$$c_k = \int \overline{a_k(y)}\psi(y)\,dy,$$

and (34)

$$f_k = \int \overline{a_k(y)}\,f(y)\,dy,$$

respectively. Clearly, the determinant of this algebraic system is $D(\bar{\lambda})$. Accordingly, the transposed integral equation (33) also possesses a unique solution whenever (19) does. Also, the eigenvalues of the homogeneous part of Eq. (33), that is,

$$\psi(x) = \lambda \int \overline{K(y, x)}\psi(y)\,dy \tag{35}$$

are the complex conjugates of those for (31). The eigenvectors of the homogeneous system $(\mathbf{I} - \lambda\bar{\mathbf{A}}^{\mathrm{T}})\mathbf{c} = 0$, are, in general, different from the corresponding eigenvectors of system (32). The same applies to the eigenfunctions of the transposed integral equation (35). Because the geometric multiplicity r of λ_i for (31) is the same as that of $\bar{\lambda}_i$ for (35), the number of linearly independent eigenfunctions of the transposed equation (35) corresponding to $\bar{\lambda}_i$ are also r in number, say, $\psi_{i1}, \psi_{i2}, \ldots, \psi_{ir}$ which we assume to be normalized. Accordingly, any solution $\psi_i(x)$ of (35) corresponding to the eigenvalue λ_i is of the form $\psi_i(x) = \sum_{k=1}^{n} \beta_k \psi_{ik}(x)$, where β_i are arbitrary constants. Incidentally, it can be easily proved that the eigenfunctions $g(x)$ and $\psi(x)$ corresponding to eigenvalues λ_1 and $\bar{\lambda}_2$ $(\lambda_1 \neq \lambda_2)$ of the homogeneous integral equation (31) and its transpose (35) respectively, are orthogonal.

This analysis is sufficient for us to prove that the necessary and sufficient condition for Eq. (19) to have a solution for $\lambda = \lambda_i$, a root of $D(\lambda) = 0$, is that $f(x)$ be orthogonal to the r eigenfunctions ψ_{ij}, $j = 1, \ldots, r$, of the transposed equation (35). The necessary part follows from the fact that if Eq. (19) for $\lambda = \lambda_i$ admits a certain solution $g(x)$, then

$$\begin{aligned}
&\int f(x)\overline{\psi_{ij}(x)}\,dx \\
&\quad = \int g(x)\overline{\psi_{ij}(x)}\,dx \\
&\qquad - \lambda_i \int \overline{\psi_{ij}(x)}\,dx \int K(x, y)g(y)\,dy \\
&\quad = \int g(x)\overline{\psi_{ij}}(x)\,dx \\
&\qquad - \left(\lambda_i \int \overline{g(y)}\,dy \int \overline{K(x, y)}\psi_{ij}(x)\,dx\right) \\
&\quad = 0
\end{aligned}$$

because $\bar{\lambda}_i$ and $\psi_{ij}(x)$ are an eigenvalue and a corresponding eigenfunction of (35). For the proof of the sufficiency, we appeal to the corresponding condition of orthogonality for the linear algebraic system which assures us that the inhomogeneous system (25) reduces to only $n - r$ independent equations (i.e., the rank of the matrix $(I - \lambda\mathbf{A})$ is exactly $p = n - r$ and therefore the system ($(\mathbf{I} - \lambda\mathbf{A})\mathbf{c} = \mathbf{f}$ is soluble). Substituting this value of $\mathbf{c}$ in (22) we have the required solution of (19).

This analysis is true for a general integrable kernel. Fredholm gave three theorems in this connection and they bear his name. These theorems are of great importance in general discussion but are of little use in constructing closed form solutions or obtaining solutions numerically. Fredholm's first theorem gives the same formula as (30a) where the resolvent kernel is

$$\Gamma(x, y; \lambda) = D(x, y; \lambda)/D(\lambda), \qquad D(\lambda) \neq 0, \quad (36)$$

which is a meromorphic function of the complex variable λ, being the ratio of two entire functions $D(x, y; \lambda)$ and $D(\lambda)$ which are given by suitable Fredholm series of form similar to (30b). The other two theorems discuss the case $D(\lambda) = 0$ for a general kernel. The discussion given above and these three theorems add up to the following important result.

A. The Fredholm Alternative Theorem

For a fixed λ, either the integral equation (19) possesses one and only one solution $g(x)$ for integrable functions $f(x)$ and $K(x, y)$ (in particular the solution $g(x) = 0$ for the homogeneous equation (31)), or the homogeneous equation (31) possesses a finite number r of linearly independent solutions g_{ij}, $j = 1, \ldots, r$, with respect to the eigenvalue $\lambda = \lambda_i$. In the first case, the transposed inhomogeneous equation (33) also possesses a unique solution. In the second case, the transposed homogeneous equation (35) also has r linearly independent solutions $\psi_{ij}(x)$, $j = 1, \ldots, r$, corresponding to the eigenvalues λ_i; and the inhomogeneous integral equation (19) has a solution if and only if the given function $f(x)$ is orthogonal to all the eigenfunctions $\psi_{ij}(x)$. In this case the general solution of the integral equation (19) is determined only up to an additive linear combination $\sum_{j=1}^{r} \alpha_j g_{ij}(x)$.

IV. THE FREDHOLM OPERATOR

We have observed in Section I that the Fredholm operator $Kg(x) = \int K(x, y) g(y)\, dy$ is linear (i.e., $K(\alpha g_1 + \beta g_2) = \alpha K g_1 + \beta K g_2$, where α and β are arbitrary complex numbers). In this section we study some general results for this operator. For this purpose we consider a linear space of an infinite dimension with inner product defined by (4) (i.e., $\langle f, g \rangle = \int f(x) \bar{g}(x)\, dx$). This inner product is a complex number and satisfies the following axioms:

(a) $\langle f, f \rangle = 0$ iff $f = 0$.
(b) $\langle \alpha f_1 + \beta f_2, g \rangle = \alpha \langle f_1, g \rangle + \beta \langle f_2, g \rangle$.
(c) $\langle f, g \rangle = \overline{\langle g, f \rangle}$.

The norm $\| f \|$ defined by (4) generates the natural metric $d(f, g) = \| f - g \|$. Furthermore, we have the Cauchy–Schwarz and Minkowski inequalities as given by (5) and (6), respectively.

An important concept in the study of metric spaces is that of completeness. A metric space is called complete if every Cauchy sequence of functions in this space is a convergent sequence (i.e., the limit is in this space). A *Hilbert space* H is an inner product linear space that is complete in its natural metric. An important example is the space of square integrable functions on the interval $[a, b]$. It is denoted as $\mathscr{L}_2[a, b]$, called $\mathscr{L}_2$ space in the sequel.

An operator K is called *bounded* if there exists a constant $M > 0$, such that $\| Kg \| \leq M \| g \|$ for all $g \in \mathscr{L}_2$. We can prove that the Fredholm operator with an $\mathscr{L}_2$ kernel is bounded by starting with the relation $f = Kg$. Then by using the Cauchy–Schwarz inequality we have

$$|f(x)|^2 = \left| \int K(x, y) g(y) \right|^2 dy \leq \int |K(x, y)|^2\, dy \int |g(y)|^2\, dy.$$

Integrating both sides of this relation we find that $\| f \| = \| Kg \| \leq \| g \| [\iint |K(x, y)|^2\, dx\, dy]^{1/2}$ and we have established the boundedness of K. The norm $\| K \|$ of an operator K is defined as

$$\| K \| = \sup(\| Kg \| / \| g \|) \quad (37a)$$

or

$$\| K \| = (\sup \| Kg \|; \| g \| = 1). \quad (37b)$$

The operator K is called continuous in a Hilbert space if whenever $\{g_n\}$ is a sequence in the domain of K with limit g, then $Kg_n \to Kg$. A linear operator is continuous if it is bounded and conversely.

A set S is called precompact if a convergent subsequence can be extracted from any sequence of elements in S. A bounded linear operator K is called compact if it transforms any bounded set in H onto a precompact set. Any bounded operator K, whose range is finite-dimensional, is compact because it transforms a bounded set in H into a bounded finite-dimensional set which is necessarily precompact. Many interesting integral operators are compact. For instance, if the Hilbert space is $\mathscr{L}_2$ space and $K(x, y)$ is a degenerate kernel $\sum_{i=1}^{n} a_i(x) b_i(y)$, then K is a compact operator. This follows by observing that

$$Kg = \int \left[\sum_{i=1}^{n} a_i(x) b_i(y) g(y) \right] dy = \sum_{i=1}^{n} c_i a_i(x)$$

(i.e., the range of K is a finite-dimensional subspace of $\mathscr{L}_2$). Furthermore,

$$\|Kg\| = \left\| \sum_{i=1}^{n} c_i a_i(x) \right\| \le \sum_{i=1}^{n} |c_i| \|a_i\|$$

$$\le \sum_{i=1}^{n} \|a_i\| \int |b_i(y)||g_i(y)|\, dy.$$

Finally, by applying the Cauchy–Schwarz inequality we have $\|Kg\| \le M\|g\|$, where $M = \sum_{i=1}^{n} \|a_i\|\|b_i\|$. Accordingly, K is a bounded linear operator with finite-dimensional range and hence it is compact.

The following property of compact operators will prove useful in the next section. Let K be a compact operator on the Hilbert space H, and L be a bounded operator. Then both KL and LK are compact operators. To prove this property for the case of LK we let $\{f_n\}$ be a uniformly bounded sequence in H. Since K is compact it contains a subsequence $\{f_{n'}\}$ such that $\|LKf_{n'} - LKf_{m'}\| \le \|L\|\|Kf_{n'} - Kf_{m'}\|$. This means that $\{LKf_n\}$ is also a Cauchy sequence. In the case of KL, we observe that if $\{f_n\}$ is uniformly bounded, and L is bounded, then $\{Lf_n\}$ is also uniformly bounded. The compactness of K now assures us that there exists a subsequence $\{KLf_{n'}\}$ which is a Cauchy sequence. Thus, KL is also compact. As a particular case we find that if K is compact then so is K^2.

There are many interesting results regarding the compact operators. Some of them are as follows.

1. If $\{K_n\}$ is a sequence of compact operators on a Hilbert space H, such that for some K we have $\lim_{n\to\infty} \|K - K_n\| = 0$, then K is compact.
2. If $K(x, y)$ is continuous for all $a \le x, y \le b$ then K is a compact operator on $\mathscr{L}_2[a, b]$.
3. An $\mathscr{L}_2$ kernel K (i.e., $\iint |K(x, y)|^2\, dx\, dy < \infty$) is a compact operator.

V. HERMITIAN KERNELS AND THE HILBERT–SCHMIDT THEORY

Let us now consider a technique quite different from the Neumann and Fredholm series. This technique is based on considering the eigenvalues and eigenfunctions of the homogeneous integral equation with *Hermitian* kernel (i.e., $K(x, y) = \overline{K(y, x)}$ (then K is called the Hermitian operator). For real K it becomes $K(x, y) = K(y, x)$ (i.e., a symmetric kernel). We shall restrict ourselves to the Hilbert space $\mathscr{L}_2$ of square integrable functions and will benefit from the concepts of the previous section. Because

$$\begin{aligned}\langle K\phi, \psi\rangle &= \int \bar{\psi}(x)\left[\int K(x, y)\phi(y)\, dy\right] dx \\ &= \int \phi(y)\left[\int K(x, y)\bar{\psi}(x)\, dx\right] dy \\ &= \int \phi(x)\left[\int K(y, x)\bar{\psi}(y)\, dy\right] dx \\ &= \langle \phi, \bar{K}\psi\rangle, \end{aligned} \tag{38}$$

the operator $\bar{K}(y, x)$ is called the *adjoint* operator. When K is Hermitian, this result becomes $\langle K\phi, \psi\rangle = \langle \phi, K\psi\rangle$ (i.e., K is *selfadjoint*). On the other hand, $\langle K\phi, \phi\rangle = \overline{\langle \phi, K\phi\rangle}$. Combining these two results we observe that the inner product $\langle K\phi, \phi\rangle$ is always real and the converse is also true.

Systems of orthogonal functions play an important role in this section so we give a brief account here. A finite or an infinite set $\{\phi_k\}$ is said to be an orthogonal set if $\langle \phi_i, \phi_j\rangle = 0, i \ne j$. If none of the elements of this set is zero vector, it is said to be a proper orthogonal set. A set is orthonormal if $\langle \phi_i, \phi_j\rangle = \delta_{ij}$, where δ_{ij} is the Kronecker delta which is zero for $i \ne j$ and 1 if $i = j$. As defined in section 1. a function ϕ for which $\|\phi\| = 1$ is said to be normalized. Given a finite or a countably infinite independent set of functions $\{\psi_n\}$, we can replace them by an equivalent set $\{\phi_n\}$ which is orthonormal. This is achieved by the so-called *Gram–Schmidt* procedure:

$$\begin{aligned}\phi_1 &= \frac{\psi_1}{\|\psi_1\|} \\ \phi_1 &= \frac{\psi_2 - \langle \psi_2, \phi_1\rangle\phi_1}{\|\psi_2 - \langle \psi_2, \phi_1\rangle\phi_1\|} \\ &\vdots \\ \phi_n &= \frac{\psi_n - \sum_{i=1}^{n-1}\langle \psi_n, \phi_i\rangle\phi_i}{\|\psi_n - \sum_{i=1}^{n-1}\langle \psi_n, \phi_i\rangle\phi_i\|}\end{aligned}$$

as is easily verified. In case we are given a set of orthogonal functions then we can convert it into an orthonormal set simply by dividing each function by its norm.

Starting from an arbitrary orthonormal system we can construct the theory of Fourier series on the same lines as the trigonometric series. This is achieved if we attempt to find the best approximation of an arbitrary function $\psi(x)$ in terms of a linear combination of an orthonormal set $\{\phi_n\}$. By this we mean that we choose the coefficients $\alpha_1, \alpha_2, \ldots, \alpha_n$ in order to minimize

$$\left\| \psi - \sum_{i=1}^{n} \alpha_i \phi_i \right\|^2 = \|\psi\|^2 + \sum_{i=1}^{n} |\langle \psi, \phi_i\rangle - \alpha_i|^2 - \sum_{i=1}^{n} |\langle \psi, \phi_i\rangle|^2. \tag{39}$$

Clearly, the minimum is achieved by setting $\alpha_i = \langle \psi, \phi_i \rangle = a_i$ (say), which are called the Fourier coefficients of ψ relative to the orthonormal system $\{\phi_n\}$. Then (39) becomes

$$\left\| \psi - \sum_{i=1}^{n} \alpha_i \phi_i \right\|^2 = \|\psi\|^2 - \sum_{i=1}^{n} |a_i|^2,$$

from which it follows that $\sum_{i=1}^{n} |a_i|^2 \leq \|\psi\|^2$. For an infinite set $\{\phi_n\}$ this inequality is

$$\sum_{i=1}^{\infty} |a_i|^2 \leq \|\psi\|^2, \tag{40}$$

which is called the *Bessel inequality*. If an orthonormal system of functions can be found in $\mathcal{L}_2$ space such that its every element can be represented linearly in terms of this system, it is called an *orthonormal basis*. Thus, we have $\psi = \sum_i \langle \psi, \phi_i \rangle \phi_i = \sum_i a_i \phi_i$. From this relation we readily derive the Parseval identity:

$$\|\psi\|^2 = \sum_{i=1}^{\infty} |\langle \psi, \phi_i \rangle|^2$$

Incidentally, if $\|\psi - \sum_{i=1}^{n} \alpha_i \phi_i\| \to 0$ as $n \to \infty$, then ψ is said to *converge in the mean* to the series $\sum_{i=1}^{\infty} \alpha_i \phi_i$. The reason for this terminology is that the norm entails the integration of the square of the function.

We are now ready to discuss the solutions of the integral equation $\lambda K\phi = \phi$. We take $K(x, y)$ to be a Hermitian kernel so that, in view of relation (38) K is self-adjoint. As such, this operator has some very interesting properties as we establish below.

A. Property 1

1. Existence of an Eigenvalue

If the Hermitian kernel is also an $\mathcal{L}_2$ function then at least one of the quantities $\pm(\|K\|)^{-1}$, where this norm is defined by (37), must be an eigenvalue of $\lambda K f = f$.

2. Proof

Because K is a Hermitian kernel, it is self-adjoint because of (38), and being an $\mathcal{L}_2$ function it is compact as mentioned in the previous section. Accordingly, we consider a sequence $\{f_n\}$ such that $\|f_n\| = 1$ and $\|K f_n\|$ converges to $\|K\|$. Note that

$$\begin{aligned} 0 &\leq \left\| K^2 f_n - \|K f_n\|^2 f_n \right\|^2 \\ &= \left\| K^2 f_n \right\|^2 - 2\|K f_n\|^2 \langle K^2 f_n,\ f_n \rangle + \|K f_n\|^4 \\ &= \left\| K^2 f_n \right\|^2 - \|K f_n\|^4 \end{aligned}$$

But $\|K f_n\|$ converges to $\|K\|$, so that $\lim_{n\to\infty} \|K^2 f_n - \|K f_n\|^2 f_n\| = 0$. In this relation we can use the fact that K^2 being the product of compact operators is compact and, therefore, we can extract a subsequence $\{f_{n'}\}$ from $\{f_n\}$ so that $\{K^2 f_{n'}\}$ converges to a function, say $\|K\|^2 g$. Thus $\lim_{n\to\infty} \|\|K^2\| g - \|K\|^2 f_{n'}\| = 0$, so that $\{f_{n'}\}$ converges to g and $K^2 g = \|K\|^2 g$. But this means that $((\|K\|)^{-1}K - 1)((\|K\|)^{-1}K + 1)g = 0$ and the result follows.

As mentioned in section III, an eigenvalue is simple if there is only one corresponding eigenfunction, otherwise the eigenvalue is called degenerate. The spectrum of K is the set of all eigenvalues, in view of the above-mentioned property we find that the *spectrum of a Hermitian kernel is never empty*.

B. Property 2

The eigenvalues of a Hermitian operator K are all real.

1. Proof

Suppose $\lambda K\phi = \phi$. Then by taking the inner product of this relation with ϕ, we have $\lambda\langle K\phi, \phi\rangle = \|\phi\|^2$ or $\lambda = \|\phi\|^2/\langle K\phi, \phi\rangle$. As already observed $\langle K\phi, \phi\rangle$ is real for a Hermitian kernel. The quantity $\|\phi\|^2$ is also real. Thus λ is real.

C. Property 3

All eigenfunctions of a Hermitian operator K corresponding to distinct eigenvalues are orthogonal.

1. Proof

Let ϕ_1 and ϕ_2 be the eigenfunctions corresponding respectively, to the distinct eigenvalues λ_1 and λ_2. Then we have $\lambda_1 K\phi_1 = \phi_1$ and $\lambda_2 K\phi_2 = \phi_2$ so that $\langle K\phi_1, \phi_2\rangle = \lambda_1^{-1}\langle \phi_1, \phi_2\rangle$ and also $\langle K\phi_1, \phi_2\rangle = \langle \phi_1, K\phi_2\rangle = \lambda_2^{-1}\langle \phi_1, \phi_2\rangle$. Thus $\lambda_2\langle \phi_1, \phi_2\rangle = \lambda_1\langle \phi_1, \phi_2\rangle$. Since $\lambda \neq \lambda_2$, we find that $\langle \phi_1, \phi_2\rangle = 0$, as desired.

D. Property 4

The multiplicity of any nonzero eigenvalue is finite for every Hermitian operator K with $\mathcal{L}_2$ kernel.

1. Proof

Let the functions $\phi_{1\lambda}(x), \phi_{2\lambda}(x), \ldots, \phi_{n\lambda}(x), \ldots$ be the linearly independent eigenfunctions which correspond to a nonzero eigenvalue λ. We appeal to the Gram–Schmidt process and then find linear combinations of

these functions which form an orthonormal system $\{u_{k\lambda}(x)\}$. Their complex conjugate functions $\{\overline{u_{k\lambda}(x)}\}$ also form an orthonormal system. Let the function $K(x, y)$ with fixed x be written as $K(x, y) \sim \sum_i a_i \overline{u_{i\lambda}}(y)$, where $a_i = \int K(x, y) u_{i\lambda}(y)\, dy = u_{i\lambda}(x)/\lambda$. By applying the Bessel inequality (40) to this series, we have $\int |K(x, y)|^2\, dy \geq \sum_i (\lambda^{-1})^2 |u_{i\lambda}(x)|^2$, which, when integrated, yields the inequality

$$\int\int |K(x, y)|^2\, dx\, dy \geq \sum_i (\lambda^{-1})^2 = \frac{m}{\lambda^2}$$

where m is the multiplicity of λ. But K is an $\mathscr{L}_2$ kernel so the left-hand side of this relation is finite. It follows that m is finite.

E. Property 5

The sequence of eigenfunctions of a Hermitian kernel K can be made orthonormal.

1. Proof

Suppose that, corresponding to a certain eigenvalue, there are m linearly independent eigenfunctions. Because K is a linear operator, every linear combination of these functions is also an eigenfunction. Thus, by the Gram–Schmidt procedure, we can get an equivalent number of eigenfunctions which are orthonormal. On the other hand, for distinct eigenvalues, the corresponding eigenfunctions are orthogonal and can be readily normalized. Combining these two parts we have established the required property.

F. Property 6

The eigenvalues of a Hermitian operator K with $\mathscr{L}_2$ kernel form a finite or an infinite sequence $\{\lambda_n\}$ with no finite limit point. Furthermore, if we include each eigenvalue in the sequence a number of times equal to its algebraic multiplicity, then

$$\sum_{n=1}^{\infty} \left(\lambda_n^{-1}\right)^2 \leq \int\int |K(x, y)|^2\, dx\, dy$$

The proof of this property can be presented by a slight extension of the arguments given in the analysis of Property 4.

G. Property 7

The set of eigenvalues of the nth iterated kernel coincide with the set of nth powers of the eigenvalues of the kernel K(x, y).

1. Proof

Let λ be an eigenvalue of K with corresponding eigenfunction $\phi(x)$ so that $(I - \lambda K)\phi = 0$, where I is the identity operator. The result of operating on both sides of this equation with the operator $(I + \lambda K)$ yields $(I - \lambda^2 K^2)\phi = 0$, or

$$\phi(x) - \lambda^2 \int K_2(x, y)\phi(y)\, dy = 0,$$

which proves that λ^2 is an eigenvalue of the kernel $K_2(x, y)$. Conversely, if λ^2 is an eigenvalue $K_2(x, y)$, with $\phi(x)$ as its corresponding eigenfunction $\phi(x)$, we have

$$(I - \lambda^2 K^2)\phi = 0$$

or

$$(I - \lambda K)(I + \lambda K)\phi = 0$$

If λ is an eigenvalue of K this equation is satisfied and we have established the property for $n = 2$. Otherwise, we set $[(I + \lambda K)]\phi(x) = \mathscr{X}(x)$ so that the above equation becomes $(I - \lambda K)\mathscr{X}(x) = 0$. Since we have assumed that λ is not an eigenvalue of K, it follows that $\mathscr{X}(x) \equiv 0$. This means that $(I + \lambda K)\phi = 0$, or $-\lambda$ is an eigenvalue and we have again proved our result for $n = 2$. The general result follows by continuing this process.

In the next stage we wish to expand a nonzero Hermitian kernel in terms of its eigenfunctions. It may have a finite or infinite number of real eigenvalues. We order them in the sequence $\lambda_1, \lambda_2, \ldots, \lambda_n, \ldots$ in such a way that

1. Each eigenvalue is repeated as many times as its multiplicity, and
2. we enumerate these eigenvalues in an order which corresponds to their absolute values (i.e., $0 < |\lambda_1| \leq |\lambda_2| \leq \cdots \leq |\lambda_n| \leq |\lambda_{n+1}| \leq \cdots$).

Let $\phi_1(x), \phi_2(x), \ldots, \phi_n(x), \ldots$ be the sequence of corresponding orthonormalized eigenfunctions which are arranged in such a way that they are no longer repeated and are linearly independent in each group corresponding to the same eigenvalue. Thus to each eigenvalue λ_k there corresponds just one eigenfunction $\phi_k(x)$. We shall have this ordering in mind in the sequel.

Property 1 has assured us that a nonzero Hermitian kernel always has a finite, nonzero lowest eigenvalue λ_1. Let ϕ_1 be the corresponding eigenfunction. Now we remove this eigenvalue from the spectrum of K by defining the truncated kernel $K^{(2)}(x, y)$:

$$K^{(2)}(x, y) = K(x, y) - (\phi_1(x)\bar{\phi}_1(y)/\lambda_1)$$

which is also Hermitian. If $K^{(2)}(x, y)$ is nonzero then let λ_2 be its lowest eigenvalue with corresponding eigenfunction $\phi_2(x)$. Because

$$K^{(2)}\phi_1 = K\phi_1 - (\phi_1(x)/\lambda_1)\int \phi_1(y)\phi_1(y)\,dy = 0$$

we observe that $\phi_1 \neq \phi_2$ even if $\lambda_1 = \lambda_2$. Similarly, the third truncated Hermitian kernel is

$$K^{(3)}(x,y) = K^{(2)}(x,y) - \phi_2(x)\frac{\overline{\phi_2}(y)}{\lambda_2}$$
$$= K(x,y) - \sum_{k=1}^{2}\frac{\phi_k(x)\overline{\phi_k}(y)}{\lambda_k}$$

Continuing this process we have

$$K^{(n+1)}(x,y) = K(x,y) - \sum_{k=1}^{n}\frac{\phi_k(x)\overline{\phi_k}(y)}{\lambda_k}, \qquad (41)$$

which yields the $(n+1)$th lowest eigenvalue and the corresponding eigenfunction $\phi_{n+1}(x)$. Thereby we find that either this process terminates after n steps (i.e., $K^{(n+1)}(x,y) = 0$), and the kernel $K(x,y)$ is a degenerate kernel $\sum_{k=1}^{n}(\phi_k(x)\overline{\phi_k}(y)/\lambda_k)$, or the process can be continued indefinitely and there are an infinite number of eigenvalues and eigenfunctions so that

$$K(x,y) = \sum_{k=1}^{\infty}\frac{\phi_k(x)\overline{\phi_k}(y)}{\lambda_k}. \qquad (42)$$

This is called the bilinear form of the kernel. Recall that we meet a similar situation for a Hermitian matrix **A**. Indeed, by transforming to an orthonormal basis of the vector space consisting of the eigenvectors of **A** we can transform it to a diagonal matrix.

From the bilinear form (42) we derive a useful inequality. Let the sequence $\{\phi_k(x)\}$ be all the eigenfunctions of a Hermitian $\mathscr{L}_2$ kernel $K(x,y)$ with $\{\lambda_k\}$ as the corresponding eigenvalues as described and arranged in the above analysis. Then the series

$$\sum_{n=1}^{\infty}\frac{|\phi_n(x)|^2}{\lambda_n^2} < C_1^2, \qquad (43)$$

where C_1^2 is an upper bound of the integral $\int |K(x,y)|^2\,dy$. The proof follows by observing that the Fourier coefficients a_n of the function $K(x,y)$ with fixed x, with respect to the orthonormal system $\overline{\phi_n}(y)$ are $a_n = \langle K(x,y), \bar{\phi}_n(y)\rangle = \phi_n(x)\lambda_n$. Substituting these values of a_n in the Bessel inequality (40) we derive (43).

The eigenfunctions do not have to form a complete set in order to represent the functions in $\mathscr{L}_2$. Indeed, any function which can be written as "sourcewise" in terms of the kernel K (i.e., any function $f = Kh$) can be expanded in a series of the eigenfunctions of K. This is not surprising because integration smooths out irregularities or if the functions f, K, and h are represented by the series, then the convergence of the series representing f will be better than that of the series representing K and h. This important concept for a Hermitian kernel is embodied in the theorem.

H. Hilbert–Schmidt Theorem

If $f(x)$ can be written in the form

$$f(x) = \int K(x,y)h(y)\,dy, \qquad (44)$$

where K and h are in $\mathscr{L}_2$ space, then $f(x)$ can be expanded in an absolutely and uniformly convergent Fourier series with respect to the orthonormal system of eigenfunctions of K, that is,

$$f(x) = \sum_{n=1}^{\infty} f_n\phi_n(x), \quad f_n = \langle f, \phi_n\rangle. \qquad (45a)$$

The Fourier coefficients f_n are related to the corresponding coefficients h_n of $h(x)$ as

$$f_n = h_n/\lambda_n = \langle h, \phi_n\rangle/\lambda_n \qquad (45b)$$

and λ_n are the eigenvalues of K.

1. Proof

The Fourier coefficients of the function $f(x)$ with respect to the orthonormal system $\{\phi_n(x)\}$ are

$$f_n = \langle f, \phi_n\rangle = \langle Kh, \phi_n\rangle = \langle h, K\phi_n\rangle$$
$$= \langle h, \phi_n\rangle/\lambda_n = h_n/\lambda_n$$

because K is self-adjoint and $\lambda_n K\phi_n = \phi_n$. Accordingly, we can write the correspondence

$$f(x) \sim \sum_{n=1}^{\infty} f_n\phi_n(x) = \sum_{n=1}^{\infty}\frac{h_n\phi_n(x)}{\lambda_n}. \qquad (46)$$

The estimate of the remainder term for this series is

$$\left|\sum_{k=n+1}^{n+p} h_k\frac{\phi_k(x)}{\lambda_k}\right|^2 \leq \sum_{k=n+1}^{n+p} h_k^2 \sum_{k=n+1}^{n+p}\frac{|\phi_k(x)|^2}{\lambda_k^2}$$
$$\leq \sum_{k=n+1}^{n+p} h_k^2 \sum_{k=1}^{\infty}\frac{|\phi_k^2(x)|}{\lambda_k^2} \qquad (47)$$

Now the series $\sum_{k=1}^{\infty}|\phi_k^2(x)|/\lambda_k^2$ is bounded in view of relation (43) while the partial sum $\sum_{k=n+1}^{n+p} h_k^2$ can be made arbitrarily small because $h(x) \in \mathscr{L}_2$ and, as such, the series $\sum_{k=1}^{\infty} h_k^2$ is convergent. Thus, the estimate (47) can be made arbitrarily small so that series (46) converges absolutely and uniformly. Next, we show that this series converges to $f(x)$ in the mean and for this purpose we denote its partial sum as $\psi_n(x) = \sum_{m=1}^{n}(h_m/\lambda_m)\phi_m(x)$ and estimate the value $\|f(x) - \psi_n(x)\|$. Because

$$f(x) - \psi_n(x) = Kh - \sum_{m=1}^{n}\frac{h_m}{\lambda_m}\phi_m(x) = K^{(n+1)}h,$$

where K^{n+1} is the truncated kernel (41), we find that

$$\begin{aligned}\|f(x)-\psi_n(x)\|^2 &= \left\|K^{(n+1)}h\right\|^2\\ &= \left\langle K^{(n+1)}h,\, K^{(n+1)}h\right\rangle\\ &= \left\langle h,\, K^{(n+1)}K^{(n+1)}h\right\rangle\\ &= \left\langle h,\, K_2^{(n+1)}h\right\rangle \qquad (48)\end{aligned}$$

in view of the self-adjointness of the kernel $K^{(n+1)}$ and the relation $K^{(n+1)}K^{(n+1)} = K_2^{(n+1)}$. Now we use Property 7 for the Hermitian kernels and find that the least eigenvalue of the kernel $K_2^{(n+1)}$ is λ_{n+1}^2. On the other hand, Property 1 implies that

$$\begin{aligned}1/\lambda_{n+1}^2 &= \sup\left\|K^{(n+1)}h\right\|^2/\|h\|^2\\ &= \sup\left(\left\langle h,\, K_2^{(n+1)}h\right\rangle\right)/\|h\|^2.\end{aligned}$$

Combining it with (48) we get $\|f(x)-\psi_n(x)\|^2 \le \|h\|^2/\lambda_{n+1}^2$. Because $\lambda_{n+1}\to\infty$, we have proved that $\|f(x)-\psi_n(x)\|\to 0$ as $n\to\infty$.

In order to prove that $f=\psi$, where ψ is the series with partial sum ψ_n, we use the Minkowski inequality (6) and get $\|f-\psi\| \le \|f-\psi_n\| + \|\psi_n-\psi\|$. The first term on the right-handside of this inequality tends to zero as proved above. Because series (47) converges uniformly, the second term can be made as small as we want (i.e., given an arbitrarily small and positive ε we can find n large enough that $|\psi_n-\psi|<\varepsilon$). One integration then yields $\|\psi_n-\psi\|<\varepsilon(b-a)^{1/2}$ and we have proved the result.

Let us now use the foregoing theorem for solving the inhomogeneous Fredholm integral equation of the second kind:

$$g(x) = f(x) + \lambda\int K(x,y)g(y)\,dy, \qquad (49)$$

with a Hermitian $\mathscr{L}_2$ kernel. First, we assume that λ is not an eigenvalue of K. Because $g(x)-f(x)$ in this equation has the integral representation of the form (44) we expand both $g(x)$ and $f(x)$ in terms of the eigenfunctions $\phi_n(x)$ given by the homogeneous equation $\phi_n(x)=\lambda_n\int K(x,y)\phi_n(y)\,dy$. Accordingly, we set

$$g(x)=\sum_{n=1}^{\infty} g_n\phi_n(x), \qquad f(x)=\sum_{n=1}^{\infty} f_n\phi_n(x), \qquad (50)$$

where $g_n=\langle g,\phi_n\rangle$ is unknown and $f_n=\langle f,\phi_n\rangle$ is known. Substituting these expansions in (49) we obtain

$$\sum_{n=1}^{\infty} g_n\phi_n(x) = \sum_{n=1}^{\infty} f_n\phi_n(x) + \lambda\int K(x,y)\sum_{n=1}^{\infty} g_n\phi_n(y)\,dy. \qquad (51)$$

In view of the uniform convergence of the expansion, we can interchange the order of integration and summation, and get

$$\sum_{n=1}^{\infty} g_n\phi_n(x) = \sum_{n=1}^{\infty} f_n\phi_n(x) + \lambda\sum_{n=1}^{\infty}\frac{g_n\phi_n(x)}{\lambda_n} \qquad (52)$$

Now we multiply both sides of (52) by $\overline{\phi_k(x)}$ and integrate from a to b and appeal to the orthogonality of the eigenfunctions and obtain

$$g_k = f_k + (\lambda/\lambda_k)g_k \qquad (53a)$$

or

$$g_k = f_k + (\lambda/(\lambda_k-\lambda))\,f_k. \qquad (53b)$$

Substitution of (53) into (50) leads us to the required solution

$$\begin{aligned}g(x) &= \sum_{n=1}^{\infty}\left(f_n + \frac{\lambda}{(\lambda_n-\lambda)}f_n\right)\phi_n(x)\\ &= f(x) + \lambda\sum_{n=1}^{\infty}\int\frac{\phi_n(x)\overline{\phi_n}(y)}{(\lambda_n-\lambda)}f(y)\,dy\\ &= f(x) + \lambda\int\Gamma(x,y;\lambda)f(y)\,dy, \qquad (54)\end{aligned}$$

where the resolvent kernel $\Gamma(x,y;\lambda)$ is expressed by the series

$$\Gamma(x,y;\lambda)=\sum_{n=1}^{\infty}\frac{\phi_n(x)\overline{\phi_n}(y)}{\lambda_n-\lambda}, \qquad (55)$$

and we have again interchanged the integration and summation. It follows from expression (55) that the singular points of the resolvent kernel Γ corresponding to a Hermitian $\mathscr{L}_2$ kernel are simple poles and every pole is an eigenvalue of the kernel.

In the event that λ in Eq. (49) is equal to one of the eigenvalues, say, λ_p of K, solution (55) becomes infinite. To remedy it we return to relation (53) which for $k=p$ becomes $g_p=f_p+g_p$. Thus, g_p is arbitrary and $f_p=0$. This implies that $\int f(x)\phi_p(x)\,dx=0$ (i.e., $f(x)$ is orthogonal to the eigenfunction $\phi_p(x)$). If this is not the case, we have no solution. If λ_p has the algebraic multiplicity m, then there are m coefficients g_p which are arbitrary and $f(x)$ is orthogonal to all these m functions.

Integral equations arise in the process of inverting ordinary and partial differential operators. In the quest for the representation formula for the solutions of these operators so as to include the initial or boundary values in it, we arrive at integral equations. In the process there arises the theory of Green's functions which are symmetric and become the kernels of the integral equations. If they are not symmetric, then they can be symmetrized. We illustrate these concepts with the help of the Sturm–Liouville differential operator

$$L = -\frac{d}{dx}\left\{p(x)\frac{d}{dx}\right\} + q(x)$$

where $p(x)$ and $q(x)$ are continuous in the interval $[a, b]$ and in addition $p(x)$ has a continuous derivative and does not vanish in this interval. We discuss two kinds of equations, that is,

$$Ly = f(x), \qquad a \le x \le b \tag{56}$$

and

$$Ly - \lambda r(x)y = 0, \tag{57}$$

where $f(x)$ and $r(x)$ are given functions. The function $r(x)$ is continuous and nonnegative in $[a, b]$. Each of these equations is subject to the boundary conditions

$$\begin{aligned} \alpha_1 y(a) + \alpha_2 y'(a) &= 0 \\ \beta_1 y(b) + \beta_2 y'(b) &= 0. \end{aligned} \tag{58}$$

Let us assume that it is not possible to obtain a nonzero solution of system (57) and (58) for the case $\lambda = 0$ (this means that there is no eigenfunction corresponding to the eigenvalue $\lambda = 0$). Accordingly, we assume that a function ϕ_1 satisfies the boundary condition $(58)_1$: $\alpha_1\phi_1(a) + \alpha_2\phi_1'(a) = 0$ and another function ϕ_2 (independent of ϕ_1) satisfies the boundary condition $(58)_2$: $\beta_1\phi_2(b) + \beta_2\phi_2'(b) = 0$. This amounts to solving two initial value problems, namely, $L\phi_1 = 0$, $\phi_1(a) = -\alpha_2$, $\phi_1'(a) = \alpha_1$ and $L\phi_2 = 0$, $\phi_2(b) = -\beta_2$, $\phi_2'(b) = \beta_1$. With the help of these two linearly independent solutions ϕ_1 and ϕ_2 we use the method of variation of parameters and assume the solution of the inhomogeneous equation (56) as

$$y(x) = C_1(x)\phi_1(x) + C_2(x)\phi_2(x), \tag{59}$$

where C_1 and C_2 must be found from the relations

$$C_1'(x)\phi_1(x) + C_2'(x)\phi_2(x) = 0 \tag{60a}$$

$$C_1'(x)\phi_1'(x) + C_2'(x)\phi_2'(x) = -f(x)/p(x). \tag{60b}$$

We need one more relation for ϕ_1 and ϕ_2 to facilitate the solution of (56). This is found from the fact that ϕ_1 and ϕ_2 are two linearly independent solutions of the homogeneous equation $Ly = 0$. As such

$$\begin{aligned} 0 &= \phi_2 L\phi_1 - \phi_1 L\phi_2 \\ &= -\phi_2\frac{d}{dx}\left(p\frac{d\phi_1}{dx}\right) + \phi_1\frac{d}{dx}\left(p\frac{d\phi_2}{dx}\right) \\ &= -\frac{d}{dx}\left\{p\left(\phi_2\frac{d\phi_1}{dx} - \phi_1\frac{d\phi_2}{dx}\right)\right\}, \end{aligned}$$

so that the quantity within the braces is a constant. Inasmuch as ϕ_1 and ϕ_2 can be determined up to a constant factor, we can choose this expression to be

$$p\left(\phi_2\frac{d\phi_1}{dx} - \phi_1\frac{d\phi_2}{dx}\right) = -1. \tag{61}$$

From relations (60) and (61) we find that $C_1'(x) = -\phi_2(x)f(x)$ and $C_2'(x) = \phi_1(x)f(x)$. Thus

$$C_1(x) = \int_x^b \phi_2(\xi)f(\xi)\,d\xi$$

$$C_2(x) = \int_a^x \phi_1(\xi)f(\xi)\,d\xi,$$

with convenient constants of integration. Substituting these values in (59) we arrive at the solution

$$\begin{aligned} y(x) &= \phi_1(x)\int_x^b \phi_2(\xi)f(\xi)\,d\xi \\ &\quad + \phi_2(x)\int_a^x \phi_1(\xi)f(\xi)\,d\xi \\ &= \int_a^b G(x,\xi)f(\xi)\,d\xi, \end{aligned} \tag{62}$$

where the function

$$G(x,\xi) = \begin{cases} \phi_1(\xi)\phi_2(x), & \xi \le x \\ \phi_1(x)\phi_2(\xi), & \xi \ge x \end{cases} \tag{63}$$

is called the Green's function of this boundary value problem. It can be written in an elegant form by defining the regions

$$x_< = \min(x,\xi) = \begin{cases} x, & a \le x \le \xi \\ \xi, & \xi \le x \le b \end{cases}$$

$$x_> = \max(x,\xi) = \begin{cases} \xi, & a \le x \le \xi \\ x, & \xi \le x \le b. \end{cases}$$

Then $G(x,\xi) = \phi_1(x_<)\phi_2(x_>)$.

Finally, we attend to Eq. (57) whose solution follows from (62) to be

$$y(x) = \lambda\int r(\xi)G(x,\xi)y(\xi)\,d\xi. \tag{64}$$

This is an integral equation with kernel $r(\xi)G(x,\xi)$. Although this kernel is not symmetric, it can be symmetrized by setting $[r(x)]^{1/2}y(x) = g(x)$ and defining the symmetric kernel $K(x,y) = G(x,\xi)[r(x)]^{1/2}[r(\xi)]^{1/2}$. Then (64) becomes the integral equation

$$g(x) = \lambda\int K(x,y)g(y)\,dy. \tag{65}$$

If there was a term on the right-hand side of (57) we would have arrived at an inhomogeneous integral equation of the second kind. Incidentally, it can be readily verified that Eq. (64) satisfies the given boundary conditions. The case

when $\lambda = 0$ has a nonzero eigenfunction can be handled by a slight extension of the foregoing arguments.

The theory of Green's functions as derived above can be displayed very elegantly with the help of the Dirac delta function and other generalized functions.

VI. SINGULAR INTEGRAL EQUATIONS ON THE REAL LINE

An integral equation is said to be singular either if the kernel is singular within the range of integration or if one or both limits of integration are infinite. In this section we study some famous singular integral equations. They arise very frequently in various branches of physics and engineering. No general theory is available for these equations but methods are available for solving some special cases. We start with the Abel integral equation.

A. The Abel Integral Equation

This equation is

$$f(x) = \int_a^x \frac{g(y)}{(x-y)^\alpha}\,dy, \qquad 0 < \alpha < 1. \tag{66}$$

To solve it we multiply both sides of this equation by $dx/(u-x)^{1-\alpha}$ and integrate with respect to x from a to u so that we have

$$\int_a^u \frac{f(x)\,dx}{(u-x)^{1-\alpha}} = \int_a^u \frac{dx}{(u-x)^{1-\alpha}} \int_a^x \frac{g(y)\,dy}{(x-y)^\alpha}.$$

When we change the order of integration on the right-hand side of this equation we have

$$\int_a^u \frac{f(x)\,dx}{(u-x)^{1-\alpha}} = \int_a^u g(y)\,dy \int_y^u \frac{dx}{(u-x)^{1-\alpha}(x-y)^a}. \tag{67}$$

Next, we set $t = (u-x)/(u-y)$ in the second integral so that

$$\int_y^u (u-x)^{\alpha-1}(x-y)^{-\alpha}\,dx = \int_0^1 t^{\alpha-1}(1-t)^{-\alpha}\,dt = \frac{\pi}{\sin\alpha\pi},$$

where we have used the value of the Eulerian beta function $B(\alpha, 1-\alpha) = \pi \csc \alpha\pi$. Thus relation (67) becomes

$$\frac{\sin\alpha\pi}{\pi} \int_a^u \frac{f(x)\,dx}{(u-x)^{1-\alpha}} = \int_a^u g(y)\,dy. \tag{68}$$

Differentiation of this relation finally yields the solution

$$g(y) = \frac{\sin\alpha\pi}{\pi} \frac{d}{dy}\left[\int_a^y \frac{f(x)}{(y-x)^{1-\alpha}}\,dx\right]. \tag{69}$$

Similarly, the solution of the integral equation

$$\int_s^b \frac{g(y)}{(y-x)^\alpha}\,dy = f(s), \qquad 0 < \alpha < 1 \tag{70}$$

is

$$g(y) = -\frac{\sin\alpha\pi}{\pi} \frac{d}{dy}\left[\int_y^b \frac{f(x)}{(x-y)^{1-\alpha}}\,dx\right]. \tag{71}$$

There are many related integral equations which can be solved by similar steps. For instance, the solution of the integral equation

$$f(x) = \int_a^x \frac{g(y)\,dy}{[h(x)-h(y)]^\alpha}, \qquad 0 < \alpha < 1, \tag{72}$$

where the function $h(x)$ is strictly increasing differentiable function with nonzero $h'(x)$ over some interval $a \le x \le b$, is

$$g(y) = \frac{\sin\alpha\pi}{\pi} \frac{d}{dy}\left[\int_a^y \frac{h'(u)\,f(u)\,du}{[h(y)-h(u)]^{1-\alpha}}\right]. \tag{73}$$

Similarly, the solution of the integral equation

$$f(x) = \int_x^b \frac{g(y)\,dy}{[h(y)-h(x)]^\alpha}, \qquad 0 < \alpha < 1 \tag{74}$$

is

$$g(y) = -\frac{\sin\alpha\pi}{\pi} \frac{d}{dy}\left[\int_y^b \frac{h'(u)\,f(u)\,du}{[h(u)-h(y)]^{1-\alpha}}\right]. \tag{75}$$

These relations remain valid when $a \to -\infty$ and $b \to \infty$.

B. The Cauchy Integral Equation

The equation

$$g(x) = f(x) + \lambda \int_0^1 \frac{g(y)\,dy}{y-x} \tag{76}$$

is the inhomogeneous Cauchy integral equation. Here the integral is the Cauchy principal value. To solve this equation we appeal to the identity

$$\int_0^u \frac{dy}{(u-y)^{\alpha-1}y^\alpha(y-x)} = \begin{cases} \dfrac{\pi\cot\alpha\pi}{(u-x)^{1-\alpha}x^\alpha}, & 0 < x < u \\ \dfrac{-\pi\csc\alpha\pi}{(x-u)^{1-\alpha}x^\alpha}, & u < x \end{cases} \tag{77}$$

and then define the function $\phi(x,u)$ as

$$\phi(x,u) = \frac{1}{(u-x)^{1-\alpha}x^\alpha}, \qquad 0 < x < u, \tag{78}$$

where α is such that $-\pi\cot\alpha\pi = (1/\lambda)$. Then $\phi(x,u)$ is the solution of the integral equation

$$-\lambda \int_0^u \frac{\phi(y,u)}{y-x}\,dy = \phi(x,u), \qquad 0 < x < u \tag{79}$$

while

$$\int_0^u \frac{\phi(y,u)}{y-x}\,dy = -\frac{\pi \csc \alpha\pi}{(x-u)^{1-\alpha}x^{\alpha}}, \qquad u < x. \quad (80)$$

When we multiply (76) by x we get

$$\lambda \int_0^1 \frac{yg(y)\,dy}{y-x} = xg(x) - xf(x) + c, \quad (81)$$

where $c = \lambda \int_0^1 g(y)\,dy$. Next, we multiply both sides of (81) by $\phi(x,u)$ as defined by (78), integrate from 0 to u and change the order of integration. The result is

$$\begin{aligned} &-\lambda \int_0^u yg(y)\,dy \int_0^u \frac{\phi(x,u)\,dx}{x-y} \\ &-\lambda \int_u^1 yg(y)\,dy \int_0^u \frac{\phi(x,u)\,dx}{x-y} \\ &= \int_0^u xg(x)\phi(x,u)\,dx \\ &\quad - \int_0^u xf(x)\phi(x,u)\,dx + c\int_0^u \phi(x,u)\,dx. \end{aligned}$$

With the help of relations (79) and (80) and the fact that $\int_0^u \phi(x,u)\,dx = \pi \csc \alpha\pi$, the above relation becomes

$$\begin{aligned} &\lambda\pi \csc\alpha\pi \int_u^1 \frac{y^{1-\alpha}g(y)}{(y-u)^{1-\alpha}}\,dy \\ &\quad = -\int_0^u xf(x)\phi(x,u)\,dx + c\pi \csc\alpha\pi \end{aligned} \quad (82)$$

This is an Abel-type integral equation whose solution is found from the previous analysis to be

$$\begin{aligned} \lambda y^{1-\alpha}g(y) = \frac{\sin^2\alpha\pi}{\pi^2}\frac{d}{dy}\Bigg[\int_y^1 \int_0^u (u-y)^{-\alpha} \\ \times (u-x)^{\alpha-1}x^{1-\alpha} f(x)\,dx\,dy\Bigg] + \frac{c\sin\alpha\pi}{\pi(1-y)^{\alpha}} \end{aligned} \quad (83)$$

Now we use the relation $-\pi \cot\alpha\pi = 1/\lambda$ and do a little algebraic manipulation and obtain the required solution as

$$\begin{aligned} g(x) = -\frac{f(x)}{1+\pi^2\lambda^2} + \frac{\lambda}{(1+\pi^2\lambda^2)x^{1-\alpha}(1-x)^{\alpha}} \\ \times \int_0^1 \frac{(1-y)^{\alpha}y^{1-\alpha}f(y)\,dy}{y-x} \\ + \frac{c}{x^{1-\alpha}(1-x)^{\alpha}\sqrt{1+\pi^2\lambda^2}}. \end{aligned} \quad (84)$$

Finally, we set $y = (y'-a)/(b-a)$, and find from the above analysis that the solution of the integral equation

$$g(x) = f(x) + \lambda \int_a^b \frac{g(y)\,dy}{y-x} \quad (85)$$

is

$$\begin{aligned} g(x) = -\frac{f(x)}{1+\pi^2\lambda^2} + \frac{\lambda}{(1+\pi^2\lambda^2)(x-a)^{1-\alpha}(b-x)^{\alpha}} \\ \times \int_a^b \frac{(b-y)^{\alpha}(y-a)^{1-\alpha}f(y)\,dy}{y-x} \\ + \frac{c}{(x-a)^{1-\alpha}(b-x)^{\alpha}}, \end{aligned} \quad (86)$$

where c is an arbitary constant.

The solution of the Cauchy-type integral equation of the first kind:

$$\int_a^b \frac{g(y)\,dy}{y-x} = f(x), \qquad a < x < b \quad (87)$$

can be obtained with a very similar analysis and is

$$\begin{aligned} g(x) = \frac{1}{\pi^2\sqrt{(x-a)(b-x)}} \\ \times\Bigg[\int_a^b \frac{\sqrt{(y-a)(b-y)}}{x-y} f(y)\,dy + \pi c\Bigg]. \end{aligned} \quad (88)$$

In particular, when $a = -1$, $b = 1$, it follows that the solution of the *airfoil equation*

$$\frac{1}{\pi}\int_{-1}^1 \frac{g(y)\,dy}{y-x} = f(x), \qquad -1 < x < 1 \quad (89)$$

is

$$g(x) = \frac{1}{\pi\sqrt{1-x^2}}\int_{-1}^1 \frac{\sqrt{(1-y^2)}f(y)}{x-y}\,dy + \frac{c}{\sqrt{1-x^2}}. \quad (90)$$

C. Singular Integral Equations with a Logarithmic Kernel

We start with the integral equation

$$\int_{-1}^1 \ln|x-y| g_0(y)\,dy = 1, \qquad -1 < x < 1. \quad (91)$$

By setting $x = \cos\alpha$, $y = \cos\beta$, Eq. (91) becomes

$$\int_0^{\pi} \ln|\cos\alpha - \cos\beta| G(\beta)\,d\beta = 1, \quad 0 < \alpha < \pi, \quad (92)$$

where $G(\beta) = g_0(\cos\beta)\sin\beta$. Let us now expand $G(\beta) = \sum_{n=0}^{\infty} b_n \cos n\beta$ and use the summation formula

$$\ln|\cos\alpha - \cos\beta| = -\ln 2 - 2\sum_{n=1}^{\infty} \frac{\cos n\alpha \cos n\beta}{n}. \quad (93)$$

Then relation (92) becomes

$$\int_0^\pi \left[-\ln 2 - 2\sum_{n=1}^{\infty} \frac{\cos n\alpha \cos n\beta}{n} \right] \times \left[\sum_{m=0}^{\infty} b_m \cos m\beta \right] d\beta = 1,$$

from which it follows, due to orthogonality of cosine functions, that

$$-\pi b_0 \ln 2 - \sum_{n=1}^{\infty} \pi b_n \frac{\cos n\alpha}{n} = 1.$$

Thus, $b_0 = -(1/(\pi \ln 2))$, $b_n = 0$, $n \geq 1$, and we find that the solution of Eq. (91) is

$$g_0(y) = -\frac{1}{\pi \ln 2} \frac{1}{\sqrt{1-y^2}}. \tag{94}$$

In passing we observe that by substituting solution (94) in (91) we have the useful identity

$$\int_{-1}^{1} \frac{\ln|x-y|}{(1-y^2)^{1/2}}\, dy = -\pi \ln 2, \quad -1 < x < 1. \tag{95}$$

Next, we consider the integral equation

$$\int_{-1}^{1} \ln|x-y| g(y)\, dy = f(x), \quad -1 < x < 1. \tag{96}$$

Differentiation with respect to x gives

$$\int_{-1}^{1} \frac{g(y)}{x-y}\, dy = f'(x), \quad -1 < x < 1,$$

whose solution follows from (90) to be

$$g(x) = \frac{1}{\pi^2} \int_{-1}^{1} \left[\frac{1-y^2}{1-x^2} \right]^{1/2} \frac{f'(y)}{y-x}\, dy + \frac{C}{\pi\sqrt{1-x^2}}, \tag{97}$$

where $C = \int_{-1}^{1} g(y)\, dy$. To find the constant C, we multiply (96) by $1/\sqrt{(1-x^2)}$ and integrate it with respect to x from -1 to 1 and change the order of integration. The result is

$$\int_{-1}^{1} g(y)\, dy \int_{-1}^{1} \frac{\ln|x-y|}{(1-x^2)^{1/2}}\, dx = \int_{-1}^{1} \frac{f(x)}{(1-x^2)^{1/2}}\, dx,$$

which, in view of identity (95), becomes

$$(-\pi \ln 2)C = \int_{-1}^{1} \frac{f(x)}{(1-x^2)^{1/2}}\, dx.$$

Thus

$$C = -\frac{1}{\pi \ln 2} \int_{-1}^{1} \frac{f(x)}{(1-x^2)^{1/2}}\, dx,$$

which when substituted in (97) yields the solution

$$g(x) = \frac{1}{\pi^2} \int_{-1}^{1} \left(\frac{1-y^2}{1-x^2} \right)^{1/2} \frac{f'(y)}{y-x}\, dx - \frac{1}{\pi^2 \ln 2 (1-x^2)^{1/2}} \int_{-1}^{1} \frac{f(y)}{(1-y^2)^{1/2}}\, dy. \tag{98}$$

Various other forms of integral equations with logarithmic kernels can be solved in a similar fashion.

VII. THE CAUCHY KERNEL AND THE RIEMANN–HILBERT PROBLEM

For the study of the singular equations in the complex plane $\mathbb{C}$, we require a few important results from the analysis of a complex variable. We present some of these concepts needed for the Cauchy kernel. Let C be a simple, smooth, and closed curve in the complex z plane endowed with the counterclockwise orientation. The complement $\mathbb{C}\backslash C$ consists of two parts, one interior (bounded) part S_+ and the other exterior part S_-. A function $F(z)$ defined and analytic in the complement $\mathbb{C}\backslash C$ is called a *sectionally analytic* function with discontinuity contour C. Let $f(\zeta)$ be a continuous function defined for $\zeta \in C$. The Cauchy (or analytic) representation of f is the sectionally analytic function

$$F(z) = F\{f(\zeta); z\} = \frac{1}{2\pi i} \int_C \frac{f(\zeta)\, d\zeta}{\zeta - z}, \qquad z \in \mathbb{C}\backslash C. \tag{99}$$

The boundary values $F_\pm(\omega)$ of this function on both sides of C satisfy the Plemelj relations

$$F_+(\omega) = \frac{1}{2} f(\omega) - \frac{i}{2} H(f)$$
$$F_-(\omega) = -\frac{1}{2} f(\omega) - \frac{i}{2} H(f), \tag{100}$$

where $H(f) = (1/\pi) \int_C (f(\zeta)/(\zeta - \omega))\, d\zeta, \omega \in C,$ is called the Hilbert transform of f. Solving (100) for f and $H(f)$ we get

$$f = F_+ - F_- = [F]$$
$$H(f) = \frac{1}{\pi} \int_C \frac{f(\zeta)}{\zeta - \omega}\, d\zeta = i(F_+ + F_-), \tag{101}$$

where $[F]$ is called the jump of F across C.

Now let $\Phi_1(\zeta)$ and $\Phi_2(\zeta)$ be two continuous functions defined on C. The Riemann–Hilbert problem is to find the sectionally analytic function $Y(z)$ defined on $\mathbb{C}\backslash C$ whose boundary values satisfy

$$\Phi_1(\zeta) Y_+(\zeta) - \Phi_2(\zeta) Y_-(\zeta) = \Psi(\zeta), \tag{102}$$

where $\Psi(\zeta)$ is a function given on C. We assume that Φ_1 and Φ_2 never vanish on C. It is called the normality condition. When we divide both sides of the above equation by $\Phi_1(\zeta)$ we get

$$Y_+(\zeta) = \Phi(\zeta)Y_-(\zeta) + \psi(\zeta), \tag{103}$$

where $\Phi = \Phi_2/\Phi_1$ and $\psi = \Psi/\Phi_1$. When $\psi = 0$. Eq. (103) becomes the homogeneous Riemann–Hilbert problem

$$X_+(\zeta) = \Phi(\zeta)X_-(\zeta). \tag{104}$$

To solve (103) we first reduce it to the simple form

$$W_+(\zeta) = W_-(\zeta) + \psi(\zeta) \tag{105}$$

which is obtained from (103) by taking $\Phi(\zeta) = 1$ because the solution of (105) is known to have the analytic representation

$$W(z) = F\{\psi(\zeta); z\} = \frac{1}{2\pi i}\int_C \frac{\psi(\zeta)\,d\zeta}{\zeta - z}, \tag{106}$$

where we have appealed to definition (99). We first solve the homogeneous Riemann–Hilbert problem (104). For this purpose we take the logarithm of both sides of (104), and get

$$\ln X_+(\zeta) = \ln X_-(\zeta) + \ln \Phi(\zeta), \tag{107}$$

where we assume, for the time being, that $\ln \Phi(\zeta)$ is single valued on C. A particular solution of (107) is given by the analytic representation

$$\begin{aligned}\ln X(z) &= F\{\ln \Phi(\zeta); z\} \\ &= \frac{1}{2\pi i}\int_C \frac{\ln \Phi(\zeta)\,d\zeta}{\zeta - z}.\end{aligned} \tag{108}$$

or $X(z) = e^{F\{\ln \Phi(\zeta); z\}}$, which is a sectionally analytic function that never vanishes on $\mathbb{C}\backslash C$ and whose boundary values satisfy (104) because

$$\begin{aligned}\frac{X_+(\zeta)}{X_-(\zeta)} &= \exp[F_+\{\ln \Phi(\omega); \zeta\} - F_-\{\ln \Phi(\omega); \zeta\}] \\ &= \exp[\ln \Phi(\zeta)] = \Phi(\zeta).\end{aligned}$$

Note that this basic solution is normal because $X(\infty) = 1$. Now, if $Y(z)$ is any other solution of the homogeneous problem (104) then the function $Y(z)/X(z)$, which is known to be analytic on $\mathbb{C}\backslash C$, is also analytic on C because its jump across C vanishes:

$$\left[\frac{Y}{X}\right]_+ - \left[\frac{Y}{X}\right]_- = \frac{\Phi Y_-}{\Phi X_-} - \frac{Y_-}{X_-} = 0.$$

Thus, Y/X is an entire function and the most general solution of the homogeneous Riemann–Hilbert problem is $Y(z) = P(z)X(z)$ where $P(z)$ is an entire function. It is called the fundamental solution of the Riemann–Hilbert problem (fundamental in the sense that all other solutions can be obtained from it in a suitable way).

Let us now consider the case when $\ln \Phi(\zeta)$ is multiple valued on C and introduce the number k

$$k = \frac{1}{2\pi i}\Delta_c(\ln \Phi(\zeta)) = \frac{1}{2\pi}\Delta_c(\arg \ln \Phi(\zeta)), \tag{109}$$

where $\Delta_c(f(\zeta))$ denotes the increment of the function $f(\zeta)$ when the curve C is transversed in the positive direction. Thus, k is the index of the point $z = 0$ with respect to the curve C', the image of the curve C under the function $\Phi(\zeta)$. The number k, which is always an integer, is called the *index* of the Riemann–Hilbert problem.

Let $Y(z)$ be a solution of the homogeneous Riemann–Hilbert problem (104); we define the sectionally analytic function $\bar{Y}(z)$ as

$$\begin{aligned}\bar{Y}(z) &= Y(z), && z \in S_+ \\ \bar{Y}(z) &= (z - z_0)^k Y(z), && z \in S_-\end{aligned} \tag{110}$$

Thus, $\bar{Y}(z)$ satisfies the following boundary value problem where z_0 is an arbitrary point of S_+:

$$\begin{aligned}\bar{Y}_+(\zeta) &= \Phi_0(\zeta)\bar{Y}_-(\zeta), \\ \Phi_0(\zeta) &= (z - z_0)^{-k}\Phi(\zeta)\end{aligned} \tag{111}$$

Thereby $\ln \Phi_0(\zeta)$ has become single valued and we can apply the previous analysis to conclude that the solution of (111) is $\bar{Y}(z) = P(z)\bar{X}(z)$, where $P(z)$ is a polynomial and where $\bar{X}(z) = \exp[F(\ln \phi_0(\zeta); z)]$ is the fundamental solution. Then it follows from (110) that the solutions of (104) are of the form $Y(z) = P(z)X(z)$ where $P(z)$ is an arbitrary polynomial and where the fundamental solution $X(z)$ is given by

$$X(z) = \exp\left[\frac{1}{2\pi i}\int_C \frac{\ln \Phi_0(\zeta)\,d\zeta}{\zeta - z}\right], \quad z \in S_+ \tag{112a}$$

$$X(z) = (z - z_0)^{-k}\exp\left[\frac{1}{2\pi i}\int_C \frac{\ln \Phi_0(\zeta)\,d\zeta}{\zeta - z}\right] \quad z \in S_- \tag{112b}$$

Once a fundamental solution of the Riemann–Hilbert problem has been obtained, we can solve the inhomogeneous problem (103) as follows. Let $X(z)$ be a fundamental solution and let $Y(z)$ be a solution of (103) which we can write as

$$\frac{Y_+}{X_+} = \frac{Y_-}{X_-} + \frac{\psi}{X_+} \tag{113}$$

because $\Phi = X_+/X_-$. The solution of this equation with polynomial behavior at $z = \infty$ is

$$\frac{Y(z)}{X(z)} = P(z) + F\left\{\frac{\psi(\zeta)}{X_+(\zeta)}; z\right\}.$$

Thus

$$Y(z) = P(z)X(z) + X(z)F\left\{\frac{\psi(\zeta)}{X_+(\zeta)}; z\right\}. \qquad (114)$$

This formula gives the solution of the Riemann–Hilbert problem with polynomial behavior at $z=\infty$. For obtaining the solutions that vanish at $z=\infty$, it is necessary to consider the sign of the index k. When $k \geq 0$, (114) will be a solution provided the degree of P does not exceed $k-1$. When $k<0$, however, for the solution to vanish at $z=\infty$, the polynomial $P(z)$ should vanish and so should the coefficients $\alpha_1, \alpha_2, \ldots, \alpha_{-k}$ of the Taylor expansion

$$F\left\{\frac{f(\zeta)}{X_+(\zeta)}; z\right\} = \frac{\alpha_1}{z} + \frac{\alpha_2}{z^2} + \cdots \quad \text{at} \quad z=\infty.$$

We are now ready to solve one of the most important singular integral equations, namely, the Carleman integral equation:

$$a(\zeta)g(\zeta) + \frac{b(\zeta)}{\pi i}\oint_C \frac{g(\omega)}{\omega-\zeta}\,d\omega = f(\zeta) \qquad (115)$$

over a closed contour C, where $a(\zeta)$, $b(\zeta)$, and $f(\zeta)$ are given functions on C subject to the normality condition $a^2(\zeta) - b^2(\zeta) \neq 0$. To solve this equation we appeal to the analytic representation

$$G(z) = \frac{1}{2\pi i}\oint_C \frac{g(\omega)\,d\omega}{\omega - z} \qquad (116)$$

of the unknown function $g(\zeta)$. Next, we substitute the Plemelj formulas (100) in (115) and get

$$G_+(\zeta) = \Phi(\zeta)G_-(\zeta) + \psi(\zeta), \qquad (117)$$

where

$$\Phi(\zeta) = \frac{a(\zeta)-b(\zeta)}{a(\zeta)+b(\zeta)}, \quad \psi(\zeta) = \frac{f(\zeta)}{a(\zeta)+b(\zeta)}. \qquad (118)$$

Thus, we have the Riemann–Hilbert problem (117) to solve. For this purpose we consider the index (109) and then define the fundamental solution (112). Now

$$\begin{aligned} X_+(\zeta) &= \exp\{F_+[\ln[\Phi(\omega)(\omega-z_0)^{-k}]; \zeta\} \\ &= \exp\{\tfrac{1}{2}\ln[\Phi(\zeta)(\zeta-z_0)^{-k}] + \gamma(\zeta)\} \\ &= \sqrt{\Phi(\zeta)}e^{\gamma(\zeta)}/(\zeta-z_0)^{k/2}, \end{aligned} \qquad (119)$$

where

$$\gamma(\zeta) = \frac{1}{2\pi i}\oint_C \frac{\ln[\Phi(\omega)(\omega-z_0)^{-k}]}{\omega-\zeta}\,d\omega. \qquad (120)$$

Similarly,

$$X_-(\zeta) = e^{\gamma(\zeta)}/\sqrt{\Phi(\zeta)}(\zeta-z_0)^{k/2}. \qquad (121)$$

If $k \geq 0$, the solution of the Riemann–Hilbert problem (117) is given as

$$G(z) = X(z)P(z) + X(z)F\left\{\frac{f(\zeta)}{(a(\zeta)+b(\zeta))X_+(\zeta)}; z\right\}, \qquad (122)$$

where $P(z)$ is a polynomial of degree $(k-1)$ at most. If $k<0$, the solution is

$$G(z) = X(z)F\left\{\frac{f(\zeta)}{(a(\zeta)+b(\zeta))X_+(\zeta)}; z\right\}, \qquad (123)$$

provided

$$\oint_C \{(f(\zeta)\zeta^j/(a(\zeta)+b(\zeta))X_+(\zeta))\}\,d\zeta = 0$$

for

$$0 \leq j \leq -k-1.$$

Because

$$\begin{aligned} &(a(\zeta)+b(\zeta))X_+(\zeta) \\ &\quad = (a(\zeta)+b(\zeta))\sqrt{\Phi(\zeta)}(\zeta-z_0)^{-k/2}e^{\gamma(\zeta)} \\ &\quad = \sqrt{a^2(\zeta)+b^2(\zeta)}(\zeta-z_0)^{-k/2}e^{\gamma(\zeta)}, \end{aligned}$$

it follows by using the Plemelj formula $g(\zeta) = G_+(\zeta) - G_-(\zeta)$, and relations (119), (121), and (123) that the solution of the integral equation (115) is

$$\begin{aligned} g(\zeta) = \frac{a(\zeta)f(\zeta)}{a^2(\zeta)-b^2(\zeta)} &- \frac{e^{\gamma(\zeta)}(\zeta-z_0)^{-k/2}b(\zeta)}{\sqrt{a^2(\zeta)-b^2(\zeta)}\pi_i} \\ &\times \oint_C \frac{f(\omega)e^{-\gamma(\omega)}(\omega-z_0)^{k/2}\,d\omega}{\sqrt{a^2(\omega)-b^2(\omega)}(\omega-\zeta)}\omega \end{aligned} \qquad (124)$$

so long as $k<0$ and

$$\oint_C \frac{f(\omega)e^{\gamma(\omega)}(\omega-z_0)^{k/2}\omega^j}{\sqrt{a^2(\omega)-b^2(\omega)}}\,d\omega = 0 \qquad 0 \leq j \leq -k-1 \qquad (125)$$

Similarly, when $k \geq 0$ the solution becomes

$$\begin{aligned} g(\zeta) = \frac{a(\zeta)f(\zeta)}{a^2(\zeta)-b^2(\zeta)} &- \frac{e^{\gamma(\zeta)}(\zeta-z_0)^{-k/2}b(\zeta)}{\sqrt{a^2(\zeta)-b^2(\zeta)}\,\pi_i} \\ &\times\left[\oint_C \frac{f(\omega)e^{-\gamma(\omega)}(\omega-z_0)^{k/2}\,d\omega}{\sqrt{a^2(\omega)-b^2(\omega)}(\omega-\zeta)} + P(\zeta)\right], \end{aligned} \qquad (126)$$

where $P(\zeta)$ is a polynomial whose degree does not exceed $k-1$.

For the special case when a and b are constants. Eq. (115) reduces to the Cauchy integral equation

$$ag(\zeta) + \frac{b}{\pi i}\oint_C \frac{g(\omega)}{\omega - \zeta}\, d\omega = f(\zeta) \tag{127}$$

while its solution follows by observing that $k = 0$, and Φ and γ are constants. Thus, we appeal to relation (126) and find the solution to be

$$g(\zeta) = \frac{af(\zeta)}{a^2 - b^2} - \frac{b}{(a^2 - b^2)\pi i}\oint_C \frac{f(\omega)\, d\omega}{\omega - \zeta}. \tag{128}$$

VIII. WIENER–HOPF INTEGRAL EQUATION

The integral equation of the type

$$g(x) + \lambda \int_0^\infty K(x - y)g(y)\, dy = f(x), \quad 0 < x < \infty \tag{129}$$

is called the Wiener–Hopf integral equation. Its distinguishing features are the difference kernel and the semi-infinite interval. This is an eigenvalue problem in which the eigenvalue happens to be known from certain physical considerations.

To use a two-sided transform, we have to change Eq. (129) in such a way that it is valid for $x < 0$. To achieve this objective we set

$$\lambda \int_{-\infty}^\infty K(x - y)g(y) = \begin{cases} -g(x) + f(x), & 0 < x < \infty \\ h(x), & -\infty < x < 0, \end{cases} \tag{130}$$

where $h(x)$ is unknown. Next we extend the definition of the function $f(x)$, $g(x)$, and $h(x)$ as follows:

$$f(x) = 0, \quad x < 0, \quad g(x) = 0, \quad x < 0, \qquad h(x) = 0, \quad x > 0. \tag{131}$$

This enables us to write Eq. (130) as

$$g_+(x) + \lambda \int_{-\infty}^\infty K(x - y)g_+(y)\, dy = f_+(x) + h_-(x), \quad -\infty < x < \infty, \tag{132}$$

where the subscripts $\pm$ indicate the $\pm$ half line on which the function is nonvanishing. Thereby we have succeeded in transforming the Wiener–Hopf integral Eq. (129) into a convolution-type integral equation.

Let us observe some interesting features of Eq. (132): (1) We assume that the kernel $K(x - y)$ is known for all values of its arguments, namely, $-\infty < x - y < \infty$. (2) The function $h_-(x)$ is unknown and can only be evaluated after we have found $g_+(x)$. (3) Because the integral in this equation extends from $-\infty$ to $+\infty$, we must have growth limits on the functions appearing in Eq. (132). They are: $K(x) = 0(e^{-c|x|})$, $f(x) = 0(e^{dx})$, as $x \to \infty$, the function $h_-(x) = 0(e^{-e|x|})$ as $x \to -\infty$, where $c > 0$ and $d < c$. (4). We look for a solution $g_+(x) = 0(e^{dx})$ as $x \to \infty$.

Let us now apply the Fourier transform $\hat{\psi}(u)$

$$\hat{\psi}(u) = \int_{-\infty}^\infty \psi(x)e^{iux}\, dx \tag{133}$$

to both sides of equation (132) and get

$$(1 + \lambda\hat{K}(u))\hat{g}_+(u) = \hat{f}_+(u) + \hat{h}_-(u). \tag{134}$$

These Fourier transforms have the following strips of definition $\hat{K}(u)$ in $|\mathrm{Im}\, u| < c$, $\hat{g}_+(u)$ in $\mathrm{Im}\ u > d$, $f_+(u)$ in $\mathrm{Im}\ u > d$ and $\hat{h}(u)$ in $\mathrm{Im}\ u < c$. Accordingly, Eq. (134) is a well-defined equation in the strip $d < \mathrm{Im}\, u < c$.

At this stage, two splitting techniques help us in solving Eq. (134). The first one is called the quotient splitting. This is achieved by setting

$$(1 + \lambda)\hat{K}(u) = \frac{K_+(u)}{K_-(u)}, \tag{135}$$

where K_+ and K_- have their respective regions of analyticity. When we substitute Eq. (135) in Eq. (134) we obtain

$$K_+(u)\hat{g}_+(u) = K_-(u)\hat{f}_+(u) + K_-(u)\widehat{h_-}(u). \tag{136}$$

Next we split the mixed term $K_-\hat{f}_+$ in the previous equation as

$$K_-(u)\hat{f}_+(u) = p_+(u) + p_-(u) \tag{137}$$

so that Eq. (136) becomes

$$K_+(u)\hat{g}_+(u) - p_+(u) = K_-(u)\widehat{h_-}(u) + p_-(u). \tag{138}$$

Thereby we have reduced our problem to solving the Riemann–Hilbert boundary value problem as studied in the previous section.

We illustrate all the above-mentioned concepts with the help of the following example.

Let us solve the integral equation:

$$\frac{1}{4}g(x) + \int_0^\infty e^{-|x - y|}g(y)\, dy = 1. \tag{139}$$

The Fourier transform of the kernel $K(x) = e^{-|x|}$ is $\hat{K}(u) = 2/(1 + u^2)$. Because 1_+ is the Heaviside function, which is 0 for $x < 0$ and 1 for $x > 0$, we have $(1_+)^\wedge(u) = i/u$. Note that $2/(1 + u^2)$ is analytic in the strip $-1 < \mathrm{Im} < 1$, while i/u is analytic in the half plane $\mathrm{Im}\ u > 0$.

Now we process Eq (139) by the Wiener–Hopf technique, as explained previously, and find that this integral equation transforms into

$$\frac{q+u^2}{4(1+u^2)}\hat{g}_+(u) = \frac{i}{u} + \hat{h}_-(u), \quad 0 < \operatorname{Im} u < 1. \quad (140)$$

Next we split the coefficient of $g_+(u)$ in (140) as the quotient

$$\frac{9+u^2}{4(1+u^2)} = \frac{(4+3i)(4-3i)}{4(u+i)(u-i)} = \left(\frac{4+3i}{4(u+i)}\right)\Big/\left(\frac{u-i}{u-3i}\right) = \frac{K_+}{K_-}.$$

Then Eq. (140) takes the form

$$\frac{u+3i}{4(u+i)}g_+(u) = \frac{u-i}{u-3i}\frac{i}{4} + \frac{u-i}{u-3i}h_-(u). \quad (141)$$

At this stage we split the first term on the right side of (141) as the sum

$$\frac{u-i}{u-3i}\frac{i}{4} = \frac{i}{3u} + \frac{2i}{3(u-3i)},$$

so that Eq. (141) becomes

$$\frac{4+3i}{4(u+i)}\hat{g}_+(u) - \frac{i}{3u} = \frac{2i}{3(u-3i)} + \frac{u-i}{u-3i}\hat{h}_-(u). \quad (142)$$

The left side of the equation (142) is analytic in $\operatorname{Im} u > 0$, while the right side is valid in the strip $0 < \operatorname{Im} u < 1$. Because these functions are equal on $\operatorname{Im} u = 0$, they are equal everywhere by analytic continuation. Accordingly, they are equal to the same entire function $E(u)$. As the $\operatorname{Im} u \to \infty$, the left side of Eq. (142) tends to zero. Similarly, as $\operatorname{Im} u \to -\infty$, the right side of (142) tends to zero. Therefore $E(u) \equiv 0$. Since our interest is to evaluate $g_+(u)$, we evaluate the part

$$\frac{u+3i}{4(u+i)}\hat{g}_+(u) - \frac{i}{3u} = 0. \quad (143)$$

When inverted, Eq. (143) yields

$$g_+(x) = \frac{4i}{3}\frac{1}{2\pi}\int_{ia-\infty}^{ia+\infty} e^{-iux}\frac{(u+i)\,du}{u(u+3i)}. \quad (144)$$

We evaluate this integral by choosing the contour in the lower half plane. This contour consists of the line $-ia - R$ to $ia + R$, and the semicircle of radius R with center at $(0, a)$ and then we let $R \to \infty$. The value of the integral on the semicircle vanishes. Finally, with the help of the theory of residues we find that the solution is

$$g(x) = \frac{4}{9}(1 + 2e^{-3x})H(x). \quad (145)$$

IX. NONLINEAR INTEGRAL EQUATIONS

Let us finally present an elementary discussion of nonlinear integral equations. Because there are no analytic techniques by which these equations are solved, their treatment is available on ad hoc basis. A nonlinear Fredholm integral equation is of the form

$$g(x) = f(x) = \lambda \int F\{x, y, g(y)\}\,dy, \quad (146)$$

where both x and y lie in the domain (a, b) and we have omitted the limits a, b of integration as in the previous discussion. Equation (146) is called an *Uryson* equation. Perhaps the most important particular case is the *Hammerstein* equation:

$$g(x) = f(x) + \lambda \int K(x, y)F(y, g(y))\,dy. \quad (147)$$

These nonlinear integral equations are being presently studied by modern numerical methods. We shall limit ourselves to giving the iterative scheme for solving the general case (146). This scheme is similar to the one given for the linear case in Section II. For this purpose we impose the following conditions on the functions occurring in this equation. We assume that $f(x)$ is continuous in (a, b). The function $F(x, y, g(y))$ is continuous with respect to x and y in the rectangle $a \le x$, $y \le b$ and satisfies the Lipschitz condition with respect to $g(y)$ (i.e., $|F\{x, y, g_1(y)\} - F\{x, y, g_2(y)\}| \le L\,|g_1(y) - g_2(y)|$), where L is a positive constant. The continuity of F with respect to x and y assures that $|F\{x, y, g(y)\}| < M$ for bounded $g(y)$, where M is a positive constant.

Now we follow the iterative technique as given in Section II and set the first approximation for $g(x)$ to be $g^{(0)}(x) = f(x)$ and subsequent ones as

$$g^{(n)}(x) = f(x) + \lambda \int F\left\{x, y, g^{(n-1)}(y)\right\} dy \qquad n \ge 1 \quad (148)$$

Because

$$g^{(n)}(x) = \sum_{k=1}^{n}\left\{g^{(k)}(x) - g^{(k-1)}(x)\right\} + g^{(0)}(x)$$

the convergence of the sequence $g^{(n)}(x)$ is equivalent to the convergence of the series whose kth term is $(g^{(k)}(x) - g^{(k-1)}(x))$. To examine the convergence of this series we set

$$g^{(1)}(x) - g^{(0)}(x) = \lambda \int F(x, y, f(x)) = \phi(x)$$

as $g^{(0)}(x) = f(x)$, and assume that $|\phi(x)| < A$, a constant. Then we find that

$$
\begin{aligned}
&\left|g^{(k)}(x)-g^{(k-1)}(x)\right| \\
&\quad=|\lambda|\left|\int F\left\{x,y,g^{(k-1)}(y)\right\}-F\left\{x,y,g^{(k-2)}(y)\right\}dy\right| \\
&\quad\le|\lambda|\int\left|F\left\{x,y,g^{(k-1)}(y)\right\}-F\left\{x,y,g^{(k-2)}(y)\right\}\right|dy \\
&\quad\le|\lambda|L\int\left|g^{(k-1)}(y)-g^{(k-2)}(y)\right|dy \\
&\quad\le\cdots\le[|\lambda|L(b-a)]^{k-1}A.
\end{aligned}
$$

Thus, if $|\lambda|L(b-a)<1$, the series will be absolutely and uniformly convergent and $g^{(n)}(x)$ will tend to a function $g(x)$ which will be the solution of Eq. (146).

To prove the uniqueness of the solution, we let $g(x)$ and $h(x)$ be two solutions. Then the value of the difference $\psi(x)=g(x)-h(x)$ is

$$\psi(x)=\lambda\int[F\{x,y,g(y)\}-F\{x,y,h(y)\}]\,dy.$$

When we denote by $\psi_{\max}$, the maximum value of $\psi(x)$ in (a,b) and appeal to the Lipschitz continuity of F, we find that

$$|\psi(x)|<|\lambda|\int|\psi(y)\,dy|\le|\lambda|L(b-a)\psi_{\max}(x),$$

which means that $\psi_{\max}\le|\lambda|L(b-a)\psi_{\max}$. But $|\lambda|L(b-a)<1$, so we have $\psi_{\max}=0$ and the uniqueness of the solution is proved.

Let us now consider the nonlinear Volterra integral equation

$$g(x)=f(x)+\lambda\int_0^x F\{x,y,g(y)\}\,dy, \tag{149}$$

with the same conditions on the function $f(x)$ and $F\{x,y,g(y)\}$ as given above. The iterative scheme again yields the sequence $g^{(0)}(x)=f(x)$ and

$$g^{(n)}(x)=f(x)+\lambda\int_0^x F\left\{x,y,g^{(n-1)}(y)\right\}dy \qquad n\ge1 \tag{150}$$

and its convergence is equivalent to that of the series whose kth term is $g^{(k)}(x)-g^{(k-1)}(x)$. To study this convergence we observe that

$$
\begin{aligned}
g^{(1)}(x)-g^{(0)}(x)&=\lambda\int_0^x F\{x,y,\,f(y)\}\,dy \\
&\le|\lambda|\int_0^x|F\{x,y,\,f(y)\}|\,dy \\
&\le|\lambda|\int_0^x M\,dy=M|\lambda|x
\end{aligned} \tag{151}
$$

Then from (150) it follows that

$$
\begin{aligned}
&\left|g^{(k)}(x)-g^{(k-1)}(x)\right| \\
&\quad=|\lambda|\left|\int_0^x F\left\{x,y,g^{(k-1)}(y)\right\}-F\left\{x,y,g^{(k-2)}(y)\right\}dy\right| \\
&\quad\le|\lambda|\int_0^x L\left|g^{(k-1)}(y)-g^{(k-2)}(y)\right|dy \\
&\quad\le\cdots\le\frac{(L|\lambda||x|)^k}{k!}M
\end{aligned} \tag{152}
$$

But the last term in (152) is the kth term of the power series for $M\exp\{L|\lambda||x|\}$, so that the series $g^{(0)}(x)+\sum_{k=1}^{\infty}\{g^{(k)}(x)-g^{(k-1)}(x)\}$ is absolutely and uniformly convergent for all values of λ and its sum $\lim_{n\to\infty}g^{(n)}(x)$ is the solution of the integral equation (149). The uniqueness of this solution can be proved by a slight extension of the arguments presented above for the Fredholm case.

X. A TAYLOR EXPANSION TECHNIQUE

In the previous analysis we have presented the Neumann and Hilbert-Schmidt expansion techniques for solving the integral equations. Recently, it has been discovered that both the linear and nonlinear integral equations can also be solved with the help of the Taylor series. To present the basic ideas of this method, we consider the Fredholm integral equation of the second kind

$$g(x)=f(x)+\int_a^b K(x,y)g(y)\,dy \tag{153}$$

and differentiate it n times with respect to x so that we have

$$g^{(n)}(x)=f^{(n)}(x)+\int_a^b\frac{\partial^n K(x,y)}{\partial x^n}g(y)\,dy.$$

For $x=0$, the above relation becomes

$$g^{(n)}(0)=f^{(n)}(0)+\int_a^b\left.\frac{\partial^n K(x,y)}{\partial x^n}\right|_{x=0}g(y)\,dy. \tag{154}$$

When we substitute the Taylor series

$$g(y)=\sum_{m=0}^{\infty}\frac{1}{m!}g^{(m)}(0)y^m \tag{155}$$

for $g(y)$ in (154) we get

$$
\begin{aligned}
g^{(n)}(0)&=f^{(n)}(0) \\
&\quad+\int_a^b\left.\frac{\partial^n K(x,y)}{\partial x^n}\right|_{x=0}\left(\sum_{m=0}^{\infty}\frac{1}{m!}g^{(m)}(0)y^m\right)dy.
\end{aligned} \tag{156}
$$

Next, we set

$$T_{mn} = \frac{1}{m!}\int_a^b \left.\frac{\partial^n K(x,y)}{\partial x^n}\right|_{x=0} y^m\,dy \tag{157}$$

in (139) and obtain

$$g^{(n)}(0) = f^{(n)}(0) + \sum_{m=0}^{\infty} T_{mn} g^{(m)}(0), \tag{158}$$

$n = 0, 1, 2, 3, \ldots$. Accordingly, the evaluation of the solution $g(x)$ of integral equation (136) reduces to solving the above infinite system of algebraic equations for the Taylor coefficients $g^m(0)$. This is achieved by truncating this system in a suitable manner so that we get a determinate system at every step. Thus, we get an approximate solution to the desired order of accuracy. For instance, let us take (i) $n = 0$, $m = 1$, (ii) $n = 1$, $m = 1$; (iii) $n = 2$, $m = 2$, in (158) so that we get the determinate system of three equations

$$(T_{00} - 1)g(0) + T_{01}g^{(1)}(0) = -f(0) \tag{159a}$$

$$T_{10}g(0) + (T_{11} - 1)g^{(1)}(0) = -f^{(1)}(0) \tag{159b}$$

$$T_{20}g(0) + T_{21}g^{(1)}(0) + (T_{22} - 1)g^{(2)}(0) = -f^{(2)}(0) \tag{159c}$$

Equations (159a) and (159b) yield the values of $g(0)$ and $g^{(1)}(0)$, which when substituted in (159c), give the value of $g^{(2)}(0)$. Thus, we obtain the solution $g(x)$ to $O(x^2)$.

The elegance of the method lies in the fact that frequently we get an exact solution of an integral equation. We illustrate this point with the help of the integral equation

$$g(x) = (x+1)^2 + \int_{-1}^{1} (xy + x^2y^2)g(y)\,dy. \tag{160}$$

Accordingly, $f(x) = (x+1)^2$, $K(x,y) = xy + x^2y^2$, and we have

$$f(0) = 1, \quad f^{(1)}(0) = 2, \quad f^{(2)}(0) = 2$$

$$T_{00} = 0, \quad T_{01} = 0, \quad T_{10} = 0, \quad T_{11} = \frac{2}{3}$$

$$T_{20} = \frac{4}{3}, \quad T_{21} = 0, \quad T_{22} = \frac{2}{5}.$$

When we substitute these values in Eq. (159) and solve for the first three Taylor coefficients of $g(x)$, we get

$$g(0) = 1, \quad g^{(1)}(0) = 6, \quad g^{(2)}(0) = \frac{50}{9}.$$

Thus, we have

$$g(x) = 1 + 6x + \frac{25}{9}x^2,$$

which happens to be the exact solution of Eq. (160).

GLOSSARY

Coloring A labeling of a combinatorial structure (such as a graph or a knot diagram) with elements of a chosen set (called colors) according to rules that are specified in a given context.

Diagram A graphical structure intended to illustrate or embody a mathematical structure.

Fundamental group The fundamental group of a topological space is a group that is naturally defined by mappings of circles to the space. This group is used throughout topology.

Group An algebraic structure with one binary operation, satisfying the axioms that there is an identity element, every element has an inverse, and associativity. The concept of a group formalizes a general notion of symmetry.

Knot An embedding of a circle in three-dimensional space. A knot is said to be knotted if this embedding cannot be transformed topologically to a flat circle. The intent of this mathematical definition is to capture the topological aspect of a knotted rope in the space of physical experience.

Knot polynomial A method of assigning to each knot or link a polynomial that is a topological invariant of the knot or link.

Link An embedding of several disjoint circles in three-dimensional space. Two links are said to be topologically equivalent if there is an (orientation-preserving) homeomorphism of three-dimensional space that carries one link to the other one.

Quandle An algebraic invariant of knots and links closely related to the fundamental group.

Topological invariant A method of assigning a mathematical object (such as a number, a polynomial, or a group) to each of a class of topological spaces (or in the case of knots and links, to a space and collection of subspaces) so that topologically equivalent spaces (or configurations of spaces) receive the same assigned mathematical structure.

Topology The study of topological spaces—sets endowed with a notion of neighborhoods (called open sets) closed under finite intersections and arbitrary unions, such that the whole space and the empty set are both open. Topological spaces encapsulate the concept of continuity in the structure of the neighborhoods.

THIS ARTICLE constitutes an introduction to the theory of knots as it has been influenced by developments concurrent with the discovery of the Jones polynomial in 1984 and the subsequent explosion of research that followed this signal event in the mathematics of the 20th century.

I hope to give the flavor of these extraordinary events in this exposition. Even the act of tying a shoelace can become an adventure. The familiar world of string, rope, and the third dimension becomes an inexhaustible source of ideas and phenomena.

Sections 1 and 2 constitute a start on the subject of knots. Later sections introduce more technical topics. The theme of a relationship of knots with physics begins already with the Jones polynomial and the bracket model for the Jones polynomial as discussed in Section 4. Sections 5 and 6 provide an introduction to Vassiliev invariants and the remarkable relationship between Lie algebras and knot theory. The idea for the bracket model and its generalizations is to regard the knot itself as a discrete physical system and to obtain information about its topology by averaging over the states of the system. In the case of the bracket model this summation is finite and purely combinatorial. Transpositions of this idea occur throughout, involving ideas from quantum mechanics (Sections 7 and 8) and quantum field theory (Section 9). In this way knots have become a testing ground not only for topological ideas, but also for the methods of modern theoretical physics.

This article concentrates on the construction of invariants of knots and the relationships of these invariants to other mathematics (such as Lie algebras) and to physical ideas (quantum mechanics and quantum field theory). There is also a rich vein of knot theory that considers a knot as a physical object in three-dimensional space. Then one can put electrical charge on a knot and watch (in a computer) the knot repel itself to form beautiful shapes in three dimensions. Or one can think of a knot as made of thick rope and ask for an "ideal" form of the knot with minimal length-to-diameter ratio. This idea of physical knots is a current topic of research.

I. KNOT TYING AND THE REIDEMEISTER MOVES

A. Introduction

For this section it is recommended that the reader obtain a length of soft rope for the sake of direct experimentation. We begin by making some knots. In particular, we shall look at the bowline, a most useful knot. The bowline is widely used by persons who need to tie a horse to a post or their boat to a dock. It is easy and quick to make, holds exceedingly well, and can be undone in a jiffy. Figure 1 gives instructions for making the bowline. In showing the bowline we have drawn it loosely. To use it, one grabs the lower loop and pulls it tight by the upper line shown in the drawing. It tightens while maintaining the given size of the loop. Nevertheless, the knot is easily undone, as some experimentation will show.

The utility of a schema for drawing a knot is that the schema does not have to indicate all the physical properties of the knot. It is sufficient that the schema should contain the information needed to build the knot. Here is a remarkable use of language. The language of the diagrams for knots implicitly contains all their topological and physical properties, but this information may not be easily available unless the "word is made flesh" in the sense of actually building the knot from rope or cord.

Our aim is to get topological information about knots from their diagrams. Topological information is information about a knot that does not depend upon the material from which it is made and is not changed by stretching or

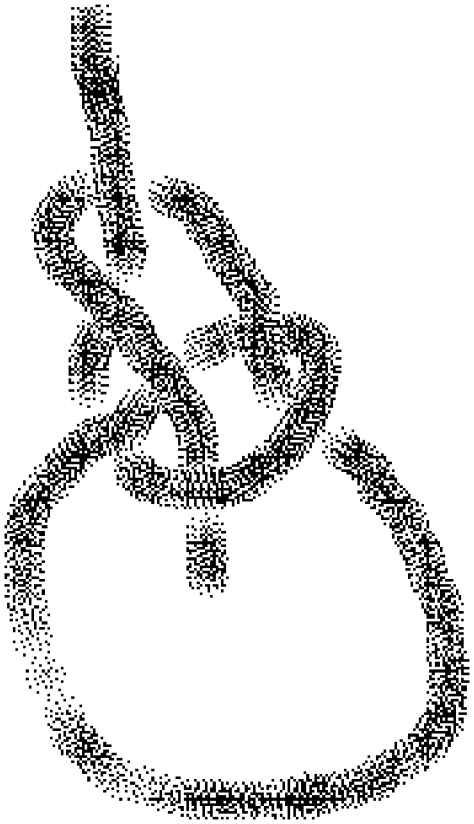

FIGURE 1 The bowline.

bending that material so long as it is not torn in the process. We do not want the knot to disappear in the course of such a stretching process by slipping over one of the ends of the rope. The knot theorist's usual convention for preventing this is to assume that the knot is formed in a closed loop of string. The trefoil knot shown in Fig. 2 is an example of such a closed, knotted loop.

A knot presented in closed-loop form is a robust object, capable of being pushed and twisted into many topologically equivalent forms. For example, the knot shown in Fig. 3 is topologically equivalent to the trefoil shown in Fig. 2.

The existence of innumerable versions of a given knot or link gives rise to a mathematical problem. To state that a loop is knotted is to state that nowhere among the infinity of forms that it can take do we find an unkotted loop. Two loops are said to be (topologically) *equivalent* if it is possible to deform one smoothly into the other so that all the intermediate stages are loops without self-intersections. In this sense a loop is knotted if it is not equivalent to a simple flat loop in the plane.

B. Reidemeister Moves

The key result that makes it possible to begin a (combinatorial) theory of knots is the theorem of Reidemeister (1948, 1932), which states that two diagrams represent equivalent loops if and only if one diagram can be obtained from the other by a finite sequence of special deformations called the *Reidemeister moves*. I shall illustrate these moves in a moment. The upshot of Reidemeister's theorem is that the topological problems about knots can all be formulated in terms of knot diagrams.

There is a famous philosophy of mathematics called "formalism" in which mathematics is considered to be

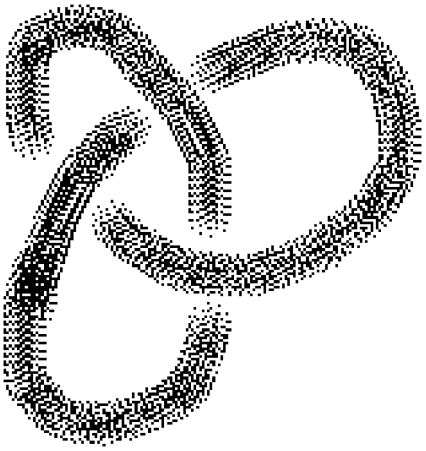

FIGURE 2 The trefoil as closed loop.

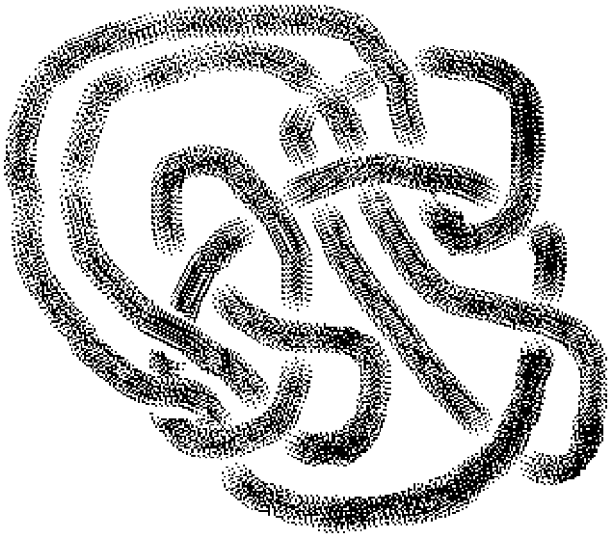

FIGURE 3 Deformed trefoil.

a game played with symbols according to specific rules. Knot theory, done with diagrams, illustrates the formalist idea very well. In the formalist point of view a specific mathematical game (formal system) can itself be an object of study for the mathematician. Each particular game may act as a coordinate system, illuminating key aspects of the subject. One can think about knots through the model of the diagrams. Other models (such as regarding the knots as specific kinds of embeddings in three-dimensional space) are equally useful in other contexts. As we shall see, the diagrams are amazingly useful, allowing us to pivot from knots to other ideas and fields and then back to topology again.

The Reidemeister moves are illustrated in Fig. 4. The moves shown in Fig. 4 are intended to indicate changes that are made in a larger diagram. These changes modify the diagram only locally as shown in the figure. Figure 5 shows a sequence of Reidemeister moves from one diagram for a trefoil knot to another. In this illustration we performed two instances of the second Reidemeister move in the first step and a combination of the second move and the third move in the second step, and used "move zero" (a topological rearrangement that does not change any of the crossing patterns) in the last step. Move zero is as important as the other Reidemeister moves, but since it does not change any essential diagrammatic relationships it is left in the background of the discussion.

C. Knots as Analog Computers

We end this section with one more illustration. This time we take the bowline and close it into a loop. A deformation then reveals that the closed-loop form of the bowline

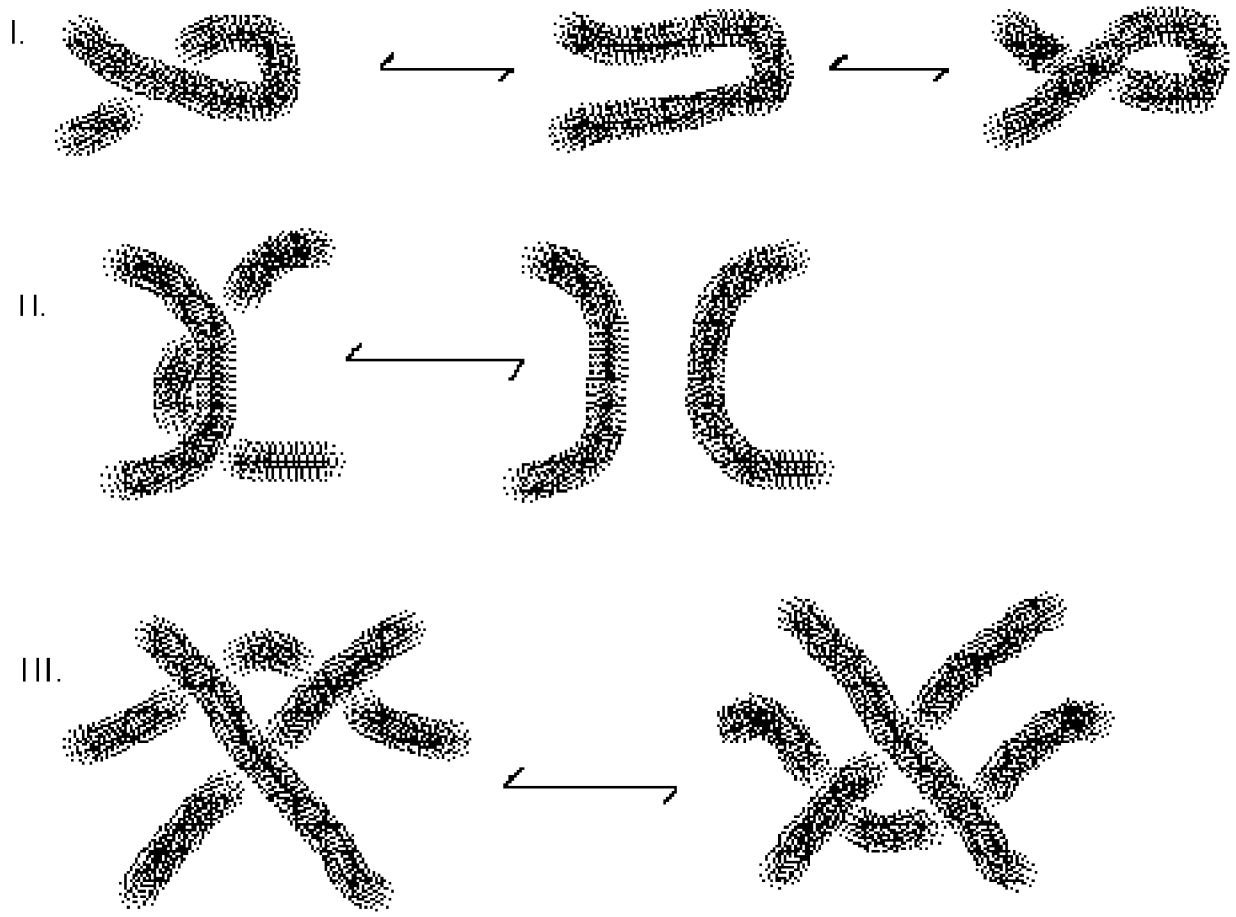

FIGURE 4 Reidemeister moves.

is topologically equivalent to two trefoils clasping one another, as shown in Fig. 6.

This deformation was discovered by making a bowline in a length of rope, closing it into a loop, and fooling about with the rope until the nice pair of clasped trefoils appeared. Note that there is more than one way to close the bowline into a loop. Figure 6 illustrates one choice. After discovering them, it took some time to find a clear pictorial pathway from the closed-loop bowline to the clasped trefoils. The pictorial pathway shown in Fig. 6 can be easily expanded to a full sequence of Reidemeister moves. In this way the model of the the knot in real rope is an analog computer that can help to find sequences of deformations that would otherwise be overlooked.

It is a curious reversal of roles that the original physical object of study becomes a computational aid for getting insight into the mathematics. Of course this is really a two-way street. The very close fit between the mathematical model for knots and the topological properties of actual knotted rope is the key ingredient. Knots are analogous to integers. Just as we believe that objects follow the laws of arithmetic, we believe that the topological properties of knotted rope follow the laws of knot topology.

II. INVARIANTS OF KNOTS AND LINKS, A FIRST PASS

We want to be able to calculate numbers (or bits of algebra such as polynomials) from given link diagrams in such a way that these numbers do not change when the diagrams are changed by Reidemeister moves. Numbers or polynomials of this kind are called *invariants* of the knot or link represented by the diagram. If we produce such invariants, then we are finding topological information about the knot or link. The easiest example of such an invariant is the linking number of two curves, which measures how many times one curve winds around another. In order to calculate the linking number we *orient* the curves. This means that each curve is equipped with a directional arrow, and we keep track of the direction of the arrow when the curve is deformed by the Reidemeister moves. If the

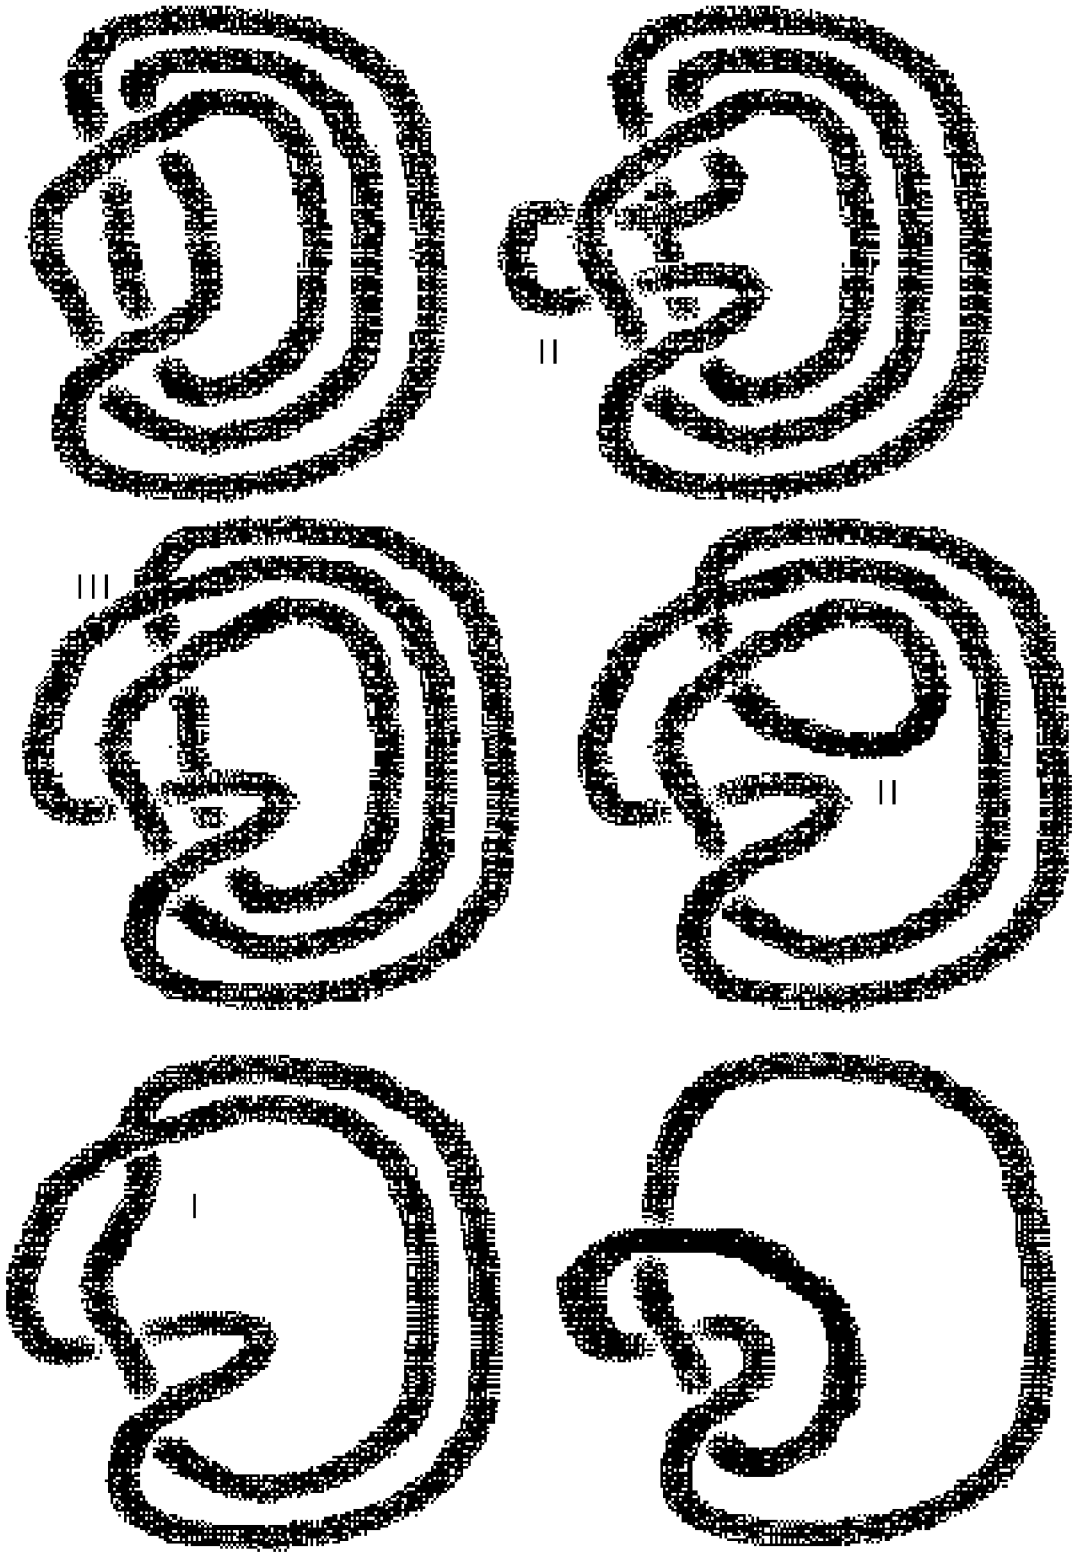

FIGURE 5 Deforming a Braid to the Trefoil Knot.

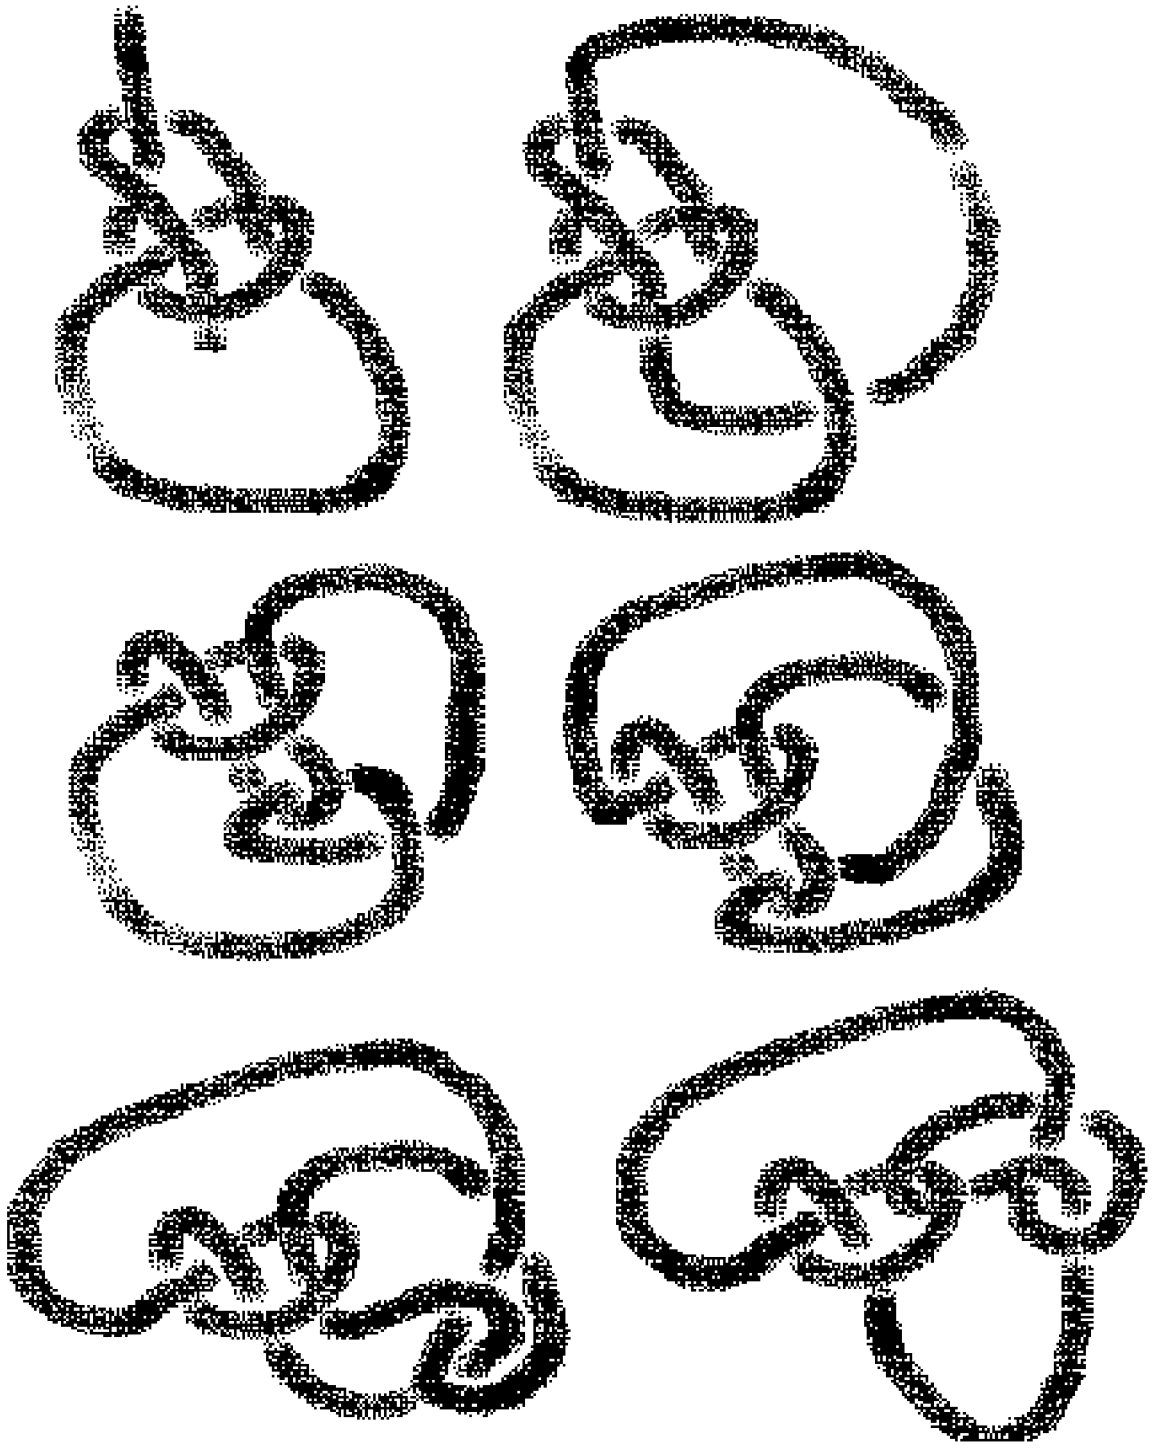

FIGURE 6 The Bowline.

curves A and B are represented by an oriented link diagram with two components, attach a sign ($+1$ or -1) to each crossing as in Fig. 7. Then the linking number $\mathrm{Lk}(A, B)$ is the sum of these signs over all the crossings of A with B.

Of course, two singly linked rings receive linking number equal to $+1$ or -1 as shown in Fig. 8.

It can be shown that the linking number is invariant under the Reidemeister moves. That is, if we take a given diagram D (representing the curves A and B) and change it

FIGURE 7 Crossing Signs.

to a new diagram E by applying one of the Reidemeister moves, then the linking number calculation for D will be the same as the calculation for E. The calculation is unaffected by the first Reidemeister move because self-crossings of a single curve do not figure in the calculation of the linking number. The second Reidemeister move either creates or destroys two crossings of opposite sign, and the third move rearranges a configuration of crossing without changing their signs.

With these observations we have in fact *proved* that the singly linked rings are indeed linked! There is no possible sequence of Reidemeister moves from these rings to two separated rings because the linking number of separated rings is equal to zero, not to plus or minus one.

It may seem a minor accomplishment to prove something as obvious as the inseparability of this simple configuration, but it is the first step in the successful application of algebraic topology to the study of knots and links. The linking number has a long and interesting history, and there are a number of ways to define it, many considerably more complicated than the sum of diagrammatic signs. We shall discuss some of these alternative definitions at the end of this section.

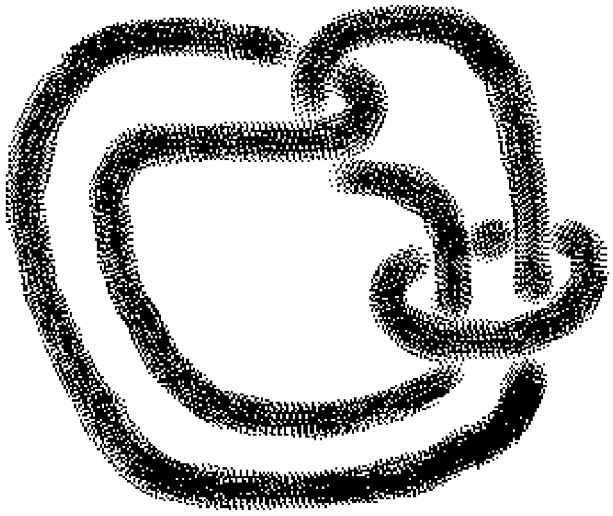

FIGURE 9 The Whitehead link.

One of the most fascinating aspects of the linking number is its limitations as an invariant. Figure 9 shows the Whitehead link, a link of two components with linking number equal to zero. The Whitehead link is indeed linked, but it requires methods more powerful than the linking number to demonstrate this fact.

Another example of this sort is the Borromean (or Ballantine) rings as shown in Fig. 10. These three rings are topologically inseparable, but if any one of them is ignored, then the other two are not linked.

Just in case these last few examples leave the reader pessimistic about the prospects of the linking number, here is a positive application. We shall use the linking number to show that the Möbius strip is not topologically equivalent to its mirror image. The Möbius strip is a circular band with a half twist in it as illustrated in Fig. 11. The Möbius

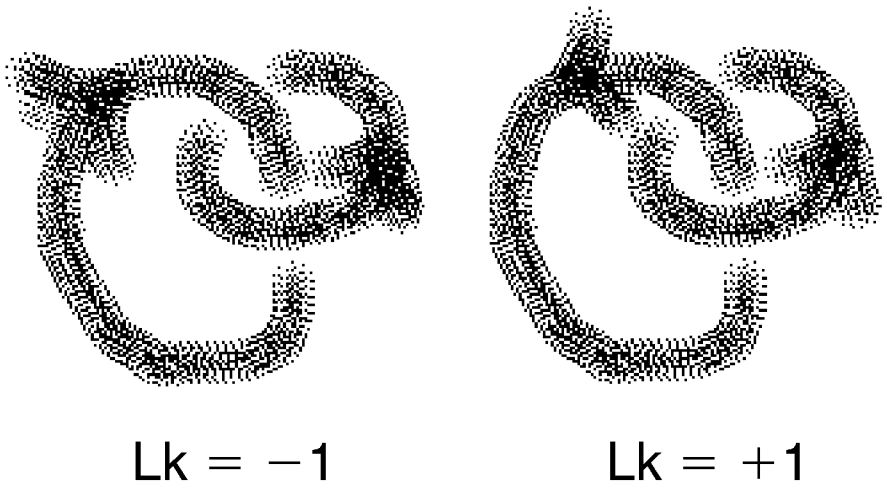

FIGURE 8 Two Linking Numbers.

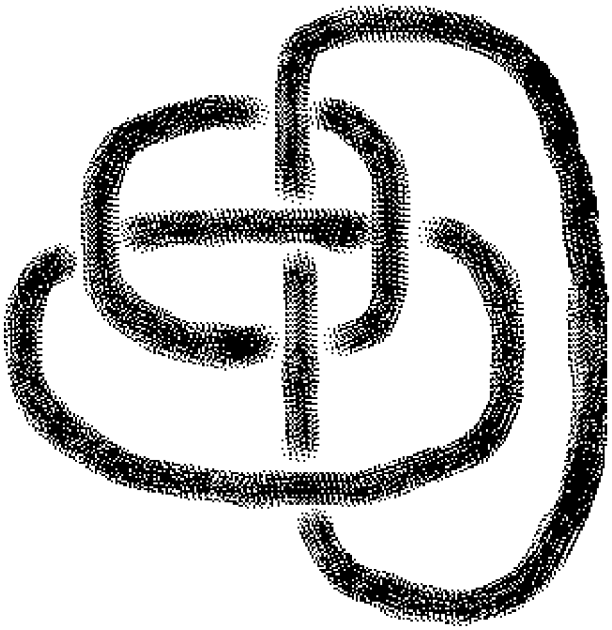

FIGURE 10 The Borromean rings.

is a justly famous example of a surface with only one side and one edge. An observer walking along the surface goes through the half-twist and arrives back where she started only to discover that she is on the other local side of the band! It requires another trip around the band to return to the original local side. As a result there is only one side to the surface in the global sense. It is as though the opposite side of the world were infinitesimally close to us by drilling into the ground, but a full circumnavigation of the globe away by external travel.

To make matters even more surprising, there are actually two Möbius bands, depending on the sense of the half twist. Call them M and M^* as illustrated in Fig. 11. If one makes these two Möbius bands from strips of paper and tries to deform one into the other without tearing the paper, one will fail (Try it!).

How can we understand the topological nature of the handedness of the Möbius band M? Draw a curve C down the center of the band M as shown in Fig. 11. Compare this curve with the space curve formed by the boundary of the band. Orient these curves in parallel and compute the linking number. It is $+1$. The very same calculation for the mirror image band M^* yields the linking number of -1.

If it were possible topologically to deform M to M^*, then the corresponding links (formed by the core curve and the boundary curve of the band) would be topologically equivalent, and hence they would have the same linking number. Since this is not the case, we conclude that M cannot be deformed to M^*.

We have shown that there are two topologically distinct Möbius bands. The two bands are mirror images of one another in the sense that each looks like the image of the other in a reflecting mirror. When an object is topologically inequivalent to its mirror image, it is said to be *chiral*. We have demonstrated the chirality of the Möbius band.

A. Three Coloring a Knot

There is a remarkable proof that the trefoil knot is knotted. This proof goes as follows: Color the three arcs of the trefoil diagram with three distinct colors, say red, blue, and purple (Fig. 12). Note that in the standard trefoil diagram three distinct colors occur at each crossing. Now adopt the following coloring rule:

- Either three colors or exactly one color occur at any crossing in the colored diagram.

Call a diagram *colored* if its arcs are colored and they satisfy this rule. Note that the standard unknot diagram is colored by simply assigning one color to its circle. A coloring does not necessarily have three colors on a given diagram. Call a diagram *three-colored* if it is colored and three colors actually appear on the diagram.

Theorem. *Every diagram that is obtained from the standard trefoil diagram by Reidemeister moves can be three-colored. Hence the trefoil diagram represents a knot.*

Rather than write a formal proof of this theorem, we illustrate the coloring process in Figs. 13 and 14. Each time a Reidemeister move is performed, it is possible to extend the coloring from the original diagram to the diagram that is obtained from the move. These extensions of colorings involve only local changes in the colorings of the original diagrams. The best way to see that this proof works is to do a few experiments. Figures 13 and 14 are a start.

Note that in the case of the second move performed in the simplifying direction, although a color is lost in the arc that disappears under the move, this color must appear elsewhere in the diagram or else it is not possible for the two arcs in the move to have different colors (since there is a path along the knot from one local arc to the other). Thus three-coloration is preserved under Reidemeister moves, whether they make the diagram simpler or more complicated. As a result, every diagram for the trefoil knot can be colored with three colors according to our rules. This proves that the trefoil is knotted, since an unknotted trefoil would have a simple circle among its diagrams, and the simple circle can be colored with only one color.

B. The Quandle and the Determinant of a Knot

There is a wide generalization of this coloring argument. We shall replace the colors by arbitrary labels for the arcs

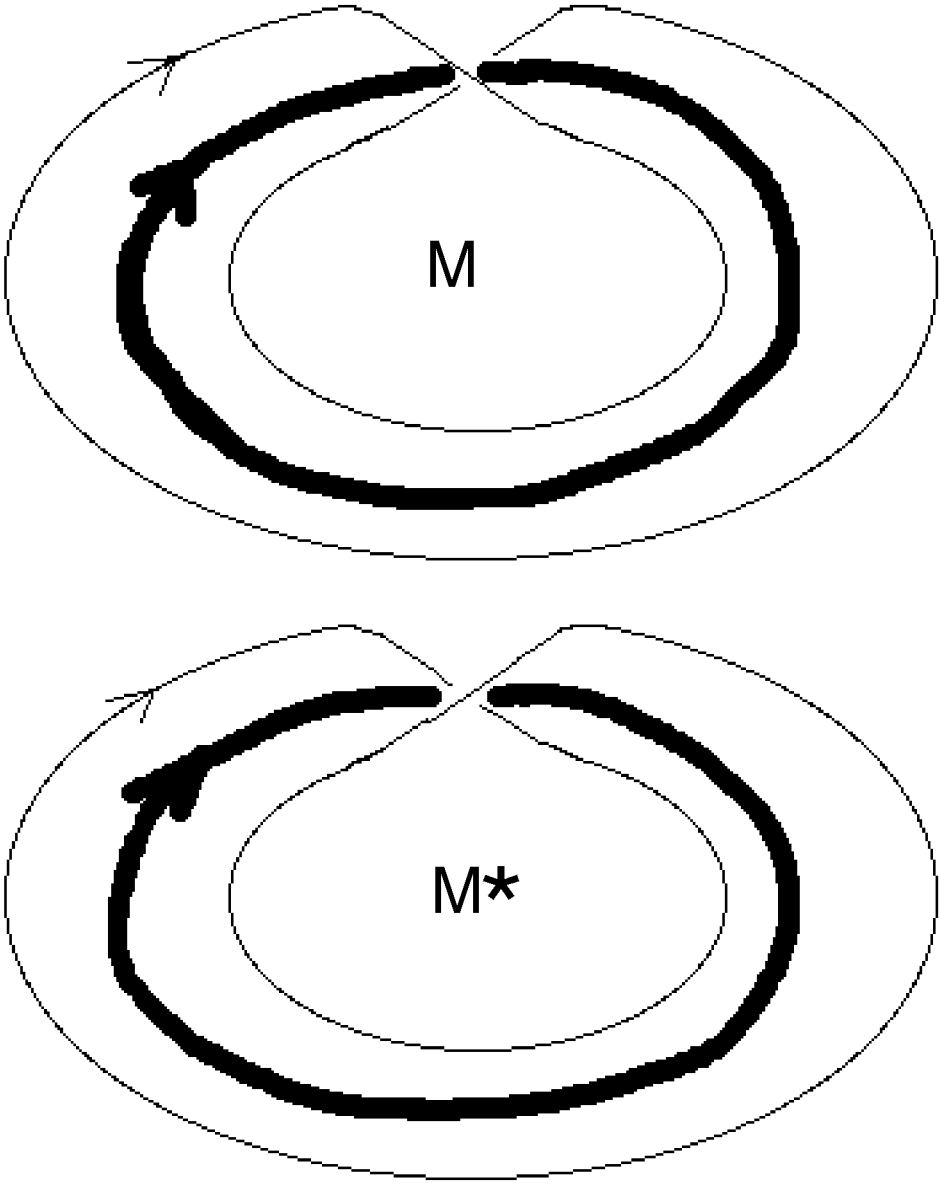

FIGURE 11 Möbius and mirror Möbius.

in the diagram and replace the coloring rule by a method for combining these labels. It turns out that a good way to articulate such a rule of combination is to make the label on one of the undercrossing arcs at a crossing a product (in the sense of this new mode of combination) of the labels of the other two arcs. In fact, we shall assume that this product operation depends upon the orientation of the arcs as shown in Fig. 15.

In Fig. 15 we show how a label A on an undercrossing arc combines with a label B on an overcrossing arc to form $C = A^* B$ or $C = A^{\#} B$ depending upon whether the overcrossing arc is oriented to the left or to the right for an observer facing the overcrossing line and standing on the arc labeled A.

This operation depends upon the orientation of the line labeled B, so that $A^* B$ corresponds to B pointing to the right for an observer approaching the crossing along A, and $A^{\#} B$ corresponds to B pointing to the left for the same observer. All of this is illustrated in Fig. 15.

The binary operations * and $^{\#}$ are not necessarily associative. For example, our original color assignments of R (red), B (blue), and P (purple) for the trefoil knot correspond to products $\mathrm{R}^*\mathrm{R} = \mathrm{R}$, $\mathrm{B}^*\mathrm{B} = \mathrm{B}$, $\mathrm{P}^*\mathrm{P} = \mathrm{P}$, $\mathrm{R}^*\mathrm{B} = \mathrm{P}$,

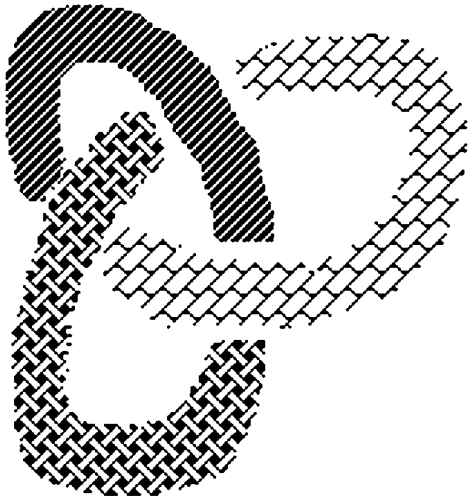

FIGURE 12 The three-colored trefoil.

$B^*P = R$, $P^*R = B$. Then $R^*(B^*P) = R^*R = R$ and $(R^*B)^*P = P^*P = P$.

We shall insist that these operations satisfy a number of identities so that the labeling is compatible with the Reidemeister moves.

Figure 16 illustrates the diagrammatic justification for the following algebraic rules about * and $^\#$. An algebraic system satisfying these rules is called a *quandle*.

1. $A^*A = A$ and $A^\#A = A$ for any label A.
2. $(A^*B)^\#B = A$ and $(A^\#B)^*B = A$ for any labels A and B.
3. $(A^*B)^*C = (A^*C)^*(B^*C)$ and $(A^\#B)^\#C = (A^\#C)^\#(B^\#C)$ for any labels A, B, C.

These rules correspond, respectively, to the Reidemeister moves 1–3. Labelings that obey these rules can

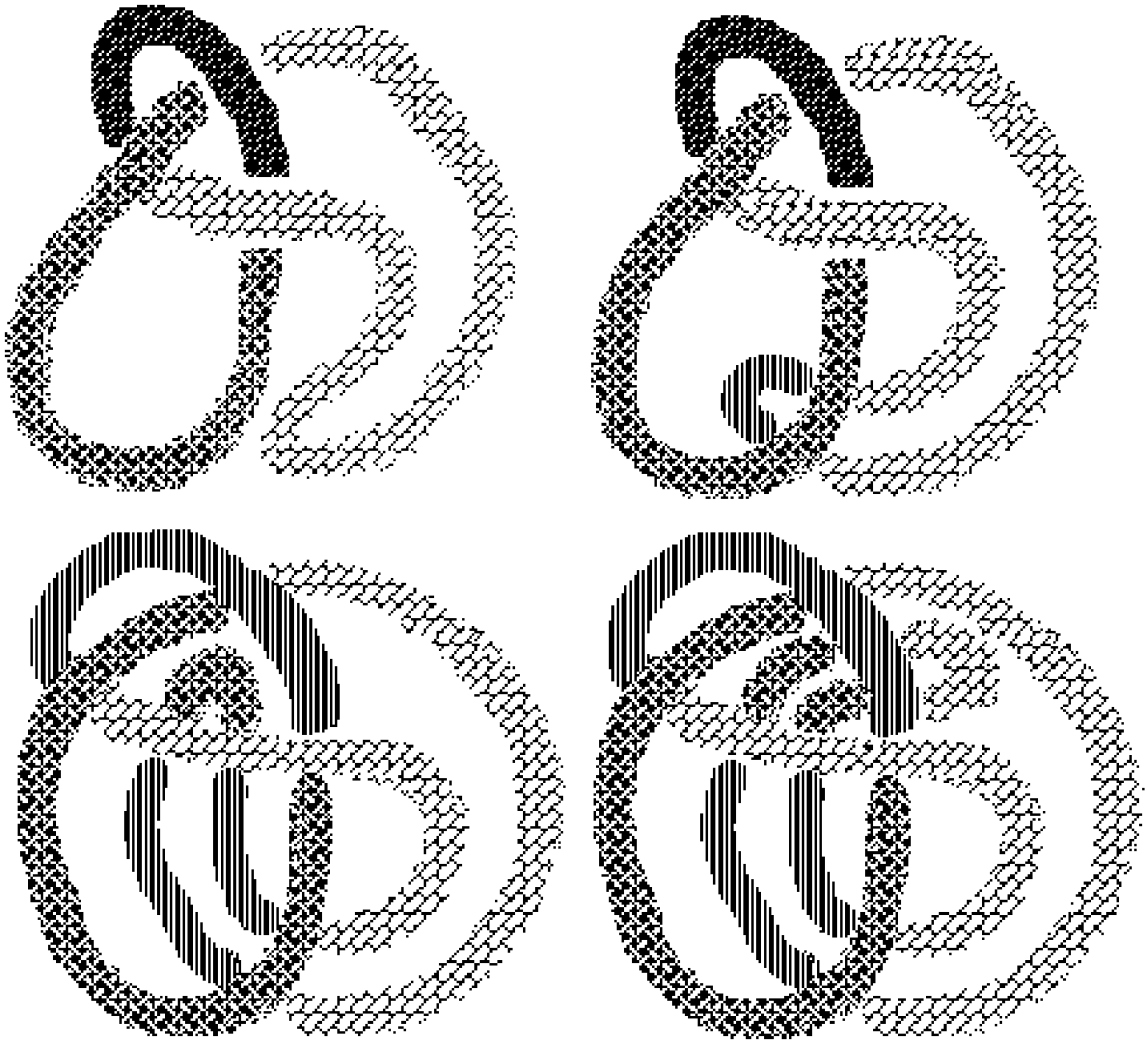

FIGURE 13 Inheriting coloring under the type 2 move.

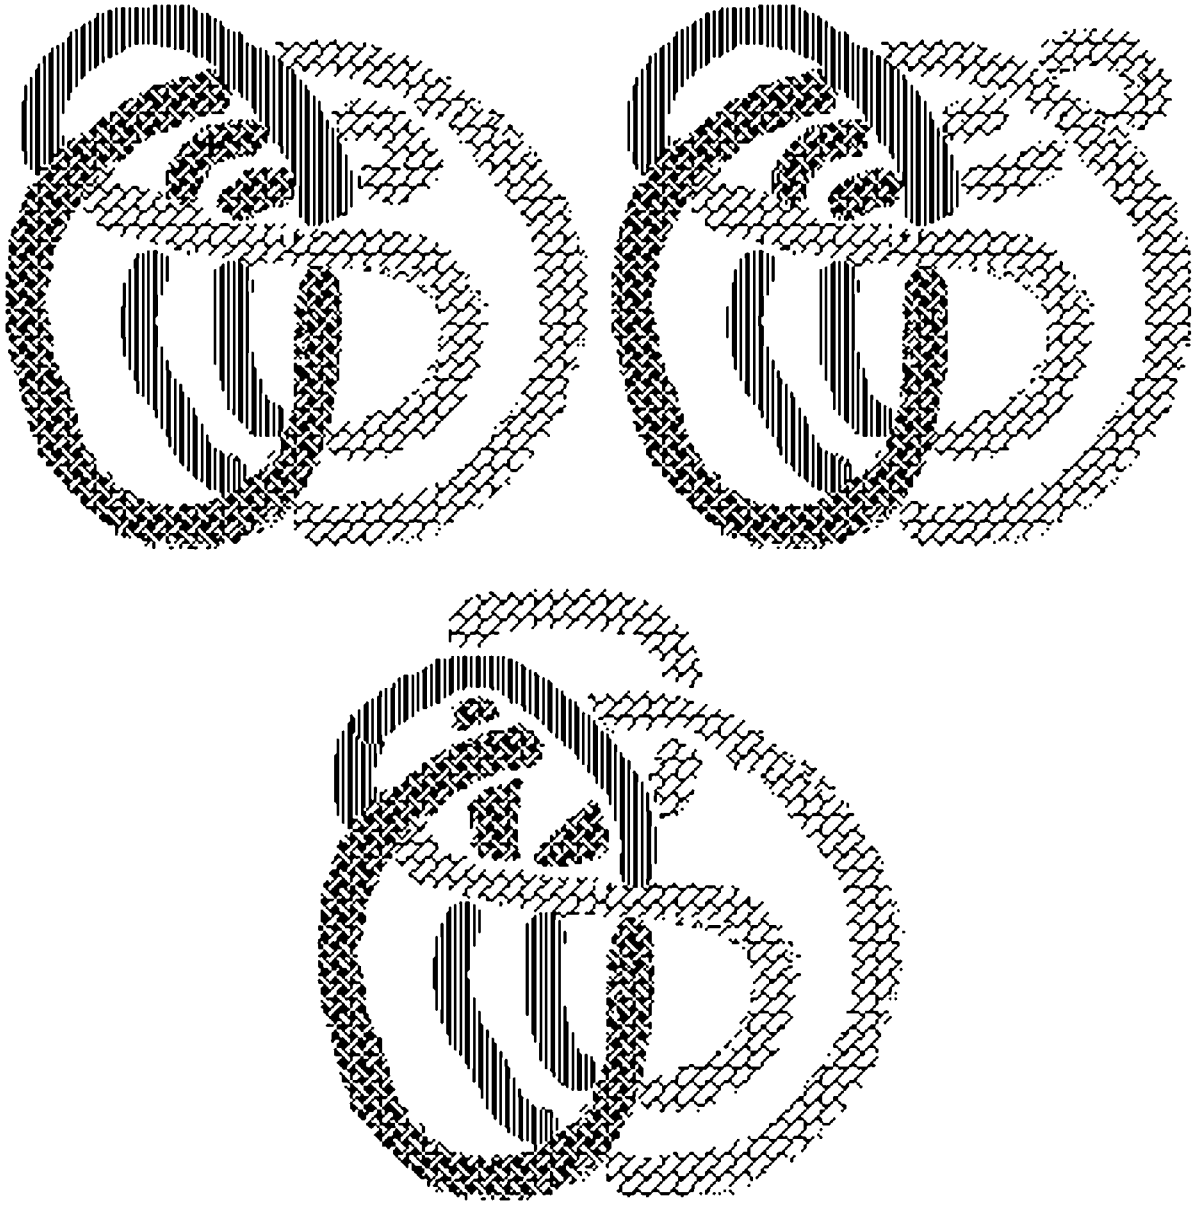

FIGURE 14 Coloring under type 2 and 3 moves.

be handled just like the three-coloring that we have already studied. In particular, a given labeling of a knot diagram means that it is possible to label (satisfying the rules given above for the labels) any diagram that is related to it by a sequence of Reidemeister moves. However, not all the labels will necessarily appear on every related diagram, and for a given coloring scheme and a given knot, certain special restrictions can arise.

To illustrate this, consider the color rule for numbers: $A^*B = A^\#B = 2B - A$. This satisfies the axioms, as is easy to see. Figure 17 shows how, on the trefoil, such a coloring must obey the equations $A^*B = C$, $C^*A = B$, $B^*C = A$. Hence $2B - A = C$, $2A - C = B$, $2C - B = A$. For example, if $A = 0$ and $B = 1$, then $C = 2B - A = 2$ and $A = 2C - B = 4 - 1 = 3$. We need $3 = 0$. Hence this system of equations will be satisfied for appropriate labelings in $\mathrm{Z}/3\mathrm{Z}$, the integers modulo three, a modular number system.

For the reader unfamiliar with the concept of modular number system, consider a standard clock whose dial is labeled with the hours 1, 2, 3, . . . , 11, 12. We ask what time is it 4 hr past the hour of 10? The answer is 2, and one can say that in the arithmetic of this clock $10 + 4 = 2$. In

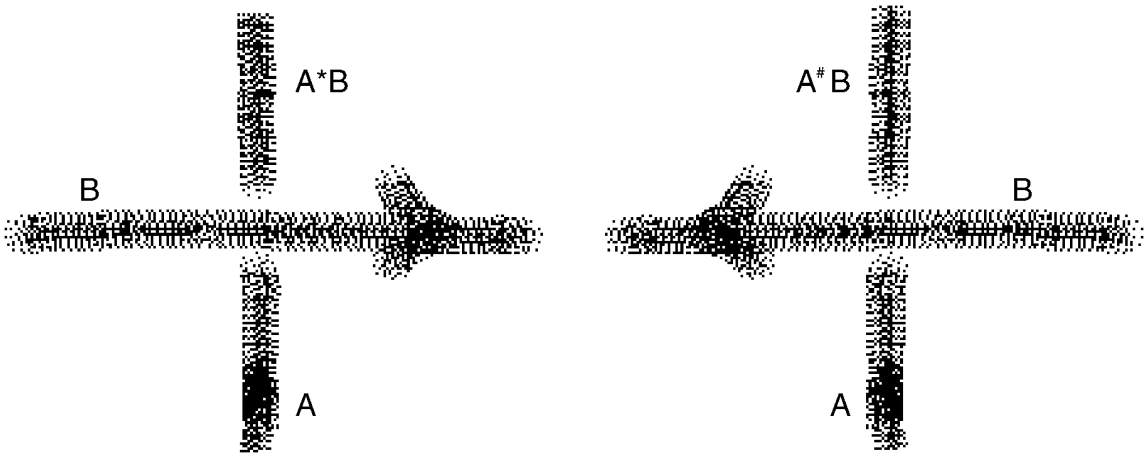

FIGURE 15 The quandle operation.

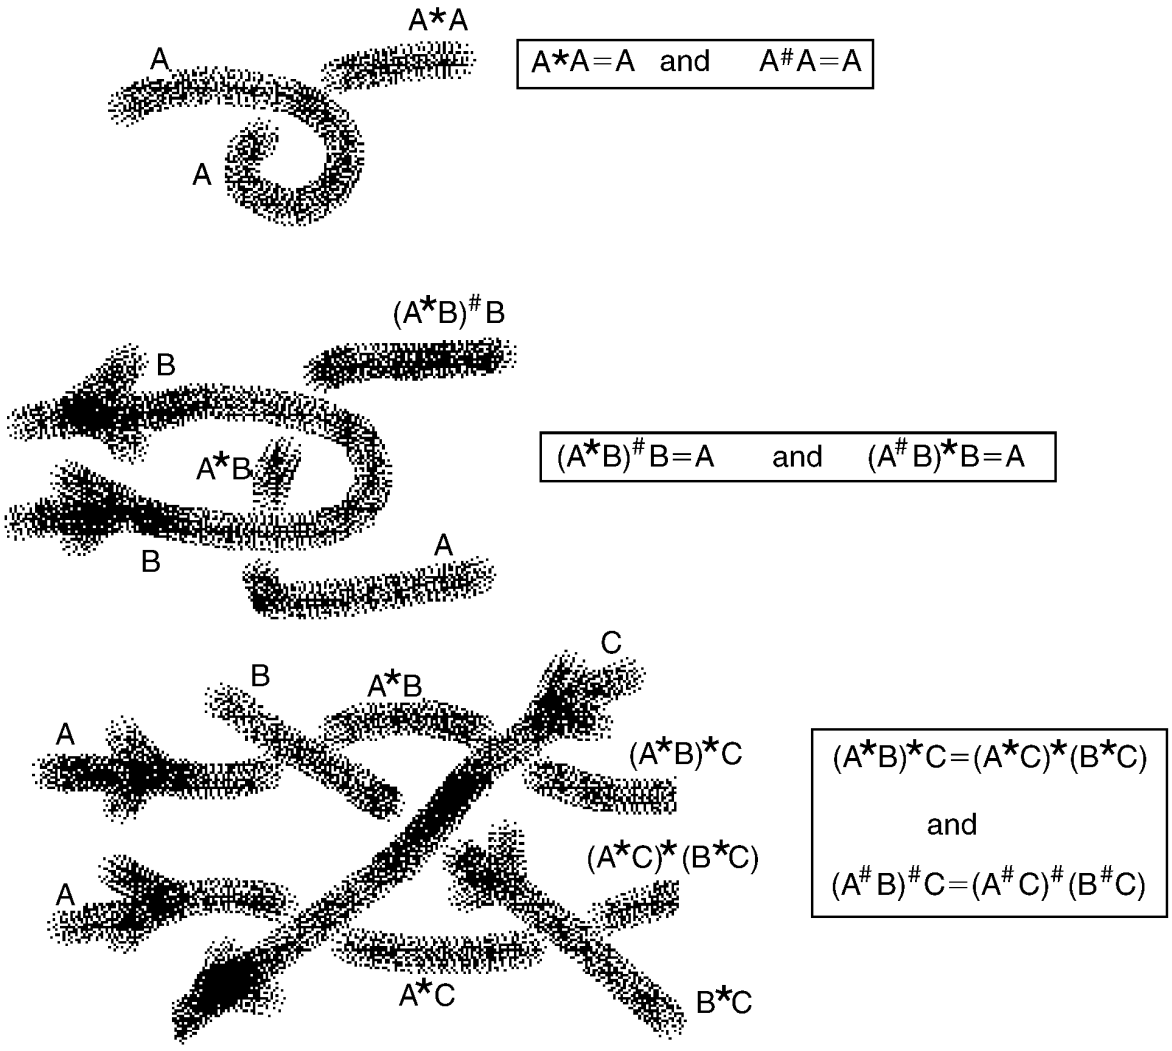

FIGURE 16 Quandle identities.

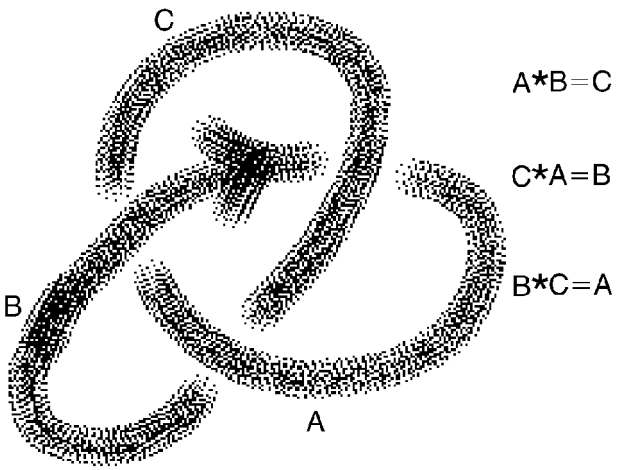

FIGURE 17 Equations for the trefoil knot.

fact $12 = 0$ in this arithmetic because adding 12 hr to the time does not change the time indicated on the clock. We work in clock arithmetic by remembering to set blocks of 12 hr to zero. One can multiply in this arithmetic as well. The square of the present time is 1 o'clock; what time is it? The answer is 7 since 7 squared is 49 and 49 is equal to 1 on the clock.

We say that the clock represents a modular number system $Z/12Z$ with modulus 12. It is convenient in mathematics to think of the elements of $Z/12Z$ as the set $\{0, 1, 2, \ldots, 11\}$. Since $0 = 12$ this takes care of all the hours.

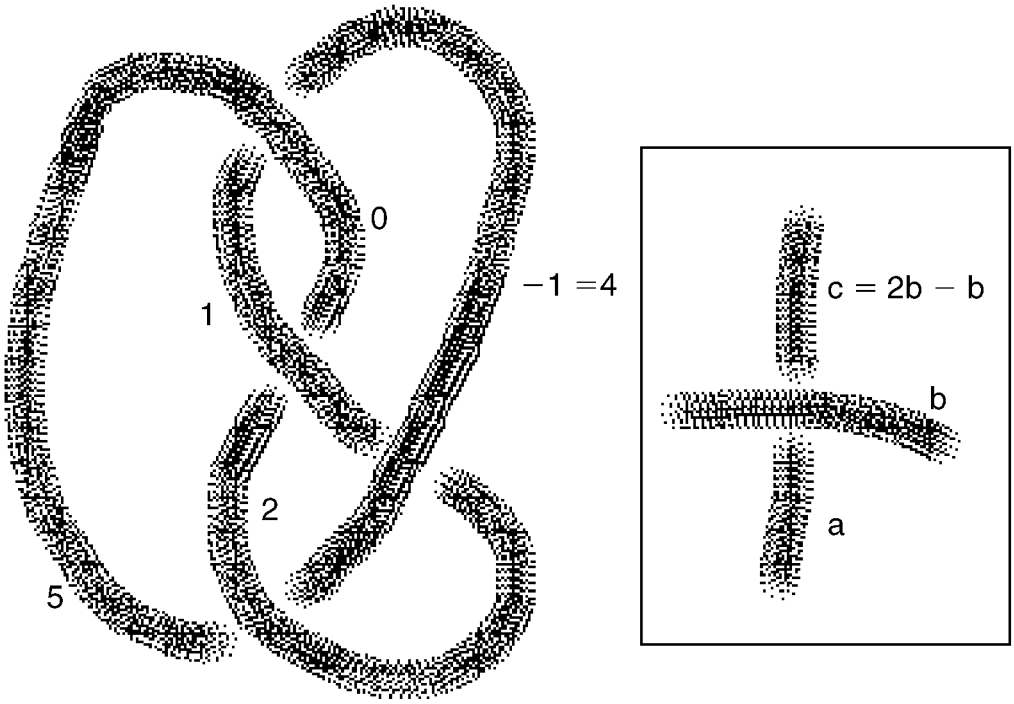
In general we can consider Z/nZ, where n is any positive integer modulus. The resulting modular number system has elements $\{0, 1, 2, \ldots, n-1\}$ and is handled just as though there were a clock with n hours rather than 12.

In such a system one says that $x = y \pmod{n}$ if the difference between x and y is divisible by n. For example, $49 = 1 \pmod{12}$ since $49 - 1 = 48$ is divisible by 12.

The modular number system $Z/3Z$ reproduces exactly the three coloring of the trefoil, and we see that the number 3 emerges as a characteristic of the equations associated with the knot. In fact, *3 is the value of a determinant that is associated with these equations*, and its absolute value is an invariant of the knot. For more about this construction, see Kauffman (1993, Part 1, Chapter 13).

Here is another example: For the figure eight knot E, we have that the modulus is 5. This shows that E is indeed knotted and that it is distinct from the trefoil. We can color (label) the figure eight knot with five "colors" 0, 1, 2, 3, and 4 with the rule $A^*B = 2B - A \pmod{5}$. See Fig. 18.

Note that in coloring the figure eight knot we have only used four of the five available "colors" from the set $\{0, 1, 2, 3, 4\}$. Figure 18 uses the colors 0, 1, 2, and 4. The



Labeling the Figure Eight Knot from the Integers Modulo Five

FIGURE 18 Five colors for the figure eight knot.

coloring number of a knot or link K is the least number of colors (greater than 1) needed to color it in the $2B - A$ fashion for *any* diagram of K. It is a nice exercise to verify that the coloring number of the figure eight knot is indeed four. In general the coloring number of knot or link is not easy to determine. This is an example of a topological invariant that has subtle combinatorial properties.

Other knots and links mentioned in this section can be shown to be knotted and linked by the modular method. The reader should try it for the Borromean rings and the Whitehead link.

The coloring (labeling) rules as we have formalized them can be described as axioms for an algebra associated with the knot. This is called the quandle. It has been generalized to the crystal, the interlock algebra, and the rack. The quandle is itself a generalization of the fundamental group of the knot complement.

C. The Alexander Polynomial

The modular labeling method has a marvellous generalization to the Alexander polynomial of the knot. This comes about through generalized coloring rules $A^*B = tA + (1-t)B$ and $A^\#B = t^{-1}A + (1-t^{-1})B$, where t is an indeterminate. It is a nice exercise to verify that these rules satisfy the axioms for the quandle. This algebraic structure is called the Alexander module.

The case $t = -1$ gives the rule $2B - A$ that we have already considered. By coloring diagrams with arbitrary t, we obtain a polynomial that generalizes the modulus. This polynomial is the Alexander polynomial.

Alexander (1923) described it differently in his original paper, and there is a remarkable history to the development of this invariant. See, for example Crowell and Fox (1963) and Kauffman (1987b) for more information. The flavor of this relationship can be seen by doing a little experiment in labeling the trefoil diagram shown in Fig. 19. The circularity inherent in the knot diagram results in relations that must be satisfied by the module action. In Fig. 19 we see directly by labeling the diagram that if arc **1** is labeled 0 and arc **2** is labeled A, then $(t + (1-t)^2)A = 0$. In fact, $t + (1-t)^2 = t^2 - t + 1$ is the Alexander polynomial of the trefoil knot. The Alexander polynomial is an algebraic modulus for the knot.

III. THE JONES POLYNOMIAL

Our next topic describes an invariant of knots and links of quite a different character than the modulus or the Alexander polynomial of the knot. It is a "polynomial" invariant of knots and links discovered by Jones (1985). Jones' invariant, usually denoted $V_K(t)$, is a polynomial in the variable $t^{1/2}$ and its inverse $t^{-1/2}$. One says that $V_K(t)$ is a Laurent polynomial in $t^{1/2}$. Superficially, the Jones polynomial appears to be just another polynomial invariant of knots and links, somewhat similar to the Alexander polynomial. When I say that the Jones polynomial is of a different

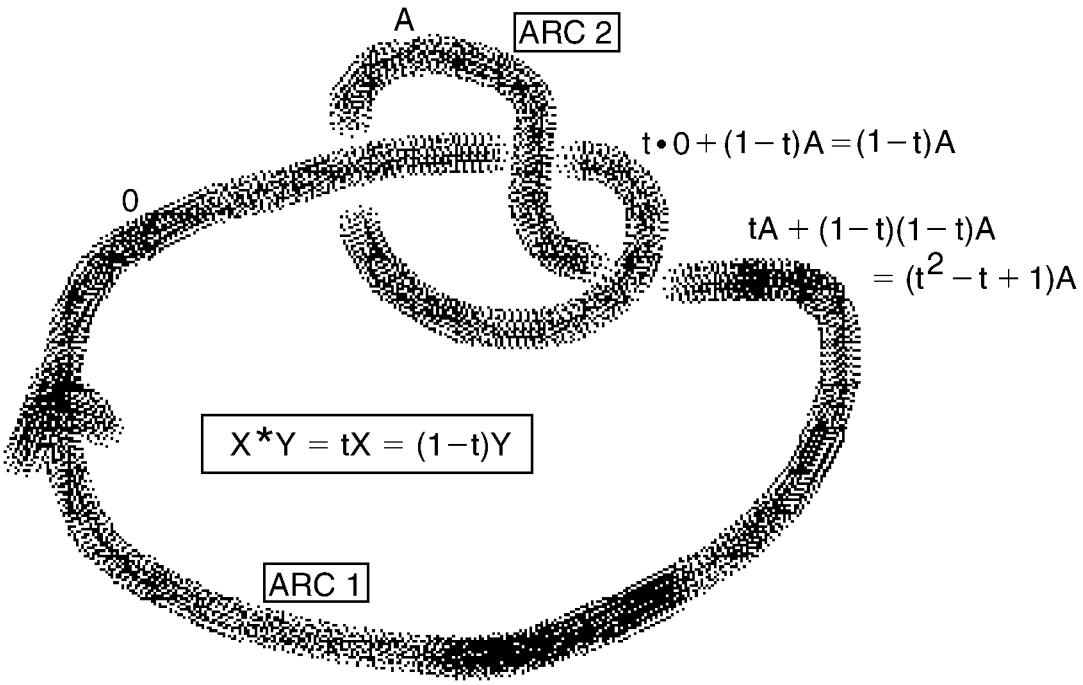


FIGURE 19 Alexander polynomial of the trefoil knot.

character, I mean something deeper, and it will take a little while to explain this difference. A little history will help.

The Alexander polynomial was discovered in the 1920s and until 1984 no one had found another polynomial invariant of knots and links that was not a simple generalization of the Alexander polynomial. Jones discovered a new polynomial invariant of knots and links that had some very remarkable properties. The Alexander polynomial cannot detect the difference between any knot and its mirror image. What made the Jones polynomial such an exciting discovery for knot theorists was the fact that it could detect the difference between many knots and their mirror images. Later, other properties began to emerge. It became a key tool in proving properties of alternating links (and generalizations) that had been conjectured since the last century (see, eg., Murasugi, 1987a, b, Kauffman 1987a and Thistlewaite 1987).

It turns out the the Jones polynomial is intimately related to a number of topics in mathematical physics. Curiously, it is actually easier to define and verify the properties of the Jones polynomial than for any other invariant in the theory of knots (except of course the linking number). We shall devote this section to the defining properties of the Jones polynomial, and later sections to the relationships with physics.

Here is a set of axioms for the Jones polynomial. The polynomial was not discovered in the form of these axioms. The axioms are in a format analogous to the framework that Conway (1970; Kauffman, 1980, 1983) discovered for the Alexander polynomial. I am starting with these axioms because they give a quick access to the polynomial and to sample computations.

1. Axioms for the Jones Polynomial

1. If two oriented links K and K' are ambient isotopic, then $V_K(t) = V_{K'}(t)$.
2. If U is an unknotted loop, then $V_U(t) = 1$.
3. If K_+, K_-, and K_0 are three links with diagrams that differ only as shown in the neighborhood of a single crossing site for K_+ and K_- (see Fig. 20), then $t^{-1}V_{K_+}(t) - tV_{K_-}(t) = (t^{1/2} - t^{-1/2})V_{K_0}(t)$.

The axioms for $V_K(t)$ are a consequence of Jones' original definition of his invariant. He was led to this invariant by a trail that began with the study of von Neumann algebras (a branch of algebra directly related to quantum theory and to statistical mechanics) and ended in braids, knots, and links. The Jones polynomial has a distinctly different flavor from the Conway–Alexander polynomial, even though it can be axiomatized in a very similar way. In fact, this similarity of axiomatics points to a common generalization [the Homfly(Pt) polynomial] and to another generalization (the Kauffman polynomial) and then to further generalizations in the connection with statistical mechanics (see, e.g., Kauffman, 1989).

To this date no one has found a knotted loop that the Jones polynomial does not declare to be knotted. Thus one can make the following conjecture:

Conjecture. If a single-component loop K is knotted, then $V_K(t)$ is not equal to one.

While it is possible that the Jones polynomial is able to detect the property of being knotted, it is not a complete classifier for knots. There are inequivalent pairs of knots that have the same Jones polynomial. Such a pair is shown in Fig. 21. These two knots, the Kinoshita–Terasaka knot and the Conway knot, have the same Jones polynomial but are different topologically. Incidentally these two knots are examples of knots whose knottedness cannot be detected by the Alexander polynomial.

Let us use the axioms to compute the Jones polynomial for the trefoil knot. To this end, there is a useful device called the *skein tree*. A skein tree is obtained from a given knot or link diagram by recording the knots and links obtained from this diagram by smoothing or switching crossings. Each node of the tree is a knot or link. The nodes farthest from the original knot or link are unknotted or unlinked. Such a tree can be produced from a given knot or link by using the fact that any knot or link diagram can

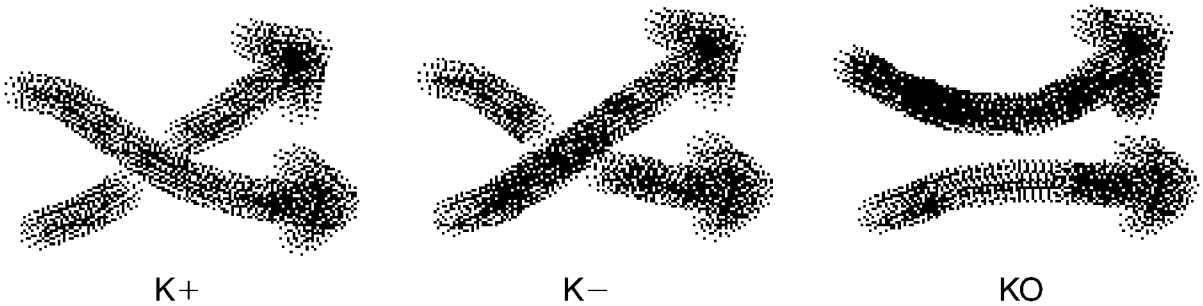

FIGURE 20 Skein Triple.

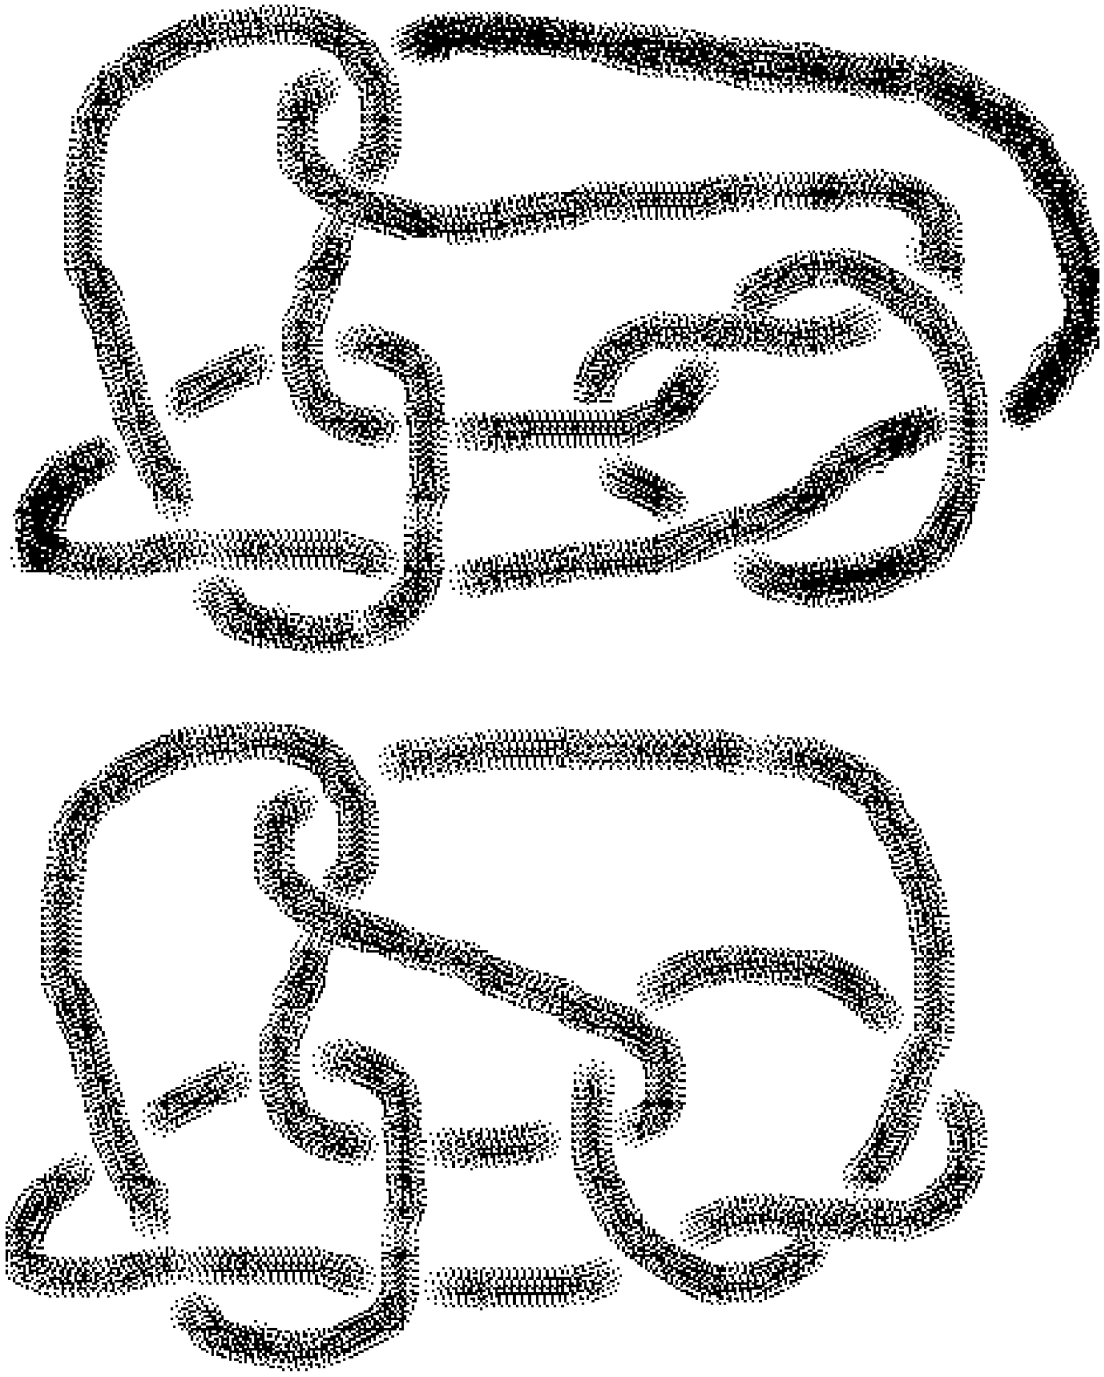

FIGURE 21 (Top) Conway Knot. (Bottom) Kinoshita-Terasaka Knot. Two Knots with trivial Alexander Polynomial.

be transformed into an unknotted (unlinked) diagram by a sequence of crossing switches.

Figure 22 illustrates a "standard unknot diagram." This diagram is drawn by starting at the arrowhead in the figure and tracing the diagram in such a way that one always draws an overcrossing before drawing an undercrossing. This is the easiest possible knot diagram to draw since one never has to make any corrections: one just passes under when one wants to cross an an already created line in the diagram. Standard unknot diagrams are always unknotted. Trying the one in Fig. 22 will show why this is so.

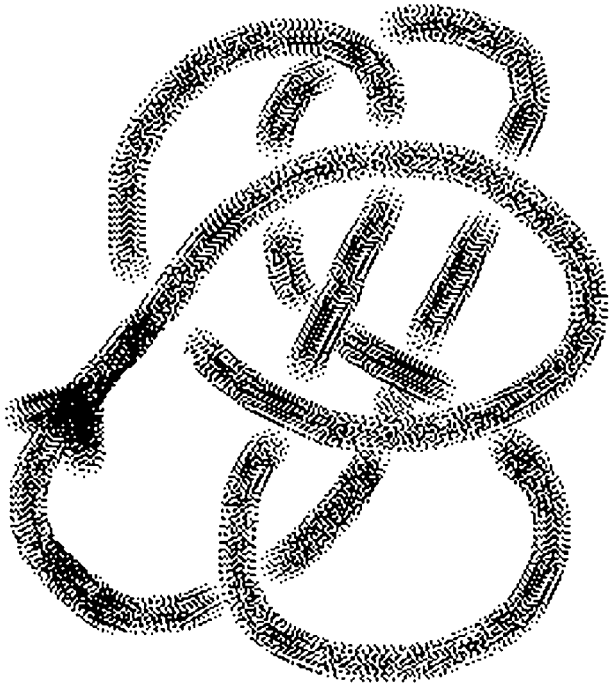

FIGURE 22 A standard unknot.

Using the fact that standard unknot diagrams are available, we can use the difference between a given diagram K and a standard unknot with the same plane projection to give a procedure for switching crossings to unknot the diagram K. This switching procedure can be used to produce a skein tree for calculating the Jones polynomial of K.

Figure 23 shows a skein tree for the computation of the Jones polynomial of the trefoil knot. The tree reduces the calculation of the Jones polynomial of the trefoil diagram to the calculation of certain unknots and unlinks. In order to see how to calculate an unlink it is useful to observe the behavior of the axioms in this case:

$$t^{-1}V_{U_+} - tV_{U_-} = (t^{1/2} - t^{-1/2})V_{U_0}.$$

Here U^+ and U^- denote unknots with single positive and negative twists in them, respectively. U_0, obtained by smoothing the crossing of U_+ or U_-, is an unlinked pair of circles with no twists. See Fig. 24.

Therefore $(t^{-1} - t)1 = (t^{1/2} - t^{-1/2})V_{U_0}$.

Hence $d = V_{U_0} = (t^{-1} - t)/(t^{1/2} - t^{-1/2}) = -(t^{1/2} + t^{-1/2})$.

Thus, we see that an extra unknotted component of the link multiplies the invariant by $d = -(t^{1/2} + t^{-1/2})$. For T the trefoil knot, U the unknot, and L the link of two unknotted circles as shown in Fig. 23, we find that

$$t^{-1}V_T - tV_U = (t^{1/2} - t^{-1/2})V_L,$$
$$t^{-1}V_L - td = (t^{1/2} - t^{-1/2})V_U.$$

Thus, $V_L = t(td + (t^{1/2} - t^{-1/2})) = -t^{5/2} - t^{1/2}$.
Hence

$$\begin{aligned} V_T &= t(t + (t^{1/2} - t^{-1/2})V_L) \\ &= t(t + (t^{1/2} - t^{-1/2})(-t^{5/2} - t^{1/2})) \\ &= t(t - t^3 - t + t^2 + 1) = t(-t^3 + t^2 + 1) \\ &= -t^4 + t^3 + t. \end{aligned}$$

The same calculation applied to the mirror image T^* (obtained by reversing all the crossings of T) of the trefoil yields the invariant $V_{T^*} = -t^{-4} + t^{-3} + t^{-1}$. This shows how the Jones polynomial discriminates between the trefoil and its mirror image, thereby proving that there is no ambient isotopy from T to T^*.

This method of calculating the Jones polynomial from its axioms does not tell us why the invariant works. It is possible to analyze this method of calculation and show that it does not depend upon the choices that one makes in the process and that it gives topological information about the knot or link in question. There is a different way to proceed that leads to a very nice formula for the Jones polynomial as a sum over "states" of the diagram. In this formulation, the polynomial is well defined from the beginning, and we can see the topological invariance arise in the course of adjusting certain parameters of a well-defined function. Our next topic is this state summation model for the Jones polynomial.

IV. THE BRACKET STATE SUM

In the last section we gave axioms for the Jones polynomial and showed how to compute it by skein calculations from these axioms. In this section we shall show one way to prove that the Jones polynomial is well defined by these axioms and that it is an invariant of ambient isotopy of links in three-dimensional space. In order to accomplish this aim, we shall give a different definition of the polynomial as a certain summation over combinatorial configurations associated with the given link diagram. This summation will be called a *state summation model* for the Jones polynomial.

In fact, we shall first construct a state summation called the *bracket polynomial* and then explain how to modify the bracket polynomial to obtain the Jones polynomial. The bracket polynomial has a rather natural development, and is defined for unoriented link diagrams.

We work with diagrams for unoriented knots and links. To each crossing in the diagram assign two *local states*

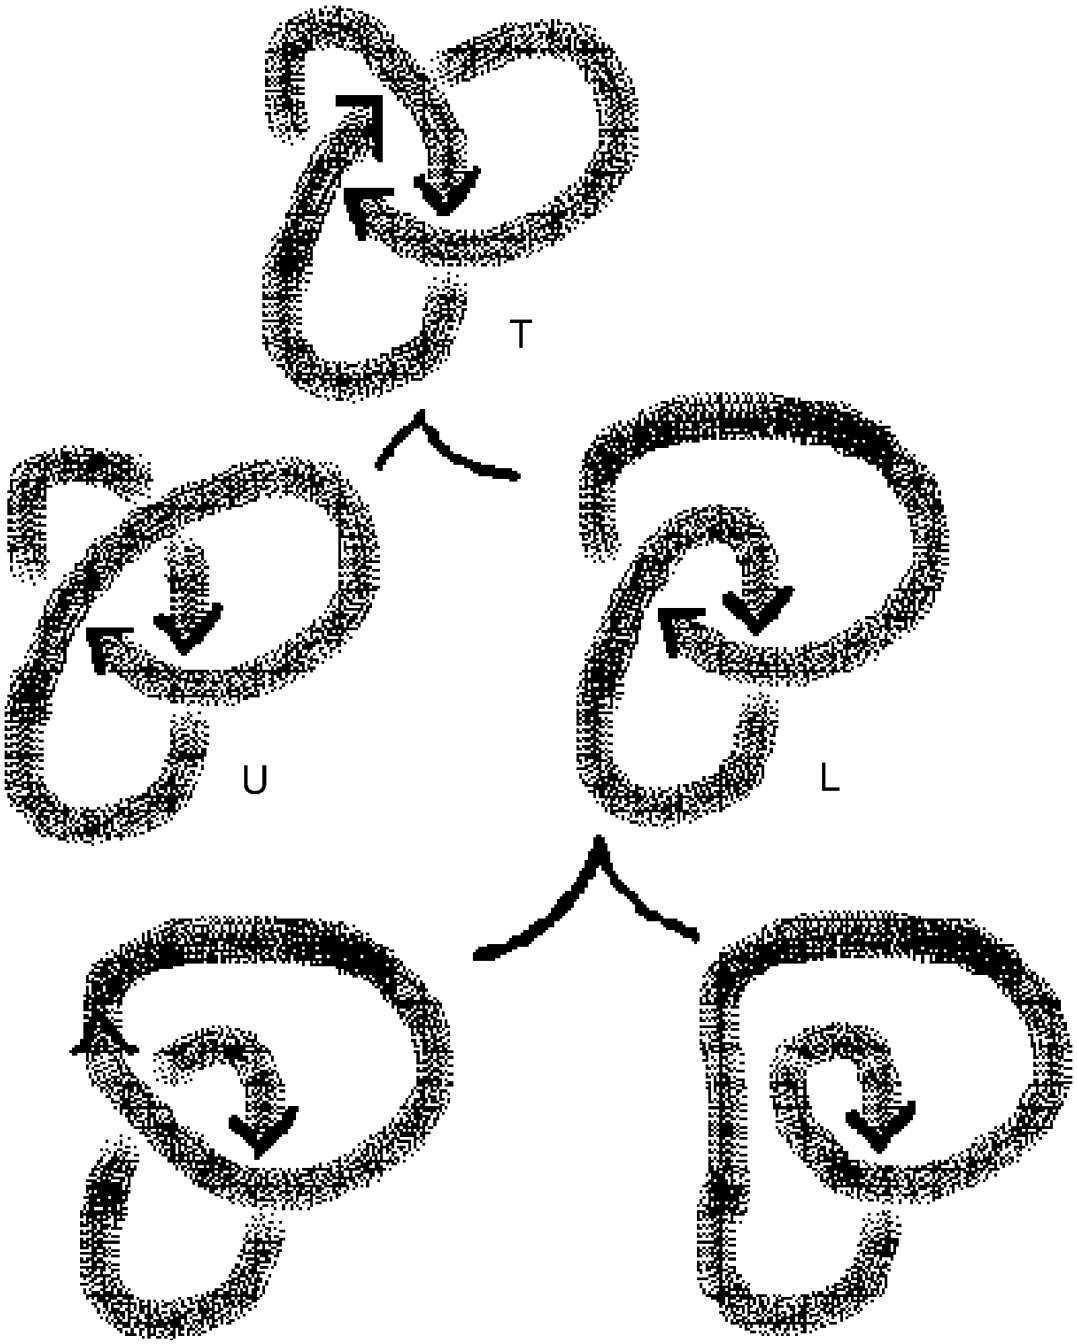

FIGURE 23 Trefoil skein tree.

with labels A and B as shown in Fig. 25. (In the A state the regions swept out by a counterclockwise turn of the overcrossing line are joined. In the B state the regions swept out by a clockwise turn of the overcrossing line are joined.)

A state S of a diagram K consists in a choice of local state for each crossing of K. Thus a diagram with N crossings will have $2U$ states. Two states S and S' of the trefoil diagram are indicated in Fig. 26. States are evaluated in two ways. These ways are denoted by $\langle K \mid S \rangle$ and by $\|S\|$. The *norm* of the state S, $\|S\|$, is defined to be one less than the number of closed curves in the plane described by S. In the example in Fig. 26, we have $\|S\| = 1$ and $\|S'\| = 0$. The evaluation $\langle K \mid S \rangle$ is defined to be the product of all the state labels (A and B) in the state. Thus, in Fig. 26, we have, $\langle K \mid S \rangle = A^3$ and $\langle K \mid S' \rangle = A^2 B$.

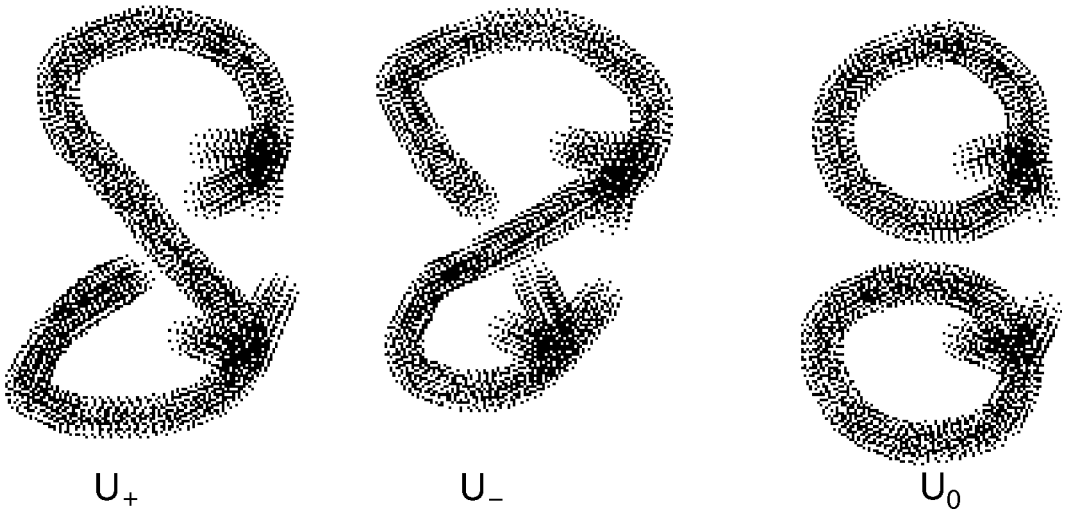

FIGURE 24 Skein Triple for Au Unknot.

Taking variables A, B, and d, we define the state summation associated with a given diagram K by the formula

$$\langle K \rangle = \sum \langle K \mid S \rangle d^{\|S\|}.$$

In other words, for each state we take the product of the labels for that state multiplied by d raised to the number of loops in the state. $\langle K \rangle$ is the summation of this state evaluation over all the states in the diagram for K. (The notation S means "sum over all instances of S.") We will show that the state summation $\langle K \rangle$ is invariant under the second and third Reidemeister moves if we take $B = 1/A$ and $d = -(A^2 + B^2)$. A normalization then enables us to obtain invariance under all three Reidemeister moves, and hence topological information about knots and links. [See Kauffman (1987a) for more information about the bracket and its relationship with the Jones polynomial.] There is a great deal of topological information in the calculations that ensue from the bracket polynomial. In particular, one can distinguish many knots from their mirror images, and it is possible that the bracket calculation can detect whether a given diagram is actually knotted.

A. First Steps in Bracketology

The first constructions related to the bracket polynomial are quite elementary. There are two basic formulas that are reminiscent of the exchange relations we have already seen for the Jones polynomial. These formulas are

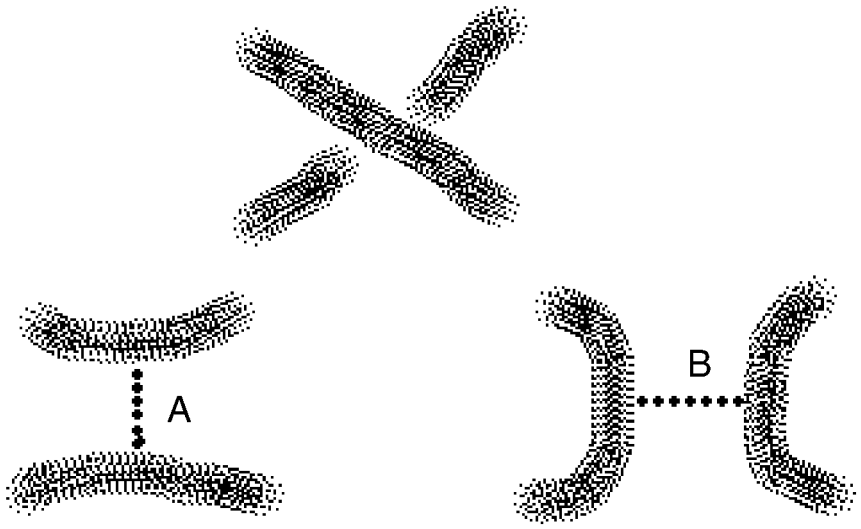

FIGURE 25 States of a Crossing.

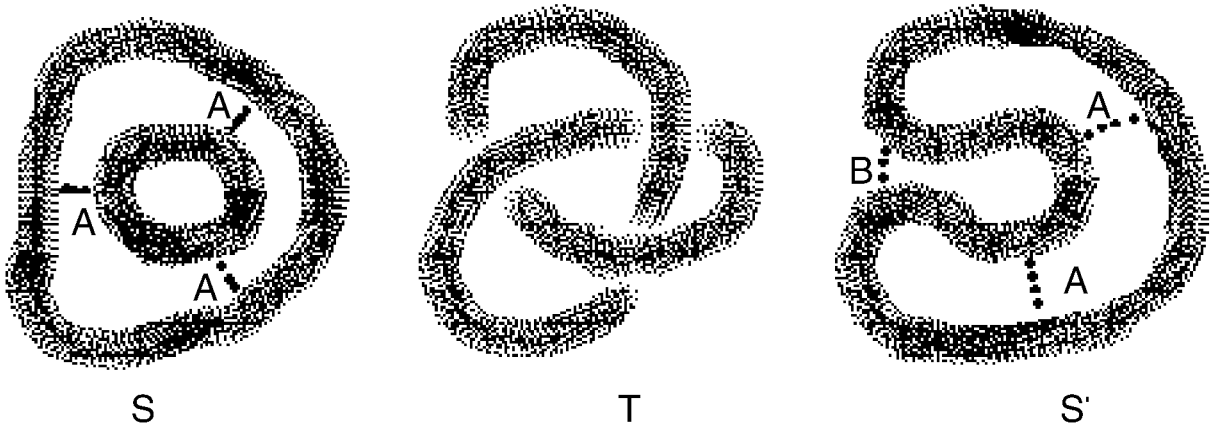

FIGURE 26 Two States of the Trefoil Knot.

as shown in Fig. 27. Here the small diagrams indicate parts of larger diagrams that are otherwise identical. Formula 1 just says that the state summation breaks up into two sums with respect to a given crossing in the diagram. In one sum, we have made a smooothing of type A at the crossing, while in the other sum we have made a smoothing of type B. The factors of A and B indicated in the formula are the contributions to the product of vertex weights from this crossing. All the rest of the two partial sums can be interpreted as bracket evaluations of the smoothed diagrams.

Formula 2 in Fig. 27 just states that an extra, simple closed curve in a diagram multiplies its bracket evaluation by the loop value d. Note that a single loop receives the value 1.

With the help of these two formulas, we can compute some basic bracket evaluations. Note that we have not yet specialized the variables A, B, and d. We shall analyze just what specialization will produce an invariant of knots and links. The advantage to having set up the definition of the bracket polynomial in this way is exactly that we have a method of labeling link diagrams with algebra, and it is possible to then adjust the evaluation so that it is invariant under Reidemeister moves. To this end, the next lemma tells us how the general bracket behaves under a Reidemeister move of type two. Essential diagrams for this lemma are in Fig. 28.

Lemma. Let K be a given link diagram, and let K' denote a diagram that is obtained from K by performing a type 2 Reidemeister move in the simplifying direction (eliminating two crossings from K). Let K'' be the diagram obtained from K by replacing the site of the type 2 move by two arcs in the opposite

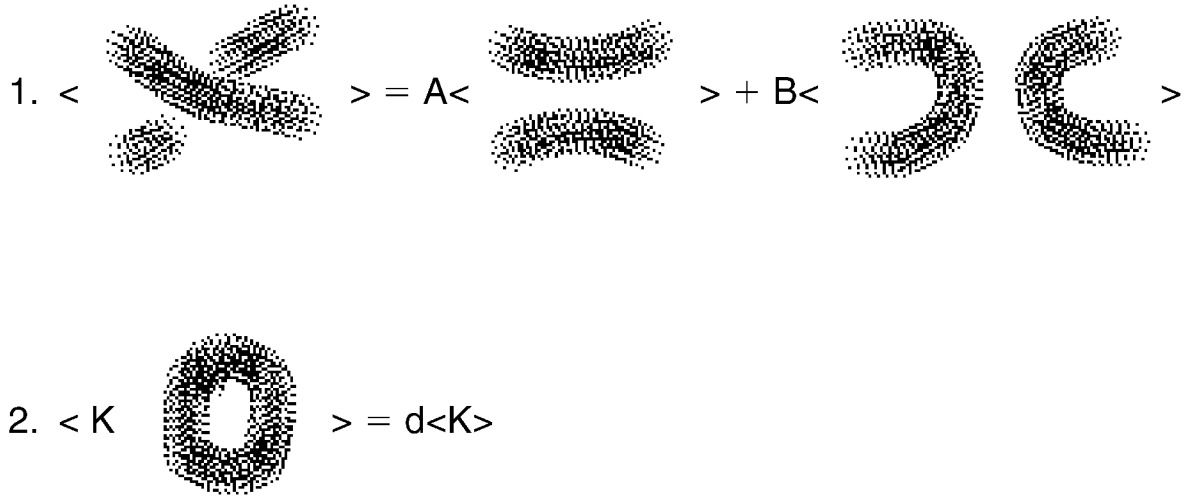

FIGURE 27 Bracket equations.

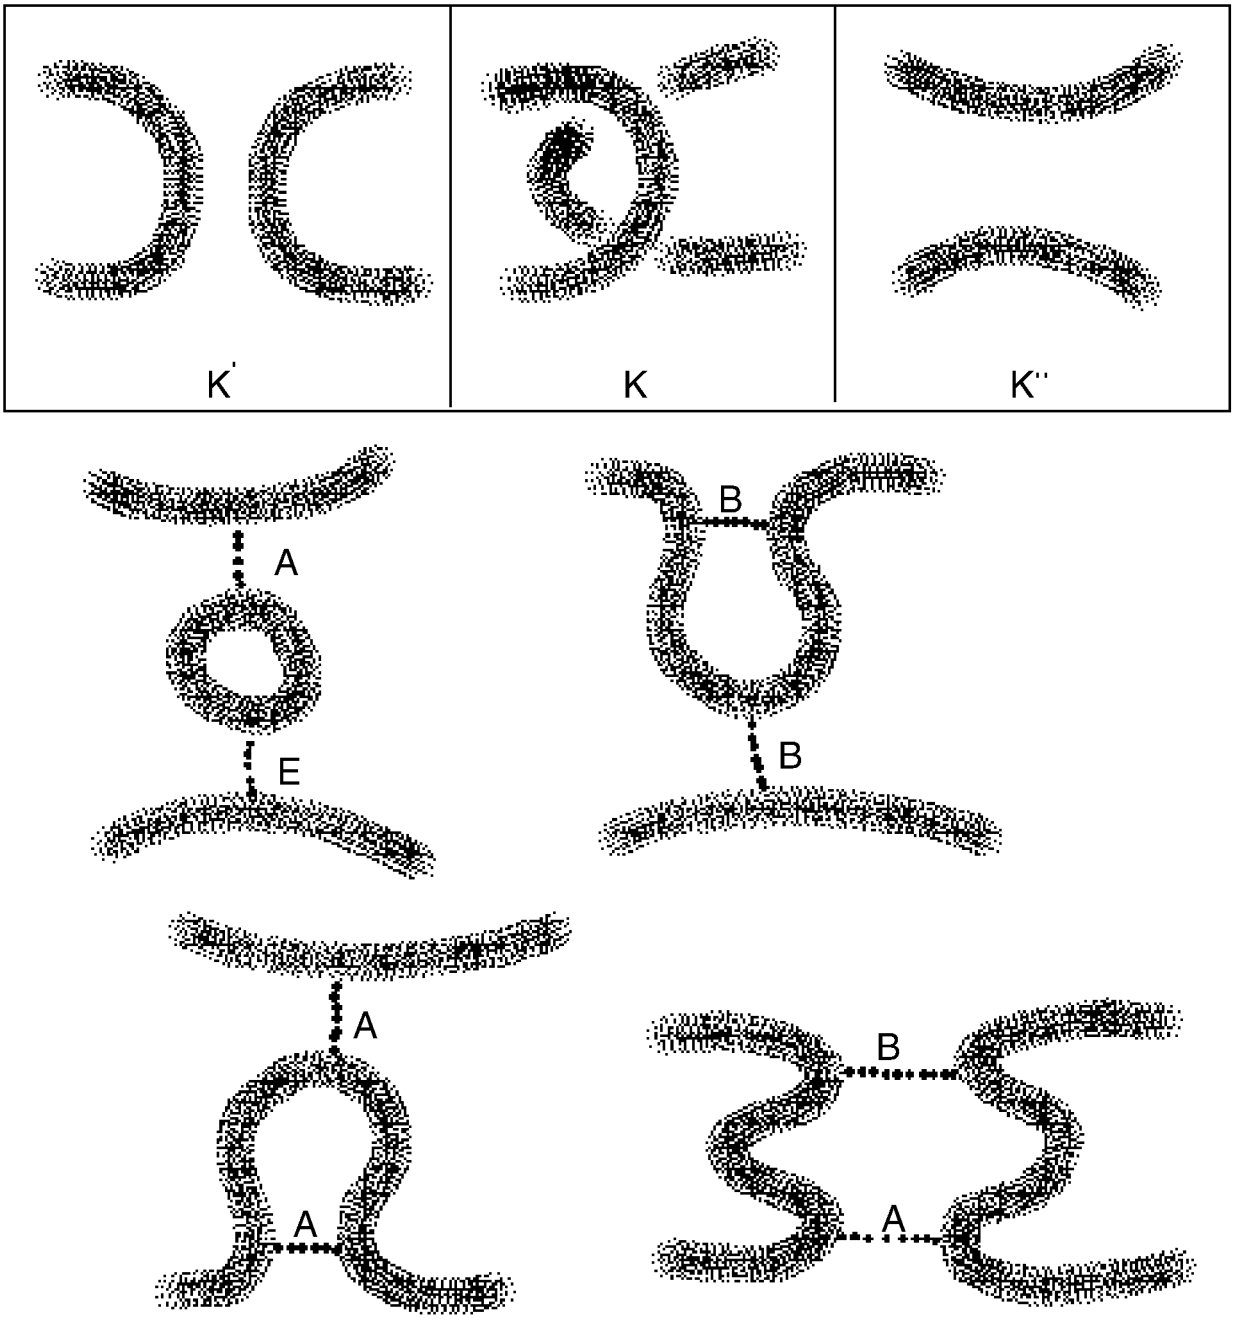

FIGURE 28 Type 2 changes.

pattern to the form of the simplified site in K'. (The diagrams in Fig. 28 illustrate this construction.) Then $\langle K\rangle = AB\langle K'\rangle + (ABd + A^2 + B^2)\langle K''\rangle$.

Proof. Consider the four local state configurations that are obtained from the diagram K on the left-hand side of the equation, as illustrated in Fig. 28. The formula follows from the fact that one of these states has coefficient AB and the other three have the same underlying diagram and respective coefficients ABd (after converting the loop to a value d), A^2, and B^2. This completes the proof of the Lemma.

With the help of this lemma it is now obvious that if we choose $B = 1/A$ and $d + A^2 + B^2 = 0$, then $\langle K\rangle$ is invariant under the second Reidemeister move.

Once this choice is made, the resulting specialized bracket is invariant under the third Reidemeister move, as illustrated in Fig. 29.

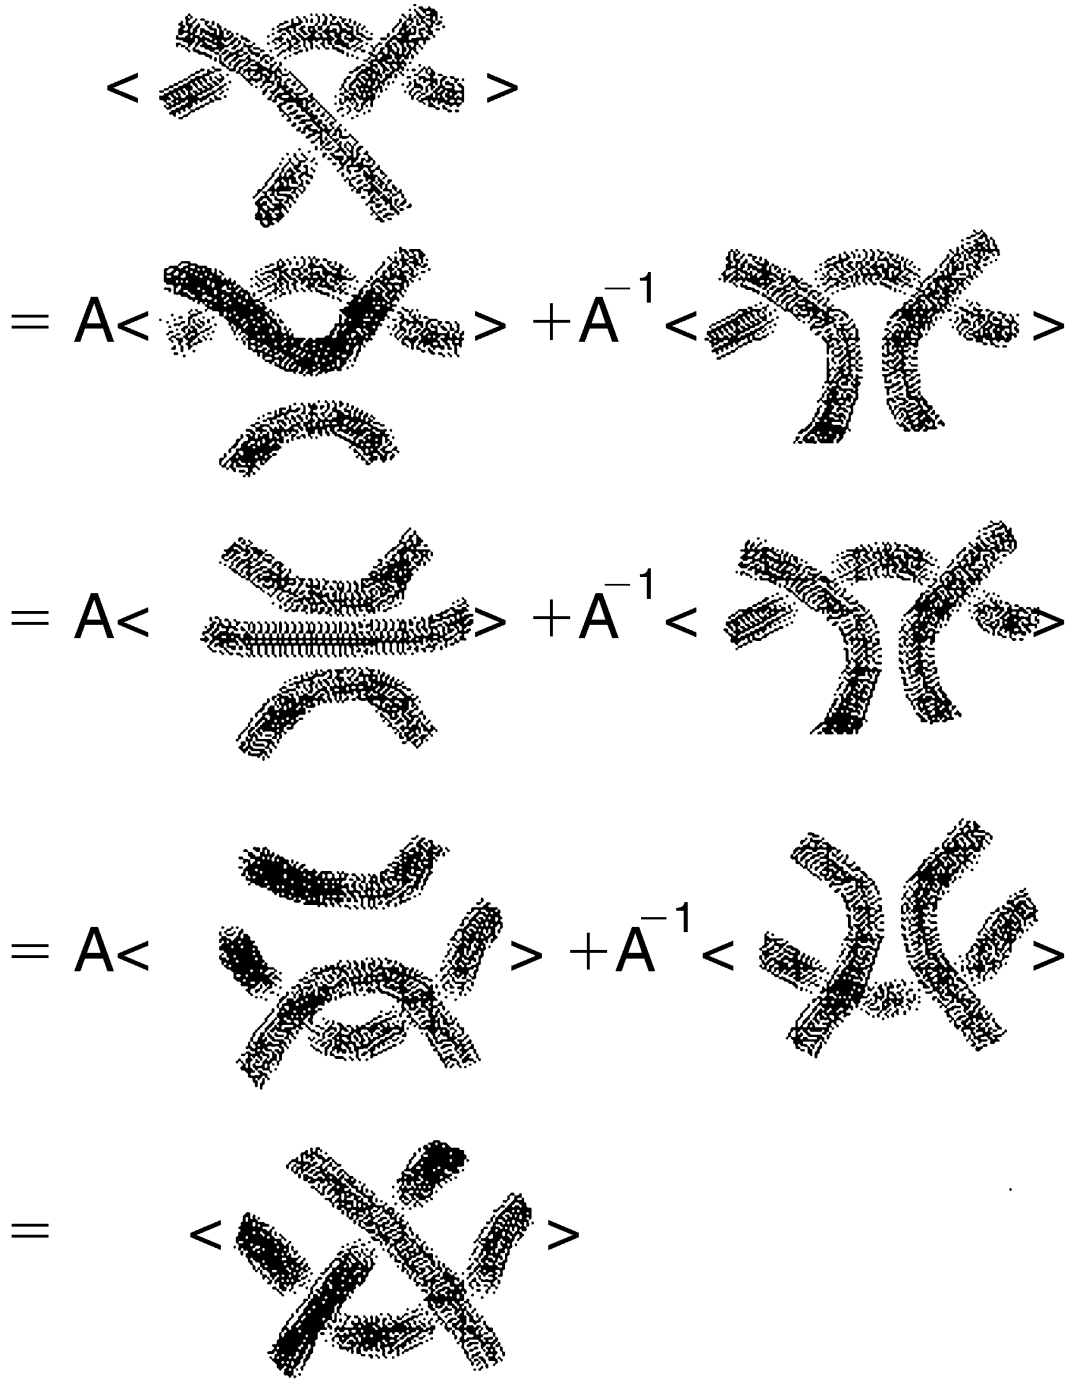

FIGURE 29 Type 3 invariance of the bracket.

Finally, we can investigate bracket behavior under the first Reidemeister move.

Lemma. Let $\langle K \rangle$ denote the bracket state sum with $B = A^{-1}$ and $d = -A^2 - A^{-2}$. Then $\langle K \rangle$ is invariant under the Reidemeister moves 2 and 3 and on move 1 behaves as shown:

$$\langle K(+) \rangle = (-A^3)\langle K \rangle,$$
$$\langle K(-) \rangle = (-A^{-3})\langle K \rangle.$$

Here $K(+)$ denotes a diagram with a simplifying move of type 1 available where the crossing that is to be removed has type $+1$. K is the diagram obtained from $K(+)$ by doing the type 1 move. Similarly, $K(-)$ denotes a diagram

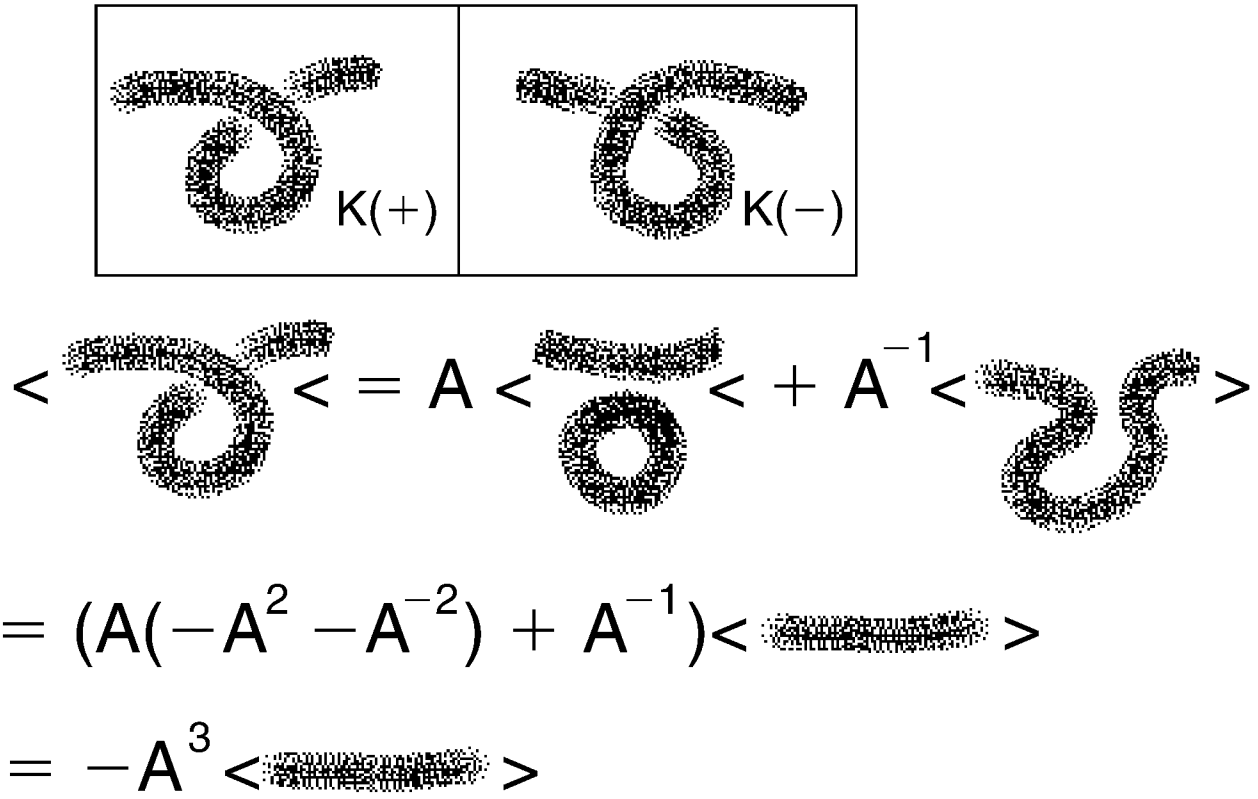

FIGURE 30 Bracket under type 1 move.

with a simplifying move of type 1 available where the crossing that is to be removed has type -1. Figure 30 illustrates the diagrams for $K(+)$ and $K(-)$.

Proof. See Fig. 30 for the behavior under type 1 moves. We have already verified the other statements in this lemma.

B. Framing Philosophy, Twist and Writhe

Is it unfortunate that the bracket is not invariant under the first Reidemeister move? No, it is fortunate! First of all, the matter is easy to fix by a little adjustment: Let K be an oriented knot or link, and define the *writhe* of K, denoted $w(K)$, to be the sum of the signs of all the crossings in K. Thus, the writhe of the right-handed trefoil knot is three. The writhe has the following behavior under Reidemeister moves:

(i) $w(K)$ is invariant under the second and third Reidemeister moves.

(ii) $w(K)$ changes by plus or minus one under the first Reidemeister move:

$$w(K(+)) = w(K) + 1$$
$$w(K(-)) = w(K) - 1.$$

(Here we use the notation of the previous lemma as shown in Fig. 30.)

Thus the writhe behaves in a parallel way to the bracket on the type 1 moves, and we can combine writhe and bracket to make a new calculation that is invariant under all three Reidemeister moves. We call the fully invariant calculation the "f-polynomial" and define it by the equation

$$f_K(A) = (-A^3)^{-w(K)}\langle K\rangle(A).$$

Up to this normalization, the bracket gives a model for the original Jones polynomial. The precise relationship is that $V_K(t) = f_K(t^{-1/4})$, where $w(K)$ is the sum of the crossing signs of the oriented link K, and $\langle K\rangle$ is the bracket polynomial obtained by ignoring the orientation of K.

We shall return to this relationship with the Jones polynomial in a moment, but first a little extra mathematical philosophy: Another way to view the fact of the bracket's lack of invariance under the first Reidemeister move is to see that the bracket is an invariant of knotted and linked bands embedded in three-dimensional space. Regard a link diagram as shorthand for an embedding of bands as shown in Fig. 31.

Figure 31 illustrates a link diagram for the trefoil knot in a thick, dark mode of drawing. This diagram is juxtaposed

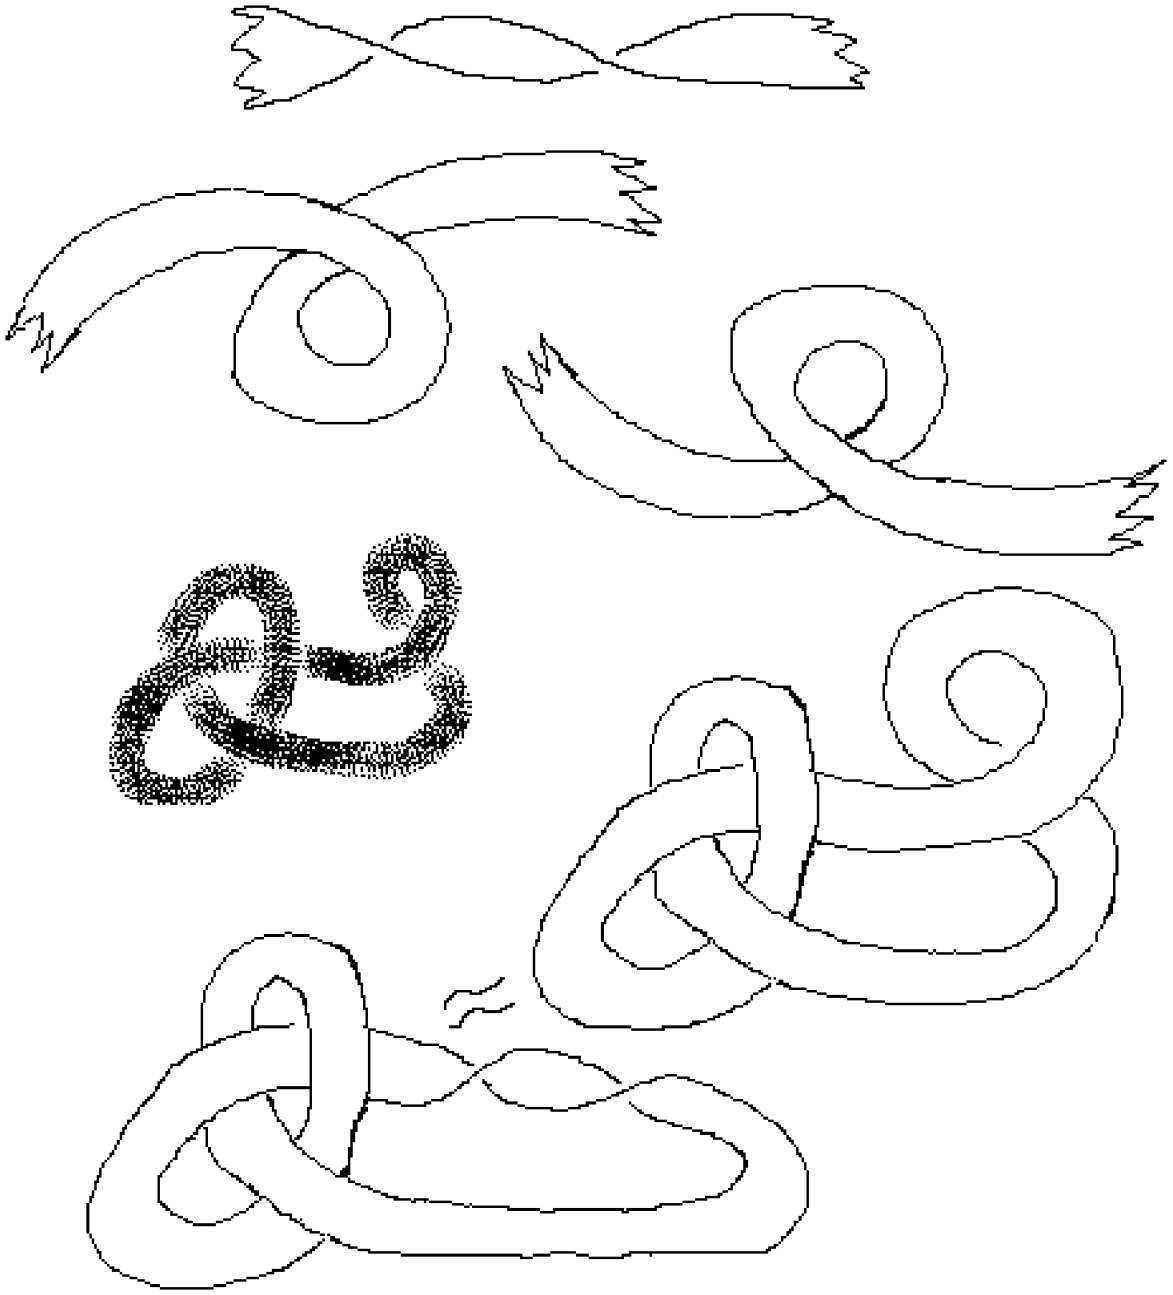

FIGURE 31 Bands and twists.

with a drawing of a knotted band that parallels that knot diagram. The band has two boundary components that proceed (mostly in the plane) parallel to one another. The curl in the knot diagram becomes a flat curl in the band that is ambient isotopic to a full twist (two half-twists) in the band. This isotopy is indicated in Fig. 31. The top of Fig. 31 shows a full twist in a band and two flat curls that both give rise to this same full twist by ambient isotopy that leaves their ends fixed. Each component of a link diagram is replaced by a paralleled version: the analog of a ribbbon-like strip of paper attached to itself with an even number of half-twists. The first Reidemeister move no longer applies to this shorthand since we can, at best, replace a curl by a twist as shown in Fig. 31.

In fact, as Fig. 31 shows, there are two distinct curls corresponding to a single full twist of a band. The bracket (and the writhe) behave the same way on both of these twists. This means that we can reinterpret the bracket as an invariant of the topological embeddings of knotted, linked, and twisted bands in three-dimensional space. This means

that the bracket has a fully three-dimensional interpretation, although its definition depends upon the use of planar projections.

C. Calculating the Bracket

Figure 32 shows a tree for calculating the bracket polynomial of the trefoil knot T.

It follows at once from the behavior of the bracket on curls that the contributions of the three (farthest from the trefoil itself) branches of this tree add to give the bracket polynomial of the trefoil:

$$\begin{aligned}\langle T\rangle &= A^2(-A^3) + AA^{-1}(-A^{-3}) + A^{-1}(-A^{-3})^2\\ &= -A^5 - A^{-3} + A^{-7}.\end{aligned}$$

Hence,

$$f_T = (-A^3)^{-w(T)}\langle T\rangle = A^{-4} + A^{-12} - A^{-16}.$$

Note that we managed only three branches in the tree for this calculation rather than the full expansion into the eight states. A savings like this is always possible because we know how the bracket behaves on curls. The resulting expansion gives a sum of monomials and is useful for thinking about the properties of the invariant.

D. Mirror Mirror

The knot K^* obtained by reversing all the crossings of K is called the mirror image of K. The knot K^* is the mirror

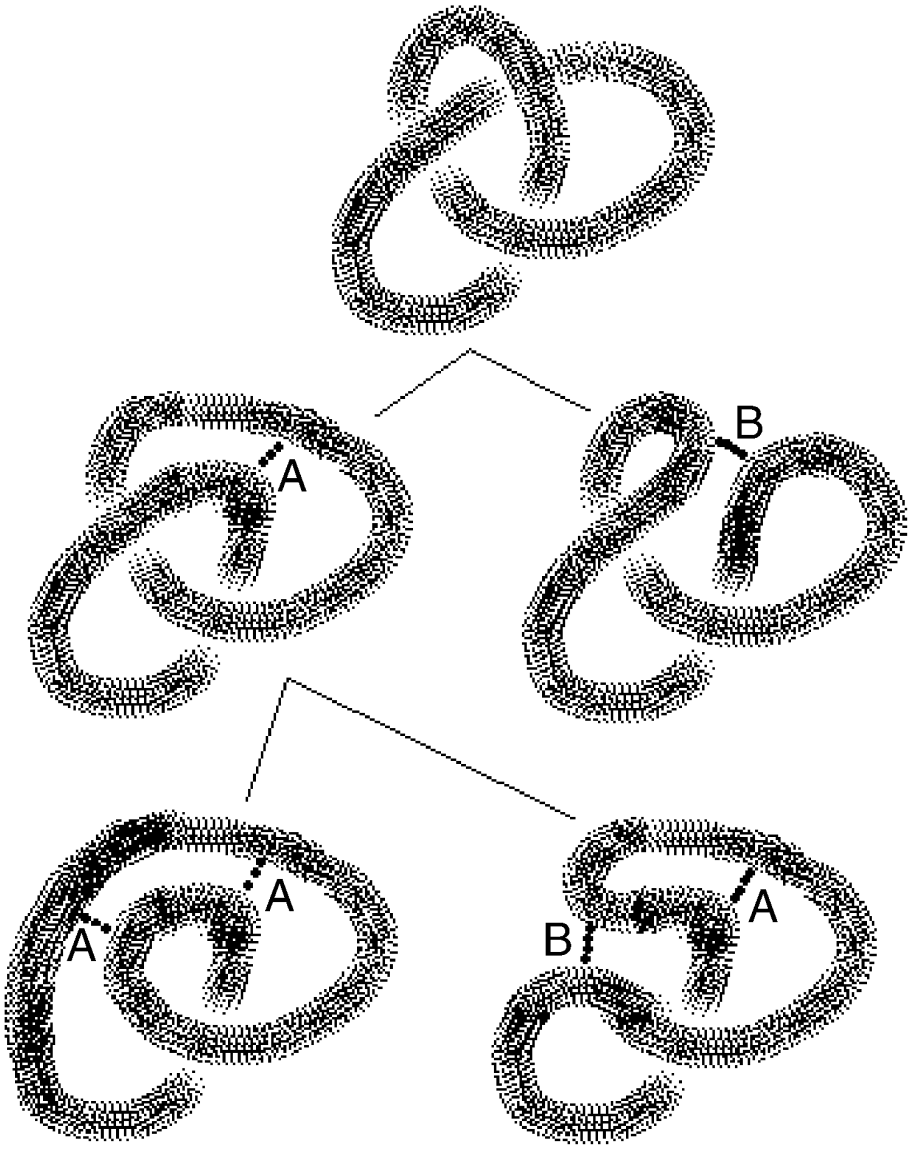

FIGURE 32 Tree for bracket of trefoil.

image of the knot that would ensue if the plane on which the knot is drawn were a mirror. It is easy to see that $\langle K^* \rangle(A) = \langle K \rangle(A^{-1})$ and that $f_{K^*}(A) = f_K(A^{-1})$. Thus, if K is ambient isotopic to K^* (all three Reidemeister moves allowed), then

$$f_K(A) = f_{K^*}(A) = f_K(A^{-1}).$$

Returning to the evaluation of the f-invariant for the trefoil, note that $f_T(A^{-1})$ is not equal to $f_T(A)$. Therefore, the trefoil knot T and its mirror image T^* are topologically distinct. The proof that we have given for it is the simplest proof known to this author. Note that we have given a complete proof of this fact, starting with the Reidemeister moves, constructing and applying the bracket invariant.

A knot is said to be *chiral* if it is not ambient isotopic to its mirror image. The words chiral and *chirality* come from physical chemistry and natural science. A knot that is equivalent to its mirror image is said to be *achiral*. (or *amphicheiral* in the speech of knot theorists). Many knots are achiral. The reader may enjoy verifying that the figure eight knot shown in Fig. 33 is ambient isotopic to its mirror image.

A complete understanding of the problem of determining whether a knot is chiral remains in the far distance. The new invariants of knots and links have enhanced our understanding of this difficult question.

E. Return to the Jones Polynomial

Now let us verify that the bracket does indeed give a model for the Jones polynomial. To see this, consider $f_K(A) = (-A^3)^{-w(K)} \langle K \rangle(A)$. Since the writhe $w(K)$ is obtained by summing signs over all the crossings of K, we can interpret the factor $(-A^3)^{-w(K)}$ as the product of contributions of $(-A^3)$ or $(-A^3)^{-1}$, one from each crossing and depending upon the sign of the crossing. Thus we can write an oriented state expansion formula for f_K as shown below, where K_+ and K_- denote links with corresponding sites with oriented crossings, K_0 is the result of smoothing the crossing in an oriented fashion, and $K_\&$ is the result of smoothing the crossing against the orientation:

$$f_{K+} = (-A^3)^{-1} A f_{K_0} + (-A^3)^{-1} A - 1 f_{K\&}.$$

Hence,

$$f_{K_+} = -A^{-2} f_{K_0} - A^{-4} f_{K_\&}$$

and similarly, for a negative crossing,

$$f_{K_-} = -A^2 f_{K_0} - A^4 f_{K_\&}.$$

Letting $V_K(t) = f_K(t^{-1/4})$, we have

$$V_{K_+} = -t^{1/2} V_{K_0} - t V_{K_\&}$$
$$V_{K_-} = -t^{-1/2} V_{K_0} - t^{-1} V_{K_\&}.$$

Therefore,

$$t^{-1} V_{K_+} - t V_{K_-} = (t^{1/2} - t^{-1/2}) V_{K_0}.$$

We leave the rest of the verification that $V_K(t)$ is the Jones polynomial (see Section 3) to the reader (check that it has the right behavior on unknotted loops).

V. VASSILIEV INVARIANTS

We have seen how it is fundamental to take the difference of an invariant at a positive crossing and at a negative crossing, leaving the rest of the diagram alone. The earliest

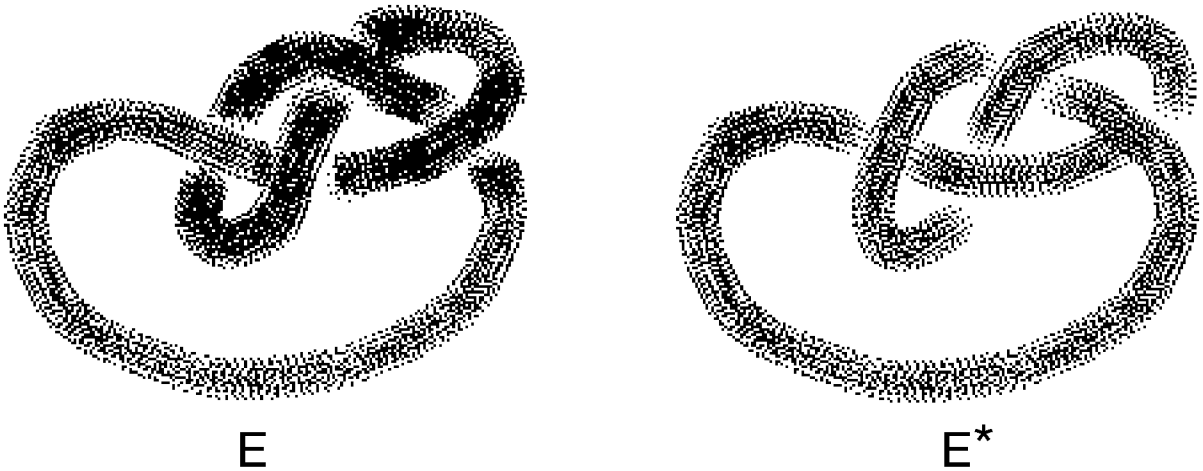

FIGURE 33 Figure eight knot and its mirror image.

instance of this is the Conway polynomial $C_K(z)$ with its exchange identity

$$C_{K_+} - C_{K_-} = zC_{K_0}.$$

Vassiliev (1990) gave new meaning to this sort of identity by thinking of the structure of the entire space of all mappings of a circle into three-dimensional space. This space of mappings includes mappings with singularities where two points on a curve touch. He interpreted the equation

$$Z_{K_+} - Z_{K_-} = Z_{K_\#}$$

as describing the difference of values across a singular embedding $K_\#$, where $K_\#$ has a transverse singularity in the knot space as illustrated in Fig. 34. (In a transverse singularity the curve touches itself along two different directions.)

The Vassiliev formula serves to define the value of the invariant on a singular embedding in terms of the the values on two knots "on either side" of this embedding. This Vassiliev formula serves to describe a method of extending a given invariant of knots to a corresponding invariant of embedded graphs with controlled singularities of this transverse type. This idea had been considered before Vassiliev. Vassiliev carried out his program of analyzing the singular knot space using techniques of algebraic topology, and in the course of this investigation he discovered a key concept that had been completely overlooked in the context of graph invariants. That concept is the idea of an invariant of *finite type*.

Definition. We shall say that Z_G is an invariant of *finite type i* if Z_G vanishes for all graphs with greater than i nodes.

This concept was extracted from Vassiliev's work by Birman and Lin (1993). A (rigid vertex) invariant of knotted graphs is a *Vassiliev invariant of finite type i* if it satisfies the identity

$$Z_{K_+} - Z_{K_-} = Z_{K_\#}$$

and it is of finite type i. In *rigid vertex isotopy* the cyclic order at the vertex is preserved, so that the vertex behaves like a rigid disk with flexible strings attached to it at specific points.

Vassiliev invariants form an extraordinary class of knot invariants. It is an open problem whether the Vassiliev invariants are sufficient to distinguish knots that are topologically distinct.

Vassiliev began an analysis of the combinatorial conditions on graph evaluations that could support such invariants. The key observation is the following result:

Lemma. If Z_G is a Vassiliev invariant of finite type i, then Z_G is independent of the embedding of the graph G when G has i vertices.

Proof. Suppose that G is an embedded graph G with i nodes. If we switch a crossing in G to form G', then the exchange relation for the Vassiliev invariant says that $Z_G - Z_{G'} = Z_{G''}$, where G'' has one more node than G or G'. But then G'' has $i+1$ nodes and hence $Z_{G''} = 0$. Therefore $Z_G = Z_{G'}$. This shows that we can switch crossings in any embedding of G without changing the value of Z_G. It follows from this that Z_G is independent of the embedding and depends only on the graph G. This completes the proof of the lemma.

For a Vassiliev invariant of type i, there is important information in the values it takes on graphs with exactly i nodes. These evaluations do not depend upon the embedding type of the graph. However, not just any such graphical evaluation will extend to give a topological invariant of knots and graphs. There are necessary conditions.

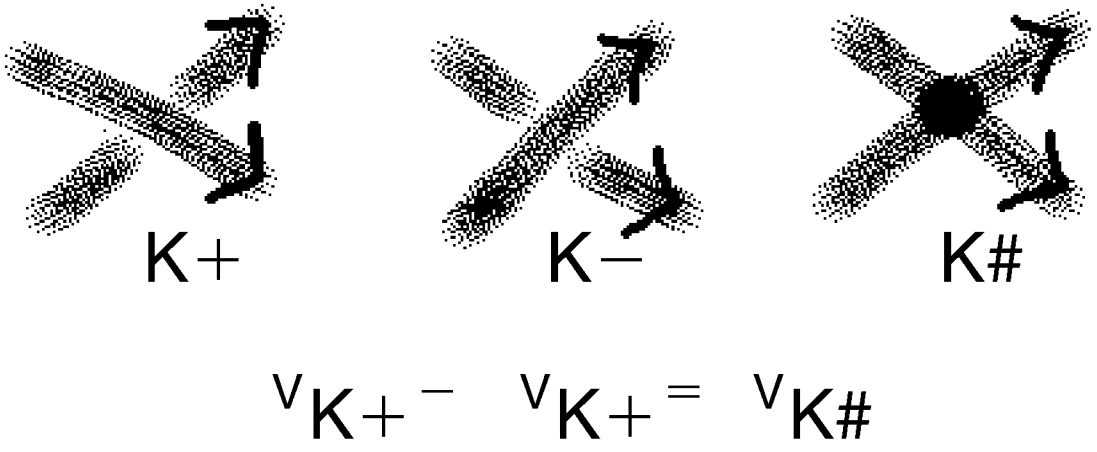

FIGURE 34 Difference equation.

Vassiliev found a version of these conditions through his analysis of the knot space and Stanford (1996) discovered the beautiful topological meaning of these conditions in relation to the switching identity. Stanford's argument goes as follows: Consider a singular crossing that has an arc from the diagram passing underneath it as shown in Fig. 35. Four crossing switches will take that arc above the singular crossing and return the diagram to a position that is topologically equivalent to its original position.

Each crossing switch gives an equation. There are four equations. Add them up and one gets an identity among the values of the invariant on four diagrams. Call this *the four-term relation*. This identity is illustrated in the second box in Fig. 35.

Now recall from the lemma we proved above that for a Vassiliev invariant of type i, the graphs with i nodes have values that are independent of their embeddings in three-dimensional space. This means that at the *top level* (the i-noded graphs for a Vassiliev invariant of type i will be called the top level) the four-term relations will be relations among the evaluations of abstract graphs. At the top level the four-term relations will be purely combinatorial conditions related to the topology.

How shall we think of abstract four-valent graphs corresponding to singular embeddings of a knot? An abstract knot is just a circle. An abstract singular knot is a circle with pairs of points marked that become the singular points in the embedding. Indicate these paired points by arcs between them. Call the resulting structure a *chord diagram*. See the example at the beginning of Fig. 36.

In the language of the chord diagrams the four-term relation at the top level (see the discussion of the top level in the paragraph above) becomes the equation shown in Fig. 36. This can be seen by translating the relation in Fig. 35 into the language of chord diagrams. In Fig. 36 we indicated parts of the chord diagram that are neighbors by showing an outer bracket connecting them. Those sites that are neighbors can have no other chords between them. Otherwise there can be many chords in these diagrams that are not indicated, just so long as the diagrams in the equation for the four-term relation differ only as shown in the figure.

If one can write down a top-level evaluation of chord diagrams that satisfies the four-term relation, then one has the raw data for a Vassiliev invariant. Such an evaluation of chord diagrams is called a *weight system* for a Vassiliev invariant. By the theorems of Kontsevich (1994) and Bar-Natan (1995), these raw data guarantee the existence of at least one invariant that satisfies the top-level evaluation.

The world is rife with Vassiliev invariants. Birman and Lin (1993) showed directly that the Jones polynomial and its generalizations give rise to Vassiliev invariants. In the case of the Jones polynomial here is an easy proof of their result:

Theorem. Let $V_G(t)$ denote the Jones polynomial extended to rigid vertex 4-valent graphs by the formula $V_{K_+} - V_{K_-} = V_{K_\#}$. Let $v_i(G)$ denote the coefficient of x^i in the expansion of $V_G(\exp(x))$. Then $v_i(G)$ is a Vassiliev invariant of type i.

Proof. Use the identities from the end of Section 4:

$$V_{K_+} = -t^{1/2}V_{K_0} - tV_{K_\&},$$
$$V_{K_-} = -t^{-1/2}V_{K_0} - t^{-1}V_{K_\&}.$$

Substitute $t = \exp(x)$. It follows at once that $V_{K_\#} = V_{K_+} - V_{K_-}$ is divisible by x. Hence V_G is divisible by x^i when G has i nodes. This implies that the coefficients $v_i(G) = 0$ if G has more than i nodes. Hence the coefficients $v_i(G)$ are of finite type, proving the theorem.

With the help of theorems of this type it is possible to study Vassiliev invariants by studying the structure of known invariants of knots and links. In particular it is possible to justify the structure of many weight systems in terms of known invariants. We shall not go into these sorts of investigations in this exposition. The next section shows how the algebraic study of Lie algebras is directly related to the construction of Vassiliev invariants. This is one beginning of a whole world of relationships between knot theory and algebra.

VI. VASSILIEV INVARIANTS AND LIE ALGEBRAS

The subject of Lie algebras is an algebraic study with a remarkable connection with the topology of knots and links. The purpose of this section is to first give a brief introduction to the concept of a Lie algebra and then to show the deep connection between these algebras and the structure of Vassiliev invariants for knots and links, as described in the previous section.

In order to understand the idea behind a Lie algebra it is helpful to first consider the concept of a group. A set G is said to be a *group* if it has a single binary operation * such that:

1. Given a and b in G, then a^*b is also in G.
2. If a, b, c are in G, then $(a^*b)^*c = a^*(b^*c)$.
3. There is an element E in G such that $E^*a = a^*E = a$ for all a in G.
4. Given a in G, there exists an element a^{-1} in G such that $a^*a^{-1} = a^{-1*}a = E$.

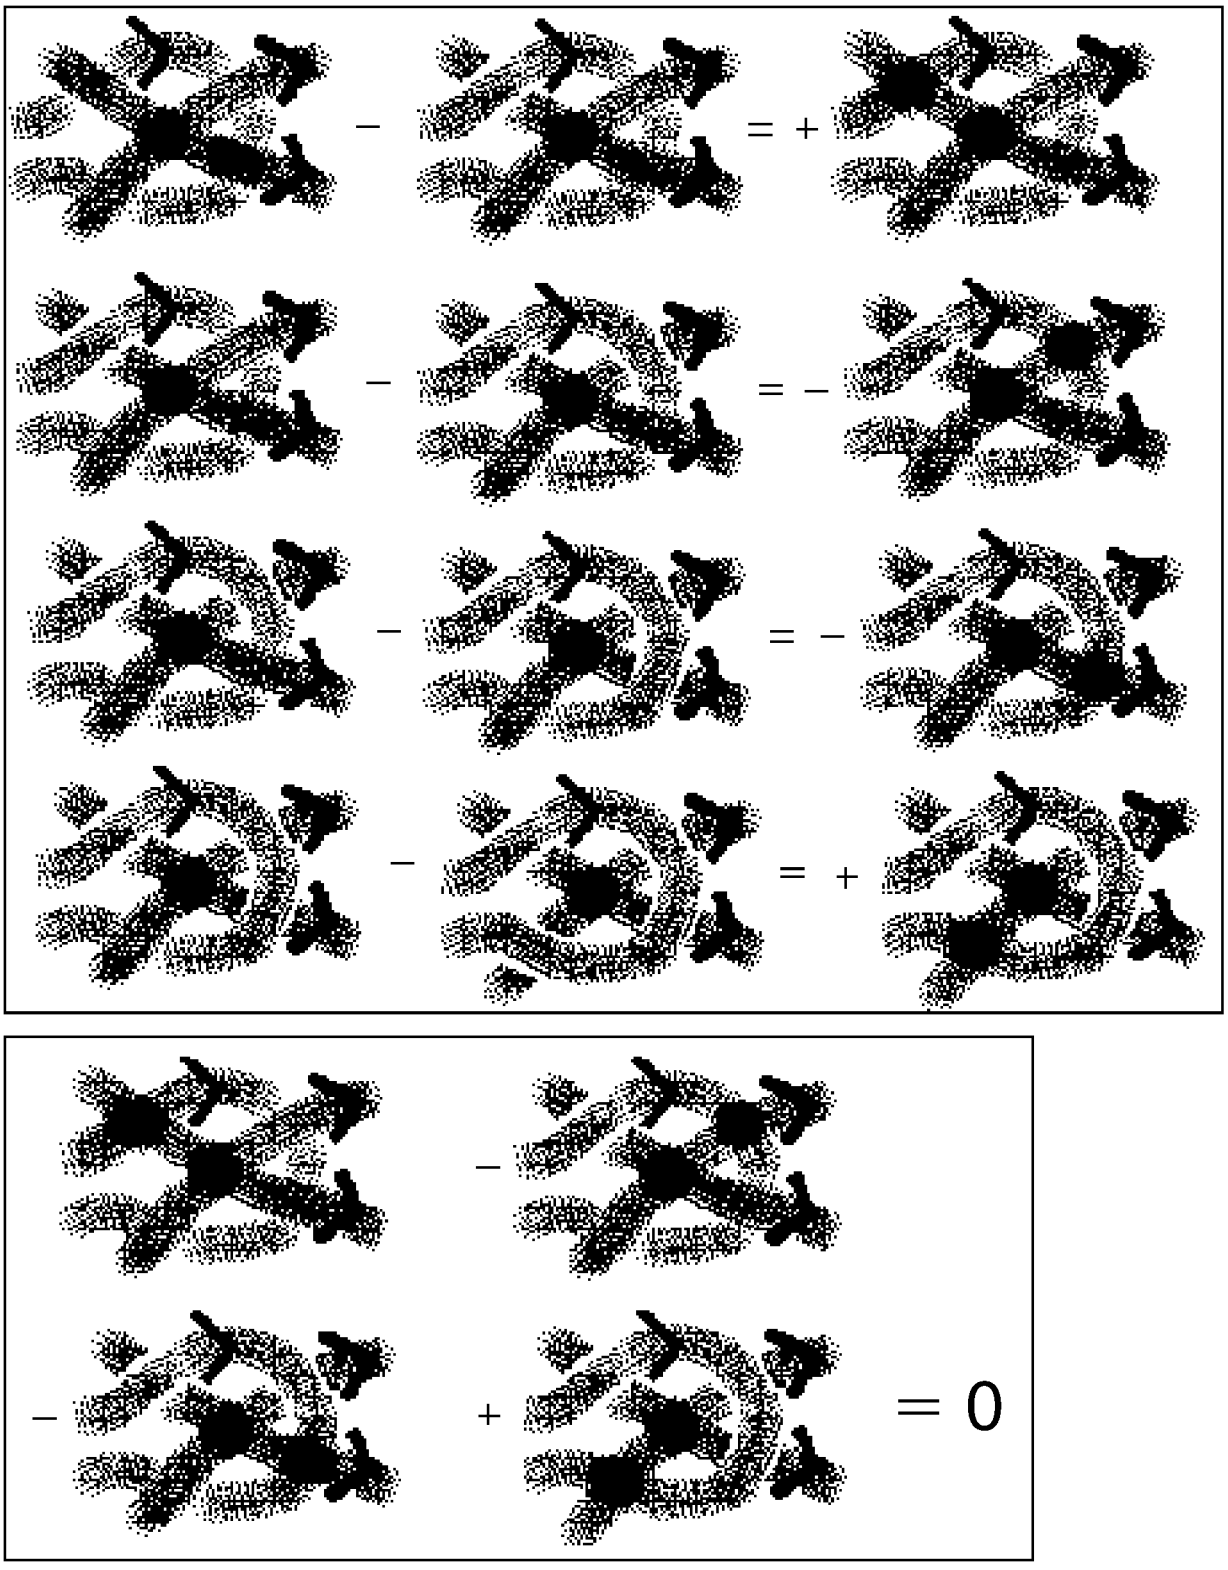

FIGURE 35 Embedded four-term relation.

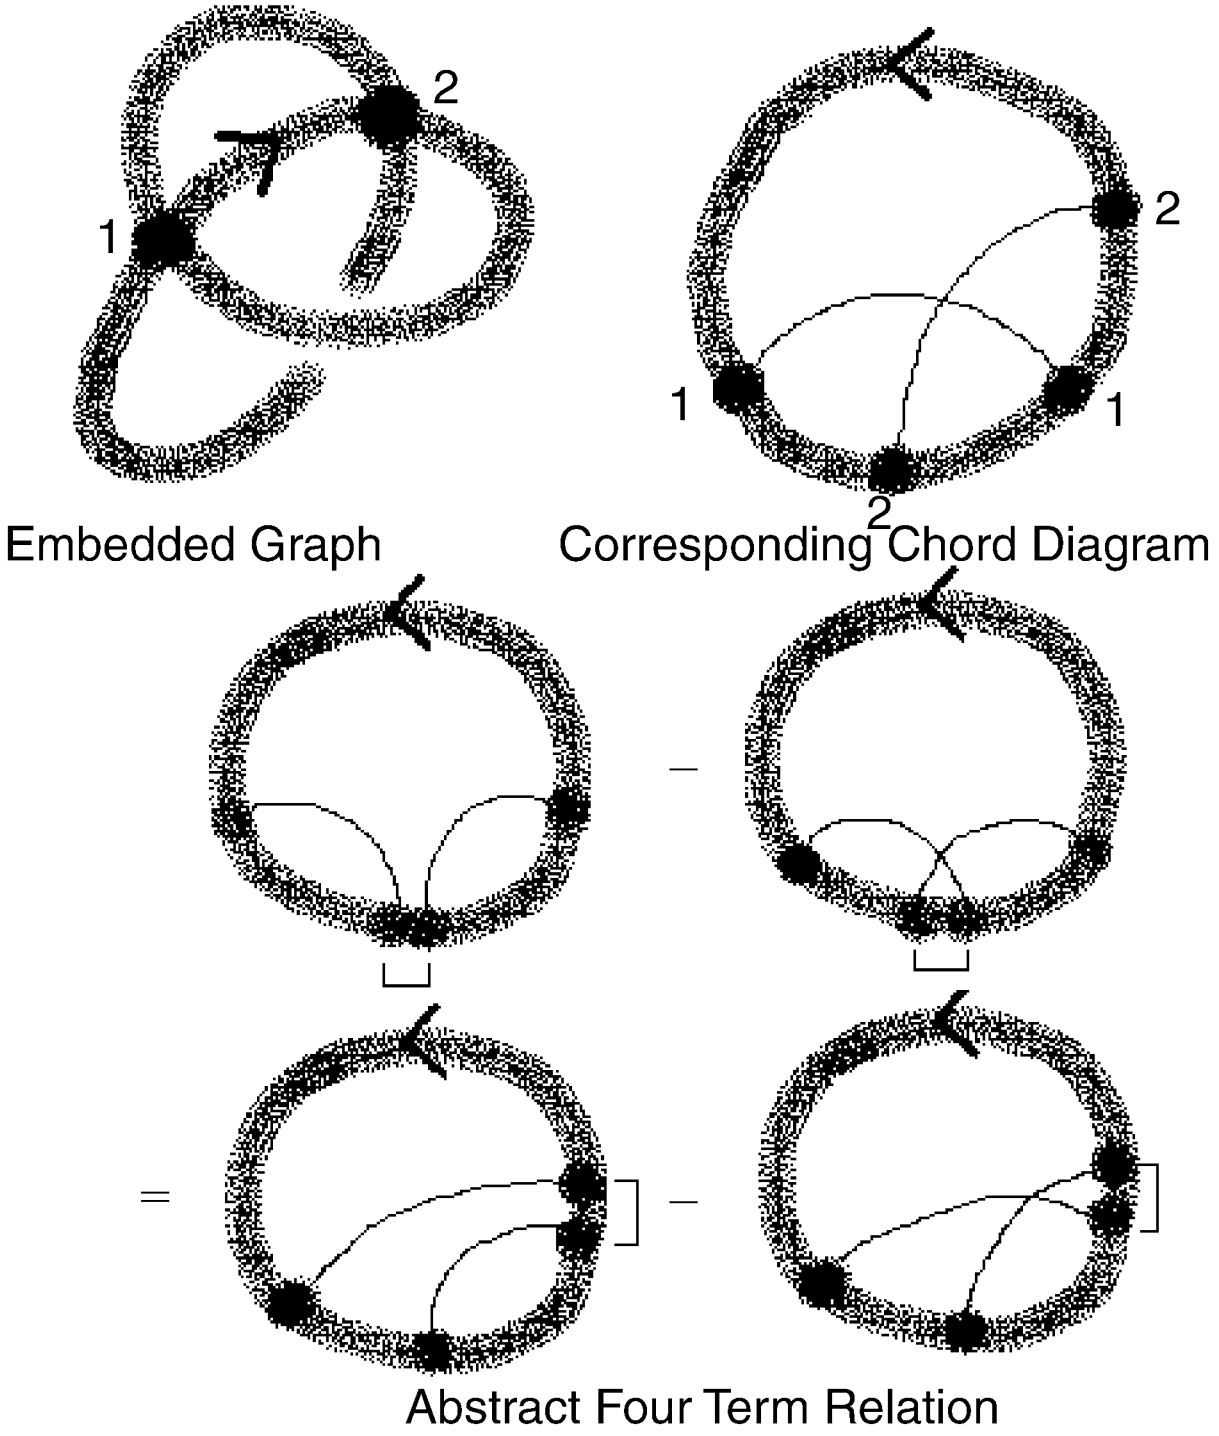

FIGURE 36 Abstract four-term relation via chord diagrams.

One of the most fertile sources of groups is matrix algebra. Recall that an $n \times n$ matrix A is an array of numbers A_{ij} (real or complex) $A = (A_{ij})$, where i and j range in value from 1 to n. One defines the product of two matrices by the formula $(AB)_{ij} = \sum_k A_{ik} B_{kj}$, where k runs from 1 to n in this summation.

For our purposes it is essential to have a diagrammatic representation for matrix multiplication. This

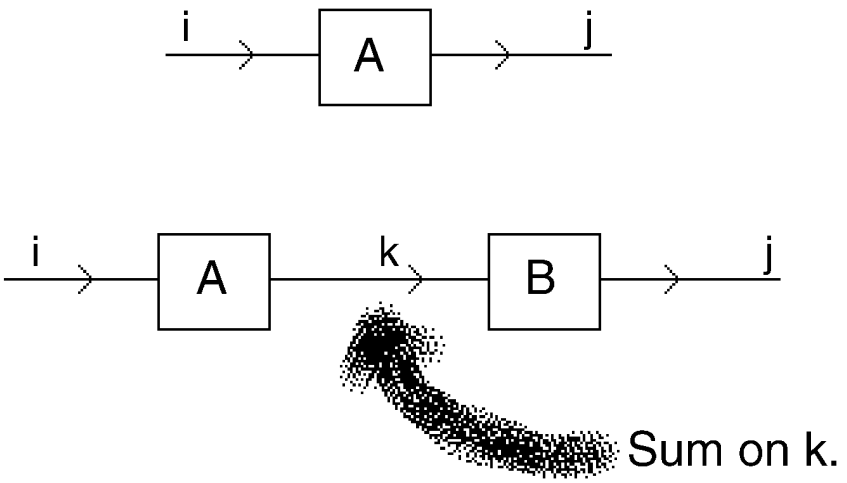

FIGURE 37

representation is illustrated in Fig. 37. Each matrix is represented by a labeled box with one arrow that enters the box and one arrow that leaves the box. The entering arrow corresponds to the left index i in A_{ij} and the right arrow corresponds to the right index j. In multiplying two matrices A and B together to form AB we tie the outgoing arrow of A to the ingoing arrow of B. By convention, an arrow that has no free ends connotes the summation over all possible choices of index for that arrow.

Many facts about matrices become quite transparent in this notation. For example, the *trace* of A, denoted tr(A), is the sum of the diagonal entries A_{ii} where i ranges from one to n. The diagrammatic proof of the basic formula $\mathrm{tr}(AB) = tr(BA)$ is illustrated in Fig. 38.

For a given value of n, we let $M_n(R)$ denote the set of all $n \times n$ matrices with coefficients in the real numbers R. We let $A^*B = AB$ denote the product of matrices and we let E denote the matrix whose entries are given by $E_{ii} = 1$ for all i and $E_{ij} = 0$ if i is not equal to j. With this choice of multiplication and identity element E, $M_n(R)$ satisfies the first three axioms for a group. However, there are matrices A that have no inverse (A^{-1} so that $AA^{-1} = E$). For

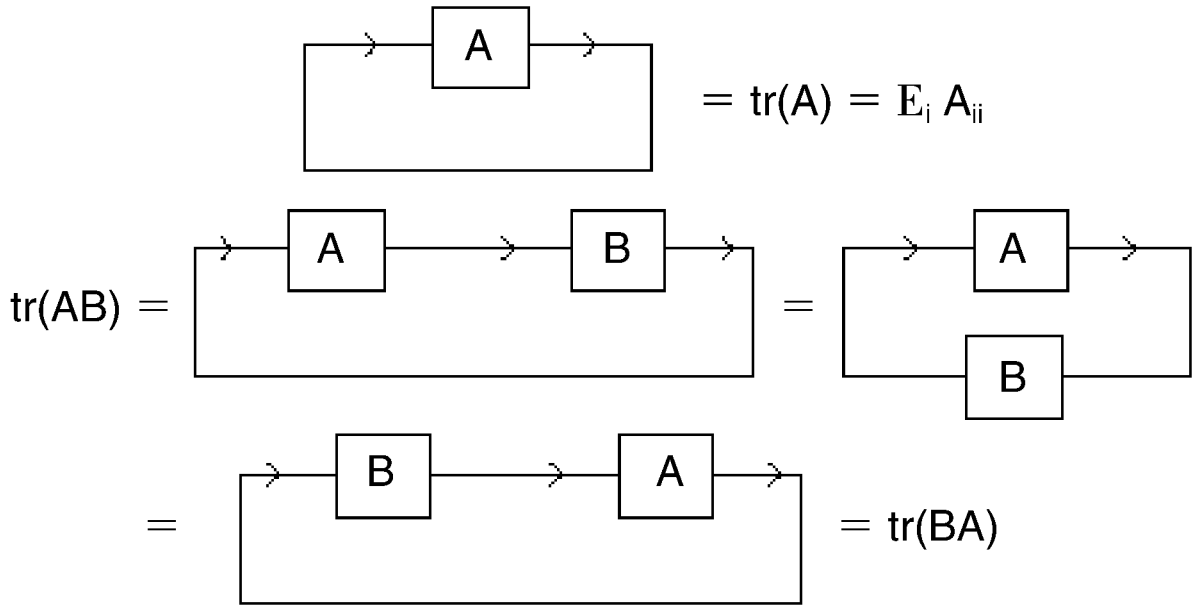

FIGURE 38 Diagrams for Matrix Trace.

example the matrix 0, all of whose entries are zero, is a matrix without an inverse. Thus $M_n(R)$ is not itself a group.

There is a criterion for a matrix to have an inverse. This is simply that the determinant Det(A) should be nonzero. Thus the largest group of matrices of size $n \times n$ that we can devise is the set of all matrices A such that Det(A) is nonzero. This is called the *general linear group* and is denoted by $GL_n(R)$. There are many interesting subgroups of this large group of matrices. One example is the group $Sl_{(n)}$ of all matrices with determinant equal to one. We may also restrict to *orthogonal* matrices A over R. These are invertible matrices A such that $A^t = A^{-1}$, where A^t denotes the transpose of the matrix A: $A^t_{ij} = A_{ji}$. The group of orthogonal matrices is denoted by $O(n)$.

The intersection of $O(n)$ and $Sl_{(n)}$ is denoted $SO(n)$. $SO(n)$ consists of the orthogonal matrices of determinant equal to one. In the case $n = 2$, $SO(2)$ consists of rotations of the plane that fix the origin, and in the case of $n = 3$, $SO(3)$ consists of rotations of three-dimensional space about specified axes.

$SO(3)$ has a fascinating collection of finite subgroups including the symmetries of the classical regular solids: the tetrahedron, the cube, the octahedron, the dodecahedron, and the icosahedron. Ultimately, the matrix groups become a language for the precise expression of symmetry.

We now ask when a matrix A can be written in the form

$$A = e^B = E + (1/1!)B + (1/2!)B^2 + (1/3!)B^3 + \cdots$$

for some other matrix B. Since $e^B = \text{limit}(E + B/m)^m$, where the limit is taken as m approaches infinity, we can regard $(E + B/m)$, for m large, as an "infinitesimal" version of the matrix A, and one refers to B as an "infinitesimal generator" for A. It is interesting and mathematically significant to compare the algebraic properties of A and B. The key property for this comparison is the determinant equation

$$\text{Det}(e^B) = e^{\text{tr}(B)},$$

where tr(B) denotes the trace of B. (One way to prove this identity is to use the Jordan canonical form for the matrix and the fact that similar matrices have the same trace and determinant.)

For example, if $\text{Det}(e^B) = 1$, then we need that $\text{tr}(B) = 0$. This means that elements of $Sl_{(n)}$ are the exponentials of matrices with trace equal to zero.

Let $sl_{(n)}$ denote the set of $n \times n$ matrices with trace equal to zero. The set $sl_{(n)}$ is not closed under matrix multiplication, but it is closed under the *Lie bracket* (or *commutator*) operation $[B, C] = BC - CB$.

$$\begin{aligned} &\text{If } \text{tr}(B) = \text{tr}(C) = 0, \text{ then} \\ &\text{tr}[B, C] = \text{tr}(BC - CB) = \text{tr}(BC) - \text{tr}(CB) \\ &\qquad = \text{tr}(BC) - \text{tr}(BC) = 0 \end{aligned}$$

(since $\text{tr}(BC) = \text{tr}(CB)$ for any matrices B and C). Thus, if B and C belong to $sl_{(n)}$, then $[B, C]$ also belongs to $sl_{(n)}$. This closure under the bracket operation leads directly to the notion of a Lie algebra.

Definition. A Lie algebra is a vector space L over a field F that is closed under a binary operation, called the *Lie bracket* and denoted by $[B, C]$ for B and C in L. The bracket is assumed to satisfy the following axioms.

1. $[X, Y] = -[Y, X]$ for all X and Y in L.
2. $[aX + bY, Z] = a[X, Z] + b[Y, Z]$ for all a and b in F and X, Y, Z in L.
3. $[X, [Y, Z]] + [Z, [X, Y]] + [Y, [Z, X]] = 0$.

This last identity is called the *Jacobi identity*. It is easy to verify that the bracket operation $[B, C] = BC - CB$ on the vector space of all $n \times n$ matrices over F (e.g., $F = R$) satisfies the axioms given above. Thus, we have so far seen that $sl_{(n)}$ is a Lie algebra that is naturally associated with the group of matrices $SL_{(n)}$. In fact, $sl(n)$ generates $SL_{(n)}$ by exponentiation.

There is a general pattern. Each matrix group has its corresponding Lie algebra. The classification of matrix groups is simplified by a corresponding classification of Lie algebras. As a result, the Lie algebras are a subject in their own right. It has often happened that Lie algebras are connected mathematically with subjects different from their original roots in group theory.

In our context the Lie algebras turn out to be related to the formation of weight systems for Vassiliev invariants. One way to see this is to just take the case of matrix Lie algebras with commutator brackets and interpret diagrammatically the formula that states that the Lie algebra is closed under the bracket operation. This formula states that there is a basis $\{T^1, T^2, \ldots, T^m\}$ for the Lie algebra as a vector space over F such that each T^a is an $n \times n$ matrix and such that

$$T^a T^b - T^b T^a = f_{abc} T^c,$$

where f_{abc} is a set of constants in F depending on the three indices a, b, c (running from 1 to n). The right-hand side of this equation connotes a summation over all values of the index $c = 1, \ldots, n$. The left-hand side is the commutator of T^a and T^b for any given choice of a and b.

In Fig. 39 we diagram this equation using the conventions for diagrammatic matrix multiplication explained in this section. The structure constants f_{abc} are represented by a graphical vertex with three lines attached to it, one for a, one for b, and one for c. For the purpose of discussion,

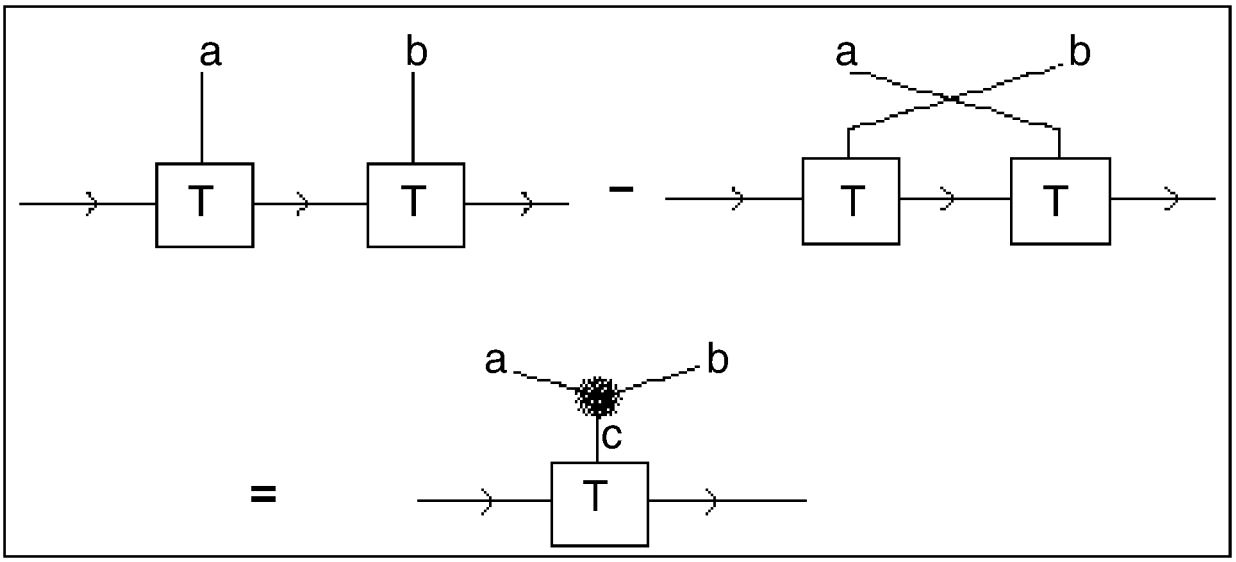

FIGURE 39 Diagrammatic Lic Algebra.

we shall assume that f_c^{ab} is dependent only on the cyclic order of *abc*. It is convenient to regard the graphical vertex as representing a "tensor" that has this cyclic invariance since this means that we can slide the diagram for the structure constant tensor around in the plane so long as we keep the cyclic order of its legs unchanged. Such bases can be obtained in many cases of matrix Lie algebras, and the results that we outline can be generalized in any case.

Figure 40 shows a formal version of the commutator relation of Fig. 39, except that the labels and indices have been removed and the boxes for matrix elements have been replaced by graphical vertices. Imagine that the terms in this formal version of the commutator relation are parts of chord diagrams as illustrated with examples in this figure. In other words, recall the method of chord diagrams from the last section and imagine that along with the chords there are also trivalent graphical vertices among the chords, and that these vertices are related to commutators as shown in the figure. Finally, Fig. 41 shows a formal derivation of the four-term relation for chord diagrams from the diagrammatic commutator identity. This means that the four-term relation that we derived from topological considerations in the last section is intimately related to the basic structure of a Lie algebra. This is the essence of the relationship of Vassiliev invariants with Lie algebras and their generalizations.

Concretely, the relationship we have just described means that it is possible to construct weight systems for Vassiliev invariants by using matrix Lie algebras. To see how this works see Fig. 42. Here we indicated a chord diagram D and a corresponding diagram involving matrices T^a from a Lie algebra basis. The second diagram represents the sum of traces $\mathrm{wt}(D) = \sum \mathrm{tr}(T^a T^b T^c T^a T^b T^c)$, where we are summing over all values for the indices a, b, and c. This second diagram represents the weight $\mathrm{wt}(D)$ that is assigned to the first diagram. It follows from our considerations that this weight system satisfies the four-term relation and hence, by the theorem of Kontsevich, is the top-row evaluation for a Vassiliev invariant.

This section has sketched the amazing and deep connection between Lie algebras and invariants of knots and links. The territory is even more surprising as one explores it further. First of all, it should be clear from what we have said that what is really needed here is an appropriate generalization of Lie algebras. In fact, prior to the discovery of the Vassiliev invariants, a very remarkable such generalization called "quantum groups" was discovered through work in statistical mechanics and was applied to knot theory. It was already known that quantum groups provided a strong connection between Lie algebras and their generalizations and invariants of knots and links. Now the matter of finding all weight systems challenges the resources of

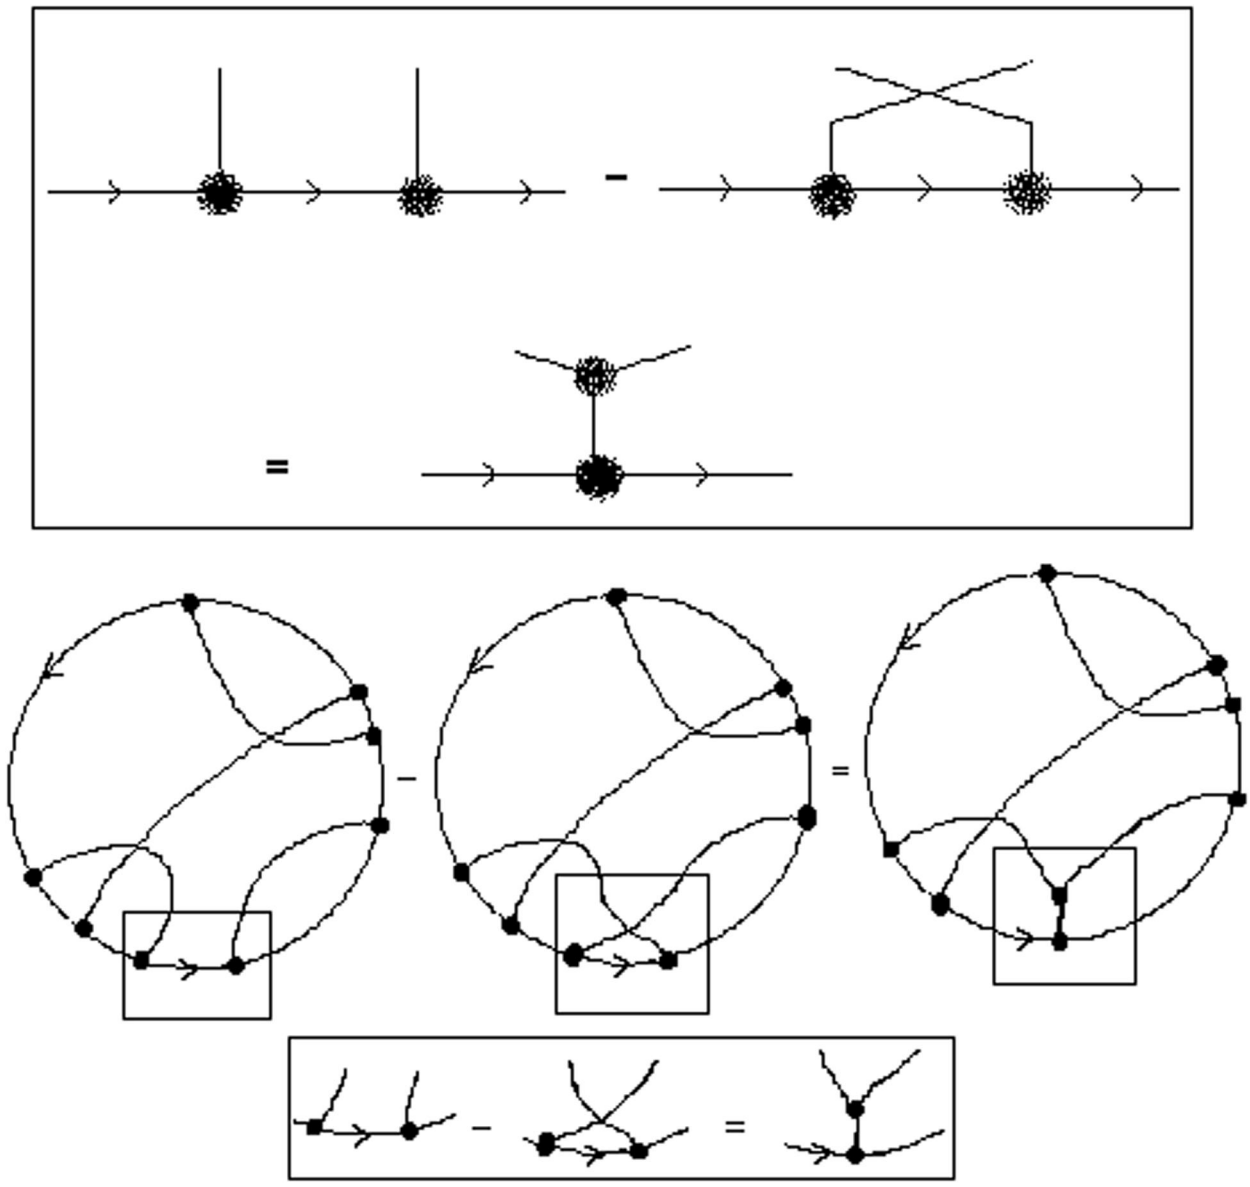

FIGURE 40 Lic Algebra and Chord Diagrams.

quantum groups and it is not known if all Vassiliev invariants can be built through the quantum groups.

In the next few sections we shall discuss the physical background behind many of the mathematical ideas discussed so far in this introduction to knot invariants.

VII. A QUICK REVIEW OF QUANTUM MECHANICS

To recall principles of quantum mechanics it is useful to have a quick historical recapitulation. Quantum mechanics really got started when Louis de Broglie introduced the fantastic notion that matter (such as an electron) is accompanied by a wave that guides its motion and produces interference phenomena just like the waves on the surface of the ocean or the diffraction effects of light going through a small aperture.

de Broglie's idea was successful in explaining the properties of atomic spectra. In this domain, his wave hypothesis led to the correct orbits and spectra of atoms, formally solving a puzzle that had been only described in ad hoc terms by the preceding theory of Niels Bohr. In Bohr's theory of the atom, the electrons are restricted to move only in certain elliptical orbits. These restrictions are placed in the theory to get agreement with the known atomic spectra,

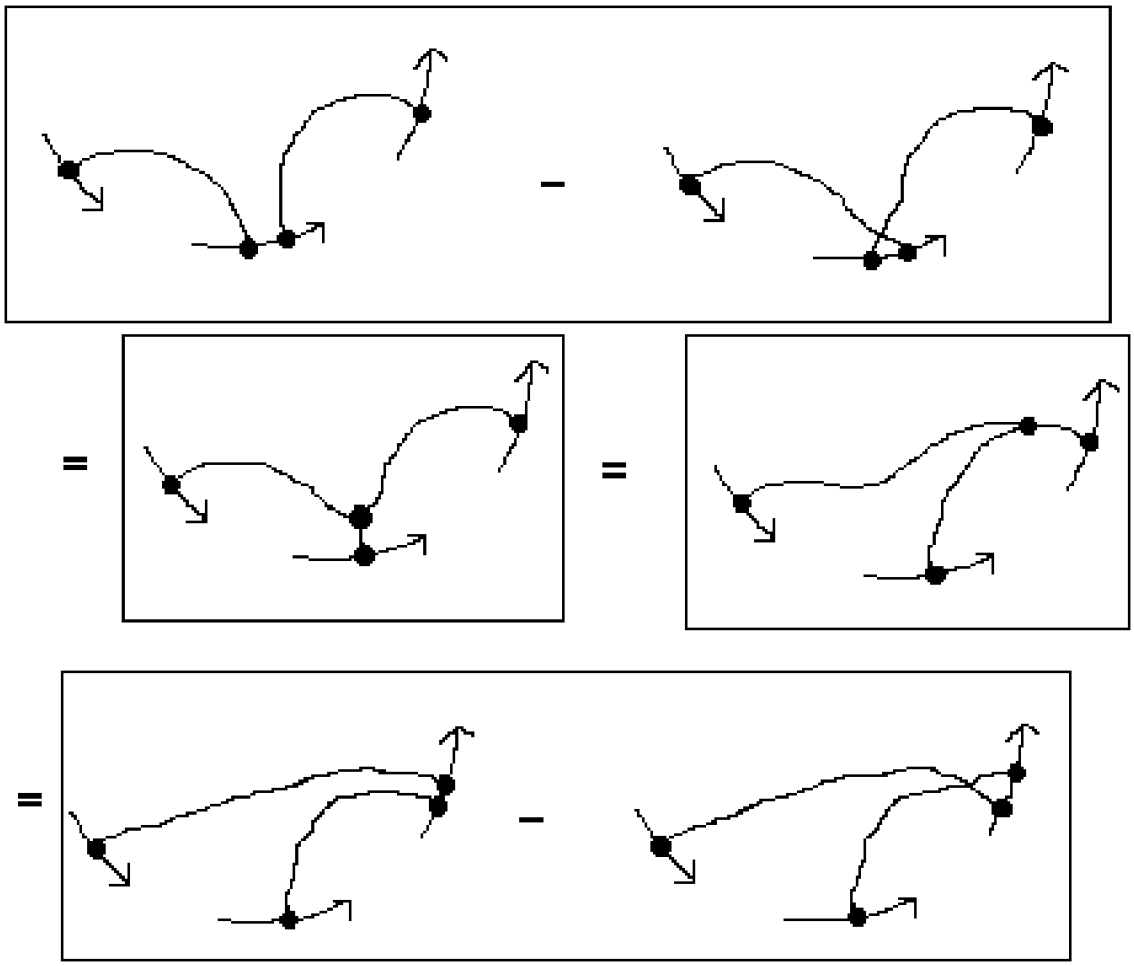

FIGURE 41 Proof of Four Term—Relation.

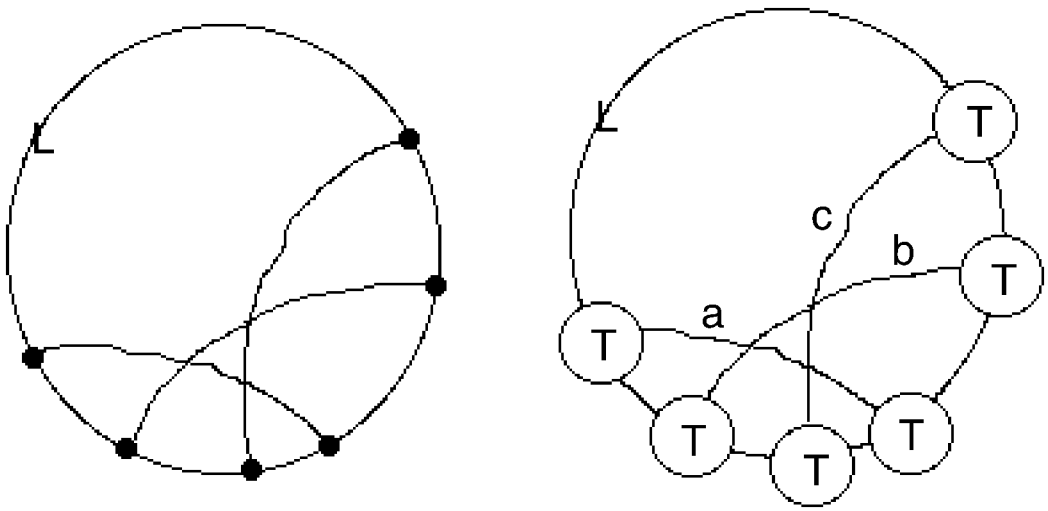

FIGURE 42 Lic Algebra Insertion in a Chord Diagram.

and to avoid a paradox! The paradox arises if one thinks of the electron as a classical particle orbiting the nucleus of the atom. Such a particle is undergoing acceleration in order to move in its orbit. Accelerated charged particles emit radiation. Therefore the electron should radiate away its energy and spiral into the nucleus! Bohr commanded the electron to only occupy certain orbits and thereby avoided the spiral death of the atom—at the expense of logical consistency.

de Broglie hypothesized a wave associated with the electron and he said that an integral multiple of the length of this wave must match the circumference of the electron orbit. Thus, not all orbits are possible, only those where the wave pattern can "bite its own tail." The mathematics works out, providing an alternative to Bohr's picture.

de Broglie had waves, but he did not have an equation describing the spatial distribution and temporal evolution of these waves. Such an equation was discovered by Erwin Schrödinger. Schrödinger relied on inspired guesswork, based on de Broglie's hypothesis, and produced a wave equation, known ever since as the Schrödinger equation. Schrödinger's equation was enormously successful, predicting fine structure of the spectrum of hydrogen and many other aspects of physics. Suddenly a new physics, *quantum mechanics*, was born from this musical hypothesis of de Broglie.

Along with the successes of quantum mechanics came a host of extraordinary problems of interpretation. What is the status of this wavefunction of Schrödinger and de Broglie. Does it connote a new element of physical reality? Is matter "nothing but" the patterning of waves in a continuum? How can the electron be a wave and still have the capacity to instantiate a very specific event at one place and one time (such as causing a bit of phosphor to glow *there* on a television screen)? Max Born developed a statistical interpretation of the wavefunction wherein the wave determines a probability for the appearance of the localized particulate phenomenon that one wanted to call an "electron." In this story the wavefunction ψ takes values in the complex numbers and the associated probability is $\psi^*\psi$, where ψ^* denotes the complex conjugate of ψ. Mathematically, this is a satisfactory recipe for dealing with the theory, but it leads to further questions about the exact character of the statistics. If quantum theory is inherently statistical, then it can give no complete information about the motion of the electron. In fact, there may be no such complete information available even in principle. Electrons manifest as particles when they are observed in a certain manner and as waves when they are observed in another, complementary manner. This is a capsule summary of the view taken by Bohr, Heisenberg, and Born. Others, including de Broglie, Einstein, and Schrödinger, hoped for a more direct and deterministic theory of nature.

As we shall see, the statistical nature of quantum theory has a formal side that can be exploited to understand the topological properties of such mundane objects as knotted ropes in space and spaces constructed by identifying the sides of polyhedra. These topological applications of quantum mechanical ideas are exciting in their own right. They may shed light on the nature of quantum theory itself.

In this section we review a bit of the mathematics of quantum theory. Recall the equation for a wave

$$f(x,t) = \sin[(2\pi/l)(x - ct)].$$

With x interpreted as the position and t and as the time, this function describes a sinusoidal wave traveling with velocity c. We define the wave number $k = 2\pi/l$ and the frequency $w = (2\pi c/l)$, where l is the wavelength. Thus we can write $f(x,t) = \sin(kx - wt)$. Note that the velocity c of the wave is given by the ratio of frequency to wave number, $c = w/k$.

de Broglie hypothesized two fundamental relationships: between energy and frequency, and between momentum and wave number. These relationships are summarized in the equations

$$E = \hbar w, \qquad p = \hbar k,$$

where E denotes the energy associated with a wave and p denotes the momentum associated with the wave. Here $\hbar = h/2\pi$, where h is Planck's constant.

For de Broglie the discrete energy levels of the orbits of electrons in an atom of hydrogen could be explained by restrictions on the vibrational modes of waves associated with the motion of the electron. His choices for the energy and the momentum in relation to a wave are not arbitrary. They are designed to be consistent with the notion that the wave or wave packet moves along with the electron. That is, the velocity of the wave packet is designed to be the velocity of the "corresponding" material particle.

It is worth illustrating how de Broglie's idea works. Consider two waves whose frequencies are very nearly the same. If we superimpose them (as a piano tuner superimposes a tuning fork with the vibration of the piano string), then there will be a new wave produced by the interference of the original waves. This new wave pattern will move at its own velocity, different (and generally smaller) than the velocity of the original waves. To be specific, let

$$f(x,t) = \sin(kx - wt), \qquad g(x,t) = \sin(k'x - w't).$$

Let

$$\begin{aligned} h(x,t) &= \sin(kx - wt) + \sin(k'x - w't) \\ &= f(x,t) + g(x,t). \end{aligned}$$

A little trigonometry shows that

$$h(x,t) = \cos\{[(k-k')/2]x - [(w-w')/2]t\} \times \sin\{[(k+k')/2]x - [(w+w')/2]t\}.$$

If we assume that k and k' are very close and that w and w' are very close, then $(k+k')/2$ is approximately k, and $(w+w')/2$ is approximately w. Thus $h(x, t)$ can be represented by

$$H(x,t) = \cos[(\delta k/2)x - (\delta w/2)t]\ f(x,t),$$

where $\delta k = (k-k')/2$ and $dw = (w-w')/2$. This means that the superposition $H(x, t)$ behaves as the waveform $f(x, t)$ carrying a slower moving "wave packet" $G(x,t) = \cos[(\delta k/2)x - (\delta w/2)t]$. See Fig. 43.

Since the wave packet (seen as the clumped oscillations in Fig. 43) has the equation $G(x,t) = \cos[(\delta k/2)x - (\delta w/2)t]$, we see that that the velocity of this wave packet is $v_g = \delta w/\delta k$. Recall that wave velocity is the ratio of frequency to wave number. Now according to de Broglie, $E = \hbar w$ and $p = \hbar k$, where E and p are the energy and momentum, respectively, associated with this wave packet. Thus we get the formula $v_g = dE/dp$. In other words, the velocity of the wave packet is the rate of change of its energy with respect to its momentum. Now this is exactly in accord with the well-known classical laws for a material particle! For such a particle, $E = mv^2/2$ and $p = mv$. Thus $E = p^2/2m$ and $dE/dp = p/m = v$.

It is this astonishing concordance between the simple wave model and the classical notions of energy and momentum that initiated the beginnings of quantum theory.

A. Schrödinger's Equation

Schrödinger answered the question, Where is the wave equation for de Broglie's waves? Writing an elementary wave in complex form

$$\psi = \psi(x,t) = \exp[i(kx - wt)],$$

we see that we can extract de Broglie's energy and momentum by differentiating:

$$i\hbar\,\partial\psi/\partial t = E_\psi \quad \text{and} \quad -i\hbar\,\partial\psi/\partial x = p_\psi.$$

This led Schrödinger to postulate *the identification of dynamical variables with operators* so that the first equation,

$$i\hbar\,\partial\psi/\partial t = E_\psi,$$

is promoted to the status of an equation of motion, while the second equation becomes the definition of momentum as an operator:

$$p = -i\hbar\,\partial/\partial x.$$

Once p is identified as an operator, the numerical value of momentum is associated with an eigenvalue of this operator, just as in the example above. In our example $p_\psi = \hbar k_\psi$.

In this formulation, the position operator is just multiplication by x itself. Once we have fixed specific operators for position and momentum, the operators for other

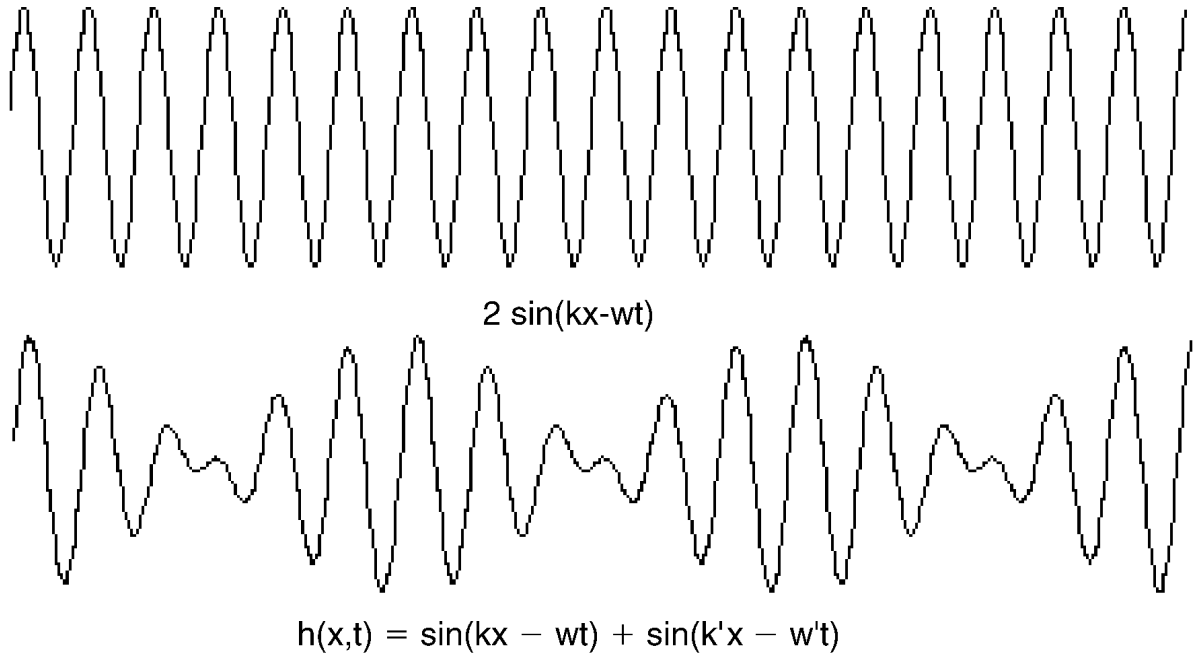

FIGURE 43 Waves and wave packets.

physical quantities can be expressed in terms of them. We obtain the energy operator by substitution of the momentum operator in the classical formula for the energy:

$$E = (1/2)mv^2 + V$$
$$E = p^2/2m + V$$
$$E = -(\hbar^2/2m)\,\partial^2/\partial x^2 + V.$$

Here V is the potential energy, and its corresponding operator depends upon the details of the application.

With this operator identification for E, Schrodinger's equation

$$i\hbar\,\partial\psi/\partial t = -(\hbar^2/2m)\,\partial^2\psi/\partial x^2 + V_\psi$$

is an equation in the first derivatives of time and in second derivatives of space. In this form of the theory one considers general solutions to the differential equation and this in turn leads to excellent results in a myriad of applications.

In quantum theory, observation is modeled by the concept of eigenvalues for corresponding operators. The quantum model of an observation is a projection of the wavefunction into an eigenstate.

An energy spectrum $\{E_k\}$ corresponds to wavefunctions ψ satisfying the Schrödinger equation such that there are constants E_k with $E_\psi = E_k\psi$. An *observable* (such as energy) E is a Hermitian operator on a Hilbert space of wavefunctions. Since Hermitian operators have real eigenvalues, this provides the link with measurement for the quantum theory.

It is important to notice that there is no mechanism postulated in this theory for how a wavefunction is "sent" into an eigenstate by an observable. Just as mathematical logic need not demand causality behind an implication between propositions, the logic of quantum mechanics does not demand a specified cause behind an observation. This absence of an assumption of causality in logic does not obviate the possibility of causality in the world. Similarly, the absence of causality in quantum observation does not obviate causality in the physical world. Nevertheless, the debate over the interpretation of quantum theory has often led its participants into asserting that causality has been demolished in physics.

Note that the operators for position and momentum satisfy the equation $xp - px = \hbar i$. This corresponds directly to the equation obtained by Heisenberg on other grounds, stating that dynamical variables can no longer necessarily commute with one another. In this way, the points of view of de Broglie, Schrödinger, and Heisenberg came together, and quantum mechanics was born. In the course of this development, interpretations varied widely. Eventually, physicists came to regard the wavefunction not as a generalized wave packet, but as a carrier of information about possible observations. In this way of thinking $\psi^*\psi$ (ψ^* denotes the complex conjugate of y) represents the probability of finding the "particle" (a particle is an observable with local spatial characteristics) at a given point in spacetime.

B. Dirac Brackets

We now discuss Dirac's notation $\langle a \mid b\rangle$ (Dirac, 1958). In this notation $\langle a|$ and $|b\rangle$ are vectors and covectors, respectively. $\langle a \mid b\rangle$ is the evaluation of $\langle a|$ by $|b\rangle$, hence it is a scalar, and in ordinary quantum mechanics it is a complex number. One can think of this as the amplitude for the state to begin in "a" and end in "b." That is, there is a process that can mediate a transition from state a to state b. Except for the fact that amplitudes are complex valued, they obey the usual laws of probability. This means that if the process can be factored into a set of all possible intermediate states $c_1, c_2, \ldots, c_n$, then the amplitude for $a \to b$ is the sum of the amplitudes for $a \to c_i \to b$. Meanwhile, the amplitude for $a \to c_i \to b$ is the product of the amplitudes of the two subconfigurations $a \to c_i$ and $c_i \to b$. Formally we have

$$\langle a \mid b\rangle = \sum \langle a \mid c_i\rangle\langle c_i \mid b\rangle,$$

where the summation is over all the intermediate states $i = 1, \ldots, n$.

In general, the amplitude for mutually disjoint processes is the *sum* of the amplitudes of the individual processes. The amplitude for a configuration of disjoint processes is the *product* of their individual amplitudes.

Dirac's division of the amplitudes into *bras* $\langle a|$ and *kets* $|b\rangle$ is done mathematically by taking a vector space V (a Hilbert space, but it can be finite dimensional) for the bras: $\langle a|$ belongs to V. The dual space V^* is the home of the kets. Thus $|b\rangle$ belongs to V^* so that $|b\rangle$ is a linear mapping $|b\rangle\colon V \to C$, where C denotes the complex numbers. We restore symmetry to the definition by realizing that an element of a vector space V can be regarded as a mapping from the complex numbers to V. Given $\langle a|\colon C \to V$, the corresponding element of V is the image of 1 (in C) under this mapping. In other words, $\langle a|(1)$ is a member of V. Now we have $\langle a|\colon C \to V$ and $|b\rangle\colon V \to C$. The composition $\langle a\|b\rangle = \langle a \mid b\rangle\colon C \to C$ is regarded as an element of C by taking the specific value $\langle a \mid b\rangle(1)$. The complex numbers are regarded as the "vacuum," and the entire amplitude $\langle a \mid b\rangle$ is a "vacuum-to-vacuum" amplitude for a process that includes the creation of the state a, its transition to b, and the annihilation of b to the vacuum once more.

Dirac notation has a life of its own. Let $P = |y\rangle\langle x|$ and $\langle x\|y\rangle = \langle x|y\rangle$. Then

$$PP = |y\rangle\langle x\|y\rangle\langle x| = |y\rangle\langle x \mid y\rangle\langle x| = \langle x \mid y\rangle P.$$

Up to a scalar multiple, P is a projection operator. That is, if we let $Q = P/\langle x \mid y\rangle$, then

$$QQ = PP/\langle x \mid y\rangle\langle x \mid y\rangle$$
$$= \langle x \mid y\rangle P/\langle x \mid y\rangle\langle x \mid y\rangle = P/\langle x \mid y\rangle = Q.$$

Thus, $QQ = Q$. In this language, the completeness of intermediate states becomes the statement that a certain sum of projections is equal to the identity: Suppose that $\sum_i |c_i\rangle\langle c_i| = 1$ (summing over i) with $\langle c_i \mid c_i\rangle = 1$ for each i. Then

$$\begin{aligned}\langle a \mid b\rangle &= \langle a \| b\rangle \\ &= \langle a| \sum |c_i\rangle\langle c_i \| b\rangle \\ &= \sum \langle a \| c_i\rangle\langle c_i \| b\rangle \\ &= \sum \langle a \mid c_i\rangle\langle c_i \mid b\rangle.\end{aligned}$$

Iterating this principle of expansion over a complete set of states leads to the most primitive form of the Feynman integral (Feynman and Hibbs, 1965). Imagine that the initial and final states a and b are points on the vertical lines $x = 0$ and $x = n + 1$, respectively, in the x–y plane, and that $(c(k)i(k), k)$ is a given point on the line $x = k$ for $0 < i(k) < m$. Suppose that the sum of projectors for each intermediate state is complete. That is, we assume that following sum is equal to one, for each k from 1 to $n - 1$:

$$|c(k)1\rangle\langle c(k)1| + \cdots + |c(k)m\rangle\langle c(k)m| = 1.$$

Applying the completeness iteratively, we obtain the following expression for the amplitude $\langle a \mid b\rangle$:

$$\langle a \mid b\rangle = \sum \langle a \mid c(1)i(1)\rangle\langle c(1)i(1) \mid c(2)i(2)\rangle \cdots$$
$$\times \langle c(n)i(n) \mid b\rangle,$$

where the sum is taken over all $i(k)$ ranging between 1 and m, and k ranging between 1 and n. Each term in this sum can be construed as a combinatorial path from a to b in the two-dimensional space of the x–y plane. Thus the amplitude for going from a to b is seen as a summation of contributions from all the "paths" connecting a to b. Feynman used this description to produce his famous path integral expression for amplitudes in quantum mechanics. His path integral takes the form

$$\int dP \exp(iS),$$

where i is the square root of minus one, the integral is taken over all paths from point a to point b, and S is the *action* for a particle to travel from a to b along a given path. For the quantum mechanics associated with a classical (Newtonian) particle the action S is given by the integral along the given path from a to b of the difference $T - V$, where T is the classical kinetic energy and V is the classical potential energy of the particle.

The beauty of Feynman's approach to quantum mechanics is that it shows the relationship between the classical and the quantum in a particularly transparent manner. Classical motion corresponds to those regions where all nearby paths contribute constructively to the summation. This classical path occurs when the variation of the action is null. To ask for those paths where the variation of the action is zero is a problem in the calculus of variations, and it leads directly to Newton's equations of motion. Thus, with the appropriate choice of action, classical and quantum points of view are unified.

The drawback of this approach lies in the unavailability at the present time of an appropriate measure theory to support all cases of the Feynman integral.

To summarize, Dirac's notation shows at once how the probabilistic interpretation for amplitudes is tied to the vector space structure of the space of states of the quantum mechanical system. Our strategy for bringing forth relations between quantum theory and topology is to pivot on the Dirac bracket. The Dirac bracket acts as intermediate between notation and linear algebra. In a very real sense, the connection of quantum mechanics with topology is an amplification of Dirac notation.

The next two sections discuss how topological invariants in low-dimensional topology are related to amplitudes in quantum mechanics. In these cases the relationship with quantum mechanics is primarily mathematical. Ideas and techniques are borrowed. It is not yet clear what the effect of this interaction will be on the physics itself.

VIII. KNOT AMPLITUDES

At the end of the last section we said that the connection of quantum mechanics with topology is an amplification of Dirac notation. Consider first a circle in a spacetime plane with time represented vertically and space horizontally (Fig. 44). The circle represents a vacuum-to-vacuum process that includes the creation of two "particles" (Fig. 45) and their subsequent annihilation (Fig. 46). In accord with our previous description, we could divide the circle into two parts, creation (a) and annihilation (b), and consider the amplitude $\langle a \mid b\rangle$. Since the diagram for the creation of the two particles ends in two separate points, it is natural to take a vector space of the form $V \otimes V$ (the tensor product of V with V) as the target for the bra and as the domain of the ket.

We imagine at least one particle property being catalogued by each dimension of V. For example, a basis of V could enumerate the spins of the created particles. If $\{e_a\}$ is a basis for V, then $\{e_a \otimes e_b\}$ forms a basis for

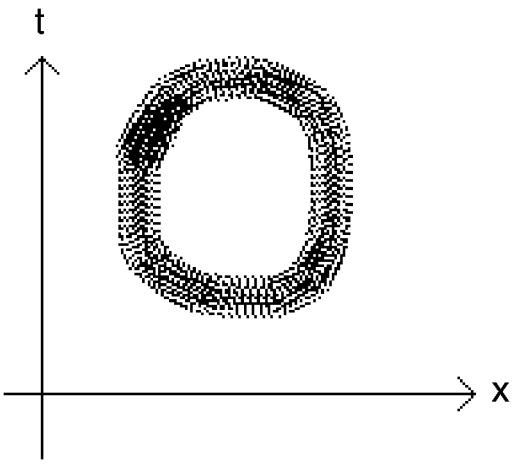

FIGURE 44 A Circle in Space Time.

$V \otimes V$. The elements of this new basis constitute all possible combinations of the particle properties. Since such combinations are multiplicative, the tensor product is the appropriate construction.

In this language the creation ket is a map CUP,

$$\text{CUP} = \langle a|: \quad C \to V \otimes V$$

and the annihilation bra is a mapping CAP,

$$\text{CAP} = |b\rangle: \quad V \otimes V \to C.$$

The first hint of topology comes when we realize that it is possible to draw a much more complicated simple closed curve in the plane that is nevertheless decomposed with respect to the vertical direction into many CUPs and CAPs. In fact, any non-self-intersecting differentiable curve can be rigidly rotated until it is in general position with respect to the vertical. It will then be seen to be decomposed into these minima and maxima. Our prescriptions for amplitudes suggest that we regard any such curve as an amplitude via its description as a mapping from C to C.

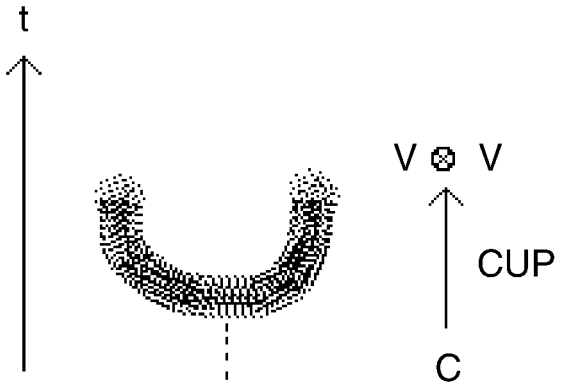

FIGURE 45 The Cup.

FIGURE 46 The Cap.

Each simple closed curve gives rise to an amplitude, but any simple closed curve in the plane is isotopic to a circle, by the Jordan curve theorem. If these are *topological amplitudes*, then they should all be equal to the original amplitude for the circle. Thus the question: What condition on creation and annihilation will insure topological amplitudes? The answer derives from the fact that all isotopies of the simple closed curves are generated by the cancellation of adjacent maxima and minima as illustrated in Fig. 47.

In composing mappings it is necessary to use the identifications

$$(V \otimes V) \otimes V = V \otimes (V \otimes V) \quad \text{and} \quad V \otimes k = k \otimes V = V.$$

Thus in Fig. 47, the composition on the left is given by

$$\begin{aligned} V &= V \otimes k \xrightarrow[1 \otimes \text{CUP}]{} V \otimes (V \otimes V) \\ &= (V \otimes V) \otimes V \xrightarrow[\text{CAP} \otimes 1]{} k \otimes V = V. \end{aligned}$$

This composition must equal the identity map on V (denoted 1 here) for the amplitudes to have a proper image of the topological cancellation.

This condition is said very simply by taking a matrix representation for the corresponding operators. Specifically, let $\{e_1, e_2, \ldots, e_n\}$ be a basis for V. Let $e_{ab} = e_a \otimes e_b$ denote the elements of the tensor basis for $V \otimes V$. Then there are matrices M_{ab} and M^{ab} such that $\text{cup}(1) = \sum M^{ab} e_{ab}$ with the summation taken over all values of a and b from 1 to n. Similarly, cap is described by $\text{cap}(e_{ab}) = Mab$. Thus, the amplitude for the circle is $\text{cap}[\text{cup}(1)] = \text{cap} \sum M^{ab} e_{ab} = \sum M^{ab} M_{ab}$.

In general, the value of the amplitude on a simple closed curve is obtained by translating it into an "abstract tensor expression" in the M_{ab} and M^{ab} and then summing over these products for all cases of repeated indices.

Returning to the topological conditions, we see that they are just that the matrices (M_{ab}) and (M^{ab}) are inverses in the sense that $\sum M^{ai} M_{ib} = \int_b^a$ and $\sum M_{ai} M^{ib} = \int_a^b$ are identity matrices.

Figure 48 shows the diagrammatic representative of the equation $\sum M^{ai} M_{ib} = \int_b^a$.

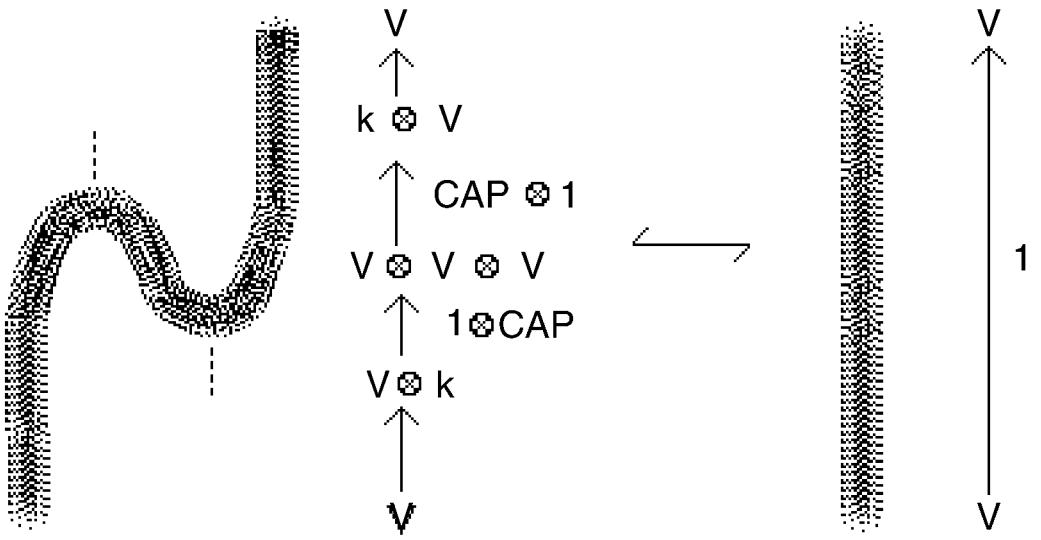

FIGURE 47 Cup–Cap Cancellation.

In the simplest case cup and cap are represented by 2×2 matrices. The topological condition implies that these matrices are inverses of each other. Thus the problem of the existence of topological amplitudes is very easily solved for simple closed curves in the plane.

Now we go to knots and links. Any knot or link can be represented by a picture that is configured with respect to a vertical direction in the plane. The picture will decompose into minima (creations) maxima (annihilations) and crossings of the two types shown below. (Here I consider knots and links that are unoriented. They do not have an intrinsic preferred direction of travel.) In Fig. 49, next to each of the crossings we have indicated mappings of $V \otimes V$ to itself, called R and $\bar{R}$, respectively. These mappings represent the transitions corresponding to these elementary configurations.

That R and $\bar{R}$ really must be inverses follows from the isotopy shown in Fig. 50 (this is the second Reidemeister move.)

We now have the vocabulary of cup, cap, R, and $\bar{R}$. Any knot or link can be written as a composition of these fragments, and consequently a choice of such mappings determines an amplitude for knots and links. In order for such an amplitude to be topological we want it to be

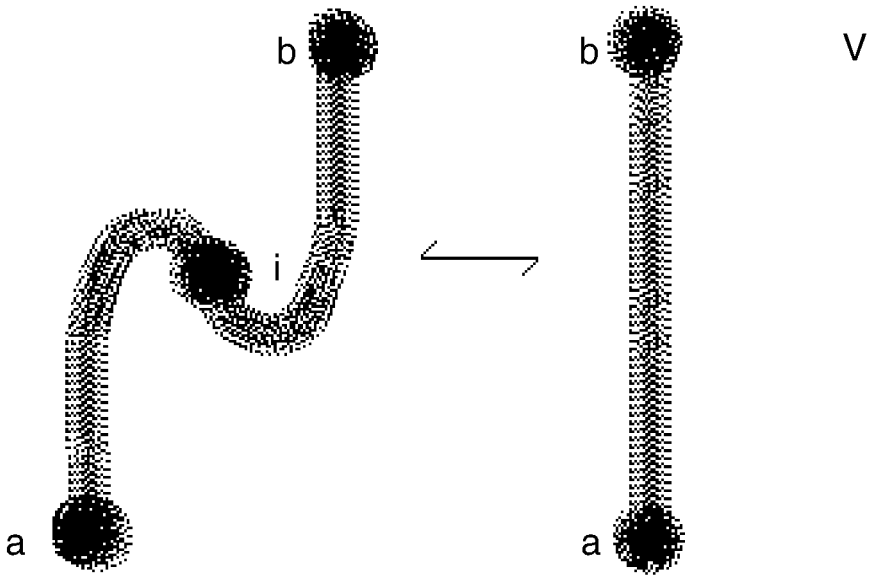

FIGURE 48 Cancellation.

