L gives the signal.

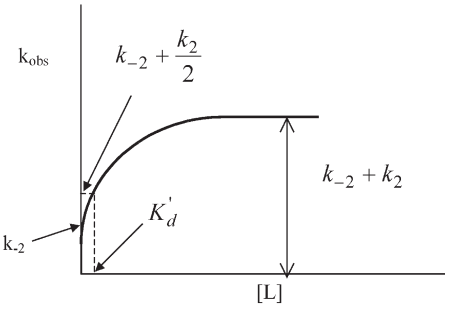

Fig. 4.13. Dependence of observed rate constant for large k_{-1} (fast first step).

The second solution simplifies to

$$k_{+1}l + \frac{k_{-1}k_{+2}}{k_{+2} + k_{-2}} \tag{51}$$

$$k_{+1}l + \frac{k_{-1}}{1 + \frac{k_{-2}}{k_{+2}}} = k_{+1}l + \frac{k_{-1}}{1 + \frac{1}{K_2}} = k_{obs} \tag{52}$$

A corresponding plot is shown in Figure 4.14.

At intermediate concentrations of L (when $k_{+1} \approx k_{+2}l + k_{-2}$), this system will show a lag phase in the kinetics of production of E^*L (comparable to the simple case of $A \rightarrow B \rightarrow C$ when the rate constants are of similar magnitude).

At concentrations at which $k_{+1}l$ is much greater than all the other rate constants, k_{obs} simplifies to:

$$k_{obs} = k_{+2} + k_{-2} \tag{53}$$

(i.e., the rate constant for production of E^*L can never be greater than the sum of k_{+2} and k_{-2}. This essentially simplifies the system to be analogous to the situation discussed previously for the rate of equilibration of A ⇄ B).

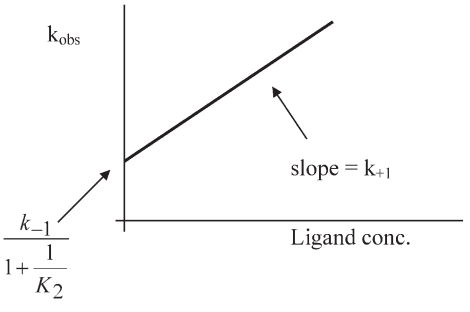

Fig. 4.14. Dependence of k_{obs} on ligand concentration for fast second step in two-step binding mechanism.

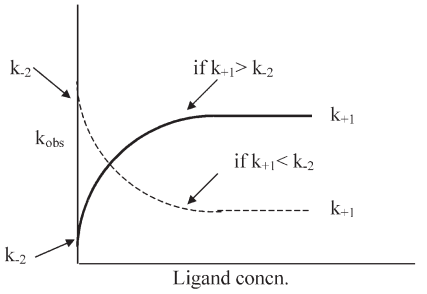

Fig. 4.15. Pre-isomerization dependence of k_{obs} on ligand concentration for large k_{-1}.

In the second possible two-step binding mechanism, a pre-binding isomerization occurs:

$$E \rightleftharpoons E^* + L \rightleftharpoons E^*L$$

In this case, k_{+2} in Eq. (49) is replaced with $k_{+2}l$:

$$\lambda_{1,2} = \frac{-[k_{+1} + k + k_{+2}l + k_{-2}] \pm \sqrt{[k_{+1} + k_{-1} + k_{+2}l + k_{-2}]^2 - 4[k_{+1}k_{-2} + k_{+2}l + k_{-1}k_{-2}]}}{2} \tag{54}$$

If E is mainly in the form without a star in the absence of the ligand, then k_{-1} must be much larger than k_{+1}.

If we also assume that $k_{-1} \gg k_{-2}$, the equation simplifies to:

$$\lambda_{1,2} = \frac{-[k_{-1} + k_{+2}l] \pm \sqrt{[k_{+1} + k_{+2}l]^2 - 4[k_{+2}lk_{+1} + k_{-1}k_{-2}]}}{2} \tag{55}$$

Again, the second term under the square root sign is much smaller than the first, so that:

$$\lambda_{1,2} = [k_{-1} + k_{+2}l] \pm [k_{-1} + k_{+2}] - \frac{1}{2} \cdot \frac{4[k_{+2}lk_{+1} + k_{-1}k_{-2}]}{[k_{-1} + k_{+2}l]}$$

$$= [k_{-1} + k_{+2}l] \quad \text{(always large and of small amplitude)}$$

or

$$\frac{k_{+2}lk_{+1} + k_{-1}k_{-2}}{k_{-1} + k_{+2}l} = \frac{k_{+1}}{1 + \dfrac{k_{-1}}{k_{+2}l}} + \frac{k_{-2}}{1 + \dfrac{k_{+2}l}{k_{-1}}}$$

$$k_{obs} = \frac{k_{+1}}{1 + \dfrac{k_{-1}}{k_{+2}l}} + \frac{k_{-2}}{1 + \dfrac{k_{+2}l}{k_{-1}}}$$

The first term tends to 0 as l tends to 0 and to k_{+1} as l tends to ∞. The second term tends to k_{-2} as l tends to 0 and to 0 as l tends to ∞. The corresponding plot is shown in Fig. 4.15.

Analysis of Chaperone Function in Vitro

Johannes Buchner and Stefan Walter

5.1
Introduction

The intention of this chapter is to provide a manual of how to identify a protein as a molecular chaperone and to carry out the experiments required for its basic characterization.

Originally, the term *molecular chaperone* had been coined by Laskey to describe the role of nucleoplasmin in the association of histones (1, 2). Later, the concept was extended to heat shock proteins by John Ellis (3, 4). He also invented the term ''chaperonin'' for GroE (Hsp60) and related proteins. Over the years, *molecular chaperone* has acquired additional meanings, some of which represent useful extensions of the original definition, whereas others, such as ''chemical chaperones'', may cause some confusion. In the first section of this chapter, we will discuss the distinct features of a molecular chaperone. We will then describe the types of reactions that can be facilitated by molecular chaperones in general and present some important functional aspects. The theoretical section concludes with a discussion of the principal assays that can be used to investigate chaperone function in vitro. In the second part of this chapter, we provide selected protocols to measure and characterize chaperone function.

Molecular chaperones are a functionally related family of proteins assisting conformational changes in proteins without becoming part of the final structure of the client protein [5–9]. Originally, the focus of the concept was on the correct association of proteins and the prevention of unspecific aggregation of polypeptide chains during protein folding. Interestingly, all major chaperones belong to the class of heat shock or stress proteins, i.e., they are synthesized in response to stress situations such as elevated temperatures. Under these conditions, proteins tend to aggregate in vivo. This was demonstrated for *E. coli* strains lacking the heat shock response [10]. In these bacteria, elevated temperature caused the accumulation of proteins in large insoluble aggregates, which resemble the so-called inclusion bodies sometimes obtained upon overexpression of recombinant proteins [11]. These experiments showed that under stress there is a strong influence of molecular chaperones on protein homeostasis. However, this seems to hold true also for physiological conditions: many molecular chaperones have homologues that are

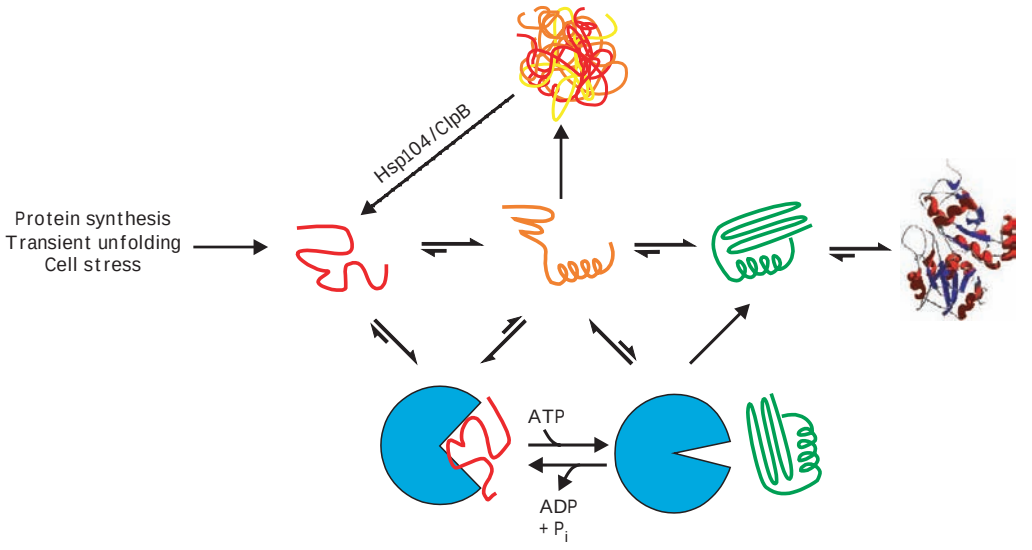

Fig. 5.1. Model for assisted protein folding by molecular chaperones. Several processes generate unfolded polypeptide chains (red), which can fold via partially structured intermediates (orange, green) to the native, biologically active state (right). Depending on the conditions and the nature of the polypeptide, a significant fraction of the molecules may form aggregates (top). The yield of cellular protein folding is significantly improved by the action of general molecular chaperones (bottom, blue). They bind to nonnative polypeptides and thus prevent their aggregation. Further, they may alter the conformation of the bound polypeptide so that once it dissociates, it is less prone to aggregation. Often, release is triggered by a change in the nucleotide state of the chaperone or by ATP hydrolysis. Recently, it was shown that some chaperones of the Hsp100 class such as ClpB and Hsp104 are able to reverse aggregation (top).

constitutively expressed [12], and some of them are essential for viability [13, 14]. This finding suggests that these helper proteins are of general importance for the folding and assembly of newly synthesized polypeptide chains. Furthermore, the observation of strong aggregation of overexpressed proteins under otherwise physiological conditions is consistent with the notion of a balance between protein synthesis/folding and chaperone expression, which has been developed through evolution and can be modulated only within a certain range.

At first glance, the concept outlined above is in conflict with the paradigm of autonomous, spontaneous protein folding established by Anfinsen and many others [15, 16]. The apparent contradiction is that if the acquisition of the unique three-dimensional structure of a protein is governed by its amino acid sequence and the resulting interactions between amino acid side chains, there should be no need for molecular chaperones (Figure 5.1). However, additional factors have to be taken into account. The most important is the possibility of unspecific intermolecular interactions during the folding process of proteins [17, 18]. This reaction depends on the concentration of unfolded or partially folded polypeptide chains and their folding kinetics. Thus, either conditions under which proteins fold slowly or high concentrations of folding proteins will favor aggregation [19]. In consequence, the fraction of molecules reaching the native state will decrease. The basic function of molecular chaperones is to counteract this nonproductive side reaction and thereby

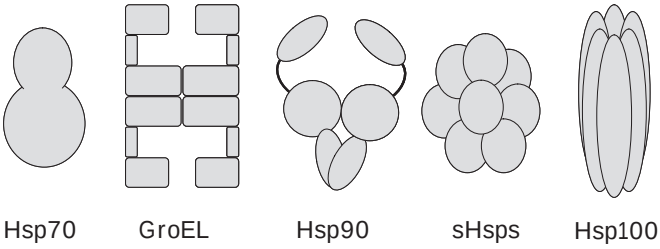

Fig. 5.2. Classes of general molecular chaperones. From left to right: Hsp70 is a monomeric chaperone consisting of an ATPase domain and a peptide-binding domain. The bacterial chaperone GroEL forms two rings comprised of seven subunits each. In the cross-section shown here, two subunits of each ring are depicted. Interactions between the subunits are mediated by the equatorial domains in the center of the molecule, which also contain the ATPase site. The dimeric Hsp90 chaperone consists of three domains. While the C-terminal domains are responsible for dimerization, the N-terminal domains bind and hydrolyze ATP. The small Hsps form large oligomeric structures that contain 24–32 identical subunits. They are the only general chaperones without ATPase function. Chaperones of the Hsp100 class form ring-shaped homohexamers. Each subunit contains two similar, but not identical, ATPase sites.

increase the efficiency of folding (Figure 5.1). Molecular chaperones do not provide steric information for the folding process and thus do not violate the concept of autonomous folding. (The information for folding is encoded solely in the amino acid sequence.) Rather, molecular chaperones assist the spontaneous folding of proteins. Interestingly, the principal possibility of assisted folding had already been hypothesized by Anfinsen in 1963 [20].

It is difficult to assess what fraction of the cellular proteome depends on molecular chaperones to reach its active conformation. But clearly not all newly synthesized proteins need their assistance. While for the chaperone role model GroE (see Chapter 20) it was shown that 40% of the *E. coli* proteins can be influenced in their folding [21], in the cell only about 10–15% may need this assistance under physiological conditions [22, 23]. Similar values were reported for other chaperones [24, 25]. Under conditions where proteins are destabilized (such as heat shock), the requirement for chaperone assistance is clearly increased.

There are only a few classes of general molecular chaperones (Figure 5.2) that have to take care of a large number of different proteins, implying that chaperones have to be promiscuous in their interaction with nonnative proteins, i.e., they must be able to recognize and handle a large variety of different proteins. With the exception of small Hsps, all of them possess an intrinsic ATPase activity (Table 5.1). ATP-dependent structural changes in molecular chaperones are essential for the conformational processing of client proteins. While some basic functional features seem to be conserved between different classes of chaperones, the structure and mode of action are completely different among individual chaperones.

5.2
Basic Functional Principles of Molecular Chaperones

The classification of an enzyme is usually based on the type of reaction it catalyzes and the substrate(s) it turns over. In the field of protein folding and molecular

[3] Unpublished data from our labs.

chaperones, applying this concept is rather difficult for three reasons. First, though we currently lack a detailed understanding of the mechanisms of protein folding, especially in the context of a living cell, we know it is a rather complex process involving multiple pathways, intermediates, and potential side reactions. As a consequence, molecular chaperones can interfere with and assist protein folding in many different ways, and in most cases our knowledge of how chaperones influence protein folding on a molecular level is very limited. A second problem arises from the heterogeneity of the substrates. As already mentioned, the in vivo substrates of most chaperones are not known in detail. However, it is clear that they include a substantial fraction of the proteome. Finally, it is very difficult to assess which conformational state(s) of these client proteins interact with a certain chaperone. In classic enzymology, reaction intermediates can often be trapped by changing the solvent conditions or temperature. Due to their low intrinsic stability, this is in general not possible for nonnative proteins. Here, a change in solvent conditions will almost always result in a change in the conformational state of the client protein. Under ''folding'' conditions, the nonnative protein will continue to ''react'' until a final state (e.g., native structure or aggregate) is reached. Therefore, great care must be taken when the structure of these intermediates is studied. Otherwise, the result will most likely not reflect the conformation of the protein at the time the sample was taken [26–29].

In the following sections, we present key features that many chaperones have in common and that we consider as the functionally most relevant.

5.2.1 Recognition of Nonnative Proteins

The most fascinating trait of a molecular chaperone is its ability to discriminate between the folded and nonnative states of a protein. It would be deleterious for the cell if chaperones would bind to native proteins or fail to recognize the accumulation of the nonnative protein species. Thus, the promiscuous general chaperones have to use a property for recognition and binding that is common to all nonnative proteins. This is the exposure of hydrophobic amino acid side chains, the hallmark of unfolded or partially folded protein structures. In the unfolded state, extended stretches of polypeptide chains containing hydrophobic residues can be recognized by chaperones. This is well documented for proteins of the Hsp70 family [30, 31]. In partially folded proteins, these residues are often clustered in areas that are part of a domain/subunit interface in the folded protein, and they will become buried in subsequent folding/association events. These regions can thus be utilized by molecular chaperones to identify potential client polypeptides, i.e., to distinguish a nonnative conformation from a native protein. The respective binding site of the chaperone usually contains a number of hydrophobic residues that interact with the substrate [32, 33]. The low specificity of hydrophobic interactions is the basis for the substrate promiscuity of molecular chaperones. Since the extended exposure of hydrophobic surfaces in an unfolded or partially folded state is an important determinant for its probability to aggregate, the shielding of these surfaces upon binding to a chaperone is a very efficient means to prevent aggregation.

Besides hydrophobicity, a polypeptide may have to meet additional requirements in order to bind to a chaperone. It was shown for GroEL that negative charges on the substrate significantly weaken interaction with the chaperone due to electrostatic repulsion [34]. In the case of DnaK (Hsp70), the preferred substrate is a stretch of hydrophobic residues flanked by basic amino acids [35, 36]. Another important aspect that can influence the affinity of a polypeptide towards a chaperone is its conformational plasticity. Due to their promiscuity, chaperones cannot provide an optimal binding surface for each of their client proteins. Consequently, the polypeptide, and to some extent the chaperone itself, may have to adjust its conformation to establish tight binding [37]. Because this process requires a certain degree of flexibility, it may serve as a second checkpoint to discriminate between native and nonnative conformations.

An important consequence of the unspecific recognition of exposed hydrophobic residues is that chaperones will not bind just one specific nonnative conformation of a protein. In contrast, it has to be assumed that all conformations exhibiting a certain degree of hydrophobicity will be recognized. In the case of GroE, the conformations that are stably bound range from completely unfolded to a native-like dimer [38, 39].

The sites of interaction with nonnative proteins are known for Hsp70 and GroEL. In the crystal structure of the protein-binding domain of DnaK (Hsp70) in complex with a short peptide [33], the peptide adopts an extended conformation and the hydrophobic side chains of the peptide make contact with the binding groove, but there are also polar interactions between Hsp70 and the peptide backbone. In the case of GroEL, the analysis of numerous point mutations together with the crystal structure indicated that the nonnative protein binds to hydrophobic residues of the apical domains, which are located on the top of the inner rim of the GroEL cylinder [32, 40]. This conclusion was confirmed several years later by the X-ray structure of a GroEL-peptide complex [41, 42]. Detailed descriptions of the substrate-binding sites and their properties can be found in the chapters dedicated to the respective molecular chaperones.

A notable exception from the theme of hydrophobic binding motifs is chaperones involved in the unfolding of proteins. Many of their client proteins adopt a fully folded conformation and thus do not expose hydrophobic surfaces. At the same time, an unambiguous signal is required to tell the chaperone which protein should be unfolded for subsequent degradation. Evolution has solved this problem by attaching specific tags, such as ubiquitin [43, 44] or the ssrA peptide [45], to these proteins, which serve as recognition sites for the respective degradation systems [46]. Little is known about the structure/sequence motifs recognized by chaperones involved in disaggregation, such as ClpB or Hsp104, as it has proved difficult to obtain stable chaperone-substrate complexes in these cases.

5.2.2
Induction of Conformational Changes in the Substrate

Prevention of aggregation by (transient) binding of partially folded proteins clearly is an important part of chaperone function in vivo. But in a number of cases, this

"buffering capacity" appears not to be the primary task. This is especially true for the ATP-consuming chaperones. An increasing amount of evidence suggests that the energy provided by ATP hydrolysis is used to induce conformational changes in the bound polypeptide. For the ClpA chaperone, Horwich and coworkers demonstrated that it can actively unfold ssrA-tagged, native GFP [47]. In this case, ATP hydrolysis is required to overcome the free energy of folding. In the case of the Hsp90 system, an immature conformation of a bound steroid hormone receptor (a client protein) is converted into a conformation that is capable of binding the hormone ligand [48, 49]. ATP binding and hydrolysis are essential for this process, as they seem to control the association of the chaperone with its various cofactors [50] (see also Chapter 23). During the whole sequence of reactions, the receptor is assumed to remain bound to the Hsp90 chaperone.

For the general chaperones, we know that conformational changes occur in the chaperone upon both ATP binding and hydrolysis [51–54]. However, much less is known about how and to what extent these changes result in conformational rearrangements in substrate proteins associated with the chaperone. As mentioned above, this is mainly because the species involved are often only transiently populated and very labile and thus are not easily susceptible to methods of structure determination. Also, the bound target protein may represent an ensemble of conformations [39].

Two mechanisms can be envisaged as to how a chaperone causes a structural change in a client protein. In both cases, a conformational change in the chaperone is induced by the binding of a ligand (ATP or a cofactor) or by ATP hydrolysis. This in turn results in a change in the nature/geometry of the substrate-binding site that weakens the interaction with the bound polypeptide. As the system ligand/chaperone tends to assume a state of minimum free energy, the substrate has two choices: (1) it may undergo structural rearrangements to adopt a conformation that has a higher affinity towards the binding site or (2) it may start to fold. Both processes will lower the free energy of the system, but in the first case the energy drop primarily results from interactions between chaperone and substrate, whereas in the second case it results solely from interactions within the client polypeptide. Although these rearrangements are driven by thermodynamics, kinetics may be important as well in defining whether binding or folding dominates for a given polypeptide conformation [55–57].

An alternative to this "passive" model is that the conformational change in the chaperone generates a "power stroke" that is used to perform work on the substrate, e.g., by moving apart two sections of the bound protein. If the substrate is a single polypeptide, this could result in a forced unfolding reaction [58]. If the substrate is an oligomeric species, e.g., a small aggregate, the power stroke may cause its dissociation into individual molecules. This "active" mechanism requires that the substrate remains associated with the chaperone during the conformational switch, which is not required in the first model. After the power stroke, the substrate will probably undergo a series of conformational relaxation reactions.

For both models, the concept of general chaperones requires that the conformational change in the substrate be encoded by its amino acid sequence rather than

being forced onto the substrate by the chaperone. The chaperone merely enables the polypeptide to use its inherent folding information.

5.2.3 Energy Consumption and Regulation of Chaperone Function

Most of the general chaperones require ATP to carry out their task (Table 5.1). Examples of ATP-hydrolyzing chaperones are GroEL; the Hsp104/ClpB proteins, which participate in the dissociation of protein aggregates; Hsp90; and Hp70, which is involved in a large variety of reactions ranging from the general folding of nascent polypeptide chains to specific functions. As stated above, the cycle of ATP binding and hydrolysis drives an iterative sequence of conformational changes in the chaperone, which may induce structural rearrangements in a bound polypeptide or trigger binding/release of client proteins and co-chaperones. In contrast to the conformational changes that occur within both the chaperone and a bound substrate protein, the ATPase activity of molecular chaperones is experimentally very easily accessible. Because of its crucial functional importance, ATP turnover is usually modulated by both the substrate and helper chaperones.

Stimulation of ATP hydrolysis in the presence of unfolded proteins or peptides has been observed, e.g., for Hsp70, Hsp90, and Hsp104 [30, 59–61]. Apparently, the binding of the substrate induces a conformational change in these chaperones that results in a state with a higher intrinsic ATPase activity. This ''activation on demand'' may serve as a means to reduce the energy consumption by the empty chaperones. In contrast, ATP hydrolysis by GroEL is only marginally affected by the presence of protein substrates.

A well-characterized example of the regulation of ATP hydrolysis by co-chaperones is the DnaK system of *E. coli* (see Chapter 15). The ATPase cycle, and thus the cycle of substrate binding and release, is governed by two potential rate-limiting steps: the hydrolysis reaction and the subsequent exchange of ADP by ATP [62]. Both steps can be accelerated by specific cofactors, namely DnaJ and GrpE [59, 63, 64]. The rates of nucleotide exchange and hydrolysis determine how fast a substrate is processed and how long it is on average associated with the ADP and ATP states of DnaK, respectively.

While Hsp70 is subject mainly to positive regulation, other chaperone systems appear to include negative regulators as well. Hsp90, which plays an essential role in the activation of many regulatory proteins such as hormone receptors and kinases, is controlled by a large number of cofactors (see Chapter 23). Two of these co-chaperones, p23 and Hop/Sti1, were found to decrease the ATPase activity by stabilizing specific conformational states of Hsp90 [50, 65]. Intriguingly, Hop/Sti1 from *S. cerevisiae* seems to have a dual regulatory function: besides its inhibitory effect on Hsp90, Sti1 was also shown to be a very potent activator of Hsp70 [66]. Another example of a negative regulator is GroES, which reduces the ATP hydrolysis of its partner protein GroEL to 10–50% depending on the conditions used [67, 68]. The role of GroES in the functional cycle of the GroE chaperone, however, goes far beyond its modulation of ATP turnover, as it is essential for the encapsu-

lation of a polypeptide in the folding compartment of the GroE particle (see Chapter 20). The example of GroES is instructive, as it demonstrates that regulation of ATP turnover may not be the most important function of a cofactor. Nevertheless, the combination of experimental simplicity and functional relevance makes the ATPase of a general chaperone a preferred choice for mechanistic studies.

Some chaperones are regulated by temperature. Hsp26, a small heat shock protein from *S. cerevisiae*, has no chaperone activity at 30 °C, the physiologic temperature for yeast. At this temperature, Hsp26 forms hollow spherical particles consisting of 24 subunits [69]. Under heat stress, e.g., at 42 °C, these large complexes dissociate into dimers that exhibit chaperone activity and bind to nonnative polypeptides. Another interesting example of temperature regulation is the hexameric chaperone/protease degP of the *E. coli* periplasm [70]. At low temperature the protein acts as a chaperone, whereas at elevated temperature it possesses proteolytic activity (see Chapter 28). The regulatory switch is thought to involve the reorientation of inhibitory domains, which block access to the active site of the protease at low temperature [71]. Interestingly, switching can also be achieved by the addition of certain peptides.

A further variation of the scheme of activating chaperones by stress conditions is the regulation of Hsp33. Here, oxidative stress leads to the formation of disulfide bonds within the chaperone and its subsequent dimerization, which is a prerequisite for efficient substrate binding [72] (see also Chapter 19).

5.3 Limits and Extensions of the Chaperone Concept

The term chaperone and the underlying concept are attractive. Therefore, it is not surprising that the term itself has been proved to be rather promiscuous, as it is increasingly used for different proteins and even non-proteinaceous molecules. In its most basic interpretation, it has been applied to all proteins that have an effect on the aggregation of another protein or that influence the yield of correct folding. Most of these proteins have hydrophobic patches on their surface and thus, irrespective of their biological function, will associate with nonnative proteins. However, to qualify for a molecular chaperone, additional requirements should be met. This includes the defined stoichiometry of the binding reaction and the regulated release of the bound polypeptide (e.g., triggered by binding of ATP).

An extension of the term chaperone are the so-called intramolecular chaperones. These are regions of proteins that are required for their productive folding without being part of the mature protein because they are cleaved off after folding is complete. Well-investigated examples include the pro-regions of subtilisin E and α-lytic protease [73, 74]. The variation of the chaperone concept is that an intramolecular chaperone is specific for one protein and is covalently attached to its target. Furthermore, these chaperones act only once: after completing their job, they are cleaved off and degraded. These properties do not agree with the basic definition of a chaperone.

Chemical chaperone is a term that has become fashionable in recent years. It refers to small molecules (not proteins or peptides) that are added to refolding reac-

tions to increase the efficiency of protein folding in vitro. For instance, the folding yields for many enzymes can be improved by adding a substrate to the refolding buffer [75–77]. These compounds are thought to stabilize critical folding intermediates by binding to the active site, thereby enhancing folding. Besides these rather specific ligands, a number of substances, the most prominent of them being Tris and arginine, were found to promote the yield of folding in many cases when present in large excess over the folding proteins (see Chapter 38). In contrast to molecular chaperones, both chemical chaperones and intramolecular chaperones cannot be regulated in their activity.

5.3.1 Co-chaperones

For many chaperones, cofactors/co-chaperones exist that seem to directly influence the function of the chaperone. Some of them are essential constituents of their respective chaperone system, while others only improve its efficiency. Often, the role of cofactors is not limited to the regulation of the ATPase function but involves the recognition of nonnative proteins. These proteins thus have features of a chaperone. The DnaJ/Hsp40 co-chaperones seem to bind unfolded proteins and transfer them to Hsp70 [62, 78]. At the same time, as mentioned above, binding of DnaJ/Hsp40 stimulates ATP hydrolysis by Hsp70. Far more complex is the situation for the Hsp90 system. Here a plethora of cofactors exist, many of which seem to be able to recognize and bind nonnative proteins as demonstrated by in vitro chaperone assays [79, 80]. There is good reason to assume that they exert this function also within the Hsp90 chaperone complex, i.e., they interact with the substrate when it is associated with Hsp90.

The term co-chaperone implies that the function of these proteins is restricted to the context of their respective chaperones. However, recent evidence suggests that this may not be true in all cases. One example is the Hsp90 co-chaperone p23, which clearly has a distinct function in the Hsp90 system but also seems to be able to disassemble transcription factor complexes bound to DNA [81]. Similarly, Cdc37 was reported to exhibit an autonomous chaperone function [82].

It is important to remember that while in vitro chaperone assays can be used to detect chaperone properties in a cofactor, their functional relevance in the context of a chaperone complex has to be addressed in subsequent experiments.

5.3.2 Specific Chaperones

In addition to the general chaperones, a number of proteins exist for which the basic definition of chaperone function applies. However, these chaperones are dedicated to one or a few target proteins. In these cases, recognition is highly specific and does not necessarily involve hydrophobic interactions. An example for this class of chaperones is Hsp47, a resident protein of the endoplasmic reticulum that is a dedicated folding factor for collagen [83]. It interacts with immature collagen, is required for its correct folding and association, and is not part of the final collagen trimer. Thus, all the criteria for a molecular chaperone are fulfilled. Colla-

gen release is not triggered by ATP hydrolysis but by changes in the pH upon transit from the ER to the Golgi [84, 85].

Another well-studied example is the pili assembly proteins of gram-negative bacteria (see Chapter 29). Here, unassembled pili subunits are bound by specific chaperones that prevent their premature association in the periplasmic space. These chaperones bind very specifically and can be considered as surrogate subunits.

5.4 Working with Molecular Chaperones

5.4.1 Natural versus Artificial Substrate Proteins

An important point in studying molecular chaperones is the choice of substrate protein. Section 5.6 of this chapter will describe several of the most commonly used chaperone substrate proteins in detail. For many of them it is clear that they do not represent authentic in vivo substrates for the chaperone studied. The question is whether this poses a limitation on the validity of the results obtained with these proteins.

For the promiscuous general chaperones and co-chaperones, the interaction with the substrate protein is relatively unspecific. As a consequence, any unfolded protein can be regarded as a bona fide substrate. Interestingly, almost all mechanistic studies on GroE have been performed with ''artificial'' substrate proteins. Using a standard set of model substrates has a number of important advantages: (1) they are commercially available at a fairly low cost, (2) they are very well characterized in their folding and aggregation properties, and (3) they allow a direct comparison among chaperones to assess functional differences (Table 5.2). Moreover, they likely reflect the spectrum of polypeptides that chaperones may encounter in the cell. The situation is different for chaperones with high substrate specificity. Here, assays with model substrate proteins may allow analysis of certain aspects of their mechanisms. However, it is desirable to use authentic substrate proteins whenever possible.

5.4.2 Stability of Chaperones

There seems to be a common misconception that chaperones are exceptionally stable proteins because they are active under conditions, such as heat shock, that lead to the unfolding of many proteins. However, it has to be considered that the heat shock response is able to protect organisms only a few degrees above their optimum growth temperature. In general, there is no selection pressure on any intracellular protein to be stable above the maximum temperature tolerated by the host. As outlined above, many chaperones are functionally important under both physiological and stress conditions, i.e., they have to be active over a broad temperature range. From a mechanistic point of view, flexibility and conformational changes are of exceptional importance for molecular chaperones since they have to interact

Tab. 5.2. Protein substrates for molecular chaperones.

	Organism	*Molecular mass (kDa)*	*$A_{280\ nm}$ (1 mg mL^{-1}, 1 cm)*	*Commercially available*	*Activity assay available*	*General handling*	*Remarks*	*References*
Alpha-glucosidase	*S. cerevisiae*	68	2.61	Yes	Yes	Good		115, 136
Alpha-lactalbumin	*Bos taurus*	14	1.7	Yes	Yes, but awkward	Very good	Permanently unfolded derivate (RCMLA)	137, 138
Citrate synthase	*Sus scrofa*	2 × 49	1.56	Yes	Yes (expensive)	Good	Model substrate	87, 107, 139
Luciferase	*Photinus pyralis*	60.7	0.59	Yes	Yes (expensive)	Very poor	Very sensitive	140–143
Insulin	*Bos taurus*	5.8	1.06	Yes	No	Good	Useful only for aggregation assays	114, 115, 144
Malate dehydrogenase	*Sus scrofa*	2 × 33	0.2	Yes	Yes	Good	Model substrate	99, 145
Maltose binding protein	*E. coli*	40.7	1.6	No	No (but change in Trp fluorescence upon folding)	Good	Spontaneous folding is decelerated by chaperones	55, 146
Rhodanese	*Bos taurus*	33	1.8	Yes	Yes (toxic)	Good	Model substrate	56, 97, 147
Rubisco	*R. rubrum*	2 × 50.5	1.11	No	Yes, but uses $^{14}CO_2$	Good	First substrate ever used for in vitro assays	139, 148, 149

with a large variety of substrate proteins. For the reasons given, it is therefore plausible that chaperones cannot be extremely stable and rigid proteins (Table 5.1). This imposes certain restrictions on the design of in vitro chaperone assays (see experimental Section).

5.5 Assays to Assess and Characterize Chaperone Function

The first in vitro assays for a molecular chaperone using purified components were presented by Lorimer and coworkers in 1989 [86]. They analyzed and dissected the function of the two components of the GroE system (GroEL and GroES) using unfolded bacterial Rubisco as a substrate protein. The methods employed included activity assays to monitor the refolding to the native state, CD spectroscopy to analyze the conformation of the nonnative substrate protein at the beginning of the reaction, and native PAGE to demonstrate a direct physical interaction between the chaperone and Rubisco. This landmark paper became a role model for numerous studies to follow. Among other things, it showed that artificially denatured proteins can serve as substrates for molecular chaperones and that they can be refolded in a strictly ATP-dependent manner. In many cases, the increase in the yield of refolded protein is due to the suppression of aggregation during refolding. This was first shown for GroE using light scattering [87].

5.5.1 Generating Nonnative Conformations of Proteins

To produce the nonnative conformation of a substrate protein, all the conditions and substances known to denature proteins can be employed. Chaotropic compounds such as guanidinium chloride (GdmCl) and urea are used if a completely unfolded state of the substrate protein is desirable. This is referred to as ''chemical unfolding.'' In these cases, the substrate protein is diluted from a high concentration of denaturant into a solution containing the chaperone. Note that for most chaperone substrates there is competition between binding to the chaperone, folding, and aggregation. Alternatively, the test protein can be unfolded at elevated temperature. In this case, the unfolded protein cannot be stored because aggregation starts shortly after the temperature increase. In assays that employ thermally unfolded model substrates, the chaperone is therefore added before the heating step. Unfolding of proteins can also be achieved at low pH (acid denaturation) or, in the case of disulfide-containing polypeptides, by reduction.

5.5.2 Aggregation Assays

Since the prevention of aggregation is one of the key biological functions of general chaperones, this test can be considered an ''activity assay.'' In the simplest case, a temperature-labile protein, such as citrate synthase, is incubated at a tem-

perature at which it starts to unfold. The subsequent aggregation process can be monitored by the extent of light scattering shown by the sample, preferably in a fluorescence spectrometer or a regular UV/VIS photometer. In the presence of a chaperone, a decrease in the scattering signal at the end of the reaction should be observed. When an excess of chaperone is used, aggregation may be suppressed completely.

However, one should be cautious not to over-interpret results obtained from aggregation experiments. The intrinsic problem with aggregation is that, as a stochastic process, it is of limited reproducibility. Moreover, it is notoriously sensitive to small changes in conditions. Therefore, it is essential to include appropriate controls. Further, it yields only qualitative data: during the time course of aggregation, there is a concomitant increase in the number of aggregates as well as in the size of the aggregates. The contribution of the two processes will be different at different time points during the kinetics. Lastly, some proteins may suppress the aggregation of a test substrate without being chaperones.

5.5.3
Detection of Complexes Between Chaperone and Substrate

Many chaperones form remarkably stable complexes with unfolded polypeptides [48, 88, 89]. As described above, complex formation is due mainly to hydrophobic interactions between the binding site on the molecular chaperone and hydrophobic patches on the surface of the substrate protein.

To obtain complexes of chaperones with nonnative proteins, a concentrated solution of a chemically unfolded test protein is added to the chaperone. Alternatively, a mixture of a thermolabile protein and a chaperone is incubated at an elevated temperature. Depending on their stability, the complexes can be identified by several methods. Usually, unbound substrate is first separated from the complexes by size-exclusion chromatography, native PAGE, centrifugation, or other methods. The presence of the test substrate in the purified complexes is then shown on SDS-PAGE gels or by immunological methods if an antibody against the substrate is available. Alternatively, the test protein can be tagged for detection with, e.g., biotin or labeled with a fluorescent marker. Labile chaperone-substrate complexes must be trapped by either chemical- or photo-cross-linking before further analyses can be carried out. An extension of this type of experiment is the identification of complexes between a chaperone and its cofactors [90] (see also Chapter 23).

5.5.4
Refolding of Denatured Substrates

This type of assay is more complex than the ones described above because (1) it requires some knowledge about the mechanism of substrate release and (2) successful refolding may depend on the presence of (co-)chaperones or other factors. The most convenient refolding assays use test substrates whose enzymatic activity can be measured without interference from the chaperone. The use of classical spectroscopic probes for folding such as fluorescence or far-UV CD may be difficult

because of the high background signal from the chaperone and (if present) ATP. However, some chaperones such as GroEL, GroES, and Hsp104 lack intrinsic tryptophans, and in these cases one may use fluorescence to directly monitor changes in the structure of Trp-containing test proteins.

The general procedure for a refolding assay is as follows. First, a complex between the chaperone and the test substrate is formed (see Section 5.5.3). Usually, it is not necessary to remove molecules that have not bound to the chaperone. Afterwards, substrate release and refolding are triggered by adding the appropriate components, e.g., GroES and ATP in the case of GroEL. At various time points, aliquots are withdrawn from the sample and the enzyme activity is determined.

5.5.5
ATPase Activity and Effect of Substrate and Cofactors

Many general chaperones have an intrinsic ATPase activity, though their rates of hydrolysis can differ significantly (Table 5.1). ATP hydrolysis by a chaperone can be measured using several assay systems (see Section 5.6). Once the basal ATPase activity has been determined, the effect of substrates and cofactors in various combinations can be tested. Concerning the substrate, a polypeptide is preferred that adopts a stable, nonnative conformation. Otherwise, its conformation and thus its effect on ATP hydrolysis may change during the experiment. Alternatively, a small peptide may be used.

A more extensive characterization of the ATPase may include the determination of enzymatic parameters such as K_M or k_{cat}, in both the absence and the presence of effectors (see Chapter 4). However, one should be aware that in the case of oligomeric chaperones, a detailed analysis can be very challenging due to homotropic and heterotropic allosteric effects [91].

5.6
Experimental Protocols

5.6.1
General Considerations

5.6.1.1 Analysis of Chaperone Stability

When setting out to analyze the function of molecular chaperones, it is highly recommended to determine the intrinsic stability of the chaperone as a first step. This enables the experimenter to choose the appropriate reaction conditions for the chaperone assays. The conformational stability against urea or GdmCl should be measured using the protocols provided in the first volume of this book (see Chapter 3 in Part I). In the case of ATP-dependent chaperones, the GdmCl- or urea-induced unfolding transitions may be recorded in the presence and absence of ATP to determine whether the ligand has an effect on protein stability. In addition to the conventional assays for determining protein stability, for molecular

chaperones it is useful to specifically determine the stability against thermal unfolding because assays at heat shock temperatures are convenient. CD spectroscopy is frequently used to monitor changes in the secondary structure with increasing temperature.

5.6.1.2 Generation of Nonnative Proteins

Because most substrates are stable proteins at ambient temperature, they have to be unfolded prior to complex formation. This can be achieved by chemical denaturation, thermal unfolding, or – in the case of some disulfide-containing proteins – reduction. Each of these methods has its own merits but may not be applicable for a certain combination of substrate and chaperone. Chemical unfolding is a very reproducible method to generate unfolded protein substrates, and the product can usually be stored for several hours. However, one has to be aware that urea slowly decomposes into cyanate, which is reactive and can covalently modify amino acid side chains [92]. Further, it has been shown for both Hsp104 and GroE that GdmCl can severely interfere with chaperone function [93, 94]. To keep the residual concentration of denaturant in the chaperone assay below 0.1 M (urea) and 0.05 M (GdmCl), respectively, one should use fairly concentrated stock solutions of unfolded polypeptide.

Unfolding substrates at elevated temperature mimics conditions of heat shock and thus could be considered the most physiologic method to generate unfolded polypeptides. Also, there are no problems arising from the addition of problematic chemicals. The main disadvantage is that thermally unfolded proteins cannot be stored, as they will start to aggregate quickly. Thus, the thermal inactivation has to take place in the presence of chaperone. This implies that the chaperone itself has to be stable under the conditions used to unfold the substrate. Also, the reproducibility is not as high as when chemical denaturation is used. In the case of proteins that contain disulfide bonds, these can be broken by the addition of reducing agents such as glutathione or DTT. This may destabilize the protein enough so that it will unfold either spontaneously or at mildly denaturing conditions. As for the previous procedures, it should be verified that the chaperone is not compromised by the reducing agent. While reducing conditions may not be a problem for cytosolic chaperones, proteins operating in a more oxidative environment such as the ER or the periplasm may not tolerate low redox potentials.

5.6.1.3 Model Substrates for Chaperone Assays

Numerous proteins have been used as substrates to investigate assisted protein folding. Due to features such as availability, ease of handling and detection, and general suitability as chaperone substrates, some of these proteins were repeatedly used and eventually became model substrates. In the following sections, we will briefly describe the most important ones. Additionally, Table 5.2 includes a number of less commonly used substrates along with selected references.

Rhodanese (Bovine Liver) Rhodanese from liver mitochondria is a small (33 kDa) monomeric enzyme that catalyzes sulfur transfer reactions [95]. It is commercially

available from several sources, but batches may differ in the degree of purity. The structure of rhodanese has been determined [96]. The reactivation of rhodanese is dependent on chaperones [97], although spontaneous refolding has been observed in the presence of lauryl maltoside, β-mercaptoethanol, and thiosulfate [75]. Rhodanese has been extensively used over the years to study assisted protein folding. One disadvantage of rhodanese is that the activity assay uses the toxic compound KCN.

Mitochondrial Malate Dehydrogenase MDH (Porcine Heart) Malate dehydrogenase is an enzyme of the mitochondrial Krebs cycle. The enzyme from *Sus scrofa* consists of two subunits of ~33 kDa each and is commercially available. Its reactivation is highly dependent on the assistance of chaperones, although spontaneous refolding occurs in the presence of high phosphate concentrations [98, 99]. The crystal structure of MDH has been solved [100]. This model substrate was extensively used to investigate the mechanism of GroEL [29, 101]. MDH can be unfolded with both urea and GdmCl. Moreover, it starts to unfold (and aggregate) at ~45 °C in Tris buffer at pH 8 [102]. MDH has been shown to form stable complexes with a number of chaperones, including sHsps (Hsp18.1) and GroEL. In addition, aggregated MDH has been used to study the disaggregation properties of the chaperone ClpB [103]. Finally, the regaining of MDH activity during refolding is easy to monitor (see Chapter 20).

Mitochondrial Citrate Synthase CS (Porcine Heart) Citrate synthase, a mitochondrial enzyme like MDH, is a homodimeric protein of two 49-kDa subunits. It is commercially available, and its crystal structure is solved at a resolution of 2.7 Å [104]. Spontaneous reactivation after denaturation by urea or GdmCl is possible only at low protein concentrations [87]. Folding of CS can be assisted by GroE in vitro and in *E. coli* [87, 105]. A convenient enzymatic assay exists that can be used to monitor the regaining of activity [106, 107].

CS is temperature-sensitive and starts to unfold above ~40 °C. Because of its low stability, CS is the substrate of choice to measure temperature-induced aggregation and its suppression by molecular chaperones. Thermal aggregation is preceded by the loss of enzymatic activity. Several molecular chaperones have been tested for their influence on the thermal aggregation and inactivation of CS [87, 107–109].

Reduced Carboxymethylated Alpha-lactalbumin RCMLA (Bovine Milk) The disadvantage of all substrates mentioned so far is that once the unfolded protein is added to the chaperone solution, its conformation is no longer defined. As a consequence, these types of substrates are not suited to carry out equilibrium studies, e.g., to determine binding constants. For these purposes, one requires a permanently unfolded polypeptide that does not aggregate. Reduced, carboxymethylated alpha-lactalbumin has been successfully employed in this context [110, 111]. It was also used as a competitive inhibitor for the binding of other nonnative proteins [112]. Its only drawback is that it is not very hydrophobic, and the resulting chaperone complexes are often rather labile.

Alpha-lactalbumin is a small protein (14.2 kDa) from bovine milk and can be purchased from a number of suppliers. Its conformational stability is highly dependent on the presence of the four disulfide bridges. To obtain a permanently unfolded version of lactalbumin, the disulfides first have to be disrupted by DTT in the presence of GdmCl (Protocol 1). This unfolded conformation can be maintained by irreversible alkylation of the eight cysteine residues with iodoacetic acid. Compared with unmodified lactalbumin, this derivative carries eight additional negative charges that increase its solubility but may interfere with the binding to certain chaperones. An alternative form can be obtained by using iodoacetamide in the alkylation step. The resulting derivative carries no additional charges but is prone to aggregation at high concentration.

Protocol 1: Preparation of RCMLA

1. Dissolve 5.6 mg alpha-lactalbumin in 305 µL 200 mM Tris/HCl pH 8.7, 7 M GdmCl, 2 mM EDTA, 20 mM DTT, and incubate for 90 min at room temperature.
2. Add 60 µL of 0.6 M iodoacetic acid in 200 mM Tris/HCl pH 7.5 (check pH!) under dark room conditions and incubate for 10 min.
3. Stop the reaction by adding 100 µL of 0.5 M reduced glutathione in 200 mM Tris/HCl pH 7.5.
4. The derivatized protein is purified via a Sephadex G25 desalting column equilibrated with 200 mM Tris/HCl pH 7.5.

5.6.2 Suppression of Aggregation

The simplest type of activity test for a chaperone determines its capability to prevent the aggregation of a model substrate. An unfolded conformation of the test substrate is first prepared. Then the aggregation of this protein is measured, in both the presence and the absence of the potential chaperone. A number of controls have to be carried out to verify that the chaperone does not aggregate itself and that the buffer in which the chaperone is stored does not change aggregation. The process of aggregation is usually monitored by the increase in light scattering. For detection, a thermostated photometer or fluorescence spectrometer is required. Aggregates can be monitored at wavelengths between 320 nm and 500 nm (no interference from aromatic residues) depending on the size of the aggregates. The scattering intensity increases with decreasing wavelengths. Since there is no linear relationship between the extent of aggregation and the light-scattering signal, we advise against using a percent scale when plotting aggregation data.