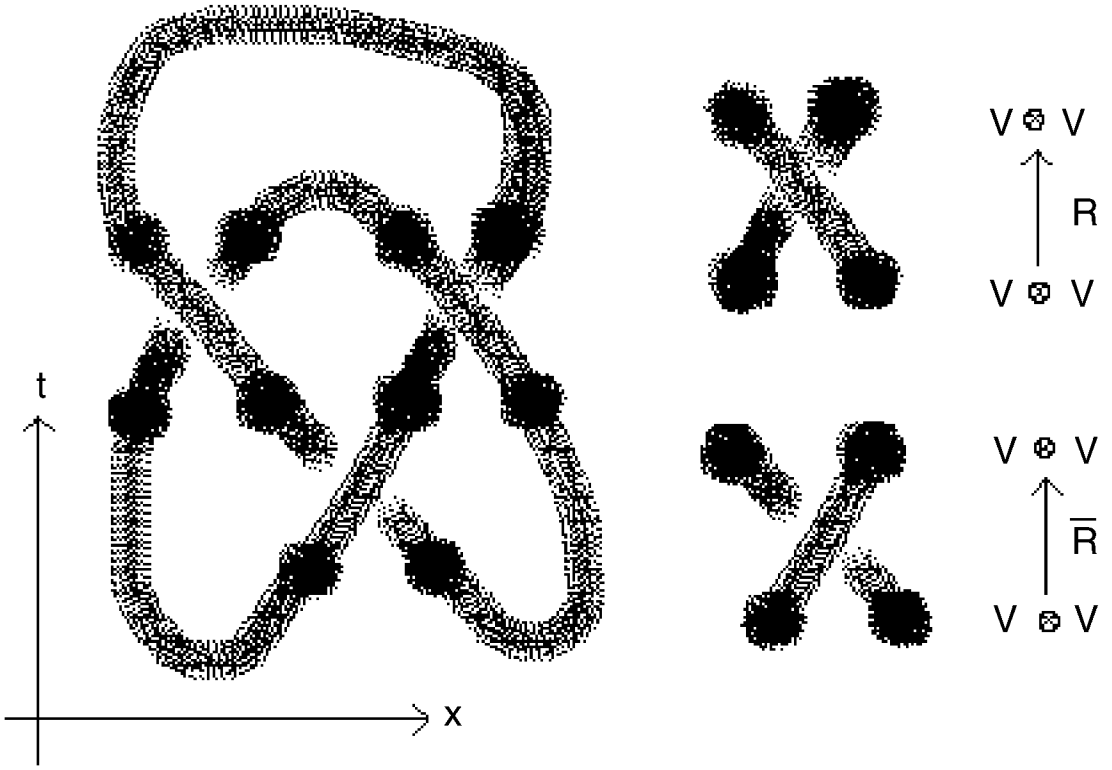

FIGURE 49

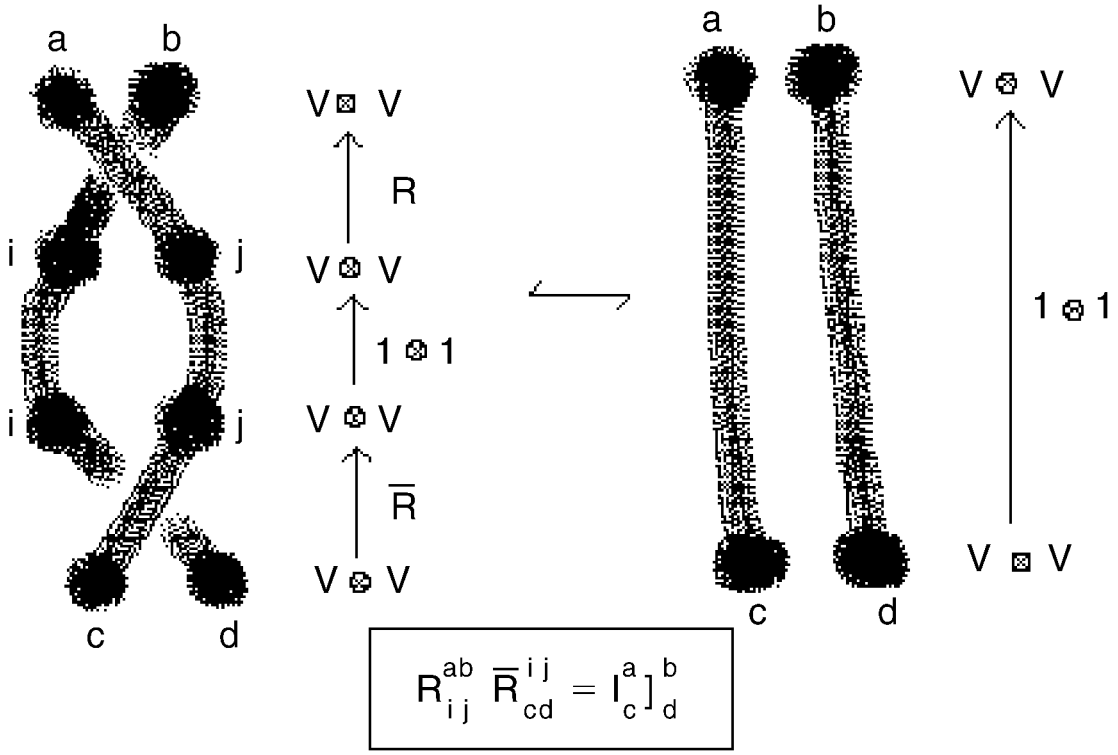

FIGURE 50 Knot as Vacuum–Vacuum Expectation.

invariant under the list of local moves on the diagrams shown in Fig. 51. These moves are an augmented list of the Reidemeister moves (see Fig. 4), adjusted to take care of the fact that the diagrams are arranged with respect to a given direction in the plane.

The equivalence relation generated by these moves is called *regular isotopy*. It is one move short of the relation known as *ambient isotopy*. The missing move is the first Reidemeister move shown in Fig. 4.

In the first Reidemeister move, a curl in the diagram is created or destroyed. Ambient isotopy (generated by all the Reidemeister moves) corresponds to the full topology of knots and links embedded in three-dimensional space. Two link diagrams are ambient isotopic via the Reidemeister moves if and only if there is a continuous family of embeddings in three dimensions leading from one link to the other. The moves give a combinatorial reformulation of the spatial topology of knots and links.

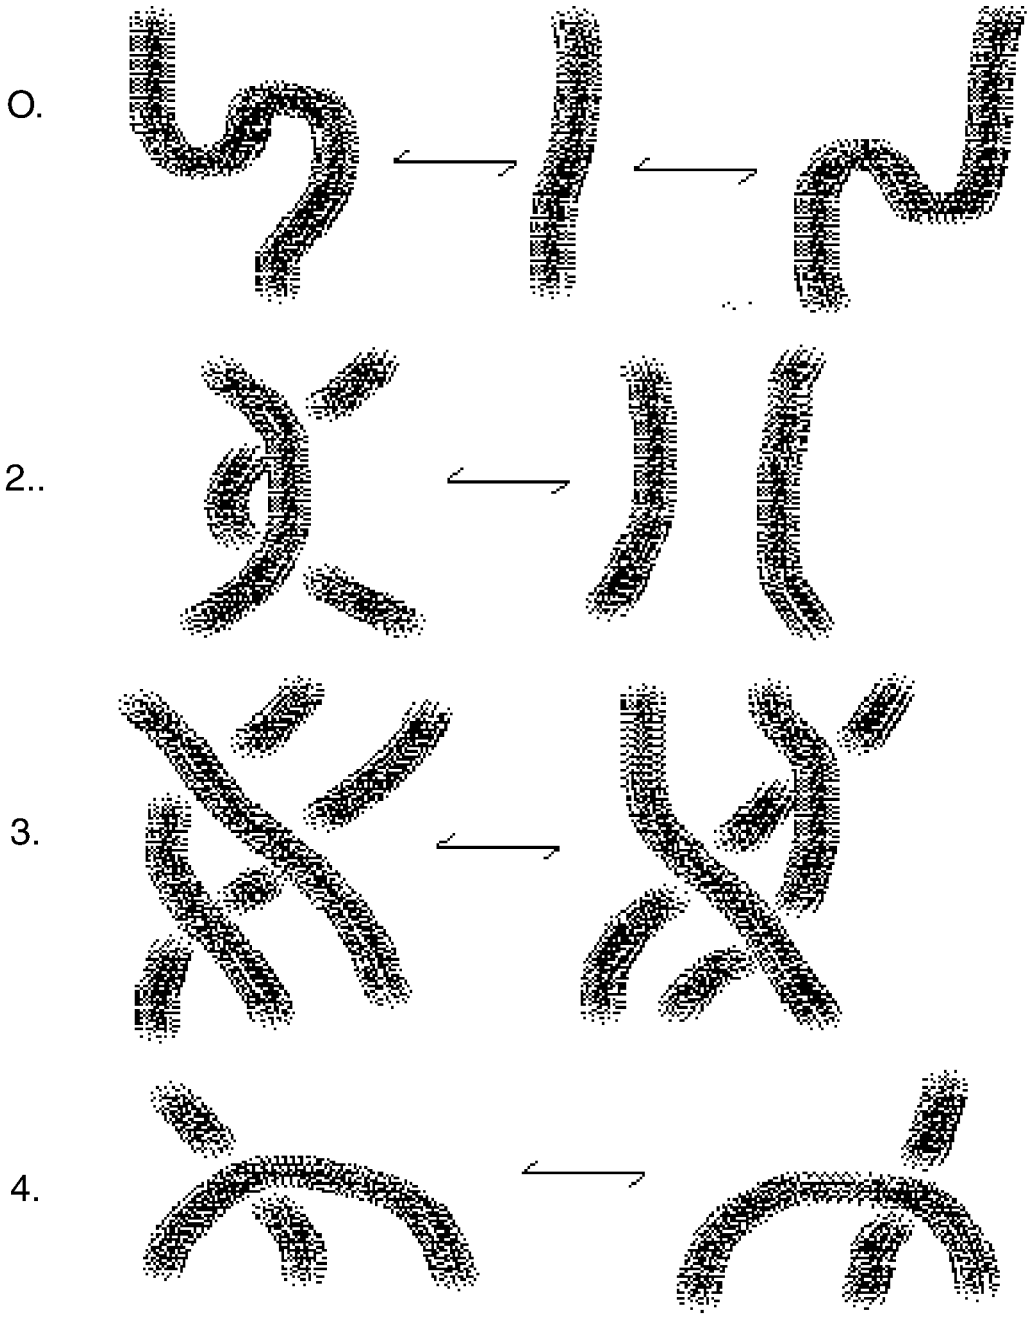

FIGURE 51 Augmented Reidemeister moves for regular isotopy.

By ignoring the first Reidemeister move, we allow the possibility that these diagrams can model framed links, that is, links with a normal vector field or, equivalently, embeddings of curves that are thickened into bands. It turns out to be fruitful to study invariants of regular isotopy. In fact, one can usually normalize an invariant of regular isotopy to obtain an invariant of ambient isotopy. We have already discussed this phenomenon with the bracket polynomial in Section 4.

As the reader can see, we have already discussed the algebraic meaning of moves 0 and 2. The other moves translate into very interesting algebra. Move 3, when translated into algebra, is the famous Yang–Baxter equation. The Yang–Baxter equation occurred for the first time in problems related to exactly solved models in statistical mechanics. All the moves taken together are directly related to the axioms for a quasi-triangular Hopf algebra ("quantum group"). We shall not go into this connection here.

There is an intimate connection between knot invariants and the structure of generalized amplitudes, as we have described them in terms of vector space mappings associated with link diagrams. This strategy for the construction of invariants is directly motivated by the concept of an amplitude in quantum mechanics. It turns out that the invariants that can actually be produced by this means (that is, by assigning finite dimensional matrices to the caps, cups and crossings) are incredibly rich. They encompass, at present, all of the known invariants of polynomial type (Alexander polynomial, Jones polynomial, and their generalizations).

It is now possible to indicate the construction of the Jones polynomial via the bracket polynomial as an amplitude, by specifying its matrices.

The cups and the caps are defined by $(M_{ab}) = (M^{ab}) = M$, where M is the 2×2 matrix (with $ii = -1$).

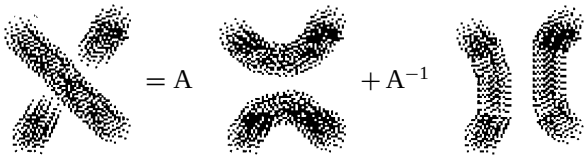
Note that $MM = I$, where I is the identity matrix. Note also that the amplitude for the circle is

$$\sum M_{ab}M^{ab} = \sum M_{ab}M_{ab} = \sum (M_{ab})^2$$
$$= (iA)^2 + (-iA^{-1})^2 = -A^2 - A^{-2}.$$

The matrix R is then defined by the equation

$$R^{ab}_{cd} = AM^{ab}M_{cd} + A^{-1}\int_c^a \int_d^b .$$

Since, diagrammatically, we identify R with a (right-handed) crossing, this equation can be written diagrammatically as



Taken together with the loop value of $A^2 - A^{-2}$,

these equations can be regarded as a recursive algorithm for computing the amplitude. This algorithm is the bracket state model for the (unnormalized) Jones polynomial. This model can be studied on its own grounds as we have already done in section 4.

IX. TOPOLOGICAL QUANTUM FIELD THEORY, FIRST STEPS

In order to further justify the idea of topology in relation to the amplification of Dirac notation, consider the following scenario. Let M be a three-dimensional manifold; that is, a space that is locally homeomorphic to Euclidean three-dimensional space. Suppose that F is a closed orientable surface inside M dividing M into two pieces M_1 and M_2. These pieces are 3-manifolds with boundary. They meet along the surface F. Now consider an amplitude $\langle M_1 \mid M_2 \rangle = Z(M)$. The form of this amplitude generalizes our previous considerations, with the surface F constituting the distinction between the "preparation" M_1 and the "detection" M_2. This generalization of the Dirac amplitude $\langle a \mid b \rangle$ amplifies the notational distinction consisting of the vertical line of the bracket to a topological distinction in a space M. The amplitude $Z(M)$ will be said to be a *topological amplitude for M* if it is a topological invariant of the 3-manifold M. Note that a topological amplitude does not depend upon the choice of surface F that divides M.

From a physical point of view the independence of the topological amplitude on the particular surface that divides the 3-manifold is the most important property. An amplitude arises in the condition of one part of the distinction carved in the 3-manifold acting as "the observed" and the other part of the distinction acting as "the observer." If the amplitude is to reflect physical (read topological) information about the underlying manifold, then it should not depend upon this particular decomposition into observer and observed. The same remarks apply to 4-manifolds and interface with ideas in relativity. We mention 3-manifolds because it is possible to describe many examples of topological amplitudes in three dimensions. The matter of four-dimensional amplitudes is a topic of current research. The notion that an amplitude be independent of the distinction producing it is prior to topology. Topological invariance

of the amplitude is a convenient and fundamental way to produce such independence.

This sudden jump to topological amplitudes has its counterpart in mathematical physics. Witten (1989) proposed a formulation of a class of 3-manifold invariants as generalized Feynman integrals taking the form $Z(M)$, where

$$Z(M) = \int dA e^{\frac{ik}{4\pi} S(M,A)}.$$

Here M denotes a 3-manifold without boundary and A is a gauge field (also called a gauge potential or gauge connection) defined on M. The gauge field is a one-form on M with values in a representation of a Lie algebra. The group corresponding to this Lie algebra is said to be the *gauge group* for this particular field. In this integral the "action" $S(M, A)$ is taken to be the integral over M of the trace of the Chern–Simons three-form $CS = A \wedge dA + (\frac{2}{3}) A \wedge A \wedge A$. (The product is the wedge product of differential forms.)

Instead of integrating over paths, the integral $Z(M)$ integrates over all gauge fields modulo gauge equivalence. This generalization from paths to fields is characteristic of quantum field theory. Quantum field theory was designed in order to accomplish the quantization of electromagnetism. In quantum electrodynamics the classical entity is the electromagnetic field. The question posed in this domain is to find the value of an amplitude for starting with one field configuration and ending with another. The analogue of all paths from point a to point b is "all fields from field A to field B."

Witten's integral $Z(M)$ is, in its form, a typical integral in quantum field theory. In its content $Z(M)$ is highly unusual. The formalism of the integral and its internal logic supports the existence of a large class of topological invariants of 3-manifolds and associated invariants of knots and links in these manifolds.

Invariants of 3-manifolds were initiated by Witten as functional integrals and at the same time defined in a combinatorial way by Reshetikhin and Turaev (1991). The Reshetikhin–Turaev definition proceeds in a way that is quite similar to the definition that we gave for the bracket model for the Jones polynomial in Section 1. It is an amazing fact that Witten's definition seems to give the very same invariants. We are not in a position to go into the details of this correspondence here. However, one theme is worth mentioning: For k large, the Witten integral is approximated by those gauge connections A for which $S(M, A)$ has zero variation with respect to change in A. These are the so-called *flat connections*. It is possible in many examples to calculate this contribution via both the functional integral and by the combinatorial definition of Reshetikhin and Turaev. In all cases, the two methods agree (see, e.g., Freed and Gompf, 1991; Lawrence and Rozansky, 1997). This is one of the pieces of evidence in a puzzle that everyone expects will eventually justify the formalism of the functional integral.

In order to obtain invariants of knots and links from Witten's integral, one adds an extra bit of machinery to the brew. The new machinery is the *Wilson loop*. The Wilson loop is an exponentiated version of integrating the gauge field along a loop K. We take this-loop K in three-space to be an embedding (a knot) or a curve with transversal self-intersections. It is usually indicated by the symbolism $\mathrm{tr}(\mathbb{P} e^{\int_K A})$, where P denotes *path-ordered integration*, that is, we are integrating and exponentiating matrix-valued functions, and one must keep track of the order of the operations. The symbol tr denotes the trace of the resulting matrix.

With the help of the Wilson loop function on knots and links, Witten writes down a functional integral for link invariants in a 3-manifold M:

$$Z(M, K) = \int dA e^{\frac{ik}{4\pi} \int (M,A)} \mathrm{tr}(\mathbb{P} e^{\int_K A}).$$

Here $S(M, A)$ is the Chern–Simons Lagrangian, as in the previous discussion.

If one takes the standard representation of the Lie algebra of $SU(2)$ as 2×2 complex matrices then it is a fascinating exercise to see that the formalism of $Z(S^3, K)$ ($S3$ denotes the three-dimensional sphere) yields the original Jones polynomial with the basic properties as discussed in Section 1. See Witten (1989) or Kauffman (1995) for discussions of this part of the heuristics.

This approach to link invariants crosses boundaries between different methods. There are close relations between $Z(S^3, K)$ and the invariants defined by Vassiliev (Kauffman, 1995), to name one facet of this complex crystal.

A. Links and the Wilson Loop

We shall now indicate an analysis of the formalism of this functional integral that reveals quite a bit about its role in knot theory. This analysis depends upon some key facts relating the curvature of the gauge field to both the Wilson loop and the Chern–Simons Lagrangian. To this end, let us recall the local coordinate structure of the gauge field $A(x)$, where x is a point in three-space. We can write $A(x) = A_h^a T_a \, dx^h$, where the index a ranges from 1 to m with the Lie algebra basis $\{T_1, T_2, T_3, \ldots, T_m\}$ and the index k goes from 1 to 3. For each choice of a and k, $A_k^a(x)$ is a smooth function defined on three-space. In $A(x)$ we sum over the values of repeated indices. The Lie algebra generators T_a are actually matrices

corresponding to a given representation of an abstract Lie algebra.

B. Difference Formula

One can deduce a difference formula for the Witten invariants from the formal properties of the functional integral. Let K_+ and K_- denote knots that differ at a single crossing with $+$ and $-$ signs, respectively, and $K_{\#\#}$ the result of replacing the crossing by a transverse singularity (i.e., with distinct tangent directions for the two local curve segments). We take $K_\#$ to denote the insertion of a graphical node at the transverse crossing, as we have done in our discussion of the Vassiliev invariant. The notation $K_{\#\#}$ indicates that the curve intersects itself in space at one point. Let $K_{\#\#}T_aT_a$ denote the result of placing the matrices of the Lie algebra basis into the Wilson line at the singular crossing as shown in Fig. 52.

These matrices become part of the big matrix product that generates the Wilson line. Then, up to order $(1/k)$ one has the difference relation

$$Z(K^+) - Z(K^-) = (4pi/k)Z\big(K_{\#\#}T_aT_a\big).$$

This formula is the key to unwrapping many properties of the knot invariants.

C. Graph Invariants and Vassiliev Invariants

Recall, from Section 5, that $V(G)$ is a Vassiliev invariant if

$$V_{K+} - V_{K-} = V_{K\#}.$$

$V(G)$ is said to be of *finite type* k if $V(G) = 0$ whenever $\#(G) > k$, where $\#(G)$ denotes the number of 4-valent nodes in the graph G. See Section 5.

With this definition in hand, let us return to the invariants derived from the functional integral $Z(K)$. We have that

$$Z(K+) - Z(K-) = \left(\frac{4\pi i}{k}\right) Z\big(K_{\#\#}T^aT^a\big).$$

This formula tells us that for the Vassiliev invariant associated with Z we have

$$Z(K\#) = \left(\frac{4\pi i}{k}\right) Z\big(K_{\#\#}T^aT^a\big).$$

Furthermore, if $V_j(K)$ denotes the coefficient of $\frac{4\pi i}{k}$ in the expansion of $Z(K)$ in powers of $(1/k)$, then the ambient difference formula implies that $(1/k)^j$ divides $Z(G)$ when G has j or more nodes. Hence $V_j(G) = 0$ if G has more than j nodes. Therefore $V_j(K)$ is a Vassiliev invariant of finite type. [This result was proved by Birman and Lin (1993) by different methods and by Bar-Natan (1995) by methods equivalent to ours.]

The fascinating thing is that the ambient difference formula, appropriately interpreted, actually tells us how to compute $V_k(G)$ when G has k nodes. This result is equivalent to the description of weight systems derived from Lie algebras that we described in Section 6. Thus the approach to link invariants via the functional integral motivates and explains the fundamental structure of Vassiliev invariants.

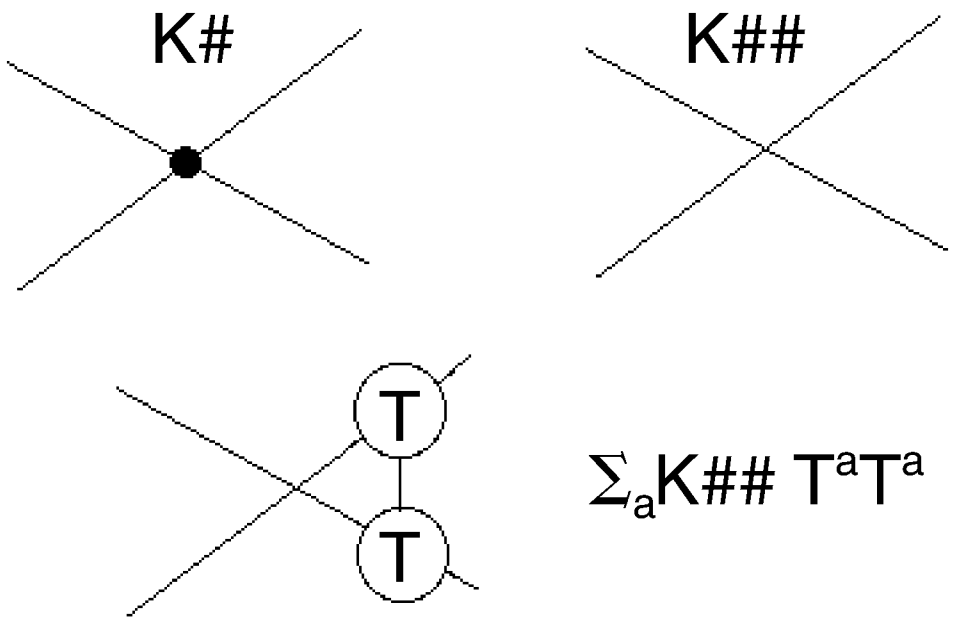


FIGURE 52 Lic Algebra Insertion.

This deep relationship between topological invariants in low-dimensional topology and quantum field theory in the sense of Witten's functional integral is still in its infancy. There will be many surprises in the future as we discover that what has so far been uncovered is only the tip of an iceberg.

ACKNOWLEDGMENT

It gives me great pleasure to thank Vaughan jones, Ed Witten, Nicolai Reshetikhin, Mario Rasetti, Sostenes Lins, Massimo Ferri, Lee Smolin, Louis Crane, David Yetter, Ray Lickorish, DeWitt Sumners, Hugh Morton, Joan Birman, John Conway, John Simon and Dennis Roseman for many conversations related to the topics of this paper. This research was partially supported by the National Science Foundation Grant DMS-2528707.

Linear Optimization

C. Roos
Delft University of Technology/University of Leiden

GLOSSARY

Bounded problem An LO-problem whose objective function is bounded from above if the problem is a maximization problem, and bounded from below if it is a minimization problem.
Canonical LO-model All constraints are inequality constraints and all variables are nonnegative.
Feasible problem An LO-problem whose feasible region is nonempty.
Feasible region The set of points satisfying all the constraints.
Infeasible problem An LO-problem whose feasible region is empty.
Integer LO-problem LO-problem whose variables are required to be integral.
Interior-point condition (IPC) There exists a feasible point for which all inequality constraints in the LO-problem are satisfied strictly.
LO-relaxation The LO-problem that arises when the integrality condition on the variables in an integer LO-problem is removed.
Polynomial method A solution method for LO-problems whose running time depends polynomially on the size of the problem.
Size of a problem Length of a binary string needed to encode an LO-problem.
Standard LO-model An LO-problem in which all constraints are equality constraints and all variables are nonnegative.
Unbounded problem An LO-problem that is not bounded.

LINEAR OPTIMIZATION (LO) is the branch of mathematics that deals with minimizing (or maximizing) a linear function whose variables are subject to linear equality or inequality constraints. The *standard form* of the LO-problem has the form

$$\begin{aligned} \text{minimize} \quad & p = \sum_{j=1}^{n} c_j x_j \\ \text{subject to} \quad & \sum_{j=1}^{n} a_{ij} x_j = b_i, \quad i = 1, \ldots, m \\ & x_j \geq 0, \quad j = 1, \ldots, n, \end{aligned}$$

or, in matrix form,

$$\begin{aligned} \text{minimize} \quad & p = c^T x \\ \text{subject to} \quad & Ax = b \\ & x \geq 0, \end{aligned} \tag{1}$$

where A is an $m \times n$ matrix and x, b, and c are vectors of dimension n, m, and m respectively. Here, $x \geq 0$ means that all entries of x are nonnegative and the superscript ^{T} refers to taking the transpose.

The relevance of the subject is due to the fact that real-life problems in many branches of applied sciences like economy, logistics, and engineering, can be modeled as LO-problems. As a result, LO is probably one of the most applied mathematical tools. The beauty of the subject is due to its rich mathematical theory, part of which has developed over the last twenty years.

I. HISTORICAL BACKGROUND

The field of LO[1] arose in the 1940s, due to important work of Dantzig, Kantorovich, Koopmans, Von Neumann, and Morgenstern. Dantzig was involved in the research project Scientific Computation of the Optimum Programs (SCOOP) at the U.S. Air Force. He visited Koopmans in June 1947 and told him of his work on linear models for the optimization of military operations. Koopmans immediately recognized the relevance of this approach for his economic models and made clear to Dantzig that the economists did not have an algorithm for solving such models. In the summer of 1947 Dantzig invented the Simplex method. Koopmans was the leader of a group of economists who developed the theory of optimal assignment of resources by using LO-models. For this work he received the Nobel prize, in 1975, together with Kantorovich.

In the autumn of 1947 another important meeting took place, when Dantzig visited Von Neumann. This meeting clarified the relation between Dantzig's work and the game theory as developed by Von Neumann and Morgenstern. Dantzig also heard for the first time of Farkas' lemma and the notion of duality in LO.

From a computational point of view the Simplex method is very simple. Only the elementary arithmetic operations addition, subtraction, division, and multiplication are performed on a rectangular table that initially contains the data of the LO-model. The number of operations, however, is so large that only relatively small models can be solved manually. Fortunately, the invention of the Simplex method coincided in time more or less with the invention of the electronic computer. The calculations could be automatized, thus paving the way for large-scale applications. Oil companies belonged to the early users of the computer code MPS/360 for LO released by IBM in 1966 and that could run on the IBM 360 computers that were introduced around that time. At the end of the 1960s and in the early 1970s, other software packages for LO became available: MPSX, and later MPSX/370 of IBM, MPS III of Exxon, the UMPIRE system for the UNIVAX 1108, APX III for the CDC computers, LAMPS (of John Forrest), and LINDO. For the history of the implementations of the Simplex method the reader is referred to W. Orchard-Hays (1990).

From a theoretical point of view the Simplex method has some properties that deserve mentioning here, because they were important in the history of LO. First, the method may *cycle*, i.e., it may happen that after hours of calculations a tableau is generated that already occurred before during the calculations. This phenomenon is called *cycling*. For a mathematical algorithm this is disastrous. It inplies that a computer program may run forever without terminating with a solution. Dantzig already recognized this danger and found a so-called *cycle-breaking* rule; as a consequence, the Simplex method always solves any LO-problem correctly.

A second property concerns the computational time. It may be expected that this time will grow with the size of the problem, i.e., with the number n of variables as well as with the number m of constraints. In practice the behavior is such that, as a rule of thumb, the computational time depends linearly on n and m. Many researchers tried to find a theoretical estimate for the computational time in terms of n and m. In all cases they ended up with a formula that is exponential in either n or m. In 1972 it became clear that this behavior is inherent to the Simplex method. In that year Klee and Minty gave an elegant example for which the computational time is exponential in n [Klee and Minty (1972)].

The result of Klee and Minty initiated a period of search for new, more efficient methods in the LO world. In 1979 the front page of the New York Times announced an important result: the Russian mathematician Khachiyan had found a new method with the desired property, the Ellipsoid method [Khachiyan (1979)]. This method is polynomial, i.e., the computational time depends polynomially on the size of the problem. Theoretically, this was an enormous breakthrough, from the practical point of view the result was disappointing. Computer programs based on the Ellipsoid method proved to be much less

[1]Historically, the field is named Linear Programming, or LP. This name was proposed shortly after World War II [Dantzig (1963)]. Since then the modern computer came to life and the word "programming" usually refers to the activity of writing computer programs. As a consequence, its use instead of the more natural word "optimization," gives rise to confusion [Williams (1990)].

efficient and less robust than those using the Simplex method. The result was an unpleasant tension between theory and practice: the theoretically efficient Ellipsoid method could not match the theoretically inefficient Simplex method.

A new breakthrough came in 1984. In that year the Indian mathematician Karmarkar published a method that reconciled theory and practice [Karmarkar (1984)]. It was again front page news. Karmarkar worked at the well-known American telephone company AT&T, and had found a completely new approach to the LO-problem. His so-called Projective method was polynomial and, as claimed by Karmarkar, was in practice at least 100 times faster than the Simplex method, especially for large-scale problems. The last claim gave rise to much commotion.

It is hard to find another mathematical result that caused so much excitement and dispute. The disputes were due to the fact that the published version of Karmarkar's method differed from the version implemented at AT&T. This was not made public. Later on the reason became clear. AT&T had made a big investment to design a computer program for LO that should be about 200 times faster than the commercial codes for solving LO-problems available at that time. A project group was formed including many prominent researchers, with the task to devise a new LO-program on the basis of Karmarkar's method. During its existence the size of the group grew from 20 to 200 researchers (R. E. Bixby and R. Vanderbei, Private communication). The system would be a hardware/software "complete" solution. For the hardware a $1 million vector/parallel machine of Alliant Computers was chosen.

About 5 years later, in 1989, the LO-package was launched under the name KORBX. In 1991, after selling one system to the military airlift command for about $4 million and one system to Delta airlines for $12 million, the venture was essentially abandoned. The LO-package was not portable, it ran only on the Alliant computer. In retrospect, this may have been the main reason for the failure of the project.

Outside AT&T much research activity took place. Initial implementations based on Karmarkar's paper proved to be about 100 times slower than the Simplex-based codes. It looked as if the Simplex method would survive this attack from the Projective method, just as it had survived the Ellipsoid method. Karmarkar, however, persisted with his claims. This inspired further worldwide research. Over a period of 10 years more than 2000 scientific publications appeared on the subject. This led to many new theoretical concepts and algorithmic ideas. These insights were immediately incorporated into computer programs. The work of Lustig, Marsten, and Shanno resulted in a computer code, called OB1, that could compete with the Simplex method. At the time that KORBX entered the market, OB1 was faster, suitable for all current computer platforms, and freely available for research purposes.

The computer code OB1 was based on a method proposed already in the 1950s by Frisch (1956), the *logarithmic barrier method.* By adjusting this method the so-called *path-following methods or interior-point methods* arose. The first term refers to the *central path* of an LO-problem; this is a curve in the interior of the feasible region that converges to an optimal solution. After its rediscovery, independently by several researchers, it became the basis of all modern interior-point methods. These methods are nothing else than numerical recipes that generate a sequence of points, on or close to the central path, that converge to an optimal solution. In this way, several efficient (i.e., polynomial) methods came to life whose practical performance justify the original claim of Karmarkar [Roos *et al.* (1997)].

In the meantime it turned out that the implementations of the Simplex method could be accelerated dramatically by implementing techniques already available in the literature. Especially Bixby (Rice University, Houston, TX) did important work in this respect. As a result an exciting competition arose between him and the makers of OB1. In some large-scale applications in the airline industry this has led to a nice synthesis of both approaches, where a close-to-optimal solution is generated by an interior-point method which is then used as input for the Simplex method to generate an exact solution.

A result of the sketched developments is that nowadays LO-problems can be solved about 1,000,000 times faster than in 1984. A factor of 1000 is due to the better algorithmic methods and the other factor of 1000 to the improvements in computer technology (Moore's law). The consequences for the applications are far-reaching. An LO-model that required 1 year of computational time 16 years ago can now be solved in about 30 seconds. It is clear that problems that require a computational time of 1 year are unsolvable from a practical point of view. Therefore, the improved performance, although of a quantitative nature, has qualitative consequences: problems that could not be solved 15 years ago can now be solved in a few seconds. This explains why the use of commercial LO-packages has shown an explosive growth during the last years.

Modern LO-packages contain both a Simplex-based solver and an interior-point solver. Some of the most well-known packages are OSL of IBM, CPLEX (based on the Simplex code of Bixby and on OB1), XPRESS-MP of Dash Associates, and MOSEK of the brothers E. D. and K. D. Andersen. The environments in which these packages are used nowadays is quite diverse: aviation industry, oil industry, engineering design, finance, water management, etc.

II. THE SIMPLEX METHOD

The Simplex method can be used to solve any LO-problem in the standard form. The method constructs a sequence of basic solutions of the problem until it either finds an optimal basic solution or detects that such a solution does not exist.

A. Reduction to Standard Form

If an LO-problem does not have the standard form it can easily be put into this form as follows.

If a constraint has the form $a_i^T x \geq b_i$ we replace it by $-a_i^T x \leq -b_i$. Thus, we may assume that the inequalities have the form $a_i^T x \leq b_i$. For each such inequality constraint we introduce a *slack variable* s_i according to $a_i^T x + s_i = b_i$. We are then left with a situation where all constraints are equality constraints. Let us write them as $Ax = b$. If b does not belong to the column space of the matrix A, then this system is inconsistent and the problem infeasible. Otherwise, we remove redundant constraints until the matrix A has full row rank. If for each variable a nonnegativity constraint exists, the problem already has the standard form. Otherwise, let F denote the index set of the "free" variables, i.e., the variables without nonnegativity constraints. The classical way to "remove" the free variables is to substitute $x_i = x_i^{(1)} - x_i^{(2)}$, with $x_i^{(1)} \geq 0$ and $x_i^{(2)} \geq 0$, for each free variable x_i. This approach, although theoretically sound, has some serious drawbacks: it increases the number of variables, and when solving the problem with an interior-point method, the new model will not satisfy the interior point condition (IPC). A better approach is as follows. Let r denote the rank of A_F (the submatrix of A formed by the columns indexed by F). As long as free variables occur in the problem formulation we choose a free variable and a constraint in which it occurs. Then, using this (equality) constraint, we express the free variable in terms of the other variables and by substitution we eliminate it from the other constraints and from the objective function. Since F has rank r, we can do this r times, and then the remaining constraints no longer contain free variables. We are left with m equality conditions, r of which express free variables in the remaining variables, while the remaining $m - r$ equalities contain no free variables. Observe that the first r equalities do not impose a condition on the feasibility of the vector x; they simply tell us how the values of r of the free variables in x can be calculated from the remaining variables. Hence, these equalities can be neglected from now on, and we are left with $m - r$ equality constraints in nonnegative variables. If the objective function still contains free variables, the problem is unbounded from below, and we have solved the problem. Otherwise, the remaining problem has the standard form.

B. Basic Solution

Let x denote any solution of $Ax = b$ and let $\sigma(x)$ denote its support:

$$\sigma(x) := \{i : x_i \neq 0\}.$$

We call x a *basic solution* if the columns in $A_{\sigma(x)}$ are linearly independent. If x is not a basic solution we can easily derive a basic solution from it, as follows. The columns in $A_{\sigma(x)}$ being linearly dependent, there exists a nonzero vector λ such that $A\lambda = 0$, with $\lambda_i = 0$ for $i \notin \sigma(x)$. Now let $\alpha \geq 0$ grow until one of coordinates in $\sigma(x)$ of $x \pm \alpha\lambda$ becomes zero and let $\bar{x}$ denote $x \pm \alpha\lambda$ for this value of α. Then $\sigma(\bar{x})$ is a proper subset of $\sigma(x)$. If $\bar{x}$ is not a basic solution the above procedure is repeated. Since $\sigma(x)$ is finite this yields a basic solution after a finite number of steps.

C. Basic Feasible Solution

Let x denote any nonnegative solution of $Ax = b$ and let $\sigma(x)$ be its support. We call x a *basic feasible solution* if x is a basic solution. If x is not a basic solution, the procedure described in Section II.B can be used to produce a nonnegative basic solution $\bar{x} = x + \alpha\lambda$ (if necessary, use $-\lambda$ instead of λ). Even more, if $p = c^T x$, we can find a basic feasible solution x such that $c^T \bar{x} \leq p$, or establish that the problem is unbounded. To this end we modify the procedure of Section II.B by taking λ such that $c^T \lambda \leq 0$. If this works it gives a basic feasible solution with the desired property. If it does not work and $c^T \lambda < 0$, it follows that $\bar{x} = x + \alpha\lambda$ remains nonnegative, however large the value of α. For large α, $c^T \bar{x}$ goes to minus infinity, proving that the problem is unbounded. If $c^T \lambda = 0$, replacing λ by $-\lambda$ provides a basic feasible solution with the same objective value.

Let us mention that, in general, interior-point methods generate a nonbasic optimal solution. Note that the procedure described above enables us to construct a basic optimal solution from any given optimal solution.

D. A Simplex Iteration

Suppose we are given a basic feasible solution $\bar{x}$. There are two main questions:

1. How can we determine whether the given solution is optimal?
2. If the solution is not optimal, how can we find a better solution?

In this section we deal with these two questions.

We assume (without loss of generality) that the problem matrix A has rank m. Since $\bar{x}$ is a basic solution, its support contains at most m indices and the corresponding columns of A are linearly independent. If necessary, we extend the support of $\bar{x}$ to obtain a set B of m indices such that the columns A_k of A with $k \in B$ are linearly independent. Any such set B is called a *basic index set* (or *basis*) for $\bar{x}$. The remaining indices are called the *nonbasic indices;* their set is denoted as N.

By construction, the submatrix A_B of A, consisting of the columns indexed by elements of B, is nonsingular. Hence, the current basic feasible solution $\bar{x}$ is given by

$$\bar{x}_B = A_B^{-1} b, \quad \bar{x}_N = 0, \tag{2}$$

and, defining $\bar{y} \in \mathbb{R}^m$ by

$$A_B^T \bar{y} = c_B, \tag{3}$$

the current objective value satisfies

$$c^T \bar{x} = c_B^T \bar{x}_B + c_N^T \bar{x}_N = c_B^T A_B^{-1} b = b^T \bar{y}. \tag{4}$$

Letting

$$\bar{s} := c - A^T \bar{y}, \tag{5}$$

we claim that $\bar{x}$ is an optimal solution if $\bar{s} \geq 0$, thus answering question (1).

Here is the proof of this claim. We rewrite the constraints as

$$A_B x_B + A_N x_N = b, \quad x_B \geq 0, \quad x_N \geq 0 \tag{6}$$

and multiply from the left by the inverse of A_B, leaving us with the equivalent system

$$x_B = \bar{x}_B - A_B^{-1} A_N x_N, \quad x_B \geq 0, \quad x_N \geq 0. \tag{7}$$

The objective function can now be written as

$$\begin{aligned} c^T x &= c_B^T x_B + c_N^T x_N \\ &= c_B^T \bar{x}_B + \left(c_N^T - c_B^T A_B^{-1} A_N\right) x_N \\ &= c_B^T \bar{x}_B + \left(c_N - A_N^T \bar{y}\right)^T x_N \\ &= c^T \bar{x} + \bar{s}_N^T x_N. \end{aligned} \tag{8}$$

Now suppose that $\bar{s} \geq 0$, and let x' be any feasible solution. Then, by Eq. (8), we have

$$c^T x' = c^T \bar{x} + \bar{s}_N^T x'_N \geq c^T \bar{x},$$

since $\bar{s}_N \geq 0$ and $x'_N \geq 0$. This proves the claim that $\bar{x}$ is optimal if $\bar{s} \geq 0$.

Next, we deal with question (2) and consider the case where $\bar{s}$ is not nonnegative. So $\bar{s}$ has at least one negative entry. Let $\bar{s}_k < 0$. Then $k \in N$, because $\bar{s}_B = 0$. Expression (8) makes clear how $c^T x$ will change if we increase x_k while leaving the other nonbasic variables zero (their current value). We then have

$$c^T x = c^T \bar{x} + \bar{s}_k x_k. \tag{9}$$

This makes clear that the objective value will decrease if x_k increases. Of course, the larger x_k, the larger the decrease of the objective value. However, when increasing x_k we have to take care of the feasibility. In this respect Eq. (7) is useful. Taking for x_N the vector with x_k in the k-position, and zeros elsewhere, we obtain x_B as a function of x_k:

$$x_B = \bar{x}_B - x_k A_B^{-1} A_k.$$

It is convenient to introduce the matrix

$$T^B := A_B^{-1} A. \tag{10}$$

Note that this is an $m \times n$ matrix whose rows are naturally indexed by the elements of B. We can now rewrite the above expression for x_B as follows:

$$x_B = \bar{x}_B - x_k T_k^B. \tag{11}$$

Hence, if $T_k^B \leq 0$ then $x_B \geq 0$ for all nonnegative values of x_k. Letting x_k go to infinity, the objective value goes to minus infinity. We conclude that the problem is unbounded if $T_k^B \leq 0$.

In the other case, when T_k^B has one or more positive entries, there exists a maximal value of x_k for which $x_B \geq 0$. In fact this value of x_k is given by

$$\tilde{x}_k = \min\left\{ \frac{\bar{x}_i}{T_{ik}^B} : T_{ik}^B > 0 \right\}. \tag{12}$$

For this value of x_k at least one (but possibly more) entries of x_B vanish. Let x_ℓ be one of these entries. Then the new solution is a basic solution with index set

$$B' := (B \cup \{k\}) \backslash \{\ell\}. \tag{13}$$

The new objective value follows from Eq. (9). If $\tilde{x}_k > 0$ the new value is smaller than $c_B^T A_B^{-1} b$, the current value.

Thus, we have answered question (2). In doing so, we have just described a typical iteration of the Simplex method. Starting with a basic feasible solution, with index set B for the basic variables, we moved to another basic feasible solution whose basic index set is given by Eq. (13). We call k the *entering index* and ℓ the *leaving index*. The entering index is chosen first: for this one may take *any* index k such that $\bar{s}_k < 0$. Given k we choose the leaving index ℓ according to the above *quotient rule* (Eq. 12). For the leaving index we may take *any* index ℓ yielding the minimal quotient in Eq. (12). The pair (k, ℓ) is called the *pivoting pair* of the Simplex iteration.

E. Simplex Tableaus

When the given LO-problem is small enough, the Simplex iteration can be performed by hand. In such cases it is usual, and useful, to make use of a so-called Simplex tableau. The Simplex tableau belonging to the basis B looks as follows.

$c^T\bar{x}$	$-\bar{s}^T$
$\bar{x}_B$	T^B

(14)

If the pivoting pair is (k, ℓ), then the Simplex tableau belonging to the new basis B' simply arises by pivoting on the element $T^B_{\ell k}$.

To illustrate the use of the Simplex tableau we consider the following LO-problem.

$$\begin{aligned} \min \quad & 3x_1 + 2x_2 \\ \text{s.t.} \quad & x_1 + x_2 \geq -1 \\ & x_1 + 2x_2 \geq 1 \\ & x_1 \geq 0, \quad x_2 \geq 0. \end{aligned}$$

By adding surplus variables x_3 and x_4 the problem assumes the standard form:

$$\begin{aligned} \min \quad & 3x_1 + 2x_2 \\ \text{s.t.} \quad & x_1 + x_2 - x_3 = -1 \\ & x_1 + 2x_2 - x_4 = 1 \\ & x_1 \geq 0, \quad x_2 \geq 0, \quad x_3 \geq 0, \quad x_4 \geq 0. \end{aligned}$$

The vector $\bar{x} = (1, 0, 2, 0)$ is a basic solution. The set B of basic indices is $\{1, 3\}$. We thus have

$$A_B = \begin{pmatrix} 1 & -1 \\ 1 & 0 \end{pmatrix}, \quad A_B^{-1} = \begin{pmatrix} 0 & 1 \\ -1 & 1 \end{pmatrix}.$$

Furthermore,

$$\bar{y} = A_B^{-T} c_B = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 3 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 3 \end{pmatrix},$$

and, using Eq. (5),

$$\bar{s} = \begin{pmatrix} 3 \\ 2 \\ 0 \\ 0 \end{pmatrix} - \begin{pmatrix} 1 & 1 \\ 1 & 2 \\ -1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} 0 \\ 3 \end{pmatrix} = \begin{pmatrix} 0 \\ -4 \\ 0 \\ 3 \end{pmatrix}.$$

Using this, the Simplex tableau for B becomes

		x_1	x_2	x_3	x_4
	3	0	4	0	−3
x_1	1	1	**2**	0	−1
x_3	2	0	1	1	−1

The variable names outside the borders serve to indicate to which variables the rows and columns belong. The tableau shows that $\bar{s}_2 = -4 < 0$. In its column we find the pivot (set in boldface) $(k, \ell) = (2, 1)$ by using the quotient rule. After the pivot we get the tableau

		x_1	x_2	x_3	x_4
	1	−2	0	0	−1
x_2	$\frac{1}{2}$	$\frac{1}{2}$	1	0	$-\frac{1}{2}$
x_3	$\frac{3}{2}$	$-\frac{1}{2}$	0	1	$-\frac{1}{2}$

Note that new basic variables are still nonnegative, as it should. But we now have $\bar{s} \geq 0$, which means that the optimal solution has been found. We read it from the last tableau: the nonbasic variables are equal to zero and the basic variables can be read from its first column: $\bar{x} = (0, \frac{1}{2}, \frac{3}{2}, 0)$. Hence, the optimal solution of the original problem is $x_1 = 0$, $x_2 = \frac{1}{2}$, and the optimal value is 1.

F. Finiteness of the Simplex Method

Unfortunately, it may happen that the new solution is not really "better" than the old one. The new objective value may be equal to the old one, and this happens exactly if $\tilde{x}_k = 0$, which means that $\bar{x}_\ell = 0$. In that case we call the iteration *degenerate*. Then no progress is made in terms of the objective value. Even worse, examples exist in which, after a sequence of degenerate iterations, the new basic index set is equal to a basic index set occurring earlier in the sequence [Avis and Chvátal (1978); Beale (1955); Hoffman (1953); Lee (1997)]. This is the so-called phenomenon of *cycling*.

It is most important to avoid cycling. Although it is impossible to avoid degenerate iterations, it is possible to avoid the occurrence of cycles. This can be achieved by using a *cycle-breaking* rule. Such a rule imposes some conditions on the choice of the entering and the leaving variable and its use guarantees that the Simplex method will never produce the same basic index set twice, see Section II.G. What does this mean? Since the number of basic index sets is finite it means that after a finite number of iterations the Simplex method terminates. There are two possible reasons for the method to terminate. The first reason is that there is no candidate for k. In that case we have

$\bar{s} \geq 0$, and as we saw before this implies the optimality of the current solution $\bar{x}$. The second possible reason for termination of the method is that after having found the entering variable k there is no candidate for ℓ; as we established earlier this implies that the problem is unbounded.

G. Cycle-Breaking Rules

One elegant way to avoid cycles is to use a so-called *least index rule*. Then, whenever there is any ambiguity in the choice of k or ℓ we choose the smallest possible index among the candidate indices. This rule was first proposed by Bland (1977).

A second cycle-breaking rule is the *lexico-graphic rule* [Danzig *et al*. (1955)]. This rule uses the lexico-graphic ordering "$\prec$" of vectors: we say that $v \prec w$ ($v, w \in \mathbb{R}^p$) if the vector $u = w - v$ is *lexicographically positive*, i.e. $u \neq 0$ and the first nonzero coordinate of u is positive. The lexicographic rule gives no condition on the choice of the entering index k, but it requires the leaving index ℓ to be taken such that the pivot element $T^B_{\ell k}$ is positive and the vector

$$\frac{\left(\bar{x}_B T^B\right)_{\ell,:}}{T^B_{\ell k}}$$

is lexicographically minimal. Here, $(\bar{x}_B T^B)$ is the matrix obtained by extending T^B to the left with the column $\bar{x}_B$. So this matrix is nothing else than the part of the Simplex tableau below its first row; $(\bar{x}_B T^B)_{\ell:}$ denotes the row of the tableau indexed by the basic variable ℓ.

If initially all rows in the tableau below the first row are lexicographically positive, which can be realized easily, then the lexicographic rule guarantees that in all subsequent tableaus this property is maintained, and that the first row is lexicographically decreasing. The last property prevents the occurrence of cycles.

H. Initialization: Two-Phase Method

In Section II.D we assumed that we were given a basic feasible solution $\bar{x}$. We show in this section how to obtain such a solution, if it exists.

We introduce *artificial variables* t_i ($1 \leq i \leq n$) and consider the problem

$$\begin{aligned} \text{minimize} \quad & e^T t \\ \text{subject to} \quad & Ax + t = b \\ & x \geq 0, \quad t \geq 0, \end{aligned} \tag{15}$$

where e denotes the all-one vector. Without loss of generality we may assume that $b \geq 0$ in Eq. (1), because otherwise we multiply constraints for which the corresponding entry in b is negative, by -1. Then $x = 0, t = b$ is a feasible solution for Eq. (15), and, obviously, this solution is basic. Hence, we can solve Eq. (15) with the Simplex method. Since Eq. (15) is a bounded problem, this yields a basic feasible solution $(\bar{x}, \bar{t})$ of Eq. (15). Now two cases can occur: $e^T \bar{t} > 0$ or $e^T \bar{t} = 0$. In the first case the problem must be infeasible, because any feasible solution of Eq. (1) yields a feasible solution to Eq. (15) with $t = 0$. In the second case $\bar{x}$ is a basic feasible solution of Eq. (1).

It is now clear that we can solve Eq. (1) with the Simplex method in two phases. In phase I we solve Eq. (15); if the problem is infeasible it is detected in this phase, otherwise we obtain a basic feasible solution of Eq. (1) that can be used in phase II to solve the problem. Phase II either yields an optimal basic solution, or detects that the problem is (feasible and) unbounded.

I. Duality

Suppose that Eq. (1) has an optimal solution. Then, by applying the Simplex method, we can obtain an optimal basic index set B and the corresponding basic feasible solution $\bar{x}$. Below, we use again the vectors $\bar{y} \in \mathbb{R}^m$ and $\bar{s} \in \mathbb{R}^n$ as introduced in Eqs. (3) and (5), respectively.

1. Dual of the Standard Problem

Recall from Section II.D that $\bar{s} \geq 0$. Hence, $(\bar{y}, \bar{s})$ is feasible for the following maximization problem:

$$\begin{aligned} \text{maximize} \quad & d = b^T y \\ \text{subject to} \quad & A^T y + s = c \\ & s \geq 0. \end{aligned} \tag{16}$$

2. Duality Results

We claim that $(\bar{y}, \bar{s})$ is an optimal solution of Eq. (16). This is a consequence of the following result.

Theorem 1 (Weak duality) Suppose that x and (y, s) are feasible for Eqs. (1) and (16), respectively. Then

$$c^T x - b^T y \geq 0.$$

Proof: We have

$$\begin{aligned} x^T s &= x^T (c - A^T y) \\ &= c^T x - (Ax)^T y = c^T x - b^T y. \end{aligned}$$

Since $x \geq 0$ and $s \geq 0$, $x^T s \geq 0$. □

Theorem 1 reveals a close relation between problems (1) and (16). From now we call these problems the *primal problem* and *dual problem*, respectively. The theorem implies that if x is feasible for the primal problem (or shortly,

primal feasible) then $c^T x$ is an upper bound for the optimal value d^* of the dual problem, and, vice versa, if (y, s) is *dual feasible* then $b^T y$ is a lower bound for the optimal value p^* of the primal problem. As a consequence, if $c^T x = b^T y$, then x is an optimal solution of the primal problem and (y, s) is an optimal solution of the dual problem. Hence, by taking $x = \bar{x}$, $y = \bar{y}$ and $s = \bar{s}$, the above claim now follows from Eq. (4).

A direct consequence of Theorem 1 is that if either of problems (1) or (16) is unbounded, then the other problem is infeasible.

In summary, if the primal problem has an optimal solution then so has the dual problem and the optimal values coincide. If the primal problem is unbounded then the dual problem is infeasible. In Section II.I.3 we will see that problem (16) also has a dual problem, which is exactly (1). Hence, we may interchange the words "primal" and "dual" in the first sentence of this paragraph. Thus, we have the following result, due to Von Neumann (1947).

Theorem 2 (Strong duality) If the primal and dual problem are both feasible then both problems have optimal solutions and their optimal values are equal. Otherwise, neither of the two problems has optimal solutions.

If neither of the two problems has optimal solutions then both are infeasible, or one is infeasible while the other is unbounded.

A second duality result is due to Goldman and Tucker (1956).

Theorem 3 (Goldman-Tucker) If both the primal and dual problem are feasible then there exists a strictly complementary pair of optimal solutions, i.e., optimal solutions x and (y, s) such that $x + s > 0$.

This duality result is less well-known. Its interest is that interior-point methods produce strictly complementary solutions (cf. Section III.J). It has recently become clear that such solutions play an important role when dealing with sensitivity analysis (cf. Section IV.B).

Let us also mention that the primal problem is infeasible if and only if there exists a vector y such that $A^T y \leq 0$ and $b^T y > 0$, and the dual problem is infeasible if and only if there exists a vector $x \geq 0$ such that $Ax = 0$ and $c^T x < 0$. These statements are examples of *theorems of the alternatives* and are equivalent to the well-known Farkas' lemma. See, e.g., Schrijver (1986).

3. Dual of a General LO-Problem

The dual of the standard problem, as given in Section II.I.3, can be reformulated in the following way:

$$\begin{aligned} &\text{maximize} && b^T y \\ &\text{subject to} && A^T y \leq c. \end{aligned}$$

TABLE I Scheme for Dualizing

$\min c^T x$	$\max b^T y$
'=' Constraint	Free variable
'≥' Constraint	Variable ≥ 0
'≤' Constraint	Variable ≤ 0
Free Variable	'=' Constraint
Variable ≥ 0	'≤' Constraint
Variable ≤ 0	'≥' Constraint

In this way we get a 1–1 correspondence between the variables in the primal problem and the constraints in the dual problem, and vice versa. Note that the primal constraints are equality constraints and the dual variables are free (i.e., without sign constraints). On the other hand, the primal variables are nonnegative and the dual constraints are inequality constraints of '≤' type. Also note that the roles of b and c are exchanged when taking the dual, and the problem matrix A is transposed.

We can associate with each LO-problem (not necessarily in the standard from) a dual problem. To this end we first put the problem in the standard from (cf. Section II.A), and then take the dual of this problem. The dual problem obtained in this way, however, in general does not have such a nice 1–1 correspondence between variables on one side and constraints on the other side. With little extra effort it is possible to reformulate the dual such that we retain a 1–1 correspondence. In this way we get a simple and natural relation between a general LO-problem and its dual, at the same time making it quite easy to write down the dual problem of an arbitrary LO-problem. The relation is shown in Table I.

The scheme can be used both from the left to the right and from the right to the left. Thus, e.g., if the primal problem is a maiximization problem, the dual problem is a minimization problem and, e.g., a '≥'-constraint in the primal problem gives rise to a nonpositive variable in the dual problem. An obvious consequence is that we may say, in short, that the dual of the dual problem is the primal problem.

J. The Dual Simplex Method

Given any basic index set B, following the method of Section II.I we can associate with B a basic solution $\bar{x}$ of the primal problem and a basic solution $(\bar{y}, \bar{s})$ of the dual problem as done in Eqs. (2), (3), and (5). Note that if $\bar{x} \geq 0$ and $\bar{s} \geq 0$ then $\bar{x}$ and $(\bar{y}, \bar{s})$ are primal and dual feasible respectively, and due to Eq. (4), these solutions are optimal. In this section we do not assume that $\bar{x}$ is primal feasible but we assume that $(\bar{y}, \bar{s})$ is dual feasible.

A typical iteration in the dual Simplex method then goes as follows. Since $\bar{x}$ is not primal feasible we may choose

an index $\ell \in B$ such that $\bar{x}_\ell < 0$. Our aim is to replace the index $\ell \in B$ by some index $k \in B$, thus getting the new basic index set [see Eq. (13)]

$$B' := (B \cup \{k\}) \backslash \{\ell\}.$$

The new Simplex tableau will be obtained by using $T^B_{\ell k}$ as pivot. Denoting the new basic solutions as $\tilde{x}$ and $(\tilde{y}, \tilde{s})$, we then have

$$\tilde{x}_\ell = \tilde{x}_\ell - \tilde{x}_k T^B_{\ell k} = 0 \tag{17}$$

and

$$\tilde{s}_i = \bar{s}_i - \frac{T^B_{\ell i}}{T^B_{\ell k}} \bar{s}_k, \quad 1 \le i \le n. \tag{18}$$

We want to have $\tilde{x}_k > 0$. Therefore, since $\bar{x}_\ell < 0$, Eq. (17) makes it clear that we need

$$T^B_{\ell k} < 0. \tag{19}$$

We further want to maintain dual feasibility, i.e., $\tilde{s} \ge 0$. Assuming Eq. (19), it is obvious that $\tilde{s}_i \ge 0$ whenever $T^B_{\ell i} \ge 0$, because $\bar{s}_i \ge 0$ and $\bar{s}_k \ge 0$. Thus, dual feasibility is maintained if and only if k is such that

$$\bar{s}_i - \frac{T^B_{\ell i}}{T^B_{\ell k}} \bar{s}_k \ge 0$$

whenever $T^B_{\ell i} < 0$. As a consequence, we obtain

$$k = \operatorname{argmin}_i \left\{ \frac{\bar{s}_i}{-T^B_{\ell i}} : T^B_{\ell i} < 0 \right\}.$$

This is the *quotient rule* for the dual Simplex method. With the given leaving index ℓ this rule finds an entering index k such that dual feasibility of the new basic solution is guaranteed.

The above method works only if there are suitable candidates for the entering index k. What if there are no such candidates? Then we have

$$\bar{x}_\ell < 0 \text{ and } T^B_{\ell k} \ge 0, \quad \text{for all } k. \tag{20}$$

Now recall from Eq. (7) that

$$x_B = \bar{x}_B - T^B_N x_N.$$

Hence, if Eq. (20) holds then we have for the ℓ-entry of any primal feasible vector x:

$$x_\ell = \bar{x}_\ell - \sum_{k \in N} T^B_{\ell k} x_k \le \bar{x}_\ell < 0,$$

showing that the problem cannot be feasible. We conclude that if no candidate for the entering variable exists then the problem is infeasible. Note that this argument does not use the dual feasibility of the current basic solution.

Let us conclude this section by mentioning that in some natural way the dual Simplex method is completely equivalent with the (primal) Simplex method as treated earlier. The natural correspondence between the two methods follows by noting that when applying the Simplex method to solve problem (1) then this also yields the solution of the dual problem (16). Therefore, since the dual of (16) is exactly (1), when solving (16) with the primal Simplex method we also obtain the solution of (1). In fact, it can be seen that applying the dual Simplex method to (1) is essentially the same as applying the primal Simplex method to (16).

With the above observation in mind it will be no surprise that cycling of the dual Simplex method can be prevented by using the *least index rule*: whenever there is any ambiguity in the choice of ℓ or k, choose the smallest possible index among the candidate indices.

K. The Criss-Cross Method

So far, we have dealt with two variants of the Simplex method: the primal Simplex method and the dual Simplex method. The primal Simplex method generates a sequence of primal feasible basic solutions, whereas the dual Simplex method uses only dual feasible basic solutions. Feasiblility is maintained by choosing the pivoting pair (k, ℓ) in each iteration according to the primal and dual quotient rule, respectively. To start such a method, one first needs to generate a feasible basic solution, thus separating the work into two phases. In Phase I a feasible basic solution is generated; this phase requires the introduction of the artificial variables. Phase II is used to generate an optimal solution.

We discuss in this section how we can avoid artificial variables, and solve the problem in one phase. The underlying idea, due to Zionts (1969), is to neglect the feasibility issue and to aim for feasibility at both sides simultaneously.

Let us call index i *primal infeasible* if $\bar{x}_i < 0$ and otherwise *primal feasible*. Similarly, index i is *dual infeasible* if $\bar{s}_i < 0$ and otherwise *dual feasible*. Recall that any basic solution satisfies $\bar{x}_N = 0$ and $\bar{s}_B = 0$. Hence, for each index either $\bar{x}_i = 0$ or $\bar{s}_i = 0$. Therefore, it is impossible for an index i to be primal infeasible and dual infeasible at the same time. If all indices are feasible then the basic solutions are optimal, and we are done. Otherwise, we take an infeasible index i. If i is dual infeasible then, putting $k := i$ we look for an index ℓ such that $T^B_{\ell k} > 0$; if such an ℓ does not exist the problem is unbounded, or infeasible. If i is primal infeasible then, putting $\ell := i$ we look for an index k such that $T^B_{\ell k} > 0$; if such a k does not exist the problem is infeasible. If a pair (k, ℓ) has been found then we perform an iteration with this pair as pivoting pair. Hoping for the best, this process is repeated.

L. Example of Cycling

Note that this so-called *criss-cross* method differs from the primal and the dual Simplex method in many ways. Since no quotient rule is used there is much more freedom in the choice of the pivoting pair, and primal and dual iterations are used in a more or less arbitrary order. It may be clear that there is no guarantee that the process will stop. In fact, it is quite easy to find examples of cycling with this method. Below is an example of a cycle that starts with the first tableau from the example in Section II.E.

		x_1	x_2	x_3	x_4
	3	0	4	0	−3
x_1	1	1	2	0	−1
x_3	2	0	**1**	1	−1

		x_1	x_2	x_3	x_4
	−5	0	0	−4	1
x_1	−3	1	0	−2	**1**
x_2	2	0	1	1	−1

		x_1	x_2	x_3	x_4
	−2	−1	0	−2	0
x_4	−3	1	0	−2	1
x_2	−1	1	1	**−1**	0

		x_1	x_2	x_3	x_4
	0	−3	−2	0	0
x_4	−1	**−1**	−2	0	1
x_3	1	−1	−1	1	0

		x_1	x_2	x_3	x_4
	3	0	4	0	−3
x_1	1	1	2	0	−1
x_3	2	0	1	1	−1

The fifth tableau is exactly the same as the first tableau.

Cycling of the criss-cross method can be prevented by the least index rule: finiteness of the criss-cross method is then guaranteed [Terlaky (1985)].

M. The Klee-Minty Example

For $m \geq 1$ we define the polytope $\mathcal{P}_m$ in $\mathbb{R}^m$ as follows:

$$\{y: \varepsilon y_{j-1} \leq y_j \leq 1 - \varepsilon y_{j-1},\ 1 \leq j \leq m\},$$

where $y_0 = 0$ and $0 \leq \varepsilon < 0.5$. We consider the LO-problem

$$\max\{y_m : y \in \mathcal{P}_m\}.$$

Note that $y = 0$ is feasible for this problem, and one easily verifies that it is a basic solution.

If $\varepsilon = 0$ then $\mathcal{P}_m$ is the m-dimensional unit cube:

$$\{y \in \mathbb{R}^m : 0 \leq y_j \leq 1,\ 1 \leq j \leq m\},$$

which has 2^m vertices. Hence, for (small) positive values of ε we can consider $\mathcal{P}^m$ as a perturbation of the unit cube. In fact, because of $0 \leq \varepsilon < 0.5$, the polytope $\mathcal{P}_m$ has also 2^m vertices. Moreover, both the primal Simplex method and the criss-cross method, when started at $y = 0$, and with the least-index rule, pass through all these vertices. Hence, the number of iterations will be $2^m - 1$, in both cases [Roos (1990) and Zionts (1969)]. See Fig. 1, which depicts the Klee-Minty path for $m = 3$. Being optimistic, let us assume that one needs 10^{-9} seconds per iteration. Then the computational time becomes $2^m \cdot 10^{-9}$ sec. For $m = 50$ this is about 13 days, and for $m = 60$ even 36.5 years!

N. Computational Issues

Despite the exponential example of Klee and Minty, in practice the Simplex method is a very powerful method. This is due to the fact that the average-case behavior is not exponential but polynomial. On the average, taken over a wide class of representative LO-problems, the number of iterations is bounded above by a polynomial in m and n. This has been shown by Smale (1983) and Borgwardt (1982). As a rule of thumb one may state that on the average the number of iterations grows linearly with the number n of variables and the number m of constraints. Actually, this number highly depends on the choice of the pivots. Quite efficient pivot rules are used nowadays. The search for a theoretically efficient pivot rule goes on. So far, the best thing a pivot rule can have is a finiteness proof. Unfortunately, for all rules with such a proof an exponential example like that of Klee and Minty exists. The history of implementations of the Simplex method is well documented in Orchard-Hays (1990).

III. INTERIOR-POINT METHODS

For a long time the Simplex algorithm was the only practical algorithm for linear optimization. Many people tried to justify the remarkable efficiency of the method by providing a theoretical bound on the number of Simplex iterations. To date, no one has yet given a polynomial bound for general problems.

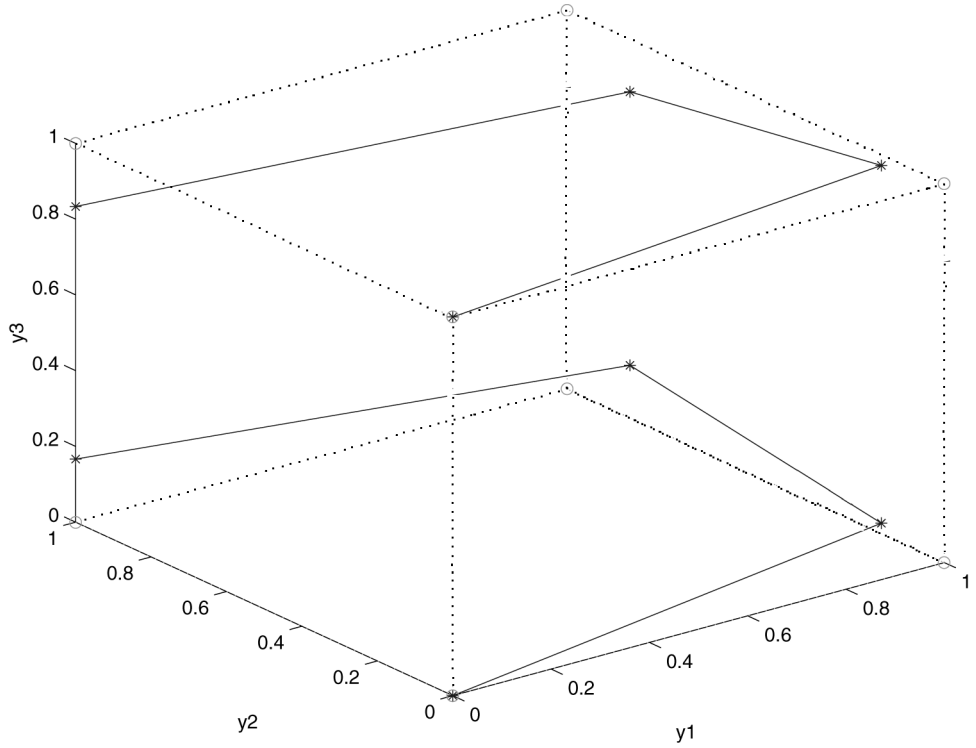

FIGURE 1 Klee-Minty path for $m = 3$.

The interest in interior-point methods for linear programming emerged from Karmarkar's contribution in 1984. He proposed a totally new method that enjoyed both polynomial complexity and practical efficiency. The field became one of the most active in the area of mathematical optimization. It introduced new ideas and techniques that now have received their own place among the basic tools in optimization. In this section we survey the theory of interior-point methods, including the analysis of their complexity.

The heart of this theory is the concept of *central path*, a continuous curve in the interior of the feasible set that converges to an optimal point. Most interior-point methods follow the central path, and can be characterized as *path-following methods*. The concept captures the basic ideas that underlie some of the most prominent interior-point methods. It provides a unified framework for a variety of existing efficient methods.

The problem we consider in this section is

$$\begin{aligned} \text{minimize} \quad & p = c^T z \\ \text{subject to} \quad & Az \geq b \\ & z \geq 0. \end{aligned} \tag{21}$$

This is the LO-problem in canonical from. The dual problem is

$$\begin{aligned} \text{minimize} \quad & d = b^T y \\ \text{subject to} \quad & A^T y \leq b \\ & y \geq 0. \end{aligned} \tag{22}$$

A. Reduction to Canonical Form

If a given LO-problem does not have the canonical form, using the method of the Section II.A the problem is first brought into the standard form (1). Choosing an arbitrary basic index set B, using the notation introduced in Section II.D, we rewrite the constraints as in Eq. (7), using also Eq. (10),

$$z_B = \bar{z}_B - T_N^B z_N, \quad z_B \geq 0, \quad z_N \geq 0,$$

and the objective function as

$$c^T z = c^T \bar{z} + \bar{s}_N^T z_N.$$

Omitting the constant term $c^T \bar{z}$ the problem gets the canonical form

$$\begin{aligned} \text{minimize} \quad & \bar{s}_N^T z_N \\ \text{subject to} \quad & -T_N^B z_N \geq -\bar{z}_B \\ & z_N \geq 0. \end{aligned}$$

B. Reduction to Feasibility Problem

By Theorem 2, if one of the two problems (21) and (22) has an optimal solution then so has the other, and then their optimal values coincide. Using also Theorem 1, this is the case if and only if the system

$$\begin{aligned} Az &\geq b, \qquad z \geq 0, \\ -A^T y &\geq -c, \quad y \geq 0, \\ b^T y - c^T z &\geq 0 \end{aligned}$$

has a solution, and any such solution provides optimal solutions for (21) and (22). With $\kappa = 1$, the above system can be rewritten as

$$\begin{pmatrix} 0 & A & -b \\ -A^T & 0 & c \\ b^T & -c^T & 0 \end{pmatrix} \begin{pmatrix} y \\ z \\ \kappa \end{pmatrix} \geq 0, \quad \begin{pmatrix} y \\ z \\ \kappa \end{pmatrix} \geq 0. \tag{23}$$

Here the zeros represent matrices (or vectors) of appropriate sizes. Note that by introducing the variable κ, the system became homogeneous: if (y, z, κ) is a solution then $\lambda(y, z, \kappa)$ is also a solution, for any positive λ. Hence, problem (23) has a solution with $\kappa = 1$ if and only if it has a solution with $\kappa > 0$. Given any solution (y, z, κ) of (23) with $\kappa > 0$, then

$$z^* = \frac{z}{\kappa}, \quad y^* = \frac{y}{\kappa}$$

are optimal solutions of (21) and (22).

Thus we may conclude that (21) and (22) have optimal solutions if and only if (23) has a solution with $\kappa > 0$. The extra variable κ is called the *homogenizing variable*. Note that problem (23) always admits the zero solution $z = 0$, $y = 0$, and $\kappa = 0$. If $\kappa = 0$ for every solution, then we may conclude that (21) and (22) have no optimal solutions, i.e., these problems are infeasible or unbounded.

C. Embedding into Self-Dual Model

To simplify notations, we use the matrix $\bar{M}$ and the vector $\bar{x}$ defined by

$$\bar{M} = \begin{pmatrix} 0 & A & -b \\ -A^T & 0 & c \\ b^T & -c^T & 0 \end{pmatrix}, \quad \bar{x} = \begin{pmatrix} y \\ z \\ \kappa \end{pmatrix}.$$

Then Eq. (23) can be written as

$$\bar{M}\bar{x} \geq 0, \quad \bar{x} \geq 0. \tag{24}$$

We need to find out whether or not this inequality system has a solution with $\kappa > 0$.

When using interior-point methods it is necessary that the IPC is satisfied. In other words, there should exist a vector $x^0 > 0$ such that $\bar{M}x^0 > 0$. The system (23) certainly does not satisfy this condition. Because if y, z, and κ solve (23) then $c^T z - b^T y = 0$, and hence the last coordinate of $M\bar{x}$ vanishes.

To circumvent this difficulty the problem is embedded into a slightly larger problem that satisfies the IPC. This goes as follows. Letting $n - 1$ denote the size of $\bar{M}$, and with e denoting the all-one vector, as usual of appropriate size, we introduce

$$r = e - \bar{M}e, \quad q = \begin{pmatrix} 0 \\ n \end{pmatrix}.$$

Now consider the system

$$\begin{pmatrix} \bar{M} & r \\ -r^T & 0 \end{pmatrix} \begin{pmatrix} \bar{x} \\ \vartheta \end{pmatrix} \geq -q, \quad \begin{pmatrix} \bar{x} \\ \vartheta \end{pmatrix} \geq 0. \tag{25}$$

Note that if $(\bar{x}, \vartheta)$ satisfies (25) and if $\vartheta = 0$, then $\bar{x}$ is a solution of (24). On the other hand, a solution $\bar{x}$ of (24) gives rise to a solution of (25) with $\vartheta = 0$ if and only if

$$r^T \bar{x} \leq n.$$

This certainly holds if $r^T \bar{x} \leq 0$; otherwise a positive multiple of $\bar{x}$ yields a solution of problem (25) with $\vartheta = 0$. We conclude that the set of solutions of (25) with $\vartheta = 0$ contains all solutions of (24), possibly up to a positive factor. The new variable ϑ is called the *lifting variable.*

We now show that the new system satisfies the IPC. In fact the all-one vector does the work. Taking $\bar{x} = e$ and $\vartheta = 1$ we get

$$\bar{M}\bar{x} + \vartheta r = \bar{M}e + r = e$$

and

$$-r^T \bar{x} = -(e - \bar{M}e)^T e = -e^T e = -n + 1,$$

where we used that $e^T \bar{M} e = 0$, since $\bar{M}$ is skew-symmetric. Hence, we obtain

$$\begin{pmatrix} \bar{M} & r \\ -r^T & 0 \end{pmatrix} \begin{pmatrix} e \\ 1 \end{pmatrix} + q = \begin{pmatrix} e \\ 1 \end{pmatrix},$$

proving the claim.

We already observed that a solution of (25) can be useful for us only if $\vartheta = 0$. How do we get such a solution? Note that, since $q \geq 0$, $\bar{x} = 0$ and $\vartheta = 0$ are feasible for problem (25). Therefore, when minimizing ϑ subject to (25) the optimal value will be equal to zero. Defining

$$M = \begin{pmatrix} \bar{M} & r \\ -r^T & 0 \end{pmatrix}, \quad x = \begin{pmatrix} \bar{x} \\ \vartheta \end{pmatrix},$$

$q^T x = n\vartheta$ vanishes if and only if $\vartheta = 0$, and thus we are interested in the optimal solutions of the problem

$$\begin{aligned} \text{minimize} \quad & q^T x \\ \text{subject to} \quad & Mx \geq -q \\ & x \geq 0. \end{aligned} \tag{26}$$

When taking the dual of this problem we get

$$\begin{aligned} \text{maximize} \quad & -q^T u \\ \text{subject to} \quad & -Mu \le q \\ & u \ge 0, \end{aligned}$$

where we used that $M^T = -M$. Since maximizing $-q^T u$ is equivalent to minimizing $q^T u$ this is exactly the same problem as (26). This is expressed by saying that problem (26) is *self-dual*.

We finally point out that the optimal set of (26) is bounded. For any feasible x let $s(x) = Mx + q$. Then

$$\begin{aligned} e^T Mx &= e^T(\bar{M}\bar{x} + \vartheta r) - r^T \bar{x} \\ &= e^T(\bar{M}\bar{x} + \vartheta r) - (e - \bar{M}e)^T \bar{x} \\ &= e^T(\bar{M}\bar{x} + \vartheta r) - e^T \bar{x} + e^T \bar{M}^T \bar{x} \\ &= \vartheta e^T r - e^T \bar{x}, \end{aligned}$$

where we used once more that $\bar{M}^T = -\bar{M}$. For the same reason we have $e^T \bar{M} e = 0$, whence $e^T r = e^T e = n - 1$. Hence,

$$e^T s(x) = \vartheta(n-1) - e^T \bar{x} + n$$

and, finally,

$$\begin{aligned} e^T x + e^T s(x) &= e^T \bar{x} + \vartheta + e^T s(x) \\ &= n(1 + \vartheta). \end{aligned}$$

Taking $\vartheta = 0$ we get

$$e^T x + e^T s(x) = n.$$

Since $x \ge 0$ and $s(x) \ge 0$, this implies that the optimal set is bounded.

D. Central Path

In the previous section we reduced the general LO-problem to the problem of solving the self-dual problem (26). This is not exactly true, however. Remember that the real issue is to find an optimal solution with a positive homogenizing variable $\kappa = x_{n-1}$, or to establish that such a solution does not exist.

Recall that the all-one vector is feasible and

$$s(e) = e, \tag{27}$$

so the IPC is satisfied. Although the M and q introduced in the previous section have a very special structure, in the analysis below we allow M to be any skew-symmetric matrix and q any nonnegative vector.

Denoting the optimal set of (26) as $\mathcal{S}$, and defining the index set B by

$$\mathcal{B} := \{i : x_i > 0 \quad \text{for some } x \in \mathcal{S}\}, \tag{28}$$

the question is whether $n - 1 \in \mathcal{B}$ or not. If the answer is yes, then any solution with positive homogenizing variable will yield optimal solutions for our original problems (21) and (22).

Since M is skew-symmetric we have for any vector u

$$u^T Mu = 0. \tag{29}$$

Hence, if x is feasible,

$$q^T x = (Mx + s(x))^T x = x^T s(x), \tag{30}$$

and x is optimal if and only if $x_i s_i(x) = 0$ for each i.

We will use a shorthand notation for the vector with coordinates $x_i s_i(x)$, namely $xs(x)$. Then the optimality conditions for problem (26) are given by

$$x \ge 0, \quad s(x) = Mx + q \ge 0, \quad xs(x) = 0. \tag{31}$$

The last condition is the *complementarity condition*.

For more appreciation of the next theorem, let us indicate that problem (31) may have multiple solutions. For example, if

$$M = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \quad q = \begin{pmatrix} 1 \\ 0 \end{pmatrix},$$

then

$$s(x) = M \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 - x_2 \\ x_1 \end{pmatrix},$$

and the solution to (31) is $x = (0, x_2)$ with $0 \le x_2 \le 1$.

Now consider the following system.

$$x \ge 0, \quad s(x) = Mx + q \ge 0, \quad xs(x) = \mu e, \tag{32}$$

where μ is any positive number.

Theorem 4 For any $\mu > 0$ the system (32) has a unique solution.

The solution of (32) is denoted as $x(\mu)$; it is called the μ-center of (26). When μ runs through all positive reals then $x(\mu)$ follows a curve in the interior of the feasible region of (26). Note that $z(\mu)/\kappa(\mu)$ and $x(\mu)/\kappa(\mu)$ are feasible solutions for the problems (21) and (22); the corresponding curves are the respective central paths of these two problems.

The central path is quite relevant for two reasons. First, observe that for any $\mu > 0$ we have

$$q^T x(\mu) = n\mu. \tag{33}$$

This is an obvious consequence of Eq. (30) and $x_i s_i(x) = \mu$ for each i. Hence, if μ approaches 0 then $q^T x(\mu)$ goes to zero, which means that $x(\mu)$ approaches the optimal set. The second reason is that not only the limit

$$x(0) := \lim_{\mu \downarrow 0} x(\mu)$$

exists but, even more importantly, that the support of $x(0)$ is the set $\mathcal{B}$. As a consequence, if we know $x(0)$, we have enough information to decide whether the homogeneous variable can be positive in the optimal set, and if this is the case we can derive from $x(0)$ optimal solutions for (21) and (22).

Path-following methods use the central path as a guide to the optimal set. Such a method starts at the point on the central path corresponding to $\mu = 1$, because the 1-center is known: due to Eq. (27) we have $x(1) = e$.

E. Conceptual Method

The parameter is μ is called *barrier parameter*. The question we have to deal with is how to obtain the μ-centers for small values of the barrier parameter.

Suppose that we know $x(\mu)$ for some $\mu > 0$, and let μ' be obtained from μ by

$$\mu' := (1 - \theta)\mu,$$

where θ is a positive constant smaller than 1. We may expect that if θ is not too large, the μ'-center will be close to the given μ-center. For the moment, let us assume that we are able to calculate the μ'-center, provided θ is not too large. Then the following conceptual algorithm can be used to find an ε-optimal solution of problem (26).

Conceptual Algorithm

Input:
An accuracy parameter $\varepsilon > 0$;
a barrier update parameter θ, $0 < \theta < 1$.
begin
$x = x(1)$; $\mu := 1$;
while $n\mu \geq \varepsilon$ **do**
begin
$\mu := (1 - \theta)\mu$;
$x := x(\mu)$;
end
end

The output of this algorithm is a feasible solution for problem (26) such that the objective value does not exceed ε. How many iterations are needed by the algorithm? The answer is provided by the following lemma.

Lemma 1 After at most

$$\left\lceil \frac{1}{\theta} \log \frac{n}{\varepsilon} \right\rceil$$

iterations we have $n\mu \leq \varepsilon$.

Proof: Initially, the objective value is n and in each iteration it is reduced by the factor $1 - \theta$. Hence, after k iterations the objective value, given by $q^T x(\mu) = n\mu$, is smaller than, or equal to ε if

$$(1 - \theta)^k n \leq \varepsilon.$$

Taking logarithms, this becomes

$$k \log(1 - \theta) + \log n \leq \log \varepsilon.$$

Since $-\log(1 - \theta) \geq \theta$, this certainly holds if

$$k\theta \geq \log n - \log \varepsilon = \log \frac{n}{\varepsilon}.$$

This implies the lemma. □

The above algorithm uses exact μ-centers. These can be obtained only by solving the nonlinear system (32). To make the algorithm more practical, we have to avoid this. This is the subject of the following sections.

F. Using Approximate Centers

Let us now assume that we have an *approximate* μ-center, i.e., a positive feasible solution x that is close to $x(\mu)$. The meaning of "close" will be made more precise later on.

We want to find a displacements Δx such that

$$x' = x + \Delta x \tag{34}$$

is the μ-center. Denoting $s' = s(x')$, and

$$s' = s + \Delta s, \tag{35}$$

neglecting the inequality constraints for the moment, this means that Δx and Δs should satisfy

$$M(x + \Delta x) + q = s + \Delta s$$

$$(x + \Delta x)(s + \Delta s) = \mu e.$$

This system can be rewritten as

$$M\Delta x = \Delta s, \tag{36}$$

$$s\Delta x + x\Delta s + \Delta x \Delta s = \mu e - xs. \tag{37}$$

The above system is nonlinear and hard to solve. Following Newton's method, we linearize the *centering condition* (37) by neglecting the quadratic term $\Delta x \Delta s$, thus obtaining the *Newton equation*

$$s\Delta x + x\Delta s = \mu e - xs. \tag{38}$$

Substitution of Eq. (36) leads to the linear equation

$$(S + XM)\,\Delta x = \mu e - xs.$$

Here $X = \mathrm{diag}(x)$ and $S = \mathrm{diag}(s)$. The coefficient matrix being nonsingular, this equation uniquely defines the *Newton direction* Δx at x to the *target* $x(\mu)$.

G. Analysis of the Newton Step

Using the notation of Eqs. (34) and (35) we may write

$$\begin{aligned} x's' &= (x+\Delta x)(s+\Delta s) \\ &= xs + (s\Delta x + x\Delta s) + \Delta x \Delta s. \end{aligned}$$

Due to the Newton equation (38) this implies

$$x's' = \mu e + \Delta x \Delta s. \tag{39}$$

Since M is skew-symmetric,

$$(\Delta x)^T \Delta s = (\Delta x)^T M \Delta x = 0,$$

proving that Δx and Δs are orthogonal. Hence, using Eq. (39)

$$q^T x' = e^T(x's') = e^T(\mu e + \Delta x \Delta s) = n\mu.$$

Thus we have shown that after the Newton step, the objective value has the value at the target $x(\mu)$.

But what about x'? We may not expect that x' coincides with $x(\mu)$, due to the "error term" $\Delta x \Delta s$ in Eq. (39). But hopefully, x' is closer to $x(\mu)$ then x. For dealing with this we need a quantity to measure proximity to $x(\mu)$. For this purpose we introduce the quantity $\delta(x, \mu)$ defined by

$$\delta(x,\mu) = \frac{1}{2}\left\| \sqrt{\frac{xs}{\mu}} - \sqrt{\frac{\mu e}{xs}} \right\|.$$

The notation, although not quite common, explains itself: all operations are meant to be coordinatewise. Note that

$$x = x(\mu) \Leftrightarrow \frac{xs}{\mu} = e \Leftrightarrow \frac{\mu e}{xs} = e.$$

Hence, if $x = x(\mu)$ then $\delta(x,\mu) = 0$ and $\delta(x,\mu) > 0$ otherwise. One may prove the following.

Theorem 5 If $\delta := \delta(x,\mu) \le 1$, then the Newton step is feasible, i.e., x' and s' are nonnegative. Moreover, if $\delta < 1$, then x' and s' are positive and

$$\delta(x', \mu) \le \frac{\delta^2}{\sqrt{2(1-\delta^2)}}.$$

This remarkable result shows not only that the Newton step is feasible if x is close enough (i.e., $\delta < 1$) to the μ-center, but also that the Newton process is quadratically convergent. Especially,

$$\delta(x,\mu) \le \frac{1}{\sqrt{2}} \Rightarrow \delta(x',\mu) \le \delta(x,\mu)^2.$$

It is now clear that with Newton's method we can obtain good approximations of the μ-center in a very efficient way.

H. Approximate Center Method

We modify the conceptual algorithm in Section III.E slightly, by replacing the statement $x := x(\mu)$ with $x := x + \Delta x$.

Approximate Center Algorithm

Input:
An accuracy parameter $\varepsilon > 0$;
a barrier update parameter θ, $0 < \theta < 1$.
begin
$x = x(1)$; $\mu := 1$;
while $n\mu \ge \varepsilon$ **do**
begin
$\mu := (1-\theta)\mu$;
$x := x + \Delta s$;
end
end

In the next section we discuss how an appropriate value of the parameter θ can be obtained, so that during the course of the algorithm the iterates are always close enough to the current μ-center to guarantee that Newton's method is quadratically convergent.

I. Complexity Analysis

At the start of the algorithm we have $\mu = 1$ and $x = x(1)$, whence $q^T x = n$ and $\delta(x,\mu) = 0$. In each iteration μ is first reduced with the factor $1-\theta$ and then the Newton step is made to the new μ-center. It will be clear that the reduction of μ has effect on the value of the proximity measure. This effect is fully described by the following lemma.

Lemma 2 Let $x > 0$ and $\mu > 0$ be such that $s = s(x) > 0$ and $q^T x = n\mu$. Moreover, let $\delta := \delta(x,\mu)$ and $\mu' = (1-\theta)\mu$. Then

$$\delta(x,\mu')^2 = (1-\theta)\delta^2 + \frac{\theta^2 n}{4(1-\theta)}.$$

Now let us have

$$q^T x = n\mu \quad \text{and} \quad \delta(x,\mu) \le \frac{1}{2} \tag{40}$$

at the start of some iteration. It certainly holds in the first iteration. We claim that these properties are maintained during the course of the algorithm if $\theta = 1/(2\sqrt{n})$.

When the barrier parameter is updated to $\mu' = (1-\theta)\mu$, the lemma gives

$$\delta(x,\mu')^2 \le \frac{1-\theta}{4} + \frac{\theta^2 n}{4(1-\theta)}.$$

Due to the choice of θ, we get

$$\delta(x,\mu')^2 < \frac{1}{4} + \frac{1}{16(1-\theta)} \le \frac{1}{4} + \frac{1}{8} < \frac{1}{2}.$$

Therefore, after the Newton step $\delta(x',\mu') \le 1/2$. Also, $q^T x' = n\mu'$. This proves the claim.

Thus we have shown that the following theorem holds.

Theorem 6 If $\theta = 1/(2\sqrt{n})$ then the algorithm with full Newton steps requires at most

$$\left\lceil 2\sqrt{n}\,\log\frac{n}{\varepsilon}\right\rceil$$

iterations. The output is a feasible $x > 0$ such that $q^T x = n\mu \le \varepsilon$ and $\delta(x,\mu) \le \frac{1}{2}$.

This theorem shows that we can get an ε-solution x of our self-dual model with ε as small as desirable. But note that x will always be an interior solution, so $x > 0$ and $s = s(x) > 0$.

A crucial question is whether the variable $\kappa = x_{n-1}$ is positive or zero in the limit, when μ goes to zero. In practice, for small enough ε it is usually no serious problem to decide which of the two cases occurs. But the theory can help us in an elegant way, as we explain in the next section. This requires some further analysis of the central path.

Before proceeding, we want to agree upon the following. This section has made clear that the conceptual algorithm of Section III.E can be turned into a practical algorithm; the iterates are no longer on the central path but move in a narrow neighborhood around the central path.

In the next sections we will assume that the iterates are on the central path, because this simplifies the analysis significantly. At the cost of some additional technicalities in the analysis we can obtain similar results for the iterates of the practical algorithm. For the technical details the reader is referred to Roos *et al.* (1997).

J. Finding the Optimal Partition

If $x \in \mathcal{S}$, $\mathcal{S}$ being the set of optimal solutions, then

$$xs(x) = 0, \quad x + s(x) \ge 0.$$

The equality represents the *complementarity property* of optimal solutions. If the inequality is strict, we say that x is a *strictly complementary solution*. Recall from Section III.D that the support of the limit point $x(0)$ of the central path is the set $\mathcal{B}$, defined by Eq. (28). Let $\mathcal{N}$ denote the complementary set. Then another property of the central path is that the support of $s(0) := s(x(0))$ is $\mathcal{N}$. As a consequence, $x(0)$ is a strictly complementary solution:

$$x(0)s(0) = 0, \quad x(0) + s(0) > 0.$$

In fact, this property can be used to prove Theorem 3 in Section II.I.2. Another consequence is that

$$\mathcal{N} := \{i : s_i > 0 \quad \text{for some } x \in \mathcal{S}\}. \tag{41}$$

The partition of the index set $\{1,\ldots,n\}$ into the classes $\mathcal{B}$ and $\mathcal{N}$ is called the *optimal partition* of (26).

We define the *condition number* of (26) by

$$\sigma := \min_i \max_{x\in\mathcal{S}} (x_i + s_i(x)).$$

The calculation of this (positive!) number is even more cumbersome than solving Eq. (26). For our purpose, however, it is sufficient to know the following lower bound

$$\sigma \ge \frac{1}{\prod_{j=1}^n \|M_j\|}, \tag{42}$$

where M_j denotes the jth column of M. For this bound we need to make the assumption that the entries of M and q are integral. In the sequel, in all the bounds where the condition number occurs, it can be safely replaced by this easily computable lower bound.

Lemma 3 For any positive μ one has

$$x_i(\mu) \ge \frac{\sigma}{n}, \quad i \in \mathcal{B},$$

$$x_i(\mu) \le \frac{n\mu}{\sigma}, \quad i \in \mathcal{N}.$$

Proof: Let $i \in \mathcal{N}$ and $\tilde{x} \in \mathcal{S}$ be such that $\tilde{s}_i := s_i(\tilde{x})$ is maximal. Then the definition of the condition number σ implies that $\tilde{s}_i \ge \sigma$. Using the skew-symmetry of M one easily sees that

$$(x(\mu) - \tilde{x})^T (s(\mu) - \tilde{s}) = 0.$$

Since $q^T\tilde{x} = \tilde{x}^T\tilde{s} = 0$, it follows that

$$x(\mu)^T\tilde{s} + s(\mu)^T\tilde{x} = n\mu.$$

This implies

$$x_i(\mu)\tilde{s}_i \le x(\mu)^T\tilde{s} \le n\mu.$$

Dividing by $\tilde{s}_i$ and using that $\tilde{s}_i \ge \sigma$ we obtain the second inequality of the lemma:

$$x_i(\mu) \le \frac{n\mu}{\tilde{s}_i} \le \frac{n\mu}{\sigma}.$$

The first inequality can be derived in a similar way. □

Lemma 3 gives a complete separation between variables in $\mathcal{B}$ and variables in $\mathcal{N}$, provided that μ is so small that

$$\frac{\sigma}{n} > \frac{n\mu}{\sigma}.$$

or, equivalently,

$$n\mu < \frac{\sigma^2}{n}.$$

Thus, applying the algorithm with

$$\varepsilon = \frac{\sigma^2}{n},$$

we obtain a solution x which reveals the optimal partition according to

$$\mathcal{B} = \{i : x_i > s_i(x)\}$$
$$\mathcal{N} = \{i : x_i < s_i(x)\}.$$

By substitution of the above value of ε in Theorem 6 the required number of iterations follows:

$$\left\lceil 2\sqrt{n}\,\log\frac{n^2}{\sigma^2}\right\rceil.$$

After this number of iterations we know if κ belongs to $\mathcal{B}$ or not. In other words, we then know whether the original problem has an optimal solution or not. In the last case we are done, otherwise we are usually interested in finding a solution. If we are interested in an ε-solution we can proceed with the algorithm until such a solution is obtained. An alternative approach may be to use the rounding procedure described in the next section, which yields an exact solution.

K. Rounding to an Exact Solution

Knowing the optimal partition, we aim for finding a strictly complementary solution of Eq. (26).

In one case this is very easy. If it happens that the set $\mathcal{B}$ in the optimal partition is empty then $x(0) = 0$ is a strictly complementary solution and we are done. Note that in that case $s(x(0))$ must be positive. Since $s(x(0)) = q$, this case can easily be seen to occur if and only if $q > 0$.

Therefore, we assume from now on that the class $\mathcal{B}$ is not empty. Assuming this we describe a rounding procedure that can be applied to any x generated by the algorithm to yield a vector $\bar{x}$ such that $\bar{x}$ and its surplus vector $\bar{s} = s(\bar{x})$ are complementary (in the sense that $\bar{x}_N = \bar{s}_B = 0$). In general, however, these $\bar{x}$ and $\bar{s}$ are not necessarily nonnegative. But, as we will see, after sufficient additional iterations of the algorithm the separation between the "small" and the "large" variables is strong enough to get a strictly complementary solution. All of this can be done in polynomial time.

Partitioning the matrix M and the vectors x and s according to the optimal partition, the relation $s = Mx + q$ can be rewritten as

$$\begin{pmatrix} s_{\mathcal{B}} \\ s_{\mathcal{N}} \end{pmatrix} = \begin{pmatrix} M_{\mathcal{BB}} & M_{\mathcal{BN}} \\ M_{\mathcal{NB}} & M_{\mathcal{NN}} \end{pmatrix} \begin{pmatrix} x_{\mathcal{B}} \\ x_{\mathcal{N}} \end{pmatrix} + \begin{pmatrix} q_{\mathcal{B}} \\ q_{\mathcal{N}} \end{pmatrix}.$$

Since $q_{\mathcal{B}}^T x_{\mathcal{B}}(0) = 0$ and $x_B(0) > 0$, it follows that $q_B = 0$. Hence, we have

$$s_{\mathcal{B}} = M_{\mathcal{BB}} x_{\mathcal{B}} + M_{\mathcal{BN}} x_{\mathcal{N}}.$$

Consider the system of equations in the unknown vector ξ given by

$$M_{BB}\xi = s_B - M_{BN} x_N. \tag{43}$$

Note that $\xi = x_{\mathcal{B}}$ is a "large" solution of (43), because the entries of x_B are "large" variables. We can easily see that Eq. (43) has more solutions. This follows by using any optimal solution $\tilde{x}$ with $\tilde{x}_{\mathcal{B}} \neq 0$. One has $\tilde{x}_{\mathcal{N}} = 0$ and $s_{\mathcal{B}}(\tilde{x}) = 0$, whence $M_{\mathcal{BB}}\tilde{x}_{\mathcal{B}} = 0$. Since $x_{\mathcal{B}}(0) \neq 0$, it follows that the matrix $M_{\mathcal{BB}}$ must be singular, and hence Eq. (43) has multiple solutions.

Now let ξ be any solution of Eq. (43) and consider the vector $\bar{x}$ defined by

$$\bar{x}_{\mathcal{B}} = x_B - \xi, \quad \bar{x}_{\mathcal{N}} = 0.$$

Define $\bar{s} = s(\bar{x})$. Since $\bar{x}_{\mathcal{N}} = 0$, we have

$$\bar{s}_{\mathcal{B}} = M_{\mathcal{BB}}\bar{x}_{\mathcal{B}} = M_{\mathcal{BB}}(x_{\mathcal{B}} - \xi) = 0.$$

Therefore, $\bar{x}_N = \bar{s}_B = 0$, showing that the vectors $\bar{x}$ and $\bar{s}$ are complementary. It will be clear, however, that the vectors $\bar{x}$ and $\bar{s}$ are not necessarily nonnegative, let alone strictly complementary. This only holds if

$$\bar{x}_B = x_B - \xi > 0, \tag{44}$$

and

$$\begin{aligned} \bar{s}_N &= M_{NB}\bar{x}_B + M_{NN}\bar{x}_N + q_N \\ &= M_{NB}(x_B - \xi) + q_N \\ &= s_N - M_{NN}x_N - M_{NB}\xi > 0. \end{aligned} \tag{45}$$

Note that if we run the algorithm long enough, $x_{\mathcal{B}}$ and $s_{\mathcal{N}}$ converge to positive vectors, whereas $x_{\mathcal{N}}$ and $s_{\mathcal{B}}$ (and hence also ξ) converge to zero. This makes it plausible that if we take ε small enough in the algorithm, then we will get a solution ξ of (43) that satisfies (44) and (45), hence giving rise to a strictly complementary solution of Eq. (43).

Omitting further details, we conclude this section by stating the main complexity result for interior-point results: when solving Eq. (43) by Gaussian elimination, an exact solution of Eq. (26) can be found after at most $7\sqrt{nL}$ iterations, where L denotes the binary size of the problem.

L. Other Interior-Point Methods

In the preceding sections we have shown that the LO-problem can be solved in polynomial time. If the problem is infeasible or unbounded then this is detected by the method, otherwise it generates an exact solution. When executed, the number of iterations will be about the same as predicted by the theory. In practice this means that the method is much slower than the Simplex method. There are several ways to make the method more efficient and

competitive to the Simplex method. We briefly discuss some of them.

1. Adaptive-Update Methods

The method we considered generates iterations in a narrow neighborhood of the central path, since at the start of each iterations we have $\delta(x,\mu) \le \frac{1}{2}$. In the theoretical analysis this property is maintained by taking small updates of the barrier barrier parameter ($\theta = 1/(2\sqrt{n})$. In practice, Newton's method behaves much better than predicted by Theorem 5. As a consequence, $\delta(x,\mu)$ will usually be much smaller than $\frac{1}{2}$. It means that we can take larger values of θ without loosing the above property. The adaptive-update method seeks to take θ as large as possible such that at the start of the next iteration we still have $\delta(x,\mu) \le \frac{1}{2}$. This strategy accelerates the method significantly and does not deteriorate the theoretical iteration bound.

2. Large-Update Methods

A popular strategy is to use larger values of θ, say $\theta = 0.5$, or even $\theta = 0.99$. In this case, after the barrier update, $\delta(x,\mu)$ will be much larger than 1, and Theorem 5 can be no longer used to measure progress. Even worse, the (full) Newton step will be no longer feasible. The remedy is to take a *damped* Newton step $x' = x + \alpha\Delta x$, with damping factor α; this factor can be chosen such that x' is feasible and at the same time the proximity decreases sufficiently to get a provable polynomial method. In practice this approach yields very efficient methods.

3. Predictor-Corrector Method

This is the most popular method. We describe a simple variant. It is based on a very greedy strategy that uses the Newton step targeting at the zero vector. So, in the definition of the Newton step one takes $\mu = 0$. The resulting direction is called the *affine scaling* direction. To stay feasible, this step is damped again, but with a greedy damping factor. As a result, after such a step we may end up far from the central path. To restore the proximity, a so-called *centering step* is taken. This is a (damped) Newton step with $\mu = q^T x/n$, where x is the current iterate. This method has not only turned out to be extremely efficient, but also has the nice property that asymptotically the objective value converges quadratically to zero.

4. Infeasible-Start Methods

To start an interior-point method one needs an interior solution of the problem at hand. Usually such a solution is not available, and then the method cannot even be started. The embedding technique, as described in Section III.C, elegantly resolves this initialization problem, at the cost of two additional variables, the homogenizing variable κ and the lifting variable ϑ. There exist other solutions to the initialization problem, leading to the so-called *infeasible-start methods*. We briefly discuss such a method for the standard form (1) and its dual (16). The centering condition for this pair of problems is simply $xs = \mu e$.

Infeasible-start methods take any two positive n-vectors x and s and an arbitrary m-vector y. These vectors may be not feasible. Defining the primal and dual residuals by

$$r_p(x) = Ax - b, \quad r_d(y,s) = A^T y + s - c,$$

respectively, the Newton-like search directions are defined by the system

$$\begin{aligned} A\Delta x &= -r_p(x) \\ A^T\Delta y + \Delta s &= -r_d(y,s) \\ x\Delta s + s\Delta x &= \mu e - xs. \end{aligned}$$

The steps are damped to keep the iterates sufficiently bounded away from zero. When starting with $y = 0$ and $x = s = \zeta e$ for some suitable ζ, under a mild condition on ζ it can be shown that within $O(n^2|\log\varepsilon|)$ iterations an ε-solution can be found [Wright (1996)]. The generated solutions are not feasible, in general, but the norms of their residuals are bounded in terms of ε.

IV. RELATED TOPICS

A. Integer Programming

Suppose we have a linear maximization problem with feasible region $\mathcal{P}$:

$$\max\{c^T x : x \in \mathcal{P}\}, \tag{46}$$

and one or more of the variables are required to be integral. In many situations it is natural to impose such a condition on the variable, for example if a variable represents a number of vehicles in the model. If all variables need to be integral the problem is called a *pure integer problem*, otherwise a *mixed integer problem*. In the next sections we restrict the discussion to pure integer problems, the generalization to mixed integer problems is straightforward.

1. Branch-and-Bound Methods

This method is an intelligent way of searching for integral solutions in $\mathcal{P}$ with an objective value that is better than the current lower bound, which is initially put to $-\infty$.

Let $\bar{x}$ be an optimal solution of Eq. (46). Suppose that $\bar{x}_i$ is fractional. Let $\mathcal{P}_1$ be the region obtained by adding the

constraint $x_i \le \lfloor \bar{x}_i \rfloor$ to $\mathcal{P}$ and let $\mathcal{P}_2$ be the region obtained by adding the constraint $x_i \ge \lfloor \bar{x}_i \rfloor + 1$ to $\mathcal{P}$. Here, $\lfloor \bar{x}_i \rfloor$ denotes the integral part of $\bar{x}_i$. Then it will be clear that the integral solution to Eq. (46) is the best of the integral solutions of the two *subproblems*

$$\max\{c^T x : x \in \mathcal{P}_i\}, \quad i = 1, 2.$$

These subproblems can be solved in a similar way: solve the LO-relaxation and if necessary *branch* to two new subproblems.

In this way a binary search tree of subproblems is generated. In principle all subproblems in the generated tree need to be solved. When a subproblem happens to have an integral solution its objective value is a lower bound for the objective value of the original problem, and such a subproblem needs no further branching; if its objective value is higher than the current lower bound we refresh the lower bound. Also, if a subproblem is infeasible no further branching is needed. All subproblems for which the optimal value of the LO-relaxation does not exceed the current lower bound can be considered as *fathomed*. If all subproblems in the tree are solved or fathomed, then there are two possibilities: the lower bound is $-\infty$ or it is a finite value. In the first case no integer solution has been found and hence the original problem has no integer solution. In the second case the subproblem that gave rise to the current lower bound provides the best integer solution.

2. Cutting-Plane Methods

If the solution $\bar{x}$ of the problem (46) is not integral, we call an inequality $a^T x \le \beta$ a *cutting plane* of (46) if $a^T \bar{x} > \beta$ whereas all integer vectors in $\mathcal{P}$ satisfy $a^T x \le \beta$. A cutting-plane method adds one or more cutting planes to the problem and then solves the resulting LO-problem. The process is repeated until an integer solution is found or a problem arises that is infeasible.

When applying the Simplex method, there is a nice systematic way to generate cutting planes from optimal tableaus, originally proposed by Gomory. These cutting planes are added to the tableau, and then the tableau is re-optimized. If necessary, the new optimal tableau is used to generate new Gomory-cuts, etc. The process converges to an integer solution, if it exists. Unfortunately, for interior-point methods the situation is not as good. No satisfactory systematic methods exist at present that produce an exact integral solution, although some promising work has been done by Mitchell and Borchers for some specific problems. Part of the problem is due to the fact that at present interior-point methods do not allow fast re-optimizing.

3. Branch-and-Cut Methods

Successful solution of integer LO-problems requires a clever combination of many different ideas. Branch-and-cut methods combine branch-and-bound and cutting-plane methods. The cutting-planes are generated throughout the branch-and-bound tree. The underlying idea is to work on getting as tight as possible bounds in each node of the tree and thus reducing the number of nodes in the search tree. Of course, there is an obvious trade-off. If many cuts are added at a node, re-optimization may slow down. In addition, keeping all the information in the tree is more difficult. On the other hand, the size of the search tree may be reduced significantly. For more details the reader is referred to Wolsey (1998).

B. Sensitivity Analysis

In practice it is often quite important to know how sensitive the optimal value is to perturbations of the data in the problem. We restrict ourselves to perturbations in the objective vector c. For perturbations in the right-hand side vector b one may consider the dual problem, which has b as objective vector, and similar results will follow.

Assuming that the given LO-problem is a minimization problem, let us consider the case where one of the coefficients of c, c_j say, is varied. It can easily be seen that the objective value is a convex and piecewise linear function of c_j. The derivative of the optimal-value function at c_j is called its *shadow price* and the linearity interval to which c_j belongs, its *range*. If c_j is a break point of the optimal value function, we need to distinguish between a left- and a right shadow price, and then the range of c_j is just a singleton.

A crucial result in this respect is that the break points are precisely the points where the optimal partition of the problem changes. If the current optimal partition is known, the range and the shadow price(s) of c_j can be obtained as follows. Assuming that the LO-problem is in standard form, the range of c_j is obtained by minimizing and maximizing c_j over the set

$$\{c_j : A^T y + s = c,\ s_{\mathcal{B}} = 0,\ s_{\mathcal{N}} \ge 0\},$$

and the shadow price(s) follow(s) by minimizing and maximizing x_j over the set

$$\{x_j : Ax = b,\ x_{\mathcal{B}} \ge 0,\ x_{\mathcal{N}} = 0\}.$$

The classical approach, as treated in all textbooks, instead of using the optimal partition in the above formulas, uses the partition formed by the classes B of basic and N of nonbasic variables for some optimal basic solution; this usually gives rise to ambiguous information [Jansen *et al.* (1997) and Roos *et al.* (1997)].

V. FURTHER EXTENSIONS

It should be noted that many phenomena in this world cannot be described adequately by a linear model, but require a nonlinear model. The solution of such models goes beyond the scope of this chapter. Some remarks are in order, however.

Inspired by the success of the interior-point approach to LO, Nesterov and Nemirovski recognized that the underlying ideas can be extended to a wide class of nonlinear optimization problems, the so-called *convex cone optimization problems*. Such problems have the form

$$\min\{c^T x : Ax = b,\ x \in \mathcal{K}\}, \tag{47}$$

where $\mathcal{K}$ denotes a *convex cone*. If $\mathcal{K} = \mathbb{R}^n_t$, the nonnegative orthant, this is exactly the standard LO-problem. The above authors showed that the interior-point approach also applies to problems of this type for different cones. Note that Eq. (47) looks like a linear problem, but one should realize that the cone $\mathcal{K}$ can hide a lot of nonlinearity. One striking example occurs when $\mathcal{K}$ is the cone of positive semidefinite matrices. For example, the nonlinear constraint $uv \geq 1$, with $u \geq 0$ and $v > 0$, can be modeled as

$$\begin{pmatrix} u & 1 \\ 1 & v \end{pmatrix} \text{ is positive semidefinite.}$$

As a consequence, the field of *semidefinite optimization* at present receives much attention. It has important applications in system theory [Boyd *et al*. (1994)] and in combinatorial optimization. Many combinatorial optimization problems admit a natural relaxation to a semidefinite optimization problem. Using this, Goemans and Williamson could generate approximate solutions of a famous and hard combinatorial problem (finding a maximal cut in a graph), not more than 13% from optimal.

It is generally believed that Karmarkar revealed only the tip of an iceberg; there is still a big mass to be explored.

Loop Groups

Andrew Pressley
King's College, London

GLOSSARY

Central extension A central extension of a group G by an Abelian group A is a group $\tilde{G}$ that has A as a central subgroup such that the quotient group $\tilde{G}/A$ is isomorphic to G.

Deformation retract A space X is a deformation retract of a space Y if the identity map $Y \to Y$ can be deformed through continuous maps to a map $Y \to X$.

Lie group A group that is also a smooth manifold such that the group operations are smooth.

Maximal torus A maximal connected Abelian subgroup of a compact Lie group.

Symplectic manifold A smooth manifold equipped with a closed 2-form that is nondegenerate at each point.

LOOP GROUPS are groups of maps from the circle into a finite-dimensional Lie group, usually assumed to be compact. They arise in many areas of mathematics and physics, such as the theory of integrable systems, singularity theory, and two-dimensional quantum field theory. The geometry and representation theory of loop groups is closely analogous to that of compact Lie groups. The central extensions of the Lie algebras of loop groups are the simplest infinite-dimensional examples of Kac–Moody algebras. (Throughout this article, G will denote a compact Lie group.)

I. BASIC PROPERTIES OF LOOP GROUPS

A. Definitions

A loop group LG is the group of maps from the circle S^1 into a Lie group G. Except where stated otherwise, the maps will be assumed to be smooth, that is, infinitely differentiable, and the group G to be compact. The group operation in LG is given by pointwise multiplication. When provided with the C^∞-topology, LG can be given the structure of an infinite-dimensional Lie group, modeled on the space $L\mathfrak{g}$ of smooth maps from S^1 into the Lie algebra $\mathfrak{g}$ of G. The model space $L\mathfrak{g}$ is a Lie algebra, again under pointwise operations, and is the Lie algebra of LG. It is called a loop algebra. There is an exponential map $L\mathfrak{g} \to LG$ induced from that of G; unlike the exponential map of G itself, that of LG is not surjective, although its image is dense in LG.

One of the many properties of loop groups that does not hold for infinite-dimensional Lie groups in general is the existence of a complexification. This is simply the group $LG_{\mathbb{C}}$ of smooth loops in the complexification $G_{\mathbb{C}}$ of G itself. Its Lie algebra is the complexification of $L\mathfrak{g}$.

B. Twisted Loop Groups

Geometrically, it LG can be thought of as the space of smooth sections of the trivial principal G-bundle on S^1. More generally, if α is any automorphism of G, one can form a G-bundle on S^1 by taking the quotient of $G \times \mathbb{R}$ by the equivalence relation that identifies (x, t) with $(\alpha(x), t + 2\pi)$ for all $x \in G$. The cross sections of this bundle form a group $L_\alpha G$ called a twisted loop group. It is clear that $L_\alpha G$ depends only on the class of α modulo inner automorphisms of G, and hence may be assumed to be of finite order if G is semi-simple. Since all G-bundles on S^1 are trivial if G is connected, any twisted loop group is isomorphic to an untwisted loop group as an abstract group. However, there are good reasons for treating them separately.

Twisted loop groups arise naturally in the study of maximal Abelian subgroups of LG. If T is a maximal torus in G, then LT is obviously a maximal Abelian subgroup of LG. More generally, if τ is any smooth loop in the space of maximal tori of G there is a maximal Abelian subgroup consisting of the loops f such that $f(\theta) \in \tau(\theta)$ for all θ. Up to isomorphism, it depends only on the free homotopy class of τ. The space of maximal tori is $G/N(T)$, where $N(T)$ is the normalizer of T in G. Its fundamental group is the Weyl group $W = N(T)/T$ of G. Hence, there is a maximal Abelian subgroup associated to every conjugacy class in W. The group associated to $w \in W$ is the twisted loop group of T associated to the automorphism of T induced by conjugation with a representative of w in $N(T)$.

C. Automorphisms

One of the most important properties of loop groups is the existence of the one-parameter group of automorphisms R_ϕ of LG that rotates a loop f rigidly through an angle ϕ:

$$R_\phi(f)(\theta) = f(\theta + \phi)$$

More generally, the group $\mathrm{Diff}(S^1)$ of all smooth differomorphisms of the circle acts as a group of automorphisms of LG. There are also the loops in the group of automorphisms of G itself.

Theorem 1. If G is simple, every automorphism of LG, even as an abstract group, is a product of these two types.

D. Polynomial Loops

Apart from the smooth loops, it is often convenient to consider other classes of loops. One of the most important is the Laurent polynomial loops; these have finite expansions

$$f(z) = \sum_{k=N}^{N} A_k z^k$$

The polynomial loops form a subgroup $L_{\mathrm{pol}}G$ of LG, but $L_{\mathrm{pol}}G$ is not a Lie group in any reasonable sense. However, it is a good approximation to LG in at least two ways:

Theorem 2. If G is any compact group, $L_{\mathrm{pol}}G$ is a deformation retract of LG. If G is also semi-simple, $L_{\mathrm{pol}}G$ is dense in LG in the C'-topology.

E. Central Extensions

Throughout this section G will be assumed to be simply-connected. A central extension of the loop algebra $L\mathfrak{g}$ by the one-dimensional Lie algebra $\mathbb{R}$ is a Lie algebra $\tilde{L}\mathfrak{g}$ that fits into a short exact sequence of the form

$$0 \to \mathbb{R} \to \tilde{L}\mathfrak{g} \to L\mathfrak{g} \to 0$$

with $\mathbb{R}$ lying in the center of $\tilde{L}\mathfrak{g}$. Every such extension is isomorphic to one corresponding to the cocycle

$$\omega(\xi, \eta) = \frac{1}{2\pi} \int_{S^1} \langle \xi, d\eta \rangle,$$

where $\langle , \rangle$ is an invariant inner product on $\mathfrak{g}$ and $\xi, \eta \in \mathfrak{g}$. This extension is the vector space $L\mathfrak{g} \oplus \mathbb{C}$ with the bracket

$$[(\xi, \lambda), (\eta, \mu)] = ([\xi, \mu], \omega(\xi, \mu))$$

Note that this cocycle is obviously invariant under the action of the group $\mathrm{Diff}^+(S^1)$ of orientation-preserving diffeomorphisms of S^1. The cocycle ω extends to a left invariant closed 2-form on LG and thus defines a cohomology class in $H^2(LG, \mathbb{R})$.

A central extension of LG by the circle group S^1 is defined in an analogous way. Such an extension gives rise by differentiation to a central extension of $L\mathfrak{g}$. The converse question is answered by the following result.

Theorem 3.

(a) There is a central extension of LG by S^1 with Lie algebra cocycle ω if and only if $\omega/2\pi$ is an integral cohomology class. In this case, the central extension $\tilde{L}\mathfrak{g}$ is unique up to isomorphism, and $\mathit{Diff}^+(S^1)$ acts on it as a group of automorphisms.
(b) If no nonzero multiple of ω is integral, $\tilde{L}\mathfrak{g}$ is not the Lie algebra of any Lie group.
(c) The class of $\omega/2\pi$ is integral if and only if $\langle \check{\alpha}, \check{\alpha} \rangle \in \mathbb{Z}$ for all coroots $\check{\alpha}$ of $\mathfrak{g}$.

(d) If G is simple, the extension of $L\mathfrak{g}$ defined by any nonzero cocycle ω of the above form is universal, in the sense that every central extension of $L\mathfrak{g}$ by any Abelian Lie algebra A arises from it via a homomorphism $A \to \mathbb{R}$.

For the definition of coroots, see the next subsection.

F. Affine Lie Algebras

The complexified central extensions $\tilde{L}\mathfrak{g}_{\mathbb{C}}$ become, after taking the semi-direct product with the one-dimensional algebra generated by the derivation $d = zd/dz$, examples of Kac–Moody algebras, and in this context they are referred to as affine Lie algebras. One can describe analogs of all the usual notions associated to finite-dimensional semi-simple Lie algebras.

Recall the decomposition

$$\mathfrak{g}_{\mathbb{C}} = \mathfrak{t}_{\mathbb{C}} \oplus \bigoplus_{\alpha} \mathfrak{g}_{\alpha}$$

where $\mathfrak{g}_{\alpha}$ is the subspace of $\mathfrak{g}$ on which the maximal torus T acts (by conjugation) via the homomorphism $\alpha : T \to S^1$. The homomorphisms that occur are called the roots of $\mathfrak{g}$. Roots are often identified with their derivatives at the identity, which are elements of the dual space $\mathfrak{t}^*$ of $\mathfrak{t}$. The element $\check{\alpha} \in [\mathfrak{g}_{\alpha}, \mathfrak{g}_{-\alpha}]$ such that $\alpha(\check{\alpha}) = 2$ is called the coroot associated to the root α.

To formulate the corresponding definitions for loop groups, consider the semi-direct product $LG \tilde{\times} S^1$, where S^1 acts on LG by rotating loops. Then $T \times S^1$ is a maximal Abelian subgroup of $LG \tilde{\times} S^1$ (T is identified with the constant loop whose image lies in T). The Weyl group of LG is thus $W_{\text{aff}} = N(T \times S^1)/(T \times S^1)$. It is called the affine Weyl group, and is isomorphic to the semi-direct product $\check{T} \tilde{\times} \mathbb{Z}$, where $\check{T}$ is the lattice of homomorphisms $S^1 \to T$.

One has the following decomposition of the complexified Lie algebra of $LG \tilde{\times} S^1$:

$$L\mathfrak{g}_{\mathbb{C}} \oplus \mathbb{C} = (\mathfrak{t}_{\mathbb{C}} \oplus \mathbb{C}) \oplus \bigoplus_{k \neq 0} \mathfrak{t}_{\mathbb{C}} z^k \oplus \bigoplus_{(\alpha,k)} \mathfrak{g}_{\alpha} z^k$$

The pairs (α, k) that occur, including those corresponding to the second summand where $\alpha = 0$, are called the roots of LG. The pair (α, k) is regarded as the homomorphism $T \times S^1 \to S^1$ given by $(t, z) \to \alpha(t) z^k$. As in the finite-dimensional case, a subset of the roots is called a simple system if every root can be written as a linear combination of the simple roots, the coefficients being integers all of which have the same sign. A root is called positive if all the coefficients are positive.

The affine Weyl group acts on the Lie algebra of $T \tilde{\times} S^1$ and is generated by the reflections in the hyperplanes $\gamma(x) = 0$, where γ runs through the simple roots of LG. The length $l(w)$ of an element $w \in W_{\text{aff}}$ is the number of reflections in a minimal expression for w.

Choose elements e_{γ} in the root space $\mathfrak{g}_{\alpha} z^k$ corresponding to each root $\gamma = (\alpha, k)$ with the property

$$[e_{\gamma}, e_{-\gamma}] = \check{\gamma}$$

for all simple roots γ of LG. Let $\gamma_1, \ldots, \gamma_l$ be the simple roots of LG and write $e_i = e_{\gamma_i}$, $f_i = e_{-\gamma_i}$. Then, the elements of e_i, f_i, $\check{\gamma}_i$, $i = 1, \ldots, l$ satisfy the following commutation relations:

$$\begin{aligned}
[\gamma_i, \gamma_j] &= 0 \\
[e_i, f_j] &= \delta_{ij} \check{\gamma}_i \\
[\check{\gamma}_i, e_j] &= a_{ij} e_j \\
[\check{\gamma}_i, f_j] &= -a_{ij} f_j \\
(\text{ad} e_i)^{-a_{ij}+1} e_j &= 0 \quad \text{if} \quad i \neq j \\
(\text{ad}\, f_i)^{-a_{ij}+1} f_j &= 0 \quad \text{if} \quad i \neq j
\end{aligned}$$

Here, a_{ij} is a square matrix of integers, called the Cartan matrix of LG, satisfying

$$\begin{aligned}
a_{ii} &= 2 \\
a_{ij} &\leq 0 \quad \text{if} \quad i \neq j \\
a_{ij} &= 0 \quad \text{if and only if} \quad a_{ij} = 0
\end{aligned}$$

Theorem 4. These relations define the universal central extension of $L\mathfrak{g}$ defined in the previous section.

If (a_{ij}) is any square matrix of integers satisfying the above conditions, then the preceding relations define a so-called Kac–Moody Lie algebra. If (a_{ij}) is positive definite, the Lie algebra is finite-dimensional and semi-simple. In the case of affine Lie algebras, $\det(a_{ij}) = 0$, but every principal minor of (a_{ij}) is positive definite. In fact, this condition characterizes the affine Lie algebras, and their twisted analogs, among Kac–Moody algebras.

The information contained in the Cartan matrix is often expressed graphically in the form of the Dynkin diagram of the Lie algebra in question. This is a graph that has one node for each generator e_i, the ith and jth nodes being joined by $a_{ij} a_{ji}$ bonds. If $|a_{ij}| > |a_{ji}|$, the bonds carry an arrow pointing toward the ith node.

II. THE FUNDAMENTAL HOMOGENEOUS SPACE

A. Differential-Geometric Properties

The homogeneous space $X = LG/G$ plays a fundamental role in the study of loop groups. It is obviously diffeomorphic to the subgroup ΩG of LG consisting of the based

loops, that is, those satisfying $f(1)=1$; however, it is better to regard it as a homogeneous space of LG, partly because its properties are closely analogous to those of the homogeneous space G/T of G, where T is a maximal torus of G; of course, G/T is not a group.

The first example of this phenomenon is that X, like G/T, is a complex manifold. This follows from the following factorization theorem, in which $L^+G_{\mathbb{C}}$ denotes the subgroup of $LG_{\mathbb{C}}$ consisting of the smooth maps $f : S^1 \to G_{\mathbb{C}}$ that extend smoothly to holomorphic maps of the disc $\{z \in \mathbb{C} : |z| < 1\}$ in to $G_{\mathbb{C}}$.

Theorem 5. $LG_{\mathbb{C}} = LG, L^+G_{\mathbb{C}}$.

This result shows that X is a homogeneous space of the complex Lie group $LG_{\mathbb{C}}$:

$$X \cong LG_{\mathbb{C}}/L^+G_{\mathbb{C}}$$

One of the most striking facts about X is that it behaves like a compact complex manifold.

Theorem 6.

(a) Every holomorphic map $X \to \mathbb{C}$ is constant on each connected component of X.
(b) If M is any compact complex manifold, the space of based holomorphic maps $M \to X$ lying in a fixed homotopy class is finite-dimensional.

The second important aspect of the geometry of X is the existence of an invariant symplectic structure. The tangent space to ΩG at the identity element is $L\mathfrak{g}/\mathfrak{g}$, where $\mathfrak{g}$ is the Lie algebra of G. The formula

$$\omega(\xi, \eta) = \frac{1}{2\pi} \int_0^{2\pi} \langle \xi(\theta), \eta'(\theta) \rangle \, d\theta$$

where $\langle , \rangle$ is an invariant inner product on $\mathfrak{g}$, defines a skew form on $L\mathfrak{g}/\mathfrak{g}$; extending by left translation gives a nondegenerate closed 2-form on X (the nondegeneracy is in the weak sense, that $\omega(\xi, \eta) = 0$ for all η implies $\xi = 0$).

Moreover, the complex structure and the symplectic structure are compatible, in the sense that they fit together to give a Kähler structure on X; this means that $\omega(J\xi, J\eta) = \omega(\xi, \eta)$ and that $\omega(\xi, J\eta)$ is a Riemannian metric on X, where $J : L\mathfrak{g}/\mathfrak{g} \to L\mathfrak{g}/\mathfrak{g}$ is the infinitesimal complex structure. The Ricmannian metric in question is the Sobolev $\frac{1}{2}$-metric, given by the L^2-norm of the $\frac{1}{2}$-th derivative.

B. Stratifications

There is a canonical real-valued function on X, the energy function, given by

$$E(f) = \frac{1}{4\pi} \int_0^{2\pi} \langle f^1 f'(\theta), f^1 f'(\theta) \rangle \, d\theta$$

The Hamiltonian vector field associated to E by the symplectic structure is the derivative of the circle action on X that rigidly rotates loops. The critical points of E are thus the homomorphisms $S^1 \to G$; they fall into conjugacy classes under the action of G and each conjugacy class is a connected, compact complex manifold; the conjugacy classes are in one-to-one correspondence with the orbits of the action of the Weyl group W of G on the lattice of homomorphisms $S^1 \to T$.

The Kähler metric on X defined above allows one to define the gradient vector field of E. Let $\{f_t\}$ be the downward gradient flow of E passing through a loop f at time $t = 0$; in other words, the solution of the ordinary differential equation

$$\frac{\partial f}{\partial t} = -\text{grad}\, E$$

Since X is infinite-dimensional, it is not clear *a priori* that this exists.

Theorem 7.

(a) The integral curve f_t of the downward gradient flow exists for all $t > 0$ for any initial loop f. The integral curve exists for all $t < 0$ if and only if the initial loop f is polynomial.
(b) For all integral curves f_t, $\lim_{t\to\infty} f_t$ exists and is a critical point of E. If f_0 is a polynomial loop, $\lim_{t\to-\infty} f_t$ exists and is a critical point of E.

For any conjugacy class C of homomorphisms $S^1 \to G$, let X_C and X^C denote the parts of X that tend to a point of C as $t \to \infty$ and as $t \to -\infty$, respectively. Note that X is the disjoint union of the X_C and $X_{\text{pol}} = L_{\text{pol}}G/G$ is the disjoint union of the X^C.

Theorem 8.

(a) For any conjugacy class C, X_C and X^C are locally closed complex submanifolds of X of finite codimension and finite dimension, respectively.
(b) The intersection of X_C and X^C is transverse and consists of the conjugacy class C.
(c) The stratum X_1 corresponding to the identity homomorphism is open and dense in the identity component of X.
(d) If λ is any homomorphism in C,

$$X_C = LG_{\mathbb{C}} \cdot \lambda$$
$$X_C = L^+_{\text{pol}}G_{\mathbb{C}} \cdot \lambda$$

Here, $LG_{\mathbb{C}}$ is the subgroup of $LG_{\mathbb{C}}$ consisting of the loops that are boundary values of holomorphic maps from the disc $|z| > 1$ in the Riemann sphere into $G_{\mathbb{C}}$.

The first half of part (c) is equivalent to the Birkhoff factorization theorem, which asserts that every loop f in $G_{\mathbb{C}}$ can be written as

$$f = f \cdot \lambda \cdot f^{+}$$

where $f^{+} \in L^{+}G_{\mathbb{C}}$.

C. Grassmannian Embedding

Let H be a separable infinite-dimensional Hilbert space equipped with a polarization, that is, an orthogonal splitting $H = H_{+} \oplus H$ into a pair of closed infinite-dimensional subspaces. The restricted general linear group $GL_{\text{res}}(H)$ is defined as the group of invertible operators on H whose block decomposition

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

with respect to the polarization has the property that b and c are Hilbert–Schmidt operators. Then a and d are necessarily Fredholm operators, and index $(a) = -\text{index}(d)$. The group $GL_{\text{res}}(H)$ is a Hilbert Lie group and has $\mathbb{Z}$ connected components determined by the index of a. Also of importance is the subgroup $U_{\text{res}}(H)$ of unitary operators in $GL_{\text{res}}(H)$.

The restricted Grassmannian $\text{Gr}(H)$ of H is defined to be the set of closed subspaces W of H such that the orthogonal projections $W \to H_{+}$ and $W \to H_{-}$ are Fredholm and Hilbert–Schmidt, respectively. The group $GL_{\text{res}}(H)$ acts transitively on $\text{Gr}(H)$. The Grassmannian $\text{Gr}(H)$ is a Hilbert manifold and is homotopy equivalent to $\mathbb{Z} \times BU$, the universal classifying space for vector bundles.

To apply this theory to loop groups, one chooses a finite-dimensional unitary representation V of G and takes H to be the space of L^2 functions on the circle with values in V. The subspaces H_{+} and H_{-} consist of the functions whose Fourier expansions are of the form $\sum_{n \geq 0} v_n z^n$ and $\sum_{n<0} v_n z^n$, respectively. The loop group $LG_{\mathbb{C}}$ acts on H, and LG acts by unitary operators.

Theorem 9. The action of $LG_{\mathbb{C}}$ on H induces a homomorphism $LG_{\mathbb{C}} \to GL_{\text{res}}(H)$ and a smooth map $X \to \text{Gr}(H)$. Both maps are embeddings if V is a faithful representation of G.

If $G = U_n$ and V is the natural representation on $\mathbb{C}^n$, the image of X_{pol} in $\text{Gr}(H)$ can be characterized as follows:

$$X_{\text{pol}} = \{W \in \text{Gr}(H) : zW \subset W \quad \text{and} \quad z^N H_{+} \subset W \subset z^{N} H_{+}\}.$$

Similar characterizations are possible for classes of loops other than polynomial and groups other than U_n.

D. Determinant Bundle and Central Extensions

If H were a finite-dimensional space, there would be a holomorphic line bundle Det on $\text{Gr}(H)$ whose fiber over $W \in \text{Gr}(H)$ is the top exterior power of W. In the infinite-dimensional case, one can still define the determinant bundle, using the fact that operators on H of the form $1 +$ (*traceclass*) have well-defined determinants. But whereas, in the finite-dimensional case, Det is homogeneous under the action of $GL(H)$, in the infinite-dimensional case only a central extension $\tilde{G}L_{\text{res}}(H)$ of $GL_{\text{res}}(H)$ by C^{+} acts on Det.

By combining this with the embedding in Proposition 9, one obtains a central extension $\tilde{L}G_{\mathbb{C}}$ of $LG_{\mathbb{C}}$; up to finite coverings, every extension of $LG_{\mathbb{C}}$ by C^{+} arises in this way. In particular, this shows that all the central extensions of LG described in Section I.E have complexifications.

III. REPRESENTATION THEORY OF LOOP GROUPS

A. Positive-Energy Representations

A representation of LG is said to be of positive energy if it extends to a representation of the semidirect product $S^1 \tilde{\times} LG$, with S^1 acting on LG by rotation, and if $e^{i\theta} \in S^1$ acts by $e^{iR\theta}$, where the spectrum of the self-adjoint operator R is bounded below. The most interesting representations of LG are those of positive energy; it turns out that these representations are projective, that is, representations of a central extension of LG. Apart from that, their properties and classification are closely analogous to those of the finite-dimensional representations of G. The irreducible positive-energy representations of LG correspond to the so-called integrable highest weight representations of affine Lie algebras.

There are also representations that are not of positive energy. For any $a \in S^1$, there is a homomorphism $LG \to G$ given by evaluating the loop at a; pulling back an irreducible representation V of G by this homomorphism gives an irreducible representation $V(a)$ of LG; every finite-dimensional irreducible representation of LG is a tensor product of representations of this form. A closely related construction is to let $f \in LG$ act on LV by $(f, v)(z) = f(az)v(z)$; tensor products of such representations are generically irreducible. Neither of these types of representations are of positive energy.

B. The Fundamental Representation and The Spin Representation

The space Γ of holomorphic sections of Det is a completion of the exterior algebra $\Lambda(H_{+} \oplus \bar{H}_{-})$, where $\bar{H}$ is the orthogonal complement of H_{+}, but with the

complex conjugate complex structure. The induced action of the central extension $\tilde{G}L_{\text{res}}(H)$ on Γ is irreducible; it is called the fundamental representation of $\tilde{G}L_{\text{res}}(H)$. "Irreducible" here means that Γ contains no proper invariant subspace that is closed in the compact-open topology. Moreover, Γ is a unitary representation of $\tilde{U}_{\text{res}}(H)$, the central extension of $U_{\text{res}}(H)$ by S^1 obtained by restricting the extension $\tilde{G}L_{\text{res}}(H)$. This means that Γ contains as a dense subspace a Hilbert space on which $\tilde{U}_{\text{res}}(H)$ acts by unitary operators.

One can define in a similar way the restricted orthogonal group $O_{\text{res}}(H_{\mathbb{R}})$ of the real Hilbert space $H_{\mathbb{R}}$ underlying H. The fundamental representation can then be realized as the spin representation of $O_{\text{res}}(H_{\mathbb{R}})$. The space of this realization is a direct sum of symmetric algebras indexed by the integers.

The isomorphism between these two realizations is called the boson-fermion correspondence, by analogy with quantum field theory. The space $\Lambda(H_+ \oplus \bar{H}_-)$ of the first realization is the Hilbert space of a system of free fermions, with H_+ and H_- being the states of a single particle of positive and negative energy, respectively. Similarly, the symmetric algebra is the Fock space of a system of free bosons.

By restricting the fundamental representation, one obtains an irreducible unitary representation of $L\tilde{U}_n$, called the basic representation of LU_n.

C. Borel–Weil Theory

To construct the positive-energy representations of LG for a general compact Lie group G, one must consider the homogeneous space $Y = LG/T$, where T is a maximal torus of G. Dividing by the action of G exhibits Y as a bundle over X with fiber G/T. For simplicity, we shall only consider the case where G is simply-connected and simple. Then Y is connected and simply connected so the complex line bundles over Y are classified by their first Chern class, which is an element of

$$H^2(Y, \mathbb{Z}) \cong \mathbb{Z} \oplus H^2(G/T) \cong \mathbb{Z} \oplus \hat{T}$$

where $\hat{T}$ is the lattice of characters of T, that is, the homomorphisms $T \to S^1$. Let $L_{n,\lambda}$ be the line bundle associated to $(n, \lambda) \in \mathbb{Z} \oplus \hat{T}$. Then we have the following classification of the positive-energy representations of LG, which is a precise analog of the Borel–Weil theorem, which describes the finitedimensional representations of G as sections of line bundles over G/T.

Theorem 10. Let G be a simply-connected, simple compact Lie group.

(a) Each complex line bundle $L_{n,\lambda}$ has a unique holomorphic structure.

(b) $L_{n,\lambda}$ has nonzero holomorphic sections if and only if (n, λ) is dominant, in the sense that

$$0 \le \lambda(\check{\alpha}) \le n\langle\check{\alpha}, \check{\alpha}\rangle$$

for every simple coroot $\check{\alpha}$ of G. Here, $\langle\ ,\ \rangle$ is the unique inner product on $\mathfrak{g}$ such that $\langle\check{\alpha}, \check{\alpha}\rangle = 2$ for every simple coroot $\check{\alpha}$.

(c) If (n, λ) is dominant, the space $\Gamma(L_{n,\lambda})$ of holomorphic sections of $L_{n,\lambda}$ is an irreducible positive-energy representation of a central extension of $LG_{\mathbb{C}}$.

(d) Every irreducible positive energy representation of LG arises in this way.

The positive integer n is called the level of the representation $\Gamma(L_{n,\lambda})$. The pair (n, λ) is usually regarded as an element of the dual of the Lie algebra of $\tilde{T}$, the part of the central extension $\tilde{L}G$ lying over T.

One can show also that every positive-energy representation of LG is unitary, and hence breaks up into a direct sum of representations of the above type. In particular, this implies that every positive-energy representation of LG extends to the complexification $LG_{\mathbb{C}}$. No such property holds for infinite-dimensional groups in general.

D. Kac Character Formula

V. Kac proved an analog for affine Lie algebras (in fact, for all symmetrizable Kac–Moody algebras) of the Weyl formula for the characters of the irreducible representations of G. The character of a representation V of $LG \tilde{\times} S^1$ is the formal power series

$$\chi_V = \sum_\gamma (\dim V_\gamma)\gamma(t, z)$$

where V_γ is the part of V on which the maximal Abelian subgroup $T \times S^1$ acts by the homomorphism γ. In some cases this can be interpreted as some kind of generalized function of $(t, z) \in T \times S^1$. The formula for the character is often written

$$\chi_V = \sum_\gamma (\dim V_\gamma)e^\gamma$$

identifying the homomorphism γ with an element of the dual of the Lie algebra of $T \times S^1$.

Kac Character Formula

Let L_V be the holomorphic line bundle on LG/T associated to a dominant element Λ of the dual of the Lie algebra of $\tilde{T}$, as in theorem 10. Let Γ_V be the space of holomorphic sections of L_V. Then the character of Γ_V, is

$$\chi_V = \frac{\sum_{w \in w_{\text{aft}}} (-1)^{l(w)} e^{w(V,\rho)^+ \rho}}{\prod_{\gamma,0}(1 - e^\gamma)}$$

Here, ρ is characterized by $\rho(\check{\gamma}) = 1$ for all simple roots γ of LG.

Regarded as functions of $z \in S^1$, these characters are boundary values of holomorphic functions in the disc $|z| < 1$. Since the group $SL_2(\mathbb{Z})$ acts on the disc by appropriate linear fractional transformations, it acts also on the space of such functions. One of the remarkable facts about the characters is that the finite-dimensional vector space spanned by the characters of the irreducible positive-energy representations of a given level is preserved by the action of $SL_2(\mathbb{Z})$. The proper explanation of this is to be found in conformal field theory.

E. Vertex Operators

Historically, the first realization of the basic representation was given in terms of so-called vertex operators, the construction and properties of which were known to physicists in dual resonance theory. The restriction of the central extension of LG to the Abelian group LT is an infinite-dimensional Heisenberg group, and thus has a canonical level 1 irreducible unitary representation, say H. One attempts to extend this representation, initially to the Lie algebra $L\mathfrak{g}$, and then to LG, by defining, for each coroot $\check{\alpha}$ of G, and each complex-valued function f on S^1, operators $V_\alpha(f)$ that obey the correct commutation relations with each other and with the generators of the action of LT on H. Since $\mathfrak{g}_{\mathbb{C}}$ is spanned by $\mathfrak{t}_{\mathbb{C}}$ and the coroots $\check{\alpha}$, this will accomplish the task of extending the representation to $L\mathfrak{g}$.

The construction works, at least in its simplest form, only when G is simply-laced, which means that all the simple coroots have the same length; the coroots can then be identified with the homomorphisms $S^1 \to T$ of minimal length. One defines

$$V_\alpha(f) = \int_0^{2\pi} f(\theta) V_\alpha(\theta)\, d\theta$$

for some "operator-valued distribution" $V_\alpha(\theta)$ on the circle. To define $V_\alpha(\theta)$, think of α as a homomorphism $S^1 \to T$. For each $\varepsilon > 0$, let $V_{\alpha,\theta,\varepsilon}$ be the element of LT such that

$$V_{\alpha,\theta,\varepsilon} = 1 \quad \text{if} \quad |\theta' - \theta| > \varepsilon$$

and such that $V_{\alpha,\theta,\varepsilon}(\theta')$ traces out the loop α when θ' goes from $\theta - \varepsilon$ to $\theta + \varepsilon$. Then the limit

$$\lim_{\varepsilon \to 0} \varepsilon^{-1} V_{\alpha,\theta,\varepsilon}$$

exists in the distributional sense and defines the required $V_\alpha(\theta)$.

The vertex operator construction is equivariant with respect to the action of diffeomorphisms of the circle. Recall from Section I that $\mathrm{Diff}(S^1)$ acts as a group of automorphisms of LG. Moreover, the action of the orientation-preserving diffeomorphisms $\mathrm{Diff}^+(S^1)$ preserves the cocycle defining the central extension LG, and $\mathrm{Diff}^+(S^1)$ acts on $\tilde{L}G$.

Theorem 11. There is a (projective) action of $\mathrm{Diff}^+(S^1)$ on all positive-energy representations of LG that intertwines with the action of LG.

More recently, the algebra of vertex operators has been formalized and generalized and is capable of describing representations of LG other than the basic one. Vertex algebras have also found other applications, notably to the construction of the "moonshine" representation of the Monster simple group.

IV. RELATIONS WITH OTHER PARTS OF MATHEMATICS

Due to limitations of space, we shall restrict discussion of applications of loop groups to the following two combinatorial topics.

A. Macdonald Identities

I. G. Macdonald discovered a remarkable series of multivariable power series identities, one for each simple compact Lie group G. When $G = SU_2$, this gives Jacobi's formula

$$\eta(q)^3 = \sum_{j \in \mathbb{Z}} (-1)^j q^{(1/24)(6j+1)^2}$$

for the cube of the Dedekind eta-function

$$\eta(q) = q^{1/24} \prod_{j=1} (1 - q^j).$$

For a general G, Macdonald's identities give an analogous formula for $\eta(q)^{\dim G}$. Kac and R. V. Moody independently observed that Macdonald's identities are precisely the statement of the Kac character formula for the triyial representation (the socalled denominator formula).

More recently, J. Lepowsky has shown that many other well-known power series identities have a Lie algebraic proof.

B. Quivers

A quiver is a finite set of points together with directed arrows joining certain pairs of points. A representation of a quiver is an assignment to each point i of a finite-dimensional vector space V_i and to each arrow going from point i to point j of a linear map from V_i to V_j. Quivers having only finitely many indecomposable representations correspond exactly to the Dynkin diagrams of simply-laced finite-dimensional complex simple Lie algebras. Quivers whose representations can be classified

correspond exactly the Dynkin diagrams of affine Lie algebras that contain no double bonds.

GLOSSARY

Bundle Superstructure over a base manifold used in the definition and analysis of geometrical entities.
Cohomology Algebraic procedure for studying global properties of spaces on manifolds, via differential forms.
Completeness Freedom from singularities, such as holes, in the underlying manifold.
Connection Fundamental geometrical object for prescribing parallelism structures on a manifold.
Curvature Tensor field carrying information about the noncommutativity of parallel transport.
Differential form Section of a bundle of antisymmetric tensors.
Geodesic General geometrical equivalent of a straight line in Euclidean geometry.
Metric tensor Fundamental tensor field for prescribing metrical geometry on a manifold.
Parallel transport Process available through a connection for the movement of geometrical entities along curves in the manifold.
Section "Slice" of a bundle that chooses one bundle point over each point of the base manifold.
Tensor field Section of a tensor bundle; similarly, vector fields.
Torsion Tensor field carrying information about the asymmetry of a connection.

MANIFOLD GEOMETRY is the latest contribution to one of the oldest branches of mathematics. It exploits modern abstract algebra and abstract analysis in the study of geometrical spaces, called manifolds, that are natural generalizations of spaces studied by Euclid. To handle the greater complexity, modern geometers created superstructures called bundles over manifolds. Through these bundles, generalizations of differential and integral calculus

allow a geometrization of diverse problems in abstract analysis and in physical field theories; they also allow the use of algebraic topological methods of cohomology to study global properties. Very elegant formulations of the concepts of parallelism and curvature arise from the geometrical object called a connection. This distinguishes the geodesic curves that generalize to a manifold the Euclidean notion of a straight line and also gives a test for completeness of the manifold.

I. PRELIMINARY NOTIONS

A. Sets and Maps

We shall accept as sufficient for our purposes the intuitive notion of a set as a collection of distinct and definite elements. Likewise, a map from a set X to a set Y is a rule that prescribes precisely one element of set Y to be related to each element of set X. Then we indicate it by a diagram like

$$f\colon X \to Y : x \mapsto f(x)$$

and speak of the map f with domain X that sends a typical element x in X to the element $f(x)$ in Y. A convenient way to view f is in terms of its graph, that is, the set of elements $(x, f(x))$ lying in the $X \times Y$ space. Every map $f : X \to Y$ defines another map bringing subsets of Y back to subsets of X

$$f^{\leftarrow}\colon \operatorname{sub} Y \to \operatorname{sub} X : B \mapsto \{x \in X \mid f(x) \in B\}$$

Usually, the sets X and Y that we shall be interested in will have some geometric structure and our maps will in some sense respect this structure. Typical problems reduced to geometrical essentials are:

1. Given sets X and Y with particular geometric structures, show that a map $f\colon X \to Y$ satisfying certain requirements exists.
2. Extend the domain of a given map.
3. Given a map $f\colon X \to Y$ and some geometric structure on Y, what geometric structure is induced on (i.e., pulled back to) X?
4. Given a map $f\colon X \to Y$ and some geometric structure on X, what geometric structure is coinduced on (i.e., pushed forward to) Y?

B. Algebra and Analysis

It turns out that two mathematical areas are intertwined in the precise formulation and solution of geometrical problems. On the one hand we need analysis to deal with concepts of nearness and change; on the other hand we need algebra to organize our calculus procedures and to represent symmetries in the geometry. Our first task is to describe the appropriate parts of analysis and algebra to explain the above use of the term "geometric structure" on a set and to explain the kinds of requirements that are often imposed on maps that arise in geometrical contexts. We shall attempt to present them together in a geometrical setting with examples. In order to have a fund of examples we need to assume a working knowledge of certain mathematical raw materials, abbreviations, and basic tools.

We shall suppose some familiarity with elementary algebra and calculus on the real and complex number fields. The analysis on them depends on the modulus or absolute value function $a \to |a|$, which yields a distance function d between two numbers a and b by

$$d(a, b) = |a - b|$$

This satisfies the geometrical requirements:

$d(a, b) = d(b, a)$	(symmetry)
$d(a, b) = 0$ if and only if $a = b$	(positive definiteness)
$d(a, c) \leqq d(a, b) + d(b, c)$	(triangle inequality)

The algebra of the real and complex numbers depends on each of them having double group structures, one under addition with identity zero and one under multiplication (excepting zero) with identity one. Recall that a group is a set with a binary operation that is associative, has identity, and admits inverses.

C. Notations

Symbol	Meaning
$\mathbb{N}$	the set of natural numbers, i.e., $1, 2, 3, \ldots$
$\mathbb{Z}$	the set of integer numbers, i.e., $0, \pm 1, \pm 2, \ldots$
$\mathbb{Q}$	the set of rational numbers, i.e., p/q for $q \neq 0$, p, q in $\mathbb{Z}$
$\mathbb{R}$	the set of real numbers, i.e., the complete geometrical line
$\mathbb{C}$	the set of complex numbers, i.e., $x + iy$ for $i = \sqrt{-1}$, x, y in $\mathbb{R}$
E^2	the real plane, i.e., two-dimensional real space
E^n	n-dimensional real space for n in $\mathbb{N}$: $E^1 = \mathbb{R}$
$\mathbb{R}^n$	the standard n-dimensional real vector space
$[0, 1]$	the interval $\{x \in \mathbb{R} \mid 0 \leqq x \leqq 1\}$
$[0, 1)$	the interval $\{x \in \mathbb{R} \mid 0 \leq x < 1\}$
$x \in X$	x is an element of set X
$A \subseteq B$	A is a set, all of whose elements are also elements of B; a *subset* of B
sub B	the set of all subsets of set B
$A = B$	$A \subseteq B$ and $B \subseteq A$; A and B are the same set
$\emptyset$	the empty set; the set with no elements
$A \cap B$	the set of elements in both subsets A and B; their *intersection*

$A \cup B$	the set of elements in one or both of subsets A or B; their *union*
$\{x \in X \mid P(x)\}$	the set of elements in X for which statement $P(x)$ is true
$\Rightarrow$	implies; then
$\Leftrightarrow$	implies and is implied by; if and only if
$A \times B$	the set of ordered pairs (a, b) such that a is in A and b is in B
$X \to Y$	a map from set X to set Y
$X \twoheadrightarrow Y$	a map from set X *onto* (the whole of) set Y
$X \simeq Y$	an equivalence of structures (iso/homeo/ diffeomorphism)
$f \circ g$ or fg	the composite map; do g then f

EXAMPLE. Denote by G the multiplicative group of unit modulus complex numbers, that is,

$$G = \{z \in \mathbb{C} \mid |z| = 1\} = \{e^{i\theta} \mid \theta \in \mathbb{R}\}$$

This group *acts on* the set of complex numbers $\mathbb{C}$ in a simple way:

$$\alpha\colon G \times \mathbb{C} \to \mathbb{C} : (e^{i\theta}, w) \mapsto e^{i\theta} w$$

that is simply to rotate each complex number $w = re^{i\phi}$ by the angle θ to give $e^{i\theta} \times re^{i\phi} = re^{i(\theta+\phi)}$, for each choice of ϕ (Fig. 1). This α is a continuous action since

1. Nearby θ values send a fixed w to nearby numbers in $\mathbb{C}$;
2. Nearby w numbers are sent to nearby numbers by a fixed θ.

Consider seeking a real map (i.e., a function)

$$f\colon \mathbb{C} \to \mathbb{R}$$

that is invariant under the above group action. Evidently we want commutativity of a diagram

$$\begin{array}{ccc} G \times \mathbb{C} & \xrightarrow{\alpha} & \mathbb{C} \\ {\scriptstyle p_2}\downarrow & & \downarrow{\scriptstyle f} \\ \mathbb{C} & \xrightarrow{f} & \mathbb{R} \end{array} \quad \text{that is}$$

$$\begin{array}{ccc} (\theta, w) & \longmapsto & e^{i\theta} w \\ \downarrow & & \downarrow \\ w & \longmapsto & ? \end{array} \quad \text{on elements}$$

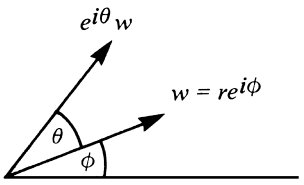

FIGURE 1 Rotation through angle θ.

Hence we seek f satisfying, for all θ and w, the condition

$$f(e^{i\theta} w) = f(w)$$

This requirement is simply rotational symmetry; that is, $f(w)$ is independent of the angular position of w. One such function is the modulus, defined for all $w = x + iy$ by

$$f(x + iy) = (x^2 + y^2)^{1/2}$$

Try repeating this example for the same group when acting as a rotation about a point other than the origin.

Whenever we have a group action on a set we wish to know the subsets left invariant by the action—if there are any. In our example they do exist and in fact they are the circles with center the origin; we call such subsets the orbits of the group action. They always form a partition of the set carrying the action into disjoint nonempty subsets. Orbits that consist of single points are called *fixed points* (the origin is one in the example). Orbits need not look like planetary orbits; for example, the action on the Euclidean plane E^2 given for the additive group of real numbers by

$$\mathbb{R} \times E^2 \xrightarrow{\alpha} E^2 : (a, (x, y)) \mapsto (x + a, y)$$

has no fixed point and orbits the horizontal lines. This latter group action is simply translation by a real number along the x axis, but in fact any other direction (or all directions) could have been used. Indeed, if we combine all rotations, translations, and reflections into one collection we get the Euclidean group, so called because it leaves invariant the essentials of Euclidean geometry, namely lengths and angles.

D. Geometrical Spaces

Euclidean geometry is the usual geometry of real n-space E^n and it is algebraically easy to handle because E^n is an affine space; this simply means that relative to any choice of origin it is equivalent to a vector space. Non-Euclidean n-dimensional geometries arise from the smooth patching together of pieces of E^n without regard for the preservation of their algebraic structures. Such patchwork structures are called n-manifolds, and they are our principal domain spaces in general geometry. Familiar examples of 2-manifolds are a sphere and a torus; evidently each has some residual local similarity to pieces of the Euclidean plane E^2 from which they are synthesized, but globally they are very different. One geometrical difference is already apparent: in the Euclidean plane the angle sum of any triangle is 180°, but it is easy to see that on a sphere we can find a triangle with sides the arcs of three great circles and having an angle sum of 270°. In fact, this angular excess is a manifestation of the presence of curvature. The formal way to handle it in general geometry is via an entity called a *connection*, which governs the definition of

parallelism on a manifold: going due north on a sphere is a curve that propagates in a parallel fashion on the curved surface, that is, maintains its direction as closely as it can. Intuitively, a connection structure provides a general geometer with a tool somewhat like the parallel rulers used by navigators.

Once we can say what we mean by the "same direction" at two different points it is meaningful to pose problems like: what is the rate of change in that direction of some entity defined on the space? By means of a connection we obtain a differential operator that precisely measures all such rates of change in an invariant (sometimes called covariant) way, that is, independently of the manner in which we choose to label the directions and points. The operator involved here is the covariant derivative and it replaces ordinary derivatives in non-Euclidean geometries, so allowing the representation of very intricate systems of differential equations such as those used in electrical engineering or for physical field theories.

Probably the most important differential operator on a manifold is the exterior derivative; this comes free with the manifold: no extra structure need be assumed. In quite a precise way it generalizes the gradient operation on scalar functions and the curl operation on vector functions that are used in vector calculus on E^3. In that sense it turns out that curvature is the "curl of the connection." We shall see how the exterior derivative characterizes some intrinsically topological properties of manifolds by means of de Rham cohomology theory.

Perverse though it may seem, no sooner do mathematicians set up a nice machinery than there arises an interest in how and why the machinery could be made to seem inadequate or defective. Clearly, if well-founded logically, then the theory (e.g., general geometry) will not have intrinsic defects. However, near the "edges" of its validity some interesting problems arise. For example, general geometry can be asked to model the environment of a physical singularity, like a black hole. This means devising a geometrical space in which something goes wrong; namely, particles disappear if they follow certain paths. It is an interesting recent result that in such a model the singularity seems to be stable: we cannot make it go away by perturbing the geometry, as done for example in quantization procedures.

II. GEOMETRICAL SPACES

A. Euclidean Spaces

The simplest Euclidean space is the one-dimensional case of the real line, E^1. As is almost always the case in mathematical processes of generalization, there are two major steps: from one to more than one, and from finitely many to infinitely many. Thus the step from E^1 to E^2, the real plane, is intuitively difficult at first meeting; but the step on, to E^4 or E^n for any finite n, is simple because the algebra and analysis are essentially unchanged. The further step to infinite dimensions is also difficult because definitions change; the kind of hurdle that arises is like the transition for polynomial functions to power series. In fact, we shall not study infinite-dimensional spaces explicitly but they will arise incidentally.

So for our purposes, a good intuitive grasp of the geometry of the real plane E^2 is a prime asset. By suppressing coordinates and other manifestations of its "twoness" we shall be able to use the algebra and analysis for higher-dimensional situations. We summarize the geometry as follows:

1. *Points* of E^2 are ordered 2-tuples of real numbers like $p = (p_1, p_2)$.
2. There is a vector difference between pairs of points, a map, diff: $E^2 \times E^2 \to \mathbb{R}^2 : (p, q) \mapsto q - p = (q_1 - p_1, q_2 - p_2)$, and this correspondence is the best possible in the sense that if we hold one of the points fixed then it is a one-to-one correspondence between all points of E^2 and all vectors of $\mathbb{R}^2$; reversing the points reverses the vector.
3. The parallelogram law holds for vector differences of points.
4. There is a distance function defined between pairs of points, the length (or norm) of their vector difference:

$$\text{dist}(p, q) = \|\text{diff}(p, q)\|$$

We use property (1) for labeling the points of the space: in E^2 each point has two coordinates, so E^2 and $\mathbb{R}^2$ are equivalent (in bijective correspondence) as sets. The vector difference map gives us two things:

1. The set of all directions at each point; this is the tangent space at the point.
2. A simple algebraic cohesion among points that facilitates the solution of problems by trigonometric methods.

Recall that in $\mathbb{R}^2$ we have the dot product between two vectors given by

$$u \cdot v = (u_1, u_2) \cdot (v_1, v_2) = u_1 v_1 + u_2 v_2$$

This also determines the length (or norm) of a vector u by

$$\|u\| = \sqrt{u \cdot u}$$

and angle θ between nonzero vectors u and v by

$$u \cdot v = \|u\| \|v\| \cos\theta$$

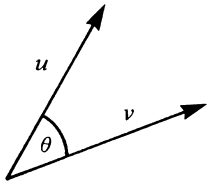

FIGURE 2 Angle between two vectors.

(see Fig. 2). Calculus on E^2 depends on the usual process of partial differentiation applied to functions of two variables taking values in $\mathbb{R}^n$. There are in particular two operators that readily generalize to E^n: grad and div.

For a differentiable real-valued map

$$f\colon E^2 \to \mathbb{R} : (x, y) \mapsto f(x, y)$$

its gradient is the vector-valued map

$$\text{grad } f\colon E^2 \to \mathbb{R}^2 : (x, y) \mapsto \left(\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y}\right)$$

grad f at $(x, y) \in E^2$ being viewed as a vector in the "tangent space" to E^2 at (x, y), that is, in the space of directions there.

For a differentiable tangent space-valued map

$$\phi\colon E^2 \to \mathbb{R}^2 : (x, y) \mapsto (\phi_1(x, y), \phi_2(x, y))$$

its divergence is the real-valued map

$$\text{div}\,\phi\colon E^2 \to \mathbb{R} : (x, y) \mapsto \frac{\partial \phi_1}{\partial x} + \frac{\partial \phi_2}{\partial y}$$

Of course we can apply div to grad f; then we get the *Laplacian*

$$\Delta f\colon E^2 \to \mathbb{R} : (x, y) \mapsto \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2}$$

Typical problems that arise in geometrical form are:

Given $X \subseteq E^2$ find $f\colon X \to \mathbb{R}$ satisfying $\Delta f = 0$ and subject to certain boundary conditions on f.

Given $X \subseteq E^2$ and $\phi\colon X \to \mathbb{R}$ find a curve

$$c\colon [0, 1] \to E^2 : t \mapsto (x(t), y(t))$$

beginning at (x_0, y_0), that is, $c(0) = (x_0, y_0)$, with tangent vector there given by $\dot{c}(0) = (u_0, v_0)$ and satisfying

$$\ddot{c} = \text{grad}\,\phi \quad \text{(at } t \text{ and } c(t) \text{ respectively)}$$

Here $\dot{c}(t) = (dx\,dt, dy/dt), \ddot{c}(t) = (d^2x/dt^2, d^2y/dt^2)$.

B. Non-Euclidean Spaces

We can obtain more general spaces, called *manifolds*, in two ways:

1. Keep the same point set (e.g., as in E^2) but use nonstandard definitions for lengths and angles of vectors in the tangent spaces.
2. Construct a new set of points (e.g., by joining pieces of E^2), then add some geometry.

In both cases we would want to meet certain compatibility conditions to avoid abrupt (i.e., not smooth) geometrical changes from place to place. In method 1 we already have all tangent spaces and may vary how we geometrize them in a smoothly changing manner. In method 2 we have only the tangent spaces for each small piece of Euclidean space so we have to make sure that they fit smoothly together, unambiguously overlapping at the joins; then we can introduce smoothly changing measures of lengths and angles for vectors over the whole space.

Method 1 would allow us to construct 2-manifolds that have the appearance of bent and twisted planes, for example, a saddle-shaped surface. However, method 1 would not allow the construction of a sphere or torus. Either of these would involve some joining together (called *identification*) of certain points of E^2. For example, to obtain a torus we begin with a rectangle in the plane, join together two edges to form a tube, then join the two open ends together. The joining process can be visualized through paper models, though this and the smoothing process at the joins can be made mathematically precise. There is a subtle point here. When we appeal intuitively to paper models it is implicit that they are viewed in three-dimensional space, and so at each point of such a model surface there is a well-defined tangent space of directions in the surface. It is actually the tangent plane at the point. In the formal mathematical process the tangent spaces can be constructed without leaving the surface. The same is true in general for n-manifolds constructed by joining and smoothing out pieces of E^n. However, there is an important theorem due to Whitney which says that we could, if we wish, view any such n-manifold as embedded in a Euclidean space of sufficiently high dimension. We saw that the torus 2-manifold needed E^3; in general an n-manifold may need E^{2n+1}.

One final point before getting to technical definitions. In geometry we often speak of "the unit circle" or "the n-sphere" when in fact there are many ways to describe these spaces. For example S^1, the unit circle, can be viewed as the set of all unimodular complex numbers or perfectly equivalently (i.e., up to structural isomorphism) as the set of vectors of unit norm in $\mathbb{R}^2$. We often do not bother to make distinctions between them.

III. MANIFOLDS AND BUNDLES

A. Manifolds

An n-manifold is a set M of points with the following properties:

1. M can support the notion of continuous functions on it; (we take M to be Hausdorff with countable base).
2. M is the union of a collection $\{U_\alpha \mid \alpha \in A\}$ of its subsets; (the collection is an open cover for M).
3. For each α in the indexing set A there is a continuous equivalence between U_α and E^n; (homeomorphisms $\phi_\alpha\colon U_\alpha \to E^n$ give coordinates).
4. The change of coordinate maps are smoothly differentiable; ($\phi_\alpha \circ \phi_\beta^{-1}$ is a diffeomorphism if $U_\alpha \cap U_\beta \neq \emptyset$).

We call the collection $\{(U_\alpha, \phi_\alpha) \mid \alpha \in A\}$ an atlas of charts for M. Properties 1–4 are clear enough but it is worth noting that 4 is meaningful because maps like $\phi_\alpha \circ \alpha_\beta^{-1}$ go between pieces of E^n on which we suppose differentiability to be well understood—namely, calculus on $\mathbb{R}^n$ attached to each point. It is property 4 that enables us to say what we mean by a map between two manifolds being differentiable. Let M' be an m-manifold with atlas $\{(V_\lambda, \psi_\lambda) \mid \lambda \in B\}$. Then a map

$$f\colon M \to M'$$

is called *differentiable* if and only if the composite maps $\psi_\lambda \circ f \circ \phi_\alpha^{-1}$ are differentiable wherever $fU_\alpha \cap V_\lambda \neq \emptyset$, for any $\alpha \in A$ and $\lambda \in B$. The reason for this is apparent from the diagram

$$\begin{array}{ccc} U_\alpha & \xrightarrow{\ f\ } & V_\lambda \cap fU_\alpha \\ {\scriptstyle \phi_\alpha^{-1}}\uparrow & & \downarrow{\scriptstyle \psi_\lambda} \\ E^n & \xrightarrow[\psi \circ f \circ \phi_\alpha^{-1}]{} & E^m \end{array}$$

Evidently, we are borrowing for manifolds the already known property of differentiability of maps from E^n to E^m. Property 4 is spoken of as giving a *differentiable* or *smooth structure* to M.

A similar trick of borrowing is employed to define T_xM, the *tangent space* to M at $x \in M$. If $x \in U_\alpha$ then we certainly have a nice vector space tangent at $\phi_\alpha(x) \in E^n$ and it is isomorphic to $\mathbb{R}^n$. The problem is that we may also have $x \in U_\beta$. In that case $\phi_\alpha \circ \phi_\beta^{-1}$ and $\phi_\beta \circ \phi_\alpha^{-1}$ have derivatives that are actually isomorphisms between the tangent spaces at $\phi_\alpha(x)$ and $\phi_\beta(x)$; in fact, they will appear as invertible Jacobian matrices with entries the partial derivatives, from calculus on $\mathbb{R}^n$. Such isomorphisms are used to take equivalence classes of E^n-tangent spaces for synthesizing T_xM. Then the process can be rounded off nicely because the derivative of a map between manifolds actually becomes a linear map between tangent spaces.

The totality of all tangent spaces to an n-manifold M is actually itself a $2n$-manifold with point set

$$TM = \bigcup_{x \in M} T_xM = \{(x, u) \mid x \in M, u \in T_xM\}$$

and atlas $\{(TU_\alpha, T\phi_\alpha) \mid \alpha \in A\}$, where $TU_\alpha = \cup_{x \in U_\alpha} T_xM$ and $T\phi_\alpha$ is the derivative of ϕ_α. We call this manifold the tangent bundle to M and it is noteworthy that it comes free with M; no further structure was needed. There is a natural smooth map onto M:

$$p\colon TM \twoheadrightarrow M : (x, u) \mapsto x$$

The *fiber* of such a map over x is

$$p^{\leftarrow}\{x\} = \{y \in TM \mid p(y) = x\}$$

which evidently coincides with T_xM and therefore looks like $\mathbb{R}^n$ for each x, though there is no unique isomorphism $T_xM \simeq \mathbb{R}^n$ actually determined for each x since each chart gives a different one. The tangent bundle is an example of an important class of structures over manifolds, the vector bundles.

B. Bundles

A *vector bundle with fiber* F (a vector space) over a manifold M is a smooth surjection $p\colon X \twoheadrightarrow M$ such that every $x \in M$ has a neighborhood U for which there is a diffeomorphism $p^{\leftarrow}U \simeq U \times F$, and isomorphism on fibers. This implies that the zero vectors in fibers are joined smoothly together and the set of all of them looks like a copy of M embedded in X. In the case of the tangent bundle over an n-manifold, $F = \mathbb{R}^n$ and the local triviality condition is

$$TU_\alpha \simeq U_\alpha \times \mathbb{R}^n$$

Thus a vector bundle over M consists of M together with copies of a vector space smoothly fitted over all points of M. We interpret the tangent bundle over M as the set of all points and directions in M.

If we have a vector bundle with fiber F over M then we may be able to use its construction to obtain another vector bundle with fiber the dual space F^* consisting of all linear functionals defined on F. One case when this is always possible is for the tangent bundle TM; we replace each tangent space T_xM by its dual $(T_xM)^*$ consisting of real-valued linear maps on T_xM. The resulting bundle is T^*M, the contangent bundle. Recall that just as we can dual vector spaces so we can dual linear maps between them by sending linear f to linear f^* where

$$\left.\begin{array}{c} F \xrightarrow{\ f\ } G \\ G^* \xrightarrow{\ f^*\ } F^* \end{array}\right\} \quad \text{with } f^*\colon \alpha \mapsto \alpha f$$

So the dual map actually goes in the reverse direction. For a finite-dimensional vector space F we may identify $(F^*)^*$, the double dual, with F itself by the natural isomorphism

$$F \simeq (F^*)^*\colon v \mapsto \hat{v}$$

where

$$v\colon F^* \to \mathbb{R} : \alpha \mapsto \alpha(v)$$

EXAMPLE. Take $M = S^1 = \{z \in \mathbb{C} \mid |z| = 1\}$, the 1-sphere. Then $TS^1 = S^1 \times \mathbb{R}$, a cylinder easily visualizable by considering each tangent line to S^1 to be represented by a vertical copy of $\mathbb{R}^1$ so that one such can be fitted to each point. Thus the tangent bundle to S^1 is a trivial product.

On the other hand, we can find another vector bundle over S^1 with fiber $\mathbb{R}^1$. This is the Möbius bundle in which the different copies of $\mathbb{R}^1$ attached to points of S^1 actually rotate through 180° as we pass once around the circle. So this bundle is not a trivial product; it is a twisted product and easily investigated by making a paper model. It is worth adding that the tangent bundle to the 2-sphere S^2 is not a trivial product, it is twisted. This is rather a deep result but quite believable when you consider the problems of stacking tangent planes on a sphere. On the other hand, there is the normal vector bundle on S^2, which is a trivial vector bundle with fiber $\mathbb{R}^1$.

Bundles can be made with fibers that are manifolds with structures other than vector spaces, for example, groups. The great importance of bundles is that they allow a crucial generalization of the concept of a map. To see this, consider the two vector bundles with fiber $\mathbb{R}^1$ over S^1 given above. Now a continuous map from S^1 to $\mathbb{R}^1$ is simply a continuous choice of a vector in $\mathbb{R}^1$ for each point in S^1. Given such a map we could draw its graph on the cylinder bundle $S^1 \times \mathbb{R}^1$ above, as a continuous curve that projects onto the whole of S^1. Equally, given such a curve then it determines uniquely a continuous map from S^1 to $\mathbb{R}^1$ by sending each point of S^1 to the vector in $\mathbb{R}^1$ cut by the curve above that point. Now consider the twisted bundle. If we draw on this a continuous curve that projects onto S^1 then we do not obtain a unique continuous map from S^1 to $\mathbb{R}^1$ because the $\mathbb{R}^1$ in which we are trying to obtain values changes continuously as we go around S^1. The precise formulation of our generalization of a map is the following.

A section of a bundle $X \overset{p}{\twoheadrightarrow} M$ with fiber F over M is a smooth map $\sigma\colon M \to X$ such that $p\sigma$ is the identity map on M. Such a section is sometimes referred to as an X-field on M. So σ smoothly chooses at each point of M an element in the fiber over that point. Thus, if $X = M \times F$, the trivial product bundle, then all sections have the form

$$\sigma\colon M \to M \times F\colon a \mapsto (a,\ f(a))$$

where

$$f\colon M \to F\colon a \mapsto f(a)$$

is a map from M to F.

Conversely, if X is not a trivial product bundle then there will be some $a \in M$ with neighborhoods U and V such that $a \in U \cap V$ with local triviality

$$\lambda\colon p^{\leftarrow}U \simeq U \times F \qquad \text{and} \qquad \mu\colon p^{\leftarrow}V \simeq V \times F$$

Therefore we have three diffeomorphisms

$$\begin{array}{ccc} & p^{\leftarrow}U \cap p^{\leftarrow}V & \\ {\scriptstyle\lambda}\swarrow & & \searrow{\scriptstyle\mu} \\ (U \cap V) \times F & \underset{\mu\lambda^{-1}}{\simeq} & (U \cap V) \times F \end{array}$$

Now, a section $\alpha\colon M \to X$ can be locally decomposed by means of λ and μ and $U \cap V$ thus:

$$\begin{array}{ccccc} & & & & (U \cap V) \times F \to F \\ & & & {\scriptstyle\lambda}\nearrow & \\ U \cap V & \overset{\sigma}{\to} & p^{\leftarrow}U \cap p^{\leftarrow}V & & \\ & & & {\scriptstyle\mu}\searrow & \\ & & & & (U \cap V) \times F \to F \end{array}$$

which on elements becomes of the form

$$\begin{array}{ccc} & & (a, \lambda(a)) \mapsto \lambda(a) \\ & \swarrow & \\ a \overset{\sigma}{\mapsto} \sigma(a) & & \\ & \searrow & \\ & & (a, \mu(a)) \mapsto \mu(a) \end{array}$$

Now, as long as λ and μ differ, then σ does not define any unique map from $U \cap V$ to F.

C. Combining Vector Bundles

We can obtain new vector bundles from old by exploiting two processes available for vector spaces: their direct sum $\oplus$ and their tensor product $\otimes$. Consider two finite-dimensional real vector spaces F and G. Then we can represent $F \oplus G$ and $F \otimes G$ in terms of any bases $\{f_1, \ldots, f_n\}$ for F and $\{g_1, \ldots, g_m\}$ for G as follows:

$$F \oplus G \text{ has basis } \{f_1, \ldots, f_n, g_1, \ldots, g_m\}$$
$$\text{dimension } n + m$$

$$F \otimes G \text{ has basis } \{f_i \otimes g_j \mid i = 1, \ldots, n;\ j = 1, \ldots, m\}$$
$$\text{dimension } nm$$

Thus, $F \oplus G$ arises from the disjoint union set of vectors in F and G (identifying the two zero vectors) and $F \otimes G$ arises from the product set of vectors, $F \times G$. The structure of $F \oplus G$ is clear enough; for example, if F is the (x, y) plane in $\mathbb{R}^3$ and G is the z axis then $F \oplus G = \mathbb{R}^2 \oplus \mathbb{R}^1 \simeq \mathbb{R}^3$. Less clear is $F \otimes G$, but in concrete applications we shall see a specific role provided for the basis vectors $f_i \otimes g_j$. With bases $\{\hat{i}, \hat{j}\}$ for $\mathbb{R}^2$ and $\{\hat{k}\}$ for $\mathbb{R}^1$ we have a basis $\{\hat{i} \otimes \hat{k}, \hat{j} \otimes \hat{k}\}$ for $\mathbb{R}^2 \otimes \mathbb{R}^1$ and so $\mathbb{R}^2 \otimes \mathbb{R}^1 \simeq \mathbb{R}^2$.

Both products $\oplus$ and $\otimes$ can be extended in an obvious way to linear maps between spaces. For example, denote by $L(F;J)$ the vector space of linear maps from vector space F to vector space J. Then with $f \in L(F;J)$ and $g \in L(G;K)$ we obtain new linear maps:

$$\begin{aligned} f \oplus g &: F \oplus G \to J \oplus K \\ &: x \oplus y \mapsto f(x) \oplus g(y) \\ f \otimes g &: F \otimes G \to J \otimes K \\ &: x \otimes y \mapsto f(x) \otimes g(y) \end{aligned}$$

In particular, $F^* = L(F;\mathbb{R})$ and a very useful equivalent formulation of $L(F;J)$ itself is obtained:

$$L(F;J) \simeq F^* \otimes J$$

For example $(\mathbb{R}^3)^* \otimes \mathbb{R}^2$ can therefore be interpreted as the space of linear maps from $\mathbb{R}^3$ to $\mathbb{R}^2$, namely the space of 2×3 matrices.

There is a third composition, also based on the tensor product, available for a vector space F with itself. This is the alternating or exterior product $F \wedge F$. In terms of the basis $\{f_1, \ldots, f_n\}$ for F:

$$\begin{aligned} F \wedge F \text{ has basis } &\{f_i \otimes f_j - f_j \otimes f_i \mid i < j\} \\ &\text{and so dimension } \tfrac{1}{2}(n^2 - n) \end{aligned}$$

We usually write $f_i \wedge f_j = \frac{1}{2}(f_i \otimes f_j - f_j \otimes f_i)$. Hence $\mathbb{R}^2 \wedge \mathbb{R}^2$ has basis $\{\hat{i} \otimes \hat{j} - \hat{j} \otimes \hat{i}\}$ and so $\mathbb{R}^2 \wedge \mathbb{R}^2 \simeq \mathbb{R}^1$. Observe that we can only have $(F \wedge F) \simeq F$ if $\frac{1}{2}(n^2 - n) = n$, that is, if $n = 3$. This fact is closely related to the existence on $\mathbb{R}^3$ only of the vector cross product $\times$ defined by

$$\hat{i} \times \hat{j} = \hat{k} \qquad \hat{j} \times \hat{k} = i \qquad \hat{i} \times \hat{k} = -\hat{j}$$

For, we can make an isomorphism

$$\mathbb{R}^3 \wedge \mathbb{R}^3 \simeq \mathbb{R}^3 \times \mathbb{R}^3$$

$$\text{by mapping linearly } \begin{cases} \hat{i} \wedge \hat{j} \mapsto \hat{i} \times \hat{j} \\ \hat{i} \wedge \hat{k} \mapsto \hat{i} \times \hat{k} \\ \hat{j} \wedge \hat{k} \mapsto \hat{j} \times \hat{k} \end{cases}$$

Once again we can use the product $\wedge$ on spaces to give a product on linear maps. For $f, g \in L(F;J)$ we obtain

$$f \wedge g : F \wedge F \to J \wedge J : x \wedge y \mapsto f(x) \wedge f(y)$$

These vector space processes can be performed smoothly over a manifold to the fibers of vector bundles. In particular, we have automatically the following vector bundles derived from the tangent bundle TM and cotangent bundle T^*M to a smooth manifold:

$$\begin{aligned} T_0^2 M &= TM \otimes TM && \text{with fiber } \mathbb{R}^n \otimes \mathbb{R}^n \\ T_2^0 M &= T^*M \otimes T^*M && \text{with fiber } (\mathbb{R}^n)^* \otimes (\mathbb{R}^n)^* \\ T_1^1 M &= TM \otimes T^*M && \text{with fiber } (\mathbb{R}^n) \otimes (\mathbb{R}^n)^* \\ A^2 M &= T^*M \wedge T^*M && \text{with fiber } (\mathbb{R}^n)^* \wedge (\mathbb{R}^n)^* \end{aligned}$$

It is clear enough how to get more factors with $\otimes$; less clear is how to get $A^{r+s}M$ from $A^r M$ and $A^s M$. We use the alternating operator (hence the A in $A^2 M$)

$$A_k : F^* \otimes F^* \otimes \cdots \otimes F^* \to A^k F^* : w \mapsto w_A$$

where

$$\begin{aligned} w_A &: F \times F \times \cdots \times F \to \mathbb{R} : (v_1, \ldots, v_k) \\ &\mapsto \frac{1}{k!} \sum_\tau \operatorname{sgn}(\tau) w\big(v_{\tau(1)}, v_{\tau(2)}, \ldots, v_{\tau(k)}\big) \end{aligned}$$

τ runs over all $k!$ permutations of $\{1, 2, \ldots, k\}$, and $\operatorname{sgn}(\tau)$ is ± 1 according as τ is an even or an odd permutation. Then we can define

$$\begin{aligned} (A^r F^*) \wedge (A^s F^*) &= A^{r+s} F^* \\ &= A_{r+s}(A^r F^* \otimes A^s F^*) \end{aligned}$$

which agrees with what we gave before for $r = s = 1$, and the exterior product turns out to be associative and distributive but anticommutative:

$$w \wedge v = (-1)^{rs} v \wedge w, \quad w \in A^r F^*, \quad v \in A^s F^*$$

It follows that if $\dim F = \dim F^* = n$ then

$$\dim A^r F^* = \binom{n}{r} = \frac{n!}{(n-r)!r!}$$

and therefore

$$\dim A^r F^* = \binom{n}{r} = \binom{n}{n-r} = \dim A^{n-r} F^*$$

so in particular

$$\begin{aligned} \dim A^n F^* &= \dim A^0 F^* = 1 \\ \dim A^k F^* &= 0 \quad \text{for } k > n \end{aligned}$$

All of this exterior algebra can be carried over to apply smoothly over a manifold M and hence give rise to $A^r M$, the alternating tensor bundles of differential r-forms or r-form bundles. The collection of all r-forms for all $r = 0, 1, \ldots$ on an n-manifold M is denoted ΛM and the exterior product gives ΛM the structure of a Grassmann or exterior algebra. The collection of all r-forms on M is denoted $\Lambda^r M$ so ΛM is the disjoint union of these over all $r = 0, 1, \ldots$. We call the $T_s^r M$ the tensor bundles and we usually adopt the conventional notation

$$T_0^0 M = A^0 M = M \times \mathbb{R}$$

for the trivial product vector bundle with fiber $\mathbb{R}^1$ over M. Much of general geometry and its applications is concerned with sections of these bundles. For example, we may point out that

1. A metric structure is determined by a section of $T_2^0 M$.
2. A connection (i.e., parallelism) structure is determined by a section of $A^2 M$.
3. Curvature of a connection is determined by a section of $T_3^1 M$.
4. On an n-dimensional configuration space of particles: the kinetic energy is a section of $T_2^0 M$ and the Lagrangian is a section of $A^n M$.

Notation

It is important to distinguish between a bundles $X \twoheadrightarrow M$ over M and its space of sections, which sometimes is denoted $\chi(X)$ or $\Gamma(X)$. However, it is common to speak of, for example, the bundle $A^r M$ of r-forms on M when properly $A^r M \xrightarrow{p} M$ is the bundle and the collection of its sections is quite different, denoted $\Lambda^r M$ by us; precisely

$$\Lambda^r M = \{\text{smooth } w\colon M \to A^r M \mid pw = 1_M\}$$

Similarly, we use $\Upsilon_s^r M$ to denote the collection of all sections of $T_s^r M$, that is, the (r, s)-tensor fields:

$$\Upsilon_s^r M = \left\{\text{smooth } v\colon M \to T_s^r M \;\middle|\; pv = 1_M\right\}$$

D. Manifolds with Boundary

The alert reader may have noticed that our definition of an n-manifold disqualifies, for example, a unit cylinder and the closed unit disk from being 2-manifolds. They simply fail to be locally like E^2 at their boundary edges; instead the edge points are homeomorphic to half-spaces like

$$\{(x, y) \in E^2 \mid y \geqq 0\}$$

Evidently such entities are likely to be needed in geometry and physics, so we shall allow such edge points in future. Spaces that have them are called *manifolds with boundary* and we shall denote the boundary of such an M by ∂M. In fact, if M is an n-manifold then ∂M is an $(n-1)$-manifold.

EXAMPLES

a. $M = \{x \in \mathbb{R}^3 \mid \|x\| \leqq 1\} =$ closed 3-ball B^3
   $\partial M = \{x \in \mathbb{R}^3 \mid \|x\| = 1\} \simeq$ 2-sphere S^2
b. Similarly, $\partial B^n \simeq S^{n-1}$ for $n \leq 1$
c. $M = [0, 1] \times S^1 =$ unit cylinder
   $\partial M = [0] \times S^1 \cup \{1\} \times S^1 \simeq$ two disjoint circles

IV. CALCULUS OF SECTIONS

A. Module of Sections

Intuitively we viewed a section of a bundle X over M as a copy of M lifted vertically up into the manifold X in such a way that each point of M goes to the fiber over itself. For this to be possible at all we need the projection of X to be surjective onto M; this we denote by $X \xrightarrow{p} M$. In a precise technical sense a section $\sigma\colon M \to X$ is actually a lift of the identity map $1_M\colon M \to M$ since we want Fig. 3 commuting, namely such that $p(\sigma(x)) = x$, that is, $\sigma(x) \in p^{\leftarrow}\{x\}$ for all $x \in M$. Vector bundles always have one smooth such section, the zero section which sends each $x \in M$ to the zero vector in the fiber $p^{\leftarrow}\{x\}$. Some vector bundles (e.g., the trivial product bundles) have a full set of linearly independent sections; such sections, of course, can never cross the zero section. Other vector bundles (e.g., the Möbius bundle over the circle, or TS^2, the tangent bundle to the ordinary sphere) do not have even one continuous section that never meets the zero section.

The fact that sections take values in fibers means that over any point in M we may use available algebraic structure in the fiber on sections passing through it. Now, the fibers are joined smoothly together, so not surprisingly we find that their algebraic structures change, but only smoothly, so we can apply much of the algebra to sections themselves. In particular, the set of sections of a vector bundle over a manifold is a vector space (infinite-dimensional) with pointwise addition and multiplication by numbers in each fiber. Furthermore, we can actually allow multiplication by numbers that vary smoothly from point to point, that is by sections of the trivial scalar bundle; this means that the set of sections of a vector bundle over a manifold is a module over the *ring* of smooth scalar-valued maps on the manifold. Thus, if σ, τ are two sections of the real vector bundle $X \twoheadrightarrow M$ and $\lambda\colon M \to \mathbb{R}$ is a smooth map, then also $\sigma + \tau$ and $\lambda\sigma$ are sections of $X \twoheadrightarrow M$ with

$$\sigma + \tau\colon M \to X : x \to \sigma(x) + \tau(x)$$

$$\lambda\sigma\colon M \to X : x \to \lambda(x)\sigma(x)$$

Much of geometrical analysis and its applications depend on the study of sections of the tensor bundles; these

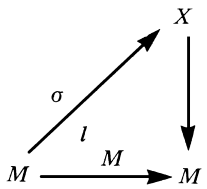

FIGURE 3 Commutative diagram for a section.

are the tensor fields. As we have seen, they are built up from sections of the tangent and cotangent bundles via the tensor product. Accordingly, we shall begin by a study of tangent and cotangent vector fields.

B. Tangent Vector Fields

From the canonical structure of TM inherent in the differentiable structure on an n-manifold M, it turns out that for each chart

$$\phi\colon U \to E^n : x \mapsto (x_1, x_2, \ldots, x_n)_x$$

the tangent space $T_x M$ has a basis $(\partial_1, \partial_2, \ldots, \partial_n)_x$, where each ∂_i is the partial differential operator $\partial/\partial x_i$ for real functions defined on neighborhoods of $\phi(x)$. Hence, for all tangent vector fields $\sigma\colon M \to TM$, on the domain of such a chart, σ appears in the form

$$\sigma\colon U \to TM : x \mapsto \left(\sigma^1\partial_1 + \sigma^1\partial_2 + \cdots + \sigma^n\partial_n\right)_x$$

with each σ^i a real function on U. A change of chart induces a change of basis and corresponding change of components of σ, both in agreement with the usual transformation law for partial derivatives. Viewing ΥM, the space of sections of TM, as a module, it is convenient to think of the map $x \mapsto (\partial_1, \partial_2, \ldots, \partial_n)_x$ as giving a basis for this module in the neighborhood U of x.

EXAMPLE. Let $M = S^2$ be the unit sphere in $\mathbb{R}^3$, explicitly:

$$M = \{(x, y, z) \in \mathbb{R}^3 \mid x^2 + y^2 + z^2 = 1\}$$

Define two charts (U, ϕ), $(V, \tilde{\phi})$ for

$$U = \{(x, y, z) \in M \mid z > 0\}$$
(the "northern hemisphere")
$$V = \{(x, y, z) \in M \mid x > 0\}$$
(the "eastern hemisphere")

by

$$\phi\colon U \to \mathbb{R}^2\colon (\mathrm{x}, \mathrm{y}, \mathrm{z}) \mapsto (x, y) = (x_1, x_2), \text{ say}$$
$$\tilde{\phi}\colon V \to \mathbb{R}^2 : (\mathrm{x}, \mathrm{y}, \mathrm{z}) \mapsto (y, z) = (\tilde{x}_1, \tilde{x}_2), \text{ say}$$

Then on $U \cap V = \{(x, y, z) \in M \mid x > 0, z > 0\}$ (the NE quadrant) we have alternative coordinates: the (x_i) or the $(\tilde{x}_i)$. These determine corresponding local basis sections:

$$(\partial_1, \partial_2) = \left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}\right)$$
$$(\tilde{\partial}_1, \tilde{\partial}_2) = \left(\frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right)$$

Evidently these are related (invertibly) by

$$\tilde{\partial}_1 = \partial_2 \qquad \text{and} \qquad \tilde{\partial}_2 = \frac{\partial x}{\partial z}\partial_1 + \frac{\partial y}{\partial z}\partial_2$$

with $x = (1 - y^2 - z^2)^{1/2}$ and $y = (1 - x^2 - z^2)^{1/2}$. Also on $U \cap V$, we could introduce angular coordinates by, say,

$$\tilde{\phi}\colon U \cap V \to \mathbb{R}^2 : (\mathrm{x}, \mathrm{y}, \mathrm{z}) \to (\theta, \psi) = (\hat{x}_1, \hat{x}_2)$$

where θ and ψ are the angles defined by

$$\left.\begin{aligned} x &= \cos\psi\cos\theta \\ y &= \cos\psi\sin\theta \\ z &= \sin\psi \end{aligned}\right\} \begin{array}{l} \text{so } \psi = 0 \text{ on the equator and } \pi/2 \text{ at} \\ \quad \text{the north pole} \\ \text{and } \theta = 0 \text{ in the positive } x \text{ direction} \\ \theta = \pm\pi/2 \text{ in the } \pm y \text{ directions} \end{array}$$

Again we get a local basis section

$$(\hat{\partial}_1, \hat{\partial}_2) = \left(\frac{\partial}{\partial\theta}, \frac{\partial}{\partial\psi}\right)$$

which is related to the original choice (∂_1, ∂_2) by

$$\hat{\partial}_1 = \frac{\partial x}{\partial\theta}\partial_1 + \frac{\partial}{\partial\theta}$$
$$\hat{\partial}_2 = \frac{\partial x}{\partial\psi}\partial_1 + \frac{\partial y}{\partial\psi}\partial_2$$

In fact, if we wish to exploit the sphericity of S^2 then the chart with (θ, ψ) coordinates is very convenient. For instance,

$$U \cap V \to TM : (\theta, \psi) \mapsto \cos\psi\,\hat{\partial}_1$$

locally models an east–west wind on the earth, decaying from the equator to the north pole. Similarly,

$$U \cap V \to TM : (\theta, \psi) \mapsto -\cos\psi\,\hat{\partial}_2$$

models a north wind.

A local flow about $x_0 \in M$ for a vector field v on M is a map for some neighborhood U of x_0 and positive ε,

$$\Phi\colon U \times (-\varepsilon, \varepsilon) \to M$$

such that $(\forall x \in U)$

a. $\Phi(x, 0) = x$.
b. $c_x\colon (-\varepsilon, \varepsilon) \to M : t \mapsto \Phi(x, t)$ is a curve with tangent vector $\dot{c}_x(t) = v(c(t))$.

Intuitively we think of Φ as a family of curves that "join up the arrows" of the vector field v. We call each curve c_x an integral curve of v through x.

EXAMPLE. Take U, V, and M as in the previous example. Then a local flow on S^2 for the vector field

$$v\colon U \cap V \to TS^2 : (\theta, \psi) \mapsto \cos\psi\,\hat{\partial}_2$$

is given by

$$\Phi\colon U\cap V\times(-\varepsilon,\varepsilon)\to M:(\theta,\psi,t)\mapsto(\alpha(t),\beta(t))$$

where the real functions, α, β must satisfy

$$\frac{d\alpha}{dt}=\cos\psi,\qquad \frac{d\beta}{dt}=0$$
$$(\alpha(0),\beta(0))=(\theta,\psi)$$

Hence $\alpha(t)=\theta+t\cos\psi$, $\beta(t)=\psi$, and the integral curves are parts of circles of latitude. There is a nice existence and uniqueness theorem for smooth local flows of smooth vector fields on manifolds. It says that through each point there is one and only one integral curve and $\Phi_t\colon x\mapsto\Phi(x,t)$ satisfies $\Phi_{t+s}=\Phi_t\circ\Phi_s$ when t,s, $(t+s)\in(-\varepsilon,\varepsilon)$. For our flow on S^2 this is satisfied for small enough s,t since $\Phi_t\colon(\theta,\psi)\mapsto\theta+t\cos\psi$. Moreover, each Φ_t *is a diffeomorphism* from U to $\Phi_i U$.

EXAMPLE. To find integral curves and hence a local flow for a vector field. We consider $M=E^2$ with its standard chart. Take the vector field

$$v\colon E^2\to TE^2:(x,y)\mapsto\partial_x+x^2\partial_y$$

It is often convenient to use (x,y) as coordinate labels instead of (x^1,x^2); then we denote their induced basis fields by $\partial_x=\partial_1$ and $\partial_y=\partial_2$. We take the open subset of E^2 given by

$$U=\left\{(x,y)\in E^2\mid|x+1|<\tfrac14,|y|<\tfrac14\right\}$$

We seek for each $a\in U$ an integral curve

$$c_a\colon\left(-\tfrac12,\tfrac12\right)\to E^2$$
$$\text{with } c_a(0)=a \text{ and } \dot c_a(t)=v(c_a(t))$$

The differential equation expands into

$$\dot c_a(t)=\dot c^1(t)\,\partial_x+\dot c^2(t)\,\partial_y=\partial_x+(c^1(t))^2\,\partial_y$$

Hence $\dot c^1(t)=1$ and $\dot c^2(t)=(c^1(t))^2$. Therefore $c^1(t)=k+t$ and $c^2(t)=\frac13(k+t)^3+l$. Taking $a=(\alpha,\beta)$ as the initial point, we find

$$c_a(t)=\left(\alpha+t,\beta-\tfrac13\alpha^3+\tfrac13(\alpha+t)^3\right)$$

Accordingly, the local flow is given by

$$\Phi_s\colon(\alpha,\beta)\mapsto\left(\alpha+s,\beta-\tfrac13\alpha^3+\tfrac13(\alpha+s)^3\right)$$

and we easily check that

$$\Phi_{t+s}=\Phi_t\Phi_s\colon(\alpha,\beta)\mapsto\left(\alpha+s+t,\ \beta-\tfrac13\alpha^3+\tfrac13(\alpha+s+t)^3\right)$$

C. Cotangent Vector Fields

Given an n-manifold M and a chart

$$\Phi\colon U\to E^n:x\mapsto(x_1,x_2,\ldots,x_n)_x$$

we obtain a set of local tangent vector fields

$$\partial_i\colon U\to TU:x\mapsto(\partial_i)_x\quad i=1,2,\ldots,n$$

that generate all tangent vector fields over U. Now, an element of T^*M is a dual vector to some tangent vector on M, that is, an element of

$$(T_xM)^*=L(T_xM;\mathbb{R})\quad\text{for some } x\in M$$

Also, if $(b_1,\ldots,b_n)$ is a basis for T_xM then it is easy to show that $(c^1,\ldots,c^n)$ is a basis for $(T_xM)^*$ with

$$c^j\colon T_xM\to\mathbb{R}:\lambda_1b_1+\cdots+\lambda_nb_n\mapsto\lambda_j\qquad j=1,2,\ldots,n$$

Hence in terms of the Kronecker symbol

$$c^j(b_i)=\delta_i^j=\begin{cases}1 & \text{if } i=j,\quad i,j=1,2,\ldots,n\\ 0 & \text{if } i\neq j\end{cases}$$

and we call $(c^1,\ldots,c^n)$ the *dual basis* to the basis $(b_1,\ldots,b_n)$. Clearly we can extend this process to the fields $(\partial_1,\ldots,\partial_n)$ and obtain their duals $(dx^1,\ldots,dx^n)$ with

$$dx^j(\partial_i)=\delta_i^j,\quad i,j=1,2,\ldots,n$$

This notation is standard and should not be confused with the unfortunate usage of dx^j in older texts to mean a small increment in coordinate x^j. The correct way to view any df is as the gradient of a real-valued function f on M. With respect to our chart diffeomorphism

$$\Phi\colon U\to E^n:x\mapsto(x_1,\ldots,x_n)_x$$

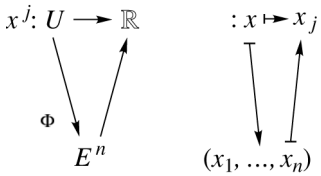
we get a restriction of f to U. Now we define

$$df\colon U\to T^*M:x\mapsto\left(f_1\,dx^1+\cdots+f_n\,dx^n\right)_x$$

where for each $i=1,\ldots,n$

$$f_i\colon E^n\to\mathbb{R}:(x_1,\ldots,x_n)\mapsto\frac{\partial f\circ\Phi^{-1}}{\partial x^i}$$

So in particular if we choose f to be x^j, that is,



then

$$dx^j\colon U\to T^*M:x\mapsto\left(\frac{\partial x_j}{\partial x_1}dx^1+\cdots+\frac{\partial x_j}{\partial x_n}dx^n\right)_x$$

But $\partial x^j/\partial x^i=\delta_i^j$ so $dx^j(x)=(dx^j)_x$, $j=1,2,\ldots,n$.

We have been careful so far to put subscript x on various entities to indicate that they vary with x. This is not always necessary and where it is clear whether we mean, for instance, a vector at x or a field about x, we shall omit such subscripts. There is another very useful notational trick: the summation convention attributed to Einstein. This is simply to sum over repeated upper and lower indices. For example, if A is an $n \times n$ matrix with entries a^i_j then we can write trace $A = a^i_i$. Thus the identity matrix has entries δ^i_j and its trace is $\delta^i_i = n$. We shall use the same convention with more than one symbol present, for instance,

$$\begin{aligned} f_1\,dx^1 + f_2\,dx^2 + \cdots + f_n\,dx^n &= f_i\,dx^i \\ v^1\partial_1 + v^2\,\partial_2 + \cdots + v^n\,\partial_n &= v^i\,\partial_i \\ h^{11}\,\partial_1 \otimes \partial_1 + h^{12}\,\partial_1 \otimes \partial_2 + \cdots + h^{nn}\,\partial_n \otimes \partial_n & \\ = h^{ij}\,\partial_i \otimes \partial_j & \end{aligned}$$

D. Commutator or Lie Bracket

Given two tangent vector fields u, v with expressions $u = u^i\,\partial_i$ and $v = v^j\,\partial_j$ in terms of local partial derivatives defined by some chart (U, Φ), then we obtain their commutator vector field

$$[u, v]\colon U \to TM : x \mapsto \left(u^i \partial_i v^j - v^i \partial_i u^j\right)\partial_j$$

Independently of any chart we can define the commutator through its action as a derivation on any smooth real function $f\colon M \to \mathbb{R}$ by

$$[u, v](f) = u(v(f)) - v(u(f))$$

A feel for what the commutator measures can be obtained by examining the flows of u and v. Suppose that these flows are, respectively, Φ and Ψ with

$$\begin{aligned} \Phi_t\colon U &\to M : x \mapsto \Phi(x, t) \\ \Psi_s\colon U &\to M : x \mapsto \Psi(x, s) \end{aligned}$$

Then it turns out that on U

$$\begin{aligned} \Phi_i \circ \Psi_s &= \Psi_s \circ \Phi_t \\ \text{if and only if } [u, v] &= \mathbf{0} \end{aligned}$$

Thus, $[u, v]$ measures the failure of the two flows to commute. It follows all vector fields v satisfy the self commuting property

$$[v, v] = \mathbf{0}$$

then the flow Φ of V reflects this in the identity $\Phi_t \circ \Phi_s = \Phi_s \circ \Phi_t = \Phi_{s+t}$ wherever all are defined on U.

E. Products of Fields

We have seen how $\otimes$ and $\oplus$ can be used in vector spaces, and it is easy to see how these operations can be performed smoothly over a manifold, so giving corresponding products on fields. Locally with respect to some chart $\phi\colon U \to E^n$, suppose that we have basis fields $\{\partial_1, \ldots, \partial_n\}$ for tangent and $\{dx^1, \ldots, dx^n\}$ for cotangent vector fields. Then we obtain, for example, the basis fields

$$\begin{aligned} &\{\partial_i \otimes \partial_j \mid i, j = 1, \ldots, n\} && \text{for } T^2_0 U \\ &\{dx^i \otimes dx^j \mid i, j = 1, \ldots, n\} && \text{for } T^0_2 U \\ &\{dx^i \wedge dx^j \mid 1 \leqq i < j \leqq n\} && \text{for } \Lambda^2 U \\ &\left\{dx^{i_1} \wedge dx^{i_2} \wedge \ldots \wedge dx^{i_r} \mid \right. \\ &\quad \left. 1 \leqq i_1 < i_2 < \ldots < i_r \leqq n\right\} && \text{for } \Lambda^r U \end{aligned}$$

To accommodate the structure of such spaces as $\Lambda^r U$ we modify the summation convention by enclosing the lower set of repeated indices in brackets to indicate that the summation is only over increasing sequences. Thus, for example, we would write for $w \in \Lambda^2 E^3$

$$\begin{aligned} w &= w_{12}\,dx^1 \wedge dx^2 + w_{13}\,dx^1 \wedge dx^3 + w_{23}\,dx^2 \wedge dx^3 \\ &= w_{(ij)}\,dx^i \wedge dx^j \end{aligned}$$

EXAMPLE. Consider the simple case $M = E^2$. Then we can illustrate two important fields with respect to the standard chart.

(1) $g\colon M \to T^0_2 M : (x_1, x_2) \mapsto \delta_{ij}\,dx^i \otimes dx^j$,

$$\delta_{ij} = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

This defines the usual metric structure on E^2, that is, the standard dot product on each tangent space $T_x M$:

$$\begin{aligned} g\left(u^k\,\partial_k, v^m\,\partial_m\right) &= \delta_{ij}\,dx^i \otimes dx^j\left(u^k\,\partial_k, v^m\,\partial_m\right) \\ &= \delta_{ij}\,u^k v^m\,dx^i \otimes dx^j(\partial_k, \partial_m) \\ &= \delta_{ij}\,u^k v^m\,\delta^i_k\,\delta^j_m \\ &= \delta_{ij}\,u^i v^j = u^1 v^1 + u^2 v^2 \end{aligned}$$

(2) $\omega\colon M \to \Lambda^2 M : (x_1, x_2) \mapsto dx^1 \wedge dx^2$

This defines the usual geometrical measure on E^2, that is, the standard parallelogram area mapped out by pairs of vectors in each tangent space $T_x M$:

$$\begin{aligned} \omega\left(u^k\,\partial_k, v^m\,\partial_m\right) &= \tfrac{1}{2}(dx^1 \otimes dx^2 - dx^2 \otimes dx^1) \\ &\quad \times\left(u^k\,\partial_k, v^m\,\partial_m\right) \\ &= \tfrac{1}{2}(u^1 v^2 - u^2 v^1) \end{aligned}$$

Both (1) and (2) generalize to E^n: g has the same form but we sum over $i, j = 1, \ldots, n$; $\omega = dx^1 \wedge \ldots \wedge dx^n$. Any change of chart induces corresponding changes in their local expressions.

F. Exterior Derivative

There is an extraordinarily useful derivative on differential forms defined locally by

$$\begin{aligned} d\colon \Lambda^r M &\to \Lambda^{r+1} M \\ \colon w_{(i_1\ldots i_r)} dx^{i_1} \wedge \ldots \wedge dx^{i_r} &\mapsto dw_{(i_1\ldots i_r)} \\ & \quad dx^{i_1} \wedge \ldots \wedge dx^{i_r} \end{aligned}$$

where $dw_{i_1\ldots i_r} = \partial_j w_{i_1\ldots i_r}\, dx^j$, the gradient of the component function. Surprisingly, this exterior derivative d is uniquely determined by the requirements:

a. $d\colon \Lambda^r M \to \Lambda^{r+1} M$ linearly
b. $d\colon \Lambda^0 M \to \Lambda^1 M : f \mapsto df$
c. $w \in \Lambda^r M$, $v \in \Lambda^s M$
$\Rightarrow d(w \wedge v) = dw \wedge v + (-1)^r w \wedge dv$
d. $d^2 = 0$

Here of course we are using $\Lambda^r M$ to denote the space of sections of the bundle.

EXAMPLE. For a real function $f \in \Lambda^0 M$, with respect to some chart

$$\begin{aligned} df &= \partial_i f\, dx^i \in \Lambda^1 M \\ d^2 f &= d(\partial_i f) \wedge dx^i \\ &= \partial_j \partial_i f\, dx^j \wedge dx^i \\ &= 0 \quad \text{since } \partial_j \partial_i f = \partial_i \partial_j r \end{aligned}$$

It is precisely $d^2 = 0$ when applied to $M = E^3$ that gives the familiar identities of ordinary vector calculus:

$$\begin{aligned} \text{curl grad } f &= 0 \\ \text{div curl } v &= 0 \end{aligned}$$

Now, we know that on an n-manifold M, $\Upsilon^* M = A^1 M$ is modeled on $(\mathbb{R}^n)^*$, which has dimension n. Hence, for $r > n$, $\Lambda^r M$ contains only zero forms. Accordingly, the exterior derivative determines a chain complex of the spaces of forms viewed as modules over real functions:

$$\begin{array}{ccccccccccc} 0 \to & \Lambda^0 M & \xrightarrow{d} & \Lambda^1 M & \xrightarrow{d} & \Lambda^2 M & \to \cdots \to & \Lambda^n M & \xrightarrow{d} & 0 \\ & \| & & \| & & & & & & \\ & M \times \mathbb{R} & & \Upsilon_1^0 M & & & & & & \end{array}$$

We always denote the zero module by 0. Properly, we should put indices on each d to indicate its domain, but often they are omitted. At each stage in all such sequences of structure-preserving maps we have a standard terminology, which can be illustrated in Fig. 4. In $\Lambda^r M$ we have two distinguished substructures:

1. r-forms sent to zero in $\Lambda^{r+1} M$, the *kernel* of

$$d\colon \Lambda^r M \to \Lambda^{r+1} M$$

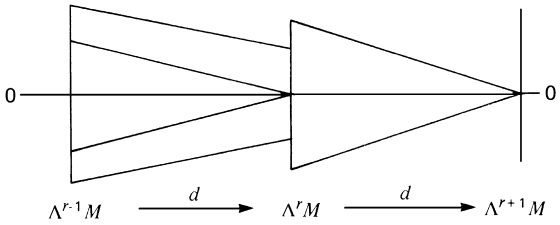


FIGURE 4 Chain complex of modules.

2. r-forms arriving from $\Lambda^{r-1} M$, the *image* of

$$d\colon \Lambda^{r-1} M \to \Lambda^r M$$

We usually abbreviate those to $\ker d$ and $\text{im } d$, and if we wish to emphasize precisely where they come from we write

$$\ker d = Z^r(M, d) \quad \text{and} \quad \text{im } d = B^r(M, d)$$

Note that it is a consequence of $d^2 = 0$ that

$$B^r(M, d) \subseteq Z^r(M, d)$$

and a consequence of the linearity of d that $B^r(M, d)$ is a submodule of $Z^r(M, d)$ and both are submodules of $\Lambda^r M$. When equality occurs we say that the sequence is exact at $\Lambda^r M$; this means that

$$\text{if } dw = 0 \text{ then } w = dv \text{ for some } v \in \Lambda^{r-1} M$$

There is a standard way to compare submodules of a module; just as for subgroups of groups and linear subspaces of vector spaces, we can take the quotient

$$H^r(M, d) = Z^r(M, d)/B^r(M, d)$$

We call $H^r(M, d)$ the rth de Rham cohomology module of M. Amazingly, it gives information about the connectivity of M by indicating the presence of $(r+1)$-dimensional holes.

EXAMPLE. To get a feel for the quotienting process, suppose that $\Lambda^r M$ looks like $\mathbb{R}^4$ and that

$$Z^r(M, d) \text{ is the 3-dimensional subspace } \mathbb{R}^3$$

$$B^r(M, d) \text{ is the } (x, y) \text{ plane in } Z^r(M, d)$$

Then

$$\begin{aligned} H^r(M, d) &= Z^r(M, d)/B^r(M, d) \\ &= \{[(x, y, z)]\} \end{aligned}$$

where $[(x, y, z)] = \{(x, y, z) \in Z^r(M, d) \mid (x, y) \in B^r(M, d)\}$. Hence $H^r(M, d)$ has one point, $[(x, y, z)]$, for each value of z and therefore is isomorphic to $\mathbb{R}^1$. Geometrically we view the quotient of $\mathbb{R}^3$ by its (x, y) subspace as the space consisting of all planes parallel to the (x, y) plane. That is, we stop distinguishing between points in the same horizontal plane; the set of such planes is isomorphic to $\mathbb{R}^1$, the z axis in $\mathbb{R}^3$.

G. Cohomology and Exactness

There are some special cases for an n-manifold M:

a. $B^0(M,d)=0$, so $H^0(M,d)\simeq Z^0(M,d)\simeq\mathbb{R}^1$ (constant f) if M is connected.
b. $Z^n(M,d)=0$, so $H^n(M,d)=0$.
c. If $Z^r(M,d)=B^r(M,d)$ then $H^r(M,d)=0$.

The cohomology module $H^r(M,d)$ measures departure from exactness of d at $\Lambda^r M$. There are traditional names for elements:

$Z^r(M,d)$ consists of *closed* r-forms, w with $dw=0$
$B^r(M,d)$ consists of *exact* r-forms, w with $w=dv$

From the quotient process it turns out that

$$u\in H^r(M,d)\Rightarrow u=w+B^r(M,d)$$

for some

$$w\in Z^r(M,d)$$

that is: two equivalent representatives of u in $Z^r(M,d)$ differ only by some $dv\in B^r(M,d)$.

A famous result of Poincaré is the following:

$$\text{if } M\simeq E^n \text{ then } H^k(M,d)=0 \text{ for all } k>0$$

Intuitively, there are no holes in Euclidean space or in any manifold that is diffeomorphic to it.

The dimension of $H^r(M,d)$ is called the rth Betti number of M; it is a topological invariant, so two manifolds that are homeomorphic (not necessarily diffeomorphic) have the same Betti numbers. The Betti numbers are finite for compact manifolds M and then they determine the Euler characteristic

$$\chi(M)=\sum_{r=0}^{\dim M}(-1)^r\dim H^r(M,d)$$

which, like the Betti numbers, can be computed by algebraic topological methods.

EXAMPLE. Take $M=S^1$, the unit circle. This is connected, so we find $H^0(S^1,d)\simeq\mathbb{R}^1$, and it is one-dimensional, so $H^r(S^1,d)=0$ for $r\geqq 2$. We find $H^1(S^1,d)$; intuitively, it should not be zero because S^1 actually surrounds a two-dimensional hole.

$$0\to\Lambda^0S^1\xrightarrow{d}\Lambda^1S^1\to 0$$

$$H^1(S^1,d)=Z^1(S^1,d)/B^1(S^1,d)$$

But $Z^1(S^1,d)=\Lambda^1S^1=\{\text{smooth } w\colon S^1\to A^1S^1=T^*S^1\}$ and $B^1(S^1,d)=\{df\mid f\in\Lambda^0S^1=\text{smoot maps } S^1\to\mathbb{R}\}$. Hence

$$H^1(S^1,d)=\{w+B^1(S^1,d)\mid w\in\Lambda^1S^1\}$$

Now Λ^1S^1 is generated by any nowhere-zero section of A^1S^1. Denote by δ^1 the element of TS^1 defined by using an angle θ for coordinate on S^1. (Properly our coordinates should take values in $\mathbb{R}^1$ but we identify 0 and 2π to save using two charts explicitly.) Let ω be the dual of δ_1; then ω is nowhere zero because δ_1 is nowhere zero. Also, by definition, for any $h\partial_1\in\Upsilon S^1$

$$\omega(h\partial_1)=h\quad\text{since }\omega(\partial_1)=1$$

Hence, any 1-form v on S^1 is given by

$$v\colon S^1\to A^1S^1:\theta\mapsto\lambda(\theta)\omega$$

for some real function λ.

Now ω is not exact (though a common notation for it is $d\theta$) since it is not the differential of any smooth real function. For suppose $\omega=df$, then we require $df(\partial_1)=1$ and hence

$$f\colon S^1\to\mathbb{R}:\theta\mapsto f(\theta)$$

must be continuous and smooth with $df/d\theta=1$ everywhere. Apparently $f(\theta)=\theta$ would satisfy this differential equation, but the problem is $f(0)\neq f(2\pi)$ so it is not continuous. Therefore $\omega+B^1(S^1,d)$ generates $H^1(S^1,d)$ and so

$$H^1(S^1,d)\simeq\mathbb{R}^1$$

which has dimension 1, corresponding to one 2-hole in S^1.

H. Derivatives of Smooth Maps

A smooth map $f\colon M\to M'$ between two manifolds preserves smooth things. Now, since the prototypes of smooth things are the tangent structures, it is not surprising that such a map induces a smooth map, the derivative of f between the tangent bundles; we denote it by $Df\colon TM\to TM'$, though sometimes Df is written Tf. This smooth map is actually between two fiber bundles so, as we would wish, it preserves fibers; moreover, since tangent bundles are vector bundles it is actually linear between tangent spaces. Hence at each $x\in M$, Df restricted to T_xM is a linear map

$$\begin{array}{ccc} D_xf\colon T_xM & \longrightarrow & T_{f(x)}M' \\ \simeq & & \simeq \\ \mathbb{R}^n & \xrightarrow[[f_{ij}]]{} & \mathbb{R}^m \end{array}$$

which, on choosing charts about x and $f(x)$, appears locally as the Jacobian matrix $[f_{ij}]$ of partial derivatives of components of f with respect to coordinates at x. As always, there is a dual to the linear map D_xF, going the other way:

$$\begin{array}{ccc} D_x F^*\colon T_{f(x)}M^* & \longrightarrow & T_x M^* \\ \simeq & & \simeq \\ \mathbb{R}^m & \xrightarrow[[f_{ij}]^t]{} & \mathbb{R}^n \end{array}$$

and its corresponding matrix representative is just the transpose of that for $D_x f$. As with the $D_x f$, their duals fit together smoothly to give a vector bundle map $(Df)^*\colon T^*M' \to T^*M$.

From Df and $(Df)^*$ it is easy to obtain induced vector bundle maps for all of the tensor bundles. So

$$\text{smooth } f\colon M \to M' \Rightarrow \text{smooth } \begin{cases} D_s^r f\colon T_s^r M \to T_s^r M' \\ \Lambda^r f\colon A^r M' \to A^r M \end{cases}$$

We often abbreviate $D_s^r f$ to f_* and $A^r f$ to f^* when we apply them to sections of these bundles.

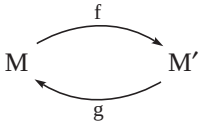
It is of fundamental importance that

$$f^*\colon \Lambda^r M' \to \Lambda^r M \qquad \begin{array}{l}\text{preserves closedness and} \\ \text{exactness of } r\text{-forms}\end{array}$$

In consequence f^* induces a linear map on cohomology:

$$H^r(f^*)\colon H^r(M', d) \to H^r(M, d)$$

Now certainly if f has a smooth inverse (i.e., f is a diffeomorphism) then each $D_x f$ and $(D_x f)^*$ would be an isomorphism and we would expect f^* to be an isomorphism of modules giving an isomorphism in cohomology. In fact, $H^r(f^*)$ is an isomorphism if f is any "smooth deformation" of a diffeomorphism. Precisely, M and M' will have the same cohomology if they have the same homotopy type, that is, if there are smooth maps such that $g \circ f$ can be smoothly deformed into (is *homotopic to*) the identity 1_M and $f \circ g$ is similarly homotopic to $1_{M'}$. The allowed smooth deformations are contracting or stretching, but without cutting or joining or introducing any holes or corners.



Having the same cohomology obviously means having the same Betti numbers.

EXAMPLE. S^1 and the punctured plane $\mathbb{R}^2\backslash\{(0,0)\}$ are of the same homotopy type because we have

$$f\colon S^1 \to \mathbb{R}^2\backslash\{(0,0)\} : x \mapsto x$$
$$g\colon \mathbb{R}^2\backslash\{(0,0)\} \to S^1 : x \mapsto x/\|x\| \quad \text{(usual norm)}$$

Then $g \circ f : S^1 \to S^1 : x \mapsto x$ is the identity. Also

$$f \circ g\colon \mathbb{R}^2\backslash\{(0,0)\} \to \mathbb{R}^2\backslash\{(0,0)\} : x \mapsto x/\|x\|$$

is a smooth deformation of the identity by the homotopy

$$F_t : \mathbb{R}^2\backslash\{(0,0)\} \to \mathbb{R}^2\backslash\{(0,0)\}$$
$$: x \mapsto (1-t)x + tx/\|x\|$$

Evidently, F_0 is the identity on $\mathbb{R}^2\backslash\{(0,0)\}$, F_1 is $f \circ g$, and F_t varies smoothly with t in the interval $[0, 1]$. In fact, the same homotopy holds good for the same map between S^n and $\mathbb{R}^{n+1}\backslash\{(0,0)\}$ ($\mathbb{R}^{n+1}$ with the origin removed). We conclude that for $0 \leqq r \leqq n$

$$H^r(S^n, d) \simeq H^r(\mathbb{R}^{n+1}\backslash\{(0,0)\}, d) \quad \text{for } n \geqq 1$$

I. Using Cohomology Data

We saw previously that $H^1(S^1, d) \simeq \mathbb{R}^1$, since there is a closed 1-form that is not exact; we now know that there must also be a closed 1-form that is not exact on the punctured plane. Equivalently, there is a smooth vector field that is not the gradient of any function, for example, rotation about the origin with velocity proportional to distance from the origin.

Table I gives the nonzero de Rham cohomology of some familiar spaces. Each entry indicates the dimension of the corresponding module of nonexact closed forms. Recall that we agreed to allow manifolds with boundary.

We can immediately infer the following, for example:

1. On a torus $S^1 \times S^1$ we can find $u, v \in \Lambda^1(S^1 \times S^1)$ such that u and v are independently directed cotangent fields and neither is a gradient field; moreover, there exists $w \in \Lambda^2(S^1 \times S^1)$ that is not

TABLE I Betti Number of Some Familiar Spaces

Space M	Dimension of $H^r(M, d)$ (Betti numbers)				
	$r=0$	$r=1$	$r=2$	$\cdots$	$r=n$
Circles S'	1	1			
Torus $S' \times S'$	1	2	1		
Sphere S^2	1	0	1		
n-sphere S^n	1	0	0	$\cdots$	1
2-sphere $+ m$ handles	1	$2m$	1		
Projective plane $\mathbb{R}P^2$	1				
$\mathbb{R}P^n$ (n even)	1				
$\mathbb{R}P^n$ (n odd)	1	0	0	$\cdots$	1
$\mathbb{R}^n$	1				
Punctured torus	1				
Klein bottle	1	1			
2-sphere $+ m$ discs replaced by Möbius strips	1	$m-1$			
n-ball B^n	1				
Punctured n-ball $B^n\backslash\{0\}$	1	0 $\cdots$			1

expressible as $\lambda\, du + \mu\, dv$ for any real functions λ, μ.

2. On a sphere S^2 there is no nongradient cotangent field: $u \in \Lambda^1 S^2 \Rightarrow u = df$ for some $f: S^2 \to \mathbb{R}$; also, there is a nonzero $w \in \Lambda^2 S^2$, which is consequently not of the form du for $u \in \Lambda^1 S^2$ since all such have $u = df$ so $du = d^2 f = 0$.
3. If M is $\mathbb{R}^n$ (or the open n-ball, $\{x \in \mathbb{R}^n \mid \|x\| < 1\}$, to which it is diffeomorphic) then every closed r-form $w \in \Lambda^r M$ is expressible as $w = du$ for some $u \in \Lambda^{r-1} M$; hence the partial differential equation $dw = 0$ has a solution.

V. METRIC GEOMETRY

In an n-manifold M we often have to measure two kinds of things: the "volume" of a piece of M or the "size" of vectors from some bundle over M. The special kind of measure function appropriate for a manifold is a volume form.

A. Volume Forms

A volume form on an m-manifold M is a nowhere-zero n-form $\mu \in \Lambda^n M$. Since $A^n M$ is a vector bundle [with fiber $(\mathbb{R}^n)^*$] there may be no such volume form.

On E^n with the standard coordinates there is a volume form namely $dx^1 \wedge dx^2 \wedge \ldots \wedge dx^n$, as we have pointed out before. Now every point of M has a neighborhood that is diffeomorphic to E^n so in each such neighborhood we could construct a local volume form by pulling it back from E^n; the problem is simply that we may not be able smoothly to join up these local expressions into a global volume form on M. A sufficient condition for effecting the joining up is easily motivated:

If (U, ϕ), (V, ψ) are two charts about $x \in U \cap V$ with coordinates $(x_1, \ldots, x_n)$ and $(y_1, \ldots, y_n)$, respectively, then

$$dx^1 \wedge \ldots \wedge dx^n = J_{\phi\psi}\, dy^1 \wedge \ldots \wedge dy^n$$

where $J_{\phi\psi}$ is the Jacobian determinant of the change of coordinates

$$J_{\phi\psi} = \det(\partial x_i / \partial y_j)$$

Plainly, a good start is if $J_{\phi\psi}$ is an everywhere positive function for enough overlapping charts to cover M; if it has this property then M is called *orientable*. In fact, being orientable is necessary and sufficient for M to admit a volume form, since from the outset we assumed that our manifolds have a Hausdorff topology with a countable base, the latter being just the property needed to ensure the proper local joining of local volume forms. Actually, integration can also be performed on manifolds that are not orientable by passing to density forms, but we shall not pursue this.

If μ is a volume form on M then so is $f\mu$ for any nowhere-zero smooth real function f, so such an f must stay the same sign on each component piece of M. Since $A^n M$ can have only one independent section, then volume forms can only differ by such a factor f. We say μ and $f\mu$ are equivalent choices of orientation if f is everywhere positive and opposite choices if f is everywhere negative.

Given a volume form μ on M and an atlas $\{(U_\alpha, \phi_\alpha) \mid \alpha \in A\}$ then it is possible to define an integral of an n-form $w \in \Lambda^n M$ by means of a technical device called a *partition of unity*. This effectively shares w out fairly among the charts involved in any overlapping. Then each ϕ_α^* carries the appropriately weighted fraction of w to $\Lambda^n E^n$, where integration is as usual, and it remains to sum up the various weighted contributions from overlapping charts. For this to give a finite answer it is necessary that the sum converge, and for this we require M to have finite volume or, if not, then w must become zero on all but a finite region of M. The technical condition is that w has compact support. The integral of w is denoted $\int_M w$ and in particular the volume of M is $\int_M \mu$.

A fundamental application of this process is in Stokes' theorem:

$$\int_M dv = \int_{\partial M} v$$

for $v \in \Lambda^{n-1} M$ with compact support

where ∂M is the boundary of an n-manifold with boundary. In this general context, integration by parts has the expression

$$\int_M df \wedge v = \int_{dM} fv - \int_M f\, dv$$

where $f \in \Lambda^0 M$.

EXAMPLE. Let M be a closed, simply connected region in E^2. Take $v \in \Lambda^1 M$ to be given in standard coordinates by

$$v = \tfrac{1}{2}(x\, dy - y\, dx)$$

Then

$$\begin{aligned} dv &= \tfrac{1}{2}(dx \wedge dy - dy \wedge dx) \\ &= dx \wedge dy \\ \int_M dv = \int_{\partial M} v \Rightarrow \int_M dx \wedge dy &= \frac{1}{2}\int_{\partial M} (x\, dy - y\, dx) \end{aligned}$$

But $dx \wedge dy$ is the usual volume form for E^2 so $\int_M dx \wedge dy$ is just the area enclosed by curve ∂M. In particular, if ∂M is the ellipse L with

$$L = \{(x = a\cos\theta, y = b\sin\theta) \in \mathbb{E}^2 \mid 0 \leqq \theta \leqq 2\pi\}$$

then

$$\begin{aligned} x\,dy - y\,dx &= (ab\cos^2\theta + ba\sin^2\theta)\,d\theta \\ &= ab\,d\theta \end{aligned}$$

and it follows that the area of the ellipse is

$$\int_M dx \wedge dy = \frac{1}{2}\int_{\partial M} ab\,d\theta = \pi ab$$

Evidently the volume form on E^3 is $dx \wedge dy \wedge dz$ and its restriction to the two-dimensional submanifold E^2 which is the (x, y) plane is simply $dx \wedge dy$. Now, the ellipse itself is a one-dimensional submanifold of E^2 and, like the circle, it supports a nowhere-zero 1-form $d\theta$. The standard volume form on the ellipse L is actually $r\,d\theta$, where $r^2 = x^2 + y^2$, and therefore the circumference of the ellipse is

$$\begin{aligned} \int_L r\,d\theta &= \int_0^{2\pi} (a^2\cos^2\theta + b^2\sin^2\theta)^{1/2}\,d\theta \\ &= a\int_0^{2\pi} (1 - e^2\sin^2\theta)^{1/2}\,d\theta \end{aligned}$$

the familiar elliptic integral with e the eccentricity $(1 - b^2/a^2)^{1/2}$.

B. Metric Tensors

A metric tensor on an n-manifold M is an element $g \in T_2^0 M$, that is, a section of $T_2^0 M$

$$g\colon M \to T_2^0 M : x \mapsto g_x \in T_x M^* \otimes T_x M^*$$

where $g_x\colon T_x M \times T_x M \to \mathbb{R} : (u, v) \mapsto g_x(u, v)$ satisfies the conditions

1. Symmetry: $g_x(u, v) = g_x(v, u)$.
2. Nondegeneracy: if $g_x(u, v) = 0$ for all $v \in T_x M$ then $u = 0$.

If $(\partial_1, \ldots, \partial_n)_x$ is a basis for $T_x M$ then its dual, $(dx^1, \ldots, dx^n)$, is a basis for $(T_x M)^*$ and so g_x is expressible in the form

$$g_x = \left(g_{ij}\,dx^i \otimes dx^j\right)_x$$

Then the symmetry condition imposes symmetry on the matrix of numbers $(g_{ij})_x$ and nondegeneracy makes its determinant nonzero.

Usually we drop the subscript x indicating the variability of g and its coordinate expression with position in M.

EXAMPLE. Take $M = E^2$ so each tangent space is isomorphic to $\mathbb{R}^2$ as the set of directions at the point. The simplest choice of metric tensor is given by the usual inner product

$$\begin{aligned} g_x\colon T_x M \times T_x M &\to \mathbb{R} \\ : \left(u^i\,\partial_i, v^j\,\partial_j\right) &\mapsto u^1 v^1 + u^2 v^2 \end{aligned}$$

and so here $g = \delta_{ij}\,dx^i \otimes dx^j$. This induces on E^2 all of the usual Euclidean geometry, including the usual volume form; it is easily generalized to E^n.

Another metric tensor on E^2 is given by

$$\begin{aligned} \eta_x\colon T_x M \times T_x M &\to \mathbb{R} \\ : \left(u^i\,\partial_i, v^j\,\partial_j\right) &\mapsto u^1 v^1 - u^2 v^2 \end{aligned}$$

and so this is expressed as

$$\eta = \eta_{ij}\,dx^i \otimes dx^j \quad \text{where } \eta_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

This induces Minkowski geometry on E^2, as used in relativity.

From the example we see that the Euclidean metric tensor satisfies a stronger condition than 2. It is $2'$. Positive definiteness: $g_x(u, v) = 0$ if and only if $u = 0$. This imposes on the matrix $(g_{ij})_x$ that its eigenvalues all be of one sign.

A metric tensor satisfying condition $2'$ is called a *Riemannian metric*; one satisfying only 2 is called an *indefinite metric* or a *pseudo-Riemannian metric*. Riemannian metric geometry includes all of the usual curved surfaces and much else; pseudo-Riemannian geometry includes space–time structures where angles and lengths are interpreted very differently from those of common experience.

Since the simplest possible choice of metric tensor gives the whole of standard Euclidean geometry on E^n, we can expect that the structure implied by any metric tensor is very rich indeed. This is the case, but before investigating it we should consider existence questions. Now, an n-manifold consists of copies of E^n smoothly joined together and we have a standard metric tensor on each patch of E^n, so we are once again faced with patching them together in a consistent way. The same trick works as for volume forms: we use a partition of unity to share out fairly the contributions of each overlapping copy of E^n. Thus, all of our manifolds admit a Riemannian metric. However, whereas the module $\Lambda^n M$ of volume forms is one-dimensional and so any two differed only by a scalar function, the module $\Upsilon_2^0 M$ of sections of $T_2^0 M$ is n^2-dimensional and no particular Riemannian metric is

distinguished in general. Of course, if M is itself a submanifold of some manifold M (especially E^m for some $m \geqq n$) that has a metric tensor g, then the restriction of g to M is a metric tensor on M. This is an important source of examples.

We list next some of the important implications of an n-manifold M having a metric tensor g.

1. It induces a measure of length for a curve
$$c\colon [0,1] \to M : t \mapsto c(t)$$
The tangent vector to c at t is $\dot{c}(t) \in T_{c(t)}M$ and we define the length of c to be
$$\int_{t=0}^{t=1} |g(\dot{c}(t), \dot{c}(t))|^{1/2}\, dt$$
In coordinates, if $c(t) \in U$ for some chart (U, ϕ) then $\phi(c(t)) = (c^1(t), \ldots, c^n(t))$ and
$$\dot{c}(t) = \dot{c}^i(t)\, \partial_i \quad \text{with } \dot{c}^i = dc^i/dt.$$
Hence $g(\dot{c}, \dot{c}) = g_{ij}\dot{c}^i\dot{c}^j$.
2. There is a dual metric tensor $g^* \in \Upsilon_0^2 M$ with
$$g_x^*\colon T_xM^* \times T_xM^* \to \mathbb{R} : (\alpha, \beta) \mapsto g_x^*(\alpha, \beta)$$
with coordinate expression
$$g_x^* = \left(g^{ij}\, \partial_i \otimes \partial_j\right)_x \quad \text{and} \quad (g^{ij}) = (g_{ij})^{-1}$$
as matrices, well defined since $\det g_{ij} \neq 0$.
3. There is an isomorphism $\Upsilon_1^0 M \simeq \Upsilon_0^1 M$ of tangent and cotangent fields:
$$g_x^b\colon T_xM \to T_xM^* : v \mapsto v^*$$
$$\text{with } v^*(u = g_x(u, v))$$
which appears in coordinates as
$$g_x^b\colon v^i\, \partial_i \mapsto g_{ij}v^i\, dx^j$$
with inverse
$$g_x^\#\colon w_i\, dx^i \mapsto g^{ij}w_i\, \partial_j$$
4. These isomorphisms in 2 can be tensor-producted to give isomorphisms
$$\Upsilon_s^r M \simeq \Upsilon_m^k M \quad \text{for all } r + s = k + m$$
Consequently, we can switch among tensor fields to suit our convenience when we have a metric tensor.
5. If M is an orientable manifold then a choice of an oriented atlas (Jacobian everywhere positive on overlaps) yields a unique volume form μ_g determined locally by
$$\mu_g = |\det g_{ij}|^{1/2}\, dx^1 \wedge \cdots \wedge dx^n$$
This is nowhere zero since nondegeneracy ensures $\det g_{ij} \neq 0$. Observe that this does agree with the standard volume form on E^n, where $\det g_{ij} = 1$ everywhere.
6. If M is oriented then there is a Hodge dual isomorphism on differential forms:
$$^*\colon \Lambda^r M \to \Lambda^{n-r} M : w \mapsto {}^*w$$
To explain the construction of this isomorphism suppose that $(e^1, \ldots, e^n)_x$ is any ordered basis in the orientation for T_xM^* and ordered bases for $\Lambda^r M$ and $\Lambda^{n-r}M$ are given locally by
$$\{e^{i_1} \wedge e^{i_2} \cdots e^{i_r} \mid 1 \leqq i_1 < \cdots < i_r \leqq n\}$$
$$\{e^{j_1} \wedge e^{j_2} \cdots e^{j_{n-r}} \mid 1 \leqq j_1 < \cdots < j_{n-r} \leqq n\}$$
Then with $g_{ij} = g(e^i, e^j)$
$$^*w_{(i_1 \cdots i_r)} e^{i_1} \wedge \cdots \wedge e^{i_r} = |\det g_{ij}|^{1/2} w^*_{(j_1 \cdots j_{n-r})} e^{j_1} \wedge \cdots \wedge e^{j_{n-r}}$$
where
$$w^*_{j_1 \cdots j_{n-r}} = g^{k_1 i_1} g^{k_2 i_2} \cdots g^{k_r i_r} w_{i_1 \cdots i_r}\, \mathrm{sgn}(k \to i)$$
and $\mathrm{sgn}(k \to i)$ is the sign of the permutation
$$(i_1, \ldots, i_r, j_1, \ldots, j_{n-r}) \mapsto (k_1, \ldots, k_r, j_1, \ldots, j_{n-r})$$
Intuitively, ${}^*w$ is the "complement" of w in the volume form μ_g determined by g; in particular, we find
$$^*1 = \mu_g \qquad (1 \text{ is the constant unit real function on } M,\ 1 \in \Lambda^0 M)$$
$$^*\mu_g = (-1)^\nu \qquad (\nu \text{ is the number of negative eigenvalues of } g)$$
The appearance of * is simplest if we choose the oriented base $(e^1, \ldots, e^n)$ for T_xM^* to be orthonormal, that is, $g^*(e^i, e^j) = \pm\delta^i_j$ so $|\det g_{ij}| = 1$. In this case
$$^*(e^{i_1} \wedge \cdots \wedge e^{i_r}) = (e^{j_1} \wedge \cdots \wedge e^{j_{n-r}})$$
for any even permutation $(i_1, \ldots, i_r, j_1, \ldots, j_{n-r})$ of $(1, \ldots, n)$, and we extend the isomorphism to all r-forms by requiring it to be linear.

Some justification for the presence of $|\det g_{ij}|$ in the volume form can be seen by recalling that (g_{ij}) is the local $(n \times n)$ matrix expression of a linear map $T_xM \to T_xM^*$. For such matrix maps from $\mathbb{R}^n$ to $\mathbb{R}^n$ the determinant measures precisely the factor of volume change under the map: a unit n-cube is sent to an n-box of volume $|\det g_{ij}|$.

EXAMPLE. The equations of the elecromagnetic field on a space-time manifold can be very neatly expressed in terms of the electromagnetic 2-form $F \in \Lambda^2 M$ and dim $M = 4$.

Locally, for a basis of 1-form fields (ω^i),

$$F = F_{(ij)}\,\omega^i \wedge \omega^j$$

If we suppose that the ω^i are mutually orthogonal unit fields, then the metric tensor components (g_{ij}) are the eigenvalues of g lying along the diagonal.

The Hodge dual isomorphism gives ${}^*(\omega^i \wedge \omega^j) = \omega^m \wedge \omega^k$, where (i, j, m, k) is an even permutation of $(1, 2, 3, 4)$. So ${}^*(\omega^1 \wedge \omega^2) = \omega^3 \wedge \omega^4$ and so forth. Similarly, ${}^*(\omega^1 \wedge \omega^2 \wedge \omega^3) = \omega^4$ and so forth.

Physical theory leads to the following equations for F in regions that contain negligible amounts of matter:

$$dF = 0 \quad {}^*d^*F = J \qquad (\dagger)$$

where J is the current density. These equations correpond to the usual Maxwell's equations through the vector calculus correspondences:

$${}^*d \equiv \text{curl} \quad \text{and} \quad {}^*d^* \equiv \text{divergence}$$

Conservation of charge is expressed by

$$\text{div}\, J = 0$$

This is automatically satisfied when there is negligible matter since it becomes

$${}^*d^{**}d^*F = 0 \quad \text{because } d^2 = 0$$

However, in the presence of matter, Eq. (†) becomes

$$dA = 0 \qquad {}^*d^*B = J \quad \text{for some } A, B \in \Lambda^2 M$$

with A and B related by some transformation, perhaps linear. Once again, $d^2 = 0$ ensures conservation of charge.

Locally, $J = \rho J_i \omega^i$, where ρ is the chrage density. Then over a compact spacelike submanifold S of M we can measure the total charge Q_N and find that

$$\begin{aligned} Q_N &= \int_S \rho\omega^i \wedge \omega^2 \wedge \omega^3 = \int_S {}^*J \\ &= \int_S d^*B = \int_{\partial S} {}^*B \end{aligned}$$

VI. CONNECTION GEOMETRY

Given a tangent vector field v: $M \to TM$ it is quite likely that we shall be interested in measurings its rate of change over M. Now, v is a smooth map between smooth manifols so it induces the derivative

$$Dv\colon TM \to T(TM)$$

between the corresponding tangent bundles. Unfortunately, this is not useful as a measure of the rate of change of v on M because Dv takes values in $T(TM)$, not in TM. A connection gets us from $T(TM)$ to TM in orderly fashion.

A. Linear Connection

There are more general connections than the one that we shall use; we are interested in those that have particular significance for the structures we already have on M.

A (linear) connection on M is a splitting of the vector bundle $T(TM)$ into a direct sum of a horizontal part HM and a *vertical* part VM, with HM isomorphic to TM as vector bundles. The motivation is clear: given any vector $u \in TM$ and field v: $M \to TM$ then

$$Dv(u) \in T(TM) \simeq HM \oplus VM$$

and we interpret the rate of change of v in the direction u as the projection of the HM part onto TM. Equivalently, we define a connection on M to ba a map ∇ that assigns to each $u \in TM$ and $v \in \Upsilon_0^1 M$ a vector $\nabla_u v$ in $T_x M$ (where $u \in T_x M$) such that

a. ∇_u is linear over $u \in T_x M$.
b. $\nabla_u v$ is linear over $v \in \Upsilon_0^1 M$.
c. $\nabla_u f v = u(f)v(x) + f(x)\nabla_u v$ if $f\colon M \to \mathbb{R}$.
d. If $w, v \in \Upsilon_0^1 M$ then so is $\nabla_w v\colon x \mapsto \nabla_{w(x)} v$.

We view $\nabla_u v$ as the rate of change of the field v in the direction of the vector u at $x \in M$ and call it the covariant derivative of v with respect to u.

By exploiting the linearity properties we can easily obtain coordinate expressions. Given a chart (U, ϕ) with cordinates $(x_1, \ldots, x_n)$ about x and basis fields $(\partial_1, \ldots, \partial_n)$ for tangent vector fields about x, any $u \in T_x M$ is of the form $u = (u^i \partial_i)_x$ and near x any vector field w is of the form $w = w^j \partial_j \in \Upsilon_0^1 U$. Now we must have

$$\begin{aligned} \nabla_u w &= \nabla_{u i_{\partial_i}} \left(w^j \partial_j\right) \in T_x M \\ &= u^i \nabla_{\partial_i} \left(w^j \partial_j\right) \quad \text{by a} \\ &= u^i \left(\left(\partial_i w^j\right) \partial_j + w^j \nabla_{\partial_i} \partial_j\right)_x \quad \text{by b and c} \end{aligned}$$

Hence ∇ is completely determined on U by specification of $\nabla_{\partial_i} \partial_j \in \mathrm{T}_0^1 U$. But any such field is of the form

$$\nabla_{\partial_i} \partial_j = \Gamma_{ij}^k \partial_k \quad \text{for some } \Gamma_{ij}^k\colon U \to \mathbb{R}$$

So locally ∇ appears as an n^3 array of smooth real functions on U. These functions are traditionally called the *Christoffel symbols* of the connection, and they will change smoothly from chart to chart. Substitution of $[(\partial y^m/\partial x^k)\,\hat{\partial}_m]$ for (∂_i) through a change of chart coordinates from $(x_1, \ldots, x_n)$ to $(y_1, \ldots, y_n)$ can be traced trough the above steps to obtain expressions for

$$\nabla_{\hat{\partial}_i} \hat{\partial}_j = \hat{\Gamma}_{ij}^k \hat{\partial}_k$$

Then the $\hat{\Gamma}^k_{ij}$ can be related to the Γ^k_{ij} through the partial derivatives $(\partial y^m/\partial x^k)$. This is one way to see that the Christoffel symbols are not components of any tensor field.

We easily extend ∇ to give covariant derivative of arbitrary tensor fields by defining for $u \in T_x M$

a. $\nabla_u f = u(f)$ for $f \in \Upsilon^0_0 M$.
b. $\nabla_u(dx^i \otimes \partial_i) = 0$ for mutually dual basis fields.
c. $\nabla_u(w \otimes v) = (\nabla_u w) \otimes v + w \otimes \nabla_u v$.

From b and c with $u = \partial_j$ we get, for example,

$$\nabla_{\partial_j}(dx^i \otimes \partial_i) = \left(\nabla_{\partial_j} dx^i\right) \otimes \partial_i + dx^i \otimes \nabla_{\partial_j} \partial_i = 0$$
$$0 = \nabla_{\partial_j} dx^k \otimes \partial_k + \Gamma^k_{ji}\, dx^i \otimes \partial_k$$

therefore

$$\nabla_{\partial_j} dx^k = -\Gamma^k_{ji}\, dx^i$$

This defines a family of 1-forms called the *connection 1-forms*.

B. Parallel Transport

Given a curve c: $[0, 1] \to M$, its tangent vector field is denoted $\dot{c}$: $[0, 1] \to TM$ and in components $\dot{c} = \dot{c}^j\, \partial_j$. If $w \in \Upsilon^r_s M$ then we say that w is parallel along c if

$$\nabla_{\dot{c}} w = 0$$

If $w = w^k\, \partial_k \in \Upsilon^1_0 M$ is parallel along c with tangent vector field $\dot{c}^j\, \partial_j = d/dt$, then

$$\nabla_{\dot{c}} w = \nabla_{\dot{c}\, j_{\partial_j}} w^k\, \partial_k = 0 \in \Upsilon^1_0 M$$

so $(\dot{c}^j \partial_j w^k)\, \partial_k + \dot{c}^j w^i\, \nabla_{\partial_j} \partial_i = 0$. Hence $dw^k/dt + (dc^j/dt) w^i\, \Gamma^k_{ji} = 0 \in \mathbb{R}, k = 1, 2, \ldots, n$. This system of n linear differential equations, which represents $\nabla_{\dot{c}} w = 0$, has a unique solution

$$w\colon [0, 1] \to TM\colon t \mapsto w_t$$

for given initial value $w(0) = w_0 \in T_{c(0)} M$. Therefore ∇ and c have defined a map

$$\tau_t\colon T_{c(0)} M \to T_{c(t)} M\colon w_0 \mapsto w_t$$

This turns out to be a very good map indeed: an isomorphism of vector spaces; it is called *parallel transport* and is available for tensor spaces also. Moreover, parallel transport allows us to express the covariant derivative as a limit of a difference, because with it we can bring all vectors and tensors along c back to $c(0)$. Let $u \in T_x M$ be any vector; $w \in \Upsilon^r_s M$ and c is any curve with $c(0) = x, \dot{c}(0) = u$; then

$$(\nabla_u w)_x = \lim_{t \to 0} \frac{\tau_t^{-1}(w(c(t))) - w(c(0))}{t}$$

EXAMPLE. Consider E^1 with $\nabla_{\partial_1} \partial_1 = \lambda$, for some constant $\lambda \in \mathbb{R}$, with respect to the standard chart.

Take c: $[0, 1] \to E^1$: $t \mapsto t$, so $\dot{c}(t) = \partial_1$.
Then τ_t: $T_{c(0)} E^1 \to T_{c(t)} E^1$: $\alpha_0 \partial_1 \mapsto \alpha(t) \partial_1$ satisfies.

$$\frac{d\alpha}{dt} + \alpha\lambda = 0 \quad \text{so } \alpha(t) = \alpha_0 e^{-\lambda t}$$

Evidently $\lambda = 0$ corresponds to the usual connection since we do not usually alter the length of vectors when we move them on E^1. Any $\lambda \neq 0$ determines a non-Euclidean parallelism structure on E^1. A similar connection could be put on S^1.

EXAMPLE. To find a local expression for the parallel transport isomorphism. We consider $M = E^2$ with the standard chart and connection ∇ having constant Christoffel symbols

$$\Gamma^1_{12} = \Gamma^1_{21} = 1 \quad \text{and all other components zero}$$

Given the curve c: $[0, 1] \to E^2$: $t \mapsto (t, t^2)$ we find the parallel vector field

$$w\colon [0, 1] \to TE^2\colon t \mapsto f(t)\, \partial_1 + g(t)\, \partial_2$$

for two independent initial tangent vectors:

a. $w(0) = \partial_1$
b. $w(0) = \partial_2$

The parallel transport condition is $\nabla_{\dot{c}} w = 0$ and we are given $\dot{c}(t) = \partial_1 + 2t\, \partial_2$. Substituting

$$\dot{f}\, \partial_1 + \dot{g}\, \partial_2 + 2tf\, \Gamma^i_{21}\, \partial_i + g\Gamma^i_{12}\, \partial_i = 0$$
$$(\dot{f} + 2tf + g)\, \partial_1 + \dot{g}\, \partial_2 = 0$$
$$\text{so } g(t) = g(0)$$

We solve $\dot{f} + 2tf + g = 0$ for constant g to give:

Case (a): $f(t) = e^{-t^2}, g(t) = g(0) = 0$.
Case (b): $f(t) = -e^{-t^2} \int_0^t e^{x^2}\, dx = k(t)$, say, and $g(t) = 1$.

Then parallel transport along c is the isomorphism

$$\tau_t\colon T_{c(0)} E^2 \to T_{c(t)} E^2$$
$$\colon \alpha\, \partial_1 + \beta\, \partial_2 \mapsto \left(\alpha e^{-t^2} + \beta k(t)\right) \partial_1 + \beta\, \partial_2$$

or in matrix form

$$\begin{pmatrix} \alpha \\ \beta \end{pmatrix} \mapsto \begin{pmatrix} e^{-t^2} & k(t) \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \end{pmatrix}$$

Evidently ∇ is not compatible with the usual metric tensor on E^2 because parallel transport is not an isometry, for instance,

$$\tau_t(\partial_1) = e^{-t^2}\, \partial_1$$

C. Geodesics

It is natural to turn the equation for parallel transport onto the curve itself: solve $\nabla_{\dot c}\dot c = 0$ for c.

Such a curve is called a *geodesic* for the connection ∇ because on the surface of the earth, viewed as a sphere with the usual connection, such curves are great circles and do "divide the earth." On an n-manifold we can always find geodesic curves going in all directions from a point but in general we may not be able to make them go very far. Accordingly, we usually define a *geodesic* through $x \in M$ with direction $u_0 \in T_x M$ in a manifold M with connection ∇ as any smooth $c\colon (-\varepsilon, \varepsilon) \to M$, for positive ε, with $c(0) = x$, $\dot c(0) = u_0$, and $\nabla_{\dot c(t)}\dot c = 0$ for all $t \in (-\varepsilon, \varepsilon)$. Cleary, if M has a boundary then a geodesic may not be extensible after it meets ∂M. Another type of inextensibility can occur if M is incomplete in some sense.

EXAMPLE. Let $M = E^2\backslash\{(0,0)\}$, the punctured plane with standard coordinates. Then the Euclidean connection has zero Christoffel symbols and the equation of a geodesic becomes

$$\nabla_{\dot c}\dot c = \nabla_{\dot c^i \partial_i}\dot c^j \partial_j = \ddot c^k \partial_k + \dot c^i \dot c^j \Gamma^k_{ij}\partial_k = 0$$

so $\ddot c^k = 0$, $k = 1, 2$. Hence the geodesics are straight lines, as we expect for a submanifold of the Euclidean plane, but they cannot pass through the origin. Thus, for example, the geodesic

$$c\colon (-\varepsilon, \varepsilon) \to M : t \mapsto (2 - 2t, 1 - t)$$

which begins at $(2, 1)$ in direction $-2\hat i - \hat j$, is only defined for $\varepsilon \leqq 1$.

EXAMPLE. To find geodesics (corresponding to free particle trajectories) in Schwarzschild space-time. Here we take $M = \mathbb{R} \times (E^3\backslash B)$ with $\mathbb{R}$ giving the time coordinate t and $E^3\backslash B$ being the Euclidean space outside a ball of some radius $k > 0$ centered on the origin. We give $E^3\backslash B$ the usual spherical polar coordinates (r, θ, ϕ) and view the region B as containing some spherically symmetric mass, like a star or planet. In general relativity, free particles falling under gravity follow geodesics. The appropriate metric tensor for this physical situation has components

$$(g_{ij}) = \begin{pmatrix} 1 - 2m/r & 0 & 0 & 0 \\ 0 & -(1-2m/r)^{-1} & 0 & 0 \\ 0 & 0 & -r^2 & 0 \\ 0 & 0 & 0 & -r^2\sin^2\theta \end{pmatrix} \quad \text{for } r > k > 2m$$

where m is the mass of the material contained in B. Denoting the coordinates (t, r, θ, ϕ) by (x_0, x_1, x_2, x_3), we find the metric connection ∇ has only the following nonzero Christoffel symbols:

$$\begin{aligned} \Gamma^1_{11} &= -\Gamma^0_{10} = -(m/r^2)(1 - 2m/r)^{-1} \\ \Gamma^2_{12} &= \Gamma^3_{13} = 1/r, \\ \Gamma^1_{33} &= \Gamma^1_{22} = -r(1 - 2m/r)\sin^2\theta \\ \Gamma^1_{00} &= (m/r^2)(1 - 2m/r), \\ \Gamma^2_{33} &= \sin\theta\cos\theta \\ \Gamma^3_{32} &= \cot\theta, \quad \text{and} \quad \Gamma^k_{ij} = \Gamma^k_{ji} \end{aligned}$$

Geodesic curves satisfy $\nabla_{\dot c}\dot c = 0$ and we consider two cases each with parameter s given by $g(\dot c, \dot c) = 1$.

1. *Circular geodesics*: $c(s) = (t(s), r(s), \theta(s), \phi(s))$ with $\dot r(s) = 0$. We shall take the plane of one of these circular orbits to be $\theta(s) = \pi/2$. Denote differentiation with respect to parameter s by a dot; then we expand $\nabla_{\dot c}\dot c = 0$ to give the system of equations

$$\begin{aligned} \ddot t = 0 &\Rightarrow \dot t = \text{const} \\ \Gamma^1_{33}(\dot\phi)^2 + \Gamma^1_{00}(\dot t)^2 = 0 &\Rightarrow (1 - 2m/r)(m/r^2(\dot t)^2 \\ &\qquad - r(\dot\phi)^2) = 0 \\ &\Rightarrow (\dot t)^2 = r^3/m(\dot\phi)^2 \\ \ddot\phi = 0 &\Rightarrow \dot\phi = \text{const} = \text{period}/2\pi \\ &\Rightarrow \text{period } T = 2\pi/\dot\phi \end{aligned}$$

   From $g(\dot c, \dot c) = 1$ we find

$$(\dot t)^2(1 - 2m/r) - r^2(\dot\phi)^2 = 1$$

   Substitution above gives circular orbits with periods

$$T = 2\pi r(r/m - 3)^{1/2} \quad r > 3m$$

   In time units, for the sun we have $2m = 10^{-5}$ sec and $t = 1$ year $\doteq 10^7\pi$ sec, for the earth orbit, so we deduce that the implied radius is $r \doteq 500$ sec, which is what we observe. Similar data can be checked for the moon or other satellites orbiting the earth. For the earth $2m \doteq 3 \times 10^{-11}$ sec.
2. *Radial geodesics:* $c(s) = (t(s), r(s), \theta(s), \phi(s))$ with θ, ϕ constant. The geodesic equation reduces on $\theta = \pi/2$ to

$$\ddot r - m/r^2(1-2m/r)^{-1}(\dot r)^2 + m/r^2(1-2m/r)(\dot t)^2 = 0$$

   and we deduce $r = -m/r^2$. Now r measures precisely the acceleration due to gravity at distance r from the center of a spherically symmetric mass m, in agreement to first approximation with Newton's theory. We find, for example, in time units, that

$$\text{on the earth} \quad \begin{cases} 2m \doteq 3 \times 10^{-11}\,\text{sec} \\ r \doteq 2.1 \times 10^{-2}\,\text{sec} \\ \ddot{r} \doteq -3/8 \times 10^{-7} \end{cases}$$

$$\text{on the moon} \quad \begin{cases} 2m \doteq 2.5 \times 10^{-13}\,\text{sec} \\ r \doteq 5.4 \times 10^{-3}\,\text{sec} \\ \ddot{r} \doteq -14/3 \times 10^{-9} \end{cases}$$

$$\text{on the sun} \quad \begin{cases} 2m \doteq 10^{-5}\,\text{sec} \\ r \doteq 2\,\text{sec} \\ \ddot{r} \doteq -1/8 \times 10^{-5} \end{cases}$$

A manifold with connection is called *geodesically complete* if all of its geodesics can be extended to infinite parameter values (or until they meet the boundary, if M is a manifold with boundary). It is known that, with their standard connections induced from being embedded in Euclidean space, the circle, sphere, and torus are all geodesically complete. Observe that on such spaces the extension of a geodesic to infinite parameter values may involve it in repeatedly convering the same points, for some geodesics become closed curves.

As might be expected, from the fact that some sufficiently small region about $x \in M$ is diffeomorphic to E^n, we can get a geodesic going in any direction. That is, for all sufficiently small initial tangent vectors $\dot{c}(0) = u_0 \in T_x M$, there is a geodesic through $c(0) = x$. To make "sufficiently small" precise we need a norm in $T_x M$, but any norm will do equivalently well. Define

$$S_x = \{u_0 \in T_x M \mid \text{ there is a geodesic } c\colon [0,1] \to M \text{ with } c(0) = x \text{ and } \dot{c}(0) = u_0\}$$

Then there is a nice map called the *exponential map at x*

$$\exp_x : S_x \to M : u_0 \mapsto c(1) \quad \text{where } c \text{ is a geodesic with } c(0) = x \text{ and } \dot{c}(0) = u_0$$

It turns out that at every point x there is someneighborhood of the zero vector in $T_x M$ on which $\exp_x$ is a diffeomorphism onto its image. If the connection is complete then $\exp_x$ is defined on all of $T_x M$ for all $x \in M$.

D. Metric Connection

We saw that any Euclidean space has a connection, the simplest possible choice, and we implied that any subset of E^n that is a manifold will inherit a unique connection. Now this is a consequence of the following result:

Every metric tensor g determines a unique connection ∇^g, called the *metric connection* or *Levi–Civita connection*. There is one obvious condition that it should satisfy:

a. $\nabla^g_u g = 0$ for all $u \in \Upsilon^1_0 M$.

This is called being *compatible* with the metric and it effectively says that the covariant derivative will always view the metric tensor (and its dual g^*) as a constant: ∇^g factors out any variability introduced by peculiarties of g. In particular, it will make parallel transport an isometry as well as an isomorphism and covariant derivatives will commute with the isomorphisms $g^\#$ and $g^\flat$ induced by g.

The second condition is less obvious at first:

b. $\nabla^g_u v - \nabla^g_v u = [u, v]$ for all $u, v \in \Upsilon^1_0 M$.

This is called being *symmetric* because it implies that with respect to any coordinates the Christoffel symbols Γ^k_{ij} are symmetric in ij.

Conditions (a) and (b) are sufficient to select a unique connection for a manifold with metric tensor. They give a system of differential equations that locally allows the Christoffel symbols to be calculated from partial derviatives of the components of g. We find that

$$\partial_k g(\partial_i, \partial_j) = g\big(\nabla^g_{\partial_k} \partial_i, \partial_j\big) + g\big(\partial_i, \nabla^g_{\partial_k} \partial_j\big)$$

from a so

$$\partial_k g_{ij} = \Gamma^m_{ki} g_{mj} + \Gamma^m_{kj} g_{im},$$

$$\nabla^g_{\partial_i} \partial_j - \nabla^g_{\partial_j} \partial_i = [\partial_i, \partial_j] = 0$$

from b so $\Gamma^k_{ij} = \Gamma^k_{ji}$. Hence we use the inverse matrix of (g_{rs}) and symmetry to give

$$\Gamma^k_{ij} = \tfrac{1}{2} g^{km}(\partial_i g_{jk} + \partial_j g_{ik} - \partial_k g_{ij})$$

It can be shown that every manifold can be given a Riemannian metric that is geodesically complete. Evidently, the fact that $(g_{ij}) = (\delta_{ij})$ everywhere on E^n immediately gives zero Christoffel symbols in the standard coordinates; however, if we use other than rectilinear coordinates, then the corresponding metric tensor components will be nonconstant and some nonzero Christoffel symbols will airse. The idea is clear: if we wish to keep Euclidean geometry but describe it with curvilinear coordinates, then we shall expect any components in these coordinates (of vectors or tensors) to alter as we parallel transport them.

EXAMPLE. To find a metric connection and equations for a parallel vector field along a given curve. We take $M = (0, 2\pi) \times S^1$, an open cylinder with identity coordinate x on the interval $(0, 2\pi)$ and angular coordinate θ on the circle S^1. Consider the expression in these coordinates of the pseudo-Riemannian metric tensor

$$(g_{ij}) = \begin{bmatrix} -(1-\cos x)^2 & 0 \\ 0 & (1-\cos x)^2 \end{bmatrix} \quad \text{at } (x, \theta) \in M$$

From symmetry and compatibility of the induced metric connection ∇ with Christoffel symbols (Γ^m_{ij}) we have

$$\Gamma^m_{ij} = \tfrac{1}{2} g^{mk}\big(\partial_i g^{jk} + \partial_j g_{ij} - \partial_k g_{ij}\big)$$
$$= \tfrac{1}{2} g^{mk}{}_k \Gamma_{ij}, \quad \text{say}$$

Substitution gives

$$({}_1\Gamma_{ij}) = \begin{bmatrix} -2\sin x(1-\cos x) & 0 \\ 0 & -2\sin x(1-\cos x) \end{bmatrix}$$

$$({}_2\Gamma_{ij}) = \begin{bmatrix} 0 & 2\sin x(1-\cos x) \\ 2\sin x(1-\cos x) & 0 \end{bmatrix}$$

Hence

$$\big(\Gamma^1_{ij}\big) = \begin{bmatrix} \sin x/(1-\cos x) & 0 \\ 0 & \sin x/(1-\cos x) \end{bmatrix}$$

$$\big(\Gamma^2_{ij}\big) = \begin{bmatrix} 0 & \sin x/(1-\cos x) \\ \sin x/(1-\cos x) & 0 \end{bmatrix}$$

For the vertical-going curve $c\colon (0, 2\pi) \to M : t \mapsto (t, 0)$ a parallel vector field is $v\colon (0, 2\pi) \to TM\colon t \mapsto f(t)\partial_x + h(t)\partial_\theta$ where $\nabla_{\dot c} v = 0$. This differential equation becomes

$$\partial_x f + f\Gamma^1_{11} = 0$$
$$\partial_x h + h\Gamma^2_{12} = 0$$

So suitable f and g must satisfy

$$\partial_x f = -\frac{\sin x}{1-\cos x} f$$

and

$$\partial_x h = -\frac{\sin x}{1-\cos x} h$$

E. Torsion of a Connection

In general, a connection ∇ need not be related to a metric tensor; for example, the (constant) connection on the unit circle S^1 with Christoffel symbol $\Gamma^1_{11} = \lambda$ for fixed $\lambda \neq 0$ does not arise as the metric connection of any metric tensor on S^1. However, it is trivially symmetric. The question of whether a connection is symmetric is independent of any metric tensor and it can be formulated in terms of the *torsion* map

$$T\colon \Upsilon^1_0 M \times \Upsilon^1_0 M \to \Upsilon^1_0 M$$
$$: (u, v) \mapsto \nabla_u v - \nabla_v u - [u, v]$$

Hence T is zero if and only if ∇ is symmetric. For the usual basis fields $(\partial_1, \ldots, \partial_n)$ arising from coordinates $(x_1, \ldots, x_n)$ we have

$$T(\partial_i, \partial_j) = \nabla_{\partial i}\partial_j - \nabla_{\partial j}\,\partial_j \quad (\text{since } [\partial_i, \partial_j] = 0)$$
$$= \Gamma^k_{ij}\,\partial_k - \Gamma^k_{ji}\,\partial_k = \big(\Gamma^k_{ij} - \Gamma^k_{ji}\big)\partial_k$$

We can interpret T as a section of $T^1_2 M$ since at each $x \in M$ we have a bilinear map

$$T\colon T_x M \times T_x M \to T_x M$$

but such maps are effectively elements of $T_x M^* \otimes T_x M^* \otimes T_x M$. Hence we may view T as a section of $T^*M \otimes T^*M \otimes TM$ and locally

$$T = \big(\Gamma^k_{ij} - \Gamma^k_{ji}\big)\, dx^i \otimes dx^j \otimes \partial_k$$

The antisymmetry of T in i and j immediately suggests and interpretation of T as some king of 2-form. This is possible but the presence of the ∂_k direction means that then we view T as a vector-valued 2-form, the torsion form

$$\Theta\colon \Upsilon^1_0 M \times \Upsilon^1_0 M \to \Upsilon^1_0 M$$

which in local coordinates becomes

$$\Theta = \tfrac{1}{2}\Gamma_{ij}\, dx^i \wedge dx^j \quad \text{where } \Gamma_{ij} = \Gamma^k_{ij}\,\partial_k$$

so locally Θ takes values in $\mathbb{R}^n \simeq T_x M$.

In much the same way, we can represent any connection by a vector-valued 1-form, the connection form

$$\omega\colon \Upsilon^1_0 M \to \Upsilon^1_1 M$$

which in local coordinates becomes

$$\omega = \omega_i\, dx^i \quad \text{where } \omega_i = \Gamma^k_{ij}\, dx^j \otimes \partial_k$$

So, locally ω takes values in $\mathbb{R}^{n^2}$, the space of $n \times n$ real matrices, which represents $T_x M^* \otimes T_x M \simeq L(T_x M, T_x M)$.

EXAMPLE. On E^2 with the standard coordinates, one connection ∇ that is not symmetric is given by the Christoffel symbols

$$\Gamma^1_{ij} = \begin{pmatrix} 1 & 8 \\ 4 & 0 \end{pmatrix} \qquad \Gamma^2_{ij} = \begin{pmatrix} 1 & 6 \\ 4 & 2 \end{pmatrix}$$

Its torsion form is $\Theta\colon \Upsilon^1_0 E^2 \times \Upsilon^1_0 E^2 \to \Upsilon^1_0 E^2$ with

$$\Theta = \big(\tfrac{1}{2}\Gamma^k_{ij}\partial_k\big)\, dx^i \wedge dx^j$$
$$= \tfrac{1}{2}(8\partial_1 + 6\partial_2)\, dx^1 \wedge dx^2$$
$$+ \tfrac{1}{2}(4\partial_1 + 4\partial_2)\, dx^2 \wedge dx^1$$
$$= \tfrac{1}{2}(4\partial_1 + 2\partial_2)\, dx^1 \wedge dx^2 \quad (\text{with values in } T_x M)$$

So

$$\Theta = (2, 1)\, dx^1 \wedge dx^2 \quad (\text{with values in } \mathbb{R}^2)$$

The connection form of this ∇ is $\omega : Y_0^1E^2 \to Y_1^1E^2$ with

$$\begin{aligned}\omega &= \left(\Gamma_{ij}^k dx^j \otimes \partial_k\right) dx^i \\ &= \begin{pmatrix} 1dx^1 \otimes \partial_1 & 8\,dx^1 \otimes \partial_2 \\ 4dx^2 \otimes \partial_1 & 0\,dx^2 \otimes \partial_2 \end{pmatrix} dx \\ &\quad + \begin{pmatrix} 1dx^1 \otimes \partial_1 & 6\,dx^1 \otimes \partial_2 \\ 4dx^1 \otimes \partial_1 & 4\,dx^2 \otimes \partial_1 \end{pmatrix} dx^2\end{aligned}$$

So

$$\omega = \begin{pmatrix} 1 & 8 \\ 4 & 0 \end{pmatrix} dx^1 + \begin{pmatrix} 1 & 6 \\ 4 & 2 \end{pmatrix} dx^2 \quad \text{(with values in } \mathbb{R}^{2\times 2}\text{)}$$

F. Curvature of a Connection

Intuitively we perceive that the unit sphere in E^3 has curvature but the (x, y) plane there has not; both are 2-manifolds inheriting a metric connection from Euclidean E^3. A geometer detects the presence of curvature by taking a tangent vector around closed curves by parallel transport. If upon return to the starting point the transported vector is always the same as the initial vector, then the connection used for the parallel transport is called *flat*; otherwise it is called *curved*. The amount of curvature at different points and in different directions is measured by the curvature map

$$\begin{aligned} R\colon \Upsilon_0^1M \times \Upsilon_0^1M &\to L\left(\Upsilon_0^1M, T_0^1M\right) \\ : (u, v) &\mapsto R(u, v)\end{aligned}$$

where $R(u, v)\colon \Upsilon_0^1M \to \Upsilon_0^1M : w \mapsto \nabla_u\nabla_v w - \nabla_v\nabla_u w - \nabla_{[u,v]}w$. Since $L(\Upsilon_0^1M, \Upsilon_0^1M) \simeq \Upsilon_1^1M$, we can consider R to be a member of $L(\Upsilon_0^2M, \Upsilon_1^1M) \simeq \Upsilon_3^1M$, that is, a $\binom{1}{3}$-tensor field. Observe that $R(u, v) = -R(v, u)$.

We interpret $R(u, v)$ at a point x as a map of T_xM to itself that is a limiting case of parallel transport around a curvilinear parallelogram determined by $u(x), v(x) \in T_xM$. In components,

$$R(\partial_i, \partial_j)w = \nabla_{\partial_i}\nabla_{\partial_j}w - \nabla_{\partial_j}\nabla_{\partial_i}w \quad \text{since } [\partial_i, \partial_j] = 0$$

so

$$\begin{aligned} R(\partial_i, \partial_j)\partial_k &= \nabla_{\partial_i}\left(\Gamma_{jk}^m\partial_m\right) - \nabla_{\partial_j}\left(\Gamma_{ik}^m\partial_m\right) \\ &= \left(\partial_i\Gamma_{jk}^m + \Gamma_{jk}^l\Gamma_{il}^m\right)\partial_m - \left(\partial_j\Gamma_{ik}^m + \Gamma_{jk}^l\Gamma_{jl}^m\right)\partial_m \\ &= \left(\partial_i\Gamma_{ik}^m - \partial_j\Gamma_{jk}^m + \Gamma_{jk}^l\Gamma_{il}^m - \Gamma_{ik}^l\Gamma_{jl}^m\right)\partial_m \\ &= R_{ijk}^m\,\partial_m\end{aligned}$$

So as a $\binom{1}{3}$-tensor field

$$R = R_{ijk}^m\partial_m \otimes dx^i \otimes dx^j \otimes dx^k$$

Most conveniently we can interpret R as a vector-valued 2-form, the curvature form

$$\Omega\colon \Upsilon_0^1M \to \Upsilon_1^1M$$

which in local coordinates becomes

$$\Omega = \Omega_{(ij)}\,dx^i \wedge dx^j$$

where $\Omega_{ij} = (\partial_i\Gamma_{jk}^m - \Gamma_{ik}^l\Gamma_{jl}^m)\,\partial_m \otimes dx^k$. So, locally Ω takes values in $T_xM \otimes T_xM^* \simeq \mathbb{R}^{n^2}$, giving a matrix representing the limiting parallel transport map of vectors from T_xM around a parallelogram defined by ∂_i, ∂_j.

It is easy to extend the exterior product and exterior derivative to vector-valued r-forms, just by applying the usual operations to their components. When we do this connection, curvature, and torsion forms we obtain the famous structural equations of E. Cartan, for example,

$$\Omega(u, v) = d\omega(u, v) + \tfrac{1}{2}[\omega(u), \omega(v)] \quad u, v \in \Upsilon^1M$$

EXAMPLE. The previously mentioned Schwarzschild metric tensor on $M = \mathbb{R} \times E^3\backslash B$ with coordinates (t, r, θ, ϕ) is of the form

$$(g_{ij}) = \begin{pmatrix} -f^2(r) & 0 & 0 & 0 \\ 0 & f^{-2}(r) & 0 & 0 \\ 0 & 0 & r^2 & 0 \\ 0 & 0 & 0 & r^2\sin^2\theta \end{pmatrix}$$

with f a function of r

As before we let indices run 0, 1, 2, 3. Evidently, a basis of mutually orthogonal unit 1-form fields, that is, of orthonormal fields, is given by

$$(\omega^i) = (f\,dt,\ f^{-1}\,dr, r\,d\theta, r\sin\theta\,d\phi)$$

Their exterior derivatives satisfy the structural equations

$$d\omega^i = -\omega_j^i \wedge \omega^j \quad \text{where } \omega_j^i = \Gamma_{jk}^i\omega^k$$

and

$$\Omega_j^i = d\omega_j^i + \omega_k^i \wedge \omega_j^k \quad \text{where } \Omega_j^i = R_{l(ij)}^k w^i \wedge \omega^j$$

Computation of the derivatives yields the following with $\dot{f}$ denoting the derivative of f with respect to r:

$$\begin{aligned} d\omega^0 &= \dot{f}\omega^1 \wedge \omega^0 \\ d\omega^1 &= 0 \\ d\omega^2 &= (f/r)\omega^1 \wedge \omega^2 \\ d\omega^3 &= (f/r)\omega^1 \wedge \omega^3 + (\cot\theta)/r\,\omega^2 \wedge \omega^3\end{aligned}$$

Then we deduce that the only nonzero ω_j^i are

$$\begin{aligned} &\omega_1^2 = -\omega_2^1 = f/r\omega^2 \quad \text{so } d\omega_1^2 = f\dot{f}/r\omega^1 \wedge \omega^2 \\ &\omega_1^3 = -\omega_3^1 = f/r\omega^3 \quad \text{so } d\omega_1^3 = f\dot{f}/r\omega^1 \wedge \omega^2 + f/r\cot\theta\,\omega^2 \wedge \omega^3 \\ &\omega_1^0 = \omega_0^1 = \dot{f}\omega^0 \quad \text{so } d\omega_1^0 = (\dot{f}^2 + f\dot{f})\omega^1 \wedge \omega^0 \\ &\omega_2^3 = -\omega_3^2 = (\cot\theta)/r\omega^3 \quad \text{so } d\omega_2^3 = -1/r^2\omega^2 \wedge \omega^3\end{aligned}$$

By inspection of the second structural equation we find

$$\Omega_1^0 = (ff' + f'^2)\omega^1 \wedge \omega^0$$
$$\Omega_2^0 = ff'/r\,\omega^3 \wedge \omega^0$$
$$\Omega_1^3 = ff'/r\,\omega^1 \wedge \omega^3 + f/r^2 \cot\theta\,\omega^2 \wedge \omega^3$$
$$\Omega_1^2 = ff'/r\,\omega^1 \wedge \omega^2$$
$$\Omega_2^3 = (f^2 - 1)/r^2\,\omega^2 \wedge \omega^3$$
$$\Omega_3^0 = ff'/r\,\omega^3 \wedge \omega^0$$

Then from the definition of the curvature form we obtain the components R^k_{lij} of the Riemann curvature tensor. For example,

$$R^2_{332} = R^3_{223} = (f^2/r^2) - (1/r^2)$$

Einstein's equation in general relativity can be written

$$R^k_{ijk} = R^0_{ij0} + R^1_{ij1} + R^2_{ij2} + R^3_{ij3} = 0$$

It results in two differential equations for f, reducible to

$$f^2 + r\,(d/dr)(f^2) - 1 = 0$$

which admits the solution we encountered before:

$$f(r) = (1 - 2m/r)^{1/2}$$

VII. SINGULAR GEOMETRY

In this section we shall look, albeit briefly, at some situations where the geometry goes wrong. We have seen that if we start with a nice geometrical space, like Euclidean E^2, we can introduce singular behavior by removing points. Spaces obtained by such removal operations are manifestly incomplete. The interesting thing is that some geometrical spaces are not of this type but are incomplete; in other words some singular behavior still persists after all removed points are replaced.

A. Riemannian Completeness

It is an interesting geometrical problem to describe just what constitutes a singularity and where it is in such spaces. Geodesic completeness is one obvious criterion and it solves the problem for Riemannian manifolds: there is a geodesic singularity in a region $U \subseteq M$ if there is a geodesic that enters U and does not leave but cannot be extended. It can be shown by means of the Hopf-Rinow theorem that this criterion covers all other curves as well: a Riemannian manifold (without boundary) is complete with respect to all curves if and only if it is complete with respect to all geodesics. A sufficient condition for a Riemannian manifold to be geodesically complete is for it to be compact, for instance, a closed and bounded subset of some Euclidean E^n. Spheres and the torus are of this kind. It is not a necessary condition because E^n itself is complete but not compact. In a connected, complete Riemannian manifold any two points can be connected by a geodesic that is minimal in length relative to all joining curves between the points. Of course, in any Riemannian manifold, "small enough" regions are always complete.

B. Connection Completeness

Geodesics do not tell the whole story about completeness in non-Riemannian manifolds. It is possible to have geodesic completeness but some other curves may be incomplete in any reasonable definition. For example, it is possible to contrive a model space-time that is geodesically complete but in which an observer, in a rocket say, could with finite energy follow a trajectory that cannot be extended beyond a certain finite time. Such an observer would disappear from that universe. Most realistic cosmological models imply space-time geometries that are of this kind, simply because gravity is attractive.

We are faced with the problem: does a given curve $c\colon [0, 1) \to M$ admit a continuous extension by one point to the closed interval [0, 1]? If not, then we say that the curve is *inextensible*. This in itself need not imply a problem of incompleteness since, in the Euclidean plane,

$$c\colon [0, 1) \to E^2 : t \mapsto (0, (1 - t)^{-1} - 1)$$

begins at the origin and proceeds to cover the whole positive y axis but we cannot extend it to a domain including $t = 1$. The additional test that we need to make is for some kind of finiteness property. In the presence of a Riemannian metric we could use the length of the curve. Clearly, though inextensible the above curve is not finite in length, so we do not wish to infer from it any intrinsic incompleteness of the space E^2. In the absence of suitable measurements for length, as in pseudo-Riemannian manifolds, we need another device to test for finiteness. The natural one, which arises when we have a connection, depends on the use of parallel transport along the given curve.

C. *b*-Incompleteness

Let $c\colon [0, 1) \to M$ be a curve in manifold M with connection ∇ and choose a basis (b_i) for $T_{c(0)}M$. Then the parallel transport isomorphism of tangent spaces along the curve's path, say,

$$\tau_t\colon T_{c(0)}M \to T_{c(t)}M : u^i b_i \mapsto u^i \tau(b_i) = u^i \beta_i(t)$$

defines a basis $(\beta_i(t))$ for each $T_{c(t)}M$. Now, any n-dimensional vector space, once we have chosen a basis,

has a unique isomorphism with $\mathbb{R}^n$ simply by taking components with respect to that basis. Next, tmr^n has a natural norm

$$\|(x^i)\| = ((x^1)^2 + (x^2)^2 + \cdots + (x^n)^2)^{1/2}$$

So, given the choice of basis $(b_i) = (\beta_i(0))$ at $c(0)$ for our tangent spaces, we can use its parallel transported image to define a b length for the tangent vector

$$\dot{c}(t) = \dot{c}^i(t)\beta_i(t) \quad \text{to } c \text{ at } t$$

namely

$$\|\dot{c}(t)\|_b = \|(\dot{c}^i(t))\|$$

This gives us a b length of the curve with respect to basis (b_i) at $c(0)$, defined by

$$L_b(c) = \int_0^t \|\dot{c}(t)\|_b \, dt$$

In a space-time manifold, a choice of basis for one tangent space is effectively a choice of reference frame of directions and scale of units, that is, an observer. Clearly our b length will vary with the choice of the observer. However, what does not vary is whether it is finite or not. One choice of initial basis (b_i) at $c(0)$ is sufficient to test for finiteness of b-length with respect to any basis.

Accordingly, we say that curve c is b incomplete if it is inextensible and has finite b length. This definition only needs the presence of a connection, not a metric tensor. When we do have a Riemannian metric connection then the finiteness of b length is equivalent to the finitness of ordinary length. We say that a manifold with connection is b incomplete if it contains a b-incomplete curve. A Riemannian manifold is actually b incomplete if and only if it is geodesically incomplete, but this is not the case for pseudo-Riemannian manifolds.

When it was discovered that all realistic models of the universe, relativistic or otherwise, are likely to be incomplete, it was natural to enquire if this was merely an inadequacy of the field theory of gravity. Thus, it might be hoped than an appropriate quantum theory of gravity would be such as to average out any classical singularities. Unfortunately, there is no single quantum theory of gravity that is accepted by all. One theory, geometrical quantization, when applied to a massless Klein–Gordon scalar field on a curved space-time could not prevent the collapse of the state vector: the incompleteness found in the classical geometry could not be quantized away. More generally, it was shown that if there is b incompleteness with respect to one connection then there will be b incompleteness with respect to any nearby connection. So the singularity is stable under perturbations of the connection and unlikely to be removable by any quantum theory of gravity.

VIII. TOPOLOGY, GEOMETRY, AND PHYSICS

The 20th century enjoyed a wealth of developments from the interplay of formal mathematics and natural sciences, and in no other area is this as rich in results as that involving geometry, topology, and theoretical physics. One of the most remarkable families of recent results has been in the work of Freedman and Donaldson that led to their award of Fields Medals at the International Congress of Mathematicians in 1986. An amazing but easily comprehended result is that there are copies of $\mathbb{R}^4$ that are topologically indistinguishable from ordinary $\mathbb{R}^4$ but which have different manifold structures—namely, there are exotic 4-spaces and this happens in no other dimension.

In simple terms, we could say that whereas on all $\mathbb{R}^n$ for $n = 1, 2, 3, 5, 6, \ldots$, there is only one way to set up calculus, in the case of $\mathbb{R}^4$ there are infinitely many different ways to do it. It was already known that there were exotic 7-spheres (but none of lower dimension), but the new results led to the existence of exotic closed 4-manifolds. Many compact (topological) 4-manifolds cannot be given a differentiable structure and those that do admit differentiable structures may allow infinitely many. Interestingly, this was proved by using the methods of Yang-Mills theory from physics. The obstructions to differentiable structures arise from the theory of connections associated with the Yang-Mills equations and instantons. Thus, Donaldson gave an application of physical gauge field theory to geometrical topology.

Cosmology has provided rich areas of application for the curved pseudo-Riemannian geometry needed for general relativity theory and it has generated very precise expriments to detect the physical consequences. In general relativity, spacetime has its curvature controlled by the matter distribution and the curvature controls how freely gravitating bodies will move.

The usual model for a simple, homogeneous isotropic spacetime is $\mathbb{R}^4$ with the Friedmann-Robertson-Walker metric tensor, given by the arclength expression

$$ds^2 = c^2\,dt^2 - a(t)^2\left(\frac{dr^2}{1-kr^2} + r^2(\sin^2\theta\,d\phi^2 + d\theta^2)\right).$$

Here, $k = 1, 0, -1$ depending on whether the universe is closed, flat, or open, respectively. In the case $k = 1$, space is represented at each instant t by a sphere of radius $a(t)$.

Geodesics represent the trajectories of particles free from all influences other than gravitational interactions with the matter in the universe. Photons follow null geodesics, which lie on the boundary of local null cones ($ds^2 = 0$) determined by the constancy of the speed of light. Free material particles follow timelike geodesics but even those subject to acceleration are nevertheless

constrained to lie locally in the interior ($ds^2 > 0$) of null cones of directions.

In the Friedmann-Robertson-Walker cosmological model, the wavelength of electromagnetic radiation emitted from a distant source at time t and observed at time t_0 has redshift relative to the local wavelength given by:

$$\frac{\lambda_{\text{source}}}{\lambda_{\text{local}}} = 1 + z = \frac{a(t_0)}{a(t)}.$$

Free, initially thermal radiation energy remains thermal during the expansion of the universe, with temperature proportional to $a(t)^{-1}$ and the relative expansion rate of the spacelike surfaces is given by

$$\left(\frac{1}{a}\frac{da}{dt}\right)^2 = H^2 = \frac{8}{3}\pi G\rho + \frac{k^2}{a^2} + \frac{1}{3}\Lambda$$

Here, G is the gravitational constant, H is Hubble's constant at time t, Λ is the cosmological constant and ρ is the mean matter density. The critical mean density that corresponds to $k = 0$ when $\Lambda = 0$, is given at the present epoch when $H = H_0$, by

$$\rho_{\text{crit}} = \frac{3H_0^2}{8\pi G}$$

A recent trend has been to allow Λ to differ from zero, since there is evidence that the present mean matter density is less than the critical mean density ρ_{crit}.

A Hot Big Bang some 12 Giga years ago, at $t = 0$ in the Friedmann-Robertson-Walker model, followed by an adiabatic expansion controlled by general relativity, is the broad scenario most widely accepted by cosmologists. It accounts well for the relative abundance of the lightest nuclides and for the observable microwave background radiation. However, there are some intriguing difficulties. The matter in typical galaxies arose from fluctuations within the first year after the Big Bang, because later the scales would have been too large for causal effects to occur. This gives rise to the question of the origin and nature of the fluctuations in the hot dense early phase; "cosmic inflation" is a currently favored way to answer this question. This notion involves an initial period of exponentially accelerating expansion lasting $\sim 10^{-32}$ sec, caused by a positive cosmological constant, which physicists associate with a hypothetical scalar field or "inflaton." Such an inflation period would precede the normal evolution of $a(t)$. A special case of interest is when $k = 0$, the mean matter density is zero $\rho = 0$, and the cosmological constant Λ is positive in Friedmann-Robertson-Walker spacetime. This corresponds to the de Sitter cosmological model, which happens also to be the limiting scenario for all indefinitely expanding models with $\Lambda > 0$. In de Sitter spacetime, the cosmic inflation corresponds to $a(t) \propto e^{\sqrt{\Lambda/3}t}$.

Rather surprisingly, general relativistic cosmology coupled with deep space observations lead cosmologists to conclude that most of the matter in galaxies and clusters is dark matter and so is invisible as far as electromagnetic emission or absorption is concerned. The matter is known to be there through gravitational effects and it is dominant at all scales of structure larger than galactic cores, but it is unclear what form it takes. Inference from interpreting gravitational effects on infrared spectral redshifts indicates the presence of supergalactic sheetlike clusters containing about 60% of all galaxies. The remaining galaxies seem to be about equally shared between dense filamentary conglomerations ("walls") and sparse filaments. This disposition of matter leaves large voids in the observable univese and the distribution of the sizes of these voids is also an active research area.

Quasars and active galactic nuclei need some source of energy and one possibility is for this to consist of massive black holes, of size 10^7–10^9 solar masses. The simplest geometry for an otherwise empty spacetime containing an isolated black hole with mass M is that of the Schwarzschild model. There we have

$$ds^2 = (1 - 2M/r)\,dt^2 - \frac{dr^2}{1 - 2M/r} + r^2(\sin^2\theta\, d\phi^2 + d\theta^2).$$

The event horizon consists of the surface at $r = 2M$, from which neither photons nor material particles can escape to the outside and through which any nearby particles will be drawn toward the central singularity at $r = 0$. In fact, quantum theory may allow a tunneling escape of matter and a consequential reduction of mass as a result of pair production just outside the event horizon, if only one of the pair is drawn in. Infalling matter swept up by a black hole in a galactic core could generate radiation energy through its acceleration toward the event horizon.

GLOSSARY

Church-Turing thesis Claim that every computable function can be computed by a Turing machine.
Computability theory Study of computable functions on the natural numbers.
Continuum hypothesis Conjecture that there are only two sizes of infinite sets of real numbers.
Database Finite, typically relational structure.
First-order logic Mathematical model of the part of language built up from the propositional connectives and the quantifiers.
Incompleteness phenomenon Gödel's discovery, that sufficiently strong axiomatic theories cannot decide all propositions which they can express.
Model theory Study of formal definability in first-order structures.
Paradox Counterintuitive truth.
Peano arithmetic Axiomatic theory of natural numbers.
Proof theory Study of inference in formal systems independently of their interpretation.
Propositional connectives The linguistic constructs "and," "not," "or," and "implies."
Quantifiers The linguistic constructs "there exists" and "for all."
Turing machine Mathematical model of computing device with unbounded memory.
Unsolvable problem A problem whose solution requires a non-existent algorithm.

NARROWLY CONSTRUED, mathematical logic is the study of *definition* and *inference* in mathematical models of fragments of language, especially the *first-order logic* fragment. Logic has made critical contributions to the foundations of science, especially through the work of Kurt Gödel, and it also has numerous applications. For *set theory* and *theoretical computer science*, these applications are so important, that parts of these fields are normally included in the modern, broad conception of the discipline.

I. PROPOSITIONAL LOGIC, $\mathbb{PL}$

Each logic $\mathbb{L}$ has a *syntax* which delineates the grammatically correct linguistic expressions of $\mathbb{L}$, a *semantics* which assigns meaning to the correct expressions, and a structured *system of proofs* which specifies the rules by which some $\mathbb{L}$-expressions can be inferred from others.

There are other words to describe these things: *formal language* is sometimes used to describe a plain syntax, *formal system* often identifies a syntax together with an inference system (but without an interpretation), and *abstract logic* has been used to refer to a syntax together with an interpretation, leaving inference aside. It is, however, a fundamental feature of logic that it draws clean distinctions and studies the connections among these three aspects of language. We explain them first in the simplest example of the "logic of propositions," which is part of many important logics.

A. Propositional Syntax

The *symbols* of $\mathbb{PL}$ are the *connectives*

$$\neg \text{ (not)} \quad \& \text{ (and)} \quad \vee \text{ (or)} \quad \rightarrow \text{ (implies, if-then)}$$

the two parentheses '(', ')', and an infinite list of (formal) propositional variables P_0, P_1, P_2, ... which intuitively stand for declarative propositions, things like "John loves Mary" or "3 is a prime number." It has only one category of grammatically correct expressions, the *formulas*, which are *strings* (finite sequences) of symbols defined inductively by the following conditions:

1. Each P_i is a formula.
2. If A and B are formulas, then so are the expressions

$$\neg A \quad (A \,\&\, B) \quad (A \vee B) \quad (A \rightarrow B)$$

For example, if P and Q are propositional variables, then $(P \rightarrow Q)$ and $(P \vee \neg P)$ are formulas, which we read as "if P then Q" and "either P or not P."

The inductive definition gives a precise specification of exactly which strings of symbols are formulas, and also insures that each formula is either *prime*, i.e., just a variable P_i, or it can be constructed in exactly one way from its simpler *immediate parts*, by one of the connectives. This makes it possible to prove properties of formulas and to define operations on them by *structural induction* on their definition.

More propositional connectives can be introduced as "abbreviations" of formula combinations, e.g.,

$$A \leftrightarrow B \equiv ((A \rightarrow B) \,\&\, (B \rightarrow A))$$

$$A \vee B \vee C \equiv (A \vee (B \vee C)).$$

TABLE I Truth Value Semantics

A	B	$\neg A$	$(A \,\&\, B)$	$(A \vee B)$	$(A \rightarrow B)$
1	1	0	1	1	1
1	0	0	0	1	0
0	1	1	0	1	1
0	0	1	0	0	1

B. Propositional Semantics

If B stands for some *true* proposition, then $\neg B$ is false, independently of the "meaning" or internal structure of B. This is an instance of a general *Compositionality Principle for* $\mathbb{PL}$: The truth value of a formula depends only on the truth values of its immediate parts. The semantics of $\mathbb{PL}$ comprise the rules for computing truth values, and they can be summarized in Table I, where 1 stands for "truth" and 0 for "falsity." By the first line of this table, for example, if A and B are both true, then $\neg A$ is false while $(A \,\&\, B)$, $(A \vee B)$, and $(A \rightarrow B)$ are all true. Notice that if A is false, then $(A \rightarrow B)$ is reckoned to be true no matter what the truth value of B, so that "if the moon is made of cheese, then $1 + 1 = 5$" is true (on the plausible assumption that the moon is not made of cheese). This *material implication* assumed by Propositional Logic has been attacked as counterintuitive, but it agrees with mathematical practice and it is the only useful interpretation of implication which accords with the Compositionality Principle.

Using these rules, we can construct for each formula A a *truth table* which tabulates its truth value under all assignments of truth values to the variables. For example, the truth table for $(Q \rightarrow P)$ consists of the first three columns of Table II while the first two and the last column give the truth table for $(P \rightarrow (Q \rightarrow P))$.

If n variables occur in a formula A, then the truth table for A has 2^n rows and determines an n-ary *bit function* v_A, with arguments and values in the two-element set $\{1, 0\}$. By the *Definitional Completeness Theorem*, every n-ary bit function is v_A for some A, so that the formulas of $\mathbb{PL}$ provide definitions (or "symbolic representations") for all bit functions.

TABLE II Truth Table

P	Q	$(Q \rightarrow P)$	$(P \rightarrow (Q \rightarrow P))$
1	1	1	1
1	0	1	1
0	0	1	1
0	1	0	1

A formula A is a *semantic consequence of* a set of formulas T (or T*-valid*) if every assignment to the variables which *satisfies* (makes true) all the formulas in T also satisfies A. We write

$$T \models A \Leftrightarrow A \text{ is } T\text{-valid},$$

and $\models A$, in the important special case when T is empty, in which case A is called a *tautology*. A formula A is *satisfiable* if some assignment satisfies it, i.e., if $\neg A$ is not a tautology. Let

$$A \sim B \Leftrightarrow \{A\} \models B \text{ and } \{B\} \models A$$
$$\Leftrightarrow \models A \leftrightarrow B,$$

and call A and B *equivalent* if $A \sim B$. Equivalent formulas define the same bit function, and they can be substituted for each other without changing truth values. Clearly

$$(A \rightarrow B) \sim (\neg A \vee B),$$

so that the implication connective is superfluous. In fact, every formula is equivalent to one in *disjunctive normal form*, i.e., a disjunction $A_1 \vee \cdots \vee A_k$ where each A_i is a conjunction of variables or negations of variables (*literals*).

C. Applications to Circuits

Each formula A with n variables can be realized by a *switching circuit* $C(A)$ with n *inputs* and one *output*, so that $C(\mathsf{P}_i)$ consists of just one input-output edge, $C(A \,\&\, B)$ is constructed by joining $C(A)$ and $C(B)$ with an *and-gate*, etc. Figure 1 exhibits the circuit for $((\mathsf{P}_1 \,\&\, \mathsf{P}_2) \rightarrow \mathsf{P}_3)$ using the equivalent formula without implications, so that only $\neg$-, &-, and $\vee$-gates are required. These are restricted circuits, of *fan-in* (maximum number of edges into a node) 2 and *fan-out* 1, but the *Definitional Completeness Theorem* implies that every n-ary bit function can be computed by some *formula circuit* $C(A)$.

There are basically two useful measures of circuit complexity, and both of them are faithfully mirrored in formulas. The *number of gates* of $C(A)$ is exactly the number of connectives in A and measures *size complexity* (construction cost), while the *depth* of $C(A)$, which measures the *time complexity* of computation, is exactly the *rank* of A, defined inductively so that $\mathrm{rk}(\mathsf{P}_i) = 1$, $\mathrm{rk}(A \,\&\, B) = \max(\mathrm{rk}(A), \mathrm{rk}(B)) + 1$ and similarly for the other connectives. One can now use natural manipulations of formulas to construct circuits which compute a given bit function with minimum size or time complexity, or to establish optimality results for the computation of bit functions by appealing to the formula representations of the circuits which realize them. For example, using disjunctive normal forms, one sees immediately that (if we do not care about cost), *every n-ary bit function can be computed by an unbounded fan-in circuit in no more than* 3 *time units*. There is, in general, a substantial *trade-off* between the size and time complexity of the circuits which compute a given bit function.

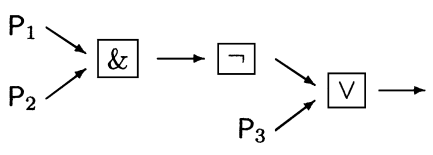

FIGURE 1 The circuit for $(\neg((\mathsf{P}_1 \,\&\, \mathsf{P}_2) \vee \mathsf{P}_3)$.

D. The Satisfiability Problem

The assertion that "$C(A)$ and $C(B)$ never give the same output on the same inputs" means precisely that "$(A \leftrightarrow \neg B)$ is a tautology," so that to detect that A and B do not have this *safety property* we need to determine whether the formula $\neg(A \leftrightarrow \neg B)$ is *satisfiable*.

Because of such natural formulations of "error detection" for circuits relative to given specifications, it is very important to find efficient algorithms for determining whether a given formula is satisfiable. The problem is of *non-deterministically polynomial time complexity* (*NP*), because it can be resolved by guessing ("non-deterministically") some assignment and then verifying that it satisfies A in a number of steps which is bounded by a polynomial in the length of A; and it is *NP*-complete, i.e., every *NP*-problem can be "reduced" to it by a polynomial reduction. This is a basic result of S. Cook, who introduced the complexity class *NP*, showed that it contains a large number of important problems, and asked if it coincides with the (seemingly) smaller class P of "feasible," *deterministically polynomial time* problems. The question whether $P = NP$ is the fundamental open problem of complexity theory; it amounts simply to the question whether the satisfiability problem can be solved by a deterministic, polynomial algorithm.

E. Propositional Inference

A *proof* of a formula A from a set of hypotheses T is any finite sequence

$$A_0, A_1, \ldots, A_{n-1}, A$$

which ends with A, and such that each A_i is either in T, or a $\mathbb{PL}$*-axiom*, or follows from previously listed formulas by a *rule of inference*. To make this notion precise we need to specify a set of $\mathbb{PL}$-axioms and rules of inference; and for these to be useful, it should be that they are few and easy to understand, and that the formulas provable from T are exactly the T-tautologies.

We need just one, binary *inference rule*:

$$\frac{A \qquad (A \to B)}{B} \text{ (Modus Ponens)}$$

This is *sound*, i.e., $\{A, (A \to B)\} \models B$, so that if A and $(A \to B)$ are both T-tautologies, then so is B.

An axiom is any instance of the following *axiom schemes*, where A, B, and C are arbitrary formulas and we have omitted several parentheses which pedantry would require:

(1) $A \to (B \to A)$
(2) $(A \to B) \to ((A \to (B \to C)) \to (A \to C))$
(3) $A \to (B \to (A \,\&\, B))$
(4) $(A \,\&\, B) \to A$ (4′) $(A \,\&\, B) \to B$
(5) $A \to (A \vee B)$ (5′) $B \to (A \vee B)$
(6) $(A \to C) \to ((B \to C) \to ((A \vee B) \to C))$
(7) $(A \to B) \to ((A \to \neg B) \to \neg A)$
(8) $\neg\neg A \to A$

These are all tautologies, and so every formula provable from T is T-valid. We write

$$T \vdash A \Leftrightarrow \text{there is a proof of } A \text{ from } T,$$

and it is not hard now to establish the basic

Soundness and Completeness Theorem for $\mathbb{PL}$. *For all sets* T *and any* A,

$$T \models A \Leftrightarrow T \vdash A.$$

F. Boolean Algebras

A *Boolean algebra* is a set $\mathcal{B}$ with at least two, distinct elements 0 and 1, a unary *complementation operation* $'$, and binary *infimum* $\cap$ and *supremum* $\cup$ operations such that certain properties hold. The standard example is the set $\mathcal{P}(M)$ of all subsets of some nonempty set M, with $0 = \emptyset$, $1 = M$ and the usual complementation, intersection and union operations, which for a singleton M gives the two-element set $\{1, 0\}$ of truth values; but there are others, e.g., the set of all finite and cofinite subsets of some infinite set, the set of all "closed and open" subsets of a topological space, etc.

Each formula A with n variables defines an n-ary function on every Boolean algebra $\mathcal{B}$, simply by letting the propositional variables range over $\mathcal{B}$ and replacing $\neg$, &, and $\vee$ and $\to$ by $'$, $\cap$, $\cup$, and $\Rightarrow$ respectively, where

$$x \Rightarrow y = x' \cup y$$

on $\mathcal{B}$. Now the axioms for a Boolean algebra insure that *every propositional axiom defines a function with constant value* 1—in fact the particular choice of axiomatization for Boolean algebras (and there are many) is quite irrelevant as long as this fact obtains; and then the Completeness Theorem implies that *two formulas* A *and* B *define the same* n*-ary operation on all Boolean algebras exactly when* $A \sim B$, i.e., when A and B define the same bit function.

Boolean algebras have many important applications in mathematics (to measure theory, among other things), and they are the subject of the classical *Stone Representation Theorem* which identifies them all (up to isomorphism) with sub-algebras of powerset algebras. In logic they are mostly used through the "nonstandard" *Boolean semantics* of this subsection, which extend to richer logics and provide a powerful tool for *independence* (unprovability) results.

II. FIRST-ORDER LOGIC, $\mathbb{FOL}$

Consider the claim:

If everybody has a mother, and every mother loves her children, then everybody is loved by somebody.

It is certainly true, it has the "linguistic form" of many similar (more substantial) claims in mathematics, and it appears to be *true by virtue of its form* and not because of any special properties of the words "mother," "love," etc. First-Order Logic makes it possible to express complex assertions of this type and to show that they are true *by logic alone*. The symbolic expression of this one will be

$$[(\forall x)(\exists y)M(x, y) \,\&\, (\forall x)(\forall y)[M(x, y) \to L(y, x)]] \to (\forall x)(\exists y)L(y, x),$$

give-or-take a few parentheses and brackets which will be required to make the syntax completely precise.

A. First-Order Syntax

The symbols of $\mathbb{FOL}$ are the propositional connectives, the parentheses, the *quantifiers*

$$\forall \text{ (for all)} \qquad \exists \text{ (there exists)}$$

the comma ',', the identity symbol '=', an infinite list $\mathsf{v}_0, \mathsf{v}_1, \ldots$ of *individual variables* which will denote arbitrary objects in some domain, and for each $n = 0, 1, \ldots$, two infinite lists of *function* and *relational symbols*

$$\mathsf{f}_0^n, \mathsf{f}_1^n, \ldots, \qquad \mathsf{P}_0^n, \mathsf{P}_1^n, \ldots,$$

which will stand for n-ary functions and relations on the objects.

There are two categories of grammatically correct expressions in $\mathbb{FOL}$, *terms* and *formulas*, defined recursively by the following conditions.

T1. Each variable v_i is a term.

T2. If $t_1, \ldots, t_n$ are terms, then (the string) $\mathsf{f}_i^n(t_1, \ldots, t_n)$ is also a term. When $n = 0$, we write simply f_i^0.

F1. If $t_1, \ldots, t_n$ are terms, then the expressions

$$t_1 = t_2 \quad \mathsf{P}_i^n(t_1, \ldots, t_n)$$

are formulas, the latter written simply P_i when $n = 0$.

F2. If A and B are formulas, then so are the expressions

$$\neg A \quad (A \,\&\, B) \quad (A \vee B) \quad (A \to B)$$

F3. If A is a formula, then so are the expressions

$$(\forall \mathsf{v}_i)A \quad (\exists \mathsf{v}_i)A$$

Notice that by the notational convention in F1, all $\mathbb{PL}$-formulas are also $\mathbb{FOL}$-formulas.

This logic is called *first order* because quantification is only allowed over individuals; if we add formula formation rules

$$\left(\forall \mathsf{P}_i^n\right)A \quad \left(\exists \mathsf{P}_i^n\right)A$$

we obtain the formulas of *second-order logic*, $\mathbb{SOL}$.

Consider the simple formula

$$(\exists \mathsf{v}_2)\left(\neg \mathsf{v}_2 = \mathsf{v}_1 \,\&\, \mathsf{P}_1^1(\mathsf{v}_2)\right). \tag{1}$$

Its "translation" into English by the reading of the symbols we have introduced is

some object other than v_1 has the property P_1^1

which is exactly how we would translate the result of substituting v_3 for v_2 in it,

$$(\exists \mathsf{v}_3)\left(\neg \mathsf{v}_3 = \mathsf{v}_1 \,\&\, \mathsf{P}_1^1(\mathsf{v}_3)\right).$$

This is because both occurrences of v_2 in Eq. (1) are *bound* by the quantifier $\exists \mathsf{v}_2$, just as the occurrences of x are bound by the dx in $\int_0^1 x^2 dx$ and can be replaced by y without changing the meaning of the definite integral. On the other hand, the occurrence of v_1 in Eq. (1) is *free*, because it is not within the scope of any quantifier, and so the interpretation of v_1 clearly affects the meaning of Eq. (1).

Using the same simple example, consider the results of substituting $\mathsf{f}_0^1(\mathsf{v}_3)$ and $\mathsf{f}_0^1(\mathsf{v}_2)$ for v_1 in Eq. (1),

$$(\exists \mathsf{v}_2)\left(\neg \mathsf{v}_2 = \mathsf{f}_0^1(\mathsf{v}_3) \,\&\, \mathsf{P}_1^1(\mathsf{v}_2)\right),$$

$$(\exists \mathsf{v}_2)\left(\neg \mathsf{v}_2 = \mathsf{f}_0^1(\mathsf{v}_2) \,\&\, \mathsf{P}_1^1(\mathsf{v}_2)\right).$$

The first of these says of $\mathsf{f}_0^1(\mathsf{v}_3)$ what Eq. (1) says of v_2, but the second says that "something is not a fixed point of f_0^1 and has property P_1^1," which is quite different—evidently because the variable v_2 in $\mathsf{f}_0^1(\mathsf{v}_2)$ is "caught" by the quantifier $\exists \mathsf{v}_2$. The first is a *free substitution* (causing no confusion) while the second is not. We will denote the result of substituting the term t for the free occurrences of the variable x in some formula A by

$$A\{x :\equiv t\}$$

and we will tacitly assume that all substitutions are free.

Formulas of $\mathbb{FOL}$ are too messy to write down, and so we often resort to "informal descriptions" of them like the example about mothers loving their children above, recipes, really, from which the full, grammatically correct formula could (in principle) be constructed.

B. First-Order Semantics

Whether Eq. (1) is true or false depends on the object v_1, on the function f_0^1, on the property P_1^1, and (most significantly) on the range of objects over which we interpret the existential quantifier—where do we search for things which may or may not satisfy P_1^1?

To interpret the formulas of $\mathbb{FOL}$ we must be given a *domain* D and an *interpretation* $\imath$, a function which assigns an object $\imath(\mathsf{v}_i)$ in D to each individual variable, an n-ary function $\imath(\mathsf{f}_i^n)$ on D to each n-ary function symbol f_i^n, and an n-ary relation $\imath(\mathsf{P}_i^n)$ on D to each P_i^n. Using these, first we extend inductively $\imath$ to all terms by

$$\imath\left(\mathsf{f}_i^n(t_1, \ldots, t_n)\right) = \left(\imath\left(\mathsf{f}_i^n\right)\right)(\imath(t_1), \ldots, \imath(t_n)),$$

so that $\imath(t)$ is some object in D. To assign truth values to formulas, define first, for each variable x and d in D, the *update*

$$\jmath = \imath\{x := d\},$$

which agrees with $\imath$ on all function and relation symbols, and also on all individual variables, except that $\jmath(x) = d$. With the help of this basic operation, we can state in Table III the classical *Tarski truth conditions* which determine the truth of formulas relative to a fixed domain D and an interpretation $\imath$. The *truth value* of a formula A relative to an interpretation $\imath$ is 1 if $\imath \models A$ and 0 otherwise, and the *Compositionality Principle* extends to $\mathbb{FOL}$ in a straightforward manner and implies the following basic fact: the truth value of A relative to $\imath$ depends only on the

TABLE III The Tarski Truth Conditions

$\imath \models t_1 = t_2 \Leftrightarrow \imath(t_1) = \imath(t_2)$
$\imath \models \mathsf{P}_i^n(t_1, \ldots, t_n) \Leftrightarrow (\imath(\mathsf{P}_i^n))(\imath(t_1), \ldots, \imath(t_n))$
$\imath \models \neg \mathrm{A} \Leftrightarrow \imath \not\models A$
$\imath \models (A \,\&\, B) \Leftrightarrow \imath \models A$ and $\imath \models B$
$\imath \models (A \vee B) \Leftrightarrow \imath \models A$ or $\imath \models B$
$\imath \models (A \to B) \Leftrightarrow \imath \not\models A$ or $\imath \models B$
$\imath \models (\forall \mathsf{v}_i)A \Leftrightarrow$ for all d in D, $\imath\{\mathsf{v}_i := d\} \models A$
$\imath \models (\exists \mathsf{v}_i)A \Leftrightarrow$ for some d in D, $\imath\{\mathsf{v}_i := d\} \models A$

values of ι on the function and relation symbols which occur in A, and on the values $\iota(x)$ for the individual variables which occur *free* in A.

The Tarski conditions do nothing more than translate formulas into English, in effect identifying $\mathbb{FOL}$ with a precisely formulated, small but very expressive fragment of natural language.

C. Structures

A *vocabulary* (or *signature*) is any finite sequence $\sigma = \{\mathsf{f}_1, \ldots, \mathsf{f}_k, \mathsf{P}_1, \ldots, \mathsf{P}_l\}$ of function and relation symbols, and $\mathbb{FOL}(\sigma)$ is the part of $\mathbb{FOL}$ whose formulas involve only the function and relation symbols of σ. The idea is to think of $\mathsf{f}_1, \ldots, \mathsf{f}_k$ and $\mathsf{P}_1, \ldots, \mathsf{P}_l$ as constants, denoting fixed functions and relations on some set D, and to use the formulas of $\mathbb{FOL}(\sigma)$ to study definability in *structures*

$$M = (D_M, f_1, \ldots, f_k, P_1, \ldots, P_l)$$

of vocabulary σ, where the *universe* D_M of M is any nonempty set, and $f_1, \ldots, f_k, P_1, \ldots, P_l$ are functions and relations which can be assigned to the vocabulary symbols, e.g., such that f_i is n-ary if f_i is n-ary.

An *M-assignment* is any function α from the variables to D_M, and it extends naturally to an interpretation α_M by the association of f_i with f_i and P_i with P_i; the standard notation for *structure satisfaction* is

$$M, \alpha \models A \Leftrightarrow \alpha_M \models A.$$

Formulas of $\mathbb{FOL}(\sigma)$ with no free variables are called *sentences* and (by the Compositionality Principle) they are simply true or false in every σ-structure, without reference to any assignment. They define properties of structures. We write

$$M \models A \Leftrightarrow \text{ for any (and hence all) } \alpha, \quad M, \alpha \models A \quad (A \text{ a sentence}),$$

and if $M \models A$, we say that M *satisfies* A or *is a model of* A.

While sentences define properties of structures, formulas with free variables can be used to define relations on structures. If, for example, A has at most one free variable x, we set

$$R_A(d) \Leftrightarrow M, \alpha\{x := d\} \models A,$$

where α is any assignment, since its only relevant value is updated in this definition. In the same way, formulas with n free variables define n-ary *relations* on σ-structures, the *first-order definable* relations of M. A function $f : D_M^n \to D_M$ is first-order definable if its graph

$$G_f(x_1, \ldots, x_n, w) \Leftrightarrow w = f(x_1, \ldots, x_n)$$

is first-order definable. Some examples:

A *directed graph* is a structure $G = (D, E)$, where E is a binary "edge" relation on the set of "nodes" G, and it is a *graph* (undirected) if it satisfies the sentence

$$(\forall x)(\forall y)[E(x, y) \to E(y, x)].$$

Complete graphs (cliques) are characterized by the sentence

$$(\forall x)(\forall y)E(x, y),$$

while "diameter ≤ 2" is defined by

$$(\forall x)(\forall y)[x = y \vee E(x, y) \vee (\exists z)[E(x, z) \,\&\, E(z, y)]].$$

Finite directed and undirected graphs are used to model many notions in computer science, e.g., circuits.

A *semigroup* (monoid) with identity is a structure $(S, e, \cdot)$ where the identity e is some specified member of S, $\cdot$ is a binary "multiplication" on S, and the following sentences are true:

$$(\forall x)(\forall y)[x \cdot (y \cdot z) = (x \cdot y) \cdot z],$$
$$(\forall x)(x \cdot e = x \,\&\, e \cdot x = x).$$

Here and in the sequel we write $t_1 \cdot t_2$ rather than the pedantically correct $\cdot(t_1, t_2)$.

In addition to semigroups, there are *groups*, *rings*, *fields*, and *ordered fields*, *vector spaces*, and any number of other structures which are the stuff of "abstract" algebra. These classes of structures are all characterized by first-order axioms, and the use of methods from logic is becoming increasingly important in their study.

Two structures M_1 and M_2 are *isomorphic* if some one-to-one correspondence between their universes carries the functions and relations of M_1 to those of M_2. *Isomorphic structures satisfy the same first-order sentences*, but the converse is not true, as we will see in Section II.F.

D. Databases

In the most general terms, a *database* is just a finite structure, typically *relational*, i.e., without functions, only relations. "Finite" does not mean "small" or "simple," and in the interesting applications databases are huge structures of large and complex vocabularies, with basic relations such as "x is an employee born in year n," "y is the supervisor of x," etc. Properties of structures are usually called *queries* in database theory, and one of the main tasks in the field is to develop representations for databases which support fast algorithms for *updating*, entering new information in the base, and *data testing*, determining the truth or falsity of queries. As it happens, updating and data testing for first-order queries can be done very efficiently, and so database systems, including the industry standard SQL make heavy use of methods from first-order logic.

Motivated by database theory, a good deal of research has been done since the 1970s in *Finite Model Theory*, the mathematical and logical study of finite structures. For a rather surprising, basic result, let

$$\begin{aligned}&\mathrm{Prob}_\sigma[M \models A : |D_M| = n]\\ &\quad = \text{the proportion of } \sigma\text{-structures}\\ &\qquad\qquad \text{of size } n \text{ which satisfy } A,\end{aligned}$$

where structures are counted "up to isomorphism."

The $\mathbb{FOL}$ 0-1 Law. For each sentence A of $\mathbb{FOL}(\sigma)$ in a relational vocabulary, either

$$\lim_{n\to\infty} \mathrm{Prob}_\sigma[M \models A : |D_M| = n] = 1,$$

or

$$\lim_{n\to\infty} \mathrm{Prob}_\sigma[M \models A : |D_M| = n] = 0,$$

i.e., either A or $\neg A$ is asymptotically true.

More advanced work in this area is concerned primarily with the algorithmic analysis of queries on finite structures, especially in logics richer than $\mathbb{FOL}$.

E. Arithmetic

Most basic is the structure of arithmetic

$$N = (\mathbb{N}, 0, 1, +, \cdot),$$

where $\mathbb{N} = \{0, 1, \ldots\}$ is the set of (non-negative) *natural numbers* and $+$ and $\cdot$ are the operations of addition and multiplication. The first-order definable relations and functions on N are called *arithmetical*, and they obviously include addition, multiplication, and the ordering on $\mathbb{N}$, which is defined by the formula

$$x \leq y \equiv (\exists z)[x + z = y].$$

By a basic lemma of Gödel, if a function f is determined from arithmetical functions g and h by the equations

$$\begin{cases} f(0, \vec{x}) = g(\vec{x}) \\ f(y+1, \vec{x}) = h(f(y, \vec{x}), y, \vec{x}), \end{cases} \tag{2}$$

then f is also arithmetical. Thus *exponentiation* x^y is arithmetical, with $g(x) = 1$, $h(w, y, x) = w \cdot x$, and, with some work, so is the function $p(x)$ which enumerates the prime numbers,

$$p(0) = 2, \;\; p(1) = 3, \;\; p(2) = 5, \ldots.$$

In fact, the scheme of *Primitive Recursion* (2) is the basic method by which functions are introduced in number theory, so that, with some work, all fundamental number theoretic relations and functions are arithmetical, and all celebrated theorems and open problems of the theory of numbers are expressed by first-order sentences of N. These include the Prime Number Theorem, Fermat's Last (Wiles') Theorem, and the (still open) question whether there exist infinitely many twin pairs of prime numbers.

F. Model Theory

The mathematical theory of structures starts with the following basic result:

Compactness and Skolem-Löwenheim Theorem. If every finite subset of a set of sentences T has a model, then T has a countable model.

For an impressive application, let (in the vocabulary of arithmetic)

$$\Delta_0 \equiv 0, \quad \Delta_{m+1} \equiv (\Delta_m + 1),$$

so that the *numeral* Δ_m is about the simplest term which denotes the number m, add a constant $\mathbf{c}$ to the language, and let

$$\begin{aligned}T = &\{A : N \models A\}\\ &\cup \{\Delta_0 \leq \mathbf{c}, \Delta_1 \leq \mathbf{c}, \Delta_2 \leq \mathbf{c}, \ldots\}.\end{aligned}$$

Every finite subset S of T has a model, namely

$$N_S = (\mathbb{N}, 0, 1, +, \cdot, m),$$

where the object m which interprets $\mathbf{c}$ is some number bigger than all the numerals which occur in formulas of S. So T has a countable model

$$N_T = (\bar{\mathbb{N}}, \bar{0}, \bar{1}, \bar{+}, \bar{\cdot}, c),$$

and then $\bar{N} = (\bar{\mathbb{N}}, \bar{0}, \bar{1}, \bar{+}, \bar{\cdot})$ is a structure for the vocabulary of arithmetic which satisfies all the first-order sentences true in the "standard" structure N but is not isomorphic with N—because it has in it some object c which is "larger" than all the interpretations of the numerals Δ_0. $\Delta_1, \ldots$. It follows that, with all its expressiveness, First-Order Logic does not capture the isomorphism type of complex structures such as N.

These *nonstandard* models of arithmetic were constructed by Skolem in the 1930s. Later, in the 1950s, Abraham, Robinson constructed by the same methods *nonstandard models of analysis*, and provided firm foundations for the classical Calculus of Leibnitz with its infinitesimals and "infinitely large" real numbers.

Model Theory has advanced immensely since the early work of Tarski, Abraham Robinson and Malcev. Especially with the contributions of Shelah in the 1970s and, more recently, Hrushovsky, it has become one of the most mathematically sophisticated branches of logic, with substantial applications to algebra and number theory.

G. First-Order Inference

The proof system of First-Order Logic is an extension of that for Propositional Logic, first by *identity axioms* which insure that $=$ is an equivalence relation and a *congruence*

for all function and relation symbols, e.g., for unary function symbols,

$$(\forall x)(\forall y)[x = y \rightarrow f(x) = f(y)].$$

In addition, there are two axioms for the quantifiers,

$$A\{x :\equiv t\} \rightarrow (\exists x)A \quad (\forall x)A \rightarrow A\{x :\equiv t\},$$

assuming that the term substitutions are free; and there are two new inference rules,

$$\frac{C \rightarrow A}{C \rightarrow (\forall x)A} \qquad \frac{A \rightarrow C}{(\exists x)A \rightarrow C}$$

which can be used only when the variable x is not free in C. Proofs from a set T of $\mathbb{FOL}(\sigma)$ sentences are defined exactly as for $\mathbb{PL}$, and we set again

$$T \vdash A \Leftrightarrow \text{there is a proof of } A \text{ from } T.$$

Notice that without the restriction on the quantifier rules, the sequence

$$P(x) \rightarrow P(x), \quad P(x) \rightarrow (\forall x)P(x),$$
$$(\exists x)P(x) \rightarrow (\forall x)P(x)$$

would be a proof of $(\exists x)P(x) \rightarrow (\forall x)P(x)$, which is, obviously, not valid. With the restriction, however, for every structure M, if every M-assignment satisfies the hypothesis of either new rule, then every M-assignment satisfies the conclusion, so that the quantifier inference rules are *sound*.

H. Gödel's Completeness Theorem

A *model* of a set of sentences T in $\mathbb{FOL}(\sigma)$ is any structure M which satisfies every A in T, in symbols

$$M \models T \Leftrightarrow \text{for all } A \text{ in } T,\ M \models A.$$

We also write

$$T \models A \Leftrightarrow \text{for all } M,$$
$$M \models T \Rightarrow M \models A,$$

which extends to $\mathbb{FOL}(\sigma)$ the *semantic consequence* relation of $\mathbb{PL}$. From the comments above:

Soundness Theorem for $\mathbb{FOL}$. If $T \vdash A$, then $T \models A$.

The fundamental fact about First-Order Logic is the converse of this result:

Completeness of $\mathbb{FOL}$. If $T \models A$, then $T \vdash A$.

It may be argued that the semantic consequence relation $T \models A$ captures the intuitive notion *A follows from the assumptions in T by logic alone*, in the sense that it insures that A is true whenever all the hypotheses in T are true, independently of the meaning of the function and relation symbols. Granting that and considering the strong expressibility of First-Order Logic discussed in Section II.C above, we may then argue further that the Completeness Theorem answers definitively (for science) the ancient question of *what follows from what by logic alone*: a proposition A follows from certain assumptions T as a matter of logic (and independently of the facts), if A and T can all be expressed faithfully as $\mathbb{FOL}(\sigma)$ assertions about some σ-structure M, and $T \vdash A$. On this view, it is hard to overemphasize the importance of this result for the foundations of mathematics and science.

Incidentally, there is an obvious extension of the Tarski conditions to Second-Order Logic, e.g.,

$$\iota \models (\forall \mathsf{P}_i^n)A \Leftrightarrow \text{for all } n\text{-ary } P \text{ on } D,$$
$$\iota\{\mathsf{P}_i^n :\equiv P\} \models A.$$

However, there is no useful Completeness Theorem for $\mathbb{SOL}$, as we will see in Section IV.F.

I. Proof Theory

If Model Theory is the study of semantics independently of inference, then Proof Theory can be viewed as the mathematical investigation of formal proofs independently of interpretation. This has always been one of the most active research areas of logic, and it has been invigorated in recent years by its substantial applications to computer science, including *automated deduction*, an important component of *artificial intelligence*. Key to these applications—and the basic result of Proof Theory—is the *Extended Normal Form Theorem* of Gentzen, whose somewhat weaker (but simpler) Herbrand version is fairly easy to describe.

There are four Herbrand inference rules, and they apply to n-ary disjunctions

$$A_1 \vee \cdots \vee A_n.$$

Two of them are *structural*, and they clearly preserve meaning: you can interchange the order of the disjuncts, or delete one of two occurrences of the same disjunct. The other two are *quantifier rules*,

$$\frac{A_1 \vee \cdots \vee A_n\{x :\equiv t\}}{A_1 \vee \cdots \vee (\exists x)A_n} \qquad \frac{A_1 \vee \cdots \vee A_n}{A_1 \vee \cdots \vee (\forall x)A_n}\ *$$

where the $*$ indicates that the $\forall$-rule can only be used if the variable x is not free in its conclusion. The result applies only to sentences without identity and in *prenex normal form*, i.e., looking like

$$(\mathsf{Q}_1 x_1) \cdots (\mathsf{Q}_n)B$$

where each Q_i is $\forall$ or $\exists$ and B is quantifier-free.

Herbrand's Theorem. Every provable $=-$free sentence A of $\mathbb{FOL}(\sigma)$ in prenex form can be derived from a provable quantifier-free disjunction by the four Herbrand rules.

The restriction to prenex sentences is not essential, because every formula can be converted to an equivalent prenex one by the application of simple rules which can be added to the system.

The theorem asserts (in part) that every provable sentence A has a "normal" proof, in which only formulas of "quantifier rank" no greater than A occur. This is a powerful tool for proof-theoretic studies. As for applications, all automated deduction systems use Herbrand-like inference systems (or their Gentzen variants), and the programming language PROLOG is based entirely on this idea.

The proof of Herbrand's Theorem is constructive: an algorithm is defined, which computes for each proof Π of a prenex sentence A a Herbrand proof Π', and then it is shown by simple, combinatorial arguments that Π', indeed, proves A. The additional, effective content is significant for the foundational applications of the theorem (for example to consistency proofs), and also in the applications to automated deduction.

It should be emphasized that the simplistic slogans "Model Theory = no inference" and "Proof Theory = no semantics" are often honored in the breach: like the Completeness Theorem, most fundamental results of logic are about connections between truth and proof, and some of the deepest results in one part of the discipline depend on methods and ideas from the other.

III. GÖDEL'S INCOMPLETENESS THEOREM

Having established that $\mathbb{FOL}$ proves all *logical truths*, it is natural to ask if it can also prove—from some natural set of axioms—all *mathematical truths*. This is not possible, by Gödel's fundamental result, whose special case for *arithmetical truths* we discuss in this section.

A. The Incompleteness of Peano Arithmetic

The classical *Peano axioms* for arithmetic comprise the properties of the successor

$$x+1 \neq 0 \qquad x+1 = y+1 \to x = y, \tag{3}$$

the recursive definitions of addition and multiplication,

$$\begin{cases} x+0 = x \\ x+(y+1) = (x+y)+1, \end{cases} \tag{4}$$

$$\begin{cases} x\cdot 0 = 0 \\ x\cdot(y+1) = x\cdot y + x, \end{cases} \tag{5}$$

and the *Induction Axiom* which cannot be expressed fully in First-Order Logic. Its Second-Order Logic version is

$$(\forall P)[(P(0)\ \&\ (\forall x)(P(x) \to P(x+1))) \to (\forall x)P(x)],$$

and the best we can do in $\mathbb{FOL}$ is to adopt the Axiom Scheme

$$(A\{y :\equiv 0\}\ \&\ (\forall x)(A\{y :\equiv x\} \to A\{y :\equiv x+1\})) \to (\forall x)A\{y :\equiv x\}. \tag{6}$$

The set PA of (first-order) Peano axioms is obtained by taking the correctly spelled versions of all the formulas in (3)–(6) and adding enough universal quantifiers in front of them so that they become sentences. This is a very strong set of axioms, it can prove all simple properties of numbers and most of their deep properties too—although proving a theorem from PA is harder than proving it using, say, methods from analysis, and number theorists distinguish and value "elementary proofs" in PA.

Gödel's First Incompleteness Theorem. There is a sentence $\mathbf{g}$ in $\mathbb{FOL}(0, 1, +, \cdot)$, such that $N \models \mathbf{g}$ but $\mathsf{PA} \not\vdash \mathbf{g}$.

One's first thought is that we can overcome this "incompleteness phenomenon" by strengthening PA, perhaps add Gödel's own $\mathbf{g}$ to it, or use the Second-Order Logic version of the Induction Axiom along with a suitable axiomatization of Second-Order Logic. None of this helps: Gödel's fundamental discovery is that first-order truth in N (and every other sufficiently rich structure) simply cannot be presented usefully as an "axiomatic theory." We will make this precise in a more general version of the Incompleteness Theorem in the next section.

B. Coding (Gödel numbering)

The basic ingredients of the proof of the Incompleteness Theorem are *coding* and *self-reference*.

In analytic geometry we "code" (represent) points in the plane by pairs of real numbers, their coordinates, so we can translate geometrical questions into algebraic problems and solve them by calculation. Gödel's basic idea is to code the syntactic objects of $\mathbb{FOL}(0, 1, +, \cdot)$—terms, formulas, proofs—by natural numbers, so that their properties are translated into properties of numbers, which can then be expressed in $\mathbb{FOL}(0, 1, +, \cdot)$ and (perhaps) proved in PA.

Since all syntactic objects are strings of symbols, if we view a proof $A_1, \ldots, A_{n-1}$ as a sequence of formulas separated by commas, it is enough to code strings, and we can do this in (at least) one simple-minded way: we enumerate the symbols of the language

$$\begin{array}{cccccccccccccccc} \neg & \& & \vee & \to & (&) & \forall & \exists & , & = & 0 & 1 & + & \cdot & \mathsf{v}_0 & \mathsf{v}_1 \ \cdots \\ 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 13 & 14 & 15 & 16 \ \cdots \end{array}$$

and we set

$$[a_0 a_1 a_2 \cdots a_m] = 2^{n_0} 3^{n_1} 5^{n_2} \cdots p(m)^{n_m},$$

where n_i is the code of the symbol a_i and $p(i)$ is the ith prime number. For example, the (correctly spelled) prime formula

$$+(\mathsf{v}_1, 0) = \mathsf{v}_0$$

has the horrendously large code

$$2^{13}3^5 5^{16}7^9 11^{11}13^6 17^{10}19^{15}.$$

The size of codes is irrelevant: what matters is that every string of symbols (and hence every term, formula and proof) has a code from which it can be reconstructed, by the *Unique Factorization Theorem* for numbers; and (more significantly) that PA is powerful enough to express and prove simple properties of formulas and proofs, thus translated into properties of numbers. For example, if Δ_n is the numeral denoting n, as above, then PA can prove all true, basic relations among numerals, e.g.,

$$m + n = k \Rightarrow \mathsf{PA} \vdash \Delta_m + \Delta_n = \Delta_k.$$

Less trivially, the basic (coded) *proof relation*

$\mathrm{Proof}_{\mathsf{PA}}(a, p) \Leftrightarrow a$ is the code of some sentence A and p is the code of a proof of A from PA

is defined by some formula $\mathsf{Proof}_{\mathsf{PA}}$ with v_1 and v_2 free, and PA can prove its basic properties, e.g.,

$$\mathrm{Proof}_{\mathsf{PA}}(a, p) \Rightarrow \mathsf{PA} \vdash \mathsf{Proof}_{\mathsf{PA}}\{\mathsf{v}_1 :\equiv \Delta_a, \mathsf{v}_2 :\equiv \Delta_p\}.$$

Similarly, the relation

$D(a, p) \Leftrightarrow a$ is the code of some formula A with only v_1 free, and p is the code of a PA-proof of $A\{\mathsf{v}_1 :\equiv \Delta_a\}$

is defined by some formula D with just $\mathsf{v}_1, \mathsf{v}_2$ free. Set

$$A \equiv (\forall \mathsf{v}_2)\neg \mathsf{D}$$

so that only v_1 is free in A, and if a is the code of A, set

$$\mathbf{g} \equiv A\{\mathsf{v}_1 :\equiv \Delta_a\}.$$

Unscrambling the definitions, **g** asserts that *there is no* PA-*proof of* $A\{\mathsf{v}_1 :\equiv \Delta_a\}$; but **g** *is* $A\{\mathsf{v}_1 :\equiv \Delta_a\}$, so that **g** claims its own unprovability; and a careful analysis of the situation shows that, indeed, **g** cannot be provable in PA, else PA would prove a contradiction. This also shows, that **g** is true.

It is not that simple, of course, and much delicate analysis and computation must be done to establish that $D(a, p)$ is arithmetical and to derive a formal contradiction from the assumption that **g** is PA-provable. Key to the proof is the "self-reference" in the definition of $D(a, p)$, which uses the coding, and the argument depends on the strength (not the weakness) of the axiomatic system PA. Coding and self-reference have become standard tools of logic since Gödel's work, and they have found substantial applications in many areas, including computer science and set theory.

IV. COMPUTABILITY

It is easy to determine whether an arbitrary equation $a_0 + a_1 x + \cdots + a_n x^n = 0$ with integer coefficients $a_0, \ldots, a_n$ has integer solutions, since every integer root must divide a_0, and so all we have to do is to test the finitely many divisors of a_0. The problem is not so easy for equations in k unknowns

$$\sum_{r_1+\cdots+r_k \le n} a_{r_1,\ldots,r_n} x_1^{r_1} x_2^{r_2} \cdots x_k^{r_k} = 0, \tag{7}$$

and it is much more interesting, in fact

to find an algorithm which determines whether Eq. (7) has a solution

is No. 10 in David Hilbert's famous 1900 list of 23 open problems in mathematics. Diophantine equations are notoriously difficult to solve, and one might suspect that no algorithm would do the job, but how can you prove such an assertion? Using ideas and techniques from Gödel's work and motivated by questions arising from it, logicians developed, in the 1930s, a tool for establishing *absolute unsolvability results* of this kind which led to some spectacular applications, including a rigorous proof of the unsolvability of Hilbert's 10th.

The most direct approach was by Turing, who reasoned that algorithms should be implemented by "mechanical devices" and introduced "abstract machines" that can perform symbolic computations some ten years before digital computers were invented.

A. Turing Machines

A Turing machine M is determined by a finite alphabet $S_M = \{s_0, \ldots, s_k\}$, a finite set $Q_M = \{q_0, \ldots, q_m\}$ of (internal) *states*, and a finite table of *transitions* of the form

$$q, s \mapsto q', s', m$$

where q, q' are states, s, s' are in S_M or the special "blank" symbol $\sqcup$, and *the move* m is -1, 0, or $+1$. No two transitions are *activated* by the same pair q, s on the left. We imagine that, at any moment, M is in some internal state q and sits in front of an infinite "tape" with symbols in some of its *cells*. The machine can only "see" the symbol s just in front of it, and does nothing (*halts*) unless one of its transitions is activated by the pair q, s; in which case

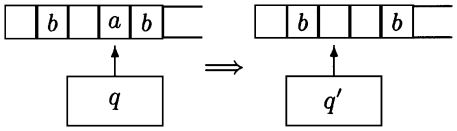

FIGURE 2 $q, a \mapsto q', \sqcup, -1$.

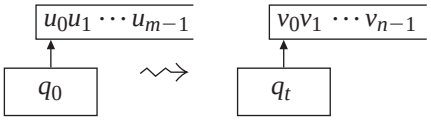
it switches to state q', it replaces s by s' on the tape, and it moves left (if it can), right or none-at-all, depending on whether m is -1, $+1$ or 0 (Fig. 2).

A machine M starts computing facing the leftmost cell, with an arbitrary string *input* $u = u_0 \cdots u_{m-1}$ on the tape,



and it may *diverge* (never halt), for example if $u = 11$ and M has the two transitions

$$q_0, 1 \mapsto q_0, 1, +1 \quad q_0, \sqcup \mapsto q_0, 1, +1$$

If it halts, then its *output* on u is the string $M[u] = v_0 \cdots v_{n-1}$ at the left end of the tape, until the first blank (and it is possible that $M[u]$ is empty.)

Finally, M *computes* a string function $f : S_1^* \to S_2^*$ if $S_1 \cup S_2 \subseteq S_M$ and for every string $u \in S_1^*$, $M[u] = f(u)$. By identifying each natural number n with the string $|| \cdots |$ of $n + 1$ *tallies* from the one-member alphabet $\{|\}$ (unary notation), the notion covers functions whose arguments or values are either strings or numbers. Moreover, if we code strings by numbers as above, then the transformation $u \mapsto [u]$ and its inverse can be computed by a Turing machine, so that a string function is Turing computable exactly when its "coded version" is computable, and we can safely confuse the two notions.

B. The Church-Turing Thesis

Turing argued persuasively that the symbolic computations of any "finite mechanical device" with access to unbounded memory can be simulated by one of his machines, and he has been fully justified by the subsequent developments in computers. Church had already made an equivalent (though less well justified) claim, and so the new fundamental principle carries both famous names:

The Church-Turing Thesis: A string function $f : S_1^* \to S_2^*$ is computable if and only if it can be computed by a Turing machine M on some alphabet $S_M \supseteq S_1 \cup S_2$.

The Church-Turing Thesis cannot be rigorously proved, as it identifies the intuitive, informal notion of "computability" with the precise, mathematical property of *Turing computability*. Within mathematics, it is officially a definition, much like the definitions of *arclength* or *area* in terms of integrals. But mathematical definitions are not entirely arbitrary: when we "define" the length of the circumference of a circle of radius r by an integral which computes out to $2\pi r$, we fully expect that if we draw such a circle and measure its circumference, it will turn out to be $2\pi r$, within the margin of error of our measurements. Similarly, when we prove that a certain string function f is not Turing computable, we fully expect that nobody will ever discover an algorithm which computes f, because no such algorithm exists. This is the standard method of application of the thesis.

Evidence for the Church-Turing Thesis comes from Turing's analysis, from the sixty-odd years of failed attempts to contradict it, and from the robustness of the notion of Turing computability. Many classes of functions were defined in the thirties claiming to capture the notion of "computable" from different perspectives, including Church's λ-*definable functions*, Post's *canonical systems*, the *general recursive functions* of Gödel, Herbrand, and Kleene, Kleene's μ-*recursive functions* and, in the forties, Markov's (formal) *algorithms*; each of these was proved equivalent to Turing computability, and the "simulation techniques" developed for these proofs make it seem very unlikely that some algorithm will ever be discovered which cannot be simulated by a Turing machine.

It should be emphasized, however, that the Church-Turing Thesis does not provide a rigorous definition for the notion of *algorithm*, which remains informal. Complexity results about algorithms are rigorously grounded on various so-called *computation models* which embody diverse features of actual computers. When we simulate these models by Turing machines, the time and space complexity of computations increase substantially, and so we cannot claim that the informal algorithm has been faithfully modeled. On the other hand, the time complexity increase is bound by a polynomial factor for all the known simulations, so that the class P of polynomial problems can be defined in terms of Turing machines without ambiguity.

Turing-computable functions are also called *recursive*, because of the basic Gödel-Herbrand-Kleene characterization mentioned above.

C. Unsolvable Problems

A set of strings (or *problem*) $Q \subseteq S^*$ from a finite "alphabet" S is *computable* (*recursive*, *solvable*, *decidable*) if some Turing machine M computes its *characteristic function*

$$c_Q(u) = \begin{cases} 1 & \text{if } u \in Q, \\ 0 & \text{otherwise,} \end{cases}$$

otherwise it is *unsolvable* or *undecidable*. The definitions apply to problems about natural numbers, coded in unary; to problems about $\mathbb{FOL}$-formulas, by identifying (for example) each variable v_i by a similar sequence $\mathsf{vv}\cdots\mathsf{v}$ of $i+1$ v's, so that the syntax of $\mathbb{FOL}$ is based on a finite vocabulary; and to relations (sets of n-tuples) on strings or numbers, by thinking of $u_1, \ldots, u_n$ as a single string.

Each Turing machine can be represented by a string of 0's and 1's which codes its alphabet, internal states, and transitions, and this leads to the first and most basic unsolvability result, due to Turing:

The Halting problem: It is undecidable whether an arbitrary Turing machine M halts on an arbitrary binary string u.

For the proof, Turing constructed a *universal machine* U which can simulate every other, i.e.,

$$U[\bar{M}, u] = M[u], \quad \text{if } \bar{M} \text{ is the code of } M.$$

This treatment of *programs* as *data* is, of course, routine today.

All unsolvability results are (ultimately) established by reducing the Halting Problem to them, i.e., showing that if such-and-such a function were computable, then the Halting Problem would be solvable. The proofs are often difficult and generally depend on results specific to the field in which the problem arises.

In mathematics, the problems which have been proved unsolvable include:

Hilbert's 10th: Whether a given Diophantine equation has integer solutions (Matijasevich, following work of Martin Davis, Hilary Putnam, and Julia Robinson).

The Word Problem for Groups: Whether two words denote the same element in a finitely generated, finitely presented group (P. Novikov, W. Boone).

The Homeomorphism Problem for 4-manifolds: Whether the orientable n-manifolds represented by two triangulations are homeomorphic, for $n \geq 4$ (A. Markov). This problem is solvable for 2-manifolds, by their classical representation as spheres with handles, and it is still open for 3-manifolds, pending (among other things) the resolution of the Poincaré Conjecture.

There is also a large number of unsolvable problems in computer science.

D. Undecidable Theories

A *theory* T in $\mathbb{FOL}(\sigma)$ is any set of sentences closed under consequence,

$$T \vdash A \Rightarrow A \in T.$$

The two basic examples are theories of σ-structures

$$\mathrm{Th}(M) = \{A \mid M \models A\},$$

and *axiomatic theories* of the form

$$T = \mathrm{Th}(T_0) = \{A : T_0 \vdash A\},$$

where T_0 is a decidable *set of axioms* T_0. The terminology is natural, because we would certainly demand of any "axiomatization" that it can be decided effectively whether an arbitrary sentence is an axiom.

Every decidable theory T is axiomatizable since $\mathrm{Th}(T) = T$ when T is a theory, but the converse fails, in general, and in particular for $T_0 = \emptyset$ when the vocabulary is not trivial:

Church's Theorem: If the vocabulary σ includes at least one binary function or relation symbol, then it is undecidable for a sentence A of $\mathbb{FOL}(\sigma)$ whether $\vdash A$.

A $\mathbb{FOL}(\sigma)$-theory T is *consistent* if it does not contain a contradiction $A \,\&\, \neg A$, and it is *complete* if for every sentence A, either A or $\neg A$ is in T. It is easy to verify that *every consistent, axiomatizable, complete theory is decidable*, and we can use this to formulate and prove a very general version of the Gödel Incompleteness Theorem. The key tool is the notion of *translation*.

Suppose T_1 and T_2 are theories, perhaps in different vocabularies σ_1 and σ_2—e.g., T_1 might by Th(PA), and T_2 might be some axiomatic set theory. A *translation* of T_1 into T_2 is a computable string function ρ which assigns a sentence $\rho(A)$ of $\mathbb{FOL}(\sigma_2)$ to every sentence A of $\mathbb{FOL}(\sigma_1)$ and preserves propositional logic and T_1-inference, i.e.,

$$T_2 \vdash \rho(\neg A) \leftrightarrow \neg\rho(A)$$

$$T_2 \vdash \rho(A \,\&\, B) \leftrightarrow \rho(A) \,\&\, \rho(B)$$

$$T_1 \vdash A \Rightarrow T_2 \vdash \rho(A).$$

Notice that the identity function $\rho(A) = A$ translates every theory into itself.

The Gödel Incompleteness Theorem (Rosser's form): If T is a consistent, axiomatizable theory and Peano arithmetic Th(PA) is translatable into T, then T is undecidable and hence incomplete.

In short, every consistent axiomatic system in which a reasonable amount of mathematics can be developed is undecidable and incomplete.

To state the strongest corresponding result about theories of structures, we need the simple fact that *every computable set is arithmetical*, essentially due to Gödel.

Tarski's Theorem: If $\mathrm{Th}(N)$ is translatable into $\mathrm{Th}(M)$, then $\mathrm{Th}(M)$ is not arithmetical, a fortiori it is not decidable.

To apply Tarski's Theorem, you need (in effect) to give a first-order definition of the natural numbers within the given structure. One of the first results of this type was *the undecidabilty of the theory of rational numbers* $\mathrm{Th}(\mathbb{Q}, 0, 1, +, \cdot)$ (Julia Robinson), but there are many others, and there are also many difficult open problems in this area.

On the other hand, many interesting theories are decidable, including the following:

- The theory $\mathrm{Th}(\mathbb{N}, 0, 1, +)$ of arithmetic without multiplication (Presburger).
- The theory $\mathrm{Th}(\mathbb{Q}, \leq)$. This coincides with the theory of every *dense, linear ordering without end points*.
- The theory $\mathrm{Th}(\mathbb{C}, 0, 1, +, \cdot)$ of the complex number field, which coincides with the theory of every algebraically closed field of characteristic 0 (Tarski, Abraham Robinson).
- The theory $\mathrm{Th}(\mathbb{R}, 0, 1, +, \cdot, \leq)$ of the ordered field of real numbers, which coincides with the theory of every real closed field (Tarski).

The classical result here is Tarski's decidability of the ordered field of real numbers, which (using coordinates) implies that *Euclidean geometry is decidable*, in a sense trivializing much of ancient Greek mathematics. It is still open whether the extended theory $\mathrm{Th}(\mathbb{R}, 0, 1, +, \cdot, \leq, \uparrow)$ (with $x \uparrow y = x^y$ for $x > 0$) is decidable, but there has been substantial progress in this problem with Wilkie's Theorem, that every set in $\mathbb{R}$ which is first-order definable using exponentials is a finite union of intervals.

E. The Second Incompleteness Theorem

What sorts of sentences are not provable in sufficiently strong axiomatizable theories? If $T = \mathrm{Th}(T_0)$ is axiomatizable in $\mathbb{FOL}(\sigma)$, then the (coded) proof relation

$\mathrm{Proof}_T(a, p) \Leftrightarrow a$ is the code of some sentence A in $\mathbb{FOL}(\sigma)$ and p is the code of a proof of A from T

is Turing computable, and hence arithmetical. Using this, we can construct a sentence Concis_T in the vocabulary of PA which expresses naturally the consistency of T and establish the following:

Gödel's Second Incompleteness Theorem (Rosser's form): If T is consistent, axiomatizable and ρ translates $\mathrm{Th}(\mathsf{PA})$ in T, then T cannot prove the translation $\rho(\mathsf{Consis}_T)$ of its consistency sentence.

The theorem makes it clear that we cannot axiomatize a substantial part of mathematics *in any way whatsoever* so that the consistency of the system can be established "constructively": because the (presumably simple) "constructive methods" we would be willing to use in a consistency proof should be part of the "substantial part of mathematics" we want to axiomatize. Beyond its obvious foundational significance, the Second Incompleteness Theorem has numerous applications, especially in comparing the strength of various hypotheses in Axiomatic Set Theory.

F. Hierarchies

A set Q of strings or numbers is Σ^0_2 if

$$u \in Q \Leftrightarrow (\exists x_1)(\forall x_2)R(u, x_1, x_2),$$

where the quantified variables range over natural numbers and the *matrix* R is computable, and it is Π^0_3 if, for all u

$$u \in Q \Leftrightarrow (\forall x_1)(\exists x_2)(\forall x_3)R(u, x_1, x_2, x_3)$$

with the same restrictions. The definitions extend naturally to all k, and we also set

$$\Delta^0_k = \Sigma^0_k \cap \Pi^0_k.$$

Kleene, who introduced these classes, showed that

$$\Delta^0_1 = \text{the class of recursive sets},$$

$$\begin{array}{ccccccc} & & \Sigma^0_1 & & & & \Sigma^0_2 \\ & \nwarrow & & \nwarrow & & \nwarrow & & \nwarrow \\ \Delta^0_1 & & \subsetneq & & \Delta^0_2 & & \subsetneq & & \cdots \\ & \swarrow & & \swarrow & & \swarrow & & \swarrow \\ & & \Pi^0_1 & & & & \Pi^0_2 & \end{array}$$

and that a nonempty set Q is Σ^0_1 exactly when it is *recursively* (or *computably*) *enumerable*, i.e., if

$$Q = \{f(0), f(1), \ldots\}$$

with some recursive $f : \mathbb{N} \to S^*$. Moreover, these classes increase properly and exhaust the arithmetical sets. A similar hierarchy

$$\Sigma^1_k, \Pi^1_k, \Delta^1_k$$

for the *analytical* (second-order definable) sets is constructed by allowing the quantified variables to range over the unary functions $\alpha : \mathbb{N} \to \mathbb{N}$ and the matrix to be arithmetical, so that all arithmetical sets are in Δ^1_1.

These hierarchies classify the analytical sets of natural numbers and strings by the logical complexity of their (simplest) definitions, and they are powerful tools in the theory of definability. For example, every axiomatizable theory is Σ^0_1. This rules out an axiomatization of Second-Order Logic $\mathbb{SOL}$, whose set of valid sentences (on the empty vocabulary) is not analytical. Somewhat surprisingly, it also rules out an axiomatization of the theory

$$T_f = \{A \mid \text{for all finite } (D, E), (D, E) \models A\}$$

of finite graphs, which is Π^0_1 but not Σ^0_1 (Trachtenbrot).

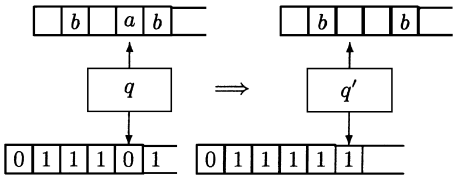


FIGURE 3 $q, a, 0 \mapsto q', \sqcup, 1, -1, +1$.

G. Turing Reducibility

Imagine a Turing machine with a second *query tape* which it handles exactly like its primary tape, implementing somewhat more complex transitions of the form

$$q, s_1, s_2 \mapsto q', s_1', s_2', m_1, m_2$$

It also has a special *query state* $q_?$, and when it goes into $q_?$, the computation stops and does not resume until some external agent (the *oracle*) replaces the contents on the query tape by some string (Fig. 3).

A string function f is *computable relative to some given* g if it can be computed by such an oracle machine, provided each time $q_?$ is reached, the string u on the query tape is replaced by the value $g(u)$. We let

$$f \leq_T g \Leftrightarrow f \text{ is computable in } g,$$

and we extend this notion of *Turing reducibility* to sets of natural numbers via their characteristic functions.

It is not hard to show that there exist Turing-incomparable sets of numbers (Kleene-Post). In fact, there exist Turing-incomparable recursively enumerable sets, but this was quite hard to prove and it was a celebrated open question for some twelve years, known as *Post's Problem*. The simultaneous, independent discovery in 1956 by Friedberg and Muchnik of the *priority method* which proved it, initiated an intense study of Turing reducibility which is still, today, one of the most active research areas of logic, the largest (and technically most sophisticated) part of *computability* or *recursion theory*.

V. RECURSION AND PROGRAMMING

In its most general form, a recursive definition of a function x is expressed by a *recursive* (or *fixed point*) *equation*

$$x(t) = f(t, x), \tag{8}$$

where the *functional* $f(t, x)$ provides a method for computing each value $x(t)$, perhaps using ("calling") other values of x in the process. It is possible to characterize the computable functions on the natural numbers using simple recursive equations of this form, generalizations of the primitive recursive definition (2) in Section III.E. Though conceptually less direct than Turing's approach through idealized machines, this modeling of computability by "recursiveness" provides a powerful tool for establishing properties of computable functions, and it is especially useful in the theory of programming languages.

A. Recursive Equations

Not every recursive equation (8) has a solution x, and some have many, e.g., the trivial $x(t) = x(t)$ which is satisfied by every function. The basic result which guarantees *canonical solutions* to a large class of recursive equations comes from the theory of *partially ordered sets*.

A *partially ordered set* or *poset* is a structure $(D, \leq_D)$, where $\leq$ is a binary relation and for all x, y, z in D,

$$x \leq_D x, \quad [x \leq_D y \,\&\, y \leq_D z] \Rightarrow x \leq_D z$$
$$[x \leq_D y \,\&\, y \leq_D x] \Rightarrow x = y;$$

a subset C of D is a *chain* if every two members of C are $\leq_D$-comparable, i.e., $x \leq_D y$ or $y \leq_D x$; and a poset D is *complete* if every chain in D has a *supremum* (least upper bound).

Every complete poset has a least element $\perp$ (the supremum of the empty chain), and every set A can be turned into a *flat poset* $A_\perp$ by adding a "bottom" below all its otherwise incomparable elements (Fig. 4). Other, basic examples include the set of all subsets of a set A (under $\subseteq$) and the set of all (finite and infinite) sequences from some set, under "extension." The Cartesian product of complete posets is complete, and, more importantly, if W is complete, then the it function spaces of all arbitrary, monotone or Scott-continuous mappings $\pi : D \to W$ are also complete, with the pointwise partial ordering

$$\pi \leq \rho \Leftrightarrow \text{for all } x, \pi(x) \leq \rho(x).$$

Here $\pi : D \to W$ is monotone if

$$x \leq_D y \Rightarrow \pi(x) \leq_W \pi(y),$$

and it is Scott-continuous if, in addition, for every chain C in D,

$$\pi(\text{supremum}(C)) = \text{supremum}(\pi[C]).$$

The Least-Fixed-Point Theorem. If $(D, \leq)$ is a complete poset and $\pi : D \to D$ is monotone, then the recursive equation

$$x = \pi(x) \tag{9}$$

has a least solution.

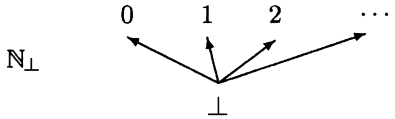

FIGURE 4 Flat poset.

The theorem is proved by setting recursively

$$x^0 = \bot, \quad x^{n+1} = \pi(x^n). \tag{10}$$

In the simplest case, which is sufficient for the applications to programming languages, the mapping π is Scott continuous, and then

$$\bar{x} = \text{supremum}\{x^0, x^1, \ldots\}$$

is the least fixed point of π. For the full result we need to extend the iteration (10) into the "transfinite," using recursion on ordinal numbers.

There is a rich theory of complete posets and various kinds of mappings on them, mostly motivated by the applications to programming, but also by earlier work in *abstract recursion*, the generalization of computability to abstract structures.

B. Programming Languages

From the mathematical point of view, a programming language $\mathbb{P}$ is very much like a logic, with a syntax, a semantics, and an *implementation*, which plays the role of an inference system.

The *syntax* is generally much more complex than that of logics, with many different categories of grammatically correct expressions. There are variables of various kinds, some of them for *functions* of specified *types*; constants which are meant to denote *acts* of interaction with the environment (input, output, interrupts); and various ways of combining grammatically correct expressions to produce new ones, using *programming constructs* like composition, "while loops," functional abstraction, and recursion. Some *closed* expressions (with no free variables) corresponding to the "sentences" of a logic are singled out, typically called *programs*. With all this complexity, the "grammar" is still specified by an induction, as it is for logics, so that it is again possible to prove properties of correct expressions and to define operations on them by *structural induction*.

In the *denotational semantics* introduced by Dana Scott, a programming language $\mathbb{P}$ is interpreted in a structure $(D, —)$ whose universe D is a complete poset, the *domain*. The points of D may include concrete *data* (words from some finite alphabet), but also functions of various sorts and complex mathematical structures which model computations, interactions, etc. For each correct expression A and each assignment α to the variables, the denotation $[\![A]\!](\alpha)$ is a point in D, determined by a structural induction of the following general form: first a (Scott-continuous) recursive equation (9) is constructed from α and the denotations of the parts of A, and then we take

$$[\![A]\!](\alpha) = \text{the least fixed point of } [x = \pi(x)].$$

The use of recursive equations is absolutely essential here, to interpret the iteration and recursive constructs which are at the heart of programming languages.

The *implementation* is a function which assigns to each program A a "machine" M_A—or, more concretely, code in the machine language of some processor—which *computes* the denotation $[\![A]\!]$ of A. In the simplest case, $[\![A]\!]$ might just be a sequence of external acts, like "printing" some file or drawing some picture on a monitor; more often $[\![A]\!]$ is a function relating input to output, or a "strategy" in some game, by which the machine responds to a sequence of external stimuli. As with inference systems, implementations come in a great variety of shapes and forms (*compilers* and *interpreters*, to name two), but they must have the basic *soundness property*, that M_A "computes" $[\![A]\!]$ in a well-understood way which relates the abstract (mathematical) denotations of programs to the behavior of machines.

Even with this grossly oversimplified description, it should be clear that the basic methodology of logic—the clean distinction between *syntax*, *semantics*, and *inference*—has had an immense influence on the development of programming languages; and that the fundamental, related notions of *symbolic computation* and *recursion* introduced by logicians in the 1930s are essential to the understanding of programming languages.

In the other direction, the study of programming languages—spurred by the need for applications—has introduced a host of interesting problems in logic, chief among them the question of *logic of programs*: What are the natural formal languages and inference systems in which the fundamental properties of programs can be expressed and rigorously proved? Much work has been done on this, but it is fair to say that the question is still open, and a formidable challenge to logicians and computer scientists.

VI. ALTERNATIVE LOGICS

From the many alternative logics which are obtained by changing the syntax, semantics or inference system of First-Order Logic, we consider, very briefly, just two.

A. Modal and Temporal Logic

Modal Logic goes back to Aristotle, the traditional founder of logic, who took *necessity* as one of the basic linguistic constructs worthy of logical study. The modern syntax is obtained by adding to $\mathbb{FOL}$ the propositional *box operator* $\Box$, so that with each formula A we have the formula $\Box A$ (with the same free variables), read *necessarily A*. The *possibility* operator is defined by the abbreviation $\Diamond A \equiv \neg\Box\neg A$.

Modal formulas are interpreted in *Kripke structures*

$$M = (W, s_0, \{M_s \mid s \in W\}, R),$$

of a specified vocabulary σ, where W is some set of *possible worlds*; s_0 is a specified "actual world"; each M_s is a σ-structure associated with the world s; and $R(s, t)$ is an *accessibility relation* on the worlds, intuitively standing for "t is a possible alternative to s." There are no fixed, general assumptions about the accessibility relation or the interpretations of the given relations on the various worlds; it could be, for example, that "Mary is John's wife" in the actual world s_0, but in alternative possible worlds John's wife might be Ellen, John may not have a wife, or he may not even exist. Assign associate objects in the possible worlds to individual variables, and the basic, semantic relation $M_s, \alpha \models A$ is defined by the Tarski conditions (for structures) with the additional clause

$$M_s, \alpha \models \Box A \Leftrightarrow \text{for all } t, \text{ if } R(s, t), \text{ then } M_t, \alpha \models A.$$

For example, if R is *transitive*,

$$R(s, t) \,\&\, R(t, t') \Longrightarrow R(s, t'),$$

then, the formula

$$\Box A \to \Box\Box A \tag{11}$$

is satisfied by all assignments, in all possible worlds, while it may fail for some A in nontransitive structures. Finally,

$$M, \alpha \models A \Leftrightarrow M_{s_0}, \alpha \models A.$$

Different conceptions of "necessity" can be modeled by placing appropriate restrictions on the accessibility relation, for example that it be transitive, linear, etc., and there is a question of constructing a suitable inference system and proving the appropriate Completeness Theorem in each case. A great deal of interesting work has been done in this area, much of it motivated by puzzles in the philosophy of language.

If we take $W = \mathbb{N}$ for the set of possible worlds, with $s_0 = 0$ and $R(s, t) \Leftrightarrow s \leq t$, and if we read $\Box A$ as "*from now on A*," we get one version of Temporal Logic, very useful for applications to computing systems. The worlds are interpreted by the *states* of some finite state machine, the propositional variables stand for properties of states, and the propositional formulas (which suffice) can express interesting properties of the system, especially if we augment the language with some additional, natural primitives like Next with the truth condition

$$M_s \models \mathsf{Next}\, A \Leftrightarrow M_{s+1} \models A.$$

For example, $\Box(p \to \mathsf{Next}\, q)$ says that "every state which has property p is followed immediately by one which has property q," and $\Diamond\Box p$ says that "p will eventually become and remain true," both interesting properties of finite state machines. This *temporal logic is decidable*, and so are various extensions of it, in which essentially all interesting *liveliness* and *fairness* properties of finite state machines can be expressed, so that one can *mechanically verify* the "correct behavior" of finite state machines. The relevant algorithms are practical, if not simple, they are used commercially, and they provide a spectacular example of the emerging field of *applied logic*.

B. Intuitionistic Logic

First-Order Intuitionistic Logic $\mathbb{FOL}_I$ has the same syntax as $\mathbb{FOL}$, and almost the same inference system: we simply replace the *Double Negation Law* $\neg\neg A \to A$, Eq. (8) in Section I.E, by the weaker

$(8)_I$ $\neg A \to (A \to B)$.

Kripke has established a Completeness Theorem for $\mathbb{FOL}_I$ using a variation of his semantics for Modal Logic, and this is useful for obtaining unprovability results for $\mathbb{FOL}_I$. The language, however, is meant to be understood constructively, and so it is not really possible to explain its semantics fully within classical mathematics. Aside from philosophical concerns, the real interest of Intuitionistic Logic comes from the proof theory of $\mathbb{FOL}_I$, which, somewhat surprisingly, also has important applications to computer science. Some sample results:

(1) For any two sentences A and B,

$$\vdash_I A \vee B \Longrightarrow \vdash_I A \text{ or } \vdash_I B,$$

and hence $\not\vdash_I p \vee \neg p$.

(2) In *Heyting Arithmetic*, i.e., the axiom system PA of Section III.A with Intuitionistic Logic, for any sentence $(\exists x)A$,

$$\mathsf{PA} \vdash_I (\exists x)A \Rightarrow \text{for some } n, \mathsf{PA} \vdash_I A\{x :\equiv \Delta_n\}.$$

(3) If $\mathsf{PA} \vdash_I (\forall x)(\exists y)A$ and $(\forall x)(\exists y)A$ is a sentence (no free variables), then there is a computable function f, such that for all n, $\mathsf{PA} \vdash_I A\{x :\equiv \Delta_n, y :\equiv \Delta_{f(n)}\}$.

This last result is obtained with Kleene's Realizability Theory, and it illustrates the following general principle: from a constructive proof of $(\forall x)(\exists y)R(x, y)$, we can extract an algorithm which computes for each x, some y such that $R(x, y)$. There are obvious applications of this idea in computer science, and much of the current research in intuitionism is motivated by it.

VII. SET THEORY

Sets are collections into a whole of definite and separate objects of our intuition or thought, according to Georg Cantor, who initiated their mathematical study in the mid 1870s. Thus the basic relation of the theory is *membership* ($\in$),

$$x \in A \Leftrightarrow x \text{ is a member of } A,$$

and a set is completely determined by its members,

$$A = B \Leftrightarrow (\text{for all } x)[x \in A \Leftrightarrow x \in B].$$

Finite sets can be simply enumerated, e.g., $A = \{0, 5, 7\}$. Infinite sets are usually specified by means of some condition $P(x)$ which characterizes their members, and we write

$$A = \{x \mid P(x)\}$$

to indicate that A "is the set of all objects which satisfy $P(x)$."

Cantor was led to the study of arbitrary, *abstract sets* in his effort to understand the structure of some specific sets of real numbers or *pointsets*, and the theory which he created still exhibits today these two related but separate concerns. The *theory of pointsets* or *descriptive set theory* is primarily a theory of definability on the real numbers, and it is characterized by its applications to other fields of mathematics, especially analysis. *Abstract set theory* is primarily a theory of *counting*, an extension of combinatorics to the transfinite. The best set-theoretic results are about the interaction between these two poles of the subject.

At about the same time as Cantor's original contributions, Gottlob Frege initiated an effort to create a *foundation of mathematics* on the basis of set theory. Frege's approach was different (he took "function" rather than "set" as his primitive notion) and his original program was overly ambitious and failed. He had the right basic idea, however, that all objects of classical mathematics can be "defined within set theory," so that their properties can be (ultimately) derived from properties of sets. It took some time for this to take hold, but it is fair to say that since the 1930s, set theory has been the official language of mathematics, just as mathematics is the official language of science. This richness of the field makes it fertile ground for logical investigations, and it is not an accident that logicians have been involved with set theory from the beginning.

A. Cardinal Arithmetic

There are exactly as many left shoes in a (normal) shoe store as there are right shoes—we can be sure of this without counting, because of the obvious one-to-one correspondence between left and right shoes. The principle here is that *equivalent sets have the same number of members*,

$$|A| = |B| \Leftrightarrow A \sim_c B, \tag{12}$$

where $A \sim_c B$ indicates that some one-to-one correspondence exists between the members of A and the members of B, and

$$|X| = \text{the number of objects in the set } X.$$

This is a basic tool in mathematics: we count a set A by establishing a one-to-one correspondence between its members and the members of some already-counted set B. Moreover, if we set

$$A \preceq_c B \Leftrightarrow \text{for some subset } C \subseteq B,\ A \sim_c C,$$

then, obviously,

$$|A| \leq |B| \Leftrightarrow A \preceq_c B, \tag{13}$$

and we can often prove indirectly that *there are objects in B which are not in A* by showing (using arithmetic) that $|A| < |B|$, so that $B \subseteq A$ is impossible.

Cantor proposed to associate a *cardinal number* $|X|$ with every (finite or infinite) set X, so that Eqs. (12) and (13) hold, and then to use similar counting and (infinite) *cardinal arithmetic* techniques in the study of arbitrary sets. One might expect problems, because a finite set cannot be equivalent with one of its proper subsets (by the so-called *Pigeonhole Principle*), while

$$\mathbb{N} = \{0, 1, 2, \ldots\} \sim_c \{0, 2, 4, \ldots\} \tag{14}$$

via the correspondence $f(n) = 2n$. Cantor showed that, despite this "paradox," his cardinal arithmetic is a powerful tool with important applications in almost all areas of mathematics.

Cantor's first fundamental discovery was that there are (at least) two infinite sizes of sets: if

$$\aleph_0 = |\mathbb{N}|, \quad \mathfrak{c} = |\mathbb{R}| = |\text{the real numbers}|$$

are the cardinal numbers of the two most basic sets in mathematics, then

$$\aleph_0 < \mathfrak{c}. \tag{15}$$

A set A is *countable* if $|A| \leq \aleph_0$, otherwise it is, like $\mathbb{R}$, *uncountable*.

To define the arithmetical operations on (possibly infinite) cardinal numbers, choose sets K, L with no members in common so that $\kappa = |K|$, $\lambda = |L|$, and set

$$\kappa + \lambda = |K \cup L|,$$
$$\kappa \cdot \lambda = K \times L,$$
$$\kappa^\lambda = |(L \to K)|.$$

Here the *union* $K \cup L$ is the set of all objects which belong to either K or L; the *Cartesian product* $K \times L$ is the set of all ordered pairs (x, y) with $x \in K$ and $y \in L$; and the *function space* $(L \to K)$ is the set of all functions $f : L \to K$. If κ and λ are finite, we get the usual sum, product and exponential, noting, in particular, that there are κ^λ functions from a set of size λ to one of size κ. Moreover, all the familiar arithmetical identities hold, e.g., addition and multiplication are associative and commutative, multiplication distributes over addition, $\kappa^0 = 1$, and

$$\kappa^{\lambda+\mu} = \kappa^\lambda \cdot \kappa^\mu, \quad (\kappa^\lambda)^\mu = \kappa^{\lambda\cdot\mu}.$$

As examples of "proofs by counting," Cantor showed first that

$$\aleph_0 + \aleph_0 = \aleph_0 \cdot \aleph_0 = \aleph_0 \tag{16}$$

(basically because of Eq. (14)), and

$$\mathfrak{c} = 2^{\aleph_0}.$$

Both of these facts are easy, but they support the computation

$$\mathfrak{c}^2 = 2^{\aleph_0} \cdot 2^{\aleph_0} = 2^{\aleph_0+\aleph_0} = 2^{\aleph_0} = \mathfrak{c},$$

which means that there is a one-to-one correspondence between the line and the plane, and, hence, between the line and real n-space, for every n. This was new, it was surprising, and it was proved by "plain arithmetic." Eventually it motivated the development of *dimension theory*, whose basic result is that there is no continuous, one-to-one correspondence of real n-space with real m-space unless $n = m$. Moreover, the set of rational numbers is countable, and so is the set of *algebraic numbers*, the solutions of polynomial equations

$$a_0 + a_1 x + a_2 x^2 + \cdots + x^n = 0$$

with integer coefficients. Thus, since $\mathbb{R}$ is uncountable, "by simple counting" *there exist transcendental* (not algebraic) *real numbers*, a famous result of Liouville's whose original proof had rested on delicate convergence arguments for infinite series. It was a "killer application" which made set theory instantly known (and somewhat notorious) in the mathematical community.

Cardinal addition and multiplication satisfy the following *absorption laws* which basically trivializes them in the infinite case:

$$\text{if } 0 < \kappa \le \lambda \text{ and } \lambda \text{ is infinite,}$$
$$\text{then } \kappa + \lambda = \kappa \cdot \lambda = \lambda.$$

For exponentiation, however, Cantor extended Eq. (15) to the general inequality

$$\kappa < 2^\kappa,$$

which provides infinitely many distinct "orders of infinity," perhaps what people meant when they referred to *Cantor's Paradise*. Exponentiation is the source of the deepest questions about infinite sets, chief among them Cantor's *Generalized Continuum Hypothesis* (GCH), the claim that for all infinite κ,

$$\text{(GCH)} \quad 2^\kappa = \kappa^+ = \text{the least cardinal number } > \kappa.$$

The "ordinary" case (CH) $2^{\aleph_0} = \aleph_0^+$ was No. 1 in Hilbert's list, it dominated set-theoretic research in the 20th century and, in a sense, it is still open today.

In addition to the cardinal numbers, which count the members of a set one, two, three, ... in the finite case, Cantor also introduced infinite versions of the *ordinal numbers* first, second, third, ... which assign position in a sequence. These are associated with "transfinite sequences," i.e., *well-ordered structures* $(A, \le)$, where $\le$ is a *linear ordering* on A (so that $x \le y$ or $y \le x$, for all x, y in A) and *every non-empty subset of A has a least element*. Every ordinal number α has a *successor* $\alpha + 1$ which defines "the next position," and every set of ordinal numbers A has a *least upper bound* $\sup A$. The least infinite ordinal number ω defines the first position with infinitely

$$0,\ 1,\ 2, \ldots \omega,\ \omega + 1,\ \omega + 2, \ldots \omega \cdot 2,\ \omega \cdot 2 + 1, \ldots$$

many predecessors, and it is a *limit ordinal*, without an immediate predecessor.

Ordinal arithmetic has fewer direct applications than the arithmetic of cardinal numbers, but well-ordered structures and ordinal numbers are the fundamental tools in the study of *transfinite iteration*, which is rich in applications. In a typical case, a function $f : A \to B$ is defined by *recursion* on some well ordered structure $(A, \le)$, and then the crucial properties of f are established by *induction* along $\le$. Moreover, the exact specification of the relation $\le$ is often unimportant: all that matters is that *some* relation well orders A, in other words that A be *well orderable*.

$$\text{(WOP)} \quad \textit{Is every set well orderable?}$$

Specifically, is the set $\mathbb{R}$ of real numbers (where many of the applications lie) well orderable? The natural ordering of $\mathbb{R}$ won't do, since (for example) $\mathbb{R}$ has no least element, and it is hard to imagine how one could arrange all the real numbers into a transfinite sequence, with each point followed by its successor and every nonempty subset having a least element. The *Continuum Problem* (whether CH is true or not) and this *Well-Ordering Problem* were the central open problems in set theory at the turn of the 20th century.

B. The Paradoxes

Cantor developed his theory on the basis of the following *General Comprehension Principle* which flows naturally from his "definition" of sets quoted in the beginning of

this section: every definite (unambiguous) property $P(x)$ of mathematical objects, has an extension, the set $A = \{x \mid P(x)\}$ which "collects into a whole" all the objects which satisfy $P(x)$, so that

$$x \in A \Leftrightarrow P(x). \tag{17}$$

But this is not generally true: because if

$$R = \{x \mid \text{ is a set and } x \notin x\},$$

then, from Eq. (17),

$$R \in R \Leftrightarrow R \text{ is a set and } R \notin R \Leftrightarrow R \notin R$$

which is absurd. The argument was discovered in 1902 by Bertrand Russell, and it was not the first contradiction in set theory. However, earlier "paradoxes" (some of them known to Cantor) were technical, not unlike the paradoxes with infinitesimals which had been commonplace in calculus some years earlier, and it was thought that they would go away in a careful development of the subject. The *Russell Paradox* is not technical, it goes to the heart of the nature of sets, and it threw the mathematical community into a spin.

L. E. J. Brouwer initiated the *intuitionistic program* which denies that abstract sets are meaningful objects of study and also rejects some of the basic principles of logic. Mathematical objects cannot be said to "exist" in any sense independent of (mental) "mathematical activity"; and to prove that *some x has property P*, one must *construct* some specific object x which has property P. It is not enough to derive a contradiction from the assumption that *no x has property P*. Intuitionism had a strong influence in the philosophy of mathematics and remains a vibrant field of study within logic, but it never carried much favor with mathematicians: too much of classical mathematics must be thrown out to satisfy its tenets.

Hilbert proposed to "save" classical mathematics from the paradoxes and Brouwer's attack by formalizing as large a part of it as possible in some first-order, axiomatic theory T, and then establishing the consistency of T by absolutely safe, *finitistic* methods. *Formalism* is the reading of *Hilbert's Program* as a philosophical view: it alleges that once T is chosen, then T is all there is—there is nothing more to mathematics but the study of the inference relation $T \vdash A$, with no reference to meaning. Aside from the impact of Gödel's Second Incompleteness Theorem (Section IV.E) which weakens it, formalism also fails to account for the applications of mathematics: it is hard to see how the existence or not of certain patterns of meaningless symbols can have any bearing on the escape velocity of a rocket.

From those reluctant to abandon the traditional, *realist* view that mathematical objects are, well, *real*, no matter how abstract and difficult to pin down, Russell first proposed to replace set theory by his famous *theory of types*: it is claimed (roughly, and in the later *simple* version due to Ramsey), that every mathematical object is of a certain (natural number) *type n*, and that every set A is of some successor type $n+1$, such that the members of A are of the immediately preceding type n. Type theory is awkward to apply and it yields only a poor shadow of Cantor's set theory, albeit without the paradoxes. It never gained favor as a true alternative to set theory, although it has been studied extensively as a logical system, it has found its own applications (especially recently, to programming languages), and many of its fundamental ideas were eventually incorporated in the reformulation of set theory which eventually prevailed.

What has prevailed is *Axiomatic Set Theory*, first proposed in 1904 by Zermelo as a pragmatic way to avoid the paradoxes by rebuilding Cantor's set theory on the basis of a few set-theoretic principles which are basic, simple, and well understood by their uses in classical mathematics. Formalists can accept it, as nothing more but the choice of a specific set of axioms, whose "truth" is irrelevant, if, at all, meaningful. But it is the realists who, in the end, have received the greatest comfort from axiomatic set theory: because the systematic development of consequences of the axioms eventually led to a narrower, more concrete concept of *set*, which ultimately justified the axioms.

Much of modern logic was created in response to the challenge of the set-theoretic paradoxes, and that is another reason why the discipline is so intimately tied with set theory.

C. Zermelo-Fraenkel Set Theory

There are eight axioms in ZFC (Zermelo-Fraenkel Set Theory with Choice), and it is assumed that they are interpreted over some given domain of *sets* $\mathbb{V}$, which comes endowed with a binary *membership* condition, $x \in y$. The formal theory ZFC is obtained by expressing these axioms by sentences of $\mathbb{FOL}(\in)$, and it requires infinitely many sentences, because the Replacement Axiom 5 requires an *axiom scheme*. Here we will describe them briefly and informally, with a few interspersed comments.

1. *Extensionality*. Two sets are equal exactly when the have the same members.
2. *Empty set and Pairing*. There is a set $\emptyset$ with no members, and for any two sets a, b, there is a set $\{a, b\}$ whose members are exactly a and b.
3. *Unionset*. For each set A, there is a set $\cup A$ whose members are the members of the members of A,
$$t \in \cup A \Leftrightarrow (\exists x)[x \in A \,\&\, t \in x].$$
4. *Powerset*. For each set A, there is a set $\mathcal{P}(A)$ whose members are all the subsets of A.

An operation $F : \mathbb{V} \to \mathbb{V}$ is definite if it is first-order definable with parameters, i.e.,

$$F(x) = G(x, a_1, \ldots, a_k)$$

where $G(x, y_1, \ldots, y_k)$ is first-order definable, Section II.C.

5. *Replacement*. The image

$$F[A] = \{F(x) \mid x \in A\}$$

of a set A by a definite operation F is a set. (This was formulated in the 1930s, primarily by Skolem, and it is much stronger than Zermelo's original *Separation Axiom*.)

For the next two axioms, we need the notion of *function* $f : A \to B$ from one set to another, which is not among our primitives, and so we need to "reduce" the notion of function to that of set. The trick is well known: first we fix some *ordered pair operation* (x, y) which satisfies the key property

$$(x, y) = (x', y') \Leftrightarrow x = x' \,\&\, y = y', \qquad (18)$$

and then we model a function f by its graph,

$$G_f = \{(x, y) \in A \times B \mid y = f(x)\},$$

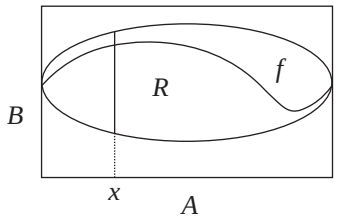
which is just a set with some special properties. It is common to use the so-called *Kuratowski pair operation*

$$(x, y) = \{x, \{x, y\}\},$$

but there are many others, and all that is needed is some operation which satisfies Eq. (18).

6. *Infinity*. There is a set I and a one-to-one function $f : I \to I$ which is not onto I, $f[I] \subsetneq I$.

Next comes Zermelo's chief contribution:



7. *Axiom of Choice* (AC). For each binary relation $R \subseteq A \times B$,

$$(\forall x \in A)(\exists y \in B)(x, y) \in R$$
$$\Rightarrow (\exists f : A \to B)(\forall x \in A)(x, f(x)) \in R.$$

In effect, AC postulates a function f which makes a choice $f(x)$ from the nonempty set $\{y \mid (x, y) \in R\}$, "simultaneously," for each $x \in A$. If B carries a well ordering $\leq$, we could take

$$f(x) = \text{the } \leq\text{-least } y \text{ such that } (x, y) \in R;$$

Zermelo showed that, conversely, AC *implies that every set is well orderable*, and identified numerous examples where the seemingly controversial AC is routinely used in mathematics. Somewhat later Hartogs showed that AC is also equivalent with the *cardinal comparability property*

$$(\forall A, B)[A \leq_c B \vee B \leq_c A]$$

without which there is no cardinal arithmetic, and this limited further opposition to AC to those who were willing to abandon completely Cantor's Paradise.

The last axiom of ZFC involves the *cummulative hierarchy of sets*, which is defined by recursion on the ordinal numbers as follows:

$$V_0 = \emptyset,$$
$$V_{\alpha+1} = \mathcal{P}(V_\alpha),$$
$$V_\lambda = \bigcup_{\alpha<\lambda} V_\alpha \quad (\text{if } \lambda \text{ is limit}).$$

8. *Foundation*. Every set is a member of some V_α.

This is a limiting axiom, not needed for the development of Cantor's set theory or its applications, but it is important because it codifies within the axiomatic theory a conception of set which replaced in the 1930s Cantor's free-wheeling notion of a "collection into a whole": each set is reached starting with "nothing" (the emptyset $\emptyset$), by "indefinite" (never ending) "iteration" of the powerset operation. Admittedly more complex than Cantor's, this notion of *grounded set* prohibits the circular constructions which lead to the paradoxes, and it can be described intuitively in sufficiently clear terms to justify the axioms.

To see how classical mathematics can be developed on the basis of these seven axioms, consider first arithmetic. A *number system* is a triple $(\mathbb{N}, 0, S)$ such that $\mathbb{N}$ is a set, $0 \in \mathbb{N}$, $S : \mathbb{N} \to \mathbb{N}$ is a one-to-one function which is never 0, and

$$[X \subseteq \mathbb{N} \,\&\, 0 \in X \,\&\, S[X] \subseteq X] \Rightarrow X = \mathbb{N};$$

we prove that there exists a number system and that every two number systems are isomorphic, and then we choose some specific number system and call its members *the natural numbers*. The real numbers are identified with some *complete ordered field*, once we prove that one such exists and any two are order isomorphic, and so forth for other structures. This process of "defining" (more accurately: *modeling faithfully*) mathematical structures in set theory has found such widespread acceptance in mathematics, that "to make a notion precise" is now viewed as synonymous with "defining it in set theory."

D. Independence Results

It is, perhaps, ironic, that the axiomatization of set theory made possible to formulate and prove its own limitations. Let ZF be the theory with axioms 1–6, i.e., without the Axiom of Choice:

Theorem. If *ZF* is consistent, then so are the theories ZFC+GCH (Gödel, 1938) and ZFC+¬CH (Paul Cohen, 1963).

In effect, ZFC can neither disprove nor prove the Continuum Hypothesis, unless a contradiction can be obtained from its "constructive" core. In addition, Cohen showed that *ZF* cannot prove the Axiom of Choice, and several additional consistency and independence results.

Gödel's proof uses an *inner model*, a sub-collection of our intended universe of sets $\mathbb{V}$: using only axioms 1–6, he defines a certain collection L of *constructible sets* and shows that if we reinterpret "set" to mean "member of L," then all the axioms of ZFC as well as GCH are true. Cohen's *forcing method* builds "virtual universes" which are "larger" than $\mathbb{V}$, and so he must describe them indirectly. This can be done with *Boolean-valued models*: a collection $M \subset \mathbb{V}$ and a binary condition E on M are defined, and then it is shown that, for a certain (complete) Boolean algebra B, the *Boolean semantics* of the "structure" (M, E) assign 1 to all the theorems of ZFC but something other than 1 to CH.

In both of these proofs, logic plays an essential role which goes much beyond providing the context in which their claims can be made precise. For example, the constructible universe L is defined by iterating the operation of taking all *first-order definable* subsets rather than $\mathcal{P}(A)$ in the cummulative hierarchy of sets, and then a strong version of the Skolem-Löwenheim Theorem is used at a crucial point to show that GCH holds in L. Through the work, initially, of Robert Solovay for forcing and Ronald Jensen for constructibility, these theories have been much generalized and continue to be very active research areas of logic, with important applications to analysis, algebra and topology.

E. Current Research in Set Theory

In one direction, set theory is more involved now with applications than ever before. Especially fruitful has been the development in the 1960s of *effective descriptive set theory*, which incorporates methods from recursion theory into the study of definability on the continuum to yield very substantial applications to analysis.

Beyond the applications, set theory has attempted to confront the fundamental problem posed by the independence results: what does one do with the Continuum Problem, now that we know that it cannot be settled in ZFC? Some have adopted a formalist view, that it is meaningless to ask "whether CH is true or not," and that "set theory is the study of all models of ZFC." This is a very active area of research.

In another direction, people have looked for *new axioms*, extending ZFC, which might provide the needed answers, and a great deal of research has been done in this direction since the 1960s. Generally speaking, two kinds of axioms have been considered. *Large cardinal axioms* are plausible generalizations of the Axiom of Infinity, which, however, have very few direct consequences for the continuum. *Determinacy hypotheses* postulate that certain (fairly simple) infinite games on the natural numbers are *determined*; somewhat technical and not especially plausible, these axioms answer most definability questions about the real numbers that are independent of ZFC, although, unfortunately, they cannot settle the Continuum Problem. In a fundamental advance made in the 1980s, Donald A. Martin, John Steel, and Hugh Woodin showed that the plausible large cardinal axioms imply the fruitful determinacy hypotheses, and so a "unified," very strong extension of ZFC has been created which is the subject of much current research. Unfortunately, it does not solve the Continuum Problem, and so the search goes on.

It may well be that set theory will continue to be dominated in the 21st century by the search for an answer to the Continuum Problem, as it certainly was during the century just ended.

Mathematical Modeling

Xavier J. R. Avula
University of Missouri, Rolla

GLOSSARY

Chaos Irregular and unpredictable system behavior that exhibits sensitive dependence on initial conditions in deterministic physical systems modeled by nonlinear equations.
Complexity Complexity is the collective behavior of a system containing many interacting subsystems that cannot be explained in terms of the observable entities.
Mathematical modeling Entire process of representing real-world phenomena in terms of mathematical equations and achieving their validity in an iterative manner.
Model Idealized representation of a real-world phenomenon. In the abstract sense, it is a set of instructions for generating behavioral data.
Modeling Act of relating real systems to models.
Artificial Neural Networks Networks of artificial neurons that are interconnected in different patterns to process information in a parallel distributed fashion much like the human brain.
Parameter identification Experimental determination of values of parameters that govern the system behavior.
Simulation Process of relating computers to models generating behavioral data.
System Set of elements plus a collection of rules governing the interrelationships between the elements and the behavior of elements over time.
System identification Determination of a system from its input and output time history.

MATHEMATICAL MODELING is a comprehensive process of representing real-world phenomena in terms of mathematical equations and extracting from them useful information for understanding and prediction. In recent

years, mathematical modeling has become a powerful tool to solve complex, interconnected, and interacting phenomena arising from the rapid developments taking place in science and technology. The success in physical sciences in terms of valid mathematical models has led scientists to extend the modeling methodology to other emerging fields of inquiry in which great strides have been made. The explosive growth of mathematical modeling activity has been a driving force behind the development of high-speed digital computers, which in turn aided model solutions in a symbiotic relationship.

I. INTRODUCTION

Modern civilization has its roots in human endeavor to understand the physical universe. The effort to systematically understand the universe and the various phenomena in it appears as a never-ending struggle imbibed with frustration and romance that sparked the imagination of humankind in the course of history. The birth of the scientific method and the ensuing pursuits have lead men and women of learning to the study of phenomena systematically and produced a vast edifice of knowledge in sciences and mathematics. Galileo (1564–1642), the famous Italian astronomer and physicist, firmly enunciated that the language of science is mathematics. The German philosopher Immanuel Kant (1724–1804), in the preface to his book "Metaphysical Foundations of Science," declared "that each particular discipline contains only as much science as it contains mathematics." No more words need to be wasted to say that science and mathematics are intertwined. If science and mathematics are intertwined, can technology, the child of science, exist without mathematics?

In striving to understand phenomena, one must not forget the Aristotelian adage, "The primary question is not what do we know but how do we know it." What we know and its reliability should be the consequence of the process that answers the question how do we know it.

The famous mathematician Hilbert, after a sojourn in the chemistry department at the University of Göttingen, said that chemistry is too difficult for chemists. The American mathematician Richard Bellman echoed that medicine is too difficult for physicians, politics is too difficult for politicians, and economics is too difficult for economists. So is engineering for engineers and physics for physicists. Then how can they be enlightened? The enlightenment comes from exploring the behavior of mathematical models of the processes they encounter in their respective endeavors.

The physical universe is an abundant source of wonder. Benevolently exploited, it is a life-enhancing system for all humankind. The regularity observed in the natural processes of the universe is best expressed and explained in mathematical terms. Mathematical description has provided the tools and motivation for numerous discoveries in cosmology and atomic phenomena, as well as in biology, material science, earth sciences and the social behavior of animal and human populations. In engineering and technology, mathematical concepts and analyses have contributed greatly to the understanding, design, and operation of complex systems. The cost and risk involved in testing a real physical or engineering system are usually prohibitive. The alternative is to develop a mathematical model of the system and investigate its performance. How many of us would "pay the price for reaching the sun and learning its shape, its size, and its substance?"

II. MATHEMATICAL MODELING

Derived from its Latin root modus, the word "model" is generally understood to stand for an object that represents a physical entity with a change of scale. For example, a model airplane is a scaled-down version of a "real" airplane by a few orders of magnitude. As any airplane model builder knows, the behavior of the model and the real airplane differ in more ways than one, in spite of their physical similarity, ensuring a missing ingredient—something that has fallen out during the model building process. What then is a mathematical model? A mathematical model is a set of mathematical equations representing a process or a system. It is a mathematical idealization of a real-world phenomenon. In the sense of the model just defined, it represents a change on the scale of abstraction. Also, the way one sees the world depends upon the structure of one's language; different languages give rise to different concepts, and to many "alternate realities." In the process of idealization, some simplifications will have been made in obtaining the mathematical model. Therefore, the mathematical model is less real than the system it is supposed to represent; it is a mathematical representation of the modeler's perception of some aspects of reality within the confines of a formal mathematical system. Nevertheless, it is an essential step in the construction of a theory. To quote Boltzmann, there is nothing as practical as a good theory.

In the process of mathematical modeling, the objective of the modeler is, in general, to construct a model of an observed phenomenon and use the model to predict its future course. In some cases, modeling is used to explain the known facts and lay a foundation for the theory behind the phenomenon. Thus, a model is a mathematical manifestation of a particular theory. Some modelers have an altruistic motive to apply the model characteristics to

interpret the behavior of phenomena outside their discipline, recognizing the underlying commonality of mathematical modeling. While this commonality is held in high esteem, some fundamental issues underlying the theory of modeling must be addressed. Some of the issues are:

How can a formal mathematical system represent a natural phenomenon?
Does the similarity of two natural systems imply that their models are similar?
How can multiple models of the same natural phenomenon be compared, and with what measure?
How to identify key observable parameters that are necessary for the construction of a plausible model?
Under what conditions the relationship between observables can be accepted as a "Law of Nature"?
How can multiple systems that behave similarly be considered as models of the same?
How is a given system related to its subsystems?
What features characterize "good" models?

Attention to these issues will allow mathematical modeling to play an essential part in the formation of scientific theories of phenomena. Scientific literature abounds with the view that the process of mathematical modeling is not unique. In some cases, the mathematical modeling procedure begins with the desire to construct a model from a set of observations made on the behavior of a system. According to the British physicist Maxwell, "the success of any physical investigation depends upon the judicious selection of what is to be observed as of primary importance." For many problems in science and technology, no wellsprings of observations exist to serve as a source in the modeling process. For example, the phenomena such as the behavior of a spacecraft in the environment of an unknown planet, the response of a structure to an earthquake, and the long-term ecological effects of an industrial effluent injected into the biosphere have no groundwork of observations. In such situations, the model-building process is originated in imagination modulated by intuition and experience. The schematic diagram of Fig. 1 depicts one of several paths in the process of mathematical modeling.

In Fig. 1 the step from A to B involves to a great extent the elements of intelligence and creativity of the modeler. In bringing out a well-defined problem from the maze of observations, the modeler shows the ability to correspond different entities—in this case, a real situation and a formalized statement of the problem. Mathematical training alone will not give an edge to the modeler at this stage. Experience, intuition, and other nonmathematical skills play an important role.

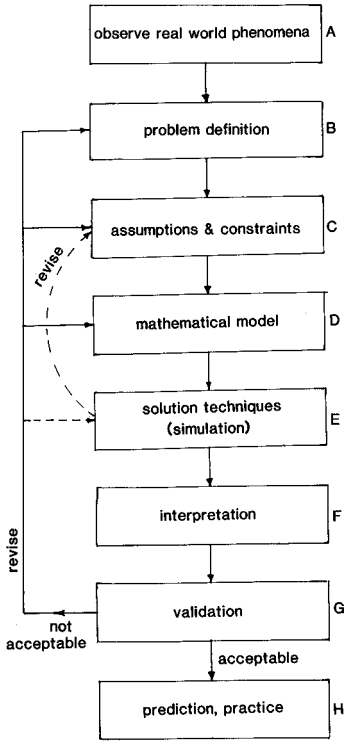

FIGURE 1 Schematic of a mathematical modeling procedure.

Once the problem is defined, a mathematical model of the real-world phenomenon is to be constructed. The real-world phenomena are exceedingly complex. It is nearly impossible to construct a model that replicates the phenomenon in its totality. The modeler must sort out the essential and significant features that need to be incorporated in the model. Once again, experience and intuition come into play. The modeler translates the features into mathematical entities and relates them under certain simplifying but realistic assumptions and constraints. Now we have a mathematical model.

A word of caution is in order. While the application of well-known equations of physics such as Newton's laws, Lagrange's, Hamilton's, and Schrödinger's equations result in mathematical models of various physical processes in the form of differential equations, there are other prescriptions such as simulation and laboratory experimentation augmented by system identification techniques for formulating models of phenomena.

A myriad of mathematical solution techniques are available to extract the system behavior from the model. By using one or more of these techniques, the solution of the model is obtained and interpreted from the viewpoint of accuracy and stability. Determination of how closely the solution approaches the original, real-world phenomenon is the next step in the modeling process. If the solution meets the imposed limits of acceptability, the model is

considered valid and then put into practice to predict a future event, or to make a decision. Otherwise, the model is invalidated, and steps B–D are repeated by revising one or more ingredients in the process. Even a scrutiny of the solution technique (step E) is worth considering. Thus the process of mathematical modeling is iterative in nature. There is no uniqueness in the model-building process.

Although the steps in the modeling process are subjective, they are somewhat similar. Figures 2 and 3, extracted from different sources, essentially have the same features presented in Fig. 1, but indicate the role of computers in mathematical modeling rather explicitly.

In recent years, the growth in mathematical modeling has been so phenomenal that it is evolving into a discipline in its own right. The offering of courses on mathematical modeling in the colleges in the United States, Europe, Asia and Australia has been on a steady increase. The international conferences and symposia on mathematical modeling and the journals that deal exclusively with mathematical modeling support this viewpoint. The proliferation of mathematical models in the scientific literature can be attributed to the explosive growth in the application of mathematical and empirical knowledge to the problems of science and technology. Even social sciences and business, which are not traditionally subjected to mathematical treatment, are not spared from the productiveness of mathematical modeling. The catalysts in the growth of mathematical modeling have been

1. The advent of the computer age with rapid developments in computer technology, specifically, the developments in speed, memory, and software
2. The developments in numerical techniques and analysis
3. The developments in systems theory and simulation
4. The progress in empirical knowledge resulting in a greater understanding of various physical processes

The role of experience and intuition in the process of mathematical modeling accord to it an air of art that makes the process subjective. However, the commonality of features in the process of mathematical modeling in all sciences and technology is so overwhelming that the subjectivity is cast as a minor essence. Let us now turn our attention to these common features that enhance the objective view of mathematical modeling.

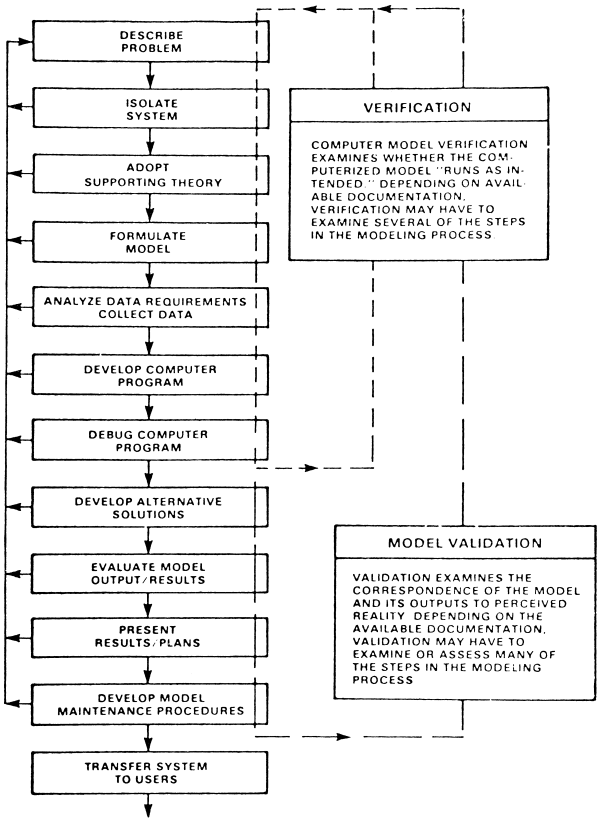

FIGURE 2 Basic steps in the modeling process. [From United States General Accounting Office (1979). PAD70-17, Guidelines for Model Evaluation, Washington, DC.]

III. CLASSIFICATION OF MATHEMATICAL MODELS

Classification of models is important to the understanding of a system's behavioral data and to interpreting or communicating the data for prediction and decision making. An understanding of the system behavior is a contribution to science, and its use for prediction and decision making constitutes technology. Mathematical models are broadly classified into dynamic and steady-state models. Obviously, the element of time is present in the dynamic models. The dynamic models are further classified into continuous-time and discrete-time models. In a continuous-time model the time advances smoothly through real numbers, while in the discrete-time model the time advances in finite jumps, each jump representing a multiple of a selected time unit.

Models constructed in terms of descriptive state variables are classified into continuous state, discrete-state, and mixed-state models. In a continuous-state model the range sets of state variables are presented by real numbers, while in a discrete-state model the variables assume a discrete set of values. In a mixed-state model both kinds of variables are present.

The broad class of continuous-time models is further subdivided into models in which the state changes continuously and those in which the state changes in discrete

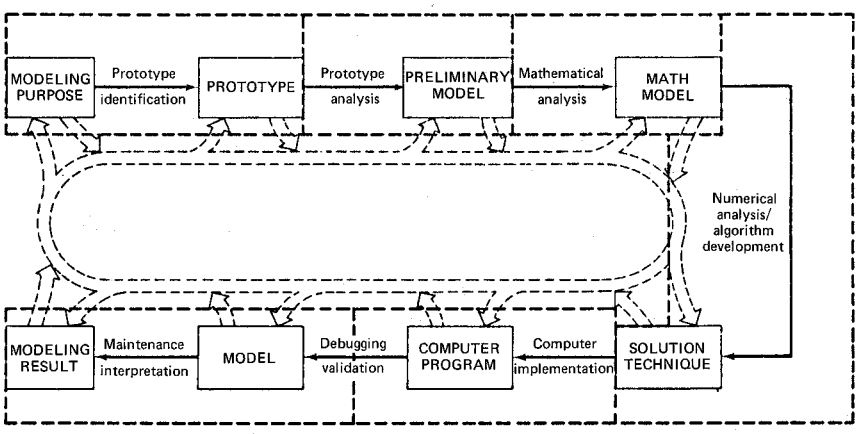

FIGURE 3 Guide to model building. [From Jacoby, L. S., and Kowilik, J. S. (1980). "Mathematical Modeling with Computers," Prentice-Hall, Englewood Cliffs, NJ.]

jumps. The former subclass of models are represented by ordinary and/or partial differential equations, for example, for the boundary-layer flow over a wing of an aircraft. On the other hand, the production line in a factory is a discrete-state system.

Yet another classification breaks down mathematical models into stochastic (or probabilistic) and deterministic models. Models with at least one random variable in their description are termed stochastic. Models other than stochastic are deterministic. In fact, deterministic is a special case of stochastic.

Another classification of models is based on how the real system interacts with the environment. If the real system is isolated from its environment, the model is called *autonomous*. If the environment exerts any kind of influence through so-called input variables from the environment without being controlled by the model, then the model is called *nonautonomous*.

When models are expressed in terms of mathematical equations, the solutions are profoundly affected by nonlinearity. Based on the type of equations, the models are classified as linear or nonlinear. These classifications can be combined with the above-mentioned model types to yield, for example, linear or nonlinear dynamic and linear or nonlinear stochastic models. Although the universe is predominantly nonlinear, some processes are linear within certain bounds. Actually, linearity can be viewed as a special case of nonlinearity. Sometimes, it is mathematically expedient to consider nonlinear processes as piece-wise linear. Systems are classified as linear if and only if they simultaneously satisfy the principle of homogeneity and the principle of superposition. The principle of homogeneity preserves the input function scale factor in transition from input to output. A system satisfies the superposition principle when the superposition of individual input functions result in a response that is the superposition of corresponding outputs. Simulations and exact solutions of linear systems of equations are well established and reported in mathematical literature.

All systems that are not linear belong to the class of nonlinear systems. As there are no general methods of solutions to solve and analyze models of nonlinear systems, simulation has become a commonly used tool for this purpose. Impacted by recent developments in numerical analysis and by advances in powerful, high-speed and high-memory digital and analog computers, simulation of nonlinear systems have blossomed into technical endeavors that are broad in scope and variety encompassing biological, ecological, social, and economic systems in addition to those in hard scientific fields such as physics, chemistry, material science, and mechanics. Modern nonlinear equations frequently encountered in simulation include, for example, the quaternion rotational equations of motion that are treated with geometric algebra which is of late applied to a range of problems in many fields of science and being promoted as a unified mathematical language in the 21st century.

Traditional quantitative techniques of modeling cannot be effectively applied to model phenomena in the so-called "soft" disciplines consisting of humanistic systems such as social, economic, ecological, and biological systems because there may arise difficulties associated with multidimensionality, subsystem interactions, inexplicable feedback mechanisms, hierarchical structures, and unpredictable behavioral dynamics. Such difficulties may also be encountered in mechanistic systems that may include some physical and engineering systems. These difficulties lead to making imprecise statements, introducing fuzziness much like human reasoning, about the characteristics and behavior of a system. An important class of models

using fuzzy sets was launched about 35 years ago. The idea of fuzzy sets is centered on the imprecision in the belonging of elements to a set. Intuitively, a fuzzy set is a set of elements that are not precise and in which there is no distinct boundary between the elements that belong to the set and those that do not. In other words, the transition from full membership to nonmembership of an element (or elements) is blurred, so that a gradation of partial membership is possible. Mathematical concepts based on this idea have been successfully applied to modeling of systems in "soft" desciplines as well as in engineering when imprecision is present. Fuzzy systems models are categorized into two types: liguistic and rule-based. An elaborate discussion of these types of models and modeling techniques is beyond the scope of this article.

IV. FORMULATION OF MATHEMATICAL MODELS

A. Conventional Modeling (Direct Modeling)

Experimental observations and measurements are generally accepted to constitute the backbone of physical sciences and engineering because of the physical insight they offer to the scientist for formulating the theory. The concepts that are developed from the observations are used as guides for the design of new experiments, which in turn are used for validation of the theory. Thus, experiments and theory have a hand-in-hand relationship. The information gathered during observation and measurement is usually presented in terms of curves, tables, block diagrams, circuit diagrams, flow diagrams, etc. for convenience of perception in the model building process. These information display techniques have been tremendously aided by the advent of high-performance computers.

Formulation of theory is equivalent to model building. Cast in mathematical terms, the theory stands as a mathematical model of reality. In the conventional sense, the first stage in model building is to propose and gather equations representing all relevant mechanisms of the phenomenon under study. Because of the diversity in the types of information available to the model builder, the equations representing the basic phenomenon may be extensive with complex interrelationships that may be difficult to untangle for easy tractability. To preserve fidelity, all equations that will have significant effect on the system behavior must be included in the model. It is always better to first produce a simple model and then refine it until it closely represents the reality, than to start with a complex model and simplify it for fear of facing mathematical difficulties.

Conventionally, the construction of mathematical models for physical and engineering phenomena begins with the application of physical laws—Newton's laws, Maxwell's laws, Kirchhoff's laws, and balance laws, which include mass balance, energy/heat balance, momentum balance, impulse balance, and entropy balance—to the phenomena being studied. In these laws, a number of relationships between the variables are expressed in terms of ordinary differential equations, partial differential equations, and difference equations. A detailed presentation of these laws is beyond the scope of this article. However, some examples are appropriate.

The first and second laws of thermodynamics in differential form are stated as

$$dU = dQ - d\mathrm{W} \tag{1}$$

$$d\mathrm{S} = dQ/T, \tag{2}$$

where U is the internal energy, Q is the heat absorbed by the system, W is the work done by the system, S is the entropy, and T is the temperature.

The fundamental law of heat conduction in one dimension is represented by the ordinary differential equation

$$dQ/dt = -k\mathrm{A}\,(dT/dx),$$

where dQ/dt is the time rate of heat transfer across the area A, k is the thermal conductivity of the medium, and dT/dx is the temperature gradient.

Newton, in his famous "Principia," expressed the second law of motion in terms of momentum, which in symbolic form becomes

$$\mathbf{F} = d\mathbf{p}/dt, \tag{3}$$

where $\mathbf{p}$ is the linear momentum (product of mass and velocity mv). This equation can be written in the familiar form as

$$\mathbf{F} = d(m\mathbf{v})/dt = m(d\mathbf{v}/dt) = \mathrm{m}\mathbf{a}, \tag{4}$$

Attempts by scientists to describe the physical world led them to the formulation of various types of partial differential equations. The mathematical model for the one-dimensional wave phenomena is the hyperbolic equation

$$\partial^2 u/\partial t^2 = c^2(\partial^2 u/\partial x^2). \tag{5}$$

The phenomena of diffusion of heat in solids is modeled by the parabolic equation derived by Fourier in the form

$$\frac{\partial u}{\partial t} = \sigma \frac{\partial^2 u}{\partial x^2}. \tag{6}$$

The Fourier heat equation in three spatial dimensions and time modeled as

$$\frac{\partial u}{\partial t} = \sigma \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} \right) \tag{7}$$

yields for steady state (with $\partial u/\partial t = 0$)

$$\nabla^2 u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0, \tag{8}$$

which is an elliptic equation, also called Laplace's equation.

An example from the conservation laws is the law of conservation of mass, which can be expressed in terms mathematical symbols as

$$(\partial\rho/\partial t) + \nabla \cdot (\rho \mathbf{v}) = 0, \tag{9}$$

where ρ is the density, $\mathbf{v}$ is the velocity vector, and ∇ stands for the operation $\lfloor \hat{i}(\partial/\partial x) + \hat{j}(\partial/\partial y) + \hat{k}(\partial/\partial z) \rfloor$ rectangular Cartesian coordinates with $\hat{i}$, $\hat{j}$, $\hat{k}$ the unit vectors along the coordinate axes x, y, z, respectively.

A universally accepted mathematical model for viscous fluid flow is the famous Navier–Stokes equation,

$$\rho(D\mathbf{v}/D\mathrm{t}) = -\nabla\rho - \nabla \times [\mu\nabla \times \mathbf{v}] + \nabla[(2\mu + \lambda)\nabla \cdot \mathbf{v} \tag{10}$$

where μ, is the coefficient of viscosity, λ is the second coefficient of viscosity, and

$$D\mathbf{v}/Dt = (\rho(\partial/\partial t) + \mathbf{v} \cdot \nabla)\mathbf{v}. \tag{11}$$

in which $\mathbf{v} \cdot \nabla$ is the convective derivative.

These and other aforementioned equations play a central role in mathematical modeling of a large variety of physical systems. In addition to differential and difference equations, there are other distinct types of equations—algebraic, integral, and functional equations—that appear prominently in mathematical modeling. Not all of these equations have closed-form, analytical solutions. The modeler has to resort to numerical and other approximation methods for solutions.

In science, the purpose of modeling has been primarily for research and understanding natural phenomena. In research, even though the immediate use of the model is not clear, one pursues it for gain in comprehension, for interpreting knowledge, and for formulating clues for further investigation. In engineering, however, in addition to research, mathematical models are used for design and control. Here the knowledge of the components of the total engineering system has to be expressed in a model compatible with design criteria, which may include some or all of stability limits, error criterion, economic yield, and safety criterion. Also, modeling for design is not just for creating a new system but also for the adaptation of an existing system for a higher (or different) performance.

To drive an engineering system in a desired fashion, some control action needs to be imposed in the form of feed-back or feed-forward control, or adaptive control. There is a wide spectrum of human-made control systems in engineering, ranging from a simple on-off control to sophisticated computer control of a spacecraft. A common feature of all control systems is the so-called uncertainty factor which might be limited by using adaptive or self-optimizing principles.

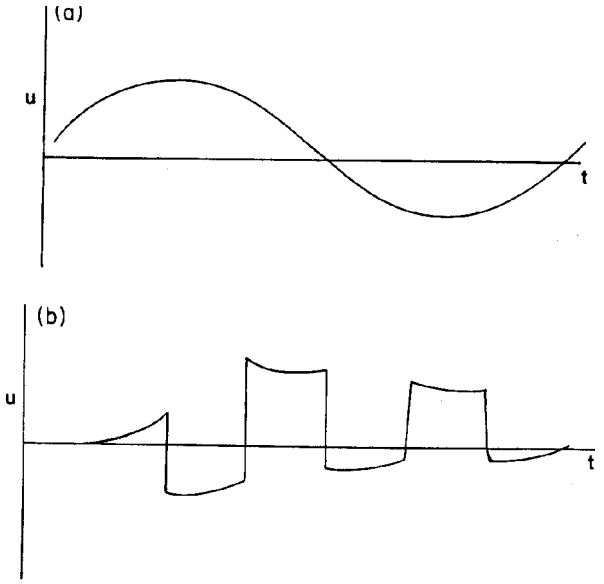

FIGURE 4 (a) Response u in Van der Pol equation for small values of the parameter 8. (b) Response ii in Van der Pol equation for large values of the parameter 8.

Even if the mathematical model representing a system is formulated in principle, it cannot be used for any practical purpose unless the range of parameters in the model is available. The importance of determining the range of parameters can be observed, for example, in the behavior of Van der Pol equation, which can be expressed as

$$(d^2u/dt^2) + \lambda(u^2 - 1)(du/dt) + u = 0. \qquad \lambda > 0 \tag{12}$$

As it can be seen in Fig. 4(a), u is almost periodic for small values of X, while for large values of λ the response of u is as shown in Fig. 4(b). The requirement to determine valid parameters leads to the identification problem. Since one cannot always have the complete knowledge of the physical aspects of phenomena for guidance to construct a model, identification of the system and its parameters becomes an important problem for which several methods have been developed in systems theory.

B. System Identification and Parameter Estimation (Inverse Modeling)

Determination of the output signal corresponding to the input time history and system characteristics is a central problem in systems theory. In contrast to this problem, given an input and output time history, can one determine

the mathematical model that describes the system behavior? This latter problem is called an inverse problem and generally is referred to as the system identification. Identification is defined as the determination, on the basis of input and output, of a system within a specified class of systems, to which the system (phenomenon) under study is equivalent. In other words, identification is the process of constructing a mathematical model of a system from prior knowledge and observations. Equivalence is often expressed in terms of an error function E, which is a function of system output y and the model output y_m, that is,

$$\mathrm{E} = \mathrm{E}(y, y_m). \tag{13}$$

Two models m_1 and m_2 , are said to be equivalent if the value of the error function is the same for both models, that is,

$$\mathrm{E}\big(y, y_{m_1}\big) = \mathrm{E}\big(y, y_{m_2}\big). \tag{14}$$

A model can be identified with reality if the value of the error function is minimum, and in recent years numerous techniques for minimizing error functions have been developed.

Although in identification problems no prior knowledge of phenomena is assumed, in reality the modeler has at least a partial understanding of the process to be modeled, through experience and intuition. In such cases the identification problem is reduced to finding the numerical values of a number of parameters (coefficients in the differential equations representing the phenomenon) and state variables. The identification problem is thus reduced to a parameter estimation problem. Parameter estimation is defined as the experimental determination of values of parameters that govern the system behavior, assuming that the structure of the process is known.

C. Methods of System Identification

1. Frequency Response Method

Certain linear stationary processes can be identified by the so-called frequency response method. In this method, sine-wave inputs are applied to the system, and the steady-state outputs in terms of the magnitude ratio and the phase shift are measured over the entire range of frequencies of interest. Knowing the output $Y(s)$ corresponding to the input $X(s)$, the system behavior (transfer function) $G(s)$ is determined (see Fig. 5) by the operation

$$G(s) = Y(s)/X(s). \tag{15}$$

This method is applicable only to stable systems, because the output $Y(s)$ for unstable systems cannot be measured.

FIGURE 5 Relationship of the transfer function $G(s)$ to the input $X(s)$ and the output $Y(s)$.

2. Step-Response Method

Step input is the simplest input that can be applied to a system, like sudden closing or opening of a valve in a hydraulic network. In reality, strict step input is physically impossible, but as long as the rise time of the step input is much shorter than the period of the highest frequency in the system, the input can be considered as a step input. Step-response problems are considered as impulse-response problems, and the determination of transfer function falls into the category of time-domain problems, which can be solved by one of the gradient methods.

3. Deconvolution Method

Sometimes the input and output of a system can be related by the convolution integral

$$y(t) = \int_0^t x(\tau)w(t-\tau)\,d\tau, \tag{16}$$

where $w(\tau)$ is the impulse response of the system. The determination of the impulse response from the input and the output is called deconvolution. Once $w(\tau)$ is determined, the system transfer function can be found by using the step response method already described.

4. Cost Function Method

In identification problems, cost means penalty for not achieving correct identification. The cost function is usually expressed as a squared error (difference between the assumed value and the actual value of a parameter) function that has to be minimized for correct, or nearly correct, parameter estimation. Cost functions are mainly of two types with some variations depending on the choice of the parameter: (1) the *maximum likelihood* (ML) cost function in which the ML estimator does not assume any prior knowledge of the parameter, and (2) the *maximum a posteriori* (MAP) cost function which considers prior knowledge of the parameter obtained by maximizing the probability density of the parameter.

5. Gradient Techniques

Gradient techniques are associated with computational methods for system identification. Here, one attempts to minimize the cost function with each iteration in a direct

fashion after expanding the cost function in Taylor series about an assumed parameter to a desired order. In the computational algorithm, one picks the variation in the parameter to make the steepest descent toward the minimum cost function. The computation is repeated until there is no significant change in the parameter value from iteration to iteration. Widely applied among these methods are the first-order, second-order, and conjugate gradient methods.

6. Quasilinearization Method

As opposed to gradient technique, this is an indirect method in which a sequence of functions is iteratively computed until the functions converge to the solution. In this method, recurrence relations are obtained in the form of linear differential equations, even if the model equation has nonlinearity in its structure—hence the name quasilinearization. This method is also called the generalized Newton–Raphson method.

Consider, for example, the nonlinear differential equation

$$dx/dt = f(x), \qquad x(0) = c, \qquad t > 0 \tag{17}$$

in which the function f is continuous in x and time t and has continuous bounded second partial derivatives with respect to x for all x and t. The function can be expanded around $x^{(0)}(t)$ in Taylor series as

$$f(x) = f\left(x^{(0)}\right) + \frac{\partial f\left(x^{(0)}\right)}{\partial x}\left(x - x^{(0)}\right) + . \tag{18}$$

Neglecting the higher-order terms and combining Eqs. (17) and (18) yields the linear differential equation

$$\frac{dx}{dt} = f\left(x^{(0)}\right) + \frac{\partial f\left(x^{(0)}\right)}{\partial x}\left(x - x^{(0)}\right) \tag{19}$$

$$x(0) = c. \tag{20}$$

Proceeding likewise, one obtains

$$\frac{dx^{(n+1)}}{dt} = f\left(x^{(n)}\right) + \frac{\partial f\left(x^{(n)}\right)}{\partial x}\left(x^{(n+1)} - x^{(n)}\right) \tag{21}$$

$$x^{(n+1)}(0) = c. \tag{22}$$

The iterative process begins with an initial approximation $x^{(0)}(t)$ and proceeds until the sequence of functions converges.

7. Invariant Imbedding

The basic idea of invariant imbedding is to change a specific problem into a general problem. The solution to a specific problem is imbedded in the solution of a more general problem for which a sequential estimate of system parameters is made in the solution procedure. Invariant imbedding converts many boundary-value problems into initial-value problems, which makes both the analysis and the computational solution easier. This form of imbedding is also useful in engineering problems where sensitivity analysis has to be performed.

V. SOLUTION TECHNIQUES

For a mathematical modeler, the entire world of applied mathematics and new mathematical concepts being developed from time to time are open for use. The advent of high-speed digital computers has aided the solution techniques and opened the doors for modeling more complex systems. Some solution techniques practiced in modeling include:

1. Rigorous analysis
2. Symmetry methods
3. Obtaining *a priori* bounds on the solutions
4. Method of isoclines
5. Perturbation theory
6. Asymptotic analysis
7. Group theory
8. Inequalities
9. Integration by parts
10. Extremum principles
11. Numerical approximations (including finite difference, finite element, boundary element methods, invariant imbedding, etc.)
12. Variational principles
13. Linearization and quasi-linearization
14. Integral methods
15. Complex-variable methods
16. Graph theory
17. Mathematical programming.

This list is by no means exhaustive. For detailed analyses of these topics, the reader must refer to textbooks on applied mathematics. There are separate textbooks for several of these topics.

VI. MODEL VALIDATION

Developing a mathematical model is a long and arduous task. In mathematical modeling, the goal of the modeler is to ensure that the model replicates the phenomena being modeled to an acceptable degree. The procedures followed to test the fidelity of the model in reproducing the real

system it represents constitute model validation. On the surface, it appears that validation is something that should be done at the end of the model construction. But, in fact, validation should be carried out throughout the modeling process. A valid model can be expected by being logically consistent at each step of the modeling process, by reexamining the assumptions and constraints without sacrificing the mathematical rigor, and by turning every stone of applicable mathematical knowledge. Is it not logical that to obtain valid model behavior one must use valid assumptions and constraints? By doing so one would obtain the most accurate model, but perhaps one difficult to solve. Suppose, by a judicious choice of a solution technique from the myriad of techniques available, the modeler determines the system behavior. This step invariably (at least in physical sciences and technology) involves a numerical approximation associated with computer programming, which should be carefully carried out and correctly implemented. To generate confidence in the model, the system behavior must be compared with the real system data. It is nearly impossible, except for some simple situations, to obtain global agreement (agreement over the entire range of parameters). Then the modeler must choose the range of validity for various model parameters and establish other criteria, such as comparison of results by different solution techniques, by which to judge the model validity.

The validity of a model should not be judged by mathematical rationality alone; nor it should be judged purely by empirical validation at the cost of mathematical and scientific principles. A combination of rationality and empiricism (logic and pragmatism) should be used in the validation. If necessary, all or some of the steps in the modeling process should be repeated several times until the model is acceptable for use.

VII. CHAOS AND COMPLEXITY

In deterministic physical and mathematical systems, when the model equations are nonlinear, the evolution of the system behavior becomes irregular and unpredictable and exhibits sensitive dependence on initial conditions. Such behavior is called *chaos*. It occurs in vibrating objects, in rotating or heated fluids and in some chemical reactions. Understanding chaotic behavior involves tracking the time evolution of nonlinear dynamical system or that of natural phenomena modeled by a set of nonlinear differential equations that arise from classical equations of physics. With the exception of some first-order equations, analytical solutions of nonlinear differential equations are either difficult or impossible. The desire to overcome this difficulty has presented a significant motivation for the advancement of numerical methods and innovations of computational algorithms that lead to novel computer architectures. New discoveries in nonlinear dynamics have created new concepts and tools such as fractal dimensions and Lyapunov exponents for detecting and quantifying chaos in physical systems. There are no formal, theoretical criteria to determine under what conditions a dynamical system in general would become chaotic. Significant effort is needed to determine how and when more general and complex physical systems will become chaotic.

Complexity is one of the most perplexing problems of systems theory. Many relatively independent subsystems that are highly interconnected and interactive manifest complex systems. As a result, the collective behavior of complex systems is reflected in reproducing the functions of truly complex, self-organizing, replicating, learning and adaptive systems. Systems consisting of a large number of interacting elements lead to a perception of complex and disorderly behavior. It is generally believed that biological systems involve more interacting elements than physical systems, and therefore the latter are simple with orderly behavior. However, recent developments in irreversible thermodynamics, in the theory of dynamical systems, and in classical mechanics have narrowed the gap between the simple and complex, and between order and disorder; under certain conditions, simple systems are also known to exhibit complex behavior. Complexity in system behavior is characterized by instabilities and bifurcations. In modeling complex behavior of a system, one must first assess the nonlinear character of the underlying dynamics and identify a set of variables that control these instabilities and bifurcations.

VIII. MODELING WITH NEURAL NETWORKS

As processes increase in complexity, they become less amenable to direct mathematical modeling based on physical laws. In the later half of the 20th century, *artificial neural networks* have made inroads into several disciplines with a wide range of applications. An artificial neural network is a network of interconnected units called artificial neurons that are connected in different patterns to process information in a parallel distributed fashion much like the human brain. A significant aspect of neural networks is their ability to learn how to process information in *supervised* and *unsupervised* modes. They are used for simulation of physical systems that are modeled by massively parallel networks. In recent years, applications have been developed for modeling simple biological structures with known functions, for the modeling of higher functions of the central nervous system, for solving complicated problems in artificial intelligence and cognitive sciences,

for pattern recognition, and for solving combinatorial optimization problems. Further applications have been extended to medical diagnosis, financial services including stock price prediction, intelligent control of engineering plants, and manufacturing. Neural networks are also well adapted to ill-posed problems, those with damaged or incomplete data.

IX. MATHEMATICAL MODELING AND COMPUTERS

In all endeavors involving mathematical modeling, one cannot fail to perceive that computers act as an interface between phenomena and the various stages of mathematical modeling, including validation and use. Spectacular advances have been achieved in modeling complex and large systems using computers by removing the need for analytical solutions to differential equations representing the systems. The advances in high-speed computers and efficient numerical algorithms have generated acceptable numerical solutions to systems of the equations hitherto intractable and thus made modeling of complicated, interconnected, and interacting systems possible. As a matter of fact, complicated mathematical models expressed in terms of nonlinear partial differential equations and new applications have been the driving force behind the development of large computing machines with huge amounts of shared memory and a processing rate of up to three trillion floating-point operations per second. The need for more efficient computers to simulate complicated models has driven the computer scientists to think innovatively in the direction of new architectures and procedures. The greatest potential for achieving higher speed lies in adding parallel processors. In recent years, neurocomputers based on artificial neural networks have been built to process information efficiently and cost-effectively, but complementary to algorithmic computing. With more developments in the computer technology on the horizon, mathematical modelers can expect to achieve more success in modeling and simulation of very complicated systems, and also in revising and reworking the old models, in which drastic simplifications had to be made in the past. Despite the advances in computers and computational technology, the role of analytical methods in deciphering mathematical models should not be overlooked because they offer a valuable insight to a wide variety of problems.

X. CONCLUDING REMARKS

In this article, mathematical modeling concepts in relation to physical sciences, engineering, and technology have been surveyed. In recent years, mathematical modeling has pervaded all branches of knowledge, bringing forth greater understanding of processes under investigation. In engineering and technology it provides the analytical basis for design and control in which predictions can be confidently made without spending valuable resources of money and effort.

Successful applications of mathematical modeling techniques in engineering sciences have led the way to extend the techniques to more exotic areas of inquiry, like nanotechnology, nuclear-reactor engineering, material science, environment, weather prediction, biological processes, space sciences, cosmology, and also social sciences. Although the general philosophy of modeling in these new areas remains the same as discussed in this article, the simulation procedures and validation criteria are different and dependent on the types of models and the disciplines they belong to.

Mathematical modeling is a vast, multidisciplinary field that pleads to engage the interest and dediation of engineers, scientists and mathematicians to solve the problems facing the humankind. A significant development in the mathematical modeling activity is the availability of very-high-speed computers, which can solve a variety of complex models. In spite of all the advances in empirical knowledge, solution techniques, and computer assistance, it must be noted that human intelligence, experience, and intuition still play a significant role in mathematical modeling.

Measure and Integration

G. de Barra
University of London

GLOSSARY

Almost everywhere (a.e.) Except on a set of measure zero.
Complement Set of points of the space not in A, denoted $\complement A$.
Countable set Set which may be enumerated or put in one-to-one correspondence with the integers.
Empty set Set with no elements. (Notation $\varnothing$.)
Measurable function Function whose values above any given value are taken in a measurable set.
Measurable set Set whose measure is defined.
Measure Quantity defined on sets usually taking a positive value, denoted $m(A)$ for A a set of real numbers or $\mu(A)$ more generally.
Set Class of objects with property P (say). (Notation $\{x : x$ satisfies $P\}$.)
Set difference Set of points of A not in B, denoted $A \setminus B$.

THE LEBESGUE THEORY of measure and integration provides the framework for considering the limiting operations of analysis as used in pure mathematics and theoretical physics. In particular it shows when sums and integrals or limits and integrals may be interchanged. It includes the study of the theory of sets in the real line or higher dimensions with special emphasis on countable operations on sets.

I. INTRODUCTION

The theory of integration arose informally. It was formalized by Riemann but in a way which restricted its application severely. These restrictions are considered in Section III. Meanwhile in applications the subject was expanding as applied mathematicians and students of probability needed results on the limits of integrals, not provided by Riemann's theory. The Lebesgue theory supplied

the main deficiencies and the limit theorems described in Section III together with the results on differentiation of Section V rounded off the subject. The needs of the applied mathematicians were provided for also by the results on the L^p spaces of functions described in Section IV and the results using product spaces of Section VI. The Lebesgue integral turns out to be the appropriate definition to deal with orthogonal expansions and with the Fourier and Laplace transforms. The needs of the probabilists were supplied by the general theory of measure in Section VII, the decomposition theorems of Section VIII, and the results on products of measure spaces in Section VI. The differentiation of measures considered in Section VIII is of central importance in functional analysis, as is seen in Section XI.

II. LEBESGUE MEASURE

For any set A contained in the real line $\mathbb{R}$ we define the *Lebesgue outer measure* (or *outer measure*) to be the quantity $m^*(A)$ given by $m^*(A) = \inf \sum_n l(l_n)$ where we are taking the infimum or greatest lower bound over all collections $\{I_n\}$ of intervals such that $A \subseteq \cup I_n$ and where $l(I)$ denotes the length of the interval I. From this definition we have immediately that $m^*(A)$ is nonnegative; $m^*(A) = 0$ if A is a one point set or empty; $m^*(A) \leqq m^*(B)$ whenever $A \subseteq B$. It is fairly easy to show that the outer measure of any interval equals the length of the interval, so outer measure has for some sets at least the properties we would desire. Also, for any sequence of sets $\{E_i\}$ it is easy to see that

$$m^*\left(\bigcup_{i=1}^{\infty} E_i\right) \leqq \sum_{i=1}^{\infty} m^*(E_i)$$

(i.e., m^* is subadditive). We, however, cannot in general assume that equality will occur here even if the sets are pairwise disjoint. The outer measure has another desirable property: the outer measure of a set is unchanged if the set is shifted to left or right (i.e., m^* is translation invariant). It also has a regularity property: for any set A and any $\varepsilon > 0$ there is an open set O containing A and such that $m^*(O) \leqq m^*(A) + \varepsilon$.

In order to achieve the desired additivity we restrict m^* to the class $\mathcal{M}$ of Lebesgue measurable sets. We define a set E to be *Lebesgue measurable* (or just *measurable*) if for each set A

$$m^*(A) = m^*(A \cap E) + m^*(A \cap \complement E)$$

So a measurable set divides an arbitrary set in an additive way as regards outer measure. It follows from this definition that intervals are measurable. Also, all sets of zero outer measure are measurable (and so therefore are all subsets of such sets). The class of measurable sets has the important property of being a σ algebra: that is, the class contains the whole space ($\mathbb{R}$ in this case) and is closed under the formation of complements and countable unions. Only the last part here presents any difficulty. Denote m^* restricted to the σ-algebra $\mathcal{M}$ by m, called *Lebesgue measure*. Then we easily have that for any sequence $\{E_i\}$ of disjoint measurable sets

$$m\left(\bigcup_{i=1}^{\infty} E_i\right) = \sum_{i=1}^{\infty} m(E_i)$$

(i.e., m is additive on disjoint measurable sets). For some purposes it is convenient to restrict the measure m still further to the Borel sets which may be defined as the smallest σ algebra containing the intervals. These sets are more natural in some contexts, but difficulties can arise from the fact that whereas for the class $\mathcal{M}$ every subset of a set of zero measure is again measurable, this is no longer true of the smaller class of Borel sets. So we confine our attention to the Lebesgue measurable sets.

It is easily seen that every nonempty open set has positive measure. From the countable additivity of m it is obvious that every countable set has zero measure. It is less obvious that there exist uncountable sets of zero measure. A standard example is the Cantor ternary set. It is formed by removing from the interval [0, 1] the middle third $(\frac{1}{3}, \frac{2}{3})$, then the middle thirds of the two remaining intervals, namely, $(\frac{1}{9}, \frac{2}{9})$ and $(\frac{7}{9}, \frac{8}{9})$, then the middle thirds of the remaining intervals, and so on. The total set removed has measure adding to 1, so the residual set (the Cantor set) has measure 0. But the Cantor set contains all the numbers between 0 and 1 with expansions to base 3 consisting of 0's and 2's. So it has the same cardinality as the set of all binary expansions, and so is uncountable. It is also true that there exist sets of the real line which are not measurable. But these sets cannot be constructed and indeed can only be shown to exist using the axiom of choice or an equivalent tool of mathematical logic. The existence of these nonmeasurable sets is not crucial for the theory, but if they did not exist the theory would lose some of its content, for all sets would be measurable.

We consider now a "continuity" property of measure. Suppose $\{E_i\}$ is a sequence of measurable sets, $E_0 \subseteq E_1 \subseteq E_2 \subseteq \cdots$. Then $m(\cup_{i-1}^{\infty} E_i) = \lim m(E_i)$. Also, if $F_0 \supseteq F_1 \supseteq F_2 \supseteq \cdots$, and $m(F_0) < \infty$, then $m(\cap_{i=1}^{\infty} F_i) = \lim m(F_i)$ where again the sets $\{F_i\}$ are supposed measurable. If, as is conventional, we write here $\lim E_i = \cup_{i-1}^{\infty} E_i$ and $\lim F_i = \cap_{i=1}^{\infty} F_i$, then this result reads $m(\lim E_i) = \lim m(E_i)$ for any increasing sequence of measurable sets and also for any decreasing sequence of sets of finite measure. Lebesgue measure also has a regularity

property stronger than that of outer measure. If E is any measurable set and ε any positive number then there exists an open set $O \supseteq E$ with $m(O \setminus E) \leqq \varepsilon$ and a closed set $F \subseteq E$ with $m(E \setminus F) \leqq \varepsilon$.

Although the sets of zero measure can be uncountable, they turn out to be negligible for the purposes of integration and we say that a property holds "almost everywhere" (a.e.) if it holds except possibly on a set of zero measure. Note that sets of infinite measure frequently occur (e.g., $[1, \infty)$ is of infinite measure). So identities or inequalities involving the measures of sets must be written carefully with this in mind. In particular, indeterminate expressions of the form $\infty - \infty$ must be avoided.

The importance of Lebesgue measurable sets is that they allow us to define measurable functions. Recall that we say a function f is continuous if the set of points x with $f(x) > \alpha$ is open, for each α (i.e., $f^{-1}(\alpha, \infty)$ is open). We define f to be *Lebesgue measurable* (or just *measurable*) if $f^{-1}(\alpha, \infty)$ is a measurable set for each α. Since open sets are measurable it follows that continuous functions are measurable. It follows easily from the definition that, if f is measurable, $\{x: f(x) = \alpha\}$ is measurable for each α. Also, the constant functions are measurable (since they are continuous). Of special importance are the characteristic functions. We denote by χ_A the characteristic function (or indicator function) of the set A: $\chi_A = 1$ on A, $\chi_A = 0$ on $\mathcal{C}A$. Then from the definition of measurable functions we have that a characteristic function χ_A is measurable if, and only if, the set A is measurable. It is also easy to see that a constant multiple cf of a measurable function f is measurable. With a little more care we can see that the sum of measurable functions is measurable. So any finite linear combination of measurable functions is measurable and the product of measurable functions is measurable.

As indicated earlier it is important in applications to deal with limiting operations. So we note that the sup and inf of any finite or countable family of measurable functions is again measurable; this uses the fact that $\mathcal{M}$ is a σ algebra allowing countable set operations. It follows that for any sequence $\{f_n\}$ of measurable functions, lim sup f_n and lim inf f_n are again measurable. Here lim sup f_n is the inf$(N \geqq 1)$ of the sup$\{f_n: n \geqq N\}$, and lim inf $f_n = -\limsup(-f_n)$. If $\lim f_n$ exists it is the common value of lim sup f_n and lim inf f_n, so we have that the limit, when it exists, of a sequence of measurable functions is again measurable. The corresponding result is not true of continuous functions. As important special cases we have that $f^+ = \max(f, 0)$, and $f^- = \max(-f, 0)$ and $|f| = f^+ + f^-$ are measurable whenever f is.

For continuous functions the sup and inf are important. For a measurable function we are more interested in ess sup f and ess inf f (the essential supremum and essential infimum of f) given by ess sup $f = \inf\{\alpha: f \leqq \alpha \text{ a.e.}\}$, ess inf $f = \sup\{\alpha: f \geqq \alpha \text{ a.e.}\}$. So if we disregard sets of measure zero we replace the sup f by the possibly smaller ess sup f and the inf f by the possibly larger ess inf f. Functions for which both of the numbers are bounded are called essentially bounded. A simple property of the essential supremum to which we refer later is that for any two measurable functions

$$\text{ess sup}\,(f + g) \leqq \text{ess sup}\, f + \text{ess sup}\, g$$

and

$$\text{ess inf}\,(f + g) \geqq \text{ess inf}\, f + \text{ess inf}\, g$$

So finite linear combinations of essentially bounded functions are again essentially bounded. As an example suppose $f(x) = 1$ for x rational, $f(x) = 0$ otherwise. The f is measurable (it is the characteristic function of a countable set which of course has measure zero), and sup $f = 1$, but ess sup $f = 0$.

All the functions considered here have been real valued. For some purposes, however, it is convenient to extend the definitions to complex-valued functions. We describe the function f as measurable if Re(f) and Im(f), the real and imaginary parts of f, are measurable in the previous sense. To avoid difficulties we shall assume that any complex-valued functions considered take only finite values. It is easy to check that $|f|$ is measurable whenever f is a complex-valued measurable function.

III. THE LEBESGUE INTEGRAL

We now show how the Lebesgue integral is defined, how its value may be obtained in practice, what the principal theorems are which make its use attractive, and how these theorems may be used in examples. We revert for the moment to real-valued functions.

As with most definitions of the integral we specify the integral for a certain basic class of functions and show how the definition can be extended to a more general class. Not all functions or even all measurable functions have integrals; the restrictions arise in a natural way from the definition. So we first consider nonnegative simple functions. These are measurable functions taking only a finite number of values. Equivalently we write the real line $\mathbb{R}$ as the union of a finite number of measurable sets

$$\mathbb{R} = \bigcup_{i=1}^{n} A_i$$

and consider the function

$$\phi(x) = \sum_{i=1}^{n} a_i \chi_{A_i}$$

where the a_i are finite nonnegative numbers and χ_{A_i}, as before, stands for the characteristic function of the set A_i. Typically, one of the a_i will be zero. As special cases of simple functions we have characteristic functions of measurable sets (or of intervals, in particular). For such a characteristic function χ_A we define the integral $\int \chi_A \, dx$ to be $m(A)$. Since we want our integral to be linear we define

$$\int \phi \, dx = \sum_{i=1}^{n} a_i m(A_i)$$

where ϕ is given as above. We use the convention that in such sums $0 \cdot \infty = 0$. This definition is extended immediately to all nonnegative measurable functions f on $\mathbb{R}$ by

$$\int f \, dx = \sup \int \phi \, dx$$

the supremum being taken over all nonnegative simple functions ϕ, $\phi \leqq f$.

This would seem to give two ways of arriving at the integral of a nonnegative simple function, but they are easily shown to give the same value. Restricting to a measurable subset E of $\mathbb{R}$ we may write $\int f\chi_E \, dx$ as $\int_E f \, dx$ for any nonnegative measurable function f; in particular, if $E = [a, b]$ this is written as just $\int_a^b f \, dx$.

From the definition we have immediately some properties of the integral for nonnegative simple functions: if

$$\phi = \sum_{i=1}^{n} a_i \chi_{A_i}$$

then

$$\int_E \phi \, dx = \sum_{i=1}^{n} m(E \cap A_i)$$

for any measurable set E; $\int_{A \cup B} \phi \, dx = \int_A \phi \, dx + \int_B \phi \, dx$ for any disjoint measurable sets A and B, so the integral is additive: $\int a\phi \, dx = a \int \phi \, dx$ for any positive number a.

From these properties and from the definition we have some properties of the integral for nonnegative measurable functions: $\int f \, dx = 0$ if, and only if, $f = 0$ a.e.; if $f \leqq g$ then $\int f \, dx \leqq \int g \, dx$ (f and g nonnegative measurable functions); if $a \geqq 0$ then $\int af \, dx = a \int f \, dx$; if A and B are measurable and $A \supseteq B$ then $\int_A f \, dx \geqq \int_B f \, dx$.

The important theorems regarding the Lebesgue integral are concerned with sequences or limits, a basic one being Fatou's lemma: let $\{f_n\}$ be a sequence of nonnegative measurable functions; then

$$\int \liminf f_n \, dx \leqq \liminf \int f_n \, dx$$

So if the sequence $\{f_n\}$ converges at each point to the function f (necessarily measurable) and if for some infinite subsequence we have

$$\int f_{n_i} \, dx \leqq A$$

then

$$\int f \, dx \leqq A$$

This result has far-reaching applications and its proof is based directly on the result of the last section that $\lim m(A_i) = m(\lim A_i)$. We must allow integrals and limits of integrals to take infinite values; since all the numbers considered here are nonnegative no difficulties can arise.

As a companion result to Fatou's lemma we have the Lebesgue monotone convergence theorem. Let $\{f_n\}$ be a sequence of nonnegative measurable functions such that for each x, $\{f_n(x)\}$ is monotone increasing. So $\{f_n(x)\}$ has a limit $f(x)$ at each point (this limit may be infinite). Then the function f is a nonnegative measurable function and $\int f \, dx = \lim \int f_n \, dx$. This follows from Fatou's lemma since $\int f \, dx \leqq \liminf \int f_n \, dx \leqq \limsup \int f_n \, dx \leqq \int f \, dx$ as $f_n \leqq f$ for all n. So equality holds.

By partitioning the range of a nonnegative measurable function f into intervals and taking the simple function which, on the measurable set for which f has its values in one such interval, takes the minimum of these values we obtain a simple function approximating to f. Choosing a sequence of finer partitions gives a sequence of simple functions tending monotonically to f. Their integrals converge monotonically to that of f and provide an alternative and more manageable definition of $\int f \, dx$. Indeed this approach shows immediately that for any finite sequence $f_i, \ldots, f_n$ of nonnegative measurable functions we have

$$\int \sum_{i=1}^{n} f_i \, dx = \sum_{i=1}^{n} \int f_i \, dx$$

This extends by the Lebesgue monotone convergence theorem to infinite sums: for any sequence $\{f_n\}$ of nonnegative measurable functions,

$$\int \sum_{n=1}^{\infty} f_n \, dx = \sum_{n=1}^{\infty} \int f_n \, dx$$

This result is very useful in applications; note that it does not require the sum on the right-hand side to be finite.

We now wish to extend the definition of the integral to functions not necessarily nonnegative. If a function f is nonnegative on the set A and negative on the complementary set $B = \complement A$ we want $\int f \, dx$ to be $\int_A f \, dx - \int_B (-f) \, dx$. Equivalently, write $f^+(x) = \max(f(x), 0)$, $f^-(x) = \max(-f(x), 0)$. Then f^+ and f^- are measurable provided f is; f^+ and f^- are nonnegative; $f = f^+ - f^-$ and $|f| = f^+ + f^-$. We define, for any measurable function f, $\int f \, dx$ as $\int f^+ \, dx - \int f^- \, dx$ provided at

least one of these integrals is finite; if both are finite we say f is *Lebesgue integrable*, or *integrable* in short. So the measurable function f is integrable provided the nonnegative measurable function $|f|$ has a finite integral. Then the integrals of integrable functions inherit the properties of the simpler integral, namely,

$$\int (af + bg)\,dx = a\int f\,dx + b\int g\,dx$$

for any integrable functions f and g; the integral is monotone: $f \leqq g$ implies $\int f\,dx \leqq \int g\,dx$; the integral is additive on sets: $\int_A f\,dx + \int_B f\,dx = \int_{A\cup B} f\,dx$ for disjoint measurable sets A and B. From the definition we have easily that $|\int f\,dx| \leq \int |f|\,dx$ for any integrable function f. Also a mean value theorem applies: if f is measurable and if g is integrable and α, β are real with $\alpha \leqq f \leqq \beta$ a.e. then $\int f|g|\,dx = \gamma \int |g|\,dx$ for some γ, $\alpha \leqq \gamma \leqq \beta$. In particular, if E is measurable with $m(E) < \infty$ and $\alpha \leqq f \leqq \beta$ on E then $\alpha m(E) \leqq \int_E f\,dx \leqq \beta m(E)$.

We come now to the main theorem of this section: Lebesgue's dominated convergence theorem. It states that if $\{f_n\}$ is a sequence of measurable functions such that $|f_n| \leqq g$ where g is integrable and if $\lim f_n = f$ a.e. then f is integrable and

$$\lim \int f_n\,dx = \int f\,dx$$

This follows immediately on applying Fatou's lemma to the nonnegative sequences $\{g + f_n\}$ and $\{g - f_n\}$ in turn. As a corollary we have that $\int |f_n - f|\,dx \to 0$ (i.e., f_n tends to f "in the mean"). It is quite easy to extend this result to a family of measurable functions indexed by a parameter. So if $\{f_\alpha\}$ is such a family and $f_\alpha \to f$ at each point as $\alpha \to \alpha_0$, and $|f_\alpha| \leqq g$, an integrable function, then f is integrable and $\lim_{\alpha\to\alpha 0} \int f_\alpha\,dx = \int f\,dx$. This version is useful in some applications; in particular it allows us to consider an integral $\int_{-\infty}^{\infty} f\,dx$ as limit of the integrals $\int_a^b f\,dx$ as $a \to -\infty$, $b \to \infty$, $|f|$ being the "dominating integrable function."

Another useful version of the dominated convergence theorem is as follows. Let $\{f_n\}$ be a sequence of integrable functions such that

$$\sum_{n=1}^{\infty} \int |f_n|\,dx < \infty$$

Then the series $\sum f_n(x)$ converges a.e., its sum $f(x)$ is integrable and $\int f\,dx = \sum_{n=1}^{\infty} \int f_n\,dx$. This follows on using the dominating function $\sum_{n=1}^{\infty} |f_n|$.

In order to apply these limiting theorems to specific examples we need to be able to obtain the integrals of elementary functions. It is easily seen, from the mean value theorem referred to earlier, that if f is a continuous function on a finite interval $[a, b]$ (so that f is certainly measurable) then f is integrable and the function $F(x) = \int_a^x f(t)\,dt (a < x < b)$ is differentiable with $F' = f$. So for continuous functions, integrals can be obtained using indefinite integrals, in the usual elementary manner. In particular the usual devices of integration by parts or by substitution, which follow from the corresponding rules for derivatives, can be applied in the integration of continuous functions.

All the theory of this section has dealt with real-valued functions. It may be extended to complex-valued functions just as in the last section. Define the complex-valued measurable function f to be integrable provided its real and imaginary parts Re f and Im f are integrable. The elementary theory will still be true as will the modulus inequality $|\int f\,dx| \leqq \int |f|\,dx$ though the proof now needs a little more care. Lebesgue's monotone convergence theorem and Fatou's lemma have no direct application but Lebesgue's dominated convergence theorem and its counterpart for series apply unchanged to a complex-valued sequence $\{f_n\}$. Indeed, to prove this one need consider only the sequences $\{\mathrm{Re}\, f_n\}$ and $\{\mathrm{Im}\, f_n\}$ separately.

We now have several theorems allowing us to take limits "under the integral sign" or to interchange summation and integration. In the case of nonnegative functions this interchange is always possible; in the general case a finiteness condition needs to be imposed. We now give a few examples showing how the theorems may be applied.

EXAMPLE 1. Show that

$$\int_0^1 \frac{x \log x}{1-x}\,dx = -\sum_1^{\infty} \frac{1}{(n+1)^2}$$

The integrand on the left-hand side may be considered on (0, 1), as one point does not affect the integral, and there it equals $\sum_0^{\infty} x^{n+1} \log x$. Since $\sum_0^{\infty} x^{n+1} \log 1/x$ is a series of nonnegative functions we may integrate it term by term to get $\sum_1^{\infty} 1/(n+1)^2$ as required.

EXAMPLE 2. Show that

$$\lim \int_0^{\infty} \frac{dx}{(1 + x/n)^n x^{1/n}} = 1$$

We may suppose $x > 0$ in the integral and write $f_n(x)$ for the integrand. Then $\lim\ f_n(x) = e^{-x}$ and $\int_0^1 e^{-x}\,dx = 1$. So we need to interchange the integral and the limit. We may construct a dominating function $g(x)$ as follows. For $0 < x < 1$,

$$(1 + x/n)^n x^{1/n} > x^{1/2} \quad (n > 1)$$

For $1 \leqq x$,

$$(1+x/n)^n x^{1/n} \geqq (1+x/n)^n$$
$$> 1 + x + \frac{1}{2}(n(n-1))x^2$$
$$> \frac{1}{4}x^2 \quad (n > 1)$$

So let $g(x) = x^{-1/2}\,(0 < x < 1)$, $g(x) = 4/x^2$ for $1 \leqq x$. Then g is integrable and the dominated convergence theorem justifies the interchange.

EXAMPLE 3. Show that

$$\int_0^1 \sin x \log x \, dx = \sum_{n=1}^{\infty} \frac{(-1)^n}{(2n)(2n)!}$$

We have

$$\sin x \log x = \sum_{n=0}^{\infty} \frac{(-1)^n x^{2n+1}}{(2n+1)!} \log x = \sum_{n=0}^{\infty} f_n(x)$$

say. But

$$\int_0^1 |f_n(x)|\, dx = (-1)^{n+1} \int_0^1 f_n(x)\, dx$$
$$= \frac{1}{(2n+2)(2n+2)!}$$

Since the sum of these terms is finite the required interchange $\sum \int f_n\, dx = \int \sum f_n\, dx$ may be carried out and yields the desired result. It is often the case, as here, that the same calculation yields the finiteness condition and provides the answer.

EXAMPLE 4. Show that

$$\int_0^{\infty} \frac{\sin t}{e^t - x}\, dt = \sum_{n=1}^{\infty} \frac{x^{n-1}}{n^2+1}, \qquad -1 \leqq x \leqq 1$$

The integrand here is

$$\lim_{N\to\infty} \sum_{n=0}^{N} e^{-t} \sin t (x e^{-t})^n$$

which is in modulus $\leq 2t/(e^t - x)$ on summing this finite series. But $2t/(e^t - x)$ is integrable and nonnegative on $(0, \infty)$ so the dominated convergence theorem may be applied to the sequence of partial sums, and we get

$$\int_0^{\infty} \frac{\sin t}{e^t - x}\, dt = \sum_{n=0}^{\infty} x^n \int_0^{\infty} e^{-(n+1)t} \sin t \, dt$$
$$= \sum_{n=0}^{\infty} \frac{x^n}{1 + (n+1)^2}$$

by the usual elementary integration by parts.

Integrals are often encountered first by the student as Riemann integrals. We recall one form of the definition. Suppose f is bounded on the finite interval $[a, b]$. Write

$$S_D = \sum_{i=1}^{n} M_i(\xi_i - \xi_{i-1})$$

where $a = \xi_0 < \xi_1 < \cdots < \xi_n = b$ is a partition D of $[a, b]$ and $M_i = \sup f$ in $[\xi_{i-1}, \xi_i]$. Similarly

$$s_D = \sum_{i=1}^{n} m_i(\xi_i - \xi_{i-1})$$

where $m_i = \inf f$ in $[\xi_{i-1}, \xi_i]$. Then f is Riemann integrable on $[a, b]$ if given $\varepsilon > 0$ there exists D such that $S_D - s_D < \varepsilon$. Over all such partitions D we have inf $S_D = \sup s_D$ with the common value as the Riemann integral of f.

Now the sums S_D, s_D may be regarded as the integrals (Lebesgue or Riemann) of step functions. When a sequence of partitions is chosen, each being a refinement of the previous one, then a monotone sequence of step functions is obtained and the limit theorems already obtained show that: if a function is bounded on a bounded interval and is Riemann integrable then it is Lebesgue integrable and the values of the integrals are the same. Of course many more functions are Lebesgue integrable than are Riemann integrable. Indeed if we examine the definition of the Riemann integral carefully we find that a function f bounded on a finite interval is Riemann integral if, and only if, there is a continuous function g which equals f a.e. This shows how restricted the class of Riemann integrable functions is and also shows that even to consider in detail the "elementary" Riemann integral we need to introduce measurable sets. The relationship is not so clear for "improper" Riemann integrals. For example, $\int_0^{\infty} x^{-1} \sin x \, dx$ exists conventionally as a Riemann integral, with a finite value, but when we try to find it as a Lebesgue integral we obtain a conditionally convergent series with $\int_0^{\infty} |x^{-1} \sin x|\, dx = \infty$, so $x^{-1} \sin x$ is not Lebesgue integrable.

Finally we note that this possibility of approximation by simpler functions which we have seen for Riemann integrable functions holds also for Lebesgue integrable functions. Indeed let f be bounded and measurable on the finite interval $[a, b]$, so f is integrable, and let $\varepsilon > 0$. Then there exists a step function h such that $\int_a^b |f - h|\, dx < \varepsilon$ and a continuous function g vanishing outside a finite interval (not necessarily identical with $[a, b]$) such that $\int_a^b |f - g|\, dx < \varepsilon$. Since, as observed after the dominated convergence theorem, $\int f\, dx$ may be regarded as the limit of integrals over finite intervals, and since in the same way the integral of an unbounded integrable function may be regarded as the limit of the integrals of bounded "truncated" functions tending to f, this result applies quite generally.

IV. THE L^p SPACES AND INEQUALITIES FOR INTEGRALS

We consider the class of real-valued measurable functions such that $|f|^p$ is integrable where p is a fixed positive number. We also introduce the convention that functions equal almost everywhere are to be identified. With this convention the class described is the space $L^p(\mathbb{R})$, or $L^p(a,b)$ if we are restricting ourselves to functions with $|f|^p$ integrable on the interval (a,b). The elements of $L^p(a,b)$ are *classes* of functions such that in each class any two functions are equal a.e. so that their integrals over all subsets of (a,b) are identical. This distinction between functions and classes of functions need not give rise to difficulty. For $p=1$ we recover the integrable functions, with the convention stated. In addition we define $L^\infty(\mathbb{R})$ to be the essentially bounded functions of Section II with the same convention. We indicate later how these definitions extend to more general measures than Lebesgue measure.

It is easily seen that if $|f|^p$, $|g|^p$ are integrable so is $|af+bg|^p$ for a,b constant. So $L^p(\mathbb{R})$ is a vector space for $0<p<\infty$. Also from the inequality for ess sup $|f+g|$ of Section II we have that $L^\infty(\mathbb{R})$ is a vector space. The spaces $L^p(a,b)$ are related in a simple way for a,b finite: if $0<p<q\leqq\infty$, then $L^q(a,b)\subset L^p(a,b)$.

The spaces $L^p(\mathbb{R})$ (or $L^p(a,b)$) for $1\leqq p\leqq\infty$ have the special property of being "normed spaces." A space X is said to be a real *normed* space if X is a real vector space and we can define a nonnegative number $\|x\|$ for each $x\in X$ in such a way that $\|x\|=0$ if, and only if, $x=0$ (the zero of the vector space), and $\|ax+by\|\leqq |a|\|x\|+|b|\|y\|$ for any real numbers a,b. In the case of L^p $(1\leqq p<\infty)$ the norm of f may be defined by $\|f\|_p=(\int|f|^p\,dx)^{1/p}$; in the case of L^∞ the norm is defined by $\|f\|_\infty=\operatorname{ess\,sup}|f|$. In each case this norm is unaffected if the function changes value on a set of measure zero, so it is genuinely a number associated with an element of the vector space L^p. It may be easily seen that for $1\leqq p\leqq\infty$, $\|f\|_p\geqq 0$ and equals zero only if f is the zero of L^p (i.e., the class of functions vanishing a.e.). Also clearly $\|af\|_p=|a|\|f\|_p$. The subadditive property of the norm on L^p (i.e., $\|f+g\|_p\leqq\|f\|_p+\|g\|_p$) is Minkowski's inequality to which we refer again later). The same property for L^∞ follows from the inequality: ess sup$|f+g|\leqq$ ess sup$|f|+$ess sup$|g|$ referred to previously. The norm on $L^\infty(a,b)$ seems different from those on $L^p(a,b)$ for $1\leqq p\leqq\infty$ but a careful limiting argument shows that if $f\in L^\infty(a,b)$ $(a,b$ finite), so that $f\in L^p(a,b)$ for each p in $(1,\infty)$, then $\lim_{p\to\infty}\|f\|_p=\|f\|_\infty$.

We now turn to three inequalities which use the idea of convex functions. The real-valued function f is *convex* if for any two numbers x, y and any number t, $0\leqq t\leqq 1$, we have

$$f(tx+(1-t)y)\leqq tf(x)-(1-t)f(y)$$

Geometrically this states that the segment jointing the points $(x,f(x))$ and $(y,f(y))$ lies above the graph of f between x and y (or more precisely, never lies before it). For example, $f(x)=e^x$ and $f(x)=x^2$ are convex functions. It is easily shown that if a function f has a second derivative f'' which is positive then f is convex. If $-f$ is convex then f is said to be *concave*. Clearly $\log x(x>0)$ is concave.

We use the inequality

$$a^{1/p}b^{1/q}\leqq(a/p)+(b/q)$$

where $a,b,p,q,>0$ and $1/p+1/q=1$. On taking logs this is equivalent to

$$1/p\log a+1/q\log b\leqq\log(a/p+b/q)$$

which follows from the concavity of $\log x$. The inequality obtained is a generalized arithmetic-geometric mean inequality and substituting

$$a=\frac{|f|^p}{(\|f\|_p)^p},\qquad b=\frac{|g|^q}{(\|g\|_q)^q}$$

and integrating we get Hölder's inequality. This states that if

$$1<p<\infty,\qquad 1<q<\infty,\qquad 1/p+1/q=1,$$
$$f\in L^p(\mathbb{R})\qquad\text{and}\qquad g\in L^q(\mathbb{R})$$

then $fg\in L^1(\mathbb{R})$ and

$$\|fg\|_1=\int|fg|\,dx$$
$$\leqq\left(\int|f|^p\,dx\right)^{1/p}\left(\int|g|^q\,dx\right)^{1/q}$$

Here p,q are described as conjugate indices; the special case $p=q=2$ is called the Cauchy-Schwarz inequality. Of course instead of $\mathbb{R}$ we may consider integrals over any interval or any measurable set. Equality occurs in Hölder's inequality if, and only if, $af^p+bg^q=0$ a.e. for some constants a,b not both zero.

If p,q are conjugate and $p\to 1$ then $q\to\infty$ so we may regard $1,\infty$ as conjugate. A special case of Hölder's inequality holds here: if $f\in L^1(\mathbb{R})$ and $g\in L^\infty(\mathbb{R})$ then $fg\in L^1(\mathbb{R})$ and

$$\|fg\|_1\leqq\|f\|_1\|g\|_\infty$$

This is quite easily proved directly.

With the help of Hölder's inequality we can easily prove Minkowski's inequality: if $p\geqq 1$ and $f,g\in L^p(\mathbb{R})$ then

$$\|f+g\|_p\leqq\|f\|_p+\|g\|_p$$

Equality holds in the case $p>1$ if, and only if, $af=bg$ a.e. where a,b are nonnegative constants, not both zero.

The special case of Minkowski's inequality for $p = \infty$ has been referred to already.

Our third inequality is Jensen's inequality. This states that if f is a measurable function defined on the interval [0, 1] and with values in the finite range $[a, b]$ and if ϕ is a convex function on $[a, b]$ then

$$\phi\left(\int_0^1 f\,dx\right) \leq \int_0^1 (\phi \circ f)\,dx$$

The proof requires a careful examination of convex functions. In the case where ϕ is *strictly convex* (i.e., the segment referred to in the definition is strictly above the graph), we have that equality occurs in Jensen's inequality if, and only if, f is constant a.e., having the value $\int_0^1 f\,dx$. An important special case is obtained by assuming h to be a nonnegative measurable function such that $\log h$ is integrable over [0, 1] and taking f to be $\log h$ and $\phi(x)$ to be e^x: then we have

$$\exp\left(\int_0^1 \log h\,dx\right) \leqq \int_0^1 h\,dx$$

By induction proofs we can show that Hölder's and Minkowski's inequalities extend to n functions. For example, for the case $n = 3$, Hölder's inequality reads: if $1 < p < \infty$, $1 < q < \infty$, $1 < r < \infty$, $1/p + 1/q + 1/r = 1$, $f \in L^p$, $g \in L^q$, and $h \in L^r$ then $fgh \in L^1$ and $\|fgh\|_1 \leqq \|f\|_p \|g\|_q \|h\|_r$.

Hölder's inequality may be used to obtain inequalities for any integral of the product of functions. For example, to obtain an upper bound for $\int_0^{\pi/2} x^{-1/4} \cos x\,dx$ take $f(x) = x^{-1/4}$, $g(x) = \cos x$, $p = q = 2$ to get the bound $(\pi/2)^{3/4}$. As a second example,

$$\int_a^b f\,dx \leqq \left(\int |f|^p\,dx\right)^{1/p} (b-a)^{1/q}$$

for conjugate p and q on taking $g(x) \equiv 1$. This shows that $L^p(a, b) \subseteq L^1(a, b)$ for $p > 1$ and in the special case $a = 0, b = 1$ is just Jensen's inequality with $\phi(x) = x^p$.

As for any normed space the norm on L^p may be used to define a distance function with the "distance" between the functions f and g in L^p defined as $d(f, g) = \|f - g\|_p$. Then Minkowski's inequality states that the triangle inequality does indeed hold if $p \geq 1$, in which case L^p is a metric space. Convergence in terms of this metric or distance function is called convergence in the mean of order p ($p \geqq 1$). So the sequence $\{f_n\}$ converges to f in the mean of order p if each $f_n \in L^p$ and $\|f_n - f\|_p \to 0$ as $n \to \infty$. The special case of $p = 1$ was referred to in Section III, in connection with Lebesgue's dominated convergence theorem. The most important property of the L^p spaces is that of completeness: every sequence which is a Cauchy sequence, in terms of the distance function d, converges. In the usual L^p notation this may be restated as follows: if $1 \leqq p < \infty$ and $\|f_n - f_m\|_p \to 0$ as $n, m \to \infty$ then there exists a function $f \in L^p(\mathbb{R})$ such that $\|f_n - f\|_p \to 0$ as $n \to \infty$. We have in addition the existence of a subsequence $\{f_{n_i}\}$ such that pointwise convergence holds: $f_{n_i} \to f$ a.e. This result is proved by Fatou's lemma and Minkowski's inequality. The corresponding result in $L^\infty(\mathbb{R})$ is also true, with a more direct proof: if each $f_n \in L^\infty(\mathbb{R})$ and $\|f_n - f_m\|_\infty \to 0$ as $n, m \to \infty$ then there exists a function $f \in L^\infty$ such that $\lim f_n = f$ a.e. and $\|f - f_n\|_\infty \to 0$ as $n \to \infty$. These results need to be used with care: even if the functions f_n are specified functions, the limit f in L^p is defined only as an element of L^p and its value at any specific point cannot be obtained. The completeness of the space L^2 is of special importance in physical applications.

V. DIFFERENTIATION AND INTEGRATION

Differentiation and integration are closely connected; since we have extended the elementary notion of integral we must deal carefully with differentiation so that this relation continues to hold. The first point to note is that continuous functions are not very relevant here; indeed continuous functions which are nowhere differentiable are easily constructed. For example, on the interval (0, 1) let $f_n(x)$ denote the distance from x to the nearest number of the form $m/10^n$ where m and n are nonnegative integers. Then f_n has a "sawtooth" graph with 10^n "teeth" and $\max f_n = \frac{1}{2} \cdot 10^{-n}$. So f_n certainly continuous, and $\sum f_n(x)$ is uniformly convergent with sum $f(x)$, say. Then f is continuous but for each $x \in (0, 1)$ by considering its decimal expansion we can show that the graph of $y = f(x)$ has no tangent at this point.

We now consider an important class of functions which although not necessarily continuous are well behaved as regards differentiability, namely, the functions of bounded variation. We suppose f is defined and finite-valued on the finite interval $[a, b]$ and take a partition $a = x_0 < x_1 < \cdots < x_k = b.$ of $[a, b]$. Then we form the sums

$$p = \sum_{i=1}^{k} (f(x_i) - f(x_{i-1}))^+$$

$$n = \sum_{i=1}^{k} (f(x_i) - f(x_{i-1}))^-$$

$$t = p + n = \sum_{i=1}^{k} |f(x_i) - f(x_{i-1})|$$

where we are using the notation $a^+ = \max(a, 0)$ and $a^- = \max(-a, 0)$. So $t, p, n, \geqq 0$ and $f(b) - f(a) = p - n$.

Taking upper bounds over all partitions of $[a, b]$, and keeping to the same function f we let $P = \sup p$, $N = \sup n$, $T = \sup t$ and call these quantities the *positive, negative*, and *total* variations of f over $[a, b]$. If T is finite, f is said to be of bounded variation over $[a, b]$ or to belong to the class $\mathrm{BV}[a, b]$. Taking suprema over partitions the relations for t, p, n give $T = p + N$ and $f(b) - f(a) = P - N$. Also, each of these variations is additive over intervals, so if $a < c < b$ then $T[a, b] = T[a, c] + T[c, b]$ and similarly for P, N. This follows immediately from the corresponding identities for t, p, n, and leads to the important result that a function f is of bounded variation over $[a, b]$ if, and only if, it may be written as the difference of two finite-valued monotone increasing functions g and h, say. These are obtained by defining $g(x) = P[a, x] + f(a)$ and $h(x) = N[a, x]$. The converse follows from the fact that any finite-valued monotone function is of bounded variation, and so therefore is the difference of two such functions. Indeed, the class of functions $\mathrm{BV}[a, b]$ forms a vector space; linear combinations of functions of bounded variations are again functions of bounded variation.

Functions of bounded variation share the "good" properties of monotone functions. Since any finite-valued monotone increasing function is continuous except possibly on a countable set the same is true for functions $f \in \mathrm{BV}[a, b]$, so in particular these functions are measurable. An example of a monotone-increasing function with a countable number of discontinuities is provided by letting $\{r_i\}$ be an enumeration of the rational numbers in $[0, 1]$ and defining $f(x) = \sum_{r_n \leqq x} 2^{-n}$. Then f is discontinuous at each rational in the interval. For an example of a function f not of bounded variation on $[0, 1]$ define f arbitrarily at $x = 0$ and let $f(x) = \sin(1/x)$ otherwise; another example is given by $f(x) = x \sin(1/x)$, $x \neq 0$, $f(0) = 0$. This example shows directly that f may be continuous but not of bounded variation.

Lebesgue proved that if $f \in \mathrm{BV}[a, b]$, then f is differentiable a.e. and its derivative is finite a.e. This is a significantly more difficult result to prove than the earlier results of this section. The two examples of the previous paragraph show that the converse of this theorem is not true.

We consider now indefinite integrals and write for any integrable function f, $F(x) = \int_a^x f\,dt$, so that F is the indefinite integral of f over the interval $[a, b]$, say, on which f is integrable. Then Lebesgue's dominated convergence theorem, applied to the family of functions $\chi_{[a,x]} f$ where $x \to x_0$ shows that F is continuous. It also follows easily from the definitions that $F \in \mathrm{BV}[a, b]$, its total variation being bounded by $\int_a^b |f|\,dt$. So F' exists a.e. and it can easily be shown that $F' = f$ a.e. in $[a, b]$. We cannot expect F to be everywhere differentiable (e.g., let f be a step function, then F' does not exist at the points of discontinuity). Nor can we assume that whenever F' exists it equals f, for we may take a continuous function as f (so that F' exists at all points) and then change f at a single point x_0. Then F is unchanged but $F'(x_0)$ cannot equal $f(x_0)$.

Indefinite integrals, however, have the important property of being absolutely continuous. A function f is said to be *absolutely continuous* on $[a, b]$ if given $\varepsilon > 0$ there exists $\delta > 0$ such that

$$\sum_{i=1}^{n} |f(x_i) - f(y_i)| < \varepsilon$$

whenever $\sum_{i=1}^{n} |x_i - y_i| < \delta$ for any finite set of disjoint intervals (x_i, y_i) in $[a, b]$. Taking the special case $n = 1$ we see that absolutely continuous functions are continuous. Considering any partition of $[a, b]$ and introducing new partition points at a distance at most δ apart we can show that every absolutely continuous function is of bounded variation.

Now for any integrable function f we have that $\int_E |f|\,dt$ tends to zero as $m(E) \to 0$. This is obvious for a bounded function f, and follows for an unbounded function since the integral of f over any set is the limit of integrals of the functions f_n where $f_n = f$ provided $|f| \leqq n$, $f_n = \pm n$ otherwise. From this it follows (with $E = \cup_{i=1}^{n} (x_i, y_i)$) that if f is integrable over $[a, b]$ its indefinite integral is absolutely continuous there. It is a little more difficult to prove the converse: every absolutely continuous function is an indefinite integral, indeed it is the indefinite integral of its derivative, a function which we know to exist a.e. That the derivative of any function of bounded variation f is measurable can be seen from the fact that it may be obtained as the limit of a sequence of ratios $g_n(x) = n(f(x + 1/n) - f(x))$ which are themselves measurable. So, on finite intervals, a function is an indefinite integral if, and only if, it is absolutely continuous.

VI. PRODUCT SPACES AND PRODUCT MEASURES

For any two spaces X and Y the *Cartesian product* $X \times Y$ is the set of ordered pairs $\{(x, y): x \in X, y \in Y\}$. We will concern ourselves with the case $X = Y = \mathbb{R}$ so that $X \times Y$ is just the plane $\mathbb{R}^2$. However, the product notation is useful for subsets of $\mathbb{R}^2$. We call a set E in $\mathbb{R}^2$ a *rectangle* if $E = A \times B$, $A \subseteq \mathbb{R}$, $B \subseteq \mathbb{R}$. For the purpose of measure and integration the important sets are the *measurable rectangles*: sets of the form $A \times B$ where A and B are measurable sets. These include as special cases the "genuine" rectangles where A and B are intervals.

From the basic measurable rectangles we can form the σ-algebra $\mathcal{M} \times \mathcal{M}$ which is the least σ algebra containing the measurable rectangles. So within $\mathcal{M} \times \mathcal{M}$ we may

form complements and countable unions. It can be shown that if we take all finite unions of measurable rectangles and then take the smallest class of sets which contains these sets and is closed under the formation of countable increasing unions and countable decreasing intersections then we get just the σ-algebra $\mathcal{M} \times \mathcal{M}$. As we shall see this is crucial for the theory. We shall call the sets of $\mathcal{M} \times \mathcal{M}$ the measurable sets of the plane. An alternative definition extends $\mathcal{M} \times \mathcal{M}$ by also including all subsets of sets of measure zero, so as to get a complete measure space (see Section VII).

For any set E in $\mathbb{R}^2$ define the *x section* of E to be the set $E_x = \{y: (x, y) \in E\}$ and the *y section* of E to be the set $E^y = \{x: (x, y) \in E\}$. These are sets in $\mathbb{R}$, not $\mathbb{R}^2$. It can be shown quite easily that measurable sets in the plane have measurable sections. We wish now to define the product measure on the sets of $\mathcal{M} \times \mathcal{M}$. This definition should provide, for the measurable rectangle $A \times B$, the measure $m(A)m(B)$. We use the result that if E is a measurable set in the plane then $\phi(x) = m(E_x)$ and $\psi(y) = m(E^y)$ are measurable functions of x and y, respectively, and

$$\int \phi \, dx = \int \psi \, dy \tag{1}$$

The common value of these integrals is then taken as the measure of E. It is clear that for the measurable rectangle $E = A \times B$, $\phi(x) = \chi_A(x)m(B)$ so $\int \phi \, dx = m(A)m(B)$. Also, $\psi(y) = \chi_B(y)m(A)$ so $\int \psi \, dy = m(A)m(B)$ also. So identity (1) holds for measurable rectangles and the measure obtained is the desired one. It holds similarly for finite unions of measurable rectangles. Using the Lebesgue monotone convergence theorem we obtain (1) for the union of monotone increasing sequences of sets $\{E_n\}$, as the sequences $\{\phi_n\}$ and $\{\psi_n\}$ are similarly monotone. Similarly for a decreasing sequence of sets $\{F_n\}$, contained in a bounded rectangle, the result for the intersection follows from the Lebesgue dominated convergence theorem. Since the plane may be written as the union of a sequence of bounded rectangles

$$\mathbb{R}^2 = \bigcup_{n,m=-\infty}^{\infty} \{[n, n+1) \times [m, m+1)\}$$

the result follows for all the sets of $\mathcal{M} \times \mathcal{M}$ on adding together the results for the component pieces.

These definitions and the sketch proof just given work equally well with general measures μ, ν say (see Section VII), with a measurable rectangle $A \times B$ having the measure $\mu(A)\nu(B)$. The only condition on the measures is that each coordinate space can be written as a countable union of sets of finite measure for μ or ν, as the case may be, so that the product space may be decomposed into a sequence of sets of finite measure as for $\mathbb{R}^2$ in the preceding paragraph.

If f is a function of x and y we may similarly define the x section of f as the function $f_x(y) = f(x, y)$ for each fixed x, and the y section of f as $f^y(x) = f(x, y)$ for each fixed y. Since measurable sets have measurable sections it follows easily that if f is measurable with respect to $\mathcal{M} \times \mathcal{M}$ then f_x and f^y are measurable with respect to m.

For any nonnegative measurable function f we have the result that the integral of f may be expressed in terms of repeated integrals in either order and both of these integrals are defined. More precisely, let f be nonnegative and measurable with respect to $\mathcal{M} \times \mathcal{M}$; write $\phi(x) = \int f_x \, dy$, $\psi(y) = \int f^y \, dx$. Then ϕ and ψ are measurable and

$$\int \phi \, dx = \int f \, dx \, dy = \int \psi \, dy \tag{2}$$

where the middle integral is the Lebesgue integral of f with respect to the product measure defined earlier in this section. Identity (2) has already been proved for the case of a function of the form χ_E by identity (1), and so for any nonnegative measurable simple function. Taking a sequence of such functions f_n increasing monotonically to f, the sections $(f_n)_x \uparrow f_x$ and $(f_n)^y \uparrow f^y$ and the Lebesgue monotone convergence theorem gives identity (2).

We need now to extend (2) to functions not necessarily nonnegative and expect now to find some finiteness condition coming in. Now, identity (2) applied to $|f|$ states that $|f|$ is integrable if, and only if, each of the iterated integrals of $|f|$ (or, more precisely, of the sections of $|f|$) is finite, and then all three integrals are equal. In this case we write f as the difference $f = f^+ - f^-$ of nonnegative measurable functions and we apply identity (2) to f^+, f^-, and their sections. On subtracting the results we get

$$\int dx \int f_x \, dy = \int f \, dx \, dy = \int dy \int f^y \, dx \tag{3}$$

So from the remarks concerning $|f|$ we deduce Fubini's theorem which states that if f is a measurable function of x and y and *either* of the iterated integrals of $|f|$ is finite then so is the other, $|f|$ is integrable and identity (3) holds for f.

An important application of this theory is in connection with the Laplace and Fourier transforms of an integrable function. We will describe the application in the Fourier transform case; the other is similar. The following result allows us to define the *convolution* of two functions. Let f and g be integrable functions; then $f(y-x)g(x)$ is an integrable function of x for almost all y and if $h(y)$ is defined for these y by $h(y) = \int f(y-x)g(x) \, dx$ then h is integrable and $\|h\|_1 \leq \|f\|_1 \|g\|_1$. To prove this we need to show that $f(y-x)g(x)$ is measurable with respect to $\mathcal{M} \times \mathcal{M}$. This is not very difficult and assuming

it we may write $H(y)=\int |f(y-x)g(x)|\,dx$. Then Fubini's theorem gives

$$\int H(y)\,dy = \int dy \int |f(y-x)g(x)|\,dx$$
$$= \int |g(x)|\,dx \int |f(y-x)|\,dy$$

Now, as noted in Section II, Lebesgue measure is invariant under translation, so we may make a translation of variables without changing the integral. Thus

$$\int |f(y-x)|\,dy = \int |f(y)|\,dy$$

and

$$\|H\|_1 \leqq \|g\|_1 \|f\|_1$$

So H and hence h is finite-valued a.e., h is integrable, and $\|h\|_1 \leqq \|f\|_1\|g\|_1$. Extending $(2\pi)^{-1/2}h$ by giving it any fixed value on the exceptional set we obtain the convolution

$$(f*g)(y) = (2\pi)^{-1/2}\int f(y-x)g(x)\,dx$$

of the integrable functions f and g. We can easily show that $f*g=g*f$ a.e. and $(f*g)*h=f*(g*h)$ a.e. for any integrable functions f, g, h. For example, to prove the first identity, let y be such that $g(y-x)f(x)$ is integrable with respect to x, so y does not lie in the exceptional set of measure zero. For such y let $t=y-x$ so that $\int g(y-x)f(x)\,dx$ becomes

$$\int g(t)f(y-t)\,dt = (2\pi)^{1/2}(f*g)(y)$$

as we may translate the variables.

For any integrable function f we may define the *Fourier transform* as the function $\hat{f}$ given by

$$\hat{f}(s) = (2\pi)^{-1/2}\int e^{-ist}f(t)\,dt$$

Then $\hat{f}$ is a continuous function, by the Lebesgue dominated convergence theorem with $|f|$ as dominating function. Also, $|\hat{f}| \leqq (2\pi)^{-1/2}\int |f|\,dt$. The convolution and the Fourier transform are related by the identity

$$\widehat{(f*g)} = \hat{f}\hat{g}$$

true for integrable functions. To see this note that

$$\widehat{(f*g)}(s) = (2\pi)^{-1}\int dt \int e^{-ist}f(t-x)g(x)\,dx$$

Then the modulus of the integrand here, $|f(t-x)g(x)|$, is integrable by the argument given for the convolution. So by Fubini's theorem we may interchange the order of integration to get

$$\widehat{(f*g)}(s) = (2\pi)^{-1}\int g(x)\left(\int e^{-ist}f(t-x)\,dt\right)dx$$
$$= (2\pi)^{-1}\int g(x)\left(\int e^{-is(t+x)}f(t)\,dt\right)dx$$
$$= (2\pi)^{-1}\int e^{-isx}g(x)\,dx \int e^{-ist}f(t)\,dt$$
$$= \hat{f}(s)\hat{g}(s)$$

as required.

The Fourier transform has been defined here for functions of $L^1(\mathbb{R})$. We may extend the definition by an approximation argument to the functions of $L^2(\mathbb{R})$ and show that $\|\hat{f}\|_2 = \|f\|_2$ (Parseval's theorem). Note that the Fourier transform though continuous and bounded need not be integrable. But if it is (i.e., when both f and $\hat{f}$ are integrable functions), we have the Fourier inversion theorem:

$$f(x) = (2\pi)^{-1/2}\int \hat{f}(t)e^{ixt}\,dt \text{ a.e.}$$

The proof is not very difficult and depends on Fubini's theorem.

VII. GENERAL MEASURES

Measures arise in various ways and in various spaces and the theory outlined above can be applied in the main provided we have an appropriate class of sets defined to be measurable. So we shall suppose we have a set or space X and on it a σ-algebra $\mathcal{S}$ of sets. On the sets of $\mathcal{S}$ our measure μ is defined and so μ is presumed to be a nonnegative set function which takes the value 0 on the empty set and which is countably additive (i.e., if $\{A_n\}$ is a sequence of disjoint sets of $\mathcal{S}$ we have $\mu(\cup_{n=1}^{\infty}A_n)=\sum_{n=1}^{\infty}\mu(A_n)$). Then the triple $\{X, \mathcal{S}, \mu\}$ is called a *measure space*. This measure space is said to be σ *finite* if we may write X as $X=\cup_{n=1}^{\infty}X_n$, $X_n\in\mathcal{S}$, and $\mu(X_n)<\infty$. It is said to be a *complete* measure space if for any set E of $\mathcal{S}$ with $\mu(E)=0$ every subset of E also belongs to $\mathcal{S}$ (and then of course has measure zero also).

EXAMPLE 1. $X=\mathbb{R}$, $\mathcal{S}=\mathcal{M}$, $\mu=m$, gives Lebesgue measure on the real line. This is σ finite and complete.

EXAMPLE 2. $X=\mathbb{R}$, $\mathcal{S}=$ Borel sets, $\mu=m$, gives Borel measure. This is also σ finite but is not complete.

EXAMPLE 3. $X=\mathbb{R}^2$, $\mathcal{S}=\mathcal{M}\times\mathcal{M}$, $\mu=m\times m$, gives planar measure. This is σ finite but not complete.

EXAMPLE 4. $X=\mathbb{N}$ the set of natural numbers; $\mathcal{S}$ is the class of all subsets of $\mathbb{N}$. Let $\sum a_n<\infty$ with $a_n\geqq 0$ and define $\mu(E)=\sum a_k$ where the summation is over all integers k in E. This measure is obviously complete and is finite for the whole space (and so trivially σ finite).

Results such as $m(\lim E_i) = \lim m(E_i)$ hold as before for monotone sequences of sets. A real function f is measurable if $f^{-1}(\alpha, \infty)$ belongs to $\mathcal{S}$, the family of measurable sets. Integration theory proceeds as before, the nonnegative simple function $\phi = \sum_{i=1}^{n} a_i \chi_{A_i}$ having the integral $\int \phi \, d\mu = \sum_{i=1}^{n} a_i \mu(A_i)$ as in Section III. Then the integral $\int f \, d\mu$ of a nonnegative measurable function is the least upper bound of such integrals for all such functions $\phi \leqq f$. The integration of functions not necessarily nonnegative and of complex-valued functions is defined as before and the same theorems hold: Fatou's lemma, the Lebesgue monotone convergence theorem, the Lebesgue dominated convergence theorem, and their variants for series. Of course the Riemann integral will not exist in general so comparisons cannot be made. Also the result noted in Section V holds in general: $\int_E |f| \, d\mu$ tends to zero as $\mu(E) \to 0$.

The constructions and inequalities obtained in Section IV will hold good for the general L^p spaces $L^p(X, \mathcal{S}, \mu)$. So will the results of Section VI, as already noted, for a pair of measures μ and ν provided we assume these to be σ finite.

For some purposes it is convenient to use a complete measure and it is an important fact that a measure may be extended in a unique way so as to be complete. We replace the σ-algebra $\mathcal{S}$ by the larger class $\mathcal{S}'$ of sets of the form $E \cup N$ where $E \in \mathcal{S}$, $E \cap N = \varnothing$, and $N \subseteq M$ where $M \in \mathcal{S}$ with $\mu(M) = 0$. Then we check that $\mathcal{S}'$ so defined is a σ algebra and define μ on $\mathcal{S}'$ by $\mu(E \cup N) = \mu(E)$. This clearly extends μ and is easily seen to give an unambiguous definition. With this construction $\{X, \mathcal{S}', \mu\}$ is a complete measure space.

If $\mu(X) = 1$ the triple $\{X, \mathcal{S}, \mu\}$ is called a probability measure space. Then a particular set of terms is used, for historical reasons, and the emphasis is on a particular type of result. In particular for "almost everywhere" one writes "almost surely," abbreviated a.s.; measurable functions are called random variables; their Fourier transforms $\phi yx = \int e^{ixt} f(t) \, d\mu(t)$ are called characteristic functions. Note that Jensen's inequality will apply directly with [0, 1] replaced by X; also that the product of probability spaces is again a probability space.

We shall consider now some further types of convergence which may be applied to sequences of functions. Let $\{f_n\}$ be a sequence of measurable functions and f a measurable function (all on the measure space $\{X, \mathcal{S}, \mu\}$). Then f_n tends to f *in measure* if for every positive ε,

$$\lim \mu\{x: |f_n(x) - f(x)| > \varepsilon\} = 0$$

If μ is a probability measure this is termed convergence *in probability*. It is easily seen that a sequence $\{f_n\}$ can tend at most to one limit function f (up to sets of measure zero). Indeed the sequence $\{f_n\}$ defines the function f a.e., in the sense that if $\{f_n\}$ is a Cauchy sequence with respect to convergence in measure so that for any $\varepsilon > 0$,

$$\lim_{n,m \to \infty} \mu\{x: |f_n(x) - f_m(x)| > \varepsilon\} = 0$$

then there exists a measurable function f so that $f_n \to f$ in measure and also for some subsequence $\{n_i\}$, $f_{n_i} \to f$ a.e. This is proved by a careful choice of ε's as elements of a convergent series.

An analog of Fatou's lemma holds for convergence in measure: Let $\{f_n\}$ be a sequence of nonnegative measurable functions and let f be a measurable function such that $f_n \to f$ in measure; then

$$\int f \, d\mu \leqq \liminf \int f_n \, d\mu$$

The proof depends on applying the original Fatou's lemma of Section III to subsequences $\{f_{n_i}\}$ tending to f a.e. There is a corresponding analog of the Lebesgue dominated convergence theorem. Let $\{f_n\}$ be a sequence of measurable functions such that $|f_n| \leqq g$, an integrable function, and let $f_n \to f$ in measure, where f is measurable. Then f is integrable, $\lim \int f_n \, d\mu = \int f \, d\mu$, and $\lim \int |f_n - f| \, d\mu = 0$ (i.e., $f_n \to f$ in the mean). This result is easily proved. Since there exists a subsequence $\{f_{n_i}\}$ with limit f a.e., we have $|f| \leqq g$ so $f \in L^1(\mu)$. Also, for each n, $g + f_n \geqq 0$ and $g + f_n \to g + f$ in measure, so by the version of Fatou's lemma just given

$$\int g \, d\mu + \int f \, d\mu \leqq \liminf \int (g + f_n) \, d\mu$$

and

$$\int f \, d\mu \leqq \liminf \int f_n \, d\mu$$

Similarly, $g - f_n \geqq 0$, whence

$$\int g \, d\mu - \int f \, d\mu \leqq \liminf \int (g - f_n) \, d\mu$$

and so

$$\int f \, d\mu \geqq \limsup \int f_n \, d\mu$$

$$\geqq \liminf \int f_n \, d\mu \geqq \int f \, d\mu$$

Therefore equality holds and the first result follows. Also it is easily seen that $|f_n - f| \to 0$ in measure. But $|f_n - f| \leqq 2g$ and so the second result follows from the first.

In $L^p(\mu)$, convergence in the sense of the norm is termed convergence in the mean of order p (i.e., $f_n \to f$ in the mean of order $p (p \geqq 1)$ if $\lim \| f_n - f \|_p = 0$). (It may be defined for any $p > 0$, but for $0 < p < 1$ the norm

notation is not appropriate.) This convergence and convergence in measure are easily shown to be related: if $f_n - f$ in the mean of order p then $f_n \to f$ in measure. For suppose not. Then there exist $\varepsilon > 0$, $\delta > 0$ such that $\mu\{x: |f_n(x) - f(x)| > \varepsilon\} > \delta$ for infinitely many n. But then $\int |f_n - f|^p \, d\mu \geqq \varepsilon^p \delta$ for infinitely many n, contradicting convergence in the mean of order p.

Another important kind of convergence is almost uniform convergence. Let $\{f_n\}$ be a sequence of measurable functions and let f be a measurable function. Then we say that $f_n \to f$ almost uniformly (abbreviated a.u.) if for any $\varepsilon > 0$ there exists a set E with $\mu(E) < \varepsilon$ and such that on the complement of E, $f_n \to f$ uniformly (i.e., given $\varepsilon' > 0$ there exists N such that for $n > N$, $|f_n(x) - f(x)| < \varepsilon'$ for all $x \in \complement E$ (N depending on ε' but not on x)). Obviously uniform convergence (on the whole space) implies almost uniform convergence (just take $E = \varnothing$ above). In the opposite direction, the sequence $\{x^n\}$ converges to zero almost uniformly on [0, 1] but not uniformly.

If $f_n \to f$ a.u., however, then $f_n \to f$ in measure. For if not then there exist positive ε and δ such that

$$\mu\{x: |f_n(x) - f(x)| > \varepsilon\} > \delta$$

for infinitely many n. But since there exists E with $\mu(E) < \delta$ and with $f_n \to f$ uniformly on $\complement E$ we get a contradiction. We can also show easily that if $f_n \to f$ a.u. then $f_n \to f$ a.e. For if m is any positive integer we can find a set E_m with $\mu(E_m) < 1/m$ and on $\complement E_m$, $f_n \to f$ uniformly. But if $x \in \cup_{m=1}^{\infty} \complement E_m$ we have $x \in \complement E_N$, say, so $\lim f_n(x) = f(x)$. Since $\complement \cup_{m=1}^{\infty} \complement E_m = \cap_{m=1}^{\infty} E_m$, a set of measure zero, the result follows.

An important result in the opposite direction is given by Egorov's theorem: on a space of finite measure convergence almost everywhere implies almost uniform convergence. We can prove this by writing for each pair of positive integers k, n,

$$E_{k,n} = \{x: |f_m(x) - f(x)| < 1/k, m \geqq n\}$$

Then as $f_m \to f$ a.e., we have

$$\mu\left(\bigcap_{n=1}^{\infty} \complement E_{k,n}\right) = 0$$

and since all measures are finite,

$$\mu(\complement E_{k,n}) \to 0 \qquad \text{as} \quad n \to \infty$$

for each fixed k. So if $\varepsilon > 0$, for an appropriate n_k we have $\mu(\complement E_{k,n_k}) < \varepsilon/2^k$. Then if $E = \cap_{k=1}^{\infty} E_{k,n_k}$ we have $\mu(\complement E) < \varepsilon$, and on E, for each k, $|f_m - f| < 1/k$ for $m \geqq n_k$. So $f_n \to f$ a.u.

With a slight variation of this proof one can show that, for dominated sequences, convergence almost everywhere implies almost uniform convergence (i.e., if $f_n \to f$ a.e. where $|f_n| \leqq g$, an integrable function, then $f_n \to f$ a.u.).

Examples can be constructed showing that certain types of convergence do not in general imply certain other ones. For instance, let χ_n^i be the characteristic function of the interval $[(i-1)/n, i/n]$, $i = 1, \ldots, n$, with [0, 1] as the whole space and using Lebesgue measure and define $\{f_n\}$ to be the sequence $\chi_1^1, \chi_2^1, \chi_2^2, \chi_3^1, \chi_3^2, \chi_3^3, \ldots$. Then $f_n = \chi_k^i$ where $\frac{1}{2}k(k-1) < n \leq \frac{1}{2}k(k+1)$, whence $\int f_n \, dx = 1/k \to 0$ as n (and thus k) $\to \infty$, so that $f_n \to 0$ in the mean. But $f_n \to 0$ a.e.; indeed for no x in [0, 1] does $f_n(x) \to 0$. Nor does $f_n \to 0$ a.u. The space here, [0, 1], has nevertheless finite measure and the sequence is dominated by the integrable function $\chi_{[0,1]}$.

VIII. THE RADON–NIKODÝM THEOREM AND SIGNED MEASURES

New measures arise from given measures in natural ways. For example, let f be a nonnegative function measurable with respect to the measure μ on the σ-algebra $\mathcal{S}$, and define ν on $\mathcal{S}$ by

$$\nu(E) = \int_E f \, d\mu$$

Then ν is a nonnegative set function, vanishing on the empty set. That ν is countably additive follows from the corollary to the Lebesgue monotone convergence theorem. For if $\{E_n\}$ is a sequence of disjoint sets in $\mathcal{S}$ then

$$\begin{aligned} \nu\left(\bigcup_{n=1}^{\infty} E_n\right) &= \int \sum_{n=1}^{\infty} \chi_{E_n} f \, d\mu \\ &= \sum_{n=1}^{\infty} \int \chi_{E_n} f \, d\mu \\ &= \sum_{n=1}^{\infty} \nu(E_n) \end{aligned}$$

So ν is a measure. The two measures μ, ν are related by the following continuity condition. If μ_1, μ_2 are any two measures on the σ-algebra $\mathcal{S}$ and $\mu_2(E) = 0$ whenever $\mu_1(E) = 0$ we say that μ_2 is *absolutely continuous* with respect to μ_1, and write $\mu_2 \ll \mu_1$. Obviously for the measure ν constructed above, $\nu \ll \mu$.

If we remove the restriction that f be nonnegative we obtain measures with negative sign. So we have the following definition: a set function ν on the σ-algebra $\mathcal{S}$ is a *signed measure* if its values are real of infinite, ν takes at most one of the values ∞ and $-\infty$,

$$\nu(\varnothing) = 0 \qquad \text{and} \qquad \nu\left(\bigcup_{i=1}^{\infty} E_i\right) = \sum_{i=1}^{\infty} \nu(E_i)$$

whenever $\{E_i\}$ is a disjoint sequence of sets of $\mathcal{S}$. Clearly every measure is a signed measure.

EXAMPLE. Let f be an integrable function on $\{X, \mathcal{S}, \mu\}$. Then $\nu(E) = \int_E f\, d\mu$ defines a signed measure. Clearly only the countable additivity needs checking, so for $E \in \mathcal{S}$ write $\nu^+(E) = \int_E f^+ d\mu$, $\nu^-(E) = \int_E f^- d\mu$. Then ν^+, ν^- are (finite) measure and

$$\begin{aligned}\nu\left(\bigcup_{i=1}^{\infty} E_i\right) &= \nu^+\left(\bigcup_{i=1}^{\infty} E_i\right) - \nu^-\left(\bigcup_{i=1}^{\infty} E_i\right) \\ &= \sum_{i=1}^{\infty} \int_{E_i} f^+\, d\mu - \sum_{i=1}^{\infty} \int_{E_i} f^-\, d\mu \\ &= \sum_{i=1}^{\infty} \int_{E_i} f\, d\mu = \sum_{i=1}^{\infty} \nu(E_i)\end{aligned}$$

In this example the signed measure ν has a decomposition as the difference of measures and there is a corresponding decompositions of the space into the sets $\{x\colon f(x) \geqq 0\}$ and $\{x\colon f(x) < 0\}$ on one of which ν acts like a measure and on the other $-\nu$ acts like a measure. More generally for any signed measure ν there is a decomposition $\nu = \nu_1 - \nu_2$ as the difference of measures for which ν_1 and ν_2 are *mutually singular* (written $\nu_1 \perp \nu_2$) (i.e., for some set $A \in \mathcal{S}$ we have $\nu_2(A) = \nu_1(\complement A) = 0$). Then ν_1 and ν_2 are said to be the *Jordan decomposition* of ν and are uniquely defined by ν. There is a corresponding decomposition of the space X as the union of disjoint sets A, B of $\mathcal{S}$ such that ν is nonnegative on the measurable subsets of A, $-\nu$ is nonnegative on the measurable subsets of B. This, the *Hahn decomposition*, is unique up to sets for which all subsets in $\mathcal{S}$ have zero ν measure. The example given above where ν is defined using an integrable function displays both the Jordan and Hahn decompositions. In the general case the Hahn decomposition is established first using an exhaustion argument to find the "largest" set on which ν acts like a nonnegative measure and the Jordan decomposition follows.

By analogy with the functions of bounded variation discussed in Section V the measure ν^+ is called the positive variation of ν, ν^- the negative variation, and $|\nu| = \nu^+ + \nu^-$ the total variation of the signed measure ν. Obviously in the example above, $|\nu|$ is given by $|\nu|(E) = \int_E |f|\, d\mu$.

The converse to the situation presented in this example is provided by the Radon-Nikodým theorem. It states that if $\{X, \mathcal{S}\, \mu\}$ is a σ-finite measure space and ν is a σ-finite measure such that $\nu \ll \mu$, then there exists a nonnegative measurable function f on X such that, for each $E \in \mathcal{S}$, $\nu(E) = \int_E f\, d\mu$. This f is unique in the convention given before; any other function with the same property agrees with f almost everywhere. The proof proceeds by reduction to the case for finite measures: write X as the union of a sequence of disjoint sets on which both μ and ν are finite, find the corresponding function f for each set, and put these functions together to get the corresponding "density function" on the whole of X. In the case of a finite measure, f is obtained as the supremum of functions g which are nonnegative, measurable, and satisfy $\int_E g\, d\mu \leqq \nu(E)$ for each E in $\mathcal{S}$. However, taking the supremum of such functions involves an uncountable family of functions so a nonmeasurable function could apparently appear. The proof reduces the operation to a countable one. The resulting function f can be regarded as the derivative of the measure ν with respect to μ and we write $f = d\nu/d\mu$. The theorem can be extended to signed measures. If μ, ν are signed measures we say ν is absolutely continuous with respect to μ if $\nu(E) = 0$ whenever $|\mu|(E) = 0$. Then ν can be written in terms of a derivative with respect to the measure μ by writing $\nu = \nu^+ + nu^-$, finding the derivatives of ν^+ and ν^- separately, and taking $d\nu/d\mu$ as their difference.

The analogy between ordinary derivatives and the Radon–Nikodým derivative $d\nu/d\mu$ goes further. The chain rule applies: if λ, μ, ν are σ finite measures such that $\nu \ll \mu$ and $\mu \ll \lambda$ then $\nu \ll \lambda$ and

$$d\nu/d\lambda = (d\nu/d\mu)(d\mu/d\lambda)$$

where equality is in the sense that this equation must hold almost everywhere (in the sense of λ). If the measure ν is defined by the integral of a function f with respect to μ this theorem takes the following form: if $\mu \ll \lambda$ where μ and λ are σ finite then there exists a measurable function g such that if $f \in L^1(X, \mu)$ then $fg \in L^1(X, \lambda)$ and for each E

$$\nu(E) = \int_E f\, d\mu = \int_E fg\, d\lambda$$

If we take any nonnegative integrable function f on the real line we may take multiple of f so as to get a function $p(x)$ such that $\nu(E) = \int_E p\, dx$ defines a probability measure with $p = d\nu/dm$ as the probability density. The Radon–Nikodým derivative of one probability measure with respect to another is important in connection with conditional probabilities and conditional expectations.

The Radon–Nikodým theorem shows that for a finite measure ν the relation $\nu \ll \mu$ is a genuine continuity property. For since $\nu(E) = \int_E f\, d\mu$ where f is an integrable function we have the result noted in Section VII that $\nu(E) \to 0$ as $\mu(E) \to 0$; more precisely, given $\varepsilon > 0$ there exists $\delta > 0$ such that whenever $\mu(E) < \delta$ we have $\nu(E) < \varepsilon$.

Example 4 in Section VII exhibits the opposite property: the measure μ defined there is concentrated on a set of zero measure (the integer points) and so cannot be given as the

integral of a density or derivative. If $\sum a_n = 1$ then we have a "discrete probability," a frequency occurrence in elementary probability. A discrete probability of the type described and Lebesgue measure are mutually singular.

We can show that given any two σ-finite measures μ and ν, we may decompose one of these, say ν, as $\nu = \nu_0 + \nu_1$ where $\nu_0 \perp \mu$ and $\nu_1 \ll \mu$. This is the Lebesgue decomposition of ν with respect to μ. It is easily proved using the Radon–Nikodým derivative f of $\lambda = \mu + \nu$ with respect to μ, so that $\mu(E) = \int_E f\, d\lambda$. If $A = \{x\colon f(x) > 0\}$ and $B = \{x\colon f(x) = 0\}$ we may write

$$\nu_0(E) = \nu(E \cap B), \qquad \nu_1(E) = \nu(E \cap A)$$

and obtain the desired decomposition. So the two constructions of new measures, one using densities and the other measures concentrated on sets of measure zero, together provide the most general σ-finite measures. The σ finiteness is essential to these results, for examples can be constructed where absolute continuity holds but no derivative exists; such examples depend on non-σ-finite measures.

IX. EXTENSIONS OF THE DEFINITION OF MEASURE

In the last section we extended the idea of measure to include measures taking negative values. These arose in a natural way in connection with the integrals of functions taking positive and negative values. If as in Section III we allow functions to take complex values we obtain complex-valued measures. But just as complex-valued measurable functions may be dealt with by considering their real and imaginary parts separately so the properties of a complex-valued measure $\mu = \mu_1 + i\mu_2$, where μ_1 and μ_2 are real measures, and the corresponding integration theory for μ may be deduced from that for μ_1 and μ_2.

More interesting considerations arise when measures are allowed to take values in a vector space. We shall consider measures taking values in the n-dimensional real vector space $\mathbb{R}^n$. (More general spaces could be considered but the essential results are already exhibited in $\mathbb{R}^n$.) An important definition is that of an atomic measure. A set A in a measure space $\{X, \mathcal{S}, \mu\}$ is an atom for μ if $\mu(A) \neq 0$ and every measurable subset of A has measure zero or $\mu(A)$. The *range* of the measure μ is the set of numbers $\{mu(E)\colon E \in \mathcal{S}\}$. Then the theorem of Liapounoff states that the range of a finite nonatomic measure with values in $\mathbb{R}^n$ is closed and convex. More precisely: let $\mu_1, \ldots, \mu_n$ be finite nonnegative nonatomic measures on X. Then the set of points in $\mathbb{R}^n$ of the form $(\mu_1(A), \mu_2(A), \ldots, \mu_n(A))$, with A ranging over the measurable subsets of X, is closed and convex. There are various proofs. In one, we consider the set $W = \{g\colon 0 \leqq g \leqq 1\}$ of L^∞ and the mapping T from W to $\mathbb{R}^n$ given by $Tg = (\int g\, d\mu_1, \ldots, \int g\, d\mu_n)$. The set W is convex and closed in the appropriate sense. Let

$$\underline{\lambda} = (\lambda_1, \ldots, \lambda_n) \in T(W)$$

Then if we show that $W_0 = T^{-1}\underline{\lambda}$ contains a characteristic function the result is proved since if E and F are measurable sets then for $0 \leq t \leq 1$

$$(t\mu_1(E) + (1-t)\mu_1(F), \ldots,$$
$$t\mu_n(E) + (1-t)\mu_n(F))$$

lies in $T(W)$. Now for any convex set a point is an extreme point if it cannot be written as the convex combination of other points of the set. There is a general result that in $\mathbb{R}^n$ every closed bounded convex set has extreme points and may be considered as the set of convex combinations of these extreme points. Now W_0 is convex, closed, and bounded; the proof ends with the demonstration that the extreme points of W_0 consist of characteristic functions, using the nonatomic property of the measures μ_i.

The result obtained is nontrivial even for ordinary measures ($n = 1$). It is obviously dependent on the nonatomic property: one could choose X as a single point with measure 1, to get a trivial counterexample. The result outlined above has applications in control theory where one wishes to know that a convex combination of states of the system is again a state of the system. It is also of importance in the investigation of higher dimensional vector spaces.

X. EXTENSIONS OF MEASURES AND LEBESGUE–STIELTJES INTEGRALS

In Section II we saw how starting with a "measure" (the length) defined on intervals we can, using an outer measure, extend this measure to a σ algebra containing the intervals. It is convenient to regard this as a two-stage process. First we extend the definition of length to give a measure on the set of finite unions of intervals, which form a ring, closed under finite unions and set differences. We then extend this measure to a σ ring closed under countable unions and under set differences. If this σ ring contains the whole space it is a σ algebra. This passage from a ring to a σ ring or σ algebra can be done in general and the result is essentially unique. An important example of this construction is provided by the construction of Lebesgue–Stieltjes measures. Take a monotone increasing finite-valued function g and for an interval $I = [a, b)$ define a measure on I by $\mu_g(I) = g(b) - g(a)$. Now, measures have continuity properties since if $I_1 \subseteq I_2 \subseteq \cdots$ we have $\mu(\cup I_i) = \lim \mu(I_i)$. So if $I_i = (a_i, b_i)$ we see that

g must be left-continuous (i.e., $g(x) \to g(x_0)$ whenever $x \to x_0, x < x_0$). Then μ_g is indeed a measure on the ring of finite unions of such intervals and extends to a measure on the Borel sets of the real line. We could, at least for the case g bounded, have chosen intervals of the form $(a, b]$ and g right-continuous. This form of the definition is more common in probability theory. The measure μ_g given by the construction outlined above is the Lebesgue–Stieltjes measure defined by g.

It is clear that points of discontinuity of g correspond to atoms of the measure μ_g, as defined in Section IX. Absolute continuity was defined for functions in Section V and for measures in Section VIII. These definitions are drawn together by the following result. Let g be a monotone increasing absolutely continuous function. Then g defines a measure on a σ algebra. If we assume that this measure has been completed, as defined in Section VII, to get the complete extension μ_g then μ_g is defined on the σ algebra $\mathcal{M}$ of Lebesgue measurable sets and $\mu_g \ll m$. Indeed the Radon-Nikodym derivative of μ_g and the derivative of g (which exists a.e.) correspond: for any a, b we have $g(b) - g(a) = \int_a^b g'\,dt$ and so $g' = d\mu_g/dm$. In this case integrals with respect to μ_g reduce to integrals with respect to Lebesgue measure:

$$\int_E f\,d\mu_g = \int_E fg'\,dt$$

These results are especially important in probability theory where the finiteness of the measure simplifies the results. Indeed let $\{X, \mathcal{S}, \mu\}$ be a probability measure space and f a finite-valued measurable function, so f is a random variable. Define a function F by $F(x) = \mu f^{-1}(-\infty, x]$ (i.e., $F(x) = \mu\{t\colon f(t) \leqq x\}$, so that $F(-\infty) = 0 \cdot F(\infty) = 1$). Then F is the distribution function of f and is a monotone increasing right-continuous function. The measure μ_F it defines agrees with the measure μf^{-1} on the intervals of $\mathbb{R}$.

XI. THE RADON–NIKODÝM PROPERTY FOR BANACH SPACES

In this section we consider measures taking their values in a Banach space, that is a normed space which is complete (the examples of L^p, L^∞ were considered in Section IV). This is more general than the finite dimensional case considered in Section X. We consider first the question of integrating functions taking values in a Banach space, with respect to a real measure. If we then set $m(A) = \int f\,d\mu$ we see that such a theory of integration gives rise to a Banach space–valued measure. Which measures are formed in this way depends on the Banach space in question, since the existence of such a function f implies that a version of the Radon–Nikodým theorem holds. The most useful version of this integral is the Bochner integral. First, we describe the details of such measures. Let Y be a Banach space with norm $\|.\|$. We will suppose that we have a space X with measurable sets $\mathcal{S}$. Then $m\colon \mathcal{S} \to Y$ is a vector measure if $m(\varnothing) = 0$ and whenever $\{A_i\}$ is a countable family of disjoint sets of $\mathcal{S}$ then $m(\cup_{i=1}^\infty A_i) = \sum_{i=1}^\infty m(A_i)$ where this sum is norm convergent, that is, the sequence of vectors $\sum_{i=1}^n m(A_i)$ converges in the normed space $(Y, \|.\|)$ as $n \to \infty$. We will suppose that the space X is equipped with a finite measure μ: for some purposes it is more convenient to assume, as we will, that $\mu(X) = 1$, that is: μ is a probability measure. The *average range* of m is the set in Y given by $AR(m) = \{m(A)/\mu(A)\colon A \in \mathcal{S}, \mu(A) > 0\}$. As in the scalar case we say the vector-valued measure m is *absolutely continuous* with respect to μ, $(m \ll \mu)$ if $\mu(A) = 0$ implies $m(A) = 0$ (zero vector).

Then to set up a theory of integration we consider simple functions as before of form $f = \sum_{i=1}^n x_i \chi_{A_i}$ with $x_i \in Y$, $A_i \in \mathcal{S}$. Then for any set $A \in \mathcal{S}$, we can define for such an $f \int_A f\,d\mu = \sum_{i=1}^n x_i \mu(A \cap A_i)$. Then generally a function $f\colon X \to Y$ is *Bochner integrable* if there is a sequence $\{f_n\}$ of simple functions with $\lim_{n\to\infty} f_n(x) = f(x)$ a.e. (μ) and $\lim_{n\to\infty} \int \|f(x) - f_n(x)\|\,d\mu = 0$. This provides an unambiguous definition if we set $\int f\,d\mu = \lim \int f_n\,d\mu$, and we then write $f \in L_Y^1(X, \mathcal{S}, \mu)$, and we say $\int f\,d\mu$ is the *Bochner integral* of f. Regarding measurability, a Y-valued function is said to be *strongly measurable* if it is the limit a.e. of simple functions. A weaker requirement is that each scalar valued function $F \circ f$ where F is a continuous linear functional on Y should be measurable in the usual sense. For functions f with $\|f\|$ integrable and which satisfy a condition on the range (always true for integrable functions), the definitions are equivalent. Much of the theory extends; for example, we have a dominated convergence theorem: we require $\|f_n(x)\| \leq g(x)$ a.e. (μ). where g is integrable and $\lim f_n(x) = f(x)$ a.e., then f is integrable, $\int f\,d\mu = \lim \int f_n\,d\mu$ and $\lim \int \|f_n - f\|\,d\mu = 0$ (i.e. f_n converges to f in the mean).

The Radon–Nikodým property turns out to be very important for when considering such vector-valued measures and functions; whether it holds depends on the geometry of Y. Let K be a closed bounded convex set in the Banach space Y. Then K has the Radon–Nikodým property (RNP) for $\{X, \mathcal{S}, \mu\}$ if for any Y-valued measure m which is absolutely continuous with respect to μ and whose average range $AR(m)$ lies in K there exists a function $f \in L_Y^1(X, \mathcal{S}, \mu)$ such that $m(A) = \int_A f\,d\mu$ for each $A \in \mathcal{S}$. More generally, if E is a closed convex (possibly unbounded) set of Y (e.g., $E = Y$), then E has the RNP for $\{X, \mathcal{S}, \mu\}$ if each closed bounded subset K of E has the RNP for $\{X, \mathcal{S}, \mu\}$. Finally, K has the RNP

if it has the RNP for each $\{X, \mathcal{S}, \mu\}$ for μ a probability measure. An example of a space *without* the RNP is at hand.

EXAMPLE 1. [Bourgin]: Let $X = [0, 1]$, $\mathcal{S}$ = Lebesgue measurable sets, μ = Lebesgue measure. Let $Y = L^1[0, 1]$ and define m by $m(A) = \chi_A$ for each $A \in \mathcal{S}$. Then $m \ll \mu$, $AR(m)$, lies in the closed unit ball of Y but Y has not the RNP. For if it had, there would exist a function $f \in L^1_Y(\mu)$ with $m(A) = \int_A f\, d\mu$ for each $A \in \mathcal{S}$. So for each x, $f(x)$ is a real-valued measurable function taking the value $f(x)(s)$ at $s \in [0, 1]$. Let I be an interval in $[0, 1]$, then for all $A \in \mathcal{S}$

$$\begin{aligned}\int_A \left(\int \chi_I(s) f(t)(s)\, ds \right) dt &= \int \chi_I(s) \left(\int_A f(t)\, dt \right) ds \\ &= \int \chi_I(s)\, m(A)(s)\, ds \\ &= \int \chi_I(s)\, \chi_A(s)\, ds \\ &= \int_A \chi_I(t)\, dt\end{aligned}$$

So

$$\int_I f(t)(s)\, ds = \int \chi_I(s) f(t)(s)\, ds = \chi_I(t)$$

outside a set of measure zero, and for such t **not** in I, $\int_I f(t)(s)\, ds = 0$. Allowing I to vary over all subintervals I_r of $[0, 1]$ with rational end-points we get an exceptional set of measure zero. Any set on which the function $f(t)$ is positive can be approximated by an interval, and choosing a subinterval I_r of this interval with $t \notin I_r$ we see that $f(t)$ must vanish a.e. for almost all t. This contradicts the fact that $\int_A f\, d\mu = \chi_A \neq 0$ for A a set of positive measure.

The RNP is closely related to the convergence of martingales, which we now describe. Let $\{\mathcal{S}_n\}$ be a sequence of sub σ-algebras of $\mathcal{S}$, with $\mathcal{S}_n \subseteq \mathcal{S}_m$ whenever $n < m$. Suppose $f_n \in L^1_Y(X, \mathcal{S}, \mu)$ for each n. Suppose also that the functions f_n are strongly $\mathcal{S}_n$ measurable for each n and that $\int_A f_n\, d\mu = \int_A f_m\, d\mu$ for each A in $\mathcal{S}_n$ provided $n < m$. Then the sequence $\{f_n, \mathcal{S}_n\}$ is a Y-valued martingale. A closed bounded convex set K in Y has the *martingale convergence property* (MCP) for $\{X, \mathcal{S}, \mu\}$ if whenever $\{f_n, \mathcal{S}_n\}$ is a martingale such that $\cup_{n=1}^{\infty} \mathcal{S}_n$ generates $\mathcal{S}$ and $f_n \in L^1_K(X, \mathcal{S}_n, \mu)$ for each n then there exists $f \in L^1_K(X, \mathcal{S}, \mu)$ such that $\lim_{n\to\infty} \| f_n(x) - f(x) \| = 0$ a.e., (μ). The corresponding statements for closed convex sets and the definition of "Y has MCP" follow exactly as for RNP. In fact a closed bounded convex set has the RNP if, and only if, it has the MCP. To see that a closed convex set K has the MCP provided it has the RNP we let $m_n(A) = \int_A f_n\, d\mu$ where μ is a probability measure and $\{f_n, \mathcal{S}_n\}$ form a martingale and $A \in \mathcal{S}_n$. Since μ is a probability measure $AR(m_n)$ lies in K. Then $\{m_n(A)\}$ converges for each A in $\cup \mathcal{S}_n$. By a limiting argument we get $\lim m_n(A) = m(A)$, which is a measure by the Vitali-Hahn-Saks Theorem. By construction $m_n \ll \mu$ and in the limit $m \ll \mu$ and $AR(m) \subseteq K$. So by the RNP there exists $f \in L^1(X, \mathcal{S}, \mu)$ such that $\int_A f\, d\mu = m(A)$ for each A in $\mathcal{S}$. By the martingale property $\int_A f\, d\mu = \int_A f_n\, d\mu$ for each $A \in \mathcal{S}_n$ and by a theorem of Lévy we deduce $\lim_{n\to\infty} \| f_n(x) - f(x) \| = 0$ a.e. (μ). This theorem of Lévy uses conditional expectations whose existence depends on the classical Radon–Nikodým result given in Section VII.

A third property of Banach spaces which turns out to be related is that of dentability. A bounded set D in Y in *s-dentable* if for each $\varepsilon > 0$ there exists x_ε in D with $x_\varepsilon \notin s\text{-}co(D \backslash U_\varepsilon(x_\varepsilon))$, where $U_\varepsilon(y)$ denotes the ball radius ε and center Y and

$$s\text{-}co B = \left\{ \sum_{i=x}^{\infty} \alpha_i x_i : x_i \in B, \alpha_i \geq 0, \sum_{i=1}^{\infty} \alpha_i = 1 \right\}.$$

Replacing *s-co* by closed convex hull, we get the stronger definition of D dentable. Drawing a diagram we see that D dentable implies that D is in some sense rotund for some part of its boundary. Dentability can be defined equivalently in terms of *slices*. For a bounded set D in Y, the *slice* $s(D, f, \alpha) = \{x : x \in D,\ f(x) > \sup_{y \in D} f(y) - \alpha\}$ where $\alpha > 0$, and f is a continuous linear functional on Y. Then it is an easy consequence of the Hahn–Banach theorem that D is dentable if, and only if, it has slices of arbitrarily small diameter. Now it follows easily from the definitions that if D is dentable then it is s-dentable. But the converse is not true, as the following example shows.

EXAMPLE 2. Let $Y = C[0, 1]$ the Banach spaces of functions continuous on $[0, 1]$ and with the norm $\| f \| = \max |f(x)|$ and let D be the unit ball $U_1[0]$ of Y. Then with $f(x) \equiv 1$ as x_ε, for any $\varepsilon > 0$, we see that D is s-dentable. However, D is not dentable for if $f \in D$ and for any fixed n we choose function $f_n^1, \ldots, f_n^n$ with $f_i^n(t) = f(t)$ for $t \notin [i - 1/n, i/n]$ and $|f_i^n(t) - f(t)| > 1/2$ for some $t \in (i - 1/n, i/n)$, for each i. Then $\| f_i^n - f \| > 1/2$ but $\| \sum_{i=1}^n 1/n\ f_i^n - f \| \leq 2/n$. So $f \in \overline{co}(D \backslash U_{1/2}(f))$. So D is not dentable. However, it can be shown by a geometrical argument that if K is a closed convex set in Y with interior K (int K) nonempty then if K is not dentable int K is not s-dentable. See Davis and Phelps for details. So every bounded set of Y is dentable if, and only if, every bounded set is s-dentable. This turns out to be the important property. Indeed, if a closed bounded convex set K has every subset s-dentable then K has the RNP.

To outline the proof: consider the special case when m is in the form

$$m(A) = \sum_{i=1}^{n} x_i \mu(A \cap B_i),$$

with $\{B_i\}$ being a partition of X into sets of positive measure and with $x_i \in K$. Then for $\mu(A) > 0$ and $A \subseteq B_i$ we have

$$\frac{m(A)}{\mu(A)} = x_i = \frac{m(B_i)}{\mu(B_i)}.$$

Set $f = \sum_{i=1}^{n} x_i \chi_{B_i}$; then for each A in $\mathcal{S}$ we have

$$\int_A f \, d\mu = \sum_{i=1}^{n} x_i \mu(A \cap B_i) = m(A).$$

So $f = dm/d\mu$ and K has the RNP. In general m will not be of this simple form, but we can approximate it by a sequence of such measures, obtaining a convergent sequence of such derivatives f_n. So we need to know that we can partition X into sets B_i such that for subsets B of B_i, with $\mu(B) > 0$, and for a suitable x in K we have $\|m(B)/\mu(B) - x_i\| < \varepsilon$. Then we use a sequence of such partitions with ε's tending to zero to obtain the approximation. So we let $E = \{m(B)/\mu(B)\colon \mu(B) > 0, B \subseteq B_i\}$, a subset of K as $AR(m) \subseteq K$. So E is s-dentable and so we can find $x_i \notin s\text{-}co(E \setminus U_\varepsilon(x_i))$, with $x_i \in E$, $x_i = m(B)/\mu(B)$, say. Suppose we can find sets C in B_i with $\|m(C)/\mu(C) - x_i\| \geq \varepsilon$. Maximizing such a family of disjoint sets C we could write $B_i = \cup_{i=1}^{\infty} C_i$ and then

$$x_i = \frac{m(B)}{\mu(B)} = \sum_{j=1}^{\infty} \frac{\mu(C_j)}{\mu(B} x_j$$

with x_j

$$= \frac{m(C_j)}{\mu(C_j)} \in E \quad \text{and} \quad \sum_{i=1}^{\infty} \frac{\mu(C_i)}{\mu(B)} = 1,$$

contradicting the s-dentability of E.

It can be shown fairly easily that if K has the MCP, then its subsets are s-dentable (Bourgin). Suppose not, so there is a subset D of K which is not s-dentable. Then a nonconvergent martingale can be constructed inductively, using the interval $[0, 1]$, $\mu =$ Lebesgue measure. So there exists a positive ε such that for each $x \in D$, $x \in s\text{-}co(D \setminus \cup_\varepsilon(x))$. At the first stage choose $x_0 \in D$, define $f_0 = x_0$ a constant function and let $\mathcal{S}_0 = \{[0, 1), \varnothing\}$, the minimal σ-algebra. By the property of D there exist $\{t_j\colon 0 < t_j < 1, \Sigma t_j = 1\}$ and points y_j of D with $\|x_0 - y_j\| \geq \varepsilon$, $\Sigma t_j y_j = x_0$. Partition $[0, 1]$ into half-open intervals B_j, one for each t_j with $\mu(B_j) = t_j$. Let $\mathcal{S}_1$ be the σ-algebra generated by $\{B_j\}$, and $f_1 = \sum_{j=1}^{\infty} y_j \chi_{B_j}$. At the next stage of the induction we partition each B_j to get a larger σ-algebra, and a function f_2. By the non-s-dentable property of D, this martingale so constructed will not converge.

This result establishes the equivalence of the properties RNP, MCP, dentability of subsets and s-dentability of subsets for a Banach space Y. Such spaces, to some extent, have the nice properties of finite dimensional spaces. Among the various other properties of such spaces is the fact that they possess the Krein–Milman property referred to in Section IX; that is, for any closed bounded convex set K in Y, K is the closed convex hull of its extreme points. Indeed we saw earlier that the space $C[0, 1]$ has a unit ball $U_1[0]$, which is not dentable: $U_1[0]$ has just two extreme points, the constant functions $+1$ and -1, so it does not possess the KMP. To prove the KMP it is sufficient to show that every bounded convex set has an extreme point. For dentable sets this can be done using the fact that they have slices of arbitrarily small diameter. A nested decreasing sequence of such slices is found the intersection of which yields the desired extreme point. For further details, related results, and references see Bourgin (1983) and Phelps (1988). We have seen that the spaces $C[0, 1]$, $L^1[0, 1]$ have not the RNP. However, the spaces L^p of Section IV for which $1 < p < \infty$ have the RNP, as have all reflexive spaces. It is not known whether the KMP implies the RNP. Another important property of finite-dimensional spaces is that convex functions are differentiable almost everywhere. To see how this extends, we say that the real-valued function f on a Banach space Y is *Frechét differentiable* at y if there exists a linear functional $\phi'(y)$ on Y such that for every $\varepsilon > 0$ there exists $\delta > 0$ such that $\|\varphi(y + x) - \varphi(y) - \varphi'(y)(x)\| \leq \varepsilon \|x\|$ whenever $\|x\| \leq \delta$. Then the space Y is said to be an *Asplund space* if every continuous convex function f on a nonempty open set D in Y is Frechét differentiable at each point y of some dense set E of D where the set E is a G_δ set, that is: $E = \cap_{i=1}^{\infty} G_i$ when the sets G_i are dense open sets of D. Then the space Y is an Asplund space, if, and only if, the Banach space Y^* of continuous linear functionals on Y has the RNP.

XII. MEASURE AND FRACTALS

Fractals are often introduced and thought of in pictorial terms. However, the underlying measure theory is important. We start with Hausdorff measure on $\mathbf{R}$. This is defined in two steps: first define the "approximating measure":

$H^*_{s,\delta}(A) = \inf \sum \ell(I_k)^s$ where the infimum is taken over all coverings of the set A by intervals $\{I_k\}$ with $\ell(I_k) \leq \delta$. Then let $H^*_s(A) = \lim H^*_{s,\delta}$ as $\delta \to 0$. This limit exists and defines Hausdorff outer measure. This *is* an outer measure, $H^*_s(\{x\}) = 0$ for each point, $H^*_s(A + x) = H^*_s(A)$, for each set A, so it is invariant under translation and, significantly, it "scales" in this way: $H^*_s(kA) = k^s H^*_s(A)$ for any positive k. Then H^*_s is a *metric outer measure*,

that is if two sets A and B are a positive distance apart, $H_s^*(A \cup B) = H_s^*(A) + H_s^*(B)$. Then Borel sets are H_s^* measurable in the usual sense: the proof requires a little care in showing that intervals are H_s^* measurable. It is easily seen that H_1^* is just Lebesgue measure. Hausdorff measure, H_s, defined by H_s^*, is used to analyze sets of zero Lebesgue measure. For it can be shown fairly easily that if $H_s^*(A) < \infty$ then $H_q^*(A) = 0$ for $q > s$. So if $0 < H_s^*(A) < \infty$ then $H_q^*(A) = \infty$ for $q < s$. So we can define (Hausdorff) dimension of a set E by: $\dim(E) = \inf\{s: H_s^*(E) = 0\}$. This provides a dimension, usually noninteger, for Borel sets in $\mathbf{R}$. All this may be generalized with, in the definition, $\ell(I_k)^s$ being replaced by $h(\ell(I_k))$ with a suitable function h, for example a monotonic increasing function $h(t)$ for $t \geq 0$ with $h(0+) = h(0) = 0$.

Hausdorff dimension can be difficult to calculate. The real numbers have dimension = 1, finite sets of points have dimension zero. For the Cantor Set, P, described in Section II, the calculation is straightforward. This set is "self-similar" in the sense that the subsets in the closed intervals $J_{1,1}$, $J_{1,2}$ left after the first "open third" $I_{1,1}$ has been removed are copies of the Cantor set scaled by 1/3 and translated. So using the "scaling property" of H described above, we get $H_s(P) = \frac{2}{3^s} H_s(P)$ and so $s = \frac{\log 2}{\log 3}$, provided we can show that $0 < H_s(P) < \infty$. This part needs care in transforming a arbitrary covering of P into coverings of the subsets of $J_{1,1}$, $J_{1,2}$ mentioned in Section III, and using the metric outer measure property. This method and result generalize immediately to the "Cantor-like set" P_ξ obtained when we remove, not the middle third, but a central open interval of positive length $1 - 2\xi$ at the first stage, with the residual intervals being of length ξ at stage one, ξ^2 at stage two, etc. The same argument gives the Hausdorff dimension of P_ξ as $-\frac{\log 2}{\log \xi}$, a number between 0 and 1. This shows that sets in $\mathbf{R}$ exist with all possible positive values of Hausdorff dimension. In forming the Cantor set we removed numbers whose expansion to base 3 contained a 1. If we remove instead those containing a 2 or those containing a zero, we get somewhat different sets whose Hausdorff dimensions were found by Best. Similar results for expansions to other bases are to be found in Weymann. Sets of finite positive H_s measure are called s-sets, or *fractals* in this context, though some writers use "fractals" to refer to sets which are self-similar at all levels of magnification.

This generalizes easily to two dimensions: from a closed square one deletes a central open cross to leave four closed squares placed at the corners: these are then similarly reduced, etc. The resulting "Cantor square" along with many examples of self-similar sets are considered in the very accessible book of Lauwerier. In two dimensions one may consider the Hausdorff dimension of a curve. With some restrictions to avoid pathological space-filling curves one finds that the curve C of length L has dimension one and Hausdorff measure $H_1(C) = L$ (Falconer, p. 24). This relates to the functions of bounded variation discussed in Section V. In three dimensions we may consider the motion of minute particles in a liquid. This erratic motion is modeled probalistically by Brownian motion. In Falconer (p. 144) we have that Brownian paths are s-sets of dimension one, with probability one. Applications to many areas are to be found in Mattila, together with a comparison of different definitions of "dimension," and which also contains a sizeable bibliography.

GLOSSARY

Constraint functions Functions that are used to define the feasible set.
Decision vector Vector of unknown variables on which the objective function is defined.
Feasible set Set of decision vectors that satisfy the constraints and over which the objective function is defined.
Global optimal solution Particular choice of the decision vector that solves the optimization problem.
Lagrangian function Function of the decision vector and the multipliers with critical points that are related to optimal solutions.
Local optimal solution Particular choice of the decision vector that yields the least value of the objective function in some relatively open subset of the feasible set.
Multipliers Coefficients of the constraint gradients in the first-order necessary conditions.
Objective function Function that is to be minimized.
Sequential quadratic programming Computational technique for solving nonlinear programs.

NONLINEAR PROGRAMMING is the study and solution of an optimization problem in which a nonlinear function of several variables is minimized over the solution set of a finite number of functional inequalities and equations. The problem can be written as:

$$\begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to:} && g_i(x) \le 0, \quad i = 1, \ldots, M \\ &&& h_j(x) = 0, \quad j = 1, \ldots, P \\ &&& x \in \Re^N, \end{aligned}$$

where the objective function f and the constraint functions, g_i and h_j, are (usually) continuously differentiable functions. The components of the vector x are called the decision variables. Such nonlinear problems find a wide range of applicability in the physical and social sciences, engineering, and the decision sciences.

I. OVERVIEW

A. Optimization and Nonlinear Programming

A significant proportion of the mathematical models formulated and studied by scientists and engineers involve some form of optimization. For physical scientists, nature seems inherently to be an optimizing force; the laws of conservation and equilibrium can be interpreted as

Encyclopedia of Physical Science and Technology, Third Edition, Volume 10

optimality conditions. Engineers build controlling devices that perform with minimal energy expenditure and design plant schedules that maximize some measure of production efficiency. Economists and other social scientists theorize that much of human behavior and development, whether individual or collective, is guided by optimization processes. Finally, modern managerial scientists use optimization methods to organize and reduce large amounts of data to make rational decisions on policy issues in the public and private sectors.

Mathematically, the most general form of an optimization model can be characterized by a set X and a real-valued function f defined on X. The set X, often called the *feasible set*, consists of the possible realizations of the model. For example, X could consist of a set of permissible trajectories for a satellite launch vehicle, the possible flight schedules for an international cargo airline, or a set of possible purchases by a consumer in a given market. Each $x \in X$ is a vector, the components of which are termed the *decision variables* of the model. The function f, called the *objective function*, is a measure by which the vectors in X are compared. Thus for these examples, $f(x)$ might represent the energy required to traverse trajectory x, the total cost for the implementation when x is an airline schedule, or the value of a consumer's purchase when x is the vector with components that are quantities of commodities.

The problem to be solved in an optimization model is

$$\text{minimize} \quad f(x), \quad x \in X.$$

That is, an $x^* \in X$ is sought such that for all other $x \in X$, $f(x^*) \leq f(x)$. The fact that the problem is formulated as a minimization rather than a maximization is not important because the above is mathematically equivalent to

$$\text{maximize} \quad -f(x), \quad x \in X.$$

The problem as stated is much too general to yield useful information. In order to be able to analyze the problem, more must be known about the properties of the set X and the function f. The general field of optimization is broken down into subfields according to these properties. Nonlinear programming is one of these subfields; traditionally, it refers to the case in which the set X is assumed to be functionally prescribed. That is, X is the intersection of a finite number of sets each of which is the solution set of a functional equation or inequality. The equations or inequalities that prescribe the feasible set are called constraints. In an optimization model, an inequality constraint may be used to represent the limits on an available resource or may be a production quota that must be exceeded. An equality constraint might represent the requirement that a consumer spend or save all of his or her income or that a trajectory begin from a designated location.

Using a functional representation of the constraint set the standard nonlinear programming problem, hereafter denoted NLP, can be formulated as

$$\begin{aligned} \text{minimize} \quad & f(x) \\ \text{subject to:} \quad & g_i(x) \leq 0, \quad i = 1, \ldots, M, \\ & h_j(x) = 0, \quad j = 1, \ldots, P, \\ & x \in \Re^N. \end{aligned}$$

The functions g_i and h_j are called the *constraint functions* and, like f, are generally assumed to be continuously differentiable. Nonlinear programming problems are distinguished from the special types of optimization problems called *linear programming* problems, in which the objective and constraint functions are affine. It is also conventional to separate nonlinear programming, which requires the decision vectors to be finite-dimensional, from problems such as those of optimal control, in which X is a subset of an infinite-dimensional space. However, the computation of the solutions to these latter problems depends on the solution of finite-dimensional approximations (see Section IV.C).

B. The Solution of a Nonlinear Program

A vector, $x^* \in X$, satisfying $f(x^*) \leq f(x)$ for all $x \in X$ is called a (global) optimal solution to NLP and the corresponding number $v^* = f(x^*)$ is called the optimal value of NLP. One of the distinguishing characteristics of nonlinear programming is that local optimal solutions are possible. Hence, $x^L \in X$ is a local optimal solution if there is an $\epsilon > 0$ such that $f(x^L) \leq f(x)$ for all $x \in X \cap \{x : |x - x^L| < \epsilon\}$ ($|z|$ represents the Euclidean length of the vector z). Unfortunately, for many nonlinear programs, global optimal solutions cannot be identified until all local optimal solutions are known. Hereafter, the term "optimal solution" will refer to a local solution unless specified otherwise.

The major theoretical questions to be answered concerning a given NLP relate to the existence, characterization, and stability of solutions. Existence refers to the determination of conditions on the objective and constraint functions under which global and local solutions are guaranteed to exist. The characterizations of a solution are theoretical conditions on a point x that are either necessary or sufficient for it to be a global or local solution. These characterizations are important for identifying the solution(s) and its properties and in the construction of algorithms for computing the solution. Stability refers to the sensitivity of the solution with respect to the perturbation of the parameters which define the objective and constraint functions. Stability is important in the practical

use of optimization because these parameters are usually not known precisely. For instance, they might be the observed mean of historical data or they might be the result of a physical measurement with its attendant errors. It is desirable, in these cases, to have assurances that the optimal solution and optimal value are not wildly inaccurate as a result of small errors in the determination of these parameters.

In most cases, it is the numerical values of an optimal solution that are ultimately needed. Thus, the computational question of how best to numerically approximate an optimal solution is equally important to the questions of theory. A computationally efficient numerical algorithm that will yield a good approximate solution to NLP must be available. Consequently, the techniques of numerical analysis and computational mathematics play a major role in nonlinear programming.

The following simple one-dimensional example illustrates the major theoretical questions in nonlinear programming:

$$\begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to:} && x - \alpha \geq 0, \\ &&& x - \beta \leq 0, \end{aligned}$$

where f is twice differentiable and $0 < \alpha < \beta$. Since the objective function is continuous and $X = [\alpha, \beta]$ is compact, the existence of a global solution is guaranteed. Elementary calculus shows that any local minimum point must satisfy $f'(x) = 0$ if $\alpha < x < \beta$, $f'(x) \geq 0$ if $x = \alpha$, or $f'(x) \leq 0$ if $x = \beta$. These necessary conditions for optimality are examples of the characterizations of the solution. Note that $\{\alpha < x < \beta, f'(x) = 0, f''(x) > 0\}$ is a sufficient (but not necessary) set of conditions for x to be a local minimum. For an example of the ideas of stability, specify $f(x) = xe^{-x}$, $\alpha = 1/2,$ and $\beta > 1$. The global optima are

$$x^* = \begin{cases} \alpha, & \beta \leq \beta^*, \\ \beta, & \beta \geq \beta^*, \end{cases}$$

where $\beta^* > 1$ satisfies

$$\beta^* e^{-\beta^*} = (1/2)e^{-(1/2)}.$$

Moreover the optimal value as a function of β is

$$v^*(\beta) = \begin{cases} (1/2)e^{-(1/2)}, & \beta \leq \beta^*, \\ \beta e^{-\beta}, & \beta \geq \beta^*. \end{cases}$$

$v^*(\beta)$ is a continuous function of the parameter β and

$$\frac{dv^*}{d\beta} = \begin{cases} 0, & \beta < \beta^*, \\ (1-\beta)e^{-\beta}, & \beta > \beta^*. \end{cases}$$

Thus, the global optimal value is differentiable except when $\beta = \beta^*$.

C. Special Types of Nonlinear Programs

The set of nonlinear programs can also be subdivided further into classes associated with special properties of the objective and constraint functions. Some of the more common classes are described in this section.

In theory, the simplest nonlinear program is the unconstrained program (i.e., the problem in which there are no constraints) where the objective function is minimized over all of $\Re^N$. These problems are important because they include many of the important *least-square models* and also because the computational algorithms for solving them are used as the foundations for algorithms for solving the more general problems. Among the constrained nonlinear programs, the easiest ones to deal with are the *convex programs*. These problems have a unique global optimal solution and no local solutions; much of the theory is analogous to that found in linear programming. Of special interest among the convex programs are the *convex quadratic programs*. In these problems, the objective function has the form

$$f(x) = \frac{1}{2}x^t Ax + a^t x,$$

where A is an $N \times N$ symmetric positive definite matrix and a is a fixed N-vector, and all of the constraints functions are affine. As will be seen, one approach to solving a general NLP is to approximate it by a quadratic program.

Two classes of problems that are currently on the forefront of research in the field of nonlinear programming are nondifferentiable and large-scale programs. *Nondifferentiable programs* are those for which the objective function is only piecewise differentiable. This class has many applications, one of the most important of which is the case in which f is itself the solution of an optimization problem; for example,

$$f(x) = \max_{\alpha \in A}\{(c_\alpha)^t x\},$$

where $\{c_\alpha\}$ is a family of vectors. The term *large-scale problems* refers to problems in which some or all of the parameters, N, M, and P are large. The theory for this class is not changed but special computational techniques are necessary to ensure that solving such a problem is feasible in terms of computer time and storage.

Although there are important applications and results associated with each of these special types of nonlinear programs, the theory and computation presented in the remainder of this article deals primarily with the general problem, the major exception is the specialization of the theory to convex programs.

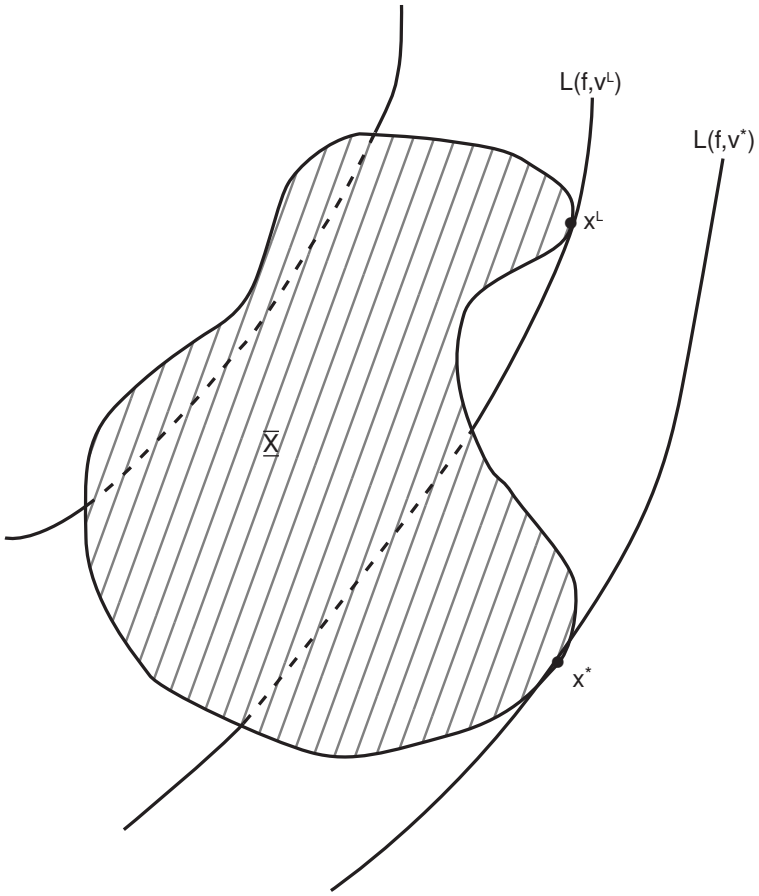

FIGURE 1 Level sets of the objective function with local and global minima.

II. THEORETICAL ASPECTS

A. The Geometry

The theoretical part of nonlinear programming is based on the geometry of the feasible set X and the underlying geometry of the objective function. This geometry can be used to motivate the basic theorems of nonlinear programming (presented later in this section) and also the algorithms used to solve the problems.

The *level sets* of a function will be important in the following development. Let w be a real-valued function defined on $\Re^N$. For each real number α, the following level sets are defined:

$$L(w, \alpha) = \{x : w(x) = \alpha\},$$

$$L^-(w, \alpha) = \{x : w(x) \leq \alpha\}.$$

With this notation, the feasible set for NLP can be written as a finite intersection of these level sets:

$$X = \left\{ \bigcap_{i=1}^{M} L^-(g_i, 0) \right\} \cap \left\{ \bigcap_{j=1}^{P} L(h_j, 0) \right\}.$$

Because the f, g_i, and h_j are assumed to be continuous, the level sets and, therefore X, will all be closed sets.

Now v^* is an optimal value for NLP if the set

$$X^* = L(f, v^*) \cap X$$

is nonempty and for each $v < v^*$, the sets

$$L(f, v) \cap X$$

are empty. Each $x^* \in X^*$ is then an optimal solution of NLP. Similarly, $x^l \in X$ is a local optimal solution for NLP with local optimal value $v^l = f(x^l)$ if for some $\epsilon > 0$ the set

$$L(f, v) \cap X \cap \{x : |x - x^l| < \epsilon\}$$

is empty for each $v < v^l$. An example of the geometry is illustrated in Fig. 1.

The set of optimal solutions is simplified when the feasible set and the level sets $L^-(f, \alpha)$ are *convex* sets. Mathematically, a subset $C \subset \Re^N$ is convex if, for every pair of vectors x and y in C and all $\lambda \in [0, 1]$, the vector $\lambda x + (1-\lambda)y$ is also in C. Thus a convex set is one that has no indentations or protuberances. If the feasible set and

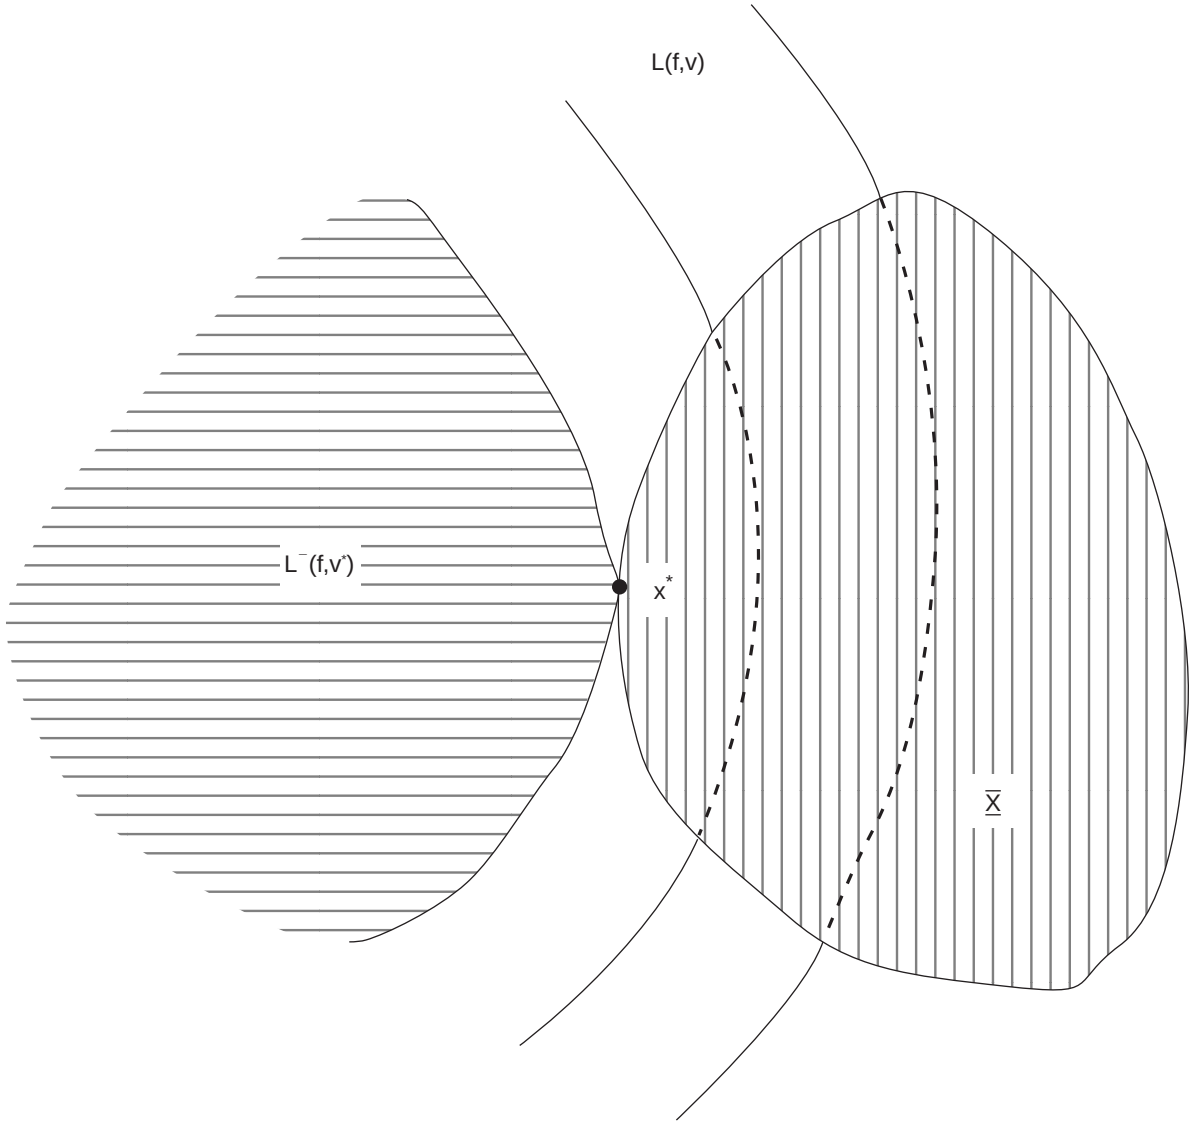

FIGURE 2 Global minimum for a convex program.

the level sets are all convex then, for any optimal solution x^l with optimal value v^l, the sets

$$L^-(f, v) \cap X$$

are empty for all $v < v^l$ and hence there are no local solutions that are not also global solutions. This situation is illustrated in Fig. 2.

These geometric conditions characterize the optimal solutions completely. However, they are not very useful in practice because the level sets cannot be easily mapped. In the next section, these geometric conditions are transformed into algebraic conditions, which will in turn yield qualitative and quantitative results for the nonlinear programs.

B. First-Order Conditions

In order to establish first-order optimally conditions the assumption that the objective and constraint functions are continuously differentiable will be used. This allows the functions to be approximated linearly about a given vector, which in turn leads to a local polyhedral approximation of the feasible set.

Given a continuously differentiable function w defined on $\Re^N$ and a vector $\hat{x}$ the affine (linear) approximation to w at $\hat{x}$ is

$$\hat{w}(x) = w(\hat{x}) + \nabla w(\hat{x})^t(x - \hat{x}),$$

where $\nabla w(\hat{x})$ is the *gradient* of w, that is, the N-dimensional column vector of partial derivatives of w at

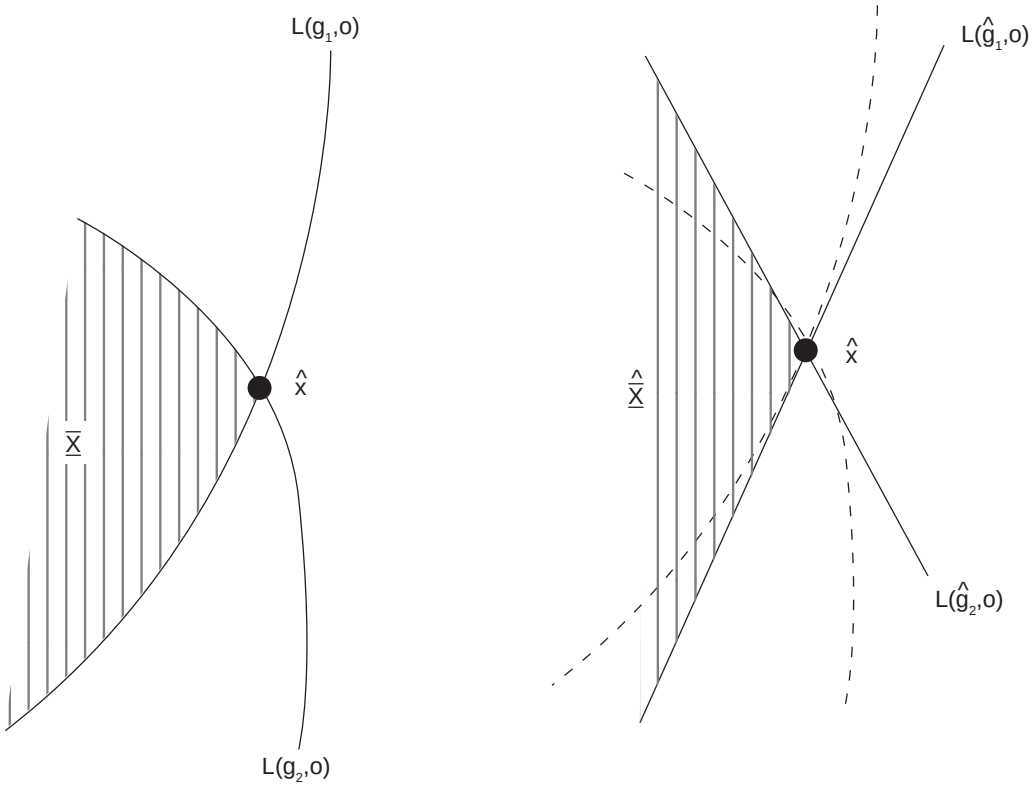

FIGURE 3 Linear approximation of the feasible set.

$\hat{x}$. If the objective and constraint functions in NLP are replaced by their affine approximations at a point $\hat{x} \in X$ then the resulting optimization problem is a linear program with a polyhedral feasible set $\hat{X}$, which serves as a local approximation of NLP (although the approximation may be poor). Figure 3 illustrates this approximation in a simple inequality-constrained case.

It can easily be shown that in the inequality-constrained case, $\hat{x}$ is an optimal solution to the approximating linear program if and only if the vector $-\nabla f(\hat{x})$ is a nonnegative combination of the gradients of the *active constraints* at $\hat{x}$ (i.e., those constraints that have value 0 at $\hat{x}$). As is seen in Fig. 4, this condition means that $\hat{f}$ cannot have a direction of decrease into the interior of $\hat{X}$ from $\hat{x}$ and hence $-\nabla f(\hat{x})$ must lie in the cone $\hat{K}$ generated by the gradients of the active inequality constraints. If equality constraints are present, the situation is slightly more complicated in that $-\nabla f(\hat{x})$ must be a combination of all of the active gradients with the coefficients of the active inequality constraint gradients being nonnegative and the coefficients of the equality constraints being unrestricted in sign; that is,

$$\nabla f(x) + \sum_{i=1}^{M} \mu_i \nabla g_i(x) + \sum_{j=1}^{P} \omega_j \nabla h_j(x) = 0$$

for some $\mu_i \geq 0$ and some ω_j.

The question that now arises is the extent to which the optimality of $\hat{x}$ for the approximating problem is related to the optimality of $\hat{x}$ for NLP. The answer is contained in the following fundamental result of nonlinear programming.

Theorem 1 (First-Order Necessary Conditions): Let $\hat{x} \in \Re^N$ and suppose that the set of active constraint gradients at $\hat{x}$,

$$\{\nabla g_i(\hat{x}) : i \text{ such that } g_i(\hat{x}) = 0\}$$
$$\cup \{\nabla h_j(\hat{x}),\ j = 1, \ldots, P\},$$

is linearly independent. Then $\hat{x}$ is a local optimal solution only if there exist vectors $\hat{\mu} \in \Re^M$ and $\hat{\omega} \in \Re^P$ such that

$$\nabla f(\hat{x}) + \sum_i \hat{\mu}_i \nabla g_i(\hat{x}) + \sum_j \hat{\omega}_j \nabla h_j(\hat{x}) = 0, \quad (1)$$

$$\hat{\mu}_i g_i(\hat{x}) = 0, \quad i = 1, \ldots, M, \quad (2)$$

$$\hat{\mu}_i \geq 0, \quad i = 1, \ldots, M, \quad (3)$$

$$g_i(\hat{x}) \leq 0, \quad i = 1, \ldots, M, \quad (4)$$

$$h_j(\hat{x}) = 0, \quad j = 1, \ldots, P. \quad (5)$$

The condition on the linear independence of the active constraint gradients is called a *constraint qualification*. It assures that the geometry at $\hat{x}$ is not so pathological

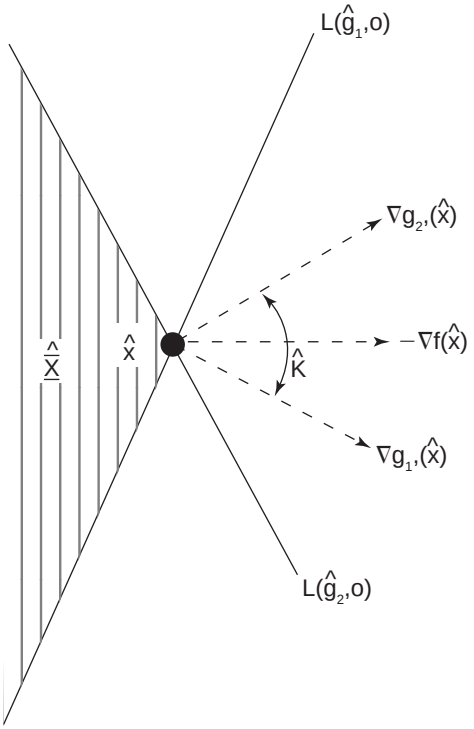

FIGURE 4 $-\nabla f(\hat{x})$ in the cone defined by the active constraint gradients.

that the set $\hat{X}$ is not a good local approximation of X. If this condition holds and $\hat{x}$ is a local optimal solution of NLP, then it is a global optimal solution to the linear approximating problem and hence conditions in Eqs. (1) and (3) hold. It is also a consequence of this constraint qualification that for a given $\hat{x}$ the corresponding $\hat{\mu}$ and $\hat{\omega}$ are unique. Conditions in Eq. (2) are called the *complementary slackness* conditions; they merely expresses the condition that $\hat{\mu}_i = 0$ if $g_i(\hat{x}) \neq 0$ [i.e., inactive constraints do not effect Eq. (1)]. Conditions in Eqs. (4) and (5) are just the feasibility conditions on $\hat{x}$.

Note that this characterization of $\hat{x}$ is a necessary condition only. It is easy to construct examples for which $\hat{x}$ satisfies Eqs. (1)–(5) but is not a local optimal solution for NLP. This is a consequence of using only linear approximations that are too coarse to reflect the true state of affairs. In order for these first-order conditions to always be sufficient for optimality as well as necessary, the problem must be convex.

A real-valued function w defined on $\Re^N$ is said to be *convex* if for every x and y in $\Re^N$ and every λ, $0 \leq \lambda \leq 1$, the following inequality holds:

$$w(\lambda x + (1-\lambda)y) \leq \lambda w(x) + (1-\lambda)w(y).$$

It can easily be established that if w is convex then the level set $L^-(w, \alpha)$ is a convex set for every α for which it is nonempty and that $L(w, \alpha)$ is convex if and only if w is an affine function. For these reasons, NLP is called a *convex program* if the functions f and g_i, $i = 1, \ldots, M$ are convex and the functions h_j, $j = 1, \ldots, P$ are affine. If NLP is convex, then X and $L^-(f, \alpha)$ are convex sets and, as indicated in the preceding section, every local optimal solution is a global optimal solution. The consequences of these facts are summarized in the following theorem.

Theorem 2: Let NLP be a convex program and assume that there is an $x^c \in X$ with $g_i(x^c) < 0$ for $i = 1, \ldots, M$. Then $\hat{x}$ is a global optimal solution of NLP if and only if there are vectors $\hat{\mu}$ and $\hat{\omega}$ such that Eqs. (1)–(5) hold.

The condition involving x^c is a standard constraint qualification for convex programs, sometimes called the Slater condition. Theorems 1 and 2 are important in that they severely limit the set of possible optimal points for NLP. These conditions are the higher-dimensional analogues of the conditions given in the example of Section I.B for locating a minimum of a nonlinear function of one variable on a closed interval. Most computational algorithms for solving NLP generate $\hat{x}$, $\hat{\mu}$, and $\hat{\omega}$ that approximately satisfy Eqs. (1)–(5).

To illustrate the application of the necessary conditions, consider the convex quadratic program

$$\begin{aligned} \text{minimize} \quad & \tfrac{1}{2}x^t Ax + a^t x \\ \text{subject to:} \quad & Bx - b \leq 0, \\ & Dx - d = 0, \end{aligned}$$

where A is an $N \times N$ positive definite matrix, B is an $M \times N$ matrix, and D is a $P \times N$ matrix of rank P. This is a convex program, and assuming that the constraint qualification of Theorem 2 holds, the solution to this problem is the solution of the conditions

$$\begin{aligned} Ax + B^t\mu + D^t\omega + a &= 0, \\ \mu^t(Bx - b) &= 0, \\ \mu &\geq 0, \\ Bx - b &\leq 0, \\ Dx - d &= 0. \end{aligned}$$

If there are no inequality constraints then this system reduces to the $(P + N)$-dimensional linear system

$$\begin{aligned} Ax + D^t\omega &= -a, \\ Dx &= d, \end{aligned}$$

which has a unique solution; namely, (x^*, ω^*), the global optimal solution and its multiplier. Thus, in this case

solving the NLP reduces to solving a linear system of equations.

Historically, the necessary conditions in theorem 1 are a part of classical mathematics for the case when there are only equality constraints; the $\hat{\omega}_j$ are known as Lagrange multipliers and Eq. (1) is then a direct consequence of the implicit function theorem. The inequality-constrained case was treated by Karush, Kuhn, and Tucker and the theory is sometimes referred to by their names. It should be noted that a more general necessary condition can be derived without assuming any constraint qualification. This result, called the Fritz John condition, differs from that of theorem 1 in that there is a coefficient, possibly zero, in front of $\nabla f(x)$ in Eq. (1).

C. Second-Order Conditions

In this section, it is assumed that the objective and constraint functions are twice continuously differentiable. For unconstrained nonlinear functions, second-order conditions are easily derived. Suppose $\hat{x}$ is a critical point of f (i.e., $\nabla f(\hat{x}) = 0$) and let $Hf(\hat{x})$ denote the Hessian matrix of f at $\hat{x}$, the symmetric matrix of second-order partial derivatives. Then $\hat{x}$ is an unconstrained local minimum of f if $Hf(\hat{x})$ is positive definite and only if $Hf(\hat{x})$ is positive semidefinite.

To state analogous conditions for the constrained problem, the Lagrangian function is introduced. This function of the $N + M + P$ variables (x, μ, ω) defined by

$$\mathcal{L}(x, \mu, \omega) = f(x) + \sum_i \mu_i g_i(x) + \sum_j \omega_j h_j(x)$$

is central to the theoretical development of the subject. Conditions in Eqs. (1)–(5) show that $(\hat{x}, \hat{\mu}, \hat{\omega})$ is a critical point of $\mathcal{L}(x, \mu, \omega)$ with respect to x and ω and satisfies

$$\frac{\partial \mathcal{L}}{\partial \mu_i}(\hat{x}, \hat{\mu}, \hat{\omega}) = g_i(\hat{x}) \leq 0.$$

The second-order conditions for NLP are given in theorems 3 and 4. In these theorems, $I(x)$ will represent the index set of active inequality constraints at x; that is,

$$I(x) = \{i : g_i(x) = 0\}.$$

Theorem 3 (Second-Order Necessary Conditions): Let $\hat{x}$ satisfy the conditions of Theorem 1 with corresponding multipliers $\hat{\mu}$ and $\hat{\omega}$. If $\hat{x}$ is a local minimum then for any vector z satisfying

$$\nabla g_i(\hat{x})^t z = 0, \quad i \in I(\hat{x}),$$
$$\nabla h_j(\hat{x})^t z = 0, \quad j = 1, \ldots, P,$$

it is the case that

$$z^t H_{xx} \mathcal{L}(\hat{x}, \hat{\mu}, \hat{\omega}) z \geq 0$$

where $H_{xx}\mathcal{L}(\hat{x}, \hat{\mu}, \hat{\omega})$ is the $N \times N$ Hessian matrix of $\mathcal{L}$ with respect to x.

The second-order necessary condition requires the Hessian of the Lagrangian to be positive semidefinite on the tangent subspace to the feasible set at $\hat{x}$. In a manner analogous to that of the unconstrained case, a second-order sufficiency condition can be obtained by the more stringent requirement that the Hessian of $\mathcal{L}$ be positive definite on this subspace.

Theorem 4 (Second-Order Sufficiency Conditions): Let $\hat{x}$, $\hat{\mu}$, and $\hat{\omega}$ satisfy conditions in Eqs. (1)–(5) of theorem 1 and suppose that for $i \in I(\hat{x})$, $\hat{\mu}_i > 0$. Further, suppose that for every nonzero z satisfying

$$\nabla g_i(\hat{x})^t z = 0, \quad i \in I(\hat{x}),$$
$$\nabla h_j(\hat{x})^t z = 0, \quad j = 1, \ldots, P,$$

it is the case that

$$z^t H_{xx} \mathcal{L}(\hat{x}, \hat{\mu}, \hat{\omega}) z > 0.$$

Then $\hat{z}$ is an isolated local minimum of NLP.

$\hat{x}$ is an isolated local minimum if there is a neighborhood of $\hat{x}$ that contains no other local solution of NLP. There are other slightly weaker versions of the second-order sufficient conditions that do not require that $i \in I(\hat{x})$ implies $\hat{\mu}_i > 0$. However, this restriction, called strict complementary slackness, is required in many important theoretical applications, including those of the next section. For twice differentiable functions it is the case that they are convex if and only if their Hessian matrices are positive semidefinite. Thus for convex programs, the Hessian of the Lagrangian is positive semidefinite and the second-order conditions are redundant, as is to be expected in light of theorem 2.

D. Stability and Duality

As stated earlier, the stability of the optimal solution and its optimal value are of major importance in applications of nonlinear programming models. Fortunately, the optimal solution and its optimal value are stable under reasonable conditions. To formally state this result, it is necessary to consider the perturbed version of NLP,

$$\begin{array}{ll} \text{minimize} & \hat{f}(x, p) \\ \text{subject to:} & \hat{g}_i(x, p) \leq 0, \quad i = 1, \ldots, M, \\ & \hat{h}_j(x, p) = 0, \quad j = 1, \ldots P, \end{array}$$

where p is a Q-vector, $\hat{f}(x, 0) = f(x)$, $\hat{g}_i(x, 0) = g_i(x)$, and $\hat{h}_j(x, 0) = h_j(x)$. Furthermore, it is assumed that

$\hat{f}, \hat{g}_i$, and $\hat{h}_j$ are continuously differentiable functions of p near $p=0$. The vector p represents the parameters of the problem. The following theorem gives conditions under which the optimal solution and multipliers are smooth functions of the perturbation.

To state the theorem, we define a *regular solution* of NLP to be a solution at which the linear independence of the active constraint gradients, strict complementary slackness, and the second-order sufficient conditions a11 hold.

Theorem 5 (Basic Perturbation Theorem): Let x^* be a regular optimal solution to NLP with multipliers μ^* and ω^*. Let $I(x^*)$ be the index set of active constraints at x^*. Then there is an $\epsilon > 0$ and functions $x^*(p), \mu^*(p), \omega^*(p)$ defined and continuously differentiable on the set $E = \{p : |p| \leq \epsilon\}$ with $x^*(0) = x^*$, $\mu^*(0) = \mu^*$, and $\omega^*(0) = \omega^*$. $x^*(p)$ is a local optimal solution to the corresponding perturbed problem and $\mu^*(p)$ and $\omega^*(p)$ are its multipliers. Moreover, the second-order sufficient conditions hold at $x^*(p)$ and $I(x^*(p)) = I(x^*)$.

One of the most important cases of perturbation occurs when p is an M-vector and $\hat{g}_i(x, p) = g_i(x) - p_i$. Under the assumptions of theorem 5, the optimal solution as a function of p, $x^*(p)$, is smooth and it can be shown that the optimal value as a function of p, $v^*(p) = f(x^*(p))$, satisfies.

$$\nabla_p v^*(0) = -\mu^*.$$

In other words, the instantaneous rate of change in the optimal value as a function of a shift in the value of g_i is the negative of the i^{th} multiplier. This gives an interpretation of the multiplier in terms of the model. For example, if the i^{th} constraint is a bound on a resource and the objective is measured in dollars, the value of additional units of that resource in terms of decreased optimal value is linearly approximated as μ_i^* dollars per unit. A similar result holds for pertubations of the equality constraints. As a result of this interpretation, the optimal multipliers are often called *shadow prices*.

The preceding observations on the properties of the multipliers lead, in linear programming, to the formulation of a *dual* linear program with the multipliers as the optimal solution. Similar, but much less complete results can be obtained for nonlinear programs. The appropriate formulation involves the Lagrangian function defined earlier. It can be shown that NLP is equivalent to the min-max problem

$$\min_x \max_{\mu \geq 0, \omega} \mathcal{L}(x, \mu, \omega).$$

The *dual problem* can then be defined as the max-min problem

$$\max_{\mu \geq 0, \omega} \min_x \mathcal{L}(x, \mu, \omega).$$

If the program is convex and the Slater condition holds then x^* is an optimal solution to NLP with multipliers μ^* and ω^* if and only if (x^*, μ^*, ω^*) is a saddle point for $\mathcal{L}(x, \mu, \omega)$ that is,

$$\mathcal{L}(x^*, \mu, \omega) \leq \mathcal{L}(x^*, \mu^*, \omega^*) \leq \mathcal{L}(x, \mu^*, \omega^*)$$

for all x, $\mu \geq 0$, and ω. Thus the values of the primal and dual problems are equal at optimality. This result fails to hold under less restrictive hypotheses on the problem NLP.

III. COMPUTATION

A. Basic Concepts

Finding a numerical approximation to the solution of a nonlinear program can be a difficult task. If the number of variables is large or the functions involved are highly nonlinear, the computation can be time consuming, even on the fastest computers. Moreover, in the case of nonconvex programs, the presence of local solutions can make the determination of a global solution problematic. The methods and procedures described as follows are concerned with approximating local solutions only.

The algorithms for approximating the solutions of NLP are all iterative in nature; that is, given an initial estimate of the solution, x^0, a sequence $\{x^k\}$ of approximate solutions is generated with each iterate, x^k, being determined successively from information gathered at the preceding iterations. It is desired that at each iteration, the new iterate is a better approximation, in some sense, of a local solution than the previous ones. In theory, the iterations should converge to a local solution, say x^*. In most algorithms approximations to the optimal multipliers, (μ^k, ω^k), are computed along with x^k at each iteration and the algorithms terminate when the approximate solutions and multipliers satisfy the first-order necessary conditions to some predetermined degree of accuracy.

In constrained optimization, in addition to minimizing f, the optimal solution must also satisfy the feasibility requirements. It is possible (even probable when there are nonlinear equality constraints) that an iterate will not be feasible. Ideally, an algorithm should be designed in such a way that, given a current iterate x^k, the new iterate x^{k+1} will be no more infeasible than x^k and will also satisfy $f(x^{k+1}) \leq f(x^k)$. Unfortunately, this is not always possible and therefore, a successful algorithm should balance the goals of feasibility and decreasing f. In the algorithms described in this article, the iterates are of the form

$$x^{k+1} = x^k + \alpha_k d^k,$$

where the vector d^k gives the direction in which a "step" is taken and and the scalar α_k, called the *step length parameter*, determines how far in this direction the next iterate lies. Another approach, called a *trust region method* can also be employed to determine the step from x^k to x^{k+1}; a reference to these methods can be found in the Bibliography.

In judging the effectiveness of an algorithm, there are three major criteria: (1) robustness, (2) rate of convergence, and (3) efficiency. The first two terms deal with theoretical issues. The term "robustness" refers to the likelihood that the algorithm will yield a sequence of iterates that converge, in theory, to a local solution regardless of the starting point x^0, whereas "rate of convergence" refers to the speed with which the iterates converge, for example, how fast the theoretical error terms, $|x^k - x^*|$, tend to zero. Finally, the "effectiveness" is concerned with practical considerations in implementing the algorithm; it includes such problems as computer time and storage requirements and numerical stability. The descriptions that follow discuss only the first two of these criteria because the third is very dependent on the particular platform and software used.

B. Unconstrained Optimization Algorithms

Any description of algorithms for solving NLP must begin with the computational algorithms for unconstrained optimization problems because the latter are fundamental to the design of the former. The algorithms for unconstrained problems are much less complex because there is no question of feasibility that must be taken into account in the choice of step direction and length. There are two basic approaches to solving the unconstrained problem to be discussed here: the basic descent method and variants of Newton's method. The former emphasizes decreasing f while the latter attempts to solve the necessary conditions, $\nabla f(x) = 0$. Each is discussed briefly as are hybridizations of the two approaches that attempt to incorporate their best properties.

For the descent method, the choice of the step direction is a direction d^k satisfying

$$\nabla f(x^k)^t d^k < 0. \tag{6}$$

Movement in this direction, called a *descent direction* will, for at least for a short distance, decrease f, and hence α_k can be chosen so that

$$f(x^{k+1}) = f\left(x^k + \alpha_k d^k\right) < f(x^k).$$

The specific choice $d^k = -\nabla f(x^k)$, gives the direction of greatest local rate of decrease in f and leads to the *steepest descent* method. In practice, α_k is chosen so as to minimize a polynomial approximation to $\phi(\alpha) = f(x^k + \alpha d^k)$ subject to the need to reduce the value of f. Under fairly reasonable conditions, these descent methods yield a convergent sequence of iterates and the limit point satisfies the equation $\nabla f(x^*) = 0$. These methods are fairly robust; their convergence not depending on the initial iterate x^0. However, the convergence rate of these descent methods is typically very slow and, consequently, they are ill-suited for general use.

The second general method is that of Newton's method and its modifications. The pure Newton method determines the step, d^k, for solving $\nabla f(x) = 0$ by

$$d^k = -[Hf(x^k)]^{-1} \nabla f(x^k),$$

where $Hf(x^k)$ is the Hessian matrix of f at x^k, and requires $\alpha_k = 1$. It is well known that if the initial iterate x^0 is sufficiently close to a local solution x^* at which the gradient $\nabla f(x^k)$ is nonzero, the iterates will converge to x^* very rapidly. In particular, they will converge at a quadratic rate, which roughly means that the number of decimal places of accuracy is doubled at each step. The biggest drawback to the use of Newton's method is its lack of robustness. Unless the vector x^0 is close to a local solution, these iterates may fail to converge or else converge to a nonminimum point.

There are a number of methods designed to obtain both the robustness of descent methods and the rapid local convergence of Newton's method. If f is a convex function, its Hessian matrix is positive definite and the Newton step is then also a descent step. Applied with a line search to determine α_k, this approach, called a *damped Newton method*, can both be robust and yield rapid local convergence. For nonconvex problems a standard approach for obtaining robustness without sacrificing rapid convergence is to use a *quasi-Newton* or *secant* method. In this type of algorithm, the Hessian matrix, $Hf(x^k)$ is approximated by a *positive definite* matrix, B_k, and the step direction is given by

$$d^k = -[B_k]^{-1} \nabla f(x^k).$$

Because B_k is positive definite, the direction d_k is a descent direction [satisfies Eq. (6)] and a line search procedure can be used to determine α_k. Because it is a descent method, this algorithm will be robust and if the B_k are relatively good approximations to the Hessians of f, the convergence rate should be close to that of Newton's method. The class of matrices that satisfy the generalized secant condition

$$B_{k+1}(x^{k+1} - x^k) = \nabla f(x^{k+1}) - \nabla f(x^k) \tag{7}$$

provide good approximations to the Hessian of f at x^{k+1}. These approximations are implemented in an algorithm by an "updating formula" of the form

$$B_{k+1} = B_k + E_k,$$

where E_k is a low rank matrix chosen so that the matrix B_{k+1} is positive definite and Eq. (7) holds. It has been shown, under relatively mild restrictions, that the descent method using appropriate secant updates will be robust and converge at a rate approaching that of Newton's method. Most modern unconstrained optimization algorithms now utilize a version of this procedure. The references on unconstrained optimization contain details for these methods.

C. Penalty and Barrier Functions

An early approach to solving NLP was to attempt to convert the constrained problem into a constrained one by incorporating the constraints into the objective function. There are basically two types of methods included in this approach: penalty methods and barrier methods. The two cases are considered separately.

Penalty methods, as the name suggests, incorporate the constraints into the objective function in such a way that infeasibility is penalized. The most common method replaces NLP by the problem of minimizing

$$P(x;\rho) = f(x) + \rho(\|h(x)\| + \|g^+(x)\|) \qquad (8)$$

where

$$g_i^+(x) = \begin{cases} 0 & \text{if } g_i(x) \le 0, \\ g_i(x) & \text{else,} \end{cases}$$

and $\|\cdot\|$ represents any norm. $\rho > 0$ is a parameter that plays a major role in the algorithm. Given a value of the parameter ρ, the minimization of P will take into consideration values of x that are infeasible but will penalize them proportionally to their "distance" from feasibility, as measured by $h(x)$ and $g^+(x)$, and to the value of ρ. If a sequence $\rho_k \to \infty$ is chosen and $x(\rho_k)$ is an unconstrained minimum of $P(x;\rho_k)$ with $x(\rho_k) \to \hat{\mathbf{x}}$, it can be shown that $\hat{\mathbf{x}}$ is a local minimum of NLP. This observation forms the basis for an algorithm for solving NLP in which x^k is taken as an approximation to $x(\rho_k)$ and is used as the starting point for minimizing $P(x, \rho_{k+1})$.

The choice of norm to be used in the definition of P is important. From an ease of computation standpoint, the Euclidean norm is the most convenient. However, the L_1 norm,

$$\|z\| = \sum_i |z_i|,$$

provides an important theoretical advantage. Although the use of the L_1 norm forces $P(x;\rho)$ to be nondifferentiable on the boundary of the feasible region, it can be shown that the following property holds.

Theorem 6: There exists a $\rho^* > 0$ such that for all $\rho > \rho^*$, an unconstrained minimum of the L_1 penalty function is an optimal solution for NLP, and conversely.

A penalty function that has the property described in this theorem is called an *exact* penalty function. This type of penalty function is important because it obviates the use of limiting processes to obtain a solution to NLP. This is not the panacea that it appears, however, because exact penalty functions are typically so complicated that they do not readily lend themselves to computational procedures; their application is less efficient than applying other techniques for solving NLP. For example, the nondifferentiability of the L_1 penalty function precludes using the gradient descent methods described above. However, the L_1 penalty function does have a use as a "merit function" in other optimization algorithms for solving NLP; as is described as follows.

Barrier methods are applied primarily to inequality-constrained problems. In particular, they are applicable when the feasible region is known to have a strictly feasible point x^0, that is, a point that satisfies $g(x^0) < 0$. The most common barrier function is the so-called *logarithmic barrier function*,

$$B(x;\rho) = f(x) - \rho \sum_{j=1}^{p} \log(-g_j(x)), \qquad (9)$$

where ρ is again a positive parameter. Another type of barrier function is the inverse barrier function,

$$V(x;\rho) = f(x) + \rho \sum_{j=1}^{p} 1/(-g_j(x)).$$

An optimization procedure for minimizing $B(x, \rho)$ for fixed positive ρ started at x^0 cannot reach the boundary of X because the log term approaches $+\infty$ as the boundary is neared; that is, the boundary defines a barrier that the optimization procedure cannot cross. As ρ gets smaller, the penalty for approaching the boundary gets smaller, so if $x(\rho k)$ represents any set of minima of $B(x;\rho_k)$ corresponding to a sequence $\rho_k \to 0$ then a limit point $\hat{\mathbf{x}}$ must be an optimal solution of NLP. There is no exact barrier function because, if the solution to NLP is on the boundary of X, it can only be reached in the limit. Nevertheless, barrier functions have also found applications to solving NLP in the guise of the interior point methods that are described as follows.

D. The Sequential Quadratic Programming Algorithm

At one time, it was common to generate approximations to the solution of NLP by linearly approximating the objective function and the constraints at a current iterate

and to use this information to generate the next iterate. These methods, as typified by the gradient projection and reduced gradient algorithms, are comparable to the descent method described for unconstrained optimization and hence are not competitive for the more complicated nonlinear constrained problems.

A more general approach that uses higher order information and has been shown to be particularly effective is the *sequential quadratic programming* algorithm. In this type of algorithm an approximation to NLP is constructed in which the constraints are approximated linearly and a quadratic approximation to the Lagrangian function is employed as an objective function. Specifically, if x^k is a current iterate for NLP, not necessarily feasible, with corresponding multiplier approximations μ^k and ω^k the following quadratic programming problem results:

$$\begin{aligned} \text{minimize} \quad & \tfrac{1}{2} d^t B_k d + \nabla_x \mathcal{L}(x^k, \mu^k, \omega^k)^t d \\ \text{subject to:} \quad & \nabla g_i(x^k)^t d + g_i(x^k) \le 0, \quad i = 1, \ldots, M, \\ & \nabla h_j(x^k)^t d + h_j(x^k) = 0, \quad j = 1, \ldots, P, \end{aligned}$$

where B_k is the Hessian to the Lagrangian with respect to x at (x^k, μ^k, ω^k), $H_{xx}\mathcal{L}(x^k, \mu^k, \omega^k)$, or an approximation thereof. If this problem is solved to obtain a solution d^k with associated multipliers y^k and z^k, then the new iterate for NLP is given by

$$x^{k+1} = x^k + \alpha_k d^k,$$

for an appropriate choice of step length α_k. Updates for the multipliers are given by

$$\mu^{k+1} = y^k \quad \text{and} \quad \omega^{k+1} = z^k.$$

The use of the Lagrangian in the objective function permits quadratic effects in the constraints to have an effect on the iteration.

As a justification for this approach, it can be seen that if the true Hessian of the Lagrangian is used in a problem with equality constraints only, then the iterate (x^{k+1}, ω^{k+1}) is identical to that obtained by using the Newton step to find a solution of the first-order conditions of NLP:

$$\begin{aligned} \nabla f(x) + \sum_{j=1}^{P} h_j(x)\omega_j &= 0 \\ h(x) &= 0, \end{aligned}$$

starting at (x^k, ω^k). A similar result holds for the case when inequality constraints are present. Thus, depending on the choice of the step length parameter, this method will yield convergence at a rate similar to that of Newton's method when started near a solution.

In the actual implementations of the algorithm, the matrices $\{B_k\}$ are often a quasi-Newton approximations just as in the algorithms for unconstrained optimization; that is, they satisfy the conditions:

$$\begin{aligned} B_{k+1}(x^{k+1} - x^k) = \nabla_x \mathcal{L}(x^{k+1}, \mu^{k+1}, \omega^{k+1}) \\ - \nabla_x \mathcal{L}(x^k, \mu^{k+1}, \omega^{k+1}). \end{aligned}$$

These matrices are updated by a rank-two matrix at each iteration and are usually chosen to be positive definite. Since the true Hessian is not positive definite except on a subspace of $\Re^N$ (see theorem 4), the use of positive definite quasi-Newton approximations will usually lead to a slower rate of convergence. Another aspect of this algorithm that requires careful implementation is the determination of the step length parameter α_k. In unconstrained optimization, the parameter is chosen so that the objective function is decreased at each step. As was described in the first section of this article, in constrained optimization there is also the requirement of achieving feasibility, or at least decreasing infeasibility. At any step this may be inconsistent with decreasing the objective function and therefore it is not clear how the choice of α_k should be made. This is where the *merit function*, mentioned in the preceding section, comes into play. In the sequential quadratic programming method, a decrease in a merit function is used to determine the step length parameter for a given iterate. The choice of merit function depends upon the particular version of the algorithm but is usually taken to be one of the standard penalty functions. For example, if the L_1 penalty function is used then at a given step, then α_k is chosen so that

$$P\left(x^k + \alpha_k d^k; \rho\right) < P(x^k, \rho).$$

Because P is decreased at each step and for large ρ a minimum of P is a minimum of NLP, this choice of α_k is justified. However, the value of ρ must generally be adjusted in the algorithm to assure that this property holds.

In spite of the complications involved in its implementation, versions of the sequential quadratic programming algorithm are considered the most effective general purpose algorithms currently available for solving the NLP.

E. Interior Point Methods

Recently, there have been developments in algorithms for NLP that involve generalizing the interior point algorithms that have been so successful in linear programming. In one approach to interior point methods, the inequality constraints are incorporated into the objective function by the use of a barrier function. A similar formulation results from considering the Newton steps for solving a perturbed

form of the first order conditions. A basic version of the latter development for the case where there are only inequality constraints is given here; more examples of the method can be found in the Bibliography.

The first order system to be solved in this method is the system of equations derived from Eqs. (1)–(5), in which a slack variable z has been added to covert the inequalities to equalities:

$$\begin{aligned} \nabla f(x) + \sum_{i=1}^{M} g_i(x)\mu_i &= 0, \\ g(x) + z &= 0, \\ g_i(x) \cdot z_i &= \beta, \quad i = 1, \ldots, M, \\ z &\geq 0, \\ \mu &\geq 0. \end{aligned}$$

This system is perturbed because the complementary slackness conditions are not satisfied at the zero level but at the β level for some $\beta > 0$. As in barrier function methods, it is assumed that there is a family of solutions $(x(\beta), z(\beta), \mu(\beta))$ to this set of equations. Under certain assumptions (usually convexity of the f and g_i functions), this set of solutions defines a curve called the *central path* that tends to a solution of NLP as $\beta \to 0$. The idea here is to use Newton steps to solve this system while decreasing β towards zero. Given a current iterate, (x^k, z^k, μ^k) with $z^k > 0$ and $\mu^k > 0$, the set of equations becomes

$$\begin{bmatrix} H_{xx}\mathcal{L}(x^k, \mu^k) & Jg(x^k)^t & 0 \\ Jg(x^k) & 0 & I \\ 0 & Z_k & U_k \end{bmatrix} \begin{bmatrix} dx \\ du \\ dz \end{bmatrix} = \begin{bmatrix} -\nabla_x \mathcal{L}(x^k, \mu^k) \\ -g(x^k) - z^k \\ \beta e - Z_k \mu^k \end{bmatrix},$$

where $Jg(x^k)$ is the Jacobian of the vector function g, Z_k and U_k are the diagonal matrices with diagonals that are z^k and μ^k, e is the vector of ones, and $\mathcal{L}$ is the Lagrangian function. The iterates are now updated by the formulas:

$$\begin{aligned} x^{k+1} &= x^k + \alpha_k\, dx, \\ z^{k+1} &= z^k + \alpha_k\, dz, \\ \mu^{k+1} &= \mu^k + \alpha_k\, du, \end{aligned}$$

where α_k is chosen to maintain the slack variables and multiplier variables as positive and to decrease an appropriate merit function. The key issue in an implementation of this algorithm is how progress toward the point on the central path corresponding to β is mixed with decrease of β. As in the the case of sequential quadratic programming, an approximation of the Hessian of the Lagrangian can be used.

IV. APPLICATIONS

A. Nonlinear Models

The description of actual nonlinear optimization models is hindered by the fact that the nonlinearities that occur in the model are usually due to technical theoretical concepts special to the particular field and hence are not easily explained to the nonspecialist. In other cases the objective or constraint functions may have little or no theoretical basis but be nonlinear functions that have been fit to historical data. Linear optimization models in production, blending, and network problems are discussed under the topic of linear programming. Many nonlinear programming models are generalizations of these linear problems in which a more accurate simulation of reality is obtained by allowing nonlinearities in the objective and constraint functions.

In models for which the objective or constraint function is a cost function, nonlinearities very often occur when economies of scale are present (i.e., when the per unit cost of a particular item decreases as the amount purchased or produced increases). In blending problems, a particular quality of the blend, for instance, the octane rating of gasoline, is a nonlinear function of the components of the mixture. In network flow problems, nonlinearities may represent increasing per unit cost of shipment as a function of the flow from node to node. Another type of nonlinearity results from the modeling of a learning process in production models; that is, the efficiency of production increases as production rises.

B. Statistical Applications

One of the most important uses of nonlinear programming is in the estimation of the parameters for a statistical distribution using the observed data. This is called maximum likelihood estimation. A related problem is the familiar regression problem in which parameters, say $\theta_i, i = 1, \ldots, N$, are estimated so that a particular nonlinear function $w(\theta)$ "best" fits a set of observed data; that is, given values of a control variable $z^k, k = 1, \ldots, L$, and a sequence of corresponding experimental responses $y^k, k = 1, \ldots, L$, values of θ are determined so that some measure of the difference vector $e \in \Re^L$, with

$$e_k = y^k - w(\theta, z^k), \quad k = 1, \ldots, L,$$

is minimized.

The most common measure is the Eucclidean norm of e, in which case, the optimization problem is

$$\begin{aligned} \sup \quad & \sum_{k=1}^{L} [y^k - w(\theta, z^k)]^2 \\ \text{subject to:} \quad & \theta \in \Theta, \end{aligned}$$

which is the so-called least squares pregression problem. Here Θ is the feasible set, which expresses any relations or restriction on the parameters. This problem, expecially for the case in which $\Theta = \Re^L$, has been exhaustively studied and many software packages are now available containing algorithms that compute a solution in an efficient manner.

C. Discretization of Infinite-Dimensional Problems

The increase in available computer power has allowed the use of finite-dimensional nonlinear programming techniques to be applied to solve discretized infinite-dimensional optimization problems. Problems generated in this manner are typically of very large dimension and often have special structure. The limiting behavior of the optimal solutions as the number of variables increases is of significance in this type of problem.

As an illustration of this problem, the simple optimal control problem of minimizing an energy function for a prescribed trajectory is formulated as follows.

$$\begin{aligned} \text{minimize} \quad & \int_a^b E(u(t))\,dt \\ \text{subject to:} \quad & dy(t)/dt = w(y(t), u(t)), \\ & y(a) = y_a, \\ & y(b) = y_b, \\ & |u(t)| \le 1, \end{aligned}$$

where a, b, y_a, and y_b are given scalars, and E and w are given real-valued functions. The object is to choose the control function $u(t)$ that solves the problem. To discretize this problem, $[a, b]$ is first partitioned so that

$$a = t_0 < t_1 < t_2 < \cdots < t_N = b.$$

Then, the following finite-dimensional nonlinear program approximates the optimal control problem.

$$\begin{aligned} \text{minimize} \quad & \sum_{j=1}^{N} E(u_j)(t_j - t_{j-1}) \\ \text{subject to:} \quad & y(t_j) - y(t_{j-1}) = (t_j - t_{j-1}) w(y(t_{j-1}), u_j), \\ & \qquad\qquad\qquad\qquad\qquad\qquad j = 1, \ldots, N, \\ & y(t_0) = y_a, \\ & y(t_N) = y_b, \\ & |u_j| \le 1, \quad j = 1, \ldots, N. \end{aligned}$$

The control $u(t)$ is approximated in this model by the piecewise constant function

$$\hat{u}(t) = u_j, \quad \text{for } t_{j-1} \le t < t_j.$$

In theory the approximation should improve as N gets large. Unfortunately, the number of variables and constraints in the nonlinear program increases and the problem becomes more difficult to solve. Problems of this type with tens of thousands of variables are not uncommon.

GLOSSARY

Congruence If $a, b, m \in \mathbb{Z}$ and $m > 0$ then $a \equiv b \pmod{m}$ stands for m divides $b - a$; written as "a is congruent to b modulo m."

Divisibility If $a, b \in \mathbb{Z}$, we write $b \mid a$ when b divides a exactly.

Equivalence relation A relation $\simeq$ on a set S that satisfies, for all $a, b, c \in S$, $a \simeq a$, if $a \simeq b$ then $b \simeq a$, and if $a \simeq b$ and $b \simeq c$ then $a \simeq c$. The congruence defined above is an example. The subset $\{x : x \simeq a\}$ of the set S, where a is a fixed member of S, is called an *equivalence class*. The relation $\simeq$ splits S into a disjoint union of such classes.

Greatest common divisor If $a, b \in \mathbb{Z}$, not both zero, then (a, b) denotes the largest integer that divides both a and b. It exists, as $\mathbb{Z}$ has unique factorization.

Integer Member of the set $\{\ldots -2, -1, 0, 1, 2, 3, \ldots\}$. To distinguish from other sets defined later we often use the term *rational integer* instead of integer. $\mathbb{Z}$ denotes the set of all integers with the usual operations and rules of addition, subtraction, and multiplication. It is an integral domain.

Order $\bigcirc, \sim$**:** $f(x) = \bigcirc(g(x))$, f has order g, stands for $\lim_{x\to\infty} |f(x)|/g(x)$ is bounded as $x \to \infty$, and $f(x) \sim g(x)$ stands for $\lim_{x\to\infty} f(x)/g(x) = 1$.

Polynomial An expression of the form $a_0x^n + a_1x^{n-1} + \cdots + a_n$ where each a_i is a constant in the underlying ring or field and x is a variable; n is called the *degree* of the polynomial. Polynomials in two or more variables are defined similarly. A polynomial is called *irreducible* if it cannot be written as a product of polynomials of smaller degree. Finally a polynomial is called *homogeneous* if each of its summands has the same degree; for example, $x^4 + 3xy^3 - xyzt$ is homogeneous of degree 4.

Prime number p is a prime if $p \in \mathbb{Z}$, $p > 1$, and if $a > 0$ and a divides p then $a = 1$ or $a = p$.

Rational function A real function of the form F/G where F and G are polynomials.

Rational number A number of the form a/b where $a, b \in \mathbb{Z}$, $(a, b) = 1$, and $b \neq 0$. $\mathbb{Q}$ denotes the set of all rational numbers with the usual operations and rules of addition, subtraction, multiplication, and division. It is a field.

Unique factorization Every element in $\mathbb{Z}$ can be represented uniquely as a product of primes. An integral domain with this property (using irreducible elements rather than primes) is called a *unique factorization domain*.

THE CENTRAL CONCERNS of number theory are the properties of the integers and rational numbers. Questions relating to individual real or complex numbers, integer matrices, algebraic number fields, points on curves, lattice points in convex regions, and similar entities are also considered. The subject has a very long history, as long as mathematics itself, and is as actively researched today as at any time in the past.

Number theory is not an organized theory in the usual sense but is a vast collection of individual topics and results, with some coherent subtheories and a long list of unsolved problems. Some of these topics are highly specialized, for example, giving a single solution to a Diophantine equation, whereas others have wide applicability, the Euclidean algorithm being an example. Methods range over virtually all mathematical disciplines, although group and field theory, linear algebra, and both real and complex analysis are the most commonly used. Problems and results are studied entirely for their own sake; the fact that many theorems are useful elsewhere is incidental.

In this article we shall treat a few of the more important topics not considered in the previous article. For each of these topics major results have been established recently, and this progress is likely to continue in the future.

The reader is referred to the article quoted above for an account of the history of the subject and the basic definitions and results concerning the properties of the integers—in particular, the fundamental theorem of arithmetic, prime numbers, greatest common divisors, and congruences. The fundamental theorem states that every integer $n > 1$ can be expressed uniquely (except for the order of the factors) as a product of prime numbers. The greatest common divisor of two integers a and b is denoted by (a, b); it can be found using the Euclidean algorithm. The basic results of congruence theory concern the conditions for the solution of linear and quadratic congruences and include the law of quadratic reciprocity of C. F. Gauss (1777–1855).

I. ALGEBRAIC NUMBER FIELDS

Algebraic numbers and integers are generalizations of rational numbers and integers, and algebraic number fields are extensions of the rational field $\mathbb{Q}$. In both cases many properties are preserved in the new situations, but not all; for example, unique factorization is often lost. Although these new notions are important in their own right, they are also important because many problems concerning the rational numbers are best treated in this more general context. For example, to show that one of Fermat's equations (see Section II.A.5) has no rational solutions we work in an algebraic extension of $\mathbb{Q}$ in which the left-hand side of the equation can be factorized into linear factors. We shall define these new notions now and discuss their relationship to the rational case.

Definition: A complex number α is called an *algebraic number* if rational numbers $c_1, \ldots, c_n$ can be found to satisfy the polynomial equation

$$\alpha^n + c_1\alpha^{n-1} + \cdots + c_n = 0.$$

The positive integer n is called the *degree* of α provided that α does not satisfy another polynomial equation whose degree is less than n. If each c_i $(i = 1, \ldots, n)$ is a rational integer (i.e., each $c_i \in \mathbb{Z}$) then α is called an *algebraic integer*.

For example, the complex numbers $2/3$, $(2 + i)/3$, and $2^{1/3}$ are algebric numbers, and 5, $\sqrt{-5}$, and $(1 + \sqrt{5})/2$ are algebraic integers. (Note that the last number is an algebraic integer because it satisfies the equation $x^2 - x - 1 = 0$). The nonalgebraic numbers, that is the transcendental numbers, are discussed in Section IV.

The algebraic number fields are defined as follows. Let α be an algebraic number of degree n, and let $\mathbb{Q}(\alpha)$ denote the set of all complex numbers of the form

$$b_0 + b_1\alpha + \cdots + b_{n-1}\alpha^{n-1},$$

where each $b_i \in \mathbb{Q}$. It can be shown that this set is closed under the usual operations of complex addition, subtraction, multiplication, and division and so is a field. It is called an *algebraic number field of degree n* over $\mathbb{Q}$ and its algebraic structure is similar to that of $\mathbb{Q}$ itself.

Given a field $K = \mathbb{Q}(\alpha)$, let O_K denote the set of algebraic integers in K. This set is closed under sums and products and so is an integral domain called the *ring of integers* in K. If α is an algebraic integer, we also define the set $\mathbb{Z}[\alpha]$ to be the collection of all expressions $g(\alpha)$ where g is a polynomial with rational integer

coefficients. Each element of $\mathbb{Z}[\alpha]$ is an algebraic integer, and so $\mathbb{Z}[\alpha] \subseteq O_K$. Note that this inclusion can be strict. For example if $\alpha = \sqrt{5}$ then $\mathbb{Z}[\alpha] = \{a + b\sqrt{5}: a, b \in \mathbb{Z}\}$, but as noted above, the number $(1 + \sqrt{5})/2$ is an algebraic integer; hence it belongs to the ring of integers of the field $\mathbb{Q}(\sqrt{5})$ but not to the domain $\mathbb{Z}[\sqrt{5}]$.

It can be shown that for each algebraic number field $K = \mathbb{Q}(\alpha)$ of degree n its ring of integers O_K has a $\mathbb{Z}$-basis $\{\gamma_1, \ldots, \gamma_n\}$. That is, algebraic integers $\gamma_1, \ldots, \gamma_n$ can be found so that each integer in O_K can be expressed in the form $c_1\gamma_1 + \cdots + c_n\gamma_n$ where $c_i \in \mathbb{Z}$, $i = 1, \ldots, n$. In the example above, the $\mathbb{Z}$-basis for O_K, where $K = \mathbb{Q}(\sqrt{5})$, is $\{1, (1 + \sqrt{5})/2\}$.

A "number theory" has been developed for these rings of integers O_K; it is similar to that for the rational case, but two main aspects are different—units and factorization. A *unit* ε in an algebraic number field K is an algebraic integer that divides 1 (that is, $\varepsilon\varepsilon' = 1$ for some $\varepsilon' \in O_K$).

In $\mathbb{Q}$ the only units are 1 and -1, but most algebraic number fields contain infinitely many units. For example, the units of the field $\mathbb{Q}(\sqrt{2})$ are $(3 + 2\sqrt{2})^m$ for each $m \in \mathbb{Z}$.

An irreducible element, which is the generalization of the notion of a prime number in $\mathbb{Z}$, is defined as follows: ξ is *irreducible* (over K) if $\xi \in O_K$, ξ is not a unit of zero, and whenever we have $\xi = \beta\gamma$, and β and γ belong to O_K, then either β or γ is a unit. Clearly, each member of O_K can be written as a product of a unit and a number of irreducible elements; but in many cases this representation is not unique, that is, K does not have unique factorization. For example, If $K = \mathbb{Q}(\sqrt{10})$, we have

$$39 = 3 \times 13 = (7 + \sqrt{10})(7 - \sqrt{10}),$$

and $3, 13, 7 + \sqrt{10}$, and $7 - \sqrt{10}$ are all irreducible elements in this field. It is an open problem to list all algebraic number fields that have unique factorization. One important case has been settled recently; that is the imaginary quadratic fields $\mathbb{Q}(\sqrt{n})$ where n is a negative integer. The only fields in this class that have unique factorization are those where $n = -1, -2, -3, -7, -11, -19, -43, -67$, and -163 (see Section IV).

The lack of unique factorization in many number fields is a severe drawback; it can be partially retrieved by introducing ideals into the theory. Let K be an algebraic number field with ring of integers O_K. An *ideal* I is a nonempty subset of O_K with the properties: if $a, b \in I$ then $a - b \in I$, and if $a \in I$ and $c \in O_K$ then $ac \in I$. Further, if I and J are ideals we define the product ideal IJ to be the set of all finite sums $\Sigma_{a_i b_j}$, where $a_i \in I$ and $b_j \in J$. Also I is called a *prime ideal* when $I \neq O_K$; and if J_1 and J_2 are ideals with $J_1 J_2 \subseteq I$ then either $J_1 = I$ or $J_2 = I$. It can be shown that each ideal I where $I \neq O_K$ (O_K acts as the identity ideal) can be represented *uniquely* in the form $I = P_1 \ldots P_n$ where each P_i is a prime ideal.

There is a close connection between the arithmetic of O_K and the arithmetic of these ideals. This is illustrated by the following important result. An ideal I is called *principal* if $I = \{at: a \in O_K\} = \langle t \rangle$ for some fixed $t \in O_K$; t is called the *generator* (of I) in O_K. We have O_K is a unique factorization domain if and only if each ideal in O_K is principal. To illustrate this theory we shall consider two examples.

(a) Let $K = \mathbb{Q}(i)$ where $i = \sqrt{-1}$. In this case the ring of integers $O_K = \{a + bi: a, b \in \mathbb{Z}\}$; it is known as the set of *Gaussian integers*. This is a unique factorization domain and so all ideals are principal. For instances the ideal $\langle 2, 3 + 3i \rangle = \{2a + (3 + 3i)b: a, b \in O_K\}$ equals the principal ideal $\langle 1 + i \rangle$ as $1 + i$ divides both 2 and $3 + 3i$ in the Gaussian integers.

(b) In our second example, let $K = \mathbb{Q}(\sqrt{10})$. Its ring of integers does not have unique factorization, and it has nonprincipal ideals. For instance, as noted above, $39 = 3 \times 13 = (7 + \sqrt{10})(7 - \sqrt{10})$, and these last four entries are irreducible in O_K. Further the ideal $\langle 3, 7 + \sqrt{10} \rangle$ is not principal because there is no $t \in O_K$ that divides both 3 and $7 + \sqrt{10}$. For the ideals we have

$$\begin{aligned} \langle 3 \rangle &= \langle 3, 7 + \sqrt{10} \rangle \langle 3, 7 - \sqrt{10} \rangle \\ \langle 13 \rangle &= \langle 13, 7 + \sqrt{10} \rangle \langle 13, 7 - \sqrt{10} \rangle \\ \langle 7 \pm \sqrt{10} \rangle &= \langle 3, 7 + \sqrt{10} \rangle \langle 3, 7 - \sqrt{10} \rangle \end{aligned}$$

and the ideal $\langle 39 \rangle$ can be written uniquely as the product of the four prime ideals $\langle 3, 7 + \sqrt{10} \rangle$, $\langle 3, 7 - \sqrt{10} \rangle$, $\langle 13, 7 + \sqrt{10} \rangle$, and $\langle 13, 7 - \sqrt{10} \rangle$.