Protocol 2, in which the aggregation of CS at 43 °C is measured, can be performed only for chaperones that are stable at this temperature. If this is not the case, chemical denaturants have to be used to destabilize the protein whose aggregation will be monitored. Two different approaches can be applied. In the cases of insulin (Protocol 3) and alpha-lactalbumin (Protocol 4), aggregation can be induced

by the addition of a reducing agent such as DTT. The B chain of reduced insulin will start to aggregate within minutes at room temperature [113]. For lactalbumin, efficient aggregation requires reduction at higher temperatures. Additionally, aggregation can be induced by diluting a concentrated solution of an unfolded test protein, e.g., in GdmCl or urea, into buffer without denaturant. In the absence of chaperones, the polypeptide will aggregate. This process can be enhanced by increasing the temperature.

As a rule of thumb, complete suppression of aggregation requires that the amount of chaperone – or, more precisely, the concentration of protein-binding sites – be at least as high as that of the aggregating polypeptide. Thus, chaperones act stoichiometrically and not catalytically. As some of the assays, especially the ones using insulin and alpha-lactalbumin, require a high concentration of the test protein, the consumption of chaperone can be considerable. Secondly, the interaction between the chaperone and the polypeptide has to be tight (see Figure 5.3, left panel). Otherwise, the irreversible process of aggregation will eventually pull all polypeptide molecules from the chaperone. In this case, a deceleration of the aggregation process may be observed in the presence of the chaperone, while the final amplitude remains unchanged (Figure 5.3, middle panel).

It may be worthwhile to check whether the test protein is indeed associated with the chaperone at the end of the aggregation assay by employing one of the methods described in the following section. If a refolding assay for the test protein is available, one can also examine whether the protein can be recovered from the chaperone complexes by transferring the sample to refolding conditions, e.g., by lowering the temperature (see Protocol 7). Finally, one should note that a positive result from an aggregation assay alone is not sufficient to classify the protein under investigation as a molecular chaperone.

Protocol 2: Thermal Aggregation of Citrate Synthase The major advantage of this assay is that it requires only small amounts of chaperone. However, the chaperone must withstand a temperature of 43 °C for at least 1 h (Figure 5.3). Tris and a number of salts such as KCl have been observed to stabilize CS and should be avoided.

1. Prepare a stock solution of 65 μM CS (monomers) in 50 mM Tris/HCl pH 8, 2 mM EDTA (if an ammonium sulfate suspension is used, the protein has to be extensively dialyzed first).
2. Remove aggregates by centrifugation at 12 000 *g* in a bench-top centrifuge.
3. Assay buffer: 50 mM HEPES/KOH pH 7.5, 150 mM KCl, 10 mM $MgCl_2$ (the buffer must be degassed and filtered through a 0.2-μm membrane before use).
4. Add 2494 μL assay buffer to a 1 × 1 cm fluorescence cuvette equipped with a stirring bar.
5. Incubate the cuvette for >5 min at 43 °C in a thermostated fluorescence spectrometer.
6. To start aggregation, add 6 μL CS solution and follow the increase in light scattering for 60 min (set both excitation and emission to 360 nm; adjust the slits to obtain a good signal/noise ratio).

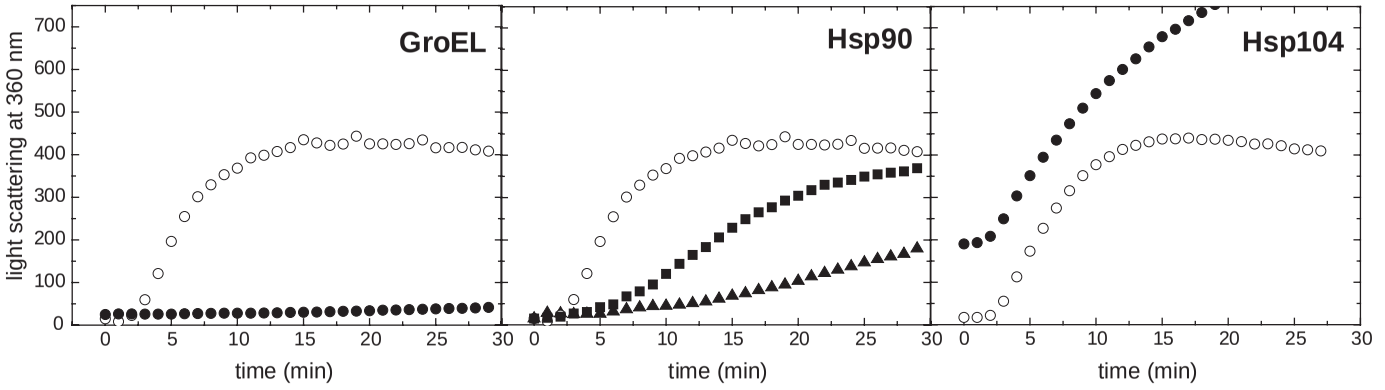

Fig. 5.3. Aggregation assays for three chaperones using citrate synthase as a test substrate. The aggregation of 0.15 μM citrate synthase (○) at 43 °C was followed by light scattering at 360 nm in a fluorescence spectrometer. (Left) In the presence of 0.2 μM GroEL (●), complete suppression of aggregation is observed. (Middle) Unlike GroEL, Hsp90 (0.1 μM ■ and 0.2 μM ▲) decreases the rate but not the extent of aggregation, indicating a transient interaction with CS. (Right) In contrast, 0.2 μM Hsp104 (●) is not able to suppress the aggregation of citrate synthase. In comparison to the reaction in the absence of the chaperone, the extent of aggregation is even increased since Hsp104 is not stable at this temperature.

7. Start a new experiment in which some of the buffer in the sample cuvette is replaced by a stock solution of your chaperone before the addition of CS; use the following chaperone concentrations: 0.1, 0.2, and 0.5 μM (the final concentration of CS in the cuvette is 0.15 μM).
8. To test the influence of the buffer in which the chaperone is stored, carry out a set of control experiments in which the chaperone is replaced by equal volumes of this buffer.
9. If an absorbance photometer is used, concentrations may have to be increased. Set the wavelength to 360 nm.

Protocol 3: Aggregation of Insulin B Chain In the presence of DTT, the three disulfide bridges within the insulin molecule are broken, and the two chains dissociate. While the A chain remains soluble, the B chain will readily start to aggregate [113, 114]. This process can be suppressed by molecular chaperones. A major disadvantage of this assay is that it consumes substantial amounts of chaperone, of which a highly concentrated stock solution is needed. The assay can be performed at different temperatures [69] and salt concentrations, but note that the extent of aggregation is very sensitive to changes in pH.

1. Dissolve 4.06 mg insulin (bovine pancreas) in 1 mL 10 mM sodium phosphate buffer pH 7 (if the protein does not dissolve, add concentrated HCl until the solution is clear, then add 10 M NaOH and adjust the pH to ∼7).
2. Keep the stock solution (∼ 700 μM) on ice.
3. Assay buffer: 50 mM Tris/HCl pH 8, 2 mM EDTA.
4. To a 120-μL UV cuvette, add 110 μL of assay buffer and 10 μL of insulin (the small sample volume minimizes chaperone consumption, but larger cuvettes may be used as well).
5. Incubate the cuvette for >5 min at 25 °C in a thermostated photometer.
6. Start the aggregation by adding 20 μL of 0.35 M DTT in assay buffer.
7. Follow the aggregation by measuring the extinction at 400 nm.
8. Start a new experiment in which some of the buffer in the sample cuvette is replaced by a stock solution of your chaperone before the addition of insulin; use the following chaperone concentrations: 25, 50, and 100 μM (the final concentration of insulin in the cuvette is 50 μM).
9. To test the influence of the buffer in which the chaperone is stored, carry out a set of control experiments in which the chaperone is replaced by equal volumes of this buffer.

Protocol 4: Aggregation of Alpha-lactalbumin The conformational stability of alpha-lactalbumin is highly dependent on the presence of the four disulfide bridges and the bound Ca^{2+}. Thus, the addition of a reducing agent such as DTT in the presence of EDTA causes the protein to unfold and aggregate [114]. This process is quite slow at 25 °C but can be significantly accelerated by raising the temperature. The best results are obtained between 25 °C and 45 °C.

1. Assay buffer: 50 mM sodium phosphate pH 7.0, 0.2 M NaCl, 2 mM EDTA.
2. 300 μM alpha-lactalbumin (bovine) in assay buffer. (Note: Aggregation is significantly inhibited by Tris and HEPES. It is therefore recommended to dialyze the chaperone against the assay buffer.)
3. Add 100 μL buffer and 20 μL alpha-lactalbumin to a 120-μL UV cuvette (the small sample volume minimizes chaperone consumption, but larger cuvettes may be used as well).
4. Incubate the cuvette for >5 min at the chosen temperature (25–45 °C) in a thermostated photometer.
5. Start the reaction with 20 μL of 0.35 M DTT in assay buffer and follow the aggregation by measuring the extinction at 500 nm.
6. Start a new experiment in which some of the buffer in the sample cuvette is replaced by a stock solution of your chaperone before the addition of alpha-lactalbumin; use the following chaperone concentrations: 25, 50, and 100 μM (the final concentration of lactalbumin in the cuvette is 43 μM).
7. To test the influence of the buffer in which the chaperone is stored, carry out a set of control experiments in which the chaperone is replaced by equal volumes of this buffer.

The kinetics of the aggregation reaction depends on the DTT concentration and is considerably faster at higher temperature. At 25 °C, complete aggregation may take several hours.

5.6.3
Complex Formation between Chaperones and Polypeptide Substrates

For the preparation of complexes with a nonnative polypeptide, an unfolded test substrate must be generated first. As mentioned in ''Generation of Nonnative Proteins'' above, it is very important to verify that the chaperone under investigation is compatible with the selected methods of protein denaturation.

Protocol 5: Preparation of Chaperone-Substrate Complexes Using Urea-denatured MDH

1. Remove stabilizing agents such as glycerol or $(NH_4)_2SO_4$ by dialysis or by passage through a desalting column (buffer: 50 mM Tris/HCl pH 7.5, 2 mM DTT); the concentration of MDH monomers after this step should be at least 150 μM (5 mg mL^{-1}).
2. To 3 μL of mMDH (150 μM), add 6 μL of 9 M urea, 50 mM Tris/HCl pH 7.5, 10 mM DTT; allow the protein to unfold for 30 min at 25 °C.
3. Prepare a solution of your chaperone (1 μM) in 198 μL 50 mM Tris/HCl pH 7.5, 10 mM DTT, 50 mM KCl and incubate at 25 °C for 5 min.
4. Add 2 μL of unfolded MDH, mix rapidly, and incubate for 15 min.
5. Spin down the sample in a bench-top centrifuge (12 000 *g*) to remove aggregated MDH.

Protocol 6: Formation of Complexes Between GroEL and Thermally Denatured CS

1. Prepare a stock solution of 65 μM CS (monomers) in 50 mM Tris/HCl pH 8, 2 mM EDTA (if an ammonium sulfate suspension is used, the protein has to be extensively dialyzed first).
2. Remove aggregates by centrifugation at 12 000 *g* in a bench-top centrifuge.
3. Aliquots are prepared, frozen in liquid nitrogen, and stored at −20 °C; once thawed, the aliquots should be used up.
4. Prepare a solution of your chaperone (1 μM) in 197 μL 50 mM HEPES/KOH pH 7.5, 50 mM KCl and incubate at 43 °C for 5 min.
5. Add 3 μL of CS and incubate for additional 30 min.
6. Remove aggregates by centrifugation at 12 000 *g* in a bench-top centrifuge.

Some applications may require concentrations of chaperone-CS complexes higher than 1 μM, as given in the protocol. This can be achieved by increasing the concentration of both CS and chaperone in the mixture. However, there may be a significant loss of CS due to aggregation.

Once the complexes between the polypeptide and the chaperone have been prepared, their composition can be examined by various methods. If binding is strong, analytical size-exclusion chromatography can be used in combination with a UV or fluorescence detection unit. In addition, the substrate polypeptide may be modified to carry a fluorescent label (Figure 5.4). This allows the direct analysis of different components in one peak. Otherwise, the elution profile may be analyzed with SDS-PAGE [115]. If complexes are only transient, as in the case of Hsp104 or Hsp70-ATP, chemical cross-linking with glutaraldehyde in combination with SDS-PAGE can be used. Other methods that have been successfully used to demonstrate physical interaction include immunoprecipitation [66], native PAGE [86, 90], and analytical ultracentrifugation [116].

5.6.4 Identification of Chaperone-binding Sites

The identification of binding sites for chaperones in a given substrate is an important issue in the context of characterizing a molecular chaperone. The experimental approaches that have been developed to address this kind of problem are rather advanced, and thus we will give only a brief outline.

For chaperones known to bind to extended peptide sequences such as the Hsp70 family members, early studies used phage display to analyze the interaction with the chaperone [117, 118]. The analysis of this large dataset of binding and non-binding peptides led to an algorithm for the prediction of BiP-binding sites in the primary sequences of proteins. The predictive power of this program was found to be about 50% for binding sequences as tested by a survey of synthetic peptides [119].

A related approach is to screen for chaperone-binding sites in proteins using sets

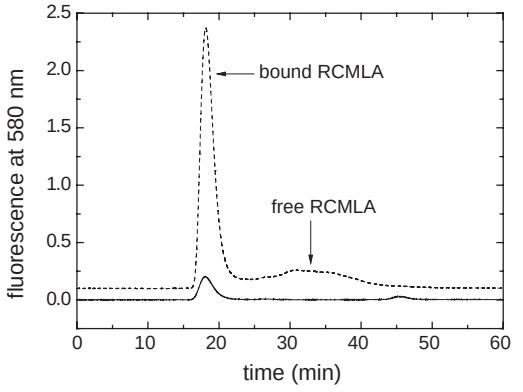

Fig. 5.4. Size-exclusion chromatography of a complex between GroEL and RCMLA (dashed line). Complexes were formed by incubating 3 μM RCMLA (labeled with tetramethylrhodamin) with 2 μM $GroEL_{14}$ for 5 min at 30 °C in 50 mM HEPES/KOH pH 7.5, 150 mM KCl, 10 mM $MgCl_2$. 100 μL of this mixture was applied to a Superdex-200 HR 10/30 column equilibrated in the same buffer. Complexes were detected by following the fluorescence of the labeled substrate. In a control experiment, GroEL alone was injected (solid line). Note that the position of the GroEL peak at 18 min is not significantly shifted upon binding of RCMLA, as the apparent molecular mass increases only marginally from ~800 kDa to ~820 kDa.

of overlapping synthetic peptides that represent the entire primary structure of the respective proteins. The peptides are immobilized on filters. This allows a correlation between sequence and signals. Binding is usually detected by antibodies against the respective chaperone in a Western blot–like manner. This technique has been successfully applied for several chaperones and target proteins [120, 121].

A caveat is that these approaches will provide information on all potential binding sites in a protein. Which of these will actually be used in vivo may depend on the kinetics of folding or on the degree of unfolding under stress conditions, similar to *N*-glycosylation sites in proteins. Moreover, this technique is unable to detect binding sites that are formed by residues distant in sequence but close in space, e.g., in a partially folded intermediate. Thus, its value may be restricted to identifying binding sites for chaperones such as Hsp70, which are known to bind consecutive stretches of amino acids.

Identifying the binding site(s) for nonnative proteins in chaperones is even more challenging. Here, chemical cross-linking of chaperone-substrate complexes and subsequent analysis of the site of interaction by protease digestion and mass spectrometry is the method of choice. Mutational analyses using deletion fragments to identify protein-binding sites should be considered with great caution because they have repeatedly yielded false or contradictory results. However, after a potential binding site has been identified biochemically, site-specific mutagenesis of residues in the respective region may be employed to further corroborate the result.

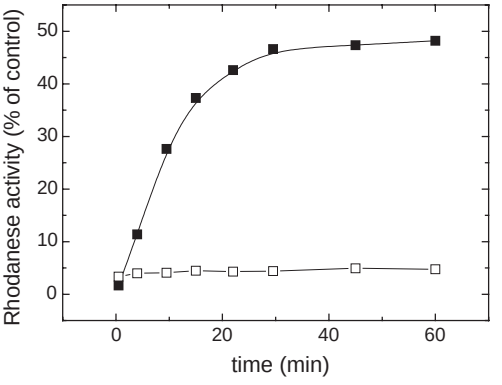

Fig. 5.5. GroE-assisted reactivation of rhodanese. Urea-denatured rhodanese (0.5 μM) was refolded in the presence of 1 μM GroEL/2 μM GroES/2 mM ATP (■) or in the absence of chaperones (□). At the indicated time points, aliquots were withdrawn from the refolding reaction, and the rhodanese activity was determined as described in Protocol 7.

5.6.5
Chaperone-mediated Refolding of Test Proteins

Usually, refolding is carried out by diluting a solution of a nonnative test enzyme, e.g., unfolded in 6 M GdmCl, into a buffer that contains the chaperone under investigation. At various time points, aliquots are withdrawn and the enzyme activity of the test protein is determined (Figure 5.5). In a control experiment, the assay is carried out with the native test enzyme instead of the unfolded protein. Concentrations, pre-incubation times, buffer conditions, etc., should be identical to the ones used in the refolding experiment. If a denaturant was used to prepare the unfolded test protein, an amount of denaturant equivalent to its residual concentration in the refolding assay should be added. This experiment yields the 100% value for the activity of the substrate, as it accounts for any changes in the enzyme activity that are due to its incubation in the refolding solution. In a further control experiment, one has to determine to what extent the enzyme refolds spontaneously. This is simply done by carrying out the refolding experiment in the absence of the chaperone but under otherwise unchanged conditions. Again, it is essential to include all additional factors such as ATP in this control, as they may stabilize or destabilize the enzyme and thus influence spontaneous refolding. Furthermore, an additional control reaction should include substantial amounts of a non-chaperone protein such as BSA, e.g., a fivefold excess over the substrate protein, to account for unspecific protein effects on refolding.

For many test proteins, spontaneous refolding can be quite efficient at certain conditions, e.g., at low protein concentration or temperature or in the presence of stabilizing reagents. To identify potential chaperones, refolding experiments should be carried out under stringent conditions where no refolding occurs in the absence of chaperones. As already mentioned, efficient refolding by the chaperone

may require further components such as ATP, cofactors, or other chaperones. Therefore, some knowledge about the chaperone under investigation has to be acquired beforehand. Once the conditions for successful reactivation of a substrate have been established, parameters such as the type or concentration of cofactors can be varied to obtain further insight into the mechanism of the chaperone.

Protocol 7: GroE-assisted Refolding of Rhodanese

Unfolding of Rhodanese

In this protocol urea is used to denature rhodanese, but 6 M GdmCl will work as well. Depending on your rhodanese stock, the protein solution may have to be concentrated by ultrafiltration prior to unfolding.

1. Remove stabilizing agents such as glycerol or $(NH_4)_2SO_4$ by dialysis or by using a desalting column (buffer: 50 mM Tris/HCl, 2 mM DTT); the concentration of rhodanese after this step should be at least 300 μM (10 mg mL^{-1}).
2. To 3.3 μL of rhodanese (300 μM), add 17 μL of 10 M urea, 50 mM Tris/HCl pH 7.5, 10 mM DTT; allow the protein to unfold for 60 min at 25 °C.

Refolding of Rhodanese by the GroE System

The concentration of rhodanese in the refolding reaction is 0.5 μM. A twofold excess of GroEL and GroES is used (Figure 5.5).

1. Prepare a solution of 1 μM $GroEL_{14}$ and 2 μM $GroES_7$ in 50 mM Tris/HCl pH 7.5, 1 mM DTT, 50 mM KCl, 10 mM $MgCl_2$, 20 mM $Na_2S_2O_3$.
2. Add 2.5 μL of unfolded rhodanese, mix rapidly, and incubate at 25 °C for 5 min.
3. Start reactivation by adding 1 mM ATP (total volume of refolding reaction: ~250 μL).
4. Withdraw aliquots of 24 μL every 4 min and measure rhodanese activity (see next section).

Note that in the refolding assay 20 mM $S_2O_3^{2-}$ is present to stabilize refolded rhodanese. To determine the extent of spontaneous refolding, conduct a control experiment without GroEL.

Enzyme Assay for Rhodanese

The enzyme test is based on a sulfur transfer reaction catalyzed by rhodanese [95]. Sulfur atoms of the substrate thiosulfate are passed onto cyanide anions, generating SCN^-. The reaction is stopped at timed intervals with a solution of iron(III)-nitrate. The concentration of the resulting red complex $[Fe(SCN)_3]$ is determined by measuring the absorbance of the samples at $\lambda = 470$ nm using a standard spectrophotometer.

EDTA is important to complex magnesia ions. This blocks the ATPase activity of residual chaperones. Otherwise, refolding would continue during the activity assay.

Caution: KCN is toxic. Work under a fume hood and wear gloves at all times.

1. Premix: 9% (v/v) formaldehyde.
2. Staining solution: 16% (w/v) $Fe(NO_3)_3$, 1 M HNO_3.
3. Prepare the number of activity tests tubes you will require (one for every time point of the refolding kinetics): 24 µL KH_2PO_4 (1 M), 12 µL EDTA (0.5 M, pH 9), 30 µL $Na_2S_2O_3$ (1 M), 30 µL KCN (1 M), 480 µL H_2O, total volume 576 µL each.
4. For each activity test tube, prepare six disposable cuvettes with 575 µL of premix solution.
5. Incubate test tubes at 25 °C.
6. Start the activity test by adding 24 µL of rhodanese-containing solution from the refolding reaction to the test tube. The final conditions of the activity tests are: 25 °C, 40 mM KH_2PO_4, 10 mM EDTA, 30 mM $S_2O_3^{2-}$, 30 mM CN^-, 20 nM rhodanese (from refolding reaction), total volume = 600 µL.
7. Every 2 min, withdraw 90 µL from the activity test tube and add it to the premix solution in the cuvette.
8. Quench sample with 325 µL staining solution and mix rapidly.
9. Measure the absorbance at 470 nm (the orange color is stable for at least 2 h).
10. Blank: cuvette with premix solution.
11. Draw a straight line by plotting absorbance at 470 nm vs. time.
12. Use slope $dA_{470\,nm}/dt$ to calculate enzymatic activity.

5.6.6 ATPase Activity

Several assay systems have been developed to monitor ATP hydrolysis. The most sensitive technique uses either α-[^{32}P]-ATP or γ-[^{32}P]-ATP. Upon hydrolysis, either radioactive phosphate or ADP is released and can be detected and quantified [122]. Another method uses the dye malachite green to determine the amount of phosphate produced by hydrolysis of ATP [123]. A more elegant approach employs a coupled enzyme system [124]. In the first step, pyruvate kinase regenerates ATP from ADP and phosphoenol pyruvate. This reaction also produces pyruvate, which is reduced in a second step catalyzed by lactate dehydrogenase under the consumption of NADH, a reaction that can be followed at 340 nm in a spectrometer. Detailed information on the experimental design and evaluation of ATPase experiments is provided in Chapter 4 of this volume.

Acknowledgments

We would like to thank V. Grimminger, B. Bösl, and K. Ruth for contributing to this chapter and M. Haslbeck and H. Wegele for critically reading the manuscript. Work in the authors' labs was supported by grants from the DFG to J.B. and S.W. and by grants from the Fonds der Chemischen Industrie to J.B.

6
Physical Methods for Studies of Fiber Formation and Structure

Thomas Scheibel and Louise Serpell

6.1
Introduction

Elucidating protein fiber assembly and analyzing the acquired regular fibrous structures have engaged the interest of scientists from different disciplines for a long time. The complexity of the problem, together with the paucity of interpretable data, has generated a large volume of literature concerned with speculations about possible assembly mechanisms and structural conformations.

Fibrous proteins are essential building blocks of life, providing a scaffold for our cells, both intracellularly and extracellularly. However, despite nearly a century of research of the assembly mechanisms and structures of fibrous protein, we have only recently begun to get insights. In the last 10 years, atomic models for some of the most important fibrous proteins have been proposed. We are increasingly knowledgeable about how fibrous proteins form and how they function (for example, the interaction of actin and myosin to produce muscular movement). Development of methods specific to the study of fibrous proteins has enabled these investigations, since fibrous proteins are generally insoluble and often heterogeneous in length, and therefore methods used for examining the structure of globular proteins cannot be used.

In this chapter, an overview of some commonly used methods to examine the assembly and structure of fibrous proteins is given. However, additional methods can be suitable to analyze fibrous proteins. Among the methods not discussed are solid-state NMR (ssNMR), near-field scanning optical microscopy (NSOM), scanning transmission electron microscopy (STEM), and light microscopy, for all of which reviews can be found elsewhere. Other complementary methods, specific for the particular protein, include cross-linking studies and antibody-binding epitope studies. These are valuable techniques that can help us to interpret structural data and contribute to the understanding of the assembly pathway, but due to space limitations they can not be discussed in this chapter.

Protein Folding Handbook. Part II. Edited by J. Buchner and T. Kiefhaber

ISBN: 3-527-30784-2

6.2
Overview: Protein Fibers Formed in Vivo

6.2.1
Amyloid Fibers

The term "amyloid" describes extracellular, fibrillar protein deposits associated with disease in humans. The deposits accumulate in various tissue types and are defined by their tinctorial and morphological properties [1]. Although the involved proteins are distinct with respect to amino acid sequence and function, the fibrils formed by different amyloidogenic proteins are structured similarly. This observation is remarkable since the soluble native forms of these proteins vary considerably: some proteins are large, some are small, and some are largely α-helical (see chapter 9 in Part I) while some are largely β-sheet (see chapter 10 in Part I). Some are intact in the fibrous form, while others are at least partially degraded. Some are cross-linked with disulfide bonds and some are not. Amyloid fibers are unusually stable and unbranched, range from 6 to 12 nm in diameter, and specifically bind the dye Congo red (CR), showing an apple-green birefringence in polarized light [2, 3]. Amyloid fibers are also rich in β-sheet structure and produce a characteristic "cross-β" X-ray diffraction pattern, consistent with a model in which stacked β-sheets form parallel to the fiber axis with individual β-strands perpendicular to the fiber axis [1, 4]. Diseases characterized by amyloids are referred to as amyloidoses (see chapters 33, 36, 37); these diseases are slow in onset and degenerative and can be found not only in humans but also in most mammals. Some of the amyloidoses are familial, while some are associated with medical treatment (e.g., hemodialysis) or infection (prion diseases), and some are sporadic (e.g., most forms of Alzheimer's disease). Certain diseases, such as the amyloidoses associated with the protein transthyretin, can be found in both sporadic and familial forms. In addition to diseases with extracellular deposits, there are others, notably Parkinson's and Huntington's disease, that appear to involve very similar aggregates, which are intracellular, and these diseases are therefore not included in the strict definition of amyloidoses [5, 6].

Amyloidogenic proteins are not found only in mammals. Studies of *Saccharomyces cerevisiae* have resulted in the discovery of proteins that have properties related to those of mammalian prions [7, 8] (see chapters 34, 35). These yeast prions have been found to convert in vitro into ordered aggregates with all the characteristics of amyloid fibers [9]. Also, amyloidogenic peptides are found in egg envelopes (chorions) of invertebrates. More than 95% of the chorion's dry mass consists of proteins that have remarkable mechanical and chemical properties that protect the oocyte and the developing embryo from a wide range of environmental hazards. About 200 proteins have been detected and classified into two major classes, A and B. Interestingly, within the chorion, protein fibrils can be detected with characteristics of amyloid fibrils. These features include a high proportion of intermolecular β-sheet, positive staining and green birefringence with CR, and detection of long, unbranched fibrils with a diameter of 4–6 nm [10, 11].

6.2.2 Silks

Arthropods produce a great variety of silks that are used in the fabrication of structures outside of the body of the animal. Silks are typically fibrous filaments or threads with diameters ranging from a few hundred nanometers to 50 μm. Insects and spiders use their silks for lifelines, nests, traps, and cocoons. Characteristically, the silk is produced in specialized glands and stored in a fluid state in the lumen of the gland. As the fluid passes through the spinning duct, a rapid transformation to the solid state takes place and the silk becomes water-insoluble [12–15]. However, some of the materials that are called silks are not produced by silk glands in the traditional sense but by extrusions of the guts, e.g., in antlions, lacewings, and many beetles [16].

The major components of traditional silks are fibrous proteins, which in the final insoluble state have a high content of regular secondary structure. Wide variations in composition and structure have been found among different silks. Therefore, the classification of silks is often based on the predominant form of regular secondary structure in the final product as determined by X-ray diffraction studies. Silks are classified as beta silks (which are rich in β-sheets; see Section 6.3.1.3), alpha silks (which resemble the X-ray diffraction pattern obtained from α-keratin and which have a much lower content of Gly and a much higher content of charged residues than any other silk; see Section 6.3.2.4), Gly-rich silks (which form a polyglycine II-like structure), and collagen-like silks (which resemble the X-ray diffraction pattern given by collagen; see Section 6.3.2.1). While silks from the class of Arachnida (spiders) are generally β-silks, in the class of Insecta all four classes of silk can be found, e.g., β-silks in the family of Bombycidae (moths, includes *Bombyx mori*, whose caterpillar is the silkworm), α-silks in the family of Apidae (bees), Gly-rich silks in the family of Blennocampinae (subspecies of sawflies), and collagen-like silks in the family of Nematinae (subspecies of sawflies) [15, 17–20]. In contrast, silks from extrusions of the guts do not form traditional silk filaments or threads; rather, they are hardened fibrous feces.

6.2.3 Collagens

Collagens are a family of highly characteristic fibrous proteins found in all multicellular animals (see chapter 30 in Part I). In combination with elastin (see Section 6.2.8), mucopolysaccharides, and mineral salts, collagens form the connective tissue responsible for the structural integrity of the animal body. The characteristic feature of a typical collagen molecule is its long, stiff, triple-stranded helical structure, in which three collagen polypeptide chains, called α-chains, are wound around each other in a rope-like superhelix (see Section 6.3.2.1). The polypeptide chains in collagens have a distinctive conformation that is intimately related to their structural function [21–25]. All collagen polypeptides have a similar primary structure, in which every third amino acid is Gly (Gly-Xaa-Yaa)$_n$ with a predominance of Pro residues at position Xaa and Yaa. Many of the Pro residues, as well

as occurring Lys residues at the position Yaa, are hydroxylated as a posttranslational modification. The repeating sequence of the collagen chain is the reason for the three-dimensional structure of collagens, which has a slightly twisted, left-handed, threefold helical conformation like that of poly(Pro) II and poly(Gly) II and entirely different from that of an α-helix [25–27]. Collagen polypeptide chains typically have about 1000 residues, but considerable variation occurs in certain types. Polypeptide chains of 1000 residues produce a collagen triple helix 1.4 nm in diameter and 300 nm in length. In vivo the triple helix of collagens is assembled correctly because the polypeptide chains are synthesized with non-helical, globular extensions of just over 100 residues at the amino-terminal and 300 residues at the carboxy-terminal ends. The carboxy-terminal extensions associate specifically and serve to align the three polypeptide chains and to nucleate assembly of the triple helix. Next, collagens aggregate side by side into microfibrils, which are thin in diameter (10–300 nm) and hundreds of micrometers long. The collagen fibrils often aggregate further into larger, cable-like bundles with several micrometers in diameter [21–23, 27].

The main types of collagen found in connective tissue are types I, II, III, V, and XI, with type I being the principal collagen of skin and bone and by far the most common. These are the fibrillar collagens and have the rope-like structure. Types IX and XII are called fibril-associated collagens, as they decorate the surface of collagen fibrils. They are thought to link these fibrils to one another and to other components of the extracellular matrix. Types IV and VII are network-forming collagens. Type IV molecules assemble into a felt-like sheet or meshwork that constitutes a major part of mature basal lamina, while type VII molecules form dimers that assemble into specialized structures called anchoring fibrils, which help to attach the basal lamina of multi-layered epithelia to the underlying connective tissue [21–23]. In some metazoans, collagens of ectodermal origin are used to construct materials outside the confines of the living organism [28, 29]. Gooseberry sawfly silk [30], selachian egg capsules [31], worm cuticle collagens [32, 33], spongin [34], and mussel byssus are a few examples of such exoskeletal collagenous materials. These threads were dubbed "collagenous" on the basis of fiber X-ray diffraction [35, 36], hydroxyproline content [37], amino acid composition [38, 39], and shrinkage temperatures [40]. The primary structure of collagenous proteins found in the mussel byssus threads, however, encodes unprecedented natural block copolymers with three major domain types: a central collagen domain, flanking elastic or stiff domains, and histidine-rich terminal domains. The elastic domains have sequence motifs that strongly resemble those of elastin (see Section 6.2.8), and the stiff domains closely resemble amorphous glycine-rich regions of spider silks (see Section 6.2.2) [41, 42].

6.2.4
Actin, Myosin, and Tropomyosin Filaments

All eukaryotic species contain actin, which is the most abundant protein in many eukaryotic cells. Actin filaments (F actin) can form both stable and labile structures

in cells. Stable actin filaments are a crucial component of the contractile apparatus of muscle cells in so-called myofibrils (see below). Many cell movements, however, depend on labile structures constructed from actin filaments. Actin filaments are about 8 nm wide and consist of a tight helix of uniformly oriented actin molecules also known as globular actin (G actin). Like a microtubule (see Section 6.2.7), an actin filament is a polar structure with two structurally different ends. The so-called minus end is relatively inert and slow growing, while the so-called plus end is faster growing [43, 44]. Some lower eukaryotes, such as yeasts, have only one actin gene encoding a single protein. All higher eukaryotes have several isoforms encoded by a family of actin genes. At least six types of actin are present in mammalian tissue, which fall into three classes depending on their isoelectric point: α actins are found in various types of muscle, whereas β and γ actins are the principal constituents of non-muscle cells. Although there are subtle differences in the properties of different forms of actin, the amino acid sequences have been highly conserved in evolution and all assemble into filaments in vitro. Polymerization of actin in vitro requires ATP as well as both monovalent and divalent cations, such as K^+ and Mg^{2+}. ATP hydrolysis weakens the bonds in the polymer (F actin) and thereby promotes depolymerization [43].

Myofibrils are cylindrical structures 1–2 μm in diameter, which in addition to thin filaments formed by actin contain thick filaments made of muscle isoforms of myosin II. Muscle myosin has two heads with ATPase and motor activity and a long, rod-like tail. A myosin II molecule is composed of two identical heavy chains, each of which is complexed to a pair of light chains. The amino-terminal portion of the heavy chain forms the motor-domain head, while the carboxy-terminal half of the heavy chain forms an extended α-helix. Two heavy chains associate by twisting their α-helical tail domains together into a coiled coil to form a stable dimer that has two heads and a single rod-like tail [45–47]. A major role of the rod-like tail is to allow the molecules to polymerize into bipolar filaments. Myosin II filaments play an important role in muscle contraction, drive membrane furrowing during cell division, and generate tension in stress fibers.

Tropomyosins are a group of proteins that bind to the sides of actin filaments and (together with troponins) regulate the interaction of the filaments with myosin in response to Ca^{2+}. They are parallel, α-helical, coiled-coil dimers. Vertebrates typically express approximately 20 different tropomyosins from alternative splicing from about four tropomyosin genes [48]. Tropomyosins exist as both homodimers and heterodimers held together by a series of salt bridges and hydrophobic interactions. They may also interact through their amino and carboxyl termini in solution (especially in low-ionic-strength buffers). There are two major groups of tropomyosin, the high- and low-molecular-weight tropomyosins. The former type exists primarily in muscle tissues (cardiac, smooth, and skeletal), whereas non-muscle tissues express both high- and low-molecular-weight tropomyosins. Tropomyosins bind cooperatively to actin filaments [49–51], probably because there is end-to-end binding of the tropomyosin molecules, but possibly also because tropomyosin restricts the movement of the filament, causing the filament repeat distance to be made more regular [52]. The binding of tropomyosin to actin is strongly

Mg^{2+}-dependent [49]. High-molecular-weight tropomyosins consist most often of 284 amino acids and bind seven actin monomers, while the low-molecular-weight tropomyosins consist of about 245–250 amino acids and span six actins.

The thick filaments of invertebrate muscles contain, in addition to myosin, the protein paramyosin, a rod-like, coiled-coil molecule similar to myosin [53]. Paramyosin filaments play an important part in certain molluscan and annelid muscles because they allow these muscles to maintain tension for prolonged periods without a large expenditure of energy.

6.2.5 Intermediate Filaments/Nuclear Lamina

Intermediate filaments are tough, durable, 10-nm wide protein fibers found in the cytoplasm of most, but not all, animal cells, particularly in cells that are subject to mechanical stress [54]. Unlike actin and tubulin, which are globular proteins, monomeric intermediate filament proteins are highly elongated, with an amino-terminal head, a carboxy-terminal tail, and a central rod domain. The central rod domain consists of an extended α-helical region containing long tandem repeats of a distinct amino acid sequence motif called heptad repeats. These repeats promote the formation of coiled-coil dimers between two parallel α-helices. Next, two of the coiled-coil dimers associate in an antiparallel manner to form a tetrameric subunit. The antiparallel arrangement of dimers implies that the tetramer and the intermediate filaments formed thereof are non-polarized structures. This distinguishes intermediate filaments from microtubules (see Section 6.2.7) and actin filaments (see Section 6.2.4), which are polarized and whose functions depend on this polarity [55–58].

The cytoplasmic intermediate filaments in vertebrate cells can be grouped into three classes: keratin filaments, vimentin/vimentin-related filaments, and neurofilaments. By far the most diverse family of these proteins is the family of α-keratins, with more than 20 distinct proteins in epithelia and over eight more so-called hard keratins in nails and hair. The α-keratins are evolutionarily distinct from β-keratins found in bird feathers, which have an entirely different structure and will not be further discussed in this context. Based on their amino acid sequence, α-keratins can be subdivided into type I (acidic) and type II (neutral/basic) keratins, which always form heterodimers of type I and type II but never homodimers [59]. Unlike keratins, the class of vimentin and vimentin-related proteins (e.g., desmin, peripherin) can form homopolymers [60]. In contrast to the first two classes of intermediate filaments, the third one, neurofilaments, is found uniquely in nerve cells, wherein they extend along the length of an axon and form its primary cytoskeletal component [61].

The nuclear lamina is a meshwork of intermediate filaments that lines the inside surface of the inner nuclear membrane in eukaryotic cells. In mammalian cells the nuclear lamina is composed of lamins, which are homologous to other intermediate filament proteins but differ from them in several ways. Lamins have a longer central rod domain, contain a nuclear localization signal, and assemble into a

two-dimensional, sheet-like lattice, which is unusually dynamic. This lattice rapidly disassembles at the start of mitosis and reassembles at the end of mitosis [61, 62].

6.2.6 Fibrinogen/Fibrin

Fibrinogen is a soluble blood plasma protein, which during the process of clotting is modified to give a derived product termed fibrin. Fibrinogen is a multifunctional adhesive protein involved in a number of important physiological and pathological processes. Its multifunctional character is connected with its complex multidomain structure. Fibrinogen consists of two identical subunits, each of which is formed by three nonidentical polypeptide chains, Aα, Bβ, and γ, all of which are linked by disulfide bonds and assemble into a highly complex structure [63–65]. Conversion of fibrinogen into fibrin takes place under the influence of the enzyme thrombin. The proteolysis results in spontaneous polymerization of fibrin and formation of an insoluble clot that prevents the loss of blood upon vascular injury. This clot serves as a provisional matrix in subsequent tissue repair. The polymerization of fibrin is a multi-step process. First, two stranded protofibrils are generated, which associate with each other laterally to produce thicker fibrils. The fibrils branch to form the fibrin clot, which is subsequently stabilized by the formation of intermolecular cross-linkages [66]. Fibrinogen is a rather inert protein, but after conversion fibrin interacts with different proteins, such as tissue-type plasminogen activator, fibronectin, and some cell receptors, and participates in different physiologically important processes, including fibrinolysis, inflammation, angiogenesis, and wound healing [67–69].

6.2.7 Microtubules

Microtubules are stiff polymers formed from molecules of tubulin. Microtubules extend throughout the cytoplasm and govern the location of membrane-bounded organelles and other cell components. Particles can use the microtubules as tracks, and motor proteins, such as kinesin and dynein, can move, e.g., organelles along the microtubules [70, 71]. The protein building blocks of microtubules, tubulins, are heterodimers consisting of two closely related and tightly linked globular polypeptides, α-tubulin and β-tubulin. In mammals there are at least six forms of α-tubulin and a similar number of forms of β-tubulin. The different tubulins are very similar and copolymerize into mixed microtubules in vitro, although they can have distinct cellular locations. A microtubule can be regarded as a cylindrical structure with a 25-nm diameter, which is built from 13 linear protofilaments, each composed of alternating α- and β-tubulin subunits and bundled in parallel to form the cylinder. Since the 13 protofilaments are aligned in parallel with the same polarity, the microtubule itself is a polar structure and it is possible to distinguish both ends [71–74]. Microtubules reflect dynamic protein polymers that can polymerize and depolymerize depending on their biological function. Tubulin will polymerize into

microtubules in vitro, as long as Mg^{2+} and GTP are present, by addition of free tubulin to the free end of the microtubule. Hydrolysis of the bound GTP takes place after assembly and weakens the bonds that hold the microtubule together. Without stabilization by cellular factors capping the free ends, microtubules become extremely unstable and disassemble [73, 75].

6.2.8 Elastic Fibers

The proteins elastin, fibrillin, and resilin occur in the highly elastic structures found in vertebrates and insects, which are at least five times more extensible than a rubber band of the same cross-sectional area. Elastin is a highly hydrophobic protein that, like collagen, is unusually rich in Pro and Gly residues, but unlike collagen it is not glycosylated and contains little hydroxyproline and no hydroxylysine. Elastin molecules are secreted into the extracellular space and assemble into elastic fibers close to the plasma membrane. After secretion, the elastin molecules become highly cross-linked between Lys residues to generate an extensive network of fibers and sheets. In its native form, elastin is devoid of regular secondary structure [76–79].

The elastic fibers are not composed solely of elastin, but the elastin core is covered with microfibrils that are composed of several glycoproteins including the large glycoprotein fibrillin [80, 81]. Microfibrils play an important part in the assembly of elastic fibers. They appear before elastin in developing tissues and seem to form a scaffold on which the secreted elastin molecules are deposited. As the elastin is deposited, the microfibrils become displaced to the periphery of the growing fiber [81].

Elastin and resilin are not known to be evolutionarily related, but their functions are similar. Resilin forms the major component in several structures in insects possessing rubber-like properties. Similar to elastin, the polypeptide chains are three-dimensionally cross-linked and are devoid of regular secondary structure. The amino acid composition of resilin resembles that of elastin insofar as the Gly content is high, but otherwise there is little sequence homology between these two proteins [19, 79, 82].

6.2.9 Flagella and Pili

Prokaryotes and archaea use a wide variety of structures to facilitate motility, most of which include fibrillar proteins. The best studied of all prokaryotic motility structures is the bacterial flagellum, which is composed of over 20 different proteins. The bacterial flagellum is a rotary structure driven from a motor at the base and a protein fiber acting as a propeller. The propeller consists of three major substructures: a filament, a hook, and a basal body. The filament is a tubular structure composed of 11 protofilaments about 20 nm in diameter, and the protofilaments are typically built by a single protein called flagellin. Less commonly, the filament

is composed of several different flagellins [83–85]. Strikingly, monomeric flagellin does not polymerize under physiological conditions. The amino- and carboxy-terminal regions of flagellin monomers are known to be intrinsically unfolded, which prevents flagellin from assembling into a nucleus for polymerization [86, 87]. Flagellin assembly is regulated through a combination of transcriptional, translational, and posttranslational regulatory mechanisms too complex to be explained in detail in this chapter. Only the unusual filament growth should be mentioned, since individual flagellin monomers are added to the growing polymer not at the base closest to the cell surface, but at the distal tip furthest from the cell, probably by passing through the hollow interior of the tubule [85, 88].

Motility is also conferred by flagella in the domain archaea, yet these structures and the sequences of the involved proteins bear little similarity to their bacterial counterparts. Rather, archaeal flagella demonstrate sequence similarity to another bacterial motility apparatus named pili. Both types of proteins have extremely hydrophobic amino acids over the first 50 amino acids and, in contrast to bacterial flagellin, are made as preproteins with short, positively charged leader peptides that are cleaved by leader peptidases. In archaea multiple flagellins are found that form a filament with a diameter of approximately 12 nm [89, 90].

Pili are responsible for various types of flagellar-independent motility, such as twitching motility in prokaryotes, and they are formed of pilins (see chapter 29). The outer diameter of a pilus fiber is about 6 nm, and, unlike in bacterial flagellum, there is no large channel in the center of the fiber. Therefore, pili grow by adding monomers at the base closest to the cell surface. The amino terminus of pilin forms α-helices, which compose the core of the pilus fiber. The outside of the pilus fiber is made of β-sheets packed against the core and an extended carboxy-terminal tail [90–92].

6.2.10
Filamentary Structures in Rod-like Viruses

Filamentous phages comprise a family of simple viruses that have only about 10 genes and grow in gram-negative bacteria. Different biological strains have been isolated, all of which have a similar virion structure and life cycle. The most prominent filamentous phage is bacteriophage fd (M13), which infects *E. coli*. The wild-type virion is a flexible rod about 6 nm in diameter and 800–2000 nm in length. Several thousand identical α-helical proteins form a helical array around a single-stranded circular DNA molecule at the core. It is assumed that the protein subunits forming the helical array pre-assemble within the membrane of the host into ribbons with the same inter-subunit interactions as in the virion. A ribbon grows by addition of newly synthesized protein subunits at one end, and at the same time the other end of a ribbon twists out of the membrane and merges into the assembling virion [93–95].

Some proteins of plant viruses, such as the tobacco mosaic virus (TMV), also form self-assembled macromolecules. The virion of TMV is a rigid rod (18×300 nm) consisting of 2130 identical virion coat protein (CP) subunits stacked in a he-

lix around a single strand of plus-sense RNA. Depending upon solution conditions, TMV CP forms three general classes of aggregates, the 4S or A protein composed of a mixture of low-ordered monomers, dimers, and trimers; the 20S disk or helix composed of approximately 38 subunits; and an extended virion-like rod. Under cellular conditions, the 20S helix makes up the predominant CP aggregate [96–99]. In the absence of RNA, the structure within the central hole of the 20S filament is disordered, but upon RNA binding structural ordering occurs, which locks the nucleoprotein complex into a virion-like helix and allows assembly to proceed [100]. Virion elongation occurs in both the 5′ and 3′ directions of the RNA. Assembly in the 5′ direction occurs rapidly and is consistent with the addition of 20S aggregates to the growing nucleoprotein rod. Assembly in the 3′ direction occurs considerably slower and is thought to involve the addition of 4S particles [97, 99].