Algebraic number theory can be viewed in two ways. In the first it is a branch of modern algebra and provides some good examples of structures for that theory to work with. In the second way, it provides a more general context in which some problems concerning the rational numbers and integers, especially Diophantine equation problems, can be viewed. For a good introduction to the whole subject see Stewart and Tall (1979).

II. DIOPHANTINE EQUATIONS

This topic is the largest and most important in number theory; it concerns the solution of polynomial equations in some specified number system, often the integers $\mathbb{Z}$ or the rational numbers $\mathbb{Q}$. The name refers to the early Greek mathematician Diophantus, who was working in Alexandria in the middle of the third century. His surviving books show that he had a highly developed knowledge of the solution of equations in integers, especially those involving sums of squares. Nowadays although, some

methods recur, a large array of ideas and arguments are used; this is particularly true when integer solutions are sought. When solutions in an algebraic number field (for example $\mathbb{Q}$) are required, a more organized theory based on ideas from algebraic geometry has been developed; we shall discuss this in the next section. A good survey of the whole topic can be found in Mordell (1969).

We begin by listing some of the major results in Diophantine equation theory. The list is by no means complete, but it will give the reader some idea of the range of theorems and methods used.

A. Some Major Results in Diophantine Equation Theory

1. Linear Diophantine Equations

If $a, b, n \in \mathbb{Z}$, then the equation

$$ax + by = n$$

has a solution in integers x and y if and only if $(a, b) \mid n$, and if x_0, y_0 is a solution then the general solution is given by $x_0 + tb/(a, b)$, $y_0 - ta/(a, b)$ where $t \in \mathbb{Z}$. The Euclidean algorithm provides a good method for finding solutions of these equations. This result is one of the most useful in the whole of number theory.

2. Pell's Equation and Quadratic Forms

Suppose d is a positive integer and not square, then the equation

$$x^2 - dy^2 = 1$$

has infinitely many integer solutions x, y generated from a fundamental solution x_0, y_0 using the relation $x + y\sqrt{d} = (x_0 + y_0\sqrt{d})^n$ for $n \in \mathbb{Z}$. The fundamental solution can be found using the continued fraction expansion for $\sqrt{d}$ (see Section IV). It is an accident that Pell's name has been attached to this equation; J.-L. Lagrange (1736–1813) gave the first proof of its solvability.

A quadratic form (over $\mathbb{Z}$) is a function $F: \mathbb{Z}^n \to \mathbb{Z}$ given by the equation

$$F(x_1, \ldots, x_n) = \sum_{i,j=1}^{n} a_{ij} x_i x_j,$$

where, for $1 \le i,\ j \le n$, a_{ij} is an integer satisfying $a_{ij} = a_{ji}$. An extensive theory has been developed for solutions of equations of the form

$$F(x_1, \ldots, x_n) = m.$$

It relies to some extent on the theory of Pell's equation discussed above. The results are generally straightforward, if a little complicated to state. Equations can have either a finite or an infinite number of solutions (this is related to the underlying geometry); in the latter case the solutions are generated by a finite set of fundamental solutions. Accounts are given in Rose (1999) [two-variable integer case] and Cassels (1978) [general field and integral domain cases].

3. Thue–Siegel–Roth Theorem

This is an example of a major class of equations that have only finitely many solutions. One version of the theorem is as follows: Suppose f is an irreducible homogeneous polynomial, without multiple roots, in the rational number variables x and y, and having degree $n > 2$. Then if the equation $f(x, y) = m$, $m \in \mathbb{Z}$, is soluble, it has only finitely many solutions. The proof uses Diophantine approximation theory (see Section IV). T. A. Skolem (1887–1963) has given an ingenious method for solving some of these equations; see Borevich and Shafarevich (1966). Also, G. Faltings has greatly extended this result; see Section III.

4. Goldbach Conjecture

Here, we look for prime number solutions only; the result has not yet been fully established. C. Goldbach (1690–1764) conjectured that every even positive integer larger than 2 can be expressed as a sum of two prime numbers. For example $10 = 7 + 3$, $100 = 53 + 47$, $1000 = 509 + 491$, etc. At the present time, no counterexample has been found and J.-R. Chen has proved that every large even integer is the sum of a prime a number that has at most two prime factors. Also, I. M. Vinogradov (1891–1983) has shown that every large odd positive integer is the sum of three primes. The proofs of both of these results are long and complex.

5. Fermat's "Last Theorem"

First proposed in 1637 and finally proved in 1995, this is undoubtedly the most famous and well-researched Diophantine equation. We shall give a brief history, for more information see Edwards (1977), Ribenboim (1979), Cornell (1997) (for a detailed account of the whole proof), and Singh (1997) (for a popular account including the recent advances).

Although of little intrinsic interest in itself, Fermat's so-called Last Theorem has had a profound influence of the development of pure mathematics over the past three and a half centuries. It states: the equation F_n

$$x^n + y^n = z^n$$

has no solution in integers x, y and z if $xyz \neq 0$ and $n > 2$. (There are solutions when $n = 2$.) In 1637, P. de Fermat

(1601–1673) proposed this result and claimed to have a proof, which has not survived, although he did prove the result in the case $n = 4$ and so showed that n can be restricted to be an odd prime number. The next step was taken by L. Euler (1707–1783) who proved Fermat's result for $n = 3$. He was the first to realize that the solution to the problem would come by working in a number system larger than the integers; he used the complex numbers in his proof. In the middle of the nineteenth century, E. E. Kummer (1810–1893) greatly extended this work and so proved the result for a large number of cases (and as a by-product helped to lay the foundation of modern algebra). Building on this and using the power of modern computers, Fermat's Last Theorem had been established for all $n < 4{,}000{,}000$ by 1980. Also by Falting's work (see next section), it was known that even if one of the equations F_n was solvable, it could only have a finite number of solutions.

In 1985, G. Frey noted an apparently simple connection between Fermat's result and some properties of a class of elliptic curves (see Section III). Frey's elliptic curves have the form

$$y^2 = x(x - a^n)(x - c^n).$$

Using these curves, he made the following conjecture: if Fermat's Last Theorem is *false* then so is the Taniyama and Weil Elliptic Curve conjecture (see the last paragraph of Section III). He noted that if $a^n - c^n = b^n$ and $a, b, c \in \mathbb{Z}$, then the discriminant Δ of the curve has the form $\Delta = (abc)^{2n}$, and so he conjectured that if an elliptic curve whose discriminant was a $2n$-power existed, then it could not satisfy the Taniyama and Weil conjecture. This implication was proved by K. Ribet in 1990. At about this time, A. Wiles began work on proving that the Taniyama and Weil conjecture is *true*, one consequence of which would be, by Frey and Ribet's result, that Fermat's result was finally proved. His work was successful for in 1995, and with some input from R. Taylor, he published his proof of the Taniyama and Weil conjecture for a large class of elliptic curves, which includes the Frey curves, and so finally established Fermat's Last Theorem 358 years after it had been first proposed. This work will surely rank as one of the greatest achievements of twentieth century mathematics.

6. Sums of Squares

Here we ask: Can a positive integer m be expressed as a sum of k squares, or l cubes, or in general as a sum of nth powers? We shall look at the squares case first. Lagrange's famous four-squares theorem states that every positive integer is a sum of four squares. The usual proof uses the so-called "infinite descent method," which is a kind of mathematical induction. By a simple counting argument we find, for our given m, positive integers t, x, y, z, w satisfying $x^2 + y^2 + z^2 + w^2 = tm$. Secondly, given this equation, a procedure is devised to give a new solution t_1, x_1, y_1, z_1, w_1 to this equation, which satisfies $0 < t_1 < t$. The result follows by finitely many applications of this procedure.

The two-square result first proved by Fermat, is: the equation

$$x^2 + y^2 = n$$

has a solution x, y provided those factors of n that are congruent to 3 modulo 4 occur in the prime factorization of n with an even power. So for example, 1, 2, 4, 5, 8, 9, 10, 13, 16, 17, and 18 are the positive integers less than 20 that can be expressed as sums of two squares. This can also be established using the infinite descent method, although many other proofs exist. The proofs of both of these results rely on the fact that the product of two sums of 2 or 4 squares is itself a sum of 2 or 4 squares, respectively. For example, we have

$$(x^2 + y^2)(z^2 + w^2) = (xz + yw)^2 + (xw - yz)^2$$

(a result known to Diophantus in the third century AD.) No similar identity is available for an odd number of squares, and so in this case different methods involving quadratic form theory are used. The three-squares theorem, first provided by Gauss, states that n can be expressed as a sum of three squares proved it is not of the form $4^a(8b + 7)$. For example, every positive integer less than 30 is a sum of three squares except 7, 15, 23, and 28.

7. Waring's Problem

More generally we can ask if all positive integers are sums of kth powers with $g(k)$ summands where g depends only on k. This is known as Waring's problem. In 1770, E. Waring (1736–1798) postulated that $g(2) = 4$ (this is Lagrange s thoerem), $g(3) = 9$, $g(4) = 19$, and so on. In 1909, D. Hilbert (1862–1943) showed that g exists for all k. It has been established that $g(3) = 9$ and $g(5) = 37$; very recently it has been shown that $g(4) = 19$, the value Waring conjectured. Further, for most $k \geq 6$, $g(k) = 2^k + A - 2$, where A denotes the largest integer less than $(3/2)^k$. For the exact result see Hardy and Wright (1954) pages 335–337.

One aspect distinguishes the case $k = 2$, discussed in Subsection 6, and the case $k > 2$; in the latter case there are a few exceptional integers that require more summands than usual. For instance only 23 and 239 need nine cubes, and if $n > 8042$ then, in all probability, six cubes are sufficient. If we let $G(k)$ denote the least number of

summands needed to express all sufficiently large positive integers as a sum of kth powers, then clearly

$$G(k) \le g(k) \quad \text{and} \quad G(2) = g(2) = 4.$$

For most k the precise value of $G(k)$ is not known. $G(3)$ lies between 4 and 7 with the most likely values 4 or 5, and $G(4) = 16$. G. H. Hardy (1877–1947) and J. E. Littlewood (1885–1977) conjectured that $G(k) \le 2k+1$ if $k \ne 2^m$, where $m > 1$, and $G(2^m) = 2^{m+2}$ again where $m > 1$. At the moment the best result known is: as $k \to \infty$, $G(k) \le (2 + c_k)k \ln k$, where $c_k \to 0$ as $k \to \infty$. For an account of this work see Vaughan (1981) and Ribenboim (1989), pages 236–245, which gives the current status of this problem when $k \le 10$.

III. ELLIPTIC CURVES

In this section we discuss the solution of two variable Diophantine equations defined over an algebraic number field. Compared with the material discussed in the previous section, a more organized theory has been developed; it uses some basic ideas from algebraic geometry. Also, it is the subject of considerable current research interest.

Let K be an algebraic number field, for example the rational field $\mathbb{Q}$, and let $A^n(K)$ denote the set of n-tuples $(x_1, \ldots, x_n)$ where each $x_i \in K$. $A^n(K)$ is called the n-dimensional *affine space* over K. On the set $A^3(K) - \{(0, 0, 0)\}$ we define the relation $\simeq$ by: $(x, y, z) \simeq (x', y', z')$ if and only if $x = x't$, $y = y't$, $z = z't$ for some nonzero $t \in K$. This is an equivalence relation, and the set of equivalence classes is called the two-dimensional *projective space* $P^2(K)$ over K. Points in this space are denoted by $(x{:}y{:}z)$. Note that by the relation $\simeq$ it is only the ratios of x, y, and z that matter; so, for example, (2:3:5), $(-4{:}-6{:}-10)$, and (26:39:65) all represent the same point.

A *curve* C in $P^2(K)$ is the set of points $(x{:}y{:}z)$ that satisfy a homogeneous polynomial equation $f(x, y, z) = 0$, and the *degree* of C is the degree of the polynomial f. A point P on C is called *singular* if the partial derivatives ($\partial f/\partial x$, etc.) at P with respect to all three variables x, y, and z are zero; unique tangents can be drawn to the curve at points that are not singular. Two curves C and C' are said to be *birationally equivalent* if each can be transformed into the other by a rational function and the correspondence is one-to-one and onto except at a finite number of points. For example $x' = 1/(x-1)$, $y' = 1/y$, $z' = 2z$ is birational. Note that the degrees of C and C' need not be identical.

We come now to the important notion of the genus of a curve.

Definition: The genus g of a curve C that has degree n and has N singular points is given by $g = \frac{1}{2}(n-1)(n-2) - N$.

It can be shown that g is a nonnegative integer and is unaltered when C is birationally transformed into a new curve C'. The genus provides an important classification, into three main classes, for the collection of all curves defined over the field K. The first class contains curves of genus zero. All curves in this class can be reduced (by birational transformations) to lines or conics, and the linear and quadratic form material discussed in the previous section applies to the associated Diophantine equations.

The second class contains the curves of genus one. Using birational transformations, all curves in this class that have at least one point whose coordinates lie in K can be represented by equations of the form

$$y^2 z = x^3 + axz^2 + bz^3, \tag{1}$$

where $a, b \in K$. They are called *elliptic curves* because they can be parametrized using elliptic functions. The *discriminant* Δ of the curve (1) is $-16(4a^3 + 27b^2)$. Many of the basic properties of this curve are determined by this quantity, for example the curve (1) is elliptic if and only if $\Delta \ne 0$ and, in the real plane, it has one component if $\Delta < 0$ and two if $\Delta > 0$. The last main class contains curves having genus larger than one. Until recently little was known about these equations. In 1922 L. J. Mordell (1888–1972) conjectured that each equation in this class has only finitely many points whose coordinates lie in K. This remarkable conjecture was established by Faltings in 1983, using advanced techniques from algebraic geometry. We have already mentioned one consequence of this work. If $n > 3$, the genus of each of the curves associated with the Fermat equation F_n (see Section II.A.5) is larger than one, and so none of these equations can have infinitely many solutions. This fact provided initial support to Wiles and others in their eventual solution of Fermat's result. Table I summarizes the main classes for the field $\mathbb{Q}$.

A. Elliptic Curves

Points on elliptic curves have an important algebraic structure that we shall discuss now. If the point $(x{:}y{:}z)$ lies on the curve C (defined over the field K) and $x, y, z \in K$, then we call the point *rational*; and we let $C(K)$ denote the set of rational points on C. Using the so-called *chord-tangent method*, $C(K)$ can be given a group structure as follows. Let us suppose that C is represented in the standard form, Eq. (1). In this case it is a cubic curve and any straight line will intersect it in at most three points. Further, if two of these points are rational than the coefficients of the

TABLE I Properties of Homogeneous Three Variable Diophantine Equations Defined Over $\mathbb{Q}$

Genus	Parametrization	Maximum number of solutions in $\mathbb{Z}$	Maximum number of solutions in $\mathbb{Q}$
0	By rational functions	Infinite	Infinite
1	By elliptic functions	Finite	Infinite but finitely generated
≥ 2	—	Finite	Finite

equation of the line through these points will belong to K, and so the third point will also be rational. This conclusion is valid even if the first two points coincide at P, that is, the line is the tangent at P.

Using this chord-tangent process we can define an addition operation on $C(K)$. Let O be the point (0:1:0), it lies on all curves of the form, Eq. (1), and it will act as the identity of the group. Suppose $P_1, P_2 \in C(K)$ and the line P_1P_2 meets C again at Q; as noted above, $Q \in C(K)$. Now construct the line OQ; it will meet C in one further rational point. This new point is called the *sum* of P_1 and P_2 and is denoted by $P_1 + P_2$. It can be shown that $C(K)$ with this operation is an Abelian group. The proof is straight-forward except for associativity, which requires a result from algebraic geometry known as Bezout's theorem. Some sample constructions are given in Fig. 1. In this example, $P_1 + P_2 = 2P$ where $2P$ denotes the tangent point $P + P$.

In 1922 Mordell showed that the Abelian group $C(\mathbb{Q})$ has only a finite number of generators; that is, all rational points on $C(\mathbb{Q})$ can be constructed by the chord-tangent method from a finite set of points. Later, A. Weil extended this to all algebraic number fields K, and the result is now called the Mordell–Weil theorem. The group $C(K)$ can be finite or infinite. Recently B. Mazur has classified all groups that can occur in the finite case when $K = \mathbb{Q}$; they are either cyclic or direct products of two cyclic groups and have orders not larger than 16.

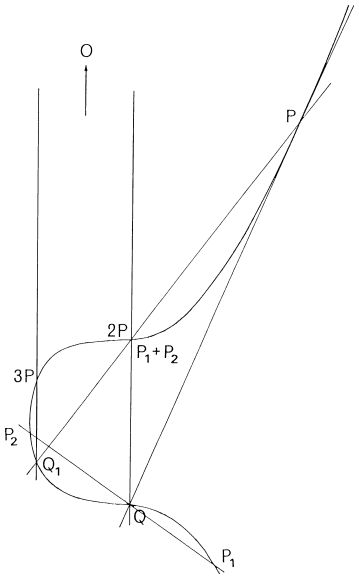

FIGURE 1 Sample constructions of rational points on elliptic curves by the chord-tangent method.

The *rank* of $C(K)$ is the number of infinite order generators of $C(K)$; it is finite by the Mordell–Weil theorem. This number has been studied extensively, and recently some results have been established. For many curves the rank is zero or one; but examples have been given in which the rank is at least 22. For a fixed field K, it is not known if the rank can be arbitrarily large or, conversely, if a constant m exists such that the rank of all elliptic curves over K is less than m.

There are many conjectures concerning these curves, the most important involve L-functions, a detailed definition of which can be found in Silverman (1986). Roughly speaking, an L-function for a curve C encodes "local" properties (that is, properties of C defined over finite fields, working modulo a prime for example) in the hope of obtaining "global" properties of C (that is, properties of C valid over the rational numbers or the complex numbers). Two main collections of conjectures have been studied; the first, due to B. Birch and H. P. F. Swinnerton–Dyer, relates the behavior of the L-function of a curve C near 1 to the rank of C over the rational numbers—there is good numerical evidence for this conjecture and it has been proved recently for some classes of curves. The second main collection of conjectures concerns the domain of definition of the L-functions in the complex plane. It is a simple matter to see that these functions are defined at most points z in the right hand side of the plane (to be precise, when the real part of z is larger than $3/2$). The Taniyama and Weil conjecture states that the domain of definition can be extended to cover the whole of the complex plane except for the point 1. It is known that if this conjecture holds for the curve C in question, and a set of related curves, then the curve is "modular" which implies that it possesses a number of useful arithmetic properties including a special type of parameterization. It is this conjecture (for a subset of all curves, called the *semistable* curves, which contains the Frey curves related to Fermat's Problem) that A. Wiles (and R. Taylor) proved in 1993/1995 [see Wiles (1995)] and which finally established that Fermat's Last Theorem is valid in all cases (see Section A.5). At the time of writing (November 1999), it has been announced by C. Breuil, B. Conrad, F. Diamond, and R. Taylor that the Taniyama and Weil conjecture is valid for all elliptic curves defined over the rational numbers, no details are available.

IV. DIOPHANTINE APPROXIMATION AND TRANSCENDENCE

These topics are concerned with the number-theoretic properties of the real and complex numbers. The starting point for this work is the question: How close can a rational number a/b approximate to a real number α assuming some restriction on the size of a and b; that is, given α can integers a and b be found to satisfy

$$\left|\alpha - \frac{a}{b}\right| < \frac{1}{f(b)} \tag{2}$$

for some suitably chosen monotone increasing function f? This is the basic question in Diophantine approximation theory. We answer this question and discuss some related topics in the subsections below.

Continued fractions play an important role in this theory; they are defined as follows. Let α be a real number and let $[\alpha]$ denote the largest integer c satisfying $c \le \alpha$; then we can write

$$\alpha = [\alpha] + 1/\alpha_1,$$

where $\alpha_1 > 1$ provided α is not an integer. We repeat this construction by setting

$$\alpha_n = [\alpha_n] + 1/\alpha_{n+1}$$

$(n = 1, 2, \ldots)$ provided α_n is not an integer. If α is a rational number this process will stop in a finite number of steps, otherwise it will continue indefinitely. We write q_0 for $[\alpha]$, q_n for $[\alpha_n]$, and $[q_0, q_1, \ldots, q_n]$ for the expression

$$q_0 + 1/(q_1 + 1/(q_2 + \cdots + 1/q_n \ldots)).$$

This is called the nth *continued fraction convergent* to α. For example, the fifth continued fraction convergent to $\sqrt{2}$ is $[1, 2, 2, 2, 2, 2]$.

A. Rational Approximation

1. Best Approximation

By a "good" rational approximation a/b to a real number α we mean that a/b is close to α, and a and b are relatively small. We define the *best approximation* to a real number α relative to n to be the rational number a/b closest to α satisfying $0 < b < n$. For example, $22/7$ is a good approximation to π; it is in fact the best approximation relative to any $n \le 56$. All good approximations to a real number α are continued fraction convergents to α.

2. Hurwitz's Theorem

The theorem of A. Hurwitz (1859–1919) puts a limit on how good approximations can be in general. It states that if α is irrational then the inequality (2) has infinitely many solutions a, b provided $f(b) \le b^2\sqrt{5}$. This result can be derived using some elementary theorems concerning continued fractions [see Rose (1999)]. It is best possible for if $\alpha = (1 + \sqrt{5})/2$ (its continued fraction representation is $[1, 1, 1, \ldots]$) and $f(b) > b^2\sqrt{5}$ then inequality (2) has only finitely many solutions. If this α and any real number whose continued fraction expansion is eventually all ones is excluded, then Hurwitz's theorem can be improved by replacing $\sqrt{5}$ by $\sqrt{8}$. Then $\sqrt{8}$ is best possible when $\alpha = \sqrt{2}$. This process continues; finally it can be shown that there are uncountably many real numbers α for which the inequality (2) has infinitely many solutions if $f(b) = 3b^2$, but only finitely many if the number 3 is replaced by a larger number.

3. Sets of Real Numbers Modulo 1

Let $((\alpha))$ denote the fractional part of α, that is $((\alpha)) = \alpha - [\alpha]$. P. L. Chebyshev (1821–1894) was the first to ask: Given α how is the set $\{((n\alpha)): n = 1, 2, \ldots\}$ distributed in the unit interval? Using the methods discussed above, he was able to show that this set is dense in the unit interval and that the distribution is uniform provided α is irrational. His methods apply to a number of similar problems.

B. Transcendental Numbers

A real or complex number that satisfies no polynomial equation with algebraic coefficients is called *transcendental*. J. Liouville (1809–1882) was the first to show that transcendental numbers exist, although using the diagonal argument of G. Cantor (1845–1918) we now know that almost all real or complex numbers have this property. On the other hand there are many specific numbers whose transcendental status is unknown. Examples of Euler's constant γ, $e + \pi$, and $\pi^{\sqrt{2}}$.

Liouville began with the inequality (2) and showed that if α is an algebraic number of degree $n (n > 1)$ then (2) has only finitely many solutions if $f(b) = b^{n+k}$ and $k > 0$. Using this he was able to show that certain real numbers are transcendental; for example the number whose decimal expansion is $0.11000100\ldots$, that is, all zeros except for 1's at the $n!$ digit places, $n = 1, 2, \ldots$. A number of this type is now called a *Liouville number*.

C. Hermite (1822–1901) introduced the main method for establishing the transcendence of a number in 1873. It begins by assuming that α is algebraic, satisfying the polynomial equation $f(\alpha) = 0$; that is the contrary of the required result. Then two properties of a formula F constructed using the coefficients of f are derived that contradict one another, and so transcendence is established. For example, the contradictory properties could be (a) F is a

positive integer and (b) F tends to zero. Hermite used this method to show that e $(=\sum_{n=1}^{\infty} 1/n!)$ is transcendental. F. Lindemann (1852–1939) extended this to show that if $\alpha_1, \ldots, \alpha_n$ are distinct algebraic numbers and $c_1, \ldots, c_n$ are nonzero algebraic numbers, then

$$c_1 e^{\alpha 1} + \cdots + c_n e^{\alpha_n} \neq 0. \tag{3}$$

Using this result he was able to show that the following numbers are transcendental where α is algebraic, nonzero, and not equal to one in the last two cases:

$$\pi, e^{\alpha}, \sin \alpha, \cos \alpha, \sinh \alpha, \cosh \alpha,$$

$$\arcsin \alpha, \text{ across}\, \alpha, \text{ and } \ln \alpha.$$

A famous problem first proposed by the ancient Greeks and known as "squaring the circle" was: Construct a square equal in area to a given circle using only a ruler and compass. Lindemann's result shows that this is impossible as $\sqrt{\pi}$ is transcendental. Further extensions of the method enabled A. O. Gelfond (1906–1968) and T. Schneider to show that if α and β are algebraic numbers, $\alpha \neq 0$ or 1, and β is irrational then α^{β} is transcendental.

One consequence of this result is: If α, β, γ and δ are nonzero algebraic numbers and no linear relation with rational coefficients exists between $\ln \beta$ and $\ln \delta$, then

$$\alpha \ln \beta + \gamma \ln \delta \neq 0.$$

In 1966, A. Baker extended this by providing a similar result with n rather than 2 summands [see Lindemann's result, inequality (3)]. A number of important applications have followed. For example, the number $e^{\alpha} \beta^{\gamma}$ is transcendental provided α, β and γ are algebraic and nonzero.

We shall mention two further applications.

(a) In Section III, we introduced the elliptic curves; Baker's result provides an effective finite bound on the number of integer (as opposed to rational number) solutions of the associated Diophantine equations.

(b) Baker's result enables us to list all those imaginary quadratic fields that have unique factorization (see Section I).

1. Mahler's Classification

The set of all real and complex numbers is divided into four classes A, S, T, and U as follows:

1. The *height* h of a polynomial f with rational integer coefficients, not all zero, is the maximum of the absolute values of its coefficients.

2. Given γ, n, and $h > 1$, let f be the polynomial with rational integer coefficients, degree at most n, and height at most h, such that $|f(\gamma)|$ takes the least nonzero value. Now let $\omega(n, h)$, ω_n, and ω, be given by

$$|f(\gamma)| = h^{-n\omega(n,h)}$$

$$\omega_n = \lim_{h\to\infty} \max_{1\leq k\leq h} \omega(n, k)$$

$$\omega = \lim_{n\to\infty} \max_{1\leq m\leq n} \omega_m$$

Finally, let ν be the least positive integer n such that $\omega_n = \infty$, and let $\nu = \infty$ if $\omega_n < \infty$ for all n.

There are four possibilities for the values of ω and ν (note ω and ν cannot both be finite). The scheme of K. Mahler (1888–1972) defines

- γ to be an A-number if and only if $\omega = 0$ and $\nu = \infty$,
- γ to be an S-number if and only if $0 < \omega < \infty$ and $\nu = \infty$,
- γ to be a T-number if and only if ω and ν are both infinite, and
- γ to be a U-number if and only if $\omega = \infty$ and ν is finite.

The following results concerning this classfication have been proved.

(a) If two numbers α and β are algebraicly dependent (i.e., $g(\alpha, \beta) = 0$ for some two-variable polynomial g) then they belong to the same class.

(b) The A-numbers are exactly the algebraic numbers, and so the S-, T-, and U-numbers are transcendental.

(c) Almost all real and complex numbers are S-numbers.

(d) The Liouville numbers are U-numbers; in the exampleof a Liouville number given above $\omega_1 = \infty$.

(e) T-numbers exist; this is a recent result of W. M. Schmidt. Many problems remain, for example it is known that π is an S- or T-number, but which? For further details on all of the results in this section see Baker (1975), LeVeque (1955), and Schmidt (1980).

V. PRIME NUMBER THEORY

The properties of the prime numbers have been studied since the time of the early Greeks Pythagoras and Euclid; even so, many questions remain unanswered today. The first major result, which is attributed to Euclid, states that the set of prime numbers is infinite. The other major result from this period is the so-called "Sieve of Eratosthenes," which is an effective method for enumerating all primes less than some fixed integer.

Two pre-eminent results have been established in modern times. They are the theorem of P. G. L. Direchlet

(1805–1859) concerning primes in arithmetic progressions and the Prime Number Theorem (PNT), which estimates the density of the primes. We shall discuss these, but we shall begin by considering some of the many unsolved problems in prime number theory. Most of the conjectures associated with these problems are backed up with ample numerical evidence, but this should be treated with some skepticism because in most cases this evidence involves only relatively small numbers. For example, most of the available numerical evidence suggests that $Li(x) > \pi(x)$ for all x. [These two prime density functions are defined below.] But it is now known that $Li(x) - \pi(x)$ changes sign infinitely often, and the first change occurs before $x = 6.69 \times 10^{370}$.

A. Conjectures Concerning Prime Numbers

1. The Twin Prime Conjecture

A brief study of a table of prime numbers shows that there are many pairs of primes p, q where $q = p + 2$; examples are 3, 5; 101, 103; 1997, 1999; and $10^9 + 7$, $10^9 + 9$. If we let $\pi_2(x)$ denote the number of prime pairs less than x;then, for instance, $\pi_2(10^3) = 35$ and $\pi_2(10^6) = 8164$. The twin prime conjecture states that $\pi_2(x) \to \infty$ as $x \to \infty$, and the likely value of $\pi_2(x)$ is $\bigcirc(\int_2^x (\ln t)^{-2}\, dt)$. Progress has been made on this conjecture, for Chen has shown that there are infinitely many pairs of integers p, $p + 2$ where p is prime and $p + 2$ has at most two factors.

2. Primes in Intervals

It is a simple matter to show that a prime occurs between n and $2n$ for all integers $n > 0$. This is known as "Bertrand's Postulate"; for a proof see Rose (1999), page 231. Using the Prime Number Theorem this result can be extended to show that for all large n there is a prime between n and $(1 + \varepsilon)n$ for any given fixed $\varepsilon > 0$. But no similar result for a smaller interval has been established. For example, it is not known if a prime occurs between n^2 and $(n + 1)^2$ for all large n.

3. Extensions of Dirichlet's Theorem

Very little information is available concerning the set D of those n for which $an + b$ is prime. (Dirichlet's theorem tells us that it is infinite.) For example, does D itself contain infinitely many primes, or any primes at all? Another proposed extension replaces the linear form $an + b$ by a quadratic one. For instance, it is not known if there are infinitely many primes of the form $n^2 + n + 1$ or $n^2 + n + p$ for some prime p.

A number of other problems concerning the primes have been discussed elswhere. These include the Goldbach conjecture (see Section II.A.4), problems concerning formulas taking prime values, and Fermat and Mersenne numbers.

We shall discuss now the two major results mentioned earlier and their connections with the Riemann hypothesis.

B. Dirichlet's Theorem

Suppose $(a, b) = 1$; this famous theorem first established in 1837 states that there are infinitely many prime numbers in the arithmetic progression $A = \{an + b, n = 1, 2, \ldots\}$. It is proved by considering a series of the form $\sum \chi(p)/p$ where the sum is taken over the primes p in A. The function χ is used to pick out elements of A and is defined using some basic group theory (it is called a multiplicative character). Second, standard analytic techniques are applied to this series to show that it diverges to infinity. Dirichlet's theorem follows, for if there were only finitely many primes in the progression A then the series would have a finite sum.

C. The Prime Number Theorem (PNT)

Let $\pi(x)$ denote the number of primes p satisfying $p \le x$. J. S. Hadamard (1865–1963) and C. de la Vallee Poussin (1866–1962) proved in 1896 that

$$\pi(x) \sim x / \ln x.$$

A more precise version of this result is

$$\pi(x) = Li(x) + \bigcirc(x/(\ln x)^2),$$

where

$$Li(x) = \lim_{\epsilon \to 0} \int_0^{1-\varepsilon} + \int_{\varepsilon+1}^{x} \frac{dt}{\ln t}.$$

There are two main proof of PNT, an analytic one and an elementary one. A typical analytic proof begins with the result: if s is a complex variable whose real part is larger than one then

$$\ln \zeta(s) = s \int_2^\infty \frac{\pi(x)}{x(x^s - 1)}\, dx. \tag{4}$$

[The zeta function $\zeta(s)$ is defined below.] An estimate for $\pi(x)$ is then-obtained by "solving" this equation for $\pi(x)$. We shall consider the error term in this process later. Elementary proofs of PNT rely on the following formula, which was established by A. Selberg in 1949.

$$\sum_{p \le x} \ln^2 p + \sum_{pq \le x} \ln p \ln q = 2x \ln x + \bigcirc(x),$$

where the sums in this formula are taken over prime values only. This is used to improve some standard estimates, and the result follows after a lengthy argument. The best estimates for $\pi(x)$ are achieved using analytic methods.

D. The Riemann Hypothesis

For a complex variable $s = \sigma + it$ we define the Riemann zeta function $\zeta(s)$ by

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}$$

for $\sigma > 1$ and $-\infty < t < \infty$. Using analytic continuation, the domain of definition can be extended to the whole complex plane, except the point 1. The connection between the prime numbers and the zeta function is given by the following result [due to Euler.]

$$\zeta(s) = \prod_p (1 - p^{-s})^{-1},$$

where the product is taken over all primes p. Taking logs of both sides we obtain

$$\ln \zeta(s) = -\sum_p \ln(1 - p^{-s})$$
$$= \sum_p p^{-s} + \text{finite error term},$$

that is, a sum taken over the prime numbers only has been expressed by standard analytic terms. The result (4) follows from this easily.

We can see from the foregoing equation that it is important to know where the zeros of the zeta function are. It has zeros at $s = -2, -4, \ldots$, and the remaining zeros lie inside the region of the complex plane bounded on the left by the imaginary axis and on the right by the vertical line passing through the point $s = 1$; this is called the *critical strip*. The hypothesis of B. Riemann (1826–1866) states that all the zeros in the critical strip lie on the central line, that is, the vertical line through the point $s = \frac{1}{2}$. Hardy showed that there are infinitely many zeros on this line, but it is not known if there are any zeros off the line. This is one of the most important unsolved problems in the whole of mathematics. One major consequence of the establishment of this hypothesis would be greatly improved estimates for many theorems in analytic number theory. We give two examples. The error term $x/(\ln x)^2$ in the prime number theorem $\pi(x) = Li(x) + \bigcirc(x/(\ln x)^2)$ could be replaced by $\sqrt{x} \ln x$ if Riemann's hypothesis was available. Second, it is known that the first quadratic nonresidue n of a prime p satisfies $n < p^{1/4+\varepsilon}$ for large p and $\varepsilon > 0$. (The integer n is a quadratic nonresidue modulo p if the congruence $x^2 \equiv n \pmod{p}$ is insoluble). If Riemann's hypothesis was available then this inequality could be replaced by $n < c(\ln p)^2$ for some constant c. For further applications of this hypothesis see Titchmarsh (1987), for the latest numerical evidence see Odlyzko (1991), and for an informal but detailed discussion of the whole topic of prime numbers see Ribenboim (1989).

VI. PARTITIONS

Unlike much of the previous material, partition theory deals with additive problems. These are often very easy to state, but much of the development is as difficult as any in number thory. Every positive integer can be expressed as a sum of smaller integers in a number of ways. If $n > 0$ and

$$n = a_1 + a_2 + \cdots + a_r$$

where each a_i is a positive integer, then the set $\{a_1, a_2, \ldots, a_r\}$ is called a *partition* of n and the individual terms $a_1, a_2, \ldots$ are called *parts*. The order of the parts is unimportant, although it is usual to write them in decreasing order. The total number of partitions of n is denoted by $p(n)$. For example, $p(5) = 7$ as

$$5, \quad 4+1, \quad 3+2, \quad 3+1+1, \quad 2+2+1,$$
$$2+1+1+1, \quad 1+1+1+1+1$$

is the set of partitions of 5.

There are many relationships between subsets of the set of partitions of an integer n. The most famous, due to Euler, states that the number of partitions of n all of whose parts are odd integers equals the number of partitions of n where no part is repeated. In the example above, the first three partitions have distinct parts while the first, fourth, and seventh have exclusively odd parts. A number of similar properties will be discussed below.

Euler's result is remarkable because there is no obvious connection between the two sets, but it becomes almost a triviality once it has been expressed in terms of generating functions. We shall define these now. Let $\{c_1, c_2, \ldots\}$ be an infinite sequence of positive integers; then the power series

$$f(q) = \sum_{n=0}^{\infty} c_n q^n$$

is called the *generating function* for this sequence. These power series are treated formally, but in most cases they are absolutely convergent when $0 < q < 1$. To prove Euler's result let $p_1(n)$ denote the number of partitions of n with exclusively odd parts and let $p_2(n)$ denote the number of partitions of n with distinct parts; then we can show that

$$\sum_{n=0}^{\infty} p_1(n) q^n = \prod_{n=1}^{\infty} (1 - q^{2n-1})^{-1}$$

and

$$\sum_{n=0}^{\infty} p_2(n) q^n = \prod_{n=1}^{\infty} (1 + q^n)$$

Now

$$\sum_{n=1}^{\infty}(1+q^n)=\prod_{n=1}^{\infty}\frac{(1-q^{2n})}{(1-q^n)}$$
$$=\prod_{n=1}^{\infty}(1-a^{2n-1})^{-1}$$

and this gives $p_1(n)=p_2(n)$ for all n.

To illustrate the theory we list some further results:

1. The number of partitions of n with at most m parts equal the number of partitions of n in which no part exceeds m.
2. The number of partitions of n in which no part occurs more than three times equals the number of partitions of n in which only odd parts may be repeated.
3. If $n\equiv 4 \pmod 5$ then $p(n)$ is divisible by 5. There are similar results for some other moduli, for example 7, 11, 25, 35, ...
4. The number of partitions of n with minimum difference two (that is $|a_i-a_j|>1$ for all i and j) equals the number of partitions of n in which each part has the form $5m+1$ or $5m+4$.

Most of these results are proved by deriving properties of the corresponding generating functions, as we did above for Euler's theorem. A typical result is: If $0<q<1$ then

$$\prod_{n=1}^{\infty}(1-q^n)=\sum_{m=-\infty}^{\infty}(-1)^m q^{m(3m-1)/2}.$$

This is called Euler's pentagonal number theorem. Using it we can give a recursive procedure for calculating $p(n)$, viz: If $n>0$, $p(0)=1$, and $p(m)=0$ if $m<0$, then

$$p(n)=p(n-1)+p(n-2)+\cdots$$
$$+(-1)^{m-1}p(n-k(3k-1)/2)$$
$$+(-1)^{m-1}p(n-k(3k-1)/2)+\cdots.$$

This provides a very efficient method for calculating $p(n)$.

The value of $p(n)$ increases rapidly with n, for instance $p(10)=42$, $p(20)=627$, and $p(30)=5604$. Hence, it is important to find an estimate of the approximate value of $p(n)$ for large n. One such estimate is

$$p(n)\sim\frac{1}{4n\sqrt{3}}e^{\pi\sqrt{2n/3}}.$$

A more accurate estimate as well as full details on all the topics mentioned in this section can be found in Andrews (1976).

VII. COMPUTATIONAL NUMBER THEORY

With the advent of modern computer systems, a new branch of number theory has developed over the past few decades which provides powerful algorithms for many aspects of the subject; Cohen (1993) gives a good introduction to the whole area. The most spectacular algorithms give very efficient methods for factorizing positive integers or for determining whether a given number is prime or not. Other algorithms include, for example, methods for finding the class group of an algebraic number field (that is, determining the ideal structure of the field, see Section I), efficient methods for dealing with large matrices, and methods for calculating the invariants associated with elliptic curves (for example the discriminant, see Section III). This work has a major bearing on cryptography, and so gives number theory a direct influence on modern commerce and public affairs. Many coding procedures used to keep the transmission of information secret are effective because it is very difficult to factorize a large positive integer, particularly if this integer has two or more large prime factors.

We shall illustrate the methods used in this theory by describing one modern procedure for factorizing a positive integer. It uses elliptic curves and was invented by H. Lenstra, further details can be found in Cohen (1993) or Rose (1999), among others. Before describing Lenstra's method, we need to consider an earlier method due to Pollard. When attempting to factorize an integer n, Pollard noted that in many cases, but by no means all, if a prime number p divides n, then $p-1$ has many small factors and hopefully all its prime factors are small. If all the prime factors of $p-1$ divide k, then $a^{p-1}-1$ divides a^k-1, Fermat's Theorem shows that p divides $a^{p-1}-1$, and hence p divides a^k-1 for $a=2,3,\ldots$. It is usual to take k to be of the form $j!$ or $LCM\,(2,3,\ldots,j)$ for some relatively small integer j. Therefore, for various choices of a and k we calculate (n,a^k-1), and if this gcd is larger than 1, then we have found a factor of n and we can continue the process until all factors have been located. Note that there are very efficient methods for calculating gcds, even if the integers involved are large.

Pollard's method fails when $p-1$ has a large prime factor. Lenstra introduced a similar method replacing the integers modulo a prime p by an elliptic curve C defined over a finite ring K. The expectation that $p-1$ has small factors in Pollard's method is replaced by the expectation that the order of points on the curve C defined over K has many small factors [if P is a point on $C(K)$, its order is the least positive integer t such that tP is the zero point, see Section III]. The ring K is the system of integers modulo n where n is the number to be factored. This integer is not prime (this is checked before the factorization algorithm is

applied because it is much easier to determine the primality status of n than it is to factorize it). Hence the ring K is not a field, that is division can fail. But this does not cause a problem because it is exactly at the point of failure that a factor of n appears. The method is as follows. We choose an elliptic curve C, a point P on C, and an integer k with many small factors, and then calculate the co-ordinates of the point kP modulo n. If this works then we have *failed* to find a factor of n, and so we repeat the process with a different C, or a different P, or a different k until we obtain a calculation that crashes. This particular calculation will have crashed because it involved a division by a factor m of n, this is equivalent to division by zero modulo n, but this is a *success* because we now have the factor m of n. Each single calculation is no more efficient than in Pollard's method. Lenstra's methods works well because (a) there is a great range of starting positions (that is, for curves C, points P and numbers k), and (b) each separate calculation can be performed extremely quickly. For example, this method was used to factorize $n = 2^{137} - 1$ on a standard issue desktop computer using the computer package PARIGP developed by H. Cohen *et al*., and in under 6 seconds it gave the answer

$$2^{137} - 1 = 3203222155964964355 69 \times 54390421836002042901 59,$$

where the two integers on the right hand side are prime. Using traditional methods, this calculation would have taken many hours.

GLOSSARY

Absolute value Absolute value of a number n is given by $|n| = n$ if $n \geq 0$ and $|n| = -n$ if $n < 0$. Absolute value of a number is always nonnegative.

Composite number Natural number larger than 1 that is not prime. The first 10 composite numbers are 4, 6, 8, 9, 10, 12, 14, 15, 16, and 18. The number 1 is neither prime nor composite.

Definite integral $\int_a^b f(x)\,dx$ is the integral from a to b of the function f with respect to the variable x.

Divisor If a, b, and c are natural numbers with $a = bc$, b and c are divisors or factors of a. Since $12 = 1 \cdot 12 = 2 \cdot 6 = 3 \cdot 4$, it follows that 1, 2, 3, 4, 6, 12 are all factors or divisors of 12.

Greatest integer function $[x]$ is the largest integer whose value does not exceed x. We have $[-1.2] = -2$, $[0.5] = 0$, and $[6.8] = 6$.

***n* factorial** $n! = 1(2)(3)\cdots(n-1)(n)$. That is, $1! = 1$, $2! = 1(2) = 2$, $3! = 1(2)(3) = 6$, and $10! = 1(2)(3)\cdots(9)(10) = 3{,}628{,}800$.

Natural logarithm Natural logarithm of the number x is written in x and is the exponent t such that $e^t = x$, where $e = 2.71828\ldots$.

Natural number Member of the set $\{1, 2, 3, \ldots\}$.

Prime number Natural number larger than 1 whose only divisors are 1 and the number itself. The first 10 primes are 2, 3, 5, 7, 11, 13, 17, 19, 23, and 29.

Proper divisor Any divisor of a natural number except the number itself. Accordingly, 1, 2, 3, 4, and 6 are proper divisors of 12.

NUMBER THEORY is the study of the properties of integers. The numbers used to count, called the counting or natural numbers, are the set $\{1, 2, 3, 4, \ldots\}$. Closely related are the integers $\{\ldots, -3, -2, -1, 0, +1, +2, +3, \ldots\}$, which, along with the operations of addition and multiplication, are the foundation upon which arithmetic is constructed. From the integers, we may construct other systems of numbers, such as the rational numbers or the real numbers. However, it is the properties of the integers and the solution of problems that can be stated in terms of integers that form the subject matter of number theory, sometimes called the higher arithmetic.

I. THE ANCIENT ROOTS OF NUMBER THEORY

A. Arithmetica versus Logistica

As ancient cultures slowly developed the concept of number and applied it to the solution of everyday problems, it was inevitable that a few people would become interested in the properties of numbers, in relations among numbers and their patterns, and in numbers as logical entities rather than as practical tools.

The use of numbers in commerce and trade, construction of temples, surveying of land, and other practical pursuits came to be known as logistica. Such activities, which could be carried on by anyone with knowledge of the proper procedures, particularly commoners or slaves, was considered a less noble endeavor than was the study of abstract properties and relations among numbers, called arithmetica. The latter was considered the province of scholars and royalty, too precious to be entrusted to the common people. In ancient times, then, the goals of arithmetic were the same as those of number theory today: the study of the properties of integers.

B. Ancient Mathematical Records

Some records have survived through the centuries to shed light on the early history of mathematics. In Czechoslovakia in 1937, a wolf bone was found on which were carved 55 notches in groups of 5. The bone, which was about 30,000 years old, suggests that before mankind learned to write there was a compulsion to record numbers.

About 3000 B.C., a mace belonging to King Menes of Egypt was inscribed with hieroglyphic symbols representing 400,000 oxen, 422,000 goats, and 120,000 prisoners. On the Columna Rostrata in Rome, erected in honor of the victory over Carthage in 260 B.C., the symbol for 100,000 was engraved 31 times, signifying the number 3,100,000.

However, surviving records indicate that early mathematics consisted of more than just recording large numbers. Clay tablets from Babylonia containing columns of numbers, which were originally thought to be merely records of business accounts, were later discovered to be mathematical texts and tables. The tablets date from about 2000 to 200 B.C. Some contain solutions to construction problems such as the calculation of areas or volumes. Others relate to business or legal matters such as the computation of interest or the division of estates. Some were tables of multiplication or squares or square roots, whereas others gave the circumferences of circles of various diameters. A table of inverses was used to reduce the operation of division to the more easily performed operation of multiplication.

The tablet designated Plimpton 332 in the Plimpton Library at Columbia University contains columns of numbers that give the hypotenuse and one leg of a right triangle. The other leg can be calculated from the Pythagorean theorem. The sizes of some numbers imply that the Babylonians possessed a general method for solving the right triangle problem. The last column of this tablet gives the value of the cosecant of the acute angle opposite the longer leg of the triangle, indicating that the Babylonians used and tabulated some of the ratios of the sides of a right triangle, as we do today in trigonometry.

The Babylonians also considered problems of a theoretical nature such as circumscribing a circle about an isosceles triangle or finding the area of a circle, the latter leading to the erroneous value of 3 for π.

Other fertile sources of knowledge of ancient mathematics are the papyrus records from Egypt. One of the most notable, the Rhind Papyrus, is displayed in the British Museum. Dating from about 1650 B.C., the Rhind Papyrus contains material copied by the scribe Ahmes from earlier records. The material consists of problems involving arithmetic as well as ideas from geometry. Some problems involved no practical applications but seemed to be posed for the reader's amusement.

Early records such as these show that ancient civilizations were highly interested in mathematics, their achievement in mathematics was considerable, and the knowledge they possessed no doubt formed the basis for works of the Greeks and others who followed.

C. Number Theory versus Numerology

Just as the science of astronomy developed hand in hand with the superstition of astrology, so the early history of number theory is interwoven with numerology, the belief that numbers possessed mystical powers and were a dominant influence in human affairs. One form of numerology was gematria, whereby numbers were assigned to letters of the alphabet, for example, $a = 1$, $b = 2$, and so forth. The numerical value of words or names could then be calculated and studied, thus revealing hidden relationships or future events. A minor nobleman might ingratiate himself with the king by showing that the numerical values of their names, that is, the sum of the letter values, were equal.

Gematria could also warn the unwary of evil as in the Biblical quotation "Here is wisdom. Let him that hath understanding count the number of the beast; for it is the number of a man and his number is six hundred three score and six." To whom the passage referred has never been determined, but during the Reformation it was common to attack an enemy by writing the enemy's name in such a way that the numbers added to 666.

D. The Pythagoreans

One of the strongest influences in ancient number theory came from the Pythagoreans, a brotherhood founded by the philosopher Pythagoras who lived around 570–500 B.C. The members of this mystical order believed that integers were the key to explaining the universe. To support their belief, they had only to point to the fact, which could be verified by trial and error, that halving the length of a vibrating string created a sound an octave higher than the original tone. Further, they knew that when tones whose frequencies were in the ratios of certain whole numbers were sounded together, the result was a harmonious chord.

On such empirical evidence as this, the Pythagoreans based a theory of the universe ruled by integers. Numbers were imbued with human traits or characteristics. Odd numbers such as 1, 3, 5 were called masculine, whereas even numbers such as 2, 4, 6 were feminine. Square numbers such as $4 = 2(2)$ represented justice, the two factors being equal. The number 6 represented the soul, 7 represented health and understanding, and 8 was the number of love and friendship.

Although few today believe in numerology, we may speculate on the origins of some associations of numbers with philosophical concepts. The number 6 is the smallest number that is the sum of all of its proper divisors: $6 = 1 + 2 + 3$. This special property may have led to the number being identified with the important concept of the soul. Again, the Bible states that the earth was created in 6 days.

A few hints of numerology still remain in the ideas that certain numbers such as 7 are "lucky" and that numbers like 13 are "unlucky." Another example is the common expression "bad news comes in threes." Although such notions are now taken lightly, we must remember that ancient people took the principles of numerology seriously and that many purely mathematical questions and problems arose from such occult investigations.

E. Pythagorean Triples

The Pythagorean theorem states that the sum of the squares of the legs of a right triangle equals the square of its hypotenuse, that is, $a^2 + b^2 = c^2$, as shown in Fig. 1. This result was certainly known before the time of Pythagoras, but whether he was the first to actually prove the theorem is unknown because of the Pythagoreans' custom of ascribing all new knowledge to the Master.

Numbers whose values satisfy the Pythagorean theorem, such as 3, 4, and 5 ($3^2 + 4^2 = 9 + 16 = 25 = 5^2$), are permissible values for the sides of a right triangle. In Egypt, men known as rope stretchers made use of the 3, 4, 5 relationship to establish right angles in surveying property or constructing buildings by stretching a rope with knots marking lengths of 3, 4, and 5 units around three stakes, as in Fig. 2.

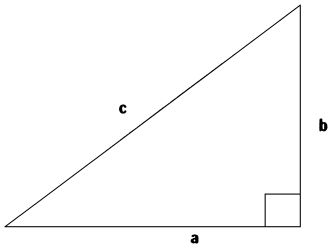

FIGURE 1 The Pythagorean theorem: $a^2 + b^2 = c^2$.

Trial and error leads to the discovery of many such Pythagorean triples, for instance, 5, 12, 13 and 8, 15, 17. It is natural to inquire whether formulas exist that will generate sets of Pythagorean triples. One method, which is attributed to Pythagoras, is as follows: Let n be any positive integer. Then $a = 2n + 1$, $b = 2n^2 + 2n$, and $c = 2n^2 + 2n + 1$ constitute a Pythagorean triple. If $n = 3$, we obtain 7, 24, 25, for which $7^2 + 24^2 = 49 + 576 = 625 = 25^2$. For $n = 4$ we have 9, 40, 41, whereby $9^2 + 40^2 = 81 + 1600 = 1681 = 41^2$. All triples generated in this way lead to triangles having a hypotenuse that is one unit longer than the larger leg.

A more general method consists of choosing integers u and v, one of which is odd and the other even, such that u and v have no common divisors other than the number 1. We then say that u and v are relatively prime. Then, letting $a = 2uv$, $b = u^2 - v^2$, and $c = u^2 + v^2$ gives the desired result. The following examples illustrate this method.

Multiplying each member of a Pythagorean triple by the same integer yields another Pythagorean triple.

u	v	a	b	c
2	1	4	3	5
4	1	8	15	17
8	5	80	39	89

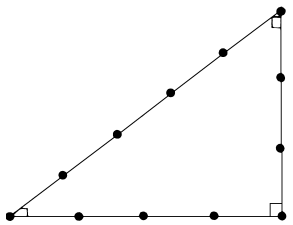

FIGURE 2 Rope stretching.

For example,

$$2(3, 4, 5) = 6, 8, 10,$$

and

$$6^2 + 8^2 = 36 + 64 = 100 = 10^2.$$

F. Prime Numbers

A subject of early investigation in number theory and one of continuing interest today is that of prime numbers. Primes are the building blocks from which all natural numbers are formed. The trial-and-error process for finding primes is a tedious and time-consuming one. It is not surprising that the search for methods or formulas for generating primes should have occupied a fundamental place in early number theory.

Eratosthenes (276–194 B.C.) devised a procedure for finding all primes less than or equal to some number N. The method, known as the Sieve of Eratosthenes, requires that the numbers from 2 to N be listed. All multiples of 2, except for 2 itself, are then crossed out, as are all multiples of 3, except for 3 itself, and so on.

2	3	~~4~~	5	~~6~~	7	~~8~~	~~9~~	~~10~~	11	~~12~~	13
~~14~~	~~15~~	~~16~~	17	~~18~~	19	~~20~~	~~21~~	~~22~~	23	~~24~~	~~25~~
~~26~~	~~27~~	~~28~~	29	~~30~~	31	~~32~~	~~33~~	~~34~~	~~35~~	~~36~~	37

After crossing out multiples of all primes whose values do not exceed $\sqrt{N}$, we have left the primes whose values do not exceed N. Clearly, any composite number N is divisible by a prime whose value is less than or equal to $\sqrt{N}$; otherwise, the product of its prime divisors would be greater than N. The sieve method can be carried out most effectively using computers. Various kinds of sieves have been applied to problems in number theory.

Euclid, who lived from about 330 to 275 B.C., is best known for the geometry contained in his great work, "The Elements." A considerable portion of this work is devoted to number theory. For example, Euclid proves that if a prime p divides the product ab, then either p divides a or p divides b, or both.

In the ninth volume of "The Elements," Euclid proved that the number of primes is infinite. To see this, suppose that only a finite number of primes exist, say $p_1, p_2, \ldots, p_n$. Then the integer $R = p_1 p_2 p_3 \ldots p_n + 1$ is either prime or composite. If R is prime, we have found a prime larger than p_n, contradicting our original assumption. If R is composite, it must be divisible by a prime p. But R is not divisible by any of the primes $p_1, p_2, p_3, \ldots, p_n$, since it leaves a remainder of 1 upon division by any of them. So p must be different from $p_1, p_2, p_3, \ldots, p_n$, again contradicting our assumption. Thus, the number of primes cannot be finite.

G. The Distribution of Primes

The knowledge that the number of primes is infinite leads to speculation about the distribution of primes throughout the set of natural numbers. In general, the density of primes is quite regular, decreasing slowly as we consider larger integers. The following table illustrates this pattern.

Range	Number of primes
2–1,000	168
1,001–2,000	135
2,001–3,000	127
3,001–4,000	120
4,001–5,000	119
⋮ ⋮	⋮
9,995,001–9,996,000	62
9,996,001–9,997,000	58
9,997,001–9,998,000	67
9,998,001–9,999,000	64
9,999,001–10,000,000	53

Despite this overall regularity in the distribution of primes, investigation of particular areas of the set of natural numbers reveals great diversity. Indeed, we can find arbitrarily long blocks of consecutive composite numbers. If $q = 2 \cdot 3 \cdot 5 \cdot \cdots \cdot p)$ is the product of all of the primes from 2 to p, then the natural numbers $q + 2$, $q + 3, q + 4, \ldots, q + p$ are all composite. But since there is no limit to the size of p, the result is established.

As an example, if we use the primes through 19, we find that 9,699,692 and the next 18 integers are all composite. Even more remarkable sequences of composite numbers are know. Thus, 370,261 is prime but the next 111 integers are composite.

H. The Fundamental Theorem of Arithmetic

Every composite number has a divisor other than 1 and the number itself. Such divisors are called proper divisors. A square number may have only one proper divisors. Thus, $49 = 7(7)$. On the other hand, a composite number may have many proper divisors, as in $36 = 2(18) = 3(12) = 4(9) = 6(6)$. Note that some of the proper divisors of 36, such as 2 and 3, are prime, whereas others, such as 4, 6, 9, 12, and 18, are themselves composite. If we continue to break the composite factors into proper divisors we obtain

$$36 = 2 \cdot 18 = 2 \cdot 2 \cdot 9 = 2 \cdot 2 \cdot 3 \cdot 3$$

$$3 \cdot 12 = 3 \cdot 3 \cdot 4 = 3 \cdot 3 \cdot 2 \cdot 2$$

$$4 \cdot 9 = 2 \cdot 2 \cdot 3 \cdot 3$$

$$6 \cdot 6 = 2 \cdot 3 \cdot 2 \cdot 3$$

Ultimately, the factorization yields $2^2 \cdot 3^2$. This illustrates the fact that if we agree to write the prime factors as powers of primes in increasing order, there is only one way to factor a given integer.

1. Fundamental Theorem of Arithmetic

Every natural number can be written uniquely as the product of primes.

Since 2 is the only even prime, for $p > 2$, consecutive primes must differ by two. The pairs of primes (3, 5), (5, 7), (11, 13), (17, 19), (29, 31), etc., are called twin primes. It has been conjectured, but never proven, that there exist an infinite number of pairs of twin primes.

Except for the triplet (3, 5, 7), not all of the numbers p, $p+2$, and $p+4$ can be prime since one of them must be divisible by 3. To see this, note that if p leaves the remainder 1 when divided by 3, $p+2$ is divisible by 3; whereas if p leaves the remainder 2, $p+4$ is divisible by 3. However, it is possible for p, $p+2$, and $p+6$ all to be prime, as in 5, 7, 11 or 17, 19, 23. Similarly, p, $p+4$ and $p+6$ may all be prime as shown by 13, 17, 19 or 37, 41, 43. It is conjectured, but as yet unproven, that there are infinitely many prime triples of each form.

Certain arithmetic sequences have been shown to contain an infinite number of primes. Thus, it is known that there are infinitely many primes of the form $4n-1$. Suppose there are only a finite number of them, say, $p_1 = 3, p_2, p_3, \ldots, p_k$. Forming $R = 4p_1p_2p_3 \cdots p_k - 1$, we see that R is not divisible by any of the primes $p_1, p_2, p_3, \ldots, p_k$. Now any integer must have one of the forms $4n, 4n+1, 4n+2$, or $4n-1$, and an odd prime must have either the form $4n-1$ or $4n+1$. The product of two numbers having the latter form also has the same form:

$$(4n_1+1)(4n_2+1) = 16n_1n_2 + 4(n_1+n_2) + 1 = 4n_3 + 1.$$

Hence if R is composite, at least one of its factors must be a prime of the form $4n-1$. But this is obviously not $p_1, p_2, p_3, \ldots, p_k$. So if R is composite, it has a factor of the form $4n-1$, which is different from the list that was assumed to include all primes of that form.

On the other hand, if R is prime, it has the form $4n-1$ and is different from $p_1, p_2, p_3, \ldots, p_k$. Either way, the assumption that the list includes all primes of the form $4n-1$ is contradicted and so the number of primes having that form cannot be finite.

In a similar fashion, we may show that there are infinitely many primes of the form $4n+1$, $6n+5$, and $8n+5$. All of these cases are included in Dirichlet's theorem, proved by Peter G. L. Dirichlet (1805–1859).

2. Dirichlet's Theorem

If a is positive and a and b are relatively prime, then there are infinitely many primes of the form $an+b$. The proof of this general result is much more difficult than the proof of specific cases.

Dirichlet's theorem stands out like an oasis in a desert wasteland. Attempts to find other functions that will generate an infinite number of primes have resulted in failure. It is not known whether such a simple sequence as n^2+1 contains an infinite number of primes.

I. Greatest Common Divisor

The basic operations of arithmetic are addition and multiplication, from which we derive the inverse operations of subtraction and division, respectively. If integers a and b are both divisible by an integer c, we say that c is a common divisor of a and b. Thus, 36 and 48 have the common divisor 2. It is easily seen that 3, 4, 6, and 12 are also common divisors of the two given numbers. The largest of these, 12, is called the greatest common divisor, or gcd, of 36 and 48, and we write $(36, 48) = 12$. Note that 2, 3, 4, and 6 all divide 12. This illustrates the theorem: If c is a common divisor of a and b, then c divides (a, b).

To show the plausibility of this theorem and to illustrate Euclid's algorithm for finding the gcd of two numbers, consider the numbers 42 and 135. We divide the larger of these two numbers by the smaller, expressing the result in the form

$$\text{dividend} = \text{quotient(divisor)} + \text{remainder}.$$

We have

$$135 = 3(42) + 9.$$

Each subsequent equation involves dividing the divisor of the previous equation by the remainder from that equation. The process stops when a zero remainder is obtained, as it must be, since the remainders form a decreasing sequence of nonnegative integers

$$\begin{aligned} 42 &= 4(9) + 6 \\ 9 &= 1(6) + 3 \\ 6 &= 2(3) + 0. \end{aligned}$$

From the last equation we see that 3 divides 6. From the next-to-the-last equation we see that 3 divides 9 since it divides the right-hand side of the equation. Similarly, 3 divides 42 and also 135. Hence, 3 is a common divisor of 42 and 135.

By rewriting the equations as

$$\begin{aligned} 135 - 3(42) &= 9 \\ 42 - 4(9) &= 6 \\ 9 - 1(6) &= 3, \end{aligned}$$

we can see that any common divisor of 135 and 42 divides 9. Also, any common divisor of 135 and 42 divides 6. Finally, we conclude that any common divisor of 135 and 42 divides 3. Hence, 3 is the gcd of 135 and 42. In general, gcd of the two numbers is always the last nonzero remainder that occurs in the algorithm.

Several results follow from Euclid's algorithm. If the product ab is divisible by c and if a and c are relatively prime, then c divides b. From this it may easily be seen that if a number is relatively prime to each of two or more numbers, it is relatively prime to their product. Also, if $(a, b) = c$, then $(ka, kb) = kc$. The latter may be verified by Euclid's algorithm. As an example, the gcd of $405 = 3(135)$ and $126 = 3(42)$ is $3(3) = 9$.

Euclid's algorithm may be used to prove the following: If c is the gcd of a and b, there exist integers x and y such that $ax + by = c$. For the preceding example, $5(135) - 16(42) = 3$. The numbers x and y can be obtained by solving for c, starting from the next-to-the-last equation and working backward to the first equation.

J. Least Common Multiple

If c is divisible by both a and b, we say that c is a common multiple of a and b. The multiples of 4 are 4, 8, 12, 16, 20, 24, etc., whereas those of 6 are 6, 12, 18, 24, etc. We find that 12 and 24 are both common multiples of 4 and 6.

The smallest of the infinite set of common multiples of a and b is called the least common multiple, or lcm, written $[a, b]$. Therefore, we have $[4, 6] = 12$.

It is easily seen that the lcm of two primes is their product. However, our previous example shows that the lcm of two numbers having a common divisor is smaller than their product. In fact, the product of two integers equals the product of their lcm and their gcd. That is, $ab = (a, b)[a, b]$.

Finding the gcd and the lcm for two numbers can be facilitated by writing each one as the product of primes. For example, $84 = 2^2(3)(7)$ and $90 = 2(3^2)(5)$. We find the gcd by taking each factor appearing in both numbers to the smallest power to which it appears in either number. So $(84, 90) = 2(3) = 6$.

We find the lcm by taking each factor appearing in either number to the largest power to which it appears in either number. So $[84, 90] = 2^2(3^2)(5)(7) = 1260$. Finally, we note that $6(1260) = 7560 = 84(90)$. The definitions of gcd and lcm can be extended to three or more numbers in a straightforward way.

K. Divisibility Rules

Before the advent of computers, finding divisors of large numbers was not an easy task. Therefore, certain divisibility rules were developed. Obviously, a number is divisible by 2 only when it is even, that is, only when it ends in 0, 2, 4, 6, or 8.

Because 100 and all higher powers of 10 are divisible by 4, a number is divisible by 4 only when it ends in 00 or when the number formed by its last two digits is divisible by 4. Only numbers ending in 0 or 5 are divisible by 5.

One hundred and all higher powers of 10 are divisible by 25. A number is divisible by 25 only when it ends in 00 or when the number formed by its last two digits is divisible by 25. Hence, a number is divisible by 25 only when it ends in 00, 25, 50, or 75.

The number 10 and all higher powers of 10 leave the remainder 1 when divided by 3. This means that the remainder from dividing a number by 3 equals the remainder from dividing the sum of the digits of that number by 3. We have $371 = 3(123) + 2$, whereas $3 + 7 + 1 = 11$ and $11 = 3(3) + 2$. Therefore, a number is divisible by 3 if and only if the sum of its digits is divisible by 3.

A similar statement holds for the divisor 9. A number is divisible by 9 if and only if the sum of its digits is divisible by 9. Thus, 12,681 is divisible by 9 since $1 + 2 + 6 + 8 + 1 = 18$ and 18 is divisible by 9. A process called casting out nines, based on the divisibility property of the number 9, can be used to check the results of addition or multiplication. For addition, the digits of each addend are added:

17	$1 + 7 = 8$		8
31	$3 + 1 = 4$		4
84	$8 + 4 = 12$	$1 + 2 = 3$	3
133			15
$1 + 3 + 3 = 7^*$			$1 + 5 = 6^*$

If the result is a two-digit number, these digits are added and so on until each addend has been reduced to a single-digit number. These resulting numbers for all of the addends are then added, the digits again being added if necessary to reduce the final result to a single-digit number.

The same process is applied to the sum, yielding a single-digit number. If these two single-digit numbers, the one from the addends and the one from the sum, are not equal, the addition is incorrect. On the other hand, if the two single-digit numbers are the same, there is no guarantee that the addition is correct. Two different errors may make these numbers the same but make the addition wrong. In particular, the error of transposing two digits will not be detected by this method. Hence, casting out nines can show that the addition process is wrong but cannot show that it is absolutely correct. The results of our example show that the original sum is incorrect.

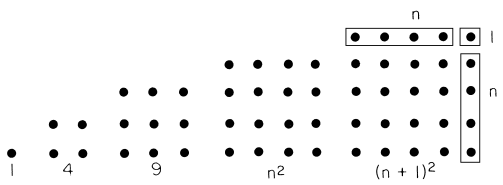

FIGURE 3 The square numbers.

For the product of two numbers the process is similar, except that the single-digit numbers of the factors are multiplied and the resulting product, reduced to a single-digit number if necessary, is compared with the single-digit number of the product. Let us check the product

$$34(28) = 942$$

$$3 + 4 = 7 \qquad 2 + 8 = 10 \qquad 9 + 4 + 2 = 15$$

$$7(10) = 70 \qquad 1 + 5 = 6^*$$

$$7 + 0 = 7^*$$

Since the two single-digit numbers are not equal, the multiplication is incorrect.

L. Figurate Numbers

It was inevitable that the Greeks would take an interest in the relationship between the two major area of mathematics, arithmetic and geometry. By associating n points with the number n and arranging the points in the shape of geometric figures, they were able to investigate relationships among the figurate or polygonal numbers. Consideration of the square numbers, Fig. 3, led to the discovery that

$$n^2 + 2n + 1 = (n + 1)^2,$$

as well as

$$1 + 3 + 5 + \cdots + 2n - 1 = n^2,$$

as shown in Fig. 4. Formulas such as these may be verified by the process of mathematical induction.

The triangular numbers are shown in Fig. 5. Consideration of the pattern in Fig. 6 leads to the relation

$$1 + 2 + 3 + \cdots + n = n(n + 1)/2.$$

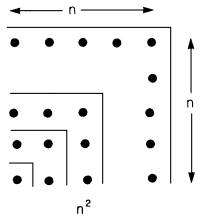

FIGURE 4 The sum of the first n odd positive integers is n^2.

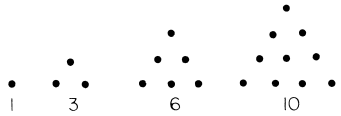

FIGURE 5 The triangular numbers.

Note that the triangular numbers arise from the pattern $1 + 2 + 3 + \cdots$, whereas the square numbers arise from $1 + 3 + 5 + 7 + \cdots$. The next logical pattern, $1 + 4 + 7 + 10 + \cdots$, gives the pentagonal numbers shown in Fig. 7.

Less obvious is the formula that gives the general expression for pentagonal numbers as

$$1 + 4 + 7 + 10 + \cdots + 3n - 2 = (3n^2 - n)/2.$$

The pattern $1 + 5 + 9 + 13 + \cdots$ yields the hexagonal numbers shown in Fig. 8. The general formula for the hexagonal numbers is

$$1 + 5 + 9 + 13 + \cdots + 4n - 3 = n(2n - 1).$$

Even more remarkable is the formula generating the nth number of the series of polygons having m sides:

$$\left(\frac{m-2}{2}\right)n^2 + \left(\frac{4-m}{2}\right)n.$$

M. Perfect Numbers

A perfect number is a natural number that is the sum of its proper divisors, such as $6 = 1 + 2 + 3$ or $28 = 1 + 2 + 4 + 7 + 14$. A general result concerning perfect numbers appears in Euclid's "The Elements."

Theorem. Let p be a prime. The number $N = 2^{p-1}(2^p - 1)$ is a perfect number when the factor $2^p - 1$ is a prime.

The first four perfect numbers generated by this formula are

$$(2^{2-1})(2^2 - 1) = 2^1(3) = 6$$

$$(2^{3-1})(2^3 - 1) = 2^2(7) = 28$$

$$(2^{5-1})(2^5 - 1) = 2^4(31) = 16(31) = 496$$

$$(2^{7-1})(2^7 - 1) = 2^6(128 - 1) = 64(127) = 8128$$

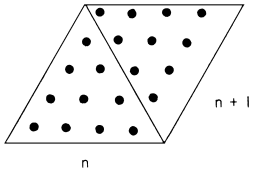

FIGURE 6 The sum of the first n positive integers is $n(n + 1)/2$.

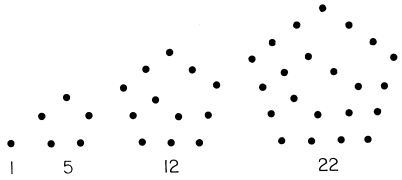

FIGURE 7 The pentagonal numbers.

However, for $p = 11$, we have $2^{11-1}(2^{11} - 1) = 2^{10}(2047)$, which is not a perfect number since $2047 = 23(89)$ is composite.

Nearly 2000 years after the appearance of this theorem, Leonhard Euler (1707–1783) proved that every even perfect number has the form given by Euclid. As a consequence, every even perfect number ends in 6 or 8. There is known to exist a perfect number that requires 54 digits to write in the base 10 system.

The existence of odd perfect numbers is as yet an unresolved question. None has ever been found and it has been shown that none can exist that is smaller than 10^{200}. This is, of course, not the same as showing that no odd perfect numbers exist.

If the sum of the proper divisors of a number is a multiple of the number itself, we call that number a multiply perfect number. For example, the divisors of 120 have a sum of 240. We call 120 a doubly perfect number or a perfect number of class 2. Other multiply perfect numbers of class 2 are 672 and 523, 776. More than 300 multiply perfect numbers have been found, including some of class 7.

Numbers for which the sum of the proper divisors is less than the number itself are called deficient numbers, the first few being 2, 3, 4, 5, 7, 8, 9, 10, and 11. Numbers for which the sum of the proper divisors is greater than the number itself are called abundant numbers, of which the first few are 12, 18, 20, 24, 30, and 36. The smallest odd abundant number is 945.

Since a prime has only the number 1 as a proper divisor, it is obvious that all primes are deficient numbers as are powers of primes. Furthermore, all divisors of a perfect number or a deficient number are deficient, whereas all multiples of a perfect number or an abundant number are abundant.

As one example of the role of abundant and deficient numbers in numerology, in the eighth century, Alcuin noted that the original Creation was accomplished in 6 days, 6 being a perfect number. However, the human race was supposed to be descended from 8 persons in the Ark, 8 being a deficient number. This implied that God's act was perfect and the latter occurrence imperfect.

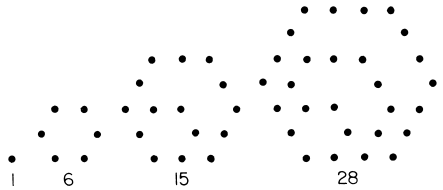

FIGURE 8 The hexagonal numbers.

Two numbers a and b are called amicable numbers if the sum of the proper divisors of a equals b and the sum of the proper divisors of b equals a. For example, the sum of the proper divisors of 220 is 284 and the sum of the proper divisors of 284 is 220. Thus, 220 and 284 form an amicable pair.

Numerologists believed that a couple could strengthen their bond of love or friendship by inscribing each of a pair of keepsakes with one of two amicable numbers, with each person retaining one of the keepsakes. If the names of the two friends could be written in such a way that the number of one name was 220 and the number of the other name was 284, the relationship would be even stronger. Other pairs of amicable numbers are 1184 and 1210 as well as 17,296 and 18,416. Nearly 400 amicable pairs have been discovered, including a pair for which each number requires 50 digits to write in the base 10 system.

N. Diophantine Equations

Diophantus lived about the third or fourth century A.D. His work, "Arithmetic," deals with the solution of certain algebraic problems in which a symbol is used to represent the unknown quantity, just as we do today. Although we do not know his dates, a problem from the "Palatine Anthology," which purports to describe the tomb of Diophantus, suggests a way of finding his age at death. The description says that God granted him the sixth part of his life for his youth, that after a twelfth part his cheeks were bearded, after a seventh part he married, a son was born in the fifth year of his marriage, the child was "half of his father," and that Diophantus grieved the remaining 4 years of his life. Interpreting "half of his father" to mean that the child's age at death was half of the age at which the father died, we have

$$X/6 + X/12 + X/7 + 5 + X/2 + 4 = X,$$

where X is Diophantus' age upon his death. Solving the equation gives $X = 84$.

In another problem, the reader is asked to find two numbers whose sum is 20 and the sum of whose squares is 208. Instead of letting one number be x and the other $20 - x$, as a modern student of algebra would do, Diophantus called the required numbers $10 + x$ and $10 - x$. Then the conditions of the problems require that $(10 + x)^2 + (10 - x)^2 = 208$, where $x = 2$ and the required numbers are 8 and 12. Diophantus' selection of $10 + x$ and $10 - x$ to represent the two numbers leads to a simpler equation to solve than does the modern approach.

Not all of the problems given by Diophantus yield integral solutions. One requires that 13, which equals the sum of the squares 4 and 9, be written as the sum of two other squares. The answer is $\frac{1}{25} + \frac{324}{25}$ or $(\frac{1}{5})^2 + (\frac{18}{5})^2$.

Neither did all of the problems have unique solutions. For example, a tax collector must collect 2 gold pieces for each man, 1 gold piece for each woman, and $\frac{1}{2}$ gold piece for each child in a certain town. If he collects 100 gold pieces from 100 residents, how many men, women, and children live in the town? The conditions lead to the equations:

$$2x + y + \tfrac{1}{2}z = 100,$$

and

$$x + y + z = 100,$$

where x, y, and z represent the number of men, women, and children, respectively. Subtracting the second equation from the first, we find

$$x - \tfrac{1}{2}z = 0 \qquad \text{or} \qquad z = 2x.$$

Thus, we know that there are twice as many children as men. (This is as far as mathematics will take us because we have two equations containing three unknowns.) We can choose to let x be any integer less than or equal to 33 and determine y and z. Some of the solutions are

x	$z = 2x$	$y = 100 - x - z$
10	20	70
20	40	40
25	50	25
33	66	1

Such a problem with multiple solutions is called an indeterminate problem. Problems whose solutions are required to be rational numbers or integers came to be known as Diophantine equations. Although Diophantus frequently gave rational as well as integral solutions to his problems, in present day terminology, the word Diophantine usually refers to problems requiring integral solutions.

O. Magic Squares

If a square is divided into n^2 smaller squares and one of the integers from 1 to n^2 is written in each of the smaller squares (using each number only once) in such a way that the sum of the integers in any row, column, or main diagonal is always the same, the result is called a magic square of order n. A few examples of magic squares are shown in Fig. 9.

Interest in magic squares dates back to about 2200 B.C. in China where the diagram of Fig. 10, called the Lo-Shu, appeared.

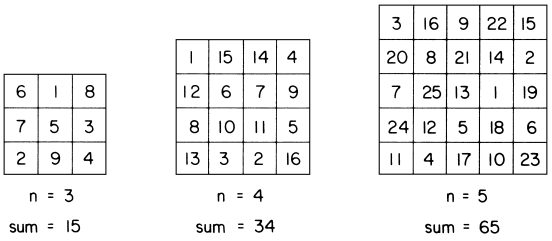

FIGURE 9 Magic squares of order 3, 4, and 5.

The sum of the integers in any row, column, or main diagonal of a magic square of order n, constructed from the integers $1, 2, 3, \ldots, n^2$, is $n(n^2+1)/2$. Such a magic square is said to be primitive. Many different rules exist for constructing magic squares, with some rules depending on whether n is odd or even.

It is easily seen that no magic squares exist of order 2. Also, any set of n^2 consecutive integers may be substituted for the integers in a magic square of order n as long as the original pattern for integers of increasing size is followed. This is, of course, equivalent to adding a constant to each number of a given magic square. Furthermore, the requirement that the integers be consecutive may be weakened to require sequences of integers that differ by a fixed amount.

For example, if we add 11 to each number in the magic square of order 3 given above, we have the result shown in Fig. 11, where the sum is $15 + 3(11) = 48$. If we replace the original integers by the sequence $20, 25, 30, \ldots$, we obtain the magic square of Fig. 12, for which the sum is 120. Certain rows or columns of a magic square can be interchanged without destroying the equal sum property.

While many purely mathematical properties have been discovered concerning magic squares, they were originally of interest because of their supposed power to ensure good fortune or to ward off evil influences. Magic squares engraved on precious metal were worn as amulets.

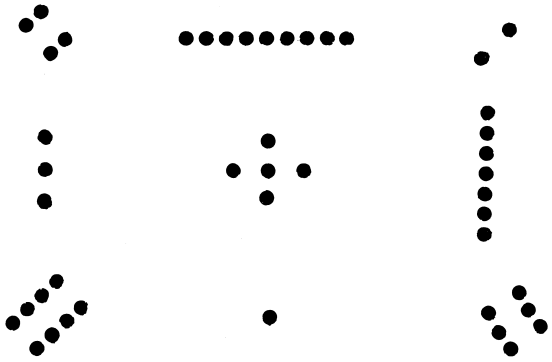

FIGURE 10 The Lo-Shu.

17	12	19
18	16	14

FIGURE 11 Magic square formed by the addition of a constant.

A magic square, when engraved on a plate of silver, was believed to protect the owner from the plague. The magic square of order 4, shown in Fig. 9, appears in Dürer's engraving Melancholia.

What must rank near the top of any list of incredible coincidences was discovered by T. E. Lobeck. Starting with the magic square of order 5, shown in Fig. 13, he substituted the nth digit in the decimal expansion of $\pi = 3.14159\ldots$ for the integer n in the magic square. The result appears in Fig. 14. The sum of each column also occurs as the sum of a row. Perhaps more amazing is the fact that the sum of the two main diagonals is $38 + 27 = 65$, which is the sum of the numbers in any row, column, or main diagonal of the original magic square.

II. CLASSICAL PROBLEMS AND RESULTS

Certain themes in number theory that had their origins in antiquity reappeared during the Middle Ages or the Renaissance. Indeed, some of them have continued to be the objects of research to this day. In this section, we examine some of the major results that have been achieved in number theory since the days of Greek mathematics, regardless of whether those results concern problems of ancient derivation or more recent origin.

A. Indeterminate Problems

We start with a simple problem. A barnyard contains chickens and goats. Altogether there are 72 legs in the barnyard. How many chickens and how many goats are there? The conditions result in the equation $4x + 2y = 72$, where x is the number of goats and y is the number of chickens. Obviously, there are a multitude of solutions for this equation, some of which we may discover by solving for one variable in terms of the other, $y = (72 - 4x)/2$:

45	20	55
50	40	30
25	60	35

x	y
10	16
15	6
-5	46
$\sqrt{2}$	$-2\sqrt{2} + 36$ etc.
$\vdots$	$\vdots$

The realities of the world preclude certain solutions such as those involving negative or irrational numbers. Even with these restrictions, there are 19 integral solutions corresponding to $x = 0, 1, 2, \ldots, 18$.

Of course, the number of variables is not restricted to 2. Consider the following problem: Thirty people enter a movie theater, paying a total of \$50. If men pay \$3 each, women \$2 each, and children \$1 each, how many men, how many women, and how many children make up the party?

If we let x equal the number of men, y the number of women, and z the number of children, we have

$$x + y + z = 30$$

and

$$3x + 2y + z = 50.$$

Subtracting the first equation from the second yields

$$2x + y = 20 \qquad \text{or} \qquad y = 20 - 2x.$$

Letting x take on the values $0, 1, 2, \ldots, 10$ gives these values for y: $20, 18, 16, \ldots, 0$. Then either equation gives these values for z: $10, 11, 12, \ldots, 20$. There are eleven solutions consisting of the triples (0, 20, 10), (1, 18, 11), (2, 16, 12), . . . , (10, 0, 20).

17	29	25	24	23	

FIGURE 14 The result of substituting the digits of π into the magic square of Fig. 13.

Sometimes, additional conditions restrict the number of solutions. In this problem, one might require that the number of women be twice the number of men, yielding the unique solution (5, 10, 15). At other times there may be an infinite number of solutions or even no solution. One renowned indeterminate problem, called the cattle problem of Archimedes, results in seven equations in eight unknowns whose solution yields extremely large numbers.

Many problems of this type, called linear indeterminate problems, originated in India. The Hindu mathematician Brahmagupta (born in 598 A.D.) authored a treatise on astronomy that included chapters devoted to mathematics. This work, "Brahma-Sphuta-Siddhanta" (or "Brahma's Correct System") includes solutions of numerous linear indeterminate equations. Also found there is the second-degree indeterminate equation $nx^2+1=y^2$, for which Brahmagupta gives the solution

$$x = 2t/(t^2-n)$$
$$y = (t^2+n)/(t^2-n),$$

where t is any integer. Thus, if $n=3$, we have $3x^2+1=y^2$ and $x=2t/(t^2-3)$ and $y=(t^2+3)/(t^2-3)$, which leads to

t	x	y
1	-1	-2
2	4	7
3	1	2

$\vdots$	$\vdots$	$\vdots$

He also states that the equation $nx^2-1=y^2$ has no integral solutions for x and y unless n is the sum of the squares of two integers. For example, $4x^2-1=y^2$ has no integral solutions, whereas $13x^2-1=y^2$ has integral solutions because $13=2^2+3^2$. One solution is $x=5$, $y=18$.

The search for general solutions was aided by the introduction of symbols for certain quantities and operations that occur frequently within a given problem. The use of this technique is credited to Diophantus. For a long period of time, mathematicians did not differentiate between problems leading to determinate or indeterminate solutions. Today, algebra students are exposed almost exclusively to determinate problems.

The following results are useful in solving certain indeterminate problems.

Theorem. If the integers a and b are relatively prime then there exist integers x and y such that $ax+by=1$. This follows directly from Euclid's algorithm and leads to

Theorem. There exist integers x and y satisfying the equation $ax+by=c$ if and only if the gcd of a and b divides c.

For example, in the equation $14x+35y=56$, we find that $(14, 35)=7$ and 7 divides 56. Dividing, we obtain the equivalent equation $2x+5y=8$. We now let $2x+5y=1$ and find the solution $x=-2$, $y=1$. Then $x=8(-2)=-16$ and $y=8(1)=8$ are solutions of $2x+5y=8$, and therefore of $14x+35y=56$. From the particular solution x_0, y_0, we can find the general solution $x=x_0+tb$ and $y=y_0-ta$, where t is any integer. In our case, $x=-16+35t$ and $y=8-14t$.

Diophantine equations involving variables to the second or higher powers can prove difficult or impossible to solve. Although many special results exist, a general method of solving any Diophantine equation or proving the nonexistence of solutions is unknown. We mention a few particular results. It is known that the equations $x^3+y^3=z^3$ and $x^4+y^4=z^4$ have no positive integral solutions.

The equation $x^4+y^4=u^4+v^4$ has general solutions that we shall not list. The smallest integral solution is $133^4+134^4=158^4+59^4$.

It has been proven that the equation $ax^n+by^n=c$ has only finitely many solutions if $n\geq 3$. More generally, Axel Thue (1863–1922) showed that if a function of x and y,

$$f(x, y)=a_nx^n+a_{n-1}x^{n-1}y+\cdots+a_1xy^{n-1}+a_0y^n,$$

with a_i integers, cannot be factored into two polynomials having integral coefficients, then the equation $f(x, y)=c$ has only a finite number of solutions for $n\geq 3$.

The equation $x^2-cy^2=1$ is known as Pell's equation, after John Pell (1610–1685), although he had no part in its solution. For any value of c there is the trivial solution $x=\pm 1$, $y=0$. If c is a square number, the left-hand side is easily factored. If c is a positive nonsquare integer, then it can be proved that the equation always has a nontrivial solution. Such solutions may not necessarily be obtained readily by trial and error. The equation $x^2-61y^2=1$ has $x=1{,}766{,}319{,}049$ and $y=226{,}153{,}980$ as its smallest positive nontrivial solution.

The foregoing discussion is meant to illustrate the wide range of problems leading to Diophantine equations, the great variety of approaches to solving such problems and the enormous difficulty that is entailed in the solution of certain of them.

B. Congruences

The theory of congruences was begun by the work of Carl Friedrich Gauss (1777–1855), which originally appeared

in his "Disquisitiones Arithmeticae" in 1801. We say that the two integers a and b are congruent for the modulus m, and write $a \equiv b(\text{mod } m)$ if their difference $a - b$ is divisible by the integer m. For example, $21 \equiv 6 \pmod 5$, since $21 - 6 = 15$ is divisible by 5. Similarly, $19 \equiv 54(\text{mod } 7)$ since $19 - 54 = -35$ is divisible by 7. However, as is easily verified, 18 is not congruent to 11(mod 3) and we write $18 \not\equiv 11(\text{mod } 3)$.

Since any integer n leaves a remainder of $0, 1, 2, \ldots, m-1$ when it is divided by m, we see that the integers can be partitioned into m classes according to the remainder obtained upon division by m. They are called the residue classes (mod m). Thus, the residue classes (mod 5) consist of

$$\begin{array}{cccccccc} \ldots, & -10, & -5, & 0, & 5, & 10, & \ldots \\ \ldots, & -9, & -4, & 1, & 6, & 11, & \ldots \\ \ldots, & -8, & -3, & 2, & 7, & 12, & \ldots \\ \ldots, & -7, & -2, & 3, & 8, & 13, & \ldots \\ \ldots, & -6, & -1, & 4, & 9, & 14, & \ldots . \end{array}$$

Obviously, any two integers within a given residue class are congruent (mod m).

Certain properties of congruences follow immediately from the definition. Thus, if $a \equiv b(\text{mod } m)$ and $c \equiv d(\text{mod } m)$, then

(1) $(a + c) \equiv (b + d)(\text{mod } m)$,
(2) $ac \equiv bd(\text{mod } m)$,
(3) $a^n \equiv b^n(\text{mod } m)$, and
(4) $a \equiv b(\text{mod } n)$ where n is a divisor of m.

Furthermore, if $a \equiv b(\text{mod } m_1)$ and $a \equiv b(\text{mod } m_2)$, then $a \equiv b(\text{mod } M)$, where M is the lcm of m_1 and m_2. So, from the congruences $17 \equiv 377(\text{mod } 24)$ and $17 \equiv 377(\text{mod } 40)$, we conclude that $17 \equiv 377(\text{mod } 360)$, where $[24, 40] = 360$.

Finally, if $ac \equiv bc(\text{mod } m)$, then $a \equiv b(\text{mod } m/d)$, where d is the gcd of c and m. Thus, when the congruence $48 \equiv 18(\text{mod } 15)$ is written as $8(6) \equiv 3(6)(\text{mod } 15)$, we see that $(6, 15) = 3$. Hence, $8 \equiv 3(\text{mod } 5)$.

To illustrate the utility of calculating with congruences, consider the problem of finding the smallest positive remainder obtained when 15^{19} is divided by 23. We have

$$\begin{aligned} 15 &\equiv -8(\text{mod } 23) \\ 15^2 &\equiv 64(\text{mod } 23) \equiv -5(\text{mod } 23) \\ 15^3 &\equiv 40(\text{mod } 23) \equiv -6(\text{mod } 23) \\ 15^4 &\equiv 25(\text{mod } 23) \equiv 2(\text{mod } 23) \\ 15^{16} &\equiv (15^4)^4(\text{mod } 23) \equiv 2^4(\text{mod } 23) \\ &\equiv 16(\text{mod } 23). \end{aligned}$$

Then,

$$\begin{aligned} 15^{19} &\equiv 15^{16}(15^3)(\text{mod } 23) \equiv 16(-6)(\text{mod } 23) \\ &\equiv -96(\text{mod } 23) \equiv 19(\text{mod } 23). \end{aligned}$$

Hence, 15^{19} leaves a remainder of 19 when divided by 23.

C. Linear Congruences

Just as in the case of linear equations, linear congruences involve the first power of a variable. Whereas linear equations yield only a single solution, linear congruences may give an unlimited number of solutions. The linear congruence $2x \equiv 6(\text{mod } 12)$ has the solution $x = 3$ as well as any integer that is congruent to 3(mod 12).

Of greater interest, however, is the question of whether two or more noncongruent solutions exists. Trial and error will show that our previous example also has the solution $x \equiv 9(\text{mod } 12)$. Also, unlike linear equations, linear congruences may have no solution. In general, $ax \equiv b(\text{mod } m)$ has solutions only when the greatest common divisor of a and m also divides b. In this case, there are exactly (a, m) noncongruent solutions.

Again, the congruence $18x \equiv 24(\text{mod } 30)$ has $(18, 30) = 6$ solutions given by the numbers 3, 8, 13, 18, 23, and 28. Note that all solutions after the first are obtained by successively adding $\frac{30}{6} = 5$ to the previous solution. On the other hand, the congruence $15x \equiv 12(\text{mod } 35)$ has no solution because $(15, 35) = 5$ does not divide 12.

Two or more linear congruences may be solved simultaneously. By listing the solutions of the two congruences $x \equiv 5(\text{mod } 7)$ and $x \equiv 4(\text{mod } 11)$, which are $12, 19, 26, 33, \ldots$ and $15, 26, 37, \ldots$, respectively, we see that 26 is a common solution. Then $x \equiv 26(\text{mod } 7 \cdot 11)$ or $x \equiv 26(\text{mod } 77)$ is the simultaneous solution.

D. Chinese Remainder Theorem

Many ancient problems involved linear congruences. Such a problem concerned the removal of eggs from a basket 2, 3, 4, 5, and 6 at a time, whereupon 1 egg remained. However, when they were removed 7 at a time, none remained. This may be stated in terms of congruences as follows: $x \equiv 1(\text{mod } 2)$, $x \equiv 1(\text{mod } 3), \ldots, x \equiv 1(\text{mod } 6)$, $x \equiv 0(\text{mod } 7)$. These are equivalent to the two congruences $x \equiv 1(\text{mod } 60)$ and $x \equiv 0(\text{mod } 7)$, which have the solution $x \equiv 301(\text{mod } 420)$.

Problems of this type are found in the works of the Chinese mathematician Sun-Tse. When each pair of moduli is relatively prime, the solution is found in the following theorem.

Chinese Remainder Theorem. Given the simultaneous congruences $x \equiv a_i(\text{mod } m_i)$ for $i = 1, 2, 3, \ldots, n$,

where $(m_i, m_j) = 1$ for all i, j, let $M = m_1 m_2 m_3 \cdots m_n$. If for each i the congruence $b_i(M/m_i) \equiv 1 (\text{mod } M/m_i)$ is solved, then the original set of congruences has the solution

$$x \equiv [a_1 b_1 (M/m_1) + a_2 b_2 (M/m_2) + a_3 b_3 (M/m_3) + \cdots + a_n b_n (M/m_n)] (\text{mod } M).$$

We illustrate the use of the Chinese remainder theorem with the following problem. A shipwrecked sailor passes the time of day by counting the coconuts he has gathered. When he counts by threes, there are 2 coconuts left over. When he counts by fives, there are 4 left over, and when he counts by sevens, there are 5 left over. How many coconuts has the sailor gathered?

The conditions of the problem lead to the congruences $x \equiv 2 (\text{mod } 3)$, $x \equiv 4 (\text{mod } 5)$, and $x \equiv 5 (\text{mod } 7)$; whence $a_1 = 2$, $m_1 = 3$, $a_2 = 4$, $m_2 = 5$, $a_3 = 5$, and $m_3 = 7$. Then $M = 3(5)(7) = 105$ and $M/m_1 = 35$, and $M/m_2 = 21$, and $M/m_3 = 15$. The new set of congruences is $35b_1 \equiv 1 (\text{mod } 3)$, $21b_2 \equiv 1 (\text{mod } 5)$ and $15b_3 \equiv 1 (\text{mod } 7)$. The solutions of the latter are $b_1 = 2$, $b_2 = 1$, and $b_3 = 1$. Thus,

$$\begin{aligned} x &\equiv [2(2)(35) + 4(1)(21) + 5(1)(15)] (\text{mod } 105) \\ &\equiv 299 (\text{mod } 105) \equiv 89 (\text{mod } 105) \end{aligned}$$

is the solution of the original set of congruences.

Other theorems of interest that involve congruences include one due to Pierre de Fermat (1601–1665) called Fermat's Little Theorem. If p is a prime number that does not divide the number a, then $a^{p-1} \equiv 1 (\text{mod } p)$.

For instance, if $p = 5$ and $a = 8$, we have $8^{5-1} = 8^4 = 4096 \equiv 1 (\text{mod } 5)$.

Fermat's little theorem is a special case of a theorem by Euler. For a positive integer n, the number of integers from 1 to n that are relatively prime to n is indicated by $\phi(n)$. Thus, $\phi(8) = 4$ since 8 is relatively prime to 1, 3, 5, and 7. Also, $\phi(11) = 10$ because 11 is relatively prime to the integers from 1 to 10. Note that for any prime p, $\phi(p) = p - 1$. We state

Euler's Theorem. If a and m are relatively prime, then $a^{\phi(m)} \equiv 1 (\text{mod } m)$.

Thus, if $a = 9$ and $m = 8$, we have $9^4 = 6561 \equiv 1 (\text{mod } 8)$, which is easily verified.

E. Wilson's Theorem

We next consider

Wilson's Theorem. The integer p is a prime if and only if $(p-1)! \equiv -1 (\text{mod } p)$.

For example, if $p = 7$, then

$$(7-1)! = 6! = 720 \equiv -1 (\text{mod } 7).$$

However, for $p = 6$,

$$(6-1)! = 5! = 120 \not\equiv -1 (\text{mod } 6).$$

Wilson's theorem is credited to John Wilson (1741–1793), although it was first proved by Joseph Louis Lagrange (1736–1813). It is noteworthy because it gives a necessary and sufficient condition for an integer to be prime. In practice, however, it is of limited use in determining the primality of integers, because the factorial expression becomes so large that its computation quickly exceeds all reasonable time limits, even on the most modern computers.

A complementary result is the following theorem.

Theorem. If n is a composite integer different from 4, then $(n-1)! \equiv 0 (\text{mod } n)$.

The fact that 1255 is composite guarantees that $(1254)! \equiv 0 (\text{mod } 1255)$.

We now examine some results for congruences involving a variable to the second or higher power. When the highest power of the variable is 2, we call the congruence a quadratic congruence, analagous to a quadratic equation. The following theorems, which are consequences of Wilson's theorem, give explicit solutions for certain quadratic congruences.

Theorem. If p is a prime having the form $4n + 1$, then the roots of the congruence $x^2 \equiv -1 (\text{mod } p)$ are

$$x \equiv \pm \left(\frac{p-1}{2} \right)! (\text{mod } p).$$

To illustrate, let $p = 13 = 4(3) + 1$. Then the congruence $x^2 \equiv -1 (\text{mod } 13)$ has the solutions

$$x \equiv \left(\frac{13-1}{2} \right)! (\text{mod } 13),$$

or

$$x \equiv 6! (\text{mod } 13) \equiv 5 (\text{mod } 13),$$

which we illustrate by

$$5^2 = 25 \equiv -1 (\text{mod } 13)$$

and

$$x \equiv -6! (\text{mod } 13) \equiv 8 (\text{mod } 13),$$

which we illustrate by

$$8^2 = 64 \equiv -1 (\text{mod } 13).$$

Any odd prime must be of the form $4n + 1$, considered previously, or of the form $4n + 3$, for which the following holds.

Theorem. If p is a prime of the form $4n+3$, then one of the congruences

$$\left(\frac{p-1}{2}\right)! \equiv \pm 1 (\text{mod } p)$$

holds. As an example, we see that when $n=3$,

$$\left(\frac{3-1}{2}\right)! = 1! = 1 \equiv 1 (\text{mod } 3)$$

and when $n=7$,

$$\left(\frac{7-1}{2}\right)! = 3! = 6 \equiv -1 (\text{mod } 7).$$

There is a complex procedure for determining whether the positive or negative sign prevails.

A more general result is contained in the following theorem.

Theorem. If p is an odd prime that does not divide the integer a, then $x^2 \equiv a (\text{mod } p)$ has a solution when $a^{(p-1)/2} \equiv 1 (\text{mod } p)$ and has no solution when $a^{(p-1)/2} \equiv -1 (\text{mod } p)$.

Let $p=7$ and $a=8$. Then $8^{(7-1)/2} = 8^3 = 512 \equiv 1 (\text{mod } 7)$, so the congruence $x^2 \equiv 8 (\text{mod } 7)$ has a solution. One easily found solution is $x \equiv 1 (\text{mod } 7)$.

On the other hand, if $p=5$ and $a=8$, then $8^{(5-1)/2} = 8^2 = 64 \equiv -1 (\text{mod } 5)$. Hence, the congruence $x^2 \equiv 8 (\text{mod } 5)$ has no solutions.

By trial and error we find that the congruence $x^2 + 5x \equiv 0 (\text{mod } 6)$ has the four solutions $x \equiv 0 (\text{mod } 6)$, $x \equiv 1 (\text{mod } 6)$, $x \equiv 3 (\text{mod } 6)$, and $x \equiv 4 (\text{mod } 6)$. However, if the modulus is prime, a polynomial congruence of degree n cannot have more than n solutions. It may have fewer than n. For example, $x^3 \equiv 1 (\text{mod } 5)$ has only the solution $x \equiv 1 (\text{mod } 5)$.

In general, in order to solve a polynomial congruence, one has only to solve polynomial congruences having moduli that are powers of a prime. We illustrate the method by considering the congruence

$$x^3 - 2x^2 + 12 \equiv 0 (\text{mod } 44).$$

Because $44 = 2^2 \cdot 11$, we write two new congruences

$$x^3 - 2x^2 + 12 \equiv 0 (\text{mod } 2^2)$$

and

$$x^3 - 2x^2 + 12 \equiv 0 (\text{mod } 11).$$

The first has the solutions $x \equiv 0 (\text{mod } 4)$ and $x \equiv 2 (\text{mod } 4)$, whereas the second has the solutions $x \equiv 1 (\text{mod } 11)$, $x \equiv 4 (\text{mod } 11)$, and $x \equiv 8 (\text{mod } 11)$. By applying the Chinese remainder theorem to pairs of these latter congruences, each pair containing a congruence of modulus 4 and a congruence of modulus 11, we find the solutions of the original congruence to be

$$x \equiv 4 (\text{mod } 44), \qquad x \equiv 8 (\text{mod } 44)$$
$$x \equiv 12 (\text{mod } 44), \qquad x \equiv 26 (\text{mod } 44)$$
$$x \equiv 30 (\text{mod } 44), \qquad x \equiv 34 (\text{mod } 44).$$

F. Quadratic Residues

We now examine the law of quadratic reciprocity, one of the most profound and powerful results in the theory of congruences. If the integers a and m are relatively prime, we say that a is a quadratic residue of m if the congruence $x^2 \equiv a (\text{mod } m)$ has a solution. If it has no solution, we say that a is a quadratic nonresidue of m. Since $x^2 \equiv 11 (\text{mod } 5)$ has the solution $x \equiv 1 (\text{mod } 5)$, we see that 11 is a quadratic residue of 5. However, $x^2 \equiv 13 (\text{mod } 5)$ has no solution, showing that 13 is a quadratic nonresidue of 5.

The Legendre symbol simplifies discussion of quadratic reciprocity. If p is an odd prime that does not divide a, we write $(a/p) = 1$ if a is a quadratic residue of p and $(a/p) = -1$ if a is a quadratic nonresidue of p. From our previous discussion, we have $(11/5) = 1$ and $(13/5) = -1$.

We have already mentioned Euler's criterion, which states that r is a quadratic residue of an odd prime p if $r^{(p-1)/2} \equiv 1 (\text{mod } p)$ and r is a quadratic nonresidue of p if $r^{(p-1)/2} \equiv -1 (\text{mod } p)$. Thus, from the fact that $5^{(11-1)/2} = 5^5 = 3125 \equiv 1 (\text{mod } 11)$, we conclude that 5 is a quadratic residue of 11. However, $5^{(13-1)/2} = 5^6 = 15{,}625 \equiv -1 (\text{mod } 13)$, which indicates that 5 is a quadratic nonresidue of 13. Hence, $(5/13) = -1$ while $(5/11) = 1$.

Also, $x^2 \equiv 11 (\text{mod } 7)$ has the solution $x \equiv 2 (\text{mod } 7)$, so $(11/7) = 1$. However, $x^2 \equiv 7 (\text{mod } 11)$ has no solution, whence $(7/11) = -1$.

We see that in some cases $(p/q) = (q/p)$ as in $(5/13) = (13/5) = -1$ or $(11/5) = (5/11) = 1$, but in other cases $(p/q) = -(q/p)$, for example, $(11/7) = 1 \neq (7/11) = -1$. The question arises as to when equality holds and when it does not. Euler discovered a pattern that he believed answered this question, and Gauss later gave several proofs that this pattern was indeed true in all cases. The key to the pattern is the observation that every odd prime has either the form $4n+1$ or $4n+3$. If p and q are odd primes and either one of them has the form $4n+1$, then $(p/q) = (q/p)$, as in $(5/11) = (11/5)$. However, if both of the primes have the form $4n+3$, then $(p/q) = -(q/p)$. An example of the latter is $(11/7) = -(7/11)$.

The theorem is usually stated in the more elegant form

Law of Quadratic Reciprocity. When p and q are distinct odd primes then

$$(p/q)(q/p) = (-1)^{[(p-1)/2][(q-1)/2]}.$$

Gauss gave six proofs of the law of quadratic reciprocity and more than 50 proofs have been devised.

A number of assertions by Fermat can be shown to follow from the law of quadratic reciprocity, including the following.

1. Every prime of the form $8n+1$ or $8n+3$ has the form x^2+2y^2. For example, $17=3^2+2(2^2)$ or $41=3^2+2(4)^2$.
2. Every prime $3n+1$ has the form x^2+3y^2 but no prime $3n-1$ has this form.
3. Every prime $4n+1$ is the sum of two squares in only one way.

G. Formulas for Primes

A glance at a list of the first few primes is sufficient to convince one that any formula that would yield all of the primes would be a most unusual contrivance. Even the related but less demanding task of finding a formula that would produce only primes seems most formidible.

Certain formulas furnish partial results, For example, if we replace x in the function $f(x)=x^2+x+41$ with $x=0,\pm1,\pm2,\ldots,\pm39$, or -40, the result in each case is a prime. The same is true of $g(x)=x^2-79x+1601$ for $x=0,1,2,\ldots,79$. The function f is a composite of two formulas, one given by Euler in 1772, the other by Legendre in 1798.

Euler also found that $2x^2+n$ is prime for $x=0,1,\ldots,n-1$ where n is one of the numbers 3, 5, 11, or 29. Paul Pritchard discovered the imposing expression,

$$11{,}410{,}337{,}850{,}553+4{,}609{,}098{,}694{,}200x,$$

which is prime for $x=0,1,\ldots,21$.

Similar formulas of this nature exist, but it can be shown that no polynomial function having integral coefficients can generate only prime numbers for integral values of x. One need only observe the effect of calculating $f(41)=(41)^2+41+41$ to understand why any polynomial will eventually produce a composite number.

The function f given above generates primes for 80 consecutive integers. It has been conjectured that this is the largest number of consecutive primes that a quadratic polynomial can produce. All that is known for sure is that no quadratic having the form x^2+x+c, where $c>41$, can yield primes for all values of $x=0,1,2,3,\ldots,c-2$.

From algebra we know that a polynomial of degree n can be constructed to assume $n+1$ arbitrary values. Thus, the function $h(x)=-x^3/6+x^2+x/6+2$ gives the first four primes for $x=0$, 1, 2, and 3. However, a similar polynomial yielding the first 101 primes would have degree 100. The longest known arithmetic progression consisting entirely of primes is given by $223{,}092{,}870n+2{,}236{,}133{,}941$ where $n=0,1,2,\ldots,15$.

W. H. Mills proved the following remarkable theorem: There exists a real number θ such that $[\theta^{3n}]$ is prime for all positive integers n. Unfortunately, there seems to be little hope of determining the value of θ, so the theorem is presently of no use for constructing primes. Similar formulas exist for expressing p_n as a function of some parameter θ. In order to determine θ to an accuracy sufficient to calculate p_n, it proves necessary to know the primes $p_1, p_2, p_3, \ldots, p_n$. Such formulas are thus equally useless for constructing new primes, unless some method can be found for determining θ without using $p_1, p_2, p_3, \ldots, p_n$. No such method has yet been found, nor has it been proved impossible for such a method to exist. The question is thus an open one at present.

The number of primes whose values do not exceed some positive integer x is symbolized by $\pi(x)$. Thus, $\pi(12)=5$, since 2, 3, 5, 7, and 11 are primes not exceeding 12. Similarly, $\pi(13)=6$.

The method of finding primes known as the sieve of Eratosthenes leads to the formula

$$\begin{aligned}\pi(N)-\pi(\sqrt{N})+1 &= N-[N/p_1]-[N/p_2]-\cdots\\ &\quad -[N/p_k]+[N/p_1p_2]+[N/p_1p_3]+\cdots\\ &\quad +[N/p_{k-1}p_k]-[N/p_1p_2p_3]-\cdots,\end{aligned}$$

where $p_1, p_2, \ldots, p_k$ are the primes less than $\sqrt{N}$. The formula involves considerable calculation. To determine the number of primes less than one million, one needs to consider the primes less than 1000. Obviously, today's computers make such a formula vastly easier to apply and therefore more useful.

There are certain shortcuts that can be employed with the formula for $\pi(x)$; Before the advent of computers, Bertelsen determined that there are 50,847,478 primes that do not exceed one billion. An analogous formula for the number of pairs of twin primes the larger of which does not exceed N was given by G. J. Kostis and R. L. Page.

There exists a number pattern that generates primes in a curious but inefficient way:

```
                1     1
                1  2  1
             1  3  2  3  1
          1  4  3  5  2  5  3  4  1
1  5  4  7  3  8  5  7  2  7  5  8  3  7  4  5  1
```

Each successive row is formed by inserting between each consecutive pair of integers their sum. Any two consecutive entries are relatively prime. It is also true that the integer n occurs $\phi(n)$ times in the nth line, where $\phi(n)$ is the number of integers less than n and relatively prime to n. Since a prime p is relatively prime to all $p-1$ integers less than itself, we see that n is a prime if and only if it appears $n-1$ times in the nth row. Since 2 appears once in row 2, it must be a prime. Similarly, 3 appears twice in row 3 and 5 appears 4 times in row 5. However, 4 appears

only twice in row 4, making 4 a composite number. The number of integers in each row increases rapidly, there being 433 of them in row 10. Thus, the pattern is of little practical value in finding primes.

H. The Prime Number Theorem

By examining tables of prime numbers and by a great amount of trial-and-error calculation, mathematicians discovered that the quantities $\pi(x)$ and $x/\ln x$ behave in a similar fashion and that their ratio approaches 1 as x increases without bound. This was confirmed upon proof of the following theorem.

Prime Number Theorem. $\lim_{x\to\infty}[\pi(x)/(x/\ln -x)] = 1$.

This was proved independently by Hadamard and De la Vallée Poussin.

Another function that approximates $\pi(x)$ better than $x/\ln x$ is the integral logarithm, defined by

$$\mathrm{Li}(x) = \int_2^x \frac{dt}{\ln t}.$$

I. Riemann's Zeta Function

Another function of great importance in the study of the distribution of primes is Riemann's zeta function: $\zeta(s) = \Sigma_{n=1}^{\infty}(1/n^s)$. For example, $\zeta(1) = 1 + \frac{1}{2} + \frac{1}{3} + \cdots$, which may be shown to diverge and $\zeta(2) = 1 + \frac{1}{4} + \frac{1}{9} + \cdots$, which converges to $\pi^2/6$. The function converges for all $s > 1$. Its relation to prime numbers stems from an identity, which Euler discovered, that expresses the zeta function as the repeated product of a term evaluated only for primes. Many of the important functions used in studying properties of primes may be expressed as combinations of zeta functions.

While no formula exists for generating every prime, Bertrand's postulate assures us that if $n \geq 1$, there exists at least one prime p such that $n < p \leq 2n$.

J. Mersenne Primes

The study of the primality of numbers having a particular form has occupied a great deal of attention in number theory. A number of the form $M_n = 2^n - 1$ is called a Mersenne number in honor of Marin Mersenne (1588–1648). Thus, $M_2 = 3$, $M_3 = 7$, $M_4 = 15$, etc. When M_n is a prime p, it is called a Mersenne prime and the number $2^{p-1}(2^p - 1)$ is a perfect number. Furthermore, every even perfect number must be of this form. Thus, the search for even perfect numbers reduces to a search for Mersenne primes. Because $2^n - 1$ can be factored when n is composite, a Mersenne prime must have the form $M_p = 2^p - 1$. For $M_2 = 3$, the perfect number is $2(3) = 6$ and for $M_3 = 7$, the perfect number is $4(7) = 28$.

K. Fermat Numbers

Numbers of the form $2^{2^t} + 1$ are called Fermat numbers. We see that $F_0 = 3$, $F_1 = 5$, $F_2 = 17$ and $F_4 = 65{,}537$ are all primes. The next one, $F_5 = 2^{32} + 1$, is difficult to test for factors without the use of a computer. Fermat conjectured that all Fermat numbers were primes, and it was a hundred years before Euler found a counterexample. He did this by proving that any factor of a Fermat number must have the form $(2^{t+1})k + 1$. For $t = 5$, these factors are of the form $64k + 1$. He then showed that 641 is a factor of F_5.

No further primes have been discovered among the Fermat numbers and many believe that quite the opposite of Fermat's conjecture is true. Nevertheless, interest in Fermat numbers continues because of a remarkable result due to Euler. He showed that a regular polygon of N sides can be constructed with only straightedge and compass if $N = 2^k p_1 p_2 \cdots p_n$, where the p_i are Fermat primes. This unexpected connection between number theory and geometry is an example of the richness of results obtained by pondering prime numbers.

L. Twin Primes

Little is known about twin primes, not even whether an infinite number of pairs exist. By examining the first few pairs, (3,5), (5,7), (11,13), (17,19), (29,31), etc., one is led to conjecture: If p and q are twin primes both larger than 3, then they have the form $6k \pm 1$. This conjecture is readily proven. Any integer must have one of the forms $6k$, $6k \pm 1$, $6k \pm 2$, or $6k + 3$, all of which, except $6k \pm 1$, are easily seen to be composite.

The largest known pair of twin primes, discovered in 1990 by B. K. Parady, J. F. Smith, and S. Zarantonello, is

$$1706595 \times 2^{11235} \pm 1$$

M. Representation of Numbers in Certain Forms

The operation of division leads to questions of factorability of integers and to congruences, to mention only two things. So, too, does the operation of addition lead to many important questions in number theory. For example, the question of whether a given integer can be represented as the sum of an arbitrary number of squares has occupied many mathematicians over the years. For the case of two squares, we have the following theorem:

Theorem. Every prime of the form $4k + 1$ can be written as the sum of two squares.

Thus, $29 = 4(7) + 1$ has the required form and can be written $29 = 4 + 25 = 2^2 + 5^2$. A more powerful result states: An integer n can be written as the sum of two squares if and only if all of its prime factors having the form $4k + 3$ occur with even exponents. We have $5(7^2) = 245 = 49 + 196 = 7^2 + 14^2$ as the sum of two squares, whereas $7^3 = 343$ is not.

The case for three squares is settled by the following theorem:

Theorem. An integer n can be represented as the sum of three squares unless n has the form $4^e(8k + 7)$ for some integers e and k.

We see that $45 = 4 + 16 + 25 = 2^2 + 4^2 + 5^2$, whereas $60 = 4(8 + 7)$ cannot be so represented.

Lagrange proved that every positive integer is the sum of four squares. The search for the four squares that represent a certain number can be reduced to representing the prime factors of the number as the sum of four squares. An identity then gives the four squares for the original number.

The question of finding the least value of s such that every integer can be expressed as the sum of no more than s kth powers of integers is known as Waring's problem. It has long been known that every integer can be written as the sum of nine cubes. Kevin S. McCurley proved that every integer exceeding $e^{e^{13.97}}$ is a sum of seven positive integral cubes.

For fourth powers, the most that can be said is that every integer larger than $10^{10^{89}}$ can be represented as a sum of 19 fourth powers. For fifth powers, the question is unresolved. Surprisingly, for many higher powers, the problem has been solved. It is known that for $6 \le K \le 200{,}000$, every integer can be written as a sum of no more than $2^k + [(3/2)^k] - 2$ kth powers. Hence, every integer is the sum of no more than $2^6 + [(3/2)^6] - 2 = 73$ sixth powers.

We have seen that every integer can be represented as the sum of no more than nine cubes. In fact, if 23 and 239 are exempted, every integer is the sum of no more than eight cubes. Similarly, every integer larger than 454 is the sum of no more than seven cubes. One is therefore led to ask: What is the smallest number $G(k)$ of kth powers whose sum represents any sufficiently large integer? I. M. Vinogradov showed that

$$k + 1 \le G(k) \le k(3 \ln k + 11).$$

Although one of the outstanding accomplishments in number theory, this nevertheless falls short of answering the question.

From studying tables of primes, one comes to the inescapable conclusion that most integers are composite. This is true in the sense that the ratio $\pi(x)/x$ approaches zero as x approaches infinity. Nevertheless, because primes are the building blocks for all integers, research concerning their properties continues to be a major area in number theory.

We sometimes refer to numbers such as 1000 or 1,000,000 as nice round numbers because of the zeros in their base 10 representation. More generally, we consider a round number to be one having a large number of relatively small factors. Therefore, $4200 = 2^3 \cdot 3 \cdot 5^2 \cdot 7$ would be a round number but 17,858,257 = (3607)(4951) would not. It can be shown that the number of prime factors of an integer x is, on the average, of the order of $\ln(\ln x)$. That is, for all integers in a large interval, the preponderance of them have as the number of their prime factors a number close to $\ln(\ln x)$.

N. Factorization Methods

Many methods have been devised to aid in the factorization of large numbers. Fermat's factorization method depends on writing the number to be factored as the difference of two squares. If

$$n = x^2 - y^2 = (x + y)(x - y) = ab,$$

we may assume that n is odd and then a and b will also be odd. If we write $x^2 = n + y^2$, then $x \ge \sqrt{n}$. We examine $x^2 - n$ for various values of $x > \sqrt{n}$, and when the difference is a square, we have found the desired factorization.

For example, if $n = 26{,}781$, we see that $(164)^2 - 26{,}781 = 115$, which is not a square. Instead of considering $(165)^2 - 26{,}781$, $(166)^2 - 26{,}781$, etc., we can use the easier but equivalent method of adding $2x + 1$, $2x + 3$, etc., and check each result for a square.

x	$x^2 - 26{,}781$
165	$115 + 329 = 444$
166	$444 + 331 = 775$
167	$775 + 333 = 1108$
168	$1108 + 335 = 1443$
169	$1443 + 337 = 1780$
170	$1780 + 339 = 2119$
171	$2119 + 341 = 2460$
172	$2460 + 343 = 2803$
173	$2803 + 345 = 3148$
174	$3148 + 347 = 3495$
175	$3495 + 349 = 3844 = (62)^2$

Then

$$(175)^2 - 26{,}781 = (62)^2$$

or

$$26{,}781 = (175 + 62)(175 - 62) = 237(113).$$

Euler's factorization method depends on expressing the number to be factored as the sum of two squares in two different ways: $N = a^2 + b^2 = c^2 + d^2$. Then $a^2 - c^2 = d^2 - b^2$ or $(a+c)(a-c) = (d+b)(d-b)$, where we may assume that a and c are odd and b and d are even. Let k be the gcd of $a-c$ and $d-b$. Then k is even and $a - c = kl$ and $d - b = km$. Then $(a+c)kl = (d+b)km$ or $(a+c)l = (d+b)m$. We see that $a+c$ is divisible by m since $(l, m) = 1$. Thus $a + c = nm$, where n is even. Also, $nml = (d+b)m$ or $nl = d + b$. We see that n is the gcd of $a+c$ and $d+b$. The factorization is

$$N = [(k/2)^2 + (n/2)^2](m^2 + l^2).$$

For example,

$$1{,}000{,}009 = (235)^2 + (972)^2 = 3^2 + (1000)^2.$$

We have $a - c = 232$, $a + c = 238$, $d - b = 28$, and $b + d = 1972$. Then $k = (232, 28) = 4$, $n = (238, 1972) = 34$, $l = (a-c)/k = \frac{232}{4} = 58$, and $m = (d-b)/k = \frac{28}{4} = 7$. We find the factorization

$$1{,}000{,}009 = \left[\left(\tfrac{4}{2}\right)^2 + \left(\tfrac{34}{2}\right)^2\right](7^2 + 58^2) = 293(3413).$$

O. Fibonacci Numbers

Consider the following ancient problem. Assume that we have a pair of newborn rabbits, one male and one female. Suppose that at the end of two months the pair becomes mature. At the end of the third month, and every succeeding month, they produce a male–female pair. Finally, assume that the rules just stated apply to each new pair of rabbits that is born. Assuming no deaths, how many pairs of rabbits will there be at the end of any given month?

If we represent an immature pair of rabbits by an open circle and a mature pair by a shaded circle, we have the results shown in Fig. 15.

Notice that the number of mature pairs each month equals the total number of pairs from the previous month. Also, the number of immature pairs each month equals the number of mature pairs from the previous month. But, since the number of mature pairs from the previous month equals the total number of pairs from two months ago, we see that the total number of pairs in any given month is the sum of the total number of pairs from the previous two months.

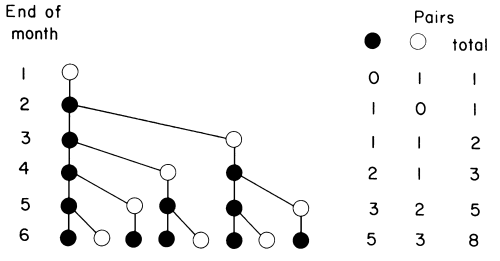

FIGURE 15 The Fibonacci sequence.

TABLE I The first 30 Fibonacci numbers

n	F_n	n	F_n	n	F_n
1	1	11	89	21	10,946
2	1	12	144	22	17,711
3	2	13	233	23	28,657
4	3	14	377	24	46,368
5	5	15	610	25	75,025
6	8	16	987	26	121,393
7	13	17	1597	27	196,418
8	21	18	2584	28	317,811
9	34	19	4181	29	514,229
10	55	20	6765	30	832,040

The sequence $1, 1, 2, 3, 5, 8, \ldots$, defined by $F_1 = 1$, $F_2 = 1$, $F_n = F_{n-1} + F_{n-2}$ for all $n \geq 3$, is called the Fibonacci sequence in honor of Leonardo of Pisa (who was known as Fibonacci, the son of Bonacci). Table I lists the first 30 terms of the Fibonacci sequence.

Many properties have been discovered for the sequence, which has been the subject of extensive study. One readily sees, for example, that every third term is divisible by 2, every fourth term is divisible by 3 and every fifth term is divisible by 5. In fact, it can be shown that every prime p divides an infinitude of Fibonacci numbers.

Several other easily discovered properties are

1. The sum of the first n Fibonacci numbers is one less than F_{n+2}.
2. $F_{n-1}F_{n+1} + 1 = F_n^2$.
3. $F_n^2 + F_{n+1}^2 = F_{2n+1}$.
4. If A, B, C, and D are four consecutive Fibonacci numbers, then $C^2 - B^2 = AD$.

The sequence is also related to patterns found in nature. For example, the seeds on the head of a sunflower lie in rows that form clockwise (CW) and counterclockwise (CCW) spirals. The numbers of spirals of each type are often consecutive Fibonacci numbers with the smaller number enumerating the CCW spirals and the larger number the CW ones. A typical sunflower will have 34 CCW and 55 CW spirals, although heads with 144 CCW and 233 CW spirals have been reported.

Other sunflower heads may have numbers of CCW and CW spirals given by consecutive Lucas numbers, named for Edouard Lucas. These numbers are 1, 3, 4, 7, 11, 18, ..., where $L_1 = 1$, $L_2 = 3$, and $L_n = L_{n-1} + L_{n-2}$ for $n \geq 3$.

If we consider the ratios F_{n+1}/F_n, we have the sequence $1, 2, 1.5, 1.666, \ldots, 1.6154, 1.679, 1.6180, \ldots$.

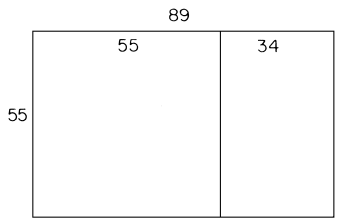

FIGURE 16 A rectangle divided in proportion to numbers in the Fibonacci sequence.

This sequence converges to the number $(1+\sqrt{5})/2 = 1.6180339\ldots$, which is the golden ratio of ancient Greece.

Another interesting relationship involves the first k Fibonacci numbers. Suppose we choose the first 11 of them: 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, and 89. We construct a rectangle having sides of 55 and 89 and then divide it into a square of side 55 and a 34-by-55 rectangle as shown in Fig. 16. Now we divide the rectangle into a square of side 34 and a 34-by-21 rectangle as in Fig. 17. We continue the process of constructing squares in the remaining rectangles until two 1-by-1 squares are constructed. Then in the 55-by-55 square, we draw a quarter circle of radius 55, in the 34-by-34 square we draw a quarter circle of radius 34 that is connected to the first quarter circle, and continue in this fashion until all of the squares have quarter circles. The resulting curve, which closely approximates the logarithmic spiral, a curve found in the shell of the chambered nautilus, is shown in Fig. 18.

III. MODERN DIRECTIONS

Research in number theory flourishes today, the results of that research appearing in numerous scholarly journals on a monthly or quarterly basis. Obviously, this article cannot begin to treat the current state of research in the field. Besides being too large in scope, the subject has become extremely abstract, with many topics which can be fully understood only by experts in the field.

High-speed computers have affected number theory by allowing the consideration of cases involving computations far beyond the capacity of the human mind. Furthermore, by performing thousands of operations a second, computers reduce the time required for certain calculations to within reasonable limits. Starting with M_{521}, the most recently discovered Mersenne primes were found with the aid of computers. Some results that were established by use of home computers have been published.

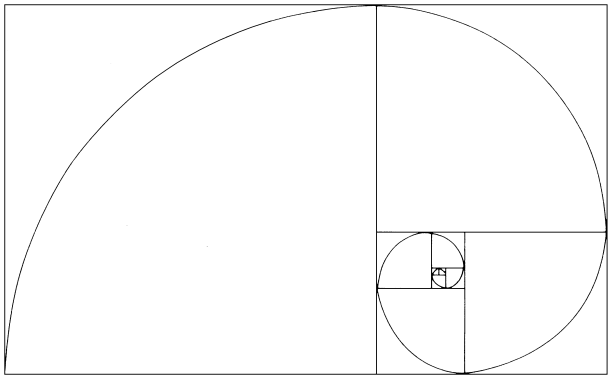

FIGURE 18 An approximation to the logarithmic spiral.

Computers have sparked renewed interest in other ancient problems. In 1974, H. J. J. teRiele announced a pair of amicable numbers, each of which has 152 digits. Using a probabilistic algorithm in conjunction with a computer, Michael O. Rabin found a pair of numbers of the order of magnitude 10^{123}, which he conjectures are twin primes.

In November, 1996, Joel Armengaud and George F. Woltman proved that $2^{1,398,269}-1$ is a Mersenne prime that would require more than 400,000 digits to write in the base 10 system and is the largest known prime.

Research in the distribution of primes continues, including the study of primes that differ by a fixed amount and gaps between primes. Sol Weintraub has found the largest known gap between primes, which consists of 682 consecutive composite numbers following the prime 61,003,096,898,749. In view of the use of computers to facilitate searches, it is safe to say that many of today's largest results will soon be surpassed.

Sometimes a long-term conjecture falls prey to a counterexample. Euler conjectured that no nth power is a sum of fewer than n nth powers; for example, no cube is the sum of fewer than 3 cubes. In 1966, L. J. Lander and T. R. Parkin found the counterexample:

$$144^5 = 27^5 + 84^5 + 110^5 + 133^5.$$

In 1921, V. Brun showed that even if the number of twin primes should be infinite, they are more thinly distributed throughout the integers than are the primes. More specifically, he showed that the sum of the reciprocals of the primes is infinite but the sum of the reciprocals of twin primes is finite.

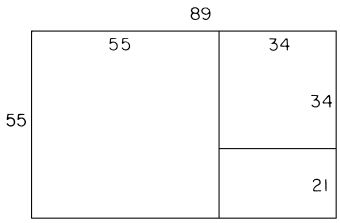

FIGURE 17 A rectangle divided in proportion to numbers in the Fibonacci sequence.

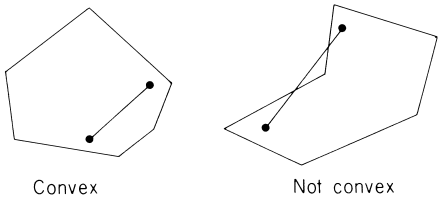

FIGURE 19 Examples of convex and nonconvex regions.

A. The Geometry of Numbers

Elementary number theory refers to those problems whose solution does not require methods from calculus. While this is still an important area in number theory, various other branches have developed in modern times. One such branch, known as the geometry of numbers, arose from a theorem by Hermann Minkowski. In its simplest form, the theorem concerns lattice points in a plane, that is, points whose coordinates are integers.

To state the theorem, we need to define a convex region in the plane, that is, a region R having the property that if any two points of R are connected by a straight line segment, all of the points of the segment will also lie in R. (See Fig. 19.)

Minkowski's theorem states that any convex region R that is symmetric about the origin and whose area is greater than 4 will contain lattice points other than the origin. (See Fig. 20.) Although seemingly self-evident, to prove the theorem requires a fair amount of work. The theorem may be extended to n dimensions and various relationships and functions defined on the lattice points of both convex and nonconvex sets. Such advanced study of lattice points constitutes the geometry of numbers.

B. Analytic Number Theory

Analytic number theory involves the use of methods from analysis or calculus, especially from the theory of complex variables, for solving problems in number theory. This branch arises from the work of Dirichlet and Georg F. B. Riemann (1826–1866), both of whom are sometimes credited with its founding.

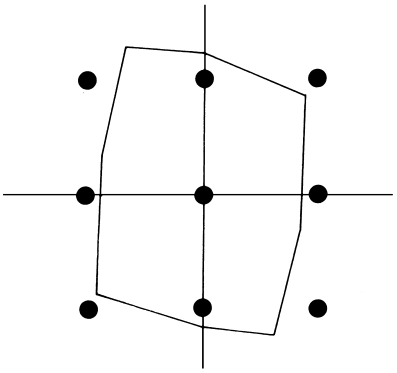

FIGURE 20 An illustration of Minkowski's theorem.

A Dirichlet series has the form $F(s) = \sum_{n=1}^{\infty}(\alpha_n/n^s)$, where α_n is an expression that can be defined for each integer n. The simplest case is $1 + 1/2^s + 1/3^s + \cdots$, which, as we have seen, is called Riemann's zeta function. Riemann's hypothesis, his only conjecture that remains unproved concerning the Riemann zeta function, states that the complex zeros of that function, that is, all zeros of the form $x + y\sqrt{-1}$, have $x = \frac{1}{2}$

This area tends to be abstract and the problems difficult, some yielding only to ingenious methods of attack. It may seem surprising that problems stated in terms of integers may require for their solution powerful methods from analysis, a branch of mathematics dealing with continuous quantities rather than the discreet set of integers. Indeed, some matters, such as the convergence of certain series, may properly be considered areas belonging to analysis.

C. Algebraic Number Theory

The branch known as algebraic number theory developed from attempts to apply concepts from number theory to sets of numbers other than the natural numbers. For example, Gauss considered numbers of the form $a + b\sqrt{-1}$, where a and b are integers. These are called the Gaussian integers and they follow a unique factorization law analogous to that of the fundamental theorem of arithmetic.

Euler, in attempting to prove Fermat's last theorem (see Section IV.B) for the case in which $n = 3$, considered numbers of the form $a + b\sqrt{-3}$, where a and b are integers. For such sets of numbers one may define primes that correspond to primes in the set of natural numbers, although some of them will be quite different from the ordinary primes.

Euler assumed, without proof, that unique factorization held for these numbers. His conclusion, although unproved, was correct. Later, Gabriel Lamé made a similar unproved assumption and announced that he had solved Fermat's last theorem. His error was quickly pointed out.

About the same time, Ernst Eduard Kummer was attempting to extend Gauss' quadratic reciprocity law to higher powers. He succeeded in showing that unique factorization does not hold for all sets of numbers. Thus, in the set of numbers $a + b\sqrt{-5}$, the number 6 has two different prime factorizations:

$$6 = 2(3) = (1 + \sqrt{-5})(1 - \sqrt{-5}).$$

An equation of the form $a_0x^n + a_1x^{n-1} + \cdots + a_n = 0$, where each a_i is rational, is said to be irreducible if the

left-hand side cannot be factored into two similar expressions. If r is a root of such an irreducible equation of degree n, then the set of all expressions that can be formed from that root by addition, subtraction, multiplication, and division by nonzero terms is called the algebraic number field of degree n generated by r.

In order to preserve the concept of unique factorization, Kummer introduced what he called ideal numbers. He was able to find a sufficient condition for Fermat's last theorem to be true and proved it for several particular cases.

Dedekind extended this concept to algebraic number fields in general by considering sets in the fields called ideals. This work led to the development of field theory, an area in which number theory overlaps another branch of modern mathematics called abstract or modern algebra.

Much research is presently conducted on Diophantine equations. A related topic is Diophantine approximation, the approximation of irrational numbers by rational numbers.

A review of current literature in number theory gives evidence of interest in old as well as new topics. Among the former are tests for divisibility, distribution of quadratic residues, Riemann's zeta function, Pythagorean triples, and the distribution of primes. Among the latter are Fortune's conjecture (see Section IV.A) and permutable primes. These are numbers such as 13 or 37 that are also prime when their digits are reversed.

IV. UNSOLVED PROBLEMS AND CONJECTURES

The natural numbers are the simplest set of numbers used in mathematics, yet the number of patterns derived from the natural numbers seems almost endless. These patterns have led mathematicians to ask questions such as: Is the pattern true for all integers? Under what conditions does the pattern hold?

A. Conjectures

When statements concerning number patterns are proved to be true, they are called theorems. Before that, they are conjectures, nothing more than educated guesses based on inductive reasoning applied to a finite number of particular cases. Conjectures, then, fall in a kind of no-man's-land between the list of facts that have been shown to be true and the host of statements that have been shown to be false. They remain there until they are proven to be true theorems or until a counterexample shows them to be false.

Some conjectures enjoy long lives before they are disproved. For example, Fermat's conjecture that numbers of the form $2^{2^t}+1$ are always prime survived for a hundred years before it died at the hands of Euler. Many other patterns are disposed of almost as quickly as they appear. As an example, consider some patterns which seem to generate primes. For $p_1^2+(p_1+1)p_2$ we have

$$2^2+3(3)=13$$
$$3^2+4(5)=29$$
$$5^2+6(7)=67$$
$$7^2+8(11)=137$$
$$11^2+12(13)=277,$$

all of which are prime. However, $13^2+14(17)=407=11(37)$.

Again, consider $p_1^{p_2}+p_1+p_2$:

$$2^3+2+3=13$$
$$3^5+3+5=251$$
$$5^7+5+7=78{,}137,$$

all of which are prime. Numbers in this sequence grow in size rapidly. Thus, $7^{11}+7+11=1{,}977{,}326{,}761$, which is harder to check for primality by use of a pocket calculator than its predecessors. Of course, it is easily handled by a modern computer. Even this is not necessary, however, since the next term $11^{13}+11+13=11^{13}+24$ is clearly divisible by 5.

The numbers 31, 331, 3331, and 33,331 are all primes. In fact, the pattern continues to yield primes until we reach 333,333,331, which is divisible by 17.

Another interesting pattern is

$$3!-2!+1!=5$$
$$4!-3!+2!-1!=19$$
$$5!-4!+3!-2!+1!=101$$
$$6!-5!+4!-3!+2!-1!=619$$
$$7!-6!+5!-4!+3!-2!+1!=4421$$
$$8!-7!+6!-5!+4!-3!+2!-1!=35{,}899,$$

which yields the primes listed. Unfortunately, the next step gives 326,981, which is divisible by 79.

The following pattern gives primes for many steps:

$$41+2=43$$
$$43+4=47$$
$$47+6=53$$
$$53+8=61$$
$$61+10=71$$
$$71+12=83.$$

In fact, it will give primes for another 33 steps before the composite number $1681 = 41^2$ appears. The pattern is made up of numbers obtained from the formula $x^2 + x + 41$, which we have previously discussed.

Finally, consider the pattern of integers in which each succeeding row is obtained by inserting the number of the row, n, between each pair of integers from row $n-1$ whose sum is n:

n														Number of terms
1							1							2
2						1	2	1						3
3					1	3	2	3	1					5
4				1	4	3	2	3	4	1				7
5		1	5	4	3	5	2	5	3	4	5	1		11
6	1	6	5	4	3	5	2	5	3	4	5	6	1	13

This pattern fails for row 10, which contains 33 terms. If we count the number of digits in each row, the tenth row contains 37 digits, a prime number. However, the 11th row contains 57 digits, a composite number.

A recent conjecture is due to Reo F. Fortune who examined the pattern

$2 + 1 = 3$	$5 - 2 = 3$
$2(3) + 1 = 7$	$11 - 6 = 5$
$2(3)(5) + 1 = 31$	$37 - 30 = 7$
$2(3)(5)(7) + 1 = 211$	$223 - 210 = 13$
$2(3)(5)(7)(11) + 1 = 2311$	$2333 - 2310 = 23$
$2(3)(5)(7)(11)(13) + 1 = 30{,}031$	$30{,}047 - 30{,}030 = 17$

The first five sums in the left-hand column are primes, but $30{,}031 = 59(509)$. However, for each sum if we find the next larger prime and subtract from it the product of consecutive primes given in that row, the result is prime. Fortune's conjecture is that this pattern always gives primes. Many feel that the conjecture is true but proving it appears to be a difficult task.

The question of whether there exist an infinite number of Mersenne primes has been unsolved for approximately 300 years, as has the companion question of the existence of an infinite number of even perfect numbers. To date, only 28 Mersenne primes are known, so the question is far from resolved.

Catalan's Conjecture, due to Eugène Charles Catalan (1814–1894), states that 8 and 9 are the only positive consecutive integral powers of integers.

In general, this suggests that $x^m - y^n = 1$, where x and y are integers greater than 0 and m and n are integers greater than 1, has as its only solution $x = 3$, $y = 2$, $m = 2$, and $n = 3$. Since m and n vary, as well as x and y, the equation above is a Diophantine equation that is not in polynomial form.

In 1974, Robert Tijdeman proved that there exists a constant k with the property that all powers of integers which equal consecutive integers are less than k. Thus, we know that there can be at most a finite number of such pairs of consecutive powers, although the work of calculating k seems too formidible to allow a definite value to be determined at present.

In 1876, Catalan also examined the sequence $P_0 = 2$ and $P_{n+1} = 2^{P_n} - 1$. Thus,

$$P_1 = 2^{P_0} - 1 = 2^2 - 1 = 3$$
$$P_2 = 2^{P_1} - 1 = 2^3 - 1 = 7$$
$$P_3 = 2^{P_2} - 1 = 2^7 - 1 = 127$$
$$P_4 = 2^{P_3} - 1 = 2^{127} - 1.$$

He speculated that P_n is prime for $n = 1, 2, 3$, and 4, all of which were subsequently verified. P_5 seems to be undecidable since it has approximately 10^{38} digits.

B. Fermat's Last Theorem

One of the most famous of all problems in number theory, unsolved for over 350 years, goes by the misnomer of Fermat's last theorem. In the margin of a copy of Diophantus' "Arithmetic," opposite a problem concerning writing a square as the sum of two squares, Fermat wrote that it is impossible to write a cube as the sum of two cubes, a fourth power as the sum of two fourth powers, and so forth. In other words, he claimed that the equation $x^n + y^n = z^n$ cannot be solved when $n > 2$.

He also claimed to "have discovered a truly marvelous demonstration of this proposition that this margin is too narrow to contain." In view of Fermat's wrong guess concerning the primality of all Fermat numbers, one must be skeptical of his claim, or at least wish he had had a supply of blank paper at hand.

Only one proof concerning number theory is known to be due to Fermat, that being found in another margin of the same book. This theorem showed that the area of a Pythagorean triangle having integral sides cannot be a square integer. This theorem leads to the proof of Fermat's last theorem for the case $n = 4$; that is, $x^4 + y^4 = z^4$ has no solutions.

Fermat claimed to be able to prove the conjecture for $n = 3$, but published no proof. Euler gave such a proof nearly 100 years later, but it contained some faulty reasoning that fortunately could be corrected.

Work on the problem progressed slowly as other mathematicians proved the conjecture true for $n = 5$, $n = 7$, and other particular values of n. It can be shown that if the conjecture is true for some integer k, then it is true for any multiple of k. Hence, it suffices to consider only odd prime powers. Partial results included showing that if the theorem is true for some value of $n > 2$, then n must exceed 4,000,000. It was also shown that any solution led to

numbers that are inconceivably exceeding the capacity of even the most modern computers.

Furthermore, it was known that $x^p + y^p = z^p$ has no solution in integers that are relatively prime to p if p is an odd prime and $q = 2p + 1$ is also prime. In 1983 Gerd Faltings proved that the formula contained in Fermat's last theorem has only finitely many rational solutions when $n > 2$. From time to time, several reputable mathematicians, as well as countless amateurs, gave purported proofs that Fermat's last theorem was true for all $n > 2$. Unfortunately, errors were discovered in each of the proofs presented before 1993.

In June, 1993, Andrew J. Wiles of Princeton University gave three lectures at Cambridge University, which culminated in a proof of Fermat's last theorem. Wiles had been interested in the problem since the age of 10 when he vowed to find a proof. His interest in the problem led him to choose mathematics as a career.

His teachers and professors advised him that he would be wasting his time pursuing such a difficult and uncertain goal. At Cambridge, his advisor guided him to the field of elliptic curves, which are curves having cubic equations and which can be used for calculating the perimeter of ellipses.

Wiles' concern for the theorem never abated, even while he did research on elliptic curves. In 1986, his determination was strengthened by the work of other mathematicians who postulated and then proved a connection between Fermat's last theorem and elliptic functions. He devoted himself completely to solving the problem and seven years later he was ready to present his proof to fellow mathematicians.

The reaction to his proof was astonishment and widespread acclaim. Verifying his proof was a slow process for two reasons: (1) his proof was 200 pages long and (2) it was estimated that elliptic curves were understood by approximately only one tenth of one percent of all professional mathematicians.

Minor errors in his proof were found and easily corrected. Then a catastrophe occurred; a flaw in the proof was discovered that could not be easily overcome. Wiles and his former student, Richard Taylor, worked tirelessly to save the proof. They finally decided to employ a different type of elliptic curv that would eliminate the error.

After 14 months Wiles began to belive that his proof would suffer the same fate as all previous ones, failure. Then, one of those events occurred that sound more like fiction than fact. They were close to giving up but on September 19, 1994 they found a way to eliminate the error and save the proof.

In June, 1997 Wiles was awarded the Wolfskehl Prize, which had been unclaimed for 89 years, for proving Fermat's last theorem. Had he not studied elliptic curves at Cambridge, Wiles might not have been prepared to do the work which led to his successful proof. Thus, his advisor unwittingly helped Wiles achieve his childhood goal.

C. Goldbach's Conjectures

Nearly 250 years ago, Christian Goldbach, in correspondence with Euler, posed two conjectures:

1. Every even number greater than or equal to 6 is the sum of two odd primes.
2. Every odd number greater than or equal to 9 is the sum of three odd primes.

The second conjecture is actually a consequence of the first, and in 1937 Vinogradoff proved that any odd number that is sufficiently large is the sum of three odd primes. How large the number has to be is not known. It has been established that if N is an even integer larger than $e^{e^{16,038}}$, then N is the sum of no more than four primes.

It is also known that every sufficiently large even integer is the sum of a prime and an integer having no more than two distinct prime factors. Complete resolution of Goldbach's conjectures awaits future results.

The question of the existence of odd perfect numbers is still unresolved. Most mathematicians are inclined to believe that perfect numbers must be even, although an odd one may be detected someday by methods as yet unimagined. It is known that any such integer must exceed 10^{50} and must have at least eight prime factors.

Number theory is the oldest branch of mathematics and concerns the simplest set of numbers, the integers. Because some of its problems can be stated in easily understood terms, it probably has attracted more amateurs than any other branch of mathematics. Although many of its problems today are stated by means of abstract technical definitions not easily mastered by the lay person, nevertheless the subject that has commanded widespread attention over the past 3000 years should remain a vital area of human learning for at least that far into the future.

GLOSSARY

Algorithm A numerical algorithm is a precise, step-by-step description of the implementation of a numerical method.

Condition A problem is ill-conditioned if a small change in the data results in a large change in the solution. Conversely, it is well-conditioned if the solution is relatively insensitive to changes in the data. The condition number is a measure of condition. It is small for a well-conditioned problem and large otherwise.

Convergence A numerical method is said to converge if the solution generated by the method approaches a solution of the problem to which it is applied—either as an iteration count becomes large, or as a discretization parameter approaches zero. The order of convergence is a measure of the rate of convergence. For example, in the case of an iteration method, the order of convergence is p if, after a sufficient number of cycles, the error after any cycle is comparable to the error of the previous cycle raised to the power p.

Data By input data for a problem, we mean numbers that are required to be provided in order for the solution process to start or continue. Output data are numbers generated by the solution process.

Error Difference between the approximation to a quantity and its true value. Relative error is the error divided by the true value. An error bound is a positive number that is known to be larger than the magnitude of an error.

Iteration Repeated process, where the input to each cycle is determined from the output of preceding cycles. The input to at least the first cycle is given in order to start the process. Criteria for stopping the iteration must be provided.

Method A numerical method is a procedure used to solve a mathematical problem through the use of numbers.

Parallel algorithm Algorithm designed to use more than one processor at the same time. The computations are organized into tasks that can be assigned to multiple processors.

Roundoff error Error introduced because of the limit to the precision (number of places) to which numbers can be represented in any finite computation.

Stability A numerical method is unstable if, when it is applied to a well-conditioned problem, a small change in the data results in a large change in the numerical solution. It is stable if the change in the solution remains small.

Truncation error Error introduced because of the limit to the number of numbers that can be used in any finite computation. For example, a variable may be represented exactly by an infinite mathematical series, but only the most significant terms can be retained. The discarded terms contribute to the truncation error in the computed solution.

Vector algorithm Algorithm designed to make efficient use of a vector processor. In a vector processor a single instruction causes the same operation to be performed on one or more sequences of numbers (vectors) in an assembly-line fashion.

NUMERICAL ANALYSIS is the study of the solution of mathematical problems through the manipulation of numbers. The solution processes are usually referred to as numerical methods, and the required sequences of numerical and logical operations, when precisely set down, are called algorithms. The solutions thus obtained are usually not exactly correct, but approximately so. In the context of science and engineering, the problems of concern are either the result of reducing the analysis of a physical situation to mathematical equations that cannot be simplified further by usual mathematical means, or the physical laws and constraints governing a system under study are "modeled" by mathematical equations—in which case, the numerical solution can be said to simulate the behavior of the system. Although numerical methods have been used for centuries (Johannes Kepler used one to determine the orbit of Mars in 1607), the development of digital computers, with their tremendous capacity for carrying out arithmetic and logical operations on numbers, has made numerical methods practical in a great variety of scientific and technological applications. Today, almost all numerical methods are carried out on computers. From an understanding of number representations and manipulations, the numerical analyst must devise the methods and design the algorithms to solve a variety of problems. In doing so, he or she must be concerned with the source and propagation of errors, and whether or not the method "converges" to a close approximation of the solution. Also, in spite of the great speed of modern computers, the matter of convergence rate and computational efficiency are of paramount importance and may determine whether or not the method is practical. A recent development in computing is the use of collections of computers to solve individual problems (parallel processing), and this requires the consideration of problem partitioning and algorithm development to take advantage of the particular computer architectures involved. It is in this area that numerical analysis and computer science are particularly closely related.

I. NUMERICAL ANALYSIS AS A SUBJECT AREA

A. The Numerical Approach to Problem Solution

The means by which physical situations and processes are described, analyzed, designed, and simulated is through mathematics. Natural laws are stated in terms of mathematical equations, and the behavior of systems that obey those laws is described by their solutions.

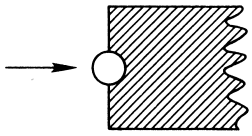
Unfortunately, the mathematics of many of the processes we would like to study quickly becomes intractable when approached by conventional means. For example, analytical solutions to most nonlinear systems of equations simply cannot be found. The best that can be done, in the traditional sense, is to attempt a series expansion of the solution.

Today, there is another approach: the problem statement and variables of interest can be approximated numerically. Analysis and problem solution can then be performed through numerical computation with the aid of high-speed digital computers. To be sure, something is lost when it becomes necessary to resort to numerical methods, because characteristics of the solution that are immediately apparent from inspection of analytical expressions may be obscured in listings of numbers; however, a numerical solution is certainly better than no solution, and sometimes its nature can be revealed by repeating the process with small changes in the data. Also, computer-generated graphs or images can often provide a sufficiently accurate visual interpretation of the solution to aid in its understanding.

The numerical approach is illustrated for a very simple problem in Fig. 1. The problem is posed in physical terms in (a), and its mathematical formulation is given in (b). In this situation we know the solution, but in more complex cases, of course, we may not.

The next step is to select or develop a numerical method. Here, we have chosen the Euler method for the solution of initial value problems involving ordinary differential equations, again because of its simplicity. Numerical methods can be thought of as operators that accept numbers as input (in this case the initial velocity

V_0, the problem parameters D and M, and the discretization parameter h) and produce other numbers as output (the successive values of time and velocity).



A ball of mass M kg, moving with velocity V_0 m/sec, strikes a block of paraffin. If the drag force per unit of velocity is D kg/sec, what is the subsequent velocity of the ball as a function of time?

(a)

$$dV/dt = -(D/M)V$$
$$V(0) = V_0$$

Note that for this problem we know the solution to be

$$V(t) = V_0 e^{-(D/M)t}$$

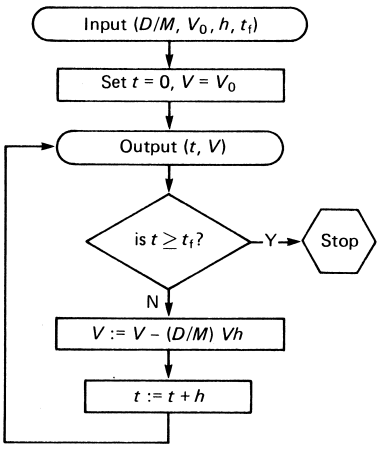
(b)

The Euler method for the solution of initial-value problems in ordinary differential equations. Given V_0

$$V_{i+1} = V_i + (dV/dt)_i h$$
$$i = 0, 1, 2, \ldots$$

where h is a selected interval length.

(c)



(d)

FIGURE 1 The numerical approach to problem solution. (a) Physical situation. (b) Mathematical formulation. (c) Numerical method. (d) Algorithm.

The final stage is to produce an algorithm, a step-by-step implementation of the method. Algorithms are thought of rather like flow charts and are usually described in an unambiguous way by means of an algorithmic or even a computer-programming language. Algorithms are recipes that could conceivably be followed by a person with pencil and paper; however, it is usual to convert them to computer programs, which can then be executed on a suitable computer.

B. Errors, Their Sources, and Propagation

We use the example of Fig. 1 to illustrate the source of errors in the numerical solution of a problem.

If we carry out the first step of the Euler method for this example, using symbols V_0, D, and M for the data, and the symbol h for the time increment, we arrive at

$$V(h) \approx V_1 = V_0[1 - (D/M)h].$$

On the other hand, we know from the series expansion for e^x, carried out to two terms with remainder, that the solution at $t = h$ is

$$V(h) = V_0 e^{-(D/M)h}$$
$$= V_0\left[1 - \left(\frac{D}{M}\right)h + \left(\frac{D}{M}\right)^2 e^{-(D/M)z}\frac{h^2}{2}\right],$$

where z appearing in the final (remainder) term has a value between 0 and h. Comparing the approximate and true values of $v(h)$, we see that the difference is

$$\varepsilon(h) = V_0(D/M)^2 e^{(-D/M)z}h^2/2,$$

where $\varepsilon(h)$ is the truncation error committed by the Euler method in carrying out the first step. Since we know that $e^{(-D/M)x}$ can be no more than 1 for any non-negative value of x, we can say that $\varepsilon(h)$ is bounded by a constant, independent of h, times h^2; that is,

$$\varepsilon(h) < Kh^2.$$

This tells us that if, for example, we halve the interval, the maximum possible truncation error for the first step will be divided by four.

We are normally interested in computing the solution out to some initially specified time, say t_f, which will require $n = t_f/h$ steps. The accumulated truncation error, which we will designate by $\varepsilon(h, t_f)$, is bounded by n times the bound for one step, thus

$$\varepsilon(h, t_f) < nKh^2 = t_f Kh.$$

This brings us to the concept of convergence. We see that as the step size h is made smaller, the answer produced by the Euler method (in the absence of any arithmetic error) for the velocity at time t_f becomes more accurate.

In fact, in the limit as h approaches zero, the answer is exact, since the error bound is then zero. Of course, it does not make sense to use a zero interval size, but the point is that we can make the error as small as we wish by selecting h sufficiently small. In this case, the truncation error in computing $V(t_f)$ is bounded in direct proportion to the interval size h, and we say that the method converges with order h.

Turning now to the computation of the solution as described by the algorithm, we first must specify values for the parameters of the problem and the initial data. Because, in any practical computing device, the number of digits allocated to a number is limited, it will probably be necessary to chop or round these numbers before they are stored. The error committed by doing this is called inherent roundoff. Also, during the course of the computation, arithmetic operations are performed that produce results with more digits than the operands, and these results must be chopped or rounded before they are stored. This error is called arithmetic roundoff. A particularly serious consequence of roundoff occurs when two numbers of nearly the same value are rounded before they are subtracted, since this can result in the loss of significant information.

It is possible to minimize the effect of roundoff error by judicious design of the algorithm. For example, the computation of the roots of a quadratic equation

$$ax^2 + bx + c = 0,$$

by the quadratic formula,

$$r = (-b \pm \sqrt{b^2 - 4ac})/2a,$$

when b is large relative to a and c, can produce a poor approximation to the smallest in magnitude root. To avoid this, it is possible to use the mathematically equivalent formula,

$$r = 2c/(-b \mp \sqrt{b^2 - 4ac})$$

for that root.

Another example is in the calculation of expressions of the type

$$\sum_{i=1}^{n} a_i b_i.$$

The results of each multiplication can be saved and added together in extended precision. (If the computer hardware cannot do this, then it can be done with the use of a special program, treating the lower and upper halves of the multiplication results as separate variables.) Then the accumulated sum may be rounded at the end of the calculation.

In order to assess the effect of an error as it is propagated through the computation, we consider an algorithm as a mapping F from a set of input numbers $X \equiv \{x_1, x_2, \ldots, x_n\}$ to a set of results $Y \equiv \{y_1, y_2, \ldots, y_m\}$ and write

$$y_i = F(x_1, x_2, \ldots, x_n), \quad i = 1, 2, \ldots, m.$$

The error propagation formula is simply a first order difference expansion of this equation, Thus,

$$\Delta y_i \approx \left(\frac{\partial F_i}{\partial x_1}\right)\Delta x_1 + \left(\frac{\partial F_1}{\partial x_2}\right)\Delta x_2 + \cdots + \left(\frac{\partial F_i}{\partial x_n}\right)\Delta x_n, \quad i = 1, 2, \ldots, m.$$

The effect on the ith output variable of an error in the jth input variable can be estimated by knowing the appropriate partial derivative. Of course, in most cases this will not be known directly; however, it may be possible to find an experimental estimate by observing the change in the output variables as the algorithm is executed with small, incremental changes in the input data, one variable at a time.

Arithmetic operations that introduce roundoff error are often treated as equivalent, exact operations with erroneous operands. By working backward, the effect of arithmetic roundoff can be reduced to an equivalent error in the input, which can then be translated to output error by the use of the error propagation formula.

C. Condition and Numerical Stability

In solving a problem numerically, it is inevitable that errors will be committed, both because of the use of a discrete method (truncation) and because of finite precision calculations (roundoff). There are two effects that can cause such errors to grow to serious proportions, one of which has to do with the problem itself, and the other due to the method which is employed.

Some problems are inherently ill-conditioned, which means that a small change in the data results in a large change in the solution. A simple example is the system of two linear equations representing the intersection of two straight lines that are nearly parallel, such as

$$y = x + 1, \quad y = 1.01x.$$

These equations have the solution (100, 101); however, if the coefficient of x is changed to $1.001x$, less than a 1% change, the solution is then (1000, 1001), which is a 900% change in x. It is important that the numerical analyst be aware that a problem is ill-conditioned. It may be possible to reformulate it to avoid the ill conditioning, or if not, to use a higher-order method and increased precision arithmetic in order to reduce the introduction of numerical error as much as possible.

Numerical instability is a condition that is due to the method employed. A simple example is the solution of a differential equation problem

$$y' = f(x, y), \quad y(0) = y_0$$

by the "midpoint method,"

$$y_{i+1} = y_{i-1} + 2hf(x_i, y_i), \quad y_1 = y_0 + hf(x_0, y_0).$$

In this method, a small error can grow as x increases, even when the problem itself is well-conditioned, because of the existence of a parasitic solution. This is explained more fully in the section on differential equations. It is a challenge to the numerical analyst to recognize instability and to provide an alternate, stable method.

II. FINITE-PRECISION NUMERICAL OPERATIONS

A. Number Representation

In our standard, positional, decimal notation, a real number is represented as

$$\pm d_n d_{n-1} \cdots d_0 . d_{-1} d_{-2} \cdots,$$

where each d is a digit, that is, a symbol representing zero or one of the first nine natural numbers, and the subscript is an index specifying the position of the digit in the number. The $\pm$ indicates that the sign may be either $+$ or $-$. The period after d_0 is called the decimal point, and it separates the integral part of the number (on the left) from the fractional part. The leading digit d_n is nonzero except when the integral part is zero.

The value of the number, which we will designate by x, is then given by

$$x = \pm\left(\sum_{i=0}^{n} d_i \times 10^i + \sum_{j=1}^{\infty} d_{-j} \times 10^{-j}\right),$$

the first sum being the value of the integral part and the second being that of the fraction.

The number of distinct symbols used to represent a single digit in the decimal system is 10 (probably because we have 10 fingers), and we say that the base of the decimal system is 10. Electronic devices depend on sensing either the presence or absence of a signal, just two possible states, which we can represent with 0 and 1. Thus, for electronic computers we need to consider the binary representation, which uses the base 2. The binary representation of a real number is

$$\pm b_n b_{n-1} \cdots b_0 . b_{-1} b_{-2} \cdots,$$

where each b (bit) is either 0 or 1. The value of this number is

$$x = \pm\left(\sum_{i=0}^{n} b_i \times 2^i + \sum_{j=1}^{\infty} b_{-j} \times 2^{-j}\right).$$

In general, for the integer base $B > 1$, a real number is represented by

$$\pm g_n g_{n-1} \cdots g_0 . g_{-1} g_{-2} \cdots,$$

where the g's are symbols for zero and the first $B - 1$ positive integers; its value is given by

$$x = \pm\left(\sum_{i=0}^{n} g_i \times B^i + \sum_{j=1}^{\infty} g_{-j} \times B^{-j}\right).$$

Commonly used bases, in addition to 10 and 2, are 8 (octal), which uses the symbols 0 through 7, and 16 (hexadecimal), which uses 0 through 9, then A, B, C, D, E, and F to represent the integer values from 10 to 15. These bases are useful because conversion to and from binary is easily accomplished through the grouping of bits three and four at a time, respectively. Table I gives representations of the first 16 positive integers for five different bases.

Arithmetic is carried out in any base system by using the same procedure as in decimal arithmetic, keeping in mind, however, that "carries" and "borrows" are dependent on the value of the base. Figure 2 gives examples of arithmetic in binary, octal, and hexadecimal.

Conversion from one base to another is accomplished by a slightly different procedure, depending on the base in which the arithmetic is to be performed. Examples are given, in Fig. 3, of conversion between octal and decimal. If the arithmetic is to be done in the base notation *from*

TABLE I The First Sixteen Natural Numbers Written in Some Different Base Notations

Decimal (base 10)	Binary (base 2)	Ternary (base 3)	Octal (base 8)	Hexadecimal (base 16)
1	1	1	1	1

which we are converting, then the procedure is to separate the integer and fractional parts. The integer part is converted by successive divisions by the base to which we are converting, as illustrated in Fig. 3 in Example 1, while the fractional part is converted by successive multiplications as illustrated in Example 2. On the other hand if the arithmetic is to be performed in the base notation to *which* we are converting, the procedure is to use the value formula

$$x = \pm\left(\sum_{i=0}^{n} g_i B^i + \sum_{j=1}^{\infty} g_{-j} B^{-j}\right)$$

as illustrated in Example 3.

B. Computer-Representable Numbers

The memory of a computer is composed of cells, called words, each consisting of a number of bits. Most computers use 8, 16, 32, or 64 bits per word. It is usual to store a single number in each word (although multiple and fractional precision modes are possible with some loss of processing speed). There are several ways in which to do this; however, if the word length is m bits, it is possible to store only 2^m different numbers in a given word. The bit positions in a word are numbered, starting with zero, from the least significant (which we can think of as the right end) bit to the most significant (left end) bit [Fig. 4(a)]. The most significant bit is usually reserved for the sign of the number, for example, 0 for a positive number and 1 for negative.

It is most efficient, in terms of the use of storage space and processing speed, to store numbers in binary form; however, it should be mentioned that it is possible to represent decimal numbers by allocating groups of four bits to each digit (binary-coded decimal). This is done in calculators and in applications where the input and output of data dominates computation [Fig. 4(b)].

In the "binary integer" mode, integers are stored, right-justified, in the computer word just as they are written in binary [Fig. 4(c)]. All of the integers from -2^{m-1} to $+2^{m-1}$ can thus be represented in a word of length m bits. Counting and indexing operations use this mode.

For more general computation, modern computers use a mode referred to as binary floating point, in which numbers are represented in the form

$$x = \pm M \times 2^t,$$

where M, the "significand," is in the range $0 \le M < 2$ and t, the "exponent," is an integer. If $M \ge 1$, the number is said to be "normalized," otherwise it is "denormalized." Thus the decimal number 358.625 (101100110.101 in binary) is represented in normalized binary floating point form as

$$+1.40087890625 \times 2^8.$$

Expressed in binary, the significand is 1.01100110101 and the exponent is 1000.

A national standard for binary floating point floating point arithmetic has been developed under the auspices of the Institute for Electrical and Electronic Engineers-(IEEE Standard 754-1985). In this standard, a single format number is stored in a 32-bit computer word with the fractional part of the significand, the "fraction," stored in binary in the least significant 23 bits. The sign is stored as 0 for a positive number and 1 for a negative number in the most significant bit. In order to accommodate negative exponents, the exponent is biased by the addition of 127 (1111111 in binary) and stored in binary in the 8 bits between the sign and fraction. Provided that the biased exponent is not 0 or 255, the number is assumed to be normalized and the integer part of the significand is implicitly taken as 1. The "precision" of a single format normalized binary floating point number is 24 bits. The single format representation of 358.625 is given in Fig. 4(d).

The number zero is stored as a 0 in every bit position, except possibly the most significant (sign). Positive zero

EXAMPLE 1. Conversion of the decimal integer 358 to octal by successive division by 8 in decimal arithmetic.

```
8)358
8) 44    R 6        Answer: 546 (base 8)
8)  5    R 4
    0    R 5
```

$$
\begin{aligned}
5 \times 8^{2} &= 320 \\
+4 \times 8^{1} &= 32 \\
+6 \times 8^{0} &= 6 \qquad \text{Answer: 385.769 ... (base 10)} \\
+6 \times 8^{-1} &= .75 \\
+1 \times 8^{-2} &= .0156 \\
+2 \times 8^{-3} &= .0039 \\
&\overline{} \\
&358.7695
\end{aligned}
$$

FIGURE 3 Conversion of base.

and negative zero are numerically equivalent but the distinction can be useful; for example, division of a positive number by negative zero produces negative infinity.

The smallest positive normalized single format number is 2^{-126}. If any operation produces a positive number that is smaller than this, the biased exponent is set to zero and the significand is shifted to the right so that the number is no longer normalized and the precision is less than 24 bits. Similarly, the largest negative normalized number is -2^{-126} and the production of a larger negative number results in a denormalized form. The generation of a denormalized number signals an underflow condition.

A biased exponent of 255 with a zero fraction indicates plus or minus infinity (e.g., the result of dividing a nonzero number by a signed zero). A biased exponent of 255 with a nonzero fraction is defined as a NaN (Not a Number). A NaN will be produced when the magnitude of the result of an operation is equal to or larger than 2^{128} (overflow condition).

The IEEE standard also defines a double format number that is stored in a 64-bit word. In the double format mode the fraction length is 52 bits, the bias is 1022, and the biased exponent length is 11 bits. The precision of a double format normalized number is 53 bits.

In order to reduce the effect of roundoff error, the floating point processing units of modern computers generally contain a number of registers that are longer than either the single or double format standard. Register to register computations take place in extended precision (also defined by the IEEE standard) and only when a result is to be stored in the computer's memory does it get shortened to single or double precision.

C. Roundoff Error

Exact arithmetic operations typically produce results that contain a greater number of significant positions than the operands. For example, the sum of 8.5 and 9.2 is 17.7 (one more significant digit than the addends) or the product of 1.234 and 1.432 is 1.767088 (the fractional part has twice as many significant digits). In a binary floating point processing unit, the exact result of an arithmetic operation on single format operands may be contained in an extended precision register; however, if the result is to be stored in single format, some loss of precision is inevitable. The shortening of a number to a lower precision is accomplished by "rounding."

There are two choices in rounding. The first is to merely discard the portion of the significand that follows the least significant bit of the shortened format; and the second is to add one (with appropriate carries to more significant positions) to the least significant bit after discarding the same portion. The default rounding mode in the IEEE standard is "round-to-nearest." This means that the choice is made

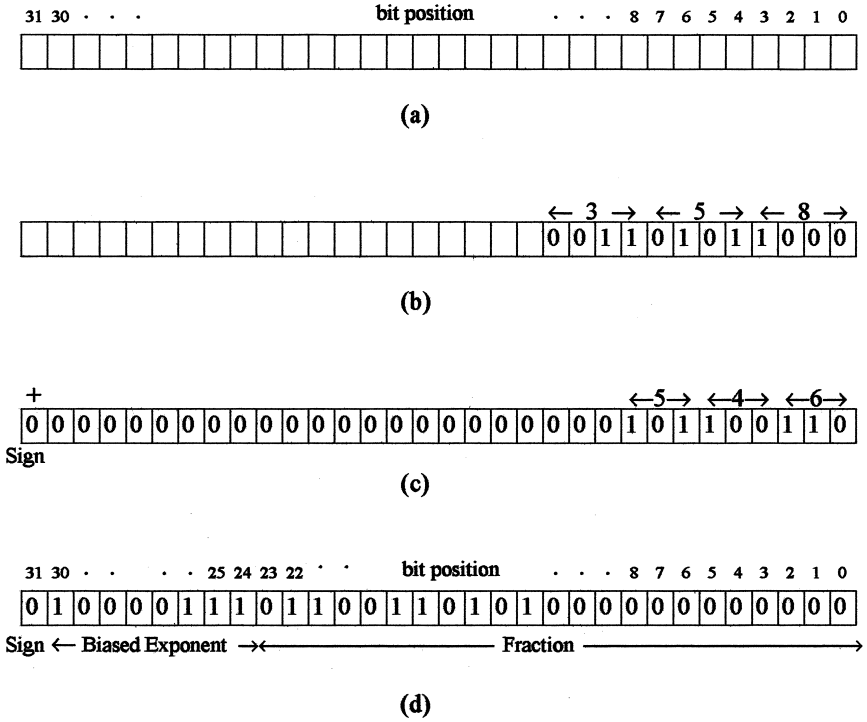

FIGURE 4 Representation of numbers in a 32 bit computer word. (a) Bit numbering convention. (b) Binary-coded decimal representation of 358. (c) Binary integer representation of +358 (+546 octal). (d) Single format floating point binary representation of +358.625.

so that the rounded number is nearest to the infinitely precise result. If both choices are equally near, then the even shortened significand is chosen.

The IEEE standard also provides for user specified "directed" rounding modes in order to reproduce results that may have been obtained on nonstandard implementations. Round-towards-zero (also referred to as chopping) always uses the first choice. Round-towards-positive-infinity uses the first choice if the number is negative and the second if it is positive. Round-towards-negative-infinity uses the first choice if the number is positive and the second if it is negative.

A bound for the relative error (magnitude of the maximum possible error divided by the exact number) is 2^{-p} for round-to-nearest and 2^{-p+1} for directed rounding, where p is the precision in bits (e.g., $p = 24$ for single format). This bound is referred to as the machine unit and designated by μ.

The generation of error in sequences of floating point operations is determined by backward error analysis. In this approach, each rounded result is supposed to be obtained by an exact calculation with numbers that are initially in error. It is possible to work backward in this manner to establish a bound on the error in the initial data that would lead to the same final result with exact arithmetic. An estimate of the accumulated error can then be obtained from the error propagation formula. Bounds for the error that have been obtained in this manner for some common sequences of calculations are shown in Table II.

The rate of convergence of iterative methods can be strongly affected by roundoff error; thus, the use of multiple extended precision registers in floating point units, in which sequences such as those shown in Table II can be executed prior to rounding to single or double format, can significantly improve the performance of the computer.

TABLE II Bounds for Errors in Some Common Floating Point Calculations

$F(x_1, x_2, \ldots, x_n)$	Absolute error bound[a]
$\sum_{i=1}^{n} x_i$	$\sum_{i=1}^{n} \lvert(n+1-i)x_i\rvert \quad (1.06\mu)$
$\prod_{i=1}^{n} x_i$	$(n-1)\prod_{i=1}^{n} \lvert x_i\rvert \quad (1.06\mu)$
$\sum_{i=1}^{n} x_i y_i$	$\sum_{i=1}^{n} \lvert(n+2-i)x_i y_i\rvert \quad (1.06\mu)$
$\sum_{i=1}^{n} a_i x^i$	$\sum_{i=1}^{n} \lvert(2i+1)a_i x^i\rvert \quad (1.06\mu)$

[a] Note: μ is the machine unit; 2^{1-p} for chopping, 2^{-p} for rounding, where p is the significand length.

III. ALGEBRAIC EQUATIONS IN A SINGLE VARIABLE

A. Background

By an algebraic equation in a single independent variable x, we will mean an equation that can be put in the form

$$f(x) = 0,$$

where f is a single-valued function of x, containing no derivatives nor integrals with respect to x. Examples are

$$x - \sin x = 10$$
$$x^3 = 2$$
$$e^x + \ln x - 3 = 0.$$

For purposes of this discussion, we will assume that f is continuous and differentiable in x. Clearly, by adding x to both sides, we have the equivalent equation

$$F(x) = f(x) + x = x.$$

A commonly occurring problem is to solve the equation in one of these two forms, by which we mean to find a value of x for which the equation is true. In the first case a solution is called a root of $f(x)$, and in the second it is called a fixed point of $F(x)$.

In the case where $f(x)$ is linear, that is, of the form

$$f(x) = ax + b, \quad a \neq 0,$$

a solution exists, is unique, and can be determined immediately for given values of a and b. If $f(x)$ is not linear, the situation is a great deal more complicated, because there may not be a solution or there may be many solutions. In order to get some understanding of the nature of the problem, it is usually advantageous to construct a graph of $f(x)$ versus x and observe if and where this graph crosses the x axis, or alternatively to graph $F(x)$ and observe if and where it crosses the line $y = x$. This is illustrated in Fig. 5.

Another complication for a nonlinear equation is that (with certain specific exceptions) it is not possible to obtain a solution in a finite number of operations. The best that can be done is to approximate a solution by making an initial numerical estimate and then to methodically refine it by obtaining a succession of (hopefully, ever closer) estimates, until there is little change between successive values. This process is referred to as iteration.

To make this more precise, suppose a solution is x^*, the initial estiamte is x_0, and successive iterations produce the infinite sequence

$$x_1, x_2, x_3, \ldots, x_i, \ldots,$$

then the absolute error of the ith iterate is $|x_i - x^*|$. The iteration is said to converge to x^* if

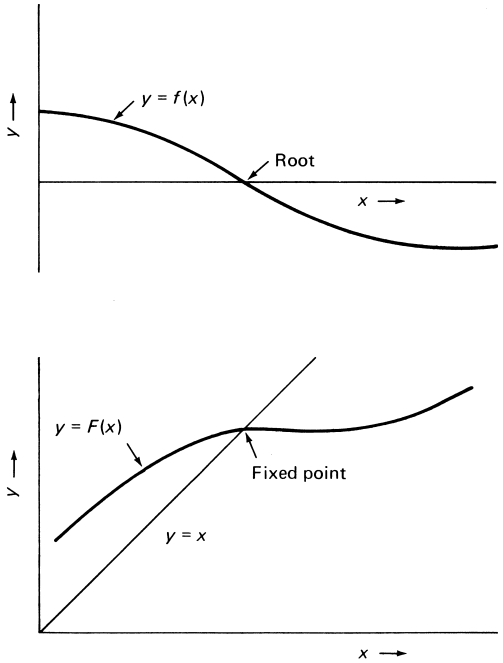

FIGURE 5 The graphical determination of a root or fixed point.

$$\lim_{i \to \infty} |x_i - x^*| = 0.$$

If $f(x)$ is continuous and differentiable, a sufficient condition for convergence is that there exists a constant C such that

$$\frac{|x_{i+1} - x^*|}{|x_i - x^*|} \leq C < 1$$

for all i greater than some threshold number. If this equation holds, the convergence is said to be of order 1, or linear. More generally, if it can be shown that there is a number $p \geq 1$ and a constant C such that

$$\frac{|x_{i+1} - x^*|}{|x_i - x^*|^p} \leq C < 1$$

for all i greater than some threshold, then the iteration converges with order p. In particular, if $p = 2$, the convergence is said to be quadratic. The higher the order of convergence, the fewer the number of iterations that should be required to home in on the solution; however, whether or not a particular iteration will converge and how rapidly it will do so depend on a number of factors, such as how close the initial estimate is to the desired solution and how close solutions are to one another. The situation of multiple, identical solutions can be particularly troublesome.

As a practical matter, a test for convergence is usually made at the end of each iteration. If

$$\frac{|x_{i+1} - x_i|}{|x_i|} < \varepsilon_1$$

for a prescribed $\varepsilon_1 > 0$, usually of the order of the machine unit μ, the iteration is stopped and the solution is taken as x_{i+1}. In the event that x_i is close to zero, however, the test must be modified to the absolute form, and the iteration is stopped when

$$|x_{i+1} - x_i| < \varepsilon_2,$$

where, again, ε_2 is a sufficiently small positive number. Finally, in the root-finding case, a termination test can be in the form

$$|f(x_{i+1})| < \varepsilon_3.$$

B. Iteration Methods

The simplest possible iteration method is the ancient method of repeated substitution, which can most readily be applied to an algebraic equation in the (fixed-point) form

$$x = F(x).$$

Starting with an initial estimate of x_0, the iteration formula is

$$x_{i+1} = F(x_i).$$

It can be shown that the method converges to x^* if

$$|F'(x)| < 1$$

for $(x^* - |x_0 - x^*|) \le x \le (x^* + |x_0 - x^*|)$; the order of convergence is linear if $F'(x^*) \neq 0$.

Bracketing methods are applied to equations in the (root) form,

$$f(x) = 0.$$

They rely on first finding two values of x, say a and b, such that $f(a)$ and $f(b)$ have opposite sign. Thus, if $f(x)$ is continuous, a root lies somewhere between a and b. Two methods for successively narrowing the interval containing the root are the bisection method and the method of false position. These methods are illustrated in Fig. 6. Their advantage is that once an interval containing a root has been found, convergence is guaranteed. On the negative side, it is not always easy to find two values that bracket a root, and the order of convergence of both of these methods is only linear. In most cases the method of false position converges more rapidly than the method of bisection; however, there are situations where it is much slower. A common approach is to start with the method of false position and then to revert to the method of bisection if convergence is not achieved after a prescribed number of iterations.

Extrapolation methods use information at previous iterations to extrapolate to a new estimate of a root. Newton's method uses the value and derivative of $f(x)$ at $x = x_i$ to extrapolate linearly to x_{i+1}; the secant method uses the latest two values of $f(x)$ to extrapolate linearly; and Muller's method uses the latest three values to perform a quadratic extrapolation. The order of convergence of these methods (to simple roots) is 2, 1.62, and 1.84, respectively, but the major disadvantage is that initial estimates must be relatively close in order to achieve convergence.

Also, Newton's method requires the computation of the function and its derivative at each step. Newton's method and the secant method are illustrated in Fig. 7.

C. Roots of Polynomials

The particular case where $f(x)$ is a polynomial of degree n, that is, to find the roots of

$$p_n(x) = a_0x^n + a_1x^{n-1} + a_2x^{n-2} + \cdots + a_n;$$
$$a_0 \neq 0$$

is a frequently occurring problem. Any of the methods of the previous section can, of course, be used for this case; however, it is sometimes possible to take advantage of the special properties of polynomials.

To start with, $p(x)$ can be evaluated for $x = \alpha$ by the following recurrence formula:

$$b_0 = a_0$$
$$b_i = \alpha b_{i-1} + a_i \qquad \text{for} \quad i = 1, 2, \ldots, n.$$

This is called the method of synthetic division, because the numbers $b_0, b_1, \ldots, b_{n-1}$ are the coefficients of the polynomial of degree $n-1$ that is the result of dividing $p(x)$ by the binomial $(x - \alpha)$. Then $p(\alpha) = b_n$ is the remainder for this division. Also, once a root x_1 has been found, that is, $p(x_1) = 0$, then the b's of the final iteration define the reduced polynomial which has for its roots the remaining $n-1$ roots of $p(x)$, so that additional roots can be sought, starting from the reduced polynomial.

The term $p'(x)$ can be evaluated for $x = \alpha$ by repeating the synthetic division process for the first $n-1$ b's; thus,

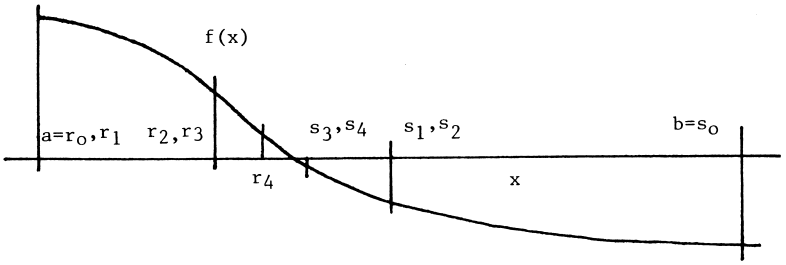
$$c_0 = b_0$$
$$c_i = \alpha c_{i-1} + b_i \qquad \text{for} \quad i = 1, 2, \ldots, n-1,$$

and

$$p'(\alpha) = c_{n-1}.$$

For this reason, Newton's method is easy to apply.

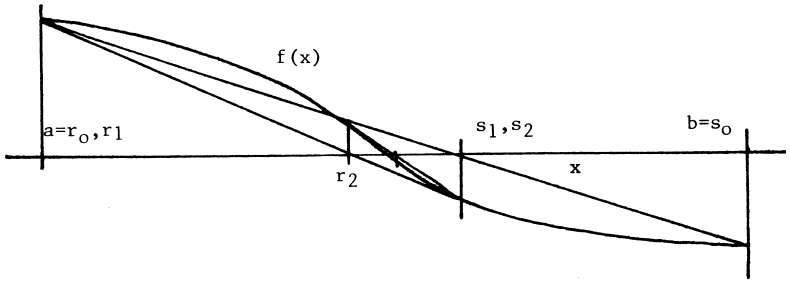
A disadvantage of the methods considered so far, except Muller's method, is that they cannot directly find the complex roots that are usually needed in the case of polynomial equations. Muller's method and Cauchy's method, which bears the same relationship to Muller's method as Newton's method does to the secant method [that is, it



Assume sgn$[f(a)f(b)] = -1$. Set $i = 0$, $r_0 = a$, $s_0 = b$.

→ Let $x_i = (r_i + s_i)/2$.
If $|r_i - s_i| < \varepsilon$, the root is $x \approx x_i$ (Stop).
If sgn$[f(r_i)f(x_i)] = -1$, set $r_{i+1} = r_i$, $s_{i+1} = x_i$.
Otherwise set $r_{i+1} = x_i$, $s_{i+1} = s_i$.
— Set $i = i + 1$.

(a)



The same as the bisection method except that

$$x_i = [s_i f(r_i) - r_i f(s_i)]/[(f(r_i) - f(s_i)]$$

(b)

FIGURE 6 Bracketing method. (a) Bisection method. (b) False position method.

uses the first and second derivative of $f(x)$ at an estimate of a root to extrapolate quadratically to the next estimate], are capable of finding complex roots and are thus more useful for the polynomial case.

A method designed for polynomial equations is due to Lin and Bairstow (not described in detail here because of its complexity). It uses synthetic division of $p(x)$ by a quadratic and iterates to reduce the linear remainder to zero. The quadratic factor thus determined may have complex conjugate roots, and the reduced polynomial has degree 2 less than $p(x)$.

The properties of polynomials can also be invoked to determine approximate locations of roots, which are often necessary in order to improve the chance of convergence of the methods discussed so far. Particularly useful in this regard is the theory of Sturm sequences, which can be used to determine the number of real roots in a prescribed interval.

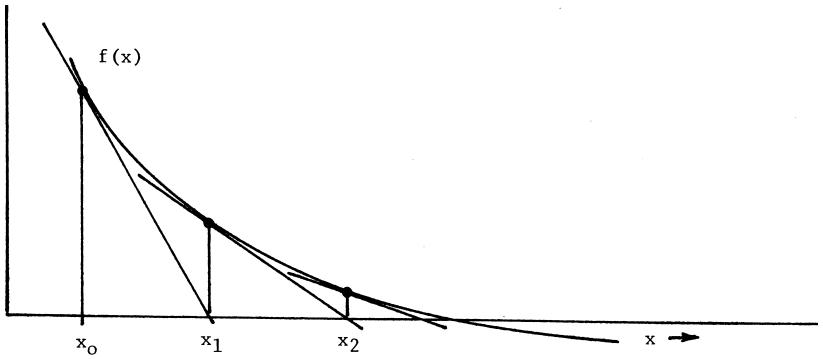
Finally, for every polynomial, a matrix can be found that has the same characteristic polynomial; thus, the problem of finding roots of a polynomial can be expressed as the problem of finding the eigenvalues of a matrix. Methods exist for finding all or selected numbers of eigenvalues of a matrix that do not depend for convergence on close estimates to start with, and are, therefore, often preferred over the methods discussed in this section. Matrix eigenvalue methods are discussed in Section V.

IV. SYSTEMS OF ALGEBRAIC EQUATIONS

A. Systems of Linear Equations

If $x_1, x_2, \ldots, x_n$ represent n variables, and $a_1, a_2, \ldots, a_n$ are given numbers (called coefficients), then the expression

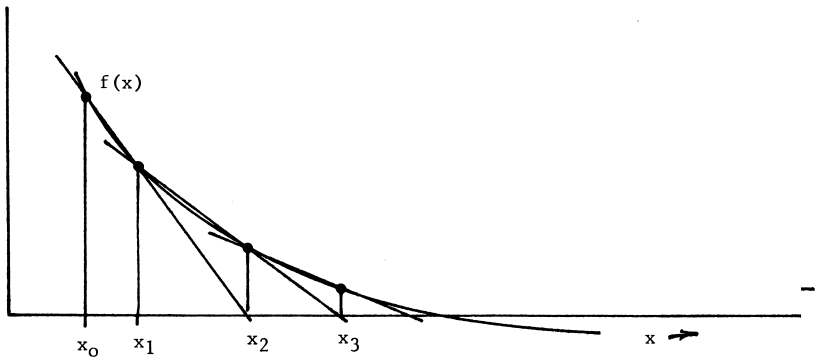
$$a_1x_1 + a_2x_2 + a_3x_3 + \cdots + a_nx_n$$



Given x_0,

$x_{i+1} = x_i - f(x_i)/f'(x_i)$; $i = 0, 1, 2, \ldots$

(a)



Given x_0 and x_1,

$x_{i+1} = x_i - (x_i - x_{i-1})f(x_i)/[f(x_i) - f(x_{i-1})]$

$i = 1, 2, 3, \ldots$

(b)

FIGURE 7 Extrapolation methods. (a) Newton's method. (b) Secant method.

is called a linear combination of the x's. The equation

$$a_1x_1 + a_2x_2 + a_3x_3 + \cdots + a_nx_n = b$$

is a linear equation. A system of m linear equations is written in the form

$$\begin{aligned}
a_{1,1}x_1 + a_{1,2}x_2 + a_{1,3}x_3 + \cdots + a_{1,n}x_n &= b_1 \\
a_{2,1}x_1 + a_{2,2}x_2 + a_{2,3}x_3 + \cdots + a_{2,n}x_n &= b_2 \\
a_{3,1}x_1 + a_{3,2}x_2 + a_{3,3}x_3 + \cdots + a_{3,n}x_n &= b_3 \\
&\vdots \\
a_{m,1}x_1 + a_{m,2}x_2 + a_{m,3}x_3 + \cdots + a_{m,n}x_n &= b_m,
\end{aligned}$$

where the subscript of the b's and the first subscript of the a's designate the equation, while the subscript of the x's and the second subscript of the a's designate the variable. We define the $m \times n$ matrix A of coefficients as the m-row by n-column array

$$A = \begin{bmatrix}
a_{1,1} & a_{1,2} & a_{1,3} & \cdots & a_{1,n} \\
a_{2,1} & a_{2,2} & a_{2,3} & \cdots & a_{2,n} \\
a_{3,1} & a_{3,2} & a_{3,23} & \cdots & a_{3,n} \\
\vdots & & & & \\
a_{m,1} & a_{m,2} & a_{m,3} & \cdots & a_{m,n}
\end{bmatrix}$$

and we define the n-vector x and the m-vector b as the columnar arrays

$$x = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ . \\ . \\ . \\ x_n \end{bmatrix} \quad b = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ . \\ . \\ . \\ b_m \end{bmatrix}.$$

The system of linear equations can now be written concisely as

$$Ax = b,$$

where the multiplication of A times x (the order of these two factors is important) is defined to form an m-vector with the ith component being the inner product of the ith row of A with the vector x

$$a_{i,1}x_1 + a_{i,2}x_2 + a_{i,3}x_3 + \cdots + a_{i,n}x_n.$$

The characteristics of a linear system are determined by the properties of the matrix A and are addressed in the subject of linear algebra. Except where we discuss overdetermined systems at the end of the next section, we will assume that A is a square matrix ($m = n$, the order of A), and that there is a unique solution, that is, a unique set of values for the variables $x_1, x_2, \ldots, x_n$ that satisfies the system of equations. Under these circumstances the solution can always be obtained by direct methods in a finite number of arithmetic operations. When n is very large or when A is sparse (has a large proportion of zero elements), it is sometimes more efficient to use an iterative method, following the same general approach as discussed in the previous section on the solution of algebraic equations in a single variable.

B. Direct Methods

If A happens to be lower triangular, that is, has the structure

$$A = \begin{bmatrix} a_{1,1} & 0 & 0 & \cdots & 0 \\ a_{2,1} & a_{2,2} & 0 & \cdots & 0 \\ a_{3,1} & a_{3,2} & a_{3,3} & \cdots & 0 \\ . & & & & . \\ . & & & & . \\ . & & & & . \\ a_{n,1} & a_{n,2} & a_{n,3} & \cdots & a_{n,n} \end{bmatrix}$$

then it is straightforward to obtain a solution by the process of forward substitution

$$x_1 = b_1/a_{1,1}$$

$$x_i = \left(b_i - \sum_{j=1}^{i-1} a_{i,j}x_j\right)/a_{i,i}, \qquad i = 2, 3, \ldots, n.$$

Similarly, if A is upper triangular, which can be visualized by reversing the order of the rows in the above matrix, then the solution can be obtained by back substitution

$$x_n = b_n/a_{n,n}$$

$$x_i = \left(b_i - \sum_{j=i+1}^{n} a_{i,j}x_j\right)/a_{i,i},$$

$$i = n-1, n-2, \ldots, 1.$$

(Note that under our assumption that there is a unique solution, it can be shown that the diagonal elements must be nonzero so that the division can always be carried out.) The number of additions and multiplications required for either process is of the order of $\frac{1}{2}n^2$, and the number of divisions is n.

The objective of direct methods for an arbitrary nonsingular matrix is to transform A into a triangular matrix. This may be done by a process that is equivalent to premultiplying A by a sequence of $n-1$ matrices. The product of two matrices is a matrix, each column is the product of the first matrix and the corresponding column of the second. Let A be designated as $A^{(0)}$; then the sequence of multiplications can be written recursively as

$$A^{(k)} = M^{(k)}A^{(k-1)}, \qquad k = 1, 2, 3, \ldots, n-1,$$

where $M^{(k)}$ is an $n \times n$ matrix with its diagonal elements equal to 1 and with 0 in every other position except, possibly, below the diagonal in the kth column, where the elements are

$$m_{i,k}^{(k)} = -a_{i,k}^{(k-1)} \big/ a_{k,k}^{(k-1)}.$$

Now $A^{(k)}$ has zeros below the diagonal through the kth column, and the final result $A^{(n-1)}$ is an upper-triangular matrix that we will denote by U. Now let L be the lower-triangular matrix that has diagonal elements equal to 1 and

$$l_{i,j} = -m_{i,j}^{(j)}$$

for all other elements with $i > j$. Multiplying L by the same sequence of matrices $M^{(k)}$, it is found that the result is the identity matrix. Thus L is the inverse of the product of the M matrices, and we have established that

$$A = LU.$$

Finding L and U is referred to as LU factorization. An example for a given 4×4 matrix is shown in Fig. 8.

The solution of the linear system $Ax = LUx = b$ can now be found by solving the two triangular systems,

$$Ly = b, \qquad Ux = y.$$

The number of additions and multiplications required for computing the elements of L and U is of the order of $\frac{1}{3}n^3$; thus for large n there is considerable savings in

$$\text{Let } A = A^{(0)} = \begin{bmatrix} 1 & 2 & 3 & 4 \\ 1 & 4 & 9 & 16 \\ 1 & 8 & 27 & 64 \\ 1 & 16 & 81 & 256 \end{bmatrix}$$

$$A^{(1)} = M^{(1)}A^{(0)}$$

$$\begin{bmatrix} 1 & 2 & 3 & 4 \\ 0 & 2 & 6 & 12 \\ 0 & 6 & 24 & 60 \\ 0 & 14 & 78 & 252 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ -1 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 2 & 3 & 4 \\ 1 & 4 & 9 & 16 \\ 1 & 8 & 27 & 64 \\ 1 & 16 & 81 & 256 \end{bmatrix}$$

$$A^{(2)} = M^{(2)}A^{(1)}$$

$$\begin{bmatrix} 1 & 2 & 3 & 4 \\ 0 & 2 & 6 & 12 \\ 0 & 0 & 6 & 24 \\ 0 & 0 & 36 & 168 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & -3 & 1 & 0 \\ 0 & -7 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 2 & 3 & 4 \\ 0 & 2 & 6 & 12 \\ 0 & 6 & 24 & 60 \\ 0 & 14 & 78 & 252 \end{bmatrix}$$

$$A^{(3)} = M^{(3)}A^{(2)}$$

$$\begin{bmatrix} 1 & 2 & 3 & 4 \\ 0 & 2 & 6 & 12 \\ 0 & 0 & 6 & 24 \\ 0 & 0 & 0 & 24 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & -6 & 1 \end{bmatrix} \begin{bmatrix} 1 & 2 & 3 & 4 \\ 0 & 2 & 6 & 12 \\ 0 & 0 & 6 & 24 \\ 0 & 0 & 36 & 168 \end{bmatrix}$$

$$L = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 3 & 1 & 0 \\ 1 & 7 & 6 & 1 \end{bmatrix} \qquad U = \begin{bmatrix} 1 & 2 & 3 & 4 \\ 0 & 2 & 6 & 12 \\ 0 & 0 & 6 & 24 \\ 0 & 0 & 0 & 24 \end{bmatrix}$$

FIGURE 8 *LU* factorization of a 4 × 4 matrix.

performing the LU factorization once, then solving the triangular systems only for each new b for which the solution may be needed.

In solving an arbitrary $n \times n$ system it can occur that, at the kth stage, the divisor $a_{k,k}^{(k-1)}$ is zero, in which case, the solution can proceed no further. Also, if not identically zero, it may be very small, which can cause relatively large arithmetic roundoff errors to be introduced. To avoid these difficulties the technique of partial pivoting is employed, in which at each stage the largest element in the column headed by the pivotal element, $a_{k,k}^{(k-1)}$ is found, and the entire row in which this element occurs is exchanged with the kth row. Partial pivoting does not change the solution since it merely changes the order in which the equations of the system appear; however, the order of elements in the vector b must be adjusted accordingly.

Pivoting is not necessary when the matrix A is diagonally dominant: $|a_{i,i}| \geq \sum_j |a_{i,j}|$ for all i, or when it is symmetric and *positive definite*, meaning that for any n-vector x that is not identically zero, the quadratic form $x^{\mathrm{T}}\mathrm{Ax}$ is positive. If A is symmetric and pivoting is not necessary, a symmetric version of LU factorization is possible in which only the elements of $A^{(k)}$ above the diagonal are computed and the elements of the $M^{(k)}$ are not saved, thereby reducing the storage required by half and the number of operations to the order of $\frac{1}{6}n^3$. In this case, after the matrix U has been computed, the solution is found by solving

$$U^T y = b, \qquad Ux = Dy,$$

where D is the diagonal of U. This is often referred to as the (root-free) Cholesky method.

Systems that have a banded structure (the matrix A has zero elements wherever the difference between the indices i and j is greater than a fixed number less than $n-1$) retain their band width during LU factorization if pivoting is not required; thus advantages in storage and computation can be realized when working with them. Matrices that are sparse within a band of some nonzero elements, however, suffer from "zerofill," which means that no advantage can be taken of sparsity with direct methods, except that by judicious exchanging of equations and order of variables, the bandwidth or profile of the matrix can sometimes be reduced, thereby reducing the number of operations required.

Before considering the error in the solution to a system of equations (either linear or nonlinear), we need to have a means to measure a vector or matrix. Just in measuring

a scalar quantity by its magnitude, we measure a vector by its "norm," if x is a vector, we write $\|x\|$ to represent the norm of x. The most commonly used norm in numerical analysis is the "infinity norm," which is defined as: $\|x\|_\infty = \max_{1\le i\le n} |x_i|$. Other norms are the 2-norm: $\|x\|_2 = \sum_{i=1}^{n} x_i^2$, and the 1-norm: $\|x\|_1 = \sum_{i=1}^{n} |x_i|$; however, these are more extensive to compute. The norm of a matrix A, that corresponds to a given vector norm is defined by: $\|A\| = \max_{\|x\|=1} \|Ax\|$.

The error introduced into the solution due to accumulated arithmetic roundoff depends on the condition of the system: that is, the degree to which small errors in the data of the problem are magnified during the computation—even assuming these computations are exact. A measure of the condition of a linear system is given by the condition number, which can be thought of as an error magnification factor; the larger the condition number, the larger will be the relative error in the solution. The condition number is defined to be the product of the norm of the matrix A with the norm of the inverse of A: $K(A) = \|A\|\,\|A^{-1}\|$. This requires the computation of a matrix inverse, which is more work than needed to solve the linear system in the first place; nevertheless, mathematical subroutines that are used to solve linear systems by direct means often give estimates of condition number.

Direct methods for the solution of linear systems of equations are exact in the sense that no error is introduced by the method; however, erroneous coefficients and right-hand sides of the equations will result in an error in the solution. Suppose that we have

$$(A + E)(x + h) = b + e,$$

where E is the matrix of errors in the coefficients and e is the vector of errors in the right hand sides, then we can show that the norm of the error h in the solution is bounded by

$$\frac{\|h\|}{\|x\|} \le \frac{K(A)}{1 - K(A)(\|E\|/\|A\|)}\left(\frac{\|e\|}{\|b\|} + \frac{\|E\|}{\|A\|}\right).$$

This inequality tells us that if A is well-conditioned, then small changes in the coefficients and right-hand sides, introduce correspondingly small changes in the solution. On the other hand, if A is ill-conditioned, small changes in the data may produce a relatively large error.

Assuming that the coefficients and right-hand side of the equations are exact, the only error that is introduced is due to the roundoff of intermediate results. Backward error analysis is used to bound the effect of roundoff errors in terms of equivalent errors in the coefficients; thus it can be shown that

$$\|E\| \le f(n)\mu \max_{i,j,k} \left|A_{i,j}^{(k)}\right|,$$

where μ is the machine unit. In practice, it has been found that when pivoting is employed, $f(n)$ is of order n, the number of equations in the system.

Before leaving this section we mention the problem of obtaining the "least squares" solution to an overdetermined system of linear equations: that is, the situation when there are more equations than unknowns. Such systems arise, for example, in smoothing observed data, as is discussed later. In this situation the system of equations is represented by

$$Ax = b,$$

where now, A is an m-row by n-column matrix with $m > n$, x is an n-vector, and b is an m-vector. There is, in general, no vector x that will satisfy this equation; however, we seek an x that minimizes the sum of the squares of the differences between the corresponding elements of Ax and b. It can be shown that such an x satisfies the equation

$$A^{\mathrm{T}}Ax = A^T b,$$

which is now an $n \times n$ system. Applying the LU factorization method to this new system is not recommended, however, because a more efficient and stable method of accomplishing the same purpose is to factor A into an $m \times n$ matrix, say Q, which has orthogonal columns (this means that $Q^{\mathrm{T}}Q = D$, an $n \times n$ diagonal matrix) and an $n \times n$ upper-triangular matrix R. This can be accomplished by premultiplying A by $(n-1)$ Householder matrices (see Section V). Thus we can obtain

$$Q^{\mathrm{T}}A = R,$$

or equivalently,

$$A = QR,$$

from which it can be established that the solution of

$$Rx = D^{-1}Q^{\mathrm{T}}b$$

is the desired least-squares solution.

C. Iteration Methods

These methods are based on the idea of splitting the matrix of a linear system into parts, which are then associated with either the left- or right-hand side of an iteration equation. For example, let

$$A = M + N.$$

Then the linear system

$$Ax = (M + N)x = b$$

can be expressed as

$$Mx = -Nx + b,$$

from which, providing M is nonsingular, we can obtain the matrix iteration equation

$$x^{(k+1)} = -M^{-1}Nx^{(k)} + M^{-1}b.$$

It can be shown that if the spectral radius (the magnitude of the largest eigenvalue) of the iteration matrix $M^{-1}N$ is less than 1, the iteration will converge for any nonzero starting estimate $x^{(0)}$.

We may split A into

$$A = E + D + F,$$

where E is the lower-triangular matrix containing the elements $e_{i,j} = a_{i,j}$ where $i > j$ and 0 otherwise, D is the diagonal matrix containing the elements $d_{i,i} = a_{i,i}$ for all i, and F is the upper-triangular matrix with elements $f_{i,j} = a_{i,j}$ when $i < j$ and 0.

The Jacobi method takes $M = D$ and $N = E + F$; thus,

$$x^{(k+1)} = -D^{-1}(E + F)x^{(k)} + D^{-1}b.$$

In terms of the individual elements of the vector x, this method can be expressed as

$$x_i^{(k+1)} = \frac{b_i - \sum_{j=1}^{i-1} a_{i,j}x_j^{(k+1)} - \sum_{j=i+1}^{n} a_{i,j}x_j^{(k)}}{a_{i,i}}, \qquad i = 1, 2, \ldots, n.$$

Thus, each element in turn is updated in terms of elements of the previous iteration only. The Jacobi method is easy to implement but is usually rather slow to converge.

The Gausss–Seidel method uses $M = E + D$ and $N = F$, so that one iteration is equivalent to solving the triangular system

$$(E + D)x^{(k+1)} = -Fx^{(k)} + b.$$

In this case, the equation for the ith element of x is

$$x_i^{(k+1)} = \frac{b_i - \sum_{j=1}^{i-1} a_{i,j}x_j^{(k+1)} - \sum_{j=i+1}^{n} a_{i,j}x_j^{(k)}}{a_{i,i}}, \qquad i = 1, 2, \ldots, n,$$

so that in updating each element, advantage is taken of the most recent value of previous elements. This method is a little more difficult to implement but usually converges more rapidly than the jacobi method.

Substantial improvement in the rate of convergence can often be achieved by introducing a relaxation factor ω, and using the iteration equation

$$(D + \omega E)x^{(k+1)} = [(1 - \omega)D - \omega F]x^{(k)} + \omega b.$$

If ω is greater than 1, this method is referred to as successive over-relaxation (SOR). In terms of the individual elements it can be expressed as the two-step process

$$r_i^{(k)} = \frac{b_i - \sum_{j=1}^{i-1} a_{i,j}x_j^{(k+1)} - \sum_{j=i+1}^{n} a_{i,j}x_j^{(k)}}{a_{i,i}}$$

$$x_i^{(k+1)} = (1 - \omega)x_i^{(k)} + r_i^{(k)}, \qquad i = 1, 2, \ldots, n,$$

where ω is usually chosen to be a number between 1 and 2; however, it is often necessary to experiment to find a value that is close to optimum.

For systems in which the matrix A is symmetric, positive definite, and relatively sparse, a class of methods based on the minimization of the quadratic functional

$$\tfrac{1}{2}x^{\mathrm{T}}Ax - b^{\mathrm{T}}x$$

with respect to the vector x has been shown to be highly efficient. The most promising of these is the "conjugate gradient" method. Starting with an initial guess x^0, the previous functional is minimized in the direction of the residual $b - Ax^0$ (this is a scalar minimization problem). Thereafter, an iterative sequence of scalar minimization is performed in directions that are mutually orthogonal with respect to the inner product $x^{\mathrm{T}}Ay$ (i.e., any two directions represented by the vectors x and y are such that $x^{\mathrm{T}}Ay$ is zero). These directions are termed "conjugate" directions. It can be shown that such a series of iterations will converge in exactly n steps; however, in practice, fewer than n iterations are required to obtain a sufficiently accurate result. The basic algorithm is given next, in which we use the inner product $\langle x, y\rangle = x^{\mathrm{T}}y$, and $r^k \equiv b - Ax^k$ is the residual at the kth step.

Choose x^0, and set $p^0 = r^0$.

For $k = 0, 1, \ldots,$

$$\alpha_k = -\langle r^k, p^k\rangle / \langle p^k, Ap^k\rangle$$
$$x^{k+1} = x^k - \alpha_k p^k$$
$$r^{k+1} = r^k + \alpha_k Ap^k$$

if

$$\|r^{k+1}\| < \varepsilon,$$

stop; otherwise

$$\beta_k = \langle r^{k+1}, r^{k+1}\rangle / \langle r^k, r^k\rangle$$
$$p^{k+1} = r^{k+1} + \beta_k p^k$$

In practice, the conjugate gradient method is used in conjunction with some form of preconditioning of the matrix A. This is still an active area of research.

D. Systems of Nonlinear Equations

The general form of a system of n nonlinear equations in n unknown variables is

$$
\begin{aligned}
f_1(x_1, x_2, x_3, \ldots, x_n) &= 0\\
f_2(x_1, x_2, x_3, \ldots, x_n) &= 0\\
&\vdots\\
f_n(x_1, x_2, x_3, \ldots, x_n) &= 0
\end{aligned}
$$

The iteration methods discussed in the last section can also be used for the nonlinear system. For example, the Jacobi method consists of making an initial estimate; then for the $(k+1)$st iteration, the ith individual equation is solved for $x_i^{(k+1)}$ in terms of the kth iteration values of all other variables. In the Gauss–Seidel method, the ith equation is solved for $x_i^{(k+1)}$ in terms of the already calculated values of $x^{(k+1)}$ from the current iteration and the rest of the variables from the previous iteration. An analogous situation exists for the successive over-relaxation method. The solution of each individual nonlinear equation is itself an iterative process, as discussed in Section III; thus for large systems there is a large amount of work. Also, convergence will only occur if the initial guess is sufficiently close to the solution.

The Newton method can be used if the partial derivatives of each equation with respect to each variable can be readily computed. This method is given by the matrix iteration equation

$$x^{(k+1)} = x^{(k)} - (J^{(k)})^{-1} f^{(k)},$$

where $x^{(k)}$ is the vector of kth iteration values of the n variables, $J^{(k)}$ is the"Jacobian" matrix of partial derivatives

$$
J^{(k)} = \begin{bmatrix}
\partial f_1/\partial x_1 & \partial f_1/\partial x_2 & \cdots & \partial f_1/\partial x_n\\
\partial f_2/\partial x_1 & \partial f_2/\partial x_2 & \cdots & \partial f_2/\partial x_n\\
\cdot & & & \cdot\\
\cdot & & & \cdot\\
\cdot & & & \cdot\\
\partial f_n/\partial x_1 & \partial f_n/\partial x_2 & \cdots & \partial f_n/\partial x_n
\end{bmatrix}
$$

evaluated at the kth iteration values of the variables, and $f(x^{(k)})$ is the vector of function values, again evaluated at the kth iteration. Note that the inverse of J is not explicitly computed, but that the system of equations

$$J^{(k)} y = f\left(x^{(k)}\right)$$

is solved. The Newton method converges more rapidly than those given above, but at the expense of computing derivatives. A number of variations of this method have been devised that approximate and rapidly update J^{-1}.

V. MATRIX EIGENPROBLEMS

A. Background

The multiplication of an $n \times n$ matrix A times an n-vector x results in a second n-vector,

$$Ax = y.$$

Thus, the operation can be thought of as a vector transformation. In general, both the length (the square root of the sum of the squares of the elements) and the orientation (relative magnitude of the elements) of the vector change. For a given matrix A, however, there are some vectors that, when premultiplied by A, do not change in orientation but only in length. That is,

$$Ax = \lambda x,$$

where λ is a scalar multiplier. Another way of stating this is

$$(A - \lambda I)x = 0.$$

This is a system of linear equations that has a nontrivial solution (not all components zero) only if $(A - \lambda I)$ is a singular matrix, that is, the determinant $\det(A - \lambda I)$ is zero. It is readily shown that $\det(A - \lambda I)$ is a polynomial of degree n in λ that has exactly n roots (allowing for multiple roots). The values of these roots are called the eigenvalues of A. For each eigenvalue λ_i, $i = 1, 2, \ldots, n$, there is a nontrivial vector $x^{(i)}$ that satisfies the equation

$$Ax^{(i)} = \lambda_i x^{(i)}$$

and any such vector is called an eigenvector corresponding to λ_i. Eigenvectors are not unique; in fact, any scalar multiple of an eigenvector is also an eigenvector corresponding to the same eigenvalue. Eigenvectors that correspond to distinct eigenvalues, however, are linearly independent.

The problems of finding eigenvalues or eigenvectors of a matrix are called eigenproblems. There are also "generalized eigenproblems," which are to find values λ or vectors x that satisfy

$$Ax = \lambda Bx$$

for any second matrix B.

Clearly, one approach for finding eigenvalues is to seek the roots of the polynomial $\det(A - \lambda I)$; however, this can be excessively time-consuming and unstable (meaning that a small error in the calculation can lead to a large error in a computed root). This approach is used only for selected eigenvalues when the matrix is symmetric and tridiagonal, in which case the polynomial can be evaluated without computing the coefficients.

The choice of a method for a specific eigenproblem depends on the properties of the matrix, whether just eigenvalues or both values and vectors are required, and whether

all or selected values are sought. The eigenvalues of symmetric matrices are real, whereas those of nonsymmetric matrices may be complex. Less computation is required for symmetric matrices, and the process is inherently more stable. Advantage can be taken of a banded structure. Finally, if the elements of A are complex, either the problem must be converted to a larger real problem, or complex arithmetic must be employed.

Most practical methods for computing eigenvalues depend on finding a similarity transformation,

$$B = C^{-1}AC,$$

where C is a nonsingular matrix that transforms A into a matrix B, whose eigenvalues can be more readily found. A similarity transformation preserves eigenvalues; that is, the eigenvalues of B are the same as those of A. In particular, if B is either diagonal or triangular, its eigenvalues are the diagonal elements.

B. Symmetric Matrices

There are two general classes of methods for finding the eigenvalues of a symmetric matrix. The first (Jacobi methods) attempts to reduce the matrix to diagonal form by iterating with similarity transformations. The second begins by reducing the matrix to tridiagonal form with a finite number of similarity transformations and then follows an iterative procedure.

The premultiplication of a two-dimensional vector by a matrix of the form

$$\begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix}$$

has the effect of rotating the vector counterclockwise through the angle θ. This matrix is therefore called a rotation matrix. By a judicious choice of θ, we can rotate the vector into a vertical orientation; that is, with its second element zero. In particular, if we consider the symmetric matrix

$$A = \begin{bmatrix} a_{11} & a_{12} \\ a_{12} & a_{22} \end{bmatrix}$$

and select $\theta = \tan^{-1}\frac{-a_{12}}{a_{11}}$, the result of premultiplying A by the rotation matrix is a matrix with zero in the lower left corner

$$\frac{1}{\sqrt{a_{11}^2 + a_{12}^2}} \begin{bmatrix} a_{11} & a_{12} \\ -a_{12} & a_{11} \end{bmatrix} \begin{bmatrix} a_{11} & a_{12} \\ a_{12} & a_{22} \end{bmatrix}$$

$$= \frac{1}{\sqrt{a_{11}^2 + a_{12}^2}} \begin{bmatrix} a_{11}^2 + a_{12}^2 & a_{11}a_{12} + a_{12}a_{22} \\ 0 & a_{11}a_{22} - a_{12}^2 \end{bmatrix}.$$

In order to preserve the eigenvalues of A, we must now complete the similarity transformation by multiplying on the right by the inverse of the rotation matrix (which has the same elements except that the signs of the off-diagonal elements are reversed). This results in the matrix

$$A^{(1)} = \frac{1}{a_{11}^2 + a_{12}^2} \times \begin{bmatrix} a_{11}^3 + 2a_{11}a_{12}^2 + a_{12}^2a_{22} & a_{11}a_{12}a_{22} - a_{12}^3 \\ a_{11}a_{12}a_{22} - a_{12}^3 & a_{11}^2a_{22} - a_{11}a_{12}^2 \end{bmatrix}.$$

The off-diagonal elements of $A^{(1)}$ are smaller in magnitude than those of A. Thus it is closer to a diagonal matrix. An iteration in which this process is repeated will converge to a diagonal matrix and the eigenvalues of A will appear on the diagonal.

For a symmetric matrix of arbitrary order, the rotation matrix required to annihilate the element of A appearing below the diagonal in the ith row and jth column is obtained by replacing the (i, i) and (j, j) elements of the identity matrix by $a_{ii}/\sqrt{a_{ii}^2 + a_{ij}^2}$, the (i, j) element by $-a_{ij}/\sqrt{a_{ii}^2 + a_{ij}^2}$, and the (j, i) element by $a_{ij}/\sqrt{a_{ii}^2 + a_{ij}^2}$. The similarity transformation involving this rotation will affect only the elements of A in these four positions. For a single iteration, a similarity transformation must be performed for each position below the diagonal until the magnitude of the element in that position falls below a predetermined threshold.

On a serial computer, the amount of work required to perform the Jacobi method and its variations exceeds that of the tridiagonalization methods described next; however, the parallelism of multiprocessor computers can be exploited more readily by the Jacobi methods. Furthermore, it has been found that the effect of roundoff error is less severe in these methods. For these reasons, they have been receiving greater attention in recent years.

The first step in the tridiagonilization method is to reduce a symmetric matrix to a tridiagonal matrix having the same eigenvalues. Although all of the off-diagonal elements of a matrix cannot be annihilated by similarity transformations in a finite number of operations, all of the elements outside of the diagonal and the adjacent super-and sub-diagonals can be. The use of rotation matrices, as above, to do this is called the "Givens" method of tridiagonalization; however, a more efficient method that annihilates all of the elements in a column below the tridiagonal in a single similarity transformation can be accomplished through the use of "Householder" matrices that have the form

$$P = (I - 2ww^{\mathrm{T}}).$$

In two dimensions, premultiplying a vector by a Householder matrix has the effect of reflecting the vector

about the line defined by w, thus these matrices are also called reflection matrices.

The vector w is chosen to have unit length, ($w^T w = 1$), which implies that $P^{-1} = P$. If $A^{(0)}$ is taken to be A, the reduction to tridiagonal from takes $n-2$ operations.

$$A^{(k)} = P^{(k)} A^{(k-1)} P^{(k)}, \quad k = 1, 2, \ldots, n-2,$$

where the w in the matrix $P^{(k)}$ is chosen to introduce zero elements in $A^{(k)}$ below the subdiagonal in column k and to the right of the superdiagonal in row k. Then $A^{(n-2)}$ is a tridiagonal matrix, which we will refer to below as $T^{(0)}$ and which has the same eigenvalues as A.

The second step depends on whether most or a few of the eigenvalues are required. If more than, say, 40% of the eigenvalues are required, then it is usual to proceed with a variant of the QR method. The kth iteration of this method consists of first factoring the matrix $T^{(k)}$ into an orthogonal matrix $Q^{(k)}$ (a matrix whose transpose is its inverse) and an upper triangular matrix $R^{(k)}$, and then multiplying these two matrices in reverse order. Thus,

$$T^{(k)} = Q^{(k)} R^{(k)}$$
$$T^{(k+1)} = R^{(k)} Q^{(k)} = Q^{(k)\mathrm{T}} T^{(k)} Q^{(k)}$$

The factorization is usually accomplished through the Gram–Schmidt orthogonalization process (or a modification thereof) on the columns of $T^{(k)}$. Each step of the method is a similarity transformation of the matrix of the previous step, thus the sequence of matrices $T^{(0)}, T^{(1)}, T^{(2)}, \ldots$ has the same eigenvalues. The sequence will converge to a diagonal matrix with elements that are those eigenvalues. The convergence can be accelerated by judicious selection of a scalar quantity σ_k, called an origin shift, which is subtracted from the diagonal elements at each step. The algorithm then becomes

$$T^{(k)} - \sigma_k I = Q^{(k)} R^{(k)}$$
$$T^{(k+1)} = R^{(k)} Q^{(k)} + \sigma_k I,$$

where k takes on values 0, 1, 2, ... Once a number sufficiently close to zero has appeared in the $t_{n,n-1}$ position, the algorithm can be applied to the $(n-1)\times(n-1)$ upper left submatrix and the origin shift adjusted accordingly, and so on until all subdiagonal elements have been reduced to zero.

Sometimes this method is implemented as the QL algorithm, in which the second factor is made to be a lower-triangular matrix instead of an upper-triangular one. The QL matrix has an advantage in convergence when, as often happens in the formulation of matrices from physical situations, the smaller elements are at the top.

The transformation matrices for all steps in the process can be accumulated to obtain the eigenvectors of A, if they are needed.

If only a few eigenvalues are required, they may be found more efficiently by computing the corresponding roots of the characteristics polynomial of the tridiagonal matrix obtained after the first stage of the above method. This is done iteratively without computing the coefficients of the polynomial, but estimates of root locations are obtained from the theory of Sturm sequences of polynomials.

The problem of computing the eigenvector corresponding to a specific eigenvalue may be solved very effectively through the process of inverse iteration: an estimate of the eigenvalue is subtracted from the diagonal elements of A to form the matrix $(A - \lambda I)$, and then the solutions to the sequence of linear systems

$$(A - \lambda I) x^{(k+1)} = x^{(k)}, \qquad k = 0, 1, 2, \ldots,$$

are found successively. (The LU factorization of $A - \lambda I$ need be performed only once.) This iteration is relatively insensitive to the first estimate $x^{(0)}$ and will converge to the required eigenvector.

C. Nonsymmetric Matrices

The problem of finding the eigenvalues of a nonsymmetric matrix is inherently less stable than the symmetric case; furthermore, some or all of the eigenvalues and eigenvectors may be complex.

The first stage is to "balance" the matrix by applying similarity tranformations in order to make the maximum element in corresponding rows and columns approximately equal. Next, the matrix is reduced to "Hessenburg form" by applying stablilized elementary similarity transformations. An upper Hessenburg matrix has the form

$$H = \begin{bmatrix} a_{1,1} & a_{1,2} & a_{1,3} & \cdots & a_{1,n} \\ a_{2,1} & a_{2,2} & a_{2,3} & \cdots & a_{2,n} \\ 0 & a_{3,2} & a_{3,3} & \cdots & a_{3,n} \\ 0 & 0 & a_{4,3} & \cdots & a_{4,n} \\ \cdot & & & \cdots & \cdot \\ \cdot & & & \cdots & \cdot \\ \cdot & & & \cdots & \cdot \\ 0 & 0 & 0 & \cdots a_{n,n-1} & a_{n,n} \end{bmatrix}$$

The elementary matrices are similar in form to those used in the LU factorization (Gaussian elimination) process, except that the pivotal element is taken to be one element below the diagonal. As in LU factorization for general matrices, the rows are interchanged to maximize the pivotal element; however, a difference is that for each elementary matrix multiplying A on the left, its inverse is multiplied on the right, and each row interchange is accompanied by the corresponding column interchange, in order to preserve the eigenvalues.

Since real nonsymmetric matrices may have complex conjugate pairs of eigenvalues, an application of the QR algorithm with origin shift as described for symmetric matrices will involve computing with complex numbers. To avoid this, the double-shift QR algorithm is usually applied to the Hessenburg matrix $H^{(0)}$ obtained in the first stage. The kth iteration of this method is

$$(H^{(k)} - \sigma_{k,1} I)(H^{(k)} - \sigma_{\sigma_{k,2}} I) = Q^{(k)} R^{(k)}$$
$$H^{(k+1)} = Q^{(k)T} H^{(k)} Q^{(k)}$$

The shifts $\sigma_{k,1}$ and $\sigma_{k,2}$ are taken to be the eigenvalues of the lowest 2×2 submatrix of $H^{(k)}$; however, when convergence of this submatrix is ascertained, the method is applied to the remaining upper submatrix in the same way. Eventually the sequence $H^{(k)}$, $k = 0, 1, 2, \ldots$, will converge to a triangular matrix, except that there will be 2×2 blocks on the diagonal for each pair of complex eigenvalues.

As before, the transformations may be accumulated if all of the eigenvectors are required. If the eigenvector associated with a specific eigenvalue is required, inverse iteration may be used (albeit with complex arithmetic if the eigenvalue is complex).

VI. NUMERICAL REPRESENTATION OF FUNCTIONS

A. Polynomial Representation and Interpolation

The exact representation of an arbitrary continuous function would require an infinite number of infinite-precision numbers. If a function is to be numerically represented for computer manipulation, it must therefore be approximated in some way.

We will consider an arbitrary function $f(x)$ in the single independent variable x, which can take on values between a and b. The general approach is to let $f(x)$ be approximated by a finite linear combination of basis functions

$$f(x) \approx \sum_{i=0}^{m} a_i \phi_i(x),$$

where the a_i are fixed coefficients and the $\phi_i(x)$ are, usually, simple functions defined for $a \le x \le b$. For example, if $\phi_i(x) = (x - x_0)^i$, $i = 0, 1, 2, \ldots m$, successive differentiation and evaluation at $x = x_0$ yields the familiar Taylor's series, truncated after the $(m+1)$-st term

$$f(x) \approx f(x_0) + (x - x_0) f'(x_0) + \left[(x - x_0)^2/2\right] f''(x_0) + \cdots + \left[(x - x_0)^m/m!\right] f^{(m)}(x_0)$$

If, instead, we identify $m+1$ distinct values of $x(x_0, x_1, x_2, \ldots, x_{m-1}, x_m)$; take $\phi_0(x) = 1$; set

$$\phi_i(x) = (x - x_0)(x - x_1)(x - x_2) \cdots (x - x_{i-1})$$

for $i = 1, 2 \ldots m$; and solve for the coefficients a_i, $i = 0, 1, 2, \ldots, m$, in turn, we arrive at the Newton general interpolation formula

$$f(x) \approx f[x_0] + f[x_0, x_1]\phi_1(x) + f[x_0, x_1, x_2]\phi_2(x) + \cdots + f[x_0, x_1, \ldots, x_m]\phi_m(x),$$

where the $f[x_0, x_1, x_2, \ldots x_i]$ for $i = 0, 1, 2, \ldots, m$ are called divided differences and may be calculated recursively, as illustrated in Table III.

The right-hand sides of both of these examples are polynomials of degree m. In the first case, the polynomial takes on the value of $f(x)$ and all of its derivatives up to $f^{(m)}(x)$

TABLE III Divided Differences

x	Zeroth order	First order	Second order	Third order
x_0	$f[x_0] = f(x_0)$			
		$f[x_0, x_1] = \dfrac{f[x_1] - f[x_0]}{(x_1 - x_0)}$		
x_1	$f[x_1] = f(x_1)$		$f[x_0, x_1, x_2] = \dfrac{f[x_1, x_2] - f[x_0, x_1]}{(x_2 - x_0)}$	
		$f[x_1, x_2] = \dfrac{f[x_2] - f[x_1]}{(x_2 - x_1)}$		$f[x_0, x_1, x_2, x_3] = \dfrac{f[x_1, x_2, x_3] - f[x_0, x_1, x_2]}{(x_3 - x_0)}$
x_2	$f[x_2] = f[x_2]$		$f[x_1, x_2, x_3] = \dfrac{f[x_2, x_3] - f[x_1, x_2]}{(x_3 - x_1)}$	
		$f[x_2, x_3] = \dfrac{f[x_3] - f[x_2]}{(x_3 - x_2)}$		$f[x_1, x_2, x_3, x_4] = \dfrac{f[x_2, x_3, x_4] - f[x_1, x_2, x_3]}{(x_4 - x_1)}$
x_3	$f[x_3] = f(x_3)$		$f[x_2, x_3, x_4] = \dfrac{f[x_3, x_4] - f[x_2, x_3]}{(x_4 - x_2)}$	
		$f[x_3, x_4] = \dfrac{f[x_4] - f[x_3]}{(x_4 - x_3)}$		
x_4	$f[x_4] = f(x_4)$			

when $x = x_0$, whereas in the second case, the polynomial takes on the value of $f(x)$ at $m+1$ different values of x. It is possible, by repeating the occurrence of the factor $(x - x_i)$ the proper number of times for any of the x_i in the construction of the basis functions of the second example, to provide for the polynomial to take on the value of $f(x_i)$ and any number of derivatives of $f(x)$ at x_i.

Polynomials constructed in this way both represent $f(x)$ numerically and can be used to interpolate $f(x)$: that is, to estimate a value of $f(x)$ (by evaluation of the polynomial) between exactly known values. In fact, as implied by the first example they may be used to extrapolate $f(x)$, meaning to estimate a value outside the interval containing all of the known values of the function.

Provided that $f(x)$ can be differentiated $m+1$ times, the error in estimating $f(x)$ for, say, $x = x^*$ can be shown to be no greater in magnitude than

$$(M/(m+1)!)\phi_{m+1}(x^*),$$

where M is the maximum value of $|f^{(m+1)}(x)|$ in the interval containing x^* and all of the x_i. This error may be small for x^* close to the center of the interval containing all the x_i, and, for this reason polynomial representation of a function using known data *local* to the point of interpolation is generally satisfactory; however, as the interpolation point approaches the extremes of the interval containing the known data, the error can become quite large. Extrapolation using high-degree polynomial representation of a function can be highly inaccurate and is not recommended.

B. Piecewise Polynomials and Splines

A commonly used approach to overcome the problem of representing a given function globally, where the use of a single high-degree polynomial will produce large errors away from the central region, is to divide the domain of the function into segments. The function is represented by a different polynomials in each segment, and these polynomials are constrained to at least have the same value at the segment boundaries. The points where the polynomials meet are called knots.

In the case of interpolating between distinct values x_i where the function $f(x_i)$ is known, it is usual to make the knots coincident with the points $(x_i,\ f(x_i))$. The simplest example is to construct a piecewise linear function by joining successive points with straight lines. Such a function is continuous over its length, but, of course, may not have a continuous derivative at the knots. If the derivatives $f'(x_i)$ are known, then in each interval defined by $x_{i-1} \le x \le x_i$, the four coefficients of a cubic polynomial

$$h_i(x) = a_i + b_i x + c_i x^2 + d_i x^3$$

can be computed to satisfy

$$\begin{aligned} h_i(x_{i-1}) &= f(x_{i-1}) \\ h_i(x_i) &= f(x_i) \\ h_i'(x_{i-1}) &= f'(x_{i-1}) \\ h_i'(x_i) &= f'(x_i). \end{aligned}$$

This is referred to as cubic Hermite interpolation and results in a piecewise cubic polynomial that is continuous and has a continuous first derivative. This concept can be extended if derivatives higher than the first are known; the interpolating polynomial is always of degree $2p+1$, where p is the highest derivative known.

The cubic spline is a very elegant mathematical function, named for the draftsman's spline curve that it models. If the points $(x_i,\ f(x_i))$ are given for $i = 0, 1, 2, \ldots, m$, then the $4m$ coefficients required to define a cubic polynomial s_i in each of the m intervals are computed from the $4m$ equations

$$\begin{aligned} s_i(x_{i-1}) &= f(x_{i-1}), && i = 1, 2, \ldots, m \\ s_i(x_i) &= f(x_i), && i = 1, 2, \ldots, m \\ s_{i+1}'(x_i) &= s_i'(x_i), && i = 1, 2, \ldots, m-1 \\ s_{i+1}''(x_i) &= s_i''(x_i), && i = 1, 2, \ldots, m-1 \\ s''(x_0) &= s''(x_m) = 0. \end{aligned}$$

The last two equations, which are the end conditions for the *natural* cubic spline, may be replaced by other conditions, such as $s'(x_0) = f'(x_0)$, $s'(x_m) = f'(x_m)$. The resulting function is continuous and has continuous first and second derivatives. This concept can be extended to other polynomial degrees, and the spline is continuous in all derivatives up to 1 less than the degree; however, for an equal number of conditions at each end, the degree must be odd. Figure 9(a) illustrates interpolation with a natural cubic spline function.

As in the case of polynomials, there is always a representation for an arbitrary piecewise polynomial $g(x)$ in the form

$$g(x) = \sum_{j=1}^{n} a_j \phi_j(x).$$

There are always as many basis functions $\phi_i(x)$ as there are matching conditions plus end conditions for the entire curve, for example, $n = m+3$ in the case of the cubic spline. There is at least one basis function associated with each knot, and they have the desirable property of local support, meaning that they are zero everywhere except close to the knot with which they are associated. Figure 9(b) illustrates the basis functions for a natural cubic spline having equally spaced knots.

The error associated with interpolation using piecewise polynomials is dependent on the degree of the polynomial and the spacing between the knots. If h is the maximum

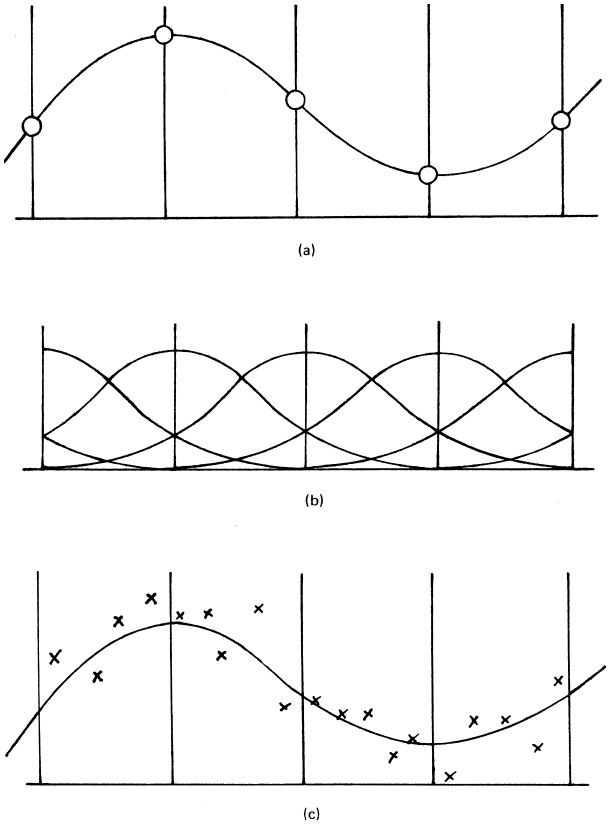


FIGURE 9 Natural cubic spline function. (a) Interpolation. (b) Basis functions. (c) Approximation.

spacing between knots and p is the degree of the polynomial, the error for an arbitrary x between x_0 and x_m is bounded by

$$|f(x) - g(x)| < Kh^{p+1},$$

where K is a constant. The error is thus said to be of order h^{p+1} and written $O(h^{p+1})$.

Even using unmodified piecewise polynomials often results in numerical representations with undesirable oscillations, or in regions where, for example, the numerical curve is convex where $f(x)$ is concave. In an attempt to overcome these problems, special functions, such as rational polynomials (ratios of polynomials) or splines with tension factors (a generalization of the spline already described that contains a parameter whose effect is to flatten the curve between the knots in the same manner as applying longitudinal tension in a mechanical spline), have been introduced in recent years. The general principle, however, is the same.

C. Approximation

Frequently, the function $f(x)$ that is to be represented numerically describes a physical situation and is known in terms of observed data x_i, $f(x_i)$, for $i = 1, 2, \ldots, m$. If this data is voluminous, the interpolating polynomials described in the last two sections require more storage than the raw data. Furthermore, any observational error in the data will tend to introduce (sometimes extreme) oscillations. It is therefore often desirable to approximate such functions with polynomials of lower degree than indicated by the number of data points, or with piecewise polynomials with widely spaced knots compared to the data intervals, but which do not necessarily take on the exact given values of $f(x_i)$. The usual technique is to attempt to find a function with these characteristics, say $g(x)$, that minimizes the sum (over all i) of the squares of the residuals,

$$r_i = f(x_i) - g(x_i).$$

A useful first step for this purpose is to determine basis functions ϕ_j for the approximating function

$$g(x) = \sum_{j=1}^{n} \alpha_j \phi_j(x).$$

In the case of piecewise polynomials, this implies choosing the knots, which are more widely spaced than the data, and not necessarily coincident with any data point. The n unknown coefficients α_j are then found by solving the overdetermined system of equations

$$\sum_{j=1}^{n} \alpha_j \phi_j(x_i) = f(x_i), \qquad i = 1, 2, \ldots, m,$$

by the least-squares method described in Section IV.B. The concept is illustrated in Fig. 9(c) for a natural cubic spline function.

In practice, numerical representation, interpolation, and approximation generally require experimentation with the degree of polynomials, placement of knots (in the case of piecewise functions), and tension factors (in the case of splines under tension), in order to obtain a fair curve. Interactive techniques using computer-generated graphics are particularly useful for this purpose.

The concepts discussed in this section carry over into multidimensional regions for the representation of functions of more than one independent variable or the parametrically defined surfaces of solid objects.

VII. DIFFERENTIATION AND INTEGRATION

A. Differentiation and Finite Differences

Once a numerical representation $g(x)$ of a function $f(x)$ has been found, it is relatively simple to differentiate it in order to obtain an approximation to the derivative of $f(x)$, that is,

$$f'(x) \approx g'(x) = \sum_{i=0}^{m} a_i \phi_i'(x).$$

Care must be exercised in doing this, however, because the error in approximating the derivative can be very much larger than the error in approximating the function itself. This can be seen by differentiating the error $f(x) - g(x)$ in any of the cases previously considered, from which it is found that the bound on the error in the derivative is one order lower than the corresponding error in the function. For example, if

$$|f(x) - g(x)| < Kh^p,$$

then

$$|f'(x) - g'(x)| < K'h^{p-1},$$

where K' is, in general, a different constant than K. When h is small, the second bound can be much larger than the first.

Nevertheless, some very useful formulas can be obtained from the Newton general interpolation formula introduced in Section VI.A. Differentiation with respect to x produces a very complicated formula, but considerable simplification can be achieved by taking the points x_i to be equally spaced along the x axis (say a distance h units apart) and by evaluating the result at one of these points. The final result is an expression for the derivative of $f(x)$ at one point in terms of h and values of $f(x)$ evaluated at multiples of h units away from that point. Such expressions, and similar ones for higher derivatives, are called finite-difference formulas.

The order in which the points are taken is actually arbitrary; thus, for $x = x_0$, the natural left-to-right ordering produces a forward-difference formula, and the reverse ordering produces a backward-difference formula. If the number of points is odd and $x = x_0$, two difference formulas can be obtained by alternating $x_1, x_2 \ldots$ to the left and right of x_0, starting first to the left and then first to the right. Averaging these two formulas results in a symmetric central-difference formula.

If the error term of the Newton interpolation formula is carried along in the derivation of these difference formulas, an estimate of the error can be obtained in each case. The power of h that appears in the error term determines the order of accuracy of the corresponding formula.

Table IV gives the coefficients and error estimate for second-, fourth-, and sixth-order accurate central-difference approximations of $f'(x_0)$ and $f''(x_0)$; and second- and fourth-order accurate approximations to $f^{(3)}(x_0)$ and $f^{(4)}(x_0)$. For example, a second-order accurate finite-difference approximation to the first derivative of $f(x)$ at $x = x_0$ is

$$\left[-\tfrac{1}{2} f(x_0 - h) + \tfrac{1}{2} f(x_0 + h) \right] / h.$$

Note that z, appearing in the error term, is some point in the domain of the corresponding finite-difference formula.

B. Integration

The interpolation formulas introduced in Sections VI.A and VI.B can also be used as starting points to develop formulas for numerical integration (sometimes called quadrature). Given a function $f(x)$ and values for lower and upper limits of integration a and b, the objective is to obtain approximations to

$$I = \int_a^b f(x)\, dx.$$

The domain of integration is partitioned into n intervals by the points $x_0 = a, x_1, x_2, \ldots, x_n = b$, where the ith interval is defined by $x_{i-1} \le x \le x_i$. The simplest method, which corresponds to $m = 0$ in the Newton interpolation formula, is to approximate $f(x)$ by the constant value $f(x_{i-1})$ in the ith interval. Thus

$$I_i = \int_{x_{i-1}}^{x_i} f(x)\, dx \approx (x_i - x_{i-1}) f(x_{i-1})$$

and

$$I = \sum_{i=1}^{n} I_i \approx \sum_{i=1}^{n} (x_i - x_{i-1}) f(x_{i-1}).$$

This method is referred to as rectangle integration and is illustrated graphically in Fig. 10(a). If all of the intervals are of equal length h, it can be established by integrating the error term in the interpolation formula that the error in I is of order h [bounded in absolute value by Kh, where K is a constant depending only on $f(x)$].

A more accurate method is derived in similar fashion by taking $m = 1$ in the Newton interpolation formula. In this case it is found that

$$I_i \approx (x_i - x_{i-1})[f(x_{i-1}) + f(x_i)]/2$$

and

$$I \approx [(x_i - x_0) f(x_0) + \sum_{i=1}^{n-1} (x_{i+1} - x_{i-1}) f(x_i) + (x_n - x_{n-1}) f(x_n)]/2.$$

This method is known as trapezoidal integration and is illustrated in Fig. 10(b). The error for equal intervals of length h is of order h^2.

Carrying this concept one step further and assuming that $f(x)$ may also be evaluated at the midpoint of each interval, a method called Simpson rule integration, which is of order h^4 for equal intervals of length h, can be derived from a symmetric version of the interpolation formula with $m = 2$. Here

TABLE IV Coefficients of Central-Difference Approximations and Error Estimates for Derivatives

First derivative								
Order	$x-3h$	$x-2h$	$x-h$	x	$x+h$	$x+2h$	$x+3h$	Error
2			$-\frac{1}{2}$	0	$\frac{1}{2}$			$-\frac{1}{6}f^{(3)}(z)h^2$
4		$\frac{1}{12}$	$-\frac{2}{3}$	0	$\frac{2}{3}$	$-\frac{1}{12}$		$\frac{1}{30}f^{(5)}(z)h^4$
6	$-\frac{1}{60}$	$\frac{3}{20}$	$-\frac{3}{4}$	0	$\frac{3}{4}$	$-\frac{3}{20}$	$\frac{1}{60}$	$-\frac{1}{140}f^{(7)}(z)h^6$
Second derivative								
Order	$x-3h$	$x-2h$	$x-h$	x	$x+h$	$x+2h$	$x+3h$	Error

2		$-\frac{1}{2}$	1	0	-1	$\frac{1}{2}$		$-\frac{1}{4}f^{(5)}(z)h^2$
4	$\frac{1}{8}$	-1	$\frac{13}{8}$	0	$-\frac{13}{8}$	1	$-\frac{1}{8}$	$\frac{7}{120}f^{(7)}(z)h^4$
Fourth derivative								
Order	$x-3h$	$x-2h$	$x-h$	x	$x+h$	$x+2h$	$x+3h$	Error
2		1	-4	6	-4	1		$-\frac{1}{6}f^{(6)}(z)h^2$
4	$-\frac{1}{6}$	2	$-\frac{13}{2}$	$\frac{28}{3}$	$-\frac{13}{2}$	2	$-\frac{1}{6}$	$\frac{7}{240}f^{(8)}(z)h^4$

$$I_i \approx (x_i - x_{i-1})[f(x_{i-1}) + 4f((x_{i-1}+x_i)/2 + f(x_i)]/6$$

and

$$I \approx \left[(x_1 - x_0)f(x_0) + \sum_{i=1}^{n}(x_{i+1} - x_{i-1})f(x_i) + 4\sum_{i=1}^{n-1}(x_i - x_{i-1})f((x_{i-1}+x_i)/2) + (x_n - x_{n-1})f(x_n)\right] \Big/ 6$$

This is illustrated in Fig. 10(c).

In the situation where $f(x)$ can be evaluated for any given x, the choice of the partition points x_i in the above methods can be optimized by adaptive procedures. One such method, called adaptive Romberg integration, uses the trapezoidal method on a single interval equal to the whole range of integration to form, say $T_{0,0}$, and then with two intervals for the first and second half of the range to form, $T_{0,1}$. These two results are combined into

$$T_{1,1} = (4T_{0,1} - T_{0,0})/3,$$

which has the effect of eliminating the principal part of the error. The difference between the two results is also compared with a predetermined tolerance, and if it is sufficiently small $T_{1,1}$ is taken as the final result. If not, each of the two intervals is again halved and the procedure is repeated for both intervals. The pattern is continued with successive halving of the intervals, except that whenever two successive results for a particular interval are sufficiently close, that interval is no longer reduced and the current value of the integral over that interval is held constant

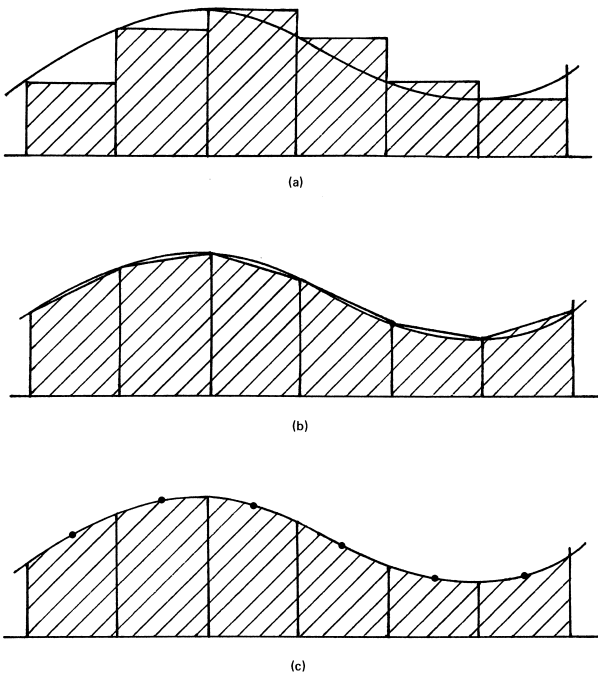

FIGURE 10 Numerical integration. (a) Rectangle method. (b) Trapezoidal method. (c) Simpson's method.

until the final result is obtained. At each stage of mesh refinement, a combination of results can be used to further reduce the error in a manner similar (but not necessarily identical) to $T_{1,1}$.

In situations where $f(x)$ cannot be evaluated but is tabulated for given values of x, integration of the spline interpolation formulas or of the approximation formulas obtained in the previous section may be used.

It should be noted that, in contrast to numerical differentiation, the order of a numerical integration method is greater than that of the interpolation or approximation formula from which it is derived. This is a reflection of the fact that integration is a well-conditioned process, whereas differentiation is ill-conditioned.

VIII. DIFFERENTIAL EQUATIONS

A. Ordinary Differential Equations—Initial-Value Problems

A first-order ordinary differential equation (ODE) in the independent variable x is usually written as

$$y'(x) = f(x, y(x)),$$

where f is a given function of the variables x and y, and y is an unknown function of x. Such an equation is to hold for a domain of x, say $a \le x \le b$. There are, in general, an infinite number of functions $y(x)$ that satisfy this equation, but under some rather mild restrictions on f, there is a unique solution that also satisfies the initial condition.

$$y(a) = y_0.$$

In realistic situations, it is usually impossible to find an analytic expression for the solution; thus a numerical approximation is often sought.

The general approach is to compute approximations to $y(x)$ at monotone increasing, discrete values of x, that is, $x_1, x_2, \ldots, x_i, \ldots$, where $x_{i+1} - x_i = h_i$ is a positive number (the step size). In what follows, we denote the computed approximate value of $y(x_i)$ by y_i.

There are two broad classes of methods for the numerical solution of the above problem: single-step methods compute y_{i+1} using only the previously computed y_i, whereas multiple-step methods use several previously computed values, say $y_{i-k}, y_{i-k+1}, \ldots, y_i$.

As a starting point for the discussion of single-step methods, we recall the Taylor's series expansion of $y(x_{i+1})$ with respect to $y(x_i)$:

$$y(x_{i+1}) = y(x_i) + h_i y'(x_i) + h_i^2 y''(x_i)/2 + \cdots.$$

By truncating this series after a specific number of terms and by differentiating the original differential equation the required number of times to obtain derivatives of $y(x)$ higher than l (remembering to use the chain rule in differentiating $f(x, y)$, we can obtain formulas of the form

$$y_{i+1} = y_i + h_i(f)_i + h_i^2(f_x + f_y f)_i/2 + \cdots.$$

Here the subscripts x and y denote differentiation and the subscript i following the parentheses denotes evaluation using data obtained at the previous step.

The particularly simple Euler method is obtained in this way by truncating after the second term on the right:

$$y_{i+1} = y_i + h_i f(x_i, y_i)$$

If we assume for the moment that the data at $x = x_i$ is exact, then the terms in the series that are discarded represent the error introduced in y_{i+1} in integrating from x_i to x_{i+1}. This is called the local truncation error. In the case of the Euler method, the local truncation error is bounded in absolute value by a constant times h_i^2. The formula is applied successively in stepping to the right from y_0; thus the error accumulates as the solution is developed. It can be shown that for a uniform interval length h the accumulated truncation error at a given value of x is bounded by a constant times h; thus the Euler method is said to be of order h, or first-order accurate. This method is illustrated in Fig. 11(a) for the problem $y' = -y, y(0) = 1$, using several different values of h.

In most situations it is not possible to compute the derivatives of $f(x, y)$ that are required for higher order

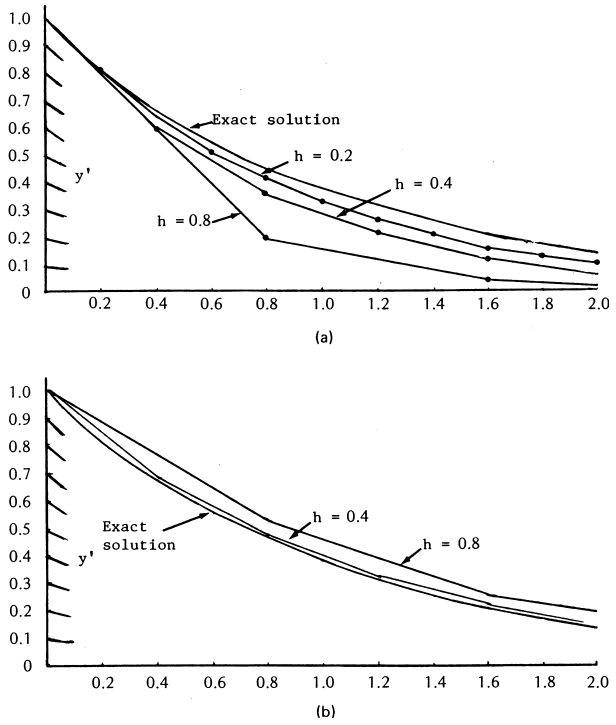

FIGURE 11 Numerical solution of an ordinary differential equation initial-value problem: $y' = -y$; $y_0 = 1$. (The solution is $y = e^{-x}$.) (a) Euler method. (b) Heun method.

versions of the Taylor method; however, the popular Runge–Kutta methods can be shown to be equivalent. For example, a second-order Runge–Kutta method, sometimes called the Heun method or the trapezoidal method, is given by

$$y_{i+1} = y_i + h_i(k_1 + k_2)/2,$$

where

$$k_1 = f(x_i, y_i)$$

and

$$k_2 = f(x_{i+1}, y_i + h_i k_1).$$

The Heun method is illustrated in Fig. 11(b) for the same problem as for the Euler method, showing the improved accuracy. The commonly used fourth-order Runge–Kutta method is given by

$$y_{i+1} = y_i + h_i(k_1 + 2k_2 + 2k_3 + k_4)/6,$$

where

$$k_1 = f(x_i, y_i)$$
$$k_2 = f(x_i + h_i/2, y_i + h_i k_1/2)$$
$$k_3 = f(x_i + h_i/2, y_i + h_i k_2/2)$$
$$k_4 = f(x_i, y_i + h_i k_3)$$

Single-step methods have the advantage that the step size h_i can be easily changed at each step so that, when the solution is changing rapidly with respect to x, the step size can be diminished; alternatively, when the solution is changing slowly, it may be increased. It is possible to automate this during the solution process by estimating the error at a given step and then to halve, double, or retain the current step size depending on the magnitude of this estimate.

Most of the computation that is needed to numerically solve an initial-value ODE problem is in the evaluation of $f(x, y)$ for different values of the variables x and y. Because single-step methods require many evaluations of this function per step, they may be prohibitively slow for complex problems. The multistep methods require fewer evaluations of $f(x, y)$ per step for the same order of truncation. They are based on the approach of integrating the differential equation from x_i to x_{i+1}, where $f(x, y)$ is replaced by a polynomial $p(x)$ of degree (say) k, which interpolates $f(x, y)$ at the $k + 1$ previously computed points (x_j, y_j), $j = i - k, 1 - k + 1, \ldots, i$. Thus,

$$y_{i+1} - y_i = \int_{x_i}^{x_{i+1}} y'\,dx \approx \int_{x_i}^{x_{i+1}} p(x)\,dx.$$

In the case where $k = 3$ and the interval between points is a uniform length h, we can derive in this way, the fourth-order Adams–Bashforth formula

$$y_{i+1} = y_i + h(55 f_i - 59 f_{i-1} + 37 f_{i-2} - 9 f_{i-3})/24.$$

Although more efficient in terms of the number of evaluations of $f(x, y)$, multistep methods do suffer from some disadvantages.

1. Special start-up procedures are required to obtain the needed, previously computed values of y_i.
2. Complicated restart procedures are required whenever it is necessary to change the interval size.
3. These methods tend to be numerically unstable, meaning that small, initial errors tend to grow as x increases.

To help alleviate the third problem—which is explained a little more completely in the next section—an initial multistep formula is used to predict a value for y_{i+1}, and this is followed up with a compatible corrector formula. A suitable corrector for the Adams–Bashforth method is the Adams–Moulton formula,

$$y_{i+1} = y_i + h(9 f_{i+1} + 19 f_i - 5 f_{i-1} + f_{i-2})/24$$

where f_{i+1} is computed using the predicted y_{i+1}.

Before ending this section we mention that methods for the solution of a single first-order differential

equation carry over to *systems* of first-order differential equations

$$\begin{aligned} y_1' &= f_1(x, y_1, y_2, \ldots, y_n) \\ y_2' &= f_2(x, y_1, y_2, \ldots, y_n) \\ &\vdots \\ y_n' &= f_n(x, y_1, y_2, \ldots, y_n) \end{aligned}$$

Here, the subscript refers to one of the n dependent variables, rather than evaluation at a discrete value of x. We can express this system in exactly the same way as a single equation if we merely take y to represent the vector of dependent variables.

Finally, higher-order differential equations (containing second and higher derivatives) can be reduced to a system of first-order differential equations by treating each derivative of each dependent variable as a separate variable in a first order system. Thus the equation

$$y'' + ay' + by + c = 0$$

can be written as

$$y_1' = -ay_1 - by_2 - c, \quad y_2' = y_1$$

B. Numerical Instability and Stiffness

Numerical instability is a phenomenon due to the numerical method used to solve a problem—not the problem itself. It may be illustrated in the context of initial-value problems for differential equations by attempting to solve

$$y' = -y; \quad y(0) = 1$$

using the simple two-step (midpoint) method with constant h:

$$y_{i+1} = y_{i-1} + 2hf(x_i, y_i)$$

Substituting $-y$ for $f(x, y)$, we have

$$y_{i+1} = y_{i-1} - 2hy_i$$

which is a second-order difference equation. Since the exact solution to the problem is known to be $y(x) = e^{-x}$, we can take $y(0) = 1$ and $y(h) = e^{-h}$ for the initial data corresponding to $i = 0$ and $i = 1$ in the difference equation. The solution to the difference equation can now be determined using standard techniques to be

$$\begin{aligned} y_i = {} & A(-h + \sqrt{(h^2+1)})^i \\ & + B(-h - \sqrt{(h^2+1)})^i \end{aligned}$$

where

$$A = (1 + (e^{-h} + h)/\sqrt{(h^2+1)})/2$$

and

$$B = (1 - (e^{-h} + h)/\sqrt{(h^2+1)})/2$$

If we fix a value of $x = ih$ and substitute x/h for i in the expression for the solution to the difference equation, and then take the limit as h goes to 0, we see that A goes to 1, B goes to 0, and the solution becomes

$$\lim_{h\to 0} y_{x/h} = \lim_{h\to 0}(1-h)^{x/h} = e^x$$

which is consistent with the exact solution. However, for any *finite* h, B is not 0 and the second term contains a factor greater than 1 that is raised to the ith power. The second term is called a parasitic solution, which, as x (and therefore i) increases, will eventually dominate, generating alternate positive and negative numbers of increasing magnitude. This phenomenon is illustrated in Fig. 12(a) for the example of the midpoint method applied to the same problem as the Euler method in Fig. 11(a). Note that for a step size of 0.4 the midpoint method diverges from the solution, whereas the Euler method, having a lower order of accuracy, does not. A possible cure for this type of instability is to apply, at each step, a correction based on an implicit formula of the same order as the original method. By implicit we mean depending on y_{i+1}, which, of course, is the value we wish

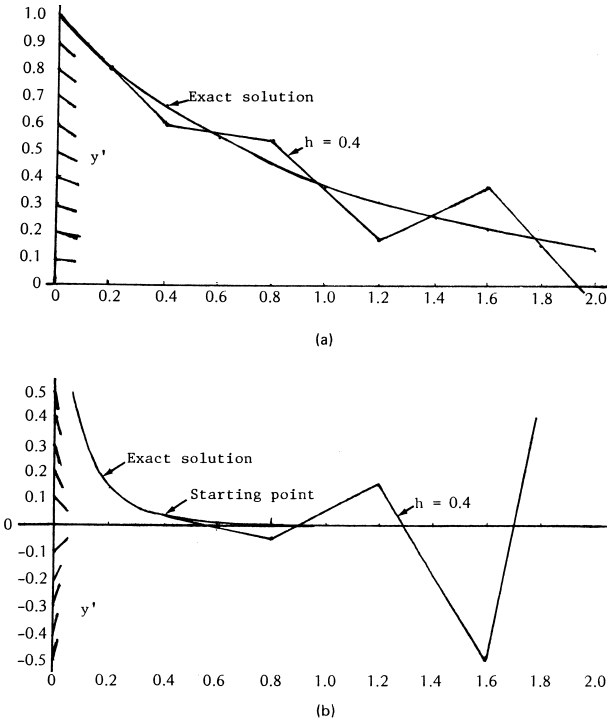

FIGURE 12 Instability and stiffness in the numerical solution of an initial-value ordinary differential equation problem: (a) $y' = -y; y_0 = y(0) = 1$ by midpoint method: illustrates instability; (b) $y' = -10y; y(0) = 1 : y_0 = y(0.4) = e^{-0.4}$, Euler method: illustrates stiffness.

to correct. As an example, the second-order trapezoidal method

$$y_{i+1} = y_i + h_{i+1}(f_i + f_{i+1})/2$$

may be used, where f_{i+1} is computed from the value of y_{i+1} obtained from the method previously given.

In contrast to numerical instability, the problem of *stiffness* is associated with the problem to be solved and is due to the function $f(x, y)$ changing greatly in response to small changes in y. The usual example given is the problem

$$y' = -Ky, \quad y(0) = 1,$$

where K is a large number, say 1000. If a standard numerical method is used to solve this problem, a very small step size is needed at the start to track the rapidly changing solution $y = e^{-Kx}$. As x grows large, however, y changes slowly with respect to x, which suggests that the interval size could be enlarged. Unfortunately, though, a small error in computing y produces a large error in y', which in turn produces a large error in the next value of y unless the interval is very small. This phenomenon is illustrated for the Euler method in Fig. 12(b) for $K = 10$, starting at $x = 0.4$ and using a step size of 0.4. In this example, h would have to remain less than 0.2 in order to maintain stability, even though once x is greater than 0.4 there is little change in the solution. The usual approach to overcome this problem is, for each step, to follow a prediction formula with an implicit correction formula, solving for y_{i+1} with a high-order iteration method (e.g., Newton's method).

It should be mentioned here that mathematical subroutine packages, which are available for most scientific computer systems, contain carefully designed routines that are tailored for a variety of problem types. The problems of instability and stiffness illustrate pitfalls in using arbitrary methods for the solution of initial-value problems in ordinary differential equations without due care; however, with proper selection, the available mathematical subroutines can usually be relied on for near-optimum solutions.

C. Ordinary Differential Equations—Boundary-Value Problems

A necessary condition for a unique solution to an ordinary differential equation is that the solution satisfy some prescribed auxiliary conditions. The number of such conditions must equal the order of the equation. In the case of initial value problems, these conditions are the initial values of the solution and all of its derivatives up to an order 1 less than the order of the equation. It is also possible, in the case of equations of second order or higher, to prescribe values of the solution or its derivatives at more than one value of the independent variable. Such problems are referred to as boundary-value problems. For example, a second-order, two-point boundary-value problem is

$$f(x, y, y', y'') = 0 \qquad \text{for} \quad a \le x \le b$$

and

$$y(a) = \alpha, \quad y(b) = \beta,$$

where α and β are known values.

There are several distinctly different approaches to obtaining numerical solutions to boundary-value problems, and the choice may depend on a number of factors, including experience with similar problems.

As stated at the end of Section VIII.A, it is possible to formulate an ordinary differential equation of second order or higher as a system of first-order equations. If this is done for a boundary-value problem, not all of the initial conditions will be known; however, if estimates are made for the missing initial conditions, the solution can proceed as an initial-value problem, and its value (or value of its derivatives) at the later boundaries can be compared with known data.

Methods based on this approach are known as shooting methods and are relatively easy to set up for computer solution, since good subroutines are usually available for initial-value problems.

If the differential equation is linear, which is true if all derivatives appear only as multiples of constants or functions of x, then it is possible to make a precise correction to the initial data after the first trial; thus, a final solution can be obtained with two initial-value solutions. If the equation is not linear, the initial-value problem must be repeated, with successive estimates of the unknown initial conditions being made in the manner of the secant method, until all boundary conditions are met.

A second approach is to approximate the derivatives that appear in the differential equation with finite differences. The domain of the problem is first partitioned into, say, m intervals by selecting the points $x_0 = a, x_1, x_2, \ldots, x_i, \ldots, x_m = b$. Since the differential equation must hold at each of the interior points ($i = 1, 2, \ldots, m-1$), we have $m-1$ equations involving discrete values of x, y, and derivatives of y. Finite-difference approximations to the derivatives involve the value of y at neighboring points; for example,

$$y_i' \approx (y_{i+1} - y_{i-1})/2h$$

and

$$y_i'' \approx (y_{i-1} - 2y_i + y_{i+1})/h^2$$

are second-order approximations to $y'(x)$ and $y''(x)$ at the point defined by the index i when the partition intervals are a uniform length h. Since y_0 and y_m are determined by

the boundary data, we are left with a system of $m-1$ algebraic equations in the $m-1$ unknown values of y. These equations will be linear or nonlinear depending on the linearity of the differential equation and will be banded. The solution to the algebraic equations is a discrete representation to the solution to the differential equation, which is of the same order of accuracy with respect to the interval length as is the finite-difference approximation used for the derivatives (assuming the exact solution of the algebraic system).

Yet another approach will be illustrated for the solution of the linear two-point boundary-value problem

$$Ly(x) \equiv y''(x) + p(x)y'(x) + q(x)y(x) = r(x)$$
$$y(a) = y(b) = 0.$$

The symbol L is defined in the above expression to represent the linear operation applied to $y(x)$, in order to simplify the notation. The solution $y(x)$ is represented in terms of, say, m predefined basis functions

$$y(x) \approx \sum_{j=1}^{m} a_j \phi_j(x),$$

where the $\phi_j(x)$ satisfy the boundary conditions and the a_j are coefficients to be determined.

There are several ways in which this may be accomplished. *Collocation* is to substitute the approximation for $y(x)$ and its derivatives into the differential equation and evaluate at m interior points to obtain a system of m algebraic equations for the as. *Least squares* is to do the same thing for more than m interior points and then to solve the resulting over-determined system by a least squares technique.

In order to discuss the Galerkin method, we must first give two definitions.

1. The "inner product" of two functions $g(x)$ and $h(x)$ on $a \le x \le b$ is denoted by $\langle g(x), h(x)\rangle$ and is defined by

$$\langle g(x), h(x)\rangle \equiv \int_a^b g(x)h(x)\, dx.$$

2. The functions $g(x)$ and $h(x)$ are orthogonal on $a \le x \le b$ if

$$\langle g(x), h(x)\rangle = 0.$$

The Galerkin method seeks to find the coefficients a_j in the above approximation to $y(x)$ by setting the residual

$$R(x) \equiv L\sum_{j=1}^{m} a_j \phi_j(x) - r(x)$$

orthogonal to each of the basis functions. Thus,

$$\langle \phi_i(x), R(x)\rangle = 0 \qquad i = 1, 2, \ldots, m.$$

This leads to the system of linear equations

$$[L_{i,j}]\{a_j\} = \{r_i\},$$

where the elements of the matrix $[L_{i,j}]$ and vector $\{r_i\}$ are

$$L_{i,j} = \langle \phi_i(x), L\phi_j(x)\rangle$$

and

$$r_i = \langle \phi_i(x), r(x)\rangle,$$

respectively.

There are a number of choices for the selection of the basis functions. They must be linearly independent in order that the linear system for the solution of the coefficients be nonsingular. It is also desirable, but not essential, that they be mutually orthogonal. Frequent choices are trigonometric functions or orthogonal polynomials such as Tchebycheff polynomials. If the domain of the problem is partitioned, as described for the finite-difference methods, then it is possible to construct basis functions for piecewise polynomials having local support—that is, being zero everywhere except on a single interval or its immediate neighbors (for example the basis functions for the cubic spline). This choice is the prototype for the finite element methods and has the advantage that the resulting linear systems have a banded structure.

In order to solve a nonlinear problem using one of the above methods, it is necessary to linearize the problem by expanding about an initial estimate of the solution. For example, for the problem given at the beginning of this section, assume a solution estimate $y^{(0)}(x)$ and expand $f(x, y, y', y'')$ about this estimate:

$$f(x, y, y', y'') \approx f(x, y^{(0)}, y^{(0)}, y^{(0)''}) + (\partial f/\partial y)^{(0)}\Delta y + (\partial f/\partial y')^{(0)}\Delta y' + (\partial f/\partial y'')^{(0)}\Delta y''$$

The superscript (0) implies substitution of $y^{(0)}(x)$ for $y(x)$. When set to zero, the right-hand side is a linear equation in the increment $y(x)$, which may be solved by one of the above techniques using the boundary conditions $y(a) = y(b) = 0$. The solution may then be added to $y^{(0)}$ to obtain an improved estimate, and the process is repeated until two successive estimates are sufficiently close.

D. Partial Differential Equations

The numerical solution of problems involving differential equations in two or more independent variables is a highly complex procedure, generally requiring extensive analysis and the customizing of approaches to suit the problem at hand. The procedure breaks down into several interdependent subtasks.

First, a description of the domain of the problem must be given in mathematical or numerical terms. This often

involves problems in geometry modeling, such as solid-object representation, or wire-frame or patch representation of surfaces.

Second, a computational mesh must be inscribed in the domain. It is best that the mesh conform to the boundary surfaces; it needs to be fine where the variables of the problem are known to change rapidly, and coarse where they do not, and finally, the mesh surfaces should be as close to orthogonal as possible. It is often desirable to set up a transformation from a physical mesh that is not rectangular to a uniform rectangular mesh, but if this is done, the governing differential equations and boundary conditions must be transformed to the new domain.

The next step is to discretize the governing equations and boundary conditions.

If the problem is elliptic, the techniques discussed under two-point boundary-value problems for ordinary equations will apply, as modified for multidimensional domains. The most popular technique is to approximate derivatives by finite differences, which leads to finite-difference equation for each interior grid point (there may be many thousands of these). Finite-element methods, based on multidimensional basis functions defined over small subdomains, are also used quite frequently in conjunction with collocation, least squares, or Galerkin's method to arrive at an algebraic system of equations. Finally, orthogonal basis functions defined over the entire domain are sometimes used in conjunction with Galerkin's method (examples are the so-called spectral methods).

If the problem is parabolic, the domain will be open in one dimension (usually time), and the solution will be given on an initial surface or volume. In this case, the solution is developed in increments of time. An "explicit" finite difference method defines the solution at a mesh point at time $t + \Delta t$ (where Δt is the time increment) in terms of neighboring mesh points at time t; however, such methods are unstable except for very small increments of time. An "implicit" finite difference method, on the other hand, defines the solution at a mesh point at time $t + \Delta t$ in terms of neighboring points at both t and $t + \Delta t$. Although more stable, the implicit methods require the solution of systems of equations at each time step. A popular method called alternating direction implicit (ADI) defines the solution at a point at time $t + \Delta t$ in terms of neighboring points at time t and points along a line (or plane for three-dimensional problems) at time $t + \Delta t$, then for the next time step uses the same procedure except the line or plane is orthogonal to the first; the solution continues as the name suggests.

If the problem is hyperbolic, the domain will again be open in one dimension. The initial solution and its derivative with respect to the open variable will be given. In this case, the direction of the (real) characteristic lines can be inferred from the initial data, and the solution can be computed incrementally along these lines.

It should be mentioned that in all cases higher-order methods can be devised through the use of high-order difference formulas and techniques analogous to those used for high-order initial-value problems for ordinary differential equations; however, difficulties may arise near the boundaries and in incorporating boundary data in a consistent manner.

The final step is to decide how to solve the system of algebraic equations that arises from the discretization of the problem (other than in the purely explicit situation). The most difficult case is the elliptic one. If the governing equation is linear, then so will be the algebraic system, and it may be possible to use Gaussian elimination, although the size and sparsity of the system will probably dictate an iterative method. Unfortunately, in most realistic situations the governing equations will be nonlinear. As in the ordinary differential equation case, it may be possible to linearize about an estimate of the solution, then solve a sequence of linear correction problems. Alternatively, a somewhat artificial technique that is frequently adopted, is to add a time derivative term to the elliptic equation, then solve the resulting parabolic equation, using something like the ADI method with a solution estimate for an initial condition.

IX. RECENT DEVELOPMENTS

The recent increase in speed, memory capacity, and parallelism in computers has influenced advances in numerical analysis. These factors have permitted attempts to solve very large and complex problems, such as the simulation of flow fields in irregular geometric domains, and have led to the development of algorithms to take advantage of parallel computers and vector processors.

A. Large, Sparse Matrices

Very large PDE problems tend to produce large matrices that have relatively few nonzero entries. This has led to the development of encoding techniques for storing only the nonzero entries of large, sparse matrices in the memory of computers and to special schemes for manipulating them (for example, to multiply a sparse matrix times a vector, or to multiply two such matrices). Direct methods for the solution of linear systems of equations, $Ax = b$, such as Gaussian elimination or Cholesky decomposition, progressively generate nonzero numbers in positions where there were previously zeros—resulting in a prohibitive increase in storage and number of computations for large, sparse systems. To minimize this effect, methods have been devised that reorganize the equations. SPARSPAK, a package of computer codes for working with large, sparse

matrices, has been written by investigators at the University of Waterloo, Canada.

B. Iterative Methods

Iterative methods for the solution of linear systems, as discussed in Section IV.C, have the advantage that they preserve sparsity; thus, they are the methods of choice for many large problems. Much progress has been made with the preconditioned conjugate gradient method. If the system of linear equations to be solved is $Ax = b$, then by preconditioning we mean finding a nonsingular symmetric matrix, C, such that the condition number of $\hat{A} = C^{-1}AC^{-1}$ is smaller than the condition number of A. The related system $\hat{A}\hat{x} = \hat{b}$, where $\hat{x} = Cx$ and $\hat{b} = Cb$, is solved by the conjugate gradient method. Careful preconditioning will substantially improve the convergence rate. The physics of the problem may assist in determining the preconditioning matrix, but there are now software packages (e.g., the Yale University PCGPAK) that contain quite robust, general purpose codes that provide preconditioning based upon analysis of the matrix A.

For the extraction of eigenvalues of large, sparse matrices, the Householder method (Section V.B) for tridiagonalizing a symmetric matrix also suffers from the problem of nonzero fill. This has led to renewed interest in the Lanczos method, which is closely related to the conjugate gradient method for solving linear systems. The Lanczos method is based on the idea of successively generating a sequence of orthonormal vectors that form the columns of a matrix Q, such that $AQ = QT$, where A is the symmetric $n \times n$ matrix whose eigenvalues are sought, and T is a symmetric, $m \times m$, $m \leq n$, tridiagonal matrix. Even though T has a smaller order than A, its eigenvalues will be among those of A. At any stage, the eigenvalues of T may be found by use of the QR algorithm (Section V.B). The eigenvalues of A will appear in descending order of magnitude as additional vectors of Q are found. Arithmetic roundoff error can be a problem in this method; thus, a number of varients that selectively reorthogonalize the generated vectors have been devised. It is considered an iterative method, since the procedure is normally terminated before all n possible orthogonal vectors have been found. For both the preconditioned conjugate method and the Lanczos method, variants are possible that work with some nonsymetric problems.

For elliptic PDE problems, an iterative method known as the multigrid method has become very popular. The domain of the problem is discretized through the construction of a grid which is then subdivided in successively finer scales. The PDE is discretized on the finest grid, resulting in a linear system to be solved. An iterative method such as Gauss–Seidel is used, but after a few iterations the solution is "injected" onto the next coursest grid and the procedure is repeated. After the first (coursest) grid is reached in this manner, the solution is interpolated back to a finer grid and the cycle is repeated. The advantage of this procedure is that the low frequency components of the error in the solution are damped out as the high frequency components are. The overall solution scheme is highly efficient.

C. Parallel and Vector Algorithms

Increased net computation rate is achieved through parallel operation of processors (parallel computers) and in assembly line techniques for performing arithmetic operations on arrays of numbers (vector processors). Unfortunately, at the present time, different computer architectures place different emphasis on these approaches. Some computers use a small number of powerful vector processors while others contain a large number of relatively simple processors. Generally speaking, the algorithms discussed in this article are equally applicable to different architectures; however, the implementation must be carefully thought out to take maximum advantage of the particular features. One class of algorithms, particularly suited to parallel computers, is that of domain decomposition. Here the domain of a problem is divided into subdomains and the governing differential equations are solved simultaneously on each domain by different processors. The critical problem in these methods is that of matching data at the interface between the subdomains. A common approach is to provide for a region of overlap at the interface.

D. New Approximation Methods

As mentioned in Sections VIII.C and D, an approach frequently used for representing a function $y(x)$ in a computer (particularly if it is the solution of a differential equation) is to define a finite set of basis functions, $\{\phi_j(x)\}_{j=1}^{N}$, and to set

$$\hat{y}(x) = \sum_{j=1}^{N} a_j \phi_j(x),$$

where the a_j are to be determined. Basis functions that have received much attention in recent years are the spectral functions such as trigonometric functions or the Chebychev polynomials. They have the advantage of exponential accuracy and efficient computation (the latter through use of Fast Fourier Transform approaches). Although spectral methods present some difficulties when applied to problems with irregular boundaries or discontinuous solutions (e.g., shocks), considerable progress has been made in their application to a wide variety of practical problems.

A new form of basis function, referred to as a wavelet and characterized by the Morlet wavelet

$$\phi_{a,b}(x) = e^{i\omega_0 x} e^{-b(x-a)^2},$$

is being actively investigated. This function is globally defined, yet its value is insignificant except in a small region centered on $x = a$. A family of such functions can be generated by assigning different values to the parameters a and b (shift and dilation) in order to match the characteristics of $y(x)$. Methods based on wavelet basis functions appear to have the advantages of the spectral methods while still having the flexibility to model rapid spatial changes.

GLOSSARY

Decision analysis Determination of rational decisions in the face of uncertainty.
Fuzzy set theory Mathematical theory of decision based on nonbinary logic of set inclusion.
Mathematical programming Optimization of real functions subject to constraints.
Operations research Use of scientific methodology in studying operational systems.
Queueing theory Mathematical theory for the analysis and optimization of units demanding service at a facility.
Simulation Representation of the essence, without the reality, of the system under study for the purposes of analysis and design.
Stochastic process Process that evolves over time in a nondeterministic fashion.

OPERATIONS RESEARCH (OR) deals with the analytical study of operational systems, where the latter are defined as systems that are subject to human decision. This is a vast collection, which includes, among others, production, transportation, warehousing, agriculture, communications, education, forestry, defense, trade, economic, and government systems. OR is mainly concerned with the study of the structure of such systems and with observing their behavior, first to gain basic understanding of their nature and of the factors that influence their performance, and second to modify their performance, with an eye toward improving such performance. Such improvement is achieved through the optimal allocation of resources, or the optimal utilization of existing resources. The approach of OR is in harmony with the classical view of the scientific approach, which embodies observation, modeling and establishing hypotheses to explain the phenomena under study, the validation of both models and hypotheses, and the use of these theories and models to describe the performance of the system under modified conditions.

Operations research is strongly based in the mathematical and physical and engineering sciences, with the computer and its technology playing an increasingly important role in the implementation of its findings. Its methodology

borrows from, and contributes to, the fields of mathematical programming, discrete mathematics, stochastic processes, control and optimal control, and economics and econometrics, among others. An OR study may concern itself with a small system, such as an individual assembly line or a truck route, or with a large system such as a multimodal evacuation system in case of emergency.

Typically, OR is a graduate program of instruction, with introductory treatment given at the undergraduate level in departments of mathematics, statistics, industrial engineering, and business. Its graduates are in high demand at both the master's and doctoral levels in industry, consulting, research centers, universities, and government.

I. PERSPECTIVE

Operations research (OR) is the use of scientific methodology in studying operational systems. A system is any collection of items that are related. Systems of concern to OR are purposeful systems, so that the objective(s) of study can be made purposeful also. Operational systems are systems whose design and/or operation require human decision making. OR provides the means for making the most effective decisions—some of which are concerned mainly with design (e.g., the optimal design of equipment and/or administrative organizations), while others are mainly operational in nature (e.g., the optimal operation of existing equipment and/or administrative organizations). The strength and versatility of OR stem from its diagnostic power through observation and modeling, as well as from its prescriptive power through analysis and synthesis. The techniques used are continually being improved and expanded, with the aid of both basic and applied research.

OR is interdisciplinary in nature, drawing on (and contributing to) the theories and techniques from many fields, including mathematics, statistics, computer science, engineering, economics, and the physical sciences. In distilling from such theories and practices those that apply to a given system, the OR practitioner initially acts like a scientist—one who observes how the system responds to various stimuli, so that it can be described by a model, mathematical or otherwise, that is capable of predicting the consequences of the various possible decisions. Although the insight produced from constructing such a model is frequently very valuable in itself, the OR practitioner usually goes on to thoroughly analyze the model—with the ultimate goal of determining those decisions that would make the given system perform as well as possible. In doing so, additional equipment and/or administrative organizations are frequently designed and/or synthesized.

OR practitioners have been confronted with a wide variety of real-world problems, varying from the optimal design of power plants in the face of uncertain demand over a planning horizon that extends for several decades, to the scheduling of flight arrivals and departures at an airport. They have found employment in both industry and government, as well as in the military (where OR originated during World War II). Most importantly, new applications are continually arising, with many originating from relatively recent societal problems, such as food and energy production and distribution, health services delivery, pollution control, and transportation planning.

Operations research has oftentimes been confounded with "systems science," or "systems engineering," and the terms have been used interchangeably. There is a difference. Traditionally, systems engineering has been identified with hardware systems, while OR has been identified with software. Systems science is concerned with more global problems and is more abstract in its approach than OR. A systems study may involve societal and/or biological components that have not been successfully quantified, while OR tends to be mostly concerned with more quantifiable problem settings, and rarely, if ever, has it concerned itself with biological systems.

A. Historical Perspective

OR was "born" during World War II, when the Allied Military Command sought the assistance of the scientific community to resolve certain operational problems (hence the British name of "operational research"), though it is generally recognized that the application of science in military affairs dates back to the days of Archimedes. Teams were formed of a variety of disciplines according to the problem in hand, mostly composed of physicists, mathematicians, statisticians, economists, and engineers. The reports of their investigations make penetrating and delightful reading, covering a wide spectrum of problems from the optimal depth to detonate antisubmarine devices to the arming of merchant ships to maximize the safety of convoys.

After World War II, progress of OR in the United States followed a different path from Europe. The devastation in Europe necessitated the rapid dismemberment of the military establishment and the conversion to civilian economy. This, in turn, shifted the contribution of OR to the industrial and commercial enterprises, where OR was rapidly accepted as a novel approach to the resolution of managerial problems. On the other hand, because of the ensuing cold war between the two superpowers after World War II, OR continued its close association with the military in the United States, with significant work sponsored by defense-related establishments such as the RAND Corp. of Santa Monica, California, the Office of Naval Research in Washington, D.C., and the Army Research Office in Durham, North Carolina. The shift to predominantly

civilian applications did not take hold in the United States except at a later date, in the early 1960s. Since then, it has flourished with the progress in computer technology, and has gained, together with its alter ego "management science," wide acceptance in the mainstream of corporate America, state and local government, and the service industry. In the nonmilitary domain, OR was received with a great deal of skepticism because of the long-standing tradition of "scientific management" in industry. It had to earn its colors by demonstrating its worthiness at all levels of application: strategic, tactical, and technical.

A discipline is distinguished by its field of application, its methodology, and the specialized education and training its practitioners must receive to qualify for working in the discipline. OR is no exception. At the time of this writing, there exist over 40 institutions of higher learning in the United States alone that offer advanced degrees (master and doctorate) in OR (see the next section). Furthermore, a number of professional societies have sprung up to serve the new scientific community, of which we mention the Institute for Operations Research and Management Science (INFORMS) and a number of OR societies all over the world (the United Kingdom, France, the Federal Republic of Germany, India, etc.) that are united in the International Federation of Operations Research Societies. Many other scientific and professional societies have "divisions" and/or "special interest groups" in OR (such as the Institute of Industrial Engineers and the Institute of Electrical and Electronics Engineers, among others).

The following sections give a synopsis of the methodologies, models, and fields of application of OR. For more information, consult the bibliography.

B. The Education and Training of the OR Practitioner/Researcher

Of necessity, the early OR professionals were "migrants" from other disciplines. Gradually, as the methodologies peculiar to the nascent field were developed, there also evolved a need for education and training in these methodologies, as well as the need to refine, hone, and expand them; the latter are evident activities of research.

One may identify several types of OR education: formal, semiformal, informal, and on-the-job. Formal education consists of regular university or college programs and courses for which credit is earned. There are a few undergraduate courses throughout the United States that may be designated as "OR courses"; these are typically offered in the departments of mathematics, statistics, and industrial engineering. The majority of formal education is at the graduate (master or doctoral) levels. The reason is simply that sufficient background has to be gained in the traditional mathematical and physical sciences before the student can absorb the new and more advanced concepts of OR. Normally, such background constitutes a large proportion of the requirements for a baccalaureate degree in a field of engineering or the mathematical sciences (mathematics, statistics, and computer science).

Schools of engineering seem to have embraced OR more than any other school, followed by graduate schools of business, and trailed by schools of mathematical sciences. On a percentage basis, formal OR educational programs are about 50% imbedded in regular engineering departments (with the lion's share going to industrial engineering), 30% in business schools, 12% in independent OR departments or interdisciplinary programs, 5% imbedded in regular mathematical sciences departments (mostly departments of statistics), and a miniscule fraction labeled "other."

Semiformal education can be gained through a plethora of short courses offered on a regular basis by universities and consulting firms alike. A typical course runs for 1–3 weeks, and ranges in level from the elementary to the advanced. Recently, however, interest in and attendance at introductory short courses has been waning, reflecting the existence of a pool of persons with formal OR education who are more inclined to attend a 3-day seminar aimed at mastering some new speciality that they perceive as important to their performance in their regular jobs.

Informal education is shouldered mostly by the professional societies and their local chapters (especially (INFORMS)), through the plethora of media of communication available to them (meetings, publications, special interest groups, circulars).

Perhaps the most effective learning is experiential or on-the-job learning. One learns more easily and more quickly if one is motivated by direct applicability of what is learned to one's immediate concern. Indeed, the other three forms of education are of little worth to the OR practitioner unless they are directly relevant to his/her assigned tasks. Learning is best as an apprentice to an experienced professional.

What is the subject matter of a "proper" OR program of instruction? Here is a "maximal list" at the doctoral level. What is actually studied will depend largely on the area of expertise sought by the individual. As to be expected, mathematics plays a dominant role in this list.

Mathematics: Discrete mathematics, calculus through real and functional analysis, complex analysis, linear algebra, modern algebra, topology and measure theory, probability theory.

Statistics: Inference, design of experiments, sequential analysis, time series analysis, decision theory.

Computer science: Data structures, complexity and theory of algorithms, graphs, artificial intelligence.

Operations research: The topics covered under "methodologies" in this article define specialization in OR, and all, or at least a majority of them, should be covered in

depth. Broadly speaking, one must gain proficiency in three broad areas: mathematical programming, stochastic systems, and optimal control theory.

C. The Conduct of an OR Study

Succinctly stated, the steps of an OR study do not differ significantly from those of the "scientific method" in general. Any differences present reflect the "purposeful" character of OR (in contrast with the pursuit of knowledge that characterizes "pure" scientific investigations). In particular, one may define eight steps as follows.

1. Define the objectives of the study. Other words commonly used are the deliverables, the goal of the study, and what the project is supposed to accomplish.
2. Develop the project plan. This should include the resources needed, their timing, and the activities to be undertaken.
3. Define the problem(s). Equivalently, diagnose "what is wrong" with the operational system. This is a vital step, since the wrong diagnosis will eventually lead to the wrong remedial action unless corrected later.
4. Determine the problem boundaries. Realize that systems do not exist in isolation, and that everything is related to everything else. But a study, no matter how global it is intended to be, cannot encompass all activities. At some point a decision must be made to define what shall be of concern to the OR study, and what shall be excluded and taken as "exogenous input."
5. Develop the model. It is a mathematical/computer/analog representation of the problem(s) as defined in Step 4. Such representation defines the controllable decision variables and the relations among them, the constraints imposed internally or externally that limit the analyst's freedom of action, and the criterion (or criteria) against which decisions can be measured. In model development we include also the specification of the data required and the method by which it is to be collected.
6. Develop the computational approach. In reality, one undertakes steps 5 and 6 concurrently, since they cannot be logically separated. The construction of a model of the system under investigation is dependent on the technology available to the analyst for securing answers, and conversely. In the development of the computational approach we also include any programming/debugging required to accomplish the computations specified.
7. Collect data and validate the model. Model validation has many components. They are:
   (a) Plausibility: Does the model fit special cases for which actual data are available?
   (b) Consistency: Are results logical when major parameters are varied (especially to extremes)?
   (c) Sensitivity: Are the relative magnitudes of changes in outputs appropriate for small changes in the inputs?
   (d) Workability: Is the model easy to solve routinely if that is required by the operational system?
8. Implement the proposed solution. This is more easily said than done. The real worth of the study will depend heavily on the degree of cooperation and participation of the various individuals or organizations involved in realizing the benefits anticipated by the OR study through its implementation.

II. MATHEMATICAL PROGRAMMING

The field of mathematical programming is a vast and rich mosaic of problems of optimizing a (real) function subject to constraints.

Unconstrained optimization has occupied mathematicians for centuries, especially since the development of calculus, and continues to do so. Constrained optimization, on the other hand, is a latecomer, with roots dating back to the work of Lagrange in the mid-nineteenth century. In the late 1940s, it came to the forefront with the resolution of the linear programming problem, which, to many scholars, marks the real birth of OR. Since then, the fever has not abated. The following sections give but a glimpse of this nascent field that is full of vitality and promise.

A. Linear Programming (LP)

The LP model may be defined mathematically as (the criterion function)

$$\text{optimize (maximize or minimize) } x_0 = \sum_j c_j x_j \qquad (1)$$

subject to (the constraint set)

$$\sum_j a_{ij} x_j (\leq, =, \text{ or } \geq) b_i \geq 0 \qquad i = 1, 2, \ldots, m \qquad (2)$$

$$x_j \geq 0 \qquad \text{for all} \qquad j = 1, 2, \ldots, n.$$

The basic assumptions of the LP model are (1) linearity (i.e., proportionality) of both criterion and constraints and (2) nonnegativity of variables (whence a feasible solution must lie in the positive orthant of the n-dimensional Euclidean space). The mathematical model has the following economic interpretation. There are n "activities" and $x_j \geq 0$ is the level at which activity j is undertaken. There are m "resources." Activity j, when carried out at unit level, consumes a_{ij} units of resource i. The objective is to optimize a linear function of the levels of the activities.

The LP defined by Eqs. (1) and (2) can be solved by the simplex method, proposed by Dantzig in 1947. For a long time this method reigned supreme because it was

the only known approach to the solution of LPs. However, the repertoire has been enriched by two other approaches: the "ellipsoid" method of Khatchiyan, and the "interior" method of Karmarkar. Active research is underway in several quarters around the world to polish all three approaches, and perhaps develop new ones.

The central theoretical result of LP is duality theory, usually credited to the mathematician von Neumann. It simply asserts that to each LP that is formulated, which is called the "primal LP," there is a "dual LP" that can be easily derived from it. Duality theory helped link LP with the theory of games, originally proposed by von Neumann and Morgenstern in 1944. The "marriage" between these two theories enriched both, and led to spectacular developments in the theory of economic planning.

Special structures of the coefficients of the LP model give rise to specialized, and therefore much simpler, algorithms. This, in turn, enables us to solve much larger problems (as measured by the number of constraints and/or the number of variables) with the same expenditure of (computing) effort. Prominent among these special cases are:

1. *The transportation model*, so designated because it represents the problem of shipping a homogeneous commodity of limited availability from "sources" to satisfy demand at "destinations." Here, all the coefficients of the A matrix of Eq. (2) assume the values $+1$ or 0, and any column vector of A has exactly two nonzero entries. The right-hand side coefficients are arbitrary nonnegative real numbers. Because of the *unimodular* characteristic of the matrix A, if the vector b is integer, then the optimal solution is also integer.

2. *The assignment model*, so called because it represents the problem of assigning n "jobs" to n "machines," in which the "worth" of an assignment varies. (In these scenarios, it is common that the number of jobs equals the number of machines, though such a restriction is not necessary.) The assignment model may be regarded as even a special case of the transportation model, in which the vector b is a vector of $+1$'s. It is solved by a "primal–dual" algorithm dubbed the "Hungarian method" by its originator.

3. *Flow networks*. There are two types of networks that lend themselves to treatment via LP: "regular" or "simple" flow networks, which conserve flow through the arcs, and "generalized" flow networks, in which entering flow in an arc is multiplied by a constant factor as it flows through the arc. Specialized algorithms have been devised for both types of networks, with, as to be expected, simple flow networks providing richer theory and simpler algorithms.

LP also provides the algorithmic vehicle for solving quadratic programming problems. A quadratic program possesses a quadratic criterion function of the form

$$\text{optimize} \quad x_0 = cx + x^t Dx,$$

where D is a symmetric matrix of rank n, assumed to be definite positive, subject to *linear* constraints of the form

$$Ax + IS = b \qquad x, S \geq 0,$$

where S is a slack vector of size m.

LP is, by definition, a deterministic model in continuous variables, the x_j's. However, there are applications in which probabilistic information is included directly in the formulation, yielding stochastic LP. Another approach is via chance-constrained LP, in which the constraints are stated in probabilistic terms.

Finally, LP is a model of optimization of a single criterion function. But it has been extended to optimization under multiple criteria. Then it is better known under the title *goal programming*.

B. Integer Programming (IP), Graphs, and Combinatorial Optimization

Loosely speaking, IP is the domain of mathematical optimization in which some or all of the problem variables are restricted to be integers. Combinatorial optimization is closely linked to IP, and is concerned with seeking the best subset of items (decisions, activities, etc.) satisfying particular criteria from a structured finite set of alternatives. An example of IP would be any LP whose variables are restricted to be integers, in which case one speaks of integer LP (ILP), which is clearly an abuse of language since the integer requirement vitiates the host of properties commonly associated with linearity! An example of combinatorial optimization would be to determine the minimum set of arcs in a connected graph $G = (N, A)$ which "covers" all the nodes.

As was hinted above, the presence of the integer requirement often transforms a solvable problem into an unsolvable one, or at least one that is several orders of magnitude more difficult than its continuous-variable analog. For instance, a LP in one constraint is trivially solvable in one pass by the so-called "greedy algorithm," while the same problem in integer variables is the notorious knapsack problem (KnP), which is NP-complete!

Interest in IP, and in particular in ILP, stems from the ease with which numerous real-life problems can be modeled with the use of IP. For instance, investment problems in which only a subset of the projects can be undertaken at any one time; scheduling problems in which precedence among the activities must be respected; problems in which a fixed cost is incurred only if the activity is undertaken, otherwise no cost is incurred (the so-called fixed-charge problems); and many other "matching," "covering," and "route selection" problems, to name but a few, have been successfully modeled using integer variables. Another

area of application in which ILP proves invaluable is in the piecewise linear approximation of a separable nonlinear function. If the nonlinear function is convex (concave) and the criterion is minimization (maximization), then there is no need to appeal to ILP; but if it is not, then an ILP formulation is mandatory.

ILPs may be solved by the use of the cutting plane method, originally proposed by Gomory in 1958, which treats the problem as a (regular) LP but continues to add constraints to eliminate portions of the feasible convex polytope without cutting any integer feasible point until the optimum integer point is reached. Another solution approach, which has generality beyond the linear case, is implicit enumeration through branch-and-bound (B&B). This approach, if permitted to run to completion, terminates with the optimum, and if it is aborted before that time it yields upper and lower bounds on the value of the optimum together with a feasible, albeit not necessarily optimal, point.

Some ILP problems have the fortunate property that their solution as regular LP problems (i.e., ignoring the integer requirements) automatically assigns integer values to the variables, such as in the classical "transportation" and "assignment" problems (already discussed). Consequently, the regular LP methods are entirely sufficient to solve these problems, and no special IP techniques are required. Other IP problems may possess special structures that invite special algorithms (such as Bender's decomposition procedure in the fixed-charge problem). Finally, it is interesting to note that the *linear* KnP, while being the simplest ILP, is also the archetype of all ILP problems, since it is possible to reduce $m \geq 2$ equations of any ILP to a single Diophantine equation through the appropriate choice of multipliers of the equations and linearly combining the equations with these multipliers.

It is extremely difficult, if not impossible, to disentangle the discussion of IP from that of "combinatorial optimization." Furthermore, the two are entwined with the *theory of graphs*. For instance, the "set covering problem" mentioned may be rightly classified as a "graph theoretic" problem!

A graph is a collection of nodes and arcs connecting them, which is a different kind of graph from the common one in analytic geometry and calculus. The theory of graphs is concerned with the structure of these connections among the nodes. When parameters are added to the graph, one usually refers to the questions asked then as "network" problems. For instance, the following is a graph-theoretic problem (famous under the name Hamiltonian circuit): does there exist a closed path (i.e., a path whose start and terminal nodes coincide) that passes by every node of the graph once and only once? On the other hand, the transportation problem of LP stated above may be represented as a ("bipartite") graph in which the "source" and "destination" locations are represented by nodes, and the route between every source–destination pair is represented by an arc (in this case, the arc is directed from the source node to the destination node). However, since the question asked relates to the cost of shipping, the model is usually referred to as a network model of the LP problem.

The theory of graphs has its genesis in the work of Euler in the eighteenth century (we refer to the famous "seven bridges of Konigsburg" problem and the theory that resulted from it), with sporadic contributions from different mathematicians over the past two and a half centuries. OR called upon, and contributed to, graph theory when it was realized that several discrete optimization problems that originated in the application of OR could be fruitfully modeled as graph theoretic problems. Examples are the matching, set covering, the "number of trees," the "four color," and the "traveling salesman" problems. The nascent field of computer science and technology added to the interest in graph theory. For instance, the theory of combinatorial complexity boasts numerous examples of NP-complete and NP-hard problems from graph-theoretic problems.

C. Variational Inequality and Complementarity Problems (VI & CP)

The existence and computation of economic and game theoretic equilibria have been of great interest to the academic and professional communities since the mid-1960s. The early developments include the fixed point approach and nonlinear optimization models. However, the former lacks computational efficiency and the latter lacks the generality for solving large scale equilibrium problems. Starting in the late 1970s and early 1980s, finite dimensional variational inequality and nonlinear complementarity problems have emerged as promising candidates.

The nonlinear complementarity problem first appeared in Richard Cottle's PhD dissertation in 1964. But the name "*complementarity problem*" was coined later in 1970 by Cottle, Habetler, and Lemke in dealing a linear case problem. The classical "variational inequality problem" was introduced by Philip Hartman and Guido Stampacchia in 1966 in the context of calculus of variations and optimal control theory for solving nonlinear elliptic differential equations. The finite dimensional variational inequality problems has taken its own tangent to become a new field since the late 1970s.

Let X be a nonempty subset of R^n and F be a mapping from R^n to itself. The *variational inequality problem*,

commonly denoted by $VI(X, F)$, is to find a vector $x^* \in X$ such that

$$F(x^*)^T(x - x^*) \geq 0, \quad \text{for all} \quad x \in X.$$

One typically assumes that X is a closed and convex set; in fact, X is often polyhedral in applications.

When F becomes a point-to-set mapping (called multifunctions) from R^n into a subset of R^n, the *generalized variational inequality problem*, denoted by $GVI(X, F)$, is to find vectors $x^* \in X$ and $y^* \in F(x^*)$ such that

$$(x - x^*)^T y^* \geq 0, \quad \text{for all} \quad x \in X.$$

When X is further generalized as a point-to-set mapping in $GVI(X, F)$, then the corresponding problem is called a *generalized quasivariational inequality problem*.

For X being a convex cone in R^n and F being a mapping from R^n to itself, the *generalized complementarity problem*, denoted by $GCP(X, F)$, is to find a vector $x^* \in X$ such that

$$F(x^*) \in Y \quad \text{and} \quad F(x^*)^T x^* = 0,$$

where $Y = \{y \in R^n \mid x^T y \geq 0, \forall x \in X\}$ is the dual cone of X. In case $X = Y = R^n_+$, the first orthant of R^n, the problem becomes the commonly seen (*nonlinear*) *complementarity problem*.

Karamardian was the first one to show that when X is a convex cone, then $x^* \in X$ solves the problem $VI(X, F)$ if and only if x^* solves the problem $GCP(X, F)$. In other words, every generalized complementarity problems is a variational inequality problem, but the converse is not true in general.

The existence and uniqueness of solutions to (generalized) variational inequality and (generalized) nonlinear complementarity problems have been extensively studied in the past three decades. The most basic result on the existence of a solution to the problem $VI(X, F)$ requires that X be compact and convex and F be continuous. Many corollaries have been derived from this basic result by replacing or relaxing the requirements on X and F. The most basic result on the existence and uniqueness of the solution to the variational inequality problem requires that F be strongly monotone over X.

Various computational algorithms including the pivoting scheme, fixed point methods, linear approximation methods, projection methods, simplicial decomposition methods, proximal point methods, cost approximation methods, and continuation methods have been developed in the past several decades. These solution methods basically are the traditional *sequential algorithms*. In order to solve real-life large scale variational inequality and complementarity problems, developing *parallel algorithms* takes high priority.