6.2.11
Protein Fibers Used by Viruses and Bacteriophages to Bind to Their Hosts

Certain viruses and bacteriophages use fibrous proteins to bind to their host receptors. Examples are adenovirus, reovirus, and the T-even bacteriophages, such as bacteriophage T4. The fibers of adenovirus, reovirus, and T4 share common structural features: they are slim and elongated trimers with asymmetric morphologies, and the proteins consist of an amino-terminal part that binds to the viral capsid, a thin shaft, and a globular carboxy-terminal domain that attaches to a cell receptor. Strikingly, the fibers formed of these proteins are resistant to proteases, heat, and, under certain conditions, sodium dodecyl sulfate (SDS) [101]. The assembly of the tail spike from *Salmonella* phage P22 is the most extensively studied model system and has allowed detailed study of in vitro and in vivo folding pathways in light of structural information [102].

6.3
Overview: Fiber Structures

Structural elucidation of fibrous proteins is nontrivial and often involves the use of several structural techniques combined to derive a model structure. Structural studies have often involved X-ray crystallography from single crystals of monomeric or complexed proteins to elucidate the structure of fibrous protein subunits. Electron microscopy with helical image reconstruction and X-ray fiber diffraction have then been used to examine the structure of the fiber, and, where possible, modeling of a crystal structure has been matched with the electron microscopy maps or X-ray diffraction data. Protein fiber structures that have been extensively studied include natural proteins such as actin, tubulin, collagen, intermediate filaments, silk, myosin, and tropomyosin as well as misfolded protein fibers such as amyloid, paired helical filaments, and serpin polymers. In this section, a few selected examples will be discussed.

6.3.1 Study of the Structure of β-sheet-containing Proteins

6.3.1.1 Amyloid

Amyloid fibrils extracted from tissue are extremely difficult to study due to contaminants and the degree of order within the fibrils themselves. For this reason, structural studies of amyloid fibrils have concentrated on examining the structure of amyloid formed in vitro from various peptides with homology to known amyloid-forming proteins. It was clear from the early work of Eanes and Glenner [2] that amyloid fibrils resembled cross-β silk (see Section 6.3.1.3), in that the fiber diffraction pattern gave the cross-β diffraction signals. This means that the diffraction pattern consists of two major diffraction signals at 4.7 Å and around 10 Å, on perpendicular axes, that correspond to the spacing between hydrogen-bonded β-strands and the intersheet distance, respectively. Models of amyloid fibrils have been built using X-ray diffraction data [1, 103–106], solid-state NMR data [107–109], and electron microscopy [110, 111]. Many of these models have a common core structure in which the β-strands run perpendicular to the fiber axis and are hydrogen-bonded along the length of the fiber. Whether the amyloid fibrils are composed of parallel or antiparallel β-sheets may vary depending on the composite protein. X-ray diffraction and FTIR data from various amyloid fibrils have suggested an antiparallel β-sheet arrangement for some amyloid fibrils formed from short peptides [105]. Solid-state NMR data from full-length Aβ peptides appear to be consistent with a parallel arrangement [108]. Alternative models of amyloid fibril core structure involving β-helical structure have been suggested [112, 113]. The mature amyloid fibril is thought to be composed of several protofilaments; evidence for this comes from electron microscopy [111, 114] and atomic force microscopy data [115].

6.3.1.2 Paired Helical Filaments

Paired helical filaments (PHFs) are found deposited in disease and are composed of the microtubule-associated protein Tau [116]. PHFs are found in neurofibrillary tangles (NFT) in Alzheimer's disease brains as well as in a group of neurodegenerative diseases collectively known as the tauopathies. Electron microscopy structural work on PHFs has revealed that the filaments are composed of two strands twisted around one another, giving the characteristic appearance [117]. Straight filaments (SF) have also been isolated and are thought to be composed of the same building blocks. Calculated cross-sectional views showed that C-shaped subunits make up each strand for both PHFs and SFs [117]. More recently, X-ray and electron diffraction from synthetic and isolated PHFs have revealed a cross-β structural arrangement, similar to that shown for amyloid [118], indicating that the core structure of PHFs may share the generic amyloid-like structure.

6.3.1.3 β-Silks

All silk fibroins appear to contain crystalline regions or regions of long-range order, interspersed with short-range-ordered, non-crystalline regions [14]. Silks spun by

different organisms vary in the arrangement, proportions, and length of the crystalline and non-crystalline regions. Generally, β-pleated sheets are packed into tight crystalline arrays with spacer regions of more loosely associated β-sheets, α-helices, and/or β-spirals [14]. X-ray fiber diffraction has been used extensively to examine the structure of silks made by different spiders and insects [14]. The crystalline domains of *Bombyx mori* fibroin silk are composed of repeating glycine-alanine residues and form an antiparallel arrangement of β-pleated strands that run parallel to the fiber axis. For this structural arrangement, a model was proposed by Marsh, Corey, and Pauling [119], in which the intersheet distance is about 5.3 Å, which accommodates the small side chains. A recent refinement of the model [120] showed that the methyl groups of the alanine residues alternately point to either side of the sheet structure along the hydrogen-bonding direction, so that the structure consists of two antipolar, antiparallel β-sheet structures. Major ampullate (dragline) silk from the spider *Nephila clavipes* has been examined by X-ray diffraction and solid-state NMR, and, again, the silk structure is dominated by β-strands aligned parallel to the fiber axis [121]. Tussah silk, which is the silk of the caterpillar of the moth *Antherea mylitta*, also has an antiparallel arrangement of β-strands parallel to the fiber axis and gives an X-ray diffraction pattern similar to that of *Bombyx mori* silk, although some significant differences are observed. These differences are thought to arise from different modes of sheet packing due to the high polyalanine content of Tussah silk [19].

Cross-β silk was identified in the egg stalk of the green lacewing fly, *Chrysopa flava* [122]. The X-ray diffraction pattern was examined in detail and found to arise from an arrangement where the β-strands run orthogonal to the fiber axis and hydrogen bonding extends between the strands forming a β-sheet that runs the length of the fiber. A model was proposed by Geddes et al. [4] in which the β-pleated strand folded back on to itself to form antiparallel β-sheet ribbons. The length of the β-strands was about 25 Å, giving the ribbon a width of 25 Å. Several ribbons then stacked together in the crystallite. This model has been used as the basis of the amyloid core structure (see Section 6.3.1.1).

6.3.1.4 β-Sheet-containing Viral Fibers

Adenovirus fiber shaft, P22 tail spike, and bacteriophage T4 short and long fibers are known to be predominantly β-sheet-structured [101]. The shaft regions of the adenovirus and bacteriophage T4 fibers contain repeating sequences, indicating that they might fold into regular, repeating structures. The adenovirus type-2 fiber shaft has been shown to fold into a novel triple β-spiral. The crystal structure of a four-repeat fragment was solved and showed that each repeat folded into an extended β-strand that runs parallel to the fiber axis [123]. Each β-strand is followed by a sharp β-turn enabled by the positioning of a proline or glycine residue, and the turn is then followed by another β-strand, which runs backward at an angle of about 45° to the fiber shaft axis. This fold results in an elongated molecule with β-strands spiraling around the fiber axis. A model of the fiber shaft suggests a diameter of around 15–22 Å and a length of around 300 Å. This fold is also thought to be included in other viral fiber structures (e.g., reovirus structure).

Several proteins have been shown to fold into a parallel β-helix, including pectate lyase [124] and the bacteriophage P22 tail spike [125]. These have right-handed, single-chain helices that have a bean-shaped cross-section, and the β-strands run perpendicular to the long axis. Left-handed β-helices (e.g., UDP *N*-acetylglucosamine acyltransferase) have a triangular cross-section, as each turn of the helix is made up of three β-strands, connected by short linkers [126]. A triple β-helix fold has been identified in part of the short-tail fiber of bacteriophage T4, gp12. It has a triangular cross-section and is made up of three intertwined chains [127]. The β-strands are again perpendicular to the long axis. This arrangement has also been identified in a region of P22 tail spike, and a similar fold has been found in bacteriophage T4 protein gp5. The arrangement forms the needle used by T4 to puncture host cell membranes [128]. Very recently, the structure of the T4 baseplate-tail complex was determined to 12 Å by cryo-electron microscopy, and this has enabled the known crystal structures to be fitted into the cryo-electron microscopy map to build up a full structure of the T4 tail tube and the arrangement of proteins at the baseplate [129].

6.3.2 α-Helix-containing Protein Fibers

6.3.2.1 Collagen

The structure of the collagen superfamily has been studied for over 50 years. Collagen has a complex supramolecular structure, involving the interaction of different molecules giving different functions. It has a characteristic periodic structure, forming many levels of association [130]. The primary structure consists of a repeating motif, Gly-Xaa-Yaa, interspersed by more variable regions. The secondary structure involves the central domain of collagen α-chain folding into a tight, right-handed helix with an axial residue-to-residue distance determined by the spacing of the Pro residues (Xaa) and hydroxyprolines (Yaa). This arrangement results in a Gly residue row following a slightly left-handed helix winding around the coil, and this is responsible for the packing to form the tertiary structure, a triple helix, where the Glys are buried inside the supercoiled molecules [130]. Depending on the collagen type, the triple helices may be comprised of differing collagen chains or of three identical chains [130]. The triple helix is a long, rod-like molecule around 1.5 nm wide. Recently, the crystal structure of the collagen triple helix formed synthetically from $[(\text{Pro-Pro-Gly})_{10}]_3$ peptide was solved to a resolution of 1.3 Å [25] (Figure 6.1). The triple helix undergoes fibrillogenesis to form supramolecular structures. Non-helical ends that do not contain the Gly-Xaa-Yaa sequence are known as the telopeptides. Many models of the molecular packing have been presented (summarized in Ref. [130]). The most recent model of type I collagen appears to fit data from X-ray diffraction, electron microscopy, and cross-linking studies [130]. The proposed model is a one-dimensional, staggered, left-handed microfibril. The packing allows for interconnections between the microfibrils via the telopeptides [131]. This model was deduced by careful testing of several models to compare calculated and observed X-ray diffraction data [132].

Fig. 6.1. Collagen triple helix model: the crystal structure of $[(\text{Pro-Pro-Gly})_{10}]_3$ (PDB: 1K6F.pdb) [25]. The three chains of the collagen-like peptide are represented as space-filling models and a ribbon model.

6.3.2.2 **Tropomyosin**

Tropomyosin molecules are arranged within the thin filament of muscle bound to actin filaments (see below). The molecules are two-chain, α-helical, coiled-coil proteins around 400 Å in length that link end to end to form continuous strands. The crystal structure of full-length tropomyosin was solved from low-resolution X-ray diffraction data with a contribution from electron microscopy, revealing a pitch of around 140 Å [133, 134].

6.3.2.3 **Intermediate Filaments**

Knowledge of the structural detail of the intermediate filament (IF) is incomplete at present. However, the primary sequence of the central rod domain of the cytoplasmic IF proteins (cytokeratin 18, cytokeratin 8, vimentin, neurofilament L protein, and nuclear laminin), reveals the heptad repeat characteristic of coiled-coil structures [58]. Coiled coils were first identified by X-ray diffraction from oriented α-keratin in hair and quill [135]. A model for the structure of vimentin has been proposed, using crystallographic structure of short fragments of conserved regions of vimentin [136]. The structure reveals the four coiled-coil regions interspersed with linker regions. The dimers assemble to form tetramers, which then associate

into rod-like filaments (about 60 nm long and 16 nm in diameter), known as unit-length filaments (ULFs). Finally, the ULFs anneal longitudinally to form extended filaments [58]. These mature filaments undergo some internal rearrangement that results in the final diameter being 11 nm. The arrangement and association of the dimers has been examined using cross-linking studies as well as analysis of X-ray fiber diffraction patterns and electron micrographs [58]. From these studies it has been proposed that two oppositely oriented, left-handed coiled coils may wind around one another to form a left-handed super helix with a pitch of around 140–180 Å. Cryo-electron microscopy and X-ray diffraction from hard α-keratin have suggested that the IFs have a low density core with a diameter of around 3 nm. It has been suggested that the ULFs may be a circular assembly of tetramers arranged as a hollow cylinder. Upon compaction, when the ULFs anneal into an extended filament, the lateral packing of the dimers alters and four dimers form octameric protofilaments that pack more densely, resulting in a much narrower hollow center [58].

6.3.3 Protein Polymers Consisting of a Mixture of Secondary Structure

6.3.3.1 Tubulin

The structure of microtubules has been studied using cryo-electron microscopy, electron diffraction, and X-ray crystallography. The structure of a bacterial homologue of tubulin called FtsZ has also been solved using X-ray diffraction [137], and synthetic polymers of FtsZ have been studied by electron microscopy and image reconstruction [138]. Tubulin exists as $\alpha\beta$ heterodimers that polymerize into protofilaments that make up the microtubule. The crystal structure of tubulin heterodimers was solved by electron crystallography [139] from two-dimension crys-

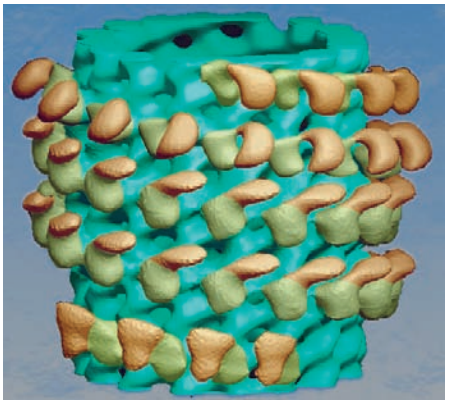

Fig. 6.2. Structure of the microtubule from electron microscopy image reconstruction. The microtubule is shown in green with directly bound kinesin heads in yellow and tethered heads of kinesin dimers in orange. Thanks to Linda A. Amos, LMB, Cambridge for the donation of this figure.

tals of zinc-induced tubulin sheets in ice, and the structural interpretation was supported by the X-ray crystal structure of FtsZ [137]. Each monomer is a compact ellipsoid made up of three domains, an amino terminal nucleotide-binding domain, a smaller second domain, and a helical carboxy terminal domain [140]. The tubulin heterodimers polymerize in a polar fashion to make longitudinal protofilaments that in turn bundle to form the microtubule. The dimer structure was docked into 20-Å maps from cryo-electron microscopy of microtubules, creating a near-atomic model of the microtubule [140]. This model revealed that the carboxy terminal helices form a crest on the outside of the protofilaments and that the long loops define the microtubule lumen [140]. The microtubule is polar, with plus and minus ends, and the structure showed that the exchangeable nucleotide bound to β-tubulin was exposed at the plus end of the microtubule, whereas the proposed catalytic residue in α-tubulin was exposed at the minus end.

Cryo-electron microscopy and helical image reconstruction techniques have proved particularly powerful in examining the arrangement and interaction of motor proteins bound to microtubules [141]. Three-dimensional maps of microtubules decorated with motor domains or kinesin in different nucleotide states could be compared to naturally occurring microtubules (Figure 6.2, see p. 211) [141].

6.3.3.2 Actin and Myosin Filaments

The structure of actin filaments has been extensively studied using X-ray diffraction and electron microscopy [142]. Early work by Hanson and Lowry [143] revealed the basic geometry of F-actin by negative stain electron microscopy. Major advances were made when the crystal structure of actin was solved in complex with DNase I [144]. Since then, a more detailed picture of the structure of the actin filament has been built up [145, 146] by positioning the atomic resolution crystal structure against X-ray diffraction data. The filament is composed of actin monomers arranged in a left-handed helix with 13 monomers per six turns. The pitch is about 59 Å and the separation between monomers is about 27.5 Å. Two strands of actin monomers slowly twist around one another, with a cross-over repeat of 360–380 Å. Tropomyosin chains bind along the actin filament in the grooves between the two actin strands. Each tropomyosin has a troponin complex bound, and the positioning of the troponin marks a 385-Å repeat along the axis of the actin filaments.

X-ray fiber diffraction has been utilized to examine changes in the structure of muscle fibers in order to try to understand the mechanism of muscle contraction [147]. Muscular force is produced when myosin filaments interact with actin filaments by an ATP-dependent process. Time-resolved, low-angle diffraction patterns from muscle in various states can be taken and the positions and intensities of signal can be compared [147] to allow conclusions to be made about the movement of various components of the muscle fibers.

Myosin filaments make up the thick filaments of striated muscle and the structure has also been examined using X-ray diffraction and electron microscopy. Modeling of the arrangement of the myosin heads from X-ray and electron microscopy data have been performed, but the arrangement of the heads has been inconclu-

sive. Four arrangements of the heads are possible, whereby the heads may be parallel or antiparallel. In each case the two heads may lie on the same helical track in a compact arrangement or on neighboring tracks in a splayed arrangement [148]. Recent work on electron microscopy data from filaments of the spider *Brachypelma smithi* (tarantula) [149] tested the four possible arrangements by fitting the crystal structure of myosin heads [150] into the map generated from electron microscopy of negatively stained thick filaments. A good fit was obtained when the myosin heads were arranged antiparallel and packed on the same helical ridge.

6.4 Methods to Study Fiber Assembly

6.4.1 Circular Dichroism Measurements for Monitoring Structural Changes Upon Fiber Assembly

6.4.1.1 Theory of CD

Circular dichroism (CD) is a phenomenon that gives information about the unequal absorption of left- and right-handed circularly polarized light by optically active molecules in solution [151–154] (see chapter 2 in Part I). CD signals are observed in the same spectral regions as the absorption bands of a particular compound, if the respective chromophores or the molecular environment of the compound are asymmetric. CD signals of proteins occur mainly in two spectral regions. The far-UV or amide region (170–250 nm) is dominated by contributions of the peptide bonds, whereas CD signals in the near-UV region (250–320 nm) originate from aromatic amino acids. In addition, disulfide bonds give rise to minor CD signals around 250 nm. The two main spectral regions give different kinds of information about protein structure.

CD signals in the amide region contain information about the peptide bonds and the secondary structure of a protein and are frequently employed to monitor changes in secondary structure in the course of structural transitions [155–157]. Since many fiber-forming proteins undergo certain conformational changes upon fiber assembly (e.g., from an intrinsically unfolded state to a β-sheet-rich fiber as seen in some amyloid-forming proteins; see Figure 6.3), far-UV CD measurements can be used to monitor the kinetics of fiber assembly.

CD signals in the near-UV region are observed when aromatic side chains are immobilized in a folded protein and thus transferred to an asymmetric environment. Since Tyr and Phe residues yield in very small near-UV CD signals, only Trp residues lead to utilizable near-UV CD spectra. The CD signal of aromatic residues is very small in the absence of ordered structure (e.g., in short peptides) and therefore serves as a good tool for monitoring fiber assembly of peptides (in case Trp residues are present). The magnitude as well as the wavelengths of the aromatic CD signals cannot be predicted, since they depend on the structural and electronic environment of the immobilized chromophores. Therefore, the individ-

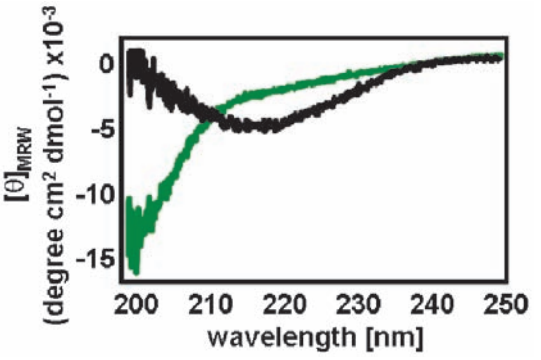

Fig. 6.3. Far-UV CD spectra of the yeast prion protein Sup35p-NM [9]. The green line represents the spectrum of soluble protein that depicts a random coil conformation. The black line represents the spectrum of protein after fiber assembly, which reflects a β-sheet-rich conformation.

ual peaks in the complex near-UV CD spectrum of a protein usually cannot be assigned to transitions in the vicinity of specific amino acid side chains. However, the near-UV CD spectrum represents a highly sensitive criterion for the structural state of a protein. It can thus be used as a fingerprint for either conformational state, the soluble and the fibrous one [156, 157].

6.4.1.2 Experimental Guide to Measure CD Spectra and Structural Transition Kinetics

Preferably only fused quartz cuvettes that display high transparency below 200 nm and are not birefringent should be used. Their quality can be examined by recording the CD of the thoroughly cleaned empty cuvettes, which should coincide with the instruments' baseline in the absence of the cell. Deviations occur if the cell is birefringent or, more likely, if traces of impurities, such as residual proteins, cover the glass surface. The contribution of buffers and salts to the total absorbance of the sample should be as small as possible. This poses severe restrictions on the choice of solvents for CD measurements, particularly in the far-UV region. Therefore, absorbance values for salts and buffers have to be determined in the far-UV region prior to the measurement. Common denaturants such as urea and guanidinium chloride absorb strongly in the far-UV region, which restricts their use to wavelengths above 210 nm. Only highly purified salts and denaturants should be used to avoid interference from absorbing contaminants. Oxygen absorbs light below 200 nm, which makes it necessary to degas solvents for measurements in this region prior to the CD measurement. The cell compartment and the optics of the instrument should be purged with nitrogen [152, 156].

The following considerations are important for an optimal choice of protein concentration: path length and solvent condition. A good signal-to-noise ratio is achieved when the absorbance is around 1.0, but in general it should stay below 2.0. The magnitude of the CD depends on the protein concentration, and therefore

its contribution to the total optical density of the sample should be as high as possible. This implies that the absorbance of the solvent should be as small as possible. Absorbance spectra of the samples prior to the CD experiment should be recorded to determine the protein concentration necessary for the calculation of the molar CD and to select the optimal conditions for the CD measurement. Most buffers are transparent in the near-UV region, and path lengths of 1 cm or more can be selected in this spectral region. For measurements in the far-UV region, short path lengths (0.2–0.01 cm) and increased protein concentrations should be employed to minimize the contributions of the solvent to the total absorbance. As a rule, 0.1-cm cells can be used for the spectral region down to 200 nm. For measurements extending below 200 nm, 0.01-cm cells are advisable. Solutions to be employed for CD measurements should be filtered or centrifuged to remove dust or other solid suspended particles. The presence of light scattering in CD measurements leads to artifacts that result in anomalous, red-shifted spectra. Since light scattering increases during assembly of protein fibers, this point has to be taken into consideration before evaluating the received data. When protein samples are exposed to UV light around 220 nm for an extended time, as is frequently the case when measuring far-UV CD spectra or conformational transition kinetics, photochemical damage can occur. It is advisable to examine some functional or structural properties of the protein under investigation after long-term CD measurements [152, 155, 156].

6.4.2 Intrinsic Fluorescence Measurements to Analyze Structural Changes

6.4.2.1 Theory of Protein Fluorescence

Fluorescence emission is observed when, after excitation, an electron returns from the first excited state back to the ground state (see chapter 2 in Part I). As the lifetime of the excited state is long, a broad range of interactions or perturbations can influence this state and thereby the emission spectrum. Fluorescence is thus an excellent probe to investigate conformational changes of proteins and fiber assembly [158–162].