D. Nonlinear Programming (NLP)

The theory of nonlinear programming is the mathematical theory of optimizing (maximizing or minimizing) a nonlinear real function of a set of variables $x_1, \ldots, x_n$ subject to inequality and/or equality aggregate constraints in which the aggregating (real) functions are also nonlinear in the variables. The general mathematical form is to

$$\text{optimize} \quad f(X), X = (x_1, \ldots, x_n) \tag{3}$$

subject to

$$\begin{aligned} g_j(X) &\leq 0 \qquad j = 1, \ldots, m \\ h_j(X) &= 0 \qquad j = 1, \ldots, k, \end{aligned} \tag{4}$$

where $f: R^n \to R$, $g: R^n \to R^m$, and $h: R^n \to R^k$, that is, f, g, and h are functions that map each point of the n-dimensional real Euclidean space R^n into R, R^m, and R^k, respectively.

As can be suspected, nonlinear programming provides a general paradigm for many problems in the physical and social (in particular, economic) sciences. Unfortunately, unlike LP, there does not exist an algorithm that is universally applicable to all NLP models. What are available, though, are conditions for an optimum to exist, which, in many instances, characterize the optimum sufficiently well to lead to an algorithm for achieving it. Among these we mention the following.

1. The (necessary and sufficient) conditions of Kuhn and Tucker: under the assumptions that the functions f, g, and h are differentiable and that g and h satisfy a particular constraint qualification at the optimum.
2. The (necessary) conditions of Kuhn and Tucker: under the assumptions that f, g, and h are twice continuously differentiable around the optimum.
3. The (necessary and sufficient) first-order conditions of the augmented Lagrangean, due to Mangasarian: under the assumptions that f, g, and h are differentiable and that the constraint qualification is satisfied by g and h at the optimum.
4. The (necessary and sufficient) gradient projection conditions, due to Levitin and Polyak: under the assumptions that f is differentiable at the optimum, g is continuous and convex on R^n, and h is linear.

As in LP, duality theory also plays a central role in theoretical as well as computational investigations in NLP.

Practically speaking, one cannot guarantee global optimality of the solution achieved utilizing any algorithm except in very special circumstances. Research is directed toward speeding up the rate of convergence to a (local) optimum, and the devising of a sequence of starting points

of the algorithm to result in a high probability of capturing the global optimum.

E. Geometric Programming (GP)

Geometric programming is concerned with the optimization of an arbitrary real-valued function g over a subset $S \subset R^n$, which is restricted to be the intersect of the function domain C with an arbitrary cone $X \subset R^n$ (which is, in fact, a vector space for most examples). To fix ideas, consider the following definition of GP:

Determine

$$f = \inf_{x \in s} g(x) \qquad \text{where} \qquad S = X \cap C \tag{5}$$

and the optimal solution set

$$S^* = \{x \in S \mid g(x) = f\}.$$

Each optimization problem can generally be formulated as Problem (5) in more than one way by suitably choosing the function g and the cone X. The most striking example of the utility of GP was demonstrated in the study of the minimization of signomials by Zener and Duffin. A *signomial* (sometimes referred to as a generalized polynomial) is any function with the form

$$P(y) = \sum_i c_i \prod_j y_j^{a_{ij}}, \tag{6}$$

where the coefficients c_i and the exponents a_{ij} are arbitrary constants but the independent variables y_j are restricted to be positive. When the c_i coefficients of the signomials are positive, which is the case in the majority of problems stemming from economic or physical laws of nature, they are termed *posynomials*.

To cast the problem of minimizing $P(y)$ in the format of Eq. (5), simply make the change of variables

$$x_i = \sum_j a_{ij} \log y_j \qquad i = 1, 2, \ldots, n$$

and then infer that minimizing $P(y)$ is equivalent to solving Eq. (5) when

$$C = R^n \qquad g(x) = \sum_i c_i e^x$$

and

$$X = \text{column space of } [a_{ij}].$$

The advantages of studying this problem rather than its signomial predecessor are numerous. For example, unlike the signomial P of Eq. (6), the exponential function g is completely separable in the variables x_i. Consequently, if y^* minimizes a posynomial P, then the corresponding x^* must be a unique optimal solution to Eq. (5); in which event the set of all y that minimize P can be obtained from x^* simply by solving the displayed system of equations, a task that is relatively easy because the system is clearly linear in terms of $\log y_j$, $j = 1, 2, \ldots, m$.

GP can be generalized to explicitly incorporate *constraints*. The mathematical formalism must then be carefully structured to make sharp distinction between "cone conditions" of the form $x \in X$ and constraints of the form $g_i(x^i) \leq 0$, $i \in I$, where I is a positive integer index set.

The theory of GP can be gainfully partitioned into several topics. Optimality conditions describe important properties possessed by all optimal solutions, and in many cases collectively characterize all optimal solutions. Saddle-point characterizations of optimality can be used to introduce the even more significant concepts of duality, which, in turn, provides important existence and uniqueness assertions for optimal solutions, as well as provide useful algorithmic concepts. Duality is also a key ingredient in "parametric programming" and "sensitivity analysis."

F. Dynamic Programming (DP)

The name dynamic programming is not indicative of the scope or content of the subject, which led many scholars to prefer the expanded title: "DP: the programming of sequential decision processes." Loosely speaking, this asserts that DP is a mathematical theory of optimization. It also identifies DP with decision systems that evolve in a *sequential and dynamic* fashion.

DP possesses formalism. But unlike other areas of mathematical programming, many optimization problems that are normally stated in the form of other mathematical programs (such as ILP, NLP) can be cast in the formalism of DP. Consequently, DP is considered to be more of an approach, a way of thinking about a problem, rather than a fixed mathematical statement in which a problem is cast.

A DP model is structured from five elements that reflect the sequential paradigm underlying the approach. These are stages, states, state transformation function, stage reward function, and total system reward function. Following is a brief and somewhat loose description of each of these elements. A stage is an epoch of decision making. A state is either an "input" (i.e., start) or "output" (i.e., terminal) state, and is a parameter or a set of parameters (i.e., a vector) that summarizes the past history of the system and enables one to make a decision (hopefully optimal) at the current stage and all subsequent stages. A (state) transformation function is a mapping from the cartesian product of the input state space and stage decision space to the output state space at each stage. A stage reward is a real function that maps the cartesian product of the input state space and the stage decision space into the real line. Finally, the system reward function is a real function that maps the individual stage rewards into the real line. Let

the system be modeled with N stages, and let n index the stages. Let

s_n denote the input state to stage n, $s_n \in S_n$
x_n denote the decision made, $x_n \in X_n$
$\tilde{s}_n$ denote the output state and be defined by the state transformation function $\tilde{s}_n = t_n(s_n, d_n)$, $\tilde{s}_n \in \tilde{s}_n$
r_n denote the "reward" and be defined by $r_n = g_n(s_n, d_n)$
R_N denote the system reward and be defined by $R_N = R_N(r_1, r_2, \ldots, r_N)$.

Under the DP paradigm, the system is envisioned to evolve in stages. At any stage it starts in some state and, depending on the decision made, two events take place: it is transformed into another (output) state, and a reward is received.

The central concept of DP is embodied in its *principle of optimality*, first enunciated by Bellman, and is traditionally stated as:

An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first transition.

The principle is manifested in the *extremal equation* of DP, given as

$$f(n, s_n) = \text{opt}x_n[r_n(s_n, x_n) \circ f_n(s_n)] \quad \text{for} \quad n = 1, 2, \ldots, N \qquad (7)$$
$$f(0, s_1) = r_0(s_0) \qquad \text{a "terminal" reward}$$

where $s_n \in S_n$, $x_n \in X_n$.

There are several distinguishing themes of DP that are not shared by other mathematical programming models. First, the problem of interest is embedded in a much richer set of optimization problems. (The term "flooding" is sometimes used to indicate this fact.) The price paid for such enrichment is increased computational difficulty, sometimes to the point of impracticality (the so-called "curse of dimensionality"). Second, the problem of concern is transformed from its original setting, which usually involves the simultaneous optimization over N variables, to N optimizations, each in only one variable. Third, if iterations are halted at any intermediate point, one usually has the optimal solution of a partial problem.

The concepts of DP are easily extendable in two important directions. The first is to stochastic systems, that is, systems that involve probabilistic elements either in their evolution (in time, space, etc.) or in their payoff. This extension gave rise to the field of Markov programming, and has spurred significant advances in the theory of optimization of queues. The second is to systems with unbounded number of stages. As $N \to \infty$, the stage designation in the extremal equation of Eq. (7) disappears and the resultant equation is commonly referred to as the "functional equation of DP" because the same function $f(\cdot, \cdot)$ appears on both sides of the equality sign. Finally, there is a strong link between the formalism of DP and the theory of optimal control.

G. Entropy Optimization (EO)

The term "entropy" was coined by Rudolf Clausius around 1865 as a measure of the amount of energy in a thermodynamic system. Claude Shannon gave a new meaning to this term in 1948 as "a measure of uncertainty" in the context of communication theory. With E. T. Jaynes "maximum entropy principle" and its variations, the the concept of using Shannon's entropy to select a probability distribution that complies with known observations about an unknown distribution and yet remains most noncommittal (i.e., the one that carries a maximum amount of entropy) has penetrated a wide range of disciplines in science, engineering, and management.

Let $\mathbf{Y}$ denote a random variable with n possible outcomes $\{y_1, \ldots, y_n\}$ and $x = \{x_1, \ldots, x_n\}$ represents the corresponding probability mass function. Let $g_1, \ldots, g_m$ be m functions defined on $\mathbf{Y}$ with known expected values $a_1, \ldots, a_m$, respectively. The probability distribution determined according to the 'principle of maximum entropy' can be stated as a linearly constrained concave optimization problem:

$$\text{Maximize} \quad \sum_{j=1}^{n} x_j \log x_j$$
$$\text{s.t.} \quad \sum_{j=1}^{n} x_j g_i(y_j) = a_i, \quad i = 1, \ldots, m,$$
$$\sum_{j=1}^{n} x_j = 1, \quad x_j \geq 0, \quad j = 1, \ldots, n.$$

When the expectation is replaced by a moment function of higher order or a general nonlinear function of $\mathbf{x}$, the corresponding entropy optimization problem becomes versatile but difficult. Moreover, when a prior distribution $p = (p_1, \ldots, p_n)$ is given, the objective of achieving "maximum entropy" can be replaced achieving "minimum cross-entropy," which is defined by

$$\text{Minimize} \quad \sum_{j=1}^{n} x_j \log(x_j / p_j).$$

Various entropy optimization models have proven their usefulness with successful applications in image reconstruction, statistical inference, queueing theory, spectral

analysis, statistical mechanics, transportation planning, urban and regional planning, input–output analysis, portfolio investment, information analysis, and linear and nonlinear programming. Major solution methods for entropy optimization include the Bregman's balancing method, multiplicative algebraic reconstruction technique (MART), Newton's method, generalized iterative scaling method (GISM), interior-point method, and the unconstrained convex dual programming approach.

H. "Soft Optimization": Meta-Heuristics and Compusearch Approaches

Formal optimization theory as described in sections II, A through E have their limitations, to varying degrees, as the size of the problem (as measured by the number of variables and number of constraints) increases. Then the frontal attack on the problem becomes infeasible, and one must resort to alternative approaches to achieve meaningful answers. The gamut of approaches proposed for this purpose have been invariably labeled as "soft optimization," "meta-heuristics," and "compusearch" approaches. As the names indicate, these are approaches that do not *guarantee* optimality but approximate it to varying degrees. Also as the names indicate, the approaches rely heavily on *heuristics*, and on *organized search using the computer*.

A possible taxonomy of these approaches is as follows.

1. *Neighborhood search methods* work on complete feasible points (such as a complete schedule or a complete allocation of resources) and try to improve them at each step. They are so-called because they normally stop when they find an optimum, which is most probably a local one, and because at each step they study the local "neighborhood" of a given complete solution. The definition of that "neighborhood" is precisely what distinguishes one approach from another. They normally are constituted from three procedures: one which provides an initial (feasible) point, one which provides other feasible points in the "neighborhood," and a function which provides the "measure of performance" of a given point. They are usually classified depending on the use of these three procedures inside some general schemes. There are *stochastic* and *deterministic* schemes, depending on whether there is use of random decisions within the solution schema; and between *no-null* and *null* threshold schemes, depending on whether a neighbor can be selected that is worse, but only if the loss is smaller than a given computed threshold. The most popular approaches falling in this class are *simulated annealing* (SA), *tabu-search* (TS), and *genetic algorithms* (GA). The first two techniques, SA and TS, are very similar to one another. The last technique, GA, is somewhat more abstract; it can be argued that SA and TS are special cases of GA.

2. *Splitting-up methods* follow the dictum of "divide and conquer." It splits the original problem into two or more subproblems that are smaller in size and hence easier to solve optimally. The ingenuity of the analyst lies in how to split the original problem into the subproblems, and how to recombine the optima of the smaller problems in an answer to the original, global, problem. The splitting may be done *hierarchically* (e.g., strategic vs. tactical vs. *operational*), or *structually* (e.g., resource usage constraints vs. temporal constraints), or over the *set of solutions* such as in branch-and-bound (BaB). *Filtered beam* search methods constitute a further restriction on the BaB approach because it further restricts the search among the "descendents" of a particular node in the BaB search tree to a selected class. Others are ignored.

3. *Model changing methods*, better known as *relaxation methods*, "relax" (i.e., delete or replace) an original requirement of the problem. For example, ignore integer requirements and solve assuming continuous variables, then round off the solution in some rational fashion. Or approximate nonlinear relations by linear one. Or restrict the class of solutions sought, such as in flowshops scheduling problems where the restriction is to "permutation schedules"; etc.

4. *Artificial intelligence methods* include *constraint-guided search, expert systems*, and *knowledge-based procedures*. Limitation of space does not permit a more extensive discussion of these approaches, but they may be briefly described as search methods that are guided by using the available information intelligently. This information may be in the form of the constraints under which the process is functioning; or in the form of how established "experts" have solved the same, or similar, problems before, or on available classification of problems arising in the same class (such classification is sometimes referred to as "*artificial memory*").

III. STOCHASTIC PROCESSES

"Stochastic" is the Greek word for "random," which is much less forbidding. However, stochastic is commonly used to connote a process that evolves randomly over time, which leads to the mathematical definition of a stochastic process (SP) as "an indexed family of random variables," in which the indexing occurs over time.

The presentation that follows is couched in the vernacular of classical concepts of uncertainty, based on the calculus of probability and bivalent logic. Section IV discusses the fuzzy paradigm, which presents a different view of uncertainty that is based on "belonging" as a matter of degree.

Interest in SPs stems from their prevalence in real-world phenomena, such as waiting lines (or queues), Brownian motion, and the analysis of time series.

There are several issues for study in SPs: the construction of models that represent observed phenomena, the theoretical analysis of models of SPs, the solution of problems by either of the two approaches available (analytical and simulation), and the statistical analysis of data from SPs for either estimation of parameters or evaluation of performance. The field has gained prominence in recent years because of the need to optimize the design and utilization of networks of computer systems.

Theoretical research and applications in the field of SPs have resulted in a rough taxonomy along the following lines: random walk, Markov chains, recurrent events, renewal processes, martingales, and cumulative processes. A brief discussion of these topics follows.

Random walk is the name given to the following process. Let $X_1, X_2, \ldots$ be a sequence of real-valued, identically distributed, mutually independent random variables, (r.v.'s) and let $S_0 = 0$, $S_n = \sum_{i-1}^{n} X_i$, for $n = 1, 2, \ldots$. Then $\{S_n\}$ is a random walk. Many questions can be asked relative to this process, some of theoretical interest, and others of practical significance depending on the physical interpretation of the r.v.'s X_t. For instance, suppose X_t is of bounded variation; does there exist a limit to the arithmetic mean S_n/n? Or, if X_t represents profit or loss over a short period (say 1 month), what is the probability that $S_T < A$, where T is a finite planning horizon (say 1 year) and A is a least desirable cash-in-hand amount?

A recurrent event, as the name indicates, is an event that recurs over time. Imagine an event A to happen at times $S_0, S_1, S_2, \ldots$, where $S_n = X_0 + \cdots + X_n$ for $n = 0, 1, 2, \ldots$. The most important underlying assumption is that the r.v.'s $X_1, X_2, \ldots$ are independent and identically distributed (i.i.d.), taken to be multiples of some fixed period $w > 0$. (For simplicity, and with no loss of generality, it is usual to take $w = 1$.) Set $f_j = \Pr\{X_n = j\}$, $j = 1, 2, \ldots$. The case $X_0 = 0$ (i.e., when the process starts with event A occurring at the origin of the time scale) is what is usually meant by a recurrent event process. The more general situation, in which X_0 has some arbitrary distribution, is called a delayed recurrent event process. Let u_n be the probability that A occurs at time n, and let N_n be the number of occurrences of A in the time interval $[0, n]$. Thus $u_n = \Pr\{N_n > N_{n-1}\}$. Noting that $u_0 = 1$, it is easy to show that, for example,

$$E[N_n] = 1 + u_1 + u_2 + \cdots + u_n = U_n,$$

and that, if $m_1 = E[X_j] < \infty$, then

$$E[N_n] \approx n/m_1 \qquad \text{as} \quad n \to \infty.$$

If the X's happen (with probability 1) to be multiples of some integer greater than unity, then the recurrent event process is said to be *periodic*; otherwise, it is called *aperiodic*.

Let $f = \sum_1^\infty f_n$. If $f < 1$, then the event A is said to be *transient*; otherwise it is *persistent* (i.e., when $f = 1$). Actually, it is possible to show that event A is transient iff $\sum_0^\infty u_n < \infty$, and that, in such a case, $f = 1 - (1/\sum_0^\infty u_n)$.

Suppose the system under study can exist at any given moment in one, and only one, of a sequence of possible states, identified as, say, $s_0, s_1, s_2, \ldots$, finite or infinite. Suppose that in one unit of time the system "moves" from its present state to another one (which may be the same current state, in which case it is said that the system has undergone a "virtual movement"). Suppose further that, given that it is in state s_i, the probability that it moves to state s_j is p_{ij}, and that the selection of the next state of the system is independent of all previous history of the process except for the fact that it is presently in s_i. Such a system is called *Markov chain*. If the probability of move is dependent on the (absolute) time at which the transition occurs, written $p_{ij}(t)$, then the system is the more general Markov process.

If the transition from state i to state j does not occur in unit time, as was assumed in Markov chains, but the system sojourns (waits) in state i for a period of time whose duration is an r.v., denoted by T_{ij}, then the process is known as a *semi-Markov* process.

Markov and semi-Markov chains and processes are perhaps the most extensively studied models of stochastic processes, because of their valid representation of many real-world situations.

Renewal processes are the continuous-time analog of the recurrent event processes on the "discrete" time scale. Let $\{X_n\}$ be an infinite sequence of i.i.d. nonnegative r.v.'s, with distribution function $F(x) = \Pr\{X_n \le x\}$, and moments $m_1 = E[X_j]$, $m_2 = E[X_j^2]$, etc. We assume the renewal event to occur at times $0, S_1, S_2, \ldots, S_n, \ldots$, where S_n is defined as before. Denote the number of renewals in the time interval $(0, x)$ by $N(x)$. Let $H(x)$ denote the expected number of renewals by time x, the renewal function. Then it is known that it satisfies the integral equation

$$H(x) = F(x) + \int_0^x H(x - z)F(dz),$$

which is a commonly encountered equation in many OR models.

The elementary renewal theorem states that $H(x) \approx x/m_1$; the more profound Blackwell's theorem states that, for every fixed $c > 0$, $H(x + c) - H(x) \to c/m_1$, as $x \to \infty$, with the understanding that $(m_1)^{-1}$ is interpreted

as zero if $m_1 = \infty$. The key renewal theorem states that for a variety of absolutely integrable functions $k(x)$, as $x \to \infty$,

$$\int_0^x k(x-z)H(dz) \to (1/m_1)\int_0^\infty k(z)\,dz.$$

Martingales are models of SPs with the property that the expected value of the nth r.v., conditional upon knowledge of all "earlier" values of the r.v.'s, shall be equal to its $(n-1)$st value; or, mathematically,

$$E[X_n : X_1, X_2, \ldots, X_{n-1}] = X_{n-1}, \tag{8}$$

for $n = 1, 2, \ldots$, where $X_1, X_2, \ldots$ is an infinite sequence of r.v.'s such that $E[|X_j|] < \infty$ for all $j = 1, 2, \ldots$. The condition of Eq. (8) is quite general, since it does not require independence.

Although, to date, martingales have not played an important role in OR, it is anticipated that their use will increase because of the power their theory brings to bear on problems. For instance, a shortcut to the solution of some quite messy problems may be found via the optional stopping result, which asserts that, under some rather general conditions, a martingale (that is relatively easy) is derived from another martingale (that is difficult) by specifying a rule by which the latter may be "terminated."

A stationary process refers to the r.v.'s $\{X(t)\}$, $-\infty < t < \infty$, in continuous time, or to r.v.'s $\{X_t\}$, $-\infty < t < \infty$ and integer, in discrete time. The terms *time series* are commonly reserved for the discrete time stationary process. The sequence $\{X_t\}$ is stationary in the strict sense if the following conditions are satisfied: for every finite integer $n > 0$, every set of n integers $(k_1, k_2, \ldots, k_n)$, and every set of n reals $(x_1, x_2, \ldots, x_n)$, the $\Pr\{X_{k_1+r} \le x_1, X_{k_2+r} \le x_2, \ldots, X_{k_n+r} \le x_n\}$, is independent of the integer r, $-\infty < r < \infty$. Although many OR problems satisfy these conditions, it is acknowledged that an even wider class of problems satisfies the (weaker) secondorder conditions: (1) $E[X_t]$ and $E[X_t]^2$ exist for all t and are independent of n, and (2) if $m = E[X_t]$, the product moment $E[(X_{t_1} - m)(X_{t_2} - m)]$ is a function of $|t_1 - t_2|$ only.

Consider the real-valued second-order stationary process $\{X_t\}$. There exists a distribution function $F(\cdot)$ on the interval $[0, \pi)$ such that

$$\rho(n) = \int_0^\pi (\cos n\lambda)F(d\lambda), \tag{9}$$

for $n = 0, \pm 1, \pm 2, \ldots$ where $\rho(\cdot)$ is the autocorrelation function. The values of the autocorrelation function are thus seen to be the Fourier coefficients of a spectral distribution $F(\cdot)$. The converse of this statement is also true: if $F(\cdot)$ is any distribution function on $[0, \pi)$, then there exists a real-valued stationary (second order) process whose autocorrelation function is given by Eq. (9). In many problems, $F(u) = \int_0^u f(w)\,dw$, and the density function $f(w)$ is called the *spectral density*. The spectral distribution plays a significant role in the analysis of stationary processes.

A. Waiting-Line Theory

Also referred to as "queueing theory," this is the mathematical theory for the analysis and optimization of units demanding service at a facility. The problem is defined in terms of three constituents: (1) the input process: the source of arrivals, the type of arrivals, and the interarrival times; (2) the service mechanism: the number of servers, the number of customers getting served at any time, and the duration and mode of service; and (3) the queue discipline: all the factors regarding the rules of conduct of the queue, such as the priority in which jobs are processed by the facility.

The analysis of queueing systems is aimed at understanding the system behavior relative to certain major characteristics, such as the time variation of the queue length $Q(t)$, the time variation of the customer waiting time $W(t)$, and the time variation of the occupancy of the service mechanism. Various modifications of these characteristics are also of concern, such as throughput time (total time spent by the customer in the system), busy cycle (sum of two adjacent busy and idle periods), and server utilization (fraction of time the server is busy).

There are two problems associated with the study of queueing systems that demand special mention. They are the statistical estimation problem, and the operational problems inherent in the design, control, and measurement of effectiveness of such systems. Evidently, the results obtained from analysis shall depend, to a large extent, on the validity of the estimated parameters and on the operational structure of the system.

In formulating a queueing model for a system, one applies direct observation to the determination of its structure and discipline; but in the determination of the form and properties of the input and service processes, one must rely on statistical techniques. These comprise four major steps: (1) collection of data, (2) tests for stationarity in time, (3) tests for independence of arrival times and/or service times, and (4) tests for specific distributions, which involve the estimation and tests of hypotheses regarding specific parameters and forms of distribution. The most popular models structured for such studies are the Poisson process of events, the Erlangian model, and the hyperexponential model.

1. Stationarity

Real-life systems exhibit some sort of stable behavior in the long run. In terms of system characteristics, this

translates into the properties of the processes $\{Q(t)\}$ and $\{W(t)\}$ as $t \to \infty$ and $\{Q_n\}$ and $\{W_n\}$ as $n \to \infty$, where Q_n and W_n refer to the discrete-time analogs. In such a case, denote, for convenience, $Q(\infty)$ by Q and $W(\infty)$ by W, while retaining Q_∞ and W_∞ for the discrete time measures. As always, one seeks system performance indices, preferably given by simple measures. One of the most used performance measures is the server utilization, given by the traffic intensity

$$\rho = \frac{\text{effective arrival rate}}{\text{effective service rate}}.$$

2. The Single-Server Queue with Poisson Arrival and Exponential Service

This is the so-designated "M/M/1 queue," where the first symbol designates the input behavior, the second the output behavior, and the third the number of servers, and the "M" indicates Markovian. This process has been used more often than any other system in queueing theory. Let λ and μ be the arrival and service rates, respectively. Then the traffic intensity $\rho = \lambda/\mu$. Let $\pi_j = \Pr\{Q = j\}$, $j = 0, 1, 2, \ldots$. We have

$$\pi_j = (1-\rho)\rho^j \qquad j = 0, 1, 2, \ldots$$

$$E[Q] = \frac{\rho}{1-\rho} \qquad \text{and} \qquad \mathrm{Var}[Q] = \frac{\rho}{(1-\rho)^2}.$$

When the queue discipline is FCFS (first-come first-served), and noting that the waiting time of a customer is equivalent to the service load of the server, one gets

$$F(x) = \Pr\{W \le x\} = 1 - \rho e^{-\mu(1-\rho)x}$$

$$E[W] = \frac{\rho}{\mu(1-\rho)}$$

and

$$\mathrm{Var}[W] = \frac{\rho(2-\rho)}{\mu^2(1-\rho)^2}.$$

The following two relations are then immediately derived:

$$\frac{1}{\mu}E[Q] = E[W]$$

and

$$E[Q] = \lambda E\left[W + \frac{1}{\mu}\right].$$

Of these, the first is true only when the service times are exponential, and the second relation is true under very general conditions.

The speed with which the distribution of $Q(t)$ approaches its limiting value $\{\pi_j\}_{j=0}^{\infty}$ is given by its relaxation time $t \approx 2\lambda/(\mu-\lambda)^2$. Further, the asymptotic behavior of $E[Q(t)]$, $\mathrm{Var}[Q(t)]$, and $\Pr\{[Q(t)/\sqrt{2\lambda t}] \le x\}$, as well as similar results for $W(t)$, have been evaluated.

Apart from the completely random input, exponential service, and single-server queue, others have come under scrutiny. Unfortunately, the results of these models are not as rich as the M/M/1. We name a few that have received more extensive treatment.

The queue M/G/1, in which the input is Markovian, the service distribution is "general," and there is only one server.

The queue GI/M/1, in which the input possesses general distribution, the service is Markovian, and there is only one server. Results similar to those of the queue M/G/1 are available.

The queue GI/G/1, in which both arrival and service systems possess general distributions, but still one server. Let $F(x) = \Pr\{W_\infty < x\}$ and $K(x) = \Pr\{X_n \le x\}$; then

$$F(x) = -\int_{0^-}^{\infty} F(y)\, dK(x-y) \qquad (x \ge 0).$$

In special cases this equation may be solved to derive exact distributions. For the applicationsoriented individual, the following three results are significant.

1. Little's formula: $E[Q] = \lambda E[W + V]$, where V is an r.v. representing the service time.
2. Heavy-traffic approximation: when the traffic intensity is close to 1, and under the usual assumptions of independence, the waiting time distribution is approximately negative exponential with mean

$$\frac{1}{2}\left[\frac{\text{interarrival time variance} + \text{service time variance}}{\text{mean interarrival time} - \text{mean service time}}\right]$$

if the denominator is small compared with the square root of the numerator.

3. Bounds for $E[W]$:

$$l \le E[W] \le \frac{\text{interarrival time variance} + \text{service time variance}}{2(\text{mean interarrival time})(1-\rho)}$$

where l is the unique solution of the equation

$$x = \int_{-x}^{\infty} [1 - K(u)]\, du \qquad x \ge 0, \qquad \rho < 1.$$

3. Multi-Server Queues

These have been extensively analyzed under the assumption of Markovian arrival and service mechanisms. Let λ and μ be the arrival and service rates and $\rho = \lambda/s\mu$, where s is the number of (identical) servers. Then

$$\pi_j = \begin{cases} \dfrac{(s\rho)^j}{j!}\pi_0 & 0 \le j \le s \\ \dfrac{(s\rho)^j}{s^{j-s}s!}\pi_0 & j \ge s, \end{cases}$$

where

$$\pi_0 = \left[\sum_0^{s-1} \frac{(s\rho)^j}{j!} + \frac{(s\rho)}{s!}(1-\rho)^{-1} \right]^{-1}.$$

Also,

$$E[Q] = s\rho + \frac{\rho\pi_s}{(1-\rho)^2}$$

and

$$E[W] = \frac{\pi_s}{s\mu(1-\rho)^2}.$$

4. Finite Queues

The real world is replete with systems in which $Q(t)$ has a finite limit. Such systems can be purely loss systems or loss and delay systems. In a loss system, customers arriving when all the servers are busy are denied service and are lost to the system. In a loss and delay system, such customers wait provided the number in the system does not exceed a fixed number, which is the upper bound on the size of the queue.

5. Other Queueing Systems

Many queueing systems encountered in practice are more complex than the systems discussed above, which, in the most part, have simple structure and queue disciplines. The complexity is reflected in the three characteristics enumerated in the first paragraph. For instance, arrival may be in bulk, or the service is offered in quanta of fixed length, or the queue discipline incorporates priorities that change dynamically based on the arriving customer characteristics, etc.

B. Simulation

It would be presumptuous of OR to claim simulation as its own, since simulation has been advanced by other researchers, such as physicists, and used by them extensively long before the advent of OR on the scene. However, it is a fact that OR has adopted simulation, and in particular Monte Carlo methods, as among its most prominent tools, and thus helped popularize the approach well beyond the confines of theoretical studies in particle physics.

To simulate, according to a dictionary definition, is "to feign, to attain the essence of without the reality." In substance, therefore, every representation is a form of simulation and must involve some reduction or change from reality. As it is commonly used in the OR community, simulation is understood to be "digital simulation," and stands for "the use of numerical computation and, in particular, statistical sampling of a mathematical model to arrive at results such as estimates of probabilities of certain responses" [Gaver (1978) in Bibliography].

The degree of difference between the simulation and the real system depends, of necessity, on the objective of simulation. That objective is usually either the understanding of the behavior of the system (which may lead to the discovery of some "laws" governing the system), or the evaluation of various strategies relative to a criterion or a set of criteria in the hope of choosing the best decision (from among the given set of alternatives).

All simulation models are input–output models. In other words, they are descriptive, since they represent the structure of the systems they purport to emulate. They are also functional models, since they yield the output of any system given the input to its interacting subsystems. Another way to characterize a simulation model is that it is an "if . . . then . . . " device; that is, if a certain input is specified, which includes any strategy, then the output can be determined.

It immediately follows that a simulation is a model that is "run" rather than "solved" in order to obtain results. Consequently, by its very nature, simulation is incapable of generating its own "answer." The latter must be provided from the "outside." Simulation is therefore a tool of analysis of the behavior of the system under any specified conditions. Furthermore, simulation is not a theory—rather, it is a problem-solving methodology. The following is a brief list of the most prominent among the reasons for adopting the methodology of simulation.

1. Simulation may be used in the absence of any compressed and complete mathematical formulation of the problem or when great difficulty is encountered in solving such a formulation if one exists.
2. Simulation may be the only possible way of experimentation because of the difficulty of conducting the experiments and observing the phenomena in their actual environment.
3. It is a very powerful educational and training device because it enables the experimentor to "play with" the simulation.
4. It affords complete control over time, since a phenomenon may be "speeded up" or "slowed down" at will in the simulation.
5. It can be used as a check on analytical solutions.

Some simulations may involve humans in the conduct of the experiment, and these are referred to as participative simulations. In such cases, the model must be constructed to cope with external inputs to the simulation from the participating individuals. When competition is present as an integral part of the simulation, it is usually referred to

as "gaming." Such "play" of the simulation is often used in business and warfare contexts.

The conduct of a simulation study, assuming that the problem has been well defined, generally involves five steps.

1. Model formulation.
2. The definition and collection of the necessary data.
3. The design of experiment and the set up of hypotheses tested.
4. The running of the simulation, and the statistical analysis of its results.
5. Model validation.

The final phase of a simulation study, or, for that matter, any study, is to communicate the results of the study to the interested party who sponsored the study in the first place.

Simulation, and in particular Monte Carlo simulation, has spawned several research areas, of which we name the following two.

1. The generation of random numbers—that is, numbers that can be considered as uniformly distributed between 0 and 1. For the generation of random variables that follow a given distribution, the following methods have been used: the transformation method (for the exponential, Gaussian, and log-normal distributions); the composition method (for the gamma family, Poisson, and binomial distributions); and the rejection method (also for the gamma function as well as the beta distribution).
2. Variance reduction. These are sampling methods that result in estimates that possess smaller variance than would otherwise be obtained by "straightforward" sampling. The approaches are: antithetic variates, stratification, importance sampling, and control variates and regression.

Simulation may be viewed as a methodology that rests on three premises: the *model*, the *probabilistic framework* for the inputs and *statistical* design and analysis of the outputs, and the *language* used in constructing the simulation. There are several commercially available languages, all of which are designed to relieve the analyst of the chore of writing his or her own computer code, and to let the analyst concentrate on the other two aspects of the simulation, which are typically the analyst's forte. Among the more popular of discrete event simulation languages available are GPSS/H, Awesim, and Arena. A more recent development in the design and construction of simulations is *object-oriented simulation* (OOS). It views the process being simulated as a set of interacting "objects," hence the name, and the modes of interaction are themselves defined by other "objects." The object collections, or "classes," encapsulate the characteristics and functionality of the entities pertaining to the domain of interest. Simulations thus constructed have distinct advantages over others; in particular, the use of "*encapsulation*" (the attachment of pertinent characteristics to the objects), "*inheritance*" (the use of previously developed classes of objects), *polymorphism* (the same property applies to different objects), *run-time binding* (the tying of variables to the values generated at run time), *extensibility* (the ability of the user to modify the internal logic of the simulation), and *parametrized typing* (the characterization of the object class *via* parameters of the process). Some of these characteristics are shared by other non-OOS languages, but only OOS-based languages possess all of them. The ease and power of OOS can be easily gleaned from its optic. The concept of OOS simulation started with Simula, followed by Smalltalk, which eventually led to Eiffel and C++ as the general programming languages for object-oriented programming. A lucid exposition of the philosophy and structure of OOS simulations may be found in Joines and Roberts (1998).

The idea of simulation is so patently simple that it is not easy to resist the temptation to adopt the simulation approach in almost every problem one encounters. Care should be taken when such adoption is decided upon because of the following reasons. (1) To construct a simulation is a time-consuming and expensive undertaking that requires a high caliber of talent that is often not available. (2) There are several problems that are intrinsic to the process of simulation and to the manner in which a simulation is constructed, which, if not resolved in the correct manner, may confound the experiments and yield wrong results. (3) Simulation is imprecise and there is no measure of the degree of its imprecision. Unless the experimental design was laid out well at the outset, one can easily get swamped in the data spewed out by the computer that signifies very little. (4) Because the output of a digital simulation is in numbers, a certain degree of definitiveness is accorded to the results, and more is read in them than is really justified.

C. Decision Analysis

The term "decision analysis" (DA) is typically used to denote the activities of "rational" decision in the face of uncertainty. The definition of "rationality" is embodied in a set of axioms that, if accepted by the decision maker, should also require acceptance of the procedures and consequent actions. By its very definition, DA is a normative theory of decision: it does not claim to explain how individuals decide, but rather how they should decide.

DA is based on the assumptions that (a) a decision results in a set of outcomes, about which the decision maker possesses judgment (subjective or otherwise) relative to their likelihood of occurrence, and (b) the decision maker exhibits preference among the outcomes on the basis of its utility.

Decision problems that are legitimately considered in the purview of DA usually exhibit some or all of the following characteristics: multiple objectives and criteria, which are necessarily conflicting; the presence of intangibles and/or nonmeasurables; uncertainty in the data (which is typically sample data rather than population data), as well as in the outcome of a decision and its payoff (or utility); group decision makers who do not necessarily share the same utility function; and nonstatic behavior over time.

It is common to discuss DA relative to four stages.

1. Structuring the decision problem, which includes the specification of the alternative courses of action, the delineation of the objectives and the criteria, and the specification of the degree to which these objectives might be achieved by the various alternatives.
2. Describing likelihoods of the possible consequences of each alternative decision in quantitative terms.
3. Assigning preferences to the possible consequences on the basis of individual or group utility functions.
4. Deciding rationally among the alternative courses of action on the basis of the information provided. This step also contains sensitivity analysis.

Reference has been made above to the axioms of DA. These have been and continue to be the subject of extensive studies that are aimed at reducing them to the bare minimum independent set. A consequence of these axioms is the acceptance of the principles of maximizing the expected utility as the ultimate criterion in the process of decision. Some of these axioms have come to bear distinctive names, such as the axiom of existence of relative preference, or the axiom of transitivity, or the axiom of substitutability.

Theoretical issues in DA span three areas. The first is the problem of assessment of utility of an individual decision maker or a group of individual decision makers. The second is the quantification of judgemental uncertainties, that is, the assignment of probability measures to the various possible outcomes of a decision. And the third is the methodological approaches to determining the best decision. Imbedded in this last issue are the problems of the value of "perfect information" and the decision to acquire (or not to acquire) additional information; and the issue of sensitivity of the value of the outcome to the various model parameters.

D. Theory of Games

The theory of games is the brainchild of the great mathematician von Neumann, and it was first presented to the scientific community in the (now classical) book by von Neumann and Morgenstern in 1944. It is a normative theory of behavior in situations of conflict, and does not attempt to describe actual human behavior but specifies "rational" behavior, where the definition of "rationality" is based on a set of axioms that, if accepted, dictate the outcome. The theory of games is a mathematical model par excellence. Apart from its intellectual achievement, the theory has found application in situations of conflict in oligopolistic economics and in defense. In economics, it represents a departure from the "Robinson Crusoe" economics of a single entrepreneur in a free market, which is the model that had dominated economic thought for over two centuries.

A conflict situation, henceforth referred to as a "game situation," is either between two parties (a "two-person" game) or among several parties (an "n-person" game). In either case, the total "wealth" of all players is either fixed or variable. In the former case, the gain of one (or some) player(s) must be balanced by the loss of the other(s), and the game is referred to as "zero-sum." In the latter case, the total wealth of all players may be increased or decreased, and the game is referred to as "non-zero-sum." The fundamental difference between the two-person and the n-person game is the possibility of the presence of "collusion" among some of the players in the n-person game, which is clearly absent from the two-person game (else the game situation would be vitiated).

1. Representation of a Game

A game is represented either in extensive form or in matrix form. The extensive form of an n-person game gives, in logical order, the several possible moves in a game. Each move is assigned either to a player (personal move) or to chance (random move). At a personal move, the options available to the player and the information given to the player are made explicit. At a random move, a probability distribution is specified. Finally, at each terminal position of the game, a payoff or outcome can be expressed by a vector $(p_i, \ldots, p_n)$, where p_i represents the utility to player i of the given outcome.

Generally, the extensive form is represented by a game tree with a distinguished node as the initial node. Thereafter, each node of the tree represents a position of the game, and each arc a move. Information is indicated by the use of information sets: essentially, two positions belong to the same information set if the same player must move at each position and the player cannot distinguish between them.

A player "moves" according to a particular strategy, which tells which alternative to choose at each information set. If a player has k information sets, and r_i alternatives at set i, then, in total, the player has $r_1 r_2 \cdots r_k$ strategies for the game. The normal form of an n-person game is the function that assigns the vector of expected payoffs $p_i(\cdot)$ to each n-tuple of strategies. An n-tuple $(\sigma_1, \sigma_2, \ldots, \sigma_n)$ of strategies is said to be an equilibrium n-tuple if, for every player i, and for every strategy s_i of player i,

$$p_i(\sigma_1, \sigma_2, \ldots, \sigma_i, \ldots, \sigma_n) \geq p_i(\sigma_1, \sigma_2, \ldots, s_i, \ldots, \sigma_n).$$

Consequently, none of the players can "gain" by a unilateral change of strategies.

2. Zero-Sum Two-Person Games

The two players are commonly referred to as I and II. The gain to one player, say I, is necessarily the loss to II, and conversely. Then the payoff to both players can be represented by a single number a_{ij}, which, by convention, is the "gain" of I when I adopts decision i and II adopts decision j. (These two decisions are referred to as pure strategies, as opposed to randomized strategies, which assign a probability measure to each possible decision.) By a "strategy set" is meant the set of decisions available to a player. If the strategy sets S_{I} and S_{II} are finite, then the normal form can be represented by a matrix $A = (a_{ij})$, where the rows represent (pure) strategies for I, the columns are (pure) strategies for II, and a_{ij} is the payoff (from II to I) if I chooses the ith row, and II the jth column. An equilibrium pair, or a saddle point, is defined as a pair of (pure) strategies $\sigma^* \in S_{\mathrm{I}}$ and $\tau^* \in S_{\mathrm{II}}$ for which

$$P(\sigma^*, \tau) \geq P(\sigma^*, \tau^*) \geq P(\sigma, \tau^*),$$

where P is the payoff to player I. The fundamental theorem of two-person zero-sum games (the minmax theorem) asserts the existence of pair of randomization vectors x and y ($x_i \geq 0$ and $\Sigma x_i = 1$; similarly for $\{y_j\}$) so that

$$\min_{y \in Y} \max_{x \in X} x^t A y = \max_{x \in X} \min_{y \in Y} x^t A y.$$

The common value of these two is known as the value of the game. The variables $\{x_i\}$ and $\{y_j\}$ are determined as the solution of a linear program and its dual.

3. Some Extensions

1. *Constrained games*. These arise when there is some extraneous constraint on the mixed strategies, so that not all mixed strategies are permissible. The optimal constrained strategies are obtained by solving a pair of mutually dual linear programs.

2. *Infinite games*. These arise when the sets of pure strategies for a game are infinite. In general, the loss of compactness destroys the validity of the minmax theorem. The most extensively studied form of this class is the so-called "game on the square," in which the pure strategy sets of either player are isomorphic to the unit interval [0, 1]. Unfortunately, no analytic methods exist for solving such games except through approximation by finite games.

3. *Multistage games*. A multistage game occurs when, at fixed intervals, both players are given perfect information. Each of these intervals marks a stage of the game. In this case, the problem can be simplified by the employment of dynamic programming.

4. *Differential games*. These are, essentially, multistage games with continuous time. The transition from state to state is then described by means of differential equations. The usual assumption is that two players together control the motion of a particle in n-dimensional space. Thus, if the particle is in position x at time t, its motion is determined by a differential equation that embodies the control vectors ϕ and ψ of the two players. The game ends when the point x reaches some preassigned terminal surface. Two types of payoff are usually adopted: an integral payoff $\int_0^T K(x; \phi; \psi)\, dt$ for some function K from the beginning of the game at time 0 until its termination at time T; and a terminal payoff equal to some function defined on the terminal surface of the game. More generally, the total payoff may be expressed as a sum of these two.

4. Two-Person Non-Zero-Sum Games

The essential difference is that now the gain of one player need not be the loss to the other. Consequently, the two players need not act against each other and may act cooperatively to gain an advantage to both. Under such cooperative play, preplay communication, binding contracts, and correlated strategies are permitted.

Noncooperative games are characterized by two payoff functions $A(\sigma, \tau)$ and $B(\sigma, \tau)$ defined for all pairs of strategies (σ, τ), and corresponding to the payoffs for players I and II, respectively. If the strategy sets are finite, then the functions A and B can be represented as matrices $A = [a_{ij}]$ and $B = [b_{ij}]$, and the game is said to be a bimatrix game. In general, equilibrium pairs of pure strategies need not exist. However, it has been shown that every bimatrix game has at least one equilibrium pair of mixed strategies. Unfortunately, equilibrium pairs for non-zero-sum games are not a totally satisfactory solution concept, because, first, there may be more than one equilibrium pair but with distinct payoffs to the two players, and, second, the equilibrium pair need not yield the best payoff to both players!

In cooperative games it is assumed that both players can do better by acting together than separately against each other. This cooperation must be paid for, thus giving rise to bargaining. In the simplest case, the game is defined by a subset S of the Euclidean space, representing the (joint) payoffs that the two players can obtain by cooperation, and two numbers, u_0 and v_0, representing the amount that each player can obtain without the other's cooperation. It is agreed that S should be closed, convex, and bounded above. Then, the set of Nash axioms leads to the conclusion that the players "should" agree to obtain that point (u^*, v^*) in S that maximizes the product

$$(u - u_0)(v - v_0),$$

subject, of course, to $u^* \geq u_0$, $v^* \geq v_0$. This point is known as the Nash point, and can be shown to be unique.

In the more general case, each player can affect the other even when no agreement is reached. Then the game will have a more complicated structure, consisting of two payoff functions $A(\sigma, \tau)$ and $B(\sigma, \tau)$, which will be obtained if no agreement can be reached, and a set S similar to that discussed above. The idea then is that the strategies σ and τ are used as threats, to be implemented only if no agreement is reached. Then, with each player knowing the other's threat, bargaining can be conducted. It stands to reason then that the outcome of the bargaining, and of the game itself, will depend—to some extent at least—on the threats made. Then the objective would be to maximize the product

$$[u - A(\sigma, \tau)][v - B(\sigma, \tau)],$$

subject to the constraints $(u, v) \in S$, $u \geq A(\sigma, \tau)$, and $v \geq B(\sigma, \tau)$. From this point of view, the point (u^*, v^*) is the logical outcome of the threat pair (σ, τ). The equilibrium pairs (σ, τ) are now defined in terms, not of the (threat) payoffs, but rather of the logical outcome (u^*, v^*).

5. *n*-Person Games

As in the two-person non-zero-sum games, a distinction is made between cooperative and noncooperative games. For noncooperative games, however, there is little difference between the n-person and the two-person theories.

For cooperative n-person games, the interest is on collusion among the players, which is exhibited in the formation of coalitions. Thus such games are usually studied in their characteristic function form, which tells us how much utility the members of a coalition can guarantee for themselves (if the coalition forms). It is assumed that this global utility can be divided among the members of the coalition according to predetermined side payment conditions. Thus, if $N = \{1, 2, \ldots, n\}$ is the set of players and S is a subset of N, then the characteristic function is a function v that assigns a real number $v(S)$ to the subset S satisfying

$$\begin{aligned} v(\Phi) &= 0 \qquad & v(S \cup T) &\geq v(S) \\ &+ v(T) \qquad & \text{if } S \cap T &= \Phi \end{aligned}$$

and the superadditivity condition, which is sometimes weakened to

$$v(S \cup \{i\}) \geq v(S) + v(\{i\}) \qquad \text{if} \quad i \notin S.$$

The elements of N are the players, and the non-empty subsets of N are the coalitions.

Some additional basic concepts of n-person games are S-equivalence normalization, normalization, dominance, the core of a game, a stable set, the Shapley value, the bargaining set, and no-side-payments games (which assume that only certain divisions of the winnings of a coalition are possible or permissible).

E. Gaming

Gaming is the use of games not as normative models of behavior but to study and/or deduce human behavior under conditions of conflict. The exercise is used in teaching and training, experimentation, entertainment, and therapy. It is also used in "operational gaming" to determine the likely outcome of policies that may be chosen by the decision maker.

IV. THE FUZZY PARADIGM

For many centuries, scientists insisted that physical science should strive for certainty in all its manifestations (like the precise law of Newtonian mechanics), and uncertainty was regarded as unscientific and should be avoided by all means. By the end of the 19th century, the study of physical processes at the molecular level made scientists realize that uncertainty is not only an unavoidable plague, but it is essential to the understanding of nature. This understanding led to the creation of statistical mechanics. The role played by probability theory, which captures uncertainty of a certain type, in statistical mechanics is just like calculus, which involves no uncertainty, in Newtonian mechanics. Starting with the 20th century, scientists began to notice that most problems of interest and substance are usually nondeterministic, but not as a result of randomness that could yield probabilistic distributions. The seemingly unique connection between uncertainty and probability theory is no longer taken for granted, and it was felt that for the advancement of science and technology a non-probabilistic paradigm is needed in dealing with uncertainty.

Even though some modern concepts of uncertainty, such as Max Black's *vagueness*, were envisioned in the early part of the 20th century, it is generally agreed that Lotfi A. Zadeh's publication of "Fuzzy Sets" in 1965 is truly monumental. The new theory mathematically defines sets with boundaries that are not precise by assigning a 'degree of belongingness' to each of the elements. It challenged not only probability theory as the sole agent for uncertainty, but also Aristotle's two-valued logic that probability theory is based on. In the new paradigm, science is no longer "black or white"—"To be *and* Not to be" could coexist to certain degree. This capability of expressing gradual transition from membership to non-membership provides scientists not only a meaningful measurement of uncertainty, but also a meaningful representation of vague concepts expressed in natural language.

As pointed out by Zadeh, a fundamental paradigm shift underlying the organization of Fuzzy Set Theory is through *fuzzification* (using gradual membership). A field X and a theory Y can be fuzzified by replacing the concept of regular "crisp" sets in X and Y by that of fuzzy sets. In application to fields such as arithmetic, topology, graph theory, logic, mathematical programming, neural networks, stability theory, pattern recognition, and decision making, fuzzification leads to fuzzy arithmetic, fuzzy topology, fuzzy graph theory, fuzzy logic, fuzzy mathematical programming, fuzzy neural networks, fuzzy stability theory, fuzzy pattern recognition, and fuzzy decision making. What we are witnessing today and what we expect to witness tomorrow is a growing number of fuzzified fields and theories—a grand paradigm shift.

A. Fuzzy Sets

Let X be a collection of objects of interest. A *fuzzy set* $\tilde{A}$ in X is a set of ordered pairs

$$\tilde{A} = \{(x, \mu_{\tilde{A}}(x)) \mid x \in X\},$$

where $\mu_{\tilde{A}}(x)$ is a mapping from X to a membership space M, called the "membership function," that specifies the grade of membership (or degree of compatibility or degree of truth) of x in $\tilde{A}$. M is usually taken to be the closed real interval $[0, 1]$. In case M is taken to be $\{0, 1\}$, then $\tilde{A}$ reduces to a regular crisp set A in X.

The membership function is obviously the crucial component that defines a fuzzy set. The basic set-theoretic operations on fuzzy sets can also be defined through the membership functions. Given that $\tilde{A}$ and $\tilde{B}$ are two fuzzy sets in X, then

1. The intersection of these two fuzzy sets is a fuzzy set $\tilde{C} = \tilde{A} \cap \tilde{B}$, with a membership function
$$\mu_{\tilde{C}}(x) = \min\{\mu_{\tilde{A}}(x),\ \mu_{\tilde{B}}(x)\}, \qquad \forall x \in X;$$
2. The union of these two fuzzy sets is a fuzzy set $\tilde{D} = \tilde{A} \cup \tilde{B}$, with a membership function
$$\mu_{\tilde{D}}(x) = \max\{\mu_{\tilde{A}}(x),\ \mu_{\tilde{B}}(x)\}, \qquad \forall x \in X;$$
3. The complement of fuzzy set $\tilde{A}$ is a fuzzy set $\tilde{A}^C$, with a membership function
$$\mu_{\tilde{A}^C}(x) = 1 - \mu_{\tilde{A}}(x), \qquad \forall x \in X.$$

In a more general setting, the "min-operator" for intersection (the "logical and") and the "max-operator" for union (the "logical or") can be replaced by the so-called "t-norms" and "s-norms," respectively.

B. Fuzzy Measures

A fuzzy measure is an extension of the classical measure, essentially by relaxing the "additivity property." Let X be a set of interest (universe) and F be a Borel field of X. A set function g defined on F is called a *fuzzy measure*, if the following conditions are met.

1. $g(\phi) = 0$, $g(X) = 1$.
2. If $A, B \in F$ and $A \subseteq B$, then $g(A) \leq g(B)$.
3. If $A_n \in F$ and $A_1 \subseteq A_2 \subseteq \cdots$ then $\lim_{n\to\infty} g(A_n) = g(\lim_{n\to\infty} A_n)$.

Commonly seen fuzzy measures include the "belief measures," "plausibility measures," "necessity measures," and "possibility measures." In particular, the ordinary probability measure falls in the intersection of the plausibility and belief measures.

C. Fuzzy Arithmetic

One class of the most frequently used fuzzy sets is the so-called fuzzy numbers. A *fuzzy number* $\tilde{n}$ is a fuzzy set whose membership function assumes positive values in an interval around the real number n and peaks at n. For manipulation purposes, a formal definition of $\tilde{n}$ specifically requires that $\mu_{\tilde{n}}(n) = 1$ and the left branch of the membership function is piecewise continuous and nondecreasing (starts with value 0 and ends with value 1), while the right branch is piecewise continuous and nonincreasing (starts with value 1 and ends with 0).

Fuzzy numbers can perform arithmetic operations like ordinary numbers, but special attention should be given to make sure that a positive fuzzy number does not assume any non-positive value at any degree, similarly, a negative fuzzy number does not assume any non-negative value at any degree. Given that $\tilde{m}$ and $\tilde{n}$ are two fuzzy numbers and

"$\circ$" is a binary arithmetic operation (like addition, multiplication, subtraction, and division), then the membership function of a new fuzzy number $\tilde{m} \circ \tilde{n}$ is defined by the extension principle as

$$\mu_{\tilde{m}\circ\tilde{n}}(z) = \sup_{z=x\circ y} \min\{\mu_{\tilde{m}}(x), \mu_{\tilde{n}}(y)\}, \quad \forall z \in R.$$

The concept of fuzzy numbers plays a key role in formulating *quantitative fuzzy variables*, those variables whose states are fuzzy numbers. When, in addition, the fuzzy numbers represent linguistic concepts, such as *small, very tall, sort of young*, as interpreted in a particular context, the resulting constructs are usually called *linguistic variables*.

D. Fuzzy Relations

Fuzzy relations are widely used in the fuzzy paradigm. A fuzzy relation is an extension of an ordinary relation. It allows the expressions involving ambiguity such as "x and y are almost the same" or "z is much bigger than w."

Let X and Y be two sets of interest. A *fuzzy relation* $\tilde{R}$ between X and Y (or from X to Y) is a fuzzy set of the form

$$\tilde{R} = \{((x, y), \mu_{\tilde{R}}(x, y)) \mid x \in X, y \in Y\}.$$

In case $X = Y$, $\tilde{R}$ is known as a *fuzzy relation on* X. When X and Y are finite sets, say $X = \{x_1, \ldots, x_m\}$ and $Y = \{y_1, \ldots, y_n\}$, then a fuzzy relation can be represented as a *fuzzy matrix*:

$$\tilde{R} = [\mu_{\tilde{R}}(x_i, y_j)], \quad i = 1, \ldots, m; \quad j = 1, \ldots, n.$$

If $\tilde{R}$ is a fuzzy relation between X and Y and $\tilde{S}$ is a fuzzy relation between Y and Z, then the *composition* of these two fuzzy relations is a fuzzy relation $\tilde{R} \circ \tilde{S}$ between X and Z, whose membership function can be defined via the extension principle as:

$$\mu_{\tilde{R}\circ\tilde{S}}(x, z) = \max_{y\in Y} \min\{\mu_{\tilde{R}}(x, y), \mu_{\tilde{S}}(y, z)\}, \quad \forall x \in X, z \in Z.$$

The "max" and "min" operators can be replaced with general "s-norms" and "t-norms" for different applications. A very important class of fuzzy applications is to characterize a fuzzy system with fuzzy input and output by the so-called "fuzzy relational equation."

Let $\tilde{A}$ be a fuzzy set of X (viewed as a fuzzy relation on X) and $\tilde{R}$ be a fuzzy relation from X to Y, then the composition of $\tilde{A}$ and $\tilde{R}$ defines a fuzzy set $\tilde{B}$ in Y by the following *fuzzy relational equation*

$$\tilde{A} \circ \tilde{R} = \tilde{B},$$

with

$$\mu_{\tilde{B}}(y) = \max_{x\in X} \min\{\mu_{\tilde{A}}(x), \mu_{\tilde{R}}(x, y)\}, \quad \forall y \in Y.$$

In the above fuzzy relational equation, $\tilde{R}$ represents the dynamics of a fuzzy system with fuzzy input $\tilde{A}$ and fuzzy output $\tilde{B}$. A "fuzzy diagnosis system" first uses some known pairs of fuzzy input and output to build the so-called "cause-symptom" fuzzy relation $\tilde{R}$, and then use individual "fuzzy symptom" ($\tilde{B}$) to identify (infer) possible "causes" ($\tilde{A}$). How to effectively solve fuzzy relational equations remains a challenging job, even though many algorithms have been proposed by researchers in the field.

E. Fuzzy Logic

Logic is the study of the methods and principles of reasoning in all its possible forms. As bases for reasoning, different logics can be distinguished essentially by three "context independent" items, namely, the "truth values," "vocabulary" (operators), and "reasoning procedure" (tautologies, syllogisms).

In the classical Boolean logic, the truth value of a logic variable (say A, B, etc.) can be 0 (representing false) or 1 (representing truth), but not both at the same time. The vocabulary (operators) is defined by these truth values via the well-known "truth table." Actually, all operators can be represented as a combination of a sequence of "not" and "or" operators (or, equivalently, a sequence of "not" and "and" operators). For example, the "implication" operation of (A implies B) can be represented as (*not* (A) or B). The reasoning procedure is generally based on the tautologies, such as

- *modus ponens*: (A and (A implies B)) implies B,
- *modus tollens*: (*not* (B) and (A implies B)) implies *not* (A),
- *syllogism*: ((A implies B) and (B implies C)) implies (A implies C)

Note that every tautology remains a tautology when any of its variables is replaced with an arbitrary logic formula. This property is fundamental to the "rule of inference," referred to as a "rule of substitution" in the reasoning procedure.

Fuzzy logic is an extension of set theoretic multivalued logic in which the logic values are linguistic variables that may assume any value in the interval [0, 1]. Although there exist different philosophies to define fuzzy vocabulary (logic operators), given that $\tilde{A}$ in X and $\tilde{B}$ in Y, a common practice based on Zadeh's original idea defines the following.

$$\mu_{not(\tilde{A})}(x) = 1 - \mu_{\tilde{A}}(x), \quad \forall x \in X,$$

$$\mu_{\tilde{A}\ and\ \tilde{B}}(x, y) = \min\{\mu_{\tilde{A}}(x), \mu_{\tilde{B}}(y)\}, \quad \forall x \in X, y \in Y,$$

$$\mu_{\tilde{A}\ or\ \tilde{B}}(x, y) = \max\{\mu_{\tilde{A}}(x), \mu_{\tilde{B}}(y)\}, \quad \forall x \in X, y \in Y,$$

$$\mu_{\tilde{A}\Rightarrow\tilde{B}}(x, y) = \max\{1 - \mu_{\tilde{A}}(x), \mu_{\tilde{B}}(y)\}, \quad \forall x \in X, \quad y \in Y.$$

Another commonly practiced definition (less meaningful, but easy to compute) due to E.H. Mamdani is to replace the last equation with

$$\mu_{\tilde{A}\Rightarrow\tilde{B}}(x, y) = \min\{\mu_{\tilde{A}}(x), \mu_{\tilde{B}}(y)\}, \quad \forall x \in X,\ y \in Y.$$

Fuzzy reasoning is referred to as "approximate reasoning" As mentioned before, in the classical Boolean logic, inference rules are based on the various tautologies. Fuzzy logic generalizes these inferences to facilitate approximate reasoning by using the so-called "composition rule of inference." In fact, approximate reasoning can be carried out by the composition rule of fuzzy relations.

A *generalized modus ponens* reads like

$$(\tilde{A}' \text{and} (\tilde{A} \text{ implies } \tilde{B})) \text{ implies } \tilde{B}'.$$

Note that when $\tilde{A}' = \tilde{A}$ and $\tilde{B}' = \tilde{B}$ in the crisp case, we have the classical *modus ponens*. The deviation of fuzzy set $\tilde{A}'$ from $\tilde{A}$ results in an approximation in the reasoning process. For example, the fact of ((this tomato is very red) and the rule of (if a tomato is red then it is ripe)) results in a conclusion of (this tomato is very ripe). Note that a fuzzy implication rule, $\tilde{A} \Rightarrow \tilde{B}$, is actually a fuzzy relation from X to Y. Moreover, the fuzzy set $\tilde{A}'$ is a fuzzy relation on X itself. Hence the generalized modus ponens can be represented by a fuzzy relational equation

$$\tilde{B}' = \tilde{A}' \circ (\tilde{A} \Rightarrow \tilde{B}),$$

with

$$\mu_{\tilde{B}'}(y) = \max_{x\in X} \min\{\mu_{\tilde{A}'}(x),\ \mu_{\tilde{A}\Rightarrow\tilde{B}}(x, y)\}, \quad \forall y \in Y.$$

In a similar fashion, the *generalized modus tollens* can be defined as

$$(\tilde{B}' \text{ and } (\tilde{A} \text{ implies } \tilde{B})) \text{ implies } \tilde{A}'.$$

Note that when $\tilde{B}' = \tilde{B}^C$ and $\tilde{A}' = \tilde{A}^C$ in the crisp case, we have the classical *modus tollens*. We also have

$$\mu_{\tilde{A}'}(x) = \max_{y\in Y} \min\{\mu_{\tilde{B}'}(y), \mu_{\tilde{A}\Rightarrow\tilde{B}}(x, y)\}, \quad \forall x \in X.$$

As to the *generalized syllogism*, one can view it as

$$((\tilde{A} \text{ implies } \tilde{B}) \text{ and } (\tilde{B} \text{ implies } \tilde{C})) \text{ implies } (\tilde{A} \text{ implies } \tilde{C})$$

with

$$\mu_{\tilde{A}\Rightarrow\tilde{C}}(x, z) = \max_{y\in Y} \min\{\mu_{\tilde{A}\Rightarrow\tilde{B}}(x, y), \mu_{\tilde{B}\Rightarrow\tilde{C}}(y, z)\}, \quad \forall x \in X,\ z \in Z.$$

More complicated fuzzy reasoning involving more than two premises can always be reduced to the unions (and intersections) of simple fuzzy reasoning with two premises. This property is particularly important in the area of 'fuzzy control' which applies a set of fuzzy 'if-then rules' to gain control for desired output of a fuzzy system.

V. SELECTED MODELS OF COMMON PROCESSES

OR has been successfully applied in a wide spectrum of operational systems. In this section is an abbreviated roster of these fields of application.

A. Aggregate Production Planning

One of the earliest fields of applications of OR was in the planning of aggregate production capacity and production quantity for the firm, as exemplified by the (now classical) study of Holt, Modigliani, Muth, and Simon in 1960 on a paint company. Briefly, assuming that quadratic cost functions may be considered as reasonable approximations to the actual costs of varying the workforce, the production schedule, and inventory about their respective "ideal" values, the authors were successful in modeling the total cost incurred by the firm over the finite horizon, and in deriving their famous "linear decision rules," which purport to regulate all three variables mentioned above. Several extensions of the basic model have been proposed in the literature since its appearance, but all lack the elegant simplicity of the original contribution.

If linear approximations are acceptable, even within a narrow interval, then linear programming can be used to advantage.

The "economic manufacturing quantity" (EMQ) is perhaps the most venerated of all simple mathematical models for optimizing production, and has been used by industrial engineers since 1916, long before the advent of OR. Unfortunately, the assumptions of the model were extremely restrictive: infinite planning horizon, continuous time, constant demand that is infinitely divisible, no stock-out condition permitted, and only two costs to contend with: the cost of setup and the cost of storing a unit of the product per unit time, both of which were assumed constant over time and invariant with the quantity produced. With the methodology of OR in hand, it has been possible to step out of the confinement of the EMQ model to the "economic lot scheduling problem" (ELSP) under discrete time and dynamically varying demand from period to period for a finite planning horizon, and, furthermore, to treat stochastic demand, with backlogging of demand permitted, with or without limitation on capacity, with linear or nonlinear costs that may vary with time, with or without the so-called "fixed charge" penalty that is incurred whenever setup is undertaken.

B. Sequencing and Scheduling

To sequence a finite set of tasks is to define the order in which they are to be performed. If the time at which each task is started is also defined, one ends with a schedule. Clearly, then, a schedule implies a sequence (and in fact the two terms are often used interchangeably in deterministic systems), but the converse need not be true in the case of uncertain task durations and fewer processors than tasks. In the latter case, it is understood that what is discussed is the sequence, although one continues to speak of the "schedule."

Attempts have been made to establish a strict taxonomy of scheduling problems, but with little success, mainly because of the extensive variety that can be met in practice, and the minute differences that exist among many of them. Typically, the problem is defined in terms of the following parameters.

1. The number of jobs to be scheduled. It is typically assumed that all tasks are available at the same time. However, it is easy to deviate from this assumption when job availabilities vary and the precise number of jobs to be processed is not known *a priori*.

2. The number of machines available for processing the jobs, the "route" of each job over the machines, and its processing times. The one-machine case, despite its deceiving simplicity, gives rise to extremely knotty scheduling problems, which are best exemplified by the renowned traveling salesman problem, in which a salesman is required to call on each of N cities once, and return to his base city having covered the shortest distance possible. In the case of $m > 1$ machines, the very arrangement of these machines relative to the job routes gives rise to an astronomical variety of problems. For instance, if all jobs possess the same route, with one machine per station, then the shop is known as a flowshop. Of course, flowshops exist in which stations have several machines "in parallel," which may or may not be identical. On the other hand, if there is no discernible pattern to the job routes, then one is faced with a jobshop. Setup times (and setup costs) may or may not be present, and they may or may not be sequence-dependent.

3. The pattern of processing the jobs. It is normally assumed that a machine can process one job at a time and, moreover, that each job can be processed at any time by only one machine. However, deviations from this assumption are quite common, where a machine (or operator) serves two or more jobs simultaneously (time-shared) or, more commonly, a job is served by two or more machines at the same time. Usually the jobs are permitted to queue ahead of a work station, but instances exist where such queueing is prohibited.

4. The relation, if any, among the jobs. Normally, the jobs are assumed to be independent. But they may also be "related" to each other either by precedence or some other relation. Assembly operations are common examples of jobs related by "tree-type" precedence.

5. The criterion function. Here, one again encounters a wide variety of measures of performance, depending on whether or not the jobs are "due-dated." These criteria typically refer to (a) the jobs (e.g., minimize the number of jobs tardy), (b) the values of the jobs (e.g., minimize the total cost of tardiness for due-dated jobs). (c) the machines (e.g., maximize the minimum machine occupancy), and (d) the value of the machine times (e.g., minimize the cost of machine idle time).

The methodologies used in resolving scheduling problems are as varied as the problems posed, and range over the full spectrum of discrete and combinatorial optimization, branch-and-bound methods, and heuristics. The latter methodology is gaining in popularity because the overwhelming majority of scheduling problems are in the class NP-hard, so that there is little hope of finding a procedure that resolves large-scale problems in reasonable and finite time.

C. Inventory Management

This has also been one of the earliest fruitful areas of application of OR, since it is intimately tied to production capacity planning, though not necessarily so. Development has progressed along two main streams of thought: the first is pragmatic and descriptive, and attempts to measure the various components of the system (statistical properties of demand for stocked items, the cost elements of carrying and replenishing inventories, the stratification of items according to some scheme, etc.); the second is formal and prescriptive, and attempts to specify what to stock, how much to stock, and when and where to stock it in the case of multiechelon inventory and distribution systems.

Pure inventory systems (i.e., ones that are divorced from production) are rare, and are typically found in applications such as water resources management and retail stores, Typically, however, in agriculture as well as in industry, inventory is linked to production, although the link may be intentionally weakened to divorce one from the other. This is done at the expense of increasing inventory.

An inventory problem is defined in terms of the following parameters.

1. The number of items in stock, their demand characteristics [deterministic or stochastic, constant (stationary) or variable (dynamic) over time], their physical characteristics (volume, dimensions, weight, physical/chemical

properties, and their rate of deterioration, if any), their relations to each other (if any), and their value and volume–price variation over the planning horizon.

2. The structure of the inventorying system, which may be single-echelon or multiechelon.

3. The criterion function. Basically, there are two schools of thought: one relates to "cost," or value, and the other to "service level." The two are intertwined, since "customer satisfaction" or the lack of it may be recast in monetary terms, though often this is well nigh impossible to accomplish because of the presence of nonmeasurable entities in the concept of "service" to customers.

Inventory management under stochastic demand draws heavily on, and has contributed significantly to, the theory of stochastic processes. In addition, it has spurred the rapid development of the theory of dynamic programming.

D. Project Planning and Control

For decades, the only quasianalytical tool available to project managers for the planning, control, and evaluation of performance of projects was the reputable Gantt chart. Then the concepts of CPM (for critical path method) and PERT (for program evaluation and review technique) appeared in 1959 in the seminal papers of Kelley and Walker and of Malcolm, Roseboom, Clark, and Fazar, respectively, and transformed the picture radically, ushering in the era of activity networks as the models for the interacting activities of the project. Both models (CPM and PERT) represent an activity, either by an arrow (in the activity-on-arc mode of representation) or by a node (in the activity-on-node mode of representation), and represent precedence by the direction of the arrow in the first mode, and by an arrow linking the nodes in the second mode of representation. The difference between the two models lies in the attempt of PERT to take cognizance at the outset of the fact that activity durations are random variables. The two models have enriched the vocabulary of OR with terms such as the critical path, activity floats (four such floats are defined for each activity), event slack, the probability distribution function of project completion time, path criticality index, and activity criticality index.

CPM and PERT have spurred intensive and extensive research in theoretical as well as applied problems that have plagued managers for a long time, especially relative to the following:

1. The estimation of the various statistical parameters in the PERT model, such as the probability distribution function of the various "key events" of the project, the criticality indices of paths and of activities, the ranking of activities according to their criticality, etc. Such estimation is accomplished through any of four approaches: exact analytical models, approximation schemes, bounding methods, and Monte Carlo sampling.

2. The optimal project "compression" in the CPM model under specified time–cost tradeoff functions, such as linear, concave, convex, and quadratic.

3. The optimal scheduling of activities and/or allocation of limited resources to the activities (or, alternatively, the optimal acquisition of resources and their allocation to activities) to complete a project in a specified time. Due to the extreme complexity of this problem (which has been demonstrated to be in the class of NP-hard problems), the approach to its resolution has been typically through the use of heuristics.

The models of CPM and PERT take the logic of the precedence relations among the activities of the project as given and that all the activities shall be deterministically realized. It is easy to visualize situations in which this need not be true. Such realization gave rise to the concepts of GERT (for graphical evaluation and review technique) and GAN (for generalized activity networks). These two models added much needed flexibility in the analytical (especially, simulation) study of complex systems.

Project planning and control algorithms have been programmed on almost all mainframe computers, and there is ample availability of such procedures on mini- and microcomputers. Such software does not presently involve any optimization or probability calculations, but is limited to performing the calculations on time and resource utilizations for any specified input in the CPM model. It is anticipated that the future will see further developments along these lines.

E. Facilities Location and Layout

The term "facility" can be defined broadly to encompass a factory (or a system of factories), a school (or a system of schools), a hospital (or a system of health delivery units), a warehouse (or a system of warehouses), etc. Problems of location and layout may refer to either a totally new set of facilities, or to a new facility (or facilities) that fit into an existing system, or to the redesign of an old facility.

The criteria adopted in the design of facilities typically relate to either cost or benefit, and are usually directed to either optimizing a weighted sum of functions of the costs incurred (or the utilities derived), or to the "minmax" (or "max-min") vernacular (e.g., maximize the minimum utility derived by the users).

A distinction is usually made between "continuous" and "discrete" location and facility design problems, mainly

because of the difference in methodologies used for the resolution of the problems posed. These methodologies are either mathematical programming or discrete and combinatorial optimization, respectively.

Real-life facility location and design problems are usually of formidable character that defies strict analytical treatment—hence the resort to approximations and heuristics. At the present time, there exists a large number of computerized facility layout programs, some of which are available on the microcomputer, and none of which claims optimality of the solution reached.

The nascent field of "microchip" design has spurred renewed interest in the optimization of layout in two and three dimensions, since there is great incentive to carefully place the maximum number of "gates" that perform different logic functions on the chip to achieve maximum packing of logic and extremely high speed of operation. Though the limits of physical proximity may have been recently approached, the optimization of the layout can still stand improvement.

F. Maintenance and Replacement

Maintenance and replacement usually stand for the variety of activities that are undertaken in controlling the condition of "equipment," including inspection, repair and overhaul, and replacement. OR has found a fertile field of application in determining the timing and degree of action, especially when such action involves the disruption of operations, such as when the equipment in question is a part of a larger system.

The basic purpose of inspection is to determine the condition of the equipment and, depending on the result of such determination, take action, which may range from "do nothing" to replacement. The equipment may be operated intermittently or continuously, and may or may not deteriorate at deterministic or stochastic rates.

Overhaul is taken to mean the restorative maintenance action that is taken before equipment has reached a defined failed state, while a repair is made after the failed state has occurred. The main decisions associated with overhaul and repair are the determination of (1) the interval between overhauls and (2) the degree to which equipment should be overhauled or repaired.

Replacement implies that the "new" condition is achieved on completion of the action. Deterministic replacement problems refer to equipment whose behavior (e.g., deterioration) may be described deterministically, while stochastic replacement problems refer to equipment whose behavior is uncertain and can best be described in probabilistic terms. The literature discusses "finite" versus "infinite" planning horizons, though the difference may be insignificant since a long, although finite, horizon with small time unit behaves very much like an infinitely long horizon.

Maintenance and replacement, whether or not they are analytically studied through OR methodologies, do not just "happen," but are made to happen through strategic and tactical decisions on the part of management to install such actions in a cohesive total system. The activity impacts many other facets of the enterprise that hitherto were thought to be unrelated, or at best weakly related, such as product quality, system productivity, and incentive payment to employees. Recognition of these facts has given added emphasis to studies in this area.

VI. SELECTED FIELDS OF APPLICATION

This article has chosen a few "models of common processes" for expanded treatment. Here, it is desired to mention a few of the "fields of human activities" to which OR has been applied. Obviously, the two discussions are intertwined. For instance, if inventory is discussed under the tutelage of a "model of a common process," it also clearly refers to the activity of inventory management as a "field of human activity." The same is true for production, project planning and control, etc.

Bearing this in mind, one can still legitimately contend that government is an overall activity and a field of human involvement, rather than a model of anything. OR has found application in all levels of government: local, state, and federal. In particular, OR has been, and continues to be, extensively involved in defense studies, where it originated, as was pointed out in the historical perspective given at the beginning of this treatise. Education is clearly a local and state responsibility, and OR has been applied to its manpower planning, facility planning, scheduling of classrooms, routing of school buses, resource allocation, and racial balance. It is a matter of taste whether health systems are included in discussions of government services or not; but OR has indeed been applied to the design and operation of health systems in all its aspects (emergency services, medical information systems, out- and in-patient services, patient screening, manpower planning). The infrastructure for transportation systems is the responsibility of government, either local or federal. Starting with traffic demand forecasting, OR has been applied to the design of the network and the facilities on the network that serve specific purposes (such as toll booths, maintenance and repair facilities), as well as to the modification of existing transportation networks through expansion or reorientation. Equilibrium, or steady-state, traffic flow conditions, bottleneck links, minimal cutsets that separate specific nodes (or subsets of nodes) of the network from each other, and minimal cover

nodes (i.e., the minimum number of nodes whose removal, together with the links incident on them, would disconnect all nodes of the network) have all been legitimate problems of transportation networks that have been studied by the methods of OR.

Furthermore, industry that is involved in transportation, such as the airline and trucking industries (and to a lesser extent the railroads) have extensively used OR in all aspects of their respective operations: capacity planning, resource allocation, short-term scheduling of operations, maintenance, repair, and replacement.

The utilities have seen extensive application of OR. In fact, telephony may be credited with the invention and subsequent development of waiting-line theory. It also has given impetus to, and has provided a fertile field of application for, the science and art of simulation, both analog and digital. Electric utilities have also provided a fertile field of application for OR in what is termed "operations planning," which includes "dispatching" [i.e., the allocation of electric load (demand for electricity) among electric power generators], hydrothermal coordination (when the source of power is multifaceted), security (i.e., operating the system so that creditable disturbances, such as the sudden loss of the most heavily loaded generating unit or transmission circuit, will not cause the outage of any other facility), maintenance scheduling, generation expansion planning, and transmission expansion planning. The last two applications involve heavy investment in plant and personnel that extends over a horizon of several decades and must rely on accurate forecasts of future demands for electricity.

GLOSSARY

Animals Clusters in which every cluster containing the same number of sites has the same importance in averages over all clusters; correspond to percolation clusters with concentration $p \to 0$.
Bond Connection between two neighboring sites.
Cluster Group of neighboring occupied sites.
Concentration Probability p that a site is occupied.
Conductivity Ratio of electric current density to electric field.
Diffusion Motion on a lattice where at every step the new direction is selected randomly, that is, independent of the previously selected direction.
Fractal Object the mass of which increases with $(\text{length})^D$, where D differs from the Euclidean dimension d of the lattice into which the fractal is embedded.
Incipient infinite network Infinite network at the percolation threshold.
Infinite network In an infinite lattice, an infinitely large cluster; in finite systems, usually the largest cluster.
Site Single element of a lattice.
Threshold That concentration p of occupied sites at which for the first time an infinite network appears in an infinite system if p increases; denoted as p_c and often called the percolation threshold.

THE THEORY OF PERCOLATION aims to obtain quantitative estimates for the properties of disordered systems. In its simplest mathematical version, one considers a periodic lattice of sites, each of which is randomly occupied (with probability p) or empty (with probability $1 - p$). Such a lattice contains clusters of neighboring occupied sites. A simple example is shown in Fig. 1. As the concentration increases from zero, larger and larger clusters appear. The mean size of these clusters grows with p and diverges at a well-defined threshold concentration p_c. For $p > p_c$ there exists an "infinite" cluster, which connects the two sides of an arbitrarily large sample.

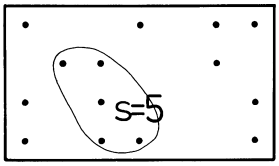

FIGURE 1 Example of site percolation and clusters.

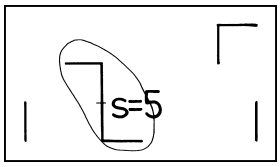

FIGURE 2 Example of bond percolation and clusters.

I. INTRODUCTION

Although the percolation problem is easily defined by one simple rule, it cannot be solved exactly. As we show in Section II, the model has very interesting properties, which exhibit universal features (independent, e.g., of details of the lattice). These features are closely related to the special geometric structure of the infinite cluster at p_c, which exhibits self-similarity, that is, invariance under the change of length scale. Graphs that have such properties, called fractals, can be described as having noninteger (fractal) dimensionality.

In this article we restrict ourselves to the simplest meaning of the complex concept of self-similarity: A structure is self-similar if subsections of the structure have a mass M proportional to some power of their linear dimension L, at least for large L:

$$M \propto L^D$$

In special cases, like the Sierpinski structures to be mentioned in Section III, the concept of self-similarity attains a more direct geometric meaning, which for percolation clusters is valid only in the average sense.

The absence of a basic length scale inherent in self-similar structures is shared by many systems that undergo continuous phase transitions. Power laws like $M(L) \propto L^D$ appear in these structures for similar and other quantities. Scaling theory describes the interrelation of the exponents of the power laws describing different quantities. The study of the changes in the properties of systems when the length scale is changed was the basis for 1982 Nobel Laureate K. Wilson's renormalization group theory explaining scaling and universality.

Although the percolation problem is defined in geometric and statistical terms, it has had many applications in the physical sciences. Historically, the first percolation theory came from chemistry in connection with polymer gelation during World War II. Usually, polymers are linear structures, but sometimes branches occur. Macromolecules with many branches may form an infinite network that is no longer a liquid solution. The formation of pudding is an example of this so-called sol-to-gel transition or gelation; the pudding is a jelly. Another example is the boiling of an egg, where the initially more liquid egg becomes more solid after it is heated for some time. In these cases, the molecules are always there, but the chemical bonds between them are either formed or not formed. For the primitive case of our lattice this means that we need here a modified form of percolation: All sites are occupied, but bonds between neighboring sites are formed randomly with probability p and remain absent with probability $1 - p$. A cluster is a group of neighboring sites connected by bonds formed between them.

We call the second type of problem bond percolation (Fig. 2), whereas the first case defined earlier is called site percolation (Fig. 1). P. Flory, and by a different method W. Stockmayer, solved the gelation problem with approximations that make it equivalent to bond percolation on the so-called Bethe lattice of Fig. 3, which contains no cyclic links and which ignores the constraint that two different parts of the macromolecule have to keep a certain minimum distance from one another and cannot occupy the same volume. This Flory–Stockmayer, or classical, theory plays a role in gelation similar to that of the van der Waals equation for the gas-to-liquid transition or the molecular field approximation for the ferromagnetic Curie point. In particular, all three examples predict a sharp phase transition; that is, a qualitative change takes place in the system at a certain value of a continuous variable. With increasing temperature T, the difference between a liquid and its vapor vanishes at the critical point, and the spontaneous magnetization of a ferromagnet vanishes at the Curie temperature. Similarly, with increasing time the heated polymer solution gels at the gel point.

What is the nature of this phase transition? Figures 1 and 2 make it plausible that the polymer solution becomes more solidlike once an infinite network of connected molecules is formed, that is, once an infinite cluster

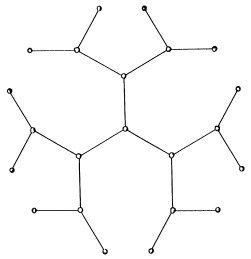

FIGURE 3 Central part of a Bethe lattice.

is formed in an infinitely large sample at the percolation threshold p_c. In the Flory–Stockmayer theory that threshold is

$$p_c = 1/(f-1) \tag{1}$$

where the functionality f is the maximum number of bonds a molecule can form with its neighbors. Equation (1) holds for both site and bond percolation on the Bethe lattice ($f = 3$ in the example of Fig. 3). The name percolation and its application to regular lattices, as in Figs. 1 and 2, were introduced in 1957.

In spite of its history, the gelation phenomenon is not that application on which modern percolation theory is usually tested. The main interest of physicists in percolation centered on the critical phenomena in the immediate neighborhood of the percolation threshold p_c, described by critical exponents to be defined later. Not many experiments are performed with real polymers to determine reliably the critical exponents of gelation. The most precise information exists about the behavior of the viscosity, which diverges as one approaches the sol-to-gel transition from the sol. However, here the connection between the viscosity and the geometric cluster properties of percolation theory is not entirely clear. Clearer are the predictions of percolation theory for the fraction of mass contained in the infinite network or for the average mass and diameter of clusters as measured by light scattering. There now seems to be a consensus that experimental critical exponents for masses and diameters agree with those of lattice percolation, while elasticity and viscosity are still under discussion.

More successful was the application of percolation to thin films of materials sputtered onto a surface. Small droplets form, which grow to larger sizes if more material is added. Here a one-to-one correspondence between laboratory experiment and computer simulation of percolation was established, for example, for the fractal nature of the largest cluster, as reflected by the dependence of its "mass" on the system size.

II. SIMPLE STATIC PROPERTIES OF PERCOLATION

Perhaps the most fundamental question of percolation theory is, what is the value p_c of the percolation threshold; that is, what is the probability p_c for which an infinite network is first formed in an infinite lattice? This problem can be investigated by exact mathematics, by expansion of suitable quantities into power series in p or $1-p$, and by computer simulation. The results for common two- to four-dimensional lattices are given in Table I. Here the results for triangular site, square bond, triangular bond, and honeycomb bond percolation are exact; the others are numerical estimates, usually accurate to the last decimal given here. We see that Eq. (1) is not fulfilled but describes the general trend: The more neighbors a site has, the smaller is the percolation threshold.

TABLE I Percolation Thresholds for Common Lattices

Lattice	Site	Bond
Honeycomb	0.696	0.653
Square	0.593	0.500
Triangular	0.500	0.347
Simple cubic	0.312	0.249
bcc[a]	0.245	0.178
fcc[b]	0.198	0.119
$d = 4$[c]	0.197	0.160

[a] bcc, Body centered cubic.
[b] fcc, Face centered cubic.
[c] $d = 4$, Four-dimensional hypercubic lattice.

It is rather easy to produce by computer a percolation picture, as in Fig. 4. One simply lets the computer go through a large two-dimensional array and, at every array element, decides with the help of a random number whether that site is full or empty. If the random number is distributed evenly between zero and unity, the site is taken as occupied for random numbers smaller than p, and empty otherwise.

It is not so easy to count clusters in a sample like Fig. 4 or to determine whether there is a cluster connecting the top and the bottom of the sample. That aim can be achieved efficiently with the Hoshen–Kopelman algorithm. There is a fortran program for counting clusters in bond percolation on simple cubic lattices. Only one line of a two-dimensional lattice, or one plane in three dimensions, has to be stored at any one time in the computer. Each cluster that is started new when we go through the lattice is given an index, and an index of index. If later two initially separated clusters merge into one cluster, this fact is recorded by changing the index of the involved index. The index itself remains unchanged; we do not have to go back in the lattice to relabel previously investigated sites. Fast computers can handle each site within a few microseconds; as of January 1987 the largest system simulated to our knowledge was a $160{,}000 \times 160{,}000$ square lattice.

One may also investigate which fraction P_∞ of sites belongs to the infinite network in an infinite system or to the largest cluster in a finite system (in the limit of system size $\to \infty$). Obviously for probability p below the threshold p_c this fraction, often called the percolation probability P_∞, is zero. One may instead look at the mean cluster size S, which is found if one selects randomly an occupied lattice site, counts how large the cluster is to which it

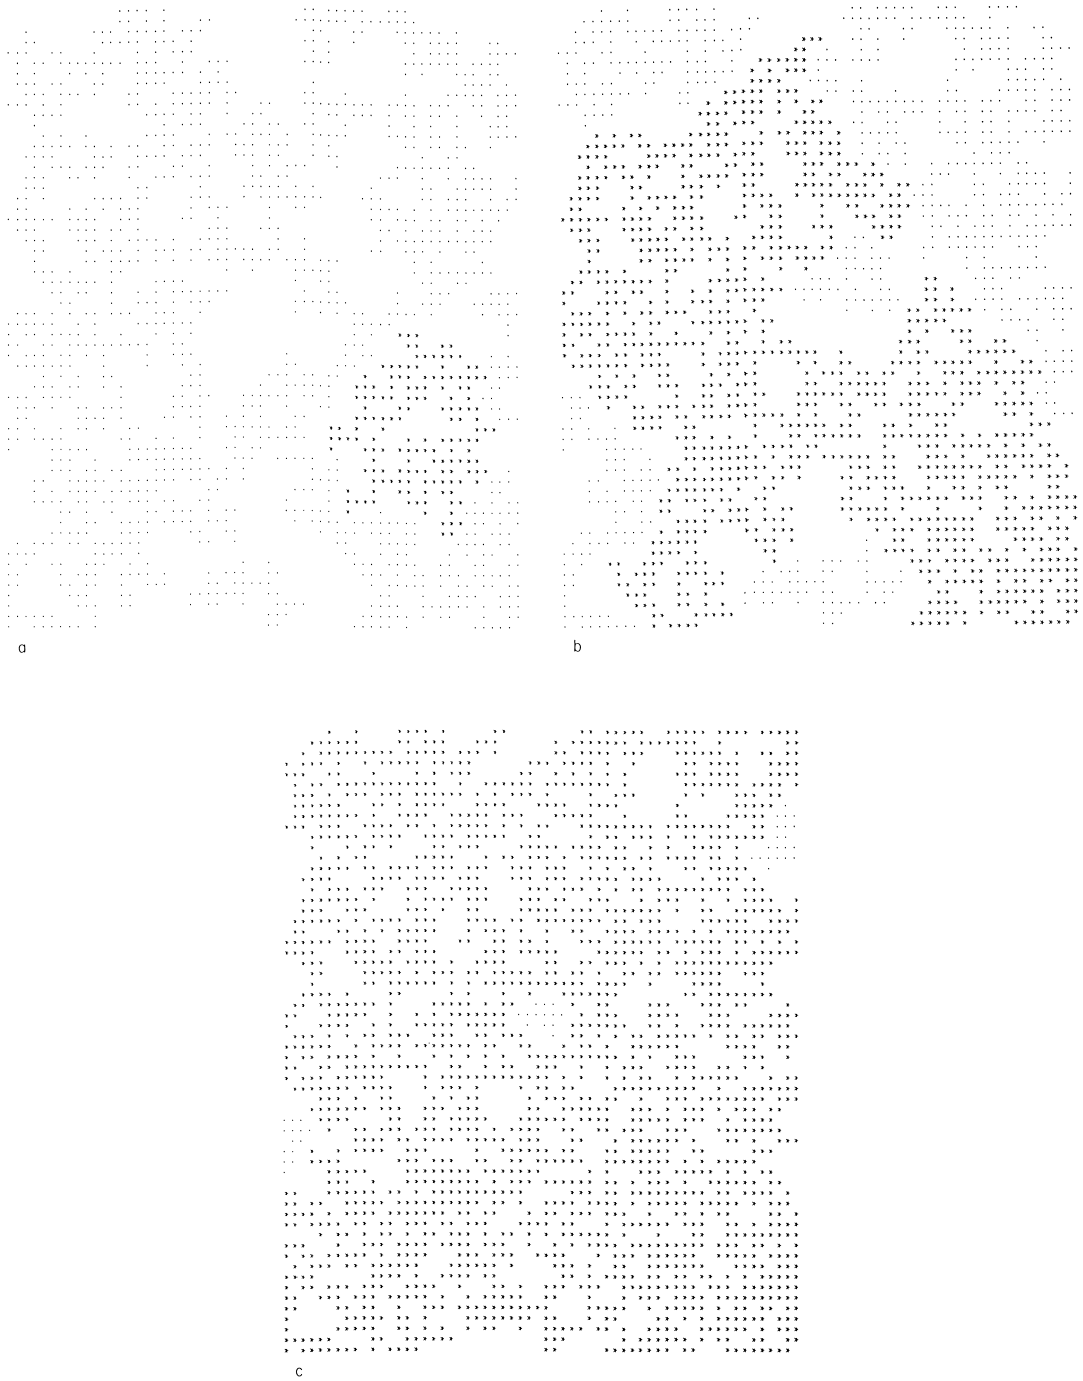

FIGURE 4 Clusters of sites connected by bonds formed in random site percolation on a square lattice (a) below ($p = .543$), (b) at ($p = .593$), and (c) above ($p = .643$) the percolation threshold. The largest cluster is denoted by stars, the smaller clusters containing >10 sites by dots.

belongs, and averages over all lattice sites selected in this way. It is plausible that this mean cluster size S diverges if the percolation threshold p_c is approached from below since, above this threshold, an infinite network is present. Finally, one may define a correlation length ξ as the root mean square average distance between two randomly selected occupied sites within the same cluster. In short, ξ is a typical cluster radius; and this length must also diverge

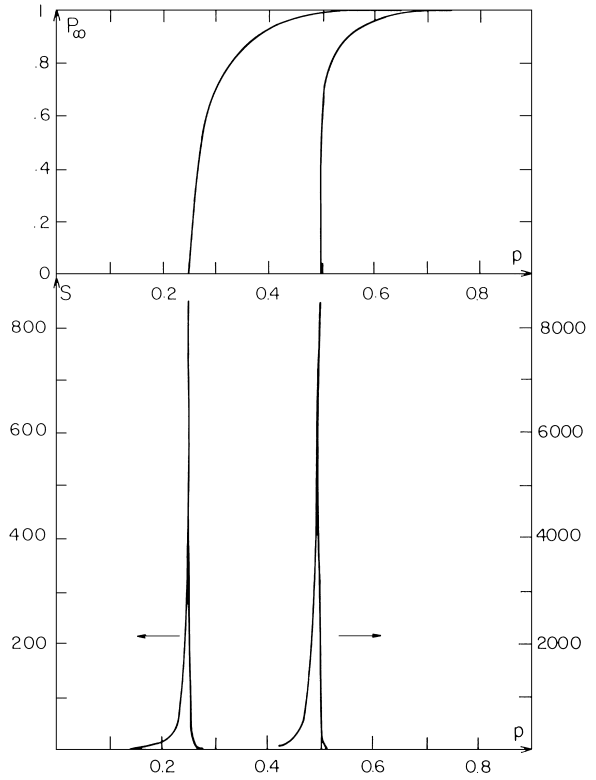

FIGURE 5 Variation of percolation probability P_∞ and mean cluster size S for bond percolation on the square ($p_c = .50$) and simple cubic ($p_c = .249$) lattice.

if $p \to p_c$ from below. For p above p_c one can define a finite mean cluster size S and a finite correlation length ξ by restricting the initially selected sites to be on some finite cluster, not on the infinite network.

How do the quantities P_∞, S, and ξ vanish or diverge at the threshold? Figure 5 shows the variation of P_∞ and S on the square and simple cubic lattices (bond percolation). For p very close to p_c the curves may be fit by power laws:

$$P_\infty \propto (p - p_c)^\beta, \qquad p > p_c \tag{2a}$$

$$S \propto (p_c - p)^{-\gamma}, \qquad p < p_c \tag{2b}$$

$$\xi \propto (p_c - p)^{-\nu}, \qquad p < p_c \tag{2c}$$

These proportionalities are supposed to be valid only asymptotically for $p \to p_c$, just as $\sin(x) = x$ is valid only for $x \to 0$. With the above restriction to finite clusters, Eqs. (2b) and (2c) also apply to the case $p > p_c$, with $p_c - p$ replaced by $p - p_c$ and with a different proportionality constant. The quantities β, γ, and ν and similar exponents governing other power laws are called critical exponents. A large part of modern percolation research has centered on these critical exponents. Similar exponents have been thoroughly investigated for critical phenomena near many other phase transitions. These critical phenomena refer to the asymptotic region $p \to p_c$, length $\to \infty$, time $\to \infty$, ..., on which we also concentrate for percolation.

TABLE II Values of Percolation Exponents in Two and Three Dimensions and for High Dimensions[a]

Exponent	$d = 2$	$d = 3$	$d \to \infty$
β	$\frac{5}{36}$	0.42	1
γ	$\frac{43}{18}$	1.80	1
ν	$\frac{4}{3}$	0.88	$\frac{1}{2}$
σ	$\frac{36}{91}$	0.45	$\frac{1}{2}$
τ	$\frac{187}{91}$	2.19	$\frac{5}{2}$
$D(p = p_c)$	$\frac{91}{48}$	2.52	4
$D(p < p_c)$	1.56	2	4
$D(p > p_c)$	2	3	4
μ	1.3	2.0	3

[a] Rational numbers presumably are exact; the others are numerical estimates [μ is defined in Eq. (15)].

Values of the exponents β, γ, and ν are listed in Table II. Unlike Table I, this table contains only one entry for all the two-dimensional (and one for all the three-dimensional) lattices, all of which have the same exponents. This universality is one of the main reasons that critical exponents for percolation theory have attracted so much attention. Our understanding of universality is based in part on self-similarity, as explained in Section III.

III. FRACTALS, SCALING, AND RENORMALIZATION

One of the powerful methods of confirming Eq. (2) uses extrapolation of data obtained in numerical simulations. These are done on finite lattices of size L^d ($L \times L$ in two dimensions, $L \times L \times L$ for three dimensions). Above p_c, if the correlation length ξ is small compared with L, the largest cluster fills the sample uniformly, with a density equal to P_∞. Thus, the number of sites in the sample that belong to this cluster is

$$M(L) = L^d P_\infty \propto L^d (p - p_c)^\beta \propto L^d \xi^{-\beta/\nu} \tag{3}$$

This situation is exhibited in Fig. 4c. As p decreases toward p_c, the correlation length ξ gradually increases. Since ξ represents a typical size of a finite cluster, it also represents a typical size of the "empty" areas in the infinite cluster. As can be seen from Fig. 4c, at $p = p_c + 0.05$ there appear empty areas of *all* sizes up to ~7 lattice units, which is a rough estimate of ξ. The appearance of all these sizes reflects the property of self-similarity at distances smaller than ξ.

If one continues to decrease p all the way to p_c (Fig. 4b), ξ diverges to infinity and the picture in Fig. 4b contains empty islands (i.e., lattice sites not belonging to the largest cluster) at *all* length scales. A direct counting of the number M of sites on the largest cluster within the sample now yields

$$M(L) \propto L^D \tag{4}$$

with D having the noninteger values listed in Table II. Since D replaces d in the power of L, as compared with Eq. (3), it is natural to consider D as a generalized "fractal" dimensionality.

A power law dependence like Eq. (4) characterizes fractal graphs, an example of which is shown in Fig. 6. In this example, called the Sierpinski carpet, the number of filled squares changes by a factor of 8 when the length scale changes by a factor of 3, so that $8 = 3^D$, or $D = \log 8/\log 3 = 1.893$. Indeed, fractals like the Sierpinski carpet have been widely used to investigate some of the properties of the infinite cluster at p_c.

Looking at Fig. 4c, one may divide it into unit squares of sizes $\xi \times \xi$. Within each square the cluster is self-similar, obeying Eq. (4), whereas the squares form a uniform distribution. Since the number of squares is $(L/\xi)^d$, and their "mass" (number of occupied sites on the largest cluster) scales as ξ^D, we find that the total mass scales as $\xi^D(L/\xi)^d \propto L^d \xi^{D-d}$. Comparison with Eq. (3) now yields

$$D = d - \beta/\nu \tag{5}$$

The power laws in Eq. (2) are direct consequences of the self-similarity.

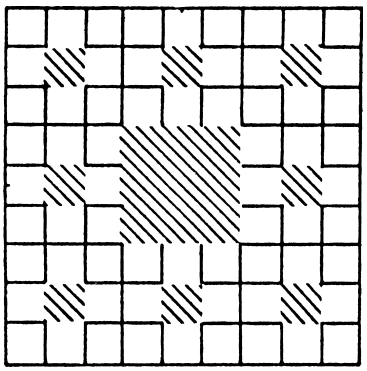

FIGURE 6 Example of a Sierpinski carpet as a model for large clusters at the percolation threshold. Empty squares are shadowed; all other squares are occupied and will be divided in the next iteration into nine squares, of which the center square will be empty. The length L of this structure is the number of elementary squares on each side; it increases by a factor of 3 at each iteration. The "mass" M of the cluster is the number of occupied elementary squares in it; it increases by a factor of 8 at each iteration. Thus, $M = L^D$, and the fractal dimension $D = \log 8/\log 3 = 1.893$ is close to that of the largest percolation cluster at the threshold, $D = \frac{91}{48} = 1.896$.

More generally, Eqs. (3) and (4) can be combined into a scaling form (with $+$ for $p > p_c$ and $-$ for $p < p_c$):

$$M(L, \xi) = L^D m_{\pm}(L/\xi) = L^D \tilde{m}\big((p - p_c)L^{1/\nu}\big) \tag{6}$$

We see that ξ is the only relevant length scale in the problem, so that the dependence of the ratio M/L^D on L should be only through the ratio L/ξ (i.e., L is measured in units of ξ). The scaling function $m_+(z)$ has the limiting behavior $m_+ \to$ const for $z \ll 1$ and $m_+(z) \propto z^{\beta/\nu}$ for $z \gg 1$. Equation (6) can be interpreted as describing a crossover from the fractal dimension D at $L \ll \xi$ to the Euclidean dimension d at $L \gg \xi$. For $L \gg \xi$ one may thus say that $D(p > p_c) = d$, at least for $d < 6$ (Table II).

Measurements of $M(L, \xi, p)$ yield the exponents D, β, and ν and indeed confirm the scaling form [Eq. (6)]. A direct indication of universality arises from the fact that Eq. (5) has been shown to apply not only to simple model computer experiments, but also to the electron microscope picture of real sputtered films (Fig. 7). Note that our theories refer to percolation on lattices, whereas these experiments are done on a continuum. However, computer simulations of continuum percolation seem to give the same exponents as lattice percolation.

Scaling forms like Eq. (6) can be written for other quantities, for example, for the mean cluster size,

$$S = L^{\gamma/\nu} s_{\pm}(L/\xi) = L^{\gamma/\nu} \tilde{s}\big((p - p_c)L^{1/\nu}\big) \tag{7}$$

They are called finite size scaling and are crucial in the analysis of data from small samples. In many computer simulations, exponent ratios like γ/ν can be estimated more accurately through Eq. (7) and its analogs than the exponents γ and ν separately through Eq. (2).

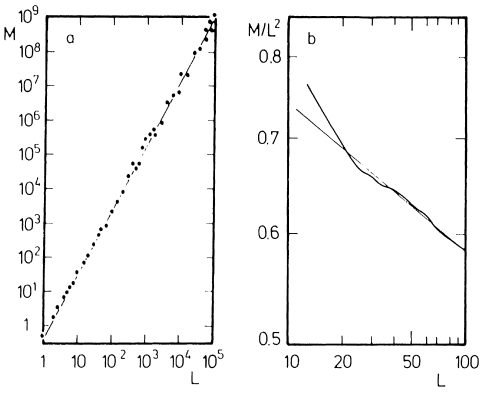

FIGURE 7 (a) Log–log plot of the number of sites, $M(L)$, in the largest cluster of an $L \times L$ triangular lattice at its site percolation threshold. The slope of the straight line is the fractal dimension $D = \frac{91}{48}$. (b) Log–log plot of the fraction of sites, $M(L)/L^d$, measured experimentally on sputtered metal films of size $L \times L$ at their two-dimensional percolation threshold. The slope of the straight line is the prediction $D - d = -\beta/\nu = -\frac{5}{48}$ of percolation theory. The experimental data are summarized by the wavy line.

As can be seen qualitatively from Fig. 4, finite clusters also exhibit self-similar features. Indeed, similar to Eq. (6), the average linear size R_s of a finite cluster with s sites is expected to behave as

$$R_s = s^{1/D} r_{\pm}(s/\xi^D) = s^{1/D} \tilde{r}\big((p - p_c)s^{\sigma}\big) \qquad (8)$$

with

$$\sigma = 1/(D\nu) \qquad (9)$$

Assumption (9) shows that the finite clusters have the same fractal dimension as the largest cluster as long as $R_s \ll \xi$, or $s \ll \xi^D$. The probability of finding much larger finite clusters of size $R_s \gg \xi$ is exponentially small. However, the function $r_{\pm}$ or $\tilde{r}$ yields a different behavior in that limit. For $p > p_c$ these rare large clusters are very compact, and $R_s \propto s^{1/d}$, that is, $D(p > p_c) = d$. In contrast, the rare large clusters found for $p < p_c$ are very loosely structured. These clusters turn out to have a lower fractal dimension $D(p < p_c)$, called that of lattice animals and listed in Table II. These lattice animals (percolation clusters for $p \to 0$) may be a model for branched polymers in a very dilute solution, where interactions between different macromolecules are negligible. In contrast, percolation clusters near p_c may be a model for gelation, the formation of an infinite network out of many intermediate-size macromolecules.

Scaling relations like Eq. (6) or (8) were introduced into percolation theory as phenomenological assumptions, in analogy to critical phenomena. Renormalization group arguments give further theoretical support for their validity. In a typical example of the renormalization group analysis one transforms a given dilute lattice into a coarse-grained version of itself, in which the length scale is enlarged by a factor $b (b = \sqrt{3}$ in Fig. 8). Basic cells, of b^d sites (three sites in the example), are replaced by single new sites, which are considered to be occupied if two opposite edges are connected by a cluster of previous sites, and empty otherwise. The result is a renormalized concentration p' of new sites; p' is a function of the concentration p of previous sites, $p' = R(p)$. In the simple example of Fig. 8,

$$p' = p^3 + 3p^2(1 - p)$$

since a triangle is defined as occupied if all three, or at least two, of its sites are occupied, thus connecting at least two of the three corners.

One may coarse-grain the new sites again, that is, replace b^d of the new sites by one supersite with occupation probability $R(p')$, and so on. The relation $p' = R(p)$ applies to each of these "renormalizations." After many iterations, the renormalized concentration approaches unity if one started with p near 1, and approaches zero if initially p was near 0. There exists one invariant fixed point $R(p^*) = p^* (0 < p^* < 1)$ of the transformation; in our example this fixed point is at $p^* = p_c = \frac{1}{2}$. If one starts very close to p^*, one can linearize $R(p) = p^* + (p - p^*)\Lambda + \cdots$ and set $\Lambda = b^y$:

$$p' - p^* = (p - p^*)b^y \qquad (10)$$

Since the renormalization changed the length scale by a factor b, one has $\xi' = \xi/b$. Using $\xi \propto (p - p^*)^{-\nu}$ [Eq. (2c)], one identifies $y = 1/\nu$, at least for large b.

In our example, $b = \sqrt{3}$, $b^y = \frac{3}{2}$ from expanding $R(p)$ about $p^* = \frac{1}{2}$, and thus $y = 1/\nu = \log \frac{3}{2}/\log \sqrt{3} = 0.738$, close to the correct result $y = \frac{3}{4}$ (Table II). This renormalization method for finite b is only approximate, because all collective phenomena are simulated by a small cell with only three sites. The approximation is better for larger values of b; large cells can be studied by computer simulation, whereby one checks with what probability $R(p)$ opposite edges are connected.

If one had a different (e.g., square) lattice, details of the renormalization group transformation $p \to p' = R(p)$ would change, and $p_c = R(p_c)$ is in general not valid. However, the properties near the fixed point, like the values of the critical exponents, reflect the behavior at very large length scales. On these scales, local short-range differences become irrelevant, and universality results.

Equations like (10) imply power law behavior at $p = p_c$ for the quantities of interest and yield scaling forms like Eq. (6) or (8). Another quantity of interest is the average number n_s of clusters containing s connected sites each. (We normalize these cluster numbers by dividing them by the total number of lattice sites.) This quantity is related to the finite clusters only: Since there seems to be at most a small number of infinite networks present in percolation for $d < 6$, this number divided by the lattice size goes to zero for infinite lattices. As in the above examples [Eqs. (6) and (8)], the cluster numbers n_s obey the scaling form

$$n_s = s^{-\tau} N_{\pm}(s/\xi^D) = s^{-\tau} \tilde{N}\big((p - p_c)s^{\sigma}\big) \qquad (11)$$

with the new critical exponent τ. One can now relate the mean cluster size S and the percolation probability P_∞ to the cluster numbers via

$$S \propto \sum_s s^2 n_s \qquad (12a)$$

$$P_\infty = p - \sum_s s n_s \qquad (12b)$$

at least close to the threshold. Here the sums run over all finite cluster sizes, with $s = 1$ corresponding to isolated sites. [In Eq. (12b), p has to be replaced by unity for bond percolation.] These equations lead to the scaling relations

$$\tau = 2 + \beta/(\beta + \gamma); \qquad \sigma = 1/(\beta + \gamma) \qquad (13)$$

Generally (also for other phase transitions), one describes relations between critical exponents as scaling laws. They

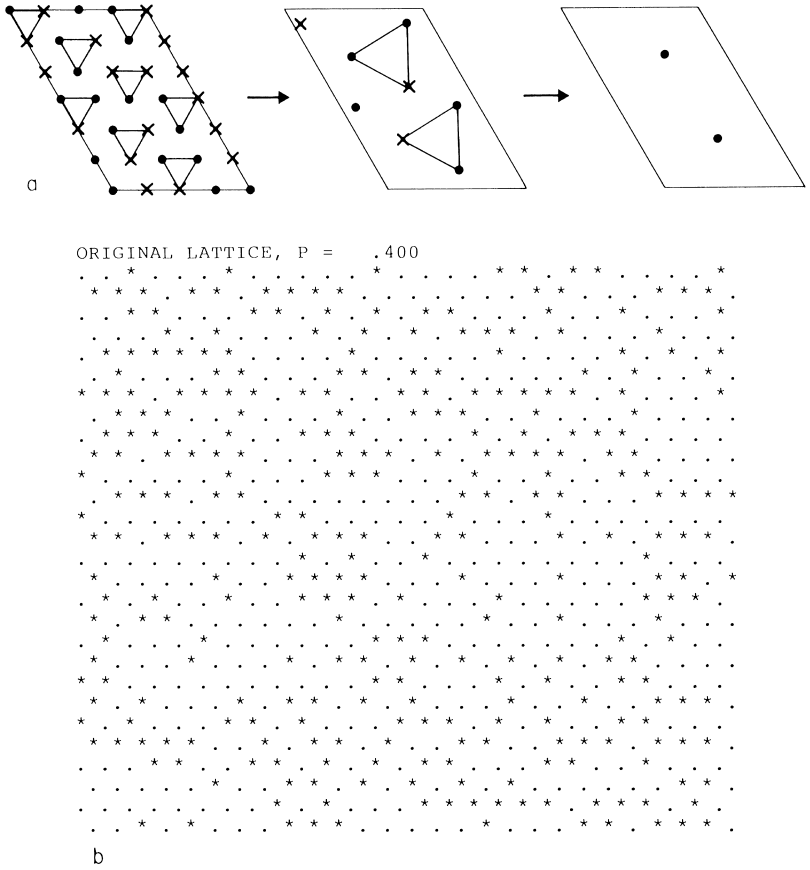

FIGURE 8 (a) Renormalization of small cells on the triangular lattice. Every lattice site (dot for occupied, cross for empty sites) belongs to one triangle; each triangle is renormalized (coarse-grained, averaged) into a new site. The new sites form again a triangular lattice, with a lattice constant $b = \sqrt{3}$ times larger than the old distance between nearest neighbors. A new site is occupied if in the small cell that it represents two opposite edges are connected. (b)–(p) Parts of a large computer-generated sample (stars for occupied and dots for empty sites). The large lattices are renormalized at an initial concentration of .4 (which is approaching zero as indicated through subsequent renormalizations), of .5 (which stays at this fixed point $\frac{1}{2}$ throughout all further iterations), and finally of .6 (which is approaching unity as indicated through subsequent renormalizations). Only for the threshold $p = .5$ is there self-similarity in the sense that the renormalized lattice has on the average the same properties as the unrenormalized lattice, apart from a change in lengths. This self-similarity is the basis of fractal properties and of scaling laws.

are derived from similarity assumptions like Eqs. (6), (7), (8), and (11). Equation (11) states that the cluster size distributions near sizes $s = s_1$ and $s = s_2$ are the same apart from a factor, provided that we scale the distance $p - p_c$ proportional to $s^{-\sigma}$ in order to keep the argument of the scaling function f in Eq. (11) the same.

The number n_s of small clusters can be evaluated exactly. For example, on a square lattice each pair of neighboring occupied sites has six empty neighbor sites (also called the perimeter) and can be oriented either horizontally or vertically. Thus, $n_s = 2p^2(1-p)^6$ for $s = 2$. For $s = 3$ we may have either a horizontal or a vertical straight line of three occupied sites [contribution $2p^3(1-p)^8$] or one of four corner configurations [contribution $4p^3(1-p)^7$]. Thus,

$$n_3/p^3 = 2(1-p)^8 + 4(1-p)^7$$

Similar, but more complicated formulas have been derived for s up to 10 or 20. They are used to express quantities like the mean cluster size S as a power series in p or $1-p$, an important technique for analyzing critical behavior. We see that for $p \to 1$ only the most compact configurations with the smallest perimeter survive. Thus, in this limit (and actually for all very large clusters above p_c) the clusters have a rather compact structure, with the radius R_s increasing as little as possible with increasing mass s, that is, $R_s \propto s^{1/d}$, as mentioned in relation to Eq. (9). In the opposite limit, $p \to 0$, for fixed size s, all cluster configurations occur equally often and one ends up with the lattice animal limit.

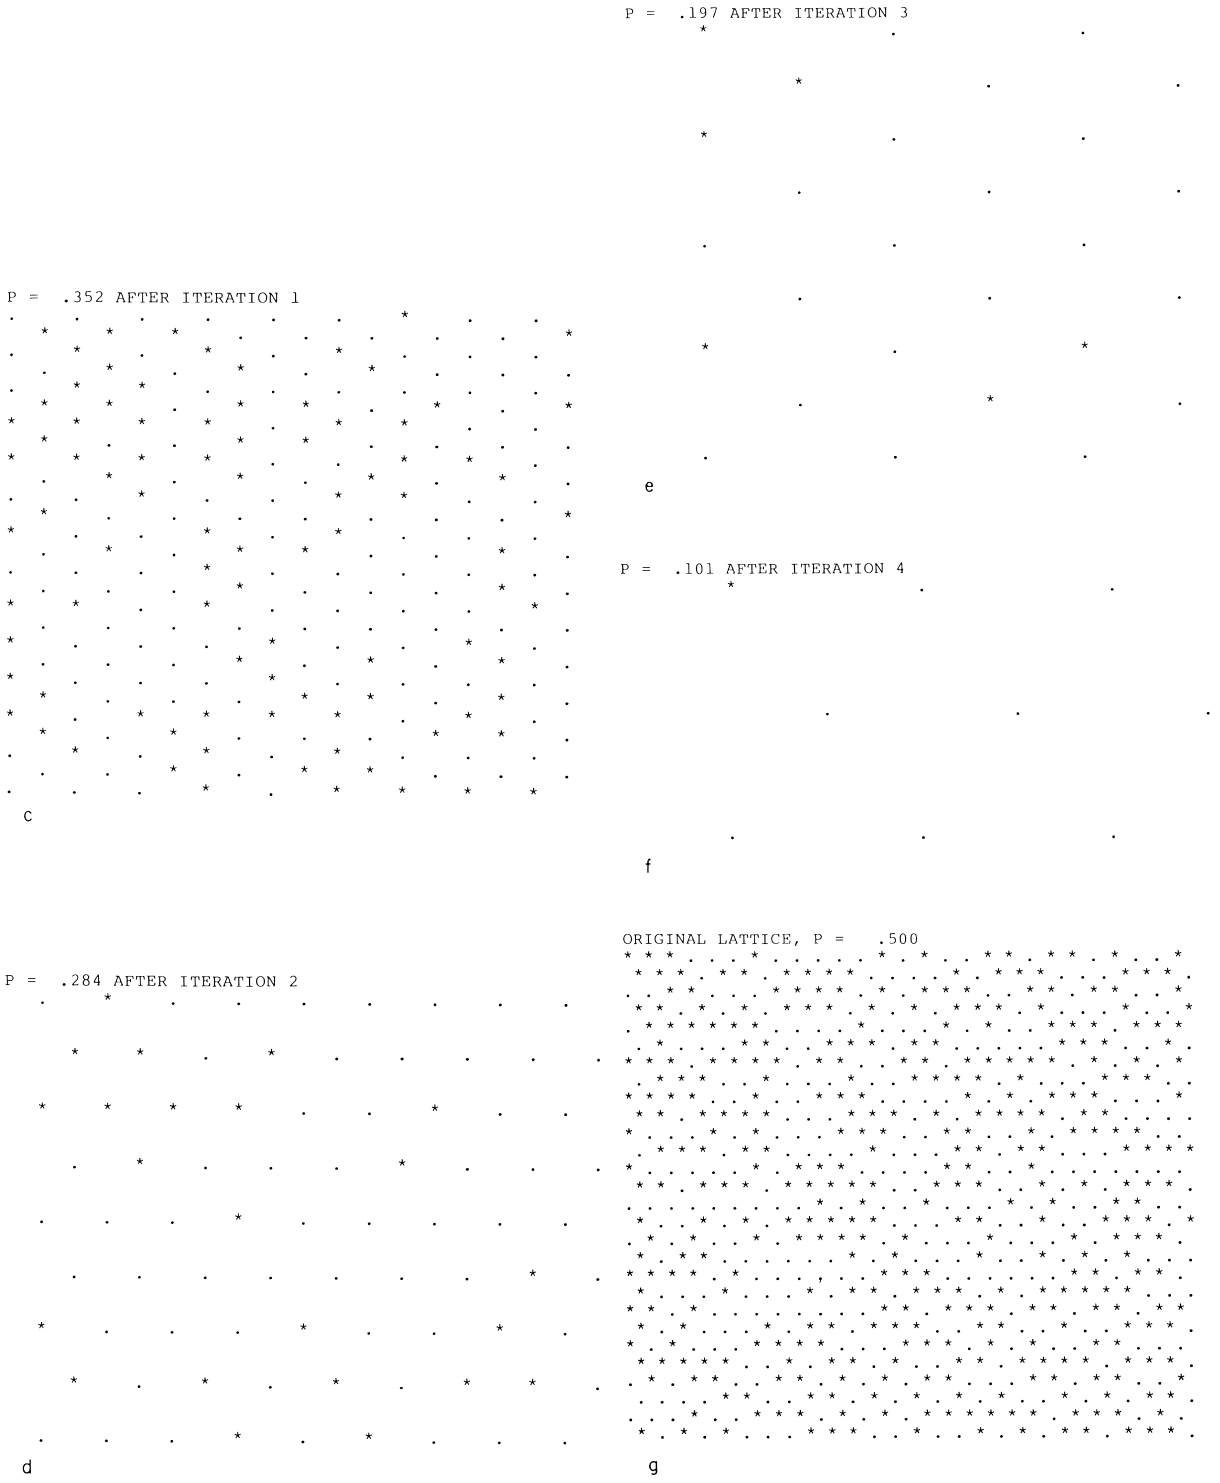

FIGURE 8 (*Continued*)

All these scaling forms [Eqs. (6), (8), and (11)] are valid only asymptotically for large clusters at or very close to the percolation threshold. Only here are the various critical exponents defined. Through the scaling laws [Eqs. (5), (9), and (13)] relating these exponents to one another, we can predict all these exponents once we know two of them. Again, this property is shared by many other phase transitions and their static critical phenomena.

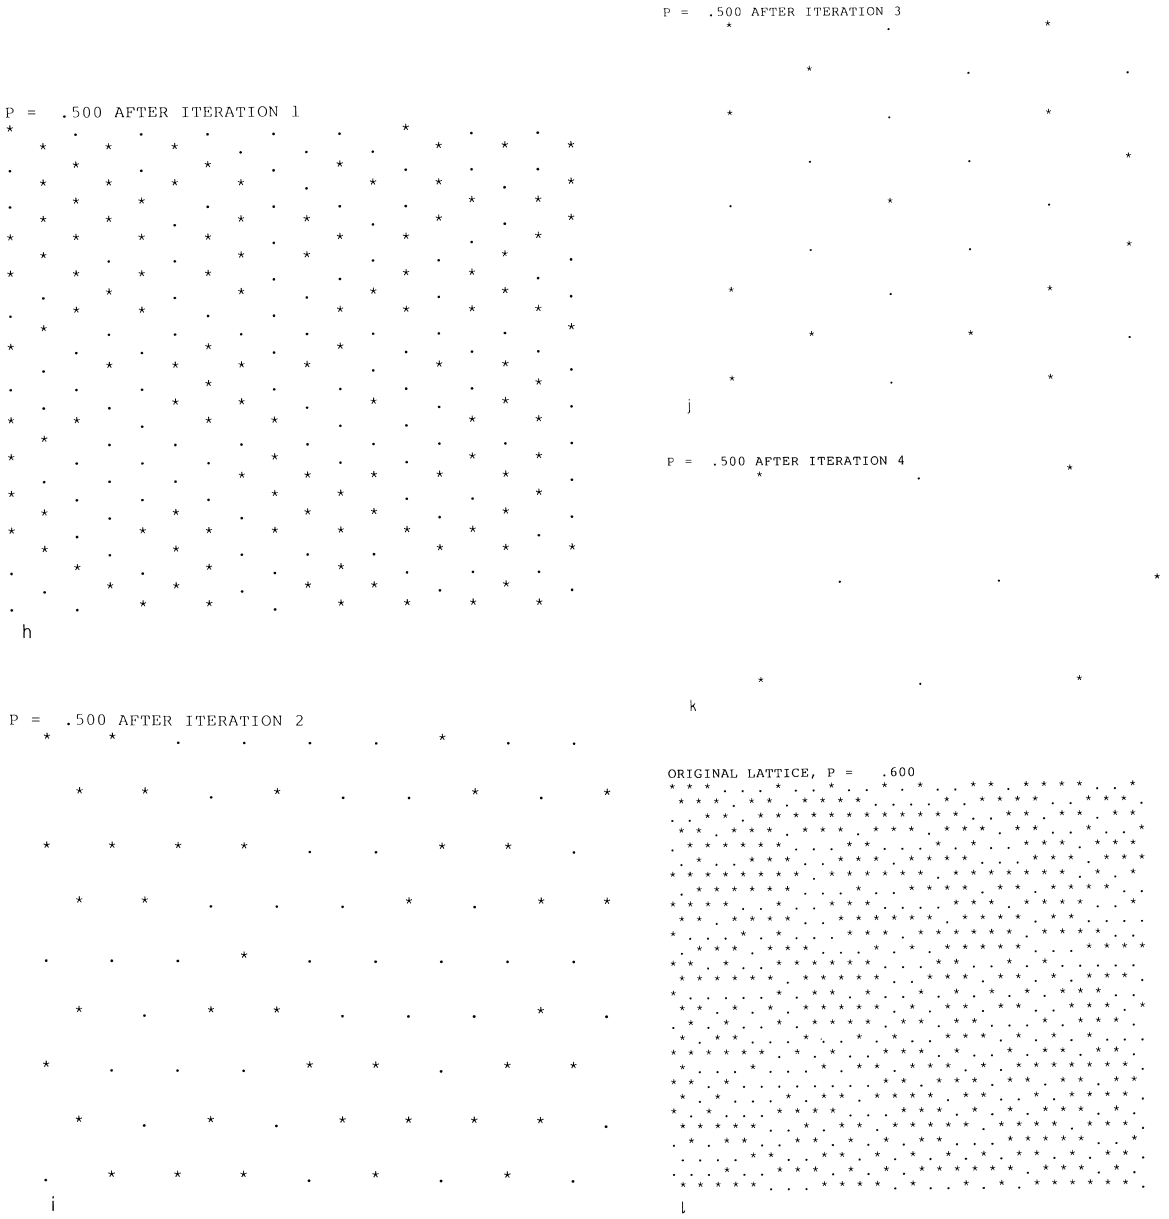

FIGURE 8 (*Continued*)

These scaling theories of percolation seem quite well confirmed by computer or laboratory experiments. For example, at the percolation threshold the cluster numbers n_s follow the simple power law $s^{-\tau}$ predicted by Eq. (11), as Fig. 9 indicates. In two dimensions there are good arguments, though no mathematically rigorous proof, that the critical exponents of percolation are rational numbers like $\nu = \frac{4}{3}$. Similar rational exponents also arise in many models for magnets and fluids where the two-dimensional exponents are known exactly. In three dimensions, no exact exponent is known, either for percolation or for magnets and fluids.

IV. KINETIC ASPECTS OF PERCOLATION

In this section we deal with percolation processes rather than percolation structures. Thus, we consider time-dependent phenomena connected with percolation.

A certain numerical method of building a percolation cluster by computer simulation can be interpreted as a time-dependent process. One starts with a given isolated site. Then one looks at the shell of neighbors surrounding that site and determines for each neighbor whether that site is occupied or empty; this process completes the first time step. In the second time step, one looks at the neighbors

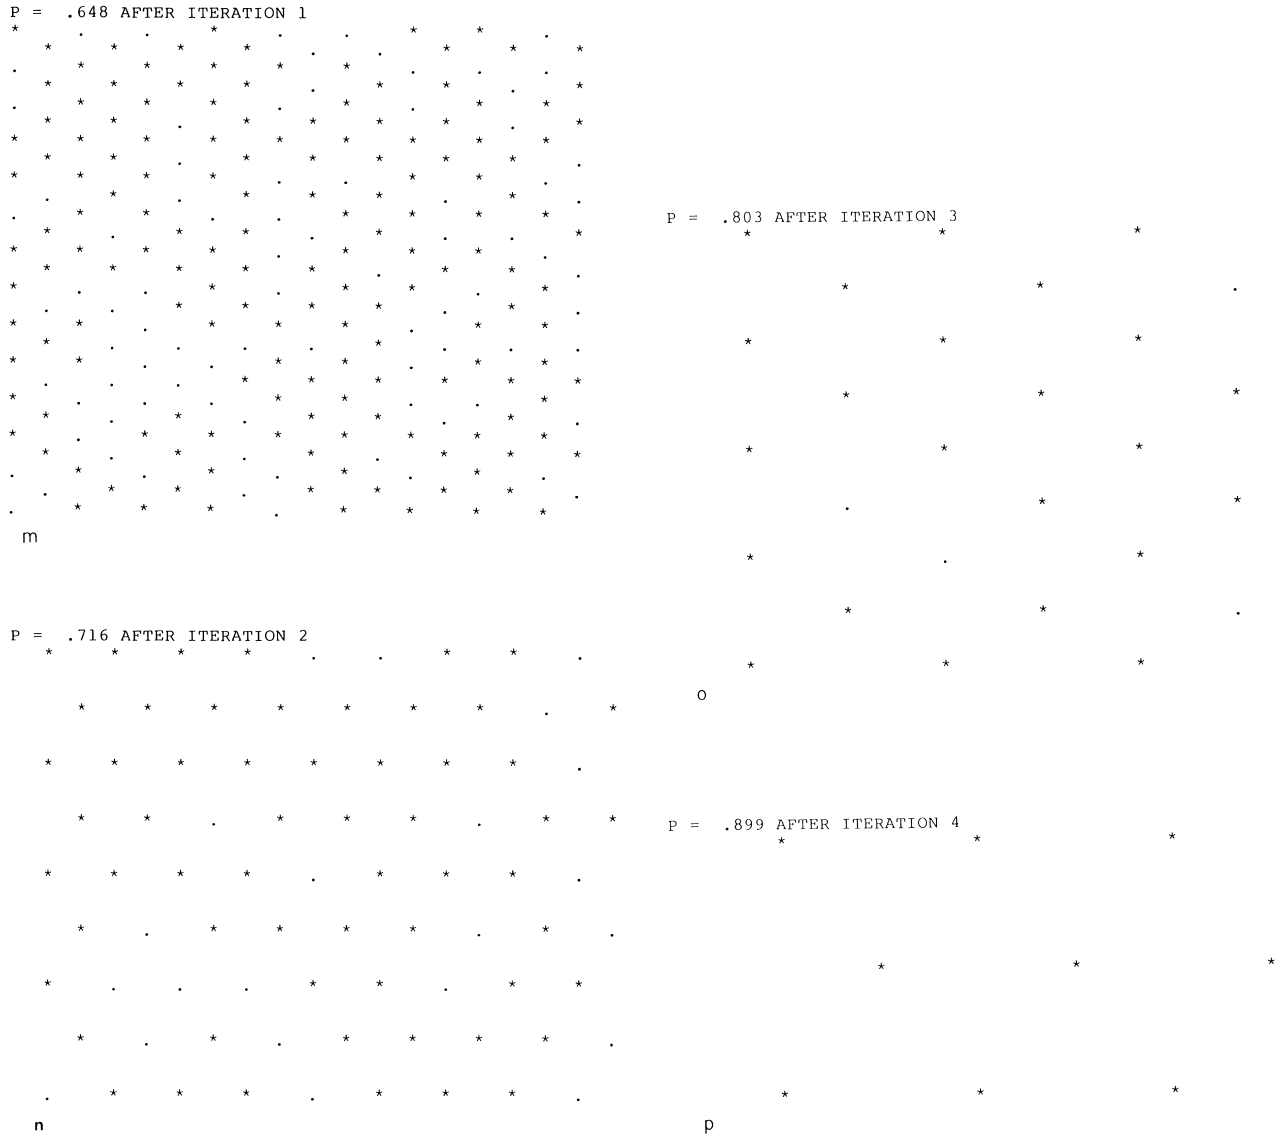

FIGURE 8 (*Continued*)

of the occupied sites that were not visited before, and so on. Once a site is identified as empty or occupied, it will always have this status during the growth process. In this way one cluster of s sites is created with a probability proportional to $n_s s$. In addition, one can count how many time steps were needed to build this cluster. For example, to build a large two-dimensional cluster of s sites, one needs a time

$$t_s \propto s^{0.6} \propto R_s^{1.1} \tag{14}$$

at the percolation threshold. In this time-dependent interpretation, percolation can be used as a model for the spread of epidemics or forest fires. At any given time, however, the cluster structure is that of random percolation, as described in the previous section. We restrict ourselves in this section to those kinetic percolation models that lead to the same static behavior as random percolation. The time t can also be interpreted as the "chemical" or "topological" distance in the sense of the shortest connection of a point with the origin, with all steps in between taken within the cluster.

A much more extensively studied transport property of percolation is the conductivity of random resistor networks. Imagine every occupied site (or bond) in the site (or bond) percolation problem to be a conductor, and every empty site or bond to be an insulator. Electric currents can flow only between neighboring conductors. The purpose of such a network is to model the electric properties of real

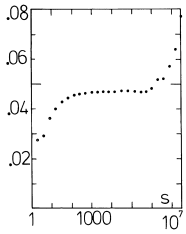

FIGURE 9 Semilogarithmic plot, versus s, of the number of clusters containing at least s sites, multiplied by $s^{\tau-1} = s^{96/91}$, at the site percolation threshold $p = .5927$ of a $160{,}000 \times 160{,}000$ square lattice with periodic boundary conditions. Each site took on average ~ 3 μsec on an IBM 3081 computer. According to the scaling assumption [Eq. (11)] $n_s \propto s^{-\tau}$, the quantity plotted here should approach a plateau for large s. The deviations for the largest cluster sizes come from the boundaries or inaccuracies in p_c (or both).

alloys of metals with insulators, the flow of fluids through porous rocks, and so on. This random resistor network has a conductivity Σ, which is zero for $p < p_c$ and nonzero for $p > p_c$, since only in the presence of an infinite network of neighboring conductors can electric charges flow from one end of the sample to the other. For p approaching the threshold p_c from above we define a new critical exponent μ through

$$\Sigma \propto (p - p_c)^{\mu} \tag{15}$$

Since at present the relation between μ and the static critical exponents like β and γ is unclear, we listed this exponent μ in Table II as if it were independent of the others. At the threshold $p = p_c$, in a finite system of linear dimension L the conductivity varies as $L^{-\mu/\nu}$, entirely analogous to Eq. (6) for the percolation probability: $P_\infty = M(L)/L^d \propto L^{-\beta/\nu}$.

One can also replace the conductors in the above random resistor network by superconductors (zero resistivity) and the insulators by resistors. Then the conductivity is infinite for $p > p_c$ due to the infinite superconducting cluster. The conductivity therefore diverges if p approaches p_c from below. The exponent for this divergence, often called s in the literature, equals μ in two dimensions and is ~ 0.75 in three.

The dynamic aspect of the conductivity becomes clearer if one looks at diffusion processes. Let us put some particle, or "walker," on an occupied site in the site percolation problem. At every time step, the walker selects randomly one of its nearest neighbors. If that neighbor is occupied, then the walker moves there; otherwise, it stays where it is. Then, in the next time step, the walker again selects a random neighbor of its current site and moves there if it is occupied. Repeated again and again, this process is like an ant in labyrinth. Many different "ant" investigations have been undertaken since then.

If all sites are occupied ($p = 1$), the above process is the usual diffusion process of a random walker on a regular lattice; the averaged squared distance traveled in time t is $R^2 = t$. This rms distance R (as the crow flies) must be distinguished from the cluster radius R_s or the renormalization function $R(p)$ of the preceding section and is also, of course, different from the chemical distance, the shortest path connecting the present site with the origin of the walk. The relation between the time t (number of steps) and the averaged distance R can be generally written as

$$t \propto R^{d_w} \tag{16}$$

with d_w representing the fractal dimensionality of the random walk. For usual diffusion (at $p = 1$) one has simply $d_w = 2$. In other words, we identify here the "mass" M of Eq. (4) with time t, a similarity that is particularly plausible if the walk is taken as a model for polymers.

If nearly all sites are empty ($p \to 0$), most walkers will start on an isolated occupied site where they cannot move at all: $R = 0$. For all $p < p_c$, only finite clusters exist, and R thus cannot increase to infinity for time $t \to \infty$. More precisely, the ant species defined above visits all sites of a finite cluster equally often, if given enough time. Thus, ants starting on clusters with s sites will walk a distance R of the order of the cluster radius R_s. An ant starts on such an s cluster with probability $n_s s$ since for the origin of a walk a large cluster is selected more often than a small cluster. Thus, R^2 approaches for long times below p_c a limit proportional to $\Sigma_s R_s^2 n_s s$. The scaling assumptions of the previous section predict this sum to diverge for $p \to p_c$:

$$R^2 \propto (p_c - p)^{-m}, \qquad m = 2\nu - \beta \tag{17}$$

This static limit was confirmed by accurate computer simulations after initial difficulties were overcome.

For p above p_c but below unity, the many holes in the infinite network slow down the diffusion of the walking ant: $R^2 < t$. Moreover, if the walk starts on a finite cluster, which it may still do even above p_c, the distance will again be limited by the cluster radius. Thus, the ant still diffuses, $R^2 \propto t$, but the diffusivity R^2/t is diminished compared with the pure case, $p = 1$. If p approaches p_c from above, this diffusivity goes to zero as $(p - p_c)^{\mu}$, since Einstein predicted diffusivities to vary as the conductivity [Eq. (15)]. (The current density is proportional to the velocity and the density of charge carriers. The velocity is the product of mobility and electric field. The ratio of current density to electric field is the conductivity. According to Einstein the mobility varies as the diffusivity.) Thus, we have for very long times near the threshold

$$R^2 \propto (p - p_c)^{\mu} t \tag{18a}$$

If we restrict the starting point to be on the infinite network only, and no longer on any occupied site, then the finite clusters no longer enter the average and the distance increases by a factor $1/P_\infty \propto (p - p_c)^{-\beta}$:

$$R^2 \propto (p - p_c)^{\mu-\beta} t \tag{18b}$$

Both types of averages, diffusion only on the infinite network or anywhere on the lattice, have been investigated by computer simulations and were found to agree with the above predictions.

Similar to the scaling assumptions [Eqs. (3), (6), and (8)] we may postulate

$$R^2 = t^{2k} f_\pm(t/t_\xi) = t^{2k} \tilde{f}\big((p - p_c)t^x\big) \tag{19a}$$

with a characteristic time

$$t_\xi \propto (p - p_c)^{-1/x} \tag{19b}$$

The scaling function $\tilde{f}(y)$ varies asymptotically in such a way that Eq. (18a) is recovered for large positive argument y and Eq. (17) for large negative y. This requirement leads to

$$2k = mx; \quad x = 1/(m + \mu); \quad m = 2\nu - \beta \tag{20a}$$

with the asymptotic behavior $f \propto y^\mu$ and $\propto(-y)^{-m}$ for large positive and negative arguments y, respectively, provided that the random walk starts on any occupied site. If instead it starts on the infinite cluster only, we have to match Eq. (18b) instead of Eq. (18a) in the diffusion regime. Denoting the corresponding exponents and scaling functions by primes, one finds

$$2k' = 2\nu x \tag{20b}$$

with the same $x' = x$ but a different scaling function $\tilde{f}'(y)$ varying as $y^{\mu-\beta}$ for $y \to \infty$.

Right at the percolation threshold $p = p_c$, the scaling functions $\tilde{f}$ and $\tilde{f}'$ approach some constants for zero argument, and one has

$$R \propto t^k \propto t^{(\nu-\beta/2)/(2\nu+\mu-\beta)} \tag{21a}$$

for walks anywhere at the percolation threshold, and

$$R \propto t^{k'} \propto t^{\nu/(2\nu+\mu-\beta)} \tag{21b}$$

for walks on the largest cluster at $p = p_c$. Thus, the squared distance R^2 does not increase linearly with t nor does it approach a constant limit for large times. Instead, it increases with some smaller power of the time, an effect also called anomalous diffusion.

From Eqs. (19b) and (20b) we see that the characteristic time varies as $t_\xi \propto \xi^{1/k'}$; it is the time to travel a distance ξ on the infinite cluster [Eq. (21b)]. The exponent $1/k'$, which is equal to the anomalous fractal dimension of the random walk on the largest cluster, is analogous to the dynamic critical exponent z in second-order phase transitions. Combined with Eq. (4), the volume spanned by the sites visited within time t is of the order $R^D \propto t^{Dk'}$. In comparison with the same quantity for random walks on the full ($p = 1$) lattice, $t^{d/2}$, the combination $d_s = 2Dk'$ has been called the fracton or spectral dimension. Numerically, d_s seems to be very close (although not exactly equal) to $\frac{4}{3}$ for percolation clusters in $d > 1$ dimensions. Were this Alexander–Orbach relation, $d_s = \frac{4}{3}$, exact, it would imply an explicit dependence of μ on the static exponents β and ν. However, because this seems to be only an approximation and no alternative relations are at present generally accepted, the critical exponent μ (and therefore k, k', or d_s) is regarded here as an independent new exponent. Possible relations between the dynamic and static exponents were the subject of much research.

Computer simulations have confirmed the above scaling theory within their numerical errors. For too short times, the exponents "measured" for k or k' are too high; a million time steps on lattices containing millions of sites might be necessary to get the three-dimensional exponent $k = 0.20$ or $k' = 0.27$ with good accuracy (Fig. 10). In two dimensions these systematic deviations for short times are smaller, and $k = 0.33$ or $k' = 0.35$ can be determined more accurately. The measurement of the diffusivity slightly above p_c [Eq. (18a)] is particularly difficult, since Eq. (19) tells us that the normal diffusion behavior can be observed only for times much longer than the characteristic time $\propto (p - p_c)^{\beta-\mu-2\nu}$. For times much shorter than this characteristic time, one observes the same anomalous diffusion as for $p = p_c$, even if p is slightly different from p_c.

As in biology, one can study more than one ant species. It does not matter much if the diffusing ant, having tried to move in a prohibited direction, immediately tries another one before time goes by. (In the earlier definition time goes by even after an unsuccessful attempt.) For this species the diffusion process is faster, but the critical exponents seem to remain the same (same dynamic universality class). Exponent oscillations periodic in the logarithm of time occur

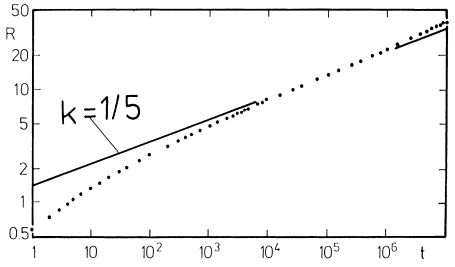

FIGURE 10 Distance R versus time t for "ant" diffusion at the percolation threshold of a 256^3 simple cubic lattice. Each step took $\sim$0.2 μsec per "ant" on a Cyber 205 vector computer. The scaling assumption [Eq. (19a)] predicts for large times $R \propto t^{0.20}$, as symbolized by the straight line in this log–log plot. The deviations for very large t are due to the finite lattice size.

if a bias is introduced, due to which one direction is chosen more often than the others. This bias corresponds to an electric field, if we identify the random walker with an electron in a disordered material; however, in that case interactions between electrons may be important and must be studied by computer simulations. A magnetic field incorporated into the "ant" model of electron diffusion does not seem to change the universality class. "Butterflies" can jump to more distant sites and not only to nearest neighbors. Finally, "termites" are diffusing random walkers on a superconductor-resistor network, and "parasites" are ants diffusing on lattice animals, as defined earlier.

V. MODIFICATIONS AND GENERALIZATIONS

The butterfly example suggests that in percolation one need not look only at clusters defined via nearest-neighbor connections. In the square site problem, when one allows sites to be connected to a cluster if they are nearest or next nearest neighbors, then the percolation threshold is lowered to $1 - p_c(\text{nn})$, where $p_c(\text{nn}) = 0.593$ is the nearest-neighbor threshold discussed so far. For other lattices no such simple relation is known. Of particular interest is the limit of long-range connections allowed between cluster sites, when $p_c \to 0$.

In all previous examples the sites (or bonds) were occupied randomly. There may also be correlations between the sites. For example, neighboring occupied sites might be bound together with a certain energy $-J$, which favors such a configuration with a probability $\propto \exp(-J/k_B T)$, where k_B is Boltzmann's constant and T the absolute temperature. Then we have the clustering problem of the lattice gas or Ising model. It seems that its critical exponents are the same as those for random percolation except when phase separation occurs due to the site–site interaction J.

For normal bond percolation, a bond once formed connects its two ends. One may instead define a bond as an arrow in which one end is connected with the other, like a one-way street, but not backward. If the preferred directions are the same throughout the lattice we get the different behavior of "directed percolation."

Among the kinetic generalizations of percolation we mention a polymerization model in which diffusion of "initiators" forms macromolecules: Chemical bonds are formed along the path of these catalysts, but not more than f bonds can emanate from one site.

More drastically different from usual percolation are diffusion-limited aggregates in which single particles diffuse from far away to a cluster, stick to it, and thus let the cluster grow. In cluster–cluster aggregation models, whole clusters diffuse toward one another and thus form larger clusters. Some aspects of this approach are well described by the Smoluchowski equation, formulated at the beginning of this century, in which the coagulation probability for two different cluster sizes s and s' is simply the product $n_s n_{s'}$, multiplied by a coefficient $K(s, s')$; by suitable assumptions for $K(s, s')$ one can reproduce at least one of the percolation exponents.

Fast viscous flow is represented by this diffusion-limited aggregation model. However, when water is injected very slowly into a porous medium filled with oil, the capillary forces dominate the viscous forces, and the dynamics is determined by the local pore radius r. Capillary forces are strongest at the narrowest pore necks. It is consistent with experimental observations to represent the displacements as a series of discrete jumps in which at each time step the water displaces oil from the smallest available pore.

In a lattice model, one assigns random numbers r in the range [0, 1], representing the pore sizes, to the sites. Growth sites are identified as the sites that belong to the "defending" fluid and are neighbors to the "invading" fluid. At every time step the invading fluid is advanced to the growth site that has the lowest random number r.

The invasion into new sites ends when the "invader" reaches the other end of the sample. For easily compressible fluids, the invaded region at that stage has the same fractal structure as the usual infinite percolation cluster. For incompressible fluids in two dimensions the amount of the trapped "residual oil" is larger, such that the fractal dimension of the invaded region is diminished to about 1.82.

VI. OTHER DEVELOPMENTS

During the second half of the 1980s it became clear that random *elastic* networks and random resistor networks may behave quite differently. The electrical conductivity of random networks of resistors and insulators vanishes at the percolation threshold with an exponent t (often also called μ). If we replace the resistors by elastic springs and omit the insulating bonds, the resulting mechanical network may become unstable against shear forces even if an infinite cluster of geometrically connected springs exists. This central-force spring model can be made more realistic by including bond-bending forces, so that, for example, on a honeycomb lattice the energy is lowest if neighboring bonds have angles of 120 or 240 degrees. Then the threshold for mechanical stability agrees with the percolation threshold in the dilute network, and Young's elastic modulus vanishes with an exponent close to the scaling prediction $t + 2\nu$, which is nearly 4 in two and three dimensions. Entropic effects are still neglected in this model and could dominate in real polymer networks at finite temperatures.

Multifractality has been observed in many parts of statistical physics, including percolating networks. When we look at moments of the cluster size distribution like $\sum_s s^q n_s$ and if we know the critical exponents of these moments for $q = 2$ and 3, then scaling theory predicts correctly the critical exponents for all larger q. The exponent simply grows linearly with q. This is not so if we look at the above random resistor networks and the moments of the voltage distribution, $\sum_b V_b^q$, where the sum goes over all bonds of the random network and V_b is the voltage drop across bond b. For these moments, $q \to 0$, $q = 2$, $q = 4$ corresponds to the size of the current-carrying backbone, the resistance, and the noise, respectively. In this case, knowledge of the critical exponents for some q values does not predict the exponents for all other positive q by a linear relation as in standard scaling theory. Instead, an infinite hierarchy of apparently independent exponents appears.

VII. CONCLUSION

We have seen that percolation, though very simple to define, has a rather rich behavior. This article has centered on its critical exponents, where two exponents (e.g., ν and D) determine the static behavior and a third (e.g., μ) seems necessary (at least presently) for the dynamic aspects. Thus, the fractal dimension D of the large clusters at the percolation does not completely determine the critical exponents, but it is certainly an important parameter for studying similarities and differences between percolation and, say, the aggregates of the preceding section.

Percolation is a good way to enter modern research without too much background in physics or mathematics. It can be used, for example, to teach scaling laws, as well as renormalization group and critical phenomena.

Perturbation Theory

Carl M. Bender
Washington University

GLOSSARY

Asymptotic matching A powerful perturbative method for obtaining accurate global approximations to the solution of singular perturbative problems for differential equations.

Boundary-layer theory A singular perturbation technique for solving a boundary-value problem for a differential-equation whose highest derivative is multiplied by ϵ.

Multiple-scale perturbation theory The most general kind of perturbation theory; this theory is based on the idea that problems exhibit various kinds of phenomena on different time scales (or distance scales). Multiple-scale perturbation theory was developed by astronomers who used it to calculate the effect of small perturbations on periodic systems.

Padé summation A particularly powerful summation method in which a formal power series, which may be divergent, is truncated and then converted to a rational fraction called a Padé approximant. The Padé approximant is designated $P_N^M(\epsilon)$. The Padé approximants converge to a limit as M and N approach ∞ even though the power series may be divergent.

Perturbation coefficients The coefficients, a_n, in the perturbation series.

Perturbation parameter A small parameter, ϵ, that, when introduced into the hard problem, converts the hard problem to an infinite sequence of relatively easy problems, each of which can be solved analytically.

Perturbation series A formal series in powers of the perturbation parameter, ϵ, that represents the answer to a hard problem.

Perturbation theory A large collection of analytical

techniques for obtaining highly accurate solutions to mathematical problems that do not have simple exact analytical solutions.

Regular perturbation problem A perturbation problem for which the perturbation series is a Taylor series; that is, the perturbation series is a series in integer powers of ϵ and this series has a nonzero radius of convergence.

Singular perturbation problem A perturbation problem for which the perturbation series is not a Taylor series and/or it does not a have nonzero radius of convergence.

Summation theory A collection of methods for accelerating the convergence of a slowly converging perturbation series and/or assigning a meaningful value to a divergent perturbation series.

Uniform approximation An asymptotic perturbative approximation valid on an extended interval.

Unperturbed problem The problem obtained by setting the perturbation parameter, ϵ, equal to zero.

WKB theory A singular perturbation technique, named after Wentzel, Kramers, and Brillouin, that is used it to construct perturbative solutions to a Schrödinger equation in which the highest derivative is multiplied by ϵ.

PERTURBATION THEORY is a large collection of analytical techniques for obtaining highly accurate solutions to mathematical problems that do not have simple exact analytical solutions. Perturbative approaches fall into two classes known as *regular* and *singular* methods. In this article the basic ideas of perturbation theory are explained and illustrated by the use of examples.

I. PERTURBATION THEORY

Perturbation theory is a large collection of powerful analytical methods for constructing highly accurate approximations to the solution of a hard mathematical problem. (By a *hard problem* we mean one for which there is no simple exact closed-form analytical solution.)

There are two possible ways to attack a hard problem; one can use numerical methods or perturbative methods. The advantage of perturbative methods is that they are analytical and therefore reveal very quickly and easily the mathematical structure and behavior of the solution. Perturbation theory works by reducing a hard problem to an infinite sequence of relatively easy problems that can be solved by elementary paper-and-pencil calculations. There are three fundamental steps in the perturbative solution of a hard problem:

i. Introduce a small parameter ϵ, called a *perturbation parameter*, into the hard problem. Inserting the parameter ϵ converts the original hard problem to an *infinite class* of hard problems, one for each value of ϵ. It is crucial, however, that for the special value $\epsilon = 0$ the problem be analytically solvable. The problem corresponding to $\epsilon = 0$ is called the *unperturbed* problem. There may be many ways to introduce the perturbation parameter ϵ and it may require art and insight to decide on the best way to do so.

ii. Assume that the solution to the infinite class of hard problems parameterized by ϵ has the form of a *perturbation series*, which is a formal power series in ϵ:

$$\text{solution}(\epsilon) = \sum_{n=0}^{\infty} a_n \epsilon^n.$$

(This strong assumption is not always valid. The solution may take the more general form of a power series multiplied by a singular function of ϵ such as $e^{1/\epsilon}$.) Then one calculates the *perturbation coefficients* a_n in the perturbation series. By assumption, the first coefficient a_0 in the series can be found analytically because it is the solution to the unperturbed problem. Typically, the higher coefficients can be found recursively, with each subsequent coefficient requiring more calculation than the previous coefficient. In general, one never expects to find all of the coefficients in the perturbation series; rather, one calculates enough coefficients to give an accurate representation of the solution. The more coefficients that one calculates, the more accurate the representation.

iii. The final step is to set $\epsilon = 1$ in the perturbation series to recover the solution to the original hard problem. While the calculation of the perturbation coefficients is a routine procedure, this step may require great subtlety because the perturbation series may be divergent at $\epsilon = 1$. Thus, to complete this final step, one may have to perform a *summation* of the perturbation series, which is a way to obtain the finite solution that is represented by the divergent perturbation series. Summation theory is crucial; without it, perturbation methods would be useful only for a small and mostly uninteresting class of problems. For a general discussion of perturbative methods see Bender and Orszag (2000), Cole (1968), Kevorkian (1981), and Nayfeh (1973, 1981).

II. ELEMENTARY ILLUSTRATIVE EXAMPLE

To illustrate the three steps of perturbation theory we consider the problem of finding the real root of the quintic polynomial equation

$$x^5 + x = 1.$$

We consider this problem to be a *hard problem* because there is no analytical quadrature formula for the roots of a polynomial whose degree is higher than 4. Newton's method gives the numerical value of the real root as

$$x = 0.75487767\cdots.$$

The first step in solving this problem perturbatively is to introduce the perturbation parameter ϵ in such a way that the unperturbed problem is exactly solvable when $\epsilon = 0$. A simple way to insert the parameter ϵ is to have it multiply the term x in the polynomial:

$$x^5 + \epsilon x = 1. \tag{1}$$

The roots of this class of polynomials are now functions of the parameter ϵ. Note that when $\epsilon = 0$, the polynomials reduce to $x^5 = 1$, whose real root can be found exactly: $x(0) = 1$.

The second step is to seek a solution for the real root in the form of a power series in ϵ:

$$x(\epsilon) = \sum_{n=0}^{\infty} a_n \epsilon^n. \tag{2}$$

Note that the first term in this series is $a_0 = 1$ because the solution to the unperturbed problem is $x(0) = 1$. If we substitute this power series into the polynomial (1), we obtain a series in powers of ϵ, whose coefficients are required to vanish. Each of these coefficients is an increasingly complicated algebraic equation, the first four of which read

$$\begin{aligned} 5a_1 + 1 &= 0, \\ 5a_2 + 10a_1^2 + a_1 &= 0, \\ 5a_3 + 20a_1a_2 + a_2 + 10a_1^3 &= 0, \\ 5a_4 + 20a_1a_3 + a_3 + 10a_2^2 + 30a_1^2a_2 + 5a_1^4 &= 0. \end{aligned}$$

While the original quintic polynomial equation cannot be solved analytically, each member of this sequence of algebraic equations is extremely easy to solve in closed form. Thus, perturbation theory has reduced a hard problem to an infinite sequence of easy problems. The first few perturbation coefficients are

$$\begin{aligned} a_1 &= -\frac{1}{5}, \quad a_2 = -\frac{1}{25}, \quad a_3 = -\frac{1}{125}, \\ a_4 &= 0, \quad a_5 = \frac{21}{15625}, \quad a_6 = \frac{78}{78125}, \end{aligned} \tag{3}$$

and so on.

The third step in the perturbative solution is to substitute the perturbation coefficients into the perturbation series (2) and to sum the series at the value $\epsilon = 1$. Using the coefficients in (3), we obtain the sixth-order result

$$x(\epsilon) = 1 - \frac{1}{5}\epsilon - \frac{1}{25}\epsilon^2 - \frac{1}{125}\epsilon^3 + \frac{21}{15625}\epsilon^5 + \frac{78}{78125}\epsilon^6 + \cdots. \tag{4}$$

Can we set $\epsilon = 1$ and sum the series to get an accurate value for the solution $x(1)$ to the original problem? For this elementary problem there is an easy way to answer this question because there is a closed-form expression for the nth perturbation coefficient:

$$a_n = \frac{\Gamma[(4n-1)/5]}{5\,\Gamma[(4-n)/5]n!}. \tag{5}$$

(Note that it is very rare to be able to find a simple, closed-form expression for the nth perturbation coefficient.) From (5), we know that the radius of convergence of the perturbation series is $1.64938\cdots$. Thus, we expect the perturbation series to yield a good approximation for the real root, and setting $\epsilon = 1$ in (4) gives the sixth-order perturbative result

$$x(0) = 0.75434\cdots,$$

which agrees with the value of the root found by Newton's method to a relative error of 0.07%. This completes the perturbative treatment of the problem. Clearly, we can determine the root to any desired accuracy if we calculate enough of the perturbation coefficients.

A. Same Problem, Different Approach

Now let us see what happens if we introduce the perturbation parameter ϵ in a different way in the first step of the perturbative solution. Let us insert the parameter ϵ so that it multiplies the x^5 term rather than the x term in the polynomial:

$$\epsilon x^5 + x = 1. \tag{6}$$

Again, the roots of this class of polynomials are functions of the parameter ϵ and when $\epsilon = 0$, the root is exactly $x(0) = 1$.

The second step in the perturbative solution is to find the coefficients b_n in the perturbation expansion

$$x(\epsilon) = \sum_{n=0}^{\infty} b_n \epsilon^n. \tag{7}$$

Substituting (7) into the polynomial equation (6) again gives a sequence of easy-to-solve algebraic equations. The sixth-order perturbation series has the form

$$x(\epsilon) = 1 - \epsilon + 5\epsilon^2 - 35\epsilon^3 + 285\epsilon^4 - 2530\epsilon^5 + 23751\epsilon^6 - \cdots. \tag{8}$$

Note that the perturbation series coefficients in (8) grow rapidly with increasing n in contrast with the perturbation

series coefficients in (4), which decay with n. It is possible to determine the growth of the series coefficients because, once again, it is possible to find a closed-form expression for the perturbation coefficients b_n:

$$b_n = (-1)^n \frac{(5n)!}{(4n+1)!\,n!}. \tag{9}$$

From this result we determine that the radius of convergence of the perturbation series (8) is $\frac{256}{3125} = 0.08192$. Hence, if we attempt to evaluate the perturbation series at $\epsilon = 1$ to recover the value of the root by direct summation of the series, we will obtain a divergent answer because we are summing the power series outside of its circle of convergence. In fact, evaluating the series (8) at $\epsilon = 1$ gives the sixth-order prediction $x(1) = 21476$, which is a totally useless result for the real root at $0.75434\cdots$.

It may thus appear that the divergence of the perturbation series prevents us completing the third step in the perturbation procedure. Fortunately, we can overcome this difficulty by using a summation procedure to sum indirectly the perturbation series outside of its circle of convergence.

III. SUMMATION THEORY

Expressing the solution to a perturbation problem as a formal series in powers of ϵ is useful in the second step of perturbation theory because, as we have seen, collecting the coefficients of powers of ϵ yields an infinite sequence of easy-to-solve problems for the perturbation coefficients. However, once the second step of perturbation theory is completed we often find that the perturbation series is not an appropriate way to represent the solution to the perturbation problem because the value $\epsilon = 1$ is larger than the radius of convergence of the series. We emphasize that it is wrong to infer from the divergence of the perturbation series does not exist at $\epsilon = 1$. Indeed, the solution may exist even though the Taylor series representation of the solution about the point $\epsilon = 0$ diverges.

In order to perform the third step of perturbation theory, we must first find a better way to represent the solution for large values of ϵ. Of the many possible ways to do this, a commonly used technique is to rewrite the Taylor series $\sum_{n=0}^{\infty} a_n \epsilon^n$ in the form of a continued fraction of the form

$$\cfrac{c_0}{1 - \cfrac{c_1\epsilon}{1 - \cfrac{c_2\epsilon}{1 - \cfrac{c_3\epsilon}{1 - \cdots}}}}.$$

Note that the Taylor coefficients a_n uniquely determine the continued-fraction coefficients c_n via a sequence of invertible equations:

$$\begin{aligned} c_0 &= a_0, \\ c_1 &= \frac{a_1}{a_0}, \\ c_2 &= \frac{a_0 a_2 - a_1^2}{a_0 a_1}, \\ c_3 &= \frac{a_0 a_1 a_3 - a_0 a_2^2}{a_0 a_1 a_2 - a_1^3}, \end{aligned}$$

and so on. (These equations are *invertible* because given the coefficients a_n, we can calculate the coefficients c_n, and given c_n we can calculate a_n.) Note that if we use these continued-fraction coefficients and calculate the Taylor expansion of the continued fraction in powers of ϵ, then we recover the Taylor series $\sum_{n=0}^{\infty} a_n \epsilon^n$.

The advantage of using a continued-fraction representation in place of a Taylor series is that the continued fraction often converges in a much larger region of the complex-ϵ plane than the Taylor series. Rather than converging in a circle, a continued fraction often converges in the entire complex plane or the entire complex plane except for a cut (a ray emanating from the origin).

If we truncate the continued-fraction representation after the coefficient c_n and rationalize the result, we obtain a ratio of two polynomials of degree M in the numerator and degree $N = M$ or $N = M + 1$ in the denominator (depending on whether n is even or odd), where $M + N = n$. This rational fraction is called the (M, N) Padé approximant of the Taylor series and it is designated $P_N^M(\epsilon)$.

To summarize, by converting a Taylor series to a Padé sequence, we replace the sequence of partial sums of the Taylor series

$$\sum_{n=0}^{K} a_n \epsilon^n \qquad (K = 0, 1, 2, 3, \cdots)$$

by a sequence of Padé approximants called the *main sequence*:

$$P_0^0(\epsilon),\ P_0^1(\epsilon),\ P_1^1(\epsilon),\ P_1^2(\epsilon), \cdots.$$

This padé sequence often converges for values of ϵ outside the circle of convergence of the Taylor series. Padé approximants are used routinely when one encounters slowly convergent or divergent power series. However, from a theoretical point of view much work needs to be done; no general and comprehensive theory concerning the convergence of Padé approximants exists. Padé summation is only one of many summation techniques available; another useful technique is called the Wynn epsilon algorithm method.

To illustrate Padé summation we use it to sum the perturbation series in (8). Recall that a direct summation of the first seven terms in this Taylor series evaluated at $\epsilon = 1$

gives the useless result $x(1) = 21476$. However, if we first convert the Taylor series to a (3,3)-Padé approximant and then evaluate this approximant at $\epsilon = 1$, we obtain the result $x(1) = 0.76369$, which agrees with the exact numerical answer to a relative error of 1.2%.

There are many good references on divergent series, acceleration of convergence, Padé theory, and continued fractions; see, for example, Borel (1975) and references therein.

IV. PERTURBATIVE SOLUTION OF DIFFERENTIAL EQUATIONS

Perturbation theory can be used to solve nontrivial differential-equation problems. Consider, for example, the Schrödinger equation initial-value problem

$$y''(x) = Q(x)y(x), \quad y(0) = 1, \quad y'(0) = 0, \qquad (10)$$

where $Q(x)$ is an arbitrary continuous function of x. This is a *hard problem* because there is no quadrature solution for a Schrödinger equation. However, it is extremely easy to solve this problem using perturbative methods. We introduce the parameter ϵ so that it multiplies the function $Q(x)$:

$$y''(x) = \epsilon Q(x)y(x), \quad y(0) = 1, \quad y'(0) = 0 \qquad (11)$$

and seek a solution in the form of a series in powers of ϵ:

$$y(x) = \sum_{n=0}^{\infty} y_n(x)\epsilon^n, \qquad (12)$$

where we incorporate the initial conditions by requiring that

$$\begin{aligned} y_0(0) &= 1, \\ y_n(0) &= 0 \quad (n \geq 1), \\ y_n'(0) &= 0 \quad (n \geq 0). \end{aligned}$$

Note that we have introduced ϵ in such a way that it is possible to solve the unperturbed problem in closed form. The solution is simply

$$y_0(x) = 1.$$

Solving the higher-order problems is equally easy. The function $y_n(x)$ is obtained by integrating the product $Q(x)y_{n-1}(x)$ twice:

$$y_n(x) = \int_0^x ds \int_0^s dt\, Q(t)y_{n-1}(t).$$

Recovering the function $y(x)$ from the perturbation series (12) is straightforward because, as we will now show, this series is rapidly convergent if $Q(x)$ is continuous. Let M be the maximum value of $|Q(x)|$ on the interval $0 \leq x \leq a$. Then, $|y_n(x)|$ is bounded by $a^n M^n/(2n)!$. Hence, only a small number of terms in the series (12) are needed to calculate the value of $y(x)$ with extremely high precision.

For further references on Perturbation methods for differential equations see Kevorkian and Cole (1996) and O'Malley (1991).

V. UNUSUAL WAYS TO INSERT THE PERTURBATION PARAMETER

An interesting and surprising way to introduce the perturbation parameter ϵ is to have it measure the nonlinearity of a problem. To illustrate this idea, let us return to the polynomial equation considered in Section II. Rather than inserting ϵ so that it multiplies the x term or the x^5 term in the polynomial equation, let us insert ϵ into the *exponential*:

$$x^{1+\epsilon} + x = 1.$$

Note that when $\epsilon = 0$, this equation can be solved exactly and the solution for the real root is $x(0) = 1/2$.

We assume that the real root $x(\epsilon)$ of this equation has a perturbation expansion in powers of ϵ of the form in (2). We then find that after substituting this series into the polynomial equation and collecting powers of ϵ, the coefficients in this expansion are

$$\begin{aligned} a_0 &= \frac{1}{2}, \\ a_1 &= \frac{1}{4}\log 2, \\ a_2 &= -\frac{1}{8}\log 2, \\ a_3 &= -\frac{1}{48}\log^3 2 + \frac{1}{32}\log^2 2 + \frac{1}{16}\log 2, \\ a_4 &= \frac{1}{32}\log^3 2 - \frac{3}{64}\log^2 2 - \frac{1}{32}\log 2, \end{aligned}$$

and so on. It can be shown that the radius of convergence of this expansion is 1. Thus, we cannot recover the positive root of the original problem by setting $\epsilon = 4$ in the perturbation expansion and summing the perturbation series directly. However, if we first convert the perturbation expansion to a Padé sequence and evaluate the Padé approximants in the sequence at $\epsilon = 4$, we obtain extremely accurate numerical results. For example, the numerical value of the (3, 3) Padé approximant is 0.75448 (relative error of 0.05%) and the numerical value of the (6, 6) Padé approximant is 0.75487654 (relative error of 0.00015%).

Let us use this technique to solve a particularly difficult boundary-value problem for a nonlinear differential

equation known as the Thomas–Fermi equation. The boundary-value problem reads

$$y''(x) = \frac{y^{3/2}(x)}{\sqrt{x}}, \quad y(0) = 1, \quad y(\infty) = 0. \tag{13}$$

This problem is particularly important in physics because it describes the distribution of electrical charge in a nucleus. The objective is to find the value of $y'(0)$. A numerical analysis of this problem gives the result

$$y'(0) = -1.5880710\cdots. \tag{14}$$

To solve this problem perturbatively, we introduce the parameter ϵ into the exponent so that it measures the nonlinearity of the problem:

$$y''(x) = y(x)\left(\frac{y(x)}{\sqrt{x}}\right)^{\epsilon}, \quad y(0) = 1, \quad y(\infty) = 0. \tag{15}$$

Note that when $\epsilon = 0$, the exact solution to the problem is $y(x) = e^{-x}$, so that $y'(0) = -1$. We then assume that $y(x)$ has a formal perturbation expansion in powers of ϵ:

$$y(x) \;=\; e^{-x} + \sum_{n=1}^{\infty} y_n(x)\epsilon^n.$$

Substituting this expansion into the boundary-value problem (15), collecting powers of ϵ, and routinely calculating the coefficient functions $y_1(x)$, $y_2(x)$, $y_3(x)$, and so on gives an accurate result for $y'(0)$. Specifically, substituting $\epsilon = 1/2$ into the first-order perturbation expansion gives $y'(0) = -1.19259$ (25% relative error), substituting $\epsilon = 1/2$ into the second-order perturbation expansion gives $y'(0) = -1.38428$ (13% relative error), and substituting $\epsilon = 1/2$ into the third-order perturbation expansion gives $y'(0) = -1.47892$ (6.9% relative error). Furthermore, the (1,2) Padé of the third-order perturbation expansion reduces the error substantially and gives $y'(0) = -1.61629$ (1.8% relative error).

This technique of introducing the perturbation parameter ϵ into the exponent of a nonlinear problem (so that ϵ is a measure of the nonlinearity of the problem) is useful for solving a wide variety of nonlinear problems (the Blasius equation, the Korteweg-de Vries equation, the Duffing equation, and so on) (Bender *et al.*, 1991).

VI. REGULAR VERSUS SINGULAR PERTURBATION THEORY

All of the examples of perturbative problems we have considered so far are called *regular* perturbation problems. The identifying characteristic of a regular perturbation problem is that the perturbation series is a power series in integer powers of ϵ and that the power series has a nonzero radius of convergence. Thus, the perturbation series is a Taylor series. If the perturbation series is not a Taylor series and/or it does not a have nonzero radius of convergence, the perturbation problem is called a *singular* perturbation problem.

Roughly speaking, in a singular perturbation problem the limit $\epsilon \to 0$ is not smooth. Rather, one observes that as the perturbation parameter ϵ vanishes, there is an abrupt change in the character of the problem. Typically, a singular perturbation problem arises if the perturbation parameter ϵ is inserted into a differential equation so that it multiplies the highest derivative in the equation. Thus, as ϵ tends to 0, the order of the differential equation decreases and the solution to the lower-order differential equation is unable to satisfy all of the boundary conditions or initial conditions. Thus, the solution abruptly ceases to exist as $\epsilon \to 0$.

In a singular perturbation problem we often cannot use the term *unperturbed problem* because the solution to the problem with ϵ set to 0 may not exist. Instead, we refer to the first term in the perturbation expansion as the *leading-order* term. The leading-order term often ceases to exist in the limit $\epsilon \to 0$.

To illustrate the kinds of abrupt changes that may occur in the limit $\epsilon \to 0$ we consider two different boundary-value problems:

$$\epsilon y''(x) + y'(x) = 0, \quad y(0) = 0, \quad y(1) = 1, \tag{16}$$

whose exact solution is

$$y(x) = \frac{1 - e^{-x/\epsilon}}{1 - e^{-1/\epsilon}}, \tag{17}$$

and

$$\epsilon y''(x) + y(x) = 0, \quad y(0) = 0, \quad y(1) = 1, \tag{18}$$

whose exact solution is

$$y(x) = \frac{\sin(x/\sqrt{\epsilon})}{\sin(x/\sqrt{\epsilon})}. \tag{19}$$

Observe that as $\epsilon \to 0$ it is not possible to satisfy the boundary conditions in these problems. Thus, in both cases the exact solutions become discontinuous in this limit. However, in the first example, the exact solution only becomes discontinuous at a point (at $x = 0$). The localized region in which the solution becomes discontinuous is called a *boundary layer.* In the second example the solution becomes discontinuous on the entire region from $x = 0$ to $x = 1$ in this limit. Singular perturbation problems in which the solution becomes discontinuous in a narrow region are solved using a perturbative technique called *boundary-layer theory*. *WKB theory* is used to solve singular perturbation problems in which the solution becomes discontinuous throughout an extended region.

Boundary-layer theory and WKB theory require the use of a technique called *asymptotic matching*. Examples of applications of these perturbation theories are considered in Sections VII and VIII (Lagerstrom, 1988).

VII. BOUNDARY-LAYER THEORY

We explain and illustrate the ideas of boundary-layer theory in the context of a simple but general example. Consider the boundary-value problem

$$\begin{aligned} y''(x) + a(x)y'(x) + b(x)y(x) &= 0, \\ y(0) = A, \qquad y(1) &= B. \end{aligned} \tag{20}$$

There is no quadrature solution to a second-order linear differential equation, so we will solve this problem as a perturbation problem. We begin by introducing the parameter ϵ into this problem. If we introduce ϵ so that it multiplies the $y'(x)$ or the $y(x)$ terms, then we have a regular perturbation problem. In this section we are concerned with the singular perturbation problem that arises if we introduce ϵ so that it multiplies the highest-derivative term in the equation:

$$\begin{aligned} \epsilon y''(x) + a(x)y'(x) + b(x)y(x) &= 0, \\ y(0) = A, \qquad y(1) &= B. \end{aligned} \tag{21}$$

We will now make a crucial technical assumption; namely, that for all x $(0 \le x \le 1)$ the function $a(x)$ is strictly positive $[a(x) > 0]$. If this assumption holds, then as $\epsilon \to 0$, the exact solution to the boundary-value problem (21) remains smooth except in a narrow boundary-layer region located at $x = 0$. We do not prove this assertion here. However, we give a simple physical argument: If we think of the variable x as representing time, then $y''(x)$ is the acceleration of a particle of mass ϵ, the $y'(x)$ term represents a friction (velocity-dependent) force, and the $y(x)$ term represents a position-dependent force. If the function $a(x)$ is positive, then the friction force causes *damping* (as opposed to runaway behavior). For very small mass ϵ, the particle accelerates rapidly and its position varies rapidly with time until the damping and position-dependent forces balance. From this point on the position of the particle is a slowly changing function of time.

We begin the analysis by considering the *outer region*; namely, all x away from $x = 0$ where the solution is slowly varying as $\epsilon \to 0$. In this region we assume that the solution has a series expansion in powers of ϵ:

$$y_{\text{out}}(x) = \sum_{n=0}^{\infty} y_n(x)\epsilon^n, \tag{22}$$

where $y_0(1) = B$, $y_n(1) = 0$ $(n \ge 1)$. Substituting this series into the differential equation (21) gives a sequence of equations for the functions $y_n(x)$:

$$\begin{aligned} a(x)y_0'(x) + b(x)y_0(x) &= 0, \\ a(x)y_1'(x) + b(x)y_1(x) &= -y_0''(x), \\ a(x)y_2'(x) + b(x)y_2(x) &= -y_1''(x), \\ a(x)y_3'(x) + b(x)y_3(x) &= -y_2''(x), \end{aligned}$$

and so on. Each of these equations can be solved in quadrature form because they are *first*-order rather than second-order linear equations.

The solution to the first of these equations is

$$y_0(x) = B \exp\left[\int_x^1 dt \frac{b(t)}{a(t)}\right], \tag{23}$$

where we have incorporated the boundary condition at $x = 1$. We can just as easily solve for the functions $y_1(x)$, $y_2(x)$, and so on.

Next, we consider the *inner region*; namely, all x near the point $x = 0$. In this region the solution becomes a rapidly varying function of x as ϵ tends to 0. Let us begin by determining the width δ of this region. We introduce the *inner variable* X by means of a scaling transformation:

$$x = \delta X. \tag{24}$$

In terms of the inner variable, the differential equation (21) reads

$$\frac{\epsilon}{\delta^2} Y_{\text{in}}''(X) + \frac{1}{\delta} a(\delta X) Y_{\text{in}}'(X) + b(\delta X) Y_{\text{in}}(X) = 0, \tag{25}$$

where $Y_{\text{in}}(X) = y(x)$.

We must now identify the distinguished limits of this equation. (A *distinguished limit* is an asymptotic dominant balance between the two largest terms in the equation.) For small ϵ, there are two possible distinguished limits. First, we can have a balance between the second and third terms with the first term being negligible. This occurs if $\delta = 1$. This distinguished limit is just the outer limit. Second, we can have a balance between the first and second terms with the third term being negligible. This occurs if $\delta = \epsilon$. It is this distinguished limit that characterizes the inner region. We conclude that the thickness of the inner region is ϵ and that the differential equation in the inner region is

$$Y_{\text{in}}''(X) + a(\epsilon X) Y_{\text{in}}'(X) + \epsilon b(\epsilon X) Y_{\text{in}}(X) = 0. \tag{26}$$

We seek a perturbative solution to this equation of the form

$$Y_{\text{in}}(X) = \sum_{n=0}^{\infty} Y_n(X)\epsilon^n. \tag{27}$$

The boundary condition $y(0) = A$ then takes the form $Y_0(0) = A$, $Y_1(0) = 0$, $Y_2(0) = 0$, $Y_3(0) = 0$, and so on. Substituting (27) into (26) and collecting powers of ϵ gives the following sequence of differential equations for the functions $Y_0(X)$, $Y_1(X)$, $Y_2(X)$, ...:

$$Y_0''(X) + a(0)Y_0'(X) = 0,$$
$$Y_1''(X) + a(0)Y_1'(X) = -a'(0)Y_0'(X) - b(0)Y_0(X),$$
$$Y_2''(X) + a(0)Y_2'(X) = -a'(0)Y_1'(X) - \frac{1}{2}a''(0)Y_0'(X) - b(0)Y_1(X) - b'(0)Y_0(X), \quad (28)$$

and so on, where we assume that $a(x)$ and $b(x)$ possess Taylor expansions about $x = 0$ of the form

$$a(x) = a(0) + a'(0)x + \frac{1}{2}a''(0)x^2 + \cdots,$$
$$b(x) = b(0) + b'(0)x + \frac{1}{2}b''(0)x^2 + \cdots.$$

Note that each of the equations in (28) is solvable because the homogeneous parts are constant-coefficient differential equations. The first of these equations has the same structure as that in (16) and its general solution is

$$Y_0(X) = C_0 + (A - C_0)e^{-a(0)X}, \quad (29)$$

where C_0 is an arbitrary constant. [The solutions for $Y_1(X)$, $Y_2(X)$, ... each contain new arbitrary constants C_1, C_2, and so on.]

The problem is now to determine the constants in $Y_n(X)$. This is accomplished by the use of asymptotic matching. We argue as follows: The exists a region in which the inner expansion (27) and the outer expansion (22) are *both* valid. The points x that are common to both regions are said to belong to the *overlap region*. In this overlap region we perform an asymptotic match by (i) finding an *asymptotic approximation of the asymptotic expansion* $Y_{\text{in}}(X)$ that is valid in the overlap region; (ii) finding an *asymptotic approximation of the asymptotic expansion* $y_{\text{out}}(x)$ that is valid in the overlap region; (iii) demanding that these two asymptotic approximations be identical in the overlap region.

We perform this procedure to leading order in ϵ as follows: The outer solution in (23) is valid throughout the entire outer region, but in the matching region, where x is small compared with 1, we have

$$y_0(x) \sim B \exp\left[\int_0^1 dt\, \frac{b(t)}{a(t)}\right].$$

The inner solution in (29) is valid throughout the entire inner region, but in the matching region, where x is large compared with ϵ, we have

$$Y_0(X) \sim C.$$

Requiring that these two approximations to the solution to the differential equation agree in the overlap region gives the result

$$C = B \exp\left[\int_0^1 dt \frac{b(t)}{a(t)}\right].$$

The process of asymptotic matching reveals the extent of the matching region. We have just seen that to leading order in ϵ the asymptotic matching occurs in the overlap region defined by

$$\epsilon \ll x \ll 1.$$

As the asymptotic matching is performed to higher order in ϵ the size of the overlap region shrinks. Typically, the overlap region to nth order in ϵ is given by

$$\epsilon \ll x \ll \epsilon^{n/(n+1)}.$$

The final step in the boundary-layer procedure is to combine the inner and outer approximations to the solution of the boundary-value problem to obtain a single expression that is a *uniform* approximation valid on the entire interval $0 \le x \le 1$. We do so by adding the inner solution to the outer solution and subtracting off the doubly-counted solution in the overlap region:

$$y_{\text{uniform}}(x) \equiv Y_{\text{in}}(X) + y_{\text{out}}(x) - y_{\text{match}}(x).$$

Thus, to leading order, we obtain

$$y_{\text{uniform},0}(x) = B \exp\left[\int_x^1 dt \frac{b(t)}{a(t)}\right] \times \left\{A - B \exp\left[\int_0^1 dt \frac{b(t)}{a(t)}\right]\right\} e^{-a(0)x/\epsilon}.$$

The function $y_{\text{uniform},0}(x)$ is a *global* approximation to $y(x)$ over the entire region in the sense that the difference between the exact solution $y(x)$ and $y_{\text{uniform},0}(x)$ is of order ϵ for all x $(0 \le x \le 1)$. The higher-order uniform asymptotic approximations to $y(x)$ require more algebra, but are routinely obtained by using the same procedure.

Boundary-layer theory can be used to solve (21) even if the restriction that $a(x)$ be strictly positive is lifted. If $a(x)$ is strictly negative, the ensuing analysis is identical except that the boundary layer occurs at the right boundary $x = 1$ instead of at $x = 0$. If $a(x)$ is not one-signed, then wherever it passes through 0 it is possible to have an *internal boundary layer* (a narrow region of rapid variation between $x = 0$ and $x = 1$).

Boundary-layer techniques also apply to differential-equations boundary-value problems in which the differential equation is not second order and even if the differential equation is nonlinear. In these more complicated problems the boundary layers that arise may be thicker or thinner than ϵ; indeed, we often find that δ is a fractional power of ϵ. Also, there may be multiple boundary layers and even nested boundary layers (boundary layers inside of boundary layers).

Boundary-layer methods are often used to solve problems in fluid mechanics for which we may assume that the viscosity of the fluid is small. For a low-viscosity fluid

flowing along a boundary surface there are two physically distinct regions. Near the boundary surface there is a narrow boundary layer in which the velocity profile of the fluid changes rapidly as a function of the distance from the boundary. Right at the boundary surface the velocity of the fluid is zero because we assume that there is a *no-slip* condition. Away from the boundary (in the outer region) the velocity profile is a slowly varying function of the distance from the boundary because the effects of the boundary do not propagate deeply into a fluid of low viscosity.

VIII. WKB THEORY

WKB theory is a perturbation technique named after Wentzel, Kramers, and Brillouin, who used it to construct perturbative solutions to the Schrödinger equation

$$\epsilon^2 y''(x) = Q(x)y(x), \tag{30}$$

where the perturbation parameter ϵ is proportional to Planck's constant $\hbar$. Problems like this cannot be solved using boundary-layer theory because for small ϵ the solution varies rapidly over regions that are not narrow. To solve (30) we seek a solutions of the form

$$y_{\mathrm{WKB}}(x) = \exp\left[\frac{1}{\epsilon}\sum_{n=0}^{\infty} S_n(x)\epsilon^n\right]. \tag{31}$$

Substituting (31) into (30) and collecting powers of ϵ gives a sequence of easy-to-solve equations for the functions $S_n(x)$:

$$\begin{aligned} [S_0'(x)]^2 &= Q(x), \\ 2S_0'(x)S_1'(x) + S_0''(x) &= 0, \\ 2S_0'(x)S_n'(x) + S_{n-1}''(x) + \sum_{j=1}^{n-1} S_j'(x)S_{n-j}'(x) &= 0 \\ (n \geq 2). \end{aligned} \tag{32}$$

The solution to the first of these equations, which is called the *eikonal* equation, is

$$S_0(x) = \pm\int^x dt\sqrt{Q(t)},$$

and substituting it into (31) gives what is known as the *geometrical-optics* approximation to $y(x)$:

$$y_{\mathrm{geometricaloptics}}(x) = \exp\left[\pm\frac{1}{\epsilon}\int^x dt\sqrt{Q(t)}\right].$$

The solution to the second of these equations, which is called the *transport* equation, is

$$S_1(x) = -\frac{1}{4}\ln Q(x).$$

Substituting both $S_0(x)$ and $S_1(x)$ into (31) gives what is known as the *physical-optics* approximation to $y(x)$:

$$y_{\text{physical optics}}(x) = Q^{-1/4}(x)\left\{C_1\exp\left[\frac{1}{\epsilon}\int_a^x dt\sqrt{Q(t)}\right] + C_2\exp\left[-\frac{1}{\epsilon}\int_a^x dt\sqrt{Q(t)}\right]\right\},$$

where the lower limit of integration is any fixed point a.

For those values of x for which $Q(x) \neq 0$ the physical-optics approximation is the leading-order asymptotic approximation to the solution $y(x)$ of the differential Eq. (30). That is, for small ϵ it differs from $y(x)$ by an amount of order ϵ. Values of x for which $Q(x) = 0$ are called *turning points* and near these turning points the physical-optics approximation is not valid. In the vicinity of a turning point at $x = x_0$, one may replace the differential Eq. (30) by

$$\epsilon^2 y''(x) = \alpha(x - x_0)y(x), \tag{33}$$

where we have replaced the function $Q(x)$ by the first term in its Taylor series:

$$Q(x) \sim \alpha(x - x_0) \qquad (|x - x_0| \ll 1).$$

The differential Eq. (33) is a scaled version of the Airy equation $y''(x) = xy(x)$ whose solutions are $\mathrm{Ai}(x)$ and $\mathrm{Bi}(x)$. Thus, to solve a differential equation of the form (30) when there is a turning point, it is necessary to match asymptotically the WKB physical optics solutions on either side of the turning point to the solution of the Airy equation in the vicinity of the turning point.

The uniform asymptotic approximation to the solution of the one-turning-point problem was first discovered by Langer. For the case $x_0 = 0$ the leading-order one-turning-point solution that vanishes as $x \to +\infty$ has the form

$$y_{\mathrm{uniform}}(x) = C\left[\frac{3}{2\epsilon}S_0(x)\right]^{1/6} Q^{-1/4}(x)\mathrm{Ai}\left[\frac{3}{2\epsilon}S_0(x)\right]^{2/3}, \tag{34}$$

where $S_0(x) = \int_0^x dt\,\sqrt{Q(t)}$ and C is an arbitrary constant.

The one-turning-point solution in (34) is exponentially decaying to the right of the turning point ($x > 0$) and oscillatory to the left of the turning point ($x < 0$). The region in which the solution decays exponentially is called the *classically forbidden* region; the region in which the solution is oscillatory is called the *classically allowed* region. These different kinds of regions underscore the differences between classical and quantum mechanics: In classical mechanics a particle may not penetrate into a region in which its kinetic energy is negative; a quantum particle may do so with exponentially small probability.

For the case of two turning points, there are two possibilities: (1) The classically allowed (oscillatory) region may lie between the two turning points, or (2) the classically forbidden region may lie between the two turning points. Let the two turning points be located at x_1 and x_2. When the classically allowed region lies between these two turning points and if the constraint that $y(x) \to 0$ as $x \to \pm\infty$ is imposed, this translates into the WKB *quantization condition*

$$\frac{1}{\epsilon}\int_{x_1}^{x_2} dt\sqrt{-Q(t)} = \left(n+\frac{1}{2}\right)\pi \qquad (n=0,1,2,\ldots). \tag{35}$$

For the case of the Schrödinger Eq. (30) in which we set $Q(x) = V(x) - E$, this quantization condition gives accurate results for the energy eigenvalues E_n for small ϵ. Also, for *fixed* ϵ it gives accurate results for E_n when n is large.

For example, for the eigenvalue problem

$$y''(x) = (x^4 - E)y(x), \qquad y(\pm\infty) = 0, \tag{36}$$

the quantization (35) condition reads

$$\int_{-E^{1/4}}^{E^{1/4}} dt\sqrt{E - t^{1/4}} = \left(n+\frac{1}{2}\right)\pi \quad (n=0,1,2,\ldots), \tag{37}$$

and from evaluating the integral we get

$$E_n \sim \left[\frac{3\Gamma\left(\frac{3}{4}\right)\left(n+\frac{1}{2}\right)\sqrt{\pi}}{\Gamma\left(\frac{1}{4}\right)}\right]^{4/3} \qquad (n\to\infty). \tag{38}$$

This result is extremely accurate. For example, the exact value of E_{10} is $50.256\cdots$, while the WKB prediction gives 50.240 (relative error of -0.03%).

When the classically forbidden region lies between these two turning points at x_1 and x_2, we have the quantum phenomenon of tunneling through a potential barrier. WKB theory predicts that the transmission coefficient T for a beam of particles of energy E incident on a potential $V(x)$, where the maximum value of $V(x)$ is greater than E, is

$$T \sim \exp\left[-\frac{2}{\epsilon}\int_{x_1}^{x_2} dt\sqrt{V(t)-E}\right] \quad (\epsilon\to 0). \tag{39}$$

Note that this tunneling probability is exponentially small but *nonvanishing*.

The WKB quantization condition (35) and tunneling amplitude (39) are the leading-order perturbative predictions. These predictions can be refined by doing higher-order WKB calculations (Bender and Orszag, 1978). More advanced treatments of WKB theory involve the use of *complex* WKB matching techniques (Berry and Mount, 1972; Dingle, 1973).

IX. PERTURBATIVE CALCULATION OF EIGENVALUES

Enormous research effort has been spent in trying to solve eigenvalue problems using perturbation theory. Consider, for example, the Schrödinger equation eigenvalue problem

$$y''(x) = [V(x) + W(x) - E]y(x), \qquad y(\pm\infty) = 0. \tag{40}$$

To solve this problem perturbatively, we may insert the perturbation parameter ϵ so that it multiplies the function $W(x)$ so long as the simpler unperturbed eigenvalue problem

$$y_0''(x) = [V(x) - E_0]y_0(x), \qquad y(\pm\infty) = 0, \tag{41}$$

can be solved exactly and in closed form.

The eigenvalues and eigenfunctions of the perturbed problem

$$\begin{aligned} &y''(x,\epsilon) = [V(x) + \epsilon W(x) - E(\epsilon)]y(x,\epsilon),\\ &y(\pm\infty) = 0, \end{aligned} \tag{42}$$

can be expressed as perturbation series (power series in ϵ). The perturbation series for each of the eigenvalues has the form

$$y(x,\epsilon) = \sum_{n=0}^{\infty} y_n(x)\epsilon^n, \qquad E(\epsilon) = \sum_{n=0}^{\infty} E_n\epsilon^n. \tag{43}$$

These series are called a Rayleigh–Schrödinger perturbation series.

One particularly elegant method for obtaining the Rayleigh–Schrödinger perturbation series for the eigenvalue $E(\epsilon)$ is to represent the coefficients in the expansion in terms of Feynman graphs. The Feynman rules for constructing and evaluating these graphs are in wide use by theoretical physicists.

A simple example of an eigenvalue problem that one can solve in terms of a Rayleigh–Schrödinger perturbation series is

$$y''(x,\epsilon) = \left[\frac{1}{4}x^2 + \epsilon\frac{1}{4}x^4 - E(\epsilon)\right]y(x,\epsilon), \quad y(\pm\infty) = 0. \tag{44}$$

For this example, called the *quartic anharmonic oscillator*, the perturbation expansion for the smallest eigenvalue is

$$E(\epsilon) \sim \frac{1}{2} + \frac{3}{4}\epsilon - \frac{21}{8}\epsilon^2 + \frac{333}{16}\epsilon^3 + \cdots. \tag{45}$$

The radius of convergence of this power series is 0. The series is asymptotic but not convergent.

The perturbation series (43) have been the object of intensive mathematical study for several decades. Among

the principal discoveries are that the radius of convergence of the series for $E(\epsilon)$, which in most cases is 0, is determined by singularities in the complex-ϵ plane which are square-root singularities. In general there are an infinite number of these singularities, and when the radius of convergence is 0, these singularities form a sequence in the complex-ϵ plane that has a limit point at the origin. The square-root singularities are points where pairs of eigenvalues become degenerate. Thus, analytically continuing around one of the square-root singularities exchanges one of the eigenvalues with another. This exchange process is called *level crossing*. (Bender and Wu, 1973; Le Guillou and Zinn-Justin, 1990; Reed and Simon, 1972; Simon, 1970).

In general, all of the energy levels are *analytic continuations of one another* and one can think of the entire spectrum as being represented by a single eigenvalue function $E(\epsilon)$ that is defined on a complex Riemann surface in the variable ϵ. Each of the eigenvalues is in one-to-one correspondence with the sheets of this Riemann surface. That is, we recover the kth eigenvalue by evaluating $E(\epsilon)$ on the kth sheet of the Riemann surface. Apparently then, quantization is a geometrical phenomenon and consists of nothing more than counting the sheets in a Riemann surface.

Furthermore, it can be shown that the function $E(\epsilon)$ is a *Stieltjes* function and, as a consequence, the Padé sequence formed from the power series (43) converges. So long as the coefficients in this series do not grow faster than $(2n)!$ this Padé sequence converges to the exact eigenvalue (see Le Guillou and Zinn-Justin, 1990). Many numerical and theoretical studies have contributed to the vast literature on the perturbation theory of eigenvalue problems.

X. MULTIPLE-SCALE PERTURBATION THEORY

The most general kind of perturbation theory, called *multiple-scale perturbation theory*, is based on the idea that physical problems exhibit various kinds of physical phenomena on different time scales (or distance scales). Multiple-scale perturbation theory was developed by astronomers who used it to calculate the effect of small perturbations on periodic systems. The objective in developing this perturbative approach was to calculate the small changes in the shapes of planetary orbits due to the weak influences of remote planets.

To illustrate the phenomenon of multiple scales we consider a very simple periodic system (a classical harmonic oscillator) subject to a small perturbing force. The model, which is described by the *Duffing* equation, consists of a particle attached to the end of a spring for which the restoring force is not just linear; rather, we consider the first nonlinear correction to Hooke's law. The position of such a particle obeys the equation

$$y''(t) + y(t) + \epsilon y^3(t) = 0. \tag{46}$$

The presence of the perturbation parameter ϵ multiplying the $y^3(t)$ term emphasizes that the deviation from Hooke's law is very small.

Let us solve the differential Eq. (46) subject to the initial conditions $y(0) = 1$ and $y'(0) = 0$. Since the perturbation problem is a *regular* perturbation problem (no abrupt changes occur as $\epsilon \to 0$), we may assume that the function $y(t)$ has a regular perturbation expansion with a nonzero radius of convergence:

$$y(t) = \sum_{n=0}^{\infty} y_n(t)\epsilon^n. \tag{47}$$

Note that the unperturbed problem $y''(t) + y(t) = 0$ is easy to solve and that the solution obeying the initial conditions is

$$y_0(t) = \cos t. \tag{48}$$

Substituting this result into the equation for $y_1(t)$ gives

$$y_1''(t) + y_1(t) = -\cos^3 t, \tag{49}$$

whose solution is

$$y_1(t) = \frac{1}{32}\cos(3t) - \frac{1}{32}\cos t - \frac{3}{8}t\,\sin t. \tag{50}$$

The third term in this equation is said to be *secular* because it grows with t. In this case it grows linearly with t because (49) represents a harmonic oscillator whose driving term, $\cos^3 t = \frac{1}{4}\cos(3t) + \frac{3}{4}\cos t$, contains the function $\cos t$, and this function oscillates at the *natural frequency* of the harmonic oscillator. Whenever a harmonic oscillator is driven on resonance, the solution grows rapidly with t.

The presence of a secular term tells us that the perturbation series (47) becomes inaccurate for large values of t, specifically $t > \frac{1}{\epsilon}$. This is because a finite number of terms in the perturbation series evidently contradict the property that the solution to the differential Eq. (46) is bounded. (To show that the solution is bounded we construct an energy integral by integrating the differential Eq. (46) once with respect to t.) The phenomenon that we observe here is quite remarkable: As is always the case in perturbation theory problems involving differential equations, when we collect powers of ϵ, we obtain a sequence of linear differential equations all of whose homogeneous parts are identical and whose inhomogeneous parts differ from order to order. What we see here is that higher orders of perturbation theory can be driven *on resonance* (that is,

they can be coupled resonantly) to lower orders of perturbation theory.

To treat the presence of secular terms in the conventional perturbation series we perform a rather fancy rearrangement of the terms in the perturbation series. In this case, we can calculate the most secular term in each order of the perturbation series. The most secular contribution to $y_n(t)$ has the form

$$\frac{1}{2n!}t^n\left(\frac{3i}{8}\right)^n e^{it} + \text{complex conjugate.} \qquad (51)$$

Substituting this term into the perturbation series and summing to all orders gives

$$y(t) = \cos\left[\left(1+\frac{3}{8}\epsilon\right)t\right] + \mathrm{O}(\epsilon). \qquad (52)$$

Note that the result is a *bounded* function of t. This calculation shows that while a finite number of terms in the perturbation expansion can exhibit secularity, an infinite rearrangement and summation of the perturbation series may no longer be secular.

More importantly, the rearrangement of the series demonstrates that various phenomena appear on different time scales. On the short time scale ($t \ll \frac{1}{\epsilon}$) the solution exhibits harmonic oscillation with frequency 1. On a longer time scale (t of order $\frac{1}{\epsilon}$) there is a frequency shift of order $\frac{3}{8}\epsilon$.

The notion that characteristic phenomena occur at different scales is apparent in all forms of perturbation theory. For example, we saw that in boundary-layer theory, there is a short-distance scale inside the boundary-layer in which the rapidly-varying inner solution occurs. The long-distance slowly-varying behavior of the outer solution is a distinctly different phenomenon. The same kind of rapidly-varying behavior (geometrical optics) and slowly varying behavior (modulation of the geometrical-optics solution to obtain the physical-optics solution) occur in WKB theory. Indeed, the techniques of boundary-layer theory may be used to derive boundary-layer theory and WKB theory from multiple-scale perturbation theory. Thus, multiple-scale perturbation theory may be regarded as the most general of all perturbation methods.

GLOSSARY

Conditional expectation If X and Y are two random variables and if $B = [Y = b]$ is given and $P(B) > 0$, then the conditional expectation of X given $Y = b$ is the usual expectation defined below calculated with the conditional probability $P(\cdot \mid B)$ in place of the original probability.

Conditional probability If A and B are two events of positive probability, then the conditional probability of A given B is the ratio of the probability of the joint occurrence of A and B to that of just B and is denoted by $P(A \mid B)$. Difficulties arise if $P(B) = 0$.

Correlation Measure of relation (interdependence) between a pair of random variables.

Distribution Each numerical value of the random variable is assigned a probability, and a set of values has the sum of the probabilities. These values of the sets constitute the function that is sometimes called a (cumulative) distribution. All the values together receive probability 1.

Expectation Population average $E(\cdot)$ of the random variable over a distribution of its values with prescribed probabilities.

Independence A class of events is mutually independent if the occurrence (nonoccurrence) of any finite subset of them has no influence on the occurrence (nonoccurrence) of the others. A class of random variables is similarly independent if all the events they determine are mutually independent.

Random variable Rule to associate a numerical value for each point of the sample space.

Sample space Space of points representing all possible (distinct) outcomes of an experiment.

Stochastic process A collection of random variables, often indexed by integers as $X_1, X_2, \ldots$ (or by real numbers as $X_s, X_t, \ldots$). Also called a random process or time series when the indexing refers to the time at which these random variables can be observed.

Variance Measure of concentration of the values of the random variable about its expectation.

PROBABILITY theory is a branch of mathematics dealing with the analysis of the behavior of observable processes and experiments involving uncertainty. Its applications are to determine or predict the outcomes of experiments with a degree of assurance when numerical values are assigned to uncertainties. These applications include games of chance or gambling, fluctuations in economic behavior or stock markets, meteorology, gene combinations, biology, physics, and in fact most aspects of scientific activity, as well as to theoretical studies such as number theory and complex variables. Probability is the basis for statistical analysis and especially for inference theory. In each of the fields of application, first one has to formulate a model, analyze its theoretical implications, and then make the intended estimation or prediction to decide the suitability of the model by experimentation.

I. HISTORICAL EVOLUTION

The fact that the outcome of an experiment cannot always be predicted with certainty has been recognized since ancient times, and in most cases previous experience was used to gauge the amount of uncertainty. This numerical assignment of uncertainty is an art that has been developed to various degrees, and its measurement, in a refined form, is known as probability. For a proper appreciation of the topic, a somewhat detailed historical sketch will be presented in this section.

There was always a fascination among the ancients for guessing the unknown, on the basis of some accumulated knowledge, by observation and then verifying or modifying the guesses with further experimentation. This was especially true with games of chance, particularly dicing, which was often termed a vice but which was never given up. Indeed, gambling was well developed by the Greeks, and Aristotle condemned it as equivalent to robbery. The great Indian epic, the *Mahābhārata*, deals with the conflict growing out of a refined dicing game. The uncertainty was later analyzed in great detail, for instance, in the Jaina philosophy. It is of interest here to discuss this development briefly because it anticipates the logical foundations of our subject.

The Jaina philosopher Bhadrabāhu (ca. 433–357 B.C.) presents in one of his writings a highly developed system that had been in existence for more than a century before him, involving a classification of uncertainties into seven categories. This is termed the *syādvāda* system having *saptabhaṅginā ya* (seven types of analysis of prediction). The original (Sanskrit) classification is as follows:

1. *syādasti* (*syād* = "perhaps," *asti* = "exists"; "Perhaps it exists.")
2. *syātnāsti* ("Perhaps it is not.")
3. *syādastinā stica* ("Perhaps it is and is not.")
4. *syādavaktavyah* ("Perhaps it is indeterminate.")
5. *syādastica avaktavyaśca* ("Perhaps it is and also indeterminate.")
6. *syādatnāstica avaktavyaśca* ("Perhaps it is not and also indeterminate.")
7. *syādasti nāstica avaktavyaśca* ("Perhaps it is and it is not and also indeterminate.")

It can be shown that these divisions exhaust the possibilities, and uncertainties may always be treated as belonging to exactly one of them. These ideas seem to have been applied to some practical problems. For instance, there are references in medieval Hindu books to the practice of giving alms to religious mendicants without ascertaining whether or not they were deserving. The question was resolved in favor of continuing the practice since on observation it was found that "only ten out of a hundred were undeserving." The implication here, in present-day terminology, is that the probability is 0.9 that a deserving person receives alms. This system was discussed by the late P. C. Mahalanobis in 1954 with source material in *Dialectica* **8,** 95–111.

Gambling as well as the probabilistic aspects of trade and commerce appear to have provided an even stronger motivation to develop the subject during the Renaissance period. By about the middle of the 16th century the first combinatorial aspect of the subject was systematically described by G. Cardano (1501–1576) in a book on gambling. The binomial coefficient formulas were already known by the 12th and 13th centuries, so that they could be used. Thus, in his work, Cardano states that the probability of an event in repeated throws of an ideal die, or a pair of dice, is the ratio of the favorable outcomes to the possible ones. It will be illuminating to discuss some classical examples since this period may be regarded as the start of a new epoch in the development of probability, particularly regarding its combinatorial aspects.

If a die is tossed once, Cardano takes the probability of any one number of its six faces to be $\frac{1}{6}$, since for the ancients dice and coins must always be fair to play. Similarly, if f is the favorable and n the total number of outcomes, he takes the probability $p_1 = f/n$ for a toss; in two repeated tosses he states that the odds are f^2 to $n^2 - f^2$, or $p_2 = f^2/n^2$; and in k tosses he obtains the *product formula* $p_k = f^k/n^k$. Cardano also considers the average proportion in m tosses, if p is the probability of a single toss, as mp. If the experiment is repeated until a desired outcome appears, then he says that for an even chance the needed number m of trials is determined from $\frac{1}{2} = mp$. Thus, for a fair die, $p_1 = \frac{1}{6}$, so that $m = 3$, and if the experiment involves two dice, then $p_2 = \frac{1}{36}$, so that $\frac{1}{2} = mp_2$

gives $m = 18$. However, Cardano realizes that this application is not correct for large m since $mp > 1$ can happen and concludes that "this is most absurd." He could not solve this problem himself.

A very similar question was considered about a century later by the French nobleman and gambler Cavalier de Méré as follows. If p_1, p_2 are as above, then de Méré notes that $4p_1 = \frac{4}{6} = 24p_2 = \frac{24}{36}$ and concludes that the probability of at least a six in the first play should be the same as at least a double six in the second one. Both have an "equal chance." With experimentation, he found that the odds favor the first experiment and lost money in the betting. He wrote to B. Pascal (1623–1662) about his dilemma, and the latter in correspondence with P. Fermat (1601–1665) showed in 1654 that a correct computation validates the experimental evidence, truly reflecting the theory. Namely, the probability of not getting a six in four tosses is $(\frac{5}{6})^4$ (by Cardano's power law) and so at least one six has the probability $= 1 - (\frac{5}{6})^4 = 0.5177$, whereas a similar computation with the second play gives the correct probability $= 1 - (\frac{35}{36})^{24} = 0.4914 < 0.5177$. This simple calculation by Fermat and Pascal a century later gave further stimulus for considering sophisticated combinatorial probability problems.

It should be noted that a similar, but slightly easier problem was also posed to Galileo Galilei (1564–1642) by one of his friends about a half-century after Cardano raised it. If three fair dice are thrown, and one desires to get the sum of 9 in one play and 10 in the other, it was thought that the probabilities should be the same since the number of distinct ways 9 and 10 can be obtained is exactly six ($9 = 6+2+1 = 5+3+1 = 5+2+2 = 4+4+1 = 4+3+2 = 3+3+3$, and $10 = 6+3+1 = 6+2+2 = 5+4+1 = 5+3+2 = 4+4+2 = 4+3+3$). But the experiments favored 10 and not 9. Galileo showed that, whereas $3+3+3 = 9$ can occur in only one way, in the second configuration 10 can be obtained in more ways and calculated the respective probabilities for 9 and 10 to be $\frac{25}{216}$ and $\frac{27}{216}$.

These examples show the problems that were beyond the techniques of the ancients and motivated the further development of probability. The Cardano–de Méré problem was satisfactorily solved by Pascal and Fermat, but this was done independently of Cardano's important work "De Ludo Aleae" ("Games of Chance"), which was published almost a century after the author's death. Cardano was a well-known physician in Milan, but he wrote important books on mathematics ("Ars Magna" in 1545 is perhaps the most important) as well as medicine. Thus, from the ancients the next important advance should be attributed to Cardano and later independently to Galileo and Fermat–Pascal. Until recently Cardano's work was not properly appreciated since it was either misunderstood or termed unintelligible because of his Latin style. It took a contemporary mathematician of the caliber of Oystein Ore of Yale University to show that everything in Cardano's book is essentially correct and that his contributions to probability are important. (Thus, the history of science is well served if the historian is also accomplished in the subject.)

Here, one should note that Cardano briefly considered certain approximations to estimating an unknown probability and thought that, for a large number of repeated trials, the proportion of favorable to possible outcomes should stabilize. This is a form of the law of large numbers, but he did not have the tools to establish it. A similar observation was also found in an early 16th-century Sanskrit manuscript of an Indian writer (named Brahmagupta), saying that the precision of the arithmetic mean increases with the number of observations. The contemporary Russian mathematical sciences historian L. E. Maistrov finds this to be "a remarkable fact" because of the early date of its formulation.

A mathematically rigorous proof of the law of large numbers was established for the zero–one-valued random variables on repeated trials, with a careful enumeration, by James Bernoulli (1654–1705) at the end of the 17th century, and it appeared in his book "Ars Conjectandi," published posthumously in 1713. This was the next significant step in the evolution of probability. The work was systematically elaborated and extended by A. de Moivre (1667–1754) and P. S. Laplace (1749–1827) in the 18th and the 19th centuries. It involved both an extension of and new ways of looking into what became known as the central limit problem, still keeping the two-valued, or Bernoulli, random variables. Precise statements of laws of large numbers are given in Section IV.

Independently repeatable experiments having the same probability for each outcome, described as "success" or "failure," were the object of Bernoulli's work, and these are called the Bernoulli trials. One denotes by X_n a two-valued function taking 1 for "success" and 0 for "failure" on the nth trial. Thus, $S_n = X_1 + \cdots + X_n$ denotes the number of successes in n Bernoulli trials. The proportion S_n/n, which changes from one experiment to another, should "stabilize" as n increases. Let $P[X_n = 1] = p$ and $P[X_n = 0] = q = 1 - p$. If $p = q = \frac{1}{2}$, then one has a fair game. Bernoulli's theorem is that for each $\varepsilon > 0$, the event $\{|(S_n/n) - p| < \varepsilon\}$ has probability arbitrarily close to 1, if n is large enough. This is a statement about the behavior of the ratio S_n/n in *different sets* of games and *not* on the fluctuations of the proportions in a *single* game of trials. The latter is a stronger statement.

Before the work of Laplace, most calculations consisted of Bernoulli trials with $p = \frac{1}{2}$. By the time that de Moivre and especially Laplace started work on the

subject, the Leibniz–Newton theory of calculus was already available, so that a finer analysis of probabilities of the events discussed above was possible. But the Laplace–de Moivre result goes farther, and the first real limit statement, now called the central limit problem, was formulated. Thus, they were able to prove the first central limit theorem as

$$P\left[a < \frac{S_n - np}{\sqrt{npq}} < b\right] \sim \frac{1}{\sqrt{2\pi}} \int_a^b e^{-x^2/2}\, dx \qquad (1)$$

for large enough n, where $0 < p = 1 - q < 1$. The functions ϕ and Φ, where $\phi(x) = (2\pi)^{-1/2} e^{-x^2/2}$ and $\Phi(x) = \int_{-\infty}^{x} \phi(t)\, dt$, appear for the first time in the works of de Moivre and Laplace, though the latter author used it more effectively in his analyses. Later C.-F. Gauss (1777–1855) also derived the same function but published his work in 1809 and noted its appearance in many different contexts. A lesser known mathematician in the United States, Robert Adrian (1775–1843), independently derived and published the function in 1808 in an obscure journal. Many people in France term Φ the Laplace distribution; in other places it is called the Gaussian distribution. In English publications, it is usually called a normal distribution. As a limit law, probabilists found it so common in physical applications that H. Poincaré (attributing it to Lippman) said that "there is something mysterious about this distribution since mathematicians think it is a law of nature and physicists are convinced that it is a mathematical theorem." It is generally regarded as the basic limit law of probability theory.

By the end of the 19th century random variables more complicated than those of Bernoulli appeared. Keeping the very appealing concept of mutual independence in mind, a generalization of the Bernoulli law of large numbers and the Laplace–de Moivre central limit theorem were obtained. Important research of P. L. Čebyšev (1821–1894), A. A. Markov (1856–1922), and A. M. Liapounov (1857–1918) contributed to this area. In another direction, E. Borel (1871–1956) proved a far stronger form of the law of large numbers for Bernoulli's random variables in 1909. He showed that $S_n/n \to p$ for almost all individual games, the exceptions constituting only zero probability. Thus, in the current language, for each $\varepsilon > 0$ and $\delta > 0$, one can find an $n_0[= n_0(\varepsilon, \delta)]$ such that for any $m \geq 1$, it is true that

$$P\left[\left|\frac{S_{n_0+k}}{n_0 + k} - p\right| < \varepsilon, k = 1, 2, \ldots, m\right] > 1 - \delta \qquad (2)$$

This is clearly a more precise result; it is called the *strong law of large numbers* and finally gives a frequency interpretation that justifies the intuitive feelings of the ancients. But these results only heightened the quest for a precise definition of probability, since the long-term average or the limiting frequency is not mathematically satisfactory. Developments of mathematical rigor by the end of the 19th century reached a stage at which an axiomatic basis of probability became necessary for it to be an accepted branch of mathematics. A respected mathematician, R. von Mises (1883–1953), worked on this problem intensely and proposed using a certain "collective" as a primitive notion to develop the frequency concept rigorously. However, this turned out to have serious defects. In despair, von Mises said in 1922 that "today probability theory is not a mathematical science." During that period a large number of important individual probabilistic limit theorems were obtained, although an acceptable axiomatic formulation was still missing. Fortunately, this was supplied by A. N. Kolmogorov in 1933, and his formulation is now universally accepted. Since then the subject has grown rapidly utilizing the abstract set functions and Lebesgue's integration. However, there are still problems, and we have no satisfactory agreement on the *interpretation* of all results. These and the salient features of modern probability will be discussed in the following sections.

It must be noted that, with the explosive growth of science in general and mathematics in particular during the last part of the 19th and early 20th centuries, a consolidation of the subject became imperative. Using the precise ideas of logic, some mathematicians tried to mold everything in the two-valued formulation so that each statement would be either true or false and the uncertainty eliminated. (Thus, according to such people, in the modern world, the *syādvāda* system could be retired.) It was soon realized, however, that this is not always the case. A simple illustration, usually attributed to H. Weyl, is as follows. Prove or disprove the statement: "If the irrational number π is expanded in decimals, then the numbers 0,1,2,3,4,5,6,7,8,9 will occur somewhere in their natural order." The truth of this assertion could not be determined for nearly a century, although π has been expanded for many millions of decimals, but probabilistically it can be ascertained quickly and positively. Only recently, in June and July of 1997, two Japanese computer scientists (Yasumasa Kanada and Daisuke Takahashi, at the University of Tokyo) using a massively parallel Hitachi machine with 2^{10} processors, have expanded and discovered the first occurrence of the above noted sequence after over 17 billion decimals (actually at 17, 387, 594, 880 th digit after the decimal point). The next five occurrences of the natural sequence are found respectively at 26, 852, 899, 245; 30, 243, 957, 439; 34, 549, 153, 953; 41, 952, 536, 161; and 43, 289, 964, 000 places. An interesting discussion of this matter is given by the Canadian number theorist J. M. Borwein (1998) where the difficulties of such a computation and precautions taken have been sketched. Thus

even from a pragmatic point of view, it is useful to have at hand, the Theory of Probability firmly founded and developed. This is precisely the purpose of the subject, and its development is proceeding at a fast pace.

II. BASIC NOTIONS OF MODERN PROBABILITY

An experiment, such as tossing a die or recording the test scores of students, is described by a probability model. All possible outcomes are represented by the distinct points of an abstract set Ω. Different combinations of these points, being subsets of Ω, are recognized as events that are of interest to the experimenter. Let these events be designated by $\mathcal{A}$. If Ω is finite, or at most countable, then $\mathcal{A}$ is taken to be the power set (the class of all subsets) of Ω. However, if Ω represents such experiments as the heights or weights of individuals or the fluctuations of an electric current, then Ω has uncountably many points and $\mathcal{A}$ has to be chosen more carefully, since taking it as a power set creates technical difficulties, for it includes many useless "events." Following the countable case and utilizing the experience of related mathematical constructs, one takes $\mathcal{A}$ to consist of all those sets of interest for the experiment and their combinations (unions, intersections, and differences) so as to create an algebraic structure. Thus, $\mathcal{A}$ will be a σ-algebra of subsets of Ω, meaning it is closed under countable unions and differences. Then it is also closed under countable intersections, and *only members of $\mathcal{A}$ will be called events*. This generally will be smaller than the power set and is the smallest class closed under the above countable operations containing all the basic collection of sets that are of interest to the experimenter. The problem here is to select the basic aggregate such that for each of its members the experimenter can prescribe a probability in a consistent manner. Let us give an example to clarify this discussion. If Ω corresponds to tossing a pair of dice, then it has 36 points representing each combination $\{(i, j): 1 \le i, j \le 6\}$, and if the dice are perfect, then each point is given the same probability, $\frac{1}{36}$. Here the consistency implies that the probabilities add on disjoint sets and the whole space gets unit weight. These values are given to the basic collection, that is, to each point in this case. The aim of the general study is that, if the experimenter can assign probabilities on the basic collection, it is possible to calculate probabilities of *all* events obtained by combining these fundamental sets with countable operations. Thus, a standard result of the subject is that it is possible to extend the probability P uniquely from the basic collection to all of $\mathcal{A}$, the σ-algebra determined by that collection. The triple $(\Omega, \mathcal{A}, P)$ is the model in Kolmogorov's setup that describes a given experiment completely.

With such a model in hand, random variables are defined as numerical functions on Ω, often called a sample space, to reflect the events relevant to the experiment. This means that, if $X : \Omega \to \mathbb{R}$, reals, $\{\omega \in \Omega: X(\omega) \in (a, b)\} \in \mathcal{A}$ (read "$\omega \in \Omega$" as ω in Ω); so $\{\ldots\}$ is an event of interest for *each* interval (a, b) of the range $\mathbb{R}$ of X. The condition is automatic if Ω is countable, since then $\mathcal{A}$ is the power set and even the weaker requirement that $\{\omega \in \Omega: X(\omega) = r\}$ be in $\mathcal{A}$, for each r in $\mathbb{R}$, suffices. Such a mapping X is a random variable, and one can calculate probabilities for all events determined by it for each interval (a, b). Thus, the basic elements of chance inherent in the model are carried over by this mapping to each interval, and hence X is called a random or chance variable. **When the basic model $(\Omega, \mathcal{A}, P)$ is not formulated carefully, people have difficulty in defining precisely what a chance variable is, and the resulting confusion sometimes leads to errors and paradoxes**. Indeed, without such a model a probability statement can have little significance.

Why does one want random variables when the basic probability model is already in hand? There are at least two reasons: (1) in order to achieve a finer mathematical analysis of the model and (2) to avoid the difficulties encountered by the ancients (e.g., the St. Petersburg paradox; see Section IV). Also, the analysis benefits by the inclusion of certain powerful techniques of calculus (e.g., Fourier transforms). These are discussed here since they aid in understanding some later developments. Thus, if $(\Omega, \mathcal{A}, P)$ is the model governing an experiment and $X: \Omega \to \mathbb{R}$ is a random variable, then with each such X, one can associate a real function F_X, called the distribution function of X, by the equation

$$F_X(x) = P[\{\omega: X(\omega) < x\}], \qquad -\infty < x < \infty \tag{3}$$

This is well defined since $\{\omega: X(\omega) < x\}$ is an event of $\mathcal{A}$, by definition of a random variable, and clearly $F_X(-\infty) = 0$, $F_X(x_1) \le F_X(x_2)$ if $x_1 \le x_2$, and $F_X(+\infty) = 1$, $\lim_{h \searrow 0} F_X(x - h) = F_X(x)$. For instance, if Ω is $\{H, T\}$ representing one toss of a coin, $\mathcal{A}$ being its power set, $P(\{H\}) = p$, $P(\{T\}) = 1 - p = q$, then $(\Omega, \mathcal{A}, P)$ is the underlying model. Let $X(H) = 1$, $X(T) = 0$; then X is called a Bernoulli random variable, and the F_X, called the Bernoulli distribution, is

$$F_X(x) = 0, \quad x \le 0; \quad F_X(x) = q, \quad 0 < x \le 1;$$
$$F_X(x) = 1, \quad x > 1$$

The following are some other examples of frequent appearance:

1. Let Ω be the set of points corresponding to all possible outcomes of tossing a coin n times, so that there are 2^n points in Ω. Taking $\mathcal{A}$ to be the power set of

Ω, define $S_n: \Omega \to \mathbb{R}$ as $S_n(\omega) =$ number of heads in $\omega \in \Omega$. Thus, $S_n(\omega) = k$ means that ω has k heads and $n-k$ tails in its representation. Then S_n is a random variable and F_{S_n}, called the binomial distribution first derived by J. Bernoulli, is given (with probability of heads $= p = 1-q$) by $F_{S_n}(x) = \sum_{k=0}^{[x]} f_{k,n}(p)$, where

$$f_{k,n}(p) = \begin{cases} 0, & k < 0 \\ \binom{n}{k} p^k q^{n-k}, & 0 \le k \le n \\ 0, & k > n \end{cases}$$

Here $\binom{n}{k}$ is the binomial coefficient $n!/k!(n-k)!$. If $n = 1$, this is the Bernoulli distribution F_X ($[x]$ is the integer part of x).

2. If $\Omega = \mathbb{R}$, $\mathcal{A} = \sigma$-algebra determined by all intervals of $\mathbb{R}$, and P is a probability on $\mathcal{A}$, $X: \Omega \to \mathbb{R}$, defined by $X(\omega) = \omega$ is a random variable, then $F_X(x) = P[X < x]$ given by

$$F_X(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-t^2/2}\, dt, \quad -\infty < x < \infty$$

is the normal distribution, already encountered in the last section.

3. If Ω, $\mathcal{A}$, and X are as in Example 2, then P or equivalently F_X given by the equation

$$F_X(x) = \frac{1}{\pi} \int_{-\infty}^{x} \frac{dt}{1+t^2}, \quad -\infty < x < \infty$$

is called the Cauchy distribution.

4. Let Ω be the set of integers, $\mathcal{A}$ the power set, and $X(\omega) = \omega$, $\omega \in \Omega$; also let $P(\{k\}) = e^{-\lambda}\lambda^k/k!$, $k = 0, 1, 2, \ldots$, and $= 0$ for other k. Then F_X is given by

$$F_X(x) = \begin{cases} 0, & x \le 0 \quad \text{or} \quad \lambda \le 0 \\ \displaystyle\sum_{0<k\le[x]} e^{-\lambda} \frac{\lambda^k}{k!}, & x > 0 \quad \text{and} \quad \lambda > 0 \end{cases}$$

This is called the Poisson distribution. It arises in the following simple manner from example 1 (and also in many other ways). If a coin is tossed repeatedly, the probability p of its landing heads changes slowly after each toss (due to impact on the floor or defective metal) but such that np is approximately a constant ($= \lambda$, say). Then the binomial probability changes to the above Poisson law. In fact from Example 1, $f_{0,n}(p) = q^n = (1-p)^n = (1-\lambda/n)^n \to e^{-\lambda}$, as $n \to \infty$ by a standard calculus result. But also

$$\frac{f_{k,n}(p)}{f_{k-1,n}(p)} = \frac{(n-k+1)p}{kq} = \frac{\lambda - [(k-1)/n]\lambda}{k(1-\lambda/n)} \to \frac{\lambda}{k} \quad \text{as} \quad n \to \infty$$

$k = 1, 2, \ldots$, so that by induction one has as $n \to \infty$:

$$f_{1,n}(p) \to \lambda e^{-\lambda}, \quad f_{2,n}(p) \to \frac{\lambda^2 e^{-\lambda}}{2!}, \ldots,$$

$$f_{k,n}(p) \to \frac{\lambda^k e^{-\lambda}}{k!}.$$

This distribution was invented by S. D. Poisson (1781–1840) in his investigations of civil and criminal matters in 1837. The same distribution was later found to arise in experiments involving radioactive emissions, telephone traffic, and so on. It can be used as a good approximation for binomial probabilities if p is small and n relatively large.

In a similar manner, Cauchy's distribution is useful in target-shooting and destruction problems and of course is the normal distribution in many areas, as noted in the introduction. One calls the random variables by the same names as their distributions. Thus, there are Bernoulli, binomial, normal, Cauchy, Poisson, and other random variables if their distributions have those names.

It is now clear how other distribution functions relating to possible games and experiments can be introduced. In fact with each increasing F, $0 = F(-\infty) \le F(x) \nearrow F(+\infty) = 1$, we can construct a probability model and a random variable on it having the given function as its distribution. Namely, one can take $\Omega = \mathbb{R}$, $\mathcal{A} =$ the σ-algebra determined by all the intervals, $X(\omega) = \omega \in \Omega$, and $P(A) = \int_A dF$, $A \in \mathcal{A}$. Then $(\Omega, \mathcal{A}, P)$ is a model, and $F = F_X$ is the distribution of X. This simple case can be extended to a family of distributions if they satisfy a natural compatibility condition. Such a result was established in 1933 by A. Kolmogorov when he presented the modern axiomatic setup giving a satisfactory basis for a rigorous theory of probability. We now discuss some intrinsic properties of this abstract model after introducing the fundamental concept of stochastic (or statistical) independence, which distinguishes this subject from other parts of mathematics and which was already used by the ancients.

In $(\Omega, \mathcal{A}, P)$, two events A, B are independent if the occurrence of one has no influence on the other, and hence the uncertainty of the joint occurrence must be greater than the individual uncertainties. This is now translated mathematically into the formula

$$P(A \text{ and } B) = P(A)P(B) \tag{4}$$

Taking $A = B$, this implies that A is independent of itself if and only if $P(A) = 0$ or 1, so that A is either an impossible or an absolutely certain event. The above concept for n events $A_1, \ldots, A_n$ must be applied with a little care. Thus, the events are *mutually independent* if for each $1 < m \le n$ the following statement holds for all $1 \le i_1 < i_2 < \cdots < i_m \le n$,

$$P\left(A_{i_1} \text{ and } A_{i_2} \ldots \text{and } A_{i_m}\right) = \prod_{k=1}^{m} P\left(A_{i_k}\right) \qquad (5)$$

so that $2^n - n - 1$ such product equations must hold. If only every pair of n events satisfies Eq. (4), then there will be $\binom{n}{2}$ equations, and such a collection is called *pairwise independent*. Both the concepts are distinct generalizations of Cardano's power formula, and Eq. (5) is the most stringent. For random variables, these conditions take the following form. Let $X_1, \ldots, X_n$ be n random variables on $(\Omega, \mathcal{A}, P)$. Then they are said to be pairwise or mutually independent accordingly as for each pair X_i, X_j

$$\begin{aligned} P[\omega\colon a_i < X_i(\omega) < b_i \quad \text{and} \quad c_j < X_j(\omega) < d_j] \\ = P[\omega\colon a_i < X_i(\omega) < b_j] \\ \times P[\omega\colon c_j < X_j(\omega) < d_j] \end{aligned} \qquad (6)$$

or for each $1 < m \le n$, $1 \le i_1 < i_2 < \cdots < i_m \le n$,

$$\begin{aligned} P[\omega\colon a_j < X_{i_j}(\omega) < b_j, \quad j = 1, \ldots, m] \\ = \prod_{j=1}^{m} P\left[\omega\colon a_j < X_{i_j}(\omega) < b_j\right] \end{aligned} \qquad (7)$$

for all real numbers $a_i < b_i, c_j < d_j$. Similarly, if $X_1, X_2, \ldots,$ is an infinite sequence of random variables, then it is called a mutually or pairwise independent collection if each of its finite subcollections satisfies Eq. (7) or (6). Sometimes a reader may wonder whether independent random variables always exist in sufficient numbers. This is a legitimate concern, but by the repetition of an experiment $(\Omega, \mathcal{A}, P)$ may be taken to be rich enough to support such collections of independent variables. This is merely a technical matter with a relatively easy solution. Thus, all these concepts are meaningful, and a nontrivial theory is built around the notion of independence.

To state these concepts with distribution functions, let $X_1, \ldots, X_n$ be random variables on $(\Omega, \mathcal{A}, P)$. Their joint (or multivariate) distribution is given by

$$\begin{aligned} F_{X_1,\ldots,X_n}(x_1, \ldots, x_n) \\ = P[\omega\colon X_1(\omega) < x_1, \ldots, X_n(\omega) < x_n] \end{aligned} \qquad (8)$$

and this is an extension of Eq. (3). If $x_2 = +\infty, \ldots, x_n = +\infty$, then the event in the right side becomes $[\omega\colon X_1(\omega) < x_1]$ and hence $F_{X_1}(x_1) = F_{X_1,\ldots,X_n}(x_1, \infty, \ldots, \infty)$ and F_{X_1} is called the marginal distribution. Similarly, F_{X_i} is defined. As an example, let $(\Omega, \mathcal{A}, P)$ be a model for tossing a die n times. Then $\Omega = A^n$, where $A = \{1, 2, \ldots, 6\}$, $\mathcal{A}$ is the power set, and $\omega \in \Omega$ is a point with n coordinates, each component being one of the integers $1, \ldots, 6$. If $X_i(\omega) = \omega(i) = i$th component of ω, then $X_i(\omega) \in A$, and X_i is a random variable. (Assuming the die to be perfect, we take $P[\omega\colon \omega(i) = 1] = (\frac{1}{6})^n$.) In the general case, $X_1, \ldots, X_n$ are mutually independent if their joint distribution is a product of the marginals:

$$\begin{aligned} F_{X_1,\ldots,X_n}(x_1, \ldots, x_n) = \prod_{i=1}^{n} F_{X_i}(x_i) \\ \text{for all} \quad -\infty < x_i < \infty \end{aligned} \qquad (9)$$

It can be shown that Eqs. (7) and (9) are equivalent conditions. In case all $F_{X_i} = F$, the X_i are called identically distributed. Thus, for Bernoulli trials, $X_1, \ldots, X_n$ are independent and identically distributed $\{0, 1\}$-valued random variables.

For any random variable X on $(\Omega, \mathcal{A}, P)$, the kth moment is defined for any $k \ge 0$ as

$$E(X^k) = \int_{\mathbb{R}} x^k \, dF(x) \quad \left(= \int_{\Omega} X^k \, dP\right) \qquad (10)$$

provided that $\int_{\mathbb{R}} |x|^k dF(x) < \infty$. If $k = 1$, $E(X)$ is the expectation (or the population mean or average) of X. The actual definition is the integral in parentheses, but its equivalence with that of the distribution F follows from Eq. (3), and this relation is termed *the fundamental law of probability*. If $Y = X - E(X)$, then Y is centered and $E(Y^2)$ is called the variance of X, denoted Var $X = \sigma_x^2$, and its positive square root σ_x is termed the *standard deviation* of X. These serve a purpose analogous to the center of gravity and moment of inertia in mechanics. For the distributions introduced above, one has the following:

Distribution	Mean	Variance	Parameter
Bernoulli	p	$p(1-p)$	$0 < p < 1$
Binomial	np	$np(1-p)$	$0 < p < 1$
Poisson	λ	λ	$\lambda > 0$
Standard normal	0	1	
Cauchy	Does not exist	Does not exist	

With these ideas in hand, J. Bernoulli's law of large numbers can be given for random variables taking more than two values. His combinatorial enumeration is no longer possible. P. L. Čebyšev was the first to obtain a generalization for which he devised a simple but powerful inequality:

A. Proposition 1 (Čebyšev's Inequality)

Let X be a random variable on $(\Omega, \mathcal{A}, P)$ with mean μ and variance σ^2. Then for any $\varepsilon > 0$,

$$P[\omega\colon |X(\omega) - \mu| > \varepsilon] \le \sigma^2/\varepsilon^2 \qquad (11)$$

B. Proposition 2

Let $X_1, X_2, \ldots$ be pairwise-independent random variables on $(\Omega, \mathcal{A}, P)$ with means $\mu_1, \mu_2, \ldots$ and variances $\sigma_1^2, \sigma_2^2, \ldots$ such that $(1/n^2)\sum_{i=1}^n \sigma_i^2 \to 0$ as $n \to \infty$. If $S_n = \sum_{i=1}^n X_i$, then

$$P\left[\omega\colon \left|\frac{S_n(\omega) - E(S_n)}{n}\right| \geq \varepsilon\right] \to 0 \quad \text{as } n \to \infty \quad (12)$$

for each $\varepsilon > 0$; that is, the sequence obeys the law of large numbers. In particular if the X_n sequence is independent and identically distributed with mean μ and variance σ^2, it always obeys the law of large numbers.

Note that, in the Bernoulli case, the X_i have a common distribution with mean p and variance $p(1-p)$, so that $(1/n^2)\sum_{i=1}^n \sigma_i^2 = p(1-p)/n \to 0$ as $n \to 0$. Thus, Bernoulli's theorem is included in Čebyšev's result. If more generally all the X_i have a common distribution, then Var $X_i = \sigma^2$ so $(1/n^2)\sum_{i=1}^n \sigma_i^2 = \sigma^2/n \to 0$, so that Eq. (12) holds, and the second part follows. Since the demonstration is simple and instructive, it will be included here.

1. Proof of 1

The event $[|X - \mu| > \varepsilon]$ is the same as $[|X-\mu|^2 > \varepsilon^2]$. Hence, using Eq. (10) and setting $Y = X - \mu$, we obtain

$$\begin{aligned}\sigma^2 = E(Y^2) &= \int_\Omega Y^2\, dP \\ &= \int_{[|Y|>\varepsilon]} Y^2\, dP + \int_{[|Y|\leq\varepsilon]} Y^2\, dP \\ &\geq \varepsilon^2 \int_{[|Y|>\varepsilon]} dP = \varepsilon^2 P[|Y| > \varepsilon].\end{aligned}$$

This is the usual integral which is replaced by a sum in the discrete case. Thus, inequality (11) is established.

2. Proof of 2

Letting $Y_i = X_i - \mu_i$, note that the pairwise independence of X_i implies the same of Y_i so that

$$\text{Var } S_n = E\left(|S_n - E(S_n)|^2\right) = E\left(\left|\sum_{i=1}^n Y_i\right|^2\right)$$

$$= \sum_{i=1}^n E\left(Y_i^2\right) + \sum_{i\neq j} E(Y_i Y_j)$$

since expectation of the sum is the sum of the expectations by linearity of integral in Eq. (10),

$$\text{Var } S_n = \sum_{i=1}^n \sigma_i^2 + \sum_{i\neq j} E(Y_i)E(Y_j) = \sum_{i=1}^n \sigma_i^2$$

since $E(Y_i) = 0$. Here the pairwise independence is used to deduce, by Eqs. (9) and (10),

$$\begin{aligned}E(Y_i Y_j) &= \iint_{\mathbb{R}^2} y_i y_j\, dF_{yi}\, dF_{Y_i} \\ &= \int_{\mathbb{R}} y_i\, dF_{Y_i} \int_{\mathbb{R}} y_j\, dF_{Y_j} \\ &= E(Y_i)E(Y_j) = 0\end{aligned}$$

Hence by Eq. (11), applied to S_n, one has

$$\begin{aligned}&P[\omega\colon |S_n(\omega) - E(S_n)| > n\varepsilon] \\ &\leq \frac{\text{Var} S_n}{n^2\varepsilon^2} = \frac{1}{\varepsilon^2 n^2}\sum_{i=1}^n \sigma_i^2 \to 0\end{aligned}$$

as $n \to \infty$, by hypothesis. So Statement 2 holds.

In the previously mentioned result, one needs only the condition that $E(Y_i Y_j) = 0$, $i \neq j$, i.e., $\{X_i, or Y_i\}_1^\infty$ is a sequence of *uncorrelated* random variables, instead of (pairwise) independence. The former is weaker than the latter condition, but the contrast is not quite evident. This will now be explained, since it also has a deep and beautiful mathematical significance. The conclusion is through Fourier transforms, plus some properties of complex functions. Thus a pair of random variables X, Y are independent if and only if their joint and individual transforms, called traditionally here characteristic functions (ch.f.s), denoted $\varphi_X(t) = E(e^{itX})$ for X, and similarly for the others, satisfy:

$$\varphi_{X,Y}(t_1, t_2) = \varphi_X(t_1)\varphi_Y(t_2), \forall t_1, t_2 \in \mathbb{R}. \quad (13)$$

Now if X and $\tilde{X}$ have the same distribution, written $X \cong \tilde{X}$, then they will have the same ch.f., and if also $Y \cong \tilde{Y}$, from (13) one gets for any real $t_1, t_2 \in \mathbb{R}$, $t_1 X + t_2 Y \cong \tilde{X} + t_2\tilde{Y}$. Since this is true for all t_1, t_2 it means that the independence of X and Y is *equivalent* to having the same distribution of $t_1 X + t_2 Y$ and $t_1\tilde{X} + t_2\tilde{Y}$ for any $t_1, t_2 \in \mathbb{R}$. On the other hand a well-known and a good sufficient moment condition for a unique dtermination of the distribution of a random variable Z is:

$$\sum_{k=1}^\infty \frac{1}{(\alpha_{2k})^{\frac{1}{2k}}} = \infty,$$

where $\alpha_k = E(|Z|^k) < \infty$. These two properties can be combined to obtain a pleasant purely analytical condition explaining the equivalence of independence and a strengthened uncorrelatedness condition as follows.

Let $Q_1(X, a)$, $Q_2(Y, b)$ be a pair of real (measurable) functions of X and Y, depending also on some parameters $a \in A \subset \mathbb{R}^s$ and $b \in B \subset \mathbb{R}^{s'}$ where A, B are closed bounded parallelepipeds in the real Euclidean spaces. For instance, Q_1, Q_2 may be taken as some polynomials with a, b as coefficients. Let φ_m, ψ_n be continuous scalar functions on $\mathbb{R}$ for each m, n, to be specified below. Consider their expectations on the basic probability space:

$$E(\varphi_m(Q_1(X,a))) = \alpha_m(a); \quad E(\psi_n(Q_2(Y,b))) = \beta_n(b),$$

and the cross-product moments

$$E(\varphi_m(Q_1(X,a))\psi_n(Q_2(Y,b))) = \gamma_{m,n}(a,b), \qquad m,n = 1,2,\ldots.$$

The function sequences φ_m, ψ_n are chosen to determine the distributions of $Q_1(X,a)$ and $Q_2(Y,b)$ uniquely. This is a substitute of the traditional moment condition recalled above. Finally suppose that there are simply connected bounded closed cylinders A_1, B_1 such that $A \subset A_1$, $B \subset B_1$ so that the moment functions α_m, β_n and $\gamma_{m,n}$ are holomorphic (of analytic) in A_1, B_1 and the product set $A_1 \times B_1$, respectively. This analyticity property of the first and second moments translates the independence hypothesis from being an abstract illusive concept to a property of (complex) function theory in the following manner.

In view of the holomorphy of the functions φ_m, ψ_n they determine the distributions of $Q_1(X,a)$ and $Q_2(Y,b)$ uniquely. Now suppose that the analytic function sequences α_m, β_n, $\gamma_{m,n}$ in the closed bounded polycylinders A_1, B_1 and $A_1 \times B_1$ satisfy the uncorrelatedness condition, namely:

$$\gamma_{m,n}(a,b) = \alpha_m(a)\beta_n(b), \quad a \in A_1, \quad b \in B_1,$$

for a finite set N of indexes, $1 \le m,n \le N < \infty$, where N depends only on the basic space on which X, Y are given. The conclusion is that *this finite set of relations on uncorrelatedness of* $\varphi_m(Q_1(X,a))$, $\psi_n(Q_2(Y,b))$ *implies, and hence is equivalent to, independence of* $Q_1(X,a)$, $Q_2(Y,b)$. The connection here depends *decisively* on some properties of complex functions of several variables, by forming the ideal generated by the infinite collection $\{\gamma_{m,n}(a,b) - \alpha_m(a)\beta_n(b), m,n \ge 1, a \in A_1, b \in B_1\}$ which then is also determined by just a **finite** set of generators of the same ideal. [Recall that an ideal is a sub ring of a ring which contains also the product of any element of a ring with an element of the ideal.] The above conclusion is a consequence of a renowned theorem of H. Cartan, the details of which are discussed, for instance, in Gunning and Rossi (1965, Chapter VIII), and a specialized version for the present purposes is given with clear exposition by Linnik (1968, pp. 83–87). In applications the functions ϕ_n, ψ_n can be chosen in different ways, for instance, as:

$$\varphi_n(x) = x^n e^{-g(x)}; \quad \psi_n(y) = y_n e^{-h(y)}, \quad n \ge 0,$$

where $g, h \ge 0$ are polynomials of degree at least 2, and $x > 0$, $y > 0$. Thus the unexpected relation between the fundamental concept of stochastic independence of random variables and its function theory counterpart with uncorrelatedness (or essential orthogonality) with a *finite set* of functions of the random variables is both an interesting and significant byproduct of some classical results in several complex variables. In the case of normal random variables the equivalence of these two concepts is well-known and simply verified. Note that if there are n random variables, in place of 2, the same conclusion extends since the basic Cartan theorem is valid in that case also.

III. SOME EXAMPLES AND PARADOXES

In this section two examples will be given to illustrate how the concepts and results of the preceding section can be used with precise descriptions, or abused if sufficient care in the description of a stochastic model is not exercised.

It is a common practice in probability to use gambling terminology to state several experiments and models, simply because no further detail of description is needed and the terms are universal. For two of the examples below the models are therefore based on coin tossing repeatedly until a kth head appears for the first time. The number of tosses can be infinite.

A. Example 1

Since the kth head may appear on the nth toss, $n \ge 1$ being any integer, our sample space Ω must consist of infinite sequences of labels "head" and "tail," which will be denoted by 1 and 0, respectively. Thus, $\omega \in \Omega$ if, for example, $\omega = (0, 1, 0, 0, \ldots, 1, 0, \ldots)$. Since every such ω can be put in a one-to-one relation with a point of the unit interval (using the dyadic expansion of reals), Ω has as (uncountably) many points, so that $\mathcal{A}$ has to be chosen with some care. Let $I_n \subset \Omega$ be an "interval," that is, $\omega \in I_n$, if and only if the first n components of ω have a prescribed pattern. For instance I_2 may have all $\omega \in \Omega$ whose first two components are (0, 1) so that $\Omega - I_2$ will have all ω with (1, 1), (1, 0), or (0, 0) as its first two coordinates. Let $\mathcal{A}$ be the smallest σ algebra containing all such I_n, $n \ge 1$. (Note that $I_n \cap I_m = I_{\min(m,n)}$ is an "interval," but $I_n \cup I_m$ or $I_n - I_m$ is not an interval, although $I_n - I_m$ can be expressed as a finite disjoint union of such intervals.) If I_n has k ones, and $n-k$ zeros, then define $P(I_n) = \binom{n}{k} p^k (1-p)^{n-k}$, where the probability of a head is p. This describes the model $(\Omega, \mathcal{A}, P)$, and, for instance, if $\tilde{I}_n$ is the set of ω's corresponding to the first head on the nth toss, then $\tilde{I}_n \in \mathcal{A}$ and $P(\tilde{I}_n) = (1-p)^{n-1}p$, since the order is fixed. Let $X(\omega)$ equal the number of zeros before the first head in ω. Then X is a countably valued random variable, since for each integer N, $\{\omega: 0 \le X(\omega) \le N\} = \tilde{I}_1 \cup \tilde{I}_2 \cup \cdots \cup \tilde{I}_{N+1} \in \mathcal{A}$. With this setup, all pertinent questions of the experiment can be answered. For instance.

$$E(X) = \sum_{n\geq 0} nP[\omega: X(\omega) = n]$$
$$= \sum_{n=0}^{\infty} nq^n p, \quad q = 1 - p$$
$$= pq \sum_{n=1}^{\infty} \frac{d}{dq}(q^n)$$
$$= pq \frac{d}{dq}\left(\frac{q}{1-q}\right) = \frac{q}{p}.$$

Similarly, Var X can be shown to be q/p^2. Higher moments are similar, but the computations are more invloved.

The same model $(\Omega, \mathcal{A}, P)$ can be used to present the following extension. If $Y(\omega)$ is the rth head after $(n-1)$ tails, then

$$P[Y = n] = \binom{n+r-2}{n-1} p^r q^{n-1}.$$
$$n = 1, 2, \ldots$$

If $r = 1$, this reduces to the previous case, called the *geometric distribution*. The general case is said to be the *negative binomial* or *Pascal distribution*. It can be shown that $E(Y) = nq/p$, Var $Y = nq/p^2$. This distribution has applications in many areas and also arises as a limit distribution for experiments describing a contagion or with "Bose–Einstein statistics" in physics.

B. Example 2

This example shows how *imprecise specification of an experiment can lead to difficulties*. The problem is known as Bertrand's paradox, and it is one of several such cases listed by J. Bertrand at the end of the nineteenth century exemplifying the difficulties with the subject at that time. Consider a circle of unit radius and inscribe an equilateral triangle in it so that its side is $\sqrt{3}$. Suppose a chord of the circle is chosen at random. What is the probability that its length exceeds the length of a side of the triangle, that is $\sqrt{3}$?

1. Solution 1

For Ω take the circle of radius 1 and $\mathcal{A}$ as the σ-algebra detemined by all concentric disks inscribed in Ω. For each $A \in \mathcal{A}$, let $P(A)$ be the proportion of the area of A contained in Ω. Then the required event is {chord of length $\geq \sqrt{3}$} $= A_0$ (say). The chord is fixed uniqely if it touches an inscribed circle. So the desired event is equivalent to the midpoint of the chord lying inside the circle of radius $\frac{1}{2}$ since that is the distance of the side of the equilateral triangle from the center. Hence, A_0 is the disk of radius $\frac{1}{2}$, and $P(A_0) = \pi(\frac{1}{2})^2/\pi = \frac{1}{4}$.

2. Solution 2

Let θ be the angle subtended by the chord at the center of the circle. Take $\Omega = [0, 2\pi]$, $\mathcal{A} = \sigma$-algebra determined by all the subintervals of Ω, and $P(A) =$ proportional length of A contained in Ω. In this model, the desired event A_0 holds if and only if $2\pi/3 < \theta < 4\pi/3$. Hence, $A_0 \in \mathcal{A}$, and $P(A_0) = (4\pi/3 - 2\pi/3)/2\pi = \frac{1}{3}$.

3. Solution 3

Since the position of the chord is uniquely determined by its distance from the center, one can take $\Omega = [0, 1]$, $\mathcal{A} = \sigma$-algebra determined by the subintervals, of Ω, and $P(A) =$ length of A as a legitimate model. Now the desired A_0 occurs if and only if the chord lies at a distance $\leq \frac{1}{2}$. Thus, $P(A_0) = \frac{1}{2}$.

Several other models can be constructed. Of the numbers $\frac{1}{4}, \frac{1}{3}, \frac{1}{2}$, which is the correct probability? Since the reasoning is correct in each case and the answers are different, one has a "paradox." Actually, all three models and hence all three answers are correct since one is conducting a *different experiment* each time. Here "chord is chosen at random" is ambiguous, since one can choose it in so many different ways, and it is necessary to indicate the method used in the "random selection." Thus, when such inconsistent results appear, it is necessary to examine the description of the problem carefully and eliminate multiple interpretations so as to express the experiment with a unique probability model $(\Omega, \mathcal{A}, P)$.

The model construction is made in detail to illustrate the basic ideas, but with experience one can visualize the procedure and reduce the calculations to a few lines. However, the underlying sample space and the resulting model should be clearly recognized. Only then should the theory be applied. Another type of paradox for evaluating conditional probabilities is given in Section V.C below.

IV. STRONG LAW OF LARGE NUMBERS AND ITS USES

In the preceding sections the laws of large numbers due to J. Bernoulli and P. L. Čebyšev were discussed. The general form says that, if $X_1, X_2, \ldots$ is a sequence of independent identically distributed random variables on $(\Omega, \mathcal{A}, P)$, with mean μ and variance σ^2, $S_n = \sum_{i=1}^{n} X_i$, then, omitting the display of $\omega \in \Omega$, one has

$$\lim_{n\to\infty} P[|S_n/n) - \mu| \geq \varepsilon] = 0,$$
$$\text{for each} \quad \varepsilon > 0. \tag{14}$$

To justify the frequency (or long-term-average) interpretation of probability, this statement is not adequate, not even for the Bernoulli variables. From the original publication

in 1713 of Bernoulli's work, the desired strong statement awaited many developments. It was only in 1909 that E. Borel succeeded in establishing the following result, as indicated in Section I, called the strong law of large numbers. If $X_1, X_2, \ldots$ are independent Bernoulli variables with the (constant) probability of success, $p, 0 < p < 1$, and $S_n = \sum_{i=1}^{n} X_i$, then

$$\lim_{n\to\infty} S_n/n = E(X_1) = p \qquad (14')$$

with probability 1. This statement means that there is a set $N \in \mathcal{A}$, $P(N) = 0$, and for each $\omega \in \Omega - N$, $S_n(\omega)/n \to p$ as $n \to \infty$. This is a much stronger statement than Eq. (14) and is also more difficult to prove. The result of Eq. (14′) initiated a new stage in probability. It was finally generalized by A. Kolmogorov in 1928 to all independent identically distributed random variables with *one moment existing* and shown to be the best result one can obtain. Let us explain the significance of this strong law.

First observe that, by Eq. (14), $|(S_n/n) - \mu|$ is likely to be small for large n, fixed, but this difference is not asserted to remain uniformly small as n is further increased. In contrast, Eq. (14′) says that the difference $|(S_n/n) - p|$ remains small for all n after a certain n_0, and this is the strength. Thus, for independent Bernoulli variables, the relative frequency S_n/n for large n gives practically the (unknown) probability p of success. This is the vindication of Cardano's feeling that these proportions "should stabilize."

The above discussion does not suggest the deeper implications of the strong law. To explain it further, we present three applications to (1) empirical distributions, (2) random walk, and (3) the St. Petersburg paradox. The last shows that the *assumptions* of Kolmogorov's generalization *should not be overlooked*.

The strong law of large numbers allows one to estimate the distribution of a random variable. Let $X_1, X_2, \ldots$ be independent random variables with a common distribution F. Typically, F is not known; at least one wants to test whether it is the assumed function. To do this consider, for each real x and positive integer n, the proportion $\nu_n(x)$ of the observations $X_1, \ldots, X_n$, which are less than x. Thus, $\nu_n(x) = (1/n)\{\text{no. of } X_i < x\}$. To see the meaning of this clearly, let $Y_i = 1$ if $X_i < x$; otherwise, $Y_i = 0$. Set $S_n(x) = \sum_{i=1}^{n} Y_i$. Then $\nu_n(x) = S_n(x)/n$. Since the Y_i are Bernoulli distributed and independent, $P[Y_i = 1] = P[X_i < x] = F(x)$, by Eq. (3). It follows by Eq. (14′) that $S_n(x)/n \to F(x)$ with probability 1. This is an application of the strong law. With some more work, one can show that this limit is uniform in x. In symbols,

$$P\left[\lim_{n\to\infty} \sup_{-\infty<x<\infty} |\nu_n(x) - F(x)| = 0\right] = 1 \qquad (15)$$

Here ν_n is called the sample or empirical distribution, and it gives a true picture of F when n is large enough. There are analogous results in the multidimensional case to estimate $F_{X_1,\ldots,X_n}$ of Eq. (8). The statement of Eq. (15) is called the Glivenko–Cantelli theorem, and its proof is not simple.

There is also a great deal of interest attached to the fact that $\nu_n(x) \to F(x)$ not only uniformly with probability one, as noted above, but that $P([\nu_n(x) \in A]) \to 0$, if $F(x) \notin A$, exponentially fast. It is a case of rare events, and the rate of decay of the probability of $[\nu_n(x) \in A]$ is of considerable interest for practical applications. [The jackpot in a national lottery is an example of a rare event and its great popular interest is evident.] In the 1930s, this aspect was investigated by N. V. Smirnov, H. Cramér and others, and as a consequence one finds that exponential decay indeed does occur. A comprehensive statement is as follows. If $Q_n(\cdot)$ is the probability distribution of the empiric function ν_n, then for each $A \subset \mathbb{R}$ (a Borel set), one has $Q_n(A)$ decreases exponentially. More precisely, $\lim_{n\to\infty} \log Q_n(A) = -\inf_{x\in A} I(x)$ where I is the *rate function* defined as complementary to the log moment (or cumulant) generating function of X_1, so that if μ is the probability distribution of X_1 (hence also of $X_i, i \geq 1$) and $\Lambda_\mu(t) = \log E(e^{tX_1})$, $x \in \mathbb{R}$, then $I(x) = \sup\{tx - \Lambda_\mu(t) : t \in \mathbb{R}\} \geq 0$. This result is also not simple, and one can consult Sanov (1957) for it and some generalizations. It leads to what is called the *large deviation theory*, and an outline of which is given in S.R.S. Varadhan (1984). There an account of how the ideas are applied to numerous problems including stochastic processes can be found.

Next a random walk example will be illustrated. Suppose that a particle moves on the x axis one step to the right or left according to whether a tossed coin falls heads or tails, respectively. When the coin is fair, the probability of a head is $\frac{1}{2}$ so that a step to the right or left is equally likely. This is called a symmetric random walk. The problem is to find the probability that the particle visits the origin or any other step. The same question can be asked if the particle moves in a plane in directions parallel to the coordinate axes. Let us consider the equiprobable (or symmetric) case for simplicity. Then with probability $\frac{1}{4}$ the particle moves one step in one of the four directions (i.e., up, down, left, or right). In three or higher dimensions, say k, the same thing takes place with probability $1/2k$, $k \geq 3$, for each step. This problem can be used as an approximation to the diffusion model in physics. The above random walk is unrestricted, but one can put barriers in one or more directions either to trap (or absorb) the particle or to turn back (or reflect) at the barrier. These are important but not simple questions.

Let us consider the one-dimensional case introduced above. Let Ω consist of all points ω, e.g., (1, 0, 0, 1, ...), composed of ones and zeros corresponding to a head and tail in an unlimited sequence of tosses. Take $\mathcal{A}$ to

be the same class as that described in the first example of Section III, and P as the corresponding probability with $p = \frac{1}{2}$. Thus, $(\Omega, \mathcal{A}, P)$ will be the same model. Let $X_k(\omega) = +1$ or -1 depending on whether the kth coordinate is 1 or 0. So $P[X_k = 1] = P[X_k = -1] = \frac{1}{2}$. Then $X_1, X_2, \ldots$ are independent Bernoulli random variables. Let $S_n = \sum_{k=1}^{n} X_k$ with $S_0 = 0$, to denote the (random) position of the particle on the line at the nth step. If the particle starts at a point h on the x axis, then one takes $Y_k = X_k - h$, so that $P[Y_k = 1] = P[Y_k = -1] = \frac{1}{2}$, and the problem reduces to the preceding case. By Eq. (14′), $S_n/n \to 0$ with probability 1 ($\sum_{k=1}^{n} Y_k/n = (S_n/n) - h \to 0$ in the general case). This implies, at least intuitively, that S_n takes 0 (or h) infinitely many times. However, a rigorous proof of the statement requires more work. Actually in 1921, G. Pólya showed that the symmetric random walk visits the origin infinitely often in one and two dimensions (so that "all roads lead to Rome" in these cases) but that in three dimensions there is positive probability that it may not return to the origin. The latter statement holds in k dimensions, $k \geq 3$. It was also found in 1940 that the probability of returning to the initial position in three dimensions is ~ 0.35. Thus, the particle drifts to infinity with greater probability than a return to the origin.

Even when the X_k's are only independent real (not necessarily Bernoulli) random variables with a common distribution, $\{S_n, n \geq 0\}$ is called a general random walk, where $S_n = \sum_{k=1}^{n} X_k$, $S_0 = 0$. If $X \in \mathbb{R}$ and if $P[|S_n - x| < \varepsilon$, for infinitely many $n] = 1$ for each $\varepsilon > 0$, then S_n is said to visit x infinitely often, and x is called a recurrent point of the random walk. A relatively deeper fact is that the origin is a recurrent point of the random walk S_n whenever $P[|S_n/n| > \varepsilon] \to 0$ as $n \to \infty$, for any $\varepsilon > 0$. In particular if the X_k have means zero, then the law of large numbers implies this. Probability theory studies the behavior (or fluctuation phenomena) of partial sums of different types of random variables. The sequence $\{S_n, n \geq 0\}$ is an instance of a random or stochastic process in which the variables are no longer Bernoulli, and hence the counting methods are insufficient. New techniques and theory are essential. In discussing the classical period and teaching of mostly simpler problems, J. L. Doob observed in 1942 (in explaining the need for a general study of stochastic processes) the following: "This calculation [with permutations and combinations] looms large in elementary courses, however, only because calculations need little mathematical preparation either for student or teacher. It is considered easier to perform long calculations than to develop a general point of view, bolstered by theory. This may be good pedagogy, up to a certain point, but gives students a false picture of the subject." This admonition is generally heeded in the later developments of the subject, and at present probability theory involves the study of genuinely broader phenomena, being motivated by special cases.

The fluctuation phenomenon of partial sums noted above is at the heart of the single- and multiple-server queuing problems, sequential analysis, and other applications. They cannot be considered here.

As a final example, we show how overlooking the moment condition of the strong law leads to a difficulty, called the St. Petersburg paradox. Suppose that a game is played with a fair coin until it falls heads. If a head falls on the nth toss, the player gets 2^n dollars and nothing otherwise. Here again the probability model $(\Omega, \mathcal{A}, P)$ is the same as in the preceding example. Let $X(\omega)$ represent the gain for the player on ω. So if the first 1 in ω is at the nth place, then $X(\omega) = 2^n$ and $P[X = 2^n] = 2^{-n}$. Let $X_1, X_2, \ldots$ be independent random variables with the same distribution as X. Thus, X_n represents the nth play. If $S_n = \sum_{k=1}^{n} X_k$, then $S_n/n \not\to$ a finite limit since $E(X) = \sum_{n=1}^{\infty} 2^n(1/2^n) = +\infty$ and the strong law of large numbers is not applicable. If $E(X) = \mu$ is finite, then $S_n/n - \mu \to 0$ with probability 1 and if μ is the entrance fee for the player per game, then it is fair. However, in the problem at hand, for any α, $S_n - n\alpha$ will be positive for large n, and hence to make the game fair, the entrance fee α must be infinite, which is a paradoxical situation. A number of modifications have been proposed from the time this "paradox" was noted by Daniel Bernoulli in 1730 in St. Petersburg. Since the hypothesis of the existence of one moment is needed for the strong law, that is not applicable here and one should not try to "bend" the result to the present case. Actually, it can be shown, by the method of truncation, that $S_n/n \log_2 n \to 1$ with probability 1, so that $(1/n)(S_n - n \log_2 n) \to 0$ and the game may be called "fair." Here, $\log_2 n$ is the logarithm to the base 2. This shows that the entrance fee should be variable from game to game ($log_2 n$ dollars), and the paradox disappears.

In reality, it turns out that if a fixed entrance fee α is charged and α is large, one has to play an extraordinarily large number n of games in order to have $S_n > n\alpha$ with probability 0.99, for instance. If the player is allowed only one game, then the situation, of course, changes. Thus, the probability that there is at least one head before N tosses is $= 1 - 2^{-N+1}$, and hence the player will suffer a loss if N is large, even though the gain is 2^N dollars if the first head appears on the Nth trial.

V. CONDITIONAL PROBABILITY AND DEPENDENCE

Thus far only independent random variables and experiments have been discussed. The next decisive step in the development is to consider classes of dependence.

Even the random walk process $\{S_n, n \geq 0\}$, with $S_n = \sum_{k=1}^{n} X_k$, $S_0 = 0$, has already involved a dependent sequence since $S_{n+1} = X_{n+1} + S_n$, and S_n's are not independent. Here a new concept is needed and it is introduced as follows.

A. Conditioning

To consider the simplest problem, let A, B be two events and, if B is known to have occurred, find the probability of A given B, denoted $P(A \mid B)$. Since the knowledge of B should be used with A, one considers $A \cap B$ (=A and B together). Assuming $P(B) > 0$, one has to look at the new class of events $\mathcal{A}(B) = \{A \cap B\colon A \text{ in } \mathcal{A}\}$ and consider $P(A \cap B)$. Since $0 \leq P(A \cap B) \leq P(B)$ and B is fixed, to make $P(A \mid B)$ a probability function [so $P(B \mid B) = 1$] one normalizes $P(A \mid B)$ as $P(A \cap B)/P(B)$ and calls $P(\cdot \mid B)$ the conditional probability on $\mathcal{A}$, given B. Note that, if A, B are independent so that intutively the occurrence of B has no "influence" on A, one gets $P(A \mid B) = P(A)$ by Eq. (4), and hence this definition extends the earlier concept. It is useful to express it as

$$P(A \text{ and } B) = P(B)P(A \mid B) \tag{16}$$

and this can be employed to calculate the left side if the right side is known. As long as $P(B) > 0$ this is well defined, but if $P(B) = 0$, then the left side is clearly zero also, so that $P(A \mid B)$ is indeterminate but Eq. (16) always makes sense. Let us set aside the indeterminate case first, and suppose that both $P(A) > 0$ and $P(B) > 0$. Then one can define $P(B \mid A)$ in the same way, and Eq. (16) implies interchanging A, B:

$$P(B \mid A) = P(B)P(A \mid B)/P(A). \tag{17}$$

This simple formula is of considerable interest in applications. A useful form is to take Ω as the union $\bigcup_{k=1}^{n} \Omega_k$, $P(\Omega_k) > 0$ for each k, and $\Omega_k \cap \Omega_{k'} = \emptyset$.Thus, Ω occurs if and only if exactly one event Ω_k occurs. Since $A = A \cap \Omega = \bigcup_{k=1}^{n}(A \cap \Omega_k)$, and $P(A) = \sum_{k=1}^{n} P(A \cap \Omega_k)$ for any event A, one has with Eq. (16)

$$P(A) = \sum_{k=1}^{n} P(\Omega_k)P(A \mid \Omega_k). \tag{18}$$

Taking $B = \Omega_k$ in Eq. (17) and using Eq. (18), one gets the *Bayes formula*:

$$P(\Omega_k \mid A) = \frac{P(A \mid \Omega_k)P(\Omega_k)}{\sum_{k=1}^{n} P(A \mid \Omega_k)P(\Omega_k)}. \tag{19}$$

This result has the following interesting interpretation. If an event takes place in one of n mutually exclusive and exhaustive ways with probability $p_k[=P(\Omega_k) > 0]$, then after observing an event A, one can calculate by Eq. (19) the conditional probability of the hypothesis Ω_k given A if $P(A \mid \Omega_k)$ and p_k are known. The practical applications of this interpretation, which are quite useful in real-life problems, will be indicated later in the section. When $P(B) = 0$, then evaluation of $P(A \mid B)$ is difficult as shown in Section C.

Let us consider now the profound significance of conditional probability. The concept, in fact, was already employed in the 17th and 18th centuries. Actually formulae (17) [and (19)] were used by the clergyman T. Bayes (1702–1761) himself. His paper was published 2 years after his death.

Here two examples are considered since they lead to the important Markovian and martingale dependencies:

1. Example 1

Suppose that an urn contains r red and b blue balls of the same physical characteristics. With each random drawing of a ball, it is returned together with c balls of its type and d balls of the other type, where c, d are integers (positive or not). The process is stopped when the number of balls of either color is likely to be negative at a drawing. This is a variation of the classical Pólya urn scheme. The probability of a sequence RB (red, blue) is given by Eq. (17) as

$$P(\text{RB}) = \frac{r}{b+r}\,\frac{b+d}{b+c+r+d}$$

and similarly

$$P(\text{BR}) = \frac{b}{b+r}\,\frac{r+c}{b+c+r+d}$$

which are generally different, since the order matters. If $c = -1$, $d = 0$, and one does not need to recognize the order of the sequence, then

$$P(\text{a red and blue}) = \frac{2br}{(b+r)(b+r-1)} = \binom{b}{1}\binom{r}{1}\Big/\binom{b+r}{2}.$$

The last formula, the more familiar one, can also be obtained without using the notion of conditional probability. On the other hand, suppose that there are two urns having $b_1 + r_1$ and $b_2 + r_2$ balls of the types described. If one flips a coin and chooses urn I if the coin falls heads and II if it is tails, with probabilities p and $q = 1 - p$, then

$$P(\text{RB}) = pP(\text{RB} \mid \text{I}) + qP(\text{RB} \mid \text{II}) \qquad \text{by formula (18)}$$

$$= p\frac{r_1}{b_1+r_1}\,\frac{b_1+d_1}{b_1+c_1+r_1+d_1} = q\frac{b_2}{b_2+r_2}\,\frac{c_2+r_2}{b_2+c_2+r_2+d_2}.$$

These results have applications in, for example, accident insurance or contagion. Using the fact that $P(B) = pP(B \mid \mathrm{I}) + qP(B \mid \mathrm{II})$, one has the conditional probability $P(\mathrm{R} \mid \mathrm{B}) = P(\mathrm{RB})/P(\mathrm{B})$, which will be different from $P(\mathrm{R})$.

2. Example 2

Let us go on to another set of ideas. We start with the classical gambler's ruin problem, which was originally proposed by the Dutch mathematician C. Huygens (1629–1695) in his book published in 1657 and was solved by A. de Moivre in 1711. The solution was also obtained by P. Montmort (1678–1719) and Nicholas Bernoulli independently at about the same time. To state it, suppose players I and II have initial fortunes of a and b dollars, and one plays against the other by tossing a coin. If the coin falls heads, I gets a dollar from II and, if if it is tails, gives a dollar to II. The game stops when I is ruined (i.e., has zero dollars) or II is ruined (so I gets $a+b$ dollars). The problem is to find the probability that I is ultimately ruined if p is the probability of a head in a toss.

Let $p_a(q_a)$ be the probability of ultimate win (ruin) of I if the starting capital is a. After the first toss, I has either $a+1$ or $a-1$ dollars. Hence Eq. (18) implies

$$q_a = pq_{a+1} + qq_{a-1}. \tag{20}$$

If $a=1$, then clearly $q_1 = pq_2 + q$, since $q_0 = 1$, and similarly $q_{a+b} = 0$ so that $q_{a+b-1} = qq_{a+b-2}$. Hence, for solving the problem, Eq. (20) can be rewritten in a more familiar form,

$$q_x = pq_{x+1} + qq_{x-1} \qquad x = 1, 2, \ldots, a+b-1 \tag{21}$$

with $q_0 = 1$, $q_{a+b} = 0$. This is a second-order difference equation, and the standard calculus method is to consider its characteristic polynomial:

$$pt^2 - t + q = 0$$

or

$$pt^2 - t + 1 - p = (t-1)(pt - q) = 0.$$

The roots are thus $t_1 = 1$, $t_2 = q/p$. The general solution of Eq. (21) is

$$q_x = At_1^x + Bt_2^x \quad \text{or} \quad q_x = A + Bx \tag{22}$$

depending on whether $t_1 \neq t_2$ or $t_1 = t_2$. Using the boundary conditions $q_0 = 1$ and $q_{a+b} = 0$, one gets, if $q \neq p$, then $A + B = 1$, $A + Bt_2^{a+b} = 0$, so that

$$B = [1 - (q/p)^{a+b}]^{-1}, \quad A = 1 - B$$

and if $q = p = \frac{1}{2}$, then $A = 1$, and $B = -(a+b)^{-1}$. Hence,

$$q_a = \frac{(q/p)^a - (q/p)^{a+b}}{1 - (q/p)^{a+b}} \qquad a = 1, 2, \ldots, a+b-1, \tag{23}$$

and when $p = q = \frac{1}{2}$,

$$q_a = 1 - \frac{a}{a+b} = \frac{b}{a+b} \qquad a = 1, 2, \ldots, a+b-1. \tag{24}$$

By interchanging p and q, as well as b and a, one gets the probability p_a of winning from Eqs. (23) and (24), satisfying $p_a + q_a = 1$, as expected. If Y denotes the ultimate gain for I, it is a random variable such that $P[Y = b] = p_a$ and $P[Y = -a] = q_a$. Thus, the expected gain for I is

$$E(Y) = -aq_a + bp_a = (a+b)p_a - a \quad \text{if } p \neq q$$
$$= -a\frac{b}{a+b} + b\frac{a}{a+b} = 0 \quad \text{if } p = q = \frac{1}{2}.$$

Thus, the second case represents a "fair" game.

B. Markov Dependence

A reason for giving the detailed description above is that the ruin problem has many variations and has motivated several important developments in probability. We indicate two of these. Let $A_1, A_2, \ldots, A_n$ be events such that $P(A_i) = a_i > 0$, for all i. Then Eq. (16) admits an obvious extension:

$$P(A_1, \ldots, A_n) = P(A_1 \text{ and } A_2 \text{ and } \ldots \text{ and } A_n)$$
$$= P(A_1)P(A_2 \mid A_1)P(A_3 \mid A_1, A_2)$$
$$\times \cdots P(a_n \mid A_1, \ldots, A_{n-1}).$$

In 1906, A. A. Markov, a pupil of P. L. Čebyšev, introduced the fecund idea of a chain dependence; namely, the conditional probability of $A_k, k > 1$, given $A_1, \ldots, A_{k-1}$, depends only on the preceding event A_{k-1}. So a sequence $A_1, A_2, \ldots, A_n$ of events, with $P(A_k) > 0$ all k, is a Markov chain if

$$P(A_1, \ldots, A_n) = P(A_1)P(A_2 \mid A_1)P(A_3 \mid A_2) \times \cdots P(A_n \mid A_{n-1}). \tag{25}$$

To use a picturesque language, setting $p_{ij} = P(A_j \mid A_i) \geq 0$, one says that a system forms a stationary Markov chain if p_{ij} is the probability of being in state j, given that in the preceding instant it was in state i; then for $i_1 < i_2 < \cdots < i_n$ one has

$$P(A_{i_1}, \ldots, A_{i_n}) = a_{i_1} p_{i_1 i_2} p_{i_2 i_3} \cdots p_{i_{n-1} i_n}, \tag{26}$$

where $a_i = P(A_i)$ is the initial probability of being in state i. The numbers p_{ij} are called stationary transition probabilities. Thus, the system is completely determined by

the set of initial probabilities and the transition probabilities. The word *stationary* is often omitted, but its significance is that the a_i's and p_{ij}'s do not depend on the particular instant and are the same starting at any time and moving in unit steps. In the contrary case, they could depend on the time variable and nonstationarity results, as shown below.

If the set of all possibilities for the system is finite, it is called a finite Markov chain, and the possibilities are states (the complete set being the state space). If the states are labeled $1, 2, \ldots, n$, and the initial probability vector is $(a_1, a_2, \ldots, a_n)$, so that $\sum_{i=1}^{n} a_i = 1$, then this and the transition

$$Q = \begin{bmatrix} p_{11} & p_{12} & \cdots & p_{1n} \\ p_{21} & p_{22} & \cdots & p_{2n} \\ \cdot & \cdot & & \cdot \\ \cdot & & \cdot & \cdot \\ \cdot & & \cdot & \cdot \\ p_{n1} & p_{n2} & \cdots & p_{nn} \end{bmatrix} \tag{27}$$

describe the Markov chain. If the number of states is infinite, then $n = +\infty$, and one has a denumerable Markov chain. Note that one always has $\sum_{j=1}^{n} p_{ij} = 1$, for each $i = 1, 2, \ldots, n$, since from each state the system moves into one of the other states. In matrix theory, such square matrices of nonnegative elements whose row sums add to 1 are called stochastic matrices. The general theory says that, conversely, with every stochastic matrix it is possible to associate a Markov chain. Thus, such a special matrix theory merges with this part of probability.

The gambler's ruin example noted above will now be expressed as a Markov chain. The possible states are $0, 1, \ldots, a+b$ where players I and II have initial fortunes of a and b dollars and the game continues between the states $1, 2, \ldots, a+b-1$, with probabilities $p_{i,i+1} = p$ and $p_{i,i-1} = q$. Also, $p_{0,0} = 1$, $p_{a+b,a+b} = 1$, and $p_{ij} = 0$ if $| i - j | \geq 2$, $p_{ii} = 0$, $1 \leq i \leq a+b-1$ since the system moves in these states. Thus, Q is a matrix of size $(a+b+1)$ by $(a+b+1)$ given by

$$Q = \begin{bmatrix} 1 & 0 & 0 & & & \cdots & 0 \\ q & 0 & p & 0 & & \cdots & 0 \\ 0 & q & 0 & p & 0 & \cdots & 0 \\ \vdots & \vdots & & \ddots & & & \vdots \\ & & & & \ddots & & \\ \vdots & \vdots & & & q & 0 & p \\ 0 & 0 & & \cdots & 0 & 0 & 1 \end{bmatrix}$$

The initial distribution is $a_i = 1$ if $i = a$, and $a_i = 0$ if $i \neq a$. This completes the description of the ruin problem as a Markov chain. There are many other applications to random walks, diffusion, birth–death processes, and the like.

A transition matrix need not have its columns sum to 1, but if it has this additional property, it is called doubly stochastic. Such chains admit special properties. Clearly, a symmetric transition matrix is doubly stochastic, and a doubly stochastic 2-by-2 matrix is symmetric, but it is easily seen that there are doubly stochastic non-symmetric matrices of order k by k for each $k \geq 3$. Symmetric transition matrices correspond to "path-reversible" chains.

In terms of random variables, these concepts are as follows. If $X_1, X_2, \ldots$ is a sequence of random variables on $(\Omega, \mathcal{A}, P)$ taking values in a fixed finite set $(\alpha_1, \ldots, \alpha_n)$, each value with positive probability, then it is termed a finite stationary Markov process if, for $k \geq 2$, one has

$$\begin{aligned} &P[X_k = \alpha_j \mid X_1 = \beta_1, \ldots, X_{k-1} = \beta_{k-1}] \\ &\quad = P[X_k = \alpha_j \mid X_{k-1} = \beta_{k-1}], \end{aligned} \tag{28}$$

where $\beta_1, \ldots, \beta_{k-1}$ are a not necessarily distinct subset of $(\alpha_1, \ldots, \alpha_m)$. Let $p_{ij} = P[X_k = \alpha_j \mid X_{k-1} = \alpha_i]$, $k = 2, 3, \ldots, n$. If p_{ij} depends also on k, then one calls $X_1, X_2, \ldots$, a (finite) nonstationary Markov process. The general theory of Markov processes, for which the range, or state space, may be uncountables, constitutes an important branch of probability with numerous applications.

A familiar example of a Markov process is the sequence $\{S_n, n \geq 1\}$, where $S_n = \sum_{k=1}^{n} X_k$ with X_k independent, and this will be stationary if the X_k all have the same distribution. This is easy to verify if all the X_k take values in the fixed finite set $(\alpha_1, \ldots, \alpha_m)$ considered above, but it is also true for any independent random variables, and then one needs to define the conditioning concept in a more general context using advanced techniques. This shows how the subject is spreading in different directions.

In the previous discussion the system was restricted to move from one state to another in one step, but higher transitions are possible and they can be easily determined. Thus, a transition from a state j to another k in n steps is the conditional probability of the system moving from j to k in n steps, denoted $p_{jk}^{(n)}$. Between j and k the chain can visit all possible neighboring states. This n-step transition probability is calculated inductively as

$$p_{jk}^{(n)} = \sum_{l} p_{jl}\, p_{lk}^{(n-1)}, \quad p_{jk}^{(1)} = p_{jk}, \quad n \geq 2,$$

where l runs through all-states of the state space. A further induction gives the *Chapman–Kolmogorov formula*:

$$p_{jk}^{(m+n)} = \sum_{l} p_{lk}^{(m)}\, p_{lk}^{(n)}, \quad m \geq 1, \quad n \geq 1. \tag{29}$$

A symbolic matrix multiplication can be used by setting $Q^{(1)} = Q = (p_{lk}^{(1)})$. Then Eq. (29) becomes

$$Q^{(m+n)} = Q^{(m)} Q^{(n)}, \tag{30}$$

and if $Q^{(0)}$ is an identity matrix, then $Q^{(n)}$ is symbolically the nth power of Q. For the general (not necessarily stationary) Markov process, set

$$p_{jk}(r,s) = P[X_s = \alpha_k \mid X_r = \alpha_j], \quad 1 \le r < s$$

which is the transition probability of the system to move from state j at the epoch r to state k at epoch s. Then Eq. (29) becomes

$$p_{jk}(r,t) = \sum_l p_{jl}(r,s)p_{lk}(s,t), \quad 1 \le r < s < t \qquad (31)$$

and writing $Q(r,s) = (p_{jk}(r,s), 1 \le j,k \le m)$, one has the general form of the **Chapman–Kolmogorov equation** as

$$Q(r,t) = Q(r,s)Q(s,t), \qquad 1 \le r < s < t \qquad (32)$$

with $Q(r,r)$ an identity. In the stationary case $Q(r,s) = Q^{(s-r)}$, which thus depends on only the time elapsed and not the instants r, s individually. The functional equations (30) and (32) have important connections in analysis. Thus, Eq. (30) is the semigroup property for stochastic matrices, whereas Eq. (32) is called the evolutionary property. This shows the far-reaching nature of the Markovian concept and suggests how probability theory creates and helps settle problems in many other areas.

There are further results in which the above Markovian dependence is replaced by kth-order Markovian dependence in the sense that the present depends not just on the immediate past but on k-preceding past values. These processes arise as solutions of certain kth-order stochastic differential equations and in other problems. They can not be discussed here.

C. Martingales

Another important random process is called a martingale. To introduce this, it is necessary to state the concept of conditional expectation. In Eq. (10) the ordinary expectation of a random variable is defined using its probability (or distribution). The same is true of conditinal expectations wherein the probability function is replaced by the conditional probability function. Thus, if X, Y are random variables with values in $(\alpha_1, \alpha_2, \ldots)$ and $P[Y = \alpha_j] > 0$, then $P[X = \alpha_i | Y = \alpha_j]$ is well defined, and the conditional expectation of X given $Y = \alpha_{j_0}$, denoted $E(X \mid Y)(\alpha_{j_0})$, is obtained as

$$E(X \mid Y)(\alpha_{j_0}) = \sum_{i \ge 1} \alpha_i P[X = \alpha_i \mid Y = \alpha_{j_0}] \qquad (33)$$

provided that the series converges absolutely for each $j_0 \ge 1$. Similarly, if $Y_1, Y_2, \ldots, Y_k$ are fixed at $\beta_1, \ldots, \beta_k$, then

$$E(X \mid Y_1, Y_2, \ldots, Y_k)(\beta_1, \ldots, \beta_k) = \sum_{i \ge 1} \alpha_i P[X = \alpha_i \mid Y_1 = \beta_1, \ldots, Y_k = \beta_k] \qquad (34)$$

when the series is absolutely convergent and the conditional probabilities are well defined. In the cases where $P[Y = \alpha_{j_0}] = 0$, there will be problems and the conditional probability is indeterminate, as seen in Eq. (16). If it is given a fixed value, the advanced theory shows that Eqs. (33) and (34) are still defined, but there will be some nonuniqueness. This does not do any harm, and there are methods of dealing with them, such that Eq. (34) can be used for most applications as though it were well defined. With this provision, one can express Eq. (33) symbolically as

$$E(X \mid Y) = \int_\Omega X(\omega) P(d\omega \mid Y),$$

and this holds if $E(|X|) < \infty$. Thus, $E(X \mid Y)$ exists and satisfies the rules of the ordinary expectation $E(X \mid X) = X$[like $E(1) = 1$] and

$$E(X_1 + aX_2 \mid Y) = E(X_1 \mid Y) + aE(X_2 \mid Y), \quad a \in \mathbb{R}.$$

Also if X, Y are independent, $E(X \mid Y) = E(X)$, and $X \ge 0$ implies $E(X \mid Y) \ge 0$ whatever the random variable Y is.

However, if $P(Y = \alpha) = 0$, then $P(d\omega \mid Y)$ is not defined by Eq. (33). So it [and hence the conditional expectation $E(X \mid Y)$] must be defined differently! To see how this may be done, rewrite Eq. (33) after multiplying both sides with $P(Y = \alpha_j)$, $\alpha_j \in B$. Then one has

$$\sum_{\alpha_j \in B} E(X \mid Y)(\alpha_j) P(Y = \alpha_j) = \sum_{\alpha_j \in B} \sum_{i \ge 1} \alpha_i P(X = \alpha_i \mid Y = \alpha_j) P(Y = \alpha_j) = \sum_{i \ge 1} \alpha_i P(X = \alpha_i, Y \in B),$$

or

$$\int_B E(X \mid Y)\, dP_Y = \int_\Omega X\, P(d\omega, B).$$

In particular $X = \chi_A$, writing $P(A \mid Y) = E(\chi_A \mid Y)$, as noted already, one deduces

$$\int_B P(A \mid Y)\, dP_Y = \int_A P(d\omega, B) = P(A \cap B). \qquad (^*)$$

This equation defines $P(A \mid Y)$ uniquely for all events A and all $B = [a < Y \le b]$, by a standard result in Real Analysis. So A. Kolmogorov proposed such a $P(\cdot \mid Y)$ as the definition of a conditional probability which needs no further restrictions, and coincides with the earlier definition in case Y takes at most countably many values. However, an evaluation of this general object is not always simple and no recipe exists. For instance, if $P(B) = 0$ and if $B_n \downarrow B$

with $P(B_n) > 0$, an approximating sequence, then (*) may be expressed as

$$\frac{1}{P_Y(B_n)} \int_{B_n} P(A \mid Y)\, dP_Y = \frac{P(A \cap B_n)}{P_Y(B_n)}, \qquad (+)$$

and then let $n \to \infty$. Now one may employ a form of the generalized Fundamental Theorem of Calculus, to get $P(A \mid Y)$ as the "derivative" $dP(A \cap \cdot)/dP_y$. Unfortunately the answer depends on the approximating sequence $\{B_n, n \geq 1\}$, unless they are selected in some sophisticated manner. This will now be illustrated by the following two examples, sometimes called the Borel-Kolmogorov and Kac-Slepian paradoxes, to emphasize the underlying deeper problem.

1. Borel-Kolmogorov paradox

Let X, Y be independent random variables with a common exponential distribution $F(x) = 1 - e^{-x}$, $x > 0$, and $= 0$ otherwise. Let $Z = \frac{(X-a)}{Y}$, $a > 0$. If $\beta \in \mathbb{R}$, $B = [Z = \beta]$, and $A = [Y < y]$, it is desired to calculate $P(A \mid B)$. Now the right side of (+) will be evaluated with two different approximations. Elementary calculations show that the joint density $f_{Y,Z}$ of Y and Z is given by

$$f_{Y,Z}(y, z) = \begin{cases} ye^{-(yz+a)-y}, & \text{for } y > 0 \text{ and } yz > -a \\ 0, & \text{otherwise.} \end{cases}$$

Then the traditional conditional density $f_{Y|Z}$ for $Z = \beta$ is $f_{Y,Z}(y, \beta)/f_Z(\beta)$ and is seen to be

$$f_{Y|Z}(y \mid \beta) = \begin{cases} y(1+\beta)^{-2}e^{-y(1+\beta)}, & \text{for } y > 0 \\ 0, & \text{otherwise.} \end{cases}$$

So $P(A \mid B) = \int_0^y f_{Y|Z}(u \mid \beta)\, du = (1+\beta)^4[1 - e^{-y(1+\beta)}(1 + y(1+\beta))]$. However, one can consider another approximation. Since $B = [Z = \beta] = [X - Y\beta = a]$ if $U = X - Y\beta$ so that $B = [U = a]$, one has the joint density of Y, U as

$$f_{Y,U}(y, u) = \begin{cases} e^{-y(1+\beta)-u}, & \text{for } u > 0, \text{ and } \beta y + u > 0 \\ 0, & \text{otherwise.} \end{cases}$$

Now the above formula for a conditional density becomes

$$f_{Y|U}(y \mid a) = \begin{cases} (1+\beta)e^{-y(1+\beta)}, & \text{for } y > 0, \text{ and } \beta y > -a \\ 0, & \text{otherwise.} \end{cases}$$

Thus $P(A \mid B) = 1 - e^{-y(1+\beta)}$, $y > 0$, which is different from the previous value, resulting in a paradox. The actual question of E. Borel and an attempt with an unsatisfactory solution by A. Kolmogorov in the 1920s, included in his Foundations (1933), is quite similar.

2. Kac-Slepian Paradox

A more natural problem arising in a concrete application has been studied by M. Kac and D. Slepian (1959), who showed that the usual approximation procedure is again unsatisfactory. A slightly specialized version of it is as follows. Let $\{X_t, t \geq 0\}$ be a Gaussian process with $E(X_t) = 0$ and covariance $E(X_s X_t) = e^{-(s-t)^2}$ so that X_t is differentiable in mean for each t, i.e., there is a Y_t such that $E([X_{t+h} - X_t]/h - Y_t)^2 \to 0$ as $h \to 0$. Then $\{Y_t, t \geq 0\}$ is also Gaussian and X_t, Y_t are independent. The Y_t process is "tangent" to the X_t process at each t. The problem is to find the conditional probability of $A_y = [Y_0 < y]$ given that the process started at a, i.e., $X_0 = a$. Since $B = [X_0 = a]$, $P(B) = 0$, the evaluation of $P(A \mid B)$ is not a simple computation from definition, and one can approximate it as in (+). Thus for each $m \in \mathbb{R}$ and $\delta > 0$ consider $B_\delta^m = \{\omega\colon X_t(\omega) = a + mt$ for some $0 \leq t \leq \delta(1+m^2)^{-1}\}$ so that B_δ^m is the event that X_t passes through the line $y = a + mt$ at a distance δ units from a, at some time t and that $P(B_\delta^m) > 0$. It is clear that $B_\delta^m \downarrow B$ as $\delta \downarrow 0$ for each m. Then one finds after some computation that, since Y_t is distributed as $N(0, 4)$,

$$\lim_{\delta \searrow 0} P\left(A_y \mid B_\delta^m\right) = \int_{-\infty}^{y} f_{Y_0|X_0}^m(u \mid a)\, du,$$

where

$$f_{Y_0|X_0}^m(u \mid a) = \frac{|u - m|\, e^{-\frac{u^2}{32}}}{32e^{-\frac{m^2}{32}} + m\int_{-m}^{m} e^{-\frac{u^2}{32}}\, dv},$$

which is different for each different $m \in \mathbb{R}$, so that there are uncountably many answers to the problem resulting in a strong paradox. The omitted computations can be found in the paper by Kac and Slepian (1959), and an extended treatment of conditioning as well as the details of the above problem in the book (Rao (1993)). Indeed this computational problem is not satisfactorily solved in the literature. A few available (satisfactory) procedures and suggestions for investigations are discussed in the last reference. However using an unambiguous abstract definition of conditional probability and expectation, it is possible to develop the general theory and this will now be briefly illustrated by introducing the concepts of martingales.

If $X_1, X_2, \ldots$ is a sequence of random variables on $(\Omega, \mathcal{A}, P)$ each having at least one moment, representing, for instance, fortunes of a gambler at epochs 1, 2,..., respectively, then it is called a *martingale* or a fair game provided that $E(X_{n+1} \mid X_1, \ldots, X_n) = X_n$; that is, the whole past being known (or given), the expected fortune on the next game is the same as on the last (or present) game. It is called a *submartingale* (or a favorable game to the gambler) if the expected fortune is at least as much as the present one, that is, $E(X_{n+1} \mid X_1, \ldots, X_n) \geq X_n$. If

the inequality is reversed, then one has a *supermartingale* (or unfavorable game). Thus, a martingale is both a sub- and a supermartingale.

A simple example of a martingale is given by $\{S_n, n \geq 1\}$, where $S_n = \sum_{k=1}^{n} X_k$, the X_n being independent random variables with zero means. Indeed,

$$\begin{aligned} E(S_{n+1} \mid S_1, \ldots, S_n) &= E(X_{n+1} + S_n \mid S_1, S_2, \ldots, S_n) \\ &= E(X_{n+1} \mid S_1, \ldots, S_n) + E(S_n \mid S_1, \ldots, S_n) \\ &= E(X_{n+1}) + S_n = 0 + S_n = S_n, \end{aligned}$$

since X_{n+1} is independent of $S_1, \ldots, S_n$, $E(X_{n+1}) = 0$ and the rules of conditional expectation given above are used. It should be observed that the sequence $\{S_n, n \geq 1\}$ is also a Markov process. In general, however, for a Markov process no moments need exist, and for a martingale only the conditioning on the first moment is required to satisfy the fair-game property. For Markov processes, the property is related to the structure of the whole (conditional) distribution. Thus, there are processes that belong to both martingale and Markov classes (the symmetric random walk is an example, and the above one is also a walk), but these classes are quite distinct and have extensive individual theories.

One of the basic questions here is the behavior of a martingale for large n. Does the game have a limit? We state the result, which applies to all the three types of martingales. The proof is somewhat intricate and cannot be discussed here.

3. Theorem

Let $\{X_n, n \geq 1\}$ be a sequence of random variables on a probability space, such that $E(|X_n|) \leq K_0 < \infty$; that is, the expected values are all bounded by K_0. If the sequence is a martingale or a sub- or supermartingale, then $X_n \to X_\infty$ with probability 1, and $E(|X_\infty|) \leq K_0$.

An application of this result is presented to illustrate its potential use. Suppose that a sequence of observations $Y_1, Y_2, \ldots$ is taken on an experiment. The observations may be dependent. It is assumed here, from prior knowledge, that these are governed by one of two probability measures P_1 and P_2 and it is desired to know from the observations which measure is more likely to govern the phenomenon. For instance, P_1 may be normal and P_2 Cauchy. In fact, both of these spread on the whole space and have single humped densities, but the normal one has thin tails, whereas the Cauchy has relatively thick tails. The above theorem helps to settle the correct underlying probability.

Let F_n and G_n be the n-dimensional distributions of the first n observations $(X_1, \ldots, X_n)$ for the probabilities P_1 and P_2, respectively, having positive densities so that

$$\begin{aligned} P_1(X_1 < x_1, \ldots, X_n < x_n) &= F_n(x_n, \ldots, x_n) \\ &= \int_{-\infty}^{x_1} \cdots \int_{-\infty}^{x_n} f_n(t_1, \ldots, t_n)\, dt_1 \ldots dt_n \\ P_2(X_1 < y_1, \ldots, X_n < y_n) &= G_n(y_1, \ldots, y_n) \\ &= \int_{-\infty}^{y_1} \cdots \int_{-\infty}^{y_n} g_n(u_1, \ldots, u_n) du_1 \cdots du_n \end{aligned}$$

and

$$f_n > 0, \quad g_n > 0.$$

Consider

$$\begin{aligned} Y_n(\omega) &= L_n(X_1(\omega), \ldots, X_n(\omega)) \\ &= \frac{g_n(X_1(\omega), \ldots, X_n(\omega))}{f_n(X_1(\omega), \ldots, X_n(\omega))}. \end{aligned}$$

The function Y_n (or L_n) is called the likelihood ratio for the probability densities of P_1 and P_2, and it plays an essential role in statistical decision theory. Since $f_n > 0$, $g_n > 0$, Y_n is well defined and is a random variable. Also by Eq. (10),

$$\begin{aligned} E_{P_1}(Y_n) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} & \frac{g_n(X_1, \ldots, x_n)}{f_n(x_1, \ldots, x_n)} \\ & \times f_n(x_1, \ldots, x_n)\, dx_1 \cdots dx_n = 1 \quad n \geq 1. \end{aligned}$$

Similarly $E_{P_2}(1/Y_n) = 1$. If we show that $\{Y_n, n \geq 1\}$ is a martingale sequence, then the above theorem implies that $Y_n \to Y$ with P_1 probability 1, and similarly $1/Y_n \to \tilde{Y}$ with P_2 probability 1. Hence, if $(\Omega, \mathcal{A}, P_1)$ is the correct model, then Y_n tends to be small for large n. The relevant statistical procedure, which is an extension by U. Grenander of a classical result due to J. Neyman and E. S. Pearson, is to reject the model with P_1 (hence, accept P_2) if, for large n, $Y_n(\omega) > \alpha$, where α is chosen such that $P_1[Y_n > \alpha] \leq 0.05$ (or 0.01). Thus, our problem hinges on the fact that $\{Y_n\}_1^\infty$ forms a martingale sequence. This property is verified as follows:

$$\begin{aligned} & E_{P_1}(Y_{n+1} \mid Y_1, \ldots, Y_n)(\omega) \\ &= E_{P_1}(Y_{n+1} \mid X_1, \ldots, X_n)(\omega) \\ &= \int_{-\infty}^{\infty} \frac{g_{n+1}(x_1, \ldots, x_n, u)}{f_{n+1}(x_1, \ldots, x_n, u)} \\ &\quad \times \tilde{P}_1(du \mid X_1, \ldots, X_n)(\omega) \\ &= \int_{-\infty}^{\infty} \frac{g_{n+1}(x_1, \ldots, x_n, u)}{f_{n+1}(x_1, \ldots, x_n, u)} \\ &\quad \times \frac{f_{n+1}(x_1, \ldots, x_n, u)}{f_n(x_1, \ldots, x_n)}\, du, \\ &= \frac{1}{f_n(x_1, \ldots, x_n)} \int_{-\infty}^{\infty} g_{n+1}(x_1, \ldots, x_n, u)\, du \end{aligned}$$

$$= \frac{g_n(x_1, \ldots, x_n)}{f_n(x_n, \ldots, x_n)} = Y_n(\omega).$$

Here we used a form of conditional probability:

$$\tilde{P}_1(u \mid X_1, \ldots, X_n)(\omega) = (\text{defined as}) \int_{-\infty}^{u} \frac{f_{n+1}(x_1, \ldots, x_n, t)}{f_n(x_1, \ldots, x_n)}\, dt,$$

where $x_k = Y_k(\omega)$. Thus, $E(Y_{n+1} \mid Y_1, \ldots, Y_n) = Y_n$ and the martingale property is verified. If f_n is not strictly positive, one can show that the Y_n sequence forms a supermartingale, and the same conclusion holds. This is an indication of uses of the martingale concept, and the theory is rich in applications to sequential analysis, differentiation theory, mathematical finance, and others. We next consider another set of dependence classes.

VI. STATIONARY AND HARMONIZABLE PROCESSES AND SPECTRA

The preceding dependence class demanded the existence of one moment for the random variables. Here another family, which assumes two moments for each random variable, is discussed. It plays an important role in electrical and communication engineering problems, among others. We consider $\{X_n, n = 0, \pm 1, \pm 2, \ldots\}$ as a doubly infinite sequence capable of representing all the past and present and observing the future of an experiment as it progresses. These random variables X_n have two moments but need not be independent. Some terminology should be introduced here.

For simplicity, let $E(X_n) = 0$. Then $\sigma_n^2 = E(|X_n|^2)$ is the variance, and $r(m, n) = E(X_m \bar{X}_n)$ is the covariance. We admit the possibility of complex values, motivated by the above-stated applications. Thus, $X_n = U_n + iV_n$, where U_n, V_n are real random variables with means zero and finite second moments. Also $\rho(m, n) = r(m, n)/\sigma_m \sigma_n$ is the correlation between X_m and X_n and is a measure of the dependence. If $\rho(m, n) = 0$ or equivalently $r(m, n) = 0$, then X_n and X_m are uncorrelated; when they have zero means, as here, they are also *orthogonal*. If $r(m, n) = \tilde{r}(m - n)$ so that the covariance is a function only of the difference of their positions, then the sequence is called *stationary*, a concept introduced by A. Khintchine in 1934. A simple example of a stationary sequence is as follows. If $Y_1, Y_2, \ldots, Y_n$ are independent with zero means and unit variances, the random variables (for a fixed n),

$$X_m = \sum_{k=1}^{n} Y_k e^{ikm}, \qquad m = 0, \pm 1, \pm 2, \ldots$$

form a stationary sequence, since $E(X_m) = 0$, and

$$r(m, m + l) = E(X_m \bar{X}_{m+l}) = \sum_{k=1}^{n} e^{-ikl} \quad [= \tilde{r}(l)]$$

depending only on l. Note that $\tilde{r}(l) \neq 0$ so that the X_m sequence is correlated. This class is again large, since one can have stationary normal (or Gaussian) processes and even a stationary Markov normal process and others. It also has an interesting and useful structure theory, some of which will be explained here.

If $\{X_n, n = 0, \pm 1, \pm 2, \ldots\}$ is a stationary process, as defined above, with a covariance function $r(\cdot)$, it is positive definite in the sense that for each set $\{\alpha_1, \ldots, \alpha_n\}$ of complex numbers

$$\sum_{k=1}^{n} \sum_{j=1}^{n} \alpha_k \bar{\alpha}_j r(k - j) = \sum_{k=1}^{n} \sum_{j=1}^{n} \alpha_k \bar{\alpha}_j E(X_k \bar{X}_j)$$
$$= E\left(\left(\sum_{k=1}^{n} \alpha_k X_k\right)\left(\sum_{j=1}^{n} \alpha_j X_j\right)\right)$$
$$= E\left(\left|\sum_{k=1}^{n} \alpha_k X_k\right|^2\right) \geq 0. \tag{35}$$

Such positive-definite functions $\{r(l), l = 0, \pm 1, \pm 2, \ldots\}$ have been studied in mathematical analysis for a long time. They can be characterized by a classical 1911 result of G. Herglotz. Thus, r is uniquely representable as

$$r(k) = \int_{-\pi}^{\pi} e^{ik\lambda}\, dG(\lambda), \qquad k = 0, \pm 1, \ldots, \tag{36}$$

where G is a nonnegative, nondecreasing, left-continuous, and bounded function on $(-\pi, \pi]$. For this it is essential that the index set be *all* integers. Then r is the Fourier coefficient of such a G, the integral being the usual Stieltjes type. Here G is called the *spectral function* of the stationary process, and it has other physical interpretations in electrical engineering problems. Representation (36) allows one to use many classical results. We present an application to a filtering problem.