The fluorescence of proteins originates from Phe, Tyr, and Trp residues, which show the following absorbance and fluorescence properties in water at neutral pH: Trp $\lambda_{max}(abs) = 280$ nm, $\varepsilon_{max}(abs) = 5600\ M^{-1}cm^{-1}$, $\lambda_{max}(fluor) = 355$ nm; Tyr $\lambda_{max}(abs) = 275$ nm, $\varepsilon_{max}(abs) = 1400\ M^{-1}cm^{-1}$, $\lambda_{max}(fluor) = 304$ nm; Phe $\lambda_{max}(abs) = 258$ nm, $\varepsilon_{max}(abs) = 200\ M^{-1}cm^{-1}$, $\lambda_{max}(fluor) = 282$ nm. In proteins that contain all three aromatic amino acids, fluorescence is usually dominated by the contribution of the Trp residues because both their absorbance at the wavelength of excitation and their quantum yield of emission are considerably higher than the respective values for Tyr and Phe residues. Phe fluorescence is typically not observed in native proteins due to its low intensity. The other factor in fluorescence is energy transfer between residues. Therefore, Phe fluorescence is also not observed because its emission is efficiently quenched by energy transfer to the other two aromatic amino acids. In proteins that contain both Tyr and Trp resi-

dues, fluorescence of Tyr is barely detectable due to the strong emission of Trp, due to wavelength shifts of Trp emission towards the wavelength of Tyr emission, and due to non-radiative energy transfer from Tyr to Trp residues in compactly folded proteins.

Changes in protein conformation very often lead to large changes in fluorescence emission, since fluorescence of aromatic amino acids depends on their environmental conditions. In Trp-containing proteins, both shifts in emission wavelength and changes in intensity can generally be observed upon conformational changes. In hydrophobic environments, such as in the interior of a folded protein or protein fibers, Trp emission occurs at lower wavelengths than in aqueous ones. The fluorescence of Trp residues can be investigated selectively by excitation at wavelengths greater than 295 nm. Due to the red shift and the increased intensity of the absorbance spectrum of Trp residues, when compared with that of Tyr residues, protein absorbance above 295 nm originates almost exclusively from Trp residues. Unlike absorbance, the changes in fluorescence upon folding can be very large, which makes intrinsic Trp fluorescence useful as a sensitive probe for conformational changes of proteins upon fiber assembly and in analyzing the kinetics thereof.

The fluorescence maximum of Tyr residues remains around 303 nm irrespective of its molecular environment. Therefore, conformational changes of proteins are accompanied by changes in the Tyr emission intensity, but not in the wavelength of emission, which makes Tyr fluorescence a less sensitive tool for studying conformational changes in comparison to Trp fluorescence [159, 160, 163, 164].

6.4.2.2 **Experimental Guide to Measure Trp Fluorescence**

Emission is usually observed at a right angle to the excitation beam. Therefore, fluorescence cuvettes are manufactured with polished surfaces on all four sides. Quartz cells are required for work in the UV region. Fluorescence is an extremely sensitive technique, so it is mandatory to avoid contamination of cuvettes and glassware with fluorescent substances. Deionized and quartz-distilled water should be used, and plastic containers that may leach out fluorescent additives should be avoided. Also, laboratory detergents usually contain strongly fluorescing substances. Fluorometer cells should be cleaned with 50% nitric acid. If detergents are used for cleansing, extensive rinsing with distilled water is required.

Any solvent can be used for fluorescent measurements, provided that it does not absorb in the spectral regions of the excitation and emission of the fluorophore to be examined, which implies that the buffers or solvent additives should not absorb or fluoresce at wavelengths greater than 250 nm. Because of the high sensitivity of fluorescence measurements, impurities and dust have to be avoided entirely. A single dust particle moving slowly through the light beam can cause severe distortions of the signal due to light scattering. It is helpful to stir the sample solution continuously during the fluorescence measurement, using tiny magnetic stirring bars placed at the bottom of the cuvette. However, in the case of fiber assembly kinetics, extreme care has to be taken that stirring does not influence the assembly/aggregation process. Magnetic stirrers that fit underneath the cuvette in the sample

compartment of the instrument and cuvettes with specially designed bottoms for magnetic bars are commercially available.

Protein emission spectra are broad and without detectable fine structure. Changes upon structural transitions frequently involve the entire fluorescence spectrum. Therefore, a variety of wavelengths and wide emission slits can be used to follow conformational changes of proteins. The fluorescence intensity generally decreases with increasing temperature. This decrease is substantial, with Tyr emission decreasing $\geq 1\%$ per degree increase in temperature and an even more pronounced temperature dependence of Trp fluorescence. In contrast, there is no linear relationship between fluorophore concentration and emission intensity. The actual form of the concentration dependence varies with the optical geometry of the fluorometer and the cell. The nonlinearity is caused by inner filter optical effects. Between the entrance window of the cells and the volume element of the sample, from which fluorescence emission is collected, the exciting light is attenuated by absorbance of the protein and the solvent. In strongly absorbing samples (i.e., at high protein concentrations), the emission intensity is actually decreased, as almost the entire incident light is absorbed before it can reach the center of the cuvette [158, 159, 161]. Since growing fibers are large enough to scatter light, light scattering as measured in the spectrofluorometer can be used as an analytic tool to investigate fiber assembly kinetics (see Section 6.4.5).

6.4.3 Covalent Fluorescent Labeling to Determine Structural Changes of Proteins with Environmentally Sensitive Fluorophores

6.4.3.1 Theory on Environmental Sensitivity of Fluorophores

Fluorescence spectra and fluorescence quantum yields are generally more dependent on the environment than are absorption spectra and extinction coefficients. For example, coupling a single fluorescein label to a protein reduces its quantum yield by approximately 60%, but decreases its extinction coefficient by only approximately 10%. Interactions between two adjacent fluorophores or between a fluorophore and other species in the surrounding environment can produce environment-sensitive fluorescence. The most common environmental influences on fluorescence properties are fluorophore-fluorophore interactions, solvent polarity, proximity and concentrations of quenching species, and pH of the aqueous medium. Environmental influences on fluorescence by quenching are the result of a bimolecular process that reduces the fluorescence quantum yield without changing the fluorescence emission spectrum. Fluorescence resonance energy transfer (FRET) is a strongly distance-dependent, excited-state interaction in which emission of one fluorophore is coupled to the excitation of another. Some excited fluorophores interact to form excimers, which are excited-state dimers that exhibit altered emission spectra [159, 165].

Several chemical groups in side chains of amino acids can be used to covalently cross-link fluorophores. Among the most important are amine and thiol groups. Amine-reactive groups are widely used to prepare protein and peptide bioconju-

gates for immunochemistry, fluorescence in situ hybridization, cell tracing, receptor labeling, and fluorescent analogue cytochemistry. In contrast, thiol-reactive dyes are principally used to prepare fluorescent proteins and peptides for probing biological structure, function, and interactions. Since the thiol functional group can be labeled with high selectivity, thiol modification is often employed to estimate both inter- and intramolecular distances using FRET. In proteins, thiol groups (also called mercaptans or sulfhydryls) are present in Cys residues. The thiol-reactive functional groups are primarily alkylating reagents including iodoacetamides, maleimides, benzylic halides, and bromomethyl ketones. Among the dyes that are particularly sensitive to environmental and conformational changes are benzoxadiazole, naphthalene, and pyrene derivatives [166]. When protein conjugates of these dyes are denatured or undergo a change in conformation, a decrease in fluorescence intensity and a shift in emission to longer wavelengths are often observed. The use of covalently linked fluorophores recently allowed the investigation of the degradation, aggregation, and fiber assembly kinetics of Aβ peptides and of the amyloid-forming NM-region of the yeast prion protein Sup35 [167–169]. These reports indicate the power of covalently attached fluorophores in determining fiber assembly mechanisms.

In addition to the broadly applicable dyes discussed above, some fluorophores are specifically crafted to label actin (e.g., phallotoxins) or tubulin, but these fluorophores are not further discussed in the context of this chapter [166].

6.4.3.2 Experimental Guide to Labeling Proteins With Fluorophores

We will focus in this section on binding of reagents that can be coupled to thiol groups on proteins or peptides to give thioether-coupled products. Most of the commercially available fluorophores react rapidly at near-neutral pH and usually can be coupled to thiol groups selectively in the presence of amine groups. Haloalkyl reagents (primarily iodoacetamides) are among the most frequently used reagents for thiol modification. In most proteins, the site of reaction is at Cys residues that either are intrinsically present or result from reduction of cystines. In addition, Met residues can sometimes react with haloalkyl reagents. Maleimides are similar to iodoacetamides in their application as reagents for thiol modification. However, they are more thiol-selective than iodoacetamides, since they do not react with His or Met residues.

For labeling in general, the protein should be dissolved in a suitable buffer at 50–100 μM at pH 8.0–8.5 (10–100 mM tris-(hydroxymethyl)-aminomethane [Tris] or *N*-(2-hydroxyethyl)-piperazine-*N*′-2-ethansulfonic acid [HEPES]) at room temperature. In this pH range, the protein thiol groups are sufficiently nucleophilic that they react almost exclusively with the reagent in the presence of the more numerous protein amines, which are protonated and relatively unreactive. Reduction of disulfide bonds in the protein is best carried out at this stage. A 10-fold molar excess of a reducing agent, such as 1,4-dithiothreit (DTT) or tris-(2-carboxyethyl) phosphine (TCEP), is usually sufficient. If DTT is used, then dialysis is required to remove the excess DTT prior to introducing the reactive dye. It is not necessary to remove excess TCEP during conjugation with iodoacetamides, haloalkyl deriva-

tives, or maleimides. It is advised to carry out thiol modifications in an oxygen-free environment, because thiols can be oxidized to disulfides, especially when the protein has been treated with DTT prior to thiol modification. A 10- to 20-mM stock solution of the reactive dye in a suitable solvent should be prepared immediately prior to use, and all stock solutions have to be protected from light as much as possible. Sufficient protein-modification reagent is added to give approximately 10–20 moles of reagent for each mole of protein. The reaction should proceed for 2 h at room temperature or overnight at 4 °C. For haloalkyl reactive dyes and to a lesser extent maleimides, it is essential to protect the reaction mixture from light as much as possible. Upon completion of the reaction with the protein, an excess of glutathione, mercaptoethanol, or other soluble low-molecular-weight thiols can be added to consume excess thiol-reactive reagent. The conjugate should be separated on a gel-filtration column, such as a Sephadex G-25 column or equivalent matrix, or by extensive dialysis to remove non-protein-bound dye. It is important to calculate the degree of labeling by determining both protein concentration and concentration of label (through the fluorophore-specific absorption) (for an overview, see Ref. [170]).

After successfully labeling the protein, the fluorescence emission of the dye can be monitored upon fiber assembly. In case the reagent was linked at a site that changes its conformation upon fiber assembly, kinetics thereof can be monitored. Commonly used dyes for such investigations are 6-acryloyl-2-dimethylaminonaphthalene (acrylodan) and *N*,*N*′-dimethyl-*N*-(iodoacetyl)-*N*′-(7-nitrobenz-2-oxa-1,3-diazol-4-yl) ethylene diamine (IANBD amide).

6.4.4 1-Anilino-8-Naphthalensulfonate (ANS) Binding to Investigate Fiber Assembly

6.4.4.1 Theory on Using ANS Fluorescence for Detecting Conformational Changes in Proteins

Fluorescent dyes can be used to investigate conformational changes of proteins without the necessity of conjugation. Some substances, such as the *N*-benzyl derivatives of 3-chloro-6-methoxy-9 aminoacridine and amino naphthalene sulfonic acids, do not fluoresce in aqueous solution but are highly fluorescent when adsorbed onto proteins, with the intensity of fluorescence depending on the structural state of the protein [171, 172]. Such fluorescent dyes exist in a soluble nonplanar form, in which the radiative transition is forbidden. The adsorbed dye, on the other hand, exists in a planar configuration, in which the transition is allowed [173]. 1-Anilino-8-naphthalensulfonate (ANS) is the most commonly used fluorescent dye for analyzing conformational changes of proteins. ANS is brilliantly fluorescent in solvents such as isopropanol, but it shows practically no fluorescence in water. ANS can bind to nonpolar (hydrophobic) sites in proteins through its anilinonaphthalene group and therefore reflects an excellent tool to investigate the unfolding of a protein, in which usually tightly packed hydrophobic patches become surface-exposed. However, ANS binding to proteins also depends on proteins' cationic charge and solution pH, since the ANS sulfonate group is also involved in the

ANS-protein interaction [174, 175]. Importantly, the dependence of ANS binding on electrostatic interaction between the sulfonate group and protein cationic groups does not require preexisting hydrophobic sites on or in the protein to start the binding reaction. Moreover, ANS fluorescence is quenched by water, so fluorescence is profoundly affected if a change in protein hydration or ANS accessibility to water occurs during binding [176]. Therefore, ANS can be used not only to monitor protein unfolding but also to analyze structural changes upon fiber assembly.

6.4.4.2 Experimental Guide to Using ANS for Monitoring Protein Fiber Assembly

ANS has been used to study the partially folded states of globular proteins as well as the binding pockets of a number of carrier proteins and enzymes. ANS has also been used to characterize fibrillar forms of proteins, such as fibronectin, islet amyloid polypeptide, or infectious isoforms of the prion protein PrP [177–180]. After binding to fibers, ANS can show an increased fluorescence and a blue shift of its fluorescence maxima. Protein concentrations should be in the range of 0.5–20 μM and ANS should be added in a 10- to 100-fold excess. The concentration of ANS can be determined by using a molar extinction coefficient of 6.8×10^3 M^{-1} cm^{-1} at 370 nm in methanol [181]. In a 1-cm cell the fluorescence inner-filter effect (see Section 6.4.2.2) becomes significant at ~30 μM ANS. Therefore, correction factors have to be used for the fluorescence of ANS when its total concentration exceeds 10 μM. The magnitude of the inner-filter effect must be experimentally determined for each instrument and whenever the instrumental configuration is altered. The magnitude of the correction depends on the wavelength range and the path length, but not on slit-width or sample turbidity for most of the instruments [182].

To determine whether ANS binds to the fibrous protein, but not to the soluble counterpart, fluorescence emission spectra should be recorded from 400–650 nm with an excitation wavelength of 380 nm. After measuring ANS fluorescence spectra before and after fiber assembly, it can be determined whether ANS serves as a tool for investigating fiber assembly of the chosen protein. Extreme care has to be taken in determining whether ANS fluorescence changes are based solely on fiber formation or whether ANS is also able to bind non-fibrous assembly intermediates. If ANS binding is specific to the fibrous form of the protein, the wavelength with maximal fluorescence differences before and after assembly can be used to monitor fiber assembly kinetics.

6.4.5 Light Scattering to Monitor Particle Growth

Hydrodynamic studies can be carried out to obtain qualitative descriptions of the shape and dimensions of macromolecules and to gain precise information on molecular geometry [183] (see chapter 19 in Part I). The interpretation of hydrodynamic measurements is always based on an assumption that the real molecule must be presented by a particle of simpler shape, characterized by a small number of geometric parameters that can be determined experimentally. As a result, the choice of an inadequate model may result in incorrect interpretation.

6.4.5.1 Theory of Classical Light Scattering

Classical light scattering is an absolute method for the determination of the molar mass of intact macromolecules, and it is particularly suited for studying large macromolecular assemblies, up to a maximum of 50×10^6 M_r. Beyond this maximum, the theory of classical light scattering, known as the ''Rayleigh-Gans-Debye'' approximation, is not valuable. Classical light scattering is the total, or time-integrated, intensity of light scattered by a macromolecular solution compared with the incident intensity for a range of concentrations and/or angles. The intensity of light scattered by a protein solution is measured as a function of angle with a light-scattering photometer. If the macromolecule solution is heterogeneous, as it is usually the case for fiber assembly reactions, M_r will be a weight-average molar mass M_w, which makes it difficult to determine precise fiber assembly kinetics [184, 185]. However, in combination with field-flow fractionation (FFF) (see Section 6.4.6), classical light scattering serves as a powerful tool to investigate the growth of protein fibers. The combination of classical light scattering with FFF is realized by using multi-angle laser light-scattering photometers (MALS). In addition, it is necessary to have a concentration detector, which is usually a highly sensitive differential refractometer equipped with a flow cell. Taken together, FFF-MALS is most valuable for the analysis of heterogeneous and polydispersed protein mixtures (see Section 6.4.6) [186–188].

6.4.5.2 Theory of Dynamic Light Scattering

The principle of dynamic light scattering (DLS) experiments is based on the high intensity, monochromaticity, collimation, and coherence of laser light. The primary parameter that comes from DLS measurements is the translational diffusion coefficient D. In DLS measurements, laser light is directed into a thermostated protein solution, and the intensity is recorded at either a single angle (90°) or multiple angles using a photomultiplier/photodetector. The intensities recorded will fluctuate with time, caused by Brownian diffusive motions of the macromolecules. This movement causes a ''Doppler'' type of wavelength broadening of the otherwise monochromatic light incident on the protein molecules. Interference with light at these wavelengths causes a fluctuation in intensity, which depends on the mobility of the protein molecules. An autocorrelator evaluates this fluctuation by a normalized intensity autocorrelation function as a function of delay time. The decay of the correlation, averaged over longer time intervals, can then be used to obtain the value of D [185]. To obtain molar mass information from the value of D, a calibration of log D versus log M_r is produced, based on globular protein standards. The logarithmic plot of the normalized autocorrelation decay is a straight line for homodispersed solutions, but will tend to curve for solutions with assembling protein fibers. The spread of diffusion coefficients is indicated by a parameter known as the polydispersity factor, which can be evaluated by computer programs. DLS is particularly valuable for the investigation of changes in macromolecular systems, when the time-scale of changes is minutes or hours and not seconds or shorter, which makes it valuable for the investigation of fiber assembly [184, 189–192].

6.4.5.3 Experimental Guide to Analyzing Fiber Assembly Using DLS

Solutions have to be as free as possible from dust and supramolecular aggregates. This requirement is met by filtering all solutions with filters of appropriate size (0.1–0.45 μm). An optimal protein concentration is 2 mg mL^{-1} for a 30-kDa protein, with proportionally lower concentrations for larger proteins. The diffusion coefficient is a sensitive function of temperature and the viscosity of the solvent in DLS measurements. Therefore, measurement and calibration have to be made at the same temperature and solvent viscosity conditions. The diffusion coefficient measured at a single concentration is an apparent one (D_{app}) because of non-ideality effects (finite volume and charge). These effects become vanishingly small as the concentration approaches zero. Importantly, for non-globular proteins (such as growing fibers) a multi-angle instrument has to be used [185].

6.4.6 Field-flow Fractionation to Monitor Particle Growth

6.4.6.1 Theory of FFF

Field-flow fractionation (FFF) is a one-phase chromatography in which high-resolution separation is achieved within a very thin flow against which a perpendicular force field is applied. This technique will be described in more detail, but it has to be mentioned that other types of fields are also used. In the cross-field technique, the flow and sample are confined within a channel consisting of two plates that are separated by a spacer foil with a typical thickness of 100–500 μm. The upper channel plate is impermeable, while the bottom channel plate is permeable and is made of a porous frit. An ultrafiltration membrane covers the bottom plate to prevent the sample from penetrating the channel. Within the flow channel, a parabolic flow profile is created due to the laminar flow of the liquid: the stream moves slower closer to the boundary edges than it does at the center of the channel flow. When the perpendicular force field is applied to the flowing, laminar stream, the analytes are driven towards the boundary layer of the channel, the so-called accumulation wall. Diffusion associated with Brownian motion in turn creates a counteracting motion. Smaller particles, which have higher diffusion rates, tend to reach an equilibrium position farther away from the accumulation wall. Thus, the velocity gradient flowing inside the channel separates different sizes of particles. Smaller particles move much more rapidly than larger particles due to their higher diffusion coefficients, which results in smaller particles eluting before larger ones. This is exactly the opposite of a size-exclusion chromatography separation, in which large molecules elute first.

With FFF separation there is no column media to interact with the samples. Even for very high-molar-mass polymers, such as protein fibers, no shearing forces are applied. The entire separation is gentle, rapid, and non-destructive, without a stationary phase that may interact, degrade, or alter the sample [193–196]. The knowledge of the actual molecular shape is of great importance for analyzing proteins using FFF. Regular and simple geometrical shapes with well-defined bound-

ary surfaces are formed by just a few macromolecules. In contrast, most dissolved macromolecules, especially protein fibers, have to be described in terms of an asymmetrical, expanded and inhomogeneous coil. Considering the complex nature of protein fiber conformations, two parameters are important: the root-mean-square radius and the hydrodynamic radius of the macromolecule. Although a theory predicts the hydrodynamic size of eluting species as a function of elution time, absolute determination of size without reference to standards, assumptions about the conformation of the particles, etc., can be obtained only by combination of FFF with multi-angle light-scattering (MALS) detectors (see Section 6.4.3) [186–188]. FFF in combination with MALS allows separation of protein fibers of different sizes and therefore serves as a tool to monitor assembly and elongation of protein fibers.

6.4.6.2 Experimental Guide to Using FFF for Monitoring Fiber Assembly

FFF reflects a unique tool for analyzing fiber assembly, since it is independent of sample impurities and sample composition. The amount of sample injected can vary widely (0.5–500 μg) because sample size has a negligible effect on the separation efficiency, as long as it is sufficiently large to yield a good detector response and sufficiently small to avoid overloading (a few micrograms is usually a suitable amount for injection). Unlike for other techniques described in this chapter, no general experimental guidelines can be provided, since the flexible operation of FFF has to be adapted for specific needs. For the two most important parameters, cross-flow and channel flow, the optimum flow rates have to be adjusted specifically for each protein investigated. At fixed flow rates, retention time significantly increases with increasing molar mass, accompanied by a growth in bandwidth. At low flow rates, separation power is sacrificed unnecessarily and rather narrow peaks are obtained. At high flow rates, detectability decreases due to increasing dilution [196–198].

6.4.7 Fiber Growth-rate Analysis Using Surface Plasmon Resonance

6.4.7.1 Theory of SPR

Surface plasmon resonance (SPR) is an optical technique that is a valuable tool for investigating biological interactions. SPR offers real-time in situ analysis of dynamic surface events and thus is, for instance, capable of defining rates of fiber growth. When light traveling through an optically dense medium (e.g., glass) reaches an interface between this medium and a medium of a lower optical density (e.g., air), a phenomenon of total internal reflection back into the dense medium occurs [199]. Although the incident light is totally internally reflected, a component of this light, the evanescent wave, penetrates the interface into the less dense medium to a distance of one wavelength [200]. In SPR measurements a monochromatic, polarized light source is used, and the interface between the two optically dense media is coated with a thin metal film (less than one wavelength of light

thick). The choice of metal used is critical, since the metal must exhibit free electron behavior. Suitable metals include silver, gold, copper, and aluminum. Silver and gold are the most commonly used, since silver provides a sharp SPR resonance peak and gold is highly stable [201]. The evanescent wave of the incoming light is able to couple with the free oscillating electrons (plasmons) in the metal film at a specific angle of incidence, and thus the plasmon resonance is resonantly excited. This causes energy from the incident light to be lost to the metal film, resulting in a reduction in the intensity of reflected light, which can be detected by a two-dimensional array of photodiodes or charge-coupled detectors. Therefore, if the refractive index directly above the metal surface changes by the adsorption of a protein layer, a change in the angle of incidence required to excite a surface plasmon will occur [202]. By monitoring the angle at which resonance occurs during an adsorption process with respect to time, an SPR adsorption profile can be obtained. The difference between the initial and the final SPR angle gives an indication of the extent of adsorption, and the positive gradient of the SPR adsorption curve determines the rate of adsorption, allowing analysis of, e.g., assembly kinetics of a growing protein fiber.

6.4.7.2 Experimental Guide to Using SPR for Fiber-growth Analysis

One of the most important parameters for SPR measurements is the surface where the molecules interact. The commercial availability of sensor chips with robust and reproducible surfaces makes SPR convenient to use. The most commonly used surface is carboxymethyl dextran (CMD) bound to a gold substrate. CMD is covalently bound to the sensor chip surface via carboxyl moieties of dextran. Functional groups on the ligand that can be used for coupling proteins include NH_2, SH, CHO, and COOH. CMD sensor chips can be regenerated by selective dissociation of the bound protein from the covalently immobilized ligand. Other commercially available sensor chips have: surfaces made of dextran matrices with a low degree of carboxylation (providing fewer negative charges), shorter carboxymethylated dextran matrices (valuable for large protein assemblies), chips with coupled nitrilotriacetic acid (designed to bind histidine-tagged molecules), chips with pre-immobilized streptavidin (for capturing biotinylated ligands), and plain gold surfaces (no dextran or hydrophobic coating), which provides the freedom to design customized surface chemistry such as self-assembled monolayers (SAM) [203]. The specific coupling chemistry has to be selected for each experiment individually. In the case of fiber growth kinetics, it is necessary to couple initiating molecules, which could be seeds, nuclei, or monomeric protein, in a manner that polymerization is not sterically hindered. This implies some fundamental knowledge on the polymerization process of the protein to be investigated. Experimental design and data processing dramatically influence the quality of SPR-derived data. However, when properly utilized, SPR can be a powerful tool for determining kinetic and equilibrium constants of molecular interactions [204]. After kinetic analysis of fiber assembly, the SPR chips can be microscopically investigated by atomic force microscopy (AFM) to obtain additional morphological insights into the assembled protein fibers (see Sections 6.4.8 and 6.5.5) [205].

6.4.8 Single-fiber Growth Imaging Using Atomic Force Microscopy

6.4.8.1 Theory of Atomic Force Microscopy

Atomic force microscopy (AFM) measures the height of a solid probe over a specimen surface. AFM has been developed as a tool for imaging biological specimens and dynamic measurements of biological interactions. AFMs operate by measuring attractive or repulsive forces between a tip and a sample, with the force between the sample and the tip causing the cantilever to bend. The magnitude of this force depends on the distance between the tip and the sample and on the chemical and mechanical properties (i.e., stiffness) of the sample. Deflection of a laser beam focused onto the end of the cantilever detects the bending of the cantilever. Since the sample is mounted on top of a ceramic piezoelectric crystal (piezo), a feedback loop between the laser detector and the piezo controls the vertical movement of the sample. Depending on the AFM design, scanners are used to translate either the sample under the cantilever or the cantilever over the sample. By scanning in either way, the local height of the sample is measured. Three-dimensional topographical maps of the surface are then constructed by plotting the local sample height versus horizontal probe tip position [206]. AFM can achieve a resolution of 10 pm and, unlike electron microscopes, can image samples in air and under liquids, thereby allowing the imaging of hydrated specimens [207, 208]. This feature can be used to monitor fiber growth as previously shown for amyloid fibril formation [115, 209–211].

In its repulsive ''contact'' mode, the instrument lightly touches a tip at the end of a leaf spring or ''cantilever'' to the sample. As a raster scan drags the tip over the sample, a detection apparatus measures the vertical deflection of the cantilever, which indicates the local sample height. Thus, in contact mode the AFM measures hard-sphere repulsion forces between the tip and sample. In tapping mode, the cantilever oscillates at its resonant frequency (often hundreds of kilohertz) and is positioned above the surface, so that it taps the surface for only a very small fraction of its oscillation period. The very short time over which this contact occurs means that lateral forces are dramatically reduced as the tip scans over the surface. Tapping mode is commonly used for poorly immobilized or soft samples. Thus, in both modes the surface topography of the biological specimen is recorded and its elevations and depressions can be accurately monitored [207, 208, 212].

6.4.8.2 Experimental Guide for Using AFM to Investigate Fiber Growth

Experiments should be carried out in tapping mode in liquid using a fluid cell, since this mode allows for higher-resolution liquid imaging than does the contact mode. The proteins should be dissolved in low-salt buffers (it is best to avoid any salts) such as 10 mM Tris/HCl or 5 mM potassium phosphate. Protein concentrations should be around 50 $\mu g\ mL^{-1}$ to obtain high-quality images. Also, atomically flat surfaces should be used to immobilize the assembling proteins. Mica is a commonly used surface material for protein attachment and fibril growth. Since slight drifts during repeated scans can occur in experiments that take several hours, com-

mon points easily visible on the surface should be chosen as a reference (such as protein aggregates or other impurities). The use of short, narrow-legged silicon nitride cantilevers (nominal spring constant 0.032 N/m) is emphasized. The best imaging results can be obtained using a tapping frequency in the range of 9 to 10 kHz. Typical scan rates are between 1 and 2 Hz, with drive amplitudes in the range of 150 to 300 mV [115, 210].

6.4.9 Dyes Specific for Detecting Amyloid Fibers

6.4.9.1 Theory on Congo Red and Thioflavin T Binding to Amyloid

Congo red (CR) is a diazo dye that binds relatively specifically to many amyloid proteins [213, 214]. The absorbance spectrum of CR changes upon binding to amyloid (Figure 6.4). Binding interactions of CR and the concomitant spectral shift depend on the structure of the amyloid, specifically the β-sheet conformation [215]. Protein fibers, which lack or contain only a minor proportion of β-sheet secondary structure, do not stain with CR. However, β-sheet secondary structure is not sufficient for CR binding, since no soluble β-sheet-rich globular protein is known to bind CR. It is suggested that CR binding occurs through a combination of both hydrophobic and electrostatic interactions [216]. The spectral shift upon binding might be caused by the stacking of several CR molecules in a defined manner along the amyloid fibers. Importantly, CR is a well-established inhibitor of fibril formation for several proteins, such as Aβ, amylin, prions, and insulin, and therefore it cannot be used to monitor fiber assembly in real time [216]. The mechanism of assembly inhibition is so far unsolved, but it could be shown that CR in addition to fibrous protein binds to native or partially unfolded conformational states and stabilizes them, which might prevent fiber formation. However, binding to the non-fibrous proteins does not lead to any spectral shift. Although binding of

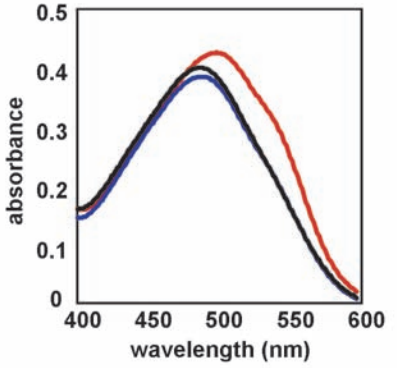

Fig. 6.4. Absorption spectra of CR in buffer (without protein) (black line), of CR in the presence of soluble yeast Sup35p-NM (blue line), and of CR in the presence of amyloid fibers assembled with Sup35p-NM (red line).

CR to amyloid fibers formed by Aβ peptides and insulin was highly specific and could be quantified [214], the fact that CR also binds to native, partially unfolded conformations of several proteins indicates that it must be used with caution as a diagnostic test for the presence of amyloid fibrils in vitro.

The benzothiazoles thioflavin S and thioflavin T (ThT) are other classical amyloid stains that bind specifically to β-sheet-rich fibers but not to monomeric or oligomeric intermediates [217, 218]. ThT proved to be particularly attractive because of a substantial hypochromic shift of the excitation maximum of the bound dye from 336 to 450 nm, permitting selective excitation of the bound species. ThT fluoresces only when it is bound to many but not all amyloid fibrils and fibrillar β-sheet species [218]. The binding reaction is rapid (completed within 30 s) and is sensitive enough to avoid significant contributions from light scattering. The advantage of ThT over CR is that ThT does not inhibit fiber assembly and can therefore also be used as a dye for real-time fiber growth, although it is important to investigate in each particular case whether ThT stimulates assembly kinetics or stabilizes the fibers [219].

6.4.9.2 Experimental Guide to Detecting Amyloid Fibers with CR and Thioflavin Binding

In a typical CR binding assay, CR binding can be quantified by a specific spectral shift. The classic CR birefringence used for histochemistry is only a qualitative technique that cannot be used for quantification. For spectral shift analysis, the amyloid fibrils should be dissolved in phosphate buffer, mixed with a solution of CR in phosphate buffer to yield a final CR concentration of 2–20 μM and incubated for 10 min, since an absorption maximum is reached after 10 min of incubation time [214]. The ratio of CR (in micromolar) to amyloid fibrils (in micrograms per milliliter, determined by the total concentration of soluble protein) should not fall below 1:5. Therefore, the total protein concentration should not exceed 100 μg μL^{-1}. The absorbance of control samples containing only CR (without protein) and only protein fibrils (without CR) should be monitored at 540 nm and 477 nm, respectively. Calculating the zeroed (to the controls) absorbances of the amyloid fibrils incubated with CR at 540 nm and 477 nm with the formula $(A_{540}/25295) - (A_{477}/46306)$ leads to the moles CR bound per liter. From this, the moles CR bound per mole protein can be calculated.

For ThT binding experiments, a stock solution of ThT is prepared at a concentration of 1 mM in double-distilled water and stored at 4 °C protected from light to prevent quenching until it is used. For high-throughput measurements, ThT fluorescence can be determined in 96-microwell plates using a fluorescence plate reader 20 μM ThT is added. To the protein fiber solutions to be incubated in 96-microwell polystyrene plates with flat bottoms. A sample volume of 200 μL is added to each well. Five replicates corresponding to five wells are measured for each sample to minimize the well-to-well variation. The plates should be covered by ELAS septum sheets and incubated without agitation or shaking. Fluorescence measurements should be performed every 30 min (excitation at 450 nm, emission at 482 nm). The read time for each well is 1 s, and the total read time for the whole

plate is approximately 3 min. Protein fiber adsorption to the plates has to be investigated by incubating protein fiber solutions in the plate for 10 min at 37 °C with stirring and by determining the protein concentration before and after incubation by measuring the UV absorbance.

Alternatively, fibril formation can be performed in glass vials. Ten-microliter aliquots are withdrawn from the glass vials and added directly to a fluorescence cuvette (1-cm path length semi-micro quartz cuvette) containing 1 mL of a ThT mixture (5 μM ThT, 50 mM Tris buffer, and 100 mM NaCl pH 7.5). Emission spectra are recorded immediately after addition of the aliquots to the ThT mixture from 470 nm to 560 nm (excitation at 450 nm). For each sample, the signal can be obtained as the ThT intensity at 482 nm, from which a blank measurement recorded prior to addition of protein to the ThT solution is subtracted.

6.5 Methods to Study Fiber Morphology and Structure

6.5.1 Scanning Electron Microscopy for Examining the Low-resolution Morphology of a Fiber Specimen

6.5.1.1 Theory of SEM

Scanning electron microscopy (SEM) involves the electron beam being passed over a conductive surface in a series of parallel lines, in a manner similar to that used in television imaging. Electrons leave the source and are focused onto the surface of a specimen as a very fine point. The probing electron beam penetrates only less than a few microns into the specimen and the electrons interact with the specimen surface, inducing a variety of radiations. Each leaves the specimen in a variety of directions and can be counted by a detector and displayed. The direction is not important; only the number of photons or electrons leaving the spot on the sample needs to be measured. The probing beam is moved to an adjacent spot on the specimen and the information is output to the display. This continues rapidly across the specimen, each point being amplified and magnified to form the image [220]. The type of information collected depends on the particular radiation being used as the information signal. The types of radiation utilized include visible light, X-rays, backscattered-electron current, and induced-specimen current [220]. Most commonly, secondary electrons emitted by the interaction of the beam are collected by a detector and the three-dimensional topographic image is built up. This technique, known as emissive mode, is commonly used for large specimens to examine morphological details. Coating the specimen in a conductive layer, usually gold coating, improves the specimen image, since the lower the atomic number of the specimen, the better the emission of secondary electrons [221]. The technique has been used extensively for the observation of silk fibers' overall morphology. In general, however, the range of resolution (typically 100 nm to 1 mm) is lower than is required for examination of most protein fibers but is ideally suited for topographic

imaging. SEM allows a large depth of field compared to the optical microscope, permitting the visualization of rough surfaces in focus across the whole specimen. In addition, the contrast within scanning micrographs provides a three-dimensional effect when the specimen is tilted with respect to the electron beam.

6.5.1.2 Experimental Guide to Examining Fibers by SEM

SEM gives information only about the external surface of the specimen. Usually, the specimen requires fixation and dehydration. Fixation is commonly performed using osmium tetroxide or formaldehyde-glutaraldehyde as a fixative, depending on the nature of the material being examined. Dehydration is usually carried out by passing the specimen though a graded series of alcohol. Freeze-drying may be used to remove water from a specimen, and this is best achieved by freeze-drying from a nonpolar solvent rather than from water (e.g., amyl acetate can be substituted for water). After freeze-drying, the specimen is warmed to room temperature before air is re-admitted to the vacuum chamber to prevent rehydration. The specimen is often coated with a thin layer of carbon to maintain the dried state and finally coated with a layer of heavy metal. Possibly, dehydration and coating may be performed within the same vacuum chamber. Critical point drying is also a method used for dehydration of some specimens. This involves replacing the water within a specimen first by a dehydrating agent, such as ethyl alcohol, followed by an intermediate liquid (e.g., amyl acetate) and a transitional liquid (e.g., carbon dioxide). This transitional liquid will be removed from the specimen at a ''critical point'' of temperature and pressure, when it becomes converted to a gas. Air drying is used less often due to the surface tension effects causing distortion in the specimen, but it is occasionally used for certain specimens.

In order to improve the electrical potential of the specimen surface, specimens are coated with a thin layer of conducting materials, since the dehydrated biological specimen usually conducts poorly and may also build up beam-induced charge, which results in artifacts. Usually, a specimen will be coated with a thin layer of carbon, followed by an outer layer of a heavy metal, commonly gold. The thin layer of gold is applied by vacuum evaporation from a tungsten filament.

The method of data collection will depend considerably upon the type of specimen [220]. In general, for biological specimens, it is thought that the acceleration should be kept low (10 kV) to reduce damage. The current should also be kept low, while enabling the collection of a relatively noise-free image. Astigmatism (i.e., a different direction focus at different points) is a very common limitation to resolution and therefore should be prevented as much as possible by maintaining the microscope to a high standard and corrected during data collection. Selection of the final aperture depends on the magnification and the depth of focus required. A large aperture (200 micron) is appropriate for high-resolution work, whereas at low magnification, depth of focus may be the prime requirement and therefore a small final aperture may be used (50 micron). It may prove useful to image the specimen at different tilts to examine different angles of the material. Data recording can be on film or, more commonly, on CCD camera. The images may then be examined in detail (Figure 6.5).

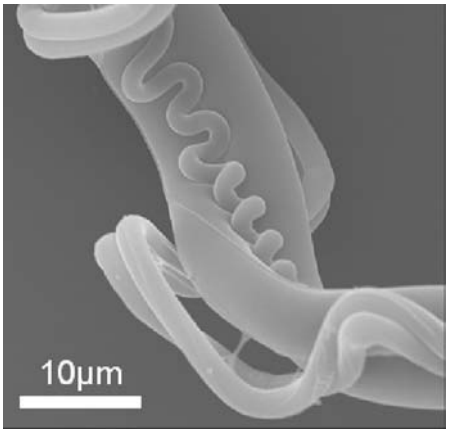

Fig. 6.5. SEM of major and minor ampullate silks collected from the garden cross spider *Araneus diadematus*.

6.5.2 Transmission Electron Microscopy for Examining Fiber Morphology and Structure

6.5.2.1 Theory of TEM

Electron micrographs represent a projection of the density distribution of the specimen onto a plane [222]. Therefore, an electron microscope image may contain sufficient information to generate the three-dimensional structure of an object. Transmission electron microscopy (TEM) is commonly used for examination of macromolecular protein assemblies, from single particles, such as viruses, to fibers, such as microtubules. Materials for TEM must be specially prepared to a thickness that allows electrons to transmit through the sample in a manner similar to how light is transmitted through materials in conventional optical microscopy. Since the wavelength of electrons is much smaller than that of light, the optimal resolution attainable for TEM images is many orders of magnitude better than that of a light microscope. This means that TEMs can reveal the finest details of internal structure – in some cases as small as individual atoms. The energy of the electrons in the TEM determines the relative degree of penetration of electrons in a specific sample or, alternatively, influences the thickness of material from which useful information may be obtained. Conventional electron microscopes tend to be run at 80–200 kV. The electron dose must be kept low to reduce radiation damage to the biological specimen. Thus, the contrast from a micrograph of biological specimens can be very poor, and therefore negative staining is required to visualize the sample. The negative stains are composed of heavy metals (such as uranyl acetate) that scatter the electrons and are electron-opaque, which results in a dark image of the stain deposited around a protein molecule or fiber.

The image visualized within the electron microscope is two-dimensional. Image reconstruction techniques can be applied to produce three-dimensional images by

single-particle averaging for globular molecules or by helical image reconstruction for fibers. Further analysis of electron micrographs is useful to exceed what is possible by visual interpretation to overcome problems such as signal detection in the presence of noise and interpretation of phase contrast images. For further discussion on analysis of images, see Section 6.5.3 on cryo-electron microscopy.

6.5.2.2 Experimental Guide to Examining Fiber Samples by TEM

The way in which the sample is prepared can vary depending on the stability of the specimen. The sample must be dehydrated since it is viewed in a vacuum. In some cases the sample is fixed prior to preparing microscope grids. The grids used for TEM can consist of a layer of plastic, such as Formvar or Pioloform, overlaid with carbon or simply a thin carbon film. The grids may be purchased ready-made or can be made to the user's specifications. Detailed procedures for making electron microscope grids can be found in Ref. [223]. Improved contrast and resolution can be obtained by using a thin-layer support, and this is best achieved by making carbon support films on mica that are then transferred to the grid. Alternatively, the carbon can be evaporated onto grids covered with a plastic film. The plastic film can then either be dissolved, leaving the thin carbon film, or left in place, resulting in more robust grids but a higher background upon imaging of a specimen.

Negative Staining for Imaging Fibrous Proteins As previously mentioned, it is usually necessary to provide contrast for visualization of a biological specimen by negative staining. These are usually heavy metal salts such as uranyl acetate, potassium phosphotungstate and ammonium molybdate. Detailed considerations of the advantages of different stains and choice of concentration are summarized in Ref. [223]. Uranyl salts give the greatest amplitude contrast but have slightly larger microcrystallinity/granularity after drying than some other negative stains, whereas potassium phosphotungstate gives fine granularity but lower image contrast [223]. Spreading agents may be a useful part of preparation of some samples. Surfactants such as *n*-octyl-*β*-glucopyranoside can be used to evenly disperse the molecules. The spreading agent can be added to the biological sample or to the negative stain. However, glow-discharge treatment of the microscope grid may be sufficient to allow even spread of the sample.

The staining procedure varies considerably among different researchers. However, the simplest technique involves the placement of droplets ($\sim$20 μL) of the specimen, several of filtered water and stain in a row, onto parafilm. The grid can then be placed facedown on each droplet in turn and for a specified amount of time. Alternatively, droplets ($\sim$4 μL) may be placed onto an upturned grid and blotted away using filter paper before the next droplet is placed on the grid.

Metal Shadowing for Enhanced Contrast of Fibrous Proteins The contrast provided by negative-stain techniques may be inadequate for visualization of rod-shaped particles, and metal shadowing may increase the contrast [224], allowing better imaging of the morphological features. Metal shadowing may be unidirectional or rotary. The protein to be examined must be in a solution of glycerol (50% v/v) and

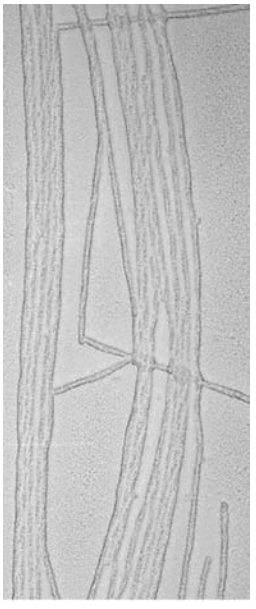

Fig. 6.6. Platinum carbon shadowing micrographs of wild-type alpha-synuclein fibrils (assembled as previously described [250]).

then be sprayed onto a piece of freshly cleaved mica and dried. The protein-covered mica is coated with platinum or another heavy metal (such as tantalum/tungsten) by evaporation and then coated with a layer of carbon. The metal/carbon replicas are then floated off onto cleaned grids and finally examined under the electron microscope. Contact prints of the micrographs provide the best images for further analysis (Figure 6.6). Details of this procedure can be found in Ref. [224].

6.5.3 Cryo-electron Microscopy for Examination of the Structure of Fibrous Proteins

6.5.3.1 Theory of Cryo-electron Microscopy

Cryo-electron microscopy allows the imaging of samples in a hydrated state encased in a thin layer of ice. No stain is required and contrast is produced by the density difference between the molecule and the vitreous (non-crystalline) ice. The samples benefit from the fact that they are not flattened by gravity, are unstained, and can be viewed at near-physiological conditions (i.e., hydrated). High-resolution data can be collected from samples at liquid nitrogen temperatures using low-dose techniques, which minimize radiation damage to the sample. Cryo-electron micrographs usually show a low signal-to-noise ratio due to the low dose of electrons, the lack of stain, and the use of small defocuses. Therefore, cryo-electron micrographs benefit from additional analysis such as Fourier filtering and

image-reconstruction techniques. High-resolution structures (to 6 Å) have been elucidated by single-particle analysis from cryo-electron micrographs of large protein molecules. Helical image reconstruction from electron micrographs can allow the elucidation of fibrous structures.

6.5.3.2 Experimental Guide to Preparing Proteins for Cryo-electron Microscopy

Cryo-electron microscopy grid preparation involves a certain amount of development to find the ideal conditions for examination of a particular protein sample. Grids are made from a holey carbon film, and the size of the holes and thickness of the carbon should be optimized for the protein molecule's size, as the thickness of the ice layer in which the protein is encased should be ideal for the size of the protein. The thickness of the ice within a carbon hole will depend on the diameter of the holes, the thickness of the carbon, and the treatment of the grid during freezing. Often, grids are glow-discharged to spread out the water layer, resulting in thinner ice, or amylamine is used to increase the thickness. Finally, the technique used for grid blotting before the sample is flash-frozen will affect the ice thickness. Holey carbon grids can be purchased or made by a procedure similar to that for making carbon films for negative-stain electron microscope grids [223]. The concentration of the fiber sample should be optimized for cryo-electron microscopy first by negative-stain EM. Ideally, the concentration should be such that several fibers are found in the scope of a micrograph but that they rarely cross over. A droplet of the fiber sample is then placed onto the optimally prepared holey carbon grids, blotted, and plunged into liquid ethane cooled by liquid nitrogen. If the procedure is carried out correctly, the grid will be covered in a thin layer of vitreous ice. The grid should be stored in liquid nitrogen until required.

Transfer to the cryo-stage specimen holder for the electron microscope must be performed at low humidity and at a temperature lower than −160 °C to prevent ice accumulation on the grid and to preserve the vitreous water. Specialized equipment to transfer the grid to the electron microscope specimen holder is available (Oxford Instruments, Gatan). The cryo-TEM must also have low vapor content; this is achieved by a liquid nitrogen pre-cooled anti-contaminator system to maintain the vitreous ice. The temperature of the specimen should then be maintained at less than −125 °C to prevent transformation of the vitreous water to crystalline cubic ice. The appearance of crystalline ice may not be visible in the microscope but can be observed as diffraction spots upon electron diffraction. Usually, cryo-electron micrographs will be collected at various defocuses in order to collect a full dataset. This is because at each defocus the contrast transfer function will pass through zero, giving rings of uncollected data in the power spectrum.