Let $\{X_n, Y_n; n = 0, \pm 1, \pm 2, \ldots\}$ be a pair of stationary series connected by the difference (also termed an autoregressive) equation

$$\Lambda X_n = X_n + a_1 X_{n-1} + \cdots + a_k X_{n-k} = Y_n, \tag{37}$$

where the a_j are constants. The X_n series is called an input and the Y_n series an output, and the linear operation Λ is termed a polynomial filter. A natural problem here is as follows: If the output is known, for what types of filters can the input be recovered? A method for solving this problem is indicated below:

If G_x and G_y are the spectral functions of the X_n and Y_n series, then Eqs. (36) and (37) give, for the covariances r_x and r_y of the series,

$$r_y(l) = E(Y_{n+l}\bar{Y}_n) = E[(\Lambda X_{n+l})(\overline{\Lambda X_n})]$$
$$= \sum_{j=0}^{k}\sum_{j'=0}^{k} a_j \bar{a}_{j'} E(X_{n-j+l}\bar{X}_{n-j'}), \quad a_0 = 1$$
$$= \sum_{j=0}^{k}\sum_{j'=0}^{k} a_j \bar{a}_{j'} r_x(j'-j+l)$$
$$= \int_{-\pi}^{\pi} \left(\sum_{j=0}^{k} a_j e^{-ij\lambda}\right)\left(\sum_{j=1}^{k} \bar{a}_j e^{ij\lambda}\right) e^{il\lambda} dG_x(\lambda). \tag{38}$$

If $p_k(z) = \sum_{j=0}^{k} a_j z^j$, the kth-order polynomial determined by the a_j's, then Eq. (38) becomes

$$\int_{-\pi}^{\pi} e^{il\lambda}\, dG_y(\lambda) = \int_{-\pi}^{\pi} \left|p_k(e^{-i\lambda})\right|^2 e^{il\lambda}\, dG_x(\lambda). \tag{39}$$

Here $p_k(z)$ is called the *characteristic polynomial* of the filter equation (37) and $\phi(\lambda) = p_k(e^{-i\lambda})$ is termed the *filter characteristic*, because the zeros of ϕ govern the behavior of Λ. To explain this, it is necessary to state a relatively advanced result established independently in 1940 by H. Cramér and A. Kolmogorov. According to this, one has

$$X_n = \int_{-\pi}^{\pi} e^{-in\lambda}\, dZ_x(\lambda), \tag{40}$$

where $\{Z_x(\lambda), -\pi < \lambda \le \pi\}$ is a random process such that for each $-\pi < \lambda_1 < \lambda_2 < \lambda_3 \le \pi$, the increments $Z_x(\lambda_3) - Z_x(\lambda_2)$ and $Z_x(\lambda_2) - Z_x(\lambda_1)$ are uncorrelated, and $E(|Z_x(\lambda_3) - Z_x(\lambda_2)|^2) = G_x(\lambda_3) - G_x(\lambda_2)$. The integral in Eq. (40) is defined with a procedure of the classical Riemann method and is called a *stochastic integral*. If $Z_y(\cdot)$ is the corresponding process for the Y_n series, Eq. (37) becomes

$$\int_{-\pi}^{\pi} e^{in\lambda}\, dZ_y(\lambda) = Y_n = \Lambda X_n = \int_{-\pi}^{\pi} \phi(\lambda) e^{in\lambda} dZ_x(\lambda), \tag{41}$$

where $\phi(\lambda)$ is the filter characteristic. Using this and the location of the zeros of $\phi(\lambda)$ or of $p_k(z)$, we shall present the solution of the problem without giving all the mathematical details.

If the roots w_j of $p_k(z) = 0$ are distinct and $|w_j| > 1$ or if some $w_j = e^{i\lambda_j}$ and at such λ_j the spectral function $G_y(\cdot)$ is continuous, then the input X_n can be expressed as

$$X_n = \int_{-\pi}^{\pi} \phi(\lambda)^{-1} e^{in\lambda}\, dZ_y(\lambda) = \sum_{j\ge 0} b_j(a_1, \ldots, a_k) Y_{n-j}, \tag{42}$$

where the b_j are constants determined by $a_1, \ldots, a_k$ [or equivalently the roots of $p_k(z)$], and the series converges in a well-defined (called a mean-square) sense. The point of the location of the roots is that X_n is obtainable completely from the past and present of the output, if they are outside the unit circle. In that case Λ is termed *physically realizable*. If the roots do not satisfy these restrictions, then, when the solution is obtainable, it involves future values in addition so that the filter is *not* physically realizable.

Most of the above questions, detailed for stationary sequences, can be considered for a closely related nonstationary class called harmonizable processes. A brief account of the latter will be included since the formulas obtained for the stationary case hold, essentially in the same form, for the general setup, thereby giving a sort of "robustness" for these results.

Thus, a sequence $\{X_n, n = 0, \pm 1, \pm 2, \ldots\}$ is termed *strongly* [*weakly*] *harmonizable* if each X_n admits a representation as a stochastic integral (40), with a fixed $\{Z_x(\lambda), -\pi < \lambda \le \pi\}$, which is a random process as before but which need not have orthogonal increments. It satisfies (i) $E(Z_x(\lambda)) = 0$, and (ii) if $E(Z_x(\lambda)\overline{Z_x}(\lambda')) = F_x(\lambda, \lambda')$ then F_x has finite Vitali [Fréchet] variation in the following sense. For any (standard) subsets A, B of $(-\pi, \pi]$

$$\text{Vitali var}(F_x)(A, B) = |F_x|(A, B)$$
$$= \sup\left\{ \sum_{i=1}^{n}\sum_{j=1}^{n} |\, F_x(A_i, B_j)\, | : \{A_i\}_1^n, \{B_j\}_1^n, \right.$$
$$\left. \text{disjoint subsets of } A \text{ and } B,\ n < \infty \right\} < \infty.$$

and

$$\text{Fréchet var}(F_x)(A, B) = \|F_x\|(A, B)$$
$$= \sup\left\{ \left| \sum_{i=1}^{n}\sum_{j=1}^{n} a_i \overline{b_j} F_x(A_i, B_i) \right| : \{A_i\}_1^n, \{B_j\}_1^n \right.$$
$$\left. \text{as above, and } |a_i| \le 1, |b_j| \le 1 \right\} < \infty.$$

It is clear that $\|F_x\|(A, B) \le |F_x|(A, B)$. There is strict inequality for the weakly harmonizable case since then $|F_x|(T, T) = +\infty$, but $\|F_x\|(T, T) < \infty$ always where $T = (-\pi, \pi]$. Thus, a (weakly or strongly) harmonizable process is the Fourier transform of a certain process with two moments finite. One can verify that the covariance $r_x(m, n) = E(X_m \overline{X_n})$ admits a representation

$$r_x(m, n) = \int_{-\pi}^{\pi}\int_{-\pi}^{\pi} e^{im\lambda - in\lambda'}\, dF_x(\lambda, \lambda'),$$
$$m, n = 0, \pm 1, \ldots. \tag{36'}$$

The function F_x is called the *spectral bi-measure* of the X_n sequence in both the weak and strong cases. In the stationary case, F_x concentrates on the diagonal of the square

$T \times T$, so that the harmonizability concept reduces to the stationary one. [For the weak harmonizability work, some care is needed regarding the integral in Eq. (36). The relevant theory of this case and its comparison with the stationary aspects, in all its detail, can be found in Chang and Rao (1986). Leaving these technicalities aside, one can proceed with the analogs of the above case.]

It is now possible to obtain the corresponding (polynomial) filter equations. Let us sketch the formulas related to Eq. (38) for the (strongly) harmonizable case. If the autoregressive or polynomial filter equation is given by Eq. (37), then Eq. (41) holds without change. If $\phi_n(\lambda)$ is the filter characteristic, then the analog of Eq. (38) becomes

$$r_y(m,n) = \int_{-\pi}^{\pi}\int_{-\pi}^{\pi} \phi_m(\lambda)\overline{\phi_n}(\lambda')e^{im\lambda - in\lambda'}\, dF_x(\lambda,\lambda').$$

When all the roots of $\phi_n(\lambda) = 0$ lie outside of the unit disc, then X_n can be represented as a series (42) in which the $Z_y(\cdot)$ of the Y_n sequence need not have orthogonal increments any longer.

The preceding discussion for harmonizable and stationary sequences has analogs for continuous parameter processes. Instead of the sequence $\{X_n, n = 0, \pm 1, \pm 2, \ldots\}$, one considers $\{X_t, t \in \mathbb{R}\}$, and $T = (-\pi, \pi]$ is replaced by $\mathbb{R}$ (the dual additive group of $\mathbb{R}$, T being the dual of the integers $\mathbb{Z}$). Thus when $E(X_t) = 0$, the covariance $r(s,t) = E(X_s \bar{X}_t)$ is given by $r(s,t) = \int_{\mathbb{R}}\int_{\mathbb{R}} e^{isu - itv}\, dF(u,v)$ and this reduces in the stationary case with $r(s,t) = r(s-t) = \int_{\mathbb{R}} e^{i(s-t)u}\, d\tilde{F}(u)$ where $\tilde{F}$ concentrates on the diagonal of $\mathbb{R} \times \mathbb{R}$, the spectral function. Then there are the corresponding statements of all the results noted above for the sequences, whose details are, for instance, in Change and Rao (1986).

Every harmonizable process is a projection of some stationary process. Thus each such process has a "stationary dilation." This intrinsic property is useful for the structural analysis of harmonizable classes. The weakness of this result is that the dilated process exists but is not usually available to the experimenter, and hence cannot be implemented in applications. However, an important consequence of this property is that each continuous linear transform of a stationary or harmonizable process is always (weakly) harmonizable, so that the last class is closed under such mappings. This fact is important for the theoretical study of these processes. [For details, see Chang and Rao (1986).]

VII. SOME REMARKS ON THE CENTRAL LIMIT PROBLEM

The preceding discussion shows that a major part of probability theory is devoted to the asymptotic analysis of various sequences of random variables. This actually started with the Bernoulli law of large numbers and the Laplace–de Moivre central limit theorem. From an applicational point of view, these results can be used only as an approximation, using a finite but large number n of observations. Then one should know the possible errors of approximation in such applications. It was P. L. Čebyšev who first emphasized the importance of this problem and obtained some useful bounds for the probabilities of these errors with his inequality. These results were refined and extended to more general types of (still independent) random variables by his students, A. A. Markov and A. M. Liapounov, the latter obtaining the most comprehensive from by 1901 of the central limit theorem, which as noted before is usually regarded as the basic limit theorem of probability theory. For the first time Liapounov employed the then new technique of Fourier transforms in his work, and it quickly became a standard tool. Before this, Markov had introduced a useful truncation method but it was not as powerful as the former. However, progress on the error estimation problem has been slow. Here we present a general result on the error estimation in the central limit problem, which was obtained independently by A. C. Berry in 1941 and in a somewhat more detailed manner by G. C. Esséen in 1945, as follows.

A. Theorem (Berry–Esséen)

Let $X_1, X_2, \ldots$ be independent random variables with three moments finite. If μ_n, σ_n^2, and β_n^3 are the mean, variance, and third absolute central moment, respectively, of X_n, and

$$S_n = \sum_{k=1}^{n} X_k; \quad \sigma^2(S_n) = \sum_{k=1}^{n} \sigma_k^2; \quad \beta_n^3(S_n) = \sum_{k=1}^{n} \beta_k^3$$

then we have ($\beta_k^3 = E(|X_k - \mu_k|^3)$)

$$\left| P\left[\frac{S_n - E(S_n)}{\sigma(S_n)} < x\right] - \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{x} e^{-t^2/2}\, dt \right| \le C_0[\beta_n(S_n)/\sigma_n(S_n)]^3 \tag{43}$$

for all $-\infty < x < \infty$ with an absolute constant $0 < C_0 < \infty$ and $n \ge 1$. If all X_n have the same distribution so that $\mu_n = \mu, \sigma_n^2 = \sigma^2$, and $\beta_n^3 = \beta^3$, then Eq. (43) solves the classical central limit problem,

$$\left| P\left[\frac{S_n - n\mu}{\sigma\sqrt{n}} < x\right] - \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{x} e^{-t^2/2}\, dt \right| < \frac{C_1}{\sqrt{n}}\left(\frac{\beta}{\sigma}\right)^3 \tag{44}$$

for all $-\infty < x < \infty$ and some constant $0 < C_1 < \infty$, $n \ge 1$.

A considerable effort has been made to determine the best constants C_0, C_1 in Eqs. (43) and (44). In 1949

H. Bergström showed that $C_0 \leq 4.8$, and after many improvements by various people, V. M. Zolotarev showed in 1966 that $C_1 \leq 1.321312$. These are not yet the best possible bounds. The importance of this theorem lies in the fact that the size of the right-side bounds, which are uniform in x, can be made smaller than a prescribed level by choosing a suitably large n. Then one can use the normal distribution for $[S_n - E(S_n)]/\sigma(S_n)$ as a satisfactory approximation.

It is clear that in Eq. (43) we have to demand that $(\beta(S_n)/\sigma(S_n)) \to 0$ as $n \to \infty$ for the limit theorem. This is automatic in Eq. (44). It can be shown that the rate of the right side of Eq. (44) is optimal. Also, as Liapounov himself showed, in bound (43), $2 + \delta$ moments suffice for some $\delta > 0$ but not $\delta = 0$. The proof of this theorem is intricate, and this is one reason the error estimation problem for other results is slow, and computer simulations are often utilized when no such theorem as above is available.

VIII. STATISTICAL INFERENCE PROBLEMS AND COMMENTS

In most work on probability, distributions of random variables are assumed to be known from prior knowledge. These functions typically contain some parameters that are not always precisely known. For instance, in a binomial distribution the probability of success p is usually not completely known since one can not be certain of the amount of bias a coin has. Similarly, in a normal distribution the parameters are the mean μ and variance σ^2, which specify the distribution. They may not be known exactly. In the case of linear filters described by Eq. (37) the structural coefficients $a_1 \ldots, a_n$ are not always available to the experimenter, and the covariance functions or equivalently their spectral functions in Eq. (36) need not be known before hand. All these parameters have to be estimated from the observed process. Even if one can assume these structural parameters, it will often be necessary to ascertain or test the validity of the prior assumptions. These problems are nontrivial, and they are essential for a successful application of probability. The aspect of probability theory dealing with these questions is inference theory, and the questions have to be answered from sampled data, for which several new criteria should be formulated. All of this belongs to what is called statistical inference theory, which forms a second step in the analysis after the basic modeling aspect of probability theory is formulated. A very brief sketch of the new questions will be given here.

The estimation of parameters can often be accomplished using the principle of least squares. This principle was first published by A. M. Legendre in 1806 but apparently had been known to C.-F. Gauss since 1795, although the latter did not publish it until 1809. Several other principles suitable for other occasions have since been devised. Some of these are maximum likelihood, minimum chi-square, minimax, and regret principles. These ideas, belonging to statistical inference, and more generally to decision theories, grew into a chapter in that subject. Thus, after finding estimators by means of the various methods, one must compare them on the basis of some other principles of "goodness" characteristics. Except in simple situations, here again asymptotic analysis and hence limit theorems of probability theory play a critical part. Often such questions lead to new studies in probability, and in fact many of the extensions of the work from mutually independent random variables to the dependent classes discussed in earlier sections arose from these applications. General limit theorems for such dependent classes as Markov processes, martingales, and stationary processes have achieved significant successes.

There are other problems in which the unknown parameters of a distribution cannot be regarded as absolute constants, especially when the repeatability of an experiment is not feasible because of cost and other considerations. For instance, testing of a space rocket is not feasible for several repeated trials because of cost. In such cases the distributions can be taken as conditional, and the parameters become the values of the conditioned random variables. Indeed, A. Rényi proposed in 1955 a conditional model in lieu of the $(\Omega, \mathcal{A}, P)$ considered thus far. This may be used in some problems. In treating the parameters as values of random variables with completely known distributions of their own, one can use the Bayes formula [Eq. (17)] and convert the problem into one of absolute probabilities. A price paid for this is to turn the independent observations of the conditional model into certain dependent ones in the resulting (higher-order) model. For some of the problems of the type noted above, this Bayesian analysis gives satisfactory results. Asymptotically, however, many of these formulations give the same results. These questions properly belong to inference theory.

At the classical finite sampling level a reference to Lehmann (1959) suffices, and at the stochastic processes level, one has to go further and refer to Grenander (1981), Hall and Heyde (1980), Liptser and Shiryayev (1977), and Rao (2000).

We shall conclude this article by pointing out that probability theory is nurtured by the most interesting problems of natural sciences and other human activities that are precisely describable but generally depend on chance. The measurement of uncertainty is partly an art, as is a construction of the underlying probability model. The twin questions of randomness and interpretation of probability statements have been set aside in the modern axiomatic

foundations of the subject. Practical implications of these questions are important. Attempts to define randomness are not so far satisfactory, since perhaps they are somewhat similar to defining "nature." The difficulty and the unsuccessful efforts can be seen from the recent (non probabilistic) popularizing account in Beltrami (1999). But practioners of the subject can and do proceed with the firmly founded axiomatic setup of Kolmogorov's with confidence in its theoretical conclusions.

Further details and proofs of all the statements made in the preceding sections may be found in the specialized literature. A representative cross-section mainly since the 1950s from introductory to relatively advanced levels, treating these subjects extensively, together with specific sources noted above, is given in the bibliography that follows.

Queueing Theory

H. M. Srivastava
University of Victoria

GLOSSARY

Balking Queueing phenomenon in which a prospective customer decides not to join a queue (and is lost to the system) after looking at the size of the queue and estimating the time he or she may have to wait before receiving service.

Generating function (or *Z* transform) Function $P(z, t)$ of two variables defined usually by

$$P(z, t) = \sum_{n=0}^{\infty} P_n(t) z^n$$

where z is a dummy variable and $P_n(t)$ denotes, for example, the probability that there are n units in the system at time t.

Laplace transform Integral transform $p_n(s)$ of the probability distribution function $P_n(t)$, defined by

$$p_n(s) = \int_0^{\infty} e^{-st} P_n(t)\, dt$$

whenever the improper integral exists, s being a dummy parameter.

Markov chain Markov process with a discrete state space.

Markov process Process with no memory extending before the previous instant (i.e., a process whose future probabilistic evolution after any time t depends only on the state of the system at time t and is independent of the history of the system before the time t).

Poisson distribution Probability distribution with density function $\mu^n e^{-\mu}/n!\,(n = 0, 1, 2, \ldots)$.

Poisson queue Queueing model in which the number of arrivals in a given duration of time follows the Poisson distribution and the service times follow the negative-exponential distribution (i.e., a probability distribution with density function $\mu e^{-\mu W}$).

Probability density function (or frequency function) Derivative $dF(x)/dx$ of a probability distribution function $F(x)$.

Probability distribution function (or cumulative probability) Function $F(x)$ of a random variable X defined, for all possible real numbers x ranging from $-\infty$ to ∞, to be the probability that $X \leqq x$, that is, $F(x) = \text{Prob}\{X \leqq x\}$.

Random variable Variable whose value depends on the outcome of a random experiment, such as the tossing of a coin, one play of a game of blackjack in Las Vegas, and so on.

Regeneration point Time epoch (instant) t at which the characteristic Markov property holds true; that is, the future probabilistic evolution of the given process depends only on the state of the process at time t, a statement of the history of the process having no predictive value.

Reneging Queueing phenomenon in which a customer, after having joined a queue, becomes impatient with waiting and leaves the queue before service starts (and is thus lost to the system).

Stochastic process Possible actual (e.g., physical) process of the real world that has some random (or stochastic) element involved in its structure.

QUEUEING THEORY (or waiting-line theory) is an important branch of applied probability theory and is used to study service systems that are prone to congestion. The subject was nonexistent 70 years ago, and it had no name 50 years ago. Today the theory of queues has an honored place among various mathematical models that represent and predict operations; indeed, queueing theory is one of the first to have been developed systematically. Some of the common applications of queueing theory range from day-to-day bank, department store, airport, and hospital queues to such industrial queues as inventories, assembly (or production) lines, and computer time-sharing systems.

I. FUNDAMENTAL CONCEPTS

The subject of queueing theory has grown out of the pioneering work done in this field by Agner Krarup Erlang (1878–1929), a Danish telephone engineer. In the first decade of the 20th century, Erlang investigated the effects of fluctuations in demand on the operation of Copenhagen's early telephone system and thus developed the first queueing model ever recorded (and also the foundation of the mathematical theory of traffic). It may be of historical interest that Erlang's queueing model antedates Lanchester's model of air warfare by more than 10 years and precedes von Neumann's model for competition by more than 30 years.

Queueing theory is a standard mathematical tool for workers in various areas of operations research. The range of applications of queueing theory has widened as operations research has extended its coverage. Typical queueing theory applications in operations research include those dealing with (1) problems of air transport, for example, the stacking of aircrafts waiting to land or the complications of passenger reservations; (2) problems in public service operations, such as hospital operation; (3) problems involving inventories, such as the spare-parts inventory of the U.S. Army; (4) problems involving the storage of water behind dams that have the potential to improve the planning and operation of hydroelectric power systems; (5) problems involving the maintenance and servicing of equipment and machines; (6) problems of rail, truck, and sea transport, such as the marshaling of yards in rail or truck transport; (7) problems in automobile traffic involving queues of cars in front of traffic lights or tollbooths, at entrances to major highways, in tunnels or behind slow cars on highways, at international border crossings, and so on; (8) queueing problems associated with banks, department stores, law courts, libraries, post offices, telephone and telex companies, and so on; and (9) problems in experimental sciences, such as experimental physics in which, for instance, one is required to correct the observed readings of elementary-particle detectors when counting at a high speed. There are examples of numerous other queueing problems that one naturally encounters in one's daily life. Thus, queueing theory has vast applications, ranging from day-to-day department store, airport, and hospital queues to industrial queues such as inventories, assembly (or production) lines, and computer time-sharing systems. In some cases we even encounter nonphysical queues like the names of candidates, say, for a job, which do indeed constitute a queue on paper.

The proliferation of queueing theory in the 75 years of its development has been rather extensive. Not only has it been immensely enriched by the opening of a wide variety of applications, but it has also been extended considerably in order to handle situations in which no queues exist. Obviously, therefore, these important extensions of queueing theory have rendered its present name somewhat anachronistic, and but for the verbal simplicity of the name *queueing theory*, the subject should be accorded a more appropriate title, such as the theory of stochastic service systems.

A. Queueing Systems

A queueing system can be described as a system having a service facility at which units of some kind (generically called "customers") arrive for service; whenever there are more units in the system than the service facility

can handle simultaneously, a queue (or waiting line) develops. The waiting units take their turn for service according to a preassigned rule, and after service they leave the system. Thus, the input to the system consists of the customers demanding service, and the output is the serviced customers. A queueing system is usually characterized by the following terms:

1. *The input process.* Let the customers arrive at the instants $t_0, t_1, t_2, \ldots$; then the interarrival times are

$$u_r = t_r - t_{r-1}, \qquad r = 1, 2, 3, \ldots. \tag{1}$$

The random variables u_r are, in general, assumed to be statistically independent, and their probability distribution $A(u)$ is called the interarrival time distribution or, simply, the arrival distribution or input distribution. The customers may come from an infinite source, as in the case of telephone calls and as is assumed in many queueing studies, or from a finite source. They may arrive singly or in groups of fixed or various sizes. The queueing system may have an upper limit on the number that can be admitted into the system, as in the case of finite waiting space.

2. *The queue discipline*. This can be described as the rule determining the formation of a queue or queues and the manner in which a customer or customers are selected for service from those waiting. The most common queue discipline is "first come, first served," according to which the units enter service in order of their arrival. Other possibilities are random selection for service, a priority rule, or even the "last come, first served" rule. In the case of priority, there may be two classes, namely, the priority class and the nonpriority class, or there may be several priority classes representing different levels of priority. Furthermore, there may be a preemptive priority discipline according to which a lower-priority unit is taken out of service whenever a higher-priority unit arrives, the service on the preempted unit resuming only when there are no higher-priority units in the system. Contrary to this is the nonpreemptive, or the head-of-the-line, priority rule, in which priorities are taken into account only at the commencement of service, and once started, the service is continued until completion. It is customary to include under this heading queueing phenomena, such as balking and reneging, depicting the behavior of the waiting customers. Customers are said to balk when, looking at the size of the queue and then estimating the time they may have to wait before service, they do not join the queue. After joining a queue, customers are said to renege if they become impatient with waiting and leave the queue before service starts.

3. *The service mechanism.* The time that elapses while a unit is being served is called its service time. The service times $v_1, v_2, v_3, \ldots$ of the successive units are assumed to be independent of one another and of the input distribution, and their probability distribution $B(v)$ is called the service-time distribution or, briefly, the service distribution. The specification of service mechanism includes the number of servers. Thus, there are single-server and multiserver systems (sometimes called single-channel and multichannel from telephone parlance). Again, in a bulk service system, service may be provided in batches of fixed or various sizes.

As is common in probability theory, if we can write

$$dA(u) = a(u)\,du; \qquad dB(v) = b(v)\,dv, \tag{2}$$

then $a(u)$ and $b(v)$ are, respectively, the interarrival time and service-time density functions.

B. Queue Parameters

For an understanding of various queueing systems and for their efficient management, the following three queue parameters are generally investigated.

1. *Queue length*. This is the number of units waiting in a queue or present in a system. In the latter case it is sometimes called the system size. The determination of the probability distribution of this discrete random variable is important for the design of the system—for example, for providing an extra server or a larger waiting space in the case of large queues.
2. *Waiting time*. This is the time a customer has to wait in a queue before being served. Sometimes the service time is also included in the waiting time. The terms *queueing time* and *waiting time* are also used depending on whether the service time is excluded or included. This evidently is a continuous variable, and its probability distribution is important from the customer's point of view. Actually, for some queueing systems (e.g., M/M/1), the queueing time is *not* continuous for $t = 0$.
3. *Busy period*. A busy period starts with the arrival of a customer who finds the system empty and ends when the system next becomes empty. However, the initial busy period may start with any number of units in the system, and for multiserver systems we can define a busy period to be the time interval during which a given number k are busy throughout. The probability distribution of the duration of a busy period is important from the server's point of view.

C. Notation

We shall follow Kendall's notation and specify a queueing system by a triple $\cdot/\cdot/\cdot$, in which the first two constituents are letters representing the form of input and

service-time distributions, respectively, and the third is a number denoting the number of servers. The following letters are used for signifying distributions:

1. M (standing for Markov) for the negative exponential interarrival or service-time distribution:

$$A(u) = 1 - e^{-\lambda u}, \qquad 0 \leqq u < \infty \tag{3}$$

or

$$B(v) = 1 - e^{-\mu v}, \qquad 0 \leqq v < \infty \tag{4}$$

according to whether M occurs in the first or the second place in the triple. From Eq. (3), it follows that the mean interarrival time is

$$\int_0^\infty u \, dA(u) = \frac{1}{\lambda}. \tag{5}$$

Similarly, from Eq. (4), the mean service time is $1/\mu$. Alternatively, we may say that λ and μ are, respectively, the mean arrival and service rates per unit time. It can easily be seen, and is commonplace in elementary probability theory, that Eq. (3) is equivalent to saying that the number of arrivals in a given duration of time follows the Poisson distribution:

$$\text{Prob}\{n \text{ arrivals in time } t\} = (\lambda t)^n e^{-\lambda t}/n! \qquad n = 0, 1, 2, \ldots. \tag{6}$$

Consequently, very often Eq. (3) is spoken of as Poisson arrivals or Poisson input. Similarly, Eq. (4) implies that the number of services rendered in a given time duration is Poisson distributed (only while the server is busy).

2. D (standing for deterministic) for constant interarrival or service times:

$$A(u) = \begin{cases} 0, & \text{if } u < 1/\lambda \\ 1, & \text{if } u \geqq 1/\lambda \end{cases} \tag{7}$$

or, equivalently, the density function

$$a(u) = \delta(u - 1/\lambda), \tag{8}$$

where $\delta(x)$ is the Dirac delta function. The situation is similar for $B(v)$ if D is in the second place.

3. E_k for the k-Erlang distribution:

$$a(u) = \{\lambda^k/(k-1)!\}u^{k-1}e^{-\lambda u}, \quad 0 \leqq u < \infty \tag{9}$$

and similarly for $B(v)$. When $k = 1$, it reduces to the negative-exponential distribution, As $k \to \infty$ such that k/λ is finite, we have the constant interarrival time case, as we shall see later.

From Eq. (9), the Laplace transform of $a(u)$ is given by [see Eq. (18)]

$$\mathcal{L}\{a(u) : s\} = [\lambda/(\lambda + s)]^k \to e^{-\Lambda s} \tag{10}$$

as $k \to \infty$ if we set $k/\lambda = \Lambda$, a finite quantity. But $e^{-\Lambda s}$ is the Laplace transform of the Dirac delta function $\delta(u - \Lambda)$, which evidently completes the proof.

4. G for general (or arbitrary) interarrival or service-time distribution. Some authors write GI for general independent input to stress independence.

Thus, for example, we write $M/E_k/1$ to denote a single-server queueing system with Poisson arrivals and k-Erlang service-time distribution, and GI/G/s for the most general case of general independent input, general service times, and s servers (channels).

Whenever it is desirable, we may use an extended notation, writing for example, $M/E_k/1{:}N$ to denote that N is the maximum allowable number in the system at any time.

D. Queue Equations

From the viewpoint of mathematical tractability, the negative-exponential interarrival or service-time distribution is the simplest, and fortunately these distributions serve as a good fit in many practical problems. We give below a mathematical model for the simplest queueing system: M/M/1. Let

$$P_n(t) = \text{Prob}\{n \text{ units in the system at time } t\}. \tag{11}$$

Now, with Poisson arrivals, we have from Eq. (6)

Prob{one arrival during the time interval

$$(t, t + \Delta t)\} = \lambda \, \Delta t \, e^{-\lambda \Delta t} = \lambda \, \Delta t + o(\Delta t). \tag{12}$$

Prob{no arrival during the time interval

$$(t, t + \Delta t)\} = 1 - \lambda \, \Delta t + o(\Delta t) \tag{13}$$

Prob{more than one arrival during the time interval

$$(t, t + \Delta t)\} = o(\Delta t), \tag{14}$$

where $o(\Delta t)$ stands for terms negligible in comparison with Δt. Similar equations, with μ in place of λ, hold true for the number of services completed during the time interval $(t, t + \Delta t)$. Thus, considering the possible transitions during the time interval $(t, t + \Delta t)$, we have, using the multiplication and addition theorems of probability,

$$P_n(t+\Delta t) = P_n(t)\{1 - \lambda \, \Delta t + o(\Delta t)\}\{1 - \mu \, \Delta t + o(\Delta t)\} + P_{n-1}(t)\{\lambda \, \Delta t + o(\Delta t)\} + P_{n+1}(t)\{\mu \, \Delta t + o(\Delta t)\} \tag{15}$$

from which, on proceeding to the limits as $\Delta t \to 0$,

$$(d/dt)P_n(t) = -(\lambda + \mu)P_n(t) + \lambda P_{n-1}(t) + \mu P_{n+1}(t), \qquad n = 1, 2, 3, \ldots. \tag{16}$$

It is easy to see that, for $n = 0$, we have

$$(d/dt)P_0(t) = -\lambda P_0(t) + \mu P_1(t). \tag{17}$$

Equations (16) and (17) constitute a system of differential–difference equations. Applying Laplace transforms of the form

$$\mathcal{L}\{P_n(t) : s\} = p_n(s) = \int_0^\infty e^{-st} P_n(t)\, dt$$

$$\mathrm{Re}(s) \geqq 0, \qquad n = 0, 1, 2, \ldots \tag{18}$$

the system can be reduced to a set of pure difference equations, whereas by using the generating function (or, as it is sometimes called, the Z transform)

$$P(z, t) = \sum_{n=0}^{\infty} P_n(t) z^n \tag{19}$$

it is reduced to a differential equation. Very often, we use both the transforms (18) and (19) and thus reduce the system of differential–difference Eqs. (16) and (17) to an algebraic equation.

II. POISSON AND NON-POISSON QUEUES

Most of the initial work on queueing theory was done under steady-state assumption, under which the probabilities P_n are independent of time, and therefore the derivatives on the left-hand sides of Eqs. (16) and (17) vanish, thus giving rise to difference equations that are usually easier to solve. Also, most of the work was initially done for Poisson queues, that is, queues with Poisson arrivals and negative-exponential service times. The negative-exponential distribution has the important Markovian or "forgetfulness" property: If, for instance, the service times have a negative-exponential distribution, then at any time the residual service time also has the same distribution. That is why in Eqs. (16) and (17) we did not have to take into account the time since the service on the unit being served began, which is called the elapsed service time. This is not the case with other distributions. However, for mathematical convenience, most of the other distributions have also been approached through the negative-exponential distribution.

We give below some well-known methods of queueing theory by means of which general non-Poisson queues (i.e., queues with general interarrival or service-time distributions) are analyzed.

A. Imbedded Markov Chain Technique

Suppose that we are considering an M/G/1 system. If we study the system only at the epochs when customers depart after service, then between any two such consecutive epochs the only possible transitions are customer arrivals for which the Markovian property is available. Such epochs or time points are called regeneration points, and the process considered at these epochs is called a Markov chain imbedded in the total process, which is non-Markovian. For a GI/M/1 system, for example, the arrival epochs are the regeneration points. A detailed discussion of non-Poisson queueing systems that are analyzed by the imbedded Markov chain technique is presented in Section VI.

B. Supplementary Variable Technique

According to this method, we study the system in continuous time but enhance the description of the system by including supplementary variables denoting the time since the last regeneration point. For example, for an M/G/1 queueing process we define $P_n(x, t)\, dx$ as the probability that at time t the number in the system is n and the elapsed service time of the unit in service lies between x and $x + dx$. Similarly, the GI/M/1 system can be dealt with by the inclusion of the elapsed time since the last arrival.

C. Phase Technique

This method consists of dividing the interarrival time or the service time into a number of phases, such that the time occupied by each phase has the negative-exponential distribution. Erlang used this method by regarding service to be completed in k fictitious phases, each of which has the same negative-exponential distribution, thus obtaining what is called a k-Erland distribution, which is, in fact, the k-fold convolution of the negative-exponential distribution with itself. For arrival distributions, we can in the same way postulate an arrival timing channel consisting of a number of phases. We may also consider the generalization, in which the number of phases is itself a random variable. One may, of course, exploit the concept of phases to study more complex queueing systems through the use of Markov chains.

III. QUEUES WITH VARIABLE PARAMETERS

In the theory of queues one often encounters studies of queueing systems in which both the interarrival and service times follow the same distribution, such as the negative-exponential distribution, the parameters of either or both of these distributions being variables. Some notable examples of queues with variable parameters are given below.

A. Queues with Time-Dependent Parameters

Consider a queueing system with Poisson arrivals and negative-exponential service times, the parameters of the

arrival and service-time distributions being, respectively, $\lambda(t)$ and $\mu(t)$, which are functions of the time t. If we let

$$P_n(t) \equiv P_{i,n}(t) = \text{Prob}\{N(t) = n \mid N(0) = i\} \qquad n, i = 0, 1, 2, \ldots, \tag{20}$$

where

$$N(t) = \text{number in the system at time } t, \tag{21}$$

then we shall obtain the following set of equations (known as Kolmogorov equations):

$$(d/dt)P_n(t) = -[\lambda(t) + \mu(t)]P_n(t) + \lambda(t)P_{n-1}(t) + \mu(t)P_{n+1}(t), \quad n \geqq 1 \tag{22}$$

$$(d/dt)P_0(t) = -\lambda(t)P_0(t) + \mu(t)P_1(t) \tag{23}$$

together with the initial conditions,

$$P_{i,n}(0) = \delta_{i,n}, \qquad n, i = 0, 1, 2, \ldots, \tag{24}$$

where $\delta_{m,n}$ is the Kronecker delta defined by

$$\delta_{m,n} = \begin{cases} 1, & \text{if} \quad m = n \\ 0, & \text{if} \quad m \neq n \end{cases}. \tag{25}$$

By suitably rescaling the time axis and on introducing a new set of dependent variables, this queueing problem can be solved by using a generating function like Eq. (19).

B. Queues with State-Dependent Parameters

In order to consider a queueing process with state-dependent parameters, let

$$P_{i,j}(t) = \text{Prob}\{\text{system state at time } t \text{ is } j \mid \text{state was } i \text{ at } t = 0\} \tag{26}$$

so that the process can be represented by the following infinite set of differential–difference equations:

$$(d/dt)P_{i,j}(t) = \lambda_{j-1}P_{i,j-1}(t) - (\lambda_j + \mu_j)P_{i,j}(t) + \mu_{j+1}P_{i,j+1}(t), \qquad j = 1, 2, 3, \ldots \tag{27}$$

$$(d/dt)P_{i,0}(t) = -\lambda_0 P_{i,0}(t) + \mu_1 P_{i,1}(t) \qquad i = 0, 1, 2, \ldots \tag{28}$$

subject to the initial conditions

$$P_{i,j}(0) = \delta_{i,j}, \quad i, j = 0, 1, 2, \ldots \tag{29}$$

in terms of the Kronecker delta $\delta_{i,j}$ defined by Eq. (25).

The initial-value problem consisting of the system of Eqs. (27) and (28), together with the initial condition (29), is usually solved by appealing to spectral theory.

C. Queues with Balking and Reneging

As a special case of queues with state-dependent parameters, we may consider an M/M/1 queueing system with further assumptions about the balking and reneging behavior of the customers. Suppose that the mean arrival and service rates are λ and μ, respectively, and that the queue discipline is first come, first served. An arriving customer balks with probability n/N and, therefore, joins the system with probability

$$e_n = 1 - n/N, \qquad n = 0, 1, 2, \ldots, N, \tag{30}$$

where n is the number in the system and N the maximum number allowed in the system. After joining the queue, each customer waits for service a certain length of time, which is evidently a random variable with the density function

$$d(t) = \alpha e^{-\alpha t}, \qquad \alpha > 0, \tag{31}$$

and if service does not begin by then, he or she departs and is lost to the system. Denoting, as usual, the transient probability of n in the system at time t by $P_n(t)$, we have the following differential–difference equations:

$$(d/dt)P_0(t) = -\lambda P_0(t) + \mu P_1(t) \tag{32}$$

$$(d/dt)P_n(t) = -[(1 - n/N)\lambda + \mu + (n-1)\alpha]P_n(t) + [1 - (n-1)/N]\lambda P_{n-1}(t) + (\mu + n\alpha)P_{n+1}(t), \qquad n = 1, 2, 3, \ldots, N-1 \tag{33}$$

$$(d/dt)P_N(t) = -[\mu + (N-1)\alpha]P_N(t) + (\lambda/N)P_{N-1}(t). \tag{34}$$

Furthermore, if P_n denotes the steady-state probability of n in the system and if

$$\gamma = \mu/\alpha \quad \text{and} \quad \delta = \lambda/(N\alpha) \tag{35}$$

then the steady-state equations are

$$0 = -N\delta P_0 + \gamma P_1 \tag{36}$$

$$0 = -[\gamma + (N-n)\delta + n - 1]P_n + (N - n + 1)\delta P_{n-1} + (\gamma + n)P_{n+1}, \quad N = 1, 2, 3, \ldots, N-1 \tag{37}$$

$$0 = -(\gamma + N - 1)P_N + \delta P_{N-1}. \tag{38}$$

These last difference equations [Eqs. (36)–(38)] can be solved in a straightforward manner. Thus, in terms of the incomplete beta function $B_x(\alpha, \beta)$ defined by

$$B_x(\alpha, \beta) = \int_0^x t^{\alpha-1}(1-t)^{\beta-1}\,dt \tag{38a}$$

we find that

$$P_0 = \frac{1 + NB_z(\gamma, N)}{z^{\gamma-1}(1-z)^N}, \tag{38b}$$

where, for convenience, $z = \delta/(1+\delta)$. Furthermore, the mean number in the queue is

$$L_q = (1+\delta)^{-1}[N\delta - (\gamma+\delta)(1-P_0)] \tag{38c}$$

the mean number in the system is

$$\begin{aligned} L &= \sum_{n=1}^{N} nN = L_q + 1 - P_0 \\ &= (1+\delta)^{-1}[N\delta - (\gamma-1)(1-P_0)] \end{aligned} \tag{38d}$$

and the probability that there are R or more in the system is

$$\begin{aligned} Q_R &= \sum_{n=R}^{N} P_n \\ &= P_0\left\{\frac{N!\Gamma(\gamma)B_z(\gamma+R-1, N-R+1)}{(N-R)!\Gamma(\gamma+R-1)z^{\gamma-1}(1-z)^N}\right\}, \end{aligned} \tag{38e}$$

where z is given as in Eq. (38b).

IV. DOUBLE-ENDED QUEUES

As an example of double-ended queues, consider the queues of taxis and passengers at a taxi stand, where at times there are passengers waiting for taxis and at other times there may be taxis waiting for passengers. Such queueing systems, sometimes called double queues, in which either the units wait in queue for service or idle servers queue up for customers, have varied applications in inventory and production processes. Obviously, in these systems there are two types of units, and interchangeably either may be called passengers (customers) and the other taxis (servers).

A. A Random Walk with Partially Reflecting Barriers

An interesting example of a double-ended queue is provided by a random walk of a particle on the entire real axis, where the particle moves one step to the right or left, respectively, with probabilities λ and μ per unit time, and there are partially reflecting barriers at positions—M and N, say. Suppose that the first barrier reflects the particle with probability r_1 and absorbs it with probability $1-r_1$ and that the second barrier reflects and absorbs the particle with probabilities r_2 and $1-r_2$, respectively. Defining

$$\begin{aligned} P_n(t) = \text{Prob}\{&\text{particle is at position } n \text{ at time } t\} \\ &-M \leqq n \leqq N \end{aligned} \tag{39}$$

we have the differential–difference equations

$$(d/dt)P_{-M}(t) = -r_1\lambda P_{-M}(t) + \mu P_{-M+1}(t), \tag{40}$$

$$\begin{aligned} (d/dt)P_{-M+1}(t) = &-(\lambda+\mu)P_{-M+1}(t) + r_1\lambda P_{-M}(t) \\ &+ \mu P_{-M+2}(t), \end{aligned} \tag{41}$$

$$\begin{aligned} (d/dt)P_n(t) = &-(\lambda+\mu)P_n(t) + \lambda P_{n-1}(t) \\ &+ \mu P_{n+1}(t) \\ &-M+2 \leqq n \leqq N-2, \end{aligned} \tag{42}$$

$$\begin{aligned} (d/dt)P_{N-1}(t) = &-(\lambda+\mu)P_{N-1}(t) + r_2\mu P_N(t) \\ &+ \lambda P_{N-2}(t), \end{aligned} \tag{43}$$

$$(d/dt)P_N(t) = -r_2\mu P_N(t) + \lambda P_{N-1}(t), \tag{44}$$

which can be solved by using the Laplace transform [Eq. (18)] and certain generating functions of the type given by Eq. (19).

By setting r_1 and r_2 equal to 0 or 1, we obtain the special cases when both of the barriers are absorbing (reflecting) and when one is absorbing and the other is reflecting. In particular, the case $r_1 = r_2 = 1$, with reflecting barriers at $-M$ and N, corresponds to the double-ended queueing model with limited waiting space for N passengers or M taxis if we define

$$P_n(t) = \begin{cases} \text{Prob}\{n \text{ passengers waiting at time } t\}, \\ \qquad\qquad n \geqq 0 \\ \text{Prob}\{-n \text{ taxis waiting at time } t\}, \\ \qquad\qquad n < 0 \end{cases} \tag{44a}$$

and we thus find that

$$\begin{aligned} P_n(t) = \beta^{n-i}\Bigg[& e^{-\alpha t}\Bigg\{ I_{i-n}(2t\sqrt{\lambda\mu}) \\ & + \sum_{j=0}^{\infty}\big[I_{2(M+N+1)(j+1)+i-n}(2t\sqrt{\lambda\mu}) \\ & + \big[I_{2(M+N+1)(j+1)-i+n}(2t\sqrt{\lambda\mu})\big]\Bigg\} \\ & + \lambda\sum_{j=0}^{\infty}\int_0^t e^{-\alpha\tau}\big\{ I_{2(M+N+1)j+2N-i-n}(2\tau\sqrt{\lambda\mu}) \\ & - 2\beta^{-1} I_{2(M+N+1)j+2N-i-n+1}(2\tau\sqrt{\lambda\mu}) \\ & + \beta^{-2} I_{2(M+N+1)j+2N-i-n+2}(2\tau\sqrt{\lambda\mu}) \\ & + I_{2(M+N+1)j+2M+i+n+2}(2\tau\sqrt{\lambda\mu}) \\ & - 2\beta^{-1} I_{2(M+N+1)j+2M+i+n+1}(2\tau\sqrt{\lambda\mu}) \\ & + \beta^{-2} I_{2(M+N+1)j+2M+i+n}(2\tau\sqrt{\lambda\mu})\big\}\, d\tau \Bigg], \end{aligned}$$

$$n = -M, -M+1, \ldots, N, \tag{44b}$$

where $I_\nu(z)$ denotes the modified Bessel function of the first kind defined by

$$I_\nu(z) = \sum_{m=0}^{\infty} \frac{(\frac{1}{2}z)^{\nu+2m}}{m!\Gamma(\nu+m+1)}, \qquad |z| < \infty \tag{44c}$$

and it is assumed that initially (at $t=0$) there are i passengers waiting.

B. Double-Ended Queues with Time-Dependent Rates

Consider a double-ended queueing problem in which the mean arrival rates of taxis and passengers are, respectively, $\alpha(t)$ and $\beta(t)$, which are functions of the time t. Let

$$P_n(t) = \begin{cases} \text{Prob}\{n \text{ taxis waiting at time } t\}, & n \geqq 0 \\ \text{Prob}\{-n \text{ passengers waiting at time } t\}, & n < 0 \end{cases} \tag{45}$$

be defined for $n = 0, \pm1, \pm2, \ldots$. Then we have the differential–difference equations

$$\begin{aligned}(d/dt)P_n(t) &= [P_{n-1}(t) - P_n(t)]\alpha(t) \\ &\quad - [P_n(t) - P_{n+1}(t)]\beta(t), \\ &\qquad n = 0, \pm1, \pm2, \ldots,\end{aligned} \tag{46}$$

which are usually solved by employing a Laurent generating function

$$F(z,t) = \sum_{n=-\infty}^{\infty} P_n(t) z^n. \tag{47}$$

Indeed, if we define

$$A(t) = \int_0^t \alpha(\tau)\, d\tau \tag{47a}$$

and

$$B(t) = \int_0^t \beta(\tau)\, d\tau, \tag{47b}$$

we shall obtain the explicit representation

$$\begin{aligned}P_n(t) &= \left[\frac{A(t)}{B(t)}\right]^{(n-i)/2} \exp(-A(t) - B(t)) \\ &\quad \times I_{n-i}(2\sqrt{A(t)B(t)}), \\ &\qquad n = 0, \pm1, \pm2, \ldots,\end{aligned} \tag{47c}$$

where $I_\nu(z)$ is defined by Eq. (44c) and i denotes the initial state of the system.

C. Double-Ended Queues with Bulk Service

We now consider a double-ended queueing system by assuming a general interarrival time distribution, with probability density $A(x)$, for customers (passengers), while the taxis arrive in a Poisson stream with mean rate μ. Suppose that there is a limited waiting space for M taxis and N passengers and that a taxi takes a fixed number S of customers from the queue, or the whole queue, whichever is less. We use the probabilities

$$P_n(x,t)\, dx, \qquad -M \leqq n \leqq N, \tag{48}$$

the meaning of which is similar to that given in Eq. (44) with the rôles of taxis and passengers reversed and with the addition that the time since the last customer arrival lies in the interval $(x, x+dx)$. Let $\eta(x)\Delta$ be the first-order probability that a customer arrives in time $(x, x+\Delta)$, given that there was no customer arrival up to x, so that

$$A(x) = \eta(x) \exp\left(- \int_0^x \eta(u)\, du \right). \tag{49}$$

Following the usual probability arguments, we can represent the queueing system by the differential–difference equations

$$\left(\frac{\partial}{\partial t} + \frac{\partial}{\partial x} + \eta(x)\right) P_{-M}(x,t) = \mu P_{-M+1}(x,t) \tag{50}$$

$$\begin{aligned}&\left(\frac{\partial}{\partial t} + \frac{\partial}{\partial x} + [\mu + \eta(x)]\right) P_n(x,t) \\ &\quad = \mu P_{n+1}(x,t), \qquad -M+1 \leqq n \leqq -1\end{aligned} \tag{51}$$

$$\left(\frac{\partial}{\partial t} + \frac{\partial}{\partial x} + [\mu + \eta(x)]\right) P_0(x,t) = \mu \sum_{j=1}^{S} P_j(x,t) \tag{52}$$

$$\begin{aligned}&\left(\frac{\partial}{\partial t} + \frac{\partial}{\partial x} + [\mu + \eta(x)]\right) P_n(x,t) \\ &\quad = \mu P_{n+S}(x,t), \qquad 1 \leqq n \leqq N - S\end{aligned} \tag{53}$$

$$\begin{aligned}&\left(\frac{\partial}{\partial t} + \frac{\partial}{\partial x} + [\mu + \eta(x)]\right) P_n(x,t) = 0, \\ &\qquad N - S + 1 \leqq n \leqq N,\end{aligned} \tag{54}$$

subject to the following boundary conditions:

$$P_{-M}(0,t) = 0 \tag{55}$$

$$\begin{aligned}P_n(0,t) &= \int_0^\infty P_n(x,t)\eta(x)\, dx, \\ &\qquad M+1 \leqq n \leqq N-1\end{aligned} \tag{56}$$

$$P_N(0,t) = \int_0^\infty [P_{N-1}(x,t) + P_N(x,t)]\eta(x)\, dx. \tag{57}$$

Assuming further that the initial state i of the system is so constrained that $0 < i < S$, we can obtain a closed-form solution of this double-ended queueing problem involving S-seated taxis, again by using a set of suitable generating functions and Laplace transforms.

V. BIRTH-AND-DEATH QUEUEING SYSTEMS

The limiting behavior of a many-server queue as the number of servers becomes large is usually studied by considering it as a birth-and-death process. Such a queueing process $X(t)$ can be defined as a continuous-time Markov chain whose state space is the set of nonnegative integers and whose transition probabilities

$$P_{i,j} = \text{Prob}\{X(t+\tau) = j | X(t) = i\} \quad i, j = 0, 1, 2, \ldots \tag{58}$$

are given by the matrix differential equation

$$(d/dt)\mathbf{P}(t) = \mathbf{A}\mathbf{P}(t) \tag{59}$$

subject to the initial condition

$$\mathbf{P}(0) = \mathbf{I}, \tag{60}$$

where $\mathbf{P}(t)$ is the infinite matrix

$$\mathbf{P}(t) = [P_{i,j}(t)], \quad i, j = 0, 1, 2, \ldots \tag{61}$$

$$\mathbf{A} = \begin{bmatrix} -(\lambda_0+\mu_0) & \lambda_0 & 0 & 0 & \cdots \\ \mu_1 & -(\lambda_1+\mu_1) & \lambda_1 & 0 & \cdots \\ 0 & \mu_2 & -(\lambda_2+\mu_2) & \lambda_2 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \end{bmatrix} \tag{62}$$

$\mathbf{I}$ is the infinite identity matrix

$$\mathbf{I} = \begin{bmatrix} 1 & 0 & 0 & \cdots \\ 0 & 1 & 0 & \cdots \\ \vdots & 0 & 1 & \cdots \\ & \vdots & 0 & \cdots \\ & & \vdots & \end{bmatrix} \tag{63}$$

and λ_i and μ_i denote, respectively, the birth and death rates per unit time when the size of the population is i.

For the n-server queue M/M/n with mean arrival rate λ and mean service rate per customer μ, the process $X_n(t)$ representing the number of customers in the system at time t is a birth-and-death queueing process of the type described above with, of course,

$$\lambda_i \equiv \lambda, \quad i = 0, 1, 2, \ldots \tag{64}$$

$$\mu_i = \begin{cases} i\mu, & \text{if } 0 \leqq i \leqq n \\ n\mu, & \text{if } i \geqq n+1 \end{cases}. \tag{65}$$

For such a queueing process, it can be shown that the parameters $\{\lambda_i\}$ and $\{\mu_i\}$ uniquely determine $P_{i,j}(t)$ defined by Eq. (58) and that the sample paths of $X_n(t)$ are jump functions with probability 1. Furthermore, in terms of the Poisson–Charlier polynomials $c_n(x, a)$ defined by

$$c_n(x; a) = \sum_{k=0}^{n} (-1)^k \binom{n}{k}\binom{x}{k} k! a^{-k} \quad a > 0; \quad x = 0, 1, 2, \ldots \tag{65a}$$

we have

$$P_{i,j}(t) = \pi_j \int_0^\infty e^{-xt} Q_i(x) Q_j(x)\, d\Psi(x) \tag{65b}$$

where, for convenience,

$$Q_k(x) = c_k(x/\mu, \lambda/\mu), \quad k \leqq n \tag{65c}$$

the sequence $\{\pi_j\}$ is defined by

$$\pi_0 = 1 \tag{65d}$$

$$\pi_n = \frac{\lambda_0 \lambda_1 \cdots \lambda_{n-1}}{\mu_1 \mu_2 \cdots \mu_n}, \quad n \geqq 1 \tag{65e}$$

and $\Psi(x)$ is a positive regular measure on $0 \leqq x < \infty$.

VI. IMBEDDED MARKOV CHAIN QUEUEING SYSTEMS

An important characteristic of a birth-and-death process is that, if at any time t the system state E_i is known, then (in principle) the state probabilities for all $t + \tau$ ($\tau \geqq 0$) are also known, irrespective of the route the system may have followed in reaching the state E_i at time t. When this holds true for a system, we may write equations relating the state probabilities at any time t to those at any other time $t + \tau$ ($\tau \geqq 0$). In fact, it can be shown that a necessary and sufficient condition for a system to possess this property, called the Markov property, is that the time between successive changes of state be negative-exponentially distributed (but not necessarily identically distributed). A process that has this characteristic Markovian property is called a Markov process.

As already pointed out in Section I, the main characteristics of a queueing system are the input process, the queue discipline, and the service mechanism, and the three main parameters of a queueing system are the queue length, the waiting time, and the busy period. In a wide variety of queueing systems, such as the Poisson queues (i.e., queues with Poisson arrival and negative-exponential service times), the queue length $N(t)$ is a Markov process because the specification of the queue length at time t is

adequate to predict its length at time $t + \tau$ ($\tau \geqq 0$). Indeed, this is true on account of the Markovian property of the Poisson distribution [Eq. (6)].

We now turn to the birth-and-death process with a view to ascertaining why, for example, an M/G/1 queue, unlike the M/M/s queue, cannot be modeled as a birth-and-death process. Denoting by $N(t)$ the number of customers in the system at time t and applying the law of total probability, we have

$$\begin{aligned}\text{Prob}\{N(t+\tau) = j\} &= \sum_{i=0}^{\infty} \text{Prob}\{N(t+\tau) = j \mid N(t) = i\} \\ &\quad \times \text{Prob}\{N(t) = i\}, \\ &\quad t \geqq 0; \quad \tau \geqq 0; \quad j = 0, 1, 2, \ldots. \end{aligned} \tag{66}$$

Equations (66) are valid for any queueing system. All that is required is first to evaluate the conditional probabilities

$$\text{Prob}\{N(t+\tau) = j \mid N(t) = i\}, \tag{67}$$

which are called the transition probabilities, and then to solve Eqs. (66) for the state probabilities

$$\text{Prob}\{N(\zeta) = k\}, \quad \zeta \geqq 0; \quad k = 0, 1, 2, \ldots. \tag{68}$$

While analyzing queueing systems that are birth-and-death processes, we tacitly assume τ to be small and let $\tau \to 0$. In view of the fact that all the transition probabilities except those representing a transition of step size 0 or ± 1 are $o(\tau)$ as $\tau \to 0$, we can avoid laborious calculations of the transition probabilities, since most of them become irrelevant as $\tau \to 0$. In principle, however, we do calculate the transition probabilities first, simply because the birth-and-death process is a Markov process; that is, the time separating successive transitions is negative-exponentially distributed, obviating the need to consider how long the system had been in state E_i at time t, or exactly how and in what way state E_i at time t evolved. This situation does not hold true in the case of a non-Poisson queue, such as the M/G/1 queue in which the service-time distribution is not assumed to be the negative-exponential distribution. Consequently, in order to specify the transition probabilities correctly we must know not only the precise state in which the system is at time t, but also exactly how long the system had been in that state. Equation (66), though not incorrect, is no longer applicable in the analysis of the M/G/1 queue.

Thus, when the input and service-time distributions assume general forms, as in various (non-Poisson) special cases of the s-server queueing system GI/G/s, the process $N(t)$ is no longer Markovian. The correct specification of such a queueing system is then provided by the vector process $[N(t), \xi(t), \eta(t)]$, where $\xi(t)$ denotes the time that has elapsed since the last arrival and $\eta(t)$ is the expended service time of the customer being served at time t. A systematic study of this vector space is theoretically possible, but the mathematical analysis to be applied is much too involved. A simpler method of analysis is therefore required for the study of these queueing models. A powerful method for the analysis of such queueing systems is provided by Palm's concept of regeneration points and Kendall's technique of imbedded Markov chains, both of which are introduced below.

A set $\mathcal{S}$ of time epochs is said to be a set of regeneration points for a stochastic process $X(t)$ if and only if, for all $t > t_0$, we have

$$\begin{aligned}&\text{Distribution}\{X(t) \mid X(t_0)\} \\ &= \text{Distribution}\{X(t) \mid X(\tau) \text{ for all } \tau \leqq t_0\}\end{aligned} \tag{69}$$

whenever t_0 is known to belong to $\mathcal{S}$. Clearly, the condition (69) implies that the development of the process $X(t)$ during $t > t_0$ is independent of the history of the process during $0 < t \leqq t_0$. In a Markov process, the entire range of t values is a set of regeneration points. By definition, a process that has a set of regeneration points is called a regenerative process.

Suppose now that there exists a denumerable $\mathcal{S}$-set of regeneration points

$$\{t_n, n = 0, 1, 2, \ldots\}$$

such that

$$0 < t_0 < t_1 < t_2 < \cdots$$

and let $X_n = X(t_n)$. Then it follows readily from the above definition that the sequence of random variables $\{X_n\}$ forms a Markov chain (which is, by definition, the discrete analog of a Markov process, so that the characteristic Markov property holds true only at discrete values of the parameter t, i.e., at a discrete set of regeneration points). This Markov chain is said to be "imbedded" in the given stochastic process $X(t)$.

In a single-server queueing process, the set of points at which the counter is free is clearly an $\mathcal{S}$-set. Another example of an $\mathcal{S}$-set is the set $\mathcal{S}_x$ consisting (for a given x) of those time epochs at which the customer at the counter has already been served for a period x.

In the case of the M/G/1 queue, with Poisson input and a general service-time distribution, the service completion points (i.e., those epochs at which the customers complete service and leave the system) are regeneration points. This is so because, whenever a customer leaves the system, either the system becomes empty or a previously waiting customer starts service; in either event the transition probabilities (and hence also the future evolution of the system) depend only on the number of customers

in the system at the service completion point. Thus, the system state at this discrete set of regeneration points is an imbedded Markov chain.

Finally, in the general case of a non-Poisson queueing system, if there exists an increasing sequence $\{t_n\}$ of regeneration points such that we can easily compute the transition probabilities associated with

$$\{N_{n+1} \mid N_n\}; \quad N_n = N(t_n),$$

where $N(t)$ denotes the queue length at time t, then the analysis using the imbedded Markov chain $\{N_n\}$ will yield valuable information concerning the process $N(t)$.

VII. EQUATIONS FOR THE M/M/1 QUEUEING SYSTEM

The M/M/1 queue is the simplest (and most interesting) of the various queueing systems presented in the preceding sections. Indeed, it is the classic example of a queueing system, and the analytical tools required for its study are rather elementary. Even though these analytical techniques do not easily carry over into more complex queueing systems, the general behavior of an M/M/1 queue is, in many respects, similar to that observed in the more complex cases. For this reason, we present here the following equations, which summarize the important results for an M/M/1 queueing system (where ρ is the traffic intensity or utilization factor and assuming steady state, wherever appropriate):

$$\begin{aligned} P_0 &= \text{Prob}\{\text{no customers in the system}\} \\ &= 1 - (\lambda/\mu) = 1 - \rho \\ P_n &= \text{Prob}\{n \text{ customers in the system}\} \\ &= \rho^n P_0(t) = \rho^n(1-\rho) \\ L &= \text{average (or mean) number of customers in the system} \\ &= \rho/(1-\rho) = \lambda/(\mu-\lambda) \end{aligned}$$

with variance

$$\begin{aligned} \sigma_L^2 &= \rho/(1-\rho)^2 \\ L_q &= \text{average (or mean) number of customers in the queue} \\ &= \rho^2/(1-\rho) = \lambda^2/[\mu(\mu-\lambda)] \\ W &= \text{average (or mean) waiting time in the system} \\ &= (1/\mu)/(1-\rho) = 1/(\mu-\lambda) \\ W_q &= \text{average (or mean) waiting time in the queue} \\ &= (\rho/\mu)/(1-\rho) = \lambda/[\mu(\mu-\lambda)] \\ L &= \lambda W; \quad L_q = \lambda W_q \end{aligned}$$

$$\begin{aligned} &\text{Prob}\{\text{interdeparture time} \leqq t\} \\ &\quad = \text{Prob}\{\text{idle period duration} \leqq t\} = 1 - e^{-\lambda t} \\ \psi(y) &= \text{probability density function of the waiting time spent by a customer in the queue before service} \\ &= \lambda(1-\rho)e^{-\mu(1-\rho)y} \\ &= (1-\lambda/\mu)\lambda e^{(\lambda-\mu)y}, \quad 0 \leqq y < \infty \\ g(y) &= \text{probability density function of the busy period (i.e., the interval of time between two successive idle periods)} \\ &= (1/y\sqrt{\rho})e^{-(\lambda+\mu)y} I_1(2y\sqrt{\lambda\mu}), \end{aligned}$$

where $I_\nu(z)$ is the modified Bessel function of the first kind defined by Eq. (44c):

$$\begin{aligned} f_n &= \text{Prob}\{n \text{ customers are served during a busy period}\} \\ &= \frac{1}{n}\binom{2n-2}{n-1}\rho^{n-1}(1+\rho)^{1-2n}. \end{aligned}$$

VIII. EXAMPLES OF APPLICATIONS

In this section we briefly consider a few examples of applications of queueing theory in today's world. Indeed, as already indicated in the previous sections, queueing theory finds applications in a wide variety of fields that may be in need of optimization. Essentially, therefore, queueing theory is used to determine the optimum number of servers by striking a balance between the cost of waiting and the cost of an idle server.

A. Typical Telephone Booth Problem

Consider a typical telephone booth problem in which customers arrive at the booth in Poisson stream with an average interarrival rate of 10 min; that is, the average time between two successive customer arrivals is 10 min. Therefore, the parameter λ is equal to 0.1 customer arrival per minute, or 6 customer arrivals per hour. Suppose also that the length of an average telephone call is exponentially distributed, with an average service time of 3 min, so that there are $\frac{1}{3}$ service activities per minute, and we may set μ equal to 20 services per hour.

In order to find the probability that a customer arriving at the booth will have to wait for service, we proceed as follows:

$$\begin{aligned} &\text{Prob}\{\text{an arriving customer must wait for service}\} \\ &\quad = 1 - P_0 = 1 - (1 - \lambda/\mu) \\ &\quad = \lambda/\mu = 6/20 = 0.3. \end{aligned}$$

Thus, there is (approximately) one chance in three that a customer arriving at the telephone booth must wait for the booth to become empty.

Next we compute the average queue length, that is, the average number of customers waiting in the queue for service.

$$\begin{aligned}&\text{Average number of customers in the queue}\\&= L_q = \lambda^2/[\mu(\mu-\lambda)]\\&= 36/(20\times 14) = 0.13\end{aligned}$$

so that an arriving customer will find (on the average) 0.13 customer ahead of him or her on arriving at the telephone booth.

Suppose now that the telephone company proposes to install a second telephone booth next to the existing one, provided that the company is convinced that an arriving customer would expect to wait at least 3 min for service (i.e., for the telephone booth to be empty). By how much does the flow of arriving customers have to increase in order to justify the installation of a second telephone booth? To answer this question, we compute λ so that the average waiting time in the queue is 3 min, or $\frac{1}{20}$ hr. Thus,

$$W_q = \lambda/[20(20-\lambda)] = 1/20,$$

which yields

$$\lambda = 10 \text{ arrivals per hour}$$

It follows that the flow of arriving customers must increase from 6 per hour to 10 per hour in order to justify the additional telephone booth.

Finally, we calculate the probability that an arriving customer will have to wait at least 10 min for the telephone booth to be empty:

$$\begin{aligned}&\text{Prob}\{\text{waiting time} \geqq \tfrac{1}{6}\text{ hr}\}\\&= \int_{1/6}^{\infty}\left(1-\frac{\lambda}{\mu}\right)\lambda e^{(\lambda-\mu)y}\,dy = -\frac{\lambda}{\mu}e^{(\lambda-\mu)y}\Big|_{1/6}^{\infty}\\&= -\frac{6}{20}e^{-14y}\Big|_{1/6}^{\infty} = (0.3)e^{-2.3} = 0.03\end{aligned}$$

Similarly, we have

$$\begin{aligned}&\text{Prob}\{\text{total time (waiting time + service time)}\\&\text{in the system} \geqq \tfrac{1}{6}\text{hr}\}\\&= \int_{1/6}^{\infty}(\mu-\lambda)e^{(\lambda-\mu)y}\,dy = -e^{(\lambda-\mu)y}\Big|_{1/6}^{\infty}\\&= -e^{-14y}\Big|_{1/6}^{\infty} = e^{-2.3} = 0.10.\end{aligned}$$

B. Queueing Problem Involving Traffic Lights

Consider an M/E_k/1 queueing system that involves the characteristics displayed by a series of k traffic lights. To study the system as a queueing problem, we let λ denote the customer (vehicle) arrival rate per minute and let μ denote the service rate per minute (i.e., the traffic lights will turn green for a period of time, allowing μ vehicles to pass through the system over a 1-min period). Then, assuming an infinite source population, an infinite queue length, and an FIFO (first-in-first-out) queue discipline, the following relationships are easily derived for this M/E_k/1 queueing system:

$$\begin{aligned}L &= \text{average number of vehicles in the system}\\&= \frac{k+1}{2k}\frac{\lambda^2}{\mu(\mu-\lambda)} + \rho\\L_q &= \text{average number of vehicles in the queue}\\&= \frac{k+1}{2k}\frac{\lambda^2}{\mu(\mu-\lambda)}\\W &= \text{average waiting time in the system}\\&= \frac{k+1}{2k}\frac{\lambda}{\mu(\mu-\lambda)} + \frac{1}{\mu}\\W_q &= \text{average waiting time in the queue}\\&= \frac{k+1}{2k}\frac{\lambda}{\mu(\mu-\lambda)}\end{aligned}$$

where, as usual, $\rho = \lambda/\mu$ and the Erlang stage parameter $k = 1, 2, 3, \ldots$.

Each of the output parameters L, L_q, W, and W_q is important in the analysis of the queueing problem associated with k traffic lights. For the sake of simplicity, let $k = 2$ (i.e., a queueing system consisting of two traffic lights) and $\mu = 7$ (i.e., seven vehicles are allowed to pass through the system over a 1-min period). The following tabulation illustrates a comparative behavior of the system when the customer (vehicle) arrival rate per minute doubles from $\lambda = 3$ to $\lambda = 6$ ($k = 2$; $\mu = 7$):

	$\lambda = 3$	$\lambda = 6$
L	1.3929	16.2857
L_q	0.9643	15.4286
W	0.4643	2.7143
W_q	0.3214	2.5714

Thus, a transition from $\lambda = 3$ to $\lambda = 6$ arrivals per minute (in a system with two traffic lights and $\mu = 7$ services per minute) has resulted in a rather significant increase in the customer's waiting time. More precisely, a customer who waits in the system (with $\lambda = 3$) for a period of ~28 sec will now have to wait in the system (with $\lambda = 6$) for ~2 min and 34 sec, that is, a waiting-time increase by a factor of

$\sim$5 as a result of the doubling of customer arrivals from 3 to 6 arrivals per minute in a system with two traffic lights and 7 services per minute.

C. Baggage Claim Problem

Many queueing systems are equipped with certain special rules for service that are markedly different from those of the classic queueing situations described in this and the preceding sections. Consider, for example, the queue of airline passengers who wish to claim their luggage from a baggage carousel.

Suppose that there are N_b bags and N_p passengers having one or more bags to claim. Note that the passengers leave an airplane and walk to the baggage claim area while the bags are removed from the airplane and transported to a conveyor belt (or some other device), where they are handled at a finite rate; therefore, the bags are not all available simultaneously. Let

$$N_b S_b(t) = \text{cumulative number of bags to become available to customers by time } t$$

so that

$$\begin{aligned} S_b(t) &= \text{fraction of bags to arrive by time } t \\ &= \text{Prob}\{\text{some arbitrarily chosen bag arrives by time } t\} \end{aligned}$$

Also let

$$N_p S_p(t) = \text{cumulative number of passengers to arrive at the baggage claim area by time } t$$

so that

$$\begin{aligned} S_p(t) &= \text{fraction of passengers to arrive by time } t \\ &= \text{Prob}\{\text{some arbitrarily chosen passenger arrives by time } t\}. \end{aligned}$$

Clearly, there are two distinct queues: a queue of bags waiting to be claimed by the owners and a queue of passengers waiting for their bags. The service facility is intended, in some fictitious manner, to unite a passenger (customer) with his or her bag or bags and to send them both on their way. Neglecting the time a passenger takes to remove his or her bag or bags from the carousel (or rack), it is easily seen that

$$\begin{aligned} &\text{Prob}\{\text{an arbitrary bag is removed from the carousel (or rack) by time } t\} \\ &= \text{Prob}\{\text{the bag has arrived by time } t \text{ and its owner has also arrived by time } t\}. \end{aligned}$$

Indeed, it is reasonable to assume that these last two events are statistically independent.

The expected cumulative number of bags to depart by time t is given by

$$\begin{aligned} Q_b(t) &= N_b \text{ Prob}\{\text{a bag has left}\} \\ &= N_b S_b(t) S_p(t) \end{aligned}$$

so that the expected number of bags in the queue of bags is

$$R_b(t) = N_b S_b(t)[1 - S_p(t)]$$

These results hold true even if some passengers have more than one bag to claim, provided that the passenger removes his or her bag from the carousel immediately even though he or she must still wait for a second bag.

IX. FURTHER DEVELOPMENTS IN RELATED AREAS

This last section is devoted to a brief exposition of some further developments in various areas related rather closely to that of queueing theory. Of the numerous such areas, we choose to briefly describe here six important ones with a view to stimulating the interested reader to further studies and research in these areas.

A. Metamodeling in Complex Computer Systems

In recent years we have encountered a remarkably significant increase in the number of approximate methods which are available for analyzing nonhomogeneous (nonproduct form) queueing network models occurring in complex computer systems. Generally speaking, these are *ad hoc* methods which usually focus on specific aspects of the involved system operation and which appear to be different from one another. Thus, it is a difficult task to clearly see the underlying principles of model development, to understand the relationship between different queueing models of the same system, or to apply the existing approximate methods to other seemingly new situations.

Metamodeling in complex computer systems is a systematic study of approximate methods in queueing network modeling and (more importantly) of the way these methods are developed; indeed, it identifies the underlying modeling process and provides tools and techniques for model development which will enable one to realistically sort through the many different methods available in the literature, understand their bases and shortcomings, and (if and when needed) apply them profitably to new and significant problems.

B. Dynamic Flows in Communication Network Models

In the design of communication networks, the fundamental problem consists in finding efficient traffic control

rules. In the case of a slightly loaded communication network, which is subjected to a stationary load, this problem is rather simple, since each user can choose a route that best serves its own interests. In the situation when the offered traffic increases, however, the problem turns out to be significantly more complex. Competition for limited network resources results in various nonlinear phenomena which can manifest themselves in deadlocks or overall network congestion. Furthermore, the procedures that did serve the interests of individual users in the slightly loaded case may now provide a poor service for *all* users when the traffic is rather heavy.

The dynamic flow theory (that is, the modeling and optimization of dynamic flows) is applicable to the analysis and synthesis of control structures for numerous types of networks; it is especially appropriate for systematically treating communication networks such as circuit and packet-switched networks.

C. Queueing Theory in Polling Systems

A polling system provides a way of serving requests by several (possibly buffered) users in a cyclic order, with generally nonzero switchover times. Polling schemes have already been applied in numerous computer-terminal communication systems, including (for example) such standard data link protocols as BSC, SDLC, and HDLC, and in local-area computer networks (e.g., token ring). In the language of queueing theory, one needs here to consider a multiple queue, cyclic service system whose congestion analysis has indeed been the subject of many investigations.

D. Scheduling Sequences and Queues

The main objective in resource scheduling is to construct a work schedule which *either* (i) completes the work at the earliest possible date by making use of the available resources, *or* (ii) makes the fullest and most efficient use of resources to complete the work by a fixed date.

One of the simplest examples of a work schedule under the aforementioned approach (i) (that is, of a work schedule constructed within the resource restraints) is provided by the case where there is a fixed labour force available, the duration and labour content of each network activity is prescibed (fixed), and it is required to determine the period of completion of the project within these limitations.

In examples of resource scheduling under the previously mentioned approach (ii), the project completion date is to be treated as an important objective. Thus it is necessary to construct a work schedule within a particular time span. Since, in this case, activities on the critical path cannot be moved without affecting the project completion date, the scheduling of noncritical activities at alternative dates (within their earliest and latest cycles) provides some flexibility (latitude) which can indeed be deployed to produce a work schedule with a view to satisfying a particular criterion such as smoothest work load, least overtime operations, etc.

Because of the obvious importance of the sequence in which activities are presented for scheduling, such activities are deliberately arranged in a priority-sequenced queue. This scheduling queue is so formed as to first consider the most important activities (that is, activities which are likely to be the most difficult to schedule). And, in order to qualify for a place at all in the scheduling queue, such activities must be available for scheduling at that point of the calculation, that is, when all preceding activities are completed.

E. Queueing Theory and Statistical Performance Evaluation of Computer Networks and Systems

The various analyses and techniques involving continuous- and discrete-time queueing models, stochastic Petri networks (which have emerged as a remarkably promising high-level performance modeling tool for systems that exhibit concurrency, synchronization, and randomness), and so on, are found to apply in the problem of statistical performance evaluation of computer networks and systems. Such problems are becoming increasingly important as we are continually seeking to design more and more sophisticated (and efficient) communication and information processing systems. The ability to predict the performance of a proposed system without actually having to construct the system is undoubtedly an extremely cost-effective design tool.

F. Boundary-Value Problems in Queueing Theory

In the analysis of certain queueing models which differ only slightly from the classical M/G/1 model (for instance, if two types of customers have to be distinguished), one is often led to the problem of solving a functional equation of the form:

$$K(p_1, p_2)\,\Phi(p_1, p_2) = A(p_1, p_2)\,\Phi(p_1, 0) + B(p_1, p_2)\Phi(0, p_2) + C(p_1, p_2)\,\Phi(0, 0) \qquad (|p_1| \le 1;\ |p_2| \le 1), \quad (70)$$

where the kernel $K(p_1, p_2)$ as well as the functions $A(p_1, p_2)$, $B(p_1, p_2)$, and $C(p_1, p_2)$ are prescribed, and $\Phi(p_1, p_2)$ is an unknown function which should be a

bivariate generating function in p_1 and in p_2 of a proper probability distribution with the set

$$\mathbb{N}_0 \times \mathbb{N}_0 \quad (\mathbb{N}_0 := \mathbb{N} \cup \{0\}; \quad \mathbb{N} := \{1, 2, 3, \ldots\})$$

as its support. Functional equations of the type given by (70) are usually investigated by first solving some Riemann–Hilbert boundary-value problems which are fomulated for the unique determination of the functions $\Phi(p_1, 0)$ and $\Phi(0, p_2)$.

GLOSSARY

Canonical correlation analysis Methodology dealing with the study of the dependence between two sets of variables.

Canonical variables Pairs of linear combinations of two sets of variables that best explain the dependence between the original sets of variables.

Discriminant analysis Methodology dealing with the classification of heterogeneous populations.

Finite intersection tests Procedures involving simultaneous tests of a finite number of hypotheses that are of interest.

Large dimensional random matrix Random matrix whose dimension increases proportionally to the degrees of freedom.

Linear discriminant functions Linear functions of the original variables that maximize the discrimination between populations.

Principal component analysis Technique of finding certain linear combinations of original variables that are important in explaining variation among experimental units.

Spectral analysis of large dimensional random matrices Theory of limiting distributions of eigenvalues of large dimensional random matrices.

Wishart distribution Distribution of the sample sums of squares and cross-products matrix when the underlying distribution of the observations is multivariate normal.

IN A NUMBER of situations, the data analysis is confronted with numerous variables or parameters. One way of finding more efficient statistical inferences is to select a smaller number of important variables or parameters, i.e., to reduce the dimension of data. The important variables selected may be the original variables or linear

combinations of the original variables. Some methods of reduction of dimensionality are principal component analysis, canonical correlation analysis, and finding the rank of the regression matrix. Sometimes the number of parameters to be estimated needs to be reduced, such as the nonexact tests by omitting the estimation of a large dimensional covariance matrix.

I. INTRODUCTION

Multivariate statistical analysis is meant to deal with high-dimensional data. On one hand, measurements on more variables must provide more information about the statistical problems. On the other hand, however, the model with more variables needs more parameters to describe and thus more efficiency would be lost due to estimation of the parameters. Therefore, suitably reducing the number of variables (i.e., excluding those of less importance) or proposing new statistical models involved with a smaller number of parameters has been become an interesting topic in both theoretical and applied statistics.

The techniques of multivariate regression analysis and canonical correlation analysis play important roles in the analysis of multivariate data in many disciplines. In the area of multivariate regression analysis, it is of interest to select a smaller number of variables that are adequate for prediction. Similarly, in canonical correlation analysis, it is of interest to select important variables that are adequate to explain the relationship between two sets of variables.

The performance of some traditional statistical approaches becomes poorer and poorer as the dimension of data increases, even breaking down when the dimension of data is larger than the degrees of freedom. Some remedies for the classical statistical methods have more or less purposely been proposed in the literature.

The main emphasis of this review is on techniques for determination of the ranks of the regression matrix and canonical correlation matrix, on methods for selection of important original variables in the areas of multivariate regression analysis and canonical correlation analysis. We also review some remedies to classical statistical tests when the latter perform poorly in dealing with high dimensional data. This review is by no means exhaustive. For lack of space, we restrict our attention to the reduction-of-dimensionality problems in the above-mentioned areas. For discussions of other important topics in multivariate analysis, the reader is referred to Anderson (1984a), Bai (1999), Gnanadesikan (1977), Krishnaiah (1980a), Krishnaiah and Kanal (1982), Kshirsagar (1972), and Rao (1973).

II. PRELIMINARIES

The following notation is used throughout this article. The transpose of a matrix A is denoted by A', whereas the inverse of a square matrix B is denoted by B^{-1}. The transpose of a conjugate of a complex matrix C is denoted by C^*. We now define elliptically symmetric distribution, complex multivariate normal distribution, and complex elliptically symmetric distribution.

A real random vector $\mathbf{x}$: $p \times 1$ is said to have elliptically symmetric distribution if its density is of the form

$$f(\mathbf{x}) = |\Sigma|^{-1/2} h[(\mathbf{x}-\boldsymbol{\mu})'\Sigma^{-1}(\mathbf{x}-\boldsymbol{\mu})] \tag{1}$$

Multivariate normal, multivariate t, and multivariate Cauchy distributions are special cases of the elliptically symmetric distribution. For more details on the elliptically symmetric distributions, the reader is referred to Kelker (1970).

A $p \times 1$ random vector $\mathbf{z} = \mathbf{x}_1 + i\mathbf{x}_2$ is said to be distributed as complex multivariate normal if the real vector $\mathbf{x}' = (\mathbf{x}_1', \mathbf{x}_2')$ is distributed as multivariate normal with mean vector $\boldsymbol{\mu}_0' = (\boldsymbol{\mu}_1', \boldsymbol{\mu}_2')$ and covariance matrix Σ_0, where

$$\Sigma_0 = \begin{pmatrix} \Sigma_1 & \Sigma_2 \\ -\Sigma_2 & \Sigma_1 \end{pmatrix} \tag{2}$$

$\Sigma_1' = \Sigma_1$ and $\Sigma_2' = -\Sigma_2$ are of order $p \times p$. The complex multivariate normal distribution was considered by Wooding (1956), Goodman (1963), and others. The density function of the complex multivariate normal distribution is of the form

$$f(\mathbf{z}) = \pi^{-p}|\Sigma|^{-1} \exp[-(\mathbf{z}-\boldsymbol{\mu})^*\Sigma^{-1}(\mathbf{z}-\boldsymbol{\mu})], \tag{3}$$

where $\Sigma = 2(\Sigma_1 - i\Sigma_2)$ and $\boldsymbol{\mu} = \boldsymbol{\mu}_1 + i\boldsymbol{\mu}_2$. Note that a complex multivariate normal distribution is uniquely determine by its mean vector $\boldsymbol{\mu} = E\mathbf{z}$ and covariance matrix $\Sigma = E(\mathbf{z}-\boldsymbol{\mu})(\mathbf{z}-\boldsymbol{\mu})^*$. For a review of the literature on complex multivariate distributions, the reader is referred to Krishnaiah (1976).

We now define the complex elliptically symmetric distribution introduced by Krishnaiah and Lin (1986). The $p \times 1$ random vector $\mathbf{z} = \mathbf{x}_1 + i\mathbf{x}_2$ is said to have a complex elliptically symmetric distribution if the real vector $\mathbf{x}' = (\mathbf{x}_1', \mathbf{x}_2')$ has an elliptically symmetric distribution with density

$$f(\mathbf{x}) = |\Sigma_0|^{-1/2} h\left[\frac{1}{2}(\mathbf{x}-\boldsymbol{\mu}_0)'\Sigma_0^{-1}(\mathbf{x}-\boldsymbol{\mu}_0)\right], \tag{4}$$

where $\boldsymbol{\mu}_0' = (\boldsymbol{\mu}_1', \boldsymbol{\mu}_2')$ and Σ_0 has the same expression as (2). Write $\Sigma = 2(\Sigma_1 - i\Sigma_2)$ and $\boldsymbol{\mu} = \boldsymbol{\mu}_1 + i\boldsymbol{\mu}_2$. By the facts that

$$(\mathbf{z}-\boldsymbol{\mu})^*\Sigma^{-1}(\mathbf{z}-\boldsymbol{\mu}) = \frac{1}{2}(\mathbf{x}-\boldsymbol{\mu}_0)'\Sigma_0^{-1}(\mathbf{x}-\boldsymbol{\mu}_0)$$

and

$$|\Sigma| = 2^p|\Sigma_0|^{1/2},$$

the density of $\mathbf{z}$ can be written in the form that

$$g(\mathbf{z}) = |\Sigma|^{-1}h[(\mathbf{z}-\boldsymbol{\mu})^*\Sigma^{-1}(\mathbf{z}-\boldsymbol{\mu})]. \tag{5}$$

Complex multivariate normal and complex multivariate t distributions are special cases of the complex elliptically symmetric distribution.

III. TESTS FOR THE RANK OF THE REGRESSION MATRIX

We first discuss procedures for testing the hypothesis on the number of significant discriminant functions. Note that this is a special case of the testing problem for the rank of regression matrix.

Let $\mathbf{x}_1, \ldots, \mathbf{x}_k$ (real) be distributed independently as multivariate normal (imnd.) with mean vectors $\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_k$ and a common covariance matrix Σ. Furthermore, let $\mathbf{x}_{ij}$ $(j = 1, 2, \ldots, n_i)$ denote the jth independent observation on $\mathbf{x}_i$. Then, the between-group sums of squares and cross-product (SP) matrix is given by

$$S_b = \sum_{i=1}^{k} n_i(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot\cdot})(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot\cdot})' \tag{6}$$

whereas the within-group SP matrix is given by

$$S_w = \sum_{i=1}^{k}\sum_{j=1}^{n_i}(\mathbf{x}_{ij} - \bar{\mathbf{x}}_{i\cdot})(\mathbf{x}_{ij} - \bar{\mathbf{x}}_{i\cdot})' \tag{7}$$

where

$$n_i\bar{\mathbf{x}}_{i\cdot} = \sum_{j=1}^{n_i}\mathbf{x}_{ij}, \quad n\bar{\mathbf{x}}_{\cdot\cdot} = \sum_{i=1}^{k}\sum_{j=1}^{n_i}\mathbf{x}_{ij}$$

and $n = n_1 + \cdots + n_k$.

Now, let $l_1 \geq \cdots \geq l_p$ denote the eigenvalues of $S_bS_w^{-1}$. Also, write

$$\Omega = \sum_{i=1}^{k} n_i(\boldsymbol{\mu}_i - \bar{\boldsymbol{\mu}})(\boldsymbol{\mu}_i - \bar{\boldsymbol{\mu}})' \tag{8}$$

where $n\boldsymbol{\mu} = (n_1\boldsymbol{\mu}_1 + \cdots + n_k\boldsymbol{\mu}_k)$. Then the rank of Ω is equal to the number of significant discriminant functions. Fisher (1939) proposed to use $T_1 = (l_{r+1} + \cdots + l_s)$ as a test statistic for testing the hypothesis that the rank of Ω is equal to r where $s = \min(p, k-1)$. In general, we can use suitable functions $\psi(l_{r+1}, \ldots, l_s)$ of $l_{r+1}, \ldots, l_s$, to test for the rank of Ω. For example, $\psi(l_{r+1}, \ldots, l_s)$ may be l_{r+1}. But the exact distributions of these statistics involve $\lambda_1, \ldots, \lambda_r$ as nuisance parameters where $\lambda_1 \geq \cdots \geq \lambda_p$ are the eigenvalues of $\Omega\Sigma^{-1}/n$.

We now discuss the asymptotic joint distribution of the eigenvalues of $S_bS_w^{-1}$ without the assumption of normality, which was derived in Bai, Krishnaiah and Liang (1986), since it is useful in implementation of some test procedures for determination of the rank of Ω under general moment conditions. For each i, let $\mathbf{x}_{i1}, \ldots, \mathbf{x}_{in_i}$ be independently, identically and elliptically symmetrically distributed (iiesd.) and have a common density of the form given in (1) with a mean vector $\boldsymbol{\mu}_i$ and a common covariance matrix Σ.

Let $l_1 \geq \cdots \geq l_p$ denote the eigenvalues of $S_bS_w^{-1}$. Also, denote by $\theta_1 \geq \cdots \geq \theta_p$ the eigenvalues of $\Omega\Sigma^{-1}/n$, whose multiplicities are given by

$$\begin{aligned}
\theta_1 = \cdots = \theta_{p_1^*} &= \delta_1 > \\
\theta_{p_1^*+1} = \cdots = \theta_{p_2^*} &= \delta_2 > \\
&\vdots \\
\theta_{p_{t-1}^*+1} = \cdots = \theta_{p_t^*} &= \delta_t > \\
\theta_{p_t^*+1} = \cdots = \theta_p &= 0
\end{aligned} \tag{9}$$

where $p_j^* = p_1 + \cdots + p_j$ $(j = 1, 2, \ldots, t+1)$, $r = p_t^*$, $p = p_1 + \cdots + p_{t+1}$, and $p_0^* = 0$.

Define

$$\begin{aligned}
u_{i_h} &= \sqrt{n}\left(2\delta_h^2 + 4\delta_h\right)^{-1/2}\left(l_{i_h} - \delta_h\right) \\
u_{r+j} &= nl_{r+j}
\end{aligned} \tag{10}$$

where $h = 1, 2, \ldots, t$, $i_h = p_{h-1}^* + 1, \ldots, p_h^*$, $j = 1, 2, \ldots, s-r$, and r is the number of nonzero eigenvalues of $\Omega\Sigma^{-1}/n$.

Now, let $n_i/n \to q_i$ $(q_i > 0)$, for $i = 1, 2, \ldots, k$. Then, Bai, Krishnaiah, and Liang (1986) proved that the random vectors $\mathbf{u}_j = (u_{p_{j-1}^*+1}, \ldots, u_{p_j^*})$, $j = 1, \ldots, t+1$, are asymptotically independent and that the limiting distribution of $\mathbf{u}_j$ as $n \to \infty$ is the same as the joint distribution of eigenvalues of the random matrix A_j, where for $j = 1, 2, \ldots, t$, the elements above or on the diagonal of A_j are independently and normally distributed (ind.) with mean zero, variance 1 for diagonal elements and 1/2 for off-diagonal elements. In other words, the random matrices $A_1, \ldots, A_t$ are distributed as standard Gaussian matrices. Also, A_{t+1}: $(p-r)\times(p-r)$ is distributed as a central Wishart matrix with $(k-1-r)$ degrees of freedom. That is, the joint limit distribution of $u_1, \ldots, u_s$ can be expressed as

$$f(u_1 \cdots u_s) = \prod_{j=1}^{t+1}\eta_j\left(u_{p_{j-1^*}+1}, \ldots, u_{p_j^*}\right). \tag{11}$$

Here $\eta_j(\cdot)$ $(j = 1, 2, \ldots, t+1)$ denotes the joint density of eigenvalues of A_j. Computational aspects of the percentage points of the individual eigenvalues of the standard Gaussian matrix and Wishart matrix are discussed

by Krishnaiah (1980b). When the underlying distribution is multivariate normal, the expression (11) was derived by Hsu (1941a), in which W. Q. Liang (personal communication) found an error in the proof. However, Bai (1985) confirmed that the final result of Hsu is still correct. Bai, Krishnaiah, and Liang (1986) extended the preceding result to the case where for each i, the observations are iid. with finite 4th moment. From the result of Bai, Krishnaiah and Liang (1986), it is obvious that when r is the rank of Ω, $n(l_{r+1}+\cdots+l_p)$ is asymptotically distributed as χ^2 with $(p-r)(k-1-r)$ degrees of freedom, provided the kurtosis of the underlying distribution is zero.

Krishnaiah (1982a) proposed the following sequential test procedure for the rank of Ω when $n_1,\ldots,n_k$ tend to infinity in such a way that $(n_i/n),\ldots,(n_k/n)$ tend to (say) $q_1,\ldots,q_k$, respectively. The hypothesis $\Omega=0$ is accepted or rejected according to

$$l_1 \underset{>}{\overset{<}{}} c_{\alpha 1} \tag{12}$$

where

$$P[l_1 \le c_{\alpha 1}|\Omega=0]=(1-\alpha_1). \tag{13}$$

If $\Omega=0$ is accepted, we do not proceed further. Otherwise, we accept or reject H_1 according to

$$l_2 \underset{>}{\overset{<}{}} c_{\alpha 2} \tag{14}$$

where

$$P[l_2 \le c_{\alpha 2}|H_1\colon l_1 > c_{\alpha 1}] = (1-\alpha_2) \tag{15}$$

and H_t denotes the hypothesis that the rank of Ω is equal to t. When H_1 is true, the asymptotic distribution of l_2 is independent of l_1. If H_1 is accepted, we do not proceed further. Otherwise, we accept or reject H_2 according as

$$l_3 \underset{>}{\overset{<}{}} c_{\alpha 3} \tag{16}$$

where

$$P[l_3 \le c_{\alpha 3}|H_2\colon l_2 > c_{\alpha 2}] = (1-\alpha_3) \tag{17}$$

We continue this method until a decision about the rank of Ω is reached.

We now discuss the problem of testing for the rank of the regression matrix. Consider the model

$$Y = XB+E \tag{18}$$

where the rows of $E\colon n\times p$ are distributed as a multivariate normal with mean vector 0 and covariance matrix Σ. Also, let $X\colon n\times q$ denote the design matrix and $B\colon q\times p$, the regression matrix. We assume that $q \ge p$. Tintner (1945) derived the likelihood ratio test (LRT) statistic for the rank of B when Σ is known. Anderson (1951) derived the following expression for the LRT statistic to test the hypothesis H_r, which states that if the rank of B is r, then the LRT is given by

$$L_r = \prod_{j=r+1}^{p}(1+l_j)^{n/2} \tag{19}$$

where $l_1 \ge \cdots \ge l_p$ denote the eigenvalues of S_1S^{-1} and

$$S_1 = Y'X(X'X)^{-1}X'Y \tag{20}$$

$$S = Y'[I-X(X'X)^{-1}X']Y \tag{21}$$

Fujikoshi (1977) derived expressions for the asymptotic distributions of the test statistics m_1T_1, m_2T_2, and m_3T_3 where

$$\begin{aligned} T_1 &= \textstyle\sum_{j=r+1}^{p}\log(1+l_j)\\ T_2 &= \textstyle\sum_{j=r+1}^{p} l_j\\ T_3 &= \textstyle\sum_{j=r+1}^{p}\left\{\frac{l_j}{1+l_j}\right\} \end{aligned} \tag{22}$$

Here m_1, m_2, and m_3 are certain correction factors. In discussion of limiting properties of these tests, we may choose m_i as n. In addition, we usually assume that $\lim(\Omega/n)=0(1)$ where $\Omega=B'(X'X)B\Sigma^{-1}$. The asymptotic distributions of nT_1, nT_2, and nT_3 under H_0 are χ^2-distribution with $(p-r)(q-r)$ degrees of freedom. Fujikoshi also derived the nonnull distributions of the above test statistics in terms of normal density and its derivatives when the eigenvalues of Ω have multiplicities.

Krishnaiah, Lin, and Wang (1985a) derived the LRT statistics for testing the hypothesis on the rank of B when the underlying distribution is elliptically symmetric. They also investigated the asymptotic distributions of the above statistics, a review of which is given below.

Let E be distributed as an elliptically symmetric distribution with density

$$f(E) = \frac{1}{|\Sigma|^{n/2}}h(tr\ \Sigma^{-1}E'E) \tag{23}$$

where $h(x)$ is a strictly decreasing and differentiable function in x. Also, let

$$\Delta = CB \tag{24}$$

where $C\colon u\times k$ is known and of rank u. Let H_{1r} denote the hypothesis that the rank of Δ is r, whereas H_{2r} denotes the hypothesis that the rows of Δ lie in an r-dimensional plane in p-dimensional space.

Now, let

$$\begin{aligned} \Pi_r(\mathbf{a}) = \{&(GF'+\mathbf{a}\mathbf{b}')D_{p\times p};\quad GG'=FF'\\ &= I_r,\ D_{p\times p}\text{ positive definite and }\mathbf{b}_{p\times 1}\}. \end{aligned}$$

Then H_{1r} is equivalent to the hypothesis that $\Delta\in\Pi_r(0)$, and H_{2r} is equivalent to $\Delta\in\Pi_r(\mathbf{1})$ where $\mathbf{1}'=(1,\ldots,1)$. Now, let

$$M = C(X'X)^{-1}C'$$
$$\widehat{B} = (X'X)^{-1}X'Y$$
$$S_h(\widehat{B}) = (C\widehat{B})'M^{-1}(C\widehat{B})$$
$$S_f(\widehat{B}) = (C\widehat{B})'\{M^{-1} - M^{-1}\mathbf{1}(\mathbf{1}'M^{-1}\mathbf{1})^{-1}\}C\widehat{B}$$
$$S = Y'(I - X(X'X)^{-1}X')Y.$$

Then, the LRT statistics for testing the hypothesis H_{1r} against $H_{1r'}$ for some $r' > r$, when Σ is known and unknown, are given respectively by

$$T_4 = \frac{h(\phi_{r+1} + \cdots + \phi_s + tr\Sigma^{-1}S)}{h(tr\Sigma^{-1}S)} \tag{25}$$

$$T_5 = \prod_{j=r+1}^{s} (1 + d_j)^{-n/2} \tag{26}$$

where $s = \min(u, p)$, $\phi_1 \geq \cdots \geq \phi_s$ are the first s largest nonzero eigenvalues of $S_h(\widehat{B})\Sigma^{-1}$, and $d_1 \geq \cdots \geq d_s$ the first s largest eigenvalues of $nS_h(\widehat{B})S^{-1}$.

Next, the LRT statistics for testing the hypothesis H_{2r} against $H_{2r'}$ for some $r' > r$ when Σ is known and unknown are given respectively by

$$T_6 = \frac{h(\psi_{r+1} + \cdots + \psi_{\bar{s}} + tr\Sigma^{-1}S)}{h(tr\Sigma^{-1}S)} \tag{27}$$

$$T_7 = \prod_{j=r+1}^{\bar{s}} (1 + l_j)^{-n/2} \tag{28}$$

where $\bar{s} = \min(u - 1, p)$, $\psi_1 \geq \cdots \geq \psi_{\bar{s}}$ are the first $\bar{s}$ largest eigenvalues of $S_f(\widehat{B})\Sigma^{-1}$, and $l_1 \geq \cdots \geq l_{\bar{s}}$ the first $\bar{s}$ largest eigenvalues of $nS_f(\widehat{B})S^{-1}$.

Krishnaiah, Lin, and Wang (1985a) also derived the LRT statistics analogous to T_4, T_5, T_6, and T_7 when the underlying distribution is complex elliptically symmetric. These authors also derived asymptotic joint distributions of $(d_1, \ldots, d_s)$ and $(l_1, \ldots, l_{\bar{s}})$. On the basis of the preceding results, they pointed out that $-2\log T_5$ and $-2\log T_7$ are distributed asymptotically as χ^2. When the underlying distribution is multivariate normal, the asymptotics for T_6 was derived in Rao (1973).

In a number of situations, it may be more realistic to assume that the rows of E are iiesd than to assume the joint distribution of the observations Y is elliptically symmetric. The two situations just described become identical when the underlying distribution is multivariate normal. Krishnaiah, Lin, and Wang (1985a) have derived asymptotic joint distributions of $(d_1, \ldots, d_s)$ and $(l_1, \ldots, l_{\bar{s}})$ when the rows of E are independently and elliptically symmetrically distributed (iesd.) with mean vector 0 and the same dispersion matrix.

IV. RANK OF REGRESSION MATRIX BY MODEL SELECTION METHODS

In the model of Eq. (18), we assume that the rows of E are iid. with mean vector 0 and covariance matrix Σ. Also, let $\Delta = CB$ be as defined in the preceding section, where we discussed the problem of testing the hypothesis that the rank of Δ is r when r is specified. But situations often arise in which the experimenter does not know which of the hypotheses $H_{10}, H_{11}, \ldots, H_{1u}$ to test. In these situations, it is of interest to select one of the models $M_0, M_1, \ldots, M_u$ where M_j denotes the model that the rank of Δ is j. We now give a review of Bai *et al.* (1989) for the determination of the rank of Δ using model selection methods.

Let

$$L(r) = \sum_{j=r+1}^{s} \phi_j + rC_n \tag{29}$$

where $-\frac{1}{2}(\phi_{r+1} + \cdots + \phi_s)$ is the logarithm of the LRT statistic for testing the hypothesis that the rank of Δ is r when Σ is known and the underlying distribution is multivariate normal. The statistics are as defined in the preceding section. Also, C_n satisfies the following conditions:

$$\text{(a)} \quad \lim_{n\to\infty}\left\{\frac{C_n}{\log n}\right\} = \infty, \quad \text{(b)} \quad \lim_{n\to\infty}\left\{\frac{C_n}{\lambda_*}\right\} = 0,$$
$$\text{(c)} \quad \lim_{n\to\infty}\left\{\frac{\lambda_*}{\log n}\right\} = \infty \tag{30}$$

where λ_* denotes the smallest eigenvalue of $X'X$. Then, according to the procedure of Bai *et al.* (1989), the rank of Δ when Σ is known is estimated with $\hat{q}$, where

$$L(\hat{q}) = \min\{L(0), L(l), \ldots, L(s)\}. \tag{31}$$

It is also proved in the work that $\hat{q}$ is a consistent estimate of the rank of Δ.

When Σ is unknown, let

$$L^*(r) = n\sum_{j=r+1}^{s} \log(1 + d_j) + rC_n, \tag{32}$$

where $d_1 \geq \cdots \geq d_s$ are the first s largest eigenvalues of $S_h(\hat{B})S^{-1}$ in the preceding section, and C_n satisfies the following conditions:

$$\lim_{n\to\infty}\left\{\frac{C_n}{\log n}\right\} = \infty \tag{33a}$$

$$\limsup_{n\to\infty}(C_n/n) < \frac{1}{3}\log 2 \tag{33b}$$

$$\lim_{n\to\infty}\left\{\frac{C_n}{\lambda_*}\right\} = 0 \tag{33c}$$

We also make the following assumptions on λ^* (the largest eigenvalue of $X'X$) and λ_*:

$$\lim_{n\to\infty}\left\{\frac{\lambda_*}{\log n}\right\}=\infty \tag{34}$$

$$\lambda^*=O\left(\frac{n\log n}{\log\log n}\right) \tag{35}$$

Then, Bai *et al*. (1989) proposed using $\hat{q}$ as an estimate of the rank of Δ where

$$L^*(\hat{q})=\min\{L^*(0),L^*(l),\ldots,L^*(s)\}$$

They also proved that $\hat{q}$ is a consistent estimate of the rank of Δ.

We may consider alternative model selection criteria similar to those considered by Akaike (1972), Rissanen (1973), and Schwartz (1978) in some other problems.

Next, consider the case when X is also stochastic and the rows of (Y, X) are imnd. with mean vector 0 and unknown covariance matrix. When B is not of full rank, Izenman (1975) considered the problem of estimation of B and the asymptotic distribution of the estimate of B. We can propose model selection procedures, similar to those discussed in present section, to determine the rank of B.

V. REDUCTION OF DIMENSIONALITY UNDER THE FANOVA MODEL

Consider the following two-way classification model with one observation per cell:

$$x_{ij}=\mu+\alpha_i+\beta_j+\eta_{ij}+\varepsilon_{ij} \tag{36}$$

for $i=1,2,\ldots,r$ and $j=1,2,\cdots,s$ where

$$\sum_{i=1}^{r}\alpha_i=\sum_{j=1}^{s}\beta_j=\sum_{i=1}^{r}\eta_{ij}=\sum_{j=1}^{s}\eta_{ij}=0 \tag{37}$$

Here μ,α_i,β_j and η_{ij}, respectively, denote the general mean, the effect due to the ith row, the effect due to the jth column, and interaction in the ith row and jth column. Without loss of generality, we assume that $r\le s$. The problem of finding the rank of the interaction matrix $\boldsymbol{\eta}=(\eta_{ij})$ is of interest and has received attention in the literature. The usual F test statistics to test the hypotheses of no row effect and no column effect were proposed in the literature under the assumption of no interactions. If there is interaction, then the F statistics are distributed as doubly noncentral F distributions instead of central F distributions (see Fang and Krishnaiah, 1984), even when the null hypotheses are true; so the usual tests are no longer valid. Thus, it is of interest to test the hypothesis that the rank of $\boldsymbol{\eta}$ is zero; this problem is known in the literature as testing for additivity. Fisher and MacKenzie (1923), Tukey (1949), and Williams (1952) are the early workers on the problem of testing for additivity when $\boldsymbol{\eta}$ has special structures. When $\boldsymbol{\eta}\neq 0$, knowledge of the rank of $\boldsymbol{\eta}$ helps to estimate the parameters more efficiently. So it is of interest to test for the rank of $\boldsymbol{\eta}$. We now discuss this problem.

Suppose $\boldsymbol{\eta}$ is of rank c. Then it is known, by singular value decomposition of the matrix, that

$$\boldsymbol{\eta}=\theta_1\boldsymbol{\mu}_1\boldsymbol{\nu}_1'+\cdots+\theta_c\boldsymbol{\mu}_c\boldsymbol{\nu}_c' \tag{38}$$

where $\theta_1^2\ge\cdots\ge\theta_c^2$ are the eigenvalues of $\boldsymbol{\eta}\boldsymbol{\eta}'$ and $\boldsymbol{\mu}_j$ and $\boldsymbol{\nu}_j$ the eigenvectors of $\boldsymbol{\eta}\boldsymbol{\eta}'$ and $\boldsymbol{\eta}'\boldsymbol{\eta}$ corresponding to θ_j^2. Now, let $l_1\ge\cdots\ge l_{r-1}$ denote the nonzero eigenvalues of DD' where $D=(d_{ij})$ and $d_{ij}=x_{ij}-\bar{x}_{i.}-\bar{x}_{.j}+\bar{x}_{..}$. Gollob (1968) considered the problem of testing the hypotheses $\theta_j=0$, and his tests are based on the assumption that all l_j are distributed independently as χ^2 variables. But the above assumption is not correct. Mandel (1969) proposed heuristically to examine the magnitude of $l_j/\gamma_j\hat{\sigma}^2$ to test for $\theta_j=0$ where $\gamma_j=E(l_j)$ and $\hat{\sigma}^2=(l_{c+1}+\cdots+l_{r-1})/(\gamma_{c+1}+\cdots+\gamma_{r-1})$. But the distributions of the above test statistics not only are complicated but also involve nuisance parameters. Corsten and van Eijnsbergen (1972) derived the following likelihood ratio test. Accept or reject H_0: $\theta_1=\cdots=\theta_c=0$ according to

$$L_1\overset{<}{>}c_{1\alpha} \tag{39}$$

where

$$P[L_1\le c_{1\alpha}|H_0]=(1-\alpha) \tag{40}$$

and $L_1=(l_1+\cdots+l_c)/(l_1+\cdots+l_{r-1})$. For $c=1$, the LRT was derived independently by Johnson and Graybill (1972). Yochmowitz and Cornell (1978) discussed the LRT for testing the hypothesis H_j: $\theta_j=\cdots=\theta_c=0$ against the alternative H_{j+1}: $\theta_j\neq 0$ and $\theta_{j+1}=\cdots=\theta_c=0$. When H_0 is true, it is known (e.g., see Johnson and Graybill, 1972) that $l_1,\ldots,l_{r-1}$ are jointly distributed as the joint distribution of the eigenvalues of the central $(r-1)\times(r-1)$ Wishart matrix W with $(s-1)$ degrees of freedom and $E(W)=(s-l)I_{r-1}$. Schuurmann, Krishnaiah, and Chattopadhyay (1973) derived the exact distribution of $l_1/(l_1+\cdots+l_{r-1})$ and $l_{r-1}/(l_1+\cdots+l_{r-1})$ when H_0 is true and computed some of the percentage points of the above statistic. Krishnaiah and Schuurmann (1974) derived the exact distributions of $l_j/(l_1+\cdots+l_{c-1})$ for $j=2,3,\ldots,c-1$ when H_0 is true. The problem of testing for the rank of $\boldsymbol{\eta}$ can be tackled by using the techniques of principal component analysis. Schuurmann, Krishnaiah, and Chattopadhyay (1973) proposed the following simultaneous test procedure in the spirit of the simultaneous test procedures

of Krishnaiah and Waikar (1971, 1972) in the area of principal component analysis. Accept or reject $\theta_i = 0$ according

$$\frac{l_i}{l_i + \cdots + l_{r-1}} \underset{>}{\overset{<}{}} c_{2\alpha} \tag{41}$$

where

$$P\left\{\frac{l_i}{l_i + \cdots + l_{r-1}} \le c_{2\alpha} | H_i\right\} = (1-\alpha) \tag{42}$$

For details of other simultaneous test procedures, the reader is referred to Krishnaiah and Yochmowitz (1980).

We now review a work of Rao (1985) on a more general problem of reduction of dimensionality.

Let Y: $n \times p$ be a random matrix that is distributed as multivariate normal with $E(Y) = M$ and the covariance matrix of $\mathbf{y}$ is $C \otimes \Sigma$, where $\mathbf{y}$ is the vector obtained by writing the rows of Y vertically one below the other, starting from the first, and C is a known positive definite matrix. Also, let S: $p \times p$ be distributed independent of Y as a central Wishart matrix with s degrees of freedom and $E(S) = s\Sigma$. Under the above model, Rao (1985) derived the LRT for testing the hypothesis H_0 that

$$H\colon M = X\psi + \Phi W' + \Gamma \tag{43}$$

where Σ has general structure of the form

$$\Sigma = \sigma_1^2 V_1 V_1' + \cdots + \sigma_f^2 V_f V_f' \tag{44}$$

where $\sigma_1^2, \ldots, \sigma_f^2$ are unknown and V_i: $p \times g_i$ $(i = 1, 2, \ldots, f)$ is a known matrix of rank g_i such that $p = g_1 + \cdots + g_f$.

In Eq. (43), $Xn \times b$ is a known matrix of rank b, W: $p \times c$ a given matrix of rank c, Ψ and Φ are matrices of unknown parameters and Γ is a matrix of specified rank $r \le \min(p-b, p-c)$. If X is an $n \times 1$ vector of unities and W is the null matrix, the above problem reduces to the problem of specifying the dimensionality of row mean vectors in M considered by Fisher (1939), Fujikoshi (1974), Krishnaiah, Lin, and Wang (1985a), and others. If X is an $n \times 1$ vector of unities and W a $p \times 1$ vector of unities, then H is the hypothesis specifying the rank of interaction in a two-way classification with one observation per cell; this problem was considered when $\Sigma = \sigma^2 I$ and $C = I$.

VI. RANK OF THE COVARIANCE MATRIX OF RANDOM EFFECTS

Consider the one-way components of the covariance model,

$$\mathbf{x}_{ij} = \boldsymbol{\mu} + \boldsymbol{\alpha}_i + \varepsilon_{ij} \tag{45}$$

for $i = 1, 2, \ldots, k$ and $j = 1, 2, \ldots, m_i$ where $\boldsymbol{\mu}$ is the general mean vector, $\boldsymbol{\alpha}_i$: $p \times 1$ the vector of random effects, ε_{ij} the vector of errors and $\mathbf{x}_{ij}$ denotes the jth observation in the ith group. Also, $\boldsymbol{\alpha}_i$ and ε_{ij} are distributed independently of each other as multivariate normal with $E(\boldsymbol{\alpha}_i) = E(\varepsilon_{ij}) = 0$, and covariance matrices are given by $\Psi = E(\boldsymbol{\alpha}_i \boldsymbol{\alpha}_i')$ and $\Sigma_1 = E(\varepsilon_{ij}\varepsilon_{ij}')$. We also assume that $E(\boldsymbol{\alpha}_i \boldsymbol{\alpha}_j') = 0$ for $i \ne j$, and $E(\varepsilon_{ij}\varepsilon_{i',j'}) = 0$ for $i \ne i'$ and/or $j \ne j'$. The covariance matrix of $\mathbf{x}_{ij}$ is given by Σ_2 where

$$\Sigma_2 = \Psi + \Sigma_1. \tag{46}$$

We assume that Ψ is not of full rank, and we are interested in finding its rank. If the rank of Ψ is r, then there exists a full rank matrix B: $(p-r) \times p$ such that $B\Phi = 0$. If the rank of Φ is zero, then we conclude that there is no difference between the effects of the groups. Knowledge about the rank of Ψ helps us estimate Ψ more efficiently.

When $m_1 = m_2 = \cdots = m_k = m$, the between-group SP matrix and within-group SP matrix are given by S_b and S_w, respectively, where

$$\begin{aligned} S_b &= m \sum_{i=1}^{k} (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot\cdot})(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot\cdot})' \\ S_w &= \sum_{i=1}^{k} \sum_{j=1}^{m} (\mathbf{x}_{ij} - \bar{\mathbf{x}}_{i\cdot})(\mathbf{x}_{ij} - \bar{\mathbf{x}}_{i\cdot})' \\ m\bar{\mathbf{x}}_{i\cdot} &= \sum_{j=1}^{m} \mathbf{x}_{ij}, \quad mk\bar{\mathbf{x}}\colon = \sum_{i=1}^{k} \sum_{j=1}^{m} \mathbf{x}_{ij} \end{aligned} \tag{47}$$

Then, S_b and S_w are distributed independently as central Wishart matrices with $(k-1)$ and $k(m-1)$ degrees of freedom, respectively, $E[S_b/(k-1)] = \Sigma_2$, $E[S_w/k(m-1)] = \Sigma_1$, and $\Sigma_2 = \Sigma_1 + m\Psi$. When the sample sizes are unequal, S_b is not distributed as a Wishart matrix. When all m_i are equal, Anderson (1984b, 1985) has derived the likelihood ratio test statistic for testing the hypothesis that the rank of Ψ is not greater than r. Schott and Saw (1984) derived the likelihood ratio test for $\text{rank}(\Psi) \le r$ against the alternative $\text{rank}(\Psi) = r + 1$.

We now discuss a more general problem considered by Rao (1983) and Zhao, Krishnaiah, and Bai (1986b). Let S_1 and S_2 be distributed independently as central Wishart matrices with n_1 and n_2 degrees of freedom, respectively, and let $E(S_i/n_i) = \Sigma_i$, for $i = 1, 2$. Also, let $\Sigma_2 = \Gamma + \Sigma_1$ where Γ is a nonnegative definite matrix. Then, we are interested in finding the rank of Γ. Rao (1983) proposed a modified LRT statistic for testing the hypothesis that the rank of Γ is a specified value. We now discuss the model selection method proposed by Zhao, Krishnaiah, and Bai

(1986b) for estimating the rank of Γ. Let $\delta_1 \geq \cdots \geq \delta_p$ denote the eigenvalues of $S_1 S_2^{-1} n_2/n_1$. Also, let

$$L_q = \prod_{i=1+\min(q,\tau)}^{p} \{(\alpha_n + \beta_n \delta_i)^{-n/2} \delta_i^{n\beta_n/2}\} \tag{48}$$

where τ denotes the number of δ_i that are greater than 1, $\alpha_n = n_1/n$, $\beta_n = n_2/n$, and $n = n_1 + n_2$. In addition, let

$$L_{qt} = \prod_{i=1+\min(q,\tau)}^{1+\min(t,\tau)} \{(\alpha_n + \beta_n \delta_i)^{-n/2} \delta_i^{n\beta_n/2}\} \tag{49}$$

Zhao, Krishnaiah, and Bai (1986b) showed that L_q is the likelihood ratio test statistic for testing H_q against the alternative that Γ is arbitrary, and L_{qt} the likelihood ratio test statistic for testing H_q against H_t $(q < t)$ where H_j denotes the hypothesis that the rank of Γ is equal to j. Now let

$$EDC(a, C_n) = -\log L_a + v(a, p) C_n \tag{50}$$

where $v(a, p) = \frac{1}{2} a(2p - a + 1)$ and C_n satisfies the following conditions:

$$\lim_{n\to\infty} \left(\frac{C_n}{n}\right) = 0 \tag{51a}$$

$$\lim_{n\to\infty} \left(\frac{C_n}{\log\log n}\right) = \infty \tag{51b}$$

Zhao, Krishnaiah, and Bai (1986b) estimated the unknown rank of Γ with $\hat{q}$ where

$$EDC(\hat{q}, C_n) = \min\{EDC(0, C_n), \ldots, EDC(p-1, C_n)\} \tag{52}$$

They have also proved that $\hat{q}$ is strongly consistent. The foregoing procedure can be used to draw inference on the rank of the covariance matrix of the vector of random effects in one-way components of the covariance model. When $\Sigma_1 = \sigma^2 I_p$, we can use the techniques of Zhao, Krishnaiah, and Bai (1986a) to find the rank of Γ.

VII. VARIABLE SELECTION IN MULTIVARIATE REGRESSION

In the area of univariate regression analysis, it is of interest to select variables that are important for prediction. Reviews of the literature on some methods of selection of variables are given in Krishnaiah (1982a) and Thompson (1978a, 1978b). In this section, we review procedures for selection of independent variables that are important for the prediction of a set of dependent variables under the classical multivariate regression model.

Consider the multivariate regression model of Eq. (18) where $X = [\mathbf{x}_1, \ldots, \mathbf{x}_q]$ and $\mathbf{x}_i$: $n \times 1$ is a vector of n independent observations on the ith independent variable $\mathbf{x}_i'$. Also, let $Y = [\mathbf{y}_1, \ldots, \mathbf{y}_p]$ where $\mathbf{y}_i$: $n \times 1$ denotes the vector of n independent observations on the ith dependent variable. Then, it is of interest to find which of the variables $\mathbf{x}_1, \ldots, \mathbf{x}_q$ are important. We can use Roy's largest root test, the $T^2_{\max}$ test, or Krishnaiah's finite intersection test for the selection of important variables. Now, let $B' = (\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_q)$ where $\boldsymbol{\beta}_i$ is of order $p \times 1$. Also, let H_i: $\boldsymbol{\beta}_i = 0$ and

$$T_i^2 = \frac{(n-q)\hat{\boldsymbol{\beta}}_i' S^{-1} \hat{\boldsymbol{\beta}}_i}{e_{ii}} \tag{53}$$

where $\hat{B} = (\hat{\boldsymbol{\beta}}_1, \ldots, \hat{\boldsymbol{\beta}}_q)' = (X'X)^{-1}(X'Y)$, $S = (S_{ij}) = Y'(I - X(X'X)^{-1}X')Y$, and $e_{ii}\Sigma$ is the covariance matrix of $\hat{\boldsymbol{\beta}}_i$. According to Roy's largest root test, we accept or reject H_i according to

$$T_i^2 \overset{<}{>} c_\alpha \tag{54}$$

where c_α is chosen such that

$$P\left[(n-q) C_L\left(S_1 S^{-1}\right) \leq q c_\alpha | H\right] = (1 - \alpha) \tag{55}$$

and $H = \cap_{i=1}^{q} H_i$, $C_L(A)$ denotes the largest eigenvalue of A, and $S_1 = Y'X(X'X)^{-1}X'Y = \hat{B}'(X'X)\hat{B}$. Percentage points of c_α are given in Krishnaiah (1980b). If we use $T^2_{\max}$ test (e.g., see Krishnaiah, 1969; and Siotani, 1959), we accept or reject H_0: rank$(B) = 0$ according as

$$T^2_{\max} \overset{<}{>} c_{\alpha 1} \tag{56}$$

where

$$P[T_i^2 \leq c_{\alpha 1}; \quad i = 1, 2, \ldots, q | H] = (1 - \alpha) \tag{57}$$

Approximate values of $c_{\alpha 1}$ can be obtained from the results of Siotani (1959, 1960, 1961) for some cases. We conclude that the independent variable x_i is important or unimportant for the prediction of $(y_1, \ldots, y_p)$ according to whether H_i is rejected or accepted. We now discuss Krishnaiah's finite intersection tests (Krishnaiah, 1965) for the selection of variables. For an illustration of the application of the finite intersection test, the reader is referred to Schmidhammer (1982).

Let Σ_k denote the top-left $k \times k$ corner of $\Sigma = (\sigma_{ij})$ and $\sigma_{k+1}^2 = |\Sigma_{k+1}|/|\Sigma_k|$ for $k = 0, 1, \ldots, p-1$ with $|\Sigma_0| = 1$. Also, let $Y_j = [\mathbf{y}_1, \ldots, \mathbf{y}_j]$, $X_j = [\mathbf{x}_1, \ldots, \mathbf{x}_j]$ and $B_j = [\boldsymbol{\beta}_1^*, \ldots, \boldsymbol{\beta}_j^*]$ for $j = 1, 2, \ldots, p$, where $\boldsymbol{\beta}_j^*$ is the jth column of B. In addition, let

$$\boldsymbol{\zeta}_j = \Sigma_j^{-1} \begin{pmatrix} \sigma_{1,j+1} \\ \vdots \\ \sigma_{j,j+1} \end{pmatrix} \tag{58}$$

for $j = 1, 2, \ldots, p-1$ and $\boldsymbol{\zeta}_0 = 0$. We know the conditional distribution of $\mathbf{y}_{j+1}$, given that Y_j is multivariate

normal with covariance matrix $\sigma_{j+1}^2 I_n$ and the mean vector

$$E_c(\mathbf{y}_{j+1}) = X\boldsymbol{\eta}_{j+1} + Y_j\boldsymbol{\zeta}_j = [X, Y_j]\begin{pmatrix}\boldsymbol{\eta}_{j+1}\\ \boldsymbol{\zeta}_j\end{pmatrix} \quad (59)$$

where $\boldsymbol{\eta}_{j+1} = \boldsymbol{\beta}_{j+1}^* - B_j\boldsymbol{\zeta}_j$ with the understanding that $\boldsymbol{\eta}_1 = \boldsymbol{\beta}_1$. Now, let H_{ij}: $\mathbf{c}_i'\boldsymbol{\eta}_j = 0$, where $\mathbf{c}_i' = (c_{i1}, \ldots, c_{iq})$ for $i = 1, 2, \ldots, q$ with

$$c_{ih} = \begin{cases} 0, & h \neq i \\ 1, & h = i \end{cases}$$

Then, the hypothesis H_i can be expressed as $H_i = \cap_{j=1}^{p} H_{ij}$. So the problem of testing the hypotheses $H_1, \ldots, H_q$ simultaneously is equivalent to testing the hypotheses H_{ij} simultaneously. Now let

$$F_{ij} = \frac{(\mathbf{c}_i'\hat{\boldsymbol{\eta}}_j)^2(n-j-q+1)}{d_{ij}s_j^2} \quad (60)$$

where $d_{ij}\sigma_j^2$ is the variance of $\mathbf{c}_i'\hat{\boldsymbol{\eta}}_j$, $\hat{\boldsymbol{\eta}}_j$ is the least squares estimate of $\boldsymbol{\eta}_j$ under the model of Eq. (59), and $s_{j+1}^2 = |S_{j+1}|/|S_j|$, where S_j is the top $j \times j$ left-hand corner of S. Then we accept or reject H_{ij} according as

$$F_{ij} \underset{>}{\overset{<}{}} F_\alpha \quad (61)$$

where

$$\begin{aligned} &P[F_{ij} \leq F_\alpha; \quad i = 1, 2, \ldots, q, \quad j = 1, 2, \ldots, p|H] \\ &= \prod_{j=1}^{p} P[F_{ij} \leq F_\alpha; \quad i = 1, 2, \ldots, q|H] \\ &= (1-\alpha) \end{aligned} \quad (62)$$

When H is true, the joint distribution of $F_{1j}, \ldots, F_{qj}$ is a multivariate F distribution with $(1, n-q-j+1)$ degrees of freedom. Evaluation of the probability integrals of the multivariate F distribution was discussed in Krishnaiah and Armitage (1970). The hypothesis H_i is accepted if $H_{i1}, \ldots, H_{ip}$ are accepted, and it is rejected otherwise. If H_i is rejected, then we conclude that the independent variable x_i is important for prediction of the set $(y_1, \ldots, y_p)$ of dependent variables. One may use the step-down procedure proposed by J. Roy (1958) also, but the lengths of the confidence intervals associated with the finite intersection tests are shorter than the lengths of the corresponding confidence intervals associated with the step-down procedure. Fujikoshi (1985) proposed a procedure, based on an information theoretic criterion, to select a subset of variables that are important for discrimination. Rao (1948) proposed a procedure to find whether the addition of some independent variables make a significant contribution in the prediction of dependent variables.

VIII. VARIABLE SELECTION IN DISCRIMINANT ANALYSIS

We now discuss the stepwise procedures for the selection of variables in the area of discriminant analysis for several groups. These procedures are used widely since computer programs for the implementation of these procedures are available in the BMDP and SPSS packages. Stepwise procedures for the selection of variables in discriminant analysis were proposed in the literature in a way similar to that for the corresponding procedures in regression analysis (Krishnaiah, 1982a).

Consider the following model:

$$E(\mathbf{y}_j) = A\boldsymbol{\theta}_j \quad (63)$$

where

$$A' = (A_1' \cdots A_k') \quad (64)$$

In the matrix A_i: $n_i \times k$, the elements in the ith column are equal to one, and other elements in the matrix are zero. Also, $\boldsymbol{\theta}_j' = (\boldsymbol{\mu}_{1j}, \ldots, \boldsymbol{\mu}_{kj})$, $\mathbf{y}_j' = (x_{1j1}, \ldots, x_{1jn_1}, \cdots, x_{kj1}, \cdots, x_{kjn_k})$, and x_{ijt} denotes observation on the jth variable, tth individual, and ith group. Let H_j: $C\boldsymbol{\theta}_j = 0$ where

$$C = \begin{pmatrix} 1 & 0 & \cdots & 0 & -1 \\ 0 & 1 & \cdots & 0 & -1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & -1 \end{pmatrix} : (k-1) \times k \quad (65)$$

Let F_j denote the usual F statistic used for testing the hypothesis H_j. Then,

$$F_j = \frac{b_{jj}(n-k)}{w_{jj}(k-1)} \quad (66)$$

where $W = (w_{ij})$ and $B = (b_{ij})$ are the within-group SP matrix and between-group SP matrix, respectively. The likelihood ratio statistic for testing H_j is given by $\Lambda(x_j)$, where

$$\Lambda(x_j) = \frac{w_{jj}}{t_{jj}} \quad (67)$$

and $t_{jj} = b_{jj} + w_{jj}$. Obviously,

$$F_j = \frac{[1-\Lambda(x_j)](n-k)}{(k-1)} \quad (68)$$

If $\max(F_1, \ldots, F_p) \leq F_{1\alpha}$, we declare that none of the variables are important for discrimination and do not proceed further. Otherwise, we select the variable corresponding to the maximum of $F_1, \ldots, F_p$ as the most important. For example, let the variable be x_1.

At the second stage we test to find out as to whether any of the remaining variables $x_2, x_3, \ldots, x_p$ give additional information for discrimination between the

populations. A measure of the degree of additional information is provided by

$$\Lambda_{j\cdot 1} = \frac{\Lambda(x_1, x_j)}{\Lambda(x_1)} \tag{69}$$

where

$$\Lambda(x_1, x_j) = \frac{\begin{vmatrix} w_{11} & w_{1j} \\ w_{j1} & w_{jj} \end{vmatrix}}{\begin{vmatrix} t_{11} & t_{1j} \\ t_{j1} & t_{jj} \end{vmatrix}} \tag{70}$$

In Eq. (69), $\Lambda(x_1, x_j)$ is the likelihood ratio test statistic for testing the hypothesis that the mean vectors of (x_1, x_j) are the same in all populations. It can be viewed as a measure of the discriminating ability of x_1 and x_j, whereas $\Lambda(x_1)$ is a measure of the degree of discrimination of the variable x_1. As the value of $\Lambda(x_1, x_j)$ decreases, the discriminating ability of x_1 and x_j increase. We can write $\Lambda_{j\cdot 1}$ as

$$\Lambda_{j\cdot 1} = \frac{w_{j\cdot 1}}{t_{j\cdot 1}} \tag{71}$$

where $w_{j\cdot 1} = w_{jj} - w_{j1}w_{11}^{-1}w_{1j}$ and $t_{j\cdot 1} = t_{jj} - t_{j1}t_{11}^{-1}t_{1j}$. Now let

$$F_{j\cdot 1} = \frac{b_{j\cdot 1}(n-k-1)}{w_{j\cdot 1}(k-1)} \tag{72}$$

where $b_{j\cdot 1} = t_{j\cdot 1} - w_{j\cdot 1}$ is the adjusted between group sum of squares. We can write Eq. (72) as

$$F_{j\cdot 1} = \frac{(n-k-1)}{(k-1)} \frac{1-\Lambda_{j\cdot 1}}{\Lambda_{j\cdot 1}} \tag{73}$$

The preceding statistic proposed by Rao (1973) is nothing but the statistic used to test the hypothesis

$$H_{j\cdot 1}\colon\ \mu_{1j} - \beta_{j\cdot 1}\mu_{11} = \cdots = \mu_{kj} - \beta_{j\cdot 1}\mu_{k1} \tag{74}$$

where $\beta_{j\cdot 1} = \alpha_{j1}\sigma_{11}^{-1}$. If $\max(F_{2\cdot 1}, \ldots, F_{p\cdot 1} \le F_{2\alpha}$, we declare that none of the variables $x_2, x_3, \ldots, x_p$ are important; here $F_{2\alpha}$ is the upper $100\alpha\%$ point of the central F distribution with $(k-1, n-k-1)$ degrees of freedom. If $\max(F_{2\cdot 1}, \ldots, F_{p\cdot 1}) > F_{2\alpha}$, the variable corresponding to the maximum of $F_{2\cdot 1}, \ldots, F_{p\cdot 1}$ is declared to be important. For simplicity of notation, let us assume that this variable is, say, x_2.

After having selected x_2, we test whether the variable (in this case x_1) selected at the first stage is also good for discrimination in the presence of the variable x_2, which is the third step. This can be tested by using the following test statistic:

$$F_{1\cdot 2} = \frac{b_{1\cdot 2}(n-k-1)}{w_{1\cdot 2}(k-1)} \tag{75}$$

where $t_{1\cdot 2} = t_{11} - t_{12}t_{11}^{-1}t_{21}$, $w_{1\cdot 2} = w_{11} - w_{12}w_{11}^{-1}w_{21}$, and $b_{1\cdot 2} = t_{1\cdot 2} - w_{1\cdot 2}$. We decide to retain or exclude x_1 from the selected subset according to

$$F_{1\cdot 2} \lessgtr F_{2\alpha}. \tag{76}$$

Here we note that

$$F_{1\cdot 2} = \frac{(n-k-1)}{(k-1)} \frac{1-\Lambda_{1\cdot 2}}{\Lambda_{1\cdot 2}} \tag{77}$$

where

$$\Lambda_{1\cdot 2} = \frac{w_{1\cdot 2}}{t_{1\cdot 2}} \tag{78}$$

$w_{1\cdot 2} = w_{11} - w_{12}w_{11}^{-1}w_{21}$ and $t_{1\cdot 2} = t_{11} - t_{12}t_{11}^{-1}t_{21}$. If $\Lambda_{1\cdot 2}^{*} = 1/\Lambda_{1\cdot 2}$, then

$$F_{1\cdot 2} = \frac{(n-k-1)}{(k-1)}(\Lambda_{1\cdot 2}^{*} - 1) \tag{79}$$

In the fourth step, we either select one of the variables $x_3, \ldots, x_p$ or decide not to select any more on the basis of the discriminating ability of these variables individually in the presence of x_1 and x_2. If we discard x_1 at the third step, then we consider the discriminating ability of the variables $x_3, \ldots, x_p$ in the presence of x_2 only. This procedure is continued until a decision is made not to select any more variables or until all the variables are selected. Suppose that after a few stages we selected $x_3, \ldots, x_j$ and that x_j is the latest addition to the selected subset. Then we test whether $x_3, \ldots, x_j$ are individually important in the presence of the remaining variables. For example, we test whether x_4 is important in the presence of the variables $x_3, x_5, x_6, \ldots, x_j$. The statistic used to test whether x_i $(i = 3, 4, \ldots, j-1)$ is important is given by

$$F_{i\cdot(3,4,\ldots,j)} = \frac{b_{i\cdot(3,4,\ldots,j)}}{w_{i\cdot(3,4,\ldots,j)}} \frac{(n-k-j+3)}{(k-1)} \tag{80}$$

with the understanding that the suffix i does not occur in the set $(3, 4, \ldots, j)$. Let

$$\Lambda_{i\cdot(3,4,\ldots,j)} = \frac{\Lambda(x_3, \ldots, x_i, x_{i+1}, \ldots, x_j)}{\Lambda(x_3, \ldots, x_{i-1}, x_{i+1}, \ldots, x_j)} \tag{81}$$

where $\Lambda(x_3, \ldots, x_i, x_{i+1}, \ldots, x_j)$ is the ratio of the determinant of the within-group SP matrix based on the variables $(x_3, \ldots, x_i, x_{i+1}, \ldots, x_j)$ and the determinant of the total SP matrix based on the same variables. Similarly, $\Lambda(x_3, \ldots, x_{i-1}, x_{i+1}, \ldots, x_j)$ can be defined. So,

$$\Lambda_{i\cdot(3,4,\ldots,j)} = \frac{w_{i\cdot(3,4,\ldots,j)}}{t_{i\cdot(3,4,\ldots,j)}} \tag{82}$$

Hence,

$$F_{i\cdot(3,4,\ldots,j)} = \frac{(n-k-f+3)}{(k-1)} \frac{(1-\Lambda_{i\cdot(3,4,\ldots,j)})}{\Lambda_{i\cdot(3,4,\ldots,j)}} \tag{83}$$

The variable x_i is retained or excluded according to whether $F_{i\cdot(3,4,\ldots,j)}$ is greater than or less than the upper $100\alpha\%$ point of the central F distribution with $(k-1, n-k-f+3)$ degrees of freedom. At any stage, we can test whether all the variables selected together will

discriminate between the groups by using many standard procedures. For example, suppose $x_1, x_2, \ldots, x_q$ are selected. Then we compute B_{11} and W_{11}, which are, respectively, the between-group SP matrix and the within-group SP matrix based on $x_1, \ldots, x_q$. They are given by

$$B_{11} = \begin{bmatrix} b_{11} & b_{12} & \cdots & b_{1q} \\ b_{21} & b_{22} & \cdots & b_{2q} \\ \cdots & \cdots & \cdots & \cdots \\ b_{q1} & b_{q2} & \cdots & b_{qq} \end{bmatrix}$$

$$W_{11} = \begin{bmatrix} w_{11} & w_{12} & \cdots & w_{1q} \\ w_{21} & w_{22} & \cdots & w_{2q} \\ \cdots & \cdots & \cdots & \cdots \\ w_{q1} & w_{q2} & \cdots & w_{qq} \end{bmatrix} \tag{84}$$

We can test whether the variables $x_1, \ldots, x_q$ together will discriminate between the populations by computing various functions of the eigenvalues of $B_{11}W_{11}^{-1}$. Some of these functions are $C_L(B_{11}W_{11}^{-1})$, $tr(B_{11}W_{11}^{-1})$, $tr(B_{11}(B_{11}+W_{11})^{-1})$, and $|B^{11}(B_{11}+W_{11})^{-1}|$. One can also use finite intersection tests.

We now have a critical look at the stepwise procedure for the selection of variables. At the first stage of the procedure, we choose the critical value $F_{1\alpha}$ such that

$$P[F_j \le F_{1\alpha} | H_j] = (1-\alpha) \tag{85}$$

Here the hypotheses $H_1, \ldots, H_q$ are tested individually. Since the decision whether or not to select any variable at the first stage is based on whether or not all the hypotheses are accepted simultaneously, it would be a natural thing to test them simultaneously and choose the critical value $F_{1\alpha}$ such that

$$P\left[F_j \le F_{1\alpha};\ j = l, 2, \ldots, p \middle| \bigcap_{j=1}^{p} H_j\right] = (1-\alpha) \tag{86}$$

The joint distribution of $F_1, \ldots, F_p$ not only is complicated but also involves nuisance parameters. But we can use Bonferroni's inequality to compute an upper bound on $F_{1\alpha}$. At the first stage, we select one variable only as the most important, and no decision is made about other variables. But this most important variable may be discarded at a later stage. So there is some inconsistency in this method that will be discussed later.

At the second stage, the critical value $F_{2\alpha}$ is chosen such that

$$P[F_{j\cdot 1} \le F_{2\alpha} | H_{j\cdot 1}] = (1-\alpha) \tag{87}$$

We go to the second stage if and only if $\max(F_1, \ldots, F_p) \ge F_{1\alpha}$. So, at the second stage, we have to compute the following conditional probabilities instead of Eq. (85) even if we are testing the hypotheses $H_{j\cdot 1}$ individually:

$$P[F_{j\cdot 1} \le F_{2\alpha} | \max(F_1, \ldots, F_p) \ge F_{1\alpha}] \tag{88}$$

It is quite complicated to compute the foregoing probabilities. Apart from it, we have to test $H_{2\cdot 1}, \ldots, H_{p\cdot 1}$ simultaneously, instead of testing them individually. At the second stage, we select the variable (say, x_2) corresponding to $\max(F_{2\cdot 1} \cdots, F_{p\cdot 1})$. The statistic $F_{j\cdot 1}$ for any given j is useful for testing whether the variable x_j gives additional information for discrimination between the groups in presence of the important variable x_1. But the variable x_1, which is declared to be the most important at the first stage, may be discarded as being unimportant at a later stage; so the procedure may not be meaningful. Apart from it, the choice of the critical values is very arbitrary, and we cannot say what the Type I error of this procedure is. In view of the points raised earlier, we do not recommend the use of the foregoing stepwise procedures. Krishnaiah (1982a) discussed the disadvantages of using forward selection and backward selection procedures for selection of variables under univariate regression models. Similar criticism applies for forward selection and backward selection procedures for selection of variables in discriminant analysis.

IX. TESTS FOR RANK OF CANONICAL CORRELATION MATRIX

It is known that the multiple correlation coefficient is the maximum correlation between a variable and linear combinations of a set of variables. Hotelling (1935, 1936) generalized this concept to two sets of variables $\mathbf{x}_1'$: $1 \times p_1$ and $\mathbf{x}_2'$: $1 \times p_2$ and introduced canonical correlation analysis. Canonical correlation analysis is useful in studying the relationship between the two sets of variables. Let the covariance matrix of $\mathbf{x}' = (\mathbf{x}_1', \mathbf{x}_2')$ be Σ, where

$$\Sigma = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix} \tag{89}$$

and Σ_{ii}: $p_i \times p_i$ is the covariance matrix of $\mathbf{x}_i$. Then $\Sigma_{11}^{-1}\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$ is known to be the canonical correlation matrix. Without loss of generality, we assume that $p_1 < p_2$ and $\rho_1^2 \ge \cdots \ge \rho_{p_1}^2$ denote the eigenvalues of $\Sigma_{11}^{-1}\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$. Here $\rho_1, \ldots, \rho_{p_1}$ are known as canonical correlations where ρ_i is the positive square root of ρ_i^2. Now let α_i and β_i denote the eigenvectors of $\Sigma_{11}^{-1}\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$ and $\Sigma_{22}^{-1}\Sigma_{21}\Sigma_{11}^{-1}\Sigma_{12}$, respectively, corresponding to ρ_i^2. Then $\alpha_i'\mathbf{x}_1, \ldots, \alpha_{p_1}'\mathbf{x}_1$ and $\beta_i'\mathbf{x}_2, \ldots, \beta_{p_1}'\mathbf{x}_2$ are known as canonical variables. One of the important problems in the area of canonical correlation analysis is to find the number of canonical correlations that are significantly different from zero. In this section, we discuss some procedures

for testing the hypothesis on the rank of the canonical correlation matrix when the underlying distribution is multivariate normal.

Let X: $n \times p$ be a random matrix such that $E(X) = 0$ and $E(X'X) = n\Sigma$. Also let

$$S = X'X = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \tag{90}$$

where S_{ij} is of order $p_i \times p_j$. In addition, let $r_1^2 \geq \cdots \geq r_{p_1}^2$ denote the eigenvalues of $S_{11}^{-1}S_{12}S_{22}^{-1}S_{21}$. Then $r_1, \ldots, r_{p_1}$ are known as the sample canonical correlations where r_i is the positive square root of r_i^2. Various functions of $r_1^2, \ldots, r_{p_1}^2$ were proposed in the literature as test statistics for determination of the rank of the canonical correlation matrix. We review these procedures in this section.

We first assume that the rows of X are imnd. In this case, Bartlett (1948) proposed a procedure for testing the hypothesis H_t, where H_t denotes $\rho_{t+1}^2 = \cdots = \rho_{p_1}^2 = 0$; he also derived the asymptotic distribution of the preceding statistic. Fujikoshi (1974) showed that the foregoing test statistic is the LRT statistic. Hsu (1941b) derived the asymptotic joint distribution of the sample canonical correlations when H_t is true. When the population canonical correlations $\rho_1, \ldots, \rho_{p_1}$ have multiplicities, and none of them is equal to zero, Fujikoshi (1978) derived the nonnull distribution of a single function of the sample canonical correlations, whereas Krishnaiah and Lee (1979) derived the asymptotic joint distribution of functions of the sample canonical correlations. The expressions derived by Krishnaiah and Lee involve multivariate normal density and multivariate Hermite polynomials. When the underlying distribution is not multivariate normal, Fang and Krishnaiah (1981, 1982) obtained results analogous to those obtained in the paper of Krishnaiah and Lee.

Now, let the joint distribution of the elements of X be elliptically symmetric, with density given by

$$f(X) = |\Sigma|^{-n/2} h(tr\,\Sigma^{-1}X'X) \tag{91}$$

Then, Krishnaiah, Lin, and Wang (1985b) showed that the LRT statistic for testing the hypothesis $\rho_{t+1} = \cdots = \rho_{p_1} = 0$ is given by

$$L(k) = \prod_{j=t+1}^{p_1} \left(1 - r_j^2\right)^{n/2}. \tag{92}$$

So the LRT statistic is the same as when the underlying distribution is multivariate normal. They also noted that the distribution of any function of $r_1^2, \ldots, r_{p_1}^2$ is independent of the form of the underlying distribution as long as the underlying distribution belongs to the family of elliptical distributions. We now review some of the work reported in the literature on canonical correlation analysis when it is assumed that the observations are iiesd. with the common density

$$f(\mathbf{x}) = |\Sigma|^{-1/2} h(\mathbf{x}'\Sigma^{-1}\mathbf{x}). \tag{93}$$

Now, let

$$c_i = \frac{\sqrt{n}\left(r_i^2 - \rho_i^2\right)}{2\rho_i^2\left(1 - \rho_i^2\right)}. \tag{94}$$

Then Muirhead and Waternaux (1980) showed that $c_1, \ldots, c_{p_1}$ are asymptotically distributed independently as normal, with mean 0 and variance $(\kappa + 1)$ when $\rho_1^2, \ldots, \rho_{p_1}^2$ are distinct. This is a special case of a result of Fang and Krishnaiah (1981, 1982). Krishnaiah, Lin, and Wang (1985b) derived the asymptotic joint distribution of the sample canonical correlations when the population canonical correlations have multiplicities and the last few population canonical correlations are zero. In particular, they showed that the joint asymptotic distribution of $(nr_{s+1}^2/\kappa + 1), \ldots, (nr_{p_1}^2/\kappa + 1)$, when H_s: $\rho_{s+1}^2 = \cdots = \rho_{p_1}^2 = 0$, is the same as the joint distribution of the eigenvalues of the central Wishart matrix W_{p_1-s} with $(p_2 - s)$ degrees of freedom and $E(W_{p_1-s}) = (p_2 - s)I_{p_1-s}$. This result is useful in the implementation of certain test procedures for H_s when the sample size is large. For example, we can use r_{s+1}^2 or $(r_{s+1}^2 + \cdots + r_{p_1}^2)$ as a test statistic for H_s.

We now discuss the problem of testing for the rank of the canonical correlation matrix under the correlated multivariate regression equations (CMRE) model considered by Kariya, Fujikoshi, and Krishnaiah (1984). Consider the CMRE model,

$$Y_i = X_i\boldsymbol{\theta}_i + E_i, \tag{95}$$

for $i = 1, 2$. In this model, the rows of (E_1, E_2) are imnd. with mean vector 0 and covariance matrix Σ, where

$$\Sigma = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix} \tag{96}$$

and Σ_{ij} is of order $p_i \times p_j$. Also, X_i: $n \times r_i$ is the design matrix and $\boldsymbol{\theta}_{ii}$: $r_i \times p_i$ is the matrix of unknown parameters for $i = 1, 2$. Without loss of generality, we assume that $p_1 \leq p_2$. Now, let

$$S = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \tag{97}$$

where $S_{ij} = Y_i'Q_iQ_jY_j$ and $Q_i = I - X_i(X_i'X_i)^{-1}X_i'$. Also, let $R = S_{11}^{-1}S_{12}S_{22}^{-1}S_{21}$. Kariya, Fujikoshi, and Krishnaiah (1984) investigated the problem of testing the hypothesis that $\rho_t^2 = \cdots = \rho_{p_1}^2 = 0$. They also derived the asymptotic distributions of three statistics in the null case and under local alternatives. We can test the hypothesis

that $\rho_t^2 = \cdots = \rho_{p_1}^2 = 0$ by considering suitable functions of $r_t^2, \ldots, r_{p_1}^2$, such as r_t^2, $r_t^2 + \cdots + r_{p_1}^2$, and so on, where $r_1^2 \geq \cdots \geq r_{p_1}^2$ are the eigenvalues of the sample canonical correlation matrix $S_{11}^{-1} S_{12} S_{22}^{-1} S_{21}$.

For an application of the canonical correlation analysis in econometrics, the reader is referred to Hannan (1967) and Chow and Ray-Chowdhuri (1967).

X. MODEL SELECTION FOR RANK OF CANONICAL CORRELATION MATRIX

Let $X' = [\mathbf{x}_1, \ldots, \mathbf{x}_n]$: $p \times n$ be a random matrix whose columns are iimnd. with common mean vector 0 and covariance matrix Σ. Let $\mathbf{x}_i$ and Σ be partitioned as $\mathbf{x}_i' = (\mathbf{x}_{i1}', \mathbf{x}_{i2}')$ and

$$\Sigma = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix} \tag{98}$$

where Σ_{ij} is of order $p_i \times p_j$ and $\mathbf{x}_{ij}$ is of order $p_j \times 1$. Let $\rho_1^2 \geq \cdots \geq \rho_s^2$ denote the first largest s eigenvalues of the population canonical correlation matrix $\Sigma_{11}^{-1}\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$, where $s = \min(p_1, p_2)$. Also, let $r_1^2 \geq \cdots \geq r_s^2$ denote the first largest s eigenvalues of $S_{11}^{-1} S_{12} S_{22}^{-1} S_{21}$, where

$$S = \sum_{j=1}^{n} \mathbf{x}_j \mathbf{x}_j' = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \tag{99}$$

and S_{ij} is of order $p_i \times p_j$. Let M_k $(k = 0, 1, \ldots, s)$ denote the model for which $\operatorname{rank}(\Sigma_{12}) = k$, that is, the number of nonzero canonical correlations is equal to k. Also, let H_k denote the hypothesis that $\operatorname{rank}(\Sigma_{12}) = k$. Let $L(k)$ denote the likelihood ratio test statistic for H_k. Then,

$$\log L(k) = \frac{n}{2} \sum_{i=k+1}^{s} \log\left(1 - r_i^2\right) \tag{100}$$

Now, let

$$G(k) = -\log L(k) + kC_n \tag{101}$$

where C_n satisfies the following conditions:

$$\lim_{n\to\infty} \left\{ \frac{C_n}{n} \right\} = 0 \tag{102a}$$

$$\liminf_{n\to\infty} \left\{ \frac{C_n}{\log\log n} \right\} = \infty \tag{102b}$$

Let q denote the true rank of Σ_{12}. Then Bai *et al.* (1989) proposed to use $\hat{q}$ as an estimate of q, where $\hat{q}$ is given by

$$G(\hat{q}) = \min\{G(0), \ldots, G(s)\} \tag{103}$$

These authors also showed that $\hat{q}$ is a strongly consistent estimate of q. Now, assume that the assumption of normality is violated, but $\mathbf{x}_1, \ldots, \mathbf{x}_n$ are iid. vectors with $E(\mathbf{x}_1) = 0$, $E(\mathbf{x}_1\mathbf{x}_1') = \Sigma$, and $E(\mathbf{x}_1'\mathbf{x}_1)^2 < \infty$. In this case, $L(k)$ need not be the LRT statistic for H_k, but we can still use it as in Eq. (101). Then Bai *et al.* (1989) showed that $\hat{q}$ in Eq. (103) is still a strongly consistent estimate of q under certain moment conditions.

XI. VARIABLE SELECTION IN CANONICAL CORRELATION ANALYSIS

Let us consider the set $(\mathbf{x}_1', \mathbf{x}_2')$ of $p_1 + p_2$ variables. We wish to select a set of r_2 important variables from the $\mathbf{x}_2$ set on the basis of the degree of dependence with the $\mathbf{x}_1$ set. There are $\binom{p_2}{r_2}$ sets. Let these sets be denoted by $\mathbf{x}_{f_i}$ and let the sample canonical correlation matrix between $\mathbf{x}_1$ set and $\mathbf{x}_{f_i}$ set be denoted by $S_{11}^{-1} S_{1f_i} S_{f_i f_i}^{-1} S_{f_i 1}$. We use the largest root of the canonical correlation matrix as a criterion to select the variables. We declare that none of these sets are important if

$$\max_i c_L\left(S_{11}^{-1} S_{1f_i} S_{f_i f_i}^{-1} S_{f_i 1}\right) \leq c_\alpha \tag{104}$$

where $c_L(A)$ denotes the largest eigenvalue of A. If

$$\max_i c_L\left(S_{11}^{-1} S_{1f_i} S_{f_i f_i}^{-1} S_{f_i 1}\right) > c_\alpha \tag{105}$$

then the set corresponding to $\max_i c_L(S_{11}^{-1} S_{1f_i} S_{f_i f_i}^{-1} S_{f_i 1})$ is declared to be the most important. The critical value c_α is chosen such that

$$P\left[\max_i c_L\left(S_{11}^{-1} S_{1f_i} S_{f_i f_i}^{-1} S_{f_i 1}\right) \leq c_\alpha | H\right] = (1 - \alpha) \tag{106}$$

and H: $\Sigma_{12} = 0$. In other words, the critical value c_α is chosen such that the probability of declaring that none of the $\binom{p_2}{r_2}$ sets is important when, in fact, none of the variables in the $\mathbf{x}_2$ set is correlated with the $\mathbf{x}_1$ set, which is $(1 - \alpha)$. But the distribution of $\max_i c_L(S_{11}^{-1} S_{1f_i} S_{f_i f_i}^{-1} S_{f_i 1})$ is very complicated to derive. So we use the following bound to get an approximate value of c_α:

$$\begin{aligned} &P\left[c_L\left(S_{11}^{-1} S_{12} S_{22}^{-1} S_{21}\right) \leq c_\alpha | H\right] \\ &\leq P\left[\max_i c_L\left(S_{11}^{-1} S_{1f_i} S_{f_i f_i}^{-1} S_{f_i 1}\right) \leq c_\alpha | H\right) = (1 - \alpha) \end{aligned} \tag{107}$$

We now discuss an alternative procedure for the selection of the best subset of r_2 variables from the $\mathbf{x}_2$ set and let $\mathbf{x}_{f_i}$ $[i = 1, 2, \ldots, \binom{p_2}{r_2}]$ denote a subset of r_2 variables from the p_2 variables $\mathbf{x}_2$. As before, let $\Sigma_{11}^{-1}\Sigma_{1f_i}\Sigma_{f_i f_i}^{-1}\Sigma_{f_i 1}$ denote the canonical correlation matrix connected with the $\mathbf{x}_1$ set and the $\mathbf{x}_{f_i}$ set. Let ψ_i denote a suitable function of the eigenvalues of the above matrix. Also, let $\hat{\psi}_i$ denote the corresponding function of the eigenvalues of $S_{11}^{-1} S_{1f_i} S_{f_i f_i}^{-1} S_{f_i 1}$. In addition, let $\psi_1, \ldots, \psi_{p_0}$ be

ordered as $\psi_{[1]}, \ldots, \psi_{[p_0]}$, where $p_0 = \binom{p_2}{r_2}$. Then the subset associated with the maximum of $\hat{\psi}_1, \ldots, \hat{\psi}_{p_0}$ is declared to be the best subset. Suppose $\hat{\psi}_i$ is the largest of $\hat{\psi}_j$. In this case, the probability of correct decision is given by the probability of $\hat{\psi}_i$ being greater than $\hat{\psi}_j$ $(j = 1, \ldots, i-1, i+1, \ldots, p_0)$ when ψ_i is greater than ψ_j for $j \neq i$. This probability involves nuisance parameters. One may use bounds that are free from nuisance parameters.

We now discuss the problem of studying the effect of additional variables on the canonical correlations. Consider two sets of variables, $\mathbf{x}_1$: $p_1 \times 1$ and $\mathbf{y}_1$: $q_1 \times 1$. Without loss of generality, we assume that $p_1 \leq q_1$. Suppose the sets of variables $\mathbf{x}_1$ and $\mathbf{y}_1$ are augmented to $\mathbf{x}$: $p \times 1$ and $\mathbf{y}$: $q \times 1$ by adding extra sets of variables $\mathbf{x}_2$: $p_2 \times 1$ and $\mathbf{y}_2$: $q_2 \times 1$, respectively. Also, we assume that $(\mathbf{x}', \mathbf{y}')$ is distributed as multivariate normal with mean vector $\boldsymbol{\mu}$ and covariance matrix Σ, where

$$\Sigma = \begin{pmatrix} \Sigma_{xx} & \Sigma_{xy} \\ \Sigma_{yx} & \Sigma_{yy} \end{pmatrix} \tag{108}$$

and Σ_{xx} is the covariance matrix of $\mathbf{x}$. Let $\rho_1 \geq \cdots \geq \rho_{p_1}$ denote the canonical correlations between the sets $\mathbf{x}_1$ and $\mathbf{y}_1$ and let $\tilde{\rho}_1 \geq \cdots \geq \tilde{\rho}_{p_1}$ denote the canonical correlations between $\mathbf{x}$ and $\mathbf{y}$. Also, let $\delta_\alpha = \tilde{\rho}_\alpha - \rho_\alpha$ for $\alpha = l, 2, \ldots, p_1$. Then $\delta_\alpha > 0$. Next, let

$$S = \begin{pmatrix} S_{xx} & S_{xy} \\ S_{yx} & S_{yy} \end{pmatrix} \tag{109}$$

denote the sample covariance matrix based on $(n+1)$ observations on $(\mathbf{x}', \mathbf{y}')$, and the sample canonical correlations $\tilde{r}_1 \geq \cdots \geq \tilde{r}_p$ are the positive square roots of the eigenvalues of $S_{xx}^{-1} S_{xy} S_{yy}^{-1} S_{yx}$. Similarly, let $r_1 \geq \cdots r_{p_1}$ denote the sample canonical correlations based on $(n+1)$ observations on $(\mathbf{x}', \mathbf{y}')$.

Now, let $f(d_1, \ldots, d_{p_1})$ be a continuously differentiable function in a neighborhood of $\mathbf{d} = \boldsymbol{\delta}$, where $\mathbf{d}' = (d_1, \ldots, d_{p_1})$ and $\boldsymbol{\delta}' = (\delta_1, \ldots, \delta_{p_1})$. Then Fujikoshi, Krishnaiah, and Schmidhammer (1987) showed that $\sqrt{n}\{f(d_1, \ldots, d_{p_1}) - f(\delta_1, \ldots, \delta_{p_1})\}$ is distributed asymptotically as normal with mean zero and certain variance σ^2. When $f(d_1, \ldots, d_{p_1}) = d_1$ and $p_1 = p$ or $q_1 = q$, the preceding result was derived by Wijsman (1986). The result of Fujikoshi, Krishnaiah, and Schmidhammer (1987) can be used to find whether the addition of new variables to one or both of the sets $\mathbf{x}_1$ and $\mathbf{y}_1$ will have an effect on functions of the canonical correlations. For example, we can draw an inference as to whether the addition of variables will increase the values of the largest canonical correlation, the sum of the canonical correlations, and so on. If there is no significant increase, we conclude that the new variables are not important in explaining the association between the two sets of variables. Fujikoshi (1985) proposed a procedure based on an information theoretic criterion to select best variables in canonical correlation analysis.

XII. DIMENSIONALITY AND DEPENDENCE IN TWO-WAY CONTINGENCY TABLE

Consider a two-way contingency table, and let p_{ij} $(i = 1, 2, \ldots, r+1;\ j = 1, 2, \ldots, s+1)$ denote the probability of an observation falling in the ith row and jth column. Without loss of generality, we assume that $r \leq s$. We consider the model

$$p_{ij} = p_{i\cdot} p_{\cdot j} \zeta_{ij} \tag{110}$$

where $p_{i\cdot} = p_{i1} + \cdots + p_{i,s+1}$, $p_{\cdot j} = p_{1j} + \cdots + p_{r+1,j}$, and $\zeta = (\zeta_{ij})$ is an unknown matrix. In a number of situations, we are interested in studying the structure of dependence between rows and columns if $p_{ij} \neq p_{i\cdot} p_{\cdot j}$. If we know the structure of dependence, we can estimate the unknown parameters more efficiently. Now, let $F = (f_{ij})$, where $f_{ij} = p_{ij} / \sqrt{p_{i\cdot} p_{\cdot j}}$. From the singular value decomposition of the matrix, it is known (e.g., see Lancaster, 1969) that

$$F = \boldsymbol{\xi}_0^* \boldsymbol{\eta}_0^{*\prime} \rho_0 + \sum_{u=1}^{r} \rho_u \boldsymbol{\xi}_u^* \boldsymbol{\eta}_u^{*\prime} \tag{111}$$

where $\rho_0 \geq \cdots \geq \rho_r$ are the positive square roots of the eigenvalues of FF', $\boldsymbol{\xi}_u^*$ is the eigenvector of FF' corresponding to ρ_u^2 and $\boldsymbol{\eta}_u^*$ is the eigenvector of $F'F$ corresponding to ρ_u^2. Here $\rho_0 = 1$, $\boldsymbol{\xi}_0^* = (\sqrt{p_{1\cdot}}, \ldots, \sqrt{p_{r+1\cdot}})'$, and $\boldsymbol{\eta}_0^* = (\sqrt{p_{\cdot 1}}, \ldots, \sqrt{p_{\cdot s+1}})'$. We now review the work of O'Neill (1978a, 1978b, 1981) and Bhaskara Rao, Krishnaiah, and Subramanyam (1985) for testing for the rank of the matrix ζ. We also review the work of Bai *et al.* (1989) for determination of the rank of ζ by using model selection methods.

Let n_{ij} denote the frequency in the ith row and jth column, $n_{i\cdot} = n_{i1} + \cdots + n_{i,s+1}$, $n_{\cdot j} = n_{1j} + \cdots + n_{r+l,j}$ and $n = \Sigma \Sigma n_{ij}$. Also, let $B = (b_{ij})$ where $b_{ij} = n_{ij} / \sqrt{n_{i\cdot} n_{\cdot j}}$. Now, let $\hat{\rho}_0^2 \geq \cdots \geq \hat{\rho}_r^2$ denote the eigenvalues of BB' where $\hat{\rho}_0 = 1$. We assume that n is fixed and the joint distribution of the cell frequencies is given by

$$n! \prod_{ij} \frac{1}{n_{ij}!} p_{ij}^{n_{ij}} \tag{112}$$

The classical test statistic for testing the hypothesis $p_{ij} = p_{i\cdot} p_{\cdot j}$ of independence is given by

$$\chi_0^2 = \sum_{i=1}^{r+1} \sum_{j=1}^{s+1} \frac{[n n_{ij} - n_{i\cdot} n_{\cdot j}]^2}{n^2 n_{i\cdot} n_{\cdot j}} \tag{113}$$

When the null hypothesis is true, χ_0^2 is distributed asymptotically as χ^2 with rs degrees of freedom. The preceding hypothesis is equivalent to the hypothesis that $\rho_1^2 = \cdots = \rho_r^2 = 0$ and one can choose $\hat{\rho}_1^2 + \cdots + \hat{\rho}_r^2$ as a test statistic. This test is equivalent to the χ^2 test for independence since $\chi_0^2 = n(\hat{\rho}_1^2 + \cdots + \hat{\rho}_r^2)$. Now, let H_t denote the hypothesis that $\rho_t^2 = 0$. This hypothesis is equivalent to the hypothesis that the rank of ζ is t. O'Neill (1978a, 1978b) showed that the joint asymptotic distribution of $n\hat{\rho}_1^2, \ldots, n\hat{\rho}_r^2$, when H is true, is the same as the joint distribution of the eigenvalues of the central Wishart matrix W with s degrees of freedom and $E(W) = sI_r$. Tables for percentage points of the largest eigenvalue of the central Wishart matrix are given in Krishnaiah (1980b).

We now review the work of Bhaskara Rao, Krishnaiah, and Subramanyam (1985) for determination of the rank of ζ. They suggested functions of $\hat{\rho}_1^2, \ldots, \hat{\rho}_r^2$ as test statistics for testing H_1. For example, one may use $\hat{\rho}_1^2, \hat{\rho}_1^2 + \cdots + \hat{\rho}_r^2$ as test statistics. These authors also suggested the following simultaneous test procedure. We accept or reject H_t, according to

$$\hat{\rho}_t^2 \gtrless c_\alpha \tag{114}$$

where

$$P[\hat{\rho}_t^2 \leq c_\alpha | H_t] = (1 - \alpha) \tag{115}$$

If H_t is accepted and H_{t-1} is rejected, then the rank of ζ is t. Bhaskara Rao, Krishnaiah, and Subramanyam (1985) derived asymptotic joint distribution of functions of $\hat{\rho}_1^2, \ldots, \hat{\rho}_r^2$ when $\rho_1^2, \ldots, \rho_r^2$ have multiplicities. O'Neill (1978a) suggested using $n(\hat{\rho}_t^2 + \cdots + \hat{\rho}_r^2)$ as a test statistic for testing the hypothesis that the rank of ζ is t. In general, we can use a suitable function of $\hat{\rho}_t^2, \ldots, \hat{\rho}_r^2$ such as the foregoing test statistic or $n\hat{\rho}_t^2$ to test the hypothesis that the rank of ζ is t. But, unfortunately, the distributions of these test statistics involve nuisance parameters even asymptotically. As an ad hoc procedure, one can replace the nuisance parameters with their consistent estimates.

Bai *et al.* (1992) proposed the following procedure for determination of the rank of $P = (p_{ij})$. Let

$$G(k) = n \sum_{j=k+1}^{r} \hat{\rho}_j^2 + kC_n \tag{116}$$

where C_n satisfies the following conditions:

$$\lim_{n\to\infty} \left(\frac{C_n}{n}\right) = 0 \tag{117a}$$

$$\lim_{n\to\infty} \left(\frac{C_n}{\log\log n}\right) = \infty \tag{117b}$$

Then the unknown rank q of P is estimated with $\hat{q}$ where $\hat{q}$ is given by

$$G(\hat{q}) = \min\{G(1), \ldots, G(r)\} \tag{118}$$

Bai, Krishnaiah, and Zhao (1992) showed that $\hat{q}$ is a consistent estimate of q.

XIII. NONEXACT TEST FOR THE TWO-SAMPLE PROBLEM

In this and the next sections, we consider the problem of reduction of dimensionality of parameters. As an example, we first consider the two-sample location problem. Suppose that $\mathbf{x}_1, \ldots, \mathbf{x}_{n_1}$ and $\mathbf{y}_1, \ldots, \mathbf{y}_{n_2}$ are random samples from two p-variate normal populations with mean vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, and a common covariance matrix Σ. Our problem is to test the hypothesis H: $\boldsymbol{\mu}_1 = \boldsymbol{\mu}_2$ against K: $\boldsymbol{\mu}_1 \neq \boldsymbol{\mu}_2$. The classical approach uses the Hotelling test (or T^2-test), with

$$T^2 = \frac{n_1 n_2}{n_1 + n_2}(\bar{\mathbf{x}} - \bar{\mathbf{y}})' A^{-1} (\bar{\mathbf{x}} - \bar{\mathbf{y}})$$

$$\bar{\mathbf{x}} = \tfrac{1}{n_1}\textstyle\sum_{i=1}^{n_1} \mathbf{x}_i, \bar{\mathbf{y}} = \tfrac{1}{n_2}\sum_{i=1}^{n_2} \mathbf{y}_i, \quad \text{and}$$

$$A = \frac{1}{n_1 + n_2 - 2}\left(\sum_{i=1}^{n_1} (\mathbf{x}_i - \bar{\mathbf{x}})(x_i - \bar{\mathbf{x}})' + \sum_{i=1}^{n_2} (\mathbf{y}_i - \bar{\mathbf{y}})(\mathbf{y}_i - \bar{\mathbf{y}})'\right)$$

The T^2 test has lots of good properties, but it is not well defined when the degrees of freedom $(n_1 + n_2 - 2)$ are less than the dimension (p) of the data.

As a remedy, Dempster (1958, 1960) proposed the so-called *nonexact test* (NET) by using the chi-square approximation technique. Dempster's method is to construct an $(n_1 + n_2) \times (n_1 + n_2)$ orthogonal matrix H with the first column consisting of $1/\sqrt{n_1 + n_2}$ and the second column consisting of $n_1 \sqrt{n_2/n_1(n_1 + n_2)}$ and $n_2 - \sqrt{n_1/n_2(n_1 + n_2)}$. Write $\mathbf{Z} = (\mathbf{z}_1, \ldots, \mathbf{z}_{n_1+n_2}) = (\mathbf{x}_1, \ldots, \mathbf{x}_{n_1}, \mathbf{y}_1, \ldots, \mathbf{y}_{n_2})$ and make a transformation

$$\mathbf{W} = (\mathbf{w}_1, \ldots, \mathbf{w}_{n_1+n_2}) = \mathbf{ZH}$$

It is easy to verify that

$$\mathbf{w}_1 \sim N_p\left(\frac{n_1\boldsymbol{\mu}_1 + n_2\boldsymbol{\mu}_2}{\sqrt{n_1 + n_2}}, \Sigma\right),$$

$$\mathbf{w}_2 \sim N_p\left(\sqrt{\frac{n_1 n_2}{n_1 + n_2}}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2), \Sigma\right)$$

and

$$\mathbf{w}_j \sim N_p(0, \Sigma) \quad \text{for} \quad j = 3, \ldots, n_1 + n_2$$

and all $\mathbf{w}_j$'s are independent of each other.

Then, Dempster used $F=(n_1+n_2-2)Q_2/(Q_3+\cdots+Q_{n_1+n_2})$ as the test statistic, where $Q_j=\mathbf{w}_j'\mathbf{w}_j$. Then, he used the χ^2 approximation for $j=3,\ldots,n_1+n_2$,

$$Q_j \simeq \sigma^2\chi_r^2 \tag{119}$$

Dempster proposed two complicated methods to estimate the parameter r, by the following equations:

$$t=\left(\frac{1}{\hat{r}_1}+\frac{1+(n_1+n_2-2)^{-1}}{3\hat{r}_1^2}\right)(n_1+n_2-3)$$

and

$$t+w=\left(\frac{1}{\hat{r}_2}+\frac{1+(n_1+n_2-2)^{-1}}{3\hat{r}_2^2}\right)(n_1+n_2-3)$$
$$+\left(\frac{1}{\hat{r}_2}+\frac{3}{2\hat{r}_2^2}\right)\binom{n_1+n_2-2}{2}$$

where $t=(n_1+n_2-2)[\ln\frac{1}{n}(\sum_{j=3}^{n_1+n_2}Q_j)]-\sum_{j=3}^{n_1+n_2}\ln Q_j$ and $w=-\sum_{3\le i<j\le n_1+n_2}\ln\sin^2\theta_{ij}$, with θ_{ij} the angle between random vectors $\mathbf{w}_i$ and $\mathbf{w}_j$.

In fact, the parameters σ^2 and r can be estimated by solving the equations

$$r\sigma^2=\mathrm{tr}(\Sigma) \quad \text{and} \quad (r^2+2r)\sigma^2=(\mathrm{tr}(\Sigma))^2+2\mathrm{tr}(\Sigma^2),$$

and Σ can be estimated by the pooled sample covariance matrix A.

The approximation (119) is also valid for $j=2$ under H. Therefore, under H, the distribution F is approximately $F_{r,r(n_1+n_2-2)}$.

Later, Bai and Saranadasa (1996) revisited Dempster's NET and found that the NET is not only a remedy for the T^2 test when $p>n_1+n_2-2$, but also much more powerful than the T^2 test in many general situations when T^2 is well defined. One difficulty in computing Dempster's test statistic is the construction of a high dimensional orthogonal matrix, and the other is the estimation of the degrees of freedom of the chi-square approximation. Bai and Saranadasa (1996) proposed a new test, the asymptotic normal test (ANT), in which the test statistic is $M=\|\overline{\mathbf{x}}-\overline{\mathbf{y}}\|^2-\tau\mathrm{tr}(A)$, where A is the pooled sample covariance matrix and $\tau=\frac{1}{n_1}+\frac{1}{n_2}$.

If we normalize M by an estimator of its variance, the ANT statistic is then given by

$$Z=\frac{\tau^{-1}M}{\sqrt{\frac{2(n_1+n_2-1)(n_1+n_2-2)}{(n_1+n_2)(n_1+n_2-3)}\left(\mathrm{tr}A^2-(n_1+n_2-2)^{-1}(\mathrm{tr}A)^2\right)}}$$

It has been shown that the ANT is asymptotically equivalent to NET, and simulations show that ANT is slightly more powerful than NET. It is easy to show that both the NET and ANT are asymptotically exact, that is, the type I error for both tests tends to the prechosen level. Simulation results show that NET and ANT gain a great amount of power with a slight loss of the exactness of the type I error. Note that *nonexact* does not mean that the error is always larger than the prechosen value.

It is worth to indicate that Bai and Saranadasa's ANT does not need the normality assumption. It requires only the existence of the 4th moment. For details of this method, the reader is referred to Bai and Saranadasa (1996).

Now, let us analyze why this happens. Under the normality assumption, if Σ is known, then the "most powerful test statistic" should be $(\overline{\mathbf{x}}-\overline{\mathbf{y}})'\Sigma^{-1}(\overline{\mathbf{x}}-\overline{\mathbf{y}})$. Since Σ is actually unknown, the matrix A plays the role of an estimator of Σ. Then there is the problem of how close A^{-1} is to the inverse of the population covariance matrix Σ^{-1}.

Let us rewrite the matrix A^{-1} in the form $\Sigma^{-1/2}S^{-1}\Sigma^{-1/2}$, where $\mathbf{S}$ is the sample covariance of $n=n_1+n_2-2$ iid random p-vectors with mean zero and identity covariance matrix. Obviously, the approximation is good if S^{-1} is close to I and not otherwise. Unfortunately, this is not really the case. By the theory of spectral analysis of large dimensional random matrix (see Bai and Yin, 1993; Yin, 1986; and Yin, Bai, and Krishnaiah, 1988), when $p/n=0.25$, the ratio of the largest eigenvalue of S^{-1} to the smallest can be as large as 9. Even when p/n is as small as 0.01, this ratio can be as large as 1.493. This shows that it is practically impossible to get a "good" estimate of the inverse covariance matrix. In other words, if the ratio $(\sqrt{n}+\sqrt{p})^2/(\sqrt{n}-\sqrt{p})^2$ is not in a tolerable range from 1 (e.g., 9 for $p/n=0.25$, 3.7 for $p/n=0.1$, and 1.493 for $p/n=0.01$), NET and ANT give better tests than T^2.

From the viewpoint of dimensionality of parameters to be estimated, we find that the T^2 test needs to estimate $\frac{1}{2}p^2+\frac{5}{2}p$ parameters (i.e., $\boldsymbol{\mu}_1$, $\boldsymbol{\mu}_2$ and Σ) and the NET and ANT need only estimate $2p+2$ parameters [i.e., $\boldsymbol{\mu}_1$, $\boldsymbol{\mu}_2$, $\mathrm{tr}(\Sigma)$, and $\mathrm{tr}(\Sigma^2)$].

A similar but simpler case is the one-sample problem. As in Bai and Saranadasa (1996), it can be shown that NET and ANT are better than the T^2 test. This phenomenon happens in many statistical inference problems, such as large contingency tables, MANOVA, discretized density estimation, linear models with large number of parameters, and the error-in-variable models. Once the dimension of the parameter is large, the performance of the classical estimators become poor and corrections may be needed.

XIV. MULTIVARIATE DISCRIMINATION ANALYSIS

Suppose that $\mathbf{x}$ is a sample drawn from one of two populations with mean vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ and a common

covariance matrix Σ. Our problem is to classify the present sample $\mathbf{x}$ into one of the two populations. If $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ and Σ are known, then the best discriminant function is $d = (\mathbf{x} - \frac{1}{2}(\boldsymbol{\mu}_1 + \boldsymbol{\mu}_2))' \Sigma^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)$, i.e., assign $\mathbf{x}$ to Population 1 if $d > 0$.

When both the mean vectors and the covariance matrix are unknown, assume that training samples $\mathbf{x}_1, \ldots, \mathbf{x}_{n_1}$ and $\mathbf{y}_1, \ldots, \mathbf{y}_{n_2}$ from the two populations are available. Then we can substitute the MLE $\overline{\mathbf{x}}$, $\overline{\mathbf{y}}$, and A of the mean vectors and covariance matrix into the discriminant function. Obviously, this is impossible if $n = n_1 + n_2 - 2 < p$. The problem is again whether this criterion has the smallest misclassification probability when p is large. If not, what discrimination criterion is better? Based on the same discussion in the last subsection, one may guess that the criterion $d = (\mathbf{x} - \frac{1}{2}(\mathbf{x} + \mathbf{y}))'(\mathbf{x} - \mathbf{y})$ should be better. Using the limiting theorems of spectral analysis of a large sample covariance matrix, this was theoretically proved in Saranadasa (1993). Simulation results presented in his paper strongly support the theoretical results, even for moderately large n and p.

Set Theory

Marion Scheepers
Boise State University

GLOSSARY

Axiom of choice The statement that for each set of pairwise disjoint nonempty sets, there exists a set which contains exactly one member from each.
Continuum hypothesis The statement that the set of real numbers has the smallest uncountable cardinality.
Determined game A two-person game which never ends in a draw and for which one of the players has a winning strategy.
Measurable cardinal An initial ordinal κ for which there is a κ-complete two-valued measure on all its subsets.
Model of set theory A mathematical object in which all the Zermelo–Fraenkel axioms, as well as the choice axiom, are true.
Ordinal A measure for the length of a well-ordered list.
Uncountable set There is no one-to-one function from the set to the integers.

SET THEORY is the discipline of mathematics concerned with the abstract concepts of "set" and "element," and their applications in mathematics. Much of mathematics can be simulated by using the simple notions of "set" and "element." Whenever this occurs set theory is a foundation for the simulated area of mathematics.

Traditionally the main sources of inspiration for set theory have been problems having roots in the study of the real line. The body of set theoretic knowledge is voluminous and diverse. Here six carefully selected classical problems will serve as an introduction to recent activity in set theory.

I. THE BEGINNINGS: GALILEI AND CANTOR

Galileo Galilei spent a significant part of the dialog during the first day in his "**Discourses and Mathematical Demonstrations Concerning Two New Sciences Pertaining to Mechanics and Local Motions**" (published in 1638) on infinite sets. In this dialog Galilei points out that there is a one-to-one function from the set of positive integers onto the set of squares of the positive integers. He concludes that these two infinite sets have the same number of elements. Then he contrasts this with: For each positive integer N there are approximately $\sqrt{N}$ positive integers whose squares are below N. Thus the

proportion of squares below N to positive integers below N is $\frac{\sqrt{N}}{N}$. This converges to zero as N increases. Thus, though the two sets have the same number of elements, one set is insignificantly small in proportion to the other. These types of contrasts—a set being "big" in one sense and "small" in another—will be called *Galilean paradoxes*.

In 1873 Cantor took the existence of a one-to-one and onto function between sets as the definition for having the same number of elements. Two sets are said to be *equinumerous* if they have the same number of elements. A set A is said to be *less numerous* than a set B if there is a one-to-one function from A to B, but no function from A to B is onto. Cantor proved: The set of positive integers is equinumerous to the set of rational numbers; the real line is equinumerous to the Cartesian plane; the real line is equinumerous to the set of all subsets of the integers. In 1873 he also proved that the set of positive integers is less numerous than the unit interval. Later he proved that every set is less numerous than the set of all its subsets. Thus, two infinite sets need not have the same number of elements. Moreover, for each infinite set, there is one with a larger number of elements. These results can be taken as the official birth of set theory.

The two most used adjectives in set theory are *countable* and *uncountable*. A set is said to be countable if there is a one-to-one function from it to the integers. Otherwise, a set is said to be uncountable.

II. BASIC CONCEPTS

Cantor's results caused a vigorous discussion among mathematicians and philosophers. Careful justification for his proof techniques were called for. Of the several axiomatizations proposed for set theory the Zermelo-Fraenkel axiomatization (denoted ZF) is currently used most universally. With little exception the axiom of choice (AC) is also used as an axiom. ZFC denotes the resulting axiom system. To date no inconsistencies have been discovered in ZFC; it is believed that there are none.

A. The ZFC Axioms

Like the axioms of group theory declare when a mathematical object is a group, the ZFC axioms declare when a mathematical object is a *model of set theory*. The members of a model of set theory are said to be *sets*. ZFC addresses only the *membership* relation among members of a model of set theory. The symbol $\in$ denotes this membership relation. For sets A and B, if $A \in B$ then A is said to be an element of B. Here is a listing of the ZFC axioms, formulated somewhat informally:

Empty-set axiom: There exists a set which has no elements (It is denoted $\emptyset$).
Power set axiom: For each set A there is a set whose only elements are the subsets of A (It is denoted $\mathcal{P}(A)$, and called the *power set of A*).
Pairing axiom: For all sets A and B there is a set whose only members are A and B (It is denoted $\{A, B\}$).
Union axiom: For each set A there is a set whose only members are sets which are members of members of A (It is denoted $\cup A$).
Comprehension axiom: For each set A, and for each set-theoretic property P, there is a set whose only elements are those elements of A having the specified property (It is denoted $\{x \in A : P(x)\}$).
Extensionality axiom: Sets A and B are equal if, and only if, they have the same elements.
Foundation axiom: Each nonempty set A has a member which itself has no members in common with A.
Infinity axiom: There is an infinite set.
Replacement axiom: For $P(\cdot, \cdot)$ a set theoretic property and A a set: If there is for each element a of A a unique b such that $P(a, b)$ is true, then there is a set B such that: for each a in A there is a b in B for which $P(a, b)$ is true.
Choice axiom: For each set A, all of whose members are nonempty and pairwise have elements in common, there is a set which contains exactly one member from each set in A.

The Comprehension- and Replacement axioms are actually infinite lists of axioms, one axiom per set-theoretic property. As Bertrand Russell pointed out, for a proper treatment of these axioms one must make precise the notion of a "set-theoretic property." Doing this would take us a little too far afield.

One must be careful with the membership relation: A model of set theory is itself a collection of objects, named "sets," and the symbol $\in$ refers to the membership relation among those. Often $\in$ is abused and also used to indicate that a set is a member of a given model of set theory. But the axioms do not permit reference to the model of set theory.

B. Ordinal Numbers

Ordinal numbers (ordinals) were introduced by Cantor. Ordinals count position in a list: first, second, third, and so on. One can formalize this concept so that it applies to infinite lists. Here is one way of using sets in a model of set theory to simulate the notion of an ordinal: An ordinal is a set A with the following properties: (i) Each element

of A is a subset of A and (ii) for B and C elements of A, either $B \in C$, or else $C \in B$, or else $B = C$.

Thus $\in$ defines a linear ordering on an ordinal. Also, for any ordinals A and B, either $A \in B$, or else $B \in A$, or else $A = B$. We call an ordinal A *smaller than* (or less than) an ordinal B if $A \in B$. The Foundation Axiom implies that the linear ordering defined on an ordinal by $\in$ contains no infinite descending sequences—i.e., it is a well-ordering. Ordinals are unique in the following sense: If A and B are ordinals and if f is a function from A onto B such that $x \in y$ if, and only if, $f(x) \in f(y)$, then $A = B$.

The empty set $\emptyset$ is an ordinal and as ordinal is denoted by 0. For each ordinal α the set $\alpha \cup \{\alpha\}$ is an ordinal, and is denoted $\alpha + 1$. The union of a set of ordinals is an ordinal. By these two facts and the ZFC axioms the list of ordinals continues indefinitely. One obtains the following picture:

$$0, 1, 2, \ldots, \omega, \omega + 1, \ldots, \omega + \omega, \ldots, \omega_1,$$
$$\omega_1 + 1, \ldots, \omega_2, \ldots, \ldots, \omega_\omega, \ldots$$

Here we have $1 = \{\emptyset\}$, $2 = \{\emptyset, \{\emptyset\}\}$, and so on. ω denotes the least infinite ordinal and is the set $\{0, 1, 2, \ldots\}$. $\omega + 1$ denotes $\omega \cup \{\omega\}$ and ω_1 denotes the smallest ordinal beyond ω for which there is no function from ω onto it. Next are the ordinals $\omega_1 + 1$, $\omega_1 + 2$, and so on. ω_2 denotes the least ordinal beyond ω_1 for which there is no function from ω_1 onto it. One defines $\omega_3, \omega_4, \ldots, \omega_n, \ldots$ (for finite n) analogously. ω_ω is the least ordinal beyond each ω_n for which there is no function from any ω_n onto it. Then comes $\omega_\omega + 1, \omega_\omega + 2, \ldots, \omega_\omega + \omega_\omega, \ldots$ and so on. $\omega_{\omega+1}$ denotes the least ordinal beyond ω_ω for which there is no function from any of the earlier ones onto it. Indeed, for each ordinal α there is a corresponding later ordinal ω_α.

An ordinal is said to be an *initial ordinal* if there is no function from an earlier ordinal onto it. It is said to be a *successor ordinal* if it is of the form $\alpha + 1$. If an ordinal is not a successor ordinal, it is said tobe a *limit ordinal*. The *cofinality* of a limit ordinal A is defined to be the least ordinal B such that there is a function f from B to A with the property that for each $a \in A$ there is a $b \in B$ with $a \in f(b)$. For example, ω is the cofinality of ω_ω, and also of $\omega_2 + \omega$. If a limit ordinal has cofinality ω, it is said to have *countable cofinality*; otherwise, it has *uncountable cofinality*. The cofinality of a limit ordinal is always an initial ordinal.

C. Simulating Mathematics in Set Theory

Much of mathematics can be simulated in set theory. Here is a simulation of number theory: Recall the simulation of ordinals: $0 = \emptyset$, $1 = \{0\}$, $2 = \{0, 1\}, \ldots$. Define the operation S by: $S(x) = x \cup \{x\}$. The ZFC axioms imply that the Peano axioms hold for the set $\omega = \{0, 1, 2, \ldots\}$, endowed with S as successor operation. Also the integers, rational-, real-, and complex numbers can be simulated in set theory.

First, simulate the notion of an ordered pair by sets as follows: Let sets x and y be given. Then $\{x, y\}$ is a set (by the pairing axiom), and is the same as the set $\{y, x\}$ (by the extensionality axiom). Since $\{x\}$ is a set, also $\{\{x\}, \{x, y\}\}$ is a set. The latter set, denoted (x, y), is the simulation of the ordered pair of x and y. One can show that if x is not equal to y, then (x, y) is not equal to (y, x) and if $(x, y) = (u, v)$, then $x = u$ and $y = v$.

For sets A and B let $A \times B$, the Cartesian product of A and B, be simulated by the set $\{(a, b): a \in A \text{ and } b \in B\}$. Subsets of $A \times B$ are used to simulate binary relations. For example, the "less than" relation between natural numbers is simulated by $\{(m, n): m \in \omega, n \in \omega, \text{ and } m \in n\}$.

To simulate integers form the Cartesian product $\omega \times \omega$. Define $\mathbb{Z}$, the set of integers, to be $\{(m, n): m \in \omega, n \in \omega, \text{ and } m = 0 \text{ or } n = 0\}$. Pairs of the form $(0, n)$ represent $-n$ and pairs of the form $(m, 0)$ represent m. Now addition, subtraction, and "less than" can be simulated.

Simulate the rational numbers from the simulation of the integers. Then simulate the real numbers from the simulation of the rational numbers by using Dedekind cuts. An ordered pair (A, B) where A and B are subsets of $\mathbb{Q}$ (the set of simulations of the rational numbers) is said to be a *Dedekind cut* if: (i) $A \cup B = \mathbb{Q}$, (ii) both A and B are nonempty, and (iii) each rational number in A is less than each rational number in B. The real numbers are simulated by such pairs, and $\mathbb{R}$ (the set of simulations of real numbers) is $\{(A, B): (A, B) \text{ it is a Dedekind cut}\}$. The order relation on the set of real numbers is simulated by declaring for the Dedekind cuts (A_1, B_1) and (A_2, B_2) that $(A_1, B_1) < (A_2, B_2)$ if A_1 is a proper subset of A_2. Then simulate the operations of addition and multiplication. The ZFC axioms imply that this simulation is an ordered field, that the completeness axiom holds, and that there are between any two real numbers a rational number.

For sets A and B a function f from A to B is simulated by the set $\{(x, f(x)): x \in A\}$. Next one simulates convergence, continuity, differentiability, integrability, and the other concepts of calculus. The ZFC axioms imply the usual theorems of calculus such as the Intermediate Value Theorem, the Fundamental Theorem of Calculus, and so on, for these simulations.

D. The Cumulative Hierarchy

Let **V** be a model of set theory which contains nothing but the essentials. What does it look like? **V** is recursively built up as follows: Put $V_0 = \emptyset$. Let α be an ordinal such that V_α has been defined. Define: $V_{\alpha+1} = \mathcal{P}(V_\alpha)$. Let β be

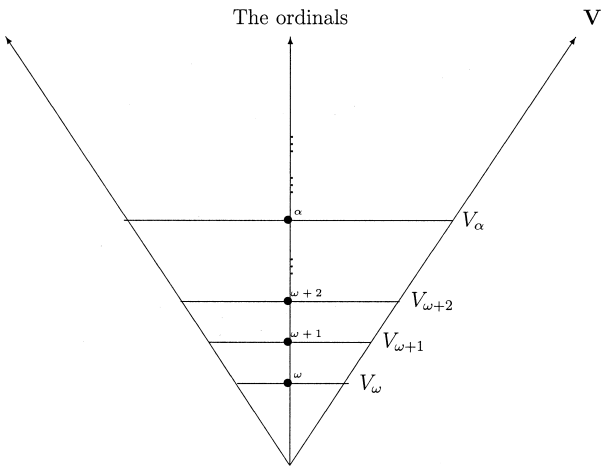

FIGURE 1 A model **V** of set theory.

a limit ordinal such that V_α is defined for each $\alpha \in \beta$. Define: $V_\beta = \cup\{V_\alpha : \alpha \in \beta\}$. Thus we have: $V_1 = \mathcal{P}(V_0)$, $V_2 = \mathcal{P}(V_1), \ldots, V_\omega = \cup\{V_n : n \in \omega\}$, $V_{\omega+1} = \mathcal{P}(V_\omega)$, and so on indefinitely.

For α less than β each element of V_α is an element of V_β. Each α is a member of $V_{\alpha+1}$. For each $\alpha > 0$ the set V_α is a model for all the ZFC axioms except perhaps the power set-, pairing-, infinity- and replacement axioms. For $\alpha > \omega$ the infinity axiom also holds in V_α. For limit ordinals $\alpha > \omega$ the pairing- and power-set axioms also hold in V_α; only the replacement axiom potentially fails. $V_{\omega+\omega}$ is a model for all ZFC axioms except replacement.

V is the collection of sets occuring as members of the V_α's. For each set X in **V** the least α with $X \in V_\alpha$ is said to be the rank of X. We write: $rank(X) = \alpha$. Here are some examples: $rank(\omega) = \omega + 1$, $rank(\mathcal{P}(\omega)) = \omega + 2$, $rank(\mathbb{R}) = \omega + 2$, $rank(\mathcal{P}(\mathbb{R})) = \omega + 3$. Figure 1 depicts **V**.

E. Cardinal Numbers

Cardinals count the number of items in a collection–like one, two, three, and so on. These are simulated as follows by ordinals: Zermelo proved that the axiom of choice is equivalent to: There is for each set an ordinal and a one-to-one function from the set onto that ordinal. For a set X the least ordinal for which there is a one-to-one function from X to that ordinal is said to be the cardinal number, or cardinality, of X and is denoted $|X|$.

The cardinals are the initial ordinals. When emphasizing cardinality characteristics, denote ω by $\aleph_0$, ω_1 by $\aleph_1$, ω_2 by $\aleph_2$, and so on. $\aleph_\omega$ is the least cardinal above each $\aleph_n$; the smallest cardinal above $\aleph_\omega$ is $\aleph_{\omega+1}$.

If a cardinal has an immediate predecessor in this list it is said to be a *successor* cardinal; otherwise, it is a *limit* cardinal. $\aleph_0$ and $\aleph_\omega$ are limit cardinals. $\aleph_1$, $\aleph_2$, and $\aleph_{\omega+1}$ are successor cardinals. The cardinal κ is said to be *singular* if its cofinality is smaller than κ. Else, κ is said to be *regular*. $\aleph_\omega$ and $\aleph_{\omega_1}$ are singular cardinals; $\aleph_1$ is regular, as is every successor cardinal.

Cantor introduced an arithmetic for ordinals and for cardinals. For both there is an addition, a multiplication and exponentiation. Ordinal arithmetic is easier than cardinal arithmetic, but both extend the usual arithmetic of the nonnegative integers.

F. Borel Sets and Projective Sets

Sets encountered in mathematical practice are usually describable in terms of simple set theoretic operations, starting from simply describable sets. Descriptive set theory is devoted to the study of such sets.

To develop a useful theory one must make precise the notions "simple set theoretic operations," and "simply describable sets." In a 1905 paper Borel defined a hierarchy of such "simple" sets as follows: Σ^0_0 is the collection of sets of real numbers which are unions of open intervals with rational boundary points; Π^0_0 is the collection of the complements of sets in Σ^0_0. For α a nonzero countable ordinal such that Π^0_β is defined for all $\beta \in \alpha$, define Σ^0_α as the set of all the unions of countably many sets from $\cup\{\Pi^0_\beta : \beta \in \alpha\}$; Π^0_α is the set of all the complements of sets in Σ^0_α.

For $\beta \in \alpha$ one has: each element of Σ^0_β or Π^0_β is in Σ^0_α and in Π^0_α. Each successively defined set in this list has members not in the previously defined sets. Sets which are elements of $\cup\{\Sigma^0_\alpha : \alpha \in \omega_1\}$ are said to be *Borel* sets.

Similar Borel hierarchies are defined for other spaces commonly used in mathematics—like the complex plane, Euclidean three-space, and the space of continuous real-valued functions on the closed unit interval. Borel sets are now the norm for what is meant by "simply describable" sets.

In mathematics sets are obtained not only as unions and complements, but also as the images of functions. Suslin discovered sets of real numbers which are not Borel, but are the continuous image of a Borel set. This discovery was the official birth of descriptive set theory.

A set of real numbers is said to be *analytic* if it is the continuous image of some Borel set. Σ^1_1 denotes the collection of analytic sets. If a set is the complement of an analytic set it is said to be co-analytic. Π^1_1 denotes the collection of co-analytic sets. For each n, Σ^1_{n+1} denotes the collection of sets which are continuous images of sets in Π^1_n, and Π^1_{n+1} denotes the collection of complements of sets in Σ^1_{n+1}.

For each n the sets in Σ^1_n or in Π^1_n are also in both Σ^1_{n+1} and Π^1_{n+1}. Each set in this list has an element which is not in any prior set in the list. If a set is in some Σ^1_n it is said to be *projective*. Suslin discovered that a projective set is a Borel set if, and only if, it is both analytic and co-analytic.

G. Gale–Stewart Games, and Determined Sets

The following game defined by Gale and Stewart in the 1950s subsumed the games considered in the 1930s by Banach, Mazur, and Ulam: Let a set S of sequences of positive integers be given. Two players, ONE and TWO, play infinitely many innings as follows: In the first inning ONE chooses a positive integer o_1, and TWO responds with t_1. In inning two ONE chooses a positive integer o_2, and TWO responds with t_2, and so on. They play an inning per positive integer. At the conclusion of these innings they have constructed a sequence $s = (o_1, t_1, \ldots, o_n, t_n, \ldots)$ of positive integers. ONE is declared the winner of this *play* s of the game if s is a member of A; otherwise, TWO wins. Let $\mathsf{G}(S)$ denote this game.

For each play of $\mathsf{G}(S)$ there is a winner, but who wins may differ from play to play. Depending on the specific properties of S the game may be more favorable to one of the players. To make the notion of "favorable" precise, we define the notions of a strategy and of a winning strategy. A strategy for player ONE is a function, F, with input the current history of the game and as output the positive integer player ONE is to choose next. Let F be a strategy for ONE. The play s is said to be an F-play if $o_1 = F(\emptyset)$, $o_2 = F(o_1, t_1), \ldots, o_{n+1} = F(o_1, t_1, \ldots, o_n, t_n), \ldots$. F is said to be a winning strategy for ONE if *every* F-play is won by ONE. The notions of a strategy and a winning strategy for TWO are defined similarly.

A set S of sequences of positive integers is said to be *determined* if one of the players has a winning strategy in the game $\mathsf{G}(S)$. If neither player has a winnings strategy then S is said to be *undetermined*. In any model of (ZFC) set theory there are undetermined sets. The choice axiom plays a critical role in this demonstration and the examples obtained from it have pathological properties. Do undetermined sets have to be "pathological"?

Using continued fractions one can show that the set of irrational numbers is essentially the set of sequences of nonnegative integers. Thus, Gale–Stewart games can be viewed as played on the real line. Are projective sets of real numbers determined?

H. The Gödel Incompleteness Theorems

Is it true that all mathematical statements about sets in a model of set theory can be proven or disproven from the ZFC axioms? According to Gödel's First Incompleteness Theorem there is for any list of axioms which is a "reasonable" extension of Peano arithmetic a statement about the objects being axiomatized such that the axioms neither prove, nor disprove the statement. Gödel's examples of such statements are not the type of statement encountered in mathematical practice. The question arose whether any of the notorious unsolved mathematical problems is such an undecidable statement. The first examples of undecidable statements arising from mathematical practice appeared in set theory, as will be seen later, but many have since been discovered in virtually all areas of infinitary mathematics.

Recall that for any limit ordinal $\alpha > \omega$ the set V_α satisfies all the ZFC axioms except perhaps the replacement axiom. If we could prove from ZFC that there is a limit ordinal $\alpha > \omega$ such that V_α also satisfies the replacement axiom, then we would have proved from ZFC that there is a set which is a model of set theory, and thus that ZFC is consistent. But Gödel's Second Incompleteness Theorem states exactly that if ZFC is consistent, then the statement "ZFC is consistent" is not decidable from ZFC. Thus, if ZFC is consistent then it cannot prove that there is a limit ordinal $\alpha > \omega$ such that the replacement axiom holds in V_α.

III. SIX PROBLEMS OF CLASSICAL SET THEORY

A. Cardinal Exponentiation

Cardinal exponentiation led to the first significant set theoretic problem. For κ a cardinal number, 2^κ is defined to be the cardinality of the power set of κ. Thus, $2^{\aleph_0}$ denotes the cardinality of $\mathcal{P}(\omega)$.

1. Cantor's Continuum Problem

$2^{\aleph_0}$ is also the cardinality of the real line. The equation $2^{\aleph_0} = \aleph_1$ is known as Cantor's Continuum Hypothesis (CH). Cantor's Continuum Problem is the question whether CH holds in every model of (ZFC) set theory.

In 1938 Gödel showed that any model of (ZF) set theory contains a "smallest inner model," now called the Constructible Universe, and denoted by **L**. (This is analogous to: Every characteristic zero field has a smallest subfield, "the" field of rational numbers.) He showed that **L** is a model of set theory and CH provably holds in **L**. Thus ZFC cannot disprove CH.

In 1963 Cohen discovered *forcing*, a method to extend a given model of set theory to a larger one. This method is analogous to extending a field to one which contains a root for a given polynomial. Cohen showed by forcing how to extend any model of set theory in which CH holds to one in which CH is false. Thus ZFC cannot prove CH. Conclusion: CH is undecidable from ZFC!

2. Exponentiation of Singular Cardinals

Cohen's breakthrough raised the question: Does ZFC impose any restrictions on the value of 2^κ? It was proved that $2^{\aleph_0}$ can be any cardinal of uncountable cofinality. Easton

showed that for κ any regular cardinal ZFC imposes no restrictions on the value of 2^κ besides (i) the cofinality of 2^κ is larger than κ, and (ii) $\kappa < \lambda$ implies $2^\kappa \leq 2^\lambda$.

For κ a singular cardinal of uncountable cofinality ZFC imposes restrictions. Silver proved: If for each $\lambda < \kappa$ the equation $2^\lambda = \lambda^+$ holds, then $2^\kappa = \kappa^+$ holds. Shortly afterwards Galvin and Hajnal proved: If $\aleph_\alpha$ has uncountable cofinality, and if for each $\kappa < \aleph_\alpha$ also $2^\kappa < \aleph_\alpha$, then $2^{\aleph_\alpha} < \aleph_{(2^{|\alpha|})^+}$.

Let $\mathrm{cof}(\kappa)$ denote the cofinality of κ. For κ singular a careful analysis indicated that the key question is: What is the value of $\kappa^{\mathrm{cof}(\kappa)}$ when $2^{\mathrm{cof}(\kappa)} < \kappa$ holds? Here $\kappa^{\mathrm{cof}(\kappa)}$ is the cardinality of the set of functions from $\mathrm{cof}(\kappa)$ to κ. Classical results imply that $2^{\mathrm{cof}(\kappa)} \neq \kappa$, and that $2^{\mathrm{cof}(\kappa)} > \kappa$ implies $\kappa^{\mathrm{cof}}(\kappa) = 2^{\mathrm{cof}(\kappa)}$. The Singular Cardinal Hypothesis (SCH) is the statement: $2^{\mathrm{cof}(\kappa)} < \kappa$ implies that $\kappa^{\mathrm{cof}(\kappa)}$ is κ^+, the smallest cardinal larger than κ.

Could SCH fail in a model of set theory? Is there in each model of set theory a cardinal κ such that $2^\kappa = \kappa^+$? Do Silver's theorem and the Galvin–Hajnal theorem hold for uncountable cardinals of countable cofinality?

3. The Perfect Subset Property

For Γ a set of subsets of the real line let $\mathrm{CH}(\Gamma)$ denote the Continuum Hypothesis for Γ, which is: Each infinite set of real numbers in Γ has cardinality either $\aleph_0$ or else $2^{\aleph_0}$. Thus, CH is $CH(\mathcal{P}(\mathbb{R}))$.

Cantor proved $CH(\Pi^0_0)$. Later, Young extended this by proving $CH(\Pi^0_1)$. By 1916 Hausdorff and independently Aleksandrov proved $CH(Borel)$. In all these results the proof was based on the notion of a perfect set: A set A of real numbers is said to be *perfect* if: (i) for each point in A there is a sequence in A with all terms different from the point, but it converges to the point, and (ii) for every convergent sequence with all terms from A, the limit of the sequence is also in A. The interval [0,1] is an example of a perfect set. Cantor's famous "middle-thirds" set is a more exotic example. Cantor proved that each perfect set has cardinality $2^{\aleph_0}$.

These results motivate the *Perfect Subset Property*: A family Γ of subsets of $\mathbb{R}$ has the perfect subset property if: Every infinite set in Γ is either countable, or else has a perfect subset. If a family of sets has the perfect subset property, then the Continuum Hypothesis for that family is witnessed by these perfect sets. Bernstein showed that not every set of real numbers of cardinality $2^{\aleph_0}$ has a perfect subset. Thus, having a perfect subset is a stronger property than having cardinality $2^{\aleph_0}$.

Suslin generalized Hausdorff and Aleksandrov's theorem by proving that the family of analytic sets has the perfect subset property. Thus $CH(\Sigma^1_1)$ holds. No proof was forthcoming that Π^1_1 has the perfect subset property. Sierpiński proved that each Π^1_1 set is a union of $\aleph_1$ Borel sets. Thus the cardinality of infinite Π^1_1 sets could be $\aleph_0$, $\aleph_1$ or $2^{\aleph_0}$.

Gödel showed that in **L** there is an uncountable Π^1_1 set with no perfect subset. Thus for Π^1_1 the perfect subset property is not provable from ZFC. Is there in every model of set theory an uncountable Π^1_1 set with no perfect subset?

B. Lebesgue Measurability

A set X of real numbers is said to have (Lebesgue) *measure zero* if there is for each positive real ϵ a sequence $(I_n : n < \infty)$ of intervals such that X is covered by their union, and the sum of their lengths is less than ϵ. Measure zero is a notion of smallness but does not mean small cardinality. One has the following Galilean paradox: The Cantor middle-thirds set of real numbers has cardinality equal to that of the real line, but has Lebesgue measure zero.

A set S of real numbers is *Lebesgue measurable* if there is a Borel set B and a measure zero set N such that $S = (B \setminus N) \cup (N \setminus B)$. Thus, a set is Lebesgue measurable if it is only "slightly" different from some Borel set: The set of points where it is different is of Lebesgue measure zero.

There is a function, μ, the Lebesgue measure, defined on the set of all Lebesgue-measurable sets such that:

1. $\mu(X) = 0$ if, and only if, X has Lebesgue measure zero.
2. If $(X_n : n < \infty)$ is a sequence of pairwise disjoint Lebesgue measurable sets, then $\mu(\cup_{n<\infty} X_n) = \sum_{n<\infty} \mu(X_n)$.

A set is Lebesgue measurable if, and only if, it is in the domain of μ. The second property in the list is called "countable additivity."

In each model of (ZFC) set theory there are Lebesgue nonmeasurable sets. The earliest examples were considered pathological. Thus: Can the Lebesgue measure be extended to a countably additive measure ν such that each set of real numbers is measurable with respect to ν? This is *the measure problem*. Are projective sets of real numbers Lebesgue measurable?

1. The Measure Problem

Banach and Kuratowski proved: In any model of set theory in which CH holds there are countably many sets of real numbers such that no countably additive extension of the Lebesgue measure measures all these sets. Thus, ZFC + CH implies a negative answer to the measure problem.

What are the properties of a model of set theory in which the Lebesgue measure can be extended to a countably additive measure ν which measures all sets of reals? Restricting such a ν to subsets of [0,1] gives a real-valued measure on [0,1]. Using a one-to-one function this measure can be transferred to any set of cardinality $2^{\aleph_0}$. Thus, the measure problem may be considered for cardinals. For the least cardinal κ which permits a real-valued measure we have $\kappa \leq 2^{\aleph_0}$ and (by the Banach-Kuratowski result) $\kappa > \aleph_1$.

Ulam proved that if there is any set at all carrying a real-valued measure then the least κ such that there is a real-valued measure on κ is either no larger than $2^{\aleph_0}$, or else carries a two-valued measure. Moreover, if κ is the least cardinal carrying a real-valued measure, then for any family of fewer than κ subsets of κ, each of measure zero, the union of the family has measure zero: This property of the measure is called κ-completeness. Ulam showed that no successor cardinal could be real-valued measurable and that a real-valued measurable cardinal could not be singular. Thus in any model of set theory where the measure problem has a positive solution there would be an uncountable cardinal number $\kappa \leq 2^{\aleph_0}$ which is not a successor cardinal, and not a singular cardinal. Such a cardinal is said to be *weakly inaccessible*.

An uncountable cardinal κ is said to be *measurable* if it carries a two-valued κ-complete measure. Ulam showed that if κ is a measurable cardinal then for each cardinal $\lambda < \kappa$ one has $2^\lambda < \kappa$. Cardinal numbers having the latter property are called *strongly inaccessible*. The concepts of weakly and strongly inaccessible cardinals made their debut in Hausdorff's works, predating Ulam's paper by more than 20 years.

a. Inaccessibility properties of cardinals, and ZFC + I. If a model of set theory contains a weakly inaccessible cardinal κ, then in $\mathbf{L}$ of that model, κ is strongly inaccessible. Moreover, if some model of set theory contains a strongly inaccessible cardinal κ then the *set* V_κ in that model is itself a model of set theory. Thus, if ZFC proved that there is a strongly inaccessible cardinal, then it would prove that there is a set which is a model of set theory. But then ZFC would prove its own consistency, violating Gödel's Second Incompleteness Theorem.

Let I denote the statement "there is a strongly inaccessible cardinal" and let ZFC + I be the extension of ZFC which includes I as an axiom. Since ZFC + I proves the consistency of ZFC it transcends ZFC in axiomatic strength. Ironically, ZFC + I also proves the consistency of ZFC + ¬I: If κ is the least strongly inaccessible cardinal in a model of set theory, then V_κ is a model of set theory which contains no strongly inaccessible cardinals.

b. Measurability properties of cardinals, and ZFC + M. Let M denote the statement "there is a measurable cardinal," and let ZFC + M be the extension of ZFC which includes M as an axiom. By Ulam's results, ZFC + M proves the consistency of ZFC + I. But ZFC + M is much stronger than ZFC + I. In fact, if in a model of set theory κ is a measurable cardinal, then in that model there are κ many strongly inaccessible cardinals below κ. Also, ZFC + M proves the consistency of ZFC + ¬M: If κ is the least measurable cardinal in a model of set theory, then V_κ is a model of set theory which contains no measurable cardinals.

Solovay showed: If there is a model of set theory in which ZFC + M holds, then there is a model of set theory in which the measure problem has a positive solution. The latter model is obtained by extending the former by means of forcing. He also showed: If there is a model of set theory in which the measure problem has a positive solution, then there is a model of set theory in which ZFC + M holds. The latter is obtained from the former by considering an appropriate inner model. In technical language, "a positive solution of the measure problem is equiconsistent with the existence of measurable cardinals."

Let $\mathbf{V}$ be a model of set theory and let $\mathbf{L}$ be the constructible universe of $\mathbf{V}$. Let κ be an uncountable measurable cardinal in $\mathbf{V}$, and let ν in $\mathbf{V}$ be a two-valued κ-complete measure. Scott showed by 1961 that ν cannot be in $\mathbf{L}$. In 1964 Rowbottom gave another dramatic example of how different $\mathbf{V}$ and $\mathbf{L}$ are: the real numbers which are in $\mathbf{L}$ is a *countable* set of $\mathbf{V}$ (most real numbers of $\mathbf{V}$ are not in $\mathbf{L}$). Kunen showed that $\mathbf{V}$ contains a canonical inner model which satsifies ZFC, contains ν, and in which ν witnesses that κ is a measurable cardinal. It is customary that $\mathbf{L}^\nu$ denote this canonical inner model. (This is analogous to the situation where for a polynomial with rational coefficients the field of complex numbers contains a canonical subfield which contains roots of that polynomial—the corresponding Galois extension of the rationals.)

It is surprising that properties of cardinal numbers much larger than $2^{\aleph_0}$ should have any influence on the real numbers. Which properties of the real line are affected by "large" cardinals? Could large cardinals in conjunction with ZFC for example decide CH?

2. Lebesgue Measurability of Projective Sets of Reals

Lusin showed that Σ^1_1 sets are Lebesgue measurable, and thus so are Π^1_1 sets. But the Σ^1_2- and Π^1_2- sets posed problems. Gödel showed that in $\mathbf{L}$ there is a set of real numbers which is both Σ^1_2 and Π^1_2, and yet not Lebesgue measurable. Is there in every model of set theory a set of real

numbers which is both Σ^1_2 and Π^1_2, and yet not Lebesgue measurable?

C. The Baire Property

Another notion of smallness emerged with the study of continuity: Nowhere denseness and *first category*. A set N of reals is *nowhere dense* if there is for each nonempty open interval U a nonempty open subinterval V such that N is disjoint from V. A set is a first category set if it is a union of countably many nowhere dense sets.

Though first category is a notion of smallness it does not imply small cardinality. One has the following Galilean paradox: The Cantor middle-thirds set has cardinality equal to that of the real line, but it is nowhere dense. Also, first category does not imply measure zero, and *vice versa*. In fact one has the following Galilean paradox: The real line is a union of two sets A and B where A has Lebesgue measure zero and B has first category.

A set S of real numbers is said to have the *Baire property* if there area Borel set B and a first category set F such that $S = (B \setminus F) \cup (F \setminus B)$. Thus, sets having the Baire property differ only "slightly" from Borel sets in that they differ from a Borel set by a first category set of points.

There are sets of real numbers which do not have the Baire property. The first examples were considered pathological. Moreover, there are many analogies between the notions of Lebesgue measure zero and first category. Do projective sets have the Baire property? Are theorems mentioning Lebesgue measurable/measure zero or Baire property/first category in their hypotheses or conclusions true when Lebesgue measurable and Baire property are interchanged, and Lebesgue measure zero and first category are interchanged?

1. Projective Sets and the Baire Property

Each Borel set has the Baire property. Lusin and Sierpiński proved that every Σ^1_1 set has the Baire property, and thus every Π^1_1 set has the Baire property. Gödel showed that in **L** there is a set of real numbers which is both Σ^1_2 and Π^1_2, but does not have the Baire property.

2. Sierpiński's Duality Program

Sierpiński observed that often a theorem remains true when all occurrences of "Lebesgue measure zero" are replaced with "first category" and vice versa. This observation is summarized by saying that "measure and category are dual notions." Erdös and Sierpiński proved that in every model of set theory in which CH holds the following is true: *Let σ be a statement involving only the notions of Lebesgue measure zero, first category, and set theoretic properties, and let σ^* be the statement obtained by interchanging all occurrences of "measure zero" and "first category" in σ. Then σ implies σ^**. The statement in italics is known as the Erdös–Sierpiński duality principle.

Does the duality principle hold in all models of set theory? Rothberger introduced the following combinatorial approach to the problem: Let $\mathcal{N}$ denote the set of all Lebesgue measure zero sets of real numbers, and let $\mathcal{M}$ denote the set of all first category sets of reals. Define the cardinal numbers:

$\mathsf{add}(\mathcal{N})$ The minimal cardinality of a family of measure zero sets whose union is not measure zero;
$\mathsf{cov}(\mathcal{N})$ The minimal cardinality of a family of measurezero sets whose union is the real line;
$\mathsf{unif}(\mathcal{N})$ The minimal cardinality of a set of real numbers which is not of measure zero;
$\mathsf{cof}(\mathcal{N})$ The minimal cardinality of a family of measure zero sets such that each measure zero set is a subset of some member of this family.

The cardinals $\mathsf{add}(\mathcal{M})$, $\mathsf{cov}(\mathcal{M})$, $\mathsf{unif}(\mathcal{M})$, and $\mathsf{cof}(\mathcal{M})$ are defined similarly.

Rothberger proved that in any model of set theory both $\mathsf{cov}(\mathcal{M}) \leq \mathsf{unif}(\mathcal{N})$ and $\mathsf{cov}(\mathcal{N}) \leq \mathsf{unif}(\mathcal{M})$ hold. This is an example of duality: Either statement is obtainable from the other by switching $\mathcal{M}$ and $\mathcal{N}$.

D. Choice and Uniformization

Any nonempty subset S of $A \times A$ can be viewed as a collection of pairwise disjoint sets as follows: For $x \in A$ define $S_x := \{(x, y) : (x, y) \in S\}$. Then the family $\{S_x : x \in A \text{ and } S_x \neq \emptyset\}$ is a collection of pairwise disjoint sets. By the axiom of choice there is a subset B of S which meets each nonempty S_x in exactly one point. It is traditional to say that *B uniformizes S* or that B is a uniformization of S.

If a collection of pairwise disjoint nonempty sets is in some sense simply definable, can a simply definable witness of the choice axiom for this collection be found? In particular, do projective subsets of $\mathbb{R} \times \mathbb{R}$ have projective uniformizations? By 1939 Kondô proved that Π^1_1 subsets of $\mathbb{R} \times \mathbb{R}$ have Π^1_1 uniformizations. This implies that Σ^1_2-sets have Σ^1_2 uniformizations. However, it was not clear if Π^1_2-sets have (any) projective uniformizations.

E. Well-Ordering the Real Line

By 1883 Cantor promoted the idea that every well-defined set can be well-ordered. Zermelo proved from ZF that this statement is equivalent to the axiom of choice. Gödel showed that the axiom of choice holds in **L** and thus cannot be disproved by ZF. Cohen showed that any model of set

theory can be extended to a model of ZF in which the axiom of choice is false. Thus, the axiom of choice also is not provable from the other axioms.

Do simply definable sets have simply definable well-orderings? One way to approach this is as follows: A well-ordering $\prec$ of a set A can be simulated as a subset of $A \times A$:

$$\prec = \{(a, b) \in A \times A : a \prec b\}.$$

Thus when a well-order of a set of reals is viewed as a subset of the plane it makes sense to ask if it is a projective set. It has long been known that only countable sets could have Σ^1_1 well-orderings.

The unit interval is a very simple Borel set. One can use Fubini's theorem and elementary properties of the Lebesgue measure to show that if $\prec$ is any well-ordering of the unit interval, then as a subset of the unit square it is nonmeasurable. This shows that a projective well-ordering of the real line is incompatible with all projective sets being Lebesgue measurable. Similarly one can use the Kuratowski-Ulam theorem (a category analog of Fubini's Theorem) to show that $\prec$ does not have the Baire property.

Gödel showed that in **L** the real line has a Σ^1_2 well-ordering. It follows that there is a Σ^1_2 subset of the plane which is not Lebesgue measurable. D.A. Martin showed that if a set of reals has a Σ^1_2 well-ordering, then it has cardinality at most $\aleph_1$. R.B. Mansfield proved the following very satisfying converse to Gödel's result: If in a model of set theory the real line has a Σ^1_2 well-ordering, then each real number of that model is present in **L**.

F. Determined Sets of Reals

A result of Banach from the 1930s showed that if a set S is determined then it has the Baire property. In the early 1960s Mycielski and Swierczkowski showed that if the set S is determined then it is Lebesgue measurable and Davis showed that the collection of determined sets have the perfect subset property. By the early 1970s it was also known that determined subsets of $\mathbb{R} \times \mathbb{R}$ have certain uniformization properties. Thus, determined sets have all the regularity properties discussed earlier. For a set Γ of subsets of the real line, let *Det*(Γ) denote that each element of Γ is determined.

As was mentioned earlier, all determined sets of reals have the basic regularity properties: They have the Baire property, the Perfect Subset property, they are Lebesgue measurable, and they have uniformization properties. All the proofs follow the same pattern: Associate an appropriate game with a property, code it as a Gale–Stewart game, then show that if either player has a winning strategy, the original set has the appropriate property.

This indicated a way to unite all the classical results about Borel sets and analytic sets: Show that these sets are determined. Work on this started in the 1950s. At first progress was slow. In 1975 D.A. Martin proved that every Borel set is determined. This made the theory of Borel sets part of the theory of determined sets.

Moreover, these properties of determined sets indicated a strategy for showing that the classical problems about projective sets are not decided by ZFC: Find a model of set theory where the appropriate collection of projective sets is determined. Then in this model of set theory projective sets have regularity properties which projective sets fail to have in **L**.

IV. MODERN SET THEORY'S VERDICT

The roots of modern set theory lie in the techniques of constructing inner models (as initiated by Gödel) and extensions of models of set theory (as initiated by Cohen) and of associating certain "large" cardinals with regularity properties of sets of real numbers (as initiated by Ulam) and "small" uncountable cardinals with combinatorial properties of families of sets of reals (as initiated by Rothberger).

A. Descriptive Set Theory, Large Cardinals and Determinacy

Solovay showed that if there is a model of set theory in which ZFC + I holds, then there is a model of set theory in which ZF + "every set of reals is Lebesgue measurable" holds. In the latter model of set theory, the full choice axiom fails but a weak version of it, sufficient to conduct classical analysis survives. He also showed that if there is a model of set theory in which ZFC + I holds, then there is a model of set theory in which every projective set of reals is Lebesgue measurable. Shelah later showed that conversely, if there is a model of set theory in which ZF + "every set of reals is Lebesgue measurable" holds, then there is a model of set theory in which ZFC + I holds. This connected the problem of Lebesgue measurability of all projective sets of real numbers with the notion of a strongly inaccessible cardinal. (We already mentioned Solovay's equiconsistency results regarding existence of measurable cardinals and extendibility of Lebesgue measure.)

These results are not direct implications of the form: If a model of set theory has a measurable cardinal, then such and such is true for sets of real numbers of that model. Instead, one finds that if some model has a targeted property then some potentially different model has some other property.

Some of the beautiful discoveries of modern set theory are to the effect that the presence of certain large cardinals in a model of set theory directly influences the properties of certain sets of real numbers in that same model of set theory. Here is an example: Suppose a model of set theory contains a measurable cardinal. By Rowbottom's theorem,

the set of real numbers of **L** of that model is countable. By Mansfield's theorem, if the set of real numbers of a model has a Σ^1_2 well-ordering, then all the reals of that model are in **L** for that model. Thus: If a model of set theory has a measurable cardinal, then the set of reals of that model does not have a Σ^1_2 well-ordering.

Here is another example: Martin showed that if a model of set theory has a measurable cardinal, then every Π^1_1 set of reals of that model is determined. This implies that every Π^1_1-set has the Perfect Subset property, and more since Kechris and Martin proved that if each Π^1_n-set of reals is determined, then each Σ^1_{n+1} set of reals is Lebesgue measurable, has the Baire property, and has the perfect subset property. Thus: If a model of set theory has a measurable cardinal, then every Σ^1_2 set of real numbers is Lebesgue measurable, has the Baire property, andΣ^1_2 has the perfect subset property.

New techniques developed by Foreman, Magidor and Shelah pointed the way to new breakthroughs regarding projective sets of real numbers. Woodin isolated the essential large cardinal property which underlies proofs of determinacy of certain projective sets. The cardinals having the (very technical) property isolated by Woodin are now called Woodin cardinals. Shelah and Woodin showed that for each n: In a model of set theory where there are n Woodin cardinals as well as a measurable cardinal above them all, each Σ^1_{n+2} set of reals is Lebesgue measurable. Martin and Steele then proved the following strengthening: For each n: In a model of set theory which has n Woodin cardinals as well as a measurable cardinal above them all each Π^1_{n+1} set of reals is determined. Moreover, they showed that it is necessary to have the measurable cardinal above the n Woodin cardinals. For they showed that if there is a model of set theory with n Woodin cardinals in it, then there is amodel of set theory with n Woodin cardinals in which the real line has a Σ^1_{n+2} well-ordering. This well-ordering is not Lebesgue measurable, and so by the Kechris-Martin theorem there is an undetermined Π^1_{n+1} set. Woodin finally proved the beautiful theorem that there is a model of set theory in which there are infinitely many Woodin cardinals if, and only if, there is a model of (ZF) set theory in which *every* set of real numbers is determined.

In view of these direct influences of large cardinals on properties of sets of real numbers one may suspect that large cardinals may directly imply something about the cardinality of the set of reals. Thus far no large cardinal ever considered had this effect. For measurable cardinals the canonical inner model for a measurable cardinal satisfies CH. Levy and Solovay also showed that given a model of set theory in which there is a measurable cardinal, it can be extended to a model in which that cardinal is still measurable, but CH fails. Thus, ZFC + M does not decide the cardinality of the real line.

B. Combinatorial Set Theory, Singular Cardinals and pcf Theory

The question whether the Singular Cardinal Hypothesis holds in every model of set theory is also intimately connected with measurable cardinals. It was namely proved that there is a model of set theory in which the Singular Cardinal Hypothesis fails if, and only if, there is a model of set theory which contains a measurable cardinal of a specific kind. The method of proof was typical: For one implication find an appropriate inner model, for the other find an appropriate extension. Moreover, Foreman and Woodin showed that if there is a model of set theory in which there are appropriate large cardinals, then there is a model of set theory where for each infinite cardinal κ, $2^\kappa > \kappa^+$.

Could Silver's theorem fail at some singular cardinal of countable cofinality? By forcing Magidor obtained from a model of set theory containing certain large cardinals a model of set theory in which for each n $2^{\aleph_n} = \aleph_{n+1}$, but $2^{\aleph_\omega} = \aleph_{\omega+2}$. Extending Magidor's work, Shelah obtained from a model of set theory containing certain large cardinals for each infinite $\alpha < \omega_1$ a model of set theory in which for each n $2^{\aleph_n} = \aleph_{n+1}$, but $2^{\aleph_\omega} = \aleph_{\alpha+1}$.

Shelah showed that for singular κ of countable cofinality ZFC imposes restrictions similar to those for singular cardinals of uncountable cofinality (as in the Galvin-Hajnal theorem) on 2^κ. For example: If for each n $2^{\aleph_n} < \aleph_\omega$ then $2^{\aleph_\omega} < \aleph_{(2^{\aleph_0})^+}$. Recently Shelah proved one of the most surprising results in cardinal arithmetic: $2^{\aleph_0} < \aleph_\omega$ implies that $\aleph_\omega^{\aleph_0} < \aleph_{\omega_4}$. It is not clear whether ω_4 is optimal. These ZFC results are a small illustration of the power of pcf theory, a new branch of combinatorial set theory.

It is unknown if $2^{\aleph_\omega}$ could exceed $\aleph_{\omega_1}$ if for each n $2^{\aleph_n} < \aleph_\omega$.

C. Combinatorial Set Theory and the Duality Program

The Sierpiński–Rothberger duality program also saw incredible development since the early 1980s. To give a flavor of this large area of research in set theory, we introduce two more combinatorially defined cardinal numbers. First, let ${}^\omega\omega$ denote the set of functions from ω to ω. For f and g such functions, $f \prec g$ denotes that $\lim_{n\to\infty}(g(n) - f(n)) = \infty$.

The symbol $\mathfrak{b}$ denotes the minimal cardinality attainable by families $\mathcal{F}$ of elements of ${}^\omega\omega$ which have the following property: There is no g in ${}^\omega\omega$ such that for each $f \in \mathcal{F}$, $f \prec g$ holds. The symbol $\mathfrak{d}$ denotes the minimal cardinality attainable by families $\mathcal{G}$ of elements of ${}^\omega\omega$ which have the following property: For each f in ${}^\omega\omega$, there is a $g \in \mathcal{G}$ such that $f \prec g$.

Rothberger proved that $\mathfrak{b}$ and $\mathfrak{d}$ are related to Lebesgue measure and first category: $\mathfrak{b} \leq \mathsf{unif}(\mathcal{M})$ and

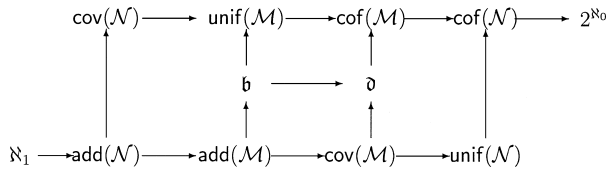

FIGURE 2 Cichoń's diagram.

$\mathrm{cov}(\mathcal{M}) \leq \mathfrak{d}$. It follows from their definitions that also $\mathfrak{b} \leq \mathfrak{d}$.

Early in the 1980s Miller proved that $\mathrm{add}(\mathcal{M}) = \min\{\mathfrak{b}, \mathrm{cov}(\mathcal{M})\}$ and that $\mathrm{cof}(\mathcal{M}) = \max\{\mathfrak{d}\}, \mathrm{unif}(\mathcal{M})\}$. Soon after Bartoszyński an independently Raisonnier and Stern proved that in every model of set theory $\mathrm{add}(\mathcal{N}) \leq \mathrm{add}(\mathcal{M})$ and $\mathrm{cof}(\mathcal{M}) \leq \mathrm{cof}(\mathcal{N})$. The surveyed results are summarized if Fig. 2. In this diagram an arrow indicates that in any model of set theory the cardinal at the initial point of the arrow is no larger than the cardinal at its terminal point.

These results indicate how to proceed to find models of set theory in which Sierpiński's duality principle fails. By the Bartoszyński–Raisonnier-Stern theorem, $\mathrm{add}(\mathcal{N}) \leq \mathrm{cov}(\mathcal{M})$ is true in any model of set theory. Thus, if the Sierpiński duality principle were true in all models of set theory, then also $\mathrm{add}(\mathcal{M}) \leq \mathrm{cov}(\mathcal{N})$ should be true in all models of set theory. Similarly, since $\mathrm{unif}(\mathcal{M}) \leq \mathrm{cof}(\mathcal{N})$ is true in all models of set theory, also $\mathrm{unif}(\mathcal{N}) \leq \mathrm{cof}(\mathcal{M})$ should be true in all models of set theory. Cohen's forcing method was used to show that ZFC does not decide any other relationships than those depicted in Fig. 2. For example, ZFC does not decide either of the inequalities $\mathrm{add}(\mathcal{M}) \leq \mathrm{cov}(\mathcal{N})$ or $\mathrm{cov}(\mathcal{N}) \leq \mathrm{add}(\mathcal{M})$. These were the first examples of "asymmetry" between measure and category given by the combinatorial agenda.

Does ZFC determine anything about the cofinalities of the cardinals in Fig. 2? For all but $\mathrm{cov}(\mathcal{N})$ it was known that these cardinals must have countable cofinality. Only late in the 1990's Shelah finally showed by forcing how to obtain from a model of set theory one in which $\mathrm{cov}(\mathcal{N}) = \aleph_\omega$.

During the 1980s and 1990s it was discovered that some of the cardinal numbers in Fig. 2 are intimately related with open covering properties of topological spaces. In the 1920s the dimension theorists Menger and Hurewicz each introduced a covering property that emerged from their research. Hurewicz showed that $\mathfrak{b}$ is the minimal cardinality of a set of reals not having his covering property, and that $\mathfrak{d}$ is the minimal cardinality of a set of real numbers not having Menger's covering property. In 1938 Rothberger introduced covering properties motivated by his study of a 1919 conjecture by Borel. In the 1980's Fremlin and Miller showed that $\mathrm{cov}(\mathcal{M})$ is the minimal cardinality of a set of real numbers which does not have the Rothberger property. In 1981 Gerlitz and Nagy introduced a covering property in connection with their study of pointwise convergence properties of continuous functions. In the 1990s Nowik, Weiss, and Scheepers showed that a set of real numbers has the Gerlitz–Nagy covering property if, and only if, it has both Hurewicz's and Rothberger's covering properties. It follows that $\mathrm{add}(\mathcal{M})$ is the minimal cardinality for a set of real numbers not having the Gerlitz–Nagy covering property.

V. CONCLUSION

It is curious that the central concept which gave rise to set theory, the notion of a one-to-one function from one set onto another, laid dormant for over two centuries after Galilei's published observations. Carl Boyer says in his well-known history book that "Galileo, like Moses, came within site of the promised land, but he could not enter it."

Though this survey attempted to be comprehensive, time- and space-constraints necessitated neglecting mention of very important work of many able set theorists. Also, many applications of set theory to other areas of mathematics had to be overlooked. Some of this material can be gleaned from the textbooks listed in the bibliography.

Solitons

A. S. Fokas
University of Cambridge

GLOSSARY

Dromion A particular solution of a nonlinear evoluation equation in two space variables which is localized in space and which moves in certain predetermined tracks (Greek "dromos").

Integrable evolution equations A distinctive class of nonlinear evolution equations which can be analyzed exactly using the inverse scattering method.

Inverse scattering transform method A method which can be used to solve the initial value problem on the infinite line for a nonlinear integrable evolution equation. It is a nonlinear generalization of the Fourier transform method.

Riemann–Hilbert problem A mathematical problem in the theory of complex-valued analytic functions.

Soliton A particular solution of a nonlinear equation which is localized in space and which retains its shape upon interaction with any other localized disturbance.

THE SOLITON was discovered in 1965 by Zabusky and Kruskal, who also introduced this name in order to emphasize the analogy with particles ("soli" for solitary and "tons" for particles). Solitons appear in a surprisingly large number of physical circumstances, including fluid mechanics, nonlinear optics, plasma physics, quantum field theory, relativity, elasticity, biological models, and nonlinear networks (Crighton, 1995). This is a consequence of the fact that a soliton is the realization of a certain physical coherence which is natural to a variety of nonlinear phenomena. These phenomena are modeled by ordinary differential equations (ODEs), partial differential equations (PDEs), singular integrodifferential equations, difference equations, cellular automata, etc. In this review we will concentrate on the occurrence of solitons in nonlinear evolution equations in one and two space dimensions.

I. INTRODUCTION

A soliton was first observed in 1834 by a British experimentalist, J. Scott Russell. He first observed a soliton while riding on horseback beside a narrow barge channel. When the boat he was observing stopped, Russell (1844, p. 311) noted that it set forth "a large solitary elevation, a rounded, smooth and well-defined heap of water, which continued its course along the channel apparently without change

of form or diminution of speed ... Such, in the month of August 1834, was my first chance interview with that singular and beautiful phenomenon." Russell, impressed by this phenomenon challenged the theoreticians of the day to explain this discovery: "It now remained to the mathematicians to predict the discovery after it happened, that is to give an a priori demonstration a posterori." This work created a controversy which, in fact, lasted almost 50 years. It was resolved by Korteweg and deVries (1895), who derived the KdV equation as an approximation to water waves,

$$\frac{\partial q}{\partial t} + 6q\frac{\partial q}{\partial x} + \frac{\partial^3 q}{\partial x^3} = 0. \tag{1}$$

This equation is a nonlinear PDE of the evolution type, where t and x are related to time and space respectively, and $q(x,t)$ is related to the height of the wave above the mean water level (see Fig. 1). The controversy was resolved because it was shown by Korteweg and deVries (1895) that Eq. (1) supports a particular solution exhibiting the behavior described by Russell. This solution, which was later called the one-soliton solution, is given by

$$q_1(x - p^2 t) = \frac{p^2/2}{\cosh^2\left[\frac{1}{2}p(x - p^2 t) + c\right]}, \tag{2}$$

where p and c are constants. The location of this soliton at time t, i.e., its maximum position, is given by $p^2 t - c/p$, its velocity is given by p^2, and its amplitude by $p^2/2$. Thus, faster solitons are higher and narrower. It should be noted that q_1 is a *traveling wave* solution, i.e., q_1 depends only on the variable $X = x - p^2 t$, thus in this case the PDE (1) reduces (after integration) to the second-order ODE

$$-p^2 q_1(X) + 3q_1^2(X) + \frac{d^2 q_1}{dX^2}(X) = 0.$$

Under the assumption that q and dq/dX tend to zero as $|X| \to \infty$, this ODE yields the solution given by Eq. (2). The problem of finding a solution describing the interaction of two one-soliton solutions is much more difficult and was not addressed by Korteweg and deVries.

The KdV equation is a particularly natural equation combining a simple dispersion with a typical quadratic convective nonlinearity. Actually, this equation is *generic*, in a sense to be explained later, and hence appears in a wide variety of applications. It is therefore surprising that the first new application, other than water waves, was as late as 1960 in plasma physics. Shortly thereafter Kruskal and Zabusky (1965), while trying to understand some puzzling experimental results of Fermi, Pasta, and Ulam, derived the KdV equation as a continuous approximation of a certain anharmonic lattice. Studying numerically the

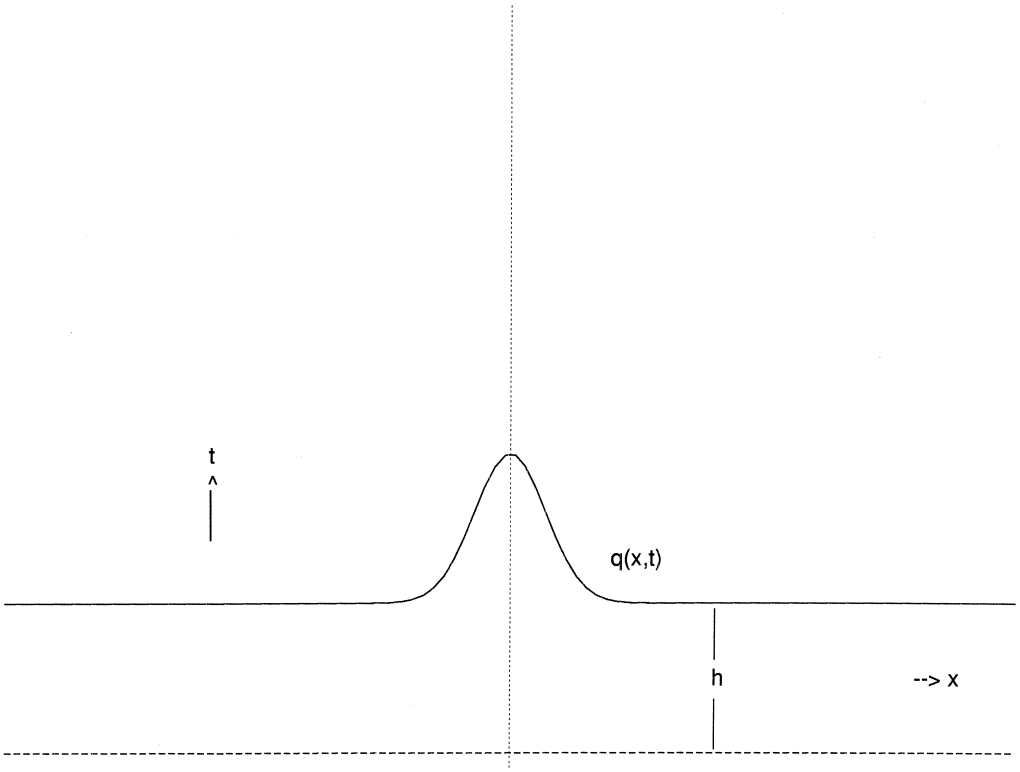

FIGURE 1 The modeling of water waves by the KdV.

interaction of two solutions of the form (2) (i.e., two solutions corresponding to two different p_1 and p_2), they discovered the defining property of solitons: After interaction these waves regained exactly the shapes they had before. This posed a new challenge to mathematicians, namely to explain analytically the interaction properties of such coherent waves. In order to resolve this challenge one needs to develop a larger class of solutions than the one-soliton solution. We note that Eq. (1) is nonlinear and no effective method to solve such nonlinear equations existed at that time.

Gardner *et al*. (1967) not only derived an explicit solution describing the interaction of an arbitrary number of solitons, but also discovered what was to evolve into a new method of mathematical physics. Regarding the explicit solution, we note that the two-soliton solution is given by

$$q_2(x,t) = \frac{2\left(p_1^2 e^{\eta_1} + p_2^2 e^{\eta_2}\right) + 4e^{\eta_1+\eta_2}(p_1-p_2)^2 + 2A_{12}\left(p_2^2 e^{2\eta_1+\eta_2} + p_1^2 e^{\eta_1+2\eta_2}\right)}{\left(1 + e^{\eta_1} + e^{\eta_2} + A_{12}e^{\eta_1+\eta_2}\right)^2}, \tag{3}$$

where

$$\eta_j = p_j x - p_j^3 t + \eta_j^0, \quad j = 1,2; \quad A_{12} = \frac{(p_1-p_2)^2}{(p_1+p_2)^2},$$

with p_j and η_j^0 constants. A snapshot of this solution with $p_1 = 1$, $p_2 = 2$ is given in Fig. 2. After some time the taller soliton will overtake the shorter one and the only effect of the interaction will be a "phase shift," i.e., a change in the position the two solitons would have reached without interaction. These statements can be verified analytically:

a. Comoving with soliton 1. Replace x by the new variable $\xi = x - p_1^2 t$ and let $t \to \pm\infty$; in this frame η_1 is constant and $\eta_2 \to \mp\infty$,

$$t \to +\infty: \quad q \to \frac{p_1^2/2}{\cosh^2\left(\frac{1}{2}\eta_1\right)}.$$

$$t \to -\infty: \quad q \to \frac{p_1^2/2}{\cosh^2\left(\frac{1}{2}\eta_1 + \frac{1}{2}\varphi_{12}\right)}, \quad \varphi_{12} = \ln(A_{12}).$$

b. Comoving with soliton 2. Replace x by the new variable $\xi = x - p_2^2 t$ and let $t \to \pm\infty$; in this frame η_2 is constant and $\eta_1 \to \pm\infty$,

$$t \to -\infty: \qquad q \to \frac{p_2^2/2}{\cosh^2\left(\frac{1}{2}\eta_2\right)}.$$

$$t \to +\infty: \qquad q \to \frac{p_2^2/2}{\cosh^2\left(\frac{1}{2}\eta_2 + \frac{1}{2}\varphi_{12}\right)}.$$

The positions of soliton 1 at $+\infty$ and at $-\infty$ are given by $\frac{1}{2}(p_1 x - p_1^3)t$ and $\frac{1}{2}[p_1(x + \varphi_{12}/p_1) - p_1^3 t]$, respectively; thus there exists a phase shift of φ_{12}/p_1. Similarly for soliton 2.

Regarding the general method introduced by Gardner *et al*. (1967), we note that if Eq. (1) is formulated on the infinite line, then the most interesting problem is the

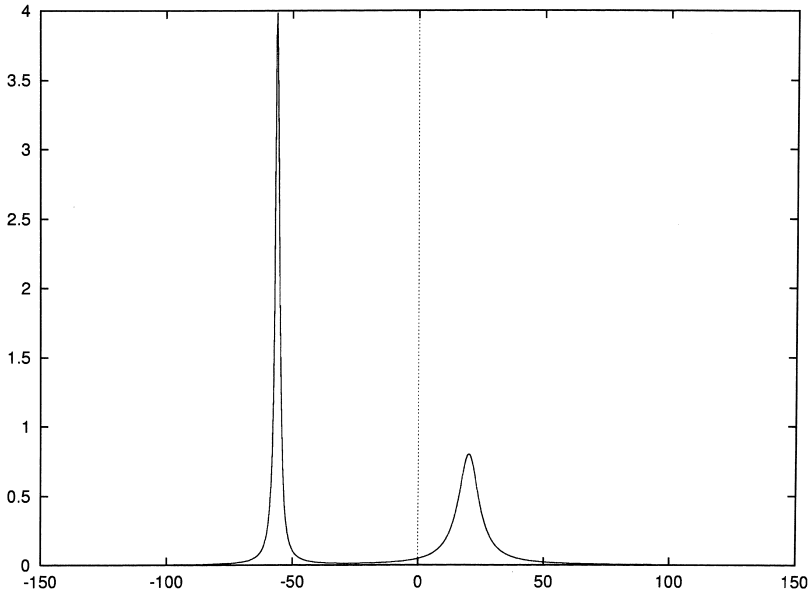

FIGURE 2 A two-soliton solution for the KdV.

solution of the initial-value problem: Given initial data $q(x,0)=q_0(x)$ which decay as $|x|\to\infty$, find $q(x,t)$, i.e., find how these data evolve under the nonlinear PDE (1). If q_0 is small and qq_x can be neglected, then Eq. (1) becomes linear and $q(x,t)$ can be found using the Fourier transform,

$$q(x,t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{ikx+ik^3t}\hat{q}_0(k)\,dk, \tag{4a}$$

where

$$\hat{q}_0(k)=\int_{-\infty}^{\infty}e^{-ikx}q_0(x)\,dx. \tag{4b}$$

The remarkable discovery of Gardner *et al.* (1967) is that for Eq. (1) there exists a nonlinear analogue of the Fourier transform capable of solving the initial value problem even if q_0 is not small. Unfortunately, this nonlinear Fourier transform cannot in general be written in closed form, thus $q(x,t)$ in general can be expressed through the solution of a linear integral equation, or more precisely through the solution of a 2×2 matrix Riemann–Hilbert problem as will be explained in Section IV. This linear integral equation is uniquely specified in terms of $q_0(x)$. For particular initial data, $q(x,t)$ can be written explicitly. For example if $q_0(x)=q_1(x)$, where $q_1(x)$ is obtained by evaluating Eq. (2) at $t=0$, then $q(x,t)=q_1(x-p^2t)$. Similarly, if $q_0(x)=q_2(x,0)$, where $q_2(x,0)$ is obtained by evaluating Eq. (3) at $t=0$, then $q(x,t)=q_2(x,t)$.

A most important question, both physically and mathematically, is the description of the long-time behavior of the solution of the above initial value problem. If the nonlinear term of Eq. (1) can be neglected, one finds a linear dispersive equation. In this case different waves travel with different wave speeds, these waves cancel each other out, and the solution decays to zero as $t\to\infty$. Indeed, using the stationary phase method to compute the large-t behavior of the integral appearing in Eq. (4a), we can show that $q(x,t)$ decays like $0(1/\sqrt{t})$ as $t\to\infty$, $x/t=O(1)$. The situation with the KdV equation is more interesting: dispersion is balanced by nonlinearity and $q(x,t)$ has a nontrivial asymptotic behavior as $t\to\infty$. Indeed, using a nonlinear analogue of the steepest descent method discovered by Deift and Zhou (see Fokas and Zakharov, 1993) to analyze the Riemann–Hilbert problem mentioned earlier, it can be shown that $q(x,t)$ asymptotes to $q_N(x,t)$, where $q_N(x,t)$ is the exact N-soliton solution. This underlines the physical and mathematical significance of solitons: *They are the coherent structures emerging from any initial data as* $t\to\infty$. This implies that if a nonlinear phenomenon is modeled by the KdV equation on the infinite line, then one can immediately predict the structure of the solution as $t\to\infty$, $x/t=O(1)$: It will consist of N ordered single solitons, where the highest soliton occurs to the right; the number N and the parameters p_j and η_j^0 depend on the particular initial data $q_0(x)$.

So far we have concentrated on the KdV equation. However, there exist numerous other equations which exhibit similar behavior. Such equations are called *integrable* and the method of solving their initial value problem is called the *inverse scattering* or *inverse spectral* method. Some of these equations together with some typical soliton solutions will be given in Section III. The inverse spectral method will be introduced in Section IV. The extension of this method to boundary value problems will be briefly discussed in Section V. In the next section we present a brief historical review of some of the important developments of soliton theory.

II. IMPORTANT DEVELOPMENTS IN SOLITON THEORY

Were the results of Gardner *et al.* (1967) a fluke, or were there other equations which could be solved in a similar way? Before this question could be answered it was necessary to extract the essence of this ingenious discovery. This was done by Lax (1968), who introduced the so-called Lax pair formulation of the KdV, namely Eq. (1) can be written as the compatibility condition of the following pair of linear eigenvalue equations for the eigenfunction $\psi(x,t,k)$:

$$\psi_{xx}+(q+k^2)\psi=0, \tag{5a}$$

$$\psi_t+(2q-4k^2)\psi_x-q_x\psi=0. \tag{5b}$$

The nonlinear Fourier transform mentioned in Section I can be obtained by performing the spectral analysis of Eq. (5a), while Eq. (5b) is used only for the determination of the time evolution of the nonlinear Fourier data, which are now called spectral data (see Section IV). Following Lax's formulation, Zakharov and Shabat (1972) solved the nonlinear Schrödinger (NLS) equation

$$iq_t+q_{xx}-2\lambda|q|^2q=0,\qquad \lambda=\pm 1 \tag{6}$$

which has ubiquitous physical applications including nonlinear optics. Soon thereafter the sine-Gordon equation

$$q_{xx}-q_{tt}=\sin q \tag{7}$$

and the modified KdV equation

$$q_t+6q^2q_x+q_{xxx}=0 \tag{8}$$

were solved (Ablowitz *et al.*, 1973; Wadati, 1972). Since then numerous nonlinear equations have been solved. Thus the mathematical technique introduced by the authors of Gardner *et al.* (1967) for the solution of a particular physical equation was applicable to a wide range

of other problems. In this way a new method in mathematical physics was born, the so-called inverse scattering (spectral) method. Among the most important equations solved by this method are a particular two-dimensional reduction of Einstein's equation and the self-dual Yang–Mills equations (Ablowitz and Clarkson, 1991).

The next important development in the theory of integrable equations was the study of the KdV with space-periodic initial data. This occurred in the mid 1970s (Belokolos *et al*., 1994). This method involves algebraic–geometric techniques; in particular, there exists a periodic analogue of the N-soliton solution which can be expressed in terms of a certain Riemann-theta function of genus N.

In the mid 1970s it was also realized that there exist *integrable ODEs*. For example, a stationary reduction of some of the equations introduced in connection with the space-periodic problem mentioned above led to the integration of some classical tops. Furthermore, the similarity reduction of some of the integrable PDEs led to the classical Painlevé equations. For example, letting $q = t^{-1/3}u(\xi)$, $\xi = xt^{-1/3}$ in the modified KdV equation (8) and integrating, we find

$$\frac{d^2u}{d\xi^2} + \frac{1}{3}\xi u + 3u^2 + \alpha = 0, \tag{9}$$

where α is a constant. This is Painlevé II, i.e., the second equation in the list of six classical ODEs introduced by Painlevé and his school around 1900. These equations are nonlinear analogues of the linear special functions such as Airy, Bessel, etc. The connection between integrable PDEs and ODEs of the Painlevé type was established by Ablowitz and Segur (1997). Their work marked a new era in the theory of these equations. Indeed, soon thereafter, Flaschka and Newell (1980) introduced an extension of the inverse spectral method, the so-called isomonodromy method, capable of integrating these equations. This method can also be used to construct nonlinear analogues of the classical connection formulas that exist for the linear special functions. For example, the Airy equation $u_{\xi\xi} = \xi u$ has the following asymptotic behavior:

$$x \to -\infty: \quad u(x) \sim \alpha(-x)^{-1/4} \sin\left[\frac{2}{3}(-x)^{3/2} + \varphi\right], \qquad \alpha < 0, \quad 0 \le \varphi < 2\pi.$$

$$x \to \infty: \quad u(x) \sim \alpha \sin\left(\varphi - \frac{\pi}{4}\right) x^{-1/4} \exp\left(\frac{2}{3}x^{3/2}\right), \qquad \varphi \ne \frac{\pi}{4}, \quad \varphi \ne \frac{5\pi}{4}.$$

Using the isomonodromy method, one can obtain the following nonlinear analogue of these formulas for Painlevé II:

$$x \to -\infty: \quad u(x) \sim \alpha(-x)^{-1/4} \times \sin\left[\frac{2}{3}(-x)^{3/2} + \frac{3}{4}\alpha^2 \ln(-x) + \varphi\right].$$

$$x \to +\infty: \quad u(x) \sim \pm\sqrt{\frac{x}{2}} \pm (2x)^{-1/4}\rho \times \cos\left[\frac{2\sqrt{2}}{3}x^{3/2} - \frac{3}{2}\rho^2 \ln x + \theta\right],$$

where ρ, θ, and s are defined respectively by

$$\rho^2 = \frac{1}{\pi} \ln \frac{1 + |s|^2}{2|\mathrm{Im}\, s|},$$

$$\theta = -\frac{3\pi}{4} - \frac{7}{2}\rho^2 \ln 2 + \arg \Gamma(i\rho^2) + \arg(1 + s^2),$$

$$s = \left(e^{\pi\alpha^2} - 1\right)^{1/2} \times \exp\left[i\frac{3}{2}\alpha^2 \ln 2 - \frac{i\pi}{4} - i \arg \Gamma\left(\frac{i\alpha^2}{2}\right) - i\varphi\right],$$

and Γ denotes the gamma function.

It was mentioned in Section I that the inverse spectral method gives rise to a matrix Riemann–Hilbert (RH) problem. A RH problem involves the determination of a function analytic in given sectors of the complex plane from the knowledge of the jumps of this function across the boundaries of these sectors. The algebraic–geometric method for solving the space-periodic initial value problem can be interpreted as formulating a RH problem which can be analyzed using functions defined on a Riemann surface. Also the isomonodromy method yields a novel RH problem (Fokas and Zhou, 1992). This implies the following interesting unification: Self-similar, decaying, and periodic initial value problems for integrable evolution equations in one space variable lead to the study of the same mathematical object, namely to the RH problem.

Every integrable nonlinear evolution equation in one spatial dimension has several integrable versions in two spatial dimensions. Two such integrable physical generalizations of the Korteweg–deVries equation are the so-called Kadomtsev–Petviashvili I (KPI) and II (KPII) equations. In the context of water waves they arise in the weakly nonlinear, weakly dispersive, weakly two-dimensional limit, and in the case of KPI when the surface tension is dominant. The nonlinear Schrödinger equation also has two physical integrable versions, known as the Davey–Stewartson I (DSI) and the DSII equations. They can be derived from the classical water wave problem in the shallow-water limit and govern the time evolution of the free surface envelope in the weakly nonlinear, weakly two-dimensional, nearly monochromatic limit. The KP and DS equations have several other physical applications.

A method for solving the Cauchy problem for decaying initial data for integrable evolution equations in two spatial dimensions emerged in the early 1980s. This method is sometimes referred to as the $\bar{\partial}$ (d-bar) method. Recall that the inverse spectral method for solving nonlinear evolution equations on the line is based on a matrix RH problem. This problem expresses the fact that there exist solutions of the associated x part of the Lax pair which are sectionally analytic. Analyticity survives in some multidimensional problems: it was shown formally by Manakov and by Fokas and Ablowitz that KPI gives rise to a *nonlocal RH problem*. However, for other multidimensional problems, such as the KPII, the underlying eigenfunctions are nowhere analytic and the RH problem must be replaced by the $\bar{\partial}$ (d-bar) problem. Actually, a $\bar{\partial}$ problem had already appeared in the work of Beals and Coifman, where the RH problem appearing in the analysis of one-dimensional systems was considered as a special case of a $\bar{\partial}$ problem. Soon thereafter it was shown (Ablowitz *et al*., 1983) that KPII required the essential use of the $\bar{\partial}$ problem. The situation for the DS equations is analogous to that of the KP equations.

The analysis of integrable singular integrodifferential equations and of integrable discrete equations, although conceptually similar to the analysis reviewed above, has certain novel features (Ablowitz and Clarkson, 1991).

The fact that integrable nonlinear equations appear in a wide range of physical applications is *not* an accident but a consequence of the fact that these equations express a certain physical coherence which is natural, at least asymptotically, to a variety of nonlinear phenomena. Indeed, Calogero and Eckhaus (see Fokas and Zakharov, 1993) showed that large classes of nonlinear evolution PDEs, characterized by a dispersive linear part and a largely arbitrary nonlinear part, after rescaling yield asymptotically equations (for the amplitude modulation) having a universal character. These "universal" equations are, therefore, likely to appear in many physical applications. Many integrable equations are precisely these "universal" models.

Related Developments

In the above review we concentrated on analytical aspects of integrable equations. However, it must be emphasized that the study of the rich mathematical structure associated with integrable equations has had a tremendous impact in modern mathematics. Examples include the following:

- The study of the space-periodic problem led to the discovery of new algebraic–geometric results such as the explicit construction of the so-called Baker–Akhiezer function. Furthermore, it has led to the explicit characterization of surfaces of constant mean curvature in connection with the Hopf conjecture.
- The study of space-periodic solutions of the KP equation has led to the solution of the Schottky classical problem of characterizing Riemann matrices in the theory of Riemann surfaces.
- The study of the quantum analogues of the classical integrable models led to beautiful connections between the Yang–Baxter equation and the Bethe ansatz, and also led to the discovery of the quantum groups.
- The study of the Hamiltonian and bi-Hamiltonian formulation of integrable equations led to novel Poisson structures and to beautiful connections with Kac–Moody–Virasoro algebras.

III. COHERENT STRUCTURES

Solitons are important *not* because they are exact solutions, but because they characterize the long-time behavior of integrable evolution equations in one space dimension. There exist two types of localized coherent structures associated with integrable evolution equations in two spatial variables: the *lumps* and the *dromions*. These solutions play a role similar to the role of solitons, namely they also characterize the long-time behavior of integrable evolution equations in two space dimensions (Fokas and Ablowitz, 1983; Fokas and Santini, 1990). The question of solving the initial value problem of a given integrable PDE and then extracting the long-time behavior of the solution is quite complicated and it involves spectral analysis and the formulation of either a RH problem or of a d-bar problem. On the other hand, having established the importance of solitons, lumps, and dromions, it is natural to develop methods for obtaining these particular solutions directly, avoiding the difficult approaches of spectral theory. There exist several such direct methods, including the so-called Bäcklund transformations, the dressing method of Zakharov and Shabat, the direct linearizing method of Fokas and Ablowitz, and the bilinear approach of Hirota.

A. Solitons

Using the bilinear approach, Hietarinta (in press) gave multisoliton solutions for a large class of integrable nonlinear PDEs in one space dimension. Here we only note that the one-soliton solution of the nonlinear Schrödinger equation (6), of the sine-Gordon equation (7), and of the modified KdV equation (8) are given, respectively, by

$$q(x,t) = \frac{p_R e^{i[p_I x + (p_R^2 - p_I^2)t + \eta]}}{\cosh[p_R(x - 2p_I t) + \eta]}, \qquad (10)$$

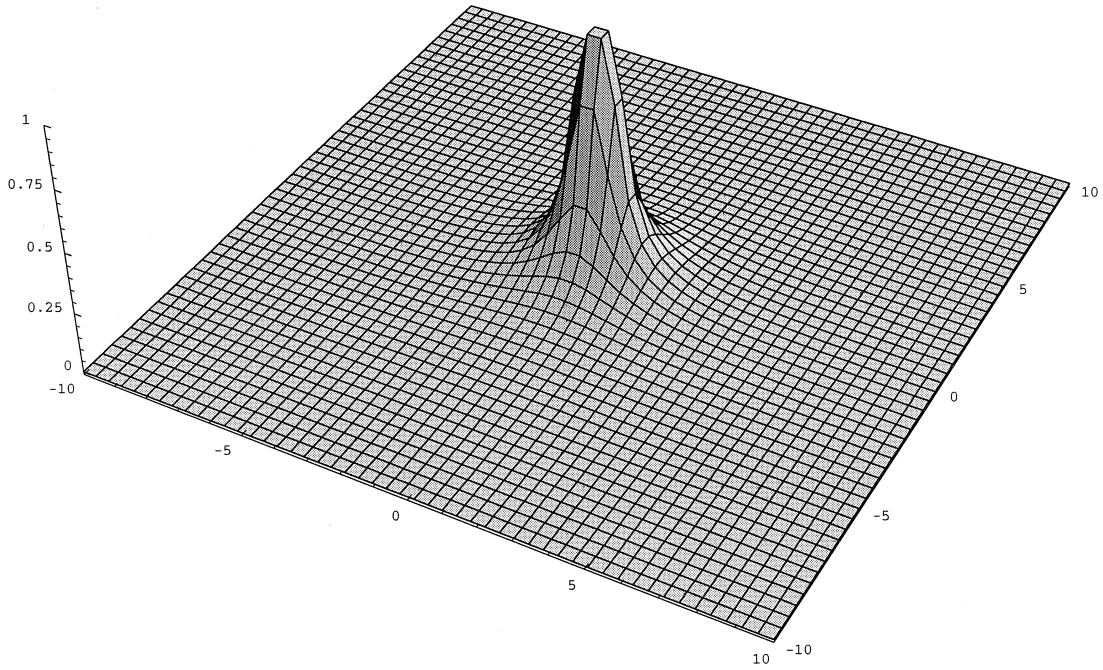

FIGURE 3 A one-lump solution for the DSII equation.

$$q(px+qt) = 4\arctan[e^{px+qt+\eta}], \quad p^2 = 1+q^2, \tag{11}$$

$$q(x-p^2t) = \frac{\pm p}{\cosh[px-p^2t+\eta]}, \tag{12}$$

where p_R, p_I, η, p, and q are real constants.

B. Lumps

The KPI equation is

$$\partial_x[q_t + 6qq_x + q_{xxx}] = 3q_{yy}. \tag{13}$$

The one-lump solution of this equation is given by

$$q(x,y,t) = 2\partial_x^2 \ln\left[|L(x,y,t)|^2 + \frac{1}{4\lambda_I^2}\right],$$
$$L = x - 2\lambda y + 12\lambda^2 t + a, \tag{14}$$
$$\lambda = \lambda_R + i\lambda_I, \qquad \lambda_I > 0,$$

where λ and a are complex constants. Several types of multilump solutions are given by Ablowitz and Villaroel (1997).

The focusing DSII equation is

$$iq_t + q_{zz} + q_{\bar{z}\bar{z}} - 2q\left(\partial_{\bar{z}}^{-1}|q|_z^2 + \partial_z^{-1}|q|_{\bar{z}}^2\right) = 0, \tag{15}$$

where $z = x + iy$, and the operator $\partial_{\bar{z}}^{-1}$ is defined by

$$\left(\partial_{\bar{z}}^{-1} f\right)(z,\bar{z}) = \frac{1}{2i\pi}\int_{\mathbb{R}^2} \frac{f(\zeta,\bar{\zeta})}{\zeta - z}\, d\zeta \wedge d\bar{\zeta}.$$

The one-lump solution of this equation is given by

$$q(z,\bar{z},t) = \frac{\beta e^{i(p^2+\bar{p}^2)t+pz-\bar{p}\bar{z}}}{|z+\alpha+2ipt|^2+|\beta|^2}, \tag{16}$$

where α, β, and p are complex constants. A typical one-lump solution is depicted in Fig. 3.

C. Dromions

The DSI equation is

$$iq_t + \left(\partial_x^2 + \partial_y^2\right)q + qu = 0, \qquad u_{xy} = 2\left(\partial_x^2 + \partial_y^2\right)|q|^2. \tag{17}$$

The one-dromion solution of this equation is given by

$$q(x,y,t) = \frac{\rho e^{X-\bar{Y}}}{\alpha e^{X+\bar{X}} + \beta e^{-Y-\bar{Y}} + \gamma e^{X+\bar{X}-Y-\bar{Y}} + \delta},$$
$$X = px + ip^2t, \qquad Y = qy + iq^2t, \tag{18}$$
$$|\rho|^2 = 4p_Rq_R(\alpha\beta - \gamma\delta),$$

where p and q are complex constants and α, β, γ, and δ are positive constants. Several types of multidromion solutions are given by Hietarinta (in press).

We conclude this section by noting that there exists another type of generalized soliton in two dimensions, namely the so-called *line-solitons*. These solutions can be constructed from the usual solitons by adding an appropriate y dependence. For example a line-soliton of the KPI equation is given by Eq. (2) where the argument of cosh

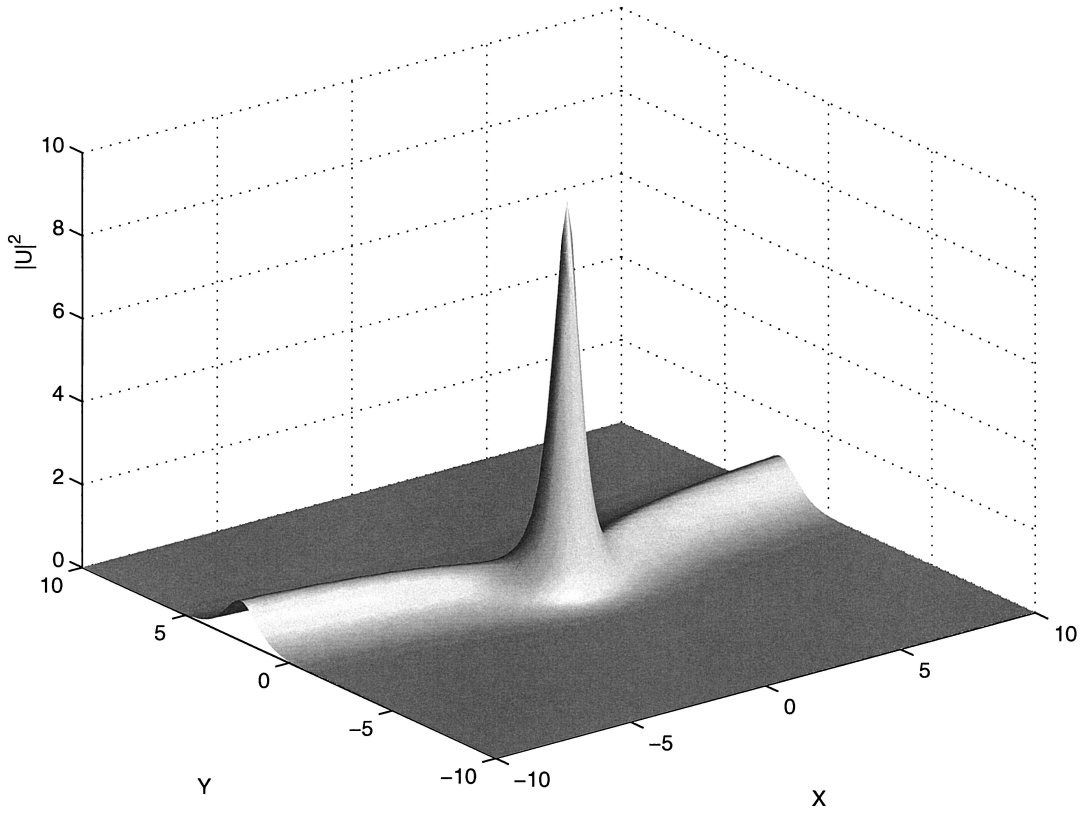

FIGURE 4 The interaction of a one-line-soliton and a one-lump for the KPI equation.

is replaced by $px + iqy + wt$, where $p^4 + pw + 3q^2 = 0$. However, there exist certain lines in the x–y plane where these solutions do *not* decay. A solution describing the interaction of a one-lump and a one-line-soliton for the KPI equation is given by

$$q(x, y, t) = 2\partial_x^2 \ln\left[|L(x, y, t)|^2 + \frac{1}{4\lambda_I^2} + bc + \frac{b}{2\lambda_I} e^{\theta(x,y,t)} + \frac{c}{2\lambda_I} e^{-\theta(x,y,t)}\right], \qquad (19)$$

where L and λ are defined in (14), b and c are nonnegative real constants, and

$$\theta(x, y, t) = 2\lambda_I\left[x - 2\lambda_R y - 4\left(\lambda_I^2 - 3\lambda_R^2\right)t\right].$$

The interaction of a one-lump and a one-line-soliton is depicted in Fig. 4.

IV. THE INVERSE SPECTRAL METHOD

The solution of the initial value problem of an integrable nonlinear evolution equation on the infinite line is based on the spectral analysis of the x part of the Lax pair. Thus for the KdV equation one must analyze Eq. (5a). This equation is the famous time-independent Schrödinger equation. We now give a physical interpretation of the relevant spectral analysis. Let the KdV equation describe the propagation of a water wave and suppose that this wave is frozen at a given instant of time. By bombarding this water wave with quantum particles, one can reconstruct its shape from knowledge of how these particles scatter. In other words, the scattering data provide an alternative description of the wave at fixed time. The mathematical expression of this description takes the form of a linear integral equation found by Faddeev (the so-called Gel'fand–Levitan–Marchenko equation) or equivalently the form of a 2×2 RH problem uniquely specified by the scattering data. This alternative description of the shape of the wave will be useful if the evolution of the scattering data is simple. This is indeed the case, namely, using Eq. (5b), it can be shown that the scattering data evolve linearly. Thus this highly nontrivial change of variables from the physical to scattering space provides a linearization of the KdV equation.

In what follows we will describe some of the relevant mathematical formulas. For simplicity we consider the NLS equation instead of the KdV equation. The associated Lax pair is given by

$$\psi_x + ik\sigma_3\psi = Q\psi, \tag{20a}$$

$$\psi_t + 2ik^2\sigma_3\psi = \left(-i|\lambda|q|^2\sigma_3 + 2kQ - iQ_x\sigma_3\right)\psi, \tag{20b}$$

where

$$\sigma_3 = \mathrm{diag}(1,-1), \qquad Q = \begin{pmatrix} 0 & q \\ \lambda\bar{q} & 0 \end{pmatrix},$$

and $\psi(x,t,k)$ is a 2×2 matrix-valued function.

If q is small, the NLS reduces to the linear equation

$$iq_t + q_{xx} = 0. \tag{21}$$

It was noted by Gel'fand and the author that linear equations also possess a Lax pair. Indeed, it can be verified that Eq. (21) is the compatibility condition of

$$\mu_x - ik\mu = q, \tag{22a}$$

$$\mu_t + ik^2\mu = iq_x - kq. \tag{22b}$$

Let $q(x,t)$ satisfy Eq. (21) in $-\infty < x < \infty$, $t > 0$, where $q_0(x)$ has sufficient smoothness and decay as $|x| \to \infty$. For example, $q(x,0) = q_0(x) \in L_1 \cap L_2$. The unique solution of this problem, which decays as $|x| \to \infty$ uniformly in t, is given by

$$q(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{ikx - ik^2t}\hat{q}_0(k)\,dk, \tag{23a}$$

$$\hat{q}_0(k) = \int_{-\infty}^{\infty} e^{-ikx}q_0(x)\,dx. \tag{23b}$$

We will rederive this solution using the Lax pair formulation (22). This seems a complicated way of deriving a simple result. However, it has an important pedagogical advantage: The conceptual steps used here are similar to the conceptual steps used for the solution of the NLS equation.

We first assume that $q(x,t)$ exists and has sufficient smoothness and decay, and we perform the spectral analysis of Eq. (22a). This means that we construct a solution μ, which for fixed $-\infty < x < \infty$, $t > 0$, is bounded in k, $k \in \mathbb{C}$, and which is of $O(1/k)$ as $k \to \infty$. Actually such a solution is sectionally holomorphic and is given by

$$\mu = \begin{cases} \mu^+, & \mathrm{Im}\,k \geq 0, \\ \mu^-, & \mathrm{Im}\,k \leq 0, \end{cases} \tag{24}$$

where μ^+, μ^- are the following particular solutions of Eq. (22a):

$$\mu^+(x,t,k) = \int_{-\infty}^{x} e^{ik(x-x')}q(x',t)\,dx' \tag{25a}$$

$$\mu^-(x,t,k) = -\int_{x}^{\infty} e^{ik(x-x')}q(x',t)\,dx'. \tag{25b}$$

Indeed, since in (25a) $x > x'$, μ^+ is bounded and analytic if $\mathrm{Im}\,k > 0$; similarly for (25b). These equations are both valid if $\mathrm{Im}\,k = 0$; in this case subtracting Eqs. (25), we find

$$\mu^+(x,t,k) - \mu^-(x,t,k) = e^{ikx}\rho(k,t), \qquad k \in \mathbb{R}, \tag{26}$$

where

$$\rho(k,t) = \int_{-\infty}^{\infty} e^{-ikx'}q(x',t)\,dx', \qquad k \in \mathbb{R}. \tag{27}$$

Equations (25) imply that $\mu = O(1/k)$. This estimate and Eq. (26) define an elementary RH problem for the scalar function $\mu(x,t,k)$. The unique solution of this problem is

$$\mu(x,t,k) = \frac{1}{2i\pi}\int_{-\infty}^{\infty} \frac{e^{ilx}\rho(l,t)}{l-k}\,dl, \qquad k \in \mathbb{C}.$$

This equation and Eq. (22a) yield

$$q(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{ikx}\rho(k,t)\,dk. \tag{28}$$

In summary, the spectral analysis of Eq. (22a) yields Eqs. (27) and (28), which are the direct and the inverse Fourier transforms, respectively.

In order to find the time evolution of the Fourier data, we use the t part of the Lax pair: Equation (25a) implies that

$$\rho(k,t) = \lim_{x\to\infty}[e^{-ikx}\mu^+(x,t,k)].$$

This equation, the assumption that $q \to 0$ as $x \to \infty$, and Eq. (22b), yield

$$\rho_t + ik^2\rho = 0.$$

Solving this equation in terms of $\rho(k,0)$, using Eq. (27) at $t = 0$, and denoting $\rho(k,0)$ by $\hat{q}_0(k)$, it follows that Eqs. (27) and (28) become Eqs. (23).

These equations can be used to construct the solution of the initial-value problem of Eq. (21) *without* the a priori assumption of existence: Given $q_0(x)$, *define* $\hat{q}_0(k)$ by Eq. (23b). Given $\hat{q}_0(k)$, *define* $q(x,t)$ by Eq. (23a). Since the dependence of $q(x,t)$ on x, t is of the form $\exp(ikx - ik^2t)$, it immediately follows that q satisfies Eq. (21). All that remains is to show that $q(x,0) = q_0(x)$, as a consequence of the inverse Fourier transform.

We now state the analogous result for the NLS equation. This result can be obtained by using Eqs. (20) instead of Eqs. (22) and following steps similar to the ones used above (Fokas, 2000).

Theorem. (Zakharov and Shabat, 1972). Let $q(x,t)$ satisfy the NLS Eq. (6) in $-\infty < x < \infty$, $t > 0$, with $q(x,0) = q_0(x) \in S(\mathbb{R})$. The defocusing NLS equation, i.e., Eq. (6) with $\lambda = 1$, has a unique global solution which

decays to zero as $|x| \to \infty$ uniformly in t. This is also the case for the focusing NLS equation, i.e., Eq. (6) with $\lambda = -1$, provided that the function $a(k)$, $\operatorname{Im} k > 0$, defined below, has at most a finite number of zeros all of which are simple and nonreal. In both cases this solution can be obtained as follows: Given $q_0(x)$, define the vector $\nu(x,k) = (\nu_1, \nu_2)^\tau$ as the unique solution of

$$\nu_{1_x} + 2ik\nu_1 = q_0(x)\nu_2, \qquad \nu_{2_x} = \lambda\bar{q}_0(x)\nu_1,$$
$$\operatorname{Im} k \geq 0, \qquad -\infty < x < \infty, \qquad \lim_{x\to\infty} \nu = (0,1)^\tau.$$

Given $\nu(x,k)$, define the functions $a(k)$ and $b(k)$ by

$$a(k) = \lim_{x\to-\infty} \nu_2(x,k), \qquad \operatorname{Im} k \geq 0;$$
$$b(k) = \lim_{x\to-\infty} \left(e^{2ikx}\nu_1(x,k)\right), \qquad k \in \mathbb{R}.$$

Given $a(k)$ and $b(k)$, define μ as the solution of the following 2×2-matrix RH problem:

1.

$$\mu^-(x,t,k) = \mu^+(x,t,k)\begin{pmatrix} 1 & -\dfrac{b(k)}{\bar{a}(k)}e^{-\theta} \\ \lambda\dfrac{\bar{b}(k)}{a(k)}e^{\theta} & 1-\lambda\dfrac{|b|^2}{|a|^2} \end{pmatrix}, \quad k \in \mathbb{R},$$

where $\mu = \mu^+$ for $\operatorname{Im} k \geq 0$, $\mu = \mu^-$ for $\operatorname{Im} k \leq 0$, and $\theta = 2i(kx + 2k^2t)$.

2.

$$\mu = I + O\left(\frac{1}{k}\right), \qquad k \to \infty.$$

3.

$$\det \mu = 1.$$

4. If $\lambda = 1$, $\mu^\pm$ are holomorphic, and if $\lambda = -1$ the first column vector of μ^+ and the second column vector μ^- are meromorphic with poles at the zeros of $a(k)$ and of $\bar{a}(\bar{k})$, respectively; the residues of these poles are given by

$$\operatorname{res}_{k_j}(\mu^+)_1 = c_j e^{\theta_j}(\mu^+)_2(k_j), \qquad \theta_j = 2i\left(k_j x + 2k_j^2 t\right),$$
$$\operatorname{res}_{\bar{k}_j}(\mu^-)_2 = -\bar{c}_j e^{\bar{\theta}_j}(\mu^-)_1(\bar{k}_j),$$

where the subscripts 1 and 2 denote the first and second column vectors. This RH has a unique solution. Given μ^+, define $q(x,t)$ by

$$q(x,t) = -2i \lim_{k\to\infty}(k\mu^+_{12}),$$

where the subscript 12 denotes the 1, 2 component of the matrix μ^+.

V. A UNIFICATION

Recently a new method for studying boundary value problems for linear and for integrable nonlinear PDEs in two dimensions has been introduced. This method provides a unification as well as a significant extension of the following three seemingly different topics: (1) The classical integral transform method for solving linear PDEs and several of its variations such as the Wiener–Hopf technique. (2) The integral representation of the solution of linear PDEs in terms of the Ehrenpreis fundamental principle. (3) The inverse spectral (scattering) method for solving the initial value problem for nonlinear integrable evolution equations.

In what follows we briefly discuss this unification.

A. Transform Methods for Linear PDEs

Almost as soon as linear two-dimensional PDE's made their appearance, d'Alembert and Euler discovered a general approach for constructing large classes of their solutions. This approach involved separating variables and superimposing solutions of the resulting ODEs. The method of separation of variables naturally led to the solution of PDEs by a transform pair. The prototypical such pair is the direct and the inverse Fourier transforms; variations of this fundamental transform include the Laplace, Mellin, sine, and cosine transforms and their discrete analogues.

The proper transform for a given boundary value problem is specified by the PDE, the domain, and the given boundary conditions. For some simple boundary value problems, there exists an algorithmic procedure for deriving the associated transform. This procedure involves constructing the Green's function of a *single* eigenvalue equation and integrating this Green's function in the complex k plane, where k denotes the eigenvalue.

The transform method has been enormously successful for solving a great variety of initial and boundary value problems. However, for sufficiently complicated problems the classical transform method fails. For example, there does not exist a proper analogue of the sine transform for solving a third-order evolution equation on the half-line. Similarly, there do not exist proper transforms for solving boundary value problems for elliptic equations even of second order and in simple domains. The failure of the transform method led to the development of several ingenious but ad hoc techniques, which include conformal mappings for the Laplace and the biharmonic equations, the Jones method and the formulation of the Wiener–Hopf factorization problem, the use of some integral representation, such as that of Sommerfeld, and the formulation of a difference equation, such as the Malyuzhinet equation.

The use of these techniques has led to the solution of several classical problems in acoustics, diffraction, electromagnetism, fluid mechanics, etc. The Wiener–Hopf technique played a central role in the solution of many of these problems.

B. The Ehrenpreis Fundamental Principle

In 1950, Schwartz posed the problem of whether, given a polynomial P on $\mathbb{C}^n$, an elementary solution of the differential operator $P(i\partial/\partial t)$, $t \in \mathbb{R}^n$, always exists, i.e., if there exists a distribution E solving $P(i\partial/\partial t)E = \delta$, where δ is the Dirac delta function. The existence of such an elementary solution was established independently by Malgrange and Ehrenpreis; both of these proofs are nonconstructive. Thus in the same decade, techniques of functional analysis were used to try to construct this elementary solution explicitly. For example, if one considers the equation

$$P\left(\frac{i\partial}{\partial t}\right)q(t) = 0, \qquad t \in \Omega, \tag{29}$$

where Ω is a convex domain in $\mathbb{R}^n$, it follows that $q(t) = e^{-ik\cdot t}$, $k \in \mathbb{C}^n$, is a solution of (29) if $P(k) = 0$. For $n = 1$, the Euler principle states that every solution of (29) is a linear combination of exponentials. The generalization of Euler's principle for $n > 1$ was established by Ehrenpreis and Palamodov and was called by Ehrenpreis the *fundamental principle*.

An elementary implication of the Ehrenpreis principle is that for the general evolution equation

$$\left(\partial_t + i\sum_0^n \alpha_j(-\partial_x)^j\right)q(x,t) = 0 \tag{30}$$

formulated in $0 < x < \infty$, $0 < t$, there exists a measure such that

$$q(x,t) = \int e^{ikx - i\omega(k)t}\, d\mu(k), \qquad \omega(k) = \sum_{j=0}^{n} \alpha_j k^j. \tag{31}$$

We note that if $n = 2$, Eq. (30) can be solved by the sine or the cosine transform. In this case it is possible to rewrite the solution in the Ehrenpreis form (31), with $d\mu$ supported on the real axis and on the positive imaginary axis.

C. Integrable Nonlinear PDEs

Integrable equations, solitons, the inverse spectral method, and the associated algebraic–geometric machinery, which were briefly mentioned in Sections I–IV, have had an important impact on modern mathematical physics. However, in spite of this success, these methods are limited. Indeed, they are applicable only to the solution of the initial value problem with either decaying or space-periodic initial data. Thus an outstanding open problem in the analysis of integrable equations became the generalization of these methods to boundary value problems. The simplest such problem is formulated on the half-line. It was mentioned earlier that the inverse spectral method on the infinite line can be thought of as a nonlinearization of the Fourier transform. Thus a natural strategy for solving a problem on the half-line is to solve the associated linear problem by an x transform and then to nonlinearize this transform. However, this strategy fails: for the Korteweg–de Vries equation it fails immediately, since the associated linear equation is $q_t + q_{xxx} = 0$, for which there does not exist an appropriate x-transform. For the nonlinear Schrödinger equation, the associated linear equation can be solved by either the sine or the cosine transform, depending on whether $q(0,t)$ or $q_x(0,t)$ is given, but neither of these transforms nonlinearizes. It is the author's opinion that this failure reflects the fact that neither of these transforms is fundamental. The fact that they are limited only to second-order equations provides further support for this claim. Indeed, there exist a new formalism for solving any linear dispersive equation on the half-line, and this formalism *can* be nonlinearized.

D. A New Method

A general approach to solving boundary value problems for two-dimensional linear and integrable nonlinear PDEs is reviewed in Fokas (2000). This method can be applied to *linear PDEs with constant coefficients* and to *integrable nonlinear* PDEs in an arbitrary domain. It involves the following three steps: (1) Given a PDE, construct two compatible linear eigenvalue equations, called a Lax pair. (2) Given a domain, perform the simultaneous spectral analysis of the Lax pair. (3) Given appropriate boundary conditions, analyze the global relation satisfied by the solution and by its derivatives on the boundary of the domain.

We now discuss the relation of this method with the three topics presented earlier.

1. Suppose that $q(x,y)$ satisfies a linear PDE. Performing the spectral analysis of the x part of the Lax pair corresponds to constructing an x-transform; similarly, performing the spectral analysis of the y part corresponds to constructing a y-transform. The advantage of the Lax pair is that it provides the tool for performing the *simultaneous* spectral analysis. This gives rise to a new transform, which in contrast to both the x- and y-transforms, is "custom-made" for the given PDE and the given domain. In this sense the new method provides the synthesis of separation of variables.

2. Suppose that $q(x,y)$ satisfies a linear PDE in a convex polygon. In this case, step 1 yields for $q(x,y)$ an

integral representation in the complex k plane, which has an explicit x and y dependence and which involves a certain function $\hat{q}(k)$, $k \in \mathbb{C}$, which we call the spectral function. This function can be expressed in terms of an integral of q and of its derivatives along the boundary of the polygon. However, some of these boundary values are unknown. Thus in order to compute $\hat{q}(k)$ [and thus $q(x, y)$] one needs to determine the part of $\hat{q}(k)$ involving the unknown boundary values. An important aspect of the new method is the understanding that this can be achieved by analyzing the *global equation* satisfied by the boundary values of q and of its derivatives. For evolution equations and for elliptic equations with simple boundary conditions, this involves the solution of a system of algebraic equations, while for elliptic equations with arbitrary boundary conditions, it involves the solution of a Riemann–Hilbert problem. For simple polygons, this Riemann–Hilbert problem is formulated on the infinite line, thus it is equivalent to a Wiener–Hopf problem. This explains the central role played by the Wiener–Hopf technique in many earlier works.

3. An important advantage of the new method is that it can be nonlinearized. Indeed, the results valid for linear PDEs obtained by this method can be generalized to integrable nonlinear PDEs.

4. For linear equations, the explicit x, y dependence of $q(x, y)$ is consistent with the Ehrenpreis formulation of the solution. Thus this method provides the concrete implementation as well as the generalization to concave domains of this fundamental principle. For nonlinear equations, it provides the extension of the Ehrenpreis principle to integrable nonlinear PDEs.

Spatial Objective Analysis

H. J. Thiébaux
National Centers for Environmental Prediction

GLOSSARY

Autoregressive Dependent on its own history, or determined by it up to random innovations.
Diagnostics Measures whose values describe the state, energy, or distribution of a property of an observed system.
Earth-oriented system One whose natural coordinates are designated with respect to the earth, in latitude, longitude, and depth, altitude, or pressure.
Global description Designation of the state of a system or the value of one of its variables at each point of its domain.
Minimum variance estimation Determination of a function or parameter values for a designated function of stochastic variables, which guarantee its having the least statistical variance among all functions or sets of parameters.
Spatial coherence Continuity of values of variables, such as temperature, salinity, or wind velocity, in a spatially continuous environment.
Unbiased Property of an estimate for a variable or parameter of having the same statistical mean value as the variable or parameter estimated.

SPATIAL OBJECTIVE ANALYSIS is a body of techniques of applied mathematics that has been developed to provide global descriptions of spatially coherent variables with data from observation points that are sparse and inhomogeneous in space. Thus, in the specific, *a spatial objective analysis* is a tensor estimate of the state of a system for each gridpoint of the domain of interest, that has been constructed from a set of irregularly spaced observations. The word *objective* identifies the construction as the outcome of applying a mathematical algorithm, in distinction to a *subjective* construction which admits the influence of individual scientific intuition.

I. INTRODUCTION

Historically, the techniques of spatial objective analysis have been developed as descriptive and diagnostic techniques of science, beginning with K. F. Gauss's pioneering work in astronomy and extended by people who are now distinguished as founders of the discipline of mathematical statistics. Areas of scientific endeavor in which spatial objective analysis is currently used include geology, atmospheric and oceanic sciences, and environmental studies.

The relative isolation of research in these different fields has led to the assignment of credits to a spectrum of scientists, each of whom had the acumen to appreciate the importance of these techniques and applied them within their own fields with outstanding results. Prominent on this roster are G. Matheron, L. S. Gandin, and R. E. Kalman.

Scientific study of large-scale, earth-oriented systems requires capabilities for constructing global descriptions with algorithms built from assumptions about spatial interrelationships of their component variables. These requirements must confront the *de facto* configuration of our habitat, which precludes spatially uniform data coverage. In fact, actual observations of global-scale phenomena, including those of remote sensing technology, may provide information that is highly nonuniform in coverage. Nonetheless, global descriptions of spatially dimensioned states of the system which accurately reflect its properties and interrelationships of its component parts must be constructed.

The techniques developed to meet these requirements may be classified by the characteristics of the information available to describe the system under study. There are two clear divisions. One presumes no history of information, of which an example would be an isolated, geological field study, producing a single "snap shot" of observations at selected locations, for a system whose properties are presumed to be relatively fixed in time. The other assumes an accumulated record of observations on a time-evolutionary system for which either the statistical relationships among states of the system at separate locations remain the same throughout the record or whose changes with time can be determined independently.

II. THE FUNDAMENTAL PROBLEM

A spatial objective analysis algorithm is a formula for providing estimates of the values of a spatially coherent variable where each gridpoint estimate is constructed from a set of "surrounding" observations. If observations recorded true values perfectly, then the objective might be to fit them perfectly with a surface whose intermediate values would provide estimates of the variable everywhere else. However, the premise is incorrect. Also, it is generally true that the signal component of the field we seek to estimate differs from the instantaneous state, or "true value," at each instant of time and point of space.

Since the distinction between the signal component of the variable at a specific location and instant of time and the value of an observation at that same location and instant is basic to the theory from which all spatial objective analysis algorithms are derived, we consider this first. The *signal component* is the value one would like to know and which the estimate is constructed to approximate. It is not the same as the value of an observation, were it possible to obtain one because an observation is a composite of the instanteous state, errors caused by imprecision of sensors and recorders, and mistakes made in the transmission of information. Furthermore, the instantaneous state at a specific location and instant of time generally reflects microscale variability, the influence of which is regarded as obscuring the signal. Accordingly, the signal component has a theoretical definition as the average of the instantaneous states over a localized region and short time interval. The construction of an algorithm for estimating the signal from actual observation reports takes into account the unwanted, noisy constituents, so that the algorithm will provide a filter for separation of signal from noise, as well as an interpolater.

The coherence in space and in time that is assumed by the theory of objective analysis is equivalent to the mathematical concept of the continuity of functions. Thus the goal of objective analysis is the creation of a spatially continuous estimator of the signal in the field variable: an algorithm that may be evaluated at any point, effectively interpolating only the signal components of the observations going into it.

Traditionally, the *signal*, $\mu(\lambda, \phi, p, t)$, and the *noise*, $\varepsilon(\lambda, \phi, p, t)$, components of observations are assumed to be additive:

$$Z(\lambda, \phi, p, t) = \mu(\lambda, \phi, p, t) + \varepsilon(\lambda, \phi, p, t);$$

and the further assumption is made that the noise is independent of the signal, in the sense that the magnitude or strength of the signal does not influence the level of noise and vise versa. The indexing parameters denote earth-oriented coordinates, respectively: longitude, latitude, pressure or altitude or depth, and time. Here $\varepsilon(\lambda, \phi, p, t)$ represents the collective influence of small-scale variability, of no inherent interest, together with instrument and transmission system errors.

A general expression for the observed value of a field variable is that of the output of a *generalized Kalman filter*, or *GKF* (see Thiébaux, 1997, for a practical discussion of this concept). In this, the indices of distinct location/time points are subsumed by the notation s and $s + \Delta$. The formulation of the GKF assumes that the true value of the field variable at any location/time may be written as a composite of its deterministic evolution and a stochastic innovation,

$$X_{s+\Delta} = \Phi_s^* \bigcirc X_s + W_{s+\Delta},$$

and that a recorded observation is a linear combination of the true value and noise from sensing, transmitting, and recording devices:

$$Z_{s+\Delta} = X_{s+\Delta} + V_{s+\Delta}.$$

Φ^* denotes the algorithm for the deterministic component of the change in X from one location/time to another, W denotes the stochastic component in the evolution of the true field, and V denotes the collective impact of the noise elements. GKF output is composed of a prediction from the proximal/previous estimate, modified by the weighted discrepancy between what is observed and predicted:

$$\hat{X}_{s+\Delta} = \Phi_s \bigcirc \hat{X}_s + K_{s+\Delta}(Z_{s+\Delta} - \Phi_s \bigcirc \hat{X}_s)$$

A distinction is made here between the true *system operator* of the field variable, Φ^*, and the *model system operator* used to generate predictions, Φ. Generally, the true operator will not be known precisely and making the assumption that they are the same will lead to erroneous deductions from a formulation that equates them. Customarily K is called the *gain matrix of the filter*, for which the formulation includes the possibility of its dependence on time and space, like that of the system operators. The generality of this representation for a spatial objective analysis is mathematically impressive. However, it is impractical to apply to the analysis of most physical systems in its full generality because the components are not known at this level of detail.

Within the present framework, an *optimal estimator* is one for which the average squared departure of values of the estimates it produces from the corresponding signal values is smallest among all possible algorithms. Since the signal is a conceptual quantity that cannot be observed, the average is the statistical mean-squared departure, and thus optimal objective analysis is *minimum variance estimation* in the classic statistical sense. Whether or not the minimum can be guaranteed depends on whether or not the multivariate statistical distribution of the field variable or of its increment from some known background field can be specified. When the relevant multivariate statistical distribution can be specified, the optimal estimator for any specified location is unique, and it is the conditional mean value of the variable at that location with respect to its joint distribution with the values of the variable at all the locations at which it is observed. We refer to this as the *ultimate objective analysis* and reserve the definition *optimal objective analysis* for what is practical in terms of our knowledge of statistical properties of the field variable. The most general way of representing the ultimate objective analysis value for any point, say a point indexed by 0 constructed with observations from m locations indexed $1, \ldots, m$, is in terms of the cumulative distribution function for Z_0 conditioned on the observed values of its m covariates $Z_1, \ldots, Z_m$. Specifically, in terms of

$$F(z_0 \mid Z_1, \ldots, Z_m) = \text{Prob}(Z_0 \leq z_0, \text{ given the values of } Z_1, \ldots, Z_m),$$

the conditional mean is

$$E(Z_0 \mid Z_1, \ldots, Z_m) = \int_{-\infty}^{+\infty} z_0 \, dF_0(z_0 \mid Z_1, \ldots, Z_m),$$

and this can be shown to provide the unique minimum of

$$E\left\{[Z_0 - g(Z_1, \ldots, Z_m)]^2\right\}$$

for all possible functions g of the set of observations. However, it clearly depends on knowing the family of multivariate distribution functions

$$F(z_0, z_1, \ldots, z_m) = \text{Prob}(Z_0 \leq z_0, Z_1 \leq z_1, \ldots, Z_m \leq z_m),$$

from which all conditional distribution functions and their conditional mean values can be derived. Many practical situations warrant the assumption that these distributions are reasonably approximated by multivariate normal distributions, and in these cases the objective analysis formulation assumes a particularly simple form.

In those circumstances in which the multivariate statistical distributions for the field variable cannot be specified, alternative approaches to objective analysis are employed. Again, the choice of a technique will depend on what assumptions can reasonably be made about boundary conditions on the variable for the region within which it is considered and characteristics of its spatial variability. The nonstatistical alternatives that will be cited in this article are referred to collectively as *empirical interpolation techniques*. There are several, each with advantages tuned to specific observation characteristics and requirements for the estimated field. *All share the disadvantage that no analysis algorithm can outperform the statistical objective analysis in circumstances in which the latter is a practical alternative*.

III. OPTIMAL STATISTICAL OBJECTIVE ANALYSIS

Here the underlying assumption is that the situation warrants application of the family of multivariate normal distributions to the differences between the true/observed values and corresponding modeled mean values. The differences between the location-specific values and the modeled mean values may be called "analysis increments." The "modeled mean values" are called "first-guess values," and these may be derived from a complex algorithm that takes into account everything in our knowledge base about the system under study, or it may be simply an ensemble average of available information or "the climatology of a geophysical field." The model detail and its accuracy in representing the system will be reflected in the spatial scale and structure of the analysis increments, presenting a trade-off between the requirement for complexity

in the first-guess algorithm and the requirement for complexity of the analysis algorithm. *The closer the model corresponds to the operation of the true system, the less structure remains in the increment field; conversely, the simpler the model, the more residual statistical structure remains to be represented.*

In any case in which a multivariate normal distribution may be assumed for the differences between the location-specific values and the modeled mean values, the optimal estimator for an analysis increment for any unobserved location is a weighted linear combination of the observed increments that are within "influence range." Observed increments are derived from observed values by differencing with corresponding modeled means. Thus, denoting observed values by $Z_1, \ldots, Z_m$ and the modeled mean values by $Z_0^f, Z_1^f, \ldots, Z_m^f$, for each point of estimate 0 and the m observing locations, respectively, the objective analysis algorithm generates point estimates:

$$\hat{Z}_0 = Z_0^f + \sum_{i=1}^{m} w_i \left(Z_i^o - Z_i^f\right). \tag{1}$$

The coefficients that provide the weights bear a direct and simple relationship to the covariance parameters of the assumed underlying normal distribution function. With double subscripts identifying the locations for the variables to which each scalar covariance σ_{ij} pertains, the between-location covariance array may be written as

$$\sum = \begin{bmatrix} \sigma_{11} & \cdots & \sigma_{1m} \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \sigma_{m1} & & \sigma_{mm} \end{bmatrix}$$

and the array whose entries are the covariances between the values of the variable at the point of estimate and at the locations of observations as

$$\sum_0 = (\sigma_{11} \cdots \sigma_{1m}).$$

With this notation the array of weights for the analysis increments is given by

$$W = \sum_0 \sum^{-1}. \tag{2}$$

As a theoretical formulation, (1) and (2) describe the *ultimate objective analysis*. In practice, the formulation requires specification of the covariance structure, which must itself be estimated, to create a working, optimal statistical objective analysis (OSOA) algorithm. It is at this point that "optimal" takes on its practical connotation and the dependence of the accuracy of the analysis on the representation of the covariance structure assumes central importance. As the word suggests, *covariance* is a measure of the strength of the relationships, or *covariability*, of increments at different locations. Its tensor representation determines the weights assigned to observed increments in OSOA.

The accuracy of the foregoing representation is of considerable significance: *If the assigned covariance values are not representative of the true statistical relationships of the increment field, the weights and therefore the analysis will be less than optimal.* A body of research has been devoted to the derivation and study of the properties of covariance functions for the representation of spatial covariance structure. Some of this has started from first principles, in the following sense. The discrepancy between an observed field and an unbiased modeled mean field is described as a spatially coherent stochastic process, for which the covariance function may be derived analytically from the spatial analogue of an autoregressive representation for a time series. Selection of the order of the autoregressive representation and assignment of values to the parameters of the covariance function require comparative fitting of candidate functions to an array of covariances computcd from data, together with the study of implicit properties of these functions versus known or theoretical properties of the increment field. These derivations have assumed stationarity of the statistical properties of the increment field and required archives of observations from fixed arrays for the determination of spatial structure.

IV. KRIGING

In circumstances in which the increment field is known to be statistically nonstationary or for which an archive of observations is not available to provide guidance for selecting a representation for the between-location covariances of analysis increments, OSOA cannot be used and an alternative technique must be selected. One practical alternative that has been developed and used extensively in a number of natural and social science settings is *Kriging*. The term is derived from the name Krige, the man to whom G. Matheron ascribes its inspirational use in the field of geology. This technique was developed to produce estimates of values of spatial processes over a geographic region with a one-time set of data from a sampling array. Kriging is a multistage procedure that first fits a trend surface to the data, then estimates the covariance structure of the residual field from the differences between the observations and the fitted surface, and, finally, corrects the point predictions of the trend surface by a constrained multivariate interpolation of the observed residuals.

The trend surface is constructed by fitting a linear combination of basis functions $h_l(s)$ to the sample data in the manner of a regression analysis. Thus the coefficients, α_l

are determined by minimizing the sum of squared differences between the surface and the observed values

$$\sum_{i=1}^{m}\left[Z_i^0 - \sum_l \alpha_l h_l(s_i)\right]^2,$$

where $s_1, \ldots, s_m$ are the locations of the observations. This provides a trend surface estimate

$$m(s) = \sum_l \alpha_l h_l(s),$$

which may be evaluated at any point of the region. In Kriging, this is referred to as the *drift* and is somewhat analogous to the role of the modeled mean field of OSOA. One important departure from OSOA is accommodation for bias that may be present in $m(s)$. Since the minimization that parametrizes the fitted surface does not guarantee its unbiasedness, Kriging constrains the weights of the linear interpolation of residuals to sum to unity.