6.5.3.3 Structural Analysis from Electron Micrographs

Data collection for revealing images of protein fibers may include systematically tilting the specimen to produce a series of images with different projections of the material. However, it may be possible to reconstruct the structure of a helical molecule using only a single image, since the high symmetry of a helical fiber allows observation of many views simultaneously [225]. In order to analyze the micro-

graph images, they must be digitized (some electron microscopes have fitted CCD cameras, thus avoiding this step). Ideally, a fiber image will be scanned such that the fiber is vertical in order to avoid interpolation resulting in loss of data at the later stages. Examination of images can be carried out using a suitable program such as Ximdisp [226]. Regions of fiber images may be selected and must be boxed and floated. This involves masking off all density not belonging to the particle and surrounding the particle box to reduce the density step at the edge of the box [227]. Fiber images may benefit from Fourier filtering and/or background subtraction. The fibers may be straightened by a number of established techniques [228]. If necessary, the image may be interpolated. Interactive Fourier transforms are calculated to look for repeating features with the fiber. If a diffraction pattern is observed, then further analysis may be carried out on the fiber image using helical image reconstruction [227, 229, 230]. The determination of the position and tilt of the helix axis must first be performed, followed by indexing of the layer line spot positions. The indexing is tested and phases are measured, allowing a reconstruction to be carried out [227, 229, 230]. This results in a three-dimensional density function for the object. This methodology can be followed in detail [222, 229].

6.5.4 Atomic Force Microscopy for Examining the Structure and Morphology of Fibrous Proteins

6.5.4.1 Experimental Guide for Using AFM to Monitor Fiber Morphology

Minimal sample preparation is necessary for visualizing amyloid fibers by atomic force microscopy (AFM) [231]. A clean, uncontaminated solution of the sample can be placed onto freshly cleaved mica, glass, or other suitable smooth support. The substrate should be thoroughly cleaned with an excess of buffer (salt-free is best) or water. In order to get good contrast and to reduce mechanical damage of the soft biological materials, the samples can be stabilized by adding covalent cross-linking agents or certain cations that are able to link the constituents of the sample to each other or to the substrate. Cooling can also stiffen the sample to reduce sample disruption and damage.

Tapping mode is most commonly used for imaging relatively soft biomolecules. The force generated between the sample and tip depends on the amplitude of free oscillation and the set point amplitude [232]. The observed amplitude of oscillation is maintained by adjusting the vertical position of the sample. The strength of tapping must be optimized for a particular sample, since tapping too hard will reduce image resolution and quality due to damage to the tip or protein. Tapping too softly might cause adhesive forces between the sample and cantilever tip, resulting in damping of oscillation and causing spurious height data for the sample [232]. Once these conditions are optimized, image data may be collected. Visual representations of the data are often generated by assigning a color or brightness to the relative height in the image. This will enable clear images of the fiber in question to be observed above the background smooth surface (Figure 6.7). Height measurements may be taken from the data, but width cannot be measured accurately due

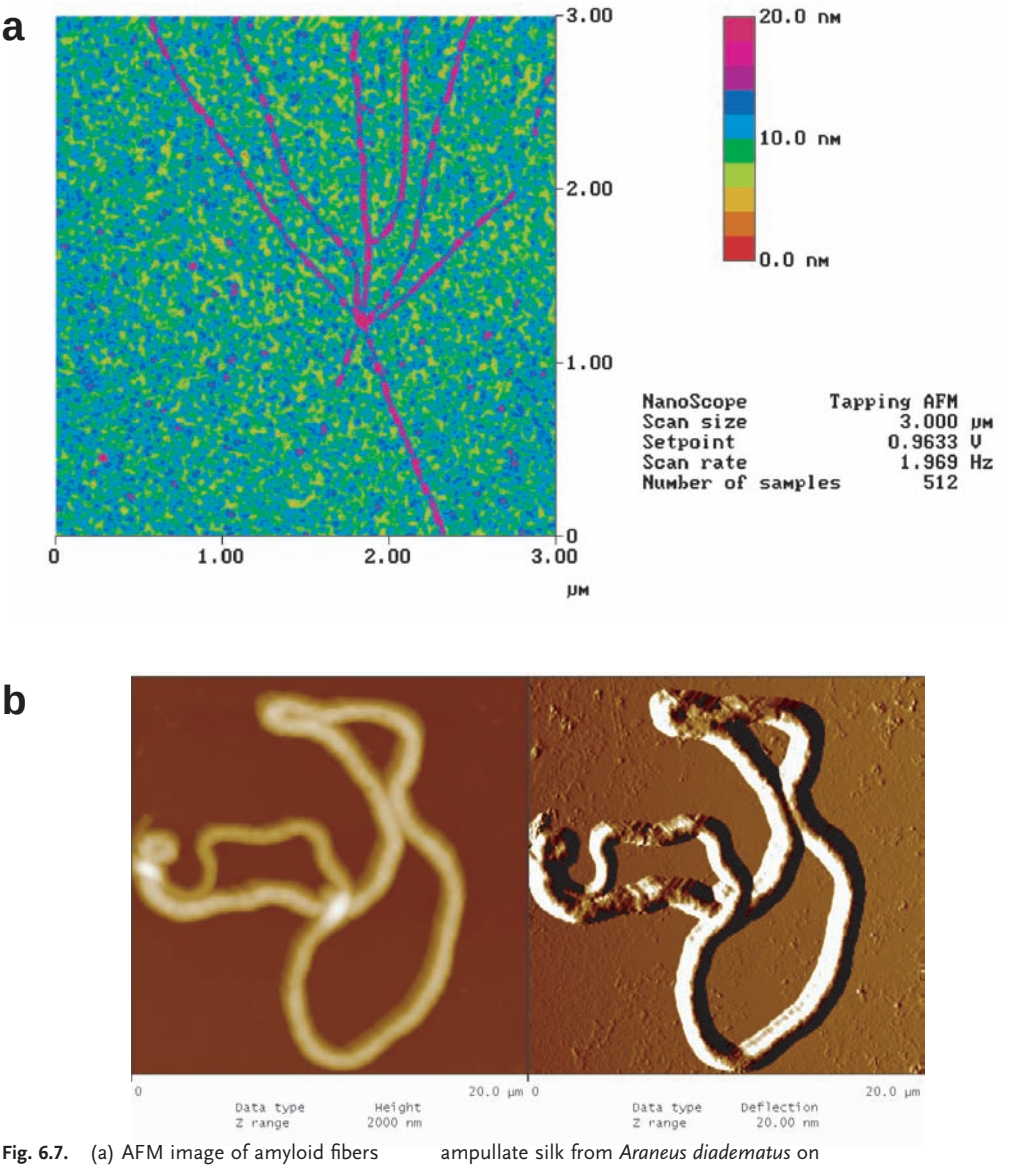

Fig. 6.7. (a) AFM image of amyloid fibers assembled with biotinylated yeast Sup35p-NM on streptavidin scanned in contact mode [251]. The scale bar gives the color code for the height information. (b) AFM images of major ampullate silk from *Araneus diadematus* on mica scanned in tapping mode. The left image reflects the sample height above the surface, and the right image depicts the tip deflection.

to the shape and size of the tip. Of course, height measurements taken from specimens in air may be affected by dehydration of the specimen, by the effect of gravity, or by the force of the cantilever compressing soft protein. However, morphological features may be clearly observed.

6.5.5 Use of X-ray Diffraction for Examining the Structure of Fibrous Proteins

6.5.5.1 Theory of X-Ray Fiber Diffraction

X-ray diffraction involves the use of proteins in an ordered arrangement. The amount of information that can be obtained is directly related to the degree of order within the diffracting object. The most ordered arrangement will be in a crystal where each identical protein molecule is arranged periodically on a three-dimensional lattice. Diffraction from crystals results in a pattern comprised of sharp spots. However, fibrous proteins usually do not crystallize due to their size, insolubility, or heterogeneity. Fibrous proteins form partly ordered structures, and standard methods of crystal structure analysis are not applicable to fibers due to the degree of disorder and number of overlapping reflections. However, X-ray fiber diffraction can be performed. Details concerning the theory of X-ray fiber diffraction may be found in Ref. [19]. For a single, isolated chain molecule, the crystalline lattice extends in only one dimension, parallel to the axis of the fiber (z-direction). The scattering appears on layer lines, and the layer planes have a separation of the reciprocal of the periodic repeat along the fiber axis. Since a single-chain molecule has no periodicity in the x- and y-directions, the scatter is a continuous function. In practice, however, a fiber specimen is composed of several chain molecules with rotational averaging. The molecules may be axial in register but arranged at all possible azimuthal orientations. These molecules are related to one another, but not by a crystallographic lattice. Therefore, a collection of chain molecules gives the scattering effect for the isolated molecules plus the effects caused by the orientation of the molecules and the packing, size, and mutual disposition of ordered regions.

Fibers are cylindrically symmetrical, so each reflection is spread out into a disk and intercepts the Ewald sphere at two symmetrical points. This means that the diffraction pattern is symmetrical. On the fiber diffraction diagram, the direction parallel to the fiber axis is known as the meridian and the perpendicular direction is the equator. Fibers are crystalline along the fiber axis and this produces strong, sharp reflections on the meridian. The degree of disorientation of the fibers relative to one another will produce more or less arcing of reflections. The appearance of diffraction arcs depends on the arrangement of crystallites (microstructure) within the material, known as the texture. Individual fibers may be aligned relative to one another, thus reducing disorientation and reducing the spread of the arcs. A sample in which the fibers have not been aligned at all will produce a diffraction pattern where the reflections appear as rings, much like a powder diffraction pattern. X-ray diffraction from a partially aligned specimen will allow distinction between the meridional and equatorial reflections. Even further orientation of the fiber within the specimen may produce a series of lines of intensity known as layer lines, running perpendicular to the meridian of the pattern. The intensities on closely spaced layer lines may overlap. In fact, it is rare to find non-overlapping reflections. If the fiber is mounted with the fiber axis normal to the X-ray beam, the diffraction pattern will be symmetrical above and below the equator (Figure 6.8).

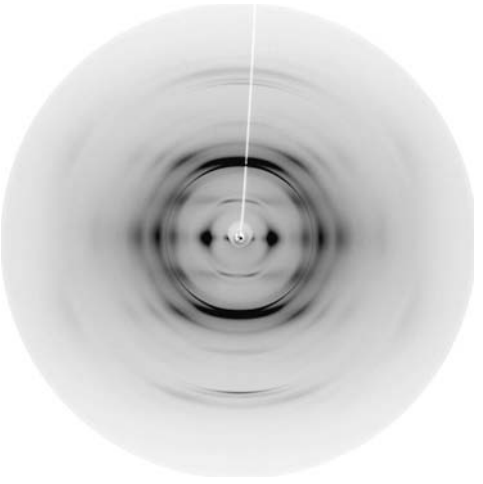

Fig. 6.8. X-ray fiber diffraction from amyloid fibrils from a short peptide homologous to the central region of Aβ peptide showing the cross-β diffraction pattern.

However, there will be regions of reciprocal space for which no data is recorded. By tilting the specimen, additional data can be collected.

6.5.5.2 Experimental Guide to X-Ray Fiber Diffraction

Sample Preparation Fibers in general are weakly diffracting, and therefore specimen preparation is particularly important. The specimen should be of an optimum size and thickness to fill the beam. Otherwise background scatter may obscure weak reflections. The amount of information that can be obtained from an X-ray fiber diffractogram is closely associated with the degree of alignment. Some fibrous proteins occur naturally in a highly oriented form (e.g., keratin and collagen). Often regions of orientation are quite limited, and therefore it can be useful to use a microfocus X-ray beam for data collection. Orientation may be improved by physical manipulation or by chemical treatment. For example, the orientation of *Chrysopa* egg stalk silk fiber orientation was increased by stretching in water or urea [4]. Preparation of oriented films and fibers from soluble fibrous proteins has involved a number of procedures that include stretching, rolling, casting films, drawing fibers from precipitate, shearing, magnetic alignment, centrifugation, and capillary flow. Long-chain molecules can be drawn from the solution in a manner similar to that used for making diffraction samples of DNA. Samples that cannot be pulled into long fibers may be aligned by hanging a drop between two wax-plugged capillary tubes arranged 1–2 mm apart [1]. Casting flat sheets is often used as a method for aligning polymers [233–235], and this can be achieved by placing a high concentration of a fiber solution on a suitable surface and allowing the solution to dry to form a thin film that can be removed from the surface (such

as Teflon). The film will show alignment of the fibers in the direction parallel to the film surface but no alignment in the perpendicular direction. Further improvement to alignment of fiber bundles or films may be achieved by annealing in high humidity. Some fibrous protein specimens are diamagnetically anisotropic [236] and may benefit from magnetic alignment [105, 237, 238]. The effect of the magnetic field on a single molecule is small, and therefore it is necessary to embed the molecules in a liquid crystal so that the molecules act together and to use a high-energy magnet [239]. The alignment can be fixed in the specimen by slow drying while the specimen is still in the magnetic field.

Data Collection Since fibrous proteins are often weak scatterers, long exposure times may be needed. Cameras specially designed for the particular qualities of the specimen may be helpful. The arrangement of the apparatus will depend on whether a high- or low-angle diffraction is being collected. The use of a helium chamber and an evacuated camera can be helpful to reduce air scatter as well as to allow the humidity around the specimen to be controlled if required. In the past, the recording of diffraction data was performed using photographic film. This allowed the placement of several films in the detector to record a range of intensities. However, it is now more common to use detectors used for crystallography, such as a MarResearch image plate or CCD cameras. If film has been used, then the diffraction image must be digitized and converted to an appropriate format for data analysis.

Data Analysis There are a number of fiber diffraction processing programs available to facilitate processing of fiber diffraction data. CCP13 [240] is a collection of programs designed to analyze high-quality diffraction patterns. FIT2D (www.esrf.fr/computing/expg/subgroups/data_analysis/FIT2D) can be used to analyze one- and two-dimensional datasets. The CCP4 suite [241] is intended for protein crystallography, but many of its components such as ipdisp and Mosflm can be utilized for examining the diffraction pattern. The data from the detector must be converted into a format compatible with the other programs in the chain. Examples of such programs are XCONV (CCP13) [147], marcvt (www.marresearch.com/software.htm) and Denzo [242]. The diffraction image must be carefully centered to avoid a systematic error while measuring spot locations. Mosflm allows this to be done by manually moving the image with respect to a series of overlaid concentric circles. XFIX (CCP13) allows the user to find the center of the pattern and to calibrate the specimen to film distance. One may also wish to correct for the shape of the image plate and determine the sample's tilt and rotation [243]. Background subtraction is often beneficial to correct for detector fog, white radiation, and X-ray scattering from air, camera components, the sample holder, and amorphous material in the specimen such as solvent and disordered polymer [244, 245]. The positions of the reflection can then be assessed. An initial survey can be carried out by noting spot locations and resolutions. This is straightforward in Mosflm, since the resolutions are calculated by clicking on spot maxima using a zoomed image. Re-

solution calculation can also be done by hand using an approximation to Bragg's law. This is the result of the product of the wavelength of the X-rays and the distance between the sample and the image plate, divided by the distance of the diffraction spot from the center of the diffraction pattern. For high-quality diffraction patterns containing diffraction peaks on layer lines, the CCP13 suite of programs allows the user to quadrant-average the diffraction pattern given the calculated tilt/rotation of the image. This image can then be processed further to include background subtraction and modeling of the position, size, shape, and intensity of the reflections.

Model Building An X-ray diffraction pattern from an unknown structure cannot directly lead to a structure since only amplitudes, but not phases, can be measured from the diffractogram. One method of solving this phase problem is by trial and error, so that from consideration of the diffraction pattern, symmetry, and chemical composition, a model is built and refined until a calculated diffraction can be generated that is similar to the observed [239]. A final model will predict the observed diffraction pattern so well that the possibility of the existence of another model that also predicts the diffraction pattern is virtually eliminated. Fibers by their nature are highly symmetrical and consist of repeating units, which reduces the number of possibilities for arrangement. Structural information about the subunits may already be available, either from crystal structures of individual monomers or from other biophysical techniques that indicate a secondary or tertiary structure. A molecular structure may be modeled using software such as LALS [246] or Cerius2 (http://www.accelrys.com/cerius2/cerius248/), which then allows the calculation of a simulated diffractogram to compare with the empirical data. Fxplor (www.molbio.vanderbilt.edu/fiber/software.html) is an extension of X-Plor, a program useful for atomic model refinement.

6.5.6 Fourier Transformed Infrared Spectroscopy

6.5.6.1 Theory of FTIR

Fourier transformed infrared spectroscopy (FTIR) has been used to gain information about the conformation of fibrous proteins. Proteins yield three major infrared bands of interest that arise from the peptide backbone. These are the amide I absorption at 1600–1700 cm^{-1}, arising from the C=O stretch; the amide II absorption at 1500–1600 cm^{-1}, arising from the N–H deformation; and the amide III absorption at 1200–1350 cm^{-1}. A N–H stretch also absorbs at about 3300 cm^{-1} [247]. The presence of hydrogen bonding within the sample shifts the energies of the peptide variations, therefore allowing the determination of the presence of α-helical and β-sheet conformations in theory. However, this is complicated in practice due to coupling between individual peptide vibrations, which leads to splitting of the bands into a series of bands. The symmetry of α-helical fibers leads to a distinctive set of bands upon aggregation from the monomer [247, 248], whereas

the spectra observed from the formation of all-β-sheet protein fibers are more subtle [248]. Observed and calculated infrared spectra from α-helix and antiparallel and parallel β-structures can be found in Ref. [247].

6.5.6.2 Experimental Guide to Determining Protein Conformation by FTIR

FTIR data collection is complicated by the fact that the bending vibrations H–O–H from water are near 1640 cm^{-1}, which can obscure the amide I band. This problem can be overcome by examination of the protein in the solid state, when little water is present, or by exchanging the hydrogen for deuterium. The D–O–D bending vibration is shifted to 1220 cm^{-1}, but care must be taken to fully exchange the H for D, since partial exchange will result in bands in the amide I region [248]. However, for examining the structure of *ex vivo* samples of fibrous proteins, exchange of deuterium may not be possible, and in order to overcome this, the signal-to-noise resolution of the data must be high. For solution samples, the use of a short path length (4–10 μm) and high protein concentration (1–50 mg mL^{-1}) should reduce the water absorbance relative to the protein signal at 1640 cm^{-1} [248]. To minimize scattering, samples may be prepared in dry state in KBr pellets by combining oven-dried KBr with the protein. The sample is then kept under vacuum and pressed (5–10 kbar) using a Carver press to form a thin, translucent pellet. This pellet can then be transferred to the transmission holder and a spectrum can be collected [248]. The spectrum is then compared with the spectrum collected from a KBr-only pellet. However, this harsh method may cause denaturation of the protein.

Alternative methods include attenuated total reflectance (ATR) FTIR, diffuse reflectance FTIR, and transmission-mode FTIR from a thin film. For ATR-FTIR, the sample is placed on a surface composed of a material of high refractive index, which is known as the internal reflection element (IRE) and is often composed of germanium or zinc selenide. The beam penetrates to the boundary between the IRE and the sample and is not transmitted through the sample. This makes this method ideal for examining fibrous proteins, and the method may be used for samples prepared as a thin film or suspension [249]. For ATR experiments, the maximum amount of light throughput is required and the amount of water vapor is reduced (by purging the system with dry nitrogen or dry air) to increase the sensitivity. Oberg et al. [249] recommend the use of out-of-compartment, horizontal, trapezoid-shaped IREs. To prepare a sample for ATR-FTIR, thin films can be prepared of the fibrous protein using a solution (50–100 μL of 0.5–1.0 mg mL^{-1}) or suspension placed onto the IRE and dried using nitrogen gas. The thin films are partly hydrated, maintaining the protein structure. Further, the limited-depth penetration of the ATR method reduces the contribution of water to the spectra [248]. Lyophilized proteins may also be spread onto the IRE for collection of spectra from powdered proteins. Alternatively, the diffuse reflectance (DRIFT) method can be used for dry samples [248]. In contrast to the ATR method, in transmission-mode FTIR, the beam passes directly through the sample [248]. High protein concentrations (2–60 mg mL^{-1}) and small path lengths (less than 10 μm) are required, although for a D_2O sample, lower protein concentrations and longer path lengths

(25–50 μm) may be used. Thin films can be prepared by drying the protein suspension or solution onto thin silver chloride disks.

Data analysis of FTIR spectra involves some expertise. Water or buffer subtraction must be performed before analysis of the spectrum. The conformation of the polypeptide chain has a signature in the amide I band. However, the bands may overlap, making interpretation difficult. This can be tackled in two ways. One approach is resolution enhancement methods or deconvolution to decrease the widths of the infrared bands and to allow determination of the overlapping components. A second approach is to use pattern-recognition methods for which software packages are available (e.g., GRAMS, Galactic Corp.).

6.6 Concluding Remarks

In the present chapter, fiber-forming proteins and methods to determine their fiber assembly and fiber morphology have been described. There is a wide variation among fibrous proteins with regard to the content of regular secondary structure. Fibers of proteins such as collagen and tropomyosin with highly elongated molecules tend to have a high content of regular secondary structure (generally greater than 90%). In contrast, fibers of globular proteins, such as actin, feather keratin, and flagellin, generally have much lower contents of regular structure (often less than 50%). In another group of proteins, comprising elastin, resilin, and the matrix proteins of mammalian keratins, the content of regular secondary structure is very small. In these cases the protein fibers are cross-linked and have rubber-like elastic properties.

So far, any attempt to correlate sequence with structure and function in fibrous proteins is highly speculative. Therefore, from a given sequence it cannot be concluded whether a protein forms fibers or not. However, the structure-function relation based on sequence data is the aim of many biologists, chemists, physicists, and material scientists. One main conformation-determining factor in fibrous proteins appears to be regions with repeating sequences. The simplest examples of repeating sequences are found among the silks, which have, for instance, runs of Gly_n. The corresponding sections of the chains adopt conformations that appear to be identical to those observed in synthetic homopolypeptides. Four other conformation-determining factors in fibrous proteins are interactions involving side chains, interactions between apolar side chains, hydrogen bond formation, and the content and distribution of Gly and Pro residues.

Aggregation studies on amyloids, collagens, myofibrils, and silks illustrate the capacity of fibrous proteins for self-assembly into filaments and other organized aggregates. The mode of aggregation is generally found to be sensitive to changes in pH, ionic strength, and the presence of other solutes, indicating that the assembly process depends upon a fine balance among various types of weak secondary bonding. Packing considerations are also clearly involved, but in the case of assembly in aqueous environment, these will be less important than in a solvent-free

crystalline phase. Several features of the self-assembly process in vivo are still not well understood, such as nucleation and termination of fiber formation. For termination of fiber formation, two possibilities can be envisaged: the assembly process could be intrinsically self-limiting, with the information residing in the individual protein molecules, or the size of the aggregate is potentially unlimited, but regulation of size is achieved through some external agency.

The future aim in investigating fibrillar proteins is to understand the kinetics of fiber assembly (which will be a basis for controlling fiber assembly) and to gain more insights into fibrous structure to learn about sequence-structure relationships. Such knowledge will be a basis for elucidating the relevance of assembly processes in cellular development, cellular structure, and cellular stability; for assessing fundamental influences leading to protein-folding diseases; and for developing products through material science.