Other significant differences between the Kriging analysis and OSOA derive from assumptions that are made in the Kriging analysis about the joint distribution of the discrepancies between the trend surface and the data to which it has been fitted. This distribution is assumed to be a multivariate normal distribution that is both stationary and isotropic. The mean, which is the bias b in the fitted surface, and the variance σ^2 are assumed to be constant over the region; and the correlation between values of the field variable at separate locations is assumed to be a function only of scalar displacement, $\rho(\|\Delta\|)$, which approaches zero with increasing separation. With this notation, between-location covariances are

$$\sigma_{ij} = \sigma^2 \varrho(\|\Delta\|), \qquad \text{with} \quad \|\Delta\| = \|s_i - s_j\|.$$

With the constraint of having only one observation at each location, the requirement for a representation of the covariances for interpolation of residuals to combine with the trend surface estimate is satisfied by constructing a "variogram." To illustrate, we let $Y(s)$ denote the residuals, which are the discrepancies between the trend surface and the data to which it has been fitted:

$$Y(s_i) = m(s_i) - Z_i^0 \qquad \text{for} \quad i = 1, \ldots, m.$$

With this notation and the foregoing assumptions about the distribution of the residuals, the expected value of the square of the difference between each pair of residuals may be written in terms of the variance and the correlation function as

$$E\left\{[Y(s_i) - Y(s_j)]^2\right\} = E\left\langle\{[Y(s_i) - b] - [Y(s_j) - b]\}^2\right\rangle$$
$$= 2\sigma^2[1 - \varrho(\|\Delta\|)].$$

Thus the expected value of $[Y(s_i) - Y(s_j)]^2/2$ is $\sigma^2[1 - \varrho(\|\Delta\|)]$. Since $\varrho(\|\Delta\|)$ approaches 0 at large separations, a plot of $[Y(s_i) - Y(s_j)]^2/2$ against the distances between observing locations $\|\Delta\| = \|s_i - s_j\|$ may be fitted with a function $\gamma(\|\Delta\|)$ whose asymptote provides an estimate of the variance σ^2 and whose normalized values provide a representation for the correlation function:

$$\hat{\varrho}(\|\Delta\|) = 1 - \gamma(\|\Delta\|)/\sigma^2.$$

V. EMPIRICAL INTERPOLATION TECHNIQUES

Spatial continuity of the variables for which analyzed fields are constructed is basic to spatial objective analysis. However, having sufficient knowledge of the properties of the stochastic elements of the observed field for a statistical objective analysis is not a requirement for the construction of a spatially continuous estimated field for the region from which observations are obtained. Under circumstances in which it is unreasonable to make explicit assumptions concerning either the definition of a mean field or the form of the statistical distribution of observed residuals from a defined mean field, other options are available. Alternatives to statistical objective analysis are referred to here as empirical interpolation techniques. These include (1) distance-weighted interpolation, (2) spline fitting, (3) function surface fitting, and (4) neural network analysis.

The formal appearance of the first item on this list is similar to a statistical objective analysis:

$$\hat{Z}_0 = \sum_{i=1}^{m} a_i Z_i^0.$$

However, the coefficients that assign weights to observed values of the analysis increments are functions only of the spatial/temporal separation between the point/time of the estimate and the locations/times of the observations. They do not take into account the possibility of significant correlations among the component observations. Nonetheless, in circumstances in which observations are fairly uniformly spaced in the region of the analysis and when the covariance structure of the analysis increments is not known, this technique can provide reasonable estimates. Distance-weighted interpolation has a long history of use in atmospheric science, where it is known as Cressman or Barnes analysis; it is the technique used to produce large-area grid-point analyses of surface temperature from satellite reports and has recently been applied in a four-dimensional objective analysis of wind profiler data (Spencer *et al.*, 1999).

Spline fitting has become a scientific art in recent years (Luo and Wahba, 1997; Luo *et al.*, 1998). It is a special case of *function surface fitting* in which several-dimensional polynomials are fitted to data within

subregions. The polynomials have fewer parameters than the number of observations, so that they perform a smoothing role as well as data fitting, and they are matched at the boundaries of the subregions for continuity. Control for excursions of the piecewise continuous surface beyond reasonable limits on the variability of the analyzed field is achieved by putting the spline under tension. Spline surface fitting has considerable flexibility for tuning the surface to match theoretical properties or response to orography. However, it requires considerable insight and attention to mathematical and physical detail, and, like all constructions made by fitting functions to data, the resulting analysis algorithm cannot be used for estimation beyond the region of the observations with confidence in the result.

Function surface fitting has been considered in outline as the first step of Kriging in which a *trend surface* is obtained by choosing the parameters for a linear combination of basis functions to be those parameter values that minimize the sum of the squared departures of the fitted surface from the observations. Basis functions may be selected to satisfy implicit spectral properties known from physical theory or an analog field, or they may be sets of orthogonal functions selected for their suitability as statistical diagnostics of the analyzed field. Recent literature on this subject is extensive in its treatment of both the theory of function surface fitting and high-speed computer techniques for data fitting. For examples, see Borzelli and Ligi (1999) and Emery and Thomson (1997).

Neural network analysis, as a practical technique for objective estimation of spatial fields, may be said to be in its infancy. However, it holds promise as a powerful technique to augment traditional linear statistical methods in data analysis and forecasting. Schematically, neural network models insert "hidden layers," referred to as *neurons*, between the input layer, i.e., the observations, and the output layer, i.e., the field estimate; and the intermediate, multiply linked pathways are modeled with nonlinear functions. This generic structure gives the technique great versility. Its practical application to data analysis and forecasting can be a rather complex process, as discussed by Hsieh and Tang (1998).

GLOSSARY

Convex set A set in Euclidean n-dimensional space E^n containing every line segment connecting two points of the set.

Convex body A compact convex set with nonempty interior.

Convex disk A convex body in the Euclidean plane E^2.

Density of a packing Intuitively, the percentage portion of space occupied by the solids arranged in the packing, a precise definition involves the notion of limit.

Dirichlet–Voronoi cell (D–V cell) A convex polyhedron associated with a ball in a ball packing, consisting of points whose distance from the center of the ball does not exceed the distance from the center of any other ball.

Face centered cubic lattice (fcc lattice) The lattice consisting of all vertices and facet centers of the cubes in a face-to-face tiling of E^3 with cubes.

Lattice The collection of vertices in a face-to-face tiling of Euclidean n-dimensional space E^n by congruent parallelepipeds, or, equivalently, the collection of integer–coefficient linear combinations of a basis for R^n.

Local density The ratio between the volume of a ball and the volume of its Dirichlet–Voronoi cell.

Lattice packing A packing whose members are translates of each other with the corresponding translation vectors forming a lattice.

Packing A collection of sets with mutually disjoint interiors.

Regular dodecahedron The 12-faceted Platonic solid—the convex polyhedron whose facets are regular pentagons.

Rhombic dodecahedron The 12-faceted convex polyhedron circumscribed about a sphere, whose facets are congruent rhombi with diagonal ratio of $\sqrt{2}$-to-1.

Sphere packing A collection of congruent solid spheres (balls) with mutually disjoint interiors.

THE CLASSICAL sphere packing conjecture, also known as the Kepler conjecture, asserts that the maximum density of a packing of Euclidean three-dimensional space E^3 with congruent balls is attained in the fcc lattice packing. The conjecture remained open for almost 400 years, until the relatively recent announcement of a

computer-aided proof by Thomas C. Hales, confirming its veracity. The interest in sphere packings, especially of the lattice type, was spurred first by their connections to number theory. More recently, the development of computer science gave a boost to the entire field of discrete geometry that includes the topics of packing, covering, and tiling. In particular, various designs of efficient error-correcting codes for electronic transmission of information, via a geometric interpretation of such codes, generated an array of dense sphere packings in Euclidean spaces of high dimension.

I. THE SPHERE PACKING PROBLEM—ITS STATEMENT AND HISTORY

In its simplest, classical form, the *sphere packing problem* asks for the most efficient way of filling space with congruent, nonoverlapping solid spheres (balls). The readily anticipated, natural solution, seen often as stacks of cannonballs in old paintings or as stacks of oranges or apples in supermarkets, is nicely described in Johannes Kepler's treatise published in year 1611, and it goes as follows. Build a triangular pyramid of congruent balls by placing a single ball (A) on top of 3 mutually tangent ones (B), then place this small stack upon a triangular layer of 6 balls (C), then again place this larger stack upon a triangular layer of 10 balls (D), and so on, as shown in Fig. 1 reproduced here from Kepler's booklet. The pattern of the stack can be extended in all directions, resulting in an arrangement

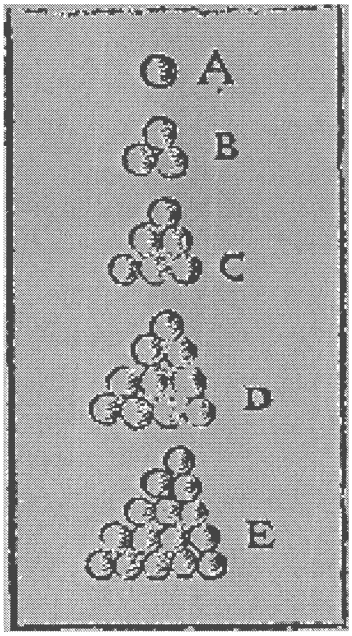

FIGURE 1 Kepler's drawing: a triangular stack of pellets.

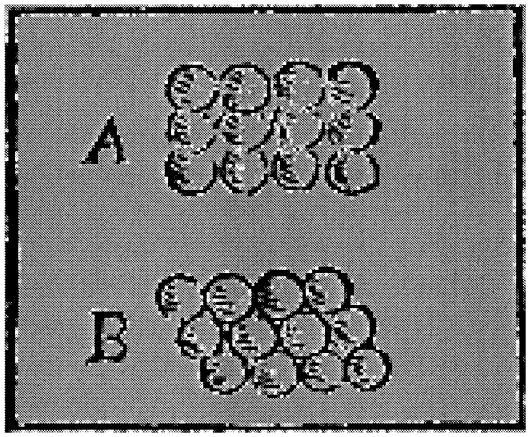

FIGURE 2 Kepler's drawing: a square layer and a triangular layer.

of mutually nonoverlapping balls (a packing) uniformly distributed throughout the whole space. This packing consists of flat layers of balls, in which the balls' centers are coplanar and form the familiar triangular pattern of points. Each ball in the packing is tangent to 12 other balls: 6 in its own layer and 3 in each of the two adjacent layers.

Kepler also describes the square pyramid pattern of packing balls, consisting of flat layers in which the balls' centers form a square grid instead of the triangular one (see Fig. 2). In this arrangement each ball is tangent to 12 other balls as well: 4 in its own layer and 4 in each of the two adjacent layers. This is not just a coincidence. Kepler observes that the two patterns, triangular and square, when extended to fill the whole space, produce essentially the same (congruent) packings, as one can be transformed into the other by a rotation.

This packing, Kepler asserts, is the "tightest possible," but neither does he specify what he precisely means by "tightness," nor does he offer even a hint of rigorous, mathematical proof of this assertion. Moreover, some of his pronouncements, such as the one he makes about partitioning space: "*space in the round cannot be divided without remainder except into cubes and rhomboids*," are simply incorrect.

Nowadays, the concept of *density* of a packing is used to measure its efficiency, or tightness, and it is defined in the following way. Let $\mathcal{P}$ be a packing consisting of solids $\{B_1, B_2, B_3, \ldots\}$, in this case congruent balls, and let $B(r)$ denote the ball of radius r centered at the origin. (The use of the term *packing* includes the implicit assumption that the interiors of the solids are mutually disjoint.) Then the density of $\mathcal{P}$ is defined as

$$d(\mathcal{P}) = \limsup_{r\to\infty} \left(\frac{1}{|B(r)|} \sum_{i=1}^{\infty} |B_i \cap B(r)| \right),$$

where the volume of a set S is denoted by $|S|$.

The density of the ball packing described by Kepler is easily computed to be $\pi/\sqrt{18} = 0.74048\ldots$. Hence, in terms of density, his assertion on the maximum tightness of a ball packing can be stated as

The density of a packing with congruent balls cannot exceed $\pi/\sqrt{18}$.

and in this form it became known as the *Kepler conjecture*.

For the sake of historical accuracy, it should be mentioned that Kepler's interest in sphere packings as a tool for investigations of the atomic structure of matter was preceded and influenced by the work of Thomas Harriot, a mathematical assistant to Sir Walter Raleigh.

Chronologically, the first rigorous result in the direction of the Kepler conjecture came in 1831, in a comment of C. F. Gauss concerning properties of positive quadratic forms. In that context, Gauss considers a special kind of ball packings, called *lattice packings*, in which the centers of the balls form a *lattice* of points, *i.e.*, the collection of vertices of congruent parallelepipeds tiling space in a face-to-face manner (for example, the *cubic lattice* is the collection of vertices in a face-to-face space tiling by cubes). Gauss proves that among all possible lattice ball packings, the densest one is unique, and that it is precisely the one described by Kepler. The lattice underlying this packing is called the *face-centered cubic lattice* or, in abbreviation, the *fcc-lattice*, since it can be described by adding to the points of a cubic lattice the centers of the faces of the cubes. The connection between lattice ball packings and number theory is discussed in the next section of this article.

The general case of the Kepler conjecture turned out to be extremely difficult to resolve, despite the common belief in its correctness and numerous attempts at a proof. Among partial results is a succession of upper bounds on the density of ball packings, gradually getting closer to, but all falling short of (above, actually) the ultimate bound of $\pi/\sqrt{18}$.

The first of such bounds was given by H. F. Blichfeldt in 1929. Blichfeldt considers the more general problem of ball packings in n-dimensional Euelidean space E^n. Analytically, the unit ball in R^n is the set B^n of points $\mathbf{x}$ with $\|\mathbf{x}\| \leq 1$, where $\|\mathbf{x}\|$ denotes the distance from $\mathbf{x}$ to the origin. Blichfeldt shows that the number $(n+2)2^{-(n+2)/2}$ is an upper bound for the density of such packings. In dimension $n = 3$, this produces an upper bound of $0.88388\ldots$, a seemingly modest result considering the conjectured least upper bound of $0.74048\ldots$, but the significance of Blichfeldt's work lies in its breakthrough nature, its generality, and the simplicity of his ingenious method. Following is a short description of Blichfeldt's idea.

Given a packing $\{B_i\}$ of R^n with unit balls, replace each ball with a concentric one of radius $\rho > 1$ (these may now overlap, like spherical clouds) and furnish each enlarged ball with a mass distribution, variable from point to point, but translation invariant from ball to ball. If the total mass density at each point of space is bounded above by a constant C, then the density of the original packing of unit balls is at most $C\omega_n/M(n)$, where ω_n is the volume of the unit ball and $M(n)$ is the mass of the enlarged ball. A suitable choice of ρ and of mass distribution can produce a meaningful density bound for ball packings in R^n. Blichfeldt obtains his bound by taking $\rho = \sqrt{2}$, setting the mass distribution as $m(p) = 2 - \text{dist}^2(p, c_i)$, where c_i is the center of B_i, and by estimating that the (total) mass density does not exceed 2 at any point.

Elaborating on Blichfeldt's technique, R. A. Rankin improved his result in 1947 and gave a bound of $0.828\ldots$ for ball packings in R^3. Rankin obtained this result by suitably refining the mass distribution function and by utilizing the newly invented at that time electronic computing machines. The computational algorithm designed by Rankin was used to obtain improvements of Blichfeldt's bound in dimensions higher than 3 as well, but by tedious, computer-aided calculations, one dimension at a time, in contrast to the compact, analytical formula given by Blichfeldt.

C. A. Rogers established in 1958 a better bound that can be described in very natural geometric terms. Consider the regular simplex of edge length 2 in E^n and the collection of $n+1$ unit balls centered at the vertices of the simplex. Let b denote the total volume of the $n+1$ sectors of the balls contained in the simplex, and let s be the volume of the simplex. Then the ratio $\sigma_n = b/s$ is the Rogers bound on the density of ball packings in n-dimensional space E^n.

For $n = 2$, the bound $\sigma_2 = \pi/\sqrt{12}$ is sharp, as it is attained in the familiar triangle-patterned circle packing of the plane (see Fig. 3). Thus, this special case of the Rogers bound provided another proof of the optimality of this circle packing, originally established by A. Thue in 1910. For $n = 3$, the Rogers bound of $\sigma_3 = 0.7797\ldots$ is considerably better than the corresponding Blichfeldt bound.

Rogers' technique is based on estimating the volume of the *Voronoi region* enclosing a ball in a packing, a useful concept that goes back to P. G. L. Dirichlet and is sometimes called the *Dirichlet cell*, or the *Dirichlet–Voronoi cell* (*D–V cell*, in abbreviation). The D–V cell of a ball consists of all points whose distance from the center of the ball does not exceed the distance from the center of any other ball of the packing. Each D–V cell is a convex polyhedron. All D–V cells of balls in a packing have

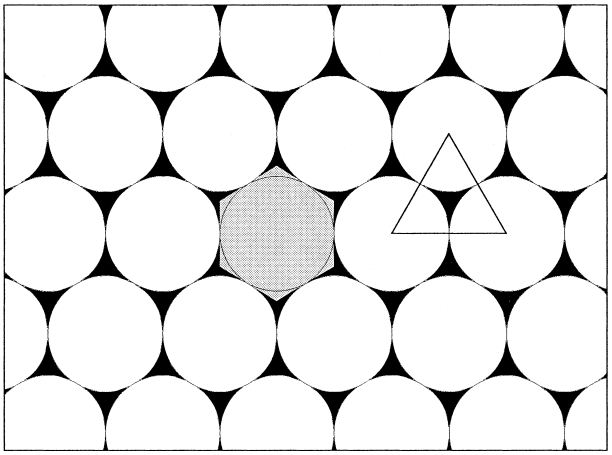

FIGURE 3 Densest circle packing. One D–V cell shown (hexagon), density's reaching Rogers bound indicated (triangle).

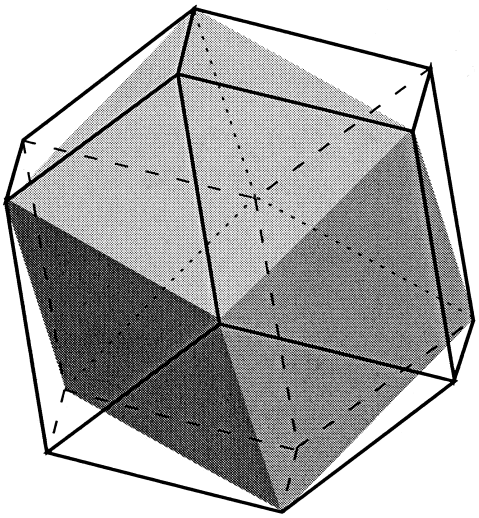

FIGURE 4 Rhombic dodecahedron. (The short diagonals of the rhombic facets form the skeleton of a cube.)

mutually disjoint interiors, and their union is the entire space. A lower bound on the volume of each D–V cell in a packing of unit balls immediately yields an upper bound on the density of the packing. The ratio between the volume of a ball and its D–V cell is called the *local density* at the ball, and the (global) density of a packing cannot exceed the maximum among its local densities. Rogers established his bound by partitioning the D–V cell radially from the ball's center into simplices and analyzing the ratio between the volume of the sector of the ball corresponding to such a simplex and the volume of the simplex.

By a refinement of Rogers' technique for $n = 3$, J. H. Lindsay improved in 1983 the upper bound to $0.77844\ldots$ and in 1993 D. J. Muder lowered it further down to $0.7731\ldots$.

Regarding the relation between the local and global densities, in the Euclidean plane E^2 the situation is relatively simple: the minimum-area D–V cell of a circular disk is the circumscribed regular hexagon, and in the triangle-patterned circle packing in which each circle is tangent to six others (see Fig. 3) each D–V cell is such a minimal regular hexagon. Thus, in E^2, the maximum global density of a circle packing is attained by maximizing the local density at each circle.

Things are not so simple in E^3: in the fcc-lattice ball packing described by Kepler, each D–V cell is a rhombic dodecahedron, a 12-faceted polyhedron circumscribed about the ball, whose every facet is a rhombus with a diagonal ratio of $\sqrt{2}$-to-1 (see Fig. 4), while D–V cells of smaller volume are easily attainable in ball packings.

For instance, the configuration of 12 unit balls tangent to a central unit ball at the midpoints of the facets of a circumscribing *regular* dodecahedron can occur, making the regular dodecahedron the D–V cell of the central ball. While the volume of the rhombic dodecahedron circumscribed about the unit ball is $4\sqrt{2} = 5.656\ldots$, the volume of the regular dodecahedron is only $5.548\ldots$. Thus, the local density of a ball packing in E^3 can be, at some balls, greater than the conjectured global maximum density.

This raises the question of the maximum local density in a ball packing. L. Fejes Tóth conjectured in 1942 that

The minimum volume D–V *cell in ball packings in* E^3 *is the regular dodecahedron.*

and this became known as the *dodecahedral conjecture*. (The upper bounds established by Rogers, Lindsay, and Muder should thus be considered as partial results toward the dodecahedral conjecture rather than the Kepler conjecture.)

Compounding the difficulty of the Kepler conjecture is the fact that, while the conjectured densest, fcc-lattice packing has local density of $\pi/\sqrt{18}$ at each of the balls, it is not the only ball packing with this property. Recall the triangle-patterned layers of this lattice packing and observe that each such layer has "deep holes" into which the balls from an adjacent layer are accommodated. But the adjacent layer occupies only one of the two triangular grids of holes, and it is possible to choose the other one for the placement of the adjacent layer instead (see Fig. 5).

These two possibilities give rise to a multitude of noncongruent layered ball packings, among which the lattice one is generated only if the shift vector from layer to layer is repeated consistently. Each of these "laminated" ball packings is of the same density, as the distance between

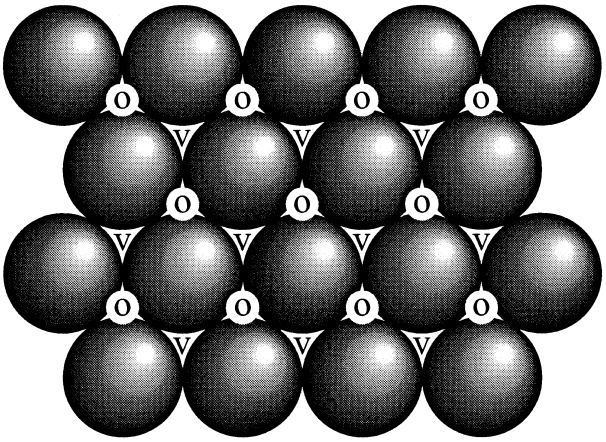

FIGURE 5 The deep holes in a triangular layer: occupied (o) and vacant (v).

the adjacent layers is the same in all of them, but in the nonlattice laminated packing the D–V cells consist, in most cases, of two congruence classes: some of them are rhombic dodecahedra, and the remaining ones form another congruence class. The exception is one particular laminated packing in which all D–V cells are of the second type (the shifts from layer to layer alternate each time). The existence of laminated packings, although not mentioned by Kepler, had already been discovered by Harriot with whom he communicated extensively on the matters of ball packing.

In each laminated packing every ball is touched by 12 balls, but the configurations of the 12 balls tangent to the central one, extracted from the laminated packings, are of two noncongruent types. Also, recall the configuration of 12 balls tangent to a central ball at the midpoints of the facets of a circumscribing regular dodecahedron. In this regular configuration, the 12 balls, while tangent to the central one, are not in contact with each other. This is so because the dihedral angle of the regular dodecahedron is smaller than 120°. Such a multitude and apparent looseness of the configurations of the 12 balls around the central one suggest the intriguing question: *What is the maximum number of congruent nonoverlapping balls that can come in contact with one ball of the same size?* This question was the subject of a famous discussion between Sir Isaac Newton and David Gregory. Newton's opinion was that 12 should be the maximum, while Gregory thought that 13 might be possible. One hundred eighty years passed before the question was settled, by R. Hoppe. Newton was right, although experiments and computations seem to give some credence to Gregory's opinion. The 12 tangent balls can be rearranged so as to make room for a 13th ball to come very close to tangency.

Realizing that local density alone is not the key to the solution of the Kepler conjecture, Fejes Tóth proposed in 1953 to consider a cluster of up to 12 D–V cells surrounding one cell, and to estimate a certain weighted average of the cell's volumes. He thereby presented a program that could potentially reduce the problem to the determination of the minimum value of a function of a finite number of variables. Considering the large number of variables involved and the overwhelming complexity of the function to be analyzed, he suggested that computers be used to carry out the astronomical amount of calculations required to complete his program.

It now appears that, due in great part to the recent development of computer technology and computing methods related to it, a confirmation of the Kepler conjecture along a program similar to that of Fejes Tóth became possible. In 1998, Thomas C. Hales announced that he completed a proof of the Kepler conjecture following years of investigations accompanied by an enormous amount of numerical calculations performed by computers. Part of the work was done by Samuel Fergusson who assisted Hales in resolving one of the critical cases. Hales' approach to the problem resembles the program of Fejes Tóth in the idea of building a space partition associated with a given ball packing and considering, along with one central ball, only a limited number of balls, not too distant from the central one. But the partition he constructs is neither of the Voronoi, nor of the dual to it, Delone type, but rather a hybrid of the two, whose definition is quite intricate, involving modifications and exceptions in several special cases.

Equally involved is the way Hales manages to balance the weights (through his elaborate "scoring system," as he calls it) to average the densities corresponding to the pieces of the partition. Even the classification of the about 5000 planar maps (i.e., the combinatorially equivalent configurations of the neighboring ball centers), too complex for a human brain to perform, was done by a computer before each case could then be analyzed and eliminated as a potential counterexample. The case analysis involved thousands of inequalities and equations, and it required a careful design of interval arithmetic to ensure the necessary computational accuracy and avoid false conclusions.

The voluminous manuscript of Hales' work describing his approach in detail and the theory behind the computations has been submitted for publication, and, at the time of the writing of this article, while believed to be essentially correct, is undergoing extensive editorial revisions. In the meantime, Hales and his student, Sean McLaughlin, announced and produced jointly a preprint with a proof of the dodecahedral conjecture, in which they utilize the strategy and computing machinery developed by Hales in his proof of the Kepler conjecture.

II. LATTICE PACKING OF BALLS—MOTIVATION FROM NUMBER THEORY

A lattice in R^n is the collection of all integer–coefficient linear combinations of a basis for R^n. Due to its periodicity, the density of the lattice packing of balls whose centers lie at the points of Λ is easily computed as the ratio between the volume of the ball and the volume of the parallelepiped spanned by the basis of Λ. The volume of the parallelepiped spanned by the vectors $\mathbf{a}_i = (a_{i1}, a_{i2}, \ldots, a_{in})$, $i = 1, \ldots, n$ is given by $|\det(\mathbf{A})|$, the absolute value of the determinant of the matrix $\mathbf{A} = (a_{ij})$. Among all lattice packings of R^n with unit balls there exists one of maximum density, and that density, denoted by $\delta_L(B^n)$, is called the *lattice packing density* of the ball.

Applications of lattice packings of balls to number theory were discovered already by Gauss, but it was H. Minkowski who by a systematic study of the theory of lattice packings developed a new branch of mathematics which he named the *geometry of numbers*. The early development of the theory of packing was motivated to a great extent by arithmetic problems. As an illustration we discuss the problem of arithmetic minimum of homogeneous positive definite quadratic forms.

Consider a lattice Λ generated by the vectors $\mathbf{a}_i = (a_{i1}, a_{i2}, \ldots, a_{in})$, $i = 1, \ldots, n$. With Λ we associate the quadratic form

$$f(\mathbf{x}) = f(x_1, \ldots, x_n) = \sum_{i=1}^{n} (a_{i1}x_1 + \cdots + a_{in}x_n)^2.$$

We investigate the minimum f_0 of $f(\mathbf{x})$ taken over nonzero integer vectors:

$$f_0 = \min_{\mathbf{x} \in Z^n} f(\mathbf{x}).$$

Observe that f_0 is nothing else but the square of the length of the shortest nonzero vector of Λ. Thus the system of balls of radius $\sqrt{f_0}/2$ centered at the elements of Λ form a packing. The density of this lattice packing is $f_0^{n/2}\omega_n/|\det(\mathbf{A})|$. Hence we get for f_0 the upper bound

$$f_0 \le \left(\frac{\delta_L(B^n)|\det(\mathbf{A})|}{\kappa_n} \right)^{2/n}.$$

This inequality is sharp. Equality is attained if the vectors $\mathbf{a}_i$ form a basis for a densest lattice packing with balls of radius $\sqrt{f_0}/2$.

Any homogeneous positive definite quadratic form

$$g(\mathbf{x}) = g(x_1, \ldots, x_n) = \sum_{i,j=1}^{n} s_{i1}x_i x_j \quad (s_{ij} = s_{ji})$$

can be written in the form

$$g(\mathbf{x}) = \sum_{i=1}^{n} (a_{i1}x_1 + \cdots + a_{in}x_n)^2$$

with appropriate constants a_{ij}. The representation is not unique but we have for any such representation that the *discriminant* $D = \det(s_{ij})$ of $g(\mathbf{x})$ is equal to $\det(\mathbf{A}^2) = (\det(a_{ij}))^2$. Thus we get the following theorem.

For each homogeneous positive definite quadratic form $g(\mathbf{x})$ with discriminant D there exists a nonzero integer vector $\mathbf{v}$ such that

$$g(\mathbf{v}) \le \left(\frac{\delta_L(B^n)D^{1/2}}{\kappa_n} \right)^{2/n}.$$

The packing density $\delta_L(B^n)$ is known for $n \le 8$. We have

$$\delta_L(B^2) = \frac{\pi}{\sqrt{12}}, \quad \delta_L(B^3) = \frac{\pi}{\sqrt{18}}, \quad \delta_L(B^4) = \frac{\pi^2}{16},$$

$$\delta_L(B^5) = \frac{\pi^2}{15\sqrt{2}}, \quad \delta_L(B^6) = \frac{\pi^3}{48\sqrt{3}}, \quad \delta_L(B^7) = \frac{\pi^3}{105},$$

$$\delta_L(B^8) = \frac{\pi^4}{384}.$$

The cases $n = 2$ and $n = 3$ were solved by J. L. Lagrange and Gauss, respectively. A. Korkin and G. Zolotarev found the values of $\delta_L(B^4)$ and $\delta_L(B^5)$ and Blichfeldt settled the cases $n = 6$, 7, and 8. There is an extensive literature dealing with the construction of efficient ball packings. We describe some of these constructions in Section IV where we give also the lattice packings of balls realizing the extreme densities $\delta_L(B^n)$ for $n \le 8$.

III. PACKING OF CONVEX BODIES

Generally, the packing theory deals with packings and lattice packings of *convex bodies*, a class of solids that includes balls. A convex body is a compact convex set with nonempty interior. Given a convex body K in E^n, a *packing with replicas of K* is a family of solids $\{K_1, K_2, K_3, \ldots\}$, each congruent to K, whose interiors are mutually disjoint. If all of the K_i's are parallel translates of each other, and if the corresponding translation vectors form a lattice, then the packing is a *lattice packing of K*. The density of a packing with replicas of K is defined in the same way as the density of a ball packing (see Section I of this article), as the corresponding lim sup. The *packing density of K*, denoted by $\delta(K)$, is defined as the supremum of the densities of all packings with congruent copies of K. According to a theorem of H. Groemer the supremum is attained. Restricting ourselves to lattice packings we obtaine the analogously defined *lattice packing density* $\delta_L(K)$ of K.

The general theory of packing of convex bodies in n dimensions is still in its early stages of development, with many of its basic problems yet to be resolved. However, the case of $n = 2$ (the plane) has been explored quite extensively and successfully. From the multitude of results on packing the plane with congruent convex disks (planar convex bodies), we choose to mention here a theorem of L. Fejes Tóth because of its significance and substantial consequences: If K is a convex disk and H is the minimum area hexagon containing K, then $\delta(K) \leq |K|/|H|$. Since the minimum area hexagon containing the circular disk is the regular circumscribed hexagon, the theorem of Fejes Tóth implies immediately the theorem of Thue on the maximum density of circle packings. Another significant consequence of the theorem of Fejes Tóth is obtained through a theorem of C. H. Dowker on centrally symmetric convex disks. Dowker proved that if K is a centrally symmetric convex disks, and $k \geq 4$ is an even integer, then among all minimum area k-sided polygons containing K there is a centrally symmetric one. Since every centrally symmetric hexagon admits a lattice tiling (*i.e.*, a lattice packing without residue) of the plane, it follows that

$$\delta(K) = |K|/|H| = \delta_L(K)$$

for every convex centrally symmetric disk.

No result analogous to the theorem of Fejes Tóth for centrally symmetric convex bodies K in dimensions higher than 2 exists, and the identity $\delta(K) = \delta_L(K)$ for such bodies does not hold true already for $n = 3$.

In 1905 Minkowski proved that for all n

$$\delta_L(B^n) \geq \zeta(n)/2^{n-1},$$

where

$$\zeta(n) = \sum_{i=1}^{\infty} i^{-n}.$$

This is a special case of the more general inequality

$$\delta_L(K) \geq \zeta(n)/2^{n-1}$$

valid for all centrally symmetric convex bodies K. This inequality bears the name of the *Minkowski–Hlawka theorem*, since it was stated implicitly by Minkowski in 1898 and proved first in 1944 by E. Hlawka. Many alternative proofs and refinements of the theorem were given, although no essential improvement is known for large n. All proofs make use of an averaging argument and thus do not say how lattices satisfying the inequality may be found. The best refinement of the Minkowski-Hlawka theorem is due to W. Schmidt who established the inequality

$$\delta_L(K) \geq cn2^{-n}$$

for every centrally symmetric convex body K and for every sufficiently large n provided $c \leq \log 2$. K. Ball used a variational argument to show the existence of lattice ball packings with a slightly greater density. He established

$$\delta_L(B^n) \geq 2(d-1)\zeta(n)/2^n,$$

which is the presently best lower bound known for $\delta_L(B^n)$.

Rogers conjectures that for sufficiently high dimensions, $\delta(B^d) > \delta_L(B^d)$. Thus far, this inequality has not been confirmed in any dimension. Moreover, except of dimensions 10, 11, and 13 (see the next section) all the best packings known are lattice packings. Also in the case of upper bounds the seeming disadvantage of lattice arrangements over general ones could not be exploited so far.

We mentioned Blichfeldt's upper bound

$$\delta(B^n) \leq \frac{n+2}{2} 2^{-n/2}$$

and its improvements by Rankin and Rogers. Although these improvements are significant in E^3, asymptotically they are only by a constant factor smaller than Blichfeldt's bound. An improvement in the exponential order of magnitude was given first by V. M. Sidelnikov in 1973. The presently best asymptotic upper bound known,

$$\delta(B^n) \leq 2^{-(0.599+o(1))d} \qquad (\text{as } d \to \infty),$$

was proved by G. A. Kabatjanskiĭ and V. I. Levenštein.

It is worth noting that the proofs of these bounds use analytic methods borrowed from coding theory. An analogue of the linear programming bound for error-correcting codes could be established first only for the ball packing problem in spherical geometry, from which the Euclidean case follows, e.g., by a Blichfeldt type argument.

Let S^n denote the n-dimensional spherical space, that is the boundary of B^{n+1}. The angular distance between two points x and y on S^n is the angle between the radii ox and oy. Let $M(n, \varphi)$ be the maximum number of caps of diameter φ forming a packing on S^n. Equivalently, $M(n, \varphi)$ is the maximum number of points on S^n all of whose angular distances are greater than or equal to φ. Still another interpretation of $M(n, \varphi)$ is that it is the maximum number of points different from the origin in E^{n+1} such that any pair of them spans an angle at the origin greater than or equal to φ.

Kabatjanskiĭ and Levenštein established the bound

$$M(n, \varphi) \leq (1-\cos\varphi)^{-n/2}\, 2^{-d(0.099+o(1))} \qquad (\text{as } d \to \infty)$$

for all $\varphi \leq \varphi^* = 62.9974\ldots^\circ$. For large values of n this bound is an essential improvement on earlier bounds by Rankin and K. Böröczky. It implies the bound for $\delta(B^n)$ as follows. In a packing of unit balls in E^n replace each ball by a concentric one of radius λ, $1 < \lambda < 2$. Consider an arbitrary point $p \in E^n$ and two centers of balls, x and y

within distance λ from p. Using the fact that the distance between x and y is at least 2, it is easy to check that the size of $\angle xpy$ is at least arccos $(1–2/\lambda^2)$. Thus, there are at most $M(n-1, \arccos(1-2/\lambda^2))$ centers of balls within distance λ from p, that is p is covered by at most $M(n-1, \arccos(1-2/\lambda^2))$ enlarged balls. Hence we obtain

$$\delta(B^n) \le \lambda^{-n} M(n-1, \arccos(1-2/\lambda^2)) \le 2^{-(0.599+o(1))d}.$$

A finite set of points on S^n is often referred to as a *spherical code*. The use of this term is justified by the following. Suppose that an information source emits words from an alphabet of size M. In order to transmit the information through a radio channel we encode the alphabet into analog symbols: with each letter we associate a function $f_i(t)$ $(0 \le t \le t_0, i = 1 \ldots, M)$, the amplitude of the radio wave to be transmitted. We assume that the radio signals have equal energy, say 1 unit and furthermore the frequency of the signals is bounded. This means that in the Fourier expansion of the signals all coefficients, except say the first $n+1$ are zero. Remembering that under right choice of the units the energy of a wave is equal to the sum of the squares of its Fourier coefficients, the signals $f_i(t)$ can be viewed as points on S^n. In order to distinguish the signals we have to keep the minimum distance among them as big as possible. We are lead to the problem considered here, just this time in the dual formulation: for given n and M we are looking for the maximum number $\varphi(n, M)$ such that M points with mutual angular distances at least $\varphi(n, M)$ can be placed on S^n.

Quite recently, H. L. Cohn and N. Elkies announced that they developed an analog of the linear programing bound for error-correcting codes to sphere packings in E^n, and used it to calculate upper bounds for the density of sphere packings, obtaining the best bounds known for dimensions 4–36. They expect that their approach can be used to solve the sphere packing problem in dimensions 8 and 24, where their bound thus obtained are extremely close to the densities of the best packings known, described in the next section as the E_8 and the Leech lattice packings, respectively.

IV. SPHERE PACKINGS AND CODES

In this section we consider further connections of sphere packings to coding theory. A *binary code* is a set of n-dimensional binary vectors (or $\{0, 1\}$-*words* of length n). The *weight* of a word is the number of its coordinates that differ from zero. The *Hamming distance* between two such vectors (or *codewords*) is the number of coordinates at which they differ. The greater the distance between two codewords, the easier it is to distinguish one from the other. Thus, reliable and efficient storage and transmission of information requires an explicitly constructed code with a large number of codewords as far from one another as possible. This can be interpreted as the sphere packing problem in the Hamming space.

A code consisting of M words of length n and with minimum Hamming distance d between any two of its words is called an (n, M, d)-code. The set of all binary words of length n is a linear space over the binary field GF(2). A code which is a subspace of that linear space is called a *linear code*, which codes are of special importance in coding theory and turn out to be interesting from a geometric point of view.

Geometrically, an (n, M, d)-code is a subset of the set of vertices of the n-dimensional unit cube. The balls of radius $\frac{1}{2}\sqrt{d}$ centered at the codewords form a packing in E^n. In a suitably chosen manner, this local sphere packing can be used to generate a periodic packing in the whole space E^n. We describe two basic constructions devised by J. Leech and N. J. A. Sloane to generate such packings.

Construction A The point $x = (x_1, x_2, \ldots, x_n)$ is a center of a sphere if x is congruent (modulo 2) to a codeword. Geometrically, this means that the unit cube, with the spheres attached to it, is translated to new positions, filling a "checkerboard" pattern in E^n. In this construction, the radii of the spheres are $\min\{1, \frac{1}{2}\sqrt{d}\}$.

Construction B This construction applies to codes in which every codeword is of even weight. The point $x = (x_1, x_2, \ldots, x_n)$ is a center of a sphere if x is congruent (modulo 2) to a codeword and $\sum_{i=1}^{n} x_i$ is divisible by 4. The radius of the spheres is $\min\{\sqrt{2}, \frac{1}{2}\sqrt{d}\}$.

Each of the constructions A and B yields a lattice packing if and only if the code on which it is based is linear.

The densest lattice packing of balls in E^n for $n = 3, 4$ and 5 is obtained by applying Construction A to the $(n, 2^{d-1}, 2)$-code consisting of all words of even weight. The densest lattice packing of balls in E^7 and E^8 can be obtained by construction A using codes obtained from an Hadamard matrix. An *Hadamard matrix* H is an $n \times n$ matrix with entries ± 1 such that $HH^T = nI$. It is known that an Hadamard matrix can exist only for $n = 1, 2$ and multiples of 4. In the case when n is a power of 2, an $n \times n$ Hadamard matrix H_n can be easily obtained by induction, setting $H_1 = (1)$ and

$$H_{2k} = \begin{pmatrix} H_k & H_k \\ H_k & -H_k \end{pmatrix}$$

for $k = 1, 2, 4, \ldots$. We consider the matrix H_8 so obtained, and observe that its first row and column contain only 1-s. Next we consider the matrix $\widetilde{H}_8$ obtained from H_8 upon replacing the $+1$'s by 0's and the -1's by 1's. The rows of $\widetilde{H}_8$ with the first column deleted form a (7, 8, 4)-code. The

codewords of this code are the vertices of a 7-dimensional regular simplex. We obtain the densest lattice packing of balls in E^7 by applying Construction A to this code. The densest lattice packing of balls in E^8 is obtained through Construction A used on the (8, 16, 4)-code consisting of the rows of H_8 together with the complements of the rows. The underlying lattice is denoted by E_8. The same lattice of balls can be obtained also by Construction B applied to the trivial (8, 2, 8)-code consisting of the all 0's and all 1's words. We mention that the densest lattice packing of balls in E^6 cannot be obtained directly by Construction A or B, but is obtained as an appropriate section of the densest lattice ball packing in E^7.

A remarkably dense lattice packing of balls in E^{24}, playing a fundamental role not only in the theory of ball packings but in group theory as well, was constructed by Leech. The construction of the Leech lattice is based on the *Golay code* G_{24}, a (24, 2^{12}, 8)-code, which can be described as follows: Let $C_{12} = (c_{ij})$, $i, j = 1, \ldots, 12$ be defined by

$$c_{ij} = \begin{cases} 0, & \text{if } i = j = 1 \text{ or } i, j \geq 2 \text{ and } i + j - 4 \\ & \text{is a quadratic residue mod 11;} \\ 1, & \text{otherwise} \end{cases}$$

and let I_{12} be the unit matrix of order 12. Then G_{24} is the 12-dimensional linear space (over $GF(2)$) spanned by the rows of the matrix (I_{12}, C_{12}). Each codeword in the Golay code is of even weight; in fact the weight of each codeword is divisible by 4.

An application of Construction B to G_{24} results in a lattice packing of balls of radius $\sqrt{2}$, which makes possible to join this packing, without overlap, with a translate of itself through the vector $(-\frac{5}{2}, \frac{1}{2}, \ldots, \frac{1}{2})$ thereby to form a new lattice packing, called, after its inventor, the *Leech lattice*. The density of this packing is $0.001930\ldots$, which compares quite favorably to the Rogers bound $\delta(B^{24}) \leq \sigma_{24} = 0.002455\ldots$. Each ball in the Leech lattice is touched by 196560 other balls, a number which happens to be the maximum possible contact number in any packing of congruent balls in E_{24}. Each of the densest known lattice packings in dimensions below 24 can be obtained as an appropriate section of the Leech lattice.

We mentioned the conjecture of Rogers according to which for sufficiently high dimensions, $\delta(B^d) > \delta_L(B^d)$. Although this inequality has not been verified for any dimension so far, in dimensions $n = 10, 11$, and 13, nonlattice ball packings denser than any *known* lattice packing have been found. These examples have been produced by applying Construction A to certain nonlinear codes.

Rush and Sloane used a modification of construction A to establish the existence of dense packings of balls and certain other convex bodies. They used to codes over larger alphabets and replaced the Hamming metric a metric generated by the convex body. For "superballs" $\{(x_1, x_2, \ldots, x_n) \in E^n : \sum_{i=1}^n x_i^\sigma \leq 1\}$ for the sequence $d_j = p_j^\sigma$ of dimensions, where p_j is an odd prime their bound exceeds the Minkowski-Hlawka bound. In a series of papers Rush improved these results further. Rush's method yields the lower bound $\delta(B^n) \geq (\frac{1}{2})^{n+o(n)}$ for the packing density of balls in E^n, which is remarkably close to the bound of the Minkowski-Hlawka Theorem. Unfortunately, the codes used in this approach cannot be explicitly given, so the method cannot be considered as "constructive."

Statistical Robustness

Bruce M. Hill
University of Michigan

GLOSSARY

Bayesian hypothesis testing Theory initiated by H. Jeffreys and developed by L. J. Savage, in which the posterior probability for a hypothesis is obtained by integrating out parameters specified by the hypothesis, using an *a priori* distribution for such parameters to weight the likelihood function.

Exchangeable Probability distribution of a finite sequence $X_1, \ldots, X_n$ of random variables is said to be exchangeable if the joint distribution of the variables is invariant under permutation, that is, all permutations of the variables have the same probability distribution.

Fiducial probability Form of post-data probability evaluation devised by R. A. Fisher, in which the observed numerical values of the data do not alter the pre-data probability distribution for certain random quantities.

Permutation Any of the sequences into which a finite set of elements can be ordered.

Post-data robustness A property of a terminal statistical decision in which the post-data expected utility obtained under *reasonable* variation in the *a priori* distribution, likelihood function, or utility function differs from the post-data expected utility of the decision by only a small percentage.

Precise measurement or stable estimation Principle formulated by L. J. Savage giving conditions under which the posterior distribution based upon a likelihood function that is sharply concentrated relative to the *a priori* distribution can be approximated by the likelihood function standardized to have unit area.

Principle of insufficient reason Principle used by T. Bayes and P. Laplace that asserts that when there are no known reasons to differentiate among a finite set of possibilities with respect to their chance of occurrence, it *may* then be appropriate to give each possibility equal probability.

Probability distribution Assignment of a unit of probability mass to various possible alternative hypotheses or outcomes.

Procedural robustness Property of a statistical or decision-making procedure in which the pre-data

expected utility obtained under *reasonable* variation in the *a priori* distribution, likelihood function, or utility function differs from the pre-data expected utility of the procedure by only a small percentage.

Random An outcome is said to be random if it is not known to be deterministic and is the result of a process that is predictable at best only in a statistical sense. Such outcomes are said to be due to chance.

I. INTRODUCTION

The word *robust* means strong, hardy, healthy. In statistics it is used to suggest that some probability evaluation or property of a decision procedure is not very sensitive to alteration of the conditions under which the evaluation is made, so that the conclusions remain essentially correct even though the precise conditions for those conclusions to hold are not satisfied. It is implicit that the evaluation or procedure is in some sense appropriate for the circumstances under consideration, since otherwise some very poor but insensitive procedures would be robust. In this article, we shall trace some important ideas concerning robustness. We shall consider robustness with respect to the prior distribution and the likelihood function, both in the post-data decision making sense and in the pre-data procedural sense. Robustness is a property which may or may not exist in any particular situation, and one may speak more generally of sensitivity analysis. Thus, if in important respects the conclusions of a statistical or decision analysis are not very sensitive to *reasonable variations* of the prior distribution, likelihood function, and utility function, then we call the analysis robust. To be more precise, this will be the case if the variation in expected utility from an action or a procedure, due to reasonable variation of the input from that of some specific prior distribution, likelihood function, or utility function, is only a small percentage of the expected utility for that specific input. Global robustness almost never holds when there is randomness, since one can always find some prior distribution, likelihood function, or utility function for which the conclusions are substantially different from those of any specified procedure. Hence it must be understood that robustness concerns only limited and reasonable variation in the input. In practice, when such limited robustness occurs it is often due to substantial common information and values, and even this is relatively rare in many important real world problems of inference and decision making.

II. ROBUSTNESS TO THE PRIOR DISTRIBUTION

Historically, one of the first questions considered concerned robustness with respect to the choice of the *a priori* probability distribution for a parameter. Probability evaluations are made either through theory, past observed frequencies, judgment, or some combination of these. This is true for both the subjective and frequentist views of probability. One of the most important ways of making such evaluations is through the principle of insufficient reason, as implicitly used by Bayes, and formulated and used by Laplace. This principle was the basis for Laplace's use of uniform distributions to evaluate probabilities by counting or combinatorical analysis. To illustrate, suppose that there are K possible values of some parameter and there is no *known* reason to distinguish one value from another with regard to its likelihood of truth. Then the principle of insufficient reason would suggest taking the probability of each possible value to be $1/K$. In the subjective approach to probability of de Finetti (1937, 1974, 1975) and Savage (1972) this is particularly natural, since if one were to be awarded a prize subject to the truth of a particular value, then one would not be able meaningfully to distinguish between the various choices, and so would be indifferent as to which value was chosen. It must be understood that this indifference is not meant as a logical rule, that is, a rule asserting that one *must* or even that one *should* be indifferent, for this is patently false. Indeed, since any two different objects are logically distinct, it is absurd to assert such indifference as a logical rule. The sun may or may not appear to rise tomorrow, but most people do not take the probability to be $1/2$. All probability evaluations are conditional on the state of information or knowledge that obtains when they are made, so that in examples such as this no sensible person would be indifferent. On the other hand, when the state of information regarding a finite number of possibilities is subjectively regarded as the same, and if one must make a choice between them, then it is difficult to see any real alternative to the principle of insufficient reason.

Bayes motivated this choice by observing that with respect to independent trials resulting in either success or failure, with the same chance on each trial, that is, a Bernoulli sequence, and where one knows little about the value of this chance, it would be reasonable to regard all possible numbers of successes in n trials as equally likely. This is a compelling evaluation, since if one were instead to take some number of successes as more likely than others, then one must know something particular to differentiate the one number or proportion from the others. It has been proven that such a subjective judgment, for each n, is essentially equivalent to giving the conventional parameter P, representing the unknown chance of a success, a uniform *a priori* distribution, that is, a Beta distribution with both parameters equal to unity.

Suppose now that one makes this evaluation, and asks whether it is robust to variations in the *a priori* distribution.

For example, consider an urn which contains only red or white balls, a known number N in all, but with an unknown proportion of red balls. Let success (1) correspond to the draw of a red ball, and failure (0) correspond to the draw of a white ball. Let H_i denote the hypothesis that there are exactly i red balls in the urn, $i = 0, \ldots, N$. An urn is picked at random, that is, with equal probability for each urn, and then a simple random sample of size n is drawn from that urn. On the basis of this sample we want to draw inference as to which urn was drawn from, that is, the proportion of red balls in that urn, and also to predict the color of the next ball to be drawn from that urn. With regard to the probabilistic prediction of the color of the next ball, this example is a special case of the general problem of inductive reasoning, as formulated by David Hume. If the *a priori* probability for each H_i is $1/(N+1)$, then it is straightforward to make the evaluation, which is equivalent to that made by Bayes, and, as $N \to \infty$, corresponds to that based upon the uniform *a priori* distribution for P. See Feller (1968, p. 123). Now, however, let us ask what happens if the probability for the hypothesis H_i is p_i instead of $1/(N+1)$. To what extent will the evaluation that we have made be robust to such variation in the *a priori* probability distribution?

There is an extremely simple method of analysis due to de Finetti (1975, p. 221). A finite sequence $X_1, \ldots, X_N$ of random variables is said to be exchangeable if the joint distributions are invariant under permutations. In other words, it is exchangeable if for each $k < N$, and each subset of (distinct) indices $j_1, \ldots, j_k$, the distribution of $X_{j_i}, \ldots, X_{j_k}$ is the same as that for $X_1, \ldots, X_k$. An infinite sequence is said to be exchangeable if each finite subsequence is exchangeable. Exchangeability is a condition expressing the judgment that order is completely irrelevant for probabilistic evaluations. This condition can itself be viewed as a consequence of the principle of insufficient reason, where the finite collection of possibilities about which one is indifferent consists of the $n!$ permutations of a given sequence of n outcomes, and one cannot differentiate one such permutation from another with respect to its chance of occurring.

Mathematically, exchangeability is a far-reaching generalization of the concept of independent identically distributed random variables. According to a celebrated theorem of de Finetti, the class of infinite exchangeable sequences consists of all mixtures of independent identically distributed sequences of random variables. See de Finetti (1937; 1975, Chapter 11), Feller (1971, p. 228), Savage (1972, p. 50). In the finite case, the class of exchangeable distributions for 0–1-valued data can be represented in terms of sampling without replacement from urns such as described above.[1] See de Finetti (1975, p. 217) and Heath and Sudderth (1976).

Consider the (potentially) infinite exchangeable sequence of 0–1-valued variables X_j, where X_j takes on the value 1 if there is a success on trial j, and is 0 otherwise. Suppose that our probability distribution for the sequence is exchangeable, and that we have observed the data $X_j = x_j$ for $j = 1, \ldots, n$, where each x_j is either 1 or 0. Denote by $\omega_r^{(n)}$ the probability that there will be r successes in the first n trials. Because of exchangeability it follows immediately that

$$\omega_r^{(n)} = \binom{n}{r} \times P(X_1 = \cdots X_r = 1, X_{r+1} = \cdots X_n = 0). \tag{1}$$

Now let us consider the evaluation of $p_r^{(n)}$, which is by definition the conditional probability that the next observation is a success, given that there were r successes in the first n trials. For the case considered by Bayes and Laplace, where P is given the uniform *a priori* distribution, it is an elementary computation that $p_r^{(n)} = (r+1)/(n+2)$. We wish to examine the extent to which this computation is robust to the *a priori* distribution for the number of successes in n trials. It follows from the definitions of exchangeability and of conditional probability that $p_r^{(n)}$ does not depend upon which r of the values x_i are 1. So let $\mathcal{D}$ represent the data in which the first r trials yield success and the next $n - r$ trials yield failures. Then

$$\begin{aligned} &P(X_{n+1} = 1 \mid \mathcal{D}) \\ &\quad = \frac{P(X_1 = \cdots X_r = X_{n+1} = 1, X_{r+1} = \cdots X_n = 0)}{P(\mathcal{D})} \\ &\quad = \frac{\omega_{r+1}^{(n+1)} \times \binom{n}{r}}{\omega_r^{(n)} \times \binom{n+1}{r+1}} \\ &\quad = \frac{[(r+1)/(n+2)]}{1 + [1 - (r+1)/(n+2)](a_{r,n} - 1)}, \end{aligned} \tag{2}$$

where $a_{r,n} = \omega_r^{(n+1)}/\omega_{r+1}^{(n+1)}$. In this evaluation, which is straightforward, apart from exchangeability it has been assumed only that $P(\mathcal{D}) > 0$.

This simple formula exhibits the robustness properties of the Bayes–Laplace evaluation. For any exchangeable distribution on the X_j such that $a_{r,n}$ is close to unity, the posterior probability that the next trial is a success

[1] For any such exchangeable sequence of length n, one must wind up with some number of successes, say i, between 0 and n. Under exchangeability all ordered sequences (or paths) leading to the same number i of successes are equally likely, and this is also true for sampling from an urn with exactly i red balls. It follows that if the probability p_i for sampling from the ith urn (which has i red balls) is taken equal to the probability of i successes in n trials for the given exchangeable sequence, then the distribution of observations from such urn sampling is the same as that for the given exchangeable sequence.

is necessarily close to $(r+1)/(n+2)$, and it is exactly equal to this value when $a_{r,n}=1$. But the condition $a_{r,n}\approx 1$ requires, from the subjective viewpoint, only the inability to distinguish sharply between the occurrence of r and $r+1$ successes in $n+1$ trials, and would often hold in practical applications, especially when n is large. Furthermore, for any fixed *a priori* distribution π for p, one can easily examine the extent to which this evaluation is robust, or insensitive to the choice of π. One obtains the classical Bayes–Laplace formula $(r+1)/(n+2)$, to a very good approximation, for any exchangeable distribution subject to the approximate truth of the condition. In this example, we have obtained a clear understanding of the nature and degree of robustness to the choice of the prior distribution for the parameter P of a Bernoulli process. Equation (2), when $r=n$ and $a_{r,n}=1$, is known as Laplace's rule of succession, which was put forth as a predictive probability for the next trial giving rise to a success when all previous trials have resulted in success and little is known beforehand about the chance of success. It is a completely valid and robust evaluation for the circumstances in which it was proposed, and agrees with common sense far more than does the maximum-likelihood estimate r/n. For example, if there has been one success in one trial, the Bayes–Laplace predictive probability that the next trial is a success is $2/3$, while the maximum-likelihood estimate is the unreasonably large value 1. Historically, there has been controversy about some applications of this formula, perhaps based upon misunderstandings regarding the intentions of Laplace.

III. PRECISE MEASUREMENT

The robustness to the prior distribution that we have exhibited in the special case of a Bernoulli process occurs in many problems in statistics. The general principle was formulated by Savage (1962) under the name *precise measurement* and again by Edwards *et al*. (1963) under the name *stable estimation*. The general description is as follows. Let Θ be a parameter (scalar or vector) for a family of probability distributions, with probability densities $f(x;\theta)$, say, relative to Lebesgue measure.[2] In other words, the parameter Θ identifies a particular probability distribution for the data. It is assumed that there is a true value for the parameter, say θ_0. We observe a sequence of random variables $X_1,\ldots,X_n$ which are conditionally independent, given θ_0, each having density $f(x;\theta_0)$. For a particular observed sequence of observations, say $X_i=x_i$ for $i=1,\ldots,n$, the realized likelihood function is the function

$$l(\theta)=\prod_{i=1}^{n} f(x_i;\theta).$$

According to all accepted statistical theory, given the truth of the model, this function carries all the information in the data and is a technically a sufficent statistic.

Under very weak conditions that often hold in practical applications, one can show that if the sample size n is sufficiently large, then it is probable that there will exist a neighborhood $\mathcal{N}$ of θ_0 in which the realized likelihood function will be unimodal with most of its mass concentrated in that neighborhood. In fact, often $l(\theta)$ can be approximated by a multivariate normal density function with center at $\hat{\theta}$, where $\hat{\theta}$ is the maximum-likelihood estimate of θ, that is, the value of the parameter that maximizes $l(\theta)$. The covariance matrix for this approximation to the likelihood function can be written as A/n, where A is a function of the observed data. For example, A is often obtained by using a quadratic approximation to $\log l(\theta)$ near $\hat{\theta}$.

Now suppose that the *a priori* density $\pi(\theta)$ for the parameter Θ is diffuse relative to $l(\theta)$, that is, $l(\theta)$ is much more concentrated than is $\pi(\theta)$, and that $\pi(\theta)$ is nearly constant in the neighborhood $\mathcal{N}$ of $\hat{\theta}$ in which almost all of the mass under the likelihood function is contained. Then it is clear that conditional upon Θ being in $\mathcal{N}$, the posterior distribution for Θ is essentially given by the likelihood function standardized to have total area 1 in $\mathcal{N}$. Furthermore, if $\pi(\theta)$ is nowhere too large outside $\mathcal{N}$, then the posterior mass to be attached to the complement of $\mathcal{N}$ will be negligible, so that the posterior distribution for Θ is well approximated by the conditional posterior distribution for Θ, given $\Theta\in\mathcal{N}$, which is essentially just the likelihood function standardized to have unit volume in $\mathcal{N}$, and so also is often well approximated by a normal density with center at $\hat{\theta}$ and covariance matrix A/n.

The collection of such results makes up the precise measurement principle of L. J. Savage. Details concerning the approximation are given in Savage (1962) and Edwards *et al.* (1963). This method of analysis constitutes one of the primary means by which robustness of the posterior distribution can be obtained, that is, substantial consensus as to the truth concerning the value of Θ, even when there are quite diverse initial opinions π among scientists. The argument does not always hold, since for individuals with relatively concentrated *a priori* distributions, the posterior mass outside the neighborhood $\mathcal{N}$ favored by the data can be large, or the *a priori* distribution may not be nearly uniformly distributed even within $\mathcal{N}$, or the integral of $l(\theta)$ may be infinite. But for large n the argument is often very useful, and sometimes even for small n. One may

[2] Measure theory is not essential here. The probability densities can be viewed as approximations to discrete mass distributions, and the integrals as approximations to the finite sums that arise in real-world scientific and decision-making problems.

view the situation as follows. The *a priori* distributions π for different individuals vary for many reasons, such as past experiences and exposure to data, different theoretical knowledge, genetic reasons, and so on. But the data of the experiment are common to all individuals and tend to bring their opinions closer together. When there is sufficiently such data the opinions of different scientists and/or decision makers tend to merge.

IV. FIDUCIAL ARGUMENT

If one assumes an infinite sequence of Bernoulli trials, Bayes and then Laplace would have in effect taken the *a priori* distribution for the Bernoulli parameter P to be uniform on the interval [0, 1]. An objection that was raised with regard to this choice was that if the parameter were transformed by a monotonic transformation, say to $\Theta = \log[P/(1-P)]$, then it would be different to take a uniform *a priori* distribution for P than to do so for Θ, and that this could lead to somewhat different results, at least for small samples, since uniformity for Θ is formally equivalent to taking the density for P to be $\pi(p) = 1/[p(1-p)]$. Similarly, if the parameter were $\log P$, then this would mean that the implicit density for P was $1/p$.[3] It was argued that each such choice for parameter was equally valid with the choice of P, that uniformity for the *a priori* distribution of each such parameter was equally valid with uniformity for P, and that therefore there was nothing special about taking the uniform distribution for P, as had been done by Bayes and Laplace.

Such arguments entirely ignore the motivation by Bayes and Laplace to avoid bias in predicting the number of successes in n trials, as well as robustness arguments such as that of de Finetti given above. However, they opened the door for the statistician R. A. Fisher initially to reject the Bayesian approach, in effect because the prior distribution for P could be chosen in many ways, with the implicit notion that the posterior distribution would not be robust with respect to the various meaningful choices for the *a priori* density of P. See Fisher (1959, p. 16).

When the sample size n is not large he was correct that in many problems of statistical inference the conditional distribution of the parameter, given the data, can be quite sensitive to the choice of the *a priori* distribution. As a means of avoiding such issues regarding the choice of the *a priori* distribution, Fisher then suggested his fiducial approach as an alternative to the method of Bayes. Initially he was under the impression that it was a totally different approach, which allowed one to go from a state of total ignorance about a parameter to a state of probabilistic knowledge concerning the parameter, based upon observational data. To illustrate the fiducial method, consider the important case of an observable variable $X \sim N(\mu, 1)$, where this notation means that, given μ, the distribution of X is the normal distribution with mean μ and variance 1. Before observing the value of X, one is therefore of the opinion that, given μ, the random quantity $X - \mu \sim N(0, 1)$. The fiducial argument asserts that after observing $X = x$, it is then the case that $x - \mu \sim N(0, 1)$, and hence also $\mu \sim N(x, 1)$, where x is the observed numerical value, and now μ is the unknown, given a probability distribution.[4] Fisher here used the older concept of probability of Bayes and Laplace, where probability is used to express a state of knowledge about an unknown quantity, which need not be random in the conventional sense, but merely unknown. Fisher never succeeded in supplying a rational argument for his evaluation but insisted that it was both plausible and logical in some unspecified sense. He thus appeared to have obtained a post-data probability distribution for the parameter without having input a prior distribution, and was therefore seemingly not subject to the various criticisms with respect to robustness of the Bayesian approach. However, precisely the same result is obtained if one uses the Bayesian approach with the *a priori* distribution for μ taken as Lebesgue measure interpreted as an improper probability distribution. Furthermore, similar relationships between the fiducial method and the Bayesian method with improper prior distributions hold in many important examples of statistical inference.

Late in his life Fisher (1959, p. 51) acknowledged:

> Probability statements derived by arguments of the fiducial type have often been called statements of 'fiducial probability'. This usage is a convenient one, so long as it is recognized that the concept of probability involved is entirely identical with the classical probability of the early writers, such as Bayes. It is only the mode of derivation which was unknown to them.

The argument that fiducial probability was in essence nothing more than a surreptitious Bayesian posterior evaluation had in fact been given by Jeffreys to Fisher in debates at the *Royal Statistical Society*. The quotation suggests that Fisher eventually consented to the arguments of Jeffreys. Fiducial analysis, when it could be justified at all, was equivalent to a special case of the Bayesian analysis with a uniform *a priori* distribution for the appropriate

[3] These last two densities are called improper because the integral over the domain is infinite. For the first, the predictive probability that the next trial is a success, given r successes in n trials, is the same as the maximum-likelihood estimate, r/n. For the second, it is $r/(n+1)$. For large n, all of the commonly recommended prior distributions for P lead approximately to r/n.

[4] A random quantity such as $X - \mu$, whose distribution remains the same after X is replaced by its observed value x, is sometimes called a pivotal quantity.

parameter. It is straightforward to prove that this is true for problems concerning location and scale parameters. Apart from this Bayesian interpretation, as an alternative method for obtaining the posterior distribution, the fiducial argument has not received much support in statistical theory.

Furthermore, an example of Edwards (1972, p. 207) shows that this argument is highly suspect as a logical argument, insofar as, if accepted, it would provide a logically valid proof for the principle of insufficient reason. But, as argued above, this principle is absurd as a *logical* rule. By *reductio ad absurdum*, the fiducial argument can then be rejected as a logical argument. Here is Edwards's example. Let there be two hypotheses concerning a number H, that it may have value $+1$ or -1. We assume in the Fisherian sense that there is no *a priori* information about the value of H. Let X be an observable random variable, also with the same two possible values. Let the probability model for the data be such that $P(X=+1 \mid H=+1)=p$ and $P(X=+1 \mid H=-1)=q$, where $p+q=1$. The probability distribution for the random quantity $Y=HX$ does not depend upon the value of H. Thus $HX=+1$ if and only if either both quantities are $+1$ or both are -1, and so

$$P(Y=+1 \mid H=+1)=P(Y=+1 \mid H=-1)=p.$$

This is a standard requirement in fiducial theory, as when the distribution of the quantity $X-\mu$ does not depend upon μ in the normality example. Now let $p=q=1/2$. In this case, the observation of X is totally uninformative with respect to the value of H. As Edwards says, "it will be universally agreed that the observation of X is so utterly uninformative about H that there is no point in even making it."

But if we apply the fiducial argument, under which we can substitute for the random variable X its observed value, say $X=+1$, it follows that the post-data or fiducial probability for the event $H=+1$ must be $1/2$. Edwards, arguing that such a conclusion cannot be valid, states "Thus, starting with absolutely no information about H, and conducting an absolutely uninformative experiment, we end up with a definite statement of probability."

There can be no more decisive demonstration than this that the fiducial argument, as a logical argument, is invalid. One can perhaps make technical objections to the example, but it seems clear that the very essence of the fiducial argument, as a logical argument, has been destroyed.[5] Of course, the example only disproves the fiducial argument as a logical argument, not as an openly *subjective* evaluation equivalent to a form of the principle of insufficient reason and only to be used in those circumstances where it is judged appropriate. In Edwards's example the Bayesian analysis would consist in taking the prior probability for each hypothesis to be .5, and then, since the experiment is totally uninformative, the posterior probability is of course also .5. Here the principle of insufficient reason *might* be employed to obtain the prior probability, whereas the fiducial argument would purport not to use the principle of insufficient reason at all, but rather to obtain the same post-data probability of .5 on the grounds of having absolutely no knowledge *a priori* as to which hypothesis was true. Just as in the examples of Jeffreys, there was an implicit *a priori* distribution involved in the use of the fiducial argument.

Despite this criticism of the fiducial argument as a logical argument, there is a sense in which it was an innovative and valuable contribution to statistical inference. To illustrate, one of the most important examples of the fiducial approach concerns the nonparametric predictive procedure discussed by 'Student' (W. S. Gossett) and Fisher, which the present author later restated and called A_n.[6] The procedure A_n asserts, for an exchangeable sequence of observable random variables in which ties have probability 0, that conditional upon the data $X_1, \ldots, X_n$, the next observation X_{n+1} is equally likely to fall in any of the open intervals between successive order statistics of the given data (Hill, 1968, p. 677). Note that unconditionally upon the data (or equivalently if the X_i for $1 \le i \le n$ were not observed) this would be immediate, since under exchangeability all orderings of the data are equally likely. Therefore X_{n+1} is unconditionally equally likely to be the largest or the smallest observation or have any other rank among the $n+1$ observations.

In this problem there is a high degree of sensitivity to the choice of the *a priori* distribution for the parameter, which is taken as the unknown distribution function in the fully nonparametric case. One can of course input a proper *a priori* distribution for the distribution function and mechanically perform a Bayesian analysis; but different reasonable choices for such an *a priori* distribution can lead to *very different* posterior distributions, and no single choice in which the conditional distribution of X_{n+1} depends on the data has been convincing. On the other hand, the unconditional probability that X_{n+1} is in each of the open intervals between consecutive order statistics is exactly $1/(n+1)$ since this probability is the same as the probability that X_{n+1} has each of the $n+1$ possible ranks, and this probability is objectively determined merely by the fundamental assumption of exchangeability with ties

[5] In the second edition of his text, Edwards indicated that he was not entirely satisfied with his own argument but gave no reasons. He may have had in mind some minor technical issues with respect to the precise definition of a pivotal quantity.

[6] See Aitchison and Dunsmore (1975) for a general discussion of predictive inference.

having probability 0. Hence this is a perfect example for the Fisherian criticism of the Bayesian approach since the unconditional probabilities are well determined, while the *a priori* distribution is highly subjective, and the conditional probabilities are quite sensitive to the choice of the *a priori* distribution.

Here is how the fiducial argument would apply. Consider a conventional formulation of statistical inference, in which the observations are conditionally independent, given Φ, with cumulative distribution function $F(x;\phi)$, where Φ is an unknown parameter. Assume that the distribution function is continuous in x for each ϕ, but is otherwise unknown. Let $X_{(i)}$ denote the ascending order statistics of the data for $i=1,\ldots,n$. Then let $\theta_i = F(X_{(i)};\phi) - F(X_{(i-1)};\phi)$ for $i=1,\ldots,n+1$, where by definition $X_{(0)}=-\infty$ and $X_{(n+1)}=\infty$. Before the data are drawn, the distribution of the θ_i is a uniform distribution on the n-dimensional simplex, that is, a special Dirichlet distribution in which all the parameters are equal to unity.[7] This is the fundamental frequentistic intuition with regard to A_n, which Fisher presumably used to put forth his proposed fiducial solution. Then Fisher (1939, 1948) applied the fiducial argument to suggest that even when the random variables $X_{(i)}$ are replaced by their observed values $x_{(i)}$, the uniform distribution for the Θ_i would still be appropriate. Fisher seemingly was unaware of the concept of exchangeability, or the close connection of this problem with the original example of Bayes, and did not address any of the criticisms or issues raised by the fiducial argument in this example.

Fisher's proposed fiducial distribution is an example of a posterior predictive distribution since whatever the rationale, it is posterior to the data and does partially specify a probability distribution for the future data. This predictive distribution is not completely specified since (in the case where ties have probability 0) what it does is to attach a probability of $1/(n+1)$ to each of the $n+1$ open intervals formed by the consecutive order statistics of the given sample and goes no further. The fiducial argument that Fisher gave for this evaluation depends upon one's willingness to persist with the pre-data evaluation of the distribution of $\theta_i = F(X_{(i)};\phi) - F(X_{(i-1)};\phi)$ *after* the $X_{(i)}$ are replaced by their observed numerical values. The question then arises as to whether there is a Bayesian analysis for which the same evaluation is also appropriate conditional upon the data for all or almost all such data, as in our discussion of other examples of the fiducial argument.

At first sight, there does not seem to be any implicit *a priori* distribution to justify this, although the conclusion is plausible when little is known about the population. However, Hill (1968, 1993) showed that A_n has both exact and approximate Bayesian justifications in the case of diffuse *a priori* knowledge about the shape of a finite population, and proposed A_n as a robust Bayesian procedure. It is exactly valid for merely simply ordered data, or for data measured on a 'rubbery scale,' as when the finite population values are distorted by some measuring instrument that is equivalent to making an unknown monotonic increasing transformation of the original values. For large n, A_n tends to agree with the empirical distribution function insofar as intervals containing a substantial number of order statistics are given very nearly the same predictive probability. Both the empirical distribution function and A_n are primary examples of robust statistical analyses, neither depending on any assumed special *a priori* information as to the shape of the finite population. A_n is the extension of the notion of a robust *a priori* distribution for a conventional parameter to the case where the parameter is the entire distribution function.

The A_n example is at the heart of some important issues concerning statistical inference. First, the fundamental objectivistic frequentist argument would support A_n on the basis that the evaluation is correct unconditionally, so that in repeated applications of the procedure the empirical frequencies would agree with the evaluation. For example, X_{n+1} would be the largest of the $n+1$ observations with a relative frequency of about $1/(n+1)$. Although one can input a proper *a priori* distribution and obtain a standard Bayesian updating for the conditional probabilities, rather than merely use the unconditional probabilities, the complexity of the problem and the sensitivity to the prior distribution dictate against doing so unless a convincing case can be made for one out of the myriad of such choices for the *a priori* distribution. This is not an argument against Bayesian updating in general, but such updating requires the greatest care in a nonrobust scenario such as this and should not be done merely for mathematical convenience.

Next, although this frequentist argument supports A_n, Hill (1968) proved for each $n \geq 1$ that there are no countably additive distributions on the observations for which the A_n evaluation holds almost surely, that is, for almost all $x_1,\ldots,x_n$. Thus either frequentists must abandon their fundamental argument regarding sensitivity and complexity or else abandon the special role of countable additivity in their theory. Furthermore, Hill (1993) showed that there do exist finitely additive processes, called splitting

[7]The Dirichlet distribution is the multivariate generalization of the Beta distribution, and the uniform Dirichlet distribution is the multivariate generalization of the uniform distribution on an interval. See DeGroot (1970, p. 49). A_n, which is a special case of H_n of Hill (1968, 1993), can be viewed as the generalization of the Bayes–Laplace analysis of binary data to the multinomial case, with an *unknown* number of categories or types. A_n is related to the Dirichlet process of Ferguson (1973). H_n allows for ties and smoothing in the framework of A_n. Both A_n and H_n are known to be coherent in the sense of de Finetti, so that a Dutch book or sure loss is not possible.

processes, for which A_n does hold almost surely, and which are thus in fact compatible with the fundamental frequentist arguments. Thus the use of A_n achieves the frequentist objective long run frequencies and also has the coherency properties of Bayesian decision procedures. Splitting processes are based upon the adherent mass distributions of de Finetti (1971, p. 240), which are in turn closely related to the Dirac functions as used by physicists and engineers. Finitely additive probability distributions provide a mathematically rigorous way to deal with conventional nonfinite measures such as Lebesgue measure.

The fiducial approach, as used in connection with A_n, can again be seen as a method of reasoning to derive a Bayesian posterior distribution by an indirect evaluation rather than in the traditional way. Whatever its defects, it was an important first step in what may be called Bayesian data analysis. See Hill (1990). It put forth a post-data probability distribution for the parameters, or for future observables, that was coherent in the sense of de Finetti, plausible in some circumstances, and robust in various respects. For example, in the case of A_1 with normal data, we have robustness to the *a priori* distribution for μ, in the sense that the fiducial conclusion holds to a good approximation whenever the prior distribution for μ is diffuse relative to the likelihood function, as is made clear by the stable estimation argument of Savage. In many examples the fiducial argument may be regarded as being equivalent to a robust Bayesian approach with a uniform *a priori* distribution for the appropriate parameter. The fiducial approach is oriented both toward scientific inference, which typically takes place in a unique context, and also to the policymaker problem of Hill (1990), which concerns repeated applications of a certain policy.[8] In circumstances where the fiducial argument is appropriate, it leads to a relatively uncontroversial and robust analysis, as is requisite in public policy issues.

V. PROCEDURAL ROBUSTNESS

Post-data robustness concerns the sensitivity to the *a priori* distribution, likelihood function, or utility function, of post-data expected loss due to terminal decisions. It is of particular importance in real-world scientific and decision-making problems, where the data are available and have been analyzed and one wishes to examine to what extent the optimal decision changes when one makes reasonable variations in the input. Procedural robustness, on the other hand concerns the pre-data evaluation of sensitivity to *a priori* distribution, likelihood function, or utility function, of the overall consequences of using a certain procedure, especially when done repeatedly under similar circumstances. In this context there is ordinarily no data analysis, and all probability distributions are prespecified before obtaining the data (see Berger, 1984, Section 3; Hill, 1990). Procedural robustness is of particular importance in assessing the value of a policy or strategy to be used repeatedly, as in bureaucratic organizations.

In connection with the controversy over the Behrens–Fisher distribution, it was discovered that the Fisherian fiducial method did not always agree with the confidence approach that became part of the Neyman–Pearson theory of statistics. See Fisher (1959, p. 95). The Neyman–Pearson departure from the Fisherian approach emphasized the behavioral properties of a procedure rather than scientific or inductive inference, and was oriented toward what may be called the policymaker problem. This theory is primarily concerned with the consequences of repeated applications of a procedure. For example, in the case of normally distributed data considered above, Neyman would argue that the interval $X \pm 1.96$ is a 95% confidence interval in the sense that under repeated application of the method, about 95% of the intervals would include the true μ. In this approach one is not concerned with individual instances of the truth or falsity of the assertions, but rather with the overall long-run consequences that follow from use of the procedure. Fuller understanding of the difference between the concepts of Neyman and Pearson and those of Fisher emerged from the work of A. Wald, who was working in the spirit of Neyman and Pearson. Based in part on earlier work of J. von Neumann dealing with game theory, he proposed a theory of admissible decision functions, as an attempt to rule out those procedures that were objectively defective. See Wald (1950).

In the conventional formulation of a statistical decision problem, there is a space of actions $\mathcal{A}$, a parameter space Θ, and observable data represented by a random variable X. A decision function d is a function that for each possible data value x specifies an action $a \in \mathcal{A}$ to be taken. The action space represents the various possible final or terminal actions that are contemplated and from among which one wishes to choose. The parameter space represents the most important aspects of reality about which one is uncertain that are believed to be relevant to the decision problem. There is also a utility function $U(\theta, a)$,[9] which represents the value to the decision maker of choosing act a when Θ is the true value of the parameter. If the true value of Θ were known, then one would need no data. One would

[8] In considering the greenhouse effect or the destruction of the environment, it is not natural (or desirable) to consider hypothetical repetitions of the overall experiment. One wants, instead, to understand the particular phenomenon in question, and to do something about it.

[9] Or alternatively, there is a loss function, $L(\theta, a)$, often taken as the negative of utility.

simply choose, for that Θ, the act that maximizes utility, $U(\theta, a)$, or minimizes loss, $L(\theta, a)$. When Θ is unknown, however, one may still have to choose an action. To help in such a choice, one can first observe relevant data, which reduces the degree of uncertainty about the value of Θ.

Wald's theory is closely related to the Bayesian theory, but not identical to it. In the Bayesian theory, at any state of knowledge about Θ, if an action must be taken, then an optimal action is to choose the value a that maximizes the expected utility, that is, that maximizes

$$\mathbf{U}(a) = EU(\theta, a),$$

where the expectation is taken with respect to the current probability distribution for Θ. Suppose the initial state of knowledge is represented by the distribution with density $\pi(\theta)$. In the Bayesian theory, after observing data $X = x$, the *a priori* distribution π is updated to become the posterior distribution π^* according to Bayes's theorem. Then one maximizes posterior expected utility by choosing an action a that maximizes $\mathbf{U}(a)$ with respect to π^*. In the decision theory of Wald one also allows the possibility that there is no prior distribution π, or if there is, it is unknown, and not to be specified subjectively. In this case one can define the concept of admissibility of a decision function without reference to the *a priori* distribution. Suppose that $L(\theta, a)$ is the loss function, and let $R(\theta) = E_{X|\theta} L(\theta, d(X))$ be the expected loss if decision function $d(X)$ is used when θ is the value of the parameter, that is, the usual risk function. We say that a decision function d_2 is inadmissible if there exists another decision function d_1 such that $R_1(\theta) \leq R_2(\theta)$ for all θ, with strict inequality for some θ. If a decision function is not inadmissible, then it is said to be admissible. One can reason as follows that inadmissible decision functions should be eliminated from consideration whenever possible.

Let Θ be a conventional parameter that determines the distribution of the random variable X and let $d_i(X)$, $i = 1, 2$, be two decision functions that depend on the value of X. Suppose that we are in a situation that is repetitive and that $L(\theta, d_i(X_j))$ is the loss to be sustained if d_i is used on the jth occasion, $j = 1, \ldots, M$. Then the expected losses, given the value of Θ, are

$$R_i(\theta) = E_{X|\theta} L(\theta, d_i(X)), \qquad i = 1, 2,$$

which are the risk functions. Here X is a generic random variable having the same distribution as each X_j. In general in this framework of repetitive situations there is the possibility of learning from one occasion to another, as for example, via data analysis. However, in some circumstances the decision functions will be mechanically implemented on a computer without the statistician or decision maker actually observing the X_j, so that no learning can take place from one occasion to another. In this case the theory is a pre-data theory of optimality, that is, before observing the data one desires an optimal policy to adopt for the given framework of repetitive decision making. We shall assume this is the case in the present discussion.

Suppose now that there is a referee who generates couples (θ_j, X_j) on a computer for $j = 1, \ldots, M$, using a probability distribution π to generate the θ_j, and some conditional distribution for X_j, given θ_j. Let the referee generate M independent couples in this way. Assume that the conditional distribution for X_j, given θ_j, is known to all concerned, but not π. In this case the loss associated with use of d_i on the jth occasion is $L(\theta_j, d_i(X_j))$. Summing over the M occasions, the actual increment in loss if d_2 were used on each occasion instead of d_1 would be $\sum_{j=1}^{M} [L(\theta_j, d_2(X_j)) - L(\theta_j, d_1(X_j))]$. The expectation of this increment, from the perspective of the referee who knows π, is then $K \times M$, where K is the π expectation of $K(\theta) = E_{X|\theta}[L(\theta, d_2(X)) - L(\theta, d_1(X))] = R_2(\theta) - R_1(\theta)$. If d_2 is dominated by d_1 in the sense of admissibility, then $R_2(\theta) - R_1(\theta) \geq 0$, with the inequality strict for some θ. So if π gives positive weight to the set of θ where the inequality is strict, then $K > 0$. This evaluation is mathematically valid for loss functions bounded from below.

If π has positive mass where $R_2(\theta) - R_1(\theta) > 0$, then from the perspective of the referee, who knows π, it would be imprudent to use d_2 in preference to d_1 because of laws pertaining to large M (laws of large numbers, central limit theorems) under which the overall loss would be regarded as likely to be large if M were large. The reference to a referee is made primarily to represent the situation where there is some mechanism which generates what might be called a 'true' distribution for Θ, so that one can assess the performance of the two decision functions from the perspective of such a distinguished distribution. It is not necessary that such a referee exist, but only the mechanism. This is the fundamental frequentist argument as to why inadmissible decision rules should be eliminated from consideration whenever possible in the case of repeated applications of a pre-data procedure. See Hill (1990) for further discussion.

Suppose that there is a referee (or mechanism) and that his distribution is π_0, which is unknown to the decision maker, who must then choose his own π without knowledge of the true π_0. A plausible method is to guess at π_0 and use the Bayes procedure for the guess. Formally, such a guess would be the decision maker's prior expectation of the referee's π_0. Because the Bayes risk is a continuous function of π, it follows that if the guess is close enough to the truth, then the risk for the procedure will be close to the risk of the optimal procedure, that is, the Bayes procedure with respect to π_0. See Blackwell and Girschick (1954, p. 147).

With respect to any statistical decision procedure we can consider robustness with respect to the choice of π and the likelihood function (or model) in the above framework. We first assume that the likelihood function is completely known, and then in the next section consider the case where it is unknown. When the parameter space and data space are finite, it is well known that if a procedure is Bayes with respect to an *a priori* distribution for which all prior probabilities are positive, then it is admissible, while if it is admissible, then it is Bayes (Blackwell and Girschick, 1954, p. 127). It follows that the Bayes procedures for such finite representations form a complete class, in the sense that for any other procedure there is a Bayes procedure that will dominate it. In fact, provided only that the data space and terminal action spaces are finite, it is possible to obtain by routine linear programming methods a Bayes procedure whose risk function is uniformly less than that of the original procedure by some $\epsilon > 0$ (Hill, 1998). Since all real-world statistical analyses are performed on a computer (or the equivalent) with finite memory, the *implementation* of any procedure is necessarily based upon a finite representation for the data, and such linear programming methods can be employed quite generally.

One of the arguments against the use of Bayes procedures concerns their lack of robustness in certain scenarios, such as that of nonparametric statistics. In these cases non-Bayesians have proposed certain relatively robust decision procedures, such as, for example, the empirical distribution function in the case of nonparametric statistics, and more generally the maximum-likelihood estimator. Typically such procedures, although robust, do not have the optimality properties of Bayes decision procedures. However, using the above-mentioned linear programming methods, one can replace such estimators or decision procedures by Bayes procedures that are uniformly better in risk than the original procedure. The resulting procedure is both robust and has the optimality properties of a Bayes procedure. When the original non-Bayes procedure can only be improved upon slightly (although uniformly) there is little reason to do so, but unfortunately many non-Bayes procedures in common use can be greatly improved upon.

VI. ROBUSTNESS TO LIKELIHOOD FUNCTION

A number of robustness studies have compared different procedures for estimation of the parameters of a distribution, for example, comparing a trimmed mean estimator with some standard estimator such as the mean, when the model under which the mean is appropriate is false. A trimmed mean is the average after deletion of a certain proportion of observations in the upper and lower tails of the sample. Suppose that the true likelihood function is a mixture of two normal distributions of the form

$$(1-\epsilon)\times n\left(x;\mu_1,\sigma_1^2\right)+\epsilon\times n\left(x;\mu_2,\sigma_2^2\right), \qquad (3)$$

where $n(x;\mu,\sigma^2)$ is the density of the normal distribution with mean μ and variance σ^2.

Such a distribution is sometimes said to be contaminated by the second component of the mixture. It is clear that in certain circumstances the trimmed mean procedure can be far superior to use of the ordinary sample mean as an estimate of μ_1, which is the mean of the uncontaminated population. This occurs because if μ_2 is very different from μ_1, then the ordinary mean will show a substantial 'bias' since it will be estimating $(1-\epsilon)\mu_1+\epsilon\mu_2$ rather than μ_1. This bias can be greatly reduced by using a trimmed mean since one can thereby eliminate many of the observations from the 'contaminating' population. On the other hand, if either $\epsilon=0$ or μ_1 is very close to μ_2, then one has greater precision by using the ordinary sample mean. Thus, there is the usual tradeoff between bias and precision in a statistical analysis, and which estimator is appropriate depends on what the true distribution is (Hill, 1980).

The basic problem is virtually identical with the policymaker problem of the previous section, except that here one must consider robustness with respect to the likelihood function as well as robustness with respect to the prior distribution. The improvement obtained by using one estimator versus another for repetitive situations is given by

$$\sum_{j=1}^{M}[L(\theta_j,d_2(\underline{X}_j))-L(\theta_j,d_1(\underline{X}_j))].$$

In this formula the d_i are any two specified estimators. For example, d_1 might be the ordinary sample mean and d_2 some trimmed mean. On the jth repetition, a sample $\underline{X}_j$ is taken from a population with true mean θ_j for the uncontaminated population, and we wish to estimate θ_j. The θ_j might themselves be a sample from some underlying population that arises in a production process, for example, θ_j might be a measure of the quality of the jth uncontaminated batch produced by the process. If the model for the jth repetition is the contaminated mixture (3) with $\mu_1=\theta_j$, then, as in the previous section, we can examine the referee's expectation of the above sum, using some prior distribution for the θ_j that reflects empirical knowledge as to how the parameter varies during the production process. In this example, the contamination might be due to a certain proportion of defective items in each batch.

Standard robustness studies often implicitly use a uniform prior distribution for the location parameters and then only consider robustness with respect to the model or

likelihood function. Empirical studies can then demonstrate the degree of improvement by using one procedure versus another. In an industrial control process where a great deal is known about the distributions, for example, about the percentage of observations that are contaminated, great improvements can be obtained by using trimmed means and other such estimators. See Andrews *et al.* (1972) for robustness studies. It would be desirable also to examine robustness to the utility or loss function, which is often of critical importance in real world problems. Although, as before, it is desirable to eliminate inadmissible or non-Bayesian procedures, sometimes the full Bayesian analysis is very difficult to carry out. Thus a full Bayesian analysis would require an *a priori* distribution for ϵ and the parameters, and perhaps even form, of the contaminating distribution. Presumably much is sometimes known from past experience about ϵ, but it might be the case that *a priori* information about the contaminating distribution was not extensive. The practicalities of the situation can then force one into approximating the Bayes procedure by conditioning on only part of the total data. See Hill (1975, 1980) for examples of such robust analyses when the full Bayesian analysis is not feasible. Even in such cases, the above method of comparison can still be used to decide between any two specified procedures.

VII. EXAMPLES OF NONROBUSTNESS

One of the primary examples of nonrobustness arises in the theory of Bayesian testing of hypotheses initiated by Harold Jeffreys and Dorothy Wrinch in the 1920s. This theory appears in Jeffreys (1961) and was developed by Savage *et al.* (1962) and Edwards *et al.* (1963).

Suppose that there are two hypotheses about reality, say H_i, for $i = 1, 2$, and we desire to choose between them. We assume that the two hypotheses form a partition so that exactly one is true. We are given data $\mathcal{D}$ to aid in the choice. Suppose that the hypothesis H_i specifies a probability distribution, or model, for the data. In particular, suppose that given this hypothesis, there is an unknown parameter Θ_i and also a probability distribution π_i for Θ_i. The parameter may be different for the two hypotheses, and the hypotheses need not be nested, that is, one need not be a special case of the other. It follows from the theory of coherency that the essential calculation, relevant to the choice of hypothesis, is that of the Bayes factor, or likelihood ratio in favor of H_1:

$$\mathcal{L} = \frac{\int l_1(\theta_1) \times \pi_1(\theta_1)\, d\theta_1}{\int l_2(\theta_2) \times \pi_2(\theta_2)\, d\theta_2}, \tag{4}$$

where $l_i(\theta_i) = P(\mathcal{D} \mid H_i)$ is the likelihood function under hypothesis H_i. One must multiply the Bayes factor by the prior odds in favor of H_1 to obtain the posterior odds, say $\mathcal{O}$. The posterior probability for hypothesis H_1 is then $\mathcal{O}/(1+\mathcal{O})$.

In typical examples, the hypothesis H_1 can be taken to be a sharp null hypothesis in the sense that if this hypothesis were known to be true, it would specify a value for the parameter Θ_1, or at least a tightly concentrated distribution π_1. The integral in the numerator of this equation can then generally be evaluated relatively easily. The nonrobustness enters in because under the hypothesis H_2, one would ordinarily use some relatively diffuse distribution π_2 for the parameter Θ_2. As discovered by Jeffreys, it is not possible simply to use a uniform distribution over Euclidean space for π_2 since then one would always accept H_1. Jeffreys suggested the use of a Cauchy distribution for π_2 to obviate this difficulty. In some real world problems of hypothesis testing, however, there is great sensitivity to the precise choice of π_2, and so the evaluation of posterior odds may not be robust. A simple concrete example that arises in forensic science is discussed by Shafer (1982).

Suppose that a crime is committed in which there is broken glass at the scene of the crime. A suspect is picked up, and it turns out that there are shards of glass on his clothes. The refractive index of the glass at the scene of the crime is θ_1, which we take as known. It is supposed that the critical evidence against the suspect is that the measured refractive index of some glass found on his clothes, x, is close to θ_1. It may be observed that it would be common sense that if glass with refractive index θ_1 is quite rare, and if x is sufficiently close to θ_1, then there can be strong evidence that the suspect is guilty. The two hypotheses are the hypothesis H_1, which asserts that the suspect is guilty of the crime, and the hypothesis H_2, which asserts that he is innocent. We will assume that one or the other of these is true, where implicitly there is some precise definition of guilt. If the suspect is guilty, we have in mind that the refractive index of the glass on his clothes, if there should be such glass, is likely to be close to θ_1; if he is innocent, then we would use some distribution, say π_2, to represent our opinions about the refractive index of glass on such a person, without any special reason to anticipate that this index might be close to θ_1. For example, one might take π_2 to be the distribution that one would use if the person were merely sampled at random from some appropriate subpopulation.

In problems of this type it is certainly not appropriate simply to choose a uniform *a priori* distribution under H_2 and mechanically perform a Bayesian analysis. The use of the Bayesian methodology serves to illustrate the basic point discovered by Jeffreys, that the conclusions can be very sensitive to the *a priori* distribution π_2. For example, if we take a sufficiently large interval and use a uniform prior distribution over this interval for the parameter, given the alternative hypothesis, then the data will support

the sharp null hypothesis. It is clear that depending upon the specification of π_2, one can obtain almost any conclusion that one wishes, and that for the analysis to have any real force there must be some reasonable grounds for the choice of π_2, for example, based upon the empirical distribution of refractive indices in some relevant subpopulation. When there are no such grounds, and with such sensitivity to the choice of π_2, no 'objective' solution is possible. *Any approach that pretends to obtain an* '*objective*' *solution in such circumstances is merely disguising the basic uncertainties involved in the problem*. When there are such grounds, then the practical force of the Bayesian approach is via sensitivity analysis. For example, taking a set of *a priori* distributions that can be agreed upon by most reasonable people, we may find that the conclusions are robust, that is, that there is overwhelming evidence of guilt or innocence. A virtue of this theory is that it makes very clear what would be requisite for a consensus among rational people.

There are numerous other examples of nonrobustness in statistics, such as in the analysis of the random effects model in Hill (1980) and, more generally, in problems with many parameters. Such nonrobustness is typically the case in important societal issues. If one asks questions concerning economic policy, or concerning the effect of capital punishment in the deterrence of crime, or concerning the existence of the greenhouse effect, or concerning methods of preventing the destruction of the environment and loss of species, or merely concerning how to dispose of our garbage, there is an extremely large number of underlying parameters of the various models, and the conclusions from even the most careful Bayesian analysis will be highly sensitive to the specification of the various *a priori* probability distributions and likelihood functions. It is really only in the simplest of examples that anything approaching an 'objective' conclusion emerges. When this occurs, it usually stems from the fiducial argument of Fisher or the stable estimation analysis of Savage, and sometimes from the Jeffreys–Savage analysis of the hypothesis testing problem. In these cases we may speak of a robust analysis, but rarely otherwise.

VIII. CONCLUSIONS

The problem of robustness in statistics has been formulated from a decision-theoretic point of view. The standard examples where such robustness occurs and leads to a consensus of opinions have been discussed. These include cases where the fiducial argument is compelling and is a robust Bayesian argument, where the principle of stable estimation holds, and where there is a consensus as to the choice of π_2 in the Jeffreys–Savage evaluation of posterior odds. To obtain a convincing statistical analysis, it is necessary to learn about real-world mechanisms that generate both parameter values and data, to obtain as nearly as possible optimal procedures to make use of such information, and finally to perform a sensitivity analysis under reasonable variation of the input. Because in real-world problems there is typically an enormous number of unknowns, it is important to recognize the limitations of all statistical procedures and to learn how to base inference and decisions upon those aspects of the problem for which there is the solidest evidence, whether about the *a priori* distribution, the likelihood function, or the utility function, rather than mechanically to implement some procedure.

GLOSSARY

Likelihood function Function that specifies how the probability of a given realized set of data depends upon unknown parameters or hypotheses under consideration.
Posterior distribution Probability distribution obtained by means of Bayes's theorem and used to represent the beliefs, knowledge, or opinions of a person after the analysis of a specific set of data.
Prior distribution Probability distribution used to represent the beliefs, knowledge, or opinions of a person prior to analysis of a specific set of data.

BAYESIAN STATISTICS is named after Thomas Bayes (1702–1761), whose posthumously published article, "An essay towards solving a problem in the doctrine of chances," initiated the modern-day subject. A biographer of Bayes, Holland (1962), writes of this article that "it ranks as one of the most famous, least understood, and controversial contributions in the history of science. . . . Thomas Bayes . . . expressed ideas in science and in the humanities which will endure as long as man retains his freedom of thought and the power to express it." Indeed, Bayes's theorem and postulate are central to the theory of Bayesian statistical inference and decision making, which in turn are central to understanding of the process of scientific induction and of the nature and limitations of human knowledge. I shall here give some history of Bayesian statistics and a guide to its key precepts. Three main topics will concern us: induction, coherency, and utility.

I. INTRODUCTION

Let us begin with induction. The British philosophers Bacon, Locke, and especially David Hume (1748) proposed notions pertaining to the way in which human beings absorb information or data, in other words, to the process of learning from experience. The theory of probability was in its infancy in the 18th century and was still largely concerned with simple games of chance. It was Bayes who first put forth a probabilistic approach to learning from experience. He carefully analyzed an example in which it was reasonable to presuppose a form of symmetry with respect to the position of balls on a level table, as described below in Section D. There are two separate aspects to the analysis of Bayes: one is the use of Bayes's theorem, which follows easily from the conventional definition of conditional probability; the other is Bayes's postulate,

which amounts to the choice of a particular *a priori* or prior distribution. Bayes's theorem states that if one has a finite partition of the sure event, that is, a finite collection of mutually exclusive and exhaustive events, say H_i, then provided that $Pr\{\text{Data}\} > 0$,

$$Pr\{H_i \mid \text{Data}\} = \frac{Pr\{\text{Data} \mid H_i\}Pr\{H_i\}}{Pr\{\text{Data}\}}, \quad i = 1, \ldots, k.$$

The prior or initial probabilities $Pr\{H_i\}$ represent beliefs, knowledge, or opinions prior to the specific data being analyzed, while the probabilities $Pr\{H_i \mid \text{Data}\}$ represent the posterior or post-data probabilities for the same hypotheses, given the data at hand.[1] The quantities $Pr\{\text{Data} \mid H_i\}$, viewed as a function of i, constitute what is today called the likelihood function. This function specifies how the probability of the observed data, which is considered fixed and given, depends upon the unknown quantity or parameter, here the hypothesis H_i. The likelihood function is central to all modern-day statistical theory (Savage, 1962, pp. 15–20) and is viewed by some as having objective validity, for example, because it may be based upon an established probability model for the data. On the other hand, the initial probabilities are often viewed as being more controversial since they may represent subjective judgment as to the truth of the various hypotheses. No one questions the validity of Bayes's theorem as a mathematical theorem, and the controversy about this theorem concerns its use for scientific inference and decision making. Those who object to its use sometimes argue against the explicit introduction of subjective judgment as represented by the $Pr\{H_i\}$. Those who support its use view subjective or personal judgment as indispensable, not only for the prior probabilities, but even with respect to the choice of a model or likelihood function for the data, and question whether any other concept of probability has real-world meaning.

It should be noted that use of Bayes's theorem is nearly tantamount to the notion that statistical inference consists in the rational updating of initial opinions, as represented by the $Pr\{H_i\}$, to become post-data opinions, as represented by the posterior probabilities $Pr\{H_i \mid \text{Data}\}$. It is in this sense that Bayesian statistics is inductive, that is, it proposes a way to learn from experience. One goes from the state of knowledge represented by the initial probabilities to that represented by the posterior probabilities, using a method which incorporates in a coherent fashion the data being analyzed. The posterior probabilities based upon a particular set of data may then be used as prior probabilities for the analysis of a new set of data. Thus the procedure is ongoing, with opinions continually being revised as new data are assimilated. It can be argued that such a method of updating probabilities is part of a formal logic for dealing with uncertainty.

In the modern Bayesian approach of de Finetti (1937, 1974) and Savage (1972), the probabilities are all interpreted as subjective or personal probabilities, representing *judgment* rather than merely past frequencies, although such frequencies may be instrumental in the evaluation of the initial probabilities. Probability itself has been a highly controversial subject, with the three primary approaches being the formalistic approach of Kolmogorov, the frequentistic approach based on the assumption of limiting frequencies, and the subjective approach. In the celebrated exchangeability theorem of de Finetti (1937) a result, scarcely less important than Bayes's theorem itself, was proved, that gave the first clear understanding of the relationship between the subjective approach and the frequency approach, and which some believe to constitute a solution to the problem of induction as formulated by Hume.

The problem that de Finetti posed and largely solved was that of justifying from a subjective point of view the importance of statistical frequencies. Suppose that we have a sequence of related events E_i for $i = 1, \ldots, N$, each of which may or may not occur, for example, where E_i is the result of the ith flip of a coin. For convenience, we can assign the value 1 to heads and 0 to tails. It is natural sometimes to view the order of the flips as irrelevant, so that any permutation of the same sequence of results is given the same probability. This leads to the notion of exchangeability, which is a symmetry condition, specifying that joint distributions of the observable random quantities are invariant under permutations of the indices. Sequences of independent and identically distributed random variables are necessarily exchangeable, but the collection of exchangeable distributions is much more general, including in addition mixtures of such sequences, and sequences that arise from sampling without replacement. De Finetti proved a representation theorem which implies that if one regards a long sequence as exchangeable, then it necessarily follows that one's opinions can be represented, approximately, by a mixture of Bernoulli sequences, that is, of sequences for which there is a 'true' (but typically unknown) probability P of heads, and such that conditional upon $P = p$, the observations are independent with probability p of giving a head (success) on each toss. The parameter P is then said to have the mixing distribution given by de Finetti's theorem. Such a representation is exact for infinite sequences, and a slight modification holds also for finite sequences, the difference amounting to that between sampling with and without replacement from an urn.

[1] It is customary to use the symbol '|' to indicate that the information to the right of this symbol is being conditioned upon.

If one observes the outcomes in a sufficiently long such sequence of exchangeable events, say E_i for $i \leq n$, where $n < N$, then it easily follows that the remaining events E_i for $n < i \leq N$ are also conditionally exchangeable, given this data, and that to a good approximation one will be led to base opinions about a future trial on the past empirical frequency with which heads (or success) has occurred; this constitutes de Finetti's justification for induction. In his work de Finetti emphasized prediction of observable quantities, rather than what is usually called inference about parameters. In other words, he was primarily interested in the posterior distribution of future observable variables, rather than in the posterior distribution for the parameter P.

The exchangeability theorem of de Finetti in fact shows that the conventional Bernoulli parameter P can be interpreted as the limiting proportion of successes, and the above mixing distribution, sometimes called the de Finetti measure, is identical with the *a priori* distribution in the sense of Bayes. Consider, for example, a large, finite number k of trials, such as flips of a coin, each of which can result in success (1) or failure (0). Assume the trials are exchangeable, and let P_k be the proportion of successes to be obtained in the k trials. The possible values for P_k are then the fractions i/k, with $0 \leq i \leq k$. Now introduce the hypothesis H_i that asserts that the proportion P_k will have the value i/k. One and only of these hypotheses must be true. Let $\pi_k(\cdot)$ represent the *a priori* probability distribution for the hypotheses, so that $\pi_k(i/k)$ is the *a priori* probability for hypothesis H_i. It can be shown that as k goes to infinity, π_k converges to the mixing distribution π for P that arises in de Finetti's representation theorem.

Now consider the sequence of observable trials X_j for $j = 1, \ldots, n$, where $X_j = 1$ if there is a success on trial j, and $X_j = 0$ if there is a failure on trial j. If k is substantially larger than n, then conditional upon the value of $P_k = p$, this sequence is approximately a Bernoulli sequence with parameter $P = p$. Since P_k is itself random, this produces, to a good approximation, a probabilistic mixture of Bernoulli sequences, with π as the weighting function for the mixture. Suppose that we now observe the results of the first n trials, so that we are given the data $X_j = x_j$ for $j = 1, \ldots, n$, where x_j is 1 or 0 depending upon the outcome of the jth trial. The likelihood function for these data is therefore approximately

$$L(i/k) = (i/k)^r \times (1 - i/k)^{n-r},$$

where $r = \sum_{i=1}^{n} x_i$ is the number of successes in the n trials.[2] If the data consist of the results of the first n trials, it follows that the posterior distribution for the parameter P_k given by Bayes's theorem is

$$\pi_k^*(i/k) = Pr\{H_i \mid \text{Data}\} \approx \frac{\pi_k(i/k) \times L(i/k)}{\sum_{i=0}^{k} \pi(i/k) \times L(i/k)}.$$

Given the outcomes of the first n trials, the posterior predictive distribution for the results of the future trials $X_{n+1}, \ldots, X_k$ can therefore be obtained by first updating the prior distribution π_k for P_k to yield the posterior distribution π_k^* for P_k and then using this posterior distribution as a mixing distribution to represent opinions about future events. For example, to predict the next observable variable X_{n+1}, we have

$$\begin{aligned} &Pr\{X_{n+1} = 1 \mid \text{Data}\} \\ &\quad = \sum_{i=0}^{k} Pr\left\{X_{n+1} = 1 \mid \text{Data}, P_k = \frac{i}{k}\right\} \times \pi_k^*(i/k) \\ &\quad = \sum_{i=0}^{k} \frac{i}{k} \times \pi_k^*(i/k). \end{aligned}$$

The same basic method can be used for the joint posterior predictive distribution of several future observations. See Savage (1972, pp. 50–55).

Thus the process of induction proceeds as follows. One first decides, using subjective judgment, whether one regards the sequence as approximately exchangeable. If so, one specifies one's prior distribution π_k for the proportion of heads in a large number k of trials. Finally, given the data, one updates this prior distribution to become a posterior distribution by means of Bayes's theorem and then uses the posterior distribution to obtain the posterior predictive probabilities for future observations. See Section D for further discussion. Since de Finetti's theorem holds not only for events, but for the most general random quantities, such a procedure is theoretically available in all problems of statistical inference based upon exchangeable sequences of observations. Although one may object for one reason or another to such a procedure, it is clearly a proposed solution to the problem of the revision of human knowledge based upon experience.

Now let us consider a justification for such a procedure based upon the notion of coherency. In the work of de Finetti (1937, 1974) the primary aim is to avoid the possibility of a Dutch book, that is, to avoid sure loss on a finite collection of gambles. Thus, suppose one has taken on a finite collection of gambles of any type whatsoever, including such things as investments, insurance, and so on. One can prove that a necessary and sufficient condition for the avoidance of sure loss of a positive amount greater than some $\epsilon > 0$ on a finite number of gambles (whether unconditional or conditional) consists in consistency with

[2] The exact likelihood function is given by a hypergeometric distribution. See Feller (1968, p. 43).

the axioms of finitely additive probability theory. In other words:

1. The probability of an event is a nonnegative number.
2. $Pr\{S\} = 1$, where S is the sure event.
3. The probability of a finite union of disjoint events is the sum of the probabilities.
4. Conditional probabilities are such that

$$Pr\{A \mid B\} = Pr\{A \text{ and } B\}/Pr\{B\},$$

provided that $Pr\{B\} > 0$.

These axioms for subjective probability theory are identical with those for the conventional probability theory of Kolmogorov (1950), except that in the latter the finite additivity of Axiom 3 above is replaced by the stronger condition of countable additivity, so that also the probability of a *denumerable* union of disjoint events is the sum of the probabilities.[3] Countable additivity has never been demonstrated within the rigorous approaches to probability theory, and is viewed by subjectivists as merely a particular continuity condition that one may or may not wish to adopt in a particular context, just as with the use of continuous functions in physics.[4] In de Finetti's theory a probability is interpretable as a price one pays for a gamble on the occurrence of an event. A conditional probability on A given B is interpreted as a price for a called-off gamble, that is, a gamble which one either wins, loses, or is called off, according as to whether both A and B occur, B but not A occurs, or B does not occur, respectively. de Finetti proposes the use of gambles involving small amounts of money to assess probabilities, so as to avoid utility complications. His theory is consistent with that of Savage (1972), who simultaneously develops subjective probability and utility.

II. DECISION MAKING

The next subject that I wish to discuss concerns the relationship of the Bayesian approach to decision making. In the work of Blaise Pascal and Daniel Bernoulli it was recognized that when one is faced with a decision problem, one is implicitly dealing with questions of judgment of truth, as represented by probability, and judgments of value, as represented by utility. A utility function is a numerical valued function defined for various 'consequences' or 'rewards.' The modern Bayesian approach to utility was first formulated by Ramsey (1926), and culminated in the theory of Savage (1972). Savage shows that one can derive both subjective probability and utility by means of the same underlying concepts and methods, which he formulated axiomatically. He begins with qualitative probability, and then shows under what circumstances it can be extended to quantitative probability. He then derives the existence of a utility function, which is such that one action is preferred to another if and only if the first yields a higher expected utility. Within his theory optimal decision-making requires specification of a prior distribution, a likelihood function, and a utility function. Given the data, one uses Bayes's theorem to update the prior probabilities to posterior probabilities and then acts in a specified decision problem so as to maximize posterior expected utility. In some contexts it is convenient to employ loss functions instead of utility functions, in which case one minimizes posterior expected loss. The utility function can be either a personal utility function or some group utility function, however, chosen. Decision procedures of this sort are called Bayes procedures. See DeGroot (1970, Chapter 8).

Although some would argue against the use of utility or loss functions in problems of statistical inference (as opposed to decision problems), others have observed that without some attempt to measure utility or loss there would be no punishment for even the most absurd procedures. It is true, however, that sometimes the utility or loss function is not well known or that there is disagreement with regard to its choice. As observed by Savage, in a formal sense one can deal with unknown parameters of a loss function just as one deals with other statistical parameters. See Savage (1972, p. 15).

There are a number of variations of the basic de Finetti coherence theory that differ with respect to details of the exact definition of sure loss. For example, some statisticians of the school of A. Wald take admissibility as defining the concept of coherence, and others take extended admissibility. Admissibility of a decision procedure means that it is not possible to find another procedure that does at least as well for every possible value of the parameter or unknown quantitity and strictly better somewhere, where performance is measured with respect to expected loss, given the parameter, for some specified loss function. Extended admissibility means that it is not possible to do better everywhere uniformly by some fixed $\epsilon > 0$. If a procedure is admissible, then it is plainly also extended admissible, so extended admissibility is a less restrictive condition. The main theorems on these subjects are to the effect that either a statistical procedure is a Bayes procedure, or a limit of Bayes procedures, or else it is

[3] In the Kolmogorov formulation Axiom 4 provides the definition of conditional probability.

[4] In his book that founded the modern measure-theoretic approach to probability, Kolmogorov (1950, p. 15) states that the axiom of countable additivity cannot be justified except by expediency. Later he developed a theory of complexity to replace some or all of conventional (non-Bayesian) probability theory.

inadmissible, or even inadmissible in the extended sense. See DeGroot (1970, p. 133). The upshot of the theory of Wald, which was formalized outside of the Bayesian theory, is that reasonable objective criteria for performance of statistical estimators or decision procedures dictate that optimal procedures are necessarily Bayes procedures.

In fact, any real-world decision procedure must necessarily be implemented on a computer with finite memory. If a specified such procedure is not a Bayes decision procedure, then it is possible to improve its risk function uniformly in the parameter by Bayes decision procedures. In other words, there exists an $\epsilon > 0$ such that no matter what the true value of the parameter or unknown, the expected loss (or risk) will be lowered by at least that ϵ. Furthermore, this can be done using simple and standard algorithms for linear programming (Hill, 1998). This result demonstrates that any non-Bayesian decision procedure is logically defective, and according to the frequency theory of probability, will lead to huge and unnecessary costs in repeated applications.

Nowadays, many statistical procedures have the word 'Bayes' attached to them, for example 'empirical Bayes' and 'intrinsic Bayes.' The use of the word 'Bayes' may be intended to suggest the desirable properties and character of genuine Bayes procedures, whether or not this is in fact the case. However, in all such examples either the procedure is in fact a genuine Bayes procedure, in which case there is no need for such adjectives as 'empirical' or 'intrinsic,' or else it can easily be improved upon uniformly by genuine Bayes procedures. Roughly, one can say that any procedure, proposed from any point of view whatsoever, is either a Bayes procedure or else is defective in an objectively verifiable sense.[5]

III. CRITICISM

Let us now turn to some of the criticisms of the Bayesian approach. Bayes's theorem was nearly lost until it was rediscovered by Laplace, who was responsible for extremely innovative uses of Bayesian methods and applications to many different areas of science and human affairs. Bayesian methods were also employed by Gauss in his theory of least squares. Later in the 19th century, however, there was criticism of some of the uses to which Bayesian methods had been put by Laplace and his disciples. This view culminated in the work of the statistician R. A. Fisher, who in his early work was a severe critic of the Bayesian approach. Fisher introduced the fiducial approach to statistical inference, which he initially believed was more objective than the Bayesian. It is one of the many ironies concerning the Bayesian approach that Fisher eventually understood that his fiducial argument was at best only a special case of Bayes's theorem, with an appropriate uniform prior distribution and using a different method to derive the posterior distribution.

This takes us back to Bayes's postulate. His example concerned the relative positions of balls on a level table relative to a specified side wall. An initial ball is rolled and then n additional balls by the same mechanism, the rolls being mutually independent. Each of the n additional balls is scored a success (1) or a failure (0) according as it is or is not closer to the specified side than the initial ball. If the data consist of r successes in n rolls following the roll of the initial ball, then Bayes obtains $(r+1)/(n+2)$ for the conditional probability that the next roll will be a success. He assumes that there is no information as to the positions of the balls, only knowledge as to which rolls gave successes and failures. Although the original rolls are independent, the comparison with the initial ball introduces exchangeable dependency, and the sequence of successes and failures in fact forms the first nontrivial example of an exchangeable sequence.[6]

Bayes's arguments were along the following lines. First, he assumed that the levelness of the table implied a uniform distribution for the distance of the initial ball from the specified side. Over a century later Poincaré's study of the roulette wheel problem provided a justification for the uniform distribution, at least if the balls were rolled with a high velocity. See Feller (1971, p. 62). In the case of a uniform distribution for the position of the initial ball relative to the specified side, if X denotes this random position and if the length of the table is taken as unity, then conditional upon $X = x$, the sequence of n successes and failures based upon the n additional rolls becomes a Bernoulli sequence with unknown parameter $P = x$. Since $P = X$ is itself random (with a uniform distribution), this generates a probability mixture of Bernoulli sequences and is exchangeable. Next, even apart from his explicit example, Bayes suggested that it would be reasonable in the case of n trials of a similar structure, about which one knew little, to take all numbers of successes in n trials as equally likely, that is, with probability $1/(n+1)$ for each of the $n+1$ possibilities. From a modern point of view, based upon de Finetti's exchangeability theorem, this approach would not require the introduction of any unknown parameters such as the P of a Bernoulli sequence. However,

[5]This need not, however, entirely rule out non-Bayesian procedures, since they sometimes provide reasonable approximations to Bayes procedures in situations which are too complex to allow for an exact Bayesian solution to be derived and implemented, at least in the present state of science and technology. However, to justify the usage of such a non-Bayesian procedure it would be necessary to examine the adequacy of the approximation in each application.

[6]The concept of exchangeability was not explicitly formulated until the 20th century.

it can be proved that if such an assignment of probability is made for each n, then implicitly one is acting as though there were a P and one had a uniform prior density function π for P, where now P can take on any value between 0 and 1.

Much of the criticism of Bayes's postulate revolves about the appropriateness of such a prior distribution in situations other than the one he explicitly considered, where it was assumed that the table was level and each position of each ball equally likely. Fisher argued that for a Bernoulli sequence, if one transforms the original parameter P to a different parameter, say $\Theta = f(P)$, where f is a nonlinear monotonic transformation mapping the unit interval into itself, then one cannot in the usual theory of probability have both P and Θ uniformly distributed. Hence he questioned the appropriateness of taking a uniform *a priori* distribution for P as opposed to a uniform *a priori* distribution for such a Θ. However, it is clear that if the *a priori* distribution is to represent a state of ignorance with regard to the proportion of successes in n trials, then any nonuniform distribution for this proportion would constitute a bias towards some particular proportions as opposed to others (Edwards, 1978).

Fuller understanding of this phenomenon revolves around the theory of precise measurement (or stable estimation) of Savage (1962, pp. 20–25) and DeGroot (1970, pp. 198ff) which built upon the work of Laplace and Harold Jeffreys. The likelihood function for the parameter P is the function $L(p) = p^r \times (1-p)^{n-r}$, where r is the number of successes in n trials and p is between 0 and 1. One can show that for sufficiently large n this function tends to be sharp or highly concentrated relative to the prior distribution π. Since by Bayes's theorem the posterior density for P is proportional to the product of the likelihood function and prior density for P, it follows under some very mild conditions that if the prior density is nearly constant in an interval of length $c/\sqrt{n}$ about the maximum-likelihood estimate,[7] for some suitable constant c, then for practical purposes the posterior distribution can be taken as just the likelihood function, standardized so as to have unit area.

This constitutes the main sense in which statistical inference can be objective, at least within the Bayesian theory. Thus, although one need not have a uniform prior distribution for P, the posterior distribution, to a good approximation, may be as though this were the case. This argument in fact provides a justification based upon robustness for Bayes's postulate in many examples. The related work of Jeffreys (1961) is based upon choices of prior distributions, sometimes called invariant or uninformative, which are not necessarily uniform in the original parameter. For example, when the parameter is positive Jeffreys ordinarily takes the logarithm of the parameter to have a uniform distribution, with related modifications for bounded parameters and other special cases. When the conditions for precise measurement obtain, this typically makes only a negligible change in the posterior distribution. Many Bayesians refer to all such prior distributions as diffuse relative to the likelihood function. A diffuse prior distribution for the empirical distribution in a finite population leads to Bayesian nonparametric statistical prediction and inference as in Hill (1968), which generalizes the original work of Bayes.

The phenomenon of precise measurement is completely general, although particularly in high-dimensional problems prior distributions are often not diffuse relative to the likelihood function. Jeffreys also initiated the development of the theory of Bayesian tests of hypotheses, which involves nondiffuse prior distributions under the alternative hypothesis. See also Savage (1962, pp. 29–33). Here the notion is that given a hypothesis, there is a prior distribution for the parameters which that hypothesis specifies. One then obtains the posterior probability for the hypothesis, given the data, using Bayes's theorem as before, except that now the probability for the data given the hypothesis is expressed as a mixture or integral, integrating out with respect to unknown parameters. Such a procedure is quite different from conventional tests of hypotheses and resolves some difficulties associated with the latter.

Another criticism of the Bayesian approach concerns its use for prediction of future observables. From its inception with Bayes and Laplace, the Bayesian approach was concerned not only with conventional statistical inference about unknown parameters, but also with the prediction of future observables. Examples include the prediction of weather, interest rates, survival times for patients given a treatment for cancer, earthquakes, or the collapse of a bridge. The Bayesian approach allows one to obtain a posterior predictive distribution for future observables as well as a posterior distribution for conventional parameters. In fact, one can first obtain the posterior distribution for any unknown parameters and then integrate out the parameters with respect to this posterior distribution to obtain the predictive distribution for future observables. For example, consider a Bernoulli sequence with (unknown) parameter P, and suppose the available experimental data are that in n trials there were exactly r successes. Let $\mathcal{D}$ represent this data, and $L(p) = p^r \times (1-p)^{n-r}$ be the likelihood function. Then

$$P(X_{n+1} = 1 \mid \mathcal{D}) = E[P \mid \mathcal{D}] = \int_0^1 p \times \pi^*(p)\, dp.$$

The above equation gives the posterior probability that the next trial is a success, given the data $\mathcal{D}$, where

[7] The maximum-likelihood estimate of a parameter is the value of the parameter that maximizes the likelihood function.

$$\pi^*(p) = \frac{\pi(p) \times L(p)}{\int_0^1 \pi(p) \times L(p)\, dp},$$

is the posterior density for P and the expectation is taken with respect to the posterior distribution.[8]

Under some mild regularity conditions, $P(X_{n+1} = 1 \mid \mathcal{D})$ has the approximate value $(r+1)/(n+2)$ when n is sufficiently large. When $r = n$, so that one has observed n successes in n trials, this rule is known as Laplace's rule of succession. See Feller (1968, p. 124) for an example of the type of criticism of this rule that used to be common before the optimal character of Bayes decision rules was fully understood. Note that for small n this rule is much more reasonable than the maximum-likelihood estimate, which is r/n. For example, when $n = 1$, the maximum-likelihood estimate is either 1 or 0, depending upon whether or not a success occurred, whereas the rule of Laplace gives either 2/3 or 1/3. The predictive point of view was particularly emphasized by de Finetti (1937, 1974), who insisted that statistical procedures should be operationally meaningful and proposed the use of scoring rules to assess the performance of individuals making predictions. Aitchison and Dunsmore (1975) provide a careful discussion of the predictive viewpoint. They argue that conventional non-Bayesian methods of prediction, which simply plug in the maximum-likelihood estimate of the parameter and make predictions as though this estimate was exactly equal to the true value, are often seriously inadequate because they do not allow for realistic posterior uncertainty about the parameter; they do not perform very well, especially in typical real-world problems, where sample sizes are not large.

In the case of prediction of future observations, few would imagine that there can be any truly objective way to make such predictions. Yet by virtue of the exchangeability theorem of de Finetti, the Bernoulli parameter P can be interpreted as simply the long-run proportion of successes, so that inference about P is equivalent to a prediction about such a future proportion. Similarly for other conventional statistical parameters. The most persistent *philosophical* objection to Bayesian procedures concerning lack of objectivity can therefore be seen in a new light. While it is true that the choice of the *a priori* distribution π is often subjective, this merely reflects the fact that in typical real-world decision problems there is a diversity of different opinions and background knowledge, so when the experimental data are not sufficiently informative this can lead to substantially different posterior distributions. There is, however, no way to avoid this, other than by restricting attention only to problems where sample sizes are so large that the *a priori* distribution more or less washes out and everyone is left with essentially the same posterior distribution, as in the Bayesian precise measurement theorem of Savage. Unfortunately it is rarely the case that the data are so informative. Since conventional 'non-Bayesian' statistical methods are typically equivalent to the use of certain special diffuse prior distributions π for the parameters of the model, they do not offer any help with respect to the question of objectivity, but merely implicitly dictate use of specific *a priori* distributions without any serious attempt at justification.

When the data are not sufficiently informative, some would argue that the arbitrariness of the *a priori* distribution prevents any useful conclusions to emerge from the analysis of the data. This may or may not be the case. It is true that in certain types of problems, particularly high-dimensional problems, the conditional probabilities given by Bayes's theorem are often highly sensitive to the *a priori* distribution. Furthermore, in such examples it may be extremely difficult to perform either the necessary mathematical analysis or appropriate computer simulations. In such cases some statisticians choose models and *a priori* distributions which make the analysis mathematically tractable, but without any other attempt at justification. This makes their conclusions both unrealistic and unconvincing to others, and is the type of pseudo-Bayesian analysis that Fisher and J. Neyman were rightly critical of. In scientific work it is not appropriate to choose models and *a priori* distributions in such arbitrary ways.

In scientific work Bayesian methods are most effective either in examples such as that of Bayes where there is cogent reason for both the model and the *a priori* distribution, or in problems where the likelihood function is sharp relative to the *a priori* distribution as in the precise measurement theory of Savage. Even when neither of the above conditions holds, in some real-world decision or scientific problems there is at least a rough consensus among knowledgeable people as to the choice of the model and *a priori* distribution, and this consensus may already largely dictate the answer to a decision problem via sensitivity analysis. Bayesian methods are most controversial when there is extreme sensitivity to both the model and the *a priori* distribution, as in nonparametric statistics, so that one can obtain virtually any answer one wants. In such examples it is better to start with some conventional non-Bayesian solution to the problem and then improve it uniformly by a Bayes procedure, using linear programming. In this case the *a priori* distribution need not reflect subjective judgment, but one at least obtains the logically desirable properties of Bayes procedures.

The modern Bayesian standpoint is that objectivity consists in the explicit consideration of specific prior distributions, likelihood functions, and utility functions;

[8] Although given here in terms of a Bernoulli sequence, the above method of evaluation is quite generally available in problems of prediction.

by analyzing sensitivity to these choices, one can delineate those problems for which a consensus can be obtained. When opinions and preferences vary considerably among different individuals, then the Bayesian theory also makes it clear that this is in fact the case, so that objectivity is not possible. This is especially important in the area of hypothesis testing, where typically the prior distribution under the alternative hypothesis cannot be chosen in an 'objective' fashion, and so the conclusions of such an analysis are highly subjective. See Borel (1965, p. 165) for an illuminating general discussion of 'objectivity' in statistics. Borel sides with H. Poincaré in making the distinction between different degrees of subjectivity, and viewing 'objectivity' as arising when subjective probabilities have the same value for many people.

Finally, a serious criticism of the Bayesian approach concerns the question of time coherency and whether the Bayesian approach requires that *all* learning should take place via Bayes's theorem. Some modern Bayesians do not believe this to be the case, and have argued for a version of Bayesian statistics in which computational complexity plays an important role, as, for example, in Bayesian data analysis. Thus realistically complex data may first be analyzed graphically or using other data-analytic techniques; new models, parameters, and hypotheses may be formulated on the basis of such techniques; and finally Bayesian methods may be used to obtain the post-data probability distribution for the parameters of such models as have been introduced via the data analysis. In this process the overriding concern must be maximization of post-data expected utility, but Bayes's theorem continues to play a fundamental role (Hacking, 1967; Hill, 1990).

IV. CONCLUSION

As in the quotation at the outset of this article, since its origin the Bayesian approach has been highly controversial, and there have been many historical curiosities and ironies concerning it. These include the fact that both Bayes's theorem and de Finetti's theorem were nearly lost, although nowadays they are considered two of the most important results in the history of science. Under the impetus of Fisher and Neyman (who did not themselves see eye to eye) the Bayesian approach was subjected to a virulent attack during the early part of the 20th century.[9] Recently, however, there has been a strong and spirited resurgence of interest in the Bayesian approach and greater understanding of its role in all of the sciences and in human decision making.

[9]See Gillman (1992) for an amusing example of how the rejection of the Bayesian theory of conditional probability led to a public controversy in the game-show problem of Marilyn vos Savant.

GLOSSARY

Ancillary A statistic with a fixed distribution, free of the parameter; for applications a physical interpretation is appropriate.

Conditioning A principle that recommends conditioning on an appropriate or relevant ancillary.

Likelihood A principle that recommends using only the observed likelihood function for statistical inference.

Probability model A mathematical construct for describing the long-run behavioral properties of a system that is actually or conceptually performable or repeatable under essentially constant conditions.

Statistical model A probability model with free parameters such that certain particular values for the parameters provide a probability model that is a good approximation to the process being examined.

Statistical reduction Sufficiency can reduce the dimension of the appropriate variable and lead to a marginal model. Conditioning can reduce the dimension of the free variable and lead to a conditional model.

STATISTICS seeks patterns and relationships within information collected concerning real world contexts. The contexts can range from sharply defined scientific issues, to social science matters, to wide-ranging industrial, commercial, or financial issues, to the contents of massive data storage devices. The information can be the collected results, tabulations, or electronic records obtained, or to be obtained, concerning the real world contexts. The patterns and relationships are the simplified descriptions including cause–effect relationships concerning the real world contexts being investigated.

Statistics is the methodology and theory for this process of extracting the important patterns and relationships from the collected information. The foundations of statistics are the basic elements of theory and principle that structure the planning and collection of information and the extraction of patterns and relationships.

I. BACKGROUND

Some elements of statistical thought were present even in Biblical times. But it was money and gamblers in 16th century France that brought mathematical skills to the calculation of probabilities for games of chance, with the intent of increasing financial gains. Also, astronomers had many precise measurements but measurement error created deviations from theoretical patterns, and the mathematical skills of Gauss, Laplace, and many others were applied to this departure of data from theory. More recently the social sciences collect data where underlying patterns are heavily masked by variation, both variation in the subject material and variation due to measurement error. In addition, in agricultural experimentation the long delay from planning to data collection provides a strong incentive to carefully plan an investigation and to carefully analyze the results in order to maximize the quantity and quality of the conclusions obtained from the long process from initial planning to final presentation. By now statistics has entered into almost all areas of human endeavor.

II. OVERVIEW

Statistics involves the planning of investigations, the carrying out of the investigation, the collection of data, the processing of the data, and the analysis through to conclusions from the investigation and data. Some of these components, however, can exist almost in isolation from the others; for example, the analysis of very large datasets on consumer choices can in practice be almost totally separate from the original collection of the data.

Early activity focused on variation in results from quite well-defined processes such as the games of chance in 16th century France. The variation or randomness in the results was formalized as probability theory, which is now a well-established component of statistical modeling.

Early formulations of this theory gave the structure needed to describe the measurement error in traditional physics and astronomy. In these areas there would be an underlying law or theory that would prescribe deterministic results and then the actual data would depart from this due typically to small measurement errors. Probability theory provided a way to model the error and this combined with the deterministic pattern led to statistical models. These were probability models but with free parameters corresponding to characteristics of the underlying deterministic process.

This type of statistical model, however, has much broader application than the traditional measurement error context. It could describe variation in the underlying material being investigated and even variation in the quantities that were of direct interest. This provides applications to the social sciences and to industrial, commercial, financial, and other areas.

Statistical methodology, however, extends far beyond this probabilistic modeling of error and variation. Small and large aggregations of data can be examined to get summary presentations, elicit patterns for further investigation, seek anomalies relative to previous patterns, and generally obtain guidance for future analysis and development often with a distinct profit motive not unrelated to that of the 16th century origins of the discipline.

As indicated above, a traditionally central part of statistics is concerned with investigations that lead to a statistical model, a probability model with free parameters corresponding to unknowns in the investigation. The primary statistical problem is then the analysis of data that are viewed as coming from this statistical model. Some areas of application may have special types of model form and be developed within related disciplines often with quite special notation. For example, actuarial science examines the lifetime of people or objects, obtaining probabilities of living, dying, or accidents in given time intervals. More recently this has extended into general insurance, financial, and related areas. Other specialized areas include operations and management research, control theory, econometrics, and many biological, industrial, management, and financial research areas. Interpreted broadly, statistics is the theory and methodology of knowledge acqusition, the use of this knowledge to manage and control, and the source of structure for many substantive areas of intellectual activity.

III. PROBABILITY MODEL

As indicated above, the development of probability methods provided the major ingredient for the development of statistics and continues as a significant core component.

A pure context involves a process or system that can be operated or performed repeatedly under essentially constant condition. For example, an ordinary six-faced die can be shaken or tossed and the upward face observed, or the time to failure can be observed when an electronic component from a stable manufacturing process is tested. The elementary probability model involves a *sample space* S of possible outcomes values, a class $\mathcal{A} = \{A\}$ of *events* or *subsets* A of S that are of interest, and a *probability* $P(A)$ for each event A. For the die $S = \{1, 2, 3, 4, 5, 6\}$, $\mathcal{A}$ consists of all possible subsets of S such as $\{2, 4, 6\}$, $\phi = \{\cdot\}$, or S itself; for a symmetrical die with implied symmetric probabilities $p(A) = \#A/6$, where $\#A$ is the number of points in A. Figure 1 shows the amount of probability at each point in S for this symmetric case. For the lifetime example, S consists of the positive real line or

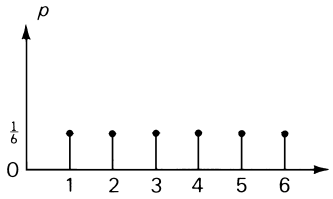

FIGURE 1 The uniform distribution on {1, 2, 3, 4, 5, 6}; the behavior for a symmetric die.

perhaps for convenience the whole real line R, $\mathcal{A}$ consists of all intervals and things predicated by intervals under countable union and intersection, and P could have many forms depending on the context. One simple possibility is the normal distribution with $P(A) = \int_A f(y)dy$, where $f(y) = (2\pi\sigma^2)^{-1/2} \exp\{-(y-\mu)^2/2\sigma^2\}$, which is located at some point μ and scaled by σ. For a location $\mu = 0$ and $\sigma = 1$, Fig. 2 shows the density function labeled $n = \infty$. The other curves provide examples from the Student family, which provides longer tailed distributions than the normal. Of course these distributions are on the whole real line, in an absolute sense, whereas the lifetime variable is necessarily positive. Nonetheless they may provide good approximations in many applications, which is the objective of probability modeling. A somewhat different possibility is provided by the exponential (θ) model $f(y;\theta) = \theta^{-1} \exp\{-y/\theta\}$ on the positive line. This can describe a constant failure rate situation and θ is the mean lifetime. This model *is* on the positive real line. Of course, other models can describe lifetime depending on the underlying process being investigated.

The probability $P(A)$ of an event A is the proportion of occurrences of the event in a long sequence of repetitions; ideally it is the limit of the proportion as the number of repetitions goes to infinity. In applications it is an empirical phenomenon that the proportion $\hat{P}_n(A)$ of occurrence of A in a long sequence of repetitions goes to a limit, or otherwise some change in conditions has occurred that has modified the process or system. This empirical phenomenon for a particular process may be difficult to verify beyond some reasonable approximation, and its assumption is typically based on the degree to which initial conditions are seen to be constant under repetitions.

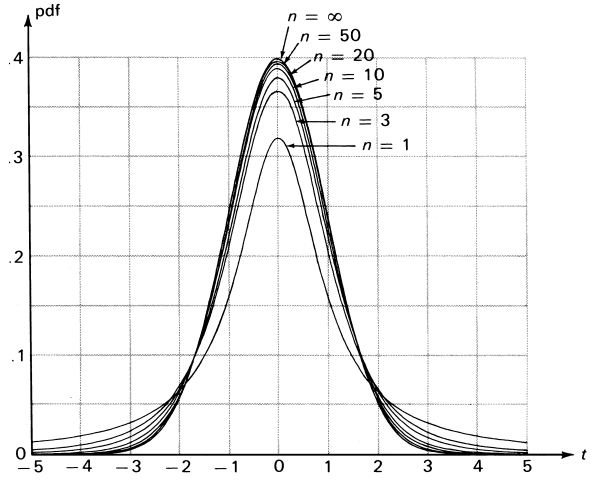

FIGURE 2 The student (n) distribution for $n = 1, 3, 5, 10, 20, 50, \infty$.

Probability theory constructs and examines very general models and develops techniques for calculating probabilities for various types of events and also techniques for calculating many important characteristics of probability models.

IV. STATISTICAL MODEL

A basic statistical model is a probability model with free parameters to allow a range of possibilities, one of which leads to a model that provides a reasonable approximation to a process or system being investigated. For example, in some context the normal (μ, σ^2) mentioned in Section III could be very appropriate. Also, the die example in Section III might be generalized to have probabilities $p_1, p_2, p_3, p_4, p_5, p_6$ at the six sample points 1, 2, 3, 4, 5, 6 where necessarily $p_i \geq 0$ and $\sum p_i = 1$, these being a consequence of probabilities viewed as proportions in a large aggregate.

Thus a general version of the basic model would have a space S, a collection $\mathcal{A}$ of subsets, and a probability measure $P(A;\theta)$ for each subset A in $\mathcal{A}$. The probability measure includes a free parameter θ in a space Ω that allows a range of possibilities for the measure; in an application it would be implicit that some one value of θ provided probabilities that closely approximated the behavior in the application.

The basic model as just described is concerned with frequencies or proportions on a space of possibilities. It does not distinguish component elements of structure or the practical significance of the various components. This basic model has been central to statistics throughout the 20th century.

Some more-structured models have been proposed. For example, in the measurement context one could model the measurement errors as $z_1, \ldots, z_n$ from some error distribution $f(z)$. The error distribution could be the standard normal in Fig. 2 or it could be one of the Student distributions with parameter value equal to, say, 6, which provides more realistic, longer tails. The statistical model would then be $y_i = \mu + \sigma z_i$ where μ and σ represent the response location and scaling. This alternative, more detailed model makes the process of statistical inference more straightforward and less arbitrary. For some details see Fraser (1979).

This raises the more general question of what further elements of structive from applications should reasonably be included in the statistical model. It also raises the question as to what modifications might arise in the statistical analyses using the more detailed or more specific models.

One modeling question was raised by Cox (1958). The context involved two measuring instruments, I_1 producing a measurement y that is normal (μ, σ_1^2), and I_2 producing a measurement y that is normal (μ, σ_2^2). A coin is tossed and depending on whether it comes up heads or tails we have $i = 1$ or 2 with probability 1/2 each; the corresponding instrument I_i is used to measure θ. The standard modeling view would use the model $f(i, y; \theta) = (1/2)g(y - \theta; \sigma_i^2)$, where $g(z, \sigma^2)$ designates a normal density with mean 0 and variance σ^2. In an application the data would be (i, y) with model $f(i, y; \theta)$. But clearly when the measurement is made the instrument that is used is known. This suggests that the model should be $g(y - \theta, \sigma_1^2)$ if $i = 1$ and $g(y - \theta, \sigma_2)$ if $i = 2$; this can viewed as the conditional model, given the value of the indicator i.

Traditional statistical theory would give quite different results for the first model than for the second model. A global model may be appropriate for certain statistical calculations. But in an application when one knows how the measurement of θ is obtained, it seems quite unrealistic for the purposes of inference to suggest that the instrument might have been different and that this alternative should be factored into the calculations.

V. STATISTICAL THEORY

Much of statistical theory through until the early decades of the 20th century was concerned with the analysis of data, say $\mathcal{D}$, together with a statistical model, say $\mathcal{M}$, representing the source of the data. Thus, what can we conclude from $(\mathcal{M}, \mathcal{D})$ concerning the unknown true value of the parameter, say θ, in the statistical model? This represented a substantial portion of the discipline until the mid-20th century and with ups and down remains a major portion of the core discipline.

Some major early workers in the 19th century such as Laplace promoted the idea of attaching a probability distribution, say $\pi(\theta)$, to the origins of the parameter θ. This might be something approximately uniform representing diffuse information concerning θ or something more local on certain ranges for θ as opposed to other ranges of values. This had been promoted earlier by Bayes (1763) and intermittently had periods of prominence through to the mid-20th century.

An alternative decision-theoretic approach was promoted by work of Neyman and Pearson (1933) and later generalized by Von Neumann and Morgenstern (1947) and Wald (1950). This approach viewed statistics as needing a decision function for any application; the data combined with the decision function would produce a decision concerning the unknown. This approach dominated most theoretical thought until 1955. There is of course the question of whether things can properly or should properly be mechanized in this way. There is also the issue of whether this methodological approach can produce sensible answers to the broad range of practical problems. By the mid 1950s there were substantial criticisms of the decision theory approach; in particular, there had been a major failure of the theory to produce reasonable statistical procedures for a broad range of problems.

In the mid-1950s publications by Fisher (1956) and Savage (1954) substantially altered the directions of statistics and opened wide areas for development. Fisher proposed insightful methods based on the earlier view of examining the model data combination $(\mathcal{D}, \mathcal{M})$. Savage favored the Bayesian approach emphasizing the use of personal priors to represent the latent views of the investigator concerning possible values for the parameters.

Both these directions opened new opportunities to a discipline that had become partially paralyzed by the decision-theoretic approach and by its inability to produce answers for wide-ranging problems.

VI. FOUNDATIONS

The foundations of statistics have changed and evolved with time. The early use of probability for statistical analysis was closely tied to the development of the least squares method, a widely used technique dating from Laplace and earlier. The Bayesian approach also comes from this same earlier period. Neither could be viewed at that time as an all-embracing foundation for statistics.

The decision theory approach, however, did present itself as an all-embracing theory: start with a model and a utility function and derive the optimum decision procedure for producing a decision from data. Its claims were all-emcompassing, but, as mentioned above, it failed to deliver for the broad needs of statistics.

The Bayesian approach has close ties to the decision-theoretic view but has more flexibility in allowing the personal prior or even in allowing many personal priors if many investigations are involved.

The frequentist approach as re-emphasized by Fisher (1956) reinvestigated the earlier approach of just analyzing a model together with data.

The Bayesian and frequentist approaches brought rather flexible and innovative directions to statistical theory after the rigidily of the decision theory approach. This was largely assisted by the increase in available computer

power. Both have since existed side by side with intermittent tensions and conflicts. The two approaches represent a major portion of statistics, have increasing overlap, and are growing closer in overall operation and objective.

VII. PRINCIPLES

As indicated above, the combination of a statistical model and data represents the core concern of statistics. Various methods and principles have evolved for the analysis and simplication of the model data combination.

A. Sufficiency Principle

Fisher (1922) defined a sufficient statistic $s(y)$ as a statistic with the property that the distribution of the basic variable y given $s(y)$ is independent of the parameter, say θ. The idea is that one would use the observed value of the sufficient statistic together with the marginal model, say $g(y;\theta)$, for that statistic, and otherwise ignore the original value of y. In a sense the actual value of y, given $s(y)$, can be viewed as an observation of pure error with no influence from the parameter θ, and as such can be viewed as irrelevant to any statistical assessment of θ. The *sufficiency principle* (S) is to use only the marginal model for the sufficient statistic in the inference process or assessment of data. As an example, consider a sample $y_1, \ldots, y_n$ from the normal (μ, σ_0^2) distribution: $\bar{y}$ is a sufficient statistic in the sense that the distribution of$(y_1, \ldots, y_n)$, given $\bar{y}$, does not depend on μ. Unfortunately, there are very few problems that admit a simple sufficient statistic that provides a dimension reduction such as the n to 1 found in this normal example. The concept and principle for sufficiency were widely accepted and adopted but turned out not to be available for most problems other than the familiar textbook cases. The detailed mathematical investigation of sufficiency thus unfortunately diverted statistical attention from seeking more fruitful directions for theory.

B. Likelihood Principle

Fisher (1922) introduced the concept of the likelihood function. The likelihood function $L(\theta; y^0)$ from data y^0 with model $f(y;\theta)$ is the density function $cf(y^0;\theta)$ examined as a function of θ for fixed data value. It would seem from a mathematical viewpoint to be a very obvious expression of what a function $f(y;\theta)$ would say about θ with $y = y^0$. It is usually examined relatively, that is, one θ value relative to another θ value, and this is expressed above by having an arbitrary constant c in the definition. The likelihood function $L^0(\theta) = L(\theta; y^0)$ or its logarithmic version $\ell^0(\theta) = \ell(\theta; y^0) = \log L(\theta; y^0)$ can be treated as a very informative numerical evaluation of one θ value relative to another. The *likelihood principle* (L) is to use only the observed value $\ell^0(\theta)$ of the likelihood function and not any other information from the original model–data combination. One could picture the plot of $\ell^0(\theta)$ on a monitor; the principle would say that this plot was the full allowable information concerning θ from the model–data combination. Thus, for the normal example in Section VII.A one would use only $\ell^0(\theta) = a - n(\theta - \bar{y}^0)/\sigma_0^2$ with a arbitrary and no other information from the original sample $(y_1^0, \ldots, y_n^0)$ or from the original model $\prod_1^n g(y_i - \theta; \sigma_0^2)$.

C. Weak Likelihood Principle

Sufficient statistics and the likelihood function as noted above date from Fisher's major 1922 paper. In Fisher (1925) he noted a very close connection between them: that the likelihood function as obtained from data was the best, later called minimal, sufficient statistic. Despite this asserted close equivalence the two concepts developed largely independently until the 1960s when informal discussion at meetings finally acknowledged that they were largely equivalent. Even now there is little general recognition of the equivalence and few introductory texts on mathematical statistics draw attention to the connection. The weak likelihood principle is to use only the observed likelihood function and the statistical model for the possible likelihood functions. Because of the link between the production of the likelihood function and the concept of minimal sufficiency it follows that the weak likelihood principle and the sufficiency principle are essentially equivalent. Note that the strong likelihood principle is to use the observed likelihood function but not any information concerning the possible likelihood function as would be given by the corresponding model.

D. Conditioning Principle

Fisher (1925) defined an ancillary statistic as one with a fixed distribution, free of the parameter of the model. In more recent language we would view an ancillary statistic as one that presents natural variation or error present in the model. The name suggests that it is supportive for a process of inference. Fisher recommended that one should condition on the value of the ancillary and thus use the conditional model given the observed value. The *ancillary principle* is to use only the conditional model and the observed value of the conditioned variable. The ancillary principle is often called the *conditioning principle* (C). As an example suppose y_1, y_2 come from the location model $f(y - \theta)$. Then it is easily seen that $a(y_1, y_2) = y_2 - y_1$ has a fixed distribution free of θ;

Fisher called it a configuration statistic. The conditional model for, say, $\bar{y}$, given $a(y_1, y_2) = a(y_1^0, y_2^0) = a^0$ is then $cf(\bar{y} - \theta - a^0/2) f(\bar{y} - \theta + a^0/2)$ and is a simple location model with parameter θ and with observed value $\bar{y} = \bar{y}^0 = (y_1^0 + y_2^0)/2$. The corresponding p value is

$$p(\theta) = \frac{\int_{-\infty}^{\bar{y}^0} f(\bar{y} - \theta - a^0/2, \bar{y} - \theta + a^0/2)\, d\bar{y}}{\int_{-\infty}^{\infty} f(\bar{y} - \theta - a^0/2, \bar{y} - \theta + a^0/2)\, d\bar{y}}$$

and it records the probability position of the observed $\bar{y}^0$ in its distribution conditional on the known error value a^0.

E. Connections among Principles

Birnbaum (1962) discussed the sufficiency (S), likelihood (L), and conditioning (C) principles from an equivalence or set-theoretic viewpoint. He showed that S plus C implied L. This caused some major stress in the statistical community, as S and C seemed well founded, while L seemed far too strong to most statisticians. Evans *et al.* (1986) then showed that C alone implied L. There seems to be no widely held resolution among members of the statistical community concerning these links. In fact many are unaware of key aspects of the conditioning principle or the arguments that support that principle. While Fisher (1925) certainly provided the key foundational approach and later (Fisher, 1934) analyzed the location and location scale models, it was the Cox (1958) example (see Section IV) concerning the measuring instruments that triggered a re-examination of the ancillary approach to inference.

An example with nonuniqueness of the ancillary statistic may be found in Fisher (1956, p. 47); also see Basu (1964) and Buehler (1982). This uncertainty kept the conditioning approach from general acceptance; indeed, it left a noticeable taint on the concept. More recent considerations, however, have emphasized a need for there to be some objective meaning for the ancillary to be used.

Objective ancillaries are central to the analysis of location-scale and transformation models when presented in terms of an error variable. Some general discussion may be found in Fraser (1968, 1979).

VIII. LIKELIHOOD ASYMPTOTICS

Recent likelihood asymptotic analysis developed from approximation theory, in particular, from the saddlepoint work of Daniels (1954) and Lugannani and Rice (1979). This led to the analysis of large sample likelihood functions (Barndorff-Nielsen, 1986; Fraser and Reid, 1995; Fraser *et al.*, 2000). With an increasing number n of coordinates and a fixed number of parameters it is found that with high accuracy, both theoretically $O(n^{-3/2})$ and empirically, there is an ancillary with an approximately fixed distribution and with a conditional distribution with the same dimension as the parameter. Also it is found that for a scalar component parameter there is a subsequent marginal distribution that provides a p value for assessing the scalar parameter. Under mild regularity the p value is unique.

In the early development of statistical inference, sufficiency was viewed as a prime focal concept, but its availability was extremely limited. The likelihood developments growing out of approximation theory have shown what the possible forms of a large sample model are and thus lead to the appropriate statistical analysis: first reduce by conditioning using the generally overlooked ancillary approach; then marginalize to obtain a p value free of the nuisance parameters. For some recent details, see Fraser *et al.* (1999, 2000).

GLOSSARY

Cluster analysis To find natural subgroups among measurements $X_1, \ldots, X_p$ on different objects. Example: The objects are stars, and the measurements are temperature, mass, redshift, bolometric reading, and distance. One can also cluster the measurements to find sets of variables that give similar information, such as redshift and distance.

Contingency table analysis To determine how membership in one feature category relates to membership in another, for objects that are classified with respect to several different features. Example: The objects are subatomic particles, and the features are charge, mass (lepton, boson, or baryon), conservation of parity and spin.

Discriminant analysis To use objects sampled from several different groups, and measurements $X_1, \ldots, X_p$ on each object, to build a classification rule that categorizes future objects into the most probable group. Example: A geologist has surface data on the mineralogy and seismology of previous drilling sites, and knows which sites produced oil. She wants to use surface data to decide whether a new site is likely to prove out.

Experimental design To determine whether different experimental treatments yield observations with different mean values. Example: One observes the lifespans of automobile tires, and the experimental treatments are manufacturer, radials versus nonradials, and weight class of the car.

Regression analysis To discover the functional relationship between a set of independent variables $X_1, \ldots, X_p$ and a dependent variable Y. Example: Y represents the breaking strength of a steel wire, and X_1 the wire's thickness, X_2 the percentage of carbon, X_3 the smelting temperature.

Time series analysis To characterize the dependence over time of sequentially observed data when neighboring values show serial correlation, and to predict future observations. Example: A meteorologist has 5 years of daily high temperature data for Gunnison, Colorado. He wants to predict tomorrow's high temperature, or model the seasonal variation in the temperature record.

MULTIVARIATE STATISTICS encompasses a diverse toolkit of methods for describing different kinds of relationships among multiple measurements. The ideas derive from the mathematical theory of probability and statistical inference. Typical multivariate procedures include cluster analysis, contingency table analysis, discriminant analysis, experimental design, regression analysis, and time series analysis. These examples illustrate some of the range of applications, but multivariate statistics includes many other topics. Even within each of these problem areas there are different approaches, depending upon the assumptions one can make about the underlying physical process.

The origins of many of the methods described in this article are rooted in work on the combination of astronomical observations and the development of the method of least squares by Pierre Simon Laplace, Adrien-Marie Legendre, and Carl Friedrich Gauss. This development occurred in the late 18th and early 19th centuries (for details, see Stigler, 1986). Systematic development of statistical theory began with work by Francis Galton, Francis Ysidro Edgeworth, Karl Pearson, and George Udny Yule during the period from 1885 to 1907. Major contributions to multivariate statistics were made in the 1920s, led by Sir Ronald Fisher, P. C. Mahalanobis, and H. Hotelling. The early applications were chiefly inspired by problems in agriculture, biology, and psychology, and methods depended strongly upon the assumption of the Gaussian (or normal) distribution for measurement noise and a linear model relating the variables of interest. As the subject has matured, the scope of application has broadened and these restrictive assumptions have been substantially weakened. Currently, a very active area is the development of computer-intensive procedures that substitute approximation for exact analytical calculation. This has enabled the extension of multivariate methods to more realistically complex problems.

I. MULTIVARIATE PROBABILITY THEORY

Before surveying the statistical theory of multivariate data, it may be useful to review some fundamental ideas from mathematical probability. These primary concepts are the distribution function, the marginal and conditional distributions, the mean and variance of a random vector, the independence of random variables, and four standard distributions: the normal (or Gaussian) distribution, the chi-squared distribution, and the multinomial distribution.

A multivariate random variable $\boldsymbol{X}$ in $\mathbb{R}^p$ is a vector whose components are random variables. The properties of that random vector are entirely determined by the corresponding multivariate distribution function $F(\boldsymbol{x})$. This distribution function is defined by

$$F(\boldsymbol{x}) = P[X_1 \leq x_1, \ldots, X_p \leq x_p],$$

so that $F(\boldsymbol{x})$ is the probability that each component of the random vector is less than or equal to the corresponding component of the argument $\boldsymbol{x}$, for all $\boldsymbol{x}$ in $\mathbb{R}^p$.

If $F(\boldsymbol{x})$ is a continuous function, then its derivative with respect to all of the components is referred to as the probability density function and is denoted by $f(\boldsymbol{x})$. If $F(\boldsymbol{x})$ is a discrete function, then its generalized derivative is referred to as the probability mass function and is also denoted by $f(\boldsymbol{x})$. The probability mass function is equal to 0 almost everywhere, but acquires increments of probability at a countable set of points in $\mathbb{R}^p$. Both the probability density function and the probability mass function are always nonnegative. Many multivariate distributions are neither completely continuous nor completely discrete, but the definition of the Riemann–Stieltjes integral handles all such cases on a common footing. For example, a basic property of any distribution function is that

$$\int_{\boldsymbol{S}} dF(\boldsymbol{x}) = 1,$$

where $dF(\boldsymbol{x})$ is the appropriate differential form. For a continuous distribution function, this $dF(\boldsymbol{x})$ is the density; for a distribution with no continuous part, the integral is equivalent to a sum over the points where the probability mass function has increments.

In statistical applications most distributions belong to families that are indexed by a parameter vector $\boldsymbol{\theta}$ (these parameters are usually a primary object of the statistical inference). When the family is specified, one often writes $F(\boldsymbol{x}; \boldsymbol{\theta})$ to indicate the dependence upon the parameter vector.

The expected value of any function $g(\boldsymbol{X})$ of the random vector $\boldsymbol{X}$ is

$$E[g(\boldsymbol{X})] = \int_{\mathbb{R}^p} g(\boldsymbol{x})\, dF(\boldsymbol{x}).$$

Some specific functions $g(\cdot)$ are particularly important. For example, the mean $\boldsymbol{\mu}$ of any random vector is

$$\boldsymbol{\mu} = E[\boldsymbol{X}] = \int_{\mathbb{R}^p} \boldsymbol{x}\, dF(\boldsymbol{x}).$$

This quantity is the average value of the random vector. Also, the covariance matrix $\boldsymbol{\Sigma}$ of $\boldsymbol{X}$ is

$$\boldsymbol{\Sigma} = E[(\boldsymbol{X}-\boldsymbol{\mu})(\boldsymbol{X}-\boldsymbol{\mu})^{\mathrm{T}}] = \int_{\mathbb{R}^p} (\boldsymbol{x}-\boldsymbol{\mu})(\boldsymbol{x}-\boldsymbol{\mu})^{\mathrm{T}}\, dF(\boldsymbol{x})$$

where the superscript T denotes the transpose. The ith diagonal entry of $\boldsymbol{\Sigma}$ is

$$\sigma_i^2 = \mathrm{var}[X_i] = \int_{-\infty}^{\infty} (x_i-\mu_i)^2\, dF(x_i),$$

which is the variance of the ith component of $\boldsymbol{X}$ considered as a univariate random variable. The square root of this variance is referred to as the standard deviation of the random variable X_i. Also, the off-diagonal entries of $\boldsymbol{\Sigma}$,

$$\begin{aligned}\sigma_{ij} &= \mathrm{cov}[X_i, X_j] \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} (x_i-\mu_i)(x_j-\mu_j)\, dF(x_i, x_j) \quad \text{for} \quad i \neq j,\end{aligned}$$

are the covariances between the ith and jth components of $\boldsymbol{X}$. Heuristically, large values of the diagonal entries of $\boldsymbol{\Sigma}$ indicate that the corresponding component varies greatly. Large positive values of the off-diagonal entries suggest that the two corresponding components tend to be large or small together, and extreme negative values suggest that one component is large when the other is small, and conversely.

The marginal distribution of a particular component X_r of a random vector $\boldsymbol{X}$ is just the univariate distribution of that random component, ignoring everything else in the vector. One can obtain the marginal distribution by integrating out all other components; i.e.,

$$\begin{aligned}F(x_r) = \int_{-\infty}^{x_r}\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty} dF(\boldsymbol{y})\, dy_1 \ldots dy_{r-1} \\ \times\, dy_{r+1}\ldots dy_p\, dy_r.\end{aligned}$$

Omitting the first integration gives the density function or the probability mass function, as appropriate. If one integrates out a smaller set of components, then one obtains the distribution of the remaining components.

From the distribution function of a random vector, one can find the conditional distribution of the first r components $X_1, \ldots, X_r$, given the values of the subsequent $p-r$ components, i.e., $X_{r+1}=x_{r+1}, \ldots, X_p = x_p$. Intuitively, one acts as though one has seen the last $p-r$ components of the random vector and wants to use these to infer the probability structure of the first r components. In order to reflect the additional information now available, one calculates the distribution obtained after conditioning upon the observed values, obtaining

$$\begin{aligned}&F(x_1, \ldots, x_r \mid x_{r+1}, \ldots, x_p) \\ &= \frac{\int_{-\infty}^{x_1}\cdots\int_{-\infty}^{x_p} f(y_1, \ldots, y_r, x_{r+1}, \ldots, x_p)\, dy_1 \ldots dy_r}{g(x_{r+1}, \ldots, x_p)}.\end{aligned}$$

Here $g(x_{r+1}, \ldots, x_p)$ denotes the joint density or mass function evaluated at the fixed values of the conditioning variables.

If $F(\boldsymbol{x})$, the joint distribution function of $\boldsymbol{X}$, can be written as the product of all of the univariate marginal distributions, then the components of $\boldsymbol{X}$ are said to be independent. One implication of independence is that observing any subset of the components of $\boldsymbol{X}$ provides no information about the values of the unobserved components. In practical applications, it is usually desirable that one's sample data $\boldsymbol{X}$ consist of independent observations; in most cases this maximizes the amount of information gathered, and also enables simpler mathematical analysis.

The concept of independence generalizes to conditional independence. Suppose that the random vector $\boldsymbol{X}$ is partitioned into three disjoint subsets, $\boldsymbol{X}_1$, $\boldsymbol{X}_2$, and $\boldsymbol{X}_3$. Then $\boldsymbol{X}_1$ and $\boldsymbol{X}_2$ are said to be conditionally independent given $\boldsymbol{X}_3 = \boldsymbol{x}_3$ if

$$F(\boldsymbol{x}_1, \boldsymbol{x}_2 \mid \boldsymbol{x}_3) = F(\boldsymbol{x}_1 \mid \boldsymbol{x}_3)F(\boldsymbol{x}_2 \mid \boldsymbol{x}_3).$$

Regarding $\boldsymbol{X}_1$, this implies that

$$F(\boldsymbol{x}_1 \mid \boldsymbol{x}_2, \boldsymbol{x}_3) = F(\boldsymbol{x}_1 \mid \boldsymbol{x}_3).$$

Heuristically, all of the conditional information about $\boldsymbol{X}_1$ is carried by $\boldsymbol{x}_3$, so that $\boldsymbol{X}_2$ is entirely redundant. An exactly symmetric relationship holds for $F(\boldsymbol{x}_1 \mid \boldsymbol{x}_2, \boldsymbol{x}_3)$.

The normal (or Gaussian, in honor of Carl Friedrich Gauss, who used it in developing the method of least squares) distribution has unique properties that make it the natural basis for much of multivariate statistical inference. For example, the Central Limit Theorem ensures that under very general conditions, as n increases, the average $\bar{\boldsymbol{X}}$ of a multivariate sample $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ from an arbitrary distribution $F(\boldsymbol{x})$ tends toward a random variable that has multivariate normal distribution with mean $\boldsymbol{\mu} = E[\boldsymbol{X}_1]$ and variance $\boldsymbol{\Sigma} = (1/n)\mathrm{Var}[\boldsymbol{X}_1]$. Also, on empirical grounds, the multivariate normal distribution offers a very adequate description of many kinds of chance error, such as those that inevitably occur in a measurement process.

The normal distribution with mean $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$ is denoted by $\mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. The normal distribution function has no closed form; however, the probability density function of a multivariate normal distribution with mean $\boldsymbol{\mu}$ and variance matrix $\boldsymbol{\Sigma}$ is

$$f(\boldsymbol{x}) = \frac{1}{(2\pi)^{p/2}|\boldsymbol{\Sigma}|^{1/2}} \exp\left[-\frac{1}{2}(\boldsymbol{\mu}-\boldsymbol{x})^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}-\boldsymbol{x})\right],$$

where the matrix $\boldsymbol{\Sigma}$ is positive definite (i.e., invertible, with all eigenvalues positive). Numerical integration is needed to determine the distribution function.

Suppose one partitions the random variable $\boldsymbol{X}$ into two subvectors, $\boldsymbol{X}_1$ of length r and $\boldsymbol{X}_2$ of length $p-r$. This induces a corresponding partition on the mean vector and the variance matrix; thus

$$\boldsymbol{X} = \begin{bmatrix} \boldsymbol{X}_1 \\ \boldsymbol{X}_2 \end{bmatrix}, \quad \boldsymbol{\mu} = \begin{bmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \end{bmatrix}, \quad \boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}_{11} & \boldsymbol{\Sigma}_{12} \\ \boldsymbol{\Sigma}_{21} & \boldsymbol{\Sigma}_{22} \end{bmatrix}.$$

Here $E[\boldsymbol{X}_1] = \mu_1$ is an $r \times 1$ vector, $\text{var}[\boldsymbol{X}_1] = \boldsymbol{\Sigma}_{11}$ is a $r \times r$ matrix, and analogous results hold for $\boldsymbol{X}_2$. All information about the covariance between components in $\boldsymbol{X}_1$ and $\boldsymbol{X}_2$ appears in $\boldsymbol{\Sigma}_{12}$, an $r \times (p-r)$ matrix with the property that $\boldsymbol{\Sigma}_{12} = \boldsymbol{\Sigma}_{21}^{\mathrm{T}}$.

If $\boldsymbol{X}$ is $\mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, then the marginal distribution of $\boldsymbol{X}_1$ is $\mathrm{N}(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_{11})$. Similarly, the conditional distribution of the first r components of $\boldsymbol{X}$, or $\boldsymbol{X}_1$, given that the last $p-r$ components are equal to $\boldsymbol{x}_2$, is multivariate normal with mean $\boldsymbol{\mu}^*$ and covariance matrix $\boldsymbol{\Sigma}^*$, where

$$\boldsymbol{\mu}^* = \boldsymbol{\mu}_1 + \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}(\boldsymbol{x}_2 - \boldsymbol{\mu}_2)$$
$$\boldsymbol{\Sigma}^* = \boldsymbol{\Sigma}_{11} - \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21}.$$

Also, $\boldsymbol{X}_1$ is independent of $\boldsymbol{X}_2$ if and only if $\boldsymbol{\Sigma}_{12} = \boldsymbol{0}$. Finally, if $\boldsymbol{X}$ is partitioned into three disjoint sets of components, $\boldsymbol{X}_1$, $\boldsymbol{X}_2$, and $\boldsymbol{X}_3$, inducing a conformable partition of the inverse covariance matrix $\boldsymbol{K} = \boldsymbol{\Sigma}^{-1}$, then $\boldsymbol{X}_1$ and $\boldsymbol{X}_2$ are conditionally independent given $\boldsymbol{X}_3$ if and only if $\boldsymbol{K}_{12} = \boldsymbol{0}$. These four properties of the normal distribution are extremely powerful, and have enabled much of the development of the theory of multivariate analysis. For simplicity, this discussion has spoken as though the partitioning divides the vector into subvectors of consecutive components, so that, for example, $\boldsymbol{X}_1$ consists of the first r components of $\boldsymbol{X}$. Actually, with more formal expression, the sense of the results holds when $\boldsymbol{X}_1$, $\boldsymbol{X}_2$, and $\boldsymbol{X}_3$ are any collections of the components of $\boldsymbol{X}$.

The chi-squared distribution is also important to multivariate inference. This is derived from the normal distribution by letting $X_1, \ldots, X_p$ be a sample of independent random variables, each $\mathrm{N}(0, 1)$, and defining the new random variable $Y = \sum_{i=1}^{p} X_i^2$. This new random variable has the chi-squared distribution with p degrees of freedom; the degrees of freedom is the parameter that indexes the family of chi-squared distributions. One can show that the mean of Y is p and the variance of Y is $2p$. Unlike the normal distribution, the chi-squared distribution is not symmetric; in particular, $f(y) = 0$ for all $y < 0$.

Using chi-squared random variables, one can define the F-distribution, which is crucial to the analysis of experimental designs (see Section III). If Y_1 is a chi-squared random variable with p_1 degrees of freedom and if Y_2 is an independent chi-squared random variable with p_2 degrees of freedom, then

$$F = \frac{Y_1/p_1}{Y_2/p_2}$$

follows an F-distribution with p_1, p_2 degrees of freedom. The F-distribution is thus characterized by two parameters, just as the univariate normal distribution is characterized by the mean and the variance.

A multinomial random vector $\boldsymbol{X}$ has components that are constrained to be integers between 0 and n, and further constrained so that the sum of the components must equal n. If one randomly tosses n balls into p boxes so that the probability that a ball falls in box i is θ_i, and if X_i denotes the number of marbles in the ith box, then the vector $\boldsymbol{X}$ with these components has a multinomial distribution with parameters n and $\boldsymbol{\theta}$. This implies that the distribution is discrete, and the probability mass function is

$$f(\boldsymbol{x}) = \binom{n}{x_1, \ldots, x_p} \theta_1^{x_1} \ldots \theta_p^{x_p}$$

for $\boldsymbol{x}$ satisfying the constraints indicated above, and where $\sum \theta_i = 1$.

The mean of the multinomial distribution is $\boldsymbol{\mu} = n\boldsymbol{\theta}$, and the entries of the covariance matrix are $\sigma_i^2 = n\theta_i(1-\theta_i)$ and $\sigma_{ij} = n\theta_i\theta_j$. The marginal distribution of X_r reduces to a multinomial distribution with $p = 2$ and parameters n, θ_r, and $1 - \theta_r$; this is also known as the binomial distribution. Similarly, the marginal distribution of any subset of the components is also multinomial, with parameters that are simple functions of the parameters of the original multinomial. The conditional distribution of $X_1, \ldots, X_r$, given $X_{r+1} = x_{r+1}, \ldots, X_p = x_p$, is an r-variate multinomial with parameters n^* and $\boldsymbol{\theta}^*$, where

$$n^* = n - \sum_{j=r+1}^{p} x_i$$
$$\theta_i^* = \frac{\theta_i}{\sum_{j=r+1}^{p} \theta_j}.$$

The multinomial distribution is particularly important in analyzing categorical data, such as arise in the form of cross-classifications or contingency tables as described Section V.

II. INFERENCE FOR THE LINEAR MODEL

The classic linear model in statistics assumes that observations are linearly related to the explanatory variables and measured with independent, normally distributed error. Thus the ith observation is written in terms of the j explanatory variables as

$$y_i = \theta_0 + \sum_{j=1}^{p} \theta_j X_{ij} + \epsilon_i$$

where $\epsilon_1, \ldots, \epsilon_n$ are independent random variables, with normal distribution having mean 0 and variance σ^2, written as $N(0, \sigma^2)$. Vector notation compactly expresses this relationship for a set of n observations:

$$\boldsymbol{y} = \boldsymbol{X\theta} + \boldsymbol{\epsilon} \tag{1}$$

where $\boldsymbol{y}$ is an $n \times 1$ vector of observations, $\boldsymbol{X}$ is $n \times (p+1)$ matrix of explanatory variables, $\boldsymbol{\theta}$ is a $(p+1) \times 1$ parameter vector, and $\boldsymbol{\epsilon}$ is a random vector with multivariate normal distribution $N(\boldsymbol{0}, \sigma^2 \boldsymbol{I})$, where $\boldsymbol{0}$ indicates that the mean of each error is 0 and $\boldsymbol{I}$ is the identity matrix (a diagonal matrix with all diagonal entries equal to 1).

If the covariance matrix does not have the form $\sigma^2 \boldsymbol{I}$, but is known to equal $\boldsymbol{\Sigma}$, a specific positive-definite matrix, then one is working in the context of the general linear model. Whenever possible, the following discussion will include such extensions.

This framework enables the mathematical theory that underlies the statistical methods of estimation and hypothesis testing. Although real data rarely conform exactly to these stringent assumptions, the procedures developed from the linear model are usually quite robust. Even when the model assumptions fail entirely, the nature of the failure can often indicate how the experiment or the analysis must be modified to achieve the desired research goals.

A. Point Estimation

A fundamental estimation strategy is to minimize a measure of discrepancy between observed values and corresponding predicted values. If $\boldsymbol{\Sigma} = \sigma^2 \boldsymbol{I}$, then a tractable discrepancy is the sum of the squared differences, and the method is referred to as ordinary least squares estimation (the method of Laplace, Legendre, and Gauss). More broadly, weighted least squares extends the approach to arbitrary $\boldsymbol{\Sigma}$ by minimizing the sum of the squared generalized distances $(\boldsymbol{y} - \boldsymbol{X\theta})^{\mathrm{T}} \boldsymbol{\Sigma}^{-1} (\boldsymbol{y} - \boldsymbol{X\theta})$. Mahalanobis (1936) used this metric to take account of the covariance structure of the data. Matrix calculus finds the solution to

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta} \in \boldsymbol{\Theta}}{\operatorname{argmin}} (\boldsymbol{y} - \boldsymbol{X\theta})^{\mathrm{T}} \boldsymbol{\Sigma}^{-1} (\boldsymbol{y} - \boldsymbol{X\theta}) \tag{2}$$

as

$$\hat{\boldsymbol{\theta}} = (\boldsymbol{X}^{\mathrm{T}} \boldsymbol{\Sigma}^{-1} \boldsymbol{X})^{-1} \boldsymbol{X}^{\mathrm{T}} \boldsymbol{\Sigma}^{-1} \boldsymbol{y}, \tag{3}$$

where $\hat{\boldsymbol{\theta}}$ is not unique unless $\boldsymbol{X}$ is of full rank and $\boldsymbol{\Sigma}$ is positive definite.

Another estimation strategy maximizes the likelihood of the observations. The likelihood function of the data is the joint probability density function, except that the observations are known quantities and parameters are treated as variables. For the general linear model, the likelihood function is

$$L(\boldsymbol{\theta}; \boldsymbol{X}, \boldsymbol{y}, \boldsymbol{\Sigma}) = (2\pi)^{-n/2} |\boldsymbol{\Sigma}|^{-n/2} \times \exp\left[-\frac{1}{2} (\boldsymbol{y} - \boldsymbol{X\theta})^{\mathrm{T}} \boldsymbol{\Sigma}^{-1} (\boldsymbol{y} - \boldsymbol{X\theta}) \right].$$

For this model, the weighted least squares estimate and the maximum likelihood estimate agree. The likelihood function is maximized at $\hat{\boldsymbol{\theta}}$ of (3).

A third strategy is to find the best invariant (or equivariant) estimator. These estimators minimize the average error penalty within a class of estimators invariant under a specified group of transformations. A typical penalty function (or loss function) is the weighted squared error; i.e., for an arbitrary positive-definite matrix $\boldsymbol{W}$, the penalty for a numerical estimate $\boldsymbol{z}$ when the true value is $\boldsymbol{\theta}$ is

$$\mathrm{L}(\boldsymbol{z}, \boldsymbol{\theta}) = (\boldsymbol{z} - \boldsymbol{\theta})^{\mathrm{T}} \boldsymbol{W} (\boldsymbol{z} - \boldsymbol{\theta}). \tag{4}$$

A typical group is the set of affine transformations of the data under the composition operation. For these choices, the estimate automatically adjusts to affine changes in the units of measurement and turns out to be $\hat{\boldsymbol{\theta}}$, as before.

For the linear model with normal error, all three estimation methods give the same result for $\boldsymbol{\theta}$, although they give somewhat different estimates for the error variances. For example, suppose $\boldsymbol{\Sigma} = \sigma^2 \boldsymbol{A}$, where $\boldsymbol{A}$ is known but σ^2 must be estimated. This simple change does not affect $\hat{\boldsymbol{\theta}}$ since σ^2 cancels in (3); however, the method of least squares finds

$$\hat{\sigma}^2_{\mathrm{LS}} = \frac{1}{n-p-1} (\boldsymbol{y} - \hat{\boldsymbol{\theta}} \boldsymbol{X})^{\mathrm{T}} \boldsymbol{A}^{-1} (\boldsymbol{y} - \hat{\boldsymbol{\theta}} \boldsymbol{X}), \tag{5}$$

while the maximum likelihood procedure finds

$$\hat{\sigma}^2_{\mathrm{MLE}} = \frac{n-p-1}{n} \hat{\sigma}^2_{\mathrm{LS}},$$

and for the natural loss function for an estimate z of σ^2 given by

$$\mathrm{L}(z, \sigma^2) = \left(\frac{z}{\sigma^2} - 1 \right)^2$$

and the group of affine transformations, the best invariant estimate is

$$\hat{\sigma}^2_{\mathrm{BIE}} = \frac{n-p-1}{n-p+1} \hat{\sigma}^2_{\mathrm{LS}}.$$

Finally, suppose that $\boldsymbol{\Sigma}$ is entirely unknown; in this case, the maximum likelihood estimator is

$$\hat{\boldsymbol{\Sigma}} = \frac{1}{n} \sum_{i=1}^{n} (\boldsymbol{X}_i - \bar{\boldsymbol{X}})(\boldsymbol{X}_i - \bar{\boldsymbol{X}})^{\mathrm{T}}.$$

This estimator is biased; i.e., $E[\hat{\boldsymbol{\Sigma}}] \neq \boldsymbol{\Sigma}$. An unbiased estimator as

$$\boldsymbol{S} = \frac{n}{n-1}\hat{\boldsymbol{\Sigma}}. \tag{6}$$

These examples show that as one relaxes the assumptions of the classical model, the estimation strategies produce substantially different estimators of the error variance. With greater departures, one can even find cases in which the estimates of the vector $\boldsymbol{\theta}$ will also differ according to the method employed.

A fourth criterion for estimation is admissibility. An estimator is inadmissible if there exists another estimator with smaller average penalty for all parameter values. Stein (1956) showed that when the parameter vector $\boldsymbol{\theta}$ contains more than two components, then $\hat{\boldsymbol{\theta}}$ is inadmissible under the loss function defined in expression (4); James and Stein (1961) found an estimator which is always slightly better than $\hat{\boldsymbol{\theta}}$. This remarkable result has had great theoretical impact, but has had little influence on applied multivariate statistics.

Lehmann and Casella (1998) give a technical survey of the various estimation and testing strategies in modern statistics and describe their merits and pitfalls from a frequentist inferential perspective.

B. Hypothesis Testing

The linear model provides a venue for exploring broad issues in the testing of parametric hypotheses. A test begins with the formulation of a null and an alternative hypothesis regarding the unknown parameter $\boldsymbol{\theta}$. Formally, one tests

$$\mathrm{H}_0\colon \quad \boldsymbol{\theta} \in \boldsymbol{\Theta}_0 \qquad \text{versus} \qquad \mathrm{H}_\mathrm{a}\colon \quad \boldsymbol{\theta} \in \boldsymbol{\Theta}_\mathrm{a}$$

where $\boldsymbol{\Theta}_0$ is the region of the parameter space conforming to the null hypothesis and $\boldsymbol{\Theta}_\mathrm{a}$ is the region conforming to the alternative, where $\boldsymbol{\Theta}_0 \cap \boldsymbol{\Theta}_\mathrm{a} = \emptyset$. In some circumstances, $\boldsymbol{\Theta}_\mathrm{a}$ is chosen to include all other possible values of the parameter, i.e., $\boldsymbol{\Theta}_0 \cup \boldsymbol{\Theta}_\mathrm{a} = \boldsymbol{\Theta}$, for $\boldsymbol{\Theta}$ the entire set of allowable values. Informally, the alternative hypothesis is either the situation that the investigator wants to show, or the conclusion that leads to a change in the status quo.

The second step involves the choice of α, the probability of rejecting H_0 when H_0 is true, and either n, the sample size, or $\beta(\boldsymbol{\theta}_1)$, the probability of failing to reject H_0 for a specific value $\boldsymbol{\theta}_1 \in \boldsymbol{\Theta}_\mathrm{a}$. For a particular statistical test, any two of α, n, and $\beta(\boldsymbol{\theta}_1)$ determine the third. Customary values for α are .05 and .01, whereas $\beta(\boldsymbol{\theta}_1)$ is often allowed to be much larger. This reflects a common view that Type I error (false rejection of H_0) is more serious than Type II error (failure to correctly reject H_0). The power of a statistical test is $1-\beta(\boldsymbol{\theta}_1)$, the probability of rejecting the null hypothesis when the alternative is true. To obtain tests that are sufficiently powerful when $\alpha = .05$, a common rule of thumb is to take $n = 20d$, where d is the dimension of $\boldsymbol{\Theta}_\mathrm{a}$ (Tabachnick and Fidell, 1989).

The third step calculates the value of a test statistic, giving a single number summary of the information in the sample that bears on the hypotheses of interest. There are many strategies for selecting a test statistic; one of the most valuable is the likelihood ratio test statistic

$$\mathrm{L}(\boldsymbol{X}) = \frac{\sup\{f(\boldsymbol{X};\boldsymbol{\theta})\colon \boldsymbol{\theta} \in \boldsymbol{\Theta}\}}{\sup\{f(\boldsymbol{X};\boldsymbol{\theta})\colon \boldsymbol{\theta} \in \boldsymbol{\Theta}_0\}}, \tag{7}$$

where $f(\boldsymbol{X};\boldsymbol{\theta})$ is the joint probability density function evaluated at the data for a particular value of $\boldsymbol{\theta}$. For simple applications, such as when $f(\boldsymbol{X};\boldsymbol{\theta})$ is the density of the normal distribution, one can calculate exactly the distribution of the test statistic when H_0 is true. Otherwise, one needs to rely on the result that, under the null hypothesis, $2\log \mathrm{L}(\boldsymbol{X})$ is asymptotically (as the sample size n increases to ∞) distributed as a chi-squared random variable with $\dim\{\boldsymbol{\Theta}\} - \dim\{\boldsymbol{\Theta}_0\}$ degrees of freedom, provided that some reasonable conditions obtain.

The fourth step compares the observed value of the test statistic to the distribution of all possible values when H_0 is true. The test rejects H_0 if the statistic lies in a "rejection" region determined by α. Most software packages calculate the p value or significance probability of the observed value of the test statistic, which represents the smallest value of α for which H_0 would be rejected. One can interpret the significance probability as the probability of obtaining a value of the test statistic that is as extreme or more extreme than the sample value actually observed when the null hypothesis is true. Thus, if the p value were $p = .04$, then the test rejects H_0 at level $\alpha = .05$ but not at level $\alpha = .01$. A common error in working with significance probabilities is to regard p as the probability that the null hypothesis is correct; this is a major mistake that can distort the entire analysis and the inferences one draws from it.

C. Confidence Regions

The linear model also motivates procedures for the construction of confidence regions. A $100(1-\alpha)\%$ confidence region in $\boldsymbol{\Theta}$ is a random volume that has probability $1-\alpha$ of containing the true value $\boldsymbol{\theta}$. Customarily, one considers 90%, 95%, or 99% confidence regions.

Once the data have been gathered and the region calculated, it is incorrect to speak of coverage probability (since $\boldsymbol{\theta}$ is surely either inside or outside); instead, one reports that the region contains $\boldsymbol{\theta}$ with $100(1-\alpha)\%$ confidence. This means that if one used the same confidence region

procedure a very large number of times for multivariate normal situations, then the long-run proportion of times that the confidence regions actually contain the true parameter values approaches $1-\alpha$. This is a frequentist interpretation, and contrasts with the statistical philosophy of Bayesian inference, described in the following subsection. In Bayesian inference the analogue of the confidence region is the credible region, in which one appropriately refers to the probability that the region contains the parameter.

As the notation suggests, there is a duality between confidence regions and hypothesis tests. A $100(1-\alpha)$ confidence region contains a point $\boldsymbol{\theta}_0$ if and only if a test of

$$\mathrm{H}_0: \quad \boldsymbol{\theta} = \boldsymbol{\theta}_0 \qquad \text{versus} \qquad \mathrm{H}_a: \quad \boldsymbol{\theta} \neq \boldsymbol{\theta}_0$$

fails to reject the null hypothesis at level α.

In this and most other multivariate normal applications, the confidence region is an ellipsoid with axes determined by the covariance matrix of the parameter estimates and center $\hat{\boldsymbol{\theta}}$. The formula for the confidence region on $\boldsymbol{\theta}$ is

$$\{\boldsymbol{\theta} \in \boldsymbol{\Theta}: (\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})^{\mathrm{T}} \boldsymbol{X}[\boldsymbol{X}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{X}]^{-1}\boldsymbol{X}^{\mathrm{T}}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}) \leq F_{p+1,n-p-1,\alpha}\}, \tag{8}$$

where $F_{p+1,n-p-1,\alpha}$ is the $(1-\alpha)$-percentile point obtained from an F-distribution with $p+1$ and $n-p-1$ degrees of freedom (the appropriateness of the F-distribution for this application is a standard exercise in elementary probability theory). If the inverse matrix is not uniquely defined, then an entire subspace of $\boldsymbol{\Theta}$ satisfies the inequality. Often $\boldsymbol{\Sigma} = \sigma^2 \boldsymbol{I}$ with σ^2 unknown. Here one can estimate σ^2 from the data by $\hat{\sigma}^2$ as in (5), replace $\hat{\sigma}^2 \boldsymbol{I}$ for $\boldsymbol{\Sigma}$ in (8), and use the critical value $F_{p+1,n-p-2,\alpha}$.

D. Bayesian Inference

The inferential paradigm described above for point estimation, hypothesis testing, and confidence regions is usually referred to as the frequentist approach to inference, and it is not universally accepted. Many statisticians prefer using Bayesian inference to draw conclusions from data, expressed directly in terms of probabilities for the parameters. The frequentist view defines the probability of an event as the proportion of times that the event occurs in a sequence of possibly hypothetical trials; the Bayesian defines the probability of the same event in terms of the formalized uncertainty regarding its occurrence, based on an *a priori* assessment of θ (i.e., a prior distribution over Θ). This in some sense removes the distinction between parameters and random variables. One implication of this prior assessment is that different Bayesian statisticians, with different states of uncertainty regarding θ, may assign different probabilities to the same event. Frequentists can also disagree, but their differences are attributable to the selection of different probability models for describing the event. Perhaps the most striking aspect of this often subtle distinction is that Bayesians view unknown parameters as random variables, whereas frequentists regard them as fixed constants. This allows Bayesians to calculate probabilities associated with the parameters, given the data, whereas frequentists can only look at probabilities of the data, given values of the parameters.

The Bayesian method first requires one to formalize the uncertainty about the unknown parameters by placing a probability distribution $\pi(\boldsymbol{\theta})$ over $\boldsymbol{\Theta}$. This prior distribution reflects beliefs about, among other things, the most probable and least probable values of $\boldsymbol{\theta}$; usually these beliefs derive from common sense and previous experience with similar data, but those who are unable to express such beliefs or are very cautious may resort to a "noninformative" prior. Bayesians often assess their own experience or they elicit probabilities from appropriate experts. The choice of a prior distribution in a particular application involves technical issues.

After selecting the prior distribution for $\boldsymbol{\theta}$, one gathers the data and uses Bayes' theorem to update the prior distribution in the light of the evidence:

$$\pi^*(\boldsymbol{\theta}) = \frac{\pi(\boldsymbol{\theta}) f(\boldsymbol{X};\boldsymbol{\theta})}{\int \pi(\boldsymbol{\psi}) f(\boldsymbol{X};\boldsymbol{\psi})\, d\boldsymbol{\psi}}.$$

This posterior distribution for $\boldsymbol{\theta}$, $\pi^*(\boldsymbol{\theta})$, is the basis for subsequent inference.

The Bayesian method illustrates how prior beliefs should change as a result of observing the data. Even if two Bayesians disagree markedly upon their choice of prior distributions, observing the same set of data typically causes them to produce posterior distributions which are more similar, and continued observation eventually compels their conclusions to converge as long as they do not assign zero probability *a priori* to different parts of the parameter space $\boldsymbol{\Theta}$ (Blackwell and Dubins, 1962).

Bayesian inference is closely linked to decision theory, which is concerned with minimizing expected losses when one must make choices without certainty as to the consequences. Rather than detail the impact of this theory on Bayesian estimation and the Bayesian analogues of hypothesis testing and confidence regions, we simply note that common Bayes estimators for $\boldsymbol{\theta}$ are the mode and the mean of the posterior distribution. Similarly, the Bayesian analogue to hypothesis testing is performed by integrating over regions of $\boldsymbol{\Theta}$ corresponding to H_a or H_0. This enables the Bayesian to state the posterior probabilities of the null and alternative hypotheses. Finally, a Bayesian analogue to a confidence region is the credible

region, which is typically the smallest volume in Θ that contains a specified proportion of the posterior probability. Bernardo and Smith (1994) provide a detailed exposition of Bayesian theory.

E. Generalized Linear Model

The generalized (as distinct from general) linear model (GLM) was developed by Nelder and Wedderburn (1972) in an extension of the classical linear model. It unifies general linear model theory, log-linear models, logit and probit models, and more exotic models developed for specific applications. This enables application of standard procedures for estimation, model verification, hypothesis testing, and prediction in a variety of linear and nonlinear problems.

The form of the GLM is

$$\boldsymbol{Y} = g(\boldsymbol{X}\boldsymbol{\beta}) + \boldsymbol{\epsilon} \tag{9}$$

where $\boldsymbol{Y}$ is the observed vector, $g(\cdot)$ is a known function, referred to as the link function, and the errors ϵ_i are (usually) independent, have mean 0, and belong to a known exponential family distribution. [Exponential family distributions include the normal, binomial, Poisson, inverse Gaussian, and many other distributions; Barndorff-Neilsen (1978) gives a detailed account of the central place of these in statistical inference.] The exponential family condition implies that the density of a single observation Y_i can be written in the form

$$f(y_i) = \exp\left\{\frac{y_i\theta_i - h(\theta_i)}{\psi} + a(y_i, \psi)\right\}, \tag{10}$$

where θ_i is referred to as the natural parameter and ψ is the dispersion parameter. One can show that

$$\frac{dh}{d\theta_i} = E\left[\beta_0 + \sum_{j=1}^{p} \beta_j X_i j\right]$$

and thus in most applications the natural choice for the link function (called the canonical link) takes $g = h'$. McCullagh and Nelder (1989) offer many examples, using both canonical and noncanonical link functions.

When the link function is the identity and one has independent and identically distributed normal errors with mean 0, then the model exactly agrees with the classical model given in (1). When the Y_i are proportions related to $\boldsymbol{X}_i^{\mathrm{T}}\boldsymbol{\beta}$ by the model given in (19), then the link function is $\log[p/(1-p)]$ and the errors are binomial; this corresponds to the logistic regression model described in the Section II. Finally, when the data are counts obtained from a Poisson distribution and the link function is $\log \mu_i$, one has the log-linear model described in Section V.

Maximum likelihood is usually the method of choice for estimating the parameters of a GLM. Hypothesis testing is typically done from likelihood ratio test principles, using a quantity known as the deviance, which can be partitioned into components and represented in an analysis of deviance table that is analogous to the analysis of variance table discussed in Section III. Most software packages and discussions of GLMs define the deviance as $-2\sum \log f(Y_i)$, where $f(Y_i)$ has the exponential family form given in (10). Distribution theory for the deviance is generally unavailable unless the dispersion parameter ψ in expression (10) is known or well estimated, as is the case for the linear model in (1). This makes formal inference difficult in many applications.

F. The Bootstrap

The inferential methods described thus far depend upon strong model assumptions and simple parameters for success. In practice, especially in multivariate problems, one rarely has accurate knowledge of the underlying distribution and fundamental parameters are complicated functionals of the distribution. Modern computer-intensive statistical methods can now substitute large-scale calculation for theoretically convenient assumptions, and this approach has greatly extended the range of multivariate applied statistics. One of the most important tools in this extension is the bootstrap, developed by Efron (1979).

The bootstrap method enables one to estimate standard errors and set confidence regions in very general situations. The key idea is that if the empirical cumulative distribution function (ECDF) of the data is approximately equal to the unknown true cumulative distribution function, then confidence regions that are constructed as if the ECDF were the true distribution are similar to the exact confidence regions that would have been set if the true distribution function were known. The same insight holds for estimating standard errors, which are the standard deviations of parameter estimates.

The empirical distribution function of a multivariate sample $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ is

$$\hat{F}_n(\boldsymbol{x}) = \sum_{i=1}^{n} I_{A(\boldsymbol{x})}(\boldsymbol{X}_i), \tag{11}$$

where

$$A(\boldsymbol{x}) = \bigcup_{j=1}^{p} (-\infty, x_j]$$

and

$$I_{A(\boldsymbol{x})}(\boldsymbol{X}_i) = \begin{cases} 1 & \text{if} \quad \boldsymbol{X}_i \in A(\boldsymbol{x}) \\ 0 & \text{otherwise.} \end{cases}$$

The Glivenko–Cantelli theorem from probability theory ensures that $\lim_{n\to\infty} \hat{F}_n = F$ for univariate random variables. Special technical conditions are needed to guarantee

large sample convergence for multivariate ECDFs. Nonetheless, the cases in which convergence fails are somewhat pathological, and most applications may safely neglect this potential difficulty. Thus, if the sample size is sufficiently large, then $\hat{F}_n$ should offer a very good approximation to the unknown F.

If F were known, then for any parameter $\boldsymbol{\theta}$ one could estimate the accuracy of an estimator by drawing a very large number m of samples of size n from F, calculating the parameter estimate of interest for each, and comparing the m estimates to the known value $\boldsymbol{\theta}$. The distribution of these parameter estimates is called the sampling distribution, and knowing it and the true $\boldsymbol{\theta}$ entirely determines the reliability of any inference. The bootstrap method assumes that the known $\hat{F}_n$ is a good estimate of F, and draws m samples of size n from $\hat{F}_n$. One calculates the estimate for each sample and uses these estimates to define the bootstrap distribution. As m increases, the bootstrap distribution converges very generally to the sampling distribution; since the parameter of interest is exactly known (at least implicitly) for the ECDF, then one can use these as proxies for the sampling distribution and θ when assessing the reliability of an inference.

Operationally, the algorithm for setting the simplest bootstrap confidence region on a parameter $\boldsymbol{\theta}(F)$ is as follows:

1. Draw a random sample $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ from the unknown distribution function $F(\boldsymbol{x})$.
2. Obtain the estimate $\hat{\boldsymbol{\theta}}$ from the sample as $\boldsymbol{\theta}(\hat{F}_n)$, where $\hat{F}_n$ is the ECDF defined in (11) and $\Theta(\cdot)$ is a functional mapping distribution functions into $\boldsymbol{\Theta}$.
3. Draw a large number m of random samples of size n from $\hat{F}_n$; we call these resamples, to distinguish them from the original data. For each resample determine the corresponding secondary ECDF; denote these by $\hat{\hat{F}}_{n1}, \ldots, \hat{\hat{F}}_{nm}$.
4. Calculate $\boldsymbol{\theta}_j = \boldsymbol{\theta}(\hat{\hat{F}}_{nj})$. Let $G(\boldsymbol{\theta})$ be the ECDF of $\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_m$.
5. Use $G(\boldsymbol{\theta})$ as though it were the sampling distribution of $\boldsymbol{\theta}$ for all inferences. Thus the bootstrap estimate of the covariance matrix of $\hat{\boldsymbol{\theta}}$ is just the covariance matrix of a random variable with distribution $G(\boldsymbol{\theta})$. Also, the bootstrap confidence region for $\boldsymbol{\theta}$ at level α is just the smallest set in $\mathbb{R}^p$ such that the probability mass of that region under $G(\boldsymbol{\theta})$ equals $1-\alpha$.

This algorithm may look complex, but it is actually very simple to implement in the form of a computer program. For estimating the standard error of a univariate parameter, it is usually sufficient to take $m = 200$; for setting a confidence region, one can take $m = 1000$. The accuracy of the bootstrap increases with the sample size n, but surprisingly good inference for a single parameter has been obtained with samples as small as 15.

More complicated bootstrap algorithms attain improved accuracy in many large-sample situations, often at the expense of increased computation. One of the easiest methods to improve bootstrap performance is to bootstrap a studentized pivot. For a univariate parameter, instead of calculating the bootstrap distribution of an estimator $\hat{\theta}$, one finds the bootstrap distribution that approximates the sampling distribution of $(\hat{\theta} - \theta)/\sqrt{\mathrm{Var}(\hat{\theta})}$. This approximation is asymptotically superior to the simple bootstrap distribution described above whenever the parameter of interest is asymptotically normally distributed. Confidence regions can be built from this pivot in a straightforward way, and the method immediately generalizes to multivariate parameters.

Other bootstrap refinements are detailed by Efron and Tibshirani (1986); Banks (1989) surveys bootstrap theory and applications. An explicit study of bootstrap performance for a large class of multivariate inference problems is described by Beran and Srivastava (1985).

G. Cross-Validation

Just as computer-intensive methods permit bootstrap confidence regions for very general problems, so does modern computing enable flexible assessment of model adequacy. A key tool for assessment is cross-validation; the implementation of this method must be tailored to the problem, but the principle applies to a tremendous range of statistical techniques. This generality is important, since in realistic applications one is usually fitting a model that only approximates the complexity of the situation. In particular, cross-validation has become the primary method for fitting spline models to complex data (Wahba, 1985) and for determining the smoothing parameters in nonparametric curve-fitting (Hastie and Tibshirani, 1990).

Before using the results of a statistical analysis, one must know how well the fitted model will describe future values of the dependent variables. This cannot be done with confidence by simply assessing the agreement between the original sample values and the model's predictions of those values; the sample was used to estimate the parameters of the model, which leads to spuriously good agreement. To adjust for this optimism, cross-validation sets aside a portion of the data, fits the hypothesized model to the remainder, and assesses the predictive accuracy against the unused data. If one then interchanges the roles of the two subsets of the data, one obtains a very efficient estimate of model adequacy. More elaborate methods for dividing the sample lead to additional gains in assessment accuracy.

Let $\mathcal{M}(\theta)$ denote the model that is assumed for the analysis. In many applications this will be the model given in (1), but in other cases it could be a much more complex form, such as (9) or (20), discussed in Section II. The cross-validation strategy proceeds as follows:

1. Partition the sample at random into k disjoint subsamples. Denote these sets by $S_1, \ldots, S_k$.
2. For $i = 1$, pool all subsamples with subscripts not equal to i. Use these pooled subsamples to estimate the parameters in the model $\mathcal{M}(\theta)$. Let $\mathcal{M}(\hat{\theta}_i)$ be the model fitted without use of subsample S_i.
3. Use the model $\mathcal{M}(\hat{\theta}_i)$ to estimate the dependent variable values in subsample S_i; record these estimates as $\hat{\boldsymbol{Y}}_i$.
4. If $i \neq k$, set $i = i + 1$ and return to step 2.
5. Link $\hat{\boldsymbol{Y}}_1, \ldots, \hat{\boldsymbol{Y}}_k$ into a vector of estimated values $\hat{\boldsymbol{Y}}$. Compare this to the observed dependent variable values $\boldsymbol{Y}$ from the sample, using whatever criterion for aggreement is most appropriate to the problem.

If one has a small dataset and is fitting a simple model, then one can partition the sample into as many subsamples as there are observations; if the dataset is large or computational time is expensive, then a coarser partition may be more useful.

In order to compare several competing models via cross-validation, one can examine the discrepancies between $\hat{\boldsymbol{Y}}$ and $\boldsymbol{Y}$ for each. The model that attains the lowest total discrepancy is generally to be preferred for predicting future dependent values. Currently, there is no general theory that enables one to assess the statistical significance of the magnitude of the difference in total discrepancy between two models except in specialized situations. Although the cross-validation criterion is not equivalent to a goodness-of-fit test for assessing a model, it often happens that similar conclusions are drawn by each procedure.

H. Missing and Censored Data

A common practical problem arises when some of the data are unavailable for analysis. In general, there are three cases: (i) some components of the $\boldsymbol{X}$ vector are missing for some of the observations, (ii) some of the observations are missing, or (iii) the response variable Y is censored. Methodologies exist to address all three cases, but the solutions that they offer are not entirely satisfactory.

Missing components commonly occur in industrial data, when certain on-line measuring devices fail, and in census or survey data, when people provide incomplete information or responses. The basic strategy for analysis is to use the complete data records to estimate or "impute" values for the records with missing data. One approach is the hot-deck method, in which an incomplete record is randomly matched with a complete record or records that show close agreement in the observed components. Alternatively, one can use regression methodology to estimate the missing values, or the EM algorithm, described by Little and Rubin (1987) and McLachlan and Krishnan (1997), iteratively to estimate both missing data and model parameters simultaneously. Kalton and Kasprzyk (1986) survey the data imputation literature for the missing components problem.

If some of the observations are missing and their absence is unrelated to the outcome, then the impact of the missing data on regression analysis is minimal. In experimental design, however, one has typically prespecified the $\boldsymbol{X}$ values so as to ensure that certain planned comparisons can be made or to guarantee that the variance of the estimates has some desirable property. Losing even a single observation can affect such goals. The strategy for salvaging as much as possible of the analysis depends upon the assumptions one is willing to make, the structure of the initial design, and the location of the missing observations. Milliken and Johnson (1984) describe the various approaches.

Censored data arise when for some of the observations, one only knows that a dependent or independent variable exceeded a certain value. The appropriate analysis depends sensitively upon the type of censoring that occurs. The three primary types are as follows.

1. Type I censoring. In this application there is a fixed threshold, and one cannot observe the precise values of data exceeding that threshold. The circumstance might arise if one's measuring instruments had a ceiling; for example, a temperature gauge in a chemical process may not be able to report values greater than 500°C, even though the process may become much hotter.

2. Type II censoring. This arises in life testing for very reliable units; here it is often infeasible to wait until all units fail before estimating the average time to failure. To avoid undue delay, one terminates the experiment after observing the rth failure. For example, one might start 100 experimental engines and terminate the experiment when the third engine fails. Thus for 97 of the cases, one only knows that their true lifetimes would have been greater than the time to third failure.

3. Random censoring. This occurs when for each observation, one observes either the true value or a random censoring variable, depending upon which is smaller. For example, one may want to estimate the time to failure of an implanted pacemaker, but some patients die of other causes, move to a new city, or cease to report for other

reasons. In these cases one only knows that the pacemaker was still working as of the time that the patient's participation stopped.

There is a large literature on censored data problems. Miller (1981) offers an excellent introduction.

References

Arnold (1981), Christensen (1996), and Graybill (1976) are standard texts on univariate linear models. Arnold and Christensen take a coordinate-free approach, whereas Graybill presents a more classical treatment in terms of explicit coordinate systems and their matrix formulation. Christensen (1991) extends these ideas to the multivariate linear model described in this section. Lehmann (1986) discusses the likelihood ratio test and other hypothesis testing strategies; Lehmann and Casella (1998) detail issues in estimation. Berger (1985) is a moderately technical treatment of Bayesian inference; DeGroot (1970) is an accessible mathematical introduction to the field. Broemeling (1985) details Bayesian methodology in the context of the linear model. McCullagh and Nelder (1989) offer the most detailed treatment of GLM procedures. For bootstrap methods, the fundamental reference is Efron (1982); a readable introduction to more recent work is Efron and Tibshirani (1986). Stone (1977) surveys the main ideas in cross-validation and Mosteller and Tukey (1968) give a detailed illustration of the approach using a nested version which both produces a cross-validation estimate and then assesses its variability. Little and Rubin (1987) and McLachlan and Krishnan (1997) discuss a large class of missing data problems; Lawless (1982) presents methodology for the analysis of censored data in the context of life testing.

III. REGRESSION ANALYSIS

Regression problems first received mature attention when Francis Galton (1888) attempted to assess the relationship, or correlation, between the heights of fathers and the heights of sons. The area developed quickly, and is now the most widely used branch of applied statistics.

Multiple linear regression is a special case of the general linear model given in (1). When $(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{X})$ is invertible, the estimate of the parameter vector $\boldsymbol{\theta}$ is unique, and inferential procedures based upon the likelihood ratio test are straightforward. Specifically, all standard hypotheses can be written in the form

$$\mathrm{H}_0: \quad \boldsymbol{A\theta} - \boldsymbol{b} = \boldsymbol{0} \qquad \text{versus} \qquad \mathrm{H}_{\mathrm{a}}: \quad \boldsymbol{A\theta} - \boldsymbol{b} \neq \boldsymbol{0} \tag{12}$$

for a square matrix $\boldsymbol{A}$ of rank q and vector $\boldsymbol{b}$ appropriate to the problem. Then, using (7), the likelihood ratio test statistic is

$$\mathrm{L}(\boldsymbol{X}) = \frac{(\boldsymbol{A\hat{\theta}} - \boldsymbol{b})^{\mathrm{T}}[\boldsymbol{A}\boldsymbol{X}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{X}\boldsymbol{A}^{\mathrm{T}}]^{-1}(\boldsymbol{A\hat{\theta}} - \boldsymbol{b})}{\boldsymbol{Y}^{\mathrm{T}}[\boldsymbol{I} - \boldsymbol{X}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{X})^{-1}\boldsymbol{X}^{\mathrm{T}}]\boldsymbol{Y}} \times \frac{n-p-1}{q}, \tag{13}$$

where p is the number of explanatory variables and q is the rank of the matrix $\boldsymbol{A}$. In most applications $\boldsymbol{\Sigma}$ is reasonably taken to be $\sigma^2\boldsymbol{I}$, where $\boldsymbol{I}$ is the identity matrix. Very often, $\boldsymbol{b}$ is $\boldsymbol{0}$.

Under the null hypothesis, the test statistic (13) follows an F-distribution with $\nu_1 = q$ numerator degrees of freedom and $\nu_2 = n - p - 1$ denominator degrees of freedom. The degrees of freedom indicate the amount of information that remains for testing the hypothesis after some of the information in the sample has been used to estimate the parameters. Each parameter estimate in linear modeling consumes a quantity of information equivalent to one observation; for nonlinear modeling, a parameter estimate uses more, often the equivalent of two to four observations.

Suppose we have fit the linear model

$$Y_i = \theta_0 + \theta_1 X_{i1} + \cdots + \theta_p X_{ip} + \epsilon_i$$

to a sample of an observation and are willing to assume independent, identically distributed normal error. Our intention is to make a level $\alpha = .01$ test of $\mathrm{H}_0: \theta_{k+1} = \cdots = \theta_p = 0$. If the null hypothesis is not rejected, this is evidence that data conform to a simpler model. To implement the test, set $\boldsymbol{b} = \boldsymbol{0}$ in (12) and take $\boldsymbol{A}$ to have all entries zero except for ones in the $(k+2)$th through $(p+1)$th positions along the diagonal (recall that our initial component of $\boldsymbol{\theta}$ is denoted θ_0, so that θ_{k+1} is the $(k+2)$th component of a vector in $\mathbb{R}^{p+1}$). Then evaluate (13) and compare its value to the $100(1-\alpha) = 99$th percentile point of an F-distribution with $p-k$ and $n-p+k$ degrees of freedom. If the value of the common variance σ^2 is unknown, then one replaces it with the estimate given by (5) and compares the test statistic to the percentile point of an F-distribution with $n-p-2$ degrees of freedom for the denominator.

As one moves away from the classical linear model, regression becomes more complicated. Analysis is slightly more difficult when $\boldsymbol{\Sigma}$ is unknown, and much more complicated when the variance of ϵ_i depends on $\boldsymbol{X}_i$. Nonconstant variance is called heteroscedasticity, and typically one must either transform the data to stabilize the variance or else use a weighted least squares algorithm. Fortunately, most inferences are insensitive to reasonably nonnormal error distributions, and regression procedures are surprisingly robust to violations of model assumptions.

Moreover, many special tricks enable one to overcome specific deficiencies in the data (Madansky, 1988).

A. Correlation Analysis

The correlation ρ between two random variables X and Y,

$$\rho = \frac{\text{cov}[X, Y]}{\sqrt{\text{var}[X]\text{var}[Y]}},$$

is a measure of the strength of the linear relationship between them. In multivariate applications, a random vector $\boldsymbol{X}$ has correlation matrix $\boldsymbol{P} = \{\rho_{ij}\}$, where ρ_{ij} denotes the correlation between the ith and jth components of $\boldsymbol{X}$. If one has a random sample $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ from a multivariate normal distribution, then the maximum likelihood estimate $\boldsymbol{R} = \{r_{ij}\}$ for $\boldsymbol{P}$ has entries

$$r_{ij} = \frac{\sum_{k=1}^{n}(X_{ki} - \bar{X}_i)(X_{kj} - \bar{X}_j)}{\sqrt{\left[\sum_{k=1}^{n}(X_{ki} - \bar{X}_i)^2\right]\left[\sum_{k=1}^{n}(X_{kj} - \bar{X}_j)^2\right]}},$$

where $\bar{X}_i$ is the average of the ith components. The matrix $\boldsymbol{R}$ is called the sample correlation matrix. In regression, it usually happens that associations involving the response variable Y are of main interest, but the correlations among the explanatory variables can profoundly affect one's conclusions.

For practical applications, one often wants to do the following:

1. Test a hypothesis about the correlation between two variables.
2. Assess the strength of the residual association between two random variables after accounting for their mutual association with a set of k other random variables.
3. Assess the strength of the association between a single random variable and the best linear combination of a set of k random variables.

The precise interpretation of the results of such analyses is sensitive to the assumption that the data are normally distributed; in particular, $\rho = 0$ implies that X and Y are completely mutually uninformative if and only if the joint distribution of X and Y is bivariate normal. Reasonable deviations from normality, however, usually have negligible effect in applications.

Two procedures are available to address the first question. For the null hypothesis that correlation ρ is equal to zero, Fisher (1915) showed that, when the data come from a multivariate normal distribution, the test statistic

$$t = r\sqrt{\frac{n-2}{1-r^2}}$$

follows the t distribution with $n-2$ degrees of freedom, where r is the sample correlation. The percentile points of these distributions, as needed for a test with a given α value, are ubiquitously tabulated.

If the null hypothesis specifies a value for ρ other than zero, say ρ_0, then no exact procedure is easily available. Fisher (1921) showed, however, that $z = \tanh^{-1} r$ is asymptotically normal with mean $\tanh^{-1}\rho$ and variance $(n-3)^{-1}$. This enables one to test H_0: $\rho = \rho_0$ versus H_a: $\rho \neq \rho_0$, by referring

$$z = \sqrt{n-3}\left(\tanh^{-1} r - \tanh^{-1}\rho_0\right)$$

to a value from a standard normal table.

The second question leads to the definition of partial correlation. This measures the association between two random variables after controlling for the effects of one or more other random variables. Here, the term "controlling for" indicates that the measure is calculated as if the other variables were all held constant; more precisely, it is the correlation of the conditional bivariate distribution of the random variables, given the values of the other random variables. Mathematically,

$$\rho_{ij.k} = \frac{\rho_{ij} - \rho_{ik}\rho_{jk}}{\sqrt{\left(1-\rho_{ik}^2\right)\left(1-\rho_{jk}^2\right)}} \tag{14}$$

is the partial correlation between the ith and jth components of $\boldsymbol{X}$, controlling for the effect of the kth. To obtain the partial correlation controlling for additional variables, one uses the recursion formula

$$\rho_{ij.k_1,\ldots,k_{s+1}} = \frac{\rho_{ij.k_1,\ldots,k_s} - \rho_{ik_{s+1}.k_1,\ldots,k_s}\rho_{jk_{s+1}.k_1,\ldots,k_s}}{\sqrt{\left(1-\rho_{ik_{s+1}.k_1,\ldots,k_s}^2\right)\left(1-\rho_{jk_{s+1}.k_1,\ldots,k_s}^2\right)}}. \tag{15}$$

To obtain the sample estimate of the partial correlation, one replaces the population values in (14) and (15) with the sample estimates obtained from applying recursion formulas to the entries of $\boldsymbol{R}$. [For more information, see Anderson (1984) and Tong (1990). These recursion formulas go back to the original work of Yule at the turn of the century.]

The third question gives rise to the multiple correlation coefficient. This is the maximum possible correlation between a given random variable and the best linear combination of a given set of random variables:

$$\rho_{Y.\boldsymbol{X}} = \frac{1}{\sigma}\sqrt{\boldsymbol{\tau}^{\text{T}}\text{var}[\boldsymbol{P}]^{-1}\boldsymbol{\tau}}, \tag{16}$$

where $\boldsymbol{\tau}$ is the vector whose jth component is the covariance between Y and the jth component of $\boldsymbol{X}$. This is clearly important in linear regression since the multiple

correlation measures how well the dependent variable Y is explained by the best linear combination of p explanatory variables. In applications, one estimates $\rho_{Y.\boldsymbol{X}}$ from sample data by replacing the values in (16) by the corresponding maximum likelihood estimates, yielding $R_{y.x}$. Distribution theory for the sample estimate of the multiple correlation coefficient was developed by Fisher (1928).

The multiple correlation coefficient can be generalized to what is known as the canonical correlation coefficient, a quantity which maximizes the correlation between linear combinations of two disjoint sets of random variables subject to constraints upon the linear combinations. This extension is important in understanding structures in the covariance matrix, and is related to topics discussed in Section V.

The square of the multiple correlation coefficient $R^2_{Y.\boldsymbol{X}}$ is referred to as the coefficient of determination. This index is frequently used to assess the success of the analysis; it can be interpreted as the proportion of the variance in Y explained by the value of the best linear combination of the explanatory variables. Since $R^2_{Y.\boldsymbol{X}}$ approaches 1 as p increases, one must adjust $R^2_{Y.\boldsymbol{X}}$ to take account of the number of components in $\boldsymbol{X}$. One such correction,

$$R^2_a = \frac{(n-1)R^2_{Y.\boldsymbol{X}} - p}{n-p-1}$$

was given by Ezekiel (1930). This method is similar in spirit to Mallows' C_p statistic, which is used in the context of variable selection (Mallows, 1973). A comparative discussion of both methods appears in Rawlings *et al.* (1998).

In the context of the multivariate linear regression model with normal errors of this section, (i) $\rho_{ij} = 0$ is equivalent to the marginal independence of X_i and X_j, (ii) $\rho_{ij.k_1,\ldots,k_{s+1}} = 0$ is equivalent to the conditional independence of X_i and X_j given $X_{k_1}, \ldots, X_{k_{s+1}}$, and (iii) $\rho_{Y.\boldsymbol{X}} = 0$ is equivalent to the independence of Y and $\boldsymbol{X}$. In Section V, these types of independence will be an integral part of the specification of models for the case where both Y and $\boldsymbol{X}$ are categorical variables instead of continuous variables.

B. Multicollinearity

A potential difficulty in linear regression is that the rows of the data matrix $\boldsymbol{X}$ are sometimes highly correlated. This is called multicollinearity; it occurs when the explanatory variables lie close to a line or plane or other proper subspace of $\mathbb{R}^p$. If carried to the extreme of perfect correlation, this implies that the covariance matrix $\boldsymbol{X}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{X}$ is not invertible, and thus the parameter estimates in (3) cannot be obtained. Multicollinearity is a common problem in observational studies, but can usually be entirely avoided in carefully designed experiments.

As an example, suppose the dependent variable is the compressive strength of an aluminium can and the explanatory variables include indices of the bowing in the can walls, obtained from both a dial gauge and a coordinate measuring machine. These two values are so highly correlated as to be almost perfectly redundant, causing multicollinearity. Similarly, multicollinearity will occur when the explanatory variables are near perfect linear functions of other explanatory variables. In chemical engineering, this happens when several explanatory variables are the proportions of additives in a mixture. If the sum of all proportions must equal one, then there is perfect correlation and the covariance matrix is singular. If one avoids this by excluding one of the proportions, then it can still happen that the excluded variable shows very little variation, inducing multicollinearity.

Conceptually, multicollinearity implies that there is less information in the sample than one would expect, given the number of measurements taken. The inferential impact of this is that the estimate $\hat{\boldsymbol{\theta}}$ is unstable, so that small perturbations in the data cause large changes in the inference. Consequently, predictions based on the fitted model can be very bad.

C. Residuals

Residuals are the differences between the observed response values and those predicted after estimating the model parameters. The residual corresponding to the ith observation Y_i with explanatory variable values $X_{i1}, \ldots, X_{ip}$ is

$$\hat{\epsilon}_i = Y_i - (\hat{\theta}_0 + \hat{\theta}_1 X_{i1} + \hat{\theta}_p X_{ip}).$$

If many residuals have large relative magnitudes, this suggests the model is wrong and a more complicated model should be fit. A single residual with very large magnitude indicates an outlier; this data point should be checked to be sure the record is accurate, and even then it is often wise to set it aside during the analysis. (Surveyors distinguish outliers from blunders; if the cause of the outlier is discovered, it is called a blunder.)

Plots of the residuals against the explanatory variables are an important tool in regression analysis. Qualitatively, a good plot of $\hat{\epsilon}_i$ versus the jth component of $\boldsymbol{X}_i$ shows an oval-shaped point cloud centered on the line $\hat{\epsilon} = 0$. We note that although in the standard model the true errors ϵ_i are independent with unknown constant variance σ^2, the corresponding estimated residuals have mean 0 but

$$\mathrm{var}[\hat{\epsilon}] = \sigma^2(\boldsymbol{I} - \boldsymbol{X}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X})^{-1}\boldsymbol{X}^{\mathrm{T}}). \qquad (17)$$

This dependence complicates the problem of identifying outliers and data values that have unusual influence on the overall inference.

One consequence of the dependence structure in (17) is that residuals near the average $\bar{\boldsymbol{X}}$ of $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ tend to be large, whereas residuals far from $\bar{\boldsymbol{X}}$ tend to be small. This happens because observations far from $\bar{\boldsymbol{X}}$ have disproportionate influence, and these are called "high leverage" cases. High leverage is undesirable since inadequacies in modeling are expected to be greatest at the extremes of the data. Values with high leverage are masked by the residuals. A partial correction for this effect is to plot the studentized residuals

$$e_i = \frac{\hat{\epsilon}_i}{\hat{\sigma}\sqrt{1 - \boldsymbol{X}_i(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X})^{-1}\boldsymbol{X}_i^{\mathrm{T}}}}$$

against the $\boldsymbol{X}_{ij}$ in place of $\hat{\epsilon}_i$. One can show that this reweights the observed residuals so that large discrepancies are more likely to occur at the extreme range of the $\boldsymbol{X}$ values.

There are many techniques for assessing a regression from functions of the fitted residuals; these include Cook's D and PRESS statistics. Belsley *et al.* (1980) survey regression diagnostics with special emphasis upon leverage, outliers, masking and influence functions. Cross-validation and the bootstrap, discussed in Section I, also enable inference about the adequacy of the model without requiring too many formal assumptions about the joint distribution of the error terms.

D. Transformations

The scope of application of the classical model can be extended through transformations of the data. Often the data collected fail to satisfy the classical assumptions; for example, the variance of the errors may not be constant over the space of the independent variables (heteroscedasticity), or the error distribution may not be normal, or the relationship of the parameters to the data may be nonlinear. In these circumstances, one can sometimes find a transformation of $(Y, \boldsymbol{X})$ that stabilizes the variance, normalizes the error, and/or linearizes the problem.

For example, in chemical kinetics, the rate R of a reaction between Z_1 moles of compound A and Z_2 moles of compound B might have the known (nonlinear) functional form

$$R_i = cZ_{i,1}^{a}Z_{i,2}^{b}e^{\epsilon_i}.$$

By taking logarithms of both sides of the equation, one gets the linear model

$$\ln R_i = \ln c + a \ln Z_{i,1} + b \ln Z_{i,2} + \epsilon_i.$$

Setting $Y_i = \ln R_i$ and $X_{i,j} = \ln Z_{i,j}$, one can attempt a standard analysis.

As another example, heteroscedasticity frequently occurs when Y_i is a proportion or percentage. Here the error variance is largest when the true value p_i is near .5 and decreases to 0 when p_i approaches 0 or 1. However, one can show that the transformed value $Z_i = \arcsin\sqrt{Y_i}$ asymptotically has constant variance, and so can be regressed against the independent variables.

A very popular set of data transformations are the Box–Cox family. These are variance-stabilizing transformations, pertinent for fitting the model

$$Y_i^{\lambda} = \boldsymbol{X}_i^{\mathrm{T}}\boldsymbol{\theta} + \epsilon_i,$$

where Y_i is constrained to be positive, $\mathrm{var}[\boldsymbol{\epsilon}] = \sigma^2\boldsymbol{I}$, and λ is an unknown exponent that is to be estimated from the data. If the data contain zeros, then it is customary to replace Y_i by $Y_i + 1$ throughout, before estimating λ. The Box–Cox family is popular because it contains many standard transformations; when $\lambda = .5$, one has a square-root transformation that is theoretically appropriate for data that arise from counts distributed as Poisson random variables. Similarly, $\lambda = -1$ is useful when observations concentrate near zero but long tails occur; one distribution-theoretic grounds, this transformation is probably appropriate when the scatterplot shows $\mathrm{var}[\epsilon_i] \propto \mathrm{E}[Y_i]^4$. Also, if $\lambda = 0$, one can show by a continuity argument that the appropriate transformation is $\log Y_i$, which is appropriate when the range of the response variable is very broad and $\mathrm{var}[\epsilon_i] \propto \mathrm{E}[Y_i]^2$.

Box and Cox (1964) offer guidelines for estimating λ, and Carroll and Rupert (1988) give more recent suggestions. In practice, many prefer to examine the data in an exploratory fashion to find a simple transformation within the Box–Cox family rather than estimate an arbitrary fraction; this honors the fact that simple transformations often correspond to scalings for variables and thus are natural models for the data. Inference is generally insensitive to small changes in the transformation.

E. Stepwise Selection

A common problem in multiple regression is an excess of explanatory variables. If one fits a model with too many independent variables (either those originally measured, or powers, products, and transformations of the data), then one can achieve spuriously good fit. The model shows very good agreement with the data, but is nearly useless for describing the true relationship or predicting future responses at particular values of the independent variables. To avoid this problem of overfit, one should include only those independent variables that explain a significant proportion of the variation in $\boldsymbol{Y}$ that is not accounted for by

variables already used in the model. This goal entails a process called variable selection.

To perform a stepwise variable selection for univariate dependent variables, one can use routines in any major software package (BMDP, SAS, SPSS, Stata, SYSTAT, S-PLUS) that implement an iterative algorithm for including variables in the model. This algorithm begins with no variables in the model. At the kth step, it adds the most valuable explanatory variable from the set of currently unincluded variables, provided that some minimal level of explanatory value is attained. Then it reviews all of the variables now in the model, removing any whose explanatory value, given the most recently added variable, has dropped below a certain threshold. Other selection procedures exist, but none stands upon a firm mathematical justification. The methods are all intrinsically nonlinear, which makes theoretical analysis very difficult. Nonetheless, empirical work indicates that variable selection will substantially improve the accuracy of most multiple regression analyses.

F. Some Special Cases

Polynomial regression illustrates a general strategy for extending linear regression so as to fit curved lines to response data. For example, one can fit a cubic equation to the data using the model

$$Y_i = \theta_0 + \theta_1 X_i + \theta_2 X_i^2 + \theta_3 X_i^3 + \epsilon_i. \qquad (18)$$

Here the powers of X are entries in different columns of the $\boldsymbol{X}$ matrix, and the linear structure of (18) ensures this is formally equivalent to the classical model. Similarly, one can handle interactions between two different kinds of explanatory variables, say X_{i1} and X_{i2}, by including terms of the form $X_{i1}^r X_{i2}^s$, where r and s are chosen by the investigator to best capture the type of interaction expected.

Logistic regression is used when the response variables are binary but the explanatory variables are not. This would be the case if one were measuring whether a steel wire breaks under a 50-kg load, where the explanatory variables might be the cross-sectional radius and the percentage of chromium. One may then use the model

$$P[Y_i = 1] = \frac{\exp(\boldsymbol{X}_i^{\mathrm{T}}\boldsymbol{\theta})}{1 + \exp(\boldsymbol{X}_i^{\mathrm{T}}\boldsymbol{\theta})}, \qquad (19)$$

where $Y_i = 1$ if the ith wire snaps, and $\boldsymbol{X}_i$ is the vector of explanatory variables for the ith wire. To justify linear regression methods, one uses the transformation

$$p_i = \ln \frac{P[Y_i = 1]}{1 - P[Y_i = 1]}$$

to obtain the linear model $p_i = \boldsymbol{X}_i^{\mathrm{T}}\boldsymbol{\theta}$. When fitting this model, it is convenient if there are multiple measurements on each combination of values for the explanatory variables; then one can use the transformed observed proportions of ones as the observations in (1). Otherwise, one can use transformed local averages of the Y_i values. Either approach gives a linear model, where the error variance depends upon $\boldsymbol{X}_i$. One way to estimate $\boldsymbol{\theta}$ in the logistic regression case is via weighted least squares. When the components of $\boldsymbol{X}$ are categorical, an alternative is provided by the maximum likelihood methods described in Section V.

The use of dummy variables greatly extends the scope of linear regression. Here one can model the effect of categorical explanatory variables in combination with continuous explanatory variables. For example, suppose one measures the temperature of heating elements from two different suppliers as a function of the electrical power supplied. The continuous explanatory variable is the power and the categorical variable is the supplier. If one defines the variable X_{1i} to be 1 if the ith element is from the first supplier and otherwise set this to 0, then one can use the linear regression form of the model in (1) to automatically fit the supplier effect. Judgment is needed in deciding to fit interaction terms with dummy variables and in handling situations with more than two categories per variable.

G. Generalized Additive Models

Recent research in computer-intensive statistics has developed methods for additive modeling that extend the linear regression model. These generalized additive models enable the practitioner to fit a flexible family of nonlinear functions. The simplest generalized additive model has the form

$$Y_i = \theta_0 + \sum_{j=1}^{p} f_j(X_{ij}) + \epsilon_i, \qquad (20)$$

where the ϵ_i are taken to be independent with constant variance and mean zero, and θ_0 and the functions f_j are unknown. Since the f_j are estimated from the data, one can avoid the traditional assumption of local linearity which is often needed to justify the model in (1) for practical applications.

If one wanted to fit arbitrary functions in p-dimensional spaces, one would require enormous numbers of observations for even very moderate values of p. This reflects the "curse of dimensionality," which implies that the local density, and hence local information, of a fixed number of uniformly spaced points in a δ-neighborhood in $\mathbb{R}^p$ goes to zero exponentially fast as p increases. Conventional linear model theory avoids this problem by considering only classes of multivariate functions on $\mathbb{R}^p$ that are linear in all variables; hence, one need estimate only

$p+1$ coefficients. Generalized additive models are more broadly applicable and contain linear models as a special subfamily. They require substantially more data than linear regression since they estimate p different functions rather than $p+1$ coefficients; nonetheless, the requisite data increase only linearly in p.

The backfitting algorithm is the key procedure used to fit generalized additive models; operationally, the algorithm proceeds as follows:

1. At the initialization step, define functions $f_j^{(0)} \equiv 1$; also, set $\theta_0 = \bar{Y}$.
2. At the ith iteration, estimate $f_j^{(i+1)}$ by
$$f_j^{(i+1)} = \mathrm{Sm}\left(\boldsymbol{Y} - \theta_0 - \sum_{k \neq j} f_k^i \mid X_{1j}, \ldots, X_{nj}\right)$$
for $j = 1, \ldots, p$.
3. Check whether $f_j^{(i+1)} = f_j^{(i)}$ for all $j = 1, \ldots, p$. If not, return to step 2; otherwise, use the $f_j^{(i)}$ as the additive functions f_j in the model.

This algorithm requires a smoothing operation, indicated by $\mathrm{Sm}(\cdot \mid \cdot)$. For large classes of sensible smoothing functions, one can prove that the backfitting algorithm converges to a unique solution.

Conceptually, the smoothing operation takes a scatterplot of the response variable Y against the jth component of the explanatory variables and returns a somewhat smoother continuous function that runs through the center of the data. As an example of a smoother, consider the local averaging function; this has the form
$$f_j(x) = \mathrm{Sm}(Y_i \mid X_{1j}, \ldots, X_{nj}) = \sum_{i=1}^{n} K(x, X_{ij}) Y_i,$$
where $K(x, x^*)$, the kernel function, is typically maximized at $x = x^*$, decreases monotonically to zero as $|x - x^*|$ increases, and satisfies
$$\int_{-\infty}^{\infty} K(x, x^*)\, dx = 1.$$
Many more-complex smoothers are available; some of the most popular are based upon cubic smoothing splines. The optimal smoother depends upon the problem in hand, but inference is usually insensitive to the particular smoother employed.

These simple generalized additive models capture nonlinearities in the directions of the coordinate axes, but cannot describe local behavior in other directions. At need, one can build in dummy variables that are products of some of the explanatory variables or even modify the backfitting algorithm to fit bivariate functions, but this rapidly becomes data-intensive and the curse of dimensionality inevitably arises. Hastie and Tibshirani (1990) survey recent work in this area.

H. Projection Pursuit Regression, MARS, and ACE

The simple generalized additive models consider sums of functions taking arguments in the natural coordinates of the space of explanatory variables. In some circumstances (such as extreme multicollinearity), it may be more sensible to use projection pursuit regression (Friedman and Stuetzle, 1981). This procedure employs the backfitting algorithm to fit a model of the form
$$Y_i = \sum_{k=1}^{r} f_k\left(\boldsymbol{\alpha}_k^{\mathrm{T}} \boldsymbol{X}_i\right) + \epsilon_i,$$
where the ϵ_i are independent with mean zero and variance σ^2, and the $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_r$ determine a set of r linear combinations of the explanatory variables. These linear combinations are similar in spirit to those used in principal components analysis (see Section IV). A salient difference is that these vectors need not be orthogonal, but in principle these are chosen to maximize the predictive accuracy of the model as assessed through cross-validation (see Section I).

Projection pursuit regression is very difficult to implement, and hard to interpret when $r > 1$. Unlike the simple generalized additive models, it is invariant to affine transformations of the data; this is an appealing property for many practical situations in which the measurements have no natural coordinate basis. In some applications one may want to include a *very* small number number of interaction terms between the explanatory variables; this can be accommodated by defining dummy variables that are products of other explanatory variables.

Friedman (1991) describes an enormous extension of the generalized additive model that depends upon multivariate adaptive regression splines (MARS). This procedure fits a model that is the weighted sum of multivariate spline basis functions, also known as tensor-spline basis functions, and takes the form
$$Y_i = \sum_{k=0}^{q} a_k B_k(X_1, \ldots, X_n) + \epsilon_i,$$
where the ϵ_i terms are, as usual, independent with mean zero and variance σ^2, and the coefficients a_k are determined in the course of cross-validation fitting. The constant term follows by setting $B_0(X_1, \ldots, X_n) \equiv 1$, and the other multivariate splines are products of univariate spline basis functions:
$$B_k(x_1, \ldots, x_n) = \prod_{s=1}^{r_k} b\left(x_{i(s,k)} \mid t_{s,k}\right), \qquad 1 \leq k \leq r.$$

Here the subscript $1 \le i(s,k) \le p$ indicates a particular explanatory variable, and the basis spline in that variable has a knot at $t_{s,k}$. The values of q, the $r_1, \ldots, r_q$, the knot sets, and the appropriate explanatory variables for inclusion are all determined adaptively from the data.

This procedure is closely related to the regression trees described by Breiman *et al.* (1984), and is a natural generalization of the recursive partitioning strategy described in Section VI. MARS admits an ANOVA-like decomposition that can be represented in a table and similarly interpreted (see Section III). Although no procedure can overcome the curse of dimensionality, MARS is designed to perform well whenever the true function has low local dimensionality. The procedure automatically accommodates interactions between variables and variable selection. Although it is very new and very computer-intensive, the methodology offers the only current approach for nonlinear multivariate modeling that begins to respond to the generality of problems encountered in practice.

A third extension of the generalized additive model permits functional transformation of the response variable as well as the explanatory variables. This depends on the ACE algorithm developed by Breiman and Friedman (1985), and it fits the model

$$g(Y_i) = \theta_0 + \sum_{j=1}^{p} f_j(X_{ij}) + \epsilon_i,$$

where all conditions are as given for (20), except now the function g is also unspecified, satisfying only the technically necessary condition that $\mathrm{var}[g(Y)] = 1$.

ACE is an acronym for alternating conditional expectations, which is the mechanism for determining the fitted functions. Given variables Y_i and $\boldsymbol{X}_i$, one wants g and $f_1, \ldots, f_p$ such that $\mathrm{E}[g(Y_i) \mid \boldsymbol{X}_i] - \sum_{j=1}^{p} f_j(X_{ij})$ resembles independent error (without loss of generality, we can ignore the constant term θ_0). Heuristically, this is accomplished by finding

$$(g, f_1, \ldots, f_p) = \operatorname{argmin}\left\{\sum_{i=1}^{n}\left[g(Y_i) - \sum_{j=1}^{p} f_j(X_{ij})\right]^2\right\},$$

where g satisfies the unit variance constraint. Operationally, one solves as this minimization problem as follows:

1. Estimate g by $g^{(0)}$, obtained by "smoothing" the Y_i values and standardizing the variance. Set $f_j^{(0)} \equiv 1$ for all $j = 1, \ldots, p$.
2. Conditional on $g^{(k-1)}(Y_i)$, apply the backfitting algorithm until convergence to find estimates $f_1^{(k)}, \ldots, f_p^{(k)}$.
3. Conditional on the sum of $f_1^{(k)}, \ldots, f_p^{(k)}$, obtain $g^{(k)}$ by applying the backfitting algorithm until convergence (this interchanges the role of the explanatory and response variables). Standardize the new function to have unit variance.
4. Test whether $e^{(k)} - e^{(k-1)} = 0$, where

$$e^{(k)} = n^{-1}\sum_{i=1}^{n}\left[g^{(k)}(Y_i) - \sum_{j=1}^{p} f_j^{(k)}(X_{ij})\right]^2.$$

If it is zero, set $g = g^{(k)}$, $f_j = f_j^{(k)}$; otherwise go to step 2.

Although it may not obvious from this representation, steps 2 and 3 calculate smoothed expectations, each conditional upon functions of either the response or the explanatory variables; this alternation gives the method its name.

The ACE analysis finds sets of functions for which the linear correlation of the transformed response variable and the sum of the transformed explanatory variables is maximized. From this perspective, ACE methodology is close kin to correlation analysis, especially the calculation of the multiple correlation coefficient. ACE does not aim directly at regression applications and has some undesirable features; for example, it treats the response and explanatory variables entirely symmetrically and it does not reproduce model transformations. Tibshirani (1988) invented a variation of ACE called AVAS, which takes automatic account of variance stabilization issues. AVAS avoids many of the deficiencies of ACE in pure regression applications, but its theoretical properties have not yet been established.

References

Multiple regression has an enormous literature. Weisberg (1980) and Rawlings *et al.* (1998) cover basic applications of univariate linear regression, and Bates and Watts (1988) treat nonlinear regression. Hawkins (1980) examines strategies for outlier detection, and Madansky (1988) gives recipes for various departures from classical univariate linear regression. Tong (1990) summarizes results that enable the calculation of various distributions for the test statistics for correlational analyses.

IV. EXPERIMENTAL DESIGN

Experimental design is a methodology for assessing the effects of different treatments or manipulations when applied in combination. As an example, suppose one wants to compare the average effects of a different filaments and b different filling gases on the lifetime of incandescent light bulbs. Both gas and filament occur together within a light bulb; besides the direct effect of each on longevity, it may be that there are interactions between particular gases

and filaments that are of research interest. Often the primary concerns are to (i) determine whether there are differences in the means corresponding to different treatment combinations and (ii) distinguish treatments whose effects upon the mean are purely additive from those whose effects depend upon interactions with other treatments applied in combination. Additional analyses may be used to determine which treatment combination yields the largest average response, or to make estimates about the relative magnitudes of various effects.

There is no unique specification of the linear statistical model that goes with a designed experiment such as the one just described. For this example, a customary parametrization is

$$Y_{ijk} = \mu + \alpha_i + \beta_j + (\alpha\beta)_{ij} + \epsilon_{ijk},$$

where $i = 1, 2, \ldots, a$; $j = 1, 2, \ldots, b$; and $k = 1, 2, \ldots, n_{ij}$. Here Y_{ijk} is the observed lifetime of the kth light bulb receiving filament i and filling gas j, μ is the average lifespan of the population of all light bulbs, α_i is the change in lifespan caused by using filament i, β_j is the change in lifespan caused by using gas j, $(\alpha\beta)_{ij}$ is the change caused by the interaction between the ith filament and the jth gas, and the ϵ_{ijk} are independent normal errors with mean zero and variance σ^2. The α_i and β_j are called main effects due to filament and filling gas, respectively; the $(\alpha\beta)_{ij}$ terms are the interactions between level i of the filament factor and level j of the filling gas factor. In terms of the linear model $\boldsymbol{Y} = \boldsymbol{X}\boldsymbol{\theta} + \boldsymbol{\epsilon}$, one has

$$\boldsymbol{\theta}^{\mathrm{T}} = (\mu, \alpha_1, \ldots, \alpha_a, \beta_1, \ldots, \beta_b, (\alpha\beta)_{11}, \ldots, (\alpha\beta)_{ab})$$

and the design matrix $\boldsymbol{X}$ consists of ones and zeros, determined by the particular levels (filament type and gas type) of the treatments applied to each of the light bulbs.

Notice that, unlike in the case of regression, the $\boldsymbol{X}$ matrix in the linear model for experimental design is not full rank. For example, the first column of $\boldsymbol{X}$ consists entirely of ones because all observations are modeled with the overall mean μ; similarly, the vector sum of the second through $(a+1)$th columns equals the first column since exactly one of $\alpha_1, \ldots, \alpha_a$ is applied to each observation. Since a $p \times p$ matrix has rank $p - k$, where k is the number of linear dependences among the columns, one can verify that this design matrix has rank $(1 + a + b + ab) - 3$. There is one linear dependence for each of the three sets of treatment parameters: the set of additive filament-type effects, indicated by α, the set of additive gas-type effects, indicated by β, and the interactions between the two sets, indicated by $(\alpha\beta)$.

This feature of experimental design models is called overparametrization, and is an inescapable property of the application. It implies that $\boldsymbol{X}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{X}$ in (5) has no unique inverse, and thus certain functions of $\boldsymbol{\theta}$, such as α_1, cannot be estimated. However, in good designs, the $\boldsymbol{X}$ matrix possesses planned structure that enables the investigator to estimate the specific functions of major research interest; these functions are linear contrasts in the treatment effects, such as $\alpha_1 - \alpha_2$. (A linear contrast in $\boldsymbol{\theta}$ is any function of the form $\sum c_i\theta_i$ for which $\sum c_i = 0$.) Additionally, observations in a good design are allocated among the different treatment combinations so as to maximize the precision in estimating contrasts of research interest.

In classical experimental design, there is often a tight constraint on the number of observations that can be taken. This motivates the development of carefully planned experiments that maximize the information gleaned from each observation. Often the aim of a design is simply to determine which factors and interactions affect the responses, so that a second experiment can be focused more efficiently upon model building.

A. Univariate Response

The analysis of variance (ANOVA) table partitions the total sample variability in an experimental design into components attributable to specific independent variables and interactions between independent variables. Under the null hypothesis that a given variable (or interaction) does not affect values of the dependent variable, one can show that the ratios of certain quantities in the ANOVA table must follow a particular F-distribution. Also, under the alternative hypothesis that there is an effect on the response variable, then the ratio follows a distribution that tends to be larger than the F-distribution. This enables the use of standard hypothesis testing and interval estimation methodology.

The standard sequence of hypothesis tests in the ANOVA model is hierarchical; one tests first for interaction effects and then for main effects. This is done because sometimes an interaction effect can "mask" a main effect, making the test for main effects spuriously insignificant. By testing the most complex interactions first, one protects the inference from errors caused by masking. Also, the interpretation of interaction effects in the absence of main effects is problematic.

In the context of the example, one first looks for the presence of nonzero interactions $\{(\alpha\beta)_{ij}\}$. If the F-test for H_0: $(\alpha\beta)_{1j} = 0$ for $i = 1, \ldots, a$, $j = 1, \ldots, b$, detects nonzero interaction effects, then both factors play a role and do so synergistically. This interaction effect means that some filling gases work better in combination with certain filaments than one would expect from their separate overall performances. If one concludes that interactions are not present, then one proceeds to test for the presence of main effects. For example, if all the α_i are zero, then the mean bulb lifespan is not affected by the

type of filament used. If some α_i are nonzero, then some filaments types are better than others. One can go beyond hypothesis testing to point and interval estimation; the former enables estimation of a specific contrast, such as the difference in average longevity between two types of filament, and the latter enables one to set a confidence interval for a contrast.

Statisticians have developed a large number of designs, each tailored to very specific applications. The following partial survey lists the major types of designs and describes their special properties.

Factorial design. There are p different factors; the kth factor has d_k levels. One takes n observations at each possible combination of factor levels, for a total of $n\Pi_{k=1}^{p} d_k$ measurements. Provided that $n > 1$, this design enables the researcher to examine all main effects, all two-way interactions between each pair of factors, all three-way interactions between each triplet of factors, and so forth down to the p-way interaction.

Fractional factorials. Factorial designs can require very large sample sizes, especially as the number of factors grows. To reduce required sample sizes, fractional factorial designs use a technique referred to as confounding. Confounding occurs when two main effects or interactions cannot be separated; if either is significant, then both will appear to be significant. Usually, a fractional factorial design attempts to confound high-order interactions with main effects; this conforms to the empirical wisdom that complex interactions are much less likely to occur than main effects. Thus the fractional designs give up the capability of estimating all possible interactions in order to gain a savings in experimental effort. A class of highly fractionated designs based upon a technique known as orthogonal arrays has become known as Taguchi designs, and these are useful when one is assessing a very large number of factors.

Block designs. Sometimes much of the observed variation is attributable to factors that are not of primary interest and are unlikely to interact with other independent variables. For example, some of the variation in time to first repair of an automobile may be explained by the day of the week on which it was manufactured. In such circumstances one can control for the day-to-day variation (referred to as the block effects) by ensuring that each of the levels of the other variables of interest occurs equally often on each manufacturing day (i.e., equally often within each block); this gives a randomized complete block design (RCBD). Blocking increases the ability of the ANOVA tests to detect and estimate with precision the effects of interest. Various refinements of this strategy are needed when one cannot expect to observe all combinations of all factor levels in a single block; these are referred to as balanced incomplete block designs (BIBs) and partially balanced incomplete block designs (PBIBs).

Analysis of covariance. This is a hybrid between experimental design and regression analysis. For example, suppose one compares the tensile strength of a steel alloy wire under two different pickling methods and two different die types, and there is covariate information on the percentage of chromium in each wire sample. In this case the analysis of covariance (ANACOVA) model is

$$Y_{ijk} = \mu + \alpha_i + \beta_j + (\alpha\beta)_{ij} + \theta Z_{ijk} + \epsilon_{ijk},$$

where Y_{ijk} is the observed tensile strength, α_i, β_j, and $(\alpha\beta)_{ij}$ represent the main effects and interaction of the pickling and die factors, and θ is a regression coefficient that measures the influence of chromium percentage Z_{ijk}. This enables one to assess the factor effects as well as the regression between the percentage of chromium and wire strength.

Nested designs. In factorial experiments, we say that the factors are crossed, meaning that each level of each factor occurs with each level of each of the other factors. This structure is not always possible. For example, one may want to compare color fastness in cloth swatches at two different plants, across the three different workshifts, using two measurements per bolt. In this case the factors are said to be nested, i.e., the observations are nested within level of bolt which is nested within level of shift which is nested within plant. It is impractical to move the workers on each shift to both locations and it is impossible to have the same bolt of cloth manufactured on two different shifts. Similarly, taking multiple measurements per bolt (referred to as subsampling) nests the observations within the bolt.

Split-plot designs. These designs are closely related to nested designs, in that certain factors of experimental interest cannot be crossed. Under traditional assumptions, this leads to two error terms, used for testing two different sets of effects. An example of a split-plot design is given in the following discussion of the analysis of variance table in the following subsection.

All of the designs listed above admit fixed, random, and mixtures of fixed and random effects models. Fixed-effects models correspond to the situation in which the levels of all factors are prespecified as part of the design. Random-effect models occur when the levels of all factors are random outcomes, and mixed models occur when some factors have fixed levels and other factors have random

levels. As an example of this distinction, suppose one has a factorial experiment that examines the nonconformance of manufactured yardsticks to target values as a function of the production machine and the operator. If the experimenter uses all production machines in the plant and chooses a set of operators at random to produce sample yardsticks on each of the machines, then the machine effect is fixed and the operator effect is random, so that one has a mixed factorial model. These different models affect the definition of θ in the linear model and the expected values of the terms in the ANOVA table.

B. Analysis of Variance Tables

The following example illustrates several of the key ideas of experimental design, including the generation and interpretation of an analysis of variance table corresponding to a reasonably representative model. It involves the analysis of data collected to assess radon concentrations in the basement and ground floors of 12 (nearly) randomly chosen Pittsburgh homes. The investigator was interested in determining the relationship between radon level of the basement and the ground floor level; the investigator also wanted to assess the effect of finished versus unfinished basements.

There were 12 homes, 6 with unfinished basements and 6 with finished basements. Levels of radon concentration were assessed for each floor of each house in three different locations, which may be viewed as subsampling. Since the finished versus unfinished effect can only be applied to an entire house, it is physically impossible to cross this with the house effect, and thus we have a split-plot design. The whole-plot treatment, which is applied to an entire block, is the finished/unfinished basement factor. The split-plot treatment, which can be crossed with the block effect, is the first floor versus basement factor. Note that the house effect is a random effect since the houses represent a random selection from a larger population; in contrast, the floor and finish effects are fixed effects.

The data are as described in Table I. A finished basement is recorded as a 1 and an unfinished basement is a 0; similarly, the basement readings are coded as 0 and the first floor readings are coded with a 1. Houses are numbered from 1 to 12. All readings are in picocuries/liter (pCi/liter).

A plot of the data within each home/floor level showed that the distribution of the readings is skewed to the right. This result, coupled with the fact that the readings depend upon counts of atomic events, suggested that a logarithmic transformation might make the data more normally distributed and within-group variances more nearly equal. This turned out to be the case, and so the following analysis uses the natural logarithms of the data in Table I, rather than the actual measurements.

TABLE I Radon Levels in 12 Pittsburgh Houses

House	Floor	Finish	Responses (pCi/liter)		
1	0	0	1.78	1.66	2.00
	1	0	0.65	0.57	0.66
2	0	1	10.91	11.46	10.49
	1	1	4.30	4.30	4.42
3	0	1	2.56	2.34	2.43
	1	1	1.62	1.72	1.49
4	0	1	5.33	5.31	5.00
	1	1	1.97	2.07	2.07
5	0	0	0.98	1.25	0.96
	1	0	.082	0.71	0.67
6	0	0	1.06	1.06	0.99
	1	0	0.58	0.83	0.87
7	0	1	1.70	1.53	1.77
	1	1	1.36	1.24	2.07
8	0	1	2.07	1.81	2.32
	1	1	0.65	0.78	0.89
9	0	0	2.03	1.86	2.35
	1	0	0.34	0.31	0.66
10	0	0	2.23	3.16	2.79
	1	0	0.29	0.48	0.57
11	0	0	1.75	1.29	1.44
	1	0	1.07	0.93	0.98
12	0	1	2.62	1.91	2.01
	1	1	1.90	1.33	2.26

Using standard statistical software in SAS, one obtains the ANOVA table shown in Table II. The first column indicates the components into which the variation in the sample is partitioned. The second column shows the degrees of freedom for each component, or, heuristically, the amount of sample information used in fitting each of the experimental factor effects of interest. The third column shows the sum of squares corresponding to each component of the partition; these are obtained as the solution of matrix expressions involving both the data and the design

TABLE II ANOVA Table for Radon Data

	Degrees of freedom	Sum of squares	Mean square	*F*-ratio
Finish	1	13.37	13.37	11.38
House(finish)	10	11.74	1.17	11.25
Floor	1	10.49	10.49	100.50
Floor × finish	1	0.53	0.53	5.08
Error	58	6.05	0.10	
Total	71	42.18		

matrix $\boldsymbol{X}$. The fourth column shows the mean squares, which are the sums of squares terms divided by the degrees of freedom within the same row. The fifth column shows the F-statistic for evaluating the significance of the effect of a particular component of the partition; this is the ratio of two terms in the mean square column. In order to determine which two mean square terms one should use in forming the F-statistic, one finds the two which have the same expectation under the null hypothesis of no component effect; the term that goes in the numerator is the term whose expectation increases under the alternative hypothesis. Much of the theory in experimental design is aimed at ensuring the existence of mean-squared terms with expectations appropriate for the formation of such test statistics.

Before reading this ANOVA table, notice that the source column identifies five components of the variation in the sample. The first four rows [finish, house(finish), floor, and floor $\times$ finish] represent effects that are of experimental interest. The error row enables an estimate of the intrinsic variance σ^2 in the observations that remains after fitting the best possible split-plot model to the data. If the experimental effects are large in comparison with this error variance, then the investigator has evidence that the effects are not simply due to random chance, but represent important features of the data. The sixth row (total) has no interpretative importance, but was originally used as an arithmetical check; modern software ensures accuracy, but it is customary to retain this row. Finally, there is an implicit sixth component of variation in addition to those listed in the first five rows, corresponding to the mean of all observations over all groups; it accounts for one degree of freedom, which is why the degrees of freedom in the last row is one less than the number of observations. Since researchers are rarely interested in hypotheses about the overall mean, it is usual to omit this component in developing the table.

When interpreting an ANOVA table, one first examines the highest order interaction. In this case, the highest order interaction is floor $\times$ finish; it corresponds to the research hypothesis that even after additive effects for floor, house, finish, and house(finish) have been accounted for, there are still significant effects that must be attributed to a synergy between the type of finish within a house's basement and the floor on which readings are taken. The reason for testing high-order interactions first is that a phenomenon called masking can occur. This is a moderately rare circumstance, in which the synergy is such that low-order effects appear insignificant, although high-order terms do not. In such cases one declares that the existence of an interaction between floor and finish effects ensures that floor and finish effects must be present even if the significance probabilities corresponding to the test statistics in the first, third, or both first and third rows are unpersuasive. For our example, the F-statistic for testing the presence of a floor $\times$ finish interaction is the ratio of the mean squared error term for the floor $\times$ finish row to the error row; this value is 5.08, and it is referred to an F-distribution with 1 and 58 degrees of freedom, using the degrees of freedom column for the corresponding rows. One finds that the significance probability is .028, which corresponds to rejecting the hypothesis of no interaction at the $\alpha = .05$ level, but not at the $\alpha = .01$ level.

Testing the floor effect is straightforward, but probably unnecessary since the interaction effect is so strong that one would attribute an insignificant result to masking and declare the floor effect to be automatically significant. Nonetheless, to illustrate the method, assume that the previous test had not been highly significant. Then one would form the F-statistic as the ratio of the mean squared term in the floor column to the mean-squared term in the error column and compare this to values from an F-distribution with 1 and 58 degrees of freedom. The test statistic is 100.5, which is highly significant; one rejects the null hypothesis that there is no floor effect at α levels less than .0001.

The house(finish) effect tests whether there are significant differences between the houses chosen in the sample. The parenthetical inclusion of finish indicates that the house effect is nested within finish; i.e., a single house can only have one kind of basement finish. Since the house effect is random, it might happen that one must take the denominator in the test statistic from some other row than the error row; however, this model is just sufficiently simple that such additional complication does not arise. So, proceeding as before, one finds the F-statistic to be 11.74, which is compared to values from an F-distribution with 10 and 58 degrees of freedom. The test rejects the hypothesis that all houses are equivalent at a level less than .0001.

An unusual feature of split-plot designs is that there are two error terms. Besides the term already discussed, one uses the house(finish) mean squared term as the denominator of the test statistic for evaluating the finish effect; thus it functions as an error term in assessing the finish effect. The justification for this depends upon the calculation of the expected mean squared terms, which shows that under the null hypothesis of no finish effect, the expected mean squared term for finish equals the expected term for house(finish). In this example, the early rejection of the hypothesis of no floor $\times$ finish effect precludes the need for further examination. However, for completeness, we note that the value of the test statistic is 11.38, which is compared to values from an F-distribution with 1 and 10 degrees of freedom. The hypothesis of no finish effect is rejected; the significance probability is .0071.

C. Simultaneous Inference

Simultaneous inference occurs when the practitioner must make judgments about more than one parameter value. A common situation is the derivation of a multivariate confidence region, as described in Section I. Using the duality between confidence regions and hypothesis tests, the confidence region is equivalent to a set of hypothesis tests about all possible linear combinations in the components of the parameter vector $\boldsymbol{\theta}$. These applications are intrinsic to multivariate analysis, and some of the methods described here apply to regression and other areas. The problem is particularly important in experimental design, where it has provoked a large literature on multiple comparisons. The driving motivation in experimental design is that one is not concerned with all possible linear combinations, but wants to maximize the power of tests that focus on a small set of linear combinations having primary research interest.

To illustrate the issue, suppose one makes k hypothesis tests about k different parameters and that each test has Type I error probability α. Then, if the null hypothesis is true for each, the probability of one or more Type I errors among the entire set of comparisons (the experimentwise Type I error rate) is $1-(1-\alpha)^k$; this goes to 1 exponentially in k. From the simultaneous inference standpoint, one is not making k decisions, but rather 2^k decisions, corresponding to each set of possible inferences about all k parameters.

As the simplest example in experimental design, suppose one has performed a one-way ANOVA comparing t different groups. If one rejects the null hypothesis that all groups have equal means, one must usually proceed to order the group means, or at least determine which group has the largest mean. In the former case, one must make $t(t-1)/2$ hypothesis tests, each having the form H_0: $\mu_i \le \mu_j$, and in the latter case, one must make $t-1$ tests, pairing the groups as if in a knockout tournament. This discussion focuses on the first case, but the ideas generalize to other applications.

The most direct attack on the multiple comparison problem depends upon the Bonferroni inequality. It asserts that

$$P\left[\bigcap_{i=1}^{k} E_i\right] \ge 1 - \sum_{i=1}^{k} P\left[E_i^c\right],$$

where E_i denotes any event and E_i^c is the complement of that event. Setting E_i to be the event that no Type I error occurs on the ith comparison, then this suggests taking the comparisonwise error rate to be $\alpha^* = \alpha/k$, where α is the desired experimentwise error rate. Unfortunately, this method becomes impractically conservative as k increases.

A second method is Fisher's Least Significant Difference (LSD) test. One begins by performing a standard ANOVA test; if this fails to reject the null hypothesis of no differences among the means, one stops. Otherwise, one does simple two-sample t-tests on all possible pairs of group means, declaring significant differences whenever these reject the null. The initial ANOVA test ensures that the overall experimentwise Type I error rate is α.

The third main approach is Tukey's Honestly Significant Difference (HSD) test, and this also applies specifically to experimental designs. Using the standard assumptions of independent sampling, normal distribution with unknown common variance σ^2, and equal sample sizes, Tukey worked out the distribution of the maximum studentized difference in sample means when, in fact, all population means are equal. Thus one performs $t(t-1)/2$ tests, declaring two groups to be significantly different when $\bar{Y}_{(j)} - \bar{Y}_{(i)} > q_{t,t(n-1),\alpha}$, where $q_{t,t(n-1),\alpha}$ is the upper $1-\alpha$ percentile point of the studentized range distribution with parameters t and $t(n-1)$. Tukey's HSD tends to be slightly more powerful than Fisher's LSD, although both maintain the same experimentwise error rate. Tukey's original work was unpublished; Miller (1981) gives a detailed account of the technique.

The fourth method is called F projection, and was developed by Scheffé (1953). It exploits the duality between confidence regions and hypothesis tests, as discussed in Section I, and its generality enables applications in many statistical contexts. From (8), we know that a simultaneous confidence region on the parameter θ is an ellipsoid in $\mathbb{R}^p$, where θ pertains to any linear model. Let $\mathcal{C}$ be a fixed q-dimensional subspace of $\mathbb{R}^p$, and let $\boldsymbol{c}^{\mathrm{T}}\boldsymbol{\theta}$ be a linear combination or contrast in the components of $\boldsymbol{\theta}$ obtained from $\boldsymbol{c} \in \mathcal{C}$. Then it can be shown that

$$P\left[\ \forall \boldsymbol{c} \in \mathcal{C},\ \boldsymbol{c}^{\mathrm{T}}\boldsymbol{\theta} \in \boldsymbol{c}^{\mathrm{T}}\hat{\boldsymbol{\theta}} \pm s\sqrt{q F_{q,n-p,\alpha}}\,\boldsymbol{c}^{\mathrm{T}}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X})^{-1}\boldsymbol{c}\right] = 1-\alpha, \tag{21}$$

where $F_{q,n-p,\alpha}$ is the usual critical point from an F-distribution with q and $n-p$ degrees of freedom. Thus, (21) defines a confidence region; by the duality between confidence regions and hypothesis tests, points within the region having components equal to zero imply that certain linear combinations correspond to null hypotheses which cannot be rejected. Since the probability content of the entire region is $1-\alpha$, then the experimentwise error rate for all tests derived from vectors in $\mathcal{C}$ is α. Appropriate choice of $\mathcal{C}$ enables one to make simultaneous test of unequal group means, nonzero regression coefficients, or many other standard applications. (The method is called F projection since the simultaneous confidence region for a particular linear combination $\boldsymbol{c}$ is the projection of the joint confidence region determined by the

F value onto the one-dimensional subspace determined by $\boldsymbol{c}$.)

Many other methods of simultaneous inference have been proposed, but these are the ones that remain most popular. No one method dominates the others in all applications. Miller (1981) gives the authoritative review of this area and provides methods for many nonstandard situations.

D. Response Surfaces and Evolutionary Operation

Response surface methodology is closely related to univariate experimental design and has broad application to industrial statistics. In this framework one has the model $Y_i = f(\boldsymbol{x}_i) + \epsilon_i$, where $f(\cdot)$ is an unknown function and the ϵ_i are independent errors having common normal distribution with 0 mean, and one wants to find the vector value $\boldsymbol{x}$ that maximizes (or minimizes) the average value of the response variable Y. The goal is to discover the maximizing vector as efficiently as possible, where efficiency implies minimizing the number of observations taken. There are many strategies for accomplishing this search; response surface designs usually use Taylor's theorem to justify a locally linear approximation to the unknown function $f(\cdot)$ and then draw observations and fit linear regression models to enable inference on the direction of steepest ascent. When the vicinity of the maximum has been reached, the linearized model is enlarged to include quadratic and cross-product terms, enabling estimation of the optimal location. Standard response surface designs include the central composite, Box–Behnken, and Plackett–Burman designs. Khuri and Cornell (1987) survey the variety of techniques used to tailor the principles of response surface analysis to particular applications.

Response surface ideas are linked to evolutionary operation (EVOP), but in the latter the dimension of the $\boldsymbol{x}$ space is usually larger and the goal is continually to learn incrementally more about optimal management of the process. The location of the maximum is allowed to change over time, so there is a sense in which these methods are structured to chase a moving target. The most common EVOP protocol is based upon a "flipped simplex" design; essentially, one always guides the process in the opposite direction (in $\boldsymbol{x}$ space) from the worst of the recent process response measurements. Box and Draper (1969) provide a pioneering discussion of EVOP strategies, based upon the principles of experimental design.

E. Multivariate Response

Experimental design methods generalize to applications in which p response variables are measured on each of n experimental objects. These are referred to as multivariate analysis of variance (MANOVA) designs, and build directly on ANOVA procedures. The extended multivariate linear response model is

$$\boldsymbol{Y} = \boldsymbol{\theta X} + \boldsymbol{\epsilon},$$

where $\boldsymbol{Y}$ is a $n \times p$ matrix whose ith row represents a vector of observations on the ith experimental unit, $\boldsymbol{\theta}$ is a $q \times p$ matrix of model parameters, and $\boldsymbol{\epsilon}$ is an $n \times p$ error matrix, usually with mean $\mathbf{0}$ and correlated rows. When the values of $\boldsymbol{X}$ are 0's and 1's arranged so that the matrix is not of full rank but has planned structure that enables estimation of pertinent linear contrasts, then the model is usually referred to as a MANOVA model.

Parameters in the MANOVA model can pertain to between-unit effects, within-unit effects, or both simultaneously. Between-unit effects correspond to the univariate models described before; inferences are based upon comparisons among the sets of units that receive the same treatment levels. Within-unit effects refer to the interplay between the different responses of each unit; for example, if one measures the change in paint reflectivity, hardness, and color on panels exposed for 6 months to two different temperature levels and two different salinity levels, then one might test whether the factorial treatment structure affects the three dependent variables. The triplets of measurements upon each panel are not independent, however, and MANOVA is designed to account for this feature. In our example, a between-unit test might examine whether the temperature effect is significant, a within-unit test might examine whether color change is greater than reflectivity change, and a between- and within-unit test might examine the effect of temperature upon the difference between changes in color and reflectivity.

The general MANOVA hypothesis test takes the form

$$\mathrm{H}_0: \quad \boldsymbol{A\theta B} = \mathbf{0} \qquad \text{versus} \qquad \mathrm{H}_a: \quad \boldsymbol{A\theta B} \neq \mathbf{0}, \quad (22)$$

where the matrix $\boldsymbol{A}$ determines the contrasts used to assess between-unit effects and the matrix $\boldsymbol{B}$ defines the contrasts for the within-unit effects. Many test statistics are available; for most applications, the choice among them is somewhat arbitrary. All customary test statistics are some function of the eigenvalues $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_p)$ of $\boldsymbol{HE}^{-1}$, where

$$\begin{aligned} \boldsymbol{H} &= \boldsymbol{B}^{\mathrm{T}}\boldsymbol{Y}^{\mathrm{T}}\boldsymbol{X}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X})^{-1}\boldsymbol{A}^{\mathrm{T}}[\boldsymbol{A}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X})^{-1}\boldsymbol{A}^{\mathrm{T}}]^{-1} \\ &\quad \times \boldsymbol{A}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X})^{-1}\boldsymbol{X}^{\mathrm{T}}\boldsymbol{YB} \qquad (23) \\ \boldsymbol{E} &= \boldsymbol{B}^{\mathrm{T}}\boldsymbol{Y}^{\mathrm{T}}[\boldsymbol{I} - \boldsymbol{X}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X})^{-1}\boldsymbol{X}^{\mathrm{T}}]\boldsymbol{YB}. \end{aligned}$$

Since the $\boldsymbol{X}$ matrix is not full rank, the Moore–Penrose generalized matrix inverse is used in (23).

A standard procedure for developing an appropriate test statistic is based upon Roy's union–intersection

principle, which relates the multivariate test statistic to a supremum over a set of univariate test statistics (Roy, 1953). Other testing criteria use test statistics based upon (i) $\Pi_{i=1}^{p}(1+\lambda_j)^{-1}$ (the likelihood ratio approach), (ii) $\sum_{i=1}^{p}\lambda_j$, or the trace of $\boldsymbol{HE}^{-1}$, and (iii) the largest eigenvalue of $\boldsymbol{HE}^{-1}$. For further details and references, see Press (1982).

Repeated-measures analysis is one of the most common applications of MANOVA. Here one has a regular univariate design, except that each experimental object is measured at several time intervals (the time steps are equal for all objects). Typically, one wants to test main effects and interactions among the factors in the univariate design and also examine time effects. One strategy for this is to treat the time variable as a separate factor in the experiment and proceed as if it were a univariate analysis. This ignores the covariance structure implicit in the correlated measurements upon the same object, but, surprisingly, the method is justified in some applications. Huynh and Feldt (1970) describe conditions on the covariance matrix that allow such tests. More generally, the MANOVA formulation of repeated measures honors the multivariate structure, and the implementation directly follows from (22) and (23) after specifying the appropriate matrices.

Profile analysis is a further refinement of repeated measures that focuses on specific questions regarding changes in measurement values over time. Assume that the between-group structure partitions the experimental objects into k groups, each corresponding to a different combination of factor levels. Plot the means of each group at each time against time. Then the three questions that profile analysis considers are:

1. Do all k plots have piecewise parallel line segments?
2. If they are all piecewise parallel, then do the line segments coincide?
3. If all line segments are coincident, then do all have zero slope?

These questions are addressed in the indicated order, since subsequent questions are statistically meaningless unless the previous null hypothesis is not rejected. Obviously, chance variation will ensure that the line segments are never perfectly parallel, coincident, or flat, and our object is to test whether the deviations from these conditions are sufficiently large as to constitute evidence that the conditions are unreasonable.

The first question, concerning piecewise parallelism, involves both within- and between-group effects. For simplicity, we assume that design structure for the between-group effects corresponds to a one-way ANOVA with k groups in a fixed-effects model. Then the appropriate matrices in (22) are

$$\boldsymbol{A}=\begin{bmatrix} 1 & -1 & 0 & \dots & 0 \\ 0 & 1 & -1 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & 1 \end{bmatrix}, \qquad \boldsymbol{B}=\begin{bmatrix} 1 & 0 & \dots & 0 \\ -1 & 1 & \dots & 0 \\ 0 & -1 & \dots & 0 \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & -1 \end{bmatrix}. \tag{24}$$

Here $\boldsymbol{A}$ is $(k-1)\times k$ and $\boldsymbol{B}$ is $p\times(p-1)$. A common test statistic is the largest eigenvalue of the matrix $\boldsymbol{HE}^{-1}$, as defined in (23).

The second question, concerning coincidence of the line segments, corresponds to taking $\boldsymbol{A}$ as in (24) and $\boldsymbol{B}=(1,\dots,1)^{\mathrm{T}}$, containing p ones. If the previous test failed to reject the null hypothesis, then one proceeds as above.

Finally, the third question, concerning the flatness of all profile plots, may be tested by taking $\boldsymbol{B}$ as in (24) and setting $\boldsymbol{A}=(n_1/n,\dots,n_k/n)$, where n_i denotes the number of objects in the ith group. Once again, if the previous two tests both failed to reject their null hypotheses, then it is meaningful to apply the standard procedure from (23) to examine the flatness hypothesis.

References

Fisher (1990) is a reprint of a timeless and readable introduction to many of these topics. Kempthorne (1952) offers a very practical account of univariate statistical designs; Christensen (1996) gives a more modern treatment from the perspective of linear models. Box *et al.* (1978) give a Bayesian tone to topic. Scheffé (1959) treats this subject at a more formal level. Practical multivariate analysis is clearly presented by Morrison (1990) and Press (1982); more theoretical treatments are available in Arnold (1981) and Anderson (1984). Kres (1983) has tables for the various test criteria for multivariate statistical hypotheses. Khuri and Cornell (1987) survey modern response surface methodology; Miller (1981) reviews the literature on simultaneous inference. Speed (1987) describes a grand unification of much of design methodology at an advanced mathematical level.

V. CLUSTER ANALYSIS

There are two major kinds of cluster analysis. Case cluster analysis starts with a set of multivariate observations $\boldsymbol{X}_1,\dots,\boldsymbol{X}_n$ and attempts to identify meaningful subgroups of similar data. Variable cluster analysis starts with

the same data and attempts to discover sets of variables that behave similarly. Less commonly, one encounters a third kind called block clustering, developed by Hartigan (1975); this procedure is available in BMDP and is designed to handle simultaneous case/variable clustering. However, this discussion will treat only the more customary cluster analyses.

To draw the distinction between case and variable clustering, suppose that one observes 500 different geological core samples. For each core sample, the vector $\boldsymbol{X}_i$ measures the percentage of different kinds of minerals found in different strata. Then a case cluster analysis would attempt to find clusters among the core samples; perhaps these would correspond to different regions in which the samples were taken. In contrast, a variable cluster analysis looks for strongly associated variables; if the percentage of pyroxenes in a given stratum shows large absolute correlation with the percentage of amphiboles, then together these form a cluster of variables. Cluster analysis of cases is often used to develop a taxonomy of the observations; cluster analysis of variables is used to identify major sources of variation within the sample or as a data reduction technique.

A. Case Cluster Analysis

The most common method for grouping cases is hierarchical agglomerative clustering. This yields a cluster tree; the top consists of each separate case, and these are joined together to form subclusters until, at the bottom, all cases are pooled in a common macrocluster. Since one clearly does not want (in general) for all cases to be joined in one cluster, one needs a rule for stopping the agglomeration algorithm before complete joining occurs. Also, one needs a rule to determine which two subclusters should be joined at the next stage in the tree building process.

There is no universally accepted stopping rule for the cluster algorithm, although many have been proposed. Milligan and Cooper (1985) report a large-scale simulation study under a range of cluster models. The cubic clustering criterion used in SAS appears to be the only widely available rule, and their study indicates that it works well. In practice, most users inspect the entire tree to find a scientifically interpretable level of case aggregation and report the corresponding clusters as meaningful conclusions.

Similar pluralism exists among subcluster joining rules. If, at a given stage in the tree-growing process, all of the subclusters appear ellipsoidal with common covariance matrix, then one should probably proceed to the next stage by combining the two subclusters whose centroids have smallest Mahalanobis distance, as calculated in (2). However, if the subclusters appear nonconvex, it is usually better to use a nearest neighbor joining rule. Many other rules exist and are available in standard packages; no theoretical consensus provides guidance for most practical situations. Jardine and Sibson (1971) prove that any hierarchical agglomerative method that enjoys certain properties must use a single-linkage rule for joining subclusters, but this is a technical result that seems largely irrelevant in applications.

Besides hierarchical agglomerative clustering, BMDP and S-PLUS enable k-means cluster analysis of cases, using a strategy pioneered by MacQueen (1967). Given a user-specified number k of clusters in the data, this analysis iteratively find k cluster centroids that minimize within-cluster distances and maximize between-cluster distances, where distance may be taken in terms of the Euclidean, Mahalanobis, or some other metric. The method is most appropriate when one has *a priori* knowledge of the number of clusters present in the data, but it can be a useful exploratory tool, especially when the observations arise from a mixture of several populations with distinct multivariate normal distributions.

From a theoretical standpoint, case cluster analysis is viewed as a finite mixture distribution problem. One has k populations, each with multivariate distribution function F_j having density f_j. The population to which a particular observation belongs is unknown; the *a priori* probability that a particular observation arises from the jth population is p_j. In this framework, the density function of an observed random vector $\boldsymbol{X}_i$ is the finite mixture

$$f(\boldsymbol{x}_i) = \sum_{j=1}^{k} p_j f_j(\boldsymbol{x}_i).$$

There are several strategies for finite mixture problems, depending on whether one knows k, the $p_1, \ldots, p_k$, and/or the distributions or family of distributions for $F_1, \ldots, F_k$. In general, these problems are extremely difficult; Titterington *et al.* (1985) indicate the obstacles and current strategies for each of the various situations that can arise.

B. Cluster Analysis of Variables

Cluster analysis of variables carries forward in the same spirit as hierarchical agglomerative clustering, except that the distances between variables are entirely determined by their absolute correlations. For example, suppose that at some stage of the tree-growing process one has formed m sets of variables, some of which may consist of only a single variable; denote these sets by $S_1, \ldots, S_m$. Then the single-linkage rule for joining subclusters combines the two sets S_i and S_j that attain

$$\max_{i \neq j} \max_{\boldsymbol{v} \in S_i, \boldsymbol{w} \in S_j} |\mathrm{corr}(\boldsymbol{v}, \boldsymbol{w})|,$$

which may be seen as a minimum distance rule. Alternatively, to maximize internal correlation among variables within common clusters, one might use the complete-linkage rule, combining subclusters that attain

$$\max_{i \neq j} \min_{\boldsymbol{v} \in S_i, \boldsymbol{w} \in S_j} |\mathrm{corr}(\boldsymbol{v}, \boldsymbol{w})|.$$

These two rules represent the extreme cases; intermediate joining rules also exist. Currently, there is no theoretically based stopping rule for variable clustering.

C. Principal Components Analysis

In many applications the aims of a cluster analysis of variables might also be served by factor analysis or a principal components analysis. These methods look for hidden structure in the data and can often discover meaningful simplifications in complex datasets. Unfortunately, both methods take a narrow view of the types of conclusions and data descriptions wanted in practice, and inferential statements make strong use of the assumption that the data arise from a multivariate normal distribution.

Principal components analysis was invented by Pearson (1901). Hotelling (1933) developed its applications and theoretical foundation. Heuristically, it makes an orthogonal transformation of the axes to an orientation that matches the shape of a p-dimensional plot of the data. This enables principal components analysis to do the following:

1. Find linear combinations of the vector components that have maximum variance, subject to certain orthogonality constraints
2. Reduce the dimensionality of the dataset
3. Transform sets of correlated random variables into uncorrelated ones.

A principal components analysis is most valuable when p, the dimensionality of the observations $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$, is large, and when the sample covariance matrix shows strong correlations. Unlike experimental design and case cluster analysis, which focus on the mean structure of the sample, principal components analysis examines the covariance structure of the data.

In applications, it is usually wise to first standardize the data so that each component has mean 0 and unit variance. The reason for this is that principal components analysis is not scale invariant, and ideally one's inference should not depend upon the units of measurement. To achieve scale invariance one needs the unknown covariance matrix. Since generally one must use the sample covariance matrix as an approximation of the true covariance matrix, the required distribution theory is quite complex.

Assume the data vectors have sample covariance matrix $\boldsymbol{S}$, calculated according to (6). The first task is to find the linear combination

$$Y_1 = \sum_{i=1}^{p} a_1 X_i = \boldsymbol{a}_1^{\mathrm{T}} \boldsymbol{X}_i \qquad \text{for} \qquad \mathbf{a}_1 \in \mathbb{R}^p,$$

which has the largest sample variance. The problem as posed is not well defined; it is necessary to add the constraint that $\boldsymbol{a}_1^{\mathrm{T}} \boldsymbol{a}_1 = 1$, as otherwise the sample variance will generally be infinite. Using Lagrange multipliers, one can show that the sample variance

$$s_{Y_1}^2 = \sum_{i=1}^{p} \sum_{j=1}^{p} a_{i1} a_{j1} S_{ij} = \boldsymbol{a}_1^{\mathrm{T}} \boldsymbol{S} \boldsymbol{a}_1$$

is maximized under the constraint when $\boldsymbol{a}_1$ is the normalized eigenvector of $\boldsymbol{S}$ corresponding to the largest eigenvalue of S. (For simplicity, we shall assume S has distinct, positive eigenvalues.) The corresponding linear combination is called the first principal component of the data. Moreover, the sample variance $s_{Y_1}^2$ equals the largest eigenvalue.

In immediate analogy, one can find the jth principal component of the data as the linear combination

$$Y_j = \boldsymbol{a}_j^{\mathrm{T}} X_j, \qquad \boldsymbol{a}_j \in \mathbb{R}^p$$

that maximizes the sample variance subject to the constraints that

$$\boldsymbol{a}_j^{\mathrm{T}} \boldsymbol{a}_j = 1, \qquad \boldsymbol{a}_j^{\mathrm{T}} \boldsymbol{a}_i = 0, \qquad i = 1, \ldots, j-1.$$

Under our simplifying assumptions, this is given by the eigenvector corresponding to the jth largest eigenvalue of $\boldsymbol{S}$. The sample variance of Y_j is given by the jth largest eigenvalue.

If one extracts the p largest principal components, then one has re-expressed the total variability in the dataset. Each observation can now be equivalently represented as a point in a p-dimensional space whose natural coordinates are given in terms of the p principal eigenvectors. Furthermore, from the construction, it is clear that the re-expressed random variables are now uncorrelated. This avoids difficulties arising from multicollinearity, and may enable better understanding of the data, provided that the linear combinations corresponding to the principal components are interpretable.

It often turns out that the information in a multidimensional dataset is actually captured in only a few dimensions, corresponding to the first q principal eigenvectors. When this occurs, one obtains valuable dimensionality reduction by ignoring the components of the re-expressed data that correspond to the least informative, or least variable, components. Asymptotic theory developed by Anderson (1984) enables statistical determination of

the significance of the variability in each component; this theory relies largely upon the assumption of a multivariate normal distribution. When the variance carried in a component ceases to be significant, one can truncate the re-expressed vectors and analyze a simpler dataset that contains essentially all of the information in the original data.

Principal components analysis has been generalized in several ways. One direction leads to factor analysis; other directions concern principal component inference for several related populations, where the nature of the relationship may take several forms. Also, modern computation has enabled substantial weakening of the distributional assumptions that underlie the inferential theory; these rely largely upon bootstrap methodology (Stauffer *et al.,* 1985) and robust estimation [see Hampel *et al.* (1986) for a survey of robust statistical methods].

D. Factor Analysis

Principal components analysis may not be the best way to extract latent structure from data. It only finds a linear transformation that corresponds to the data plot; in many applications, one wants a method that responds directly to the covariance structure of the data. In particular, one may want to describe only the common covariance of the observations instead of also including error variance and variability unique to a particular component of the measurement vectors. This situation arose, for example, in the measurement of human intelligence, and it prompted Spearman (1904) to develop the factor analytic model. This model enabled an analysis that described how different components of mental capability were associated, rather than clouding the inference with additional variability from other sources.

The factor analysis model assumes that each component of each observation $\boldsymbol{X}_i$ is a linear combination of q common factor values and a single latent value specific to the component. Formally, we write the model as

$$\begin{aligned} X_{i1} &= \lambda_{11} Z_{i1} + \cdots + \lambda_{1q} Z_{iq} + Y_{i1} \\ &\vdots \quad \vdots \\ X_{ip} &= \lambda_{p1} Z_{i1} + \cdots + \lambda_{pq} Z_{iq} + Y_{ip} \end{aligned} \tag{25}$$

where the λ_{jk} terms represent the importance (or the loading) of the kth common factor in determining the jth component value, Z_{ik} is the value of the kth component of the unmeasurable latent vector for the ith observation, and Y_{ij} is the contribution to the jth component of the ith observation that depends only upon the particular component. Research interest is focused on estimating the λ terms and the covariance matrix of the latent Z measurements.

Representing the sample $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n$ as rows in a matrix, we can express (25) as

$$\boldsymbol{X} = \boldsymbol{Z}\boldsymbol{\Lambda} + \boldsymbol{Y},$$

where $\boldsymbol{X}$ and $\boldsymbol{Y}$ are $n \times p$, $\boldsymbol{Z}$ is $n \times q$ and $\boldsymbol{\Lambda}$ is $p \times q$. The rows of $\boldsymbol{Y}$ are assumed to be independent multivariate normal random vectors with mean $\boldsymbol{0}$ and $\text{var}[Y_{ij}] = 1$. This enables the analyst to find maximum likelihood estimates of $\boldsymbol{\Lambda}$, the factor loadings, $\boldsymbol{\Sigma} = \text{var}[\boldsymbol{Y}]$, and $\boldsymbol{Z}$, the matrix containing each object's score on the q common factors. Also, it is usual to report the $p \times q$ factor structure matrix, which shows the estimated correlation between each original variable and each common factor.

Most factor analyses proceed in two stages. The first finds an initial estimate of the common factors; these are usually orthogonal and are often obtained by extracting the first q eigenvectors in a principal components analysis. The second stage rotates these factors to attain $\boldsymbol{L}$ from $\boldsymbol{\Lambda}$, where $\boldsymbol{L}$ is a simplified representation of the original factor loading relationships. Although there is no rule for defining this simple structure, Thurstone (1945) put forward some widely accepted desiderata:

1. Each column in $\boldsymbol{L}$ should contain at least q zeros.
2. Each row in $\boldsymbol{L}$ should contain at least one zero.
3. Any pair of columns should include multiple responses that have zero loadings in one of the columns.
4. If $q > 4$, then every pair of columns should have many zero entries in common rows.
5. If $q > 4$, every pair of columns should have only a few rows that are nonzero in both columns.

Heuristically, the simple structure segregates the responses into nearly mutually exclusive groups, and these groups have loadings that are high on a some factors, intermediate on a very small number of factors, and insignificant on the rest.

From a technical standpoint, the rotation in the second stage may be oblique rather than rigid; this leads to a nonorthogonal set of common factors. Also, the previous development assumed that q was known *a priori*. This is rarely the case, and various strategies exist for determining q from the data. These mostly rest on the idea of estimating the commonalities in the model, which are the proportions of variance in each of the components of the standardized observations that are explained by the posited q common factors. Operationally, the investigator uses the data to estimate the commonalities for a range of values of q. When there is strong factor analytic structure in the data, one typically sees that the estimated commonalities increase steadily in q until the best value of q occurs, and thereafter increasing values of q lead to

negligible improvements in the total proportion of variance explained.

Interpreting factor analytic studies is viewed by many as much more of an art than a science. If sensible understanding emerges from the factor loadings, then it is likely that actual structure has been discovered; however, it is almost always unwise to describe the results in terms of formal significance probabilities. Generally, factor analysis has value as a tool in exploratory data analysis, particularly in helping one to develop a taxonomy of the kinds of underlying factors that influence the observations.

References

Hartigan (1975) is the classic reference in cluster analysis of cases, and Kaufman and Rousseeuw (1990) is a modern treatment of very similar topics. Anderson (1984) gives much of the multivariate theory that underlies such variable clustering methods as principal components and factor analysis. Flury (1988) and Jolliffe (1986) provide good treatments of some of the extensions of principal component methodology, and Press (1982) gives a careful exposition of statistical methods for factor analysis and their relationship to principal component methods. Jöreskog (1970) presents these methods in the context of a more general approach to the analysis of covariance structures involving latent variables.

VI. CONTINGENCY TABLES

When the variables of interest in a study are categorical instead of continuous, then the data can be arrayed as a set of counts cross-classified according to both the explanatory and response variables in a form known as a contingency table. As is the case with the general multivariate linear model, one is interested in the relationships among the response variables, conditional on the explanatory ones, as well as the effects of the explanatory variables on the response. For example, suppose one takes a random sample of 100 automobiles, and classifies each as to (1) whether it required repair within the first year and (2) the day of the week on which it was manufactured. This yields a simple 2×7 two-way contingency table; a three-way table could be built if one also classified each car with respect to manufacturer.

The formal analysis of contingency table data goes back at least to the turn of the century and the pioneering work of Pearson (1900) and Yule (1900). A classic paper by Birch (1963) firmly established the likelihood approach to estimation for contingency table models that are linear in the logarithmic scale of the expectations of the cross-classified counts. Many of the ideas in the subsequent literature parallel those for the general linear model, although the interpretation of the loglinear model parameters has special meaning in the context of contingency tables.

A. Some Basic Notation and Results

In general one works with a vector of observed counts $\boldsymbol{x} = (x_1, x_2, \ldots, x_t)$ that are realizations of the vector of random variables $\boldsymbol{X} = (X_1, X_2, \ldots, X_t)$. The models of interest are expressed in terms of the vector of expected counts $\boldsymbol{m} = (m_1, m_2, \ldots, m_t)$, where $m_i = \mathrm{E}(X_i)$ for $i = 1, 2, \ldots, t$, or more directly in terms of the logarithms of the expected counts $\boldsymbol{\mu} = (\mu_1, \mu_2, \ldots, \mu_t)$, where $\mu_i = \log m_i$ for $i = 1, 2, \ldots, t$. When there are two binary variables of interest $t = 4$ and one can array the counts in the form of a 2×2 table:

x_1	x_2	$\leftrightarrow$	x_{11}	x_{12}
x_3	x_4		x_{21}	x_{22}

where the second tabular version uses multiple subscripts to denote the rows and columns of the table.

In a 2×2 table, the counts may be completely unconstrained, sum to a fixed total $n = \sum x_i$, or have fixed row or column totals. For the general unconstrained case one often assumes that the X_i have independent Poisson distributions with likelihood function

$$\prod_{i=1}^{t} \frac{m_i^{x_i} e^{-m_i}}{x_i!}.$$

When the counts sum to a fixed total n, then one can take $\boldsymbol{X}$ to have a multinomial distribution with likelihood function

$$\frac{n!}{x_1! x_2! \ldots x_t!} \prod_{i=1}^{t} \left(\frac{m_i}{n}\right)^{x_i}.$$

If one partitions the t cells into r sets of sizes $\{t_j\}$, with $t = \sum t_j$, and fixed sample sizes $\{n_j\}$, with $n = \sum n_j$, one has a separate multinomial distribution for each set of cells. The corresponding distribution for the table is said to be product multinomial with likelihood function

$$\prod_{j=1}^{r} \frac{n_j!}{x_{1j}! x_{2j}! \ldots x_{t_j j}!} \prod_{i=1}^{t_j} \left(\frac{m_{ij}}{n_j}\right)^{x_{ij}}.$$

Suppose that X follows the Poisson sampling model. Then the conditional distribution of $\boldsymbol{X}$ given n is multinomial and that of $\boldsymbol{X}$ given $\{n_j\}$ is product-multinomial.

In the context of the automobile manufacturing example given at the beginning of this section, the appropriate likelihood function is the multinomial, since the number

of cars was fixed at 100. However, if the cars selected were those whose owners obtained a driver's license upon a particular day, then the Poisson model would be appropriate; and, if one drew a balanced sample that took exactly 20 cars manufactured on each of the 7 days of the week, then one should use the product multinomial model.

By re-expressing $\boldsymbol{\mu} = \log \boldsymbol{m}$ using a linear model, $\boldsymbol{\mu} = \boldsymbol{\mu}(\boldsymbol{\theta})$, one focuses on the estimation of the loglinear parameters in $\boldsymbol{\theta}$. Then $\boldsymbol{\mu}$ is said to lie in the constrained linear subspace M. Under the model M, the summary statistics used to describe the likelihood function is called the minimal sufficient statistics and is given by the projection of $\boldsymbol{x}$ onto M, i.e., $P_M \boldsymbol{x}$. For the models considered in this section these projections turn out to be sums of components of $\boldsymbol{x}$. For instance, in the 2×2 table case suppose M is the model that takes that the variable corresponding to the rows to be independent of the variable corresponding to the columns, i.e., $m_{ij} = m_{i+} m_{+j}$, where the "+" indicates summation over the corresponding subscript. Then $P_M \boldsymbol{x} = \{x_{1+}, x_{2+}, x_{+1}, x_{+2}\}$. For the automobile manufacturing problem, this model of independence corresponds to asserting that day of manufacture is entirely unrelated to whether the car requires repairs within the first year.

The maximum likelihood estimates (MLEs) $\hat{\boldsymbol{m}}$ of the expected cell counts $\boldsymbol{m} = \boldsymbol{m}(\boldsymbol{\theta})$ under Poisson sampling, when they exist, are given by setting the minimal sufficient statistics equal to their expected values, i.e.,

$$P_M \hat{\boldsymbol{m}} = P_M \boldsymbol{x}.$$

Furthermore, these estimates of the expected cell counts are the same as those for the other two sampling schemes for comparably defined models. Thus, suppose one lets M^* be the loglinear model for $\boldsymbol{m}$ under product-multinomial sampling corresponding to the model M under Poisson sampling such that the multinomial constraints fix a subset of the parameters θ used to specify M. Then the MLEs of $\boldsymbol{m}$ under product-multinomial sampling for the model M^* are the same as the MLEs of $\boldsymbol{m}$ under Poisson sampling for the model M. These results were well known for the 2×2 table, going back to the work of Fisher in the 1920s, and then were extended to the three-way contingency table case by Birch (1963) and later generalized by Haberman (1974) and others.

To decide whether a model fits a vector of observed counts, Pearson (1900) introduced the chi-squared goodness-of-fit statistic. If $\hat{\boldsymbol{m}}$ is the MLE of $\boldsymbol{m}$ under a loglinear model and if M is correct, then the statistic

$$X^2 = \sum_{i=1}^{t} \frac{(x_i - \hat{m}_i)^2}{\hat{m}_i}$$

has an asymptotic χ^2 distribution with $t - s$ degrees of freedom, where s is the total number of independent constraints implied by the model M (or by M^* under the product multinomial constraints). If M is not correct, then the value of X^2 tends to be larger than one expects from a random variable with χ^2_{t-s} distribution.

Both $X^2 = \sum_{i=1}^{t} (x_i - \hat{m}_i)^2 / \hat{m}_i$ and the likelihood ratio statistic $G^2 = 2 \sum_{i=1}^{t} x_i \log(x_i / \hat{m}_i)$ are examples of goodness-of-fit measures based on the power-divergence family of statistics,

$$I^{\lambda}(\boldsymbol{p} : \boldsymbol{q}) = \lambda^{-1}(1 + \lambda)^{-1} \sum_{i=1}^{t} p_i \left[\left(\frac{p_i}{q_i} \right)^{\lambda} - 1 \right], \quad -\infty < \lambda < \infty,$$

studied by Read and Cressie (1988). The quantity $I^{\lambda}(\boldsymbol{p} : \boldsymbol{q})$ measures the divergence of the probability distributions $\boldsymbol{p} = (p_1, p_2, \ldots, p_t)$ and $\boldsymbol{q} = (q_1, q_2, \ldots, q_t)$. When one lets $\boldsymbol{x}/n = \boldsymbol{p}$ and $\hat{\boldsymbol{m}}/n = \boldsymbol{q}$ and the model M is correct, $2n I^{\lambda}(\boldsymbol{x}/n : \hat{\boldsymbol{m}}/n)$ has an asymptotic χ^2 distribution with $t - s$ degrees of freedom. For each different value of λ, one gets a test statistic that is sensitive to different alternative models for the expected counts. Setting $\lambda = 1$ corresponds to the statistic X^2 and defining the quantity in the limit as $\lambda \to 0$ yields G^2.

B. Applying the Basic Theory to Log-Linear Models for Three-Way Tables

The three-dimensional case helps to make concrete these theoretical results. Suppose one has an $I \times J \times K$ table of counts $\{x_{ijk}\}$ with a corresponding table of expectations $\{m_{ijk}\}$. The most general model in the logarithmic scale is

$$\mu_{ijk} = \log m_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)} + u_{13(ik)} + u_{23(jk)} + u_{123(ijk)}, \quad (26)$$

where the parameters (u-terms) are subject to appropriate linear constraints similar to those for ANOVA models:

$$\begin{aligned} u_{1(+)} &= u_{2(+)} = u_{3(+)} = 0, \\ u_{12(+j)} &= u_{12(i+)} = u_{13(+k)} = u_{13(i+)} = u_{23(+k)} \\ &= u_{23(j+)} = 0, \\ u_{123(+jk)} &= u_{123(i+k)} = u_{123(ij+)} = 0. \end{aligned}$$

By setting various parameters in (26) equal to zero one can get different log-linear models M.

The simplest log-linear model tests

$$\mathrm{H}_0: \quad \mu_{ijk} = \log m_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)}.$$

This corresponds to testing whether $u_{12(ij)} = u_{13(ik)} = u_{23(jk)} = u_{123(ijk)} = 0$, and implies the complete independence of variables 1, 2, and 3. Alternatively, one can include one or more two-factor terms yielding

$$\mathrm{H}_{01}: \quad \mu_{ijk} = \log m_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)},$$

which corresponds to the independence of variable 3 from variables 1 and 2 jointly, and is expressible in more standard multiplicative form as

$$m_{ijk} = m_{i++}m_{+j+}m_{++k}.$$

With two two-factor terms one has

$$\mathrm{H}_{02}: \quad \mu_{ijk} = \log m_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)} + u_{13(ik)},$$

which corresponds to the conditional independence of variables 2 and 3 given variable 1, and is expressible in multiplicative form as

$$m_{ijk} = m_{ij+}m_{i+k}/m_{i++}.$$

Finally, one has

$$\mathrm{H}_{03}: \quad \mu_{ijk} = \log m_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)} + u_{13(ik)} + u_{23(jk)},$$

which implies that there is no second-order interaction among variables 1, 2, and 3. Model H_{03} is not expressible in a multiplicative form for m_{ijk} in terms of the corresponding two-way totals m_{ij+}, m_{i+k}, and m_{+jk}.

Under Poisson sampling or multinomial, for the no-second-order-interaction model H_{03}, the minimal sufficient statistics are $P_M\boldsymbol{x} = [\{x_{ij+}\}, \{x_{i+k}\}, \{x_{+jk}\}]$. Also, the MLEs $\hat{\boldsymbol{m}}$ of the expected cell counts are the solution of equations

$$\hat{m}_{ij+} = x_{ij+} \qquad \text{for all} \quad i, j,$$
$$\hat{m}_{i+k} = x_{i+k} \qquad \text{for all} \quad i, k,$$
$$\hat{m}_{+jk} = x_{+jk} \qquad \text{for all} \quad j, k.$$

The solution of these equation requires some form of iteration; sometimes no unique solution exists. Alternatively, one could maximize the likelihood function directly, using the Newton–Raphson algorithm or some similar technique.

If one has generated the counts using product-multinomial sampling with the 1, 2-margin fixed, one has $x_{ij+} = n_{ij+}$ fixed for all i, j. For this situation one can convert model H_{03} into a linear logistic model. Suppose that variable 3 is binary. Then one can re-express the model in terms of one for the log odds (logit) of responses for variable 3 given variables 1 and 2:

$$\begin{aligned}\log(m_{ij1}/m_{ij2}) &= u + u_{1(i)} + u_{2(j)} + u_{3(1)} + u_{12(ij)} \\ &\quad + u_{13(i1)} + u_{23(j1)} - \left[u + u_{1(i)} + u_{2(j)} \right. \\ &\quad \left. + u_{3(2)} + u_{12(ij)} + u_{13(i2)} + u_{23(j2)}\right] \\ &= w + w_{1(i)} + w_{2(j)}, \end{aligned} \tag{27}$$

where $w = 2u_{3(1)}$, $w_{1(i)} = 2u_{13(i1)}$, and $w_{2(j)} = 2u_{23(j1)}$. This model has the same form as the logistic regression model of Section II [see expression (19)]. The results of the previous subsection imply that the maximum likelihood estimators for the expected counts under this model are the same as those under the no-second-order-interaction model and thus satisfy the equations in expression (27). For an $I \times J \times K$ table and model H_{03}, there is a total of $IJK - (I-1)(J-1)(K-1)$ parameters. Thus the degrees of freedom used to test the goodness of fit equals $(I-1)(J-1)(K-1)$.

TABLE III Observed Counts for $\{x_{ijk}\}$ for Industrial Study of the Rolling of Ingots for Different Soaking and Heating Times

Soaking time	Counts for given heating times				Total counts
	7	14	27	51	
1.0	10, 0	31, 0	55, 1	10, 3	106, 4
1.7	17, 0	43, 0	40, 4	1, 0	101, 4
2.2	7, 0	31, 2	21, 0	1, 0	60, 2
2.8	12, 0	31, 0	21, 1	0, 0	64, 1
4.0	9, 0	19, 0	15, 1	1, 0	44, 1
Totals	55, 0	155, 2	152, 7	13, 3	375,12
Grand total 387					

As an example, Table III contains the data from Cox and Snell (1989) for an industrial investigation designed to study effects of soaking time (variable 1) and heating time (variable 2) on whether on not an ingot is ready for rolling. The first entry in each cell is the number of ingots ready for rolling; the second entry is the number not ready.

The no-second-order-interaction model of H_{03} fits these data extremely well; $G^2 = 11.275$ with 11 degrees of freedom (the usual number 12 is reduced by 2 because the count of the number of ingots not ready for rolling in the first column of Table III is 0 and the number of ingots in the fourth row and column is 0). One can compare this value to the tabulated values of a χ^2 distribution with 11 degrees of freedom, and the observed values fall far from the right-hand tail of the distribution.

Because the two explanatory variables are ordered, a natural extension of model (27) that one might wish to explore expresses the log-odds as a simple linear function of the soaking time x_1 and the heating time x_2:

$$\mu = \theta + \theta_1 x_1 + \theta_2 x_2$$

[cf. expression (19)]. Now one no longer needs to worry about the linear constraints on the full version of model (27). The estimated equation using the method of maximum likelihood given by Cox and Snell (1989, p. 66) is

$$\mu = 5.559 - 0.0568x_1 - 0.0820x_2.$$

The coefficient of x_1 has a standard error of 0.0331, and thus the observed level of significance for testing $H_0: \theta_1 = 0$ versus $H_a: \theta_1 \neq 0$ is just under 0.10.

C. Log-Linear Models for Multi-Way Tables

The ANOVA-like log-linear models and theoretical results are useful for multi-way tables of counts. As in the three-way case, minimal sufficient statistics are marginal totals of the full table. All independence or conditional independence relationships are representable as log-linear models. These have estimated expected cell counts that can be computed directly. For all other log-linear models, we require iterative methods to compute the maximum likelihood estimates. Detail are available in Bishop *et al.* (1975).

D. Graphical Log-Linear Models

A special subset of log-linear models for multi-way tables has received considerable attention over the past decade. Darroch *et al.* (1980) define the class of graphical log-linear models as those satisfying a set of conditional independence relationships.

Suppose one considers a p-way array corresponding to the vector of p discrete random variables $\boldsymbol{Y} = (Y_1, Y_2, \ldots, Y_p)$ and let $P = \{1, 2, \ldots, p\}$ be the corresponding set of vertices. Further, let $\boldsymbol{Y}_{P/\{i,j\}}$ denote the set of $p-2$ variables excluding Y_i and Y_j. A standard notation for representing the conditional independence of Y_i and Y_j given the remaining variables is

$$Y_i \perp Y_j \mid \boldsymbol{Y}_{P/\{i,j\}}. \tag{28}$$

This conditional independence model is also itself a log-linear model for the p-way array. Graphical log-linear models correspond to the simultaneous occurrence of several such conditional independence models. They have special attractive properties in addition to the interpretation associated with these conditional independence relationships (for details, see Whittaker, 1990) and are related to the spatial theory of Markov random fields.

The conditional independence graph of $\boldsymbol{Y}$ is the undirected graph $G = (P, E)$ such that the edge between i and j is not in the edge set E if and only if $Y_i \perp Y_j \mid \boldsymbol{Y}_{P/\{i,j\}}$. There is a one-to-one correspondence between independence graphs and graphical log-linear models. Given an independence graph G, the corresponding graphical log-linear model is the one in which all u-terms containing the pairs of coordinates corresponding to edges not in E are taken to be identically zero.

Example. Suppose one constructs an independence graph for an eight-way contingency table as in Fig. 1. The edge set for this graph is

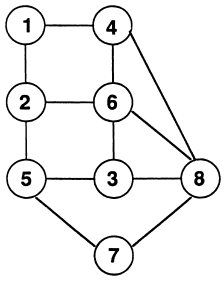

FIGURE 1 Example of an independence graph in an eight-way contingency table.

$$E = \{(1,2), (1,4), (2,6), (2,5), (3,5), (3,6), (3,8), (4,6), (4,8), (5,7), (6,8), (7,8)\}$$

and the corresponding graphical log-linear model satisfies 16 conditional independence relationships of the form given in (28). Alternatively, one can describe the loglinear model by setting the 12 two-factor u-terms corresponding to the edges not in E equal to zero, as well as all higher order terms containing them. The resulting model contains no four-factor u-terms.

Agresti (1990) and Fienberg (1980) give accessible introductions to the methodology for the analysis of multi-way contingency tables using log-linear models and estimation via the method of maximum likelihood. Bishop *et al.* (1975) and Haberman (1974) provide further technical details and methods for related structures and models. McCullagh and Nelder (1989) present log-linear models as a special case of GLIM techniques, and Santner and Duffy (1989) describe alternative methods of estimation; both consider the problem of over- and underdispersion in binary logistic response models. Douglas and Fienberg (1991) present a detailed review of log-linear and related models for cross-classified categorical data involving ordinal variables. Finally, Whittaker (1990) and Lauritzen (1996) present extensive treatments of graphical log-linear models and their continuous counterparts.

VII. DISCRIMINANT ANALYSIS

In discriminant analysis one has a preliminary learning sample that consists of n objects, each of which is measured with respect to p variables and each of which is known to belong to one of j categories. The goal is to use the learning sample to construct a classification function for future objects whose true category is unknown, but for which one can take measurements on each of the p variables.

Historically, discriminant analysis developed from a problem in botany. Fisher (1936) had measurements of sepal width, sepal length, petal width, and petal length for a sample of wild irises, each of which had been classified into one of three species by an expert botanist. Using these data, he calculated the equations for the two hyperplanes that best separated the vectors of observations in $\mathbb{R}^4$ into regions corresponding to different species. These hyperplanes were the classification (or discriminant) functions used to categorize future irises; specifically, a new iris would be measured on each of the four characteristics and then classified as belonging to the species within whose region the data vector lay.

A. Linear Discriminant Analysis

Fisher's original strategy can be formalized as follows: assume there are k populations, each having unknown mean measurement vector $\boldsymbol{\mu}_i$ and common unknown covariance matrix $\boldsymbol{\Sigma}$. The training sample consists of k independent samples, one from each population. The ith sample has n_i vector observations in $\mathbb{R}^p$, all independent; these are denoted by $\boldsymbol{X}_{i1}, \ldots, \boldsymbol{X}_{in_i}$ for $i = 1, \ldots, k$. The unknown parameters $\boldsymbol{\mu}_i$ and $\boldsymbol{\Sigma}$ are estimated as

$$\hat{\boldsymbol{\mu}}_i = \bar{\mathbf{X}}_i$$

$$\hat{\boldsymbol{S}} = \frac{1}{n-k} \sum_{i=1}^{k} \sum_{j=1}^{n_i} (\boldsymbol{X}_{ij} - \hat{\boldsymbol{\mu}}_i)(\boldsymbol{X}_{ij} - \hat{\boldsymbol{\mu}}_i)^{\mathrm{T}}$$

where $n = n_1 + \cdots + n_k$. From these, the discriminant function corresponding to the hyperplane that best separates populations r and s in the training sample is

$$W_{rs}(\boldsymbol{x}) = \boldsymbol{x}^{\mathrm{T}} \boldsymbol{S}^{-1} (\hat{\boldsymbol{\mu}}_r - \hat{\boldsymbol{\mu}}_s) - \tfrac{1}{2} (\hat{\boldsymbol{\mu}}_r - \hat{\boldsymbol{\mu}}_s)^{\mathrm{T}} \boldsymbol{S}^{-1} (\hat{\boldsymbol{\mu}}_r - \hat{\boldsymbol{\mu}}_s).$$

Thus for a new observation with measurement vector $\boldsymbol{X}$, the classification rule assigns it to population r if and only if $W_{rs}(\boldsymbol{X}) > 0$ for all $s \neq r$.

This classification rule is equivalent to assigning the observation to the group whose sample mean minimizes the estimated squared Mahalanobis distance between $\boldsymbol{X}$ and $\hat{\boldsymbol{\mu}}_r$. The procedure works well in practice, and is asymptotically optimal in a certain technical sense when the assumptions hold and the distribution for each population is normal. However, its properties are less certain when different groups have different covariance matrices or the underlying distributions are nonnormal.

A key issue in discriminant analysis is the estimation of the misclassification probabilities. Ideally, this would be done by applying the classification rule to a large number of new observations and then determining how often the group assignment was incorrect. In practice, it is often not feasible to determine the true memberships of new observations. Therefore, most computer software packages use cross-validation to enable the practitioner to estimate the misclassification rates from the training sample (Section II contains additional discussion of cross-validation methodology). In this application, cross-validation separates each observation in turn from the training sample, recomputes the discriminant functions from the remaining observations, and then uses the recomputed rule to classify the separated observations. This is done for all observations, and one counts n_{rs}, the number of times an observation from group r is misclassified as belonging to group s. From this, the estimate of the probability that linear discriminant analysis assigns a member of group r to group s is n_{rs}/n_r. Cross-validation is more accurate and less optimistic than the naive procedure, which estimates error rates from misclassifications obtained from the original assignment rule. Alternatives to cross-validation include bootstrap estimation, proposed by Efron (1983), and smoothing techniques described by Snapinn and Knoke (1985).

Another issue in implementing a discriminant analysis involves the prior probabilities of the different groups. In some applications the proportions of the different groups among new objects to be classified are expected to be similar to the proportions found in the training sample. In other applications, the proportions will be different. The accuracy of the classification rule for future observations will improve if it is customized to the situation. Most software packages permit the user to indicate the expected proportions.

Fisher's discriminant analysis is rarely used in the form described; most applications are better served by a variation that builds the discrimination functions through stepwise selection from the set of recorded variables. Very often, the number of components p in the measurement vector is large relative to the sample size, and not all of the measurement variables make distinct contributions to the classification problem. In order to prevent the procedure from overfitting the data, it is desirable to ensure that each variable used in the discriminant function explains a separate and nonnegligible proportion of the variation in group membership. This yields simpler classification rules with smaller misclassification rates. However, the stepwise discriminant analysis procedure is nonlinear, and few of its theoretical properties are understood.

B. CART Analysis

Discriminant analyses work well when the underlying assumptions are reasonably satisfied. Even with gross violations, as when the covariance matrices $\boldsymbol{\Sigma}_1, \ldots, \boldsymbol{\Sigma}_k$ are markedly unequal, it is often possible to develop asymptotically accurate procedures that show good performance in small sample settings. In practice, the three

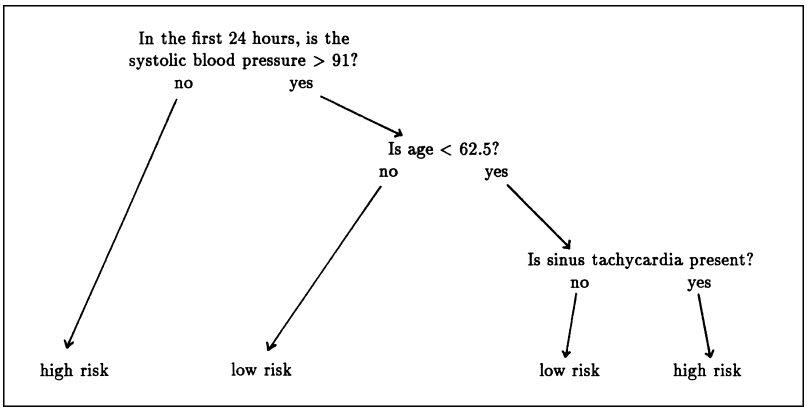

FIGURE 2 CART diagram for classifying emergency room patients into high- and low-risk groups with regard to myocardial infarction.

chief drawbacks of discriminant analysis are that it is unable to use categorical data, the discriminant functions are difficult to interpret in scientifically meaningful ways, and the theoretical framework relies on the assumption that the data arise from a mixture of normal distributions.

CART analysis is a modern, computer-intensive technique that attempts to deal with these deficiencies of discriminant analysis. CART is an acronym for "classification and regression trees"; in the context of building a classification rule, CART uses the training sample recursively to partition the space of possible measurements. The resulting rule can be represented as a decision tree, and this is generally viewed as more natural than classification according to discriminant functions. In this form, the method was developed by Breiman *et al.* (1984), and has been marketed in a commercial software package.

Operationally, CART partitions the training sample into increasingly homogeneous groups, thereby inducing a partition on the measurement space. At each stage, three criteria are considered in determining the next split for the training sample cases inside the current partition:

1. Is $X_i \leq d$ (univariate split)?
2. Is $\sum_{i=1}^{P} c_i x_i \leq d$ (linear combination split)?
3. Does $x_i \in A$ (categorical split, used when x_i is a categorical variable)?

CART searches all possible values of d, all coefficients $\{c_i\}$, and all subsets A of the possible category values to find the split which best separates the training sample cases under consideration into two groups of maximally improved homogeneity. Improvement is assessed using either Gini's index of diversity or a "twoing rule." Typically, CART splits until all cases in the training sample fall into separate partitions, and then uses a cross-validation assessment to eliminate previous partitions, thereby reducing the problem of overfit. This automatically includes estimation of misclassification probabilities and user-specified priors on category membership.

The result of a CART analysis is a classification tree. Figure 2, from Breiman *et al.* (1984), shows a tree built using a training sample from a Santa Barbara, California, emergency room. On admission, the patients complained of chest pain; doctors recorded their medical history, current profile, and eventual diagnosis. The goal of the study was to develop a classification rule that distinguished patients at high risk of myocardial infarction from those at low risk. Based on the data, CART generated the decision tree rule shown in Fig. 2. To use this tree, imagine that a new patient with chest pain enters the emergency room. First, sphygmomanometry determines whether the minimum systolic blood pressure over the initial 24-hr period is greater than 91. If not, then the patient is at high risk; otherwise, one checks the patient's age. If this is less than 62.5 years, then the patient is classified as low risk; otherwise, the doctor determines whether sinus tachycardia is present. If it is, then the patient is classified as high risk, and otherwise is declared to be at low risk. Cross-validation indicated the CART tree performed as well as discriminant analysis at distinguishing patients, and it also produced a diagnostic procedure which some view as more medically meaningful.

CART methods can also be applied to build regression models, although their popularity there has been less pronounced. Recently, CART methodology has been generalized, so that the entire strategy emerges as a special case of MARS, the procedure used for fitting locally low-dimensional structure via a generalized additive model (see Section I). However, this generalization forgoes the graphic summary illustrated in Fig. 2.

References

Lachenbruch (1975) and Flury (1997) offer good surveys of applications and topics in this area. Morrison (1990) addresses the problem from the perspective of multivariate normal data, and Dillon and Goldstein (1978) develop discriminant analysis methods that use discrete data. Anderson (1984) and Press (1982) detail the theory of discriminant analysis.

VIII. TIME SERIES ANALYSIS

Time series data arise when observations show serial correlation. Most commonly, such data occur when measurements are taken over time; for example, a control engineer might monitor the temperature of a blast furnace at 5-min intervals. However, this defining property of serial correlation would also be present in measurements of rail wear at 20-ft intervals along railroad track, or selenium concentrations assayed in mile-long steps on a river.

Theoretical analysis of time series data is computationally intensive and model sensitive. Recent research has attempted to weaken the modeling assumptions needed for forecasting and parameter estimation, but this work has not yet engendered a fundamental breakthrough that permits cookbook application of time series methodology. Nonetheless, some basic models are widely used; software that implements these models is available in all major statistical packages.

A. Detrending Data

The first step in a time series analysis is to achieve stationarity by detrending the data. Formally, a time series $\{Y(t)\}$ is strictly stationary if

$$P[Y(t_1) \le y_1, \ldots, Y(t_k) \le y_k] = P[Y(t_i + s) \le y_1, \ldots, Y(t_k + s) \le y_k]$$

for all k, s, and $\{t_i\}$. This is theoretically powerful, but rarely justified in practice. It is more realistic to hope that the data are weakly stationary, which occurs when

$$\begin{aligned} E[Y(t)] &= \mu \quad \forall t, \\ \text{var}[Y(t)] &= \sigma^2 \quad \forall t, \\ \text{cov}[Y(t), Y(t+s)] &= \gamma_s \quad \forall t, s. \end{aligned}$$

Both types of stationarity imply that the character of the series does not depend upon the time at which it is measured. Thus a stationary series shows no trend and the variance is constant throughout. Although one cannot prove stationarity, there are tests that detect specific kinds of nonstationarity (Brown *et al.,* 1975). Detrending techniques are used to adjust a dataset so that it conforms to a stationary model amenable to time series analysis.

There are three basic strategies for detrending a dataset:

1. Fit a model to the trend in the raw data and then subtract this from the time series.
2. Replace the raw values by the differences of adjacent values (this differencing operation may be repeated several times, until the new dataset passes some test of stationarity).
3. Transform the data, usually to stabilize the variance.

The first method implements a global detrending; the second performs a more flexible local correction. The third approach depends upon ideas in Section II, but will not be considered here.

Fitting a model is conceptually simple and often approximately correct in applications that involve a well-understood physical process. The usual model is

$$Y(t) = m(t) + \xi(t),$$

where $\{Y_t\}$ denotes the measurements, which we assume to be taken at equally spaced intervals indexed by t, $m(t)$ is a deterministic trend, and $\{\xi(t)\}$ is a stationary time series. As a simple example, one might analyze Newton's experiment on the rate at which a heated cannon ball cools. The deterministic idealization relates the surface temperature u to time t by the differential equation

$$\frac{du}{dt} = k(u - u_o), \tag{29}$$

where u_o is the ambient temperature and k depends upon the physical properties of the cannon ball. Newton recorded the observed temperatures $U(t_1), \ldots, U(t_n)$; these surely had correlated errors, so a plausible statistical model based on the solution to (29) is

$$U(t_i) = ce^{t_i k} + U_o + \xi(t_i). \tag{30}$$

To detrend this time series, one could estimate c, k, and u_o via nonlinear regression analysis and then subtract the estimated deterministic component from each observation. The resulting residuals $\{\hat{\xi}(t)\}$ may comprise an approximately stationary series.

Detrending methods must reflect the physical model. For example, in meteorology one can model diurnal high temperature $Y(t)$ as

$$Y(t) = p(t) + s(t) + \xi(t), \tag{31}$$

where $p(t)$ captures slow multiyear change as a random walk with polynomial drift, $s(t)$ is the seasonal component, equal to the previous year's value plus a disturbance term independent of both $p(t)$ and $\xi(t)$, and $\xi(t)$ is independent normal error with mean 0. One can remove the polynomial trend by taking d successive differences of adjacent values, where d is the degree of the polynomial. The

seasonal component is detrended by subtracting values separated by 1 year (the same strategy also removes daily, weekly, or monthly periodicities). What remains should be a stationary series whose analysis may enable accurate forecasts.

These two detrending examples correspond to two distinct approaches to time series analysis. Differencing takes the time-domain perspective, pioneered by Whittle (1951) and broadly elaborated upon by Box and Jenkins (1976). Regression modeling conforms to the spirit of the frequency- or harmonic-domain perspective, largely developed by Weiner (1949), in which one performs a Fourier decomposition of the data and discards terms that contribute meager explanation. This Fourier decomposition is comparable to regression in that finding the Fourier transform of the discrete observations is conceptually similar to fitting the model

$$Y(t) = \theta_o + \sum_{i=1}^{k} \psi_i \cos \lambda_i t + \phi_i \sin \lambda_i t + \xi(t).$$

There is no theoretical basis for preferring one style of time series analysis over the other.

B. Time-Domain Models

The time-domain methods attempt to express $Y(t)$ as a function of previous values and uncorrelated noise. The basis for this representation is the linear autoregressive moving average (ARMA) model. If differencing is used to achieve stationarity, this can be captured in the same framework as an autoregressive integrated moving average (ARIMA) model. This ARIMA generalization is very practical but not conceptually fundamental, so we shall avoid addressing it, by assuming that $\{Y(t)\}$ is weakly stationary.

There are three kinds of ARMA models: moving average models of order q, denoted by MA(q); autoregressive models of order p, denoted by AR(p); and autoregressive moving average models of orders p and q, denoted by ARMA(p, q). To discuss these, let $\{\xi(t)\}$ be a white noise process, defined as satisfying

$$\mathrm{E}[\xi(t)] = 0 \quad \forall t, \qquad \mathrm{cov}[\xi(t_i), \xi(t_j)] = 0 \qquad \forall t_i \neq t_j.$$

The time series $\{Y(t)\}$ is assumed to result from the application of a linear filter to this white noise process; i.e.,

$$Y(t) = \sum_{i=0}^{\infty} \psi_i \xi(t - i), \tag{32}$$

where $\psi_o = 1$ and the coefficients $\{\psi_j\}$ form a finite or infinite convergent sequence. Also, we define the backshift operator B, which steps back the time index of any process term one unit; e.g., $B^j Y(t) = Y(t - j)$.

The MA(q) model assumes that $Y(t)$ depends only on the recent past of the unobservable white noise process. Specifically,

$$Y(t) = \sum_{i=0}^{q} \psi_i \xi(t - i) = \Psi_q(B)\xi(t), \tag{33}$$

where $\Psi_q(B)$ is a polynomial operator in B of degree q; it is obtained from the symbolic representation of the backshift operator as the argument in the polynomial.

The AR(p) model assumes $Y(t)$ depends upon the infinite past of the white noise process through dependence on p previous terms of the time series. Thus

$$Y(t) = \xi(t) + \sum_{j=1}^{p} \phi_j Y(t - j) = \xi(t) + \Phi_p(B)Y(t), \tag{34}$$

where $\Phi_p(B)$ is a polynomial operator in B of degree p. (Differencing in this model corresponds to zeros of the polynomial Φ_p that lie on the unit circle; zeros outside the unit circle imply intrinsic nonstationarity, so it is of practical importance to check whether all zeros of Φ_p are inside the unit disk.)

The ARMA(p, q) model combines models (33) and (34), so that

$$Y(t) = \xi(t) + \sum_{j=1}^{p} \psi_j Y(t - j) + \sum_{i=1}^{q} \phi_i \xi(t - i), \tag{35}$$

or, in backshift notation, $\Phi_p(B)Y(t) = \Psi_q(B)\xi(t)$. This model is quite flexible and can fit many datasets, but one must be wary of fitting too many parameters, which leads to poor prediction.

The two basic tools for identifying a time-domain model are the estimated autocorrelation function (ACF) and partial autocorrelation function (PACF). The former represents the sample correlations r_s between all observations exactly s time units parts, so

$$r_s = \frac{\sum_{i=1}^{n-s} (Y(t_i) - \bar{\boldsymbol{Y}})(Y(t_{i+s}) - \bar{\boldsymbol{Y}})}{\sum_{i=1}^{n} (Y(t_i) - \bar{\boldsymbol{Y}})^2},$$

where $\boldsymbol{Y}$ is the mean of the series. Similarly, the estimated PACF gives the sample partial correlations (see Section II) between all observations exactly s time units apart, controlling for the intervening observations.

When the MA(q) model fits, then $r_1, \ldots, r_q$ are relatively large, but subsequent values are negligible. When the AR(p) model fits, one finds that just the first p partial correlations in the PACF are relatively large. Both the ACF and PACF are used to fit ARMA(p, q) models. Usually this model identification process is somewhat exploratory, and the choice may be revised late in the analysis. If the white noise process is Gaussian, then there is distribution theory that enables precise judgment about which terms

in the ACF and PACF are negligible; otherwise one must rely on empirical guidelines. More elaborate model identification procedures are available, such as Akaike's (1973) information criterion. These balance the explanatory value of a complex model against the loss of predictive power incurred by fitting too many parameters, using tools from information theory.

After identifying a model, one estimates the corresponding parameter values. There are several alternative parametrizations of a given model; for example, one can estimate the filter coefficients $\{\psi_i\}$ in (32) or the polynomial coefficients for the backshift operators in (35). Similarly, there are many estimation methods, and the choice of these is driven by the application and the parametrization. For the AR(p) model, the Yule–Walker equations enable linear estimation of $\Phi_1, \ldots, \Phi_p$; however, their tractability is undermined by their relatively poor performance for prediction. Modern computer-intensive calculation enables maximum likelihood, Bayesian, or iterative nonlinear least squares estimation, and the results are typically more stable.

C. Forecasting

The most common application of time series analysis is to forecast future observations. Depending upon the model and the parametrization, one may need to estimate not only the parameters, but also the terms in the white noise series. For example, if one is working with the representation in (32), then the value j steps ahead will be

$$Y(t+j) = \xi(t+j) + \sum_{i=0}^{\infty} \Psi_i \xi(j+t-i)$$

and this is estimated by

$$\hat{Y}(t+j) = \sum_{i=j}^{\infty} \hat{\Psi}_i \hat{\xi}(j+t-i)$$

since the expectations of all currently unrealized terms in the white noise process are 0. The estimated variance of the error in this forecast is

$$s_j^2 = \left(1 + \hat{\Psi}_1^2 + \cdots + \hat{\Psi}_{j-1}^2\right)\hat{\sigma}_\xi^2,$$

where $\hat{\sigma}_\xi^2$ is the sample variance of the white noise, which is calculated from the residuals $\hat{\xi}(t) = Y(t) - \hat{Y}(t)$ obtained by fitting the model to the observed series.

References

For time-domain models, Box and Jenkins (1976) is the classic reference. The frequency-domain models are described in Brockwell and Davis (1991) and Brillinger (1981). Brockwell and Davi (1996) provides an elementary introduction to time series methodology; Anderson (1984) develops the area from the perspective of multivariate analysis, and Christensen (1991) emphasizes connections with the general linear model and coordinate-free methodology.

IX. STATISTICAL SOFTWARE PACKAGES

There are many packages, libraries, and languages for computer implementation of multivariate analysis. This brief survey restricts attention to the most popular of these along with a few of the special-purpose packages that permit analyses not available from other vendors. We note that the vendors of many of these products are extremely market-conscious and therefore provide regular upgrades to incorporate improvements and extensions accomplished by benchmark competitors.

On workstations, for standard applications, the four most widely used and mature packages are BMDP, SAS, SPSS, and S-PLUS. On personal computers, DataDesk, Stata, and SYSTAT are widely available as well as versions of the workstation software. For those who plan extensive statistical programming, it is sensible to examine the software libraries IMSL and NAG, both of which offer a smorgasbord of mathematical routines useful in multivariate analysis. Finally, there are a number of commercial and noncommercial programs available that implement some of the more advanced techniques discussed previously.

BMDP, SAS, SPSS, and S-PLUS all have broadly comparable functionality and all are regularly corrected, updated, and extended. BMDP and SYSTAT have been acquired by the developer of SPSS, so analysts interested in those programs should contact SPSS, Inc. Also, there is some interplay between the major packages; SAS and BMDP enable users to call each others' routines quite flexibly. SPSS and BMDP have commands that permit users to read data that have been stored in one of the SAS formats.

The BMDP routines were originally written with biomedical and educational research applications in mind. This has led to particular emphasis on statistical techniques related to those fields, such as logistic regression, block clustering, and repeated measures designs. To get a detailed grasp of the package's capabilities, one should examine the "BMDP Statistical Software Manual" (1998).

In slight contrast, SAS has historically focused on the linear model, time series methods, graphics, and its user interface. It can link with IMSL routines, enabling mathematically sophisticated analyses. A less powerful version of SAS is available for personal computers. There are several SAS manuals that outline the available analyses in particular detail, but the core manual is the "*SAS/STAT User's Guide*" (SAS, 1999).

SPSS design was guided largely by social science applications. Originally, it concentrated upon the analysis of very large datasets, report writing, and specialized graphics, including graphic templates for the United States and Canada. The "*SPSS Base 10.0 User's Guide*" (SPSS, 1999) describes the available routines.

SYSTAT, originally developed for personal computers, includes most of the functionality available with BMDP, SAS, and SPSS. A particular strength of SYSTAT in the context of multivariate analysis is its broad capability with the multivariate general linear model, which supports analysis of very complicated experimental designs.

S-PLUS is an extension of S, a programming language developed at Bell Laboratories. It is structured so that computations treat data structures as entities, rather than lists of separate values, and it has extremely flexible graphic capabilities. Also, insofar as it is more of a language than a package, users typically develop a library of S-PLUS routines tailored to their particular applications. Venables and Ripley (1998) illustrate many multivariate analyses using S-PLUS.

DataDesk, for personal computers, implements a range of modern graphic tools for multivariate analysis. These include point-cloud rotation, which enables the user to visualize three-dimensional scatterplots of the data and methods of linking data across several graphic displays for interactive exploration. Similarly, Stata was also originally developed for personal computers, but is designed to enable easy integration with the Internet and to support database management as well as statistical analysis.

IMSL and the NAG Library of Algorithms are software libraries that enable Fortran users to call advanced routines that implement a range of mathematical and statistical functions, from sorting a vector to fitting an ARMA(p,q) model. GLIM, a specialized package for inference on the generalized linear model, is distributed by the Numerical Algorithms Group Ltd., the owners of the NAG library. CART, a program for classification and regression analysis via recursive partitioning, is marketed by Salford Systems, Inc. BUGS, for "Bayesian updating via Gibbs sampling," is noncommercial code that has revolutionized the practice of multivariate Bayesian analysis by enabling a much broader scope of practical calculation. Current details on all of the software discussed in this section may be easily found on the Internet.

GLOSSARY

Asymptotic Relative Efficiency (ARE) A measure of the performance of one procedure relative to another. For two asymptotically unbiased estimates of a parameter the ARE is the reciprocal of the ratio of their asymptotic variances.

Breakdown point The smallest proportion of corrupt data that renders an estimator meaningless.

Diagnostics Plots and statistics which are used to determine the quality of fit.

Distribution free Statistical tests whose null distributions do not depend on the underlying distribution of the data.

HBR High breakdown R estimates of the regression coefficients of a linear model.

Influence function A measure of the sensitivity of an estimator to an additional point (outlier) to the sample.

Rank-based analyses Analyses (tests of hypotheses, confidence procedures, diagnostic analyses) of models based on the fit of the model using R or HBR estimates.

R estimates Estimates of the regression coefficients of a linear model based on minimizing a norm of residuals. This norm is defined in terms of (rank) score function.

Robust Procedures whose results are not sensitive (influenced) by outlying observations.

THE TERMS nonparametric (NP) statistics or distribution-free methods have historically referred to a collection of statistical tests whose null distributions do not depend on the underlying distribution of the data; hence the term nonparametric, i.e., no parameters. Many of the early nonparametric procedures were based on replacing the data by their ranks which, before the advent of the computer, facilitated hand calculation. Contributors to this early development include Hodges, Kendall, Krsukal, Lehmann, Mann, Pitman, Spearman, Whitney, and Wilcoxon, to name a few. It is impossible to mention all the contributors to this early development. These and many more are cited in the references of the monographs listed in the following. These procedures were thought to be quick and dirty and more easily computable than classical least squares (LS) methods. They were thought, however, to be much less efficient than LS methods. Through

the work of Lehmann and Hodges (and others) in the 1950s and 1960s, though, it was found that many of these NP procedures were quite efficient. For example, if the data follow a normal distribution then many of these procedures have efficiency .955 relative to LS methods; while, if the data follow distributions with thicker tails than a normal (allow outliers like most real data), then these NP procedures are much more efficient than LS methods. The early NP procedures were essentially test statistics, but theory for related estimates and confidence intervals of location parameters were developed in the 1950s and 1960s. Taken together these NP procedures for simple location problems offer the user highly efficient and robust methods which form an attractive alternative to traditional least squares (LS) procedures. The monographs of Hájek and Šidák (1967), Puri and Sen (1971), Lehmann (1975), and Randles and Wolfe (1979) contain many references to this work and they extended the work into various settings.

LS procedures, though, generalize easily to any linear model and to most nonlinear models. The LS procedures are not model dependent. In contrast, there are very few classical nonparametric procedures for designs other than the simple location designs and, furthermore, these procedures vary with the problem. For instance, the ranking procedure for the Kruskal Wallis test of treatment effect in a one-way layout is much different than the ranking procedure for the Friedman test of treatment effect in a two-way design. Further the efficiencies of these two procedures differ widely, although both are based on linear rankings.

In geometric terms, LS procedures for estimation and testing for any linear model are based on the Euclidean norm. Although, traditional distribution-free procedures do not generalize to any linear model, rank-based procedures based on robust estimates of regression coefficients do. These estimates are based on minimizing a non-Euclidean norm. Rank-based analyses for linear models are then formulated analogous to LS analyses except this norm is substituted for the Euclidean norm. This allows a complete inference (estimation, test of linear hypotheses, confidence procedures, and diagnostic analysis of fit) for any linear model similar to LS. While in general these rank-based procedures are not distribution free, they are asymptotically distribution free. The rank-based analysis generalizes simple location rank procedures and, further, it possesses the same efficiency properties as rank procedures for simple location models. This analysis is robust to outliers in response space and can be modified to achieve high breakdown over factor space. This work on rank-based procedures has developed over the last 25 years. Monographs include the books by Hettmansperger (1984), Puri and Sen (1985), Maritz (1995), and Koul (1992). The recent monograph by Hettmansperger and McKean (1998) develops rank-based methods for location through linear models, univariate and multivariate. Discussions of robustness can be found in Hampel *et al*. (1986), Huber (1981), and Staudte and Sheather (1990).

In this article, we discuss nonparametric procedures for location models and their extension to rank-based analyses for linear models. Hettmansperger and McKean (1998) is a main reference for the methodology. Their list of references include many of the contributors who have worked on the methods discussed in this article. A more applied reference for these procedures is Hollander and Wolfe (1999).

The statistical software package Minitab (1988) contains procedures for many of these methods including rank-based analyses of linear models. Also computation of these rank-based analyses of linear models can be performed at the web site of one of the authors (http://www.stat.wmich/mckean/rank-based) or a pc-executable module can be obtained from the authors.

I. LOCATION MODELS

In this section, we consider inference procedures for one- and two-sample problems. These procedures can be used for observational studies or experimental designs. Much of our attention will focus on location problems but we will discuss scale problems at the end of the section. We will consider two-sample problems first. In terms of an experimental design, one sample represents the control (standard or placebo) while the other represents the treatment.

A. Two-Sample Location Problems

Let X denote a measurement drawn from the first population. Assume X has distribution function F and density f. Let Y denote an observation from the second population with distribution function G and density g. The natural null hypothesis is H_0: $F(x) = G(x)$; i.e., the populations are the same. Let $X_1, \ldots, X_{n_1}$ be a random sample from the first population and let $Y_1, \ldots, Y_{n_2}$ be a random sample, independent of the first, from the second population. Let $n = n_1 + n_2$ denote the size of the combined samples.

In terms of an experimental design, note that the **completely randomized design** (CRD) results in a two-sample problem. Here, n experimental units are selected at random and n_1 are randomly assigned to the control (Population I) and n_2 assigned to the treatment (Population II). The CRD, at least at the onset of the study, assures the independence within and between the sample items.

While H_0 is a natural null hypothesis, there are several interesting alternative hypotheses. One is stochastic

dominance in which Y stochastically dominates X, i.e., $G(x) \le F(x)$, with strict inequality for at least one x. For this article, unless otherwise noted, we will consider a **location model**. In this case, $G(x) = F(x - \Delta)$ for some parameter Δ. Hence, Δ is the shift in locations between the populations; for example, it is the difference in means ($\Delta = \mu_2 - \mu_1$, provided the means exist) or the difference in the population medians. In experimental design terminology, Δ is the effect between the populations. For the location model, the null hypothesis is represented by $\Delta = 0$, whereas the alternatives are usually the one- or two-sided alternatives given by

$$H_0\colon \Delta = 0 \text{ versus one of } \begin{cases} H_1\colon & \Delta > 0 \\ H_2\colon & \Delta < 0\,. \\ H_3\colon & \Delta \neq 0 \end{cases} \tag{1}$$

1. Tests

For convenience, suppose we want to test H_0 versus H_1. The **Mann–Whitney–Wilcoxon** (MWW) test procedure is to combine the two samples and then rank the items from 1 (the smallest item) to n (the largest item). Letting $R(Y_i)$ denote rank of Y_i, the test statistic is

$$T = \sum_{j=1}^{n_2} R(Y_j), \tag{2}$$

and we reject H_0 in favor of H_1 if $T \ge c$ is too large. To determine c, we need the null distribution of T. Under H_0, the Ys and Xs are drawn from the same population. Hence, any subset of n_2 elements from the set $\{1, \ldots, n\}$ are equilikely to be the chosen for the ranks of the Ys, i.e., the probability that any subset is selected is $\binom{n}{n_2}^{-1}$. Thus the null distribution of T does not depend on F. We say that T is a **distribution-free** test statistic. Tables for null distribution of T are available (see Hollander and Wolfe, 1999).

The null distribution of T is symmetric with range $\{n_2(n_2+1)/2, \ldots, n_2(n+n_1+1)/2\}$, and mean and variance

$$E_0[T] = \frac{n_2(n+1)}{2} \quad \text{and} \quad V_0[T] = \frac{n_1 n_2 (n+1)}{12}. \tag{3}$$

It also follows that the distribution of T is asymptotically normal. An asymptotically level α test is to reject H_0 in favor of H_1 if $z_T > z_\alpha$, where

$$z_T = \frac{T - E_0[T]}{\sqrt{V_0[T]}}, \tag{4}$$

$z_\alpha = \Phi^{-1}(1-\alpha)$, and Φ is the distribution function of a standard normal random variable. The asymptotic distribution provides a reasonable approximation for sample sizes as low as $n = 10$. We would, however, recommend the usual continuity correction. The asymptotic p-value using this correction is given by

$$p = 1 - \Phi\left(\frac{T - (1/2) - E_0[T]}{\sqrt{V_0[T]}}\right). \tag{5}$$

Similarly, asymptotic level α tests for H_2 or H_3 would be to reject H_0 if $z_T < -z_\alpha$ or $|z_T| > z_{\alpha/2}$, respectively.

In real data observations are often tied. The usual method for handling ties is to use the average of the ranks that would have been assigned. For example, suppose four observations all had the same value and that they would have been assigned the ranks, say, 20–23. Then each of them would be assigned the average rank, 21.5. Ties do affect the null distribution of T. Unless the number of ties is considerable, the modification is slight. For severe cases of ties, there are corrections to the variance of T available (see Hollander and Wolfe, 1999).

2. Estimation

The associated estimate of the effect Δ is obtained by **inverting** the test statistic T. Let $T(\Delta)$ be defined by

$$T(\Delta) = \sum_{j=1}^{n_2} R(Y_j - \Delta), \tag{6}$$

where $R(Y_j - \Delta)$ denotes the rank of $Y_j - \Delta$ among $X_1, \ldots, X_{n_1}$ and $Y_1 - \Delta, \ldots, Y_{n_2} - \Delta$. The associated estimate of the effect Δ, is the estimator $\hat{\Delta}$ which solves this equation

$$T(\hat{\Delta}) = E_0[T] = n_2 \frac{n+1}{2}; \tag{7}$$

hence, $\hat{\Delta}$ is the most "acceptable" null hypothesis based on the data. To obtain this point estimate, note that the rank of $Y_j - \Delta$ can be expressed as, $R(Y_j) = \#_i\{X_i < Y_j - \Delta\} + \#_i\{Y_i \le Y_j\}$. Next, define $W(\Delta) = \#_{ij}\{Y_j - X_i > \Delta\}$. By summing over j, we get the identity

$$T(\Delta) = W(\Delta) + \frac{n_2(n_2+1)}{2}. \tag{8}$$

After algebraic simplification, $\hat{\Delta}$ solves the equation,

$$W(\hat{\Delta}) = \frac{n_1 n_2}{2}. \tag{9}$$

Hence $\hat{\Delta}$ exceeds and is exceeded by half of the differences $Y_j - X_i$. Thus the associated point estimator of Δ is the **median of the differences**, i.e.,

$$\hat{\Delta} = \text{med}\{Y_j - X_i\}. \tag{10}$$

In place of the test statistic T, the equivalent test statistic $W(0)$ is often used. This version is called the **Mann–Whitney** version.

The asymptotic distribution of the estimator $\hat{\Delta}$ is

$\hat{\Delta}$ has an approximate $N\left(\Delta, \tau^2\left\{n_1^{-1}+n_2^{-1}\right\}\right)$ distribution, (11)

where τ is the scale parameter given by

$$\tau = \left(\sqrt{12}\int f^2(t)\,dt\right)^{-1}. \tag{12}$$

This is the same asymptotic distribution of the **least squares** (LS) estimator $\bar{Y}-\bar{X}$, except that the scale parameter τ replaces the LS scale parameter σ, the standard deviation of the density f.

3. Confidence Intervals

Besides a distribution-free test statistic, the Wilcoxon procedure produces a distribution-free **confidence interval**. Consider the set of $n_1 n_2$ differences $\{Y_j - X_i\}$. Denote the ordered differences by $D_{(1)} \le \cdots \le D_{(n_1 n_2)}$. Let α be given and choose $c_{\alpha/2}$ to be the lower $\alpha/2$ critical point of the MWW distribution. Then the interval $(D_{(c_{\alpha/2}+1)}, D_{(n_1 n_2 - c_{\alpha/2})})$ is a $(1-\alpha)100\%$ confidence interval for Δ. Based on the asymptotic null distribution theory for the MWW test statistic, $c_{\alpha/2}$ is approximately

$$c_{\alpha/2} \doteq \frac{n_1 n_2}{2} - z_{\alpha/2}\sqrt{\frac{n_1 n_2(n+1)}{12}} - .5. \tag{13}$$

Based on the asymptotic distribution of the estimate $\hat{\Delta}$, the interval $\hat{\Delta} \pm t_{\alpha/2,n-2}\hat{\tau}\sqrt{n_1^{-1}+n_2^{-1}}$ is an approximate $(1-\alpha)\,100\%$ symmetric confidence interval for Δ. It requires an estimate of τ which is discussed in Section II.B.

4. Efficiency

We define the **asymptotic relative efficiency** (ARE) between two asymptotically unbiased estimators to be the reciprocal of the ratio of their asymptotic variances. Hence, the ARE between the Wilcoxon and LS estimators is

$$e(\text{Wil, LS}) = \frac{\sigma^2}{\tau^2} = 12\sigma^2\left(\int f^2(t)\,dt\right)^2. \tag{14}$$

This varies with the underlying distribution. At the normal distribution, the ARE is .955; that is, the Wilcoxon procedure is 95% as efficient as the LS procedure if the true distribution is normal. If the true distribution has tails heavier than the normal then this efficiency is usually much larger than 1. An example is the contaminated normal distribution. Suppose $(1-\epsilon)100\%$ of the time the true distribution, F, is normal with standard deviation σ and $\epsilon 100\%$ of the time it is normal with standard deviation 3σ; that is, there is an $\epsilon 100\%$ probability of obtaining an outlier. For $\sigma = 3$, Table I displays the efficiencies between Wilcoxon and LS estimators for different values of ϵ. Even at 1% contamination, the Wilcoxon is more efficient.

TABLE I Efficiencies of the Wilcoxon and LS Methods for the Contaminated Normal Distribution

ϵ	.00	.01	.03	.05	.10	.15
e(Wil,LS)	.955	1.009	1.108	1.196	1.373	1.497

5. Sample Size Determination

A local approximation to the power function of the MWW test statistic can be determined similar to the asymptotic theory for the estimate. This can be used for **sample size determination** for a CRD. Consider the MWW test for the one-sided hypothesis (replace α by $\alpha/2$ for a two-sided alternative hypothesis). Suppose the level, α, and the power, γ, for a particular alternative Δ_A are specified. For convenience, assume equal sample sizes, i.e., $n_1 = n_2 = n^*$, where n^* denotes the common sample size. Under these conditions, the suggested sample size is given by

$$n^* = \left(\frac{z_\alpha - z_\gamma}{\Delta_A}\right)^2 2\tau^2. \tag{15}$$

Note that it does depend on τ which, in applications, would have to be guessed or estimated in a pilot study. For a specified distribution it can be evaluated; for instance, if the underlying density is assumed to be normal with standard deviation σ then $\tau = \sqrt{\pi/3}\sigma$. For LS, the formula for n^* would be the same, except τ would be replaced by σ. The reciprocal of the ratio of the sample sizes is the efficiency $e(\hat{\Delta}, \bar{Y}-\bar{X})$.

6. Example: Cholesterol Data

The data for this problem are drawn from a high-volume drug screen designed to find compounds which reduce low-density lipoproteins, LDL, cholesterol in quail. [See Hettmansperger and McKean (1998) for a discussion of this data set.] Here we consider the results for one drug compound. For the experiment, 30 quail were selected and 10 (Treated Group) of them (by random selection) were fed a special diet that was mixed with a drug compound while the remaining 20 (Control Group) were fed the same diet but without the drug compound. After a specified period of time, the LDL levels of the quail were measured. The data are displayed in Table II.

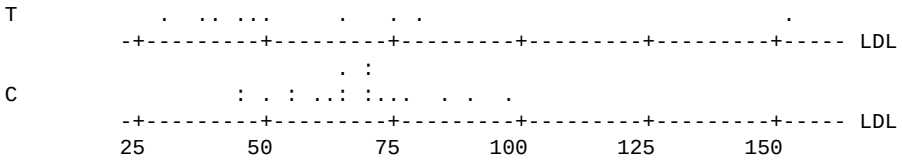
TABLE II Quail LDL Levels

Control	64	49	54	64	97	66	76	44	71	89
	70	72	71	55	60	62	46	77	86	71
Treated	40	31	50	48	152	44	74	38	81	64

Let θ_C and θ_T denote the true median levels of LDL for the control and treatment populations, respectively. The parameter of interest is $\Delta = \theta_C - \theta_T$. We are interested in the alternative hypothesis that the treatment has been effective; hence the hypotheses are

$$H_0: \Delta = 0 \text{ versus } H_A: \Delta > 0.$$

Comparison dotplots for the data are:



Note that there is one outlier, the fifth observation of the treated group, which has the value 152. For the data at hand, the treated group appears to have lower LDL levels.

The sum of the ranks of the control subjects is $T = 344.5$ (2), which leads to a standardized test value of $z_T = 1.52$ with an observed significance level of .064. The MWW indicates with marginal significance that the treatment performed better than the placebo. For comparison, the two-sample t statistic has the value $t = .56$ with a p-value of .29 which would result in the acceptance of H_0. The two-sample t analysis was impaired by the outlier.

The estimate of Δ (10) is $\hat{\Delta} = 14$ and a 90% confidence interval for Δ (13) is $(-2.01, 24.00)$. In contrast, the least squares estimate of shift is 5 and the corresponding 90% confidence interval is $(-10.25, 20.25)$.

B. Paired Designs

While the CRD is an often used design, it is usually not as efficient as the **randomized paired design** (RPD). In this design, an experimental unit is a pair or a block of length 2. For example, suppose we are testing the strength of a metal under two intensities of stress, T1 and T2. In a RPD, the piece of metal is divided in half and by random selection one of the halves is subjected to the stress level T1 while the second half is subjected to the stress level T2. At the end of the time period, let X and Y denote the strengths of the pieces under stress levels T1 and T2, respectively. Thus a pair of observations (X, Y) is obtained. In general, the data for a RPD experiment over n pairs (or blocks) consist of the pairs $(X_1, Y_1), \ldots, (X_n, Y_n)$, where X_i and Y_i denote the responses under Treatments 1 and 2, respectively, for the ith block. The observations X_i and Y_i are not independent so the two-sample analysis of the last section is not appropriate. The sample of interest, though, consists of the differences $D_1 = Y_1 - X_1, \ldots, D_n = Y_n - X_n$. Note that the target parameter remains the same, i.e., $E(D_i) = E(Y_i) - E(X_i) = \Delta$. Hence our model is

$$D_i = \Delta + e_i, \tag{16}$$

where the errors are **independent and identically distributed** (iid) with common density $h(t)$. The hypotheses of interest are given by (1).

1. Tests

For the RPD, the treatments are randomly assigned within a block. Then under the null hypothesis of no treatment effect the differences D_i are symmetrically distributed about 0 and, hence, the observations $-D_i$ and D_i should receive the same rank. These are the rankings used in the **signed-rank Wilcoxon** (**SRW**) statistic. The test statistic is given by

$$T_S = \sum_{i=1}^{n} R|D_i| \operatorname{sgn}(D_i), \tag{17}$$

where the $\operatorname{sgn}(t)$ is $1, 0$, or -1 depending on whether $t > 0$, $t = 0$ or $t < 0$, respectively. The decision is to reject $H_0: \Delta = 0$ in favor of $H_1: \Delta > 0$ if T_S is too large. Under H_0, the ranks and signs are independent of one another and the $R|D_i|$ is equilikely to be any value 1 to n. Therefore, as with the MWW test statistic, the distribution of T_S under the null hypothesis does not depend on the distribution of errors. So T_S is distribution-free under H_0. Its null distribution is symmetric with range $\{-n(n+1)/2, \ldots, n(n+1)/2\}$ and mean and variance

$$E_0[T_S] = 0 \quad \text{and} \quad V_0[T_S] = \frac{n(n+1)(2n+1)}{24}. \tag{18}$$

Tables of the null distribution can be found in Hollander and Wolfe (1999). The distribution of T_S is asymptotically normal. An asymptotically level α test is to reject H_0 if $z > z_\alpha$, where

$$z = \frac{T_S - E_0[T_S]}{\sqrt{V_0[T_S]}}. \tag{19}$$

The asymptotic distribution provides a reasonable approximation for sample sizes as low as $n = 10$. We would, however, recommend the usual continuity correction. For testing $H_0: \Delta = 0$ versus $H_1: \Delta > 0$, the asymptotic p-value using this correction is given by

$$p = 1 - \Phi\left(\frac{T_S - (1/2)}{\sqrt{V_0[T_S]}}\right). \quad (20)$$

2. Estimation

Following Section I.A, the estimate of Δ solves the equation $T_S(\Delta) = 0$, where $T_S(\Delta) = \sum_{i=1}^{n} R|D_i - \Delta| \operatorname{sgn}(D_i - \Delta)$. We can obtain a closed form solution by using the identity $T_S(\Delta) = 2U(\Delta) - (n(n+1)/2)$, where

$$U(\Delta) = \#_{i \le j}\left\{\frac{D_i + D_j}{2} > \Delta\right\}. \quad (21)$$

Thus the estimate solves the equation $U(\Delta) = (n(n+1)/4)$. Because there are $n(n+1)/2$ pairwise averages, the solution is

$$\hat{\Delta} = \underset{i \le j}{\text{med}}\left\{\frac{D_i + D_j}{2}\right\}. \quad (22)$$

This is often called the **Hodges–Lehmann** estimate.

The asymptotic distribution of the estimator $\hat{\Delta}$ is

$$\hat{\Delta} \text{ has an approximate } N(\Delta, \tau^2 n^{-1}) \text{ distribution,} \quad (23)$$

where τ is the scale parameter given by (12).

3. Confidence Intervals

Besides a distribution-free test statistic, the SRW procedure produces a distribution-free **confidence interval**. Consider the set of $M = n(n+1)/2$ pairwise averages $\{(D_i + D_j)/2\}$. Denote these ordered averages by $V_{(1)} \le \cdots \le V_{(M)}$. Let α be given and choose $c_{\alpha/2}$ to be the lower $\alpha/2$ critical point of the SRW distribution. Then the interval $(V_{(c_{\alpha/2}+1)}, V_{(M-c_{\alpha/2})})$ is a $(1-\alpha)100\%$ confidence interval for Δ. Based on the asymptotic null distribution theory for the signed-rank test statistic, $c_{\alpha/2}$ is approximately

$$c_{\alpha/2} \doteq \frac{n(n+1)}{4} - z_{\alpha/2}\sqrt{\frac{n(n+1)(2n+1)}{24}} - .5. \quad (24)$$

The interval $\hat{\Delta} \pm t_{\alpha/2,n-2}\hat{\tau}/\sqrt{n}$ is an approximate $(1-\alpha)100\%$ symmetric confidence interval for Δ.

4. Efficiency

The ARE between the SRW and LS procedures is the same as that between the MWW and the LS procedures in the two-sample location problem. The formula is given by (14) except that $f(t)$ is replaced by $h(t)$ the density of the errors in the paired model (16) and σ^2 is the variance of this density. Hence, if the errors are normally distributed then SRW procedures are 95% as efficient as LS procedures.

5. Sample Size Determination

Consider the signed-rank Wilcoxon test for the one-sided hypothesis (replace α by $\alpha/2$ for a two-sided alternative hypothesis). Suppose the level, α, and the power, γ, for a particular alternative Δ_A are specified. Let n denote the number of pairs or blocks to be selected. Under these conditions, the recommended number of pairs is given by

$$n = \left(\frac{z_\alpha - z_\gamma}{\Delta_A}\right)^2 \tau^2. \quad (25)$$

Note that it does depend on τ which, in applications, would have to be guessed or estimated in a pilot study. As in the two-sample location problem, if the underlying density of the errors is assumed to be normal with standard deviation σ then $\tau = \sqrt{\pi/3}\sigma$. For LS, the formula for n would be the same, except τ would be replaced by σ.

6. Example: Darwin Data

The data in Table III are measurements recorded by Charles Darwin in 1878. They consist of 15 pairs of heights in inches of cross-fertilized plants and self-fertilized plants (*Zea mays*), each pair grown in the same pot.

Let D_i denote the difference between the heights of the cross-fertilized and self-fertilized plants of the ith pot and let Δ denote the median of the distribution of D_i. Suppose we are interested in testing for an effect; that is, the hypotheses are H_0: $\Delta = 0$ versus H_A: $\Delta \neq 0$. The value of the signed-rank Wilcoxon statistic, (17), for these data is $T_S = 36$ with the approximate p value of .044.

TABLE III Heights of Plants

Pot	1	2	3	4	5	6	7	8
Cross-	23.500	12.000	21.000	22.000	19.125	21.500	22.125	20.375
Self-	17.375	20.375	20.000	20.000	18.375	18.625	18.625	15.250
Pot	9	10	11	12	13	14	15	
Cross-	18.250	21.625	23.250	21.000	22.125	23.000	12.000	
Self-	16.500	18.000	16.250	18.000	12.750	15.500	18.000	

The corresponding estimate of Δ is 3.13 in. and the 95% confidence interval is (.50, 5.21). The paired t-test statistic has the value of 2.15 with p value .050. The difference in sample means is 2.62 in. and the corresponding 95% confidence interval is (0, 5.23). The difference between the analyses is due to the possible outlying differences in Pots 2 and 15.

7. Paired Designs Where Pairing Is Not Randomized

There are of course designs where the pairing not randomized. An example is before and after designs. For such designs, the differences are still modeled as in (16) except that the errors are not necessarily symmetrically distributed under the null hypothesis. If symmetry is violated then the SRW test may not be distribution free under H_0. As with any analysis, we would recommend diagnostic checks such as q–q plots and boxplots to examine violations of symmetry. The following procedure is distribution free regardless of symmetry but it is not as efficient as the SRW procedure.

Consider the model (16) for the paired differences where the errors e_i are iid with common density $h(t)$ which has median 0 but which is not necessarily symmetric. Thus Δ is the population median of the D_is. The hypotheses of interest remain the same; for instance, the one-sided hypothesis that we have been discussing is still given by H_0: $\Delta = 0$ versus H_1: $\Delta > 0$. The **sign** test statistic is given by

$$S = \#_i\{D_i > 0\}. \tag{26}$$

Because the D_is are independent and identically distributed (under both H_0 and H_A), S has a **binomial** distribution with n trials and probability of success, $p = P[D_i > 0]$. We will denote this binomial distribution by $b(n, p)$. Under the null hypothesis, the median of the differences is 0; hence, S has a $b(n, 1/2)$ distribution. Thus S is distribution free under H_0. Under alternatives, though, p, and hence the distribution of S, depend on the distribution function of the errors F. Tables of the $b(n, 1/2)$ distribution are available (see Hollander and Wolfe, 1999).

The null mean and variance of S are given by

$$E_0[S] = \tfrac{n}{2} \quad \text{and} \quad V_0[S] = \tfrac{n}{4}. \tag{27}$$

The distribution of S is asymptotically normal. The large sample test rejects H_0 in favor of H_1 if $z \geq z_\alpha$, where $z = (S - E_0[S])/\sqrt{V_0[S]}$. We do caution the reader somewhat on this large sample approximation because the sign test statistic is much more discrete than the signed-rank Wilcoxon test statistic. The range of the sign test statistic consists of $n + 1$ values while the range of the SRW statistic consists of $n(n + 1) + 1$ values. Asymptotic normality sets in much faster for the SRW statistic.

The estimate of Δ corresponding to the sign test is the **median** of the differences, i.e., $\tilde{D} = \text{med}_i\, D_i$. Its asymptotic distribution is given by

$$\tilde{D} \text{ has an approximate } N\left(\Delta, \tau_S^2 n_1^{-1}\right) \text{ distribution,} \tag{28}$$

where τ_S is the scale parameter given by

$$\tau_S = (2h(0))^{-1}. \tag{29}$$

Estimates of τ_S are discussed in Section II.F.

The corresponding distribution-free confidence interval for Δ is the interval $(D_{(c_{\alpha/2}+1)}, D_{(n-c_{\alpha/2})})$, where $c_{\alpha/2}$ is the lower $\alpha/2$ critical point of the $b(n, 1/2)$ distribution. Based on asymptotic distribution of the sign test, $c_{\alpha/2}$ can be approximated as

$$c_{\alpha/2} \doteq \frac{n}{2} - z_{\alpha/2}\sqrt{\frac{n}{4}} - .5. \tag{30}$$

The ARE between sign test procedures and LS procedures is given by $e(\tilde{D}, \bar{D}) = 4h^2(0)\sigma^2$. If $h(t)$ is a normal density then $e(\tilde{D}, \bar{D}) = .63$ which is much lower than the ARE of the Wilcoxon procedures. On the other hand, if the error density $h(t)$ has very thick tails then the sign procedures can be considerably more efficient then the LS procedures. For comparisons Table IV presents the AREs of between the sign and LS procedures and between the Wilcoxon and LS procedures over the same family of contaminated normals used in Table I.

For sample size determination, simply replace τ in expression (25) by τ_S.

8. Example: Darwin Data, Continued

To illustrate the sign test, we use the Darwin data disscussed earlier. Out of the 15 differences, 13 are positive; hence, the sign test has an approximate p value of .0074. The corresponding estimate of θ is 3 in. and the approximate 95% confidence interval is (1.000, 6.125).

C. One-Sample Location Models

Let $X_1, \ldots, X_n$ be a random sample from a population of interest. Consider the location model,

TABLE IV Efficiencies of the Wilcoxon and LS Methods for the Contaminated Normal Distribution

ϵ	.00	.01	.03	.05	.10	.15
e(Wil, LS)	0.955	1.009	1.108	1.196	1.373	1.497
e(Sign, LS)	0.637	0.678	0.758	0.833	1.000	1.134

$$X_i = \theta + e_i; \qquad 1 \le i \le n, \tag{31}$$

where the random errors e_i are iid with density $h(t)$ which has median 0. Hence, θ is the median of X_i. Of course, we have already discussed this problem in the last section. The differences D_i form a single sample. Therefore the inference concerning Δ of the last section forms a complete inference (testing, estimation, and confidence intervals) for the parameter θ of this section. In particular, if we further assume that the density $h(t)$ is symmetric about 0 then the inference based on the SRW procedures can be used for θ. If this assumption cannot be made then inference based on the sign test procedures can be employed.

D. Robustness Properties

The robustness concepts, influence and breakdown, will be useful in the sequel and are easiest to describe in the one-sample setting. Let $\mathbf{X} = (X_1, \ldots, X_n)'$ be a sample from a population which has density $h(t)$ and an unknown parameter θ. Let $\hat{\theta}_n$ be an estimator of θ. The influence function of $\hat{\theta}_n$ measures the local sensitivity of $\hat{\theta}_n$ to an outlier while the breakdown point of $\hat{\theta}_n$ measures global senstivity to outliers. We first proceed with the influence function.

Let X^* be an additional point, an outlier, to the sample. Let $\hat{\theta}_{n+1}$ be the estimate based on the combined sample $(\mathbf{X}', X^*)'$. Then the rate of change of the estimator due to this outlier is

$$\frac{\hat{\theta}_{n+1} - \hat{\theta}_n}{1/(n+1)} \approx \Lambda(X^*). \tag{32}$$

The expression on the right is called the **sensitivity curve** of the estimator $\hat{\theta}_n$. It is a rate of change, a type of derivative. Hampel made this precise at the population model and called it the **influence function** of $\hat{\theta}_n$, which we will label as $\Lambda(X^*; \hat{\theta}_n)$. By (32), we have approximately that

$$\hat{\theta}_{n+1} \approx \hat{\theta}_n + \frac{1}{n+1}\Lambda\big(X^*; \hat{\theta}_n\big). \tag{33}$$

Thus, the influence function measures local sensitivity to an outlier. Assuming the estimate on a "good" sample is unbiased, then $\Lambda(X^*: \hat{\theta}_n)$ is a measure of the bias due to the outlier. Clearly, we want the influence function to be bounded; otherwise, the biasness can grow without bound as the outlier increases. We say an estimator is **bias robust** if its influence function is bounded.

It is easy to see that the influence function for the sample mean is $\Lambda(X^*; \bar{X}) = X^*$; hence, the bias of the mean is directly proportional to the outlier. The sample mean is not robust. On the other hand, the influence function of the sample median, $\tilde{X}$ is given by

$$\Lambda(X^*; \tilde{X}) = \frac{\text{sgn}(X^*)}{2h(0)},$$

which is bounded by $(2h(0))^{-1}$. Hence the sample median is robust. Next consider the Hodges–Lehmann estimate, $\hat{\theta}_{HL} = \text{med}_{i \le j}\,\{(X_i + X_j)/2\}$. Let $H(t)$ denote the distribution function corresponding to the density $h(t)$. The influence function of $\hat{\theta}_{HL}$ is given by

$$\Lambda(X^*; \hat{\theta}_{HL}) = \sqrt{12}\tau(H(X^*) - 1/2),$$

which is bounded by $\sqrt{12}\tau$ and, hence, the Wilcoxon estimate is also robust.

Similar results occur in the two-sample problem. The Wilcoxon estimate (median of differences) has bounded influence while the LS estimate (difference in the sample means) is not robust.

Next consider breakdown. As cited here, consider the sample $\mathbf{X} = (X_1, \ldots, X_n)'$ and an estimator $\hat{\theta}$. Suppose we corrupt m of the data points. Write the corrupted sample as $\mathbf{X}^{(m)} = (X_1^*, \ldots, X_m^*, X_{m+1}, \ldots, X_n)'$. Now think of the corrupt points as getting arbitrarily large. The smallest proportion of corrupt data points that results in the complete breakdown of $\hat{\theta}$ (i.e., $|\hat{\theta}|$ gets arbitrarily large) is the **finite sample breakdown** of $\hat{\theta}$. If this proportion has a limit as n gets large, we call it the **breakdown point** of $\hat{\theta}$. For example, consider the sample mean. If we corrupt one data point and drive it to infinity then $\bar{X}$ goes to infinity; hence, the finite sample breakdown of $\bar{X}$ is $1/n$ and thus its breakdown point is 0. On the other hand, we would have to corrupt half the data to breakdown the sample median, $\tilde{X}$. So the sample median has 50% breakdown. This is the largest value for a breakdown point. The Hodges–Lehmann estimate, $\hat{\theta}_{HL}$, has a breakdown point of 29%.

This discussion on breakdown extends to the two-sample problem also. In this case, though, the issue of the two sample sizes must be addressed. If the sample sizes are the same, $n_1 = n_2$ then the maximal breakdown point of an estimator is .25. The difference in sample means has breakdown 0, while the median of the differences has the maximal breakdown value of .25.

E. Two-Sample Scale Problem

In the two-sample problem, suppose the distribution functions of X and Y are given by $F_X(x) = F(x - \theta_X)$ and $F_Y(y) = F((y - \theta_Y)/\eta)$, respectively. The null hypothesis of interest is that the scales are the same, i.e.,

$$H_0: \eta = 1 \text{ versus } H_3: \eta \ne 1, \tag{34}$$

or it could be an appropriate one-sided alternative. Under the null hypothesis, $\eta = 1$, the distributions of $Y - \theta_Y$ and $X - \theta_X$ are the same. The only truly distribution-free tests for this problem are under the assumption that the

locations of X and Y are the same. In practice, though, this is an unsavory assumption. Often this hypothesis is tested before the test on locations. We instead present an asymptotically distribution-free procedure which has been shown to perform well in a Monte Carlo study over a large variety of practical situations (see Conover *et al.*, 1981). There are problems with traditional statistical tests in this area. The traditional (LS) two-sample F test for scales is only truly valid if X and Y have normal distributions. In the Monte Carlo study cited, the traditional F test had very poor performance in most situations. Its empirical α levels were much more liberal than the nominal levels. [It does not posssess robustness of validity; see also, Arnold (1981), Box (1953), and Hettmansperger and McKean (1998).]

Our strategy is to align the observations first and then employ the rank statistics on these aligned samples. Let $X_i^* = X_i - \hat{\theta}_X$ and $Y_j^* = Y_j - \hat{\theta}_Y$ denote the aligned observations, where $\hat{\theta}_X$ and $\hat{\theta}_Y$ are the sample medians of the X and Y samples, respectively. Next fold the aligned samples; i.e., obtain their absolute values. Combine these folded–aligned samples and rank them from low to high. Let $R(|Y_j^*|)$'s denote the ranks of folded–aligned Y samples. The **Fligner–Killeen** test statistic is given by

$$S_{FK}^* = \sum_{j=1}^{n_2} \left(\Phi^{-1}\left(\frac{R|Y_j^*|}{2(n+1)} + \frac{1}{2} \right) \right)^2. \tag{35}$$

The statistic S_{FK}^* is not distribution free for finite samples. If we further assume, however, that the distributions of X and Y are symmetric, then the test statistic S_{FK}^* is asymptotically distribution free. The null mean μ_{FK} and null variance σ_{FK}^2 of the statistic are given by

$$\mu_{FK} = n_2\bar{a} \quad \text{and} \quad \sigma_{FK}^2 = \frac{n_1 n_2}{n(n-1)} \sum (a(i) - \bar{a})^2, \tag{36}$$

where $a(i) = (\Phi^{-1}((i/(2(n+1))) + (1/2)))^2$. The asymptotic version of this test statistic rejects H_0 in favor of H_3 at the approximate level α if $|z_{FK}| \geq z_{\alpha/2}$, where

$$z_{FK} = \frac{S_{FK}^* - \mu_{FK}}{\sigma_{FK}}. \tag{37}$$

II. LINEAR MODELS

Suppose the responses $Y_1, \ldots, Y_n$ follow a linear model of the form

$$Y_i = \alpha + \mathbf{x}_i\boldsymbol{\beta} + e_i; \quad 1 \leq i \leq n, \tag{38}$$

where $\mathbf{x}_i$ is a $p \times 1$ vector of constants, the random errors e_i are iid with distribution function $F(t)$ and density $f(t)$, and α and the $p \times 1$ vector $\boldsymbol{\beta}$ are unknown parameters. The parameter α is the intercept parameter and the β_js are the slope parameters. We will often treat the intercept and slope parameters separately because we want to allow for skewed error distributions. (See, for example, Section IV on survival analysis.) Further, because we are including an intercept there is no loss in generality in assumimg that the predictors are centered, i.e., $\sum_{i=1}^n x_{ij} = 0$ for all j. Let $\mathbf{Y} = (Y_1, \ldots, Y_n)'$ be the vector of responses, let $\mathbf{X}_c$ be the $n \times p$ matrix of regression constants x_{ij} (subscript c denotes centered), and let $\mathbf{1}$ denote an $n \times 1$ vector of ones. Then we can write this model equivalently as

$$\mathbf{Y} = \alpha\mathbf{1} + \mathbf{X}_c\boldsymbol{\beta} + \mathbf{e}, \tag{39}$$

where $\mathbf{e}$ is the $n \times 1$ vector of errors. Let Ω denote the p-dimensional column space of $\mathbf{X}_c$. Then a third way to write the model is

$$\mathbf{Y} = \alpha\mathbf{1} + \boldsymbol{\eta} + \mathbf{e}; \boldsymbol{\eta} \in \Omega. \tag{40}$$

In this last formulation, estimation is easily described. We need to find a vector $\hat{\boldsymbol{\eta}} \in \Omega$ which lies "closest" to $\mathbf{Y}$, where "closest" is defined in terms of a distance function. In the case of LS, the Euclidean distance function is used, whereas for the Wilcoxon the distance function defined in the following is used.

We present a complete robust analysis of the linear model (39) including estimation, tests of linear hypotheses, confidence procedures, and diagnostics to check quality of fit. The estimation is based on the work of Jaeckel (1972) and the analysis is based on the work of McKean and Hettmansperger (1976, 1978). [See Hettmansperger and McKean (1998) for a complete discussion.] These are rank procedures based on a fit of a linear model and we will call it a **rank-based analysis**. If Wilcoxon scores are used we will label it as the **Wilcoxon analysis**.

A. Wilcoxon Regression Estimates

First we will briefly review the LS estimates. Since we have an intercept parameter, we can obtain the LS estimates in two parts. The estimate of $\boldsymbol{\eta}$ is given by

$$\hat{\boldsymbol{\eta}}_{LS} = \underset{\boldsymbol{\eta} \in \Omega}{\text{Argmin}} \|\mathbf{Y} - \boldsymbol{\eta}\|_{LS}, \tag{41}$$

where the norm is defined by

$$\|\mathbf{v}\|_{LS} = \sqrt{\sum_{i,j} |v_i - v_j|^2}; \quad \mathbf{v} \in R^n. \tag{42}$$

Argmin is an abreviation for the value of the argument $\boldsymbol{\eta}$ which minimizes the distance between $\mathbf{Y}$ and the subspace Ω. Using matrix algebra we get, $\hat{\boldsymbol{\eta}}_{LS} = \mathbf{H}_c\mathbf{Y}$, where $\mathbf{H}_c$ is the projection matrix $\mathbf{H}_c = \mathbf{X}_c(\mathbf{X}_c'\mathbf{X}_c)^{-1}\mathbf{X}_c'$. The LS estimate of $\boldsymbol{\beta}$ solves the equation

$$\mathbf{X}_c\boldsymbol{\beta} = \hat{\boldsymbol{\eta}}_{LS}, \tag{43}$$

i.e., $\hat{\boldsymbol{\beta}}_{LS} = (\mathbf{X}_c'\mathbf{X}_c)^{-1}\mathbf{X}_c'\mathbf{Y}$. The LS estimate of the intercept is the average of the LS residuals

$$\hat{\alpha}_{LS} = n^{-1}\sum_{i=1}^{n}(Y_i - \hat{\eta}_{LS,i}). \tag{44}$$

For the Wilcoxon estimates, we simply change the norm from the Euclidean (42) norm to the norm,

$$\|\mathbf{v}\|_W = \kappa\sum_{i,j}|v_i - v_j|, \quad \mathbf{v} \in R^n, \tag{45}$$

where $\kappa = 2(n+1)/\sqrt{3}$. The constant κ is irrelevant for the minimization but it does simplify later expressions. Then the **Wilcoxon regression** estimate of $\boldsymbol{\eta}$ is

$$\hat{\boldsymbol{\eta}}_W = \underset{\boldsymbol{\eta}\in\Omega}{\text{Argmin}}\|\mathbf{Y} - \boldsymbol{\eta}\|_W. \tag{46}$$

The estimate cannot be obtained in closed form, but since it is defined in terms of a norm, its computation requires the minimization of a convex function for which there are several good algorithms available; for example, Minitab (1988) or at the web site of one of the authors (http://www.stat.wmich/mckean/rank-based) or a pc-executable module can be obtained from the authors.

Once $\hat{\boldsymbol{\eta}}_W$ is obtained the Wilcoxon estimate of $\boldsymbol{\beta}$ solves,

$$\mathbf{X}_c\boldsymbol{\beta} = \hat{\boldsymbol{\eta}}_W, \tag{47}$$

i.e., $\hat{\boldsymbol{\beta}}_W = (\mathbf{X}_c'\mathbf{X}_c)^{-1}\mathbf{X}_c'\hat{\boldsymbol{\eta}}_W$. There are several estimates available for the intercept, but since we want to allow for skewed error distributions, the median of the residuals seems appropriate; i.e.,

$$\hat{\alpha}_S = \underset{i}{\text{med}}\{Y_i - \hat{\eta}_{W,i}\}. \tag{48}$$

The asymptotic distribution of the Wilcoxon estimates is given by

$$\hat{\mathbf{b}}_W = \begin{pmatrix}\hat{\alpha}_S\\ \hat{\boldsymbol{\beta}}_W\end{pmatrix} \text{ has an approximate } N_{p+1} \times\left(\begin{pmatrix}\alpha\\ \boldsymbol{\beta}\end{pmatrix}, \begin{bmatrix} n^{-1}\tau_S^2 & \mathbf{0}'\\ \mathbf{0} & \tau^2(\mathbf{X}_c'\mathbf{X}_c)^{-1}\end{bmatrix}\right) \text{ distribution,} \tag{49}$$

where the scale parameters τ_S and τ are given, respectively, by (29) and (12). Note that the asymptotic variance of $\hat{\boldsymbol{\beta}}_W$ differs from the asymptotic variance of the LS only by the constant of proportionality, τ^2 for the Wilcoxon and σ^2 for LS. Thus the efficiency properties of the Wilcoxon regression estimates to the LS regression estimates are the same as those in the simple location problems. As we will discuss in Section III, these Wilcoxon regression estimates have bounded influence in the **Y**-space, but unbounded influence in the **x**-space.

For later use, define the $\|\cdot\|_W$-distance between $\mathbf{Y}$ and Ω by

$$d_W(\mathbf{Y}, \Omega) = \|\mathbf{Y} - \hat{\boldsymbol{\eta}}_W\|_W. \tag{50}$$

Also, we can write the Wilcoxon norm as

$$\|\mathbf{v}\|_W = \sum_{i}^{n} a(R(v_i))v_i, \tag{51}$$

where $R(v_i)$ denotes the rank of v_i among $v_1, \ldots, v_n$ and $a(i) = \varphi_W(i/(n+1))$ and $\varphi_W(u) = \sqrt{12}(u - (1/2))$. This linear function $\varphi_W(u)$ is called the **Wilcoxon score function**. Finally, consider the norm as a function of $\boldsymbol{\beta}$, i.e.,

$$D(\boldsymbol{\beta}) = \sum_{i}^{n} a(R(Y_i - \mathbf{x}_i'\boldsymbol{\beta}))(Y_i - \mathbf{x}_i'\boldsymbol{\beta}). \tag{52}$$

This is a convex, continuous function of $\boldsymbol{\beta}$. It is often called Jaeckel's (1972) **dispersion function**. Note that the ranks involved are ranks of residuals, not of observations. Upon fitting, the residuals are estimates of iid random variables, so the ranking is similar to use of the ranking in the location models, Section I. Since the estimates are rank-based they are often referred to as **R** estimates.

B. Confidence Intervals

Formulae for approximate confidence intervals for the regression parameters based on the Wilcoxon estimates follow from the asymptotic distribution. Let $\hat{e}_{Wi} = Y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}_W$ denote the Wilcoxon residuals. Let $\hat{\tau}_S$ and $\hat{\tau}$ be the estimates of τ_S and τ based on these residuals that are discussed Section II.F. Then, in particular, $(1-\alpha)100\%$ confidence intervals for β_j and for a linear combination $\mathbf{h}'\boldsymbol{\beta}$ are given by

$$\hat{\beta}_{Wj} \pm t_{\alpha/2,n-(p+1)}\hat{\tau}\sqrt{(\mathbf{X}_c'\mathbf{X}_c)_{jj}^{-1}} \tag{53}$$

$$\mathbf{h}'\hat{\boldsymbol{\beta}}_W \pm t_{\alpha/2,n-(p+1)}\hat{\tau}\sqrt{\mathbf{h}'(\mathbf{X}_c'\mathbf{X}_c)^{-1}\mathbf{h}}, \tag{54}$$

where $t_{\alpha/2,n-(p+1)}$ is the upper $(1-\alpha/2)$ Student t-critical value with $n-(p+1)$ degrees of freedom and $(\mathbf{X}_c'\mathbf{X}_c)_{jj}^{-1}$ is the jth diagonal entry of the matrix $(\mathbf{X}_c'\mathbf{X}_c)^{-1}$. These are the same confidence intervals one would use for a LS analysis except the scale parameter τ would be replaced by σ.

C. Tests of Linear Hypotheses

Hypotheses of interest in linear models are usually expressed as a linear function of the vector of parameters $\boldsymbol{\beta}$, i.e.,

$$H_0: \mathbf{M}\boldsymbol{\beta} = \mathbf{0} \text{ versus } H_A: \mathbf{M}\boldsymbol{\beta} \neq \mathbf{0}, \tag{55}$$

where $\mathbf{M}$ is a $q \times p$ matrix of rank q. Let ω denote the $p-q$ dimensional subspace of Ω constrained by H_0; that is, $\omega = \{\boldsymbol{\eta} \in \Omega \mid \boldsymbol{\eta} = X_c\boldsymbol{\beta} \,\&\, \mathbf{M}\boldsymbol{\beta} = \mathbf{0}\}$. In this terminology, Ω is the full model subspace and ω is the reduced model subspace, i.e., the full model constrained by H_0. As shown, let $d(\mathbf{Y}, \Omega)$ and $d(\mathbf{Y}, \omega)$ be the "distances" between $\mathbf{Y}$ and each of the subspaces and let $RD = d(\mathbf{Y}, \omega) - d(\mathbf{Y}, \Omega)$ denote the reduction in distance as we pass from the full to the reduced model. Small values of RD indicate H_0 while large values indicate H_A; hence, we reject H_0 in favor of H_A, if RD is too large. If d is the squared Euclidean distance function then RD is the traditional reduction in sums of squares. If d_W is the Wilcoxon normed distance function, (50), then we will call RD the **reduction in dispersion** and label it as RD_W, i.e.,

$$RD_W = d_W(\mathbf{Y}, \omega) - d_W(\mathbf{Y}, \Omega). \tag{56}$$

A formal test statistic is given by

$$F_W = \frac{RD_W/q}{\hat{\tau}/2}. \tag{57}$$

The null asymptotic distribution of F_W is given by,

qF_W has an approximate $\chi^2(q)$ distribution under $H_0: \mathbf{M}\boldsymbol{\beta} = \mathbf{0}$, (58)

where $\chi^2(q)$ denotes a χ^2 distribution with q degrees of freedom. Empirical evidence has shown, though, that F-critical values yield better small-sample properties. An approximate level α test is

Reject $H_0: \mathbf{M}\boldsymbol{\beta} = \mathbf{0}$ in favor of $H_A: \mathbf{M}\boldsymbol{\beta} \neq \mathbf{0}$ if

$$F_W \geq F(\alpha, q, n-(p+1)), \tag{59}$$

where $F(\alpha, q, n-(p+1))$ denotes the upper α F-critical value with q and $n-(p+1)$ degrees of freedom. The test can be described in an ANOVA table that is quite similar to the traditional ANOVA table (See example in Section V.)

Besides the null behavior, the asymptotic distribution of F_W can be obtained for local alternatives. For the local alternative $\mathbf{M}\boldsymbol{\beta}^* \neq \mathbf{0}$, the asymptotic distribution of F_W is given by

qF_W has an approximate $\chi^2(q, \delta)$ with noncentrality parameter:

$$\delta = \tau^{-2}(\mathbf{M}\boldsymbol{\beta}^*)'\left[\mathbf{M}(\mathbf{X}_c\mathbf{X}_c')^{-1}\mathbf{M}'\right]^{-1}(\mathbf{M}\boldsymbol{\beta}^*). \tag{60}$$

This is the same noncentral χ^2 distribution of the LS traditional F-test statistic, except τ^2 replaces σ^2. In particular, the Wilcoxon F-test has the same efficiency properties as the Wilcoxon tests and estimates in the simple location problems. Furthermore, in the design of experiments, sample size determination can be obtained similar to the determination based on the traditional F-test, except for the use of τ^2 in place of σ^2.

Consider the special case where we are testing that all the β's are 0. For this situation, the reduced subspace is $\omega = \{\mathbf{0}\}$. Hence $d(\omega, \mathbf{Y}) = D(\mathbf{0})$, where D is the dispersion function (52) (see Section II.E).

D. Example: Telephone Data

We will illustrate Wilcoxon estimation and testing for a simple linear regression example. The response for this data set is the number of telephone calls (Table V) (tens of millions) made in Belgium for the years 1950 through 1973 and time, the years, is the predictor variable. [See Hettmansperger and McKean (1998) for original references.]

The Wilcoxon estimates of the intercept and slope are -7.13 and .145, respectively, while the LS estimates are -26 and .504. The estimate of τ is 2.90. The reason for this disparity in fits is easily seen in Panel A of Fig. 1 which is a scatterplot of the data overlaid with the LS and Wilcoxon fits. Note that the years 1964 through 1969 had a profound effect on the LS fit, whereas the Wilcoxon fit was much less sensitive to these years. The recording system for the years 1964 through 1969 differed from the other years. Panels B and C of Fig. 1 are the Studentized (see Section II.G.2) residual plots of the fits. Studentized residuals which exceed 2 in absolute value are potential outliers. Note that the internal Wilcoxon Studentized residuals clearly show that the years 1964–1969 are outliers while the internal LS Studentized residuals only detect 1969.

Panel D of Fig. 1 depicts the Wilcoxon dispersion function (52) over the interval $(-.2, .6)$. Note that Wilcoxon estimate $\hat{\beta}_R = .145$ is the minimizing value and that in the previously cited notation the minimum value $D(.145)$ is $d_W(\mathbf{Y}, \Omega)$. Next consider the hypotheses $H_0: \beta = 0$ versus $H_A: \beta \neq 0$. Note from the plot that the reduction in dispersion is given by $RD_W = D(0) - D(.145)$.

E. Coefficients of Multiple Determination

The LS coefficient of multiple determination R^2 is associated with the test of the hypothesis that all the slope parameters are 0, i.e.,

$$H_0: \boldsymbol{\beta} = \mathbf{0} \text{ versus } H_A: \text{at least one } \beta_j \neq 0. \qquad (61)$$

The statistic R^2 is the ratio in reduction in sums of squares (due to H_0) to the total variation. An immediate Wilcoxon analog to this would be the ratio of the reduction in dispersion to the **total dispersion** ($\|\mathbf{Y}\|_W = \sum\sum |Y_i - Y_j|$). For R^2 there are two sources of nonrobustness: the reduction in sums of squares and the total variation. For this analog, while the reduction in dispersion is robust, the total dispersion is not. There is a simple robust analog, however. The statistic R^2 can be written also as $R^2 = (\kappa_{n,p} F_{LS}/(1 + \kappa_{n,p} F_{LS})$, where $\kappa_{n,p} = p/(n - (p+1))$, and F_{LS} is the LS F-test for the hypotheses (61). If we replace F_{LS} by F_W we get

$$R_W = \frac{\kappa_{n,p} F_W}{1 + \kappa_{n,p} F_W}. \qquad (62)$$

Because the Wilcoxon test statistic F_W is robust, it follows that R_W is robust.

F. Estimates of the Scale Parameters τ and τ_S

The constant of proportionality τ plays a key role in the Wilcoxon analysis. In this section we define a consistent estimate of τ.

Assume we have obtained the Wilcoxon fit of the model (39). Let $\hat{\mathbf{e}}_W$ denote the vector of residuals and let $\varphi_W(u) = \sqrt{12}(u - (1/2))$ denote the Wilcoxon score function. Define the following empirical distribution function of these residuals,

$$\hat{H}_n(y) = \frac{1}{c_n n} \sum_{i=1}^{n} \sum_{j=1}^{n} \varphi_W\left(\frac{j}{n+1}\right) I\left(\left|\hat{e}_{W(i)} - \hat{e}_{W(j)}\right| \le y\right), \tag{63}$$

where $\hat{e}_{W(i)}$ denotes the ith ordered residual and $c_n = \sum_{j=1}^{n} \varphi_W(j/(n+1))$ is such that $\hat{H}_n$ is a distribution function; i.e., $\hat{H}_n(\infty) = 1$.

Let $\gamma = \tau^{-1}$. Since $\hat{H}_n$ is a distribution function, let $\hat{t}_{n,\delta}$ denote the δth quantile of $\hat{H}_n$; i.e., $\hat{t}_{n,\delta} = \hat{H}_n^{-1}(\delta)$. Then take $t_n = t_{n,\delta}/\sqrt{n}$. Our estimate of γ is given by

$$\hat{\gamma}_{n,\delta} = \frac{(\varphi_W(1) - \varphi_W(0))\hat{H}_n(t_{n,\delta}/\sqrt{n})}{2t_{n,\delta}/\sqrt{n}}. \tag{64}$$

The expression (63) for $\hat{H}_n$ contains a density estimate of f based on a rectangular kernel. Hence, in choosing δ we are really choosing a bandwidth for a density estimator. As most kernel type density estimates are sensitive to the bandwidth, $\gamma^*_{n,\delta}$ is sensitive to δ. Several small-sample studies have been done on this estimate to investigate the validity of procedures standardized by it. [See McKean and Shteather (1991) for a summary.] For moderate sample sizes where the ratio of n/p exceeds 5, the value of $\delta = .80$ yielded reasonable valid procedures. For ratios less than 5, larger values of δ, .95, yielded reasonable valid procedures. In all cases it was found that the following simple degrees of freedom correction benefited the analysis

$$\hat{\tau} = \sqrt{\frac{n}{n-p-1}}\hat{\gamma}^{-1}. \tag{65}$$

Note that this is similar to the least squares correction on the maximum likelihood estimate (under normality) of the variance. This last expression is the estimate of τ used in the sequel with $\delta = .80$.

The length of an asymptotically distribution-free 95% confidence interval for the intercept provides a simple, but reasonably valid estimate for τ_S. This is given by

$$\hat{\tau}_S = \sqrt{n}\left[\hat{e}_{W,(n/2+n^{1/2})} - \hat{e}_{W,(n/2-n^{1/2})}\right]/4. \tag{66}$$

G. Diagnostics

The assumption of a linear model is a major assumption, one that should be checked based on the data. There are many diagnostics available for Wilcoxon fits and in this section we look at several important checks.

1. Residual Plots

The major assumption of a linear model is that the errors are iid. In particular, they are to be independent of $\alpha + \mathbf{x}_i'\boldsymbol{\beta}$. A check of this assumption is the standard **residual plot** based on the fits, i.e., the plot of the residuals $\hat{e}_i$ versus $\hat{\alpha} + \mathbf{x}_i'\hat{\boldsymbol{\beta}}$. A random scatter in this plot is confirmatory of the model while patterns in the plot contradict the model. Consider fitting a misspecified model. Suppose the true model is

$$\mathbf{Y} = \mathbf{1}\alpha + \mathbf{X}_c\boldsymbol{\beta} + \mathbf{Z}_c\boldsymbol{\gamma} + \mathbf{e}, \tag{67}$$

where $\mathbf{Z}_c$ is an $n \times q$ centered matrix of constants and $\boldsymbol{\gamma} = \boldsymbol{\theta}/\sqrt{n}$, for $\boldsymbol{\theta} \neq \mathbf{0}$. Suppose, though, we fit the model $\mathbf{Y} = \mathbf{1}\alpha + \mathbf{X}_c\boldsymbol{\beta} + \mathbf{e}$. Then (based on first-order asymptotics),

$$\hat{\mathbf{Y}}_W \doteq \alpha\mathbf{1} + \mathbf{X}_c\boldsymbol{\beta} + \tau\mathbf{H}_c\boldsymbol{\varphi}_W(F(\mathbf{e})) + \mathbf{H}_c\mathbf{Z}_c\boldsymbol{\gamma} \tag{68}$$

$$\hat{\mathbf{e}}_W \doteq \mathbf{e} - \tau\mathbf{H}_c\boldsymbol{\varphi}_W(F(\mathbf{e})) + (\mathbf{I} - \mathbf{H}_c)\mathbf{Z}_c\boldsymbol{\gamma}, \tag{69}$$

where $\mathbf{H}_c = \mathbf{X}_c(\mathbf{X}_c'\mathbf{X}_c)^{-1}\mathbf{X}_c'$ and $\varphi_W(u) = \sqrt{12}(u - (1/2))$ is the Wilcoxon score function. It also follows that the LS residuals and fitted values satisfy

$$\hat{\mathbf{Y}}_{LS} = \alpha\mathbf{1} + \mathbf{X}_c\boldsymbol{\beta} + \mathbf{H}_c\mathbf{e} + \mathbf{H}\mathbf{Z}\boldsymbol{\gamma} \tag{70}$$

$$\hat{\mathbf{e}}_{LS} = \mathbf{e} - \mathbf{H}_c\mathbf{e} + (\mathbf{I} - \mathbf{H}_c)\mathbf{Z}_c\boldsymbol{\gamma}. \tag{71}$$

Suppose that the linear model (39) is correct. Then $\boldsymbol{\gamma} = \mathbf{0}$ and $\hat{\mathbf{e}}_W$ is a function of the random errors similar to $\hat{\mathbf{e}}_{LS}$; hence, it follows that a plot of $\hat{\mathbf{e}}_W$ versus $\hat{\mathbf{Y}}_W$ should generally be a random scatter, similar to the least squares residual plot.

In the case of model misspecification, note that the Wilcoxon residuals and least squares residuals have the same bias, namely, $(\mathbf{I} - \mathbf{H})\mathbf{Z}\boldsymbol{\gamma}$, which depend on the misspecified part. Hence Wilcoxon residual plots, similar to those of least squares, are useful in identifying model misspecification.

Other model violations can be discovered by this residual plot. For example, the model assumption also implies that the errors are homoscedastic, i.e., have the same variance. **Flat** residual plots, in which the residuals are randomly distributed between two horizontal lines, are confirmatory to this. Fan-shaped residual plots in which the scale of the residuals varies with the fitted value are an indication of heteroscedasticity. Outlier detection is another prime reason to obtain a residual plot. Here scaled residuals as described in the following are useful in this detection. Sine wave patterns in the plot are one indication of a time series effect. Time series effects are frequently detected by **lag plots** of the residuals, i.e., plots of $\hat{e}_i$ versus $\hat{e}_{i-k}$ for various k. Besides the plot of residuals versus fitted values, histograms and q–q plots are helpful in assessing distributional properties of the errors.

2. Studentized Residuals

Let $\hat{e}_{W,i}$ denote the ith residual based on the Wilcoxon estimate of the regression coefficients. An estimate of $\mathrm{Var}(\hat{e}_{W,i})$ is

$$\tilde{s}^2_{W,i} = \text{MAD}^2\left(1 - \hat{K}_1\frac{1}{n} - \hat{K}_2 h_{c,i}\right), \tag{72}$$

where $h_{ci} = \mathbf{x}_i(\mathbf{X}_c'\mathbf{X}_c)^{-1}\mathbf{x}_i$; $\text{MAD} = 1.483\text{med}_i\{|\hat{e}_{Wi} - \text{med}_j\hat{e}_{Wj}|\}$;

$$\hat{K}_1 = \frac{\hat{\tau}_S^2}{\hat{\sigma}^2}\left(\frac{2\hat{\delta}_S}{\hat{\tau}_S} - 1\right), \tag{73}$$

$$\hat{K}_2 = \frac{\hat{\tau}^2}{\hat{\sigma}^2}\left(\frac{2\hat{\delta}}{\hat{\tau}} - 1\right), \tag{74}$$

$$\hat{\delta}_S = \frac{1}{n-p}\sum |\hat{e}_{W,i}|, \tag{75}$$

and

$$\hat{\delta} = \frac{1}{n-p}D(\hat{\beta}_W).$$

We define the **internal R-Studentized residuals** as

$$r_{W,i} = \frac{\hat{e}_{W,i}}{\tilde{s}_{W,i}} \quad \text{for } i = 1, \ldots, n. \tag{76}$$

Notice that the Studentized residuals are adjusted for both underlying variation and location in factor space. The usual **benchmark** for Studentized residuals in ± 2; i.e., cases whose Studentized residuals exceed 2 in absolute value are deemed potential outliers which may require investigation. Studentized residuals are useful in plots featuring residuals.

H. Example: Cloud Data

We illustrate the previous discussion on a data set with one predictor. [See Hettmansperger and McKean (1998) for original references.] The dependent variable is the cloud point of a liquid, a measure of degree of crystallization in a stock. The independent variable is the percentage of I-8 in the base stock. The data are in Table VI.

Panel A of Fig. 2 displays the residual plot (R-residuals versus R-fitted values) of the R-fit of the simple linear model. The curvature in the plot indicates that this model is a poor choice and that a higher degree polynomial model would be more appropriate. Panel B of Fig. 2 displays the residual plot from the R-fit of a quadratic model. Some curvature is still present in the plot. A cubic polynomial was fitted next. Its R-residual plot, found in Panel C of Fig. 2, is much more of a random scatter than the first two plots. On the basis of residual plots the cubic polynomial is an adequate model. Panel D of Fig. 2 displays the q–q plot of the Studentized Wilcoxon residuals. Note that the points which appear to be outliers in the residual plots have Studentized absolute residuals over 2 in this plot.

Table VII offers summary statistics of the fits. The estimates of the coefficients for the models are given and for the cubic model their standard errors. Based on the estimates of τ and the coefficients of determination, it appears that the cubic model is the best of these three models. Based on these statistics, we can test several hypotheses of interest. The test statistic to test that the quadratic and cubic terms are needed is $F_W = ((13.15 - 4.76)/2)/(.332/2) = 25.27$ which is significant beyond the .000 level (degrees of freedom are 2 and 15). The test statistic to test that the cubic term is needed is $F_W = ((6.97 - 4.76)/1)/(.332/2) = 13.31$ which is significant at the .002 level (degrees of freedom are 1 and 15).

TABLE VI Cloud Data

%I-8	0	1	2	3	4	5	6	7	8	0

III. HIGH BREAKDOWN ROBUST ESTIMATES

For the robustness properties of regression estimators, we need to consider influential points in both the Y and the $\mathbf{x}$-spaces. Let $(\mathbf{x}^*, Y^*)$ be a possible influential point. The influence function of the LS estimator is $\Lambda(\hat{\beta}_{LS}; \mathbf{x}^*, Y^*) = n\sigma(\mathbf{X}_c'\mathbf{X}_c)^{-1}Y^*\mathbf{x}^*$. This function is unbounded in both the Y and the $\mathbf{x}$-spaces; hence, an outlier in response space or an outlier in factor space can impair the LS fit. The influence function of the Wilcoxon estimate is

$$\Lambda\left(\hat{\beta}_W; \mathbf{x}^*, Y^*\right) = n\tau(\mathbf{X}_c'\mathbf{X})^{-1}\varphi_W(Y^*)\mathbf{x}^*, \tag{77}$$

where $\varphi_W(u)$ is the Wilcoxon score function. Because $\varphi_W(u)$ is a bounded function, the Wilcoxon estimate has bounded influence in response space, but note that it has unbounded influence in the $\mathbf{x}$-space. So while the Wilcoxon estimate is highly efficient and robust in the Y-space it is highly sensitive to outliers in factor space. For controlled experimental designs this does not pose a problem, but for observational studies it may. Certainly, as in all cases, a residual analysis should be performed but if influential points form a cluster in factor space they may not be discovered (the so-called **masking effect**) by standard diagnostic analyses.

The weighted Wilcoxon estimate, described next, does have bounded influence in both the Y and the $\mathbf{x}$-spaces. To define our class of weights, we first need a high breakdown estimate of location and scatter (variance) in factor space. There are several estimates available. We have chosen the

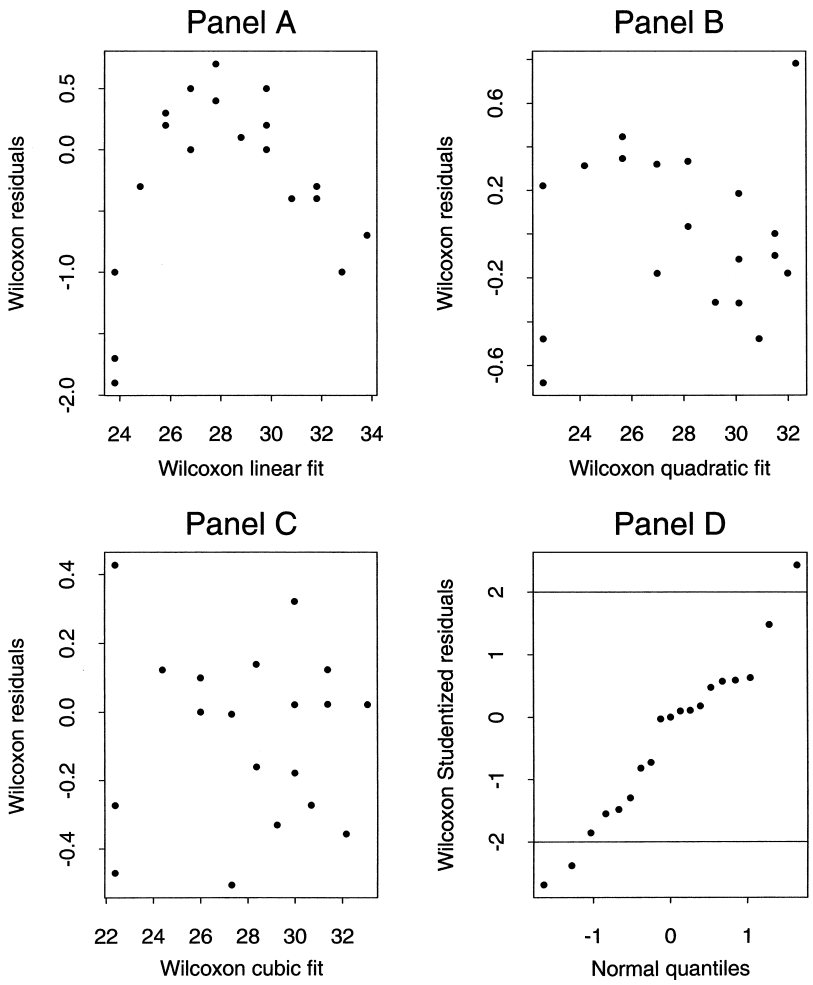

FIGURE 2 Panels A through C are the residual plots of the Wilcoxon fits of the linear, quadratic, and cubic models, respectively, for the Cloud Data. Panel D is the *q–q* plot of the Studentized residuals based on the Wilcoxon fit of the cubic model.

minimum covariance determinant (MCD) estimate of scatter. [See Rousseeuw and Van Driessen (1999) for a fast computational algorithm for the MCD.] The MCD is the ellipsoid which covers about half the data and yet has minimum determinant. This is the high breakdown estimate of scatter which we will use and which we label as $\mathbf{V}$. Let $\mathbf{v}$ be the center of this ellipsoid. We next need a high breakdown initial estimate of the regression coefficients. We have chosen to use the **least trim squares** (LTS) estimate which is Argmin $\sum_{i=1}^{h}[Y-\alpha-\mathbf{x}'\beta]^2_{(i)}$, where $h=[n/2]+1$ and (i) denotes the ith ordered residual (see Rousseeuw and Van Driessen, 1999). Let $\hat{\mathbf{e}}_0$ denote the residuals from this initial fit.

TABLE VII Wilcoxon Summary Statistics for the Cloud Data

	Model			
	Linear	**Quadratic**	**Cubic**	**(SE)**
Statistic				
$\hat{\alpha}$	28.2	28.6	28.7	(.14)
$\hat{\beta}_1$	1.00	1.05	.878	(.06)
$\hat{\beta}_2$		−.075	−.079	(.01)
$\hat{\beta}_3$			.011	(.003)
Dispersion	13.15	6.97	4.26	
$\hat{\tau}$	.737	.493	.332	
R_W	.888	.934	.959	

Define the function $\psi(t)$ by $\psi(t)=1,\ t$, or -1 according as $t\geq 1,\ -1<t<1$, or $t\leq -1$. Let σ be estimated by the initial scaling estimate MAD $=1.483\ \text{med}_i|\hat{e}_i^{(0)}-\text{med}_j\{\hat{e}_j^{(0)}\}|$. Letting $Q_i=(\mathbf{x}_i-\mathbf{v})'\mathbf{V}^{-1}(\mathbf{x}_i-\mathbf{v})$, we can write

$$m_i=\psi\left(\frac{b}{Q_i}\right)=\min\left\{1,\frac{b}{Q_i}\right\}.$$

Hence the weights can be estimated by

$$\hat{b}_{ij} = \min\left\{1, \frac{c\hat{\sigma}}{|\hat{e}_i|}\frac{\hat{\sigma}}{|\hat{e}_j|}\min\left\{1, \frac{b}{\hat{Q}_i}\right\}\min\left\{1, \frac{b}{\hat{Q}_j}\right\}\right\}, \tag{78}$$

where the tuning constants b and c are both set at 4. From this point of view, it is clear that these weights downweight both outlying points in factor space and outlying responses.

Given these weights, the HBR Wilcoxon estimate is defined as,

$$\hat{\boldsymbol{\beta}}_{HBR} = \text{Argmin} \sum_{i,j} b_{ij}|Y_i - Y_j - (\mathbf{x}_i - \mathbf{x}_j)'\boldsymbol{\beta}|. \tag{79}$$

Once the weights are determined, the estimates are obtained by minimizing a convex function; hence, a routine similar to that used to compute the Wilcoxon estimates can be used to obtain these estimates.

The HBR estimates have the following properties.

1. $\hat{\boldsymbol{\beta}}_{HBR}$ has a 50% breakdown point, provided the initial estimates used in forming the weights have 50% breakdown.
2. The influence function $\Lambda(\hat{\boldsymbol{\beta}}_{HBR}; \mathbf{x}^*, Y^*)$ is a bounded function in both the Y and the $\mathbf{x}$-spaces. Further, $\Lambda(\hat{\boldsymbol{\beta}}_{HBR}; \mathbf{x}^*, Y^*)$ is continuous everywhere and goes to zero as $(\mathbf{x}^*, Y^*)$ get large in any direction.
3. The asymptotic distribution $\hat{\boldsymbol{\beta}}_{HBR}$ is asymptotically normal with mean $\boldsymbol{\beta}$ and standard errors as discussed in the following. As with all high breakdown estimates, $\hat{\boldsymbol{\beta}}_{HBR}$ is less efficient than the Wilcoxon estimates and this loss can be substantial on "good" data sets. The HBR estimates, however, are much more efficient than the initial LTS regression estimates.

As discussed in the following, the difference between high breakdown estimates and highly efficient estimates can be a powerful diagnostic in exploring messy data sets.

A. Standard Errors of the HBR Estimates

The asymptotic variance–covariance of $\hat{\boldsymbol{\beta}}_{HBR}$ is a function of the two matrices $\boldsymbol{\Sigma}$ and $\mathbf{C}$. The matrix $\boldsymbol{\Sigma}$ is the variance–covariance matrix of a random vector $\mathbf{U}_i$ which can be approximated by the expression,

$$\hat{\mathbf{U}}_i = \frac{1}{n}\sum_{j=1}^{n}(\mathbf{x}_j - \mathbf{x}_i)\hat{b}_{ij}(1 - 2F_n(\hat{e}_i)), \tag{80}$$

where $\hat{b}_{ij}$ are the estimated weights, $\hat{e}_i$ are the HBR residuals, and F_n is the empirical distribution function of the residuals. Let $\hat{\boldsymbol{\Sigma}}$ be the sample variance–covariance matrix of $\hat{\mathbf{U}}_1, \ldots, \hat{\mathbf{U}}_n$. This serves as an estimate of $\boldsymbol{\Sigma}$.

The second matrix $\mathbf{C}$ can be approximated as $n^{-2}\mathbf{X}_c'\mathbf{A}\mathbf{X}_c$, where the (i, j) entry of $\mathbf{A}$ is $a_{ij} = -\hat{b}_{ij}/(\sqrt{12}\hat{\tau})$. Then the asymptotic variance–covariance matrix of $\hat{\boldsymbol{\beta}}_{HBR}$ can be approximated as $(4n)^{-1}\mathbf{C}^{-1}\hat{\boldsymbol{\Sigma}}\mathbf{C}^{-1}$. This can be uesd to determine asymptotic confidence intervals for linear functions of $\boldsymbol{\beta}$, for instance, the standard error of $\hat{\boldsymbol{\beta}}_{HBR,j}$ would be the square root of the jth diagonal entry of this matrix. Studentized residuals can be determined similarly.

B. Diagnostics To Differentiate between HBR and Wilcoxon Fits

For a given data set, highly efficient robust estimates and high breakdown estimates can produce very different fits. This can be due to influential points in factor space and/or curvature. High breakdown estimates tend to fit the center of the data so they may have trouble fitting areas of curvature away from the center. The diagnostics presented next indicate first whether or not the HBR and Wilcoxon fits differ and second, if they do differ, what cases are involved in the discrepancy.

First, as with the Wilcoxon estimates, estimate the intercept by the median of the HBR residuals, i.e., $\hat{\alpha}_{HBR} = \text{med}\{Y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}_{HBR}\}$. Let $\hat{\mathbf{b}}_{HBR} = (\hat{\alpha}_{HBR}, \hat{\boldsymbol{\beta}}_{HBR}')'$. Then the difference in regression estimates between HBR and Wilcoxon estimates is the vector $\hat{\mathbf{b}}_W - \hat{\mathbf{b}}_{HBR}$. This difference needs to be standardized. An effective standardization is the estimate of the variance–covariance of $\hat{\mathbf{b}}_W$. This produces the following statistic, which measures the total difference in the fits of $\hat{\mathbf{b}}_W$ and $\hat{\mathbf{b}}_{HBR}$,

$$TDBETAS_R = (\hat{\mathbf{b}}_W - \hat{\mathbf{b}}_{HBR})'\hat{\mathbf{A}}_W^{-1}(\hat{\mathbf{b}}_W - \hat{\mathbf{b}}_{HBR}), \tag{81}$$

where

$$\mathbf{A}_W = \text{Cov}\begin{pmatrix}\hat{\alpha}_W \\ \hat{\boldsymbol{\beta}}_W\end{pmatrix} = \begin{bmatrix}\tau_S^2/n & 0 \\ 0 & \tau^2(\mathbf{X}'\mathbf{X})^{-1}\end{bmatrix}.$$

Large values of $TDBETAS_R$ indicate a discrepancy between the fits. A useful cutoff value, **benchmark for** $TDBETAS_R$, is $(4(p+1)^2)/n$.

The diagnostic $TDBETAS_R$ measures the overall difference in the estimates. If it exceeds its benchmark then usually we want to determine the individual cases causing this discrepancy in the fits. As we mentioned earlier, these would be the cases to investigate to see whether they are outliers in factor space or cases involved with curvature. Let $\hat{y}_{W,i} = \hat{\alpha}_W + \mathbf{x}'\hat{\boldsymbol{\beta}}_W$ and $\hat{y}_{HBR,i} = \hat{\alpha}_{HBR} + \mathbf{x}'\hat{\boldsymbol{\beta}}_{HBR}$ denote the respective fitted values for the ith case. A statistic which detects the observations that are fitted differently is

$$CFITS_{R,i} = \frac{\hat{y}_{R,i} - \hat{y}_{GR,i}}{\left(n^{-1}\hat{\tau}_S^2 + h_{c,i}\hat{\tau}^2\right)^{\frac{1}{2}}}. \tag{82}$$

An effective **benchmark for** $CFITS_{R,i}$ is $2\sqrt{(p+1)/n}$. We should note here that the objective of the diagnostic *CFITS* is *not* outlier deletion. Rather the intent is to identify the *critical few* data points for closer study, because these critical few points often largely determine the outcome of the analysis or the direction that further analyses should take. This closer study may involve subject matter expertise, rotation and spin plots, or data-collection-site investigation for accuracy of measurements, among other things. In this regard, the proposed benchmarks are meant as a heuristic aid, not a boundary to some formal critical region.

C. Example: Stars Data

This data set is drawn from an astronomy study on the star cluster CYG OB1 which contains 47 stars. [See Hettmansperger and McKean (1998) for the data.] The response is the logarithm of the light intensity of the star while the independent variable is the logarithm of the temperature of the star. The data are shown in Panel A of Fig. 3. Note that four of the stars, called giants, are outliers in factor space while the rest of the stars fall in a point cloud. The three fits, LS, Wilcoxon, and the HBR, are overlaid on this plot of the data. Note that the HBR fit falls through the point cloud, whereas the other two fits are drawn toward the outliers in factor space. This illustrates the HBR estimates' insensitivity to outliers in factor space. Panels B and C of Fig. 3 show the residual plots for the Wilcoxon and HBR fits. The HBR fit has fitted the point cloud well and the four outlying stars stand out in the plot.

The diagnostic $TDBETAS_R$ has the value 109.9 which greatly exceeds the benchmark and, hence, numerically indicates that the fits differ. Panel D of Fig. 3 shows the casewise diagnostic $CFITS_{R,i}$ versus case. In this plot, the four giant stars clearly stand out from the rest. The plot shows that the fits for two other stars also differ. These are

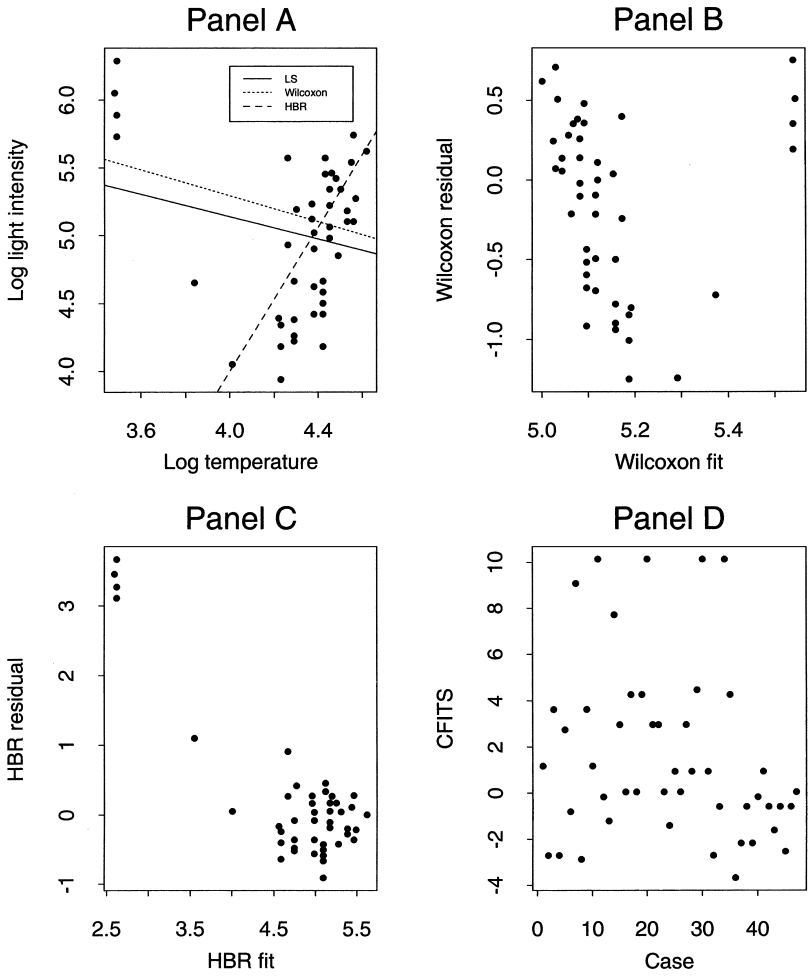

FIGURE 3 Panel A: Stars Data overlaid with LS, Wilcoxon, and HBR fits. Panel B: Wilcoxon residual plot. Panel C: HBR residual plot. Panel D: The diagnostic *CFITSR*, *i* versus case.

the stars between the giant stars and the rest of the stars as shown in Panel A.

As a final word on this example, suppose we only had the data and not the facts behind the data set. From Panel A, one might conclude that a quadratic model would be appropriate. Note that the Wilcoxon residual plot indicates a quadratic model here while the HBR residual plot does not. High breakdown estimates fit the center of the data and hence often do not detect curvature on the edge of factor space. But the diagnostics $TDBETAS_R$ and $CFITS_{R,i}$ would alert the user that the fits differ. Using further diagnostic plots, the user may be able to decide whether it is curvature or outliers in factor space which are causing the difference in fits.

IV. OPTIMAL RANK-BASED ANALYSES

Consider the linear model (38). Knowledge of the underlying density of the errors, $f(t)$, can be utilized to optimize the rank-based analysis. Recall that the Wilcoxon estimate of the regression coefficients minimizes the norm of the errors where the norm can be expressed as (51). Instead of using the Wilcoxon score function, other score functions can be selected. Suppose we select a function $\varphi(u)$ which is bounded and nondecreasing on $(0, 1)$; (without loss of generality, $\int \varphi = 0$ and $\int \varphi^2 = 1$). Denote the resulting estimate which minimizes the norm of the errors by $\hat{\boldsymbol{\beta}}_\varphi$ and call it in general an **R** estimate. This estimate has the following properties:

1. The criterion function is convex, hence, $\hat{\boldsymbol{\beta}}_\varphi$ can be obtained using the same algorithm as is used by the Wilcoxon estimate (one simply replaces the Wilcoxon score function by $\varphi(u)$).
2. The influence function of $\hat{\boldsymbol{\beta}}_\varphi$ will be bounded in response space; i.e., the estimate is bias-robust.
3. $\hat{\boldsymbol{\beta}}_\varphi$ is asymptotically normal, centered at $\boldsymbol{\beta}$, and has variance–covariance matrix $\tau_\varphi^2(\mathbf{X}_c'\mathbf{X}_c)^{-1}$, where

$$\tau_\varphi^{-1} = \int_0^1 \varphi(u)\varphi_f(u)\,du \tag{83}$$

and

$$\varphi_f(u) = -\frac{f'}{f}(F^{-1}(u)). \tag{84}$$

The scale parameter τ_φ can be computed using the same algorithm as the Wilcoxon's τ.

How do we select φ to optimize the analysis? We want to select scores so that the constant of proportionality τ_φ^2 is as small as possible or its reciprocal is as large as possible, i.e., maximize

$$\begin{aligned}\tau_\varphi^{-1} &= \int \varphi(u)\varphi_f(u)\,du \\ &= \sqrt{\int \varphi_f^2(u)\,du}\,\frac{\int \varphi(u)\varphi_f(u)\,du}{\sqrt{\int \varphi_f^2(u)\,du}\sqrt{\int \varphi^2(u)\,du}} \\ &= \text{def}\sqrt{\int \varphi_f^2(u)\,du}\;\rho. \end{aligned} \tag{85}$$

The second equation is true since the scores were standardized as shown here. In the third equation ρ is a correlation coefficient and $\int \varphi_f^2(u)\,du$ is **Fisher location information**, which we denote by $I(f)$. By the Rao–Cramér lower bound, the smallest asymptotic constant of proportionality obtainable by an asymptotically unbiased estimate is $I(f)^{-1}$. Such an estimate is called **asymptotically efficient**. Choosing a score function to maximize (85) is equivalent to choosing a score function to make $\rho = 1$. This can be achieved by taking the score function to be $\varphi(u) = \varphi_f(u)$, (84). The resulting estimate, $\hat{\boldsymbol{\beta}}_\varphi$, is **asymptotically efficient**. The previous formulation is invariant to location and scale; hence, we need to know only the form of the density.

Here are several situations with their corresponding optimal score functions.

- If the form of the error density is the **logistic**, $f(x) = e^{-x^2}/(1 + e^{-x^2})$, then the Wilcoxon score function is optimal.
- If the form of the error density is the **normal**, $f(x) = (2\pi)^{-1/2}e^{-x^2/2}$, then the optimal score function is the **normal score** function given by $\varphi(u) = \Phi^{-1}(u)$, where $\Phi(t)$ denotes the distribution function of a standard normal random variable. Hence, under normal errors, R estimates obtained by using the normal scores have the same efficiency as the LS estimates.
- If the form of the error density is the Laplace density, $f(x) = (2)^{-1}e^{-|x|}$, then the optimal score function is the **sign score** function, given by $\varphi(u) = \text{sgn}(u - (1/2))$. Sign scores generalize the sign procedures discussed in the location models. While asymptotically efficient at the Laplace distribution, they only have efficiency .63 at the normal relative to LS. If the intercept is estimated as the median of residuals then these sign score estimates are the least absolute deviation L_1 regression estimates.

Asymptotically efficient rank-based estimates can be obtained if the form of f is known. Evidently, the closer the chosen score is to φ_f, the more powerful the rank analysis will be. There are adaptive analyses in which the score function is estimated based on an initial fit. For

certain areas such as survival analysis, interesting classes of score functions can readily be formulated.

A. Survival Analysis

In this section we discuss scores which are appropriate for lifetime distributions when the log of lifetime follows a linear model, i.e., **accelerated failure time models** (see Kalbfleisch and Prentice, 1980). Let T denote the lifetime of a subject and let $\mathbf{x}$ be a $p \times 1$ vector of covariates associated with T. Let $h(t;\mathbf{x})$ denote the **hazard function** of T at time t which is the rate of failure of an item at time t.

Suppose T follows a log linear model; that is, $Y = \log T$ follows the linear model

$$Y = \alpha + \mathbf{x}'\boldsymbol{\beta} + e, \tag{86}$$

where e is a random error with density f. Exponentiating both sides we get $T = \exp\{\alpha + \mathbf{x}'\boldsymbol{\beta}\}T_0$, where $T_0 = \exp\{e\}$. Let $h_0(t)$ denote the hazard function of T_0. This is called the baseline hazard function. Then the hazard function of T is given by

$$h(t;\mathbf{x}) = h_0(t\exp\{-(\alpha + \mathbf{x}'\boldsymbol{\beta})\})\exp\{-(\alpha + \mathbf{x}'\boldsymbol{\beta})\}. \tag{87}$$

Thus the covariate $\mathbf{x}$ **accelerates** or decelerates the failure time of T.

Many of the error distributions currently used for these models are contained in the **log**-F class. In this class, $e = \log T$ is distributed down to an unknown scale parameter, as the log of an F random variable with $2m_1$ and $2m_2$ degrees of freedom. We say that e has a $GF(2m_1, 2m_2)$ distribution. In general, this class contains a variety of shapes. The distributions are symmetric for $m_1 = m_2$, positively skewed for $m_1 > m_2$, and negatively skewed for $m_1 < m_2$. For values $0 \le m_1,\ m_2 \le 1$, the distributions tend to have thicker tails. For random errors with distribution $GF(2m_1,\ 2m_2)$, the optimal rank score function is given by

$$\varphi_{m_1,m_2}(u) = (m_1 m_2(\exp\{F^{-1}(u)\} - 1))/ (m_2 + m_1\exp\{F^{-1}(u)\}), \tag{88}$$

where F is the cumulative distribution function of the $GF(2m_1,\ 2m_2)$ distribution. It follows that the scores are strictly increasing and bounded below by $-m_1$ and above by m_2. Hence an R-analysis based on these scores will have bounded influence in the Y-space.

Important subclasses of the accelerated failure time models are those where T_0 follows a Weibull distribution, i.e.,

$$f_{T_0}(t) = \lambda\gamma(\lambda t)^{\gamma-1}\exp\{-(\lambda t)^{\gamma}\}, \quad t > 0, \tag{89}$$

where λ and γ are unknown parameters. In this case it follows that the hazard function of T is proportional to the baseline hazard function with the covariate acting as the factor of proportionality, i.e.,

$$h(t;\mathbf{x}) = h_0(t)\exp\{-(\alpha + \mathbf{x}'\boldsymbol{\beta})\}. \tag{90}$$

Hence these models are called **proportional hazard models**. We can write the random error $e = \log T_0$ as $e = \xi + \gamma^{-1}W_0$, where $\xi = -\log\gamma$ and W_0 has the extreme value distribution. The optimal rank scores for these log-linear models are generated by the function

$$\varphi_{f_\epsilon}(u) = -1 - \log(1-u). \tag{91}$$

Procedures based on these scores are asymptotically equivalent to the procedures based on the **Savage** scores.

V. RANK-BASED ANALYSES OF EXPERIMENTAL DESIGNS

In this section we discuss the application of the rank-based analysis described in Section II to factorial designs and analysis of covariance designs.

A. One-Way Designs

For these designs we have a single factor, A, at k levels. The experimental design is the CRD design in which n experimental units are randomly assigned, n_i to level i, $n = \sum_{i=1}^{k} n_i$. At the end of the study, Y_{ij} denotes the response of the jth experimental unit assigned to level i. As a model, consider the **one-way** design,

$$Y_{ij} = \mu_i + e_{ij}, \quad j = 1,\ldots,n_i; \quad i = 1,\ldots,k, \tag{92}$$

where e_{ij} are iid with density $f(t)$ and μ_i is the location (e.g., mean or median) of the ith cell. Denote the vector of responses by $\mathbf{Y} = (Y_{11},\ldots,Y_{kn_k})'$, the vector of cell locations by $\boldsymbol{\mu} = (\mu_1,\ldots,\mu_k)'$, and let $\mathbf{W}$ be the $n \times k$ incidence matrix. Then we can express this model as

$$\mathbf{Y} = \mathbf{W}\boldsymbol{\mu} + \mathbf{e}. \tag{93}$$

Because a column of ones is in the column space of $\mathbf{W}$, we can always reparameterize this model so it is a linear model of the form (39). As in Section II, let Ω denote the column space of $\mathbf{W}$.

Suppose we fit this model using the Wilcoxon fit of Section II. Denote the fitted values by $\hat{\mathbf{Y}}_W$, the residuals by $\hat{\mathbf{e}}_W$, the estimate of τ by $\hat{\tau}$, and the minimum dispersion by $d_W(\mathbf{Y},\Omega)$. Also denote the scored residuals by $\mathbf{a}(R(\hat{e}_W))$, where $a(i) = \varphi_W(i/(n+1))$ and $R(\hat{e}_i)$ denote the rank of the ith residual. Other score functions besides the Wilcoxon φ_W can be used but, here, we will only discuss the results for Wilcoxon scores. Note that the ranking here is on the residuals which are estimates of iid errors.

For easy reference, let us collectively label this Wilcoxon analysis fit as

$$\mathcal{F}_W = \mathcal{F}_W(\Omega) = \{\hat{\mathbf{Y}}_W, \hat{\mathbf{e}}_W, \mathbf{a}(R(\hat{e}_W)), \hat{\tau}, d_W(\mathbf{Y}, \Omega)\}. \tag{94}$$

We are interested in the overall null hypothesis that the levels are the same; i.e.,

$$H_0: \mu_1 = \cdots = \mu_k \text{ versus } H_A: \mu_i \neq \mu_{i'} \text{ for some } i \neq i'. \tag{95}$$

Upon rejecting this hypothesis, we are usually interested in the determination of significant differences between the levels, say, of the form $\mu_i - \mu_{i'}$. Note that these are **contrasts** in the μ_is; that is, linear functions of the form $\mathbf{h}'\boldsymbol{\mu} = \sum h_i \mu_i$, where $\sum h_i = 0$.

In general let $\mathbf{M}$ be a $q \times k$ matrix whose rows are contrasts. The corresponding hypotheses are

$$H_0: \mathbf{M}\boldsymbol{\mu} = \mathbf{0} \text{ versus } H_A: \mathbf{M}\boldsymbol{\mu} \neq \mathbf{0}. \tag{96}$$

We can write the hypotheses (95) in this form by taking $\mathbf{M}$ to be the $(k-1) \times k$ matrix whose ith row is $(1, 0, \ldots, 0, -1, 0, \ldots, 0)$ with the -1 appearing in the $(i+1)$ spot.

1. Tests of General Contrasts

Based on the results discussed in Section II, a robust test of the hypotheses (96), for a given contrast matrix $\mathbf{M}$, can be obtained. Let ω be the subspace of Ω subject to the constraints $\mathbf{M}\boldsymbol{\mu} = \mathbf{0}$ stipulated by H_0. Fit the full model and obtain the minimum dispersion $d_W(\mathbf{Y}, \Omega))$ and the estimate of scale $\hat{\tau}$. Next fit the reduced model and obtain the minimum dispersion $d_W(\mathbf{Y}, \omega))$. The reduction in dispersion is $RD = d_W(\mathbf{Y}, \omega)) - d_W(\mathbf{Y}, \Omega))$ and the test statistic is $F_W = (RD/q)/(\hat{\tau}/2)$. The tests reject H_0 at level α if $F_W \geq F(\alpha, q, n-k)$. Under local alternatives, the noncentrality parameters of these Wilcoxon tests are the same as their LS counterparts, except σ^2 is replaced by τ^2. Hence, designing experiments based on power can be carried out the same way for the Wilcoxon analyses as for LS analyses.

2. Test of $H_0: \mu_1 = \cdots = \mu_k$

Briefly to test the hypotheses (95), we obtain the fit $\mathcal{F}_W$ (94) of the full model (38). The reduced model is $\mathbf{Y} = \mathbf{1}_n \mu + \mathbf{e}$; hence, the reduced model dispersion is $\|\mathbf{Y}\|_W$. The reduction in dispersion is $RD_W = \|\mathbf{Y}\|_W - d_W(\mathbf{Y}, \mathbf{W})$ and the test statistic is F_W (57). We would reject H_0 at level α if $F_W \geq F(\alpha, k-1, n-k)$.

3. Confidence Intervals for Single Contrasts

Based on (54), the Wilcoxon confidence interval for any contrast can be obtained. In particular, this confidence interval will be the same as the one based on LS except $\hat{\tau}$ will replace $\hat{\sigma}$. For example, the Wilcoxon confidence interval for the difference in levels i and i' is,

$$\hat{\mu}_{Wi} - \hat{\mu}_{Wi'} \pm t_{(\alpha/2, n-k)} \hat{\tau} \sqrt{(1/n_i) + (1/n_{i'})}, \tag{97}$$

where μ_{Wi} are the full model Wilcoxon estimate of μ_i.

4. Extensions to Multiple Comparison Procedures

Often it is desired to look at many contrasts simultaneously; e.g., all $\binom{k}{2}$ pairwise differences. **Multiple comparison procedures** (MCP) of classical analysis give assurance to the loss of overall confidence for these simultaneous investigations. As demonstrated by the previously cited confidence interval for a single contrast, these traditional procedures are easy to robustify. For the most part, it is simply replacing $\hat{\sigma}$ by $\hat{\tau}$ and using the Wilcoxon estimates of location.

5. Kruskal–Wallis Tests of $H_0: \mu_1 = \cdots = \mu_k$

As stated earlier, the reduced model for this null hypothesis is $\mathbf{Y} = \mathbf{1}_n \mu + \mathbf{e}$. Under this reduced model the ranks of the Y_{ij}'s are uniformly distributed as they are for the null hypothesis in the two-sample location problem discussed in Section I. The MWW procedure discussed for the two-sample problem naturally extends to the the k-sample problem. The responses for all k samples are combined and ranked from 1 to n. Let $\bar{R}_i$ be the average of the ranks of the responses in the ith level. Then the **Kruskal–Wallis** test statistic is given by

$$H_W = \frac{12}{n(n+1)} \sum_{i=1}^{k} n_i \left(\bar{R}_i - \frac{n+1}{2} \right)^2. \tag{98}$$

This test statistic is distribution free under H_0 but it does depend on the configuration of sample sizes. Generally, the large-sample approximation, $\chi^2(k-1)$, is used. In this case, H_0 is rejected at level α provided $H_W \geq \chi^2(\alpha, k-1)$. As a final note, the Kruskal–Wallis test is asymptotically equivalent to the drop in dispersion test F_W for this hypothesis.

6. Pseudo-Observations

In this section, we discuss a convenient way to estimate and test contrasts based on the Wilcoxon fit $\mathcal{F}_W$ (94) of the full model (38). Given the fit we define the **pseudo-observations** by

$$\tilde{\mathbf{Y}} = \hat{\mathbf{Y}}_W + \hat{\tau} \zeta \mathbf{a}(R(\hat{\mathbf{e}}_W)), \tag{99}$$

where $\zeta^2 = (n-k)(n+1)/n(n-1)$.

Let $\hat{\tilde{\mathbf{Y}}}$ and $\hat{\tilde{\mathbf{e}}}$ denote the LS fit and residuals, respectively, of the pseudo-observations (99). Then

$$\hat{\tilde{\mathbf{Y}}} = \hat{\mathbf{Y}}_W, \tag{100}$$

and

$$\hat{\tilde{\mathbf{e}}} = \hat{\tau}\zeta \mathbf{a}(R(\hat{\mathbf{e}})). \tag{101}$$

From this last expression and the definition of ζ,

$$\frac{1}{n-k}\hat{\tilde{\mathbf{e}}}'\hat{\tilde{\mathbf{e}}} = \hat{\tau}^2. \tag{102}$$

Therefore the LS fit of the pseudo-observations results in the Wilcoxon fit of model (93) and, further, the LS estimator *MSE* is $\hat{\tau}^2$. This holds for estimation of contrasts also. Suppose we have a LS routine which tests the general hypotheses (96). Then a rank-based test will result if the pseudo-observations are inputted into the LS routine. This test will be asymptotically equivalent to the drop in dispersion test.

7. Tests for Ordered Alternatives

Ordered alternatives form another important class of alternative models. These are generalizations of the one-sided alternative hypotheses in the location problems. Furthermore, powerful yet highly efficient nonparametric procedures are readily formulated for this class of alternatives.

Consider the ordered alternative H_A given by

$$H_0: \mu_1 = \cdots = \mu_k \text{ versus } H_A: \mu_1 \leq \cdots \leq \mu_k,$$

with at least one strict inequality. The **Jonckheere–Terpstra** test statistic is defined by

$$J = \sum_{s<t} W_{st},$$

where $W_{st} = \#(Y_{tj} > Y_{si})$ for $i = 1, \ldots, n_s$ and $j = 1, \ldots, n_t$. The W_{st}'s are the pairwise Mann–Whitney statistics; see the discussion at expression (8). Under H_0,

$$(a) \quad E(J) = \frac{n^2 - \sum n_t^2}{4}.$$

$$(b) \quad V(J) = \frac{n^2(2n+3) - \sum n_t^2(2n_t+3)}{72}.$$

$$(c) \quad z = (J - E(J))/\sqrt{V(J)} \text{ is approximately } N(0,1).$$

Hence, based on (a)–(c) an asymptotic test for H_0 versus H_A, is to reject H_0 if $z \geq z_\alpha$.

B. Two-Way Designs

In this section, we consider the two-way crossed factorial design. Based on this discussion extensions to higher-order designs are straightforward. [See Chapter 4 of Hettmansperger and McKean (1998).] In a two-way crossed factorial design, we have two factors: A at a levels and B at b levels, that may have an effect on the response. Each combination of the $k = ab$ factor settings is a treatment. For a completely randomized designed experiment, n experimental units are selected at random from the reference population and then n_{ij} of these units are randomly assigned to the (i, j)th treatment combination; hence, $n = \sum\sum n_{ij}$. Let Y_{ijk} denote the response for the kth unit at the (i, j)th treatment combination.

If we impose no structure on the design, then this is a one-way design with k levels. Model (93) is the full model in this case. Let $\mathcal{F}_W(\Omega)$, (94), denote the Wilcoxon fit to this model. The submodels described in the following utilize the two-way structure of the design.

An interesting submodel is the **additive model** which is given by

$$\mu_{ij} = \bar{\mu} + (\bar{\mu}_{i\cdot} - \bar{\mu}) + (\bar{\mu}_{\cdot j} - \bar{\mu}). \tag{103}$$

For the additive model, the **profile plots** (μ_{ij} versus i or j) are parallel. A diagnostic check for the additive model is to plot the **sample profile plots**, ($\hat{\mu}_{ij}$ versus i or j) and see how close the profiles are to parallel. The null hypotheses of interest for this model are the **main effect hypotheses** given by

$$H_{0A}: \bar{\mu}_{i\cdot} = \bar{\mu}_{i'\cdot} \text{ for all } i, i' = 1, \ldots a \tag{104}$$

and

$$H_{0B}: \bar{\mu}_{\cdot j} = \bar{\mu}_{\cdot j'} \text{ for all } j, j' = 1, \ldots b. \tag{105}$$

There are $a-1$ and $b-1$ free constraints for H_{0A} and H_{0B}, respectively. Under H_{0A}, the levels of A have no effect on the response.

The **interaction parameters** are defined as the differences between the full model parameters and the additive model parameters, i.e.,

$$\begin{aligned}\gamma_{ij} &= \mu_{ij} - [\bar{\mu} + (\bar{\mu}_{i\cdot} - \bar{\mu}) + (\bar{\mu}_{\cdot j} - \bar{\mu})] \\ &= \mu_{ij} - \bar{\mu}_{i\cdot} - \bar{\mu}_{\cdot j} + \bar{\mu}.\end{aligned} \tag{106}$$

The hypothesis of **no interaction** is given by

$$H_{0AB} = \gamma_{ij} = 0, \quad i = 1, \ldots, a, \quad j = 1, \ldots, b. \tag{107}$$

There are $(a-1)(b-1)$ free constraints for H_{0AB}. Under H_{0AB} the additive model holds.

These hypotheses are composed of contrasts of the μ_{ij}'s. Hence, the Wilcoxon rank-based test of these hypotheses can be obtained as discussed in Section V.A. The full model is the one way (93) with $k = ab$. Denote the Wilcoxon fit of this model by $\mathcal{F}_W(\Omega)$ as discussed in (94). For a given hypothesis, fit the reduced model, the full model constrained by the null hypothesis, and obtain the minimum dispersion. From this, the reduction in dispersion can be obtained and, hence, the test statistic F_W

as discussed in Section V.A.1. Alternatively, the pseudo-observations can be computed from $\mathcal{F}_W(\Omega)$ and a LS package can be used.

Usually the interaction hypothesis is tested first. If H_{0AB} is rejected then there is difficulty in interpretation of the main effect hypotheses, H_{0A} and H_{0B}. In the presence of interaction H_{0A} concerns the cell mean averaged over Factor B, which may have little practical significance. In this case multiple comparisons (see Section V.A.4) between cells may be of more practical significance. If H_{0AB} is not rejected then there are two schools of thought. The "pooling" school would take the additive model (103) as the new full model to test main effects. The "nonpoolers" would stick with the unstructured model (93) as the full model. In either case with little evidence of interaction present, the main effect hypotheses are much more interpretable.

1. Example: Lifetime of Motors

This data set is the result of an unbalanced two-way design. [See Hettmansperger and McKean (1998) for original references.] The responses are lifetimes of three motor insulations (1, 2, and 3), which were tested at three different temperatures (200, 225, and 250° F). The design is an unbalanced 3×3 factorial with five replicates in six of the cells and three replicates in the others. As discussed in Section IV, we considered the logs of the lifetimes as the responses. Let Y_{ijk} denote the log of the lifetime of the kth replicate at temperature level i and which used motor insulation j. These responses are displayed along with Wilcoxon estimates of the μ_{ij}'s in Table VIII.

The cell median profile plots based on the Wilcoxon estimates indicate that some interaction is present. The plot of the internal Wilcoxon Studentized residuals (not shown) versus fitted values indicates randomness but also shows several outlying data points: the fifth observation in cell (1, 1), the fifth observation in cell (2, 1), and the first observation in cell (2, 3).

Table IX is an ANOVA table for the R-analysis. Since $F(.05, 4, 30) = 2.69$, the test of interaction is significant at the .05 level. This confirms the profile plot. It is interesting to note that the least squares F-test statistic for interaction was 1.30 and, hence, was not significant. The LS analysis was impaired because of the outliers. Both main effects are significant. In the presence of interaction, though, we have interpretation difficulties with main effects.

2. Friedman's Test

For the two-way and higher-order designs, there is no analog to the Kruskal–Wallis test. Recall that the reduced model in this case consisted of a column of ones; i.e., under H_0 all levels are the same and the responses are iid. This is not true of any of the usual hypotheses discussed for the two-way model.

For the randomized block design, however, we can change the way of ranking. This produces a distribution-free test but usually at a substantial loss of efficiency. Suppose we have k treatments of interest and we employ a block design consisting of a blocks, each of length k. Within each block, we randomly assign the k experimental units to the treatments. Suppose we model the responses Y_{ij} as

$$Y_{ij} = \mu + \alpha_i + \beta_j + e_{ij}; \quad i = 1, \ldots, a, \quad j = 1, \ldots, k, \tag{108}$$

where e_{ij} are iid with density $f(t)$. We want to test

$$H_0: \beta_1 = \cdots = \beta_k \text{ versus } H_A: \beta_j \neq \beta_{j'} \text{ for some } j \neq j'.$$

TABLE VIII Data for Example, Lifetimes of Motors (hours)[a]

	Insulation		
Temperature	**1**	**2**	**3**
200°F	7.07	7.96	8.17
	7.32	8.07	8.17
	7.32	7.83	8.17
	7.32	8.07	
	8.17	8.17	
	(7.32)	(8.06)	(8.17)

	5.53	5.92	5.78
	5.70	5.92	
	5.78	6.10	
	(5.57)	(5.92)	(5.70)

[a] The last entry in each cell is the Wilcoxon estimate of the true cell median.

TABLE IX Analysis of Dispersion Table for Lifetime of Motors Data

Source	RD	**df**	MRD	F_R
Temperature (T)	26.40	2	13.20	121.7
Motor insulation (I)	3.72	2	1.86	17.2
T × I	1.24	4	.310	2.86
Error		30	.108	

Considered as a two-way fixed effects design with no interaction, this test can be handled as discussed previously using the Wilcoxon rank-based analysis. The full model is (108).

Note that under H_0 there is no treatment effect, so the observations within a block are iid (but not between blocks). Thus we rank the items from 1 to k within each block. Let R_j be the sum of the ranks for the jth treatment. Under H_0 the expectation and variance of R_j are

$$\mathrm{E}(R_j) = \frac{a(k+1)}{2} \text{ and } \mathrm{Var}(R_j) = \frac{a(k+1)(k-1)}{12}.$$

Friedman's test statistic is given by

$$K = \sum_{j=1}^{k} \left(\frac{k-1}{k}\right)\left[\frac{R_j - E(R_j)}{\sqrt{\mathrm{Var}(R_j)}}\right]^2. \qquad (109)$$

This test statistic is distribution free under H_0 and is asymptotically a $\chi^2(k-1)$ random variable. Hence, the large sample test rejects H_0 at level α if $K \geq \chi^2(\alpha, k-1)$. The efficiency of the Friedman test depends on the number of treatments. At the normal distribution, this efficiency is $.955(k/(k+1))$. For $k=2$ this is .63, as it should be because at $k=2$ the Friedman test is the same as the paired sign test discussed in Section I. Even for 10 treatments, the efficiency is only .86.

C. Analysis of Covariance

In experimental design, we attempt to control all variables other than the factors and the response variable. Often this is impossible, so along with the response we record these extraneous variables which are called **covariates** or **concomitant variables**. Hopefully these variables help explain some of the noise in the data. The traditional analysis of such data is called **analysis of covariance**.

As an example, consider the one-way model (93) with k levels and suppose we have a single covariate, say, x_{ij}. A first-order model is $y_{ij} = \mu_i + \beta x_{ij} + e_{ij}$. This model, however, assumes that the covariate behaves the same within each treatment combination. A more general model is

$$y_{ij} = \mu_i + \beta x_{ij} + \gamma_i x_{ij} + e_{ij}$$
$$j = 1, \ldots, n_i,\ i = 1, \ldots, k. \qquad (110)$$

Hence the slope at the ith level is $\beta_i = \beta + \gamma_i$ and, thus, each treatment combination has its own linear model. There are two natural hypotheses for this model: $H_{0C}: \beta_1 = \cdots = \beta_k$ and $H_{0L}: \mu_1 = \cdots = \mu_k$. If H_{0C} is true then the difference between the levels of Factor A are just the differences in the location parameters μ_i for a given value of the covariate. In this case, contrasts in these parameters are often of interest as well as the hypothesis H_{0L}. If H_{0C} is not true then the covariate and the treatment combinations interact. For example, whether one treatment combination is better than another may depend on where in factor space the responses are measured. Thus as in crossed factorial designs, the interpretation of main effect hypotheses may not be clear. The previous example is easily generalized to more than one covariate.

The Wilcoxon fit of the full model (110) proceeds as described in Section II. Model estimates of the parameters and their standard errors can be used to form confidence intervals and regions and multiple comparison procedures can be used for simultaneous inference. Reduced models appropriate for the hypotheses of interest can be obtained and the values of the test statistic F_W can be used to test them.

VI. MEASURES OF ASSOCIATION

In this section, we discuss measures of association. Our discussion will be limited mostly to the bivariate model. Let (X, Y) be a pair of random variables with the joint density $f(x, y)$. Consider a random sample $(X_1, Y_1), \ldots, (X_n, Y_n)$ drawn on (X, Y). The hypotheses of interest are

$$H_0: X \text{ and } Y \text{ are independent versus}$$
$$H_A: X \text{ and } Y \text{ are dependent.} \qquad (111)$$

A. Kendall's τ

Monotonicity is an easily understood association between X and Y. Let (X_1, Y_1) and (X_2, Y_2) be independent pairs with density $f(x, y)$. We say these pairs are **concordant** if $\mathrm{sgn}\{(X_1 - X_2)(Y_1 - Y_2)\} > 0$ and are **discordant** if $\mathrm{sgn}\{(X_1 - X_2)(Y_1 - Y_2)\} < 0$. The variables X and Y have an increasing relationship if the pairs tend to be concordant and a decreasing relationship if the pairs tend to be discordant. A population measure of this is given by **Kendall's** τ,

$$\tau = P[\mathrm{sgn}\{(X_1 - X_2)(Y_1 - Y_2)\} > 0]$$
$$- P[\mathrm{sgn}\{(X_1 - X_2)(Y_1 - Y_2)\} < 0]. \qquad (112)$$

Positive values of τ indicate increasing monotonicity, negative values indicate decreasing monotonicity, and $\tau = 0$ reflects neither. Furthermore, if X and Y are independent then $\tau = 0$. The converse of this is not true; however, the contrapositive is true, i.e., $\tau \neq 0$ implies X and Y are dependent. Based on the sample, an unbiased estimate of τ is

$$K = \binom{n}{2}^{-1} \sum_{i<j} \mathrm{sgn}\{(X_i - X_j)(Y_i - Y_j)\};. \qquad (113)$$

If X and Y are independent then the statistic K is distribution free. Correct standardization under $\tau = 0$ leads to the test statistic,

$$z_K = \frac{K}{\sqrt{n(n-1)(2n+5)/18}}, \qquad (114)$$

which is asymptotically normal under $\tau = 0$. Large values of $|z_K|$ indicate $\tau \neq 0$. A large sample level α test is to reject X and Y are independent, if $|z_K| > z_{\alpha/2}$. Note by the contrapositive statement cited here, rejection of $\tau = 0$ leads to the rejection of independence between X and Y.

B. Spearman's ρ_S

The population correlation coefficient ρ is a measure of linearity between X and Y. The usual estimate is the sample correlation coefficient given by

$$r = \frac{\sum_{i=1}^{n}(X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\sum_{i=1}^{n}(X_i - \bar{X})^2}\sqrt{\sum_{i=1}^{n}(Y_i - \bar{Y})^2}}. \qquad (115)$$

A simple rank analog is to replace X_i by $R(X_i)$, where $R(X_i)$ denotes the rank of X_i among $X_1, \ldots, X_n$, and likewise Y_i by $R(Y_i)$, where $R(Y_i)$ denotes the rank of Y_i among $Y_1, \ldots, Y_n$. Upon making this substitution, the denominator of the previous ratio is a constant. This results in the statistic,

$$r_S = \frac{\sum_{i=1}^{n}\left(R(X_i) - \frac{n+1}{2}\right)\left(R(Y_i) - \frac{n+1}{2}\right)}{n(n^2-1)/12}, \qquad (116)$$

which is called **Spearman's** ρ. Like Kendall's K statistic, r_S is an estimate of a population parameter, but it is a more complicated expression than τ. Under independence, this parameter is 0 and the statistic r_S is distribution free. Consider the standardized test statistic given by

$$z_S = \sqrt{n-1}r_s, \qquad (117)$$

which is asymptotically $N(0, 1)$ under independence. A large sample level α test is to reject independence between X and Y, if $|z_S| > z_{\alpha/2}$.

Stefan Problems

A. D. Solomon
Negev Academic College of Engineering

GLOSSARY

Ablation Melting process in which liquid formed is driven away by flow conditions at the surface, a key example being an ablating surface of a rocket during its passage through air.
Interface Surface separating the solid and liquid phases of a material undergoing melting or freezing.
Interface condition Condition, usually representing energy conservation, holding at the interface between liquid and solid.
Latent heat of melting Difference of specific internal energies of solid and liquid at the melt temperature.
Marangoni convection Convection of a fluid driven by the surface tension effects of any interfaces in the fluid. Its effect is dominant in microgravity when gravity-driven natural convection becomes ignorably small.
Melt temperature Temperature for equilibrium between liquid and solid states.
Moving boundary problem Mathematical problem of finding a function and a domain in which the function satisfies a differential equation and the domain is partly described by interface conditions holding at its bounding surface.
Mushy region Region consisting of slush (liquid mixed with fine solid particles, uniformly at the melt temperature).
Supercooled liquid Liquid at a temperature below its melt temperature.

STEFAN PROBLEMS are a class of mathematical problems arising from macroscopic models of melting and freezing. They are the mathematical models for simple phase change processes. In this article, we will describe their form by means of a specific example, their history, recent developments, and anticipated future work.

I. A CLASSICAL STEFAN PROBLEM

A. Physical Setting

The Stefan problem arises from a mathematical model of melting and freezing of materials. In their solid phase, the materials are assumed to have an ordered crystalline structure maintained by intermolecular bonds. Liquid, on the other hand, is marked by the molecules essentially maintaining their close contact, but no longer having the crystalline structure of the solid. The energy associated with this structure is the latent heat of the material (in, for example, joules per gram), and it must be added to the solid in order to melt the solid and turn it into liquid.

Melting and freezing occur at a temperature, the melt temperature, characteristic of the material. At atmospheric

pressure, water, for example, melts and freezes at 0°C.

Consider a large block of material in its solid phase and at its melt temperature everywhere. Assume that all but one of the faces of the block are insulated. At this face let us suddenly impose a temperature above the melting point. Instantaneously, we will see liquid form on the heated face. If the block is contained in a thin-walled container, for example, then the liquid will remain in the container and it will constitute an ever-growing layer between the heated container wall and the solid beyond. If the block is not in any container, then the liquid will flow away from the solid, whose melting will be driven by the imposed hot temperature at its surface. This latter process is known as ablation. In the former case the solid and liquid phases meet at an interface. The interface will be parallel to the heated face, and as time progresses, the melted region will continue to grow at the expense of the frozen region. Eventually, all of the solid will have melted and the container will be filled only with liquid.

In our experiment, the temperature of the solid remains at the melt temperature for all time: indeed, it could not decrease, since temperature declines only when heat is extracted; similarly, it could not increase without the material having melted. Thus, ice above 0°C becomes water. On the other hand, the temperature in the liquid will always rise and lie between the melt temperature and the imposed face temperature.

For our experiment of melting a block of material, the Stefan problem can be stated as follows:

- At all times after the moment when the face temperature was imposed, find the temperature at all points in the block together with the solid and liquid regions.

In the melting process the interfacial surface separating liquid and solid regions is always moving. Problems in which the boundary of the region of study is moving with time and is an unknown of the problem are called "moving boundary problems." The Stefan problem is such a moving boundary problem.

B. Mathematical Formulation

The mathematical formulation of the Stefan problem in its classical form consists in relationships between the variables of the melting process. These are the temperature distribution at all times, the location of the boundary between solid and liquid regions, the thermophysical properties of the material (solid and liquid conductivities, specific heats, etc.), and the imposed conditions (for example, the face temperature) at the exterior fixed boundary of the block. These relationships take the form of partial differential equations in the solid and liquid regions and additional conditions at the moving boundary expressing local energy conservation and temperature behavior at the interface of solid and liquid material. The resulting problem is extremely difficult, since while the temperature is varying, so is the region in which it is to be found. Thus, for our case of melting a block of material, the temperature remains constant in the solid region, while in the liquid, it must be found by solving an equation within a time-varying region whose determination is part of the problem.

To illustrate the mathematical formulation, consider the process of melting a slab of material, initially solid, occupying the interval $0 < x < \delta$. Suppose that the initial temperature of the material is the melt temperature T_{m}, and at an initial time $t = 0$, the temperature at the face $x = 0$ of the material is set for all time as the constant value $T_{\mathrm{L}} > T_{\mathrm{m}}$. As a result a melting process takes place resulting in a boundary, located at a point $x = X(t) > 0$, separating liquid to its left from solid at the melt temperature to its right. With passing time, the moving boundary $X(t)$ moves to the right until all the material is melted. Within the liquid region, the temperature $T(x, t)$ at a point x and time t obeys the heat equation

$$T_t(x, t) = \alpha T_{xx}(x, t),$$

with the subscripts denoting the corresponding partial derivatives. At the front $x = X(t)$ the temperature is identically equal to the melt temperature:

$$T(X(t), t) \equiv T_m, \qquad t > 0,$$

while for $x = 0$,

$$T(0, t) \equiv T_{\mathrm{L}}.$$

Conservation of energy at the moving boundary states that the rate at which energy arrives at the front from the left (by conduction) is equal to the rate at which heat is absorbed by the material as its heat of melting,

$$\rho L X'(t) = -k T_x(X(t), t), \qquad t > 0.$$

This condition is referred to as the Stefan condition. Here α is the thermal diffusivity of the liquid, L is the latent heat of melting, k is the liquid thermal conductivity, and ρ is the liquid density.

II. HISTORY OF THE PROBLEM

The first serious discussion of a melting/freezing problem was by G. Lame and B. Clapeyron in 1831 and focused on the scenario of our example. No solution to the problem was found, but they did state that the front depth from the

wall was proportional to the square root of the elapsed time measured from the imposition of the wall temperature.

In 1889, J. Stefan examined the process of freezing of the ground. We note that this problem is still one of intensive study, with importance in such areas as storage of heat, proper design of roadways, and the performance of heat exchangers for heat pumps. Stefan studied the problem posed by Lame and Clapeyron as well as the question of what would happen if solid and liquid blocks of the same material, the first at a temperature below the melt temperature, the second above, were brought rapidly into contact: would the solid melt, or would the liquid freeze? Each was solved in the sense that formulas for the temperature distribution and for the location of the moving boundary between phases were found for all times. We note that credit for the solution of the first problem is given to F. Neumann, who is said to have done this already in the 1860s but did not publish his result.

There are two major difficulties that must be overcome in order to find the location of solid and liquid regions and the temperature distribution as time evolves. The first is the varying nature of the regions: the second is the nonlinearity of the problem. Because of this, the linear techniques of applied mathematics of the late 19th and early 20th centuries, such as Fourier and Laplace transforms, were essentially inapplicable to the problem studied by Stefan. For this reason, no significant advances in the study or solution to problems of this type were made over a 40-year period following Stefan's work.

From the time of Stefan's work until the 1930s two kinds of activities were taking place that would bring the Stefan problem into sharper focus and render it more tractable. The first was a growing understanding of so-called generalized functions, first treated rigorously by D. Hilbert in the early 1900s. Unlike the strictly continuous and differentiable functions to which mathematical analysis had been limited before, these functions could be undefined everywhere but still, in some integrated sense, would have mathematical and physical meaning. The most famous of such functions is, of course, the delta function $\delta(x - x_0)$ representing a source of finite strength located at the single point x_0. The second development relevant to the Stefan problem was a growing tendency toward placing problems in an algorithmic setting, with a view toward computing solutions that would become a reality with the advent of computing machines.

Beginning in the 1930s, modest advances in the understanding and theoretical development of the Stefan problem began to be made. Existence, uniqueness, and continuous dependence on input parameters were proved for a number of standard problems in one space dimension. This work reached its fruition in the 1970s when for the case of one space dimension it was proved that the Stefan problem was mathematically well posed. Similarly, beginning with the space program in the 1950s, significant work was done on analytical and computational methods for melting and freezing processes, aimed at such applications as the use of waxes as thermal buffers for electronic equipment and the treatment of ablation problems. This work, performed in the engineering community, produced approximation techniques such as the Goodman and Megerlin methods that could provide accurate estimates of front location and temperature for one space dimension.

The numerical solution of Stefan problems began to be of great interest to researchers in the oil industry in the mid-1950s. Initial efforts produced specific schemes relevant to methods for driving oil to desired areas by pumping other fluids into the ground. In the 1960s, a number of researchers developed so-called weak methods based on the use of the enthalpy as the key variable (in place of temperature) for the numerical solution of the Stefan problem in any number of space dimensions for arbitrary boundary conditions. These methods continue to form the general-purpose numerical methodology for phase change problems, while such approaches as finite element methods are commonly used for specific processes of interest.

The theoretical treatment of Stefan problems in two and three dimensions remains essentially undone. Unlike one space dimension, two or more dimensions make possible almost unlimited degrees of discontinuity. Thus, for example, a sculptured ice unicorn melting in a pool of heated water can be reduced to any number of small chunks of ice at a later time.

III. RECENT WORK

In recent years, fueled by physical problems of interest and an exponentially expanding computing capability, the community of interest in the Stefan problem has expanded to include such far-flung areas as geophysics, food processing, medicine, metallurgy, and economics. This in turn has added challenging complexities to the form of the original problem explored by Stefan. We now describe some of them.

A. Mushy Zones

Suppose that a block of ice and a pool of water are both at the uniform temperature of 0°C and that the ice is ground into arbitrarily small chunks and thrown into the water. Since the chunks can be made as small as we wish, the resulting mixture, viewed on a normal length scale, is a slush that is neither solid nor liquid. In particular, its average enthalpy lies between that of solid and that of liquid at 0°C. We call such material mushy.

Mushy zones arise in a variety of situations. Certain materials solidify in such a way that the interface between solid and liquid is long and dendritic, with many treelike or columnar branches of arbitrarily small size. In this case, there is effectively a mushy zone between solid and liquid. Similarly, radioactive material is heated by its own decay heat. If a lump of solid radioactive metal is placed in an insulated container, the metal will be heated by its own internally generated heat until it reaches its normal melt temperature. Further heating will not affect its state (in principle) until a quantity of heat equal to the latent heat has been generated. Until this happens, the material is entirely mushy. In the same way, materials heated by electrical resistance, such as by welding or *in situ* vitrification, pass through a mushy stage when their enthalpy lies between that of solid and that of liquid at the melt temperature.

The theoretical treatment of mushy zones is to a large extent open. Each material solidifies in a manner characteristic of its crystal structure. Some salts, for example, exhibit very broad mushy zones under ordinary freezing while others do not; some have crystals that are long and columnar with liquid trapped in between; others have filmy dendritic fronts, again with liquid trapped in between. The use of generalized functions has enabled us to obtain general existence results even in the presence of possible mushy zones, but more precise results may well require a better understanding of the materials involved and the material-dependent aspects of the mushy zone phenomenon.

B. Supercooled Solidification

If we slowly cool a liquid in a very smooth container under very quiet conditions, we may observe that the temperature of the liquid goes below the normal melt temperature for a period of time; it then rises to the melt temperature and the liquid freezes rapidly. A liquid whose temperature is below its normal melting point is said to be supercooled. On thermodynamic grounds, a material in the liquid state but at a temperature below the normal melt temperature is unstable, and given any kind of physical or thermal perturbation, will quickly freeze. Water can be supercooled to temperatures as low as -40°C, while other materials, such as hydrated salts, can be cooled to temperatures much further below their normal melt temperature.

Numerical methods have been developed for simulating the solidification of supercooled material based on the weak solution approach.

C. Natural Convection

The density of a liquid depends on its temperature, generally decreasing with increasing temperature. Thus, any temperature gradient in the vertical direction with temperature increasing with increasing depth usually will induce a flow, or natural convection, much like that seen when heating a thick soup. Thus, the liquid formed in the course of melting a solid from the vertical side or from below will ordinarily begin to flow through natural convection, greatly enhancing heat transfer and altering the form of the relations for heat transfer in the liquid phase. The development of effective numerical methods for simulating this effect in three-dimensional space is an active area of research. In the casting of special metals and alloy systems (see Section III.D), natural convection may be a highly undesired effect. For this reason, there is a long-standing effort to explore casting and metal processing in space, where the effects of gravity are not present. However, in the microgravity of space, convection driven by surface tension, a form of natural convection known as Marangoni convection, occurs at the solid/liquid interface.

D. Alloy Solidification

In recent years, high technology in both civilian and military spheres has pushed us to develop alloys of ever-increasing precise constitution. For example, our needs for special sensors and photovoltaics have resulted in a need for very precisely structured alloy systems in their solid phase.

An alloy is a material formed by the bonding of its constituent elements and differing from both. Thus, a binary alloy of copper and nickel is defined by the relative amounts of copper and nickel present, and for each such composition it is a different material in terms of its thermophysical properties. Moreover, the liquid and solid phases of an alloy have an additional interesting property related to their coexistence. Let us briefly describe this by considering a pure material such as water.

A flat piece of ice and an adjacent body of water can coexist, that is, the ice will remain ice and the water will remain water if the temperature at the interface between them is 0°C. We say that this is a state of thermodynamic equilibrium of the two materials. In contrast, on the same thermodynamic grounds, a solid piece of an alloy with one composition is not generally in thermodynamic equilibrium with a liquid alloy of the same composition. Rather, for each composition of solid, there will be a necessarily different composition needed by a liquid to be in equilibrium with the solid. The implication of this fact for the Stefan problem is clear. When a liquid alloy solidifies, the liquid alloy adjacent to the moving interface must be of a different composition from the solid on the other side of the interface. If not, the system is unstable, as in the case of a supercooled liquid. However, in order that the composition of adjacent solid and liquid be

different there must be diffusion of the component materials, and the diffusion process must be as rapid as that of the heat transfer. Since this is generally not possible, solidification processes for alloy systems occur in the presence of a phenomenon known as constitutional supercooling, where in place of a sharp interfacial surface between solid and liquid we find a generally thick mushy zone of intermixed solid and liquid. Knowing how to adequately model this phenomenon thermodynamically, analytically, and numerically requires significant additional effort, both theoretical and numerical.

E. Ultrarapid Solidification and Melting Processes

In recent years, the tools of thermal processes have evolved from flames at relatively low temperatures and propagation speeds to lasers, which are capable of inputting large amounts of energy in time spans that can be measured in picoseconds. On mathematical grounds, this creates difficulties for the heat equation as a model of heat transfer. The heat equation has the mathematical property of transmitting thermal signals at infinite speed, an impossibility because, of course, they cannot move faster than the speed of light. This is no problem for thermal processes that have been used up to present times, for the predicted amount of heat moving at unrealistically high speeds is ignorably small. This does become a potential problem for such thermal processes as laser pulsing, and will present an ever-larger problem as mechanisms for heat transfer develop further. With this in mind, alternative mechanisms for modeling heat transfer have been developed (e.g., hyperbolic heat transfer), our understanding of which are correct is as yet poor. In addition, because rapid processes are often applied in melting situations, the correct formulation of a Stefan problem in terms of a more realistic heat transfer mechanism is of particular importance.

F. Voids

Density changes accompanying phase change processes can increase or reduce the volume of the material undergoing these changes. In the former case, one sees containers broken (such as water pipes in the winter). In the latter case, one observes containers that have buckled or the formation of voids. Voids are vapor bubbles of material formed as a result of volume reduction accompanying a phase change. For most materials, the density change upon freezing or melting is of the order of 10%. For some materials, such as lithium fluoride, they may be as great as 30%, with their formation inhibiting heat transfer and producing other problems as well.

G. Control

Since melting and freezing processes are of vital importance, their control is of great interest. A typical control situation involves "backtracking" from moving boundary location to boundary conditions (an inverse problem). Research in this area focuses largely on numerical procedures and inverse problems, and is largely open.

IV. FUTURE ACTIVITIES

In the next decades, the Stefan problem and the modeling of melting and freezing processes will be of ever-increasing interest. Future developments can be anticipated in the following areas.

A. Thermodynamics of Phase Change Processes

We will make significant progress in understanding the underlying mechanisms of freezing and melting for pure materials and alloy systems. We will also learn to better understand the thermodynamics of the interface. We note that the interface is itself an important factor in freezing and melting processes. The fact that energy is needed to maintain an interface results in a depression of the equilibrium temperature between a locally spherical crystal and adjacent liquid, a result due to Gibbs-Thomson. These efforts will encompass ultrarapid processes as well.

B. Control of Phase Change Processes

The automation of a broad variety of freezing processes with real-time control of thermal conditions at the boundary will take place in the coming decades under both gravity and microgravity conditions. The mathematics, software, and hardware needed for this control will be developed. One aspect of this capability will be in the area of latent heat thermal energy storage, that is, the storage of heat derived from intermittent sources, such as the sun, for use at a later time or in a different place. Other areas include food preservation, manufacturing of photovoltaics, and metal casting.

C. Large-Scale Simulation

The rapid development of distributed and massive computing capabilities will make it possible to perform simulations of large-scale, long-term phase change processes in three dimensions, including effects of natural convection in the melt, rapidly changing boundary conditions, and local surface effects.

D. Mathematical Analysis of the Stefan Problem

The dimensionality barrier of the analysis of the Stefan problem will be breached with well-posed results obtained for higher dimensional problems arising from pure heat transfer. In addition, significant advances will be made in coupled problems, where the effects of convection, composition, void formation, etc., are felt, and inverse problems for boundary conditions and thermophysical and diffusion parameters.

E. Testing of Simulation Software and Its Implications

The development of increasingly massive and sophisticated software products leads directly to the question of how to test this software. Thus, for example, a software package simulating loss of coolant accidents in nuclear reactors will need to include modules whose purpose is to simulate the melting of metals that come into contact with other molten metals or radioactive metals whose melting is induced by their own internally generated heat. Such modules are small parts of large codes, and the importance of the overall software package will demand their unquestioned correctness. The formulation of tests for these modules based on data input and output analysis is a major challenge because it encompasses all the material-related phenomena noted above (e.g., how to model ultrarapid melting) together with numerical analysis pitfalls (e.g., the consistency or Du-Fort Frankel-like schemes) as well as theoretical considerations (e.g., the proper formulation of inverse problems in which inputs are to be found on the basis of observed melt/freeze processes). We anticipate that the question of software testing will lead necessarily to the need for a more fundamental understanding of all aspects of the Stefan problem.

Stochastic Processes

Yûichirô Kakihara
California State University, San Bernardino

GLOSSARY

Probability space A triple consisting of a sample space Ω, a certain collection Σ of subsets of Ω, and a probability P defined on Σ.
Random variable A numerical function defined on the probability space.
Sample space The set of all possible outcomes of an experiment.
Stochastic process A collection of random variables often indexed by time.

IN AN EMPERICAL SENSE, a stochastic process is considered as the description of a random phenomenon evolving in time that is governed by certain laws of probability. Stochastic processes model fluctuations in economic behavior or stock markets, the path of a particle in a liquid, outputs of physical systems, and, in fact, most phenomena exhibiting unpredictable fluctuations. A mathematical abstraction of a stochastic process is any indexed collection of random variables defined on a fixed probability space. Probability theory is a branch of mathematics and the theory of stochastic processes is a part of it. Modern probability theory is based on Kolmogorov's axiomatic treatment using measure theory.

I. BASICS OF STOCHASTIC PROCESSES

The concept of a stochastic process is obtained as a collection of random variables, usually indexed by a time parameter. A random variable is a real- (or complex-) valued function defined on a probability space. Hence the notion of a stochastic process is a generalization of the idea of a random variable.

First we define a probability space according to Kolmogorov's axiomatic formulation. Thus a *probability space* consists of a triple (Ω, Σ, P), where Ω is a *sample space,* Σ is a σ*-algebra* of events, and P is a *probability* on Σ. Each $\omega \in \Omega$ represents an outcome of some experiment and is called a *basic event.* Each $A \in \Sigma$ is a

subset of Ω, called an *event.* Σ satisfies the following conditions:

(i) $\Omega \in \Sigma$.
(ii) $A \in \Sigma$ implies $A^c \in \Sigma$, A^c being the complement.
(iii) If $A_1, A_2, \ldots \in \Sigma$, then $\cup_{n=1}^{\infty} A_n \in \Sigma$.

P satisfies the following:

(iv) $0 \le P(A) \le 1$ for any $A \in \Sigma$.
(v) $P(\Omega) = 1$.
(vi) If $A_1, A_2, \ldots \in \Sigma$ are disjoint, then $P(\cup_{n=1}^{\infty} A_n) = \sum_{n=1}^{\infty} P(A_n)$.

In other words, the σ-algebra Σ is a collection of subsets of the sample space Ω that contains the entire event Ω and is closed under complementation and countable union. We also can say that the probabilty P is a measure taking values in $[0, 1]$ and countably additive.

Consider an experiment of rolling a die. The sample space Ω consists of six numbers 1, 2, 3, 4, 5, and 6. The σ-algebra Σ is then the set of all subsets of Ω, consisting of $2^6 = 64$ subsets. Probability is assigned $1/6$ to each $\omega = \{1\}, \ldots, \{6\}$ if the die is fair. If A is an event that the die faces up with a number less than or equal to 4, then $P(A) = 2/3$. A mapping $X: \Omega \to \mathbb{R} = (-\infty, \infty)$ is a (real) *random variable* if X is measurable, i.e., for any $x \in \mathbb{R}$,

$$\{\omega \in \Omega: X(\omega) < x\} \equiv \{X < x\} \in \Sigma. \tag{1}$$

If we denote the Borel σ-algebra of $\mathbb{R}$ by $\mathfrak{B} = \mathfrak{B}(\mathbb{R})$, then (1) is equivalent to

$$\{\omega \in \Omega: X(\omega) \in A\} \equiv \{X \in A\} \in \Sigma \tag{2}$$

for every $A \in \mathfrak{B}$. [Similarly, a complex random variable is defined as in (2) using the Borel σ-algebra $\mathfrak{B}(\mathbb{C})$ of the complex number field $\mathbb{C}$.] In this section, we shall consider real random variables unless otherwise stated. The *expectation* of a random variable X is defined by the integral of X over Ω if $E\{|X|\} < \infty$, where

$$E\{X\} = \int_{\Omega} X(\omega)\, P(d\omega).$$

Then the *distribution* of X is obtained as a probability on $(\mathbb{R}, \mathfrak{B})$:

$$P_X(A) = P(\{X \in A\}), \qquad A \in \mathfrak{B}.$$

In many cases, the distribution of a random variable determines many of its properties. The *distribution function* F_X of a random variable X is obtained as

$$F_X(x) = P_X((-\infty, x)), \qquad x \in \mathbb{R}.$$

Using the distribution function, we can write the expectation of X as the Stieltjes integral

$$E\{X\} = \int_{-\infty}^{\infty} x\, dF_X(x).$$

In a special case, there exists a *density function* p_X such that

$$F_X(x) = \int_{-\infty}^{x} p_X(r)\, dr, \qquad x \in \mathbb{R},$$

so that $p_X(x) = dF_X(x)/dx$. If

$$p(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left\{-\frac{(x-m)^2}{2\sigma^2}\right\}, \qquad x \in \mathbb{R}, \tag{3}$$

where $\sigma > 0$ and $m \in \mathbb{R}$, then p is called a *Gaussian* (or *normal*) density function and X is called a *Gaussian* (or *normal*) random variable. The probability distribution given by (3) is denoted as $N(m, \sigma^2)$. Random variables $X_1, \ldots, X_n$ are said to be *mutually independent* if their distribution functions satisfy

$$F_{X_1,\ldots,X_n}(x_1, \ldots, x_n) = F_{X_1}(x_1) \cdots F_{X_n}(x_n) \tag{4}$$

for any $x_1, \ldots, x_n \in \mathbb{R}$, where $F_{X_1,\ldots,X_n}$ is called the *joint distribution function* of $X_1, \ldots, X_n$ defined by

$$F_{X_1,\ldots,X_n}(x_1, \ldots, x_n) = P(\{X_1 < x_1, \ldots, X_n < x_n\}).$$

If the density functions exist, then (4) is equivalent to

$$p_{X_1,\ldots,X_n}(x_1, \ldots, x_n) = p_{X_1}(x_1) \cdots p_{X_n}(x_n),$$

where $p_{X_1,\ldots,X_n}$ is the density function of $F_{X_1,\ldots,X_n}$. The *characteristic function* of a random variable X is defined by

$$\Phi_X(\lambda) = E\{e^{i\lambda X}\}, \qquad \lambda \in \mathbb{R}.$$

A *stochastic process* is a collection of random variables on the same probability space indexed by a subset T of real numbers. In practice, each $t \in T$ represents a time. We usually denote a stochastic process on T by $\{X(t)\}_{t \in T}$ or simply by $\{X(t)\}$, where the underlying probability space (Ω, Σ, P) is fixed. Thus, for each $t \in T$, $X(t)$ is a random variable on (Ω, Σ, P) and its value at $\omega \in \Omega$ is denoted by $X(t, \omega)$. For each $\omega \in \Omega$, $X(\cdot, \omega)$ represents a function on T and is called a *sample path* or *realization* or *trajectory.* If T is a closed interval such as $\mathbb{R}$, $\mathbb{R}^+ = [0, \infty,)$, or $[0, 1]$, then we consider *continuous time* stochastic processes. If T is a discrete set such as $\mathbb{Z} = \{0, \pm 1, \pm 2, \ldots\}$ or $\mathbb{Z}^+ = \{0, 1, 2, \ldots\}$, then $\{X(t)\}$ is called a *discrete time* stochastic process or a *time series.*

Let $\{X(t)\}$ be a stochastic process on $T \subseteq \mathbb{R}$. Then, for $t_1, \ldots, t_n \in T$, the joint distribution function of $X(t_1), \ldots, X(t_n)$ is denoted by $F_{t_1,\ldots,t_n}(x_1, \ldots, x_n)$ and the joint density function by $p_{t_1,\ldots,t_n}(x_1, \ldots, x_n)$, if it exists, so that

$$F_{t_1,\ldots,t_n}(x_1,\ldots,x_n) = \int_{-\infty}^{x_1}\cdots\int_{-\infty}^{x_n} p_{t_1,\ldots,t_n}(r_1,\ldots,r_n)\,dr_1\cdots dr_n.$$

Then, distribution functions should satisfy the following conditions:

$$p_{t_1}(x_1) = \int_{-\infty}^{\infty} p_{t_1,t_2}(x_1,x_2)\,dx_2,$$

$$p_{t_1,\ldots,t_m}(x_1,\ldots,x_m) = \int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty} p_{t_1,\ldots,t_n}(x_1,\ldots,x_n)\,dx_{m+1}\cdots dx_n \tag{5}$$

for $m<n$, etc. This means that, if we know the higher joint distribution functions, then the lower joint distribution functions are obtained as marginal distribution functions. *Kolmogorov's* (1933) *consistency theorem* states that, if we are given a system of joint density functions $\{p_{t_1,\ldots,t_n}(x_1,\ldots,x_n)\}$ for which (5) is true and it holds under permutations of time, then there exists a real stochastic process $\{X(t)\}$ whose joint density functions are exactly this system.

II. STATISTICS OF STOCHASTIC PROCESSES

Consider a stochastic process $\{X(t)\}$ on $T\subseteq\mathbb{R}$. The *expectation* of a stochastic process $\{X(t)\}$ is a function of $t\in T$ given by

$$m(t) = E\{X(t)\}.$$

For an integer $k\geq 1$, the *kth absolute moment* of $\{X(t)\}$ is defined by a function of t as

$$M_k(t) = E\{|X(t)|^k\}.$$

$m(t)$ is sometimes called an *ensemble average* at time t. Another type of average is obtained. The *time average* of $\{X(t)\}$ on $\mathbb{R}$ is defined by

$$\overline{X}(\omega) = \lim_{s\to\infty}\frac{1}{2s}\int_{-s}^{s} X(t,\omega)\,dt.$$

$\overline{X}(\omega)$ exists for $\omega\in\Omega$ such that $X(\cdot,\omega)$ is bounded and measurable on $\mathbb{R}$ or, in particular, $X(\cdot,\omega)$ is bounded and continuous on $\mathbb{R}$. Moreover, if this is true for all $\omega\in\Omega$, then $\overline{X}(\omega)$ defines a random variable. If $m(t)\equiv m=\overline{X}(\omega)$ P-a.e., then the process $\{X(t)\}$ is said to be *ergodic*. Thus, a stochastic process is ergodic if its ensemble average is equal to its time average. Here, P-a.e. refers to P-almost everywhere.

If $M_2(t)<\infty$ for all $t\in T$, then we say that $\{X(t)\}$ is a *second-order* stochastic process. The set of all complex random variables of finite second moment forms a Hilbert space $L^2(\Omega,\Sigma,P)=L^2(P)$, where the inner product and the norm are respectively defined by

$$(X,Y)_2 = E\{X\overline{Y}\},\qquad \|X\|_2 = E\{|X|^2\}^{1/2},$$

for $X,Y\in L^2(P)$, where $\overline{z}$ is the complex conjugate of $z\in\mathbb{C}$. The *mixed moment function* of $\{X(t)\}$ is defined by

$$R(s,t) = (X(s),X(t))_2,\qquad s,t\in T.$$

Similarly, the *covariance function* of $\{X(t)\}$ is defined by

$$K(s,t) = (X(s)-m(s),X(t)-m(t))_2,\qquad s,t\in T.$$

K (and also R) is a *positive-definite kernel* on $\mathbb{R}\times\mathbb{R}$, i.e.,

$$\sum_{j,k=1}^{n}\alpha_j\overline{\alpha}_k K(t_j,t_k)\geq 0$$

for any integer $n\geq 1$, $t_1,\ldots,t_n\in T$, and $\alpha_1,\ldots,\alpha_n\in\mathbb{C}$. Moreover, a Schwarz-type inequality holds:

$$|K(s,t)|^2\leq K(s,s)K(t,t),\qquad s,t\in T.$$

A stochastic process $\{X(t)\}$ is said to be *centered* if $m(t)\equiv 0$, in which case we have $K(s,t)=R(s,t)$. The *characteristic function* of $\{X(t)\}$ is defined by

$$\Phi_t(\lambda) = E\left\{e^{i\lambda X(t)}\right\} = \int_{-\infty}^{\infty} e^{i\lambda x}\,dF_t(x),$$

$$\Phi_{t_1,\ldots,t_n}(\lambda_1,\ldots,\lambda_n) = \int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty} e^{i(\lambda_1x_1+\cdots+\lambda_nx_n)} \times dF_{t_1,\ldots,t_n}(x_1,\ldots,x_n).$$

It is easily seen that for any $\lambda,\lambda_1,\ldots,\lambda_n\in\mathbb{R}$

$$|\Phi_t(\lambda)|\leq\int_{-\infty}^{\infty} dF_t(x) = \Phi_t(0) = 1,$$

$$|\Phi_{t_1,\ldots,t_n}(\lambda_1,\ldots,\lambda_n)|\leq\Phi_{t_1,\ldots,t_n}(0,\ldots,0)=1.$$

III. SOME EXAMPLES OF STOCHASTIC PROCESSES

We now examine some special stochastic processes which are used to model physical phenomena practically.

A. Gaussian Processes

A real stochastic process $\{X(t)\}$ on $\mathbb{R}$ is said to be *Gaussian* if for every integer $n\geq 1$ its n-dimensional joint distribution is Gaussian, i.e., the density function $p_{t_1,\ldots,t_n}(x_1,\ldots,x_n)$ is of the form

$$p_{t_1,\ldots,t_n}(x_1,\ldots,x_n) = \frac{1}{(2\pi)^{n/2}|V|^{1/2}} \times\exp\left\{-\frac{1}{2}(\mathbf{x}-\mathbf{m})V^{-1}(\mathbf{x}-\mathbf{m})^{\mathrm{t}}\right\},$$

where $\mathbf{x} = (x_1, \ldots, x_n)$, $\mathbf{m} = (m(t_1), \ldots, m(t_n)) \in \mathbb{R}^n$,

$$V = ((X(t_i) - m(t_i), X(t_j) - m(t_j))_2)_{i,j}$$

is an invertible $n \times n$ positive-definite Hermitian matrix, and $|V|$ is the determinant of V, with the superscript t being the transpose. One important characteristic of Gaussian processes is that if we are given a function $m(t)$ and a positive-definite function $K(s, t)$, then we can find a (complex) Gaussian process for which $m(t)$ is its expectation and $K(s, t)$ is its covariance function. As is seen from the Central Limit Theorem, the Gaussian distribution is universal and it is reasonable to use the Gaussian assumption on a stochastic process unless there is another specific choice.

B. Markov Processes

A real stochastic process $\{X(t)\}$ on $T = \mathbb{R}, \mathbb{R}^+, \mathbb{Z}$, or $\mathbb{Z}^+ = \{0, 1, 2, \ldots\}$ is said to be a *Markov process* if for any $s_1 < \cdots < s_n < t$ it holds that

$$P\big(X(t) \in A | X(s_1) = x_{s_1}, \ldots, X(s_n) = x_{s_n}\big) = P\big(X(t) \in A \mid X(s_n) = x_{s_n}\big)$$

P-a.e. for any $A \in \Sigma$, where $P(\cdot|\cdot)$ is the conditional probability. In this case, there exits a function $P(s, x, t, A)$, called the *transition probability*, for $s, x, t \in T$ and $A \in \Sigma$, such that the following hold:

(i) For fixed $s, t \in T$, $P(s, x, t, \cdot)$ is a probability for each $x \in T$, and $P(s, \cdot, t, A)$ is $\mathfrak{B}$-measurable for each $A \in \Sigma$.

(ii) $P(s, x, s, A) = \begin{cases} 1, & x \in A, \\ 0, & x \notin A. \end{cases}$

(iii) $P(X(t) \in A \mid X(s) = x_s) = P(s, x_s, t, A)$, P-a.e.

(iv) (Chapman–Kolmogorovs equation) For fixed $s, u, t \in \mathbb{R}$

$$P(s, x, u, A) = \int_{-\infty}^{\infty} P(s, x, t, dy) P(t, y, u, A),$$

P_{X_s}-a.e.x.

Conversely, if a family of functions $\{P(s, x, t, A)\}$ is given such that (i), (ii), and (iv) hold, and a probability P_0 on $(\mathbb{R}, \mathfrak{B})$ is given, then there exists a Markov process $\{X(t)\}$ for which $P(s, x, t, A)$ is the transition probability and P_0 is the distribution of $X(0)$, i.e., the initial distribution.

There are some special Markov processes. A Markov process $\{X(t)\}$ is said to be *temporally homogeneous* if the transition probability depends on the difference of t and s, i.e., $P(s, x, t, A) = P(t - s, x, A)$. A Markov process $\{X(t)\}$ is said to be *spatially homogeneous* if $P(s, x, t, A) = P(s, t, A - x)$, where $A - x = \{y - x : y \in A\}$. A real stochastic process $\{X(t)\}$ on $\mathbb{R}^+$ is called an *additive process* if $X(0) = 0$ and for any $t_1, \ldots, t_n \in \mathbb{R}^+$ with $t_1 < \cdots < t_n$, $X(t_2) - X(t_1), \ldots, X(t_n) - X(t_{n-1})$ are mutually independent. As can be seen, each spatially homogeneous Markov process is an additive process. A stochastic process $\{X(t)\}$ on $\mathbb{R}^+$ is called a *diffusion process* if it is a Markov process such that the sample path $X(\cdot, \omega)$ is a continuous function on $\mathbb{R}^+$ for almost every $\omega \in \Omega$. If $\{X(t)\}$ is a Markov process and the range of $X(t, \cdot)$, $t \in T$, is a countable set, it is called a *Markov chain*. A *random walk* is a special case of a Markov chain.

C. Brownian Motion

The botanist R. Brown was observing pollens floating on the surface of water and discovered that these particles were moving irregularly all the time. If we consider a particle floating in the air or in the liquid as above, its motion caused by collisions with molecules of the air or the liquid is extremely irregular and regarded as a stochastic process. More precisely, if we denote the position of the particle at time t by $\mathbf{X}(t) = (X_1(t), X_2(t), X_3(t))$, then $\mathbf{X}(t)$ is a three-dimensional random variable such that $\mathbf{X}(t) - \mathbf{X}(s)$ obeys a three-dimensional Gaussian distribution. This kind of motions was considered as a class of stochastic processes and investigated by A. Einstein, N. Wiener, and P. Levy.

Here is a precise definition. A stochastic process $\{\mathbf{X}(t)\}$ on $T \subseteq \mathbb{R}$ is said to be a *Wiener process* or a *Brownian motion* if the following conditions hold:

(i) $\mathbf{X}(t, \omega) \in \mathbb{R}^d$ (d is a positive integer).

(ii) For $t_1 < \cdots < t_n$, $\mathbf{X}(t_2) - \mathbf{X}(t_1), \ldots, \mathbf{X}(t_n) - \mathbf{X}(t_{n-1})$ are mutually independent.

(iii) If $\mathbf{X}(t) = (X_1(t), \ldots, X_d(t))$, then $\{X_1(t)\}, \ldots, \{X_d(t)\}$ are mutually independent stochastic processes such that $X_i(t) - X_i(s) \approx N(0, |t - s|)$ for each i, i.e., $X_i(t) - X_i(s)$ obeys the Gaussian distribution $N(0, |t - s|)$.

It follows from the definition that a Wiener process is a temporally homogeneous additive process. Moreover, a Wiener process is a special case of a diffusion process since $S = \mathbb{R}^d$ is the state space [i.e., the range of the random variables $X(t)$, $t \in \mathbb{R}$] and the transition probabilities are given by

$$P(t, \mathbf{x}, B) = \int_B \frac{1}{(2\pi t)^{d/2}} \exp\left\{-\frac{1}{2t}|\mathbf{x} - \mathbf{y}|^2\right\} d\mathbf{y},$$

where $t > 0$, $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$, $B \in \mathfrak{B}(\mathbb{R}^d)$, and $|\mathbf{x}| = \sqrt{x_1^2 + \cdots + x_d^2}$, the norm of $\mathbf{x} = (x_1, \ldots, x_d)$.

D. Stationary Processes

Stationarity is considered as an invariance under the time shift. There are two kinds of stationarity, weak and strong. A stochastic process $\{X(t)\}$ is said to be *strongly stationary* or *stationary in the strict sense* if the joint distribution is invariant under the time shift, i.e., for any $t, t_1, \dots, t_n \in T$ and $E \in \mathfrak{B}(\mathbb{C}^n)$, the Borel σ-algebra of $\mathbb{C}^n$, it holds that

$$P((X(t_1+t), \dots, X(t_n+t)) \in E) = P((X(t_1), \dots, X(t_n)) \in E).$$

A second-order stochastic process $\{X(t)\}$ is said to be *weakly stationary* or *stationary in the wide sense* if its average is constant, if its covariance function $K(s,t)$ depends only on the difference $s-t$, and if K is continuous as a two-variable function. Clearly, if the process is of second order and the covariance function is continuous, then strong stationarity implies weak stationarity. The converse is true for Gaussian processes. In general, a strongly stationary process need not have any moment (e.g., a Cauchy stationary process). Weak stationarity will be singled out and discussed in the next section.

E. White Noise

A discrete or continuous time stochastic process $\{X(t)\}$ is called a *white noise* if $E\{X(t)\} \equiv 0$ and $K(s,t) = \delta(s-t)$, the Kronecker delta function, i.e., $= 1$ for $s = t$ and $= 0$ for $s \neq t$. A white noise does not exist in a real world. But as a mathematical model it is used in many fields. It is known that the derivative of a Wiener process as a generalized stochastic process is a white noise (cf. Section VIII).

IV. WEAKLY STATIONARY STOCHASTIC PROCESSES

Weak stationarity for second-order stochastic processes was initiated by Khintchine (1934). Let us begin with the definition again. A stochastic process $\{X(t)\}$ on $T = \mathbb{R}$ or $\mathbb{Z}$ is said to be *weakly stationary* or *wide sense stationary* if its expectation is constant and if the covariance function is continuous and depends only on the difference of the variables. In other words, $\{X(t)\}$ is weakly stationary if the following hold:

(i) $m(t) = E\{X(t)\} \equiv m$ for $t \in T$.
(ii) $K(s,t) = \tilde{K}(s-t)$ for $s, t \in T$.
(iii) $\tilde{K}(\cdot)$ is continuous on T.

If $T = \mathbb{Z}$, the condition (iii) is automatically satisfied. We may assume that $m = 0$ in (i) [since otherwise we can let $Y(t) = X(t) - m$] and consider processes on $\mathbb{R}$. Denote by $L_0^2(P)$ the closed subspace of $L^2(P)$ consisting of functions with zero expectations, i.e., $L_0^2(P) = \{X \in L^2(P): E\{X\} = 0\}$. So we consider centered processes $\{X(t)\} \subseteq L_0^2(P)$.

Let us proceed to obtain integral representations of a weakly stationary process and its covariance function, and the Kolmogorov isomorphism theorem, which states that the time and the spectral domains are isomorphic.

Thus, suppose $\{X(t)\}$ is a weakly stationary process on $\mathbb{R}$ with the (one-variable) covariance function $K(t)$. Since $K(t)$ is continuous and positive definite, there exists, by Bochner's theorem, a finite positive measure ν on $(\mathbb{R}, \mathfrak{B})$ such that

$$K(t) = \int_{-\infty}^{\infty} e^{itu}\, \nu(du), \qquad t \in \mathbb{R}. \tag{6}$$

ν is called the *spectral measure* of the process. The *time domain* $H(X)$ of $\{X(t)\}$ is defined by

$$H(X) = \mathfrak{S}\{X(t): t \in \mathbb{R}\},$$

the closed subspace of $L_0^2(P)$ spanned by the set $\{X(t): t \in \mathbb{R}\}$. To derive an integral representation of the process itself, define an operator $U(t)$ by

$$U(t)X(s) = X(s+t), \qquad s \in \mathbb{R},$$

or more generally by

$$U(t)\left(\sum_{k=1}^{n} \alpha_k X(t_k)\right) = \sum_{k=1}^{n} \alpha_k X(t_k + t),$$

where $\alpha_1, \dots, \alpha_n \in \mathbb{C}$, $t_1, \dots, t_n \in \mathbb{R}$. Then because of stationarity we see that $U(t)$ is well defined and norm preserving, and can be extended to a unitary operator on the time domain $H(X)$. Hence, by Stone's theorem, there is a spectral measure (i.e., an orthogonal projection-valued measure) E on $(\mathbb{R}, \mathfrak{B})$ such that

$$U(t) = \int_{-\infty}^{\infty} e^{itu}\, E(du), \qquad t \in \mathbb{R}.$$

Consequently we have that

$$X(t) = U(t)X(0) = \int_{-\infty}^{\infty} e^{itu}\, E(du)\, X(0), \qquad t \in \mathbb{R}.$$

If we let $\xi(A) = E(A)X(0)$ for $A \in \mathfrak{B}$, then the random quantity ξ is an $L_0^2(P)$-valued, bounded, countably additive measure, and is *orthogonally scattered*, i.e., $(\xi(A), \xi(B))_2 = 0$ if $A \cap B = \emptyset$. Therefore, we get an integral representation of the process $\{X(t)\}$ as

$$X(t) = \int_{-\infty}^{\infty} e^{itu}\, \xi(du), \qquad t \in \mathbb{R}. \tag{7}$$

By (6) and (7) we see that $\nu(A) = (\xi(A), \xi(A))_2$ for $A \in \mathfrak{B}$.

Consider the Hilbert space $L^2(\nu) = L^2(\mathbb{R}, \mathfrak{B}, \nu)$, which is called the *spectral domain* of the process $\{X(t)\}$. Then

the *Kolmogorov isomorphism theorem* states that the time domain $H(X)$ and the spectral domain $L^2(\nu)$ are isomorphic as Hilbert spaces. Moreover, the isomorphism $V: L^2(\nu) \to H(X)$ is given by

$$V(f) = \int_{-\infty}^{\infty} f(u)\,\xi(du), \qquad f \in L^2(\nu). \tag{8}$$

The importance of this theorem is that each random variable in $H(X) \subseteq L_0^2(P)$ is expressed as a vector integral of a usual function and, especially, $X(t)$ is a Fourier transform of a vector measure ξ. Furthermore, the measure ξ can be obtained from the process $X(t)$ by inversion as

$$\xi((u, v)) = \lim_{t\to\infty} \int_{-t}^{t} \frac{e^{-ivs} - e^{-ius}}{-is} X(s)\,ds, \tag{9}$$

where $u < v$, $\xi(\{u\}) = \xi(\{v\}) = 0$, and the right-hand side is a Bochner integral (cf. Section VI). Thus (9) is called the *inversion formula*.

V. CLASSES OF NONSTATIONARY STOCHASTIC PROCESSES

Stationarity in the strict sense or wide sense is very restrictive in a practical application and somewhat weaker conditions are needed in many cases. For the sake of simplicity we consider only centered second-order stochastic processes and use the space $L_0^2(P)$. The following are classes of nonstationarity.

A. Karhunen Class

Karhunen (1947) introduced a class of stochastic processes given by

$$X(t) = \int_{-\infty}^{\infty} g_t(u)\,\xi(du), \qquad t \in \mathbb{R}, \tag{10}$$

where ξ is an $L_0^2(P)$-valued orthogonally scattered measure and $\{g_t: t \in \mathbb{R}\} \subseteq L^2(\nu)$ with $\nu(\cdot) = \|\xi(\cdot)\|_2^2$. In this case the covariance function is given by

$$K(s, t) = \int_{-\infty}^{\infty} g_s(u)\overline{g_t(u)}\,\nu(du), \qquad s, t \in \mathbb{R}.$$

When $g_t(u) = e^{itu} (t \in \mathbb{R})$, $\{X(t)\}$ reduces to a weakly stationary process.

B. Harmonizable Class

Harmonizability was first introduced by Loève in the middle 1940s. Later a weaker harmonizability was defined by Rozanov (1959). These two notions were distinguished by calling them weak and strong harmonizabilities by Rao (1982).

A second-order stochastic process $\{X(t)\}$ on $\mathbb{R}$ is said to be *strongly harmonizable* if its covariance function K has a representation

$$K(s, t) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{i(su-tv)}\,\beta(du, dv), \qquad s, t \in \mathbb{R}, \tag{11}$$

for some *positive-definite bimeasure* $\beta: \mathfrak{B} \times \mathfrak{B} \to \mathbb{C}$ of bounded variation, where $\mathfrak{B} \times \mathfrak{B} = \{A \times B: A, B \in \mathfrak{B}\}$ and the total *variation* (= *Vitali variation*) is given by

$$|\beta|(\mathbb{R}, \mathbb{R}) = \sup \sum_{j=1}^{\ell}\sum_{k=1}^{n} |\beta(A_j, B_k)|,$$

the supremum being taken for all finite measurable partitions $\{A_1, \ldots, A_\ell\}$ and $\{B_1, \ldots, B_n\}$ of $\mathbb{R}$. Here, $\beta: \mathfrak{B} \times \mathfrak{B} \to \mathbb{C}$ is a *bimeasure* if $\beta(A, \cdot)$ and $\beta(\cdot, A)$ are $\mathbb{C}$-valued measures on $\mathfrak{B}$ for each $A \in \mathfrak{B}$. When β is of bounded variation, i.e., $|\beta|(\mathbb{R}, \mathbb{R}) < \infty$, β can be extended to an ordinary measure on $\mathfrak{B}(\mathbb{R}^2)$ (the Borel σ-algebra of $\mathbb{R}^2$) and (11) becomes the Lebesgue integral. When β is of unbounded variation, we need to interpret (11) as a bimeasure integral or (a weaker) MT-integral (after Morse and Transue). Since every bimeasure satisfies $\sup\{|\beta(A, B)|: A, B \in \mathfrak{B}\} < \infty$, we can show that (11) is well defined. So, $\{X(t)\}$ is said to be *weakly harmonizable* if its covariance function K is expressed as (11) for some positive-definite bimeasure β. Since the integrand $e^{i(su-tv)} = \varphi_1(u)\varphi_2(v)$, say, in the integral (11) is the product of bounded continuous functions of one variable, we can interpret the MT-integral as follows. For $A, B \in \mathfrak{B}$, φ_1 is $\beta(\cdot, B)$-integrable and φ_2 is $\beta(A, \cdot)$-integrable. Hence, letting

$$\mu_1(A) = \int_{-\infty}^{\infty} \varphi_2(v)\,\beta(A, dv), \qquad A \in \mathfrak{B},$$

$$\mu_2(B) = \int_{-\infty}^{\infty} \varphi_1(u)\,\beta(du, B), \qquad B \in \mathfrak{B},$$

we see that μ_1 and μ_2 are $\mathbb{C}$-valued measures on $\mathfrak{B}$, and φ_j is μ_j-integrable $(j = 1, 2)$. Moreover, when they have the same integral, i.e.,

$$\int_{-\infty}^{\infty} \varphi_1(u)\,\mu_1(du) = \int_{-\infty}^{\infty} \varphi_2(v)\,\mu_2(dv),$$

we denote the value by $\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \varphi_1(u)\varphi_2(v)\,\beta(du, dv)$.

An integral representation of a weakly harmonizable process $\{X(t)\}$ is obtained:

$$X(t) = \int_{-\infty}^{\infty} e^{itu}\,\xi(du), \qquad t \in \mathbb{R}, \tag{12}$$

for some $L_0^2(P)$-valued bounded measure ξ, not necessarily orthogonally scattered. The measure ξ is called the

representing measure of $\{X(t)\}$ and the inversion formula (9) is also valid. Furthermore, comparing (11) and (12), we see that

$$\beta(A, B) = (\xi(A), \xi(B))_2, \qquad A, B \in \mathfrak{B}.$$

As is easily seen, a weakly harmonizable process is weakly stationary if and only if the representing measure is orthogonally scattered. If a weakly stationary process is projected onto a closed subspace of its time domain, then the resulting process is not necessarily weakly stationary but always weakly harmonizable. The converse is known as a *stationary dilation.* That is, each weakly harmonizable process can be obtained as an orthogonal projection of some weakly stationary process.

The Kolmogorov isomorphism theorem holds for a weakly harmonizable process $\{X(t)\}$. The spectral domain of $\{X(t)\}$ is defined to be the space $\mathcal{L}_*^2(\beta)$ of all functions $f(u)$ on $\mathbb{R}$ that are *strictly integrable* with respect to the bimeasure β, in a somewhat "restricted sense." Then, the time domain $H(X)$ and the spectral domain $\mathcal{L}_*^2(\beta)$ are isomorphic Hilbert spaces, where the isomorphism is given by

$$V(f) = \int_{-\infty}^{\infty} f(u)\,\xi(du), \qquad f \in \mathcal{L}_*^2(\beta),$$

which is similar to (8). The weakly harmonizable class is a fruitful area of study with many applications because each process in this class is a Fourier transform of a vector measure and is relatively simple to handle.

C. Cramér Class

A further generalization of the Karhunen class was introduced by Cramér (1951). A stochastic process $\{X(t)\}$ is said to be *of strong Cramér class* if its covariance function is written as

$$K(s,t) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} g_s(u)\overline{g_t(v)}\,\beta(du, dv), \qquad s, t \in \mathbb{R}, \tag{13}$$

for some positive-definite bimeasure β of bounded variation and some family $\{g_t : t \in \mathbb{R}\}$ of bounded Borel functions on $\mathbb{R}$. When the bimeasure β in (13) is simply bounded, $\{X(t)\}$ is *of weak Cramér class* relative to the family $\{g_t : t \in \mathbb{R}\}$. Integral representations of such processes are available. If $\{X(t)\}$ is of weakly or strongly Cramér class, then there exists an $L_0^2(P)$-valued measure ξ such that (10) is true. As a harmonizable process has a stationary dilation, each process of Cramér class has a *Karhunen dilation,* i.e., it is expressed as an orthogonal projection of some process of Karhunen class.

D. KF Class

The concept of the spectral measure can be generalized. In the late 1950s, Kampe de Fériet, and Frankiel, and independently Parzen and Rozanov, defined the "associated spectrum" for a process $\{X(t)\}$ for which

$$\tilde{K}(h) = \lim_{t\to\infty} \frac{1}{t}\int_0^t K(s, s+h)\,ds, \qquad h \in \mathbb{R},$$

exists and is positive definite and continuous in h, where K is the covariance function of the process. In this case, by Bochner's theorem there exists a finite positive measure ν on $(\mathbb{R}, \mathfrak{B})$, called the *associated spectrum* of $\{X(t)\}$, such that

$$\tilde{K}(h) = \int_{-\infty}^{\infty} e^{ihu}\,\nu(du), \qquad h \in \mathbb{R}.$$

Such a process is said to be *of KF class* or an *asymptotically stationary* process. Unfortunately, not every process of KF class allows an integral representation of the process itself. A strongly harmonizable process is necessarily of KF class, but a weakly harmonizable process is not in general.

E. Periodically Correlated Class

The number of black spots in the surface of the Sun increases periodically every 11 years. To describe such a phenomenon we use a periodically correlated process. Here, we consider only discrete time processes, namely those on $\mathbb{Z}$. A process $\{X(t)\}$ on $\mathbb{Z}$ is said to be *periodically correlated with period* $p > 0$ if the covariance function K satisfies

$$K(s,t) = K(s+p, t+p), \qquad s, t \in \mathbb{Z}.$$

If $p = 1$, then the process is weakly stationary. So we assume $p \geq 2$.

Consider the Cartesian product space $[L_0^2(P)]^p = L_0^2(P) \times \cdots \times L_0^2(P)$. For $\mathbf{X} = (X_1, \ldots, X_p)$ and $\mathbf{Y} = (Y_1, \ldots, Y_p) \in [L_0^2(P)]^p$ define

$$(\mathbf{X}, \mathbf{Y})_{2,p} = \sum_{j=1}^{p} (X_j, Y_j)_2,$$

so that $(\cdot,\cdot)_{2,p}$ is an inner product in $[L_0^2(P)]^p$. Also define a new process $\{\mathbf{X}(t)\}$, which is $[L_0^2(P)]^p$-valued, by

$$\mathbf{X}(t) = (X(t), X(t+1), \ldots, X(t+p-1)), \qquad t \in \mathbb{Z}.$$

Then we can verify that an $L_0^2(P)$-valued process $\{X(t)\}$ is periodically correlated with period p if and only if the $[L_0^2(P)]^p$-valued process $\{\mathbf{X}(t)\}$ is weakly stationary. Moreover, note that $L_0^2(P)$ can be regarded as a closed subspace of $[L_0^2(P)]^p$ if we identify $L_0^2(P)$ with $L_0^2(P) \times \{0\} \times \cdots \times \{0\}$. Hence, if $\{X(t)\}$ is periodically

correlated with period p and $J: [L_0^2(P)]^p \to L_0^2(P)$ is the orthogonal projection, then $X(t) = J\mathbf{X}(t)$, $t \in \mathbb{Z}$. Therefore, $\{X(t)\}$ is weakly harmonizable and $\{\mathbf{X}(t)\}$ is its stationary dilation. Furthermore, it is known that $\{X(t)\}$ is strongly harmonizable.

VI. THE CALCULUS OF STOCHASTIC PROCESSES

A. Convergence

In order to talk about continuity, differentiability, and integrability of stochastic processes on $\mathbb{R}$, we need to present the notion of convergence of a sequence of random variables. Let $\{X_n\}$ be a sequence of random variables and X a random variable on a probability space (Ω, Σ, P). We say that $\{X_n\}$ converges to X:

1. *Everywhere* if $X_n(\omega) \to X(\omega)$ for every $\omega \in \Omega$
2. *Almost everywhere* (a.e.), *almost surely* (a.s.), or *with probability* 1, if $P(\{\omega \in \Omega: X_n(\omega) \to X(\omega)\}) = 1$
3. *In mean-square* or *in L^2-mean* if $\|X_n - X\|_2 \to 0$
4. *In probability* if for any $\varepsilon > 0$, $P(\{|X_n - X| > \varepsilon\}) \to 0$
5. *In distribution* if $F_n(x) \to F(x)$ for each $x \in \mathbb{R}$ for which F is continuous, where F_n and F are distribution functions of X_n and X, respectively.

When the density functions exist, the last condition is equivalent to $p_n(x) \to p(x)$ for almost all $x \in \mathbb{R}$, where p, p_n are density functions.

The interrelationship among these convergences is as follows:

everywhere convergence
⇓
a.e. convergence mean-square convergence
⇓ ⇓
convergence in probability
⇓
convergence in distribution.

B. Continuity

Consider a continuous time second-order stochastic process $\{X(t, \omega)\} = \{X(t)\}$ on $T \subseteq \mathbb{R}$. If we choose an $\omega \in \Omega$, then $X(\cdot, \omega)$ is a function of $t \in T$ (a sample path) and its continuity is discussed. We say that $\{X(t)\}$ is *continuous* a.e. or has a *sample path continuity* a.e. if, for a.e. $\omega \in \Omega$, the scalar function $X(\cdot, \omega)$ is a continuous function on T.

Another type of continuity is in the mean-square sense. $\{X(t)\}$ is said to be *continuous in mean-square* at $t_0 \in T$ if

$$\|X(t) - X(t_0)\|_2 \to 0 \qquad \text{as} \quad t \to t_0,$$

which is equivalent to the continuity of the covariance function $K(s, t)$ at (t_0, t_0). Since

$$\begin{aligned} |E\{X(t)\} - E\{X(t_0)\}| &\le E\{|X(t) - X(t_0)|\} \\ &\le \left[E\left\{|X(t) - X(t_0)|^2\right\}\right]^{1/2} \\ &= \|X(t) - X(t_0)\|_2, \end{aligned}$$

we see that the expectation of $X(t)$ is continuous at t_0 if $\{X(t)\}$ is continuous in mean-square at t_0.

C. Differentiability

Let $\{X(t, \omega)\} = \{X(t)\}$ be a second-order stochastic process on an interval $T \subseteq \mathbb{R}$. First consider a sample path differentiability. $\{X(t)\}$ has *a.e. differentiable sample path* if, for a.e. $\omega \in \Omega$, the sample path $X(\cdot, \omega)$ is differentiable. Another type of derivative is in the mean-square sense. $\{X(t)\}$ is *differentiable in mean-square* at t_0 if there is a random variable $X'(t_0)$ such that

$$\left\| \frac{X(t_0 + h) - X(t_0)}{h} - X'(t_0) \right\|_2 \to 0 \qquad \text{as} \quad h \to 0.$$

If $\{X(t)\}$ on $\mathbb{R}$ is weakly stationary with the covariance function $K(t)$, then it is differentiable in mean-square at t_0 if and only if K has the second derivative at t_0. When $\{X(t)\}$ is nonstationary with the covariance function $K(s, t)$, it is differentiable in mean-square at t_0 if $\partial^2 K / \partial s \partial t$ exists at $s = t = t_0$.

D. Integrability

Consider a second-order stochastic process $\{X(t)\}$ on $[a, b]$ and its integral

$$\int_a^b X(t, \omega)\, dt. \tag{14}$$

If, for all $\omega \in \Omega$, the sample path $X(\cdot, \omega)$ is continuous or bounded and measurable, then the integral (14) is defined as a Riemann or Lebesgue integral and defines a random variable $Y(\omega)$. If this is not the case, however, we can consider (14) in a mean-square sense. Then, the integrand is an $L_0^2(P)$-valued function $X(t)$, the measure is the Lebesgue measure dt, and the integral (14) is a *Bochner integral.* The definition of this integral is as follows: Let

$$X_n(t) = \sum_{k=1}^{k_n} 1_{A_{n,k}}(t) X_{n,k},$$

where $X_{n,k} \in L_0^2(P)$, $A_{n,k} \in \mathfrak{B}$, and $1_{A_{n,k}}(t)$ is the indicator function of $A_{n,k}$, i.e., $= 1$ if $t \in A_{n,k}$ and $= 0$ otherwise. Such a function is called a *finitely valued* measurable function. If there exists a sequence $\{X_n(t)\}$ of such functions for which

$$\|X_n(t) - X(t)\|_2 \to 0 \qquad (n \to \infty)$$

for almost all $t \in [a, b]$ in the Lebesgue measure and $\int_a^b \|X(t)\|_2 \, dt < \infty$, then we can define the Bochner integral as

$$\int_a^b X(t)\,dt = \lim_{n\to\infty} \int_a^b X_n(t)\,dt \equiv \lim_{n\to\infty} \sum_{k=1}^{k_n} X_{n,k} L(A_{n,k}),$$

$L(A_{n,k})$ being the Lebesgue measure of $A_{n,k}$, where the limit is in mean-square sense.

VII. EXPANSIONS OF STOCHASTIC PROCESSES

Since a stochastic process is regarded as a two-variable function $X(t, \omega)$ on $T \times \Omega$, it might be interesting and useful to express it as a sum of products of single-variable functions of t and ω:

$$X(t, \omega) = \sum_n \phi_n(t) X_n(\omega), \tag{15}$$

where the right-hand side is convergent in some sense, so that $\phi_n(t)$ is a time function and $X_n(\omega)$ is a random variable for $n \geq 1$. We consider three types of expressions of stochastic processes given by (15).

A. Karhunen–Loève Expansion

Let $\{X(t)\}$ be a second-order stochastic process on a finite closed interval $[a, b]$ with the covariance function $K(s, t)$. Assume that the process $\{X(t)\}$ is mean-square continuous, which is the same as saying that $K(s, t)$ is continuous as a two-variable function on $[a, b]^2$. Then it follows that $K(s, t)$ is measurable on $[a, b]^2$ and

$$\int_a^b \int_a^b |K(s,t)|^2 \, ds\, dt < \infty,$$

i.e., $K \in L^2([a, b]^2)$. Moreover, K defines an integral operator $\mathbf{K}$ on $L^2([a, b])$ in such a way that

$$(\mathbf{K}\varphi)(t) = \int_a^b K(s, t)\varphi(s)\,ds \tag{16}$$

for $\varphi \in L^2([a, b])$. Now Mercer's theorem applied to $K(s, t)$ gives an expansion of $K(s, t)$:

$$K(s, t) = \sum_{k=1}^{\infty} \lambda_k \varphi_k(s)\overline{\varphi_k(t)}, \qquad s, t \in [a, b], \tag{17}$$

where the φ_k are eigenfunctions of the operator $\mathbf{K}$ defined by (16) and the λ_k are corresponding eigenvalues:

$$(\mathbf{K}\varphi_k)(t) = \lambda_k \varphi_k(t), \qquad t \in [a, b], \tag{18}$$

and the convergence in (17) is uniform on $[a, b]^2$ and in $L^2([a, b]^2)$, i.e.,

$$\sup_{s,t\in[a,b]} \left| K(s,t) - \sum_{k=1}^{n} \lambda_k \varphi_k(s)\overline{\varphi_k(t)} \right| \to 0,$$

$$\left\| K - \sum_{k=1}^{n} \lambda_k \varphi_k \otimes \overline{\varphi_k} \right\|_2^2 \equiv \int_a^b \int_a^b \left| K(s,t) - \sum_{k=1}^{n} \lambda_k \varphi_k(s)\overline{\varphi_k(t)} \right|^2 ds\, dt \to 0$$

as $n \to \infty$, where $(\varphi_k \otimes \overline{\varphi_k})(s, t) = \varphi_k(s)\overline{\varphi_k(t)}$. Note that φ_k is continuous on $[a, b]$ and $\lambda_k > 0$ for each $k \geq 1$. For instance, if $K(s, t) = \min\{s, t\}$ on $[0, T]$, the covariance function of a one-dimensional Wiener process, then

$$\min\{s,t\} = \sum_{k=0}^{\infty} \frac{2}{T}\left(\frac{2T}{(2k+1)\pi}\right)^2 \sin\left(\frac{(2k+1)\pi}{2T}s\right) \times \sin\left(\frac{(2k+1)\pi}{2T}t\right),$$

the uniform convergence holding on $[0, T]^2$.

Now for each integer $k \geq 1$ define

$$X_k = \frac{1}{\sqrt{\lambda_k}} \int_a^b X(t)\overline{\varphi_k(t)}\, dt,$$

which is a well-defined random variable in $L^2(P)$. Here, the functions φ_k satisfy (18). Moreover, we see that $\{\varphi_k\}_{k=1}^{\infty}$ forms an orthonormal set in $L^2([a, b])$, i.e.,

$$(\varphi_j, \varphi_k)_2 = \int_a^b \varphi_j(t)\overline{\varphi_k(t)}\, dt = \delta_{jk},$$

the Kronecker delta, and that $\{X_k\}_{k=1}^{\infty}$ also forms an orthonormal set in $L^2(P)$. Finally we obtain an expansion of $X(t)$:

$$X(t) = \sum_{k=1}^{\infty} \sqrt{\lambda_k}\varphi_k(t) X_k, \tag{19}$$

where the convergence is in mean-square. Equation (19) is called the *Karhunen–Loéve expansion.* The characteristic of this expansion is that we are using two orthonormal sets $\{\varphi_k\}$ and $\{X_k\}$, and that $\{X_k\}$ is the set of Fourier

coefficients of $X(t)$ with respect to $\{\varphi_k\}$. Moreover, $\{\varphi_k\}$ is obtained as the eigenfunctions of the operator **K** associated with the covariance function of the process.

B. Sampling Theorem

Shannon's (1949) sampling theorem was obtained for deterministic functions on $\mathbb{R}$ (signal functions). This was extended to be valid for weakly stationary stochastic processes by Balakrishnan (1957).

First we consider bandlimited and finite-energy signal functions. A signal function $X(t)$ is said to be *of finite energy* if $X \in L^2(\mathbb{R})$ with the Lebesgue measure. Then its Fourier transform $\mathcal{F}X$ is defined in the mean-square sense by

$$(\mathcal{F}X)(u) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} X(t) e^{iut}\, dt = \underset{T\to\infty}{\text{l.i.m.}} \int_{-T}^{T} X(t) e^{iut}\, dt,$$

where l.i.m. means "limit in the mean" and $\mathcal{F}: L^2(\mathbb{R}) \to L^2(\mathbb{R})$ turns out to be a unitary operator. A signal function $X(t)$ is said to be *bandlimited* if there exists some constant $W > 0$ such that

$$(\mathcal{F}X)(u) = 0 \qquad \text{for almost every } u \text{ with } |u| > W.$$

Here, W is called a *bandwidth* and $[-W, W]$ a *frequency interval.*

Let $W > 0$ and define a function S_W on $\mathbb{R}$ by

$$S_W(t) = \begin{cases} \frac{W}{\pi} \frac{\sin Wt}{Wt}, & t \neq 0 \\ \frac{W}{\pi}, & t = 0. \end{cases}$$

Then, S_W is a typical example of a bandlimited function and is called a *sample function.* In fact, one can verify that

$$(\mathcal{F}S_W)(u) = \frac{1}{\sqrt{2\pi}} 1_W(u), \qquad u \in \mathbb{R},$$

where $1_W = 1_{[-W,W]}$, the indicator function of $[-W, W]$. Denote by **BLW** the set of all bandlimited signal functions with bandwidth $W > 0$. Then it is easily seen that **BLW** is a closed subspace of $L^2(\mathbb{R})$. Now the *sampling theorem* for a function in **BLW** is stated as follows: Any $X \in$ **BLW** has a sampling expansion in L^2- and L^∞-sense given by

$$X(t) = \sum_{n=-\infty}^{\infty} X\left(\frac{n\pi}{W}\right) \sqrt{\frac{W}{\pi}}\, \varphi_n(t), \tag{20}$$

where the φ_n are defined by

$$\varphi_n(t) = \sqrt{\frac{\pi}{W}}\, S_W\left(t - \frac{n\pi}{W}\right), \qquad t \in \mathbb{R}, \quad n \in \mathbb{Z},$$

$\{\varphi_n\}_{-\infty}^{\infty}$ forms a complete orthonormal system in **BLW**, and it is called a *system of sampling functions.* We can say that a sampling theorem is a Fourier expansion of an L^2-function with respect to this system of sampling functions.

A sampling theorem holds for some stochastic processes. Let $\{X(t)\}$ be an $L_0^2(\Omega)$-valued weakly harmonizable process with the representing measure ξ, i.e.,

$$X(t) = \int_{-\infty}^{\infty} e^{itu}\, \xi(du), \qquad t \in \mathbb{R}.$$

We say that $\{X(t)\}$ is *bandlimited* if there exists a $W > 0$ such that the support of ξ is contained in $[-W, W]$, i.e., $\xi(A) = 0$ if $A \cap [-W, W] = \emptyset$. If this is the case, the *sampling theorem* holds:

$$X(t, \omega) = \sum_{n=-\infty}^{\infty} X\left(\frac{n\pi}{W}, \omega\right) \frac{\sin(W(t - n\pi/W))}{W(t - n\pi/W)}, \qquad t \in \mathbb{R},$$

where the convergence is in $\|\cdot\|_2$ for each $t \in \mathbb{R}$.

C. Series Representation

The above two expansions have some restrictions. Namely, the KL expansion is valid for stochastic processes on finite closed intervals, and the sampling theorem requires bandlimitedness. To relax these conditions we consider separability of the time domain $H(X)$, which is a fairly general condition. Thus let us consider the series representation of a second-order stochastic process $\{X(t, \omega)\}$:

$$X(t, \omega) = \sum_{n=1}^{\infty} \varphi_n(t) X_n(\omega). \tag{21}$$

It is easily verified that $\{X(t, \omega)\}$ has a series representation of the form (21) if and only if the time domain $H(X)$ is separable, i.e., there exists a countable orthonormal base $\{Y_k\}_{k=1}^{\infty}$ for $H(X)$. If we choose one such base $\{X_k\}_{k=1}^{\infty}$, then the $\varphi_n(t)$ are the Fourier coefficients, i.e.,

$$\varphi_n(t) = (X(t), X_n)_2, \qquad t \in \mathbb{R}, \quad n \geq 1.$$

Moreover, the covariance function $K(s, t)$ is expressed as

$$K(s, t) = \sum_{n=1}^{\infty} \varphi_n(s) \overline{\varphi_n(t)}, \qquad s, t \in \mathbb{R}.$$

There are some sufficient conditions for a process $\{X(t)\}$ on T to have such a series representation:

1. $\{X(t)\}$ is weakly continuous on T, i.e., $(X(t), Y)_2$ is a continuous function of t for any $Y \in L_0^2(\Omega)$.
2. $\{X(t)\}$ is mean-square continuous on T.
3. The σ-algebra Σ has a countable generator.
4. T is a countable set, e.g., $\mathbb{Z}$ or $\mathbb{Z}^+$.

Since the covariance function $K(s,t)$ is positive definite, we can associate the RKHS (reproducing kernel Hilbert space) $\mathcal{H}_K$ consisting of $\mathbb{C}$-valued functions on T in a way that the following hold:

(i) $K(\cdot,t)\in\mathcal{H}_K$ for every $t\in T$.
(ii) $f(t)=(f(\cdot),K(\cdot,t))_K$ for every $f\in\mathcal{H}_K$ and $t\in T$.

Here $(\cdot,\cdot)_K$ is the inner product in $\mathcal{H}_K$. Then, an interesting fact is that, if $\{X_k\}_{k=1}^{\infty}$ is an orthonormal base in the time domain $H(X)$ and $\varphi_k(t)=(X(t),X_k)_2$ for $k\geq 1$, then $\{\varphi_k\}_{k=1}^{\infty}$ is also an orthonormal base in the RKHS $\mathcal{H}_K$. Hence we have that $H(X)$ and $\mathcal{H}_K$ are isomorphic Hilbert spaces.

VIII. EXTENSIONS OF STOCHASTIC PROCESSES

A. Finite-Dimensional Extension

So far we have considered mainly one-dimensional second-order stochastic processes $\{X(t)\}$. If there are two such processes $\{X_1(t)\}$ and $\{X_2(t)\}$, we can describe these processes as a single process by letting

$$\mathbf{X}(t)=(X_1(t),X_2(t)).$$

Hence, $\{\mathbf{X}(t)\}$ is regarded as an $[L^2(P)]^2$-valued process. If $k\geq 2$ is an integer and $\{X_j(t)\}$ $(j=1,\ldots,k)$ are one-dimensional second-order stochastic processes, then

$$\mathbf{X}(t)=(X_1(t),\ldots,X_k(t))$$

is a k-dimensional stochastic process, or an $[L^2(P)]^k$-valued process. For such a process $\{\mathbf{X}(t)\}$ the average $\mathbf{m}(t)$ is a k-dimensional vector given by

$$\mathbf{m}(t)=E\{\mathbf{X}(t)\}=(m_1(t),\ldots,m_k(t)),\qquad t\in T,$$

where $m_j(t)=E\{X_j(t)\}$, $1\leq j\leq k$, and the *scalar covariance function* $K(s,t)$ is given by

$$\begin{aligned}K(s,t)&=(\mathbf{X}(s)-\mathbf{m}(s),\mathbf{X}(t)-\mathbf{m}(t))_{2,k}\\&=\sum_{j=1}^{k}(X_j(s)-m_j(s),X_j(t)-m_j(t))_2\\&=\sum_{j=1}^{k}K_j(s,t),\end{aligned}$$

where $(\cdot,\cdot)_{2,k}$ is the inner product in $[L^2(P)]^k$ and $K_j(s,t)$ is the covariance function of $\{X_j(t)\}$. However, the scalar covariance function does not well reflect the correlatedness of $\{X_j(t)\}$ and $\{X_\ell(t)\}$ for $1\leq j,\ \ell\leq k$. The *matricial covariance function* $\mathbf{K}(s,t)$ is defined by

$$\mathbf{K}(s,t)=(K_{j\ell}(s,t))_{j,\ell},$$

where $K_{j\ell}(s,t)=(X_j(s)-m_j(s),X_\ell(t)-m_\ell(t))_2$, the *cross-covariance* of $\{X_j(t)\}$ and $\{X_\ell(t)\}$, and it expresses correlatedness among all the processes $\{X_j(t)\}$, $1\leq j\leq k$. The k-dimensional weakly stationary class and nonstationary classes (given in Section IV and V) are defined using the matricial covariance function $\mathbf{K}(s,t)$, and for many processes in these classes, the integral representations of the processes are obtained in terms of $L_0^2(P)]^k$-valued measures.

B. Infinite-Dimensional Extension

Finite-dimensional extension is rather straightforward, as seen above. However, infinite-dimensional extension needs considerably more work. One way to do this is to identify $[L_0^2(P)]^k$ with $L_0^2(P;\mathbb{C}^k)$ for each $k\geq 1$, where the latter is the space of all $\mathbb{C}^k$-valued random vectors with finite second moment and zero expectation. Then, when $k=\infty$, we replace $\mathbb{C}^k$ by an infinite-dimensional Hilbert space H. Thus we consider the Hilbert space $L_0^2(P;H)$ of all H-valued random variables X on (Ω,Σ,P) with finite second moment $\|X\|_2^2=\int_\Omega\|X(\omega)\|_H^2\,P(d\omega)<\infty$ and zero expectation, where $\|\cdot\|_H$ is the inner product norm in H. As in the finite-dimensional case, we have two kinds of covariance functions, the scalar and the operator (instead of matricial) ones. Then, we obtain the stationary and nonstationary classes mentioned above.

C. Stochastic Fields

Another type of extension of stochastic processes is to consider a time parameter set T to be other than a subset of $\mathbb{R}$. It is sometimes appropriate to replace $\mathbb{R}$ by $\mathbb{R}^k$ ($k\geq 2$, an integer) and consider stochastic processes $\{X(\mathbf{t})\}$ on $\mathbf{T}\subseteq\mathbb{R}^k$. These processes are called *stochastic fields*. When the stochastic process is depending on time t and two-dimensional location (x_1,x_2), then by letting $\mathbf{t}=(t,x_1,x_2)\in\mathbb{R}^3$, we may describe the process as $\{X(\mathbf{t})\}$. (The more abstract case is obtained by replacing $\mathbb{R}^k$ by a locally compact Abelian group G.) Most of the results obtained so far can be extended to processes on $\mathbb{R}^k$. For instance, if $\{X(\mathbf{t})\}$ is a weakly harmonizable process on $\mathbb{R}^k$ with the covariance function $K(\mathbf{t})$, then there exists an $L_0^2(\Omega)$-valued measure ξ and a positive-definite bimeasure β on $\mathfrak{B}(\mathbb{R}^k)\times\mathfrak{B}(\mathbb{R}^k)$ such that

$$X(\mathbf{t})=\int_{\mathbb{R}^k}e^{i(\mathbf{t},\mathbf{u})}\,\xi(d\mathbf{u}),\qquad \mathbf{t}\in\mathbb{R}^k,$$

$$K(\mathbf{s},\mathbf{t})=\int_{\mathbb{R}^{2k}}e^{i((\mathbf{s},\mathbf{u})-(\mathbf{t},\mathbf{v}))}\,\beta(d\mathbf{u},d\mathbf{v}),\qquad \mathbf{s},\mathbf{t}\in\mathbb{R}^k,$$

where $(\mathbf{s},\mathbf{u})=\sum_{j=1}^{k}s_ju_j$, the inner product in $\mathbb{R}^k$.

D. Generalized Stochastic Processes

Generalized stochastic processes were initiated by Itô (1953) and Gel'fand (1955). Let $\{X(t)\}$ be a stochastic process on $\mathbb{R}$ and $\mathfrak{D}$ be the set of all *test functions* on $\mathbb{R}$, i.e., $\phi \in \mathfrak{D}$ if ϕ is infinitely many times differentiable and is zero outside of some finite closed interval. Hence the dual space of $\mathfrak{D}$ is the set of *distributions* in the sense of Schwartz and not probability distributions. If

$$X(\phi) = \int_{-\infty}^{\infty} X(t)\phi(t)\,dt \tag{22}$$

is defined for each $\phi \in \mathfrak{D}$, so that $X(\phi)$ represents a random variable, then $\{X(\phi)\}$ is regarded as a stochastic process on $\mathfrak{D}$, called a *generalized stochastic process* induced by an ordinary stochastic process $\{X(t)\}$.

Here is a formal definition. Let $X(\phi, \omega)$ be a function of $\phi \in \mathfrak{D}$ and $\omega \in \Omega$ such that the following hold:

(i) $X(\cdot, \omega)$ is a distribution for a.e. $\omega \in \Omega$.
(ii) $X(\phi, \cdot)$ is a random variable for every $\phi \in \mathfrak{D}$.

Then $\{X(\phi)\}$ is called a *generalized stochastic process* on $\mathfrak{D}$. It is known that not every such process is induced by an ordinary stochastic process as in (22).

The derivative of a generalized stochastic process $\{X(\phi)\}$ can be obtained using that of distribution:

$$X'(\phi) = \langle \phi, X' \rangle = \langle -\phi', X \rangle = X(-\phi')$$

for $\phi \in \mathfrak{D}$, where $\langle \cdot, \cdot \rangle$ is a duality pair. In general, we have

$$X^{(p)}(\phi) = (-1)^p \langle \phi^{(p)}, X \rangle = (-1)^p X\left(\phi^{(p)}\right)$$

for $p \geq 2$ and $\phi \in \mathfrak{D}$. If $\{B(t)\}$ is a Brownian motion (or a Wiener process) on $\mathbb{R}$, then this induces a generalized stochastic process $\{B(\phi)\}$ on $\mathfrak{D}$. Its derivative $\{B'(\phi)\}$ is regarded as a white noise Gaussian process.

Tilings

Egon Schulte
Northeastern University

GLOSSARY

Anisohedral tile Shape that admits a monohedral tiling but no isohedral (tile-transitive) tiling.
Aperiodic prototile set Set of prototiles that admits a tiling, but each tiling is nonperiodic.
Archimedean tiling Edge-to-edge tiling of the plane by convex regular polygons whose symmetry group is vertex transitive.
Lattice tiling Tiling by translates of a single tile such that the corresponding translation vectors form a lattice.
Monohedral tiling Tiling in which the tiles are congruent to a single prototile.
Normal tiling Tiling in which the tiles are uniformly bounded in size.
Parallelotope Convex polytope that is the prototile of a lattice tiling.
Penrose tilings Certain nonperiodic tilings of the plane with an aperiodic prototile set (discovered by Penrose).
Periodic tiling Tiling for which the symmetry group is a crystallographic group (contains translations in d independent directions, where d is the dimension of the ambient space).
Prototiles A minimal collection of shapes such that each tile in the tiling is congruent to a shape in the collection.
Space-filler Convex polytope that is the prototile of a monohedral tiling.
Voronoi region For a point x in a discrete set L, the Voronoi region of x consists of all points in space that are at least as close to x as to any other point in L.

TILINGS (or tessellations) have been investigated since antiquity. Almost all variants of the question "*How can a given space be tiled by copies of one or more shapes?*" have been studied in some form or another. The types of spaces permitted have included Euclidean spaces, hyperbolic spaces, spheres, and surfaces, and the types of shapes have varied from simple polygonal or polyhedral shapes to sets with strange topological properties. Today, tiling theory is a rapidly growing field that continues to pose challenging mathematical problems to scientists and mathematicians. The discovery of quasicrystals in 1984 has sparked a surge in interest in tiling theory because of its relevance for mathematical modeling of crystals and quasicrystals.

For more than 200 years, crystallographers such as Fedorov, Voronoi, Schoenflies, and Delone have greatly influenced tiling theory and the study of crystallographic groups. Another important impetus came from the geometry of numbers, notably from Minkowski's work. Hilbert's famous list of fundamental open problems in mathematics, posed in 1900, contained an unsolved problem on discrete groups and their fundamental regions that has had a strong impact on tiling theory. In the 1970s, Grünbaum and Shephard began their comprehensive work on tilings that resulted in a beautiful book on plane tilings. To date, no complete account on tilings in higher dimensional spaces is available in the literature. The recent developments on nonperiodicity of tilings are among the most exciting in tiling theory. The mathematics of aperiodic order is still in its infancy but, when developed, should be useful for understanding quasicrystals and other disordered solid materials.

The purpose of this chapter is to give a short survey on tilings in Euclidean spaces. The discussion is essentially limited to relatively well-behaved tilings and tiles.

I. PRELIMINARY CONCEPTS

It is necessary to establish some preliminary concepts before beginning the subject of tilings itself. Unless stated otherwise, the underlying space of a tiling will always be d-dimensional Euclidean space, or simply *d-space*, E^d. This is real d-space R^d equipped with the standard inner (scalar) product given by:

$$x \cdot y = \sum_{i=1}^{d} x_i y_i,$$

$$x = (x_1, \ldots, x_d), \quad y = (y_1, \ldots, y_d) \in \mathrm{E}^d$$

The length of a vector x in E^d is denoted by $|x|$.

An *orthogonal transformation* of E^d is a linear self-mapping of E^d which preserves the inner product and hence lengths and distances. A *similarity transformation* σ of E^d is a self-mapping of E^d of the form:

$$\sigma(x) = c\lambda(x) + t \qquad (x \in \mathrm{E}^d)$$

where λ is an orthogonal transformation of E^d, c a positive scalar (giving the expansion factor), and t a vector in E^d (determining the *translation part* of σ). A (Euclidean) *isometry* of E^d is a similarity transformation with $c = 1$.

Two subsets P and Q of E^d are *congruent* (respectively, *similar*), if there exists an isometry (similarity transformation) of E^d which maps P onto Q.

Let x be a point in E^d, and let $r > 0$. Then the d-dimensional (Euclidean) *ball* $B(x, r)$ of radius r centered at x consists of all points y in E^d whose distance from x is at most r. The *unit ball* in E^d is the ball of radius 1 centered at the origin.

A subset P of E^d is *open* if every point of P admits a neighborhood (a d-dimensional ball of small positive radius) which is entirely contained in P. The union of any number of open sets is again open. A subset P of E^d is *closed* if its complement $\mathrm{E}^d \setminus P$ in E^d is open. The intersection of any number of closed sets is again closed. A subset P of E^d is *compact* if it is closed and bounded (contained in a ball of large radius). For example, every ball $B(x, r)$ is compact.

Let P be a subset of E^d. The *interior* $\mathrm{int}(P)$ of P consists of those points, called the *interior points*, of P which admit a neighborhood entirely contained in P; this is the largest open set contained in P. The interior of a ball is also called an *open ball*, in contrast to the ball itself, which is a *closed ball*. The *closure* $\mathrm{cl}(P)$ of a subset P is the intersection of all closed subsets that contain P; this is the smallest closed subset which contains P. The *boundary* $\mathrm{bd}(P)$ of P is the set $\mathrm{int}(P) \setminus \mathrm{cl}(P)$, consisting of the *boundary points* of P. For example, the *unit sphere* (centered at the origin) in E^d is the boundary of the unit ball in E^d.

Two open (respectively, closed) subsets P and Q of E^d are *homeomorphic* if there exists a bijective mapping f from P onto Q such that both f and its inverse f^{-1} are continuous; such a mapping is called a *homeomorphism* from P onto Q. A subset P of E^d is called a *topological k-ball* (respectively, *topological k-sphere*) if it is homeomorphic to a Euclidean k-ball (k-sphere). A *topological disc* is a topological 2-ball.

A subset P of E^d is *convex* if, for every two points x and y in P, the line segment joining x and y is contained in P. The intersection of any number of convex sets is again convex.

Let P be a subset of E^d. The *convex hull*, $\mathrm{conv}(P)$, of P is the intersection of all convex sets which contain P; it is the smallest convex set which contains P.

A convex *k-polyhedron* P in E^d is the intersection of finitely many closed half-spaces in E^d which is k-dimensional. If $k = d$, then P has nonempty interior in E^d, and vice versa. A convex *k-polytope* is a bounded convex k-polyhedron. A subset of E^d is a convex polytope if and only if it is the convex hull of finitely many points in E^d. Every convex d-polytope in E^d is a topological d-ball. In applications, the tiles of a tiling will often be convex polytopes.

The boundary of a convex d-polytope P in E^d splits into finitely many lower dimensional polytopes called the *faces* of P. These include the empty set (*empty face*) and P itself as *improper* faces, of dimensions -1 and d, respectively. A *proper* face F of P is the (nonempty) intersection of P with a *supporting hyperplane* of P; this is a hyperplane H of E^d that intersects P in F such that P lies entirely in

one of the two closed half-spaces bounded by H. A face of dimension 0, 1, i, or $d-1$ is also called a *vertex*, an *edge*, an *i-face*, or a *facet*, respectively. The family of all proper and improper faces of P is called the *face lattice* of P. (When ordered by set-theoretic inclusion, this partially ordered set is a lattice.) The following are two important properties of the face lattice of P: first, a face of a face is again a face (that is, if F is a face of P and G is a face of the polytope F, then G is also a face of P); and, second, the intersection of any two faces of P is again a face of P, possibly the empty face. The *boundary complex* of P, consisting of all proper faces of P (and the empty face), yields a decomposition of the boundary of P, which is a topological sphere.

Two convex d-polytopes P and Q are *combinatorially equivalent* if there exists a mapping f from the face lattice of P onto the face lattice of Q which is one-to-one and inclusion preserving; such a mapping is called a (*combinatorial*) *isomorphism*. An *automorphism* of P is a self-mapping of the face lattice of P which is an isomorphism. For example, a rectangle is combinatorially equivalent to a square and has the same number of automorphisms as the square.

A *parallelopiped* P is a convex d-polytope that is spanned by d linearly independent vectors $b_1, \ldots, b_d$ of E^d; that is, P is the set of linear combinations $\sum_{i=1}^{d} \lambda_i b_i$ with $0 \le \lambda_i \le 1$ for all $i = 1, \ldots, d$. The simplest example is the standard d-dimensional (unit) *cube* (or *hypercube*), obtained when $b_1, \ldots, b_d$ are the canonical base vectors of E^d. Any parallelopiped is combinatorially equivalent to the cube.

Groups are certain sets Γ with an algebraic structure. We shall not define the term in full generality but restrict ourselves to groups where the elements of the underlying set Γ are one-to-one self-mappings of another set X, such as nonsingular affine transformations of $X = \mathrm{E}^d$, isometries of $X = \mathrm{E}^d$, or simply bijections of X. A set Γ of this kind is called a *group* if the following two properties are satisfied: first, the composition of any two mappings in Γ is again a mapping in Γ, and, second, for every mapping in Γ, the inverse mapping also belongs to Γ. A group Γ is *finite* if the set Γ has finitely many elements; otherwise, it is *infinite*. The *order* of a finite group Γ is the number of elements of Γ.

A *subgroup* Γ' of a group Γ is a subset of Γ which itself is a group. A (*left*) *coset* of a subgroup Γ' is a subset of Γ of the form $\sigma\Gamma' := \{\sigma\gamma \mid \gamma \in \Gamma'\}$. The number of cosets of a subgroup Γ' is called the *index* of Γ' in Γ.

Two subgroups Γ' and Γ'' of a group Γ are said to be *conjugate subgroups* of Γ if there exists an element $\sigma \in \Gamma$ such that $\Gamma'' = \sigma\Gamma'\sigma^{-1} (= \{\sigma\gamma\sigma^{-1} \mid \gamma \in \Gamma'\})$.

Two groups Γ_1 and Γ_2 are said to be *isomorphic* if there exists a bijective mapping f from Γ_1 onto Γ_2 such that $f(\gamma\gamma') = f(\gamma)f(\gamma')$ for all $\gamma, \gamma' \in \Gamma_1$. Then f is called an *isomorphism* between Γ_1 and Γ_2.

Let P be a nonempty subset of E^d. A *symmetry* of P is an isometry which maps P onto itself. The set of all symmetries of P forms a group, the *symmetry group* $S(P)$ of P.

The set of all automorphisms of a convex polytope P also forms a group, the *automorphism group* $\Gamma(P)$ of P. Since each symmetry of a polytope maps faces to faces, the symmetry group $S(P)$ is a subgroup of $\Gamma(P)$; in general, $S(P)$ is a proper subgroup of $\Gamma(P)$.

As before, let Γ be a group of self-mappings of a set X. Then Γ is said to *act transitively*, or to be *transitive*, on X if for any two elements x and y in X there exists a mapping σ in Γ such that $\sigma(x) = y$. The *orbit* of an element x in X is the set of all images of x under mappings in Γ. Then Γ acts transitively on X if and only if X is the orbit of any (indeed, every) element x in X. For a given x in X, the subgroup of Γ consisting of the mappings that fix x is called the *stabilizer* of x in Γ.

For example, the *dihedral group* D_n, of order $2n$, is the symmetry group of the convex regular n-gon. The group consists of n rotations and n reflections, and it acts transitively on both the set X_1 of vertices and the set X_2 of edges. The subgroup of D_n consisting of the n rotations is denoted C_n and is a *cyclic* group of order n; that is, all elements are powers of one element, the rotation by $2\pi/n$ in this case. In these examples, as in many other instances described later, the original group Γ is a group of isometries of Euclidean space (in this case, the plane) X, but Γ can also be viewed as a group of self-mappings of the vertex-set X_1 or edge-set X_2 of the regular n-gon.

A subset P of E^d is called *discrete* if each point x in P has an open neighborhood that does not contain any other point of P.

A group Γ of isometries of E^d is called *discrete* (or, more exactly, is said to *act discretely*) if the orbit of every point x in E^d is a discrete subset of E^d. If Γ is a discrete group of isometries of E^d, then a *fundamental region* for Γ is an open set D of E^d satisfying the following two properties: first, the images of D under elements of Γ are mutually disjoint, and, second, the union of the closures of the images of D under Γ is the entire space E^d. Every discrete group of isometries has a fundamental region in E^d (whose boundary is a set of measure zero).

A *lattice* L in E^d is the group of all integral linear combinations of a set of d linearly independent vectors in E^d; these vectors form a *basis* of L. A lattice has many different bases. The lattices in E^d are precisely the discrete subgroups of (the additive group) E^d which contain d linearly independent vectors. By Z^d we denote the standard integer lattice in E^d consisting of all vectors with only integral coordinates.

If z is a point in E^d, then the *point reflection* in z is the affine mapping that takes each x in E^d to $2z - x$. A subset P of E^d is called *centrally symmetric* if it is invariant under the point reflection in a point z, called a *center of symmetry* of P. A set can have more than one center of symmetry.

II. FUNDAMENTAL CONCEPTS OF TILINGS

A. What Is a Tiling?

A *tiling* (or *tessellation* or *honeycomb*) $\mathcal{T}$ of Euclidean d-space E^d is a countable family of closed subsets T of E^d, the *tiles* of $\mathcal{T}$, which cover E^d without gaps and overlaps. This means that the union of all tiles of $\mathcal{T}$ is the entire space, and that any two distinct tiles do not have interior points in common. To rule out pathological situations we shall assume that the tiles of $\mathcal{T}$ are (closed) topological d-balls. In applications, the tiles will often be convex d-polytopes.

A tiling $\mathcal{T}$ of E^d is called *locally finite* if each point of E^d has a neighborhood that meets only finitely many tiles. Then, in fact, every bounded region of space meets only finitely many tiles. We will always assume that a tiling is locally finite.

A tiling $\mathcal{T}$ of E^d by topological d-balls is called *normal* if its tiles are uniformly bounded (that is, there exist positive real numbers r and R such that each tile contains a Euclidean ball of radius r and is contained in a Euclidean ball of radius R) and the intersection of every pair of tiles is a connected set. The latter condition is trivially satisfied if the tiles are convex d-polytopes. On the other hand, in a tiling by arbitrary topological d-balls, the intersection pattern of any two or more tiles can be rather complicated, so connectedness is a reasonable requirement for normality. Note that a normal tiling is necessarily locally finite. Figure 1 shows an example of a locally finite plane tiling by convex heptagons which is not normal.

We often do not distinguish two tilings $\mathcal{T}_1$ and $\mathcal{T}_2$ of E^d which are obtained from each other by a similarity transformation of E^d; such tilings are said to be *equal* or *the same* (this, of course, is an abuse of the standard notion of equality). In particular, we use the following notation. Two tilings $\mathcal{T}_1$ and $\mathcal{T}_2$ of E^d are called *congruent* (respectively, *similar*) if there is an isometry (similarity transformation) of E^d which maps the tiles of $\mathcal{T}_1$ onto the tiles of $\mathcal{T}_2$.

A central notion is that of a symmetry of a tiling. A Euclidean isometry of E^d is a *symmetry* of a tiling $\mathcal{T}$ if it maps each tile of $\mathcal{T}$ onto a tile of $\mathcal{T}$. The set of all symmetries of $\mathcal{T}$ forms a group, the *symmetry group* $S(\mathcal{T})$ of $\mathcal{T}$.

A *protoset*, or *prototile set*, of a tiling $\mathcal{T}$ of E^d is a minimal subset of tiles of $\mathcal{T}$ such that each tile of $\mathcal{T}$ is congruent to one of those in the subset. The tiles in the set are the *prototiles* of $\mathcal{T}$, and the protoset is said to *admit* the tiling $\mathcal{T}$. By abuse of notation, we also use this terminology for shapes and family of shapes that are under consideration for being prototiles or protosets of a tiling, respectively.

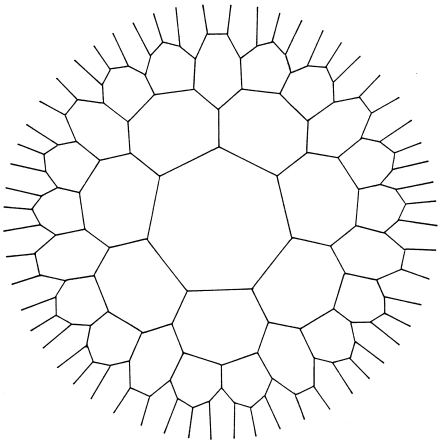

FIGURE 1 A non-normal tiling of the plane by convex heptagons, three meeting at each vertex. The tiles become longer and thinner the farther away they are from the center. [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

Tilings are closely related to packings and coverings of space. A tiling is a family of sets which cover E^d without gaps and overlaps. A *packing* is a family of sets in E^d which do not overlap; that is, no two distinct sets have interior points in common. On the other hand, a *covering* is a family of sets in E^d which leave no gaps; that is, the union of all sets is the entire space E^d. The efficiency of a packing or covering is measured by its *density*, which is a well-defined quantity provided the sets are distributed in a sufficiently regular way. The density of a packing measures the fraction of space that is covered by the sets; the density of a covering measures the average frequency with which a point of space is covered by the sets. Thus, tilings are at the same time packings and coverings of space, each with density 1.

B. Tilings by Polytopes

The best-behaved tilings of E^d are the face-to-face tilings by convex polytopes. More precisely, a tiling $\mathcal{T}$ by convex d-polytopes is said to be *face-to-face* if the intersection of any two tiles is a face of each tile, possibly the empty face. In a face-to-face tiling, the intersection of any number of tiles is a face of each of the tiles.

In a face-to-face tiling $\mathcal{T}$ of E^d by convex d-polytopes, the i-faces of the tiles are also called the *i-faces* of $\mathcal{T}$ ($i = 0, \ldots, d$). The d-faces of $\mathcal{T}$ are then the tiles of $\mathcal{T}$.

The faces of dimensions 0 and 1 are the *vertices* and *edges* of $\mathcal{T}$, and the empty set and E^d itself are considered to be *improper faces* of $\mathcal{T}$, of dimensions -1 and $d+1$, respectively. The set of all faces of $\mathcal{T}$ is called the *face lattice* of $\mathcal{T}$. (When ordered by set-theoretic inclusion, this is a lattice.) This terminology carries over to more general tilings in which the tiles are topological d-polytopes (homeomorphic images of convex d-polytopes).

Two face-to-face tilings $\mathcal{T}_1$ and $\mathcal{T}_2$ by convex d-polytopes are *combinatorially equivalent* if there exists a mapping from the face lattice of $\mathcal{T}_1$ onto the face lattice of $\mathcal{T}_2$ which is one-to-one and inclusion preserving; such a mapping is called a (*combinatorial*) *isomorphism*. An *automorphism* of a tiling $\mathcal{T}$ is a self-mapping of the face lattice of $\mathcal{T}$ which is an isomorphism. The set of all automorphisms of $\mathcal{T}$ forms a group, the *automorphism group* $\Gamma(\mathcal{T})$ of $\mathcal{T}$. This group is generally larger than the symmetry group of $\mathcal{T}$.

A mapping between the face lattices of $\mathcal{T}_1$ and $\mathcal{T}_2$ is called a *duality* if it is one-to-one and inclusion reserving. If such a mapping exists, then $\mathcal{T}_2$ is said to be a *dual* of $\mathcal{T}_1$. A tiling can have many metrically distinct duals but any two duals are isomorphic. Except for highly symmetrical tilings, not much is known about the existence and properties of dual tilings.

C. Tilings of the Plane

A lot more is known about tilings in the plane than about tilings in spaces of three or more dimensions. Let $\mathcal{T}$ be a (locally finite) plane tiling in E^2 by topological discs. We now introduce the notion of a ($\mathcal{T}$-induced) vertex or a ($\mathcal{T}$-induced) edge of $\mathcal{T}$. A point x in E^2 is called a *vertex* of $\mathcal{T}$ if it is contained in at least three tiles. Since the tiles are topological discs, each simple closed curve which bounds a tile T is divided into a finite number of closed arcs by the vertices of $\mathcal{T}$, where any two arcs are disjoint except for possibly vertices of $\mathcal{T}$. These arcs are said to be the *edges of the tile* T and are also referred to as *edges of* $\mathcal{T}$. Each vertex x of $\mathcal{T}$ is contained in finitely many edges of $\mathcal{T}$. The number of edges emanating from a vertex x is called the *valence* $v(x)$ of x; clearly, $v(x) \geq 3$ for each vertex x. Note that two tiles can intersect in several edges, where pairs of edges may or may not have vertices in common. Two tiles with a common edge are called *adjacents* of each other.

If a tile of $\mathcal{T}$ is a planar polygon, then the $\mathcal{T}$-induced vertices and edges of the tile will generally not coincide with the original vertices and edges of the tile. To avoid confusion we shall refer to the latter as the *corners* and *sides* of the polygonal tile. In a tiling $\mathcal{T}$ by polygons, the vertices and edges of the tiles may or may not coincide with the corners and sides of the polygons, respectively; if they do, then we call $\mathcal{T}$ an *edge-to-edge* tiling.

In higher dimensions, no general terminology has been introduced that deals with the distinction of an *a priori* facial structure and the $\mathcal{T}$-induced facial structure on the tiles of $\mathcal{T}$.

The notions of isomorphism, automorphism and duality introduced in the previous subsection carry over to general plane tilings, with the understanding that we now have inclusion preserving or inclusion reversing one-to-one mappings between the sets of all ($\mathcal{T}$-induced) vertices, edges, and tiles of the tilings. For every normal plane tiling $\mathcal{T}$ there exists a normal tiling which is dual to $\mathcal{T}$. In the dual, every vertex is an interior point of a tile of $\mathcal{T}$, every tile contains one vertex of $\mathcal{T}$, and any two vertices that correspond to a pair of adjacent tiles in $\mathcal{T}$ are joined by an edge (arc) that crosses the edge common to both tiles.

For normal plane tilings, there is a close relationship between combinatorial and topological equivalence of tilings. Two tilings of E^d are said to be of the *same topological type* or to be *topologically equivalent* if there is a homeomorphism of E^d which maps one onto the other. Two normal plane tilings are topologically equivalent if and only if they are combinatorially equivalent.

D. Monohedral Tilings

A tiling $\mathcal{T}$ of E^d is *monohedral* if all its tiles are congruent to a single set T, the prototile of $\mathcal{T}$. The simplest examples of monohedral tilings $\mathcal{T}$ are those in which the tiles are translates of T. If T admits such a tiling, then we say that T *tiles by translation*. In such a tiling $\mathcal{T}$, if the corresponding translation vectors form a d-dimensional lattice L in E^d, then $\mathcal{T}$ is called a *lattice tiling* (*with lattice* L). If $\mathcal{T}$ is a lattice tiling of E^d with convex d-polytopes as tiles, then the prototile T is called a *parallelotope*, or *parallelohedron* if $d = 3$. Every parallelopiped in E^d is a parallelotope, and the vectors that span it also generate the corresponding lattice.

With every lattice in E^d, and indeed with every discrete set L in E^d, is associated a tiling with tiles called *Voronoi regions* or *Dirichlet regions*. Given a point x in L, the Voronoi region $V(L, x)$ of x is the set of all points in E^d that are at least as close to x as to any other point in L; that is,

$$V(L, x) = \{y \in \mathrm{E}^d \mid |y - x| \leq |y - z| \text{ for all } z \in L\}$$

The family of all Voronoi regions $V(L, x)$ with $x \in L$ gives a face-to-face tiling $\mathcal{T}$ of E^d by convex polyhedra (polytopes if L is a lattice), called the *Voronoi tiling* for L. Figure 2 shows the Voronoi regions for a finite set of points in the plane, including those regions that are unbounded.

If L is a lattice in E^d, then the Voronoi regions are translates of the Voronoi region $V(L) := V(L, 0)$ obtained

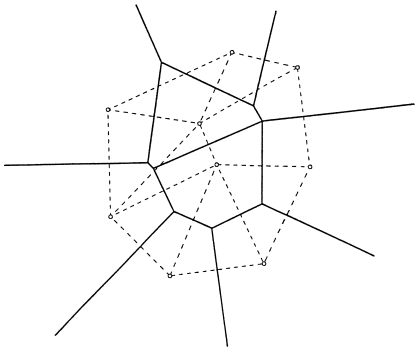

FIGURE 2 The Voronoi regions of a finite set of points in the plane. [From Schattschneider, D., and Senechal, M. (1997). *Handbook of Discrete and Computational Geometry*, (Goodman, J.E. and O'Rourke, J., eds.). CRC Press, Boca Raton.]

for $x = 0$, and $\mathcal{T}$ is a lattice tiling with $V(L)$ as prototile. In particular, the Voronoi regions are convex d-polytopes and $V(L)$ is a parallelotope. The translations by vectors in L all belong to the symmetry group of $\mathcal{T}$. The structure of the Voronoi regions of a lattice depends a great deal on the structure of the lattice itself.

The Voronoi tiling for a lattice L has a dual, called the *Delone tiling* for L, whose vertex set is L and whose tiles are called *Delone cells* (not to be confused with Delone sets defined later). The Delone cell corresponding to a vertex v of a Voronoi tiling is the convex hull of the lattice points x whose Voronoi regions $V(L, x)$ have v as a vertex.

If L is the standard integer lattice Z^d in E^d, then the Voronoi regions and Delone cells are unit cubes, and the Voronoi tiling and Delone tiling are cubical tessellations of E^d that are translates of each other.

A subset L of E^d is called a *Delone set* if there exist two positive real numbers r and R such that every ball of radius r contains at most one point of L, and every ball of radius R contains at least one point of L. The Delone sets are an important class of discrete point sets. Their Voronoi regions are again convex polytopes, but generally there is more than one shape.

There are many other important classes of monohedral tilings that we meet later on. From an artistic perspective, "spiral" tilings of the plane are among the most beautiful; see Fig. 3 for an example.

E. The Symmetry Group of a Tiling

The symmetry properties of a tiling $\mathcal{T}$ of E^d are captured by its symmetry group $S(\mathcal{T})$, which is a discrete group of Euclidean isometries of E^d. The structure of $S(\mathcal{T})$ depends essentially on its *rank* k, the number of independent translations in $S(\mathcal{T})$. Since the tiles in $\mathcal{T}$ are assumed to be topological d-balls, the group cannot contain arbitrarily small translations. In fact, the subgroup of all translations

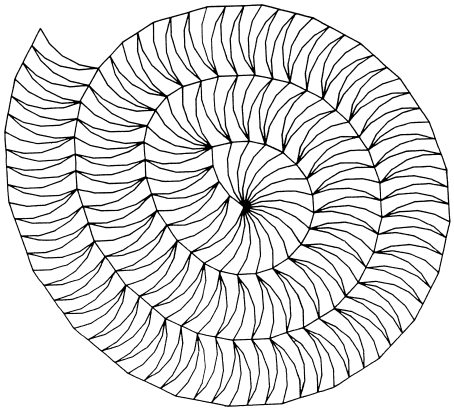

FIGURE 3 A spiral tiling of the plane. Many other spiral tilings can be constructed with the same prototile. [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

in $S(\mathcal{T})$, called the *translation subgroup* of $S(\mathcal{T})$, is in one-to-one correspondence with a k-dimensional lattice in E^d consisting of the corresponding translation vectors; here, $k = 0, 1, \ldots$ or d. A tiling $\mathcal{T}$ in E^d is called *periodic* if $S(\mathcal{T})$ contains translations in d linearly independent directions (that is, $k = d$). For example, all the tilings in Fig. 4 are periodic plane tilings; the translation subgroup is generated by two independent translations. Trivially, each lattice tiling of E^d is periodic. A tiling $\mathcal{T}$ is called *nonperiodic* if $S(\mathcal{T})$ contains no translation other than the identity (that is, $k = 0$). Note that a tiling that is not periodic need not be nonperiodic.

A group G of Euclidean isometries in E^d is called a *crystallographic group* or a *space group* if it is discrete and contains translations in d independent directions. The crystallographic groups are precisely the discrete groups of isometries in E^d whose fundamental region is compact. Two discrete groups are said to be *geometrically isomorphic* if they are conjugate subgroups in the group of all nonsingular affine transformations of E^d. Clearly, geometric isomorphism of discrete groups implies isomorphism as abstract groups. But for crystallographic groups, the converse is also true; that is, two crystallographic groups are geometrically isomorphic if and only if they are isomorphic as abstract groups. If $d = 2$, 3, or 4, the number of (geometric isomorphism) types of crystallographic groups in E^d is 17, 219, or 4783, respectively. If $d \geq 5$, the number of types in E^d is finite but is not explicitly known.

Every infinite orbit of a crystallographic group is a Delone set. The Delone sets that arise from crystallographic groups are also called *regular systems of points*.

For plane tilings $\mathcal{T}$, the three possible choices for the rank k of $S(\mathcal{T})$ lead to well-known classes of plane isometry groups:

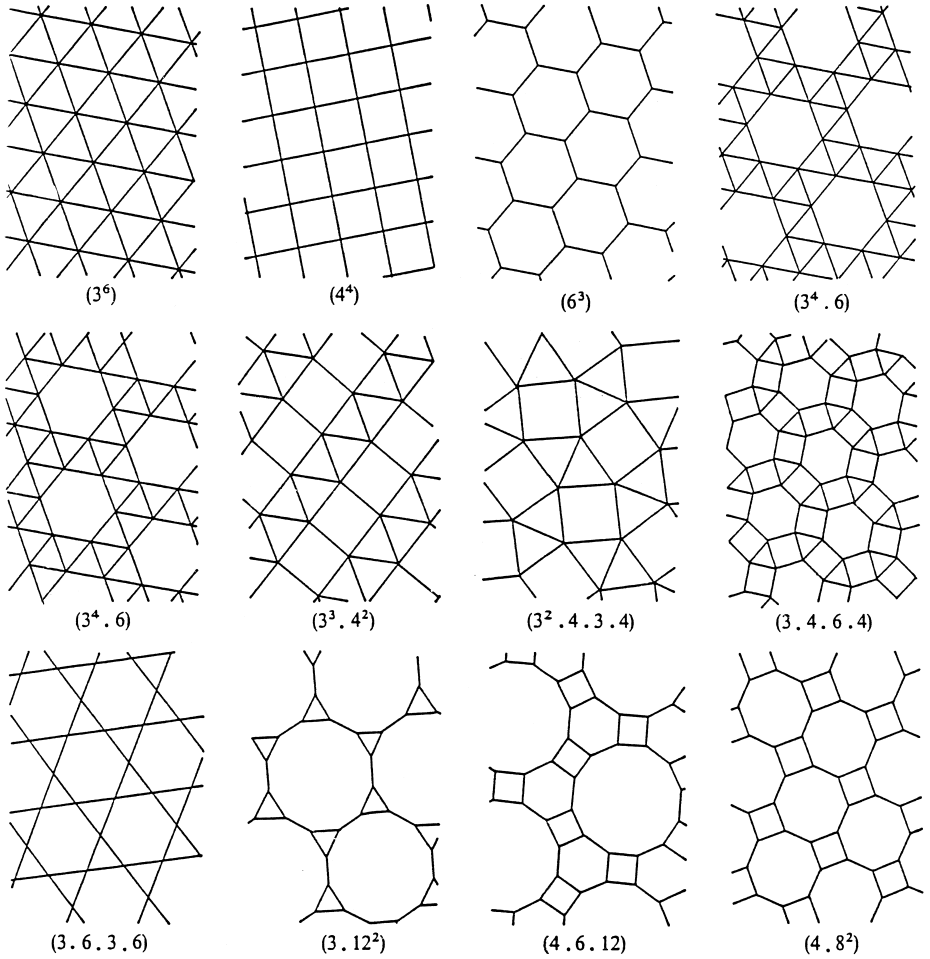

FIGURE 4 The 11 Archimedean tilings in the plane. [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

1. If $S(\mathcal{T})$ contains no translation other than the identity (that is, $k = 0$), then $S(\mathcal{T})$ is (isomorphic to) a cyclic group C_n or a dihedral group D_n for some $n \geq 1$. In this case, $\mathcal{T}$ has a *center*; that is, there is at least one point (exactly one if $n \geq 3$) of the plane that is left fixed by every symmetry of $\mathcal{T}$.

2. If $S(\mathcal{T})$ contains only translations in one independent direction, then $S(\mathcal{T})$ is (isomorphic to) one of seven groups called *strip groups* or *frieze groups*.

3. If $S(\mathcal{T})$ contains translations in two independent directions, then $\mathcal{T}$ is periodic and $S(\mathcal{T})$ is (isomorphic to) one of the 17 (*plane*) *crystallographic groups*, also known as *periodic groups* or *wallpaper groups*. (There are different sets of notations for these groups; the most common is that of the International Union of Crystallography, another is the orbifold notation proposed by Conway.)

Two tilings $\mathcal{T}_1$ and $\mathcal{T}_2$ of E^d are said to be of the *same symmetry type* if $S(\mathcal{T}_1)$ and $S(\mathcal{T}_2)$ are *geometrically isomorphic* as discrete groups.

An important problem in tiling theory is the classification of tilings $\mathcal{T}$ with respect to certain transitivity properties of $S(\mathcal{T})$. A tiling $\mathcal{T}$ of E^d is called *isohedral* if $S(\mathcal{T})$ acts transitively on the tiles of $\mathcal{T}$. Clearly, an isohedral tiling is monohedral but the converse is not true. A plane tiling $\mathcal{T}$ is said to be *isogonal* (*isotoxal*) if $S(\mathcal{T})$ acts transitively on the vertices (edges, respectively) of $\mathcal{T}$. Isogonality and isotoxality (and indeed, transitivity on the faces of any dimension) can also be studied more generally for face-to-face tilings $\mathcal{T}$ of E^d by convex d-polytopes.

A face-to-face tiling $\mathcal{T}$ of E^d is called *regular* if $S(\mathcal{T})$ acts transitively on the flags (maximal chains of mutually incident faces) of $\mathcal{T}$. These are the tilings with maximum possible symmetry. In the plane, there are only three regular tilings—namely, the well-known tilings by regular triangles, squares, and hexagons; see Fig. 4, where these tilings occur as (3^6), (4^4), and (6^3), respectively. For each dimension d, we also have the regular tessellation of E^d by d-cubes. Except for two additional exceptional

tilings in E^4, there are no other regular tilings in any dimension.

III. GENERAL CONSIDERATIONS

In this section we discuss a number of basic results which hold in any dimension. Throughout, $\mathcal{T}$ will be a locally finite tiling of E^d whose tiles are topological d-balls (that is, discs if $d = 2$). The *tiling problem* in E^d asks if there exists an algorithm which, when applied to any finite prototoset $\mathcal{S}$ (of topological d-balls) in E^d, decides whether or not $\mathcal{S}$ admits a tiling of E^d. The solution is given by the following *Undecidability Theorem*:

Theorem 1. *The tiling problem in the plane or in higher dimensional space is undecidable; that is, there exists no algorithm that decides whether or not an arbitrary finite set of prototiles admits a tiling.*

In constructing tilings we often come across the problem of having to extend a patch of tiles to a larger patch or a tiling of the entire space. By a *patch* in a tiling $\mathcal{T}$ of E^d we mean a finite collection of tiles of $\mathcal{T}$ whose union is a topological d-ball. Figure 5 shows a patch of a plane tiling.

A finite protoset $\mathcal{S}$ is said to *tile over arbitrarily large d-balls* in E^d if, for every d-ball B in E^d, the protoset admits a patch such that the union of the tiles in the patch contains B. A patch of tiles which covers a ball will generally not be extendable to a patch which covers a larger ball; that is, in constructing a global tiling it may be necessary to rearrange the tiles after each step. However, the following *Extension Theorem* holds:

Theorem 2. *Let $\mathcal{S}$ be any finite set of prototiles in E^d, each of which is a topological d-ball. If $\mathcal{S}$ tiles over arbitrarily large d-balls, then $\mathcal{S}$ admits a tiling of the entire space E^d.*

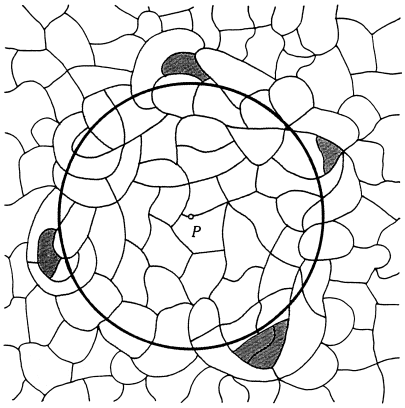

FIGURE 5 A patch of tiles in a plane tiling. The patch consists of the tiles that meet the circular disc, along with the dark-shaded tiles needed to make the arrangement a patch. [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

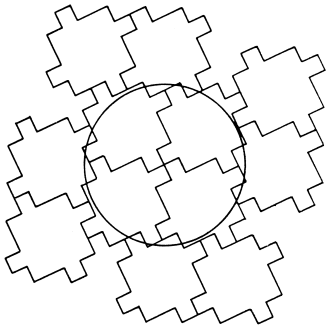

FIGURE 6 A nonextendable patch. Suitable tiles have been added to the 2×2 block of tiles in the center to make this patch nonextendable. There are similar examples based on $n \times n$ blocks for any $n \geq 2$. [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

To illustrate that rearranging of tiles may be necessary after each step, consider the patch in Fig. 6, which is the initial patch in an increasing sequence of similar patches. No patch is obtained by extending a preceding patch, yet the extension theorem implies that the given prototile admits a tiling of the entire plane.

An important class of tilings is given by the periodic tilings. For tiles that are convex polytopes, we have the following periodicity result:

Theorem 3. *Let $\mathcal{S}$ be a finite set of prototiles in E^d that are convex d-polytopes. If $\mathcal{S}$ admits a face-to-face tiling of E^d which possesses a (nontrivial) translational symmetry, then $\mathcal{S}$ also admits a tiling that is periodic (and may or may not be the same as the first tiling).*

We now discuss normality of tilings in E^d. Normality has strong implications on the frequency with which tiles are distributed along the boundary of large spherical regions in space. A *spherical patch* $P(x, r)$ in a tiling is the collection of tiles whose intersection with the ball $B(x, r)$ of radius r centered at the point x is nonempty, together with any additional tiles needed to complete the patch (that is, to make the union of its tiles homeomorphic to a topological d-ball). By $t(x, r)$ we denote the number of tiles in $P(x, r)$.

The following *Normality Lemma* implies that a normal tiling cannot have "singularities" at finite points or at infinity:

Theorem 4. *In a normal tiling $\mathcal{T}$ of E^d, the ratio of the number of tiles that meet the boundary of a spherical patch to the number of tiles in the patch itself tends to zero as the radius of the patch tends to infinity. More precisely, if x is a point in E^d and $s > 0$, then:*

$$\lim_{r\to\infty}\frac{t(x,r+s)-t(x,r)}{t(x,r)}=0$$

In a normal plane tiling, the tiles cannot have too many edges. In fact, as a consequence of the Normality Lemma we have

Theorem 5. *If all the tiles in a normal plane tiling have the same number k of edges, then* $k=3$, 4, 5, *or* 6.

Finally we note the following implication of convexity of the tiles in a tiling:

Theorem 6. *If* $\mathcal{T}$ *is a tiling of* E^d *with (compact) convex tiles, then necessarily each tile in* $\mathcal{T}$ *is a convex d-polyhedron (d-polytope, respectively).*

IV. PLANE TILINGS

Much of the attraction of plane tilings comes from their appearance in nature and art. They have been widely studied, and much more is known about tilings in the plane than about tilings in spaces of higher dimensions. We begin with some well-known classes of plane tilings; see Section II.C for basic notation.

A. Archimedean Tilings and Laves Tilings

Historically, tilings by (convex) regular polygons were the first kind to be investigated. If the tiles in an edge-to-edge tiling are congruent regular polygons, then the tiling must be one of the three regular tilings in the plane, by triangles, squares, or hexagons.

The Archimedean tilings are edge-to-edge tilings by regular polygons, not necessarily all of the same kind, in which all the vertices are surrounded in the same way by the tiles that contain it. More precisely, an edge-to-edge tiling $\mathcal{T}$ by regular polygons is said to be of *type* $(n_1.n_2.\ \ldots\ .n_r)$ if each vertex x of $\mathcal{T}$ is of *type* $n_1.n_2.\ \ldots\ .n_r$, meaning that, in a cyclic order, x is surrounded by an n_1-gon, an n_2-gon, and so on. Then, the type $(n_1.n_2.\ \ldots\ .n_r)$ of $\mathcal{T}$ is unique up to a cyclic permutation of the numbers n_i, and we will denote $\mathcal{T}$ itself by this symbol. The *Archimedian tilings* then are the eleven tilings described by the next theorem and depicted in Fig. 4; they were already enumerated by Kepler.

Theorem 7. *There exist precisely 11 distinct edge-to-edge tilings of the plane by convex regular polygons such that all vertices are of the same type*: (3^6), $(3^4.6)$, $(3^3.4^2)$, $(3^2.4.3.4)$, (3.4.6.4), (3.6.3.6), (3.12^2), (4^4), (4.6.12), (4.8^2), and (6^3).

An edge-to-edge tiling $\mathcal{T}$ of the plane is called *uniform* if it is isogonal and its tiles are convex regular polygons.

Theorem 8. *The uniform plane tilings are precisely the 11 Archimedean tilings.*

A tiling $\mathcal{T}$ by regular polygons is called *equitransitive* if each set of mutually congruent tiles forms one transitivity class with respect to the symmetry group of $\mathcal{T}$. All but one Archimedean tilings are equitransitive; the exception is $(3^4.6)$, which has two congruence classes but three transitivity classes of tiles. There are many further equitransitive tilings of both kinds, edge-to-edge or not edge-to-edge.

The Laves tilings, named after the crystallographer Laves, are monohedral tilings related to the Archimedean tilings by duality. To explain this, let $\mathcal{T}$ be a monohedral edge-to-edge tiling in which the tiles are convex r-gons. Call a vertex x of $\mathcal{T}$ *regular* if the edges emanating from x dissect a small neighbourhood of x into equiangular parts, the angle being $2\pi/v$ where v is the valence of x. If all vertices of $\mathcal{T}$ are regular and the vertices in each tile have valences $v_1, \ldots, v_r$ in $\mathcal{T}$, then we denote $\mathcal{T}$ by the symbol $[v_1.v_2.\ \ldots\ .v_r]$. Again, the symbol is unique up to a cyclic permutation of its entries. The *Laves tilings* then are the eleven tilings described by the next theorem and depicted in Fig. 7:

Theorem 9. *(a) If* $\mathcal{T}$ *is a monohedral edge-to-edge tiling of the plane by convex polygons which has only regular vertices, then its symbol is one of the 11 symbols mentioned in part b. (b) To each of the eight symbols* $[3^4.6]$, $[3^2.4.3.4]$, [3.6.3.6], [3.4.6.4], $[3.12^2]$, [4.6.12], $[4.8^2]$, *and* $[6^3]$ *corresponds a unique such tiling* $\mathcal{T}$*; to each of* $[3^3.4^2]$ *and* $[4^4]$ *corresponds a family of such tilings depending on a single real-valued parameter; and to* $[3^6]$ *corresponds a family of tilings with two such parameters.*

The Laves tiling $[v_1.v_2.\ \ldots\ .v_r]$ and the Archimedean tiling $(v_1.v_2.\ \ldots\ .v_r)$ correspond to each other by duality. The Laves tilings are isohedral; this is analogous to the Archimedean tilings being uniform.

B. Euler's Theorem

The well-known Euler Theorem for convex polytopes in ordinary space E^3 says that, if a convex polytope has v vertices, e edges, and f two-dimensional faces, then:

$$v-e+f=2$$

In this section we discuss its analogue and relatives for normal tilings $\mathcal{T}$ in the plane.

The Euler-type theorem in the plane now involves the two limits:

$$v(\mathcal{T})=\lim_{r\to\infty}\frac{v(x,r)}{t(x,r)}\qquad\text{and}\qquad e(\mathcal{T})=\lim_{r\to\infty}\frac{e(x,r)}{t(x,r)}$$

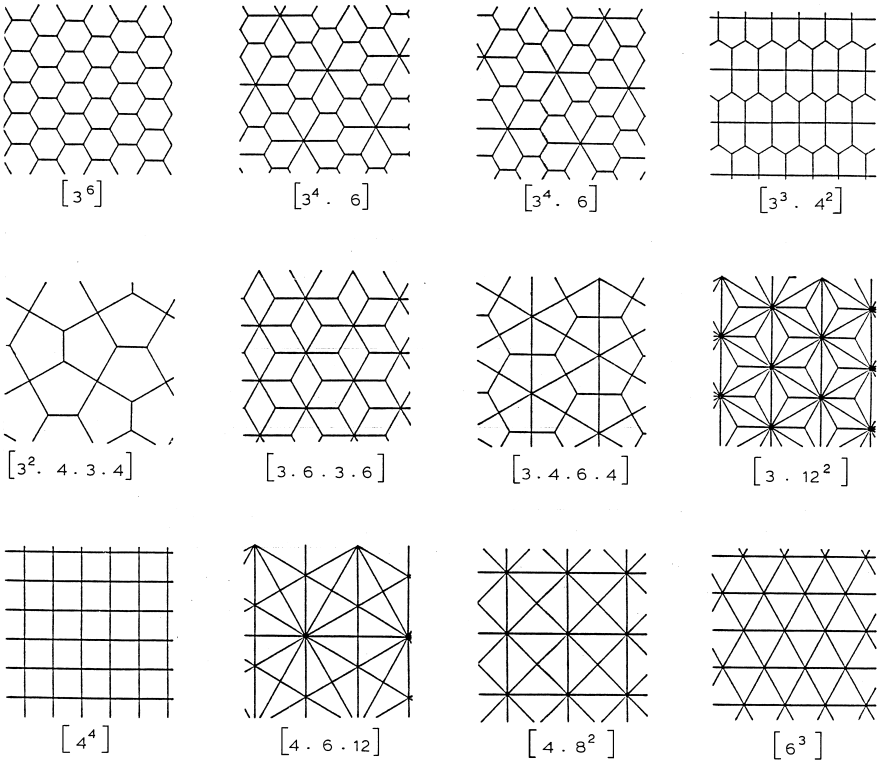

FIGURE 7 The 11 Laves tilings in the plane. [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

where x is a point in E^2, and $t(x, r)$, $e(x, r)$, and $v(x, r)$ denote the numbers of tiles, edges, and vertices, respectively, in the spherical patch $P(x, r)$. If these limits exist and are finite for some reference point x, then so for every point x in E^2, and the limits are independent of the reference point. Tilings for which these limits exist and are finite are called *balanced tilings*.

The following is known as *Euler's Theorem for Tilings*:

Theorem 10. *For a normal plane tiling $\mathcal{T}$, if one of the limits $v(\mathcal{T})$ or $e(\mathcal{T})$ exists and is finite, then so does the other. In particular, $\mathcal{T}$ is balanced and*

$$v(\mathcal{T}) - e(\mathcal{T}) + 1 = 0$$

For periodic tilings $\mathcal{T}$, this theorem can be restated as follows. Let L be the two-dimensional lattice of vectors that correspond to translations in $S(\mathcal{T})$. Choose any fundamental parallelogram P for L such that no vertex of $\mathcal{T}$ lies on a side of P, and no corner of P lies on an edge of $\mathcal{T}$. Let V, E, and T denote the numbers of vertices, edges, and tiles in P, respectively, where fractions of edges and tiles are counted appropriately. Then these numbers do not depend on the choice of the fundamental parallelogram.

The following result is known as *Euler's Theorem for Periodic Plane tilings*, and corresponds to an Euler-type theorem for tessellations of the two-dimensional torus:

Theorem 11. *If $\mathcal{T}$ is a normal plane tiling that is periodic, then $V - E - T = 0$.*

Euler's Theorem can be extended in various ways. One such extension involves the limits,

$$v_j(\mathcal{T}) = \lim_{r\to\infty} \frac{v_j(x,r)}{t(x,r)} \quad \text{and} \quad t_k(\mathcal{T}) = \lim_{r\to\infty} \frac{t_k(x,r)}{t(x,r)}$$

where $v_j(x, r)$ is the number of vertices of valence j in the patch $P(x, r)$, and $t_k(x, r)$ is the number of tiles with k adjacents in $P(x, r)$. A normal tiling $\mathcal{T}$ is called *strongly balanced* if, for some point x, all the limits $v_j(\mathcal{T})$ $(j \geq 3)$ and $t_k(\mathcal{T})$ $(k \geq 3)$ exist; then they will be finite by normality. As before, this definition does not depend on the reference point x. In any strongly balanced tiling, $v(\mathcal{T}) = \sum_{j\geq 3} v_j(\mathcal{T}) \leq \infty$ and $\sum_{k\geq 3} t_k(\mathcal{T}) = 1$; in particular, such a tiling is balanced. The following are examples of strongly balanced plane tilings: periodic tilings; tilings in which each tile has k vertices, with valences $j_1, \ldots, j_k$ (in some order); and tilings with j-valent vertices each incident with tiles that have $k_1, \ldots, k_j$ adjacents (in some order).

The equations in the next two theorems involve the relative frequences of vertices of various valences and tiles with various number of adjacents.

Theorem 12. *If $\mathcal{T}$ is a strongly balanced plane tiling, then:*

$$2\sum_{j\geq 3}(j-3)v_j(\mathcal{T})+\sum_{k\geq 3}(k-6)t_k(\mathcal{T})=0$$

$$\sum_{j\geq 3}(j-4)v_j(\mathcal{T})+\sum_{k\geq 3}(k-4)t_k(\mathcal{T})=0$$

$$\sum_{j\geq 3}(j-6)v_j(\mathcal{T})+2\sum_{k\geq 3}(k-3)t_k(\mathcal{T})=0$$

Theorem 13. *If $\mathcal{T}$ is a strongly balanced plane tiling, then:*

$$\frac{1}{\sum_{j\geq 3} j\,w_j(\mathcal{T})}+\frac{1}{\sum_{k\geq 3} k t_k(\mathcal{T})}=\frac{1}{2}$$

where $w_j(\mathcal{T}) := v_j(\mathcal{T})/v(\mathcal{T})$.

Note that the denominators on the left in Theorem 13 are the average valence of the vertices of $\mathcal{T}$ and the average number of edges of the tiles of $\mathcal{T}$. For example, for the regular tessellation of the plane by regular p-gons, q meeting at each vertex, the latter equation takes the simple form $\frac{1}{p}+\frac{1}{q}=\frac{1}{2}$. From this equation we obtain the well-known solutions $\{p,q\}=\{3,6\}$, $\{4,4\}$, and $\{6,3\}$, which correspond to the tessellations by triangles, squares, or hexagons, respectively.

C. Classification by Symmetry

In this section we discuss the classification (enumeration) of plane tilings $\mathcal{T}$ by combinatorial or metrical (euclidean) symmetry. The tiles are as usual topological discs, but convexity of the tiles is not assumed. We begin with the coarser classification by combinatorial symmetry which employs the combinatorial automorphism group $\Gamma(\mathcal{T})$ and its transitivity properties on $\mathcal{T}$. As we remarked earlier, the concepts of combinatorial equivalence and topological equivalence are the same for normal plane tilings. Any automorphism in $\Gamma(\mathcal{T})$ can be realized by a homeomorphism of the plane that preserves $\mathcal{T}$, and vice versa. The classification by combinatorial symmetry is thus the same as the classification by topological symmetry.

1. Combinatorial Symmetry

Combinatorial symmetry can occur locally or globally. In a locally symmetric tiling, the combinatorial data for the neighborhoods of tiles or vertices are all the same. In a globally symmetric tiling $\mathcal{T}$, this is also true, but now the symmetry is furnished by a combinatorial automorphism group $\Gamma(\mathcal{T})$, which acts transitively on the tiles or vertices of the tiling. We first discuss symmetry properties with respect to tiles.

Let $\mathcal{T}$ be a plane tiling, and let T be a tile of $\mathcal{T}$. With T we can associate its *valence-type* $j_1.j_2.\ \ldots\ .j_k$ provided T has k vertices which, in cyclic order, have valences $j_1, j_2, \ldots, j_k$. Then $\mathcal{T}$ is said to be *homogeneous of type* $[j_1.j_2.\ \ldots\ .j_k]$ if $\mathcal{T}$ is normal and each tile of $\mathcal{T}$ has valence-type $j_1.j_2.\ \ldots\ .j_k$. As before, these symbols for $\mathcal{T}$ and its tiles are unique up to a cyclic permutation of the entries.

A plane tiling $\mathcal{T}$ is called *homeohedral* or *combinatorially tile-transitive* if $\mathcal{T}$ is normal and $\Gamma(\mathcal{T})$ acts transitively on the tiles of $\mathcal{T}$. Each homeohedral tiling is also homogeneous.

Theorem 14. (a) *If $\mathcal{T}$ is a homogeneous plane tiling, then it has one of the 11 types* $[3^6]$, $[3^4.6]$, $[3^3.4^2]$, $[3^2.4.3.4]$, $[3.4.6.4]$, $[3.6.3.6]$, $[3.12^2]$, $[4^4]$, $[4.6.12]$, $[4.8^2]$, $[6^3]$. (b) *Each homogeneous plane tiling is homeohedral. Any two homogeneous plane tilings of the same type are combinatorially equivalent, and each type can be represented by a Laves tilings (see Theorem 9 and Fig. 7).*

We now discuss the dual concept. A tiling $\mathcal{T}$ is called *homeogonal* or *combinatorially vertex-transitive* if $\mathcal{T}$ is normal and $\Gamma(\mathcal{T})$ acts transitively on the vertices of $\mathcal{T}$. As with uniform tilings, we can associate with a homeogonal tiling $\mathcal{T}$ its *type* $(k_1.k_2.\ \ldots\ .k_j)$; here, j is the valence of any vertex x, and the j tiles that contain x have, in a suitable cyclic order, k_1 vertices, k_2 vertices, and so on. If $\mathcal{T}$ and $\mathcal{T}'$ are normal dual tilings, then $\mathcal{T}$ is homeogonal if and only if $\mathcal{T}'$ is homeohedral.

Theorem 15. (a) *If $\mathcal{T}$ is a homeogonal plane tiling, then it has one of the 11 types* (3^6), $(3^4.6)$, $(3^3.4^2)$, $(3^2.4.3.4)$, $(3.4.6.4)$, $(3.6.3.6)$, (3.12^2), (4^4), $(4.6.12)$, (4.8^2), (6^3). (b) *Any two homeogonal plane tilings of the same type are combinatorially equivalent, and each type can be represented by an Archimedean (uniform) tiling (see Theorems 7 and 8, and Fig. 4).*

A normal plane tilings $\mathcal{T}$ is said to be *homeotoxal* if its automorphism group $\Gamma(\mathcal{T})$ is edge transitive. It can be shown that there are just five "types" of homeotoxal tilings.

Normality of the tilings is essential in all these classifications. If the requirement of normality is dropped, then many further possibilities arise.

2. Metrical Symmetry

Before we investigate tilings, we introduce some terminology that applies in the wider context of classifying certain geometric objects with respect to metrical symmetries or, as we will say, *by homeomerism*. In particular, this will explain when two geometric objects are considered to be the same (of the same homeomeric type) with respect to classification purposes.

Let $\mathcal{R}$ and $\mathcal{R}'$ be two geometric objects in Euclidean space E^d, and let $S(\mathcal{R})$ and $S(\mathcal{R}')$ be their symmetry groups, respectively. Consider a homeomorphism φ of E^d which maps $\mathcal{R}$ onto $\mathcal{R}'$. Then φ is said to be *compatible*

with a symmetry σ in $S(\mathcal{R})$ if there exists a symmetry σ' in $S(\mathcal{R}')$ such that $\sigma'\varphi = \varphi\sigma$; that is, up to the one-to-one correspondence determined by the homeomorphism φ, a symmetry σ moves elements of the object $\mathcal{R}$ in the same way as σ' moves elements of $\mathcal{R}'$. We call φ *compatible with* $S(\mathcal{R})$ if φ is compatible with each symmetry σ in $S(\mathcal{R})$.

Two geometric objects $\mathcal{R}$ and $\mathcal{R}'$ in E^d are said to be *homeomeric*, or *of the same homeomeric type*, if there exists a homeomorphism φ which maps $\mathcal{R}$ onto $\mathcal{R}'$ such that φ is compatible with $S(\mathcal{R})$ and its inverse φ^{-1} is compatible with $S(\mathcal{R}')$.

These concepts apply to the classification of normal plane tilings $\mathcal{T}$ with certain transitivity properties of their symmetry group $S(\mathcal{T})$. The following three results summarize the enumeration of all homeomeric types of tilings with a tile-transitive, vertex-transitive, or edge-transitive symmetry group, respectively, yielding the homeomeric types of isohedral, isogonal, or isotoxal tilings:

Theorem 16. *There exist precisely 81 homeomeric types of normal isohedral plane tilings. Precisely 47 types can be realized by a normal isohedral edge-to-edge tiling with convex polygonal tiles.*

Theorem 17. *There exist precisely 91 homeomeric types of normal isogonal plane tilings. Precisely 63 types can be realized by normal isogonal edge-to-edge tilings with convex polygonal tiles.*

Theorem 18. *There exist precisely 26 homeomeric types of normal isotoxal plane tilings. Precisely six types can be realized by a normal isotoxal edge-to-edge tiling with convex polygonal tiles.*

The enumeration of the tilings can be accomplished in various ways. One approach is through *incidence symbols* which encode data about the local structure of the plane tilings. For example, isohedral tilings fall into 11 combinatorial classes, typified by the Laves tilings. In an isohedral tiling, every tile is surrounded in the same way, and its vertex degree sequence is given by the symbol for the corresponding Laves tiling. The incidence symbol records (in terms of edge labels and edge orientations) how each tile meets its (congruent) neighbors. The situation is similar for isogonal and isotoxal tilings. The enumeration proceeds by identifying all possible incidence symbols.

Another algorithmic approach is through *Delaney–Dress symbols*. With every tiling is associated a "barycentric subdivision," and the symbol now stores information about the way in which the symmetry group acts on this subdivision. Then the enumeration of the tilings amounts to the enumeration of all Delaney–Dress symbols of a certain type. This approach is more flexible and allows generalizations to tilings in higher dimensions. For example, the method has been applied to show that there are 88 combinatorial classes of periodic tilings in ordinary three-space for which the symmetry group acts transitively on the two-dimensional faces of the tiling.

V. MONOHEDRAL TILINGS

This section deals with monohedral tilings $\mathcal{T}$ in Euclidean spaces E^d of any dimension $d \geq 2$. Monohedral tilings have a single prototile. To determine which shapes occur as prototiles is one of the main open problems in tiling theory. The answer is not even known for polygonal prototiles in the plane, which necessarily cannot have more than six vertices. In its full generality, the prototile enumeration problem seems to be intractable in higher dimensions, so suitable restrictions must be imposed on the tiles or on the kind of tilings.

A. Lattice Tilings

Lattice tilings in E^d by convex d-polytopes have been widely studied. The interest in such tilings originated from crystallography and the geometry of numbers. Early contributions on the subject can be found in the works of Dirichlet, Fedorov, Minkowski, Voronoi, and Delone.

A tiling $\mathcal{T}$ by translates of a single prototile T is the simplest kind of monohedral tiling. Prototiles which admit such a tiling are very restricted. For example, if the prototile T is a convex d-polytope, then T and all its facets must necessarily be centrally symmetric. The translation vectors for the tiles in a tiling by translates need not necessarily come from a lattice. However, if a prototile tiles by translation, then it is natural to ask if it also admits a lattice tiling.

Theorem 19. *If a convex d-polytope T tiles E^d by translation, then T also admits (uniquely) a face-to-face lattice tiling of E^d and thus is a parallelotope.*

For nonconvex prototiles T, the analogue of Theorem 19 is generally not true. There are nonconvex star-shaped polyhedral sets T which tile E^d by translation but do not admit a lattice tiling. Examples have been found in almost all dimensions d, including $d = 3$.

Parallelotopes are the most basic space fillers. Simple examples are the Voronoi regions for lattices. The previous theorem is based on the following characterization of parallelohedra. A *belt* of a convex d-polytope T is a sequence of facets $F_0, F_1, \ldots, F_{k-1}, F_k = F_0$ of T, such that $F_{i-1} \cap F_i$ is a $(d-2)$-face of T for each $i = 1, \ldots, k$, and all these $(d-2)$-faces are parallel. If T is a centrally symmetric convex d-polytope with centrally symmetric facets, then every $(d-2)$-face G of T determines a belt of facets whose $(d-2)$-faces are parallel to G.

Theorem 20. *A convex d-polytope T is a parallelotope if and only if T and its facets are centrally symmetric and each belt of T contains four or six facets.*

In each dimension d, there is only a finite number of distinct combinatorial types of parallelotope. This follows from Minkowski's observation that a parallelotope in E^d can have at most $2(2^d - 1)$ facets. A complete list of parallelotopes is only known for $d \leq 4$. For $d = 2$, 3, or 4, the number of distinct combinatorial types of parallelotopes is 2, 5, or 52, respectively. Figure 8 shows representatives for the parallelotopes in the plane and ordinary space. In the plane, the parallelogram and the centrally symmetric hexagon are the only possible shapes. For $d = 3$, Minkowski's bound predicts that a parallelotope cannot have more than 14 facets; the maximum of 14 is attained by the truncated octahedron, which is the last parallelotope in Fig. 8.

Call a parallelotope T *primitive* if, in its unique face-to-face tiling $\mathcal{T}$, each vertex of $\mathcal{T}$ is contained in exactly $d + 1$ tiles. In E^2 and E^3, the centrally symmetric hexagon and truncated octahedron are the only types of primitive parallelotopes; in E^4, there are three distinct combinatorial types. The total number of combinatorial types of parallotopes grows very fast in dimensions $d \geq 5$, and the number of primitive types is known to be at least 223 if $d = 5$. It has been conjectured (already by Voronoi) that each parallelotope is in fact an affine image of the Voronoi region for some lattice. This is known to be true in dimensions $d \leq 4$, as well as for primitive parallelohedra in all dimensions.

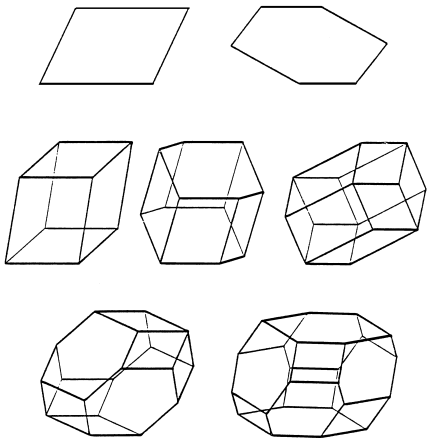

FIGURE 8 The parallelotopes in two and three dimensions. The top row shows the two possible shapes in the plane, a parallelogram, and a centrally symmetric hexagon. There are five shapes of parallelotopes in ordinary space—the parallelopiped, hexagonal prism, and rhombic dodecahedron shown in the middle row and the elongated dodecahedron and truncated octahedron shown in the bottom row. [From Schulte, E. (1993). *Handbook of Convex Geometry*, (Gruber, P. M., and Wills, J. M., eds.). Elsevier, Amsterdam.]

The d-dimensional cube obviously is a parallelotope in each dimension d. In every lattice tiling of E^d by unit d-cubes, there always is a "stack" of cubes in which each two adjacent cubes meet in a whole facet. However, for $d \geq 10$, there are nonlattice tilings of E^d by translates of unit d-cubes in which no two cubes share a whole facet. On the other hand, for $d \leq 6$, any tiling of E^d by unit d-cubes must contain at least one pair of cubes that share a whole facet.

B. Space Fillers in Dimension *d*

Convex d-polytopes which are prototiles of monohedral tilings in E^d are called *space fillers* of E^d, or *plane fillers* if $d = 2$. The enumeration of all space fillers is far from being complete, even for the planar case.

Isohedral tilings are monohedral tilings with a tile-transitive symmetry group. Convex polytopes which are prototiles of isohedral tilings are called *stereohedra*. Each stereohedron is a space filler, but the converse is not true. Indeed, a famous problem by Hilbert (posed in 1900) asked whether there exists a three-dimensional polyhedral shape that admits a monohedral tiling but no isohedral tiling of E^3. Such a prototile (in any dimension) is said to be *anisohedral*. Rephrased in terms of crystallographic groups, Hilbert's problem asked whether there exists a polyhedral space-filling tile in E^3 which is not a fundamental region for a discrete group of Euclidean isometries. Hilbert's question can be reduced to the planar case by observing that three-dimensional (and higher dimensional) anisohedral prototiles can be constructed as prisms over anisohedral planar prototiles. Several authors have discovered examples of anisohedral prototiles, beginning with Reinhardt in 1928 and Heesch in 1935. In the plane, there are anisohedral convex pentagons which admit periodic monohedral tilings. The tile in Fig. 9 is

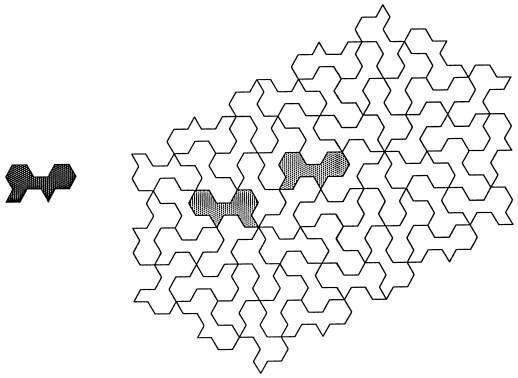

FIGURE 9 A planar anisohedral tile and its unique plane tiling. The two shaded tiles are surrounded in different ways. [From Schattschneider, D., and Senechal, M. (1997). *Handbook of Discrete and Computational Geometry*, (Goodman, J. E., and O'Rourke, J., eds.). CRC Press, Boca Raton, FL.]

anisohedral and admits a unique plane tiling; in fact, the tiling must be nonisohedral because the two shaded tiles are surrounded in different ways.

Theorem 21. *For every $d \geq 2$, there exist anisohedral space fillers that are convex d-polytopes.*

Isohedrality is a global property that a monohedral tiling may or may not have. Our next theorem is related to Hilbert's problem and describes a way to detect isohedrality of a tiling locally. We first introduce some terminology.

Let $\mathcal{T}$ be a monohedral tiling in E^d. Given a tile T of $\mathcal{T}$, the *kth corona* $C^k(T)$ of T in $\mathcal{T}$ is the set of all tiles T' in $\mathcal{T}$ for which there exists a sequence of tiles $T = T_0, T_1, \ldots, T_{m-1}, T_m = T'$ with $m \leq k$ such that $T_i \cap T_{i+1} \neq \emptyset$ for $i = 0, \ldots, m-1$. So $C^0(T)$ consists of T itself, $C^1(T)$ of the tiles that meet T, and $C^k(T)$ of the tiles that meet a tile in $C^{k-1}(T)$. It is possible that two distinct tiles T and T' of $\mathcal{T}$ have the same kth corona for some k; that is, $C^k(T) = C^k(T')$. A *centered kth corona* in $\mathcal{T}$ is a pair $(T, C^k(T))$, consisting of a tile T and its *kth* corona $C^k(T)$. A centered corona determines the original tile uniquely. Two centered kth coronas $(T, C^k(T))$ and $(T', C^k(T'))$ are said to be *congruent* (as centered coronas) if there exists an isometry γ of E^d such that $\gamma(T) = T'$ and $\gamma(C^k(T)) = C^k(T')$; here, it is not required that γ maps $\mathcal{T}$ onto itself. By $S_k(T)$ we denote the group of isometries of E^d which map the centered corona $(T, C^k(T))$ onto itself; this is the subgroup of the symmetry group $S(T)$ of the tile T which maps $C^k(T)$ onto itself. Since $S(T)$ is a finite group, the chain of subgroups $S(T) = S_0(T) \supseteq S_1(T) \supseteq \cdots \supseteq S_k(T) \supseteq \cdots$ can only contain a finite number of distinct groups.

We now have the following *Local Theorem for Tilings*, which characterizes isohedrality locally:

Theorem 22. *Let $\mathcal{T}$ be a monohedral tiling of E^d. Then $\mathcal{T}$ is isohedral if and only if there exists a positive integer k for which the following two conditions hold: first, any two centered kth coronas in $\mathcal{T}$ are congruent, and, second, $S_{k-1}(T) = S_k(T)$ for some tile (and hence all tiles) T of $\mathcal{T}$. Moreover, if the two conditions hold for k, and if T is a tile of $\mathcal{T}$, then $S_k(T)$ is the stabilizer of T in $S(\mathcal{T})$. In particular, if the prototile of $\mathcal{T}$ is asymmetric (that is, has no nontrivial symmetry), then $\mathcal{T}$ is isohedral if and only if the first condition holds with $k = 1$.*

The classification of the space fillers is one of the big open problems in tiling theory. Its complexity is already evident in the planar case, which is still unsettled. Many authors who attempted the classification for the plane believed, or even stated explicitly, that their enumeration is complete. Often this was generally accepted until a new prototile was discovered by someone else.

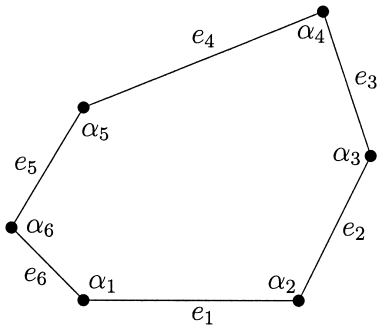

FIGURE 10 A convex hexagon with sides $e_1, \ldots, e_6$ and angles $\alpha_1, \ldots, \alpha_6$. [From Senechal, M. (1995). *Quasicrystals and Geometry*, Cambridge University Press, Cambridge.]

A plane filler must necessarily be a triangle, quadrangle, pentagon or hexagon. At present, the list of convex plane fillers comprises all triangles and all quadrangles, as well as 14 kinds of pentagons and three kinds of hexagons. To see how each triangle can tile, join two copies to form a parallelogram, and then tile the plane with congruent parallelograms. Similarly, two copies of a convex quadrangle can be joined along an edge to form a hexagon of which congruent copies tile the plane. Any convex pentagon with a pair of parallel sides is a plane filler. To describe the three kinds of hexagons that tile, label the sides of the hexagon by $e_1, \ldots, e_6$ and the angles by $\alpha_1, \ldots, \alpha_6$, as in Fig. 10. Then a convex hexagon tiles if and only if it satisfies one of the following conditions:

- $\alpha_1 + \alpha_2 + \alpha_3 = \alpha_4 + \alpha_5 + \alpha_6 = 2\pi,\ e_6 = e_3$
- $\alpha_1 + \alpha_2 + \alpha_4 = \alpha_3 + \alpha_5 + \alpha_6 = 2\pi,\ e_6 = e_3,\ e_4 = e_2$
- $\alpha_1 = \alpha_3 = \alpha_5 = 2\pi/3,\ e_6 = e_1,\ e_3 = e_2,\ e_5 = e_4$

Among these convex plane fillers, all the triangles, quadrangles, and hexagons and exactly five kinds of the pentagons admit isohedral tilings. No other convex polygons can admit isohedral plane tilings.

There is a wealth of further interesting monohedral plane tilings whose prototiles are nonconvex shapes. Examples are tilings by polyominos or polyhexes, respectively, which are composed of squares or hexagons of the regular square or hexagonal tiling of the plane. Noteworthy is also the existence of monohedral *spiral* plane tilings (see Fig. 3), whose prototiles have the remarkable property that two copies of it can completely surround a third.

The space-filler problem is most appealing in three dimensions. Many examples of space fillers have been discovered by crystallographers as Voronoi regions for suitable discrete point sets (dot patterns) in E^3. In the past, there have been several contradictory claims in the literature as to how many facets a three-dimensional space filler can have. The current world record is held by a spectacular space filler with 38 facets, which is a Voronoi region

for some discrete point set (discovered using computers). Among the five Platonic solids (the regular tetrahedron, cube, octahedron, dodecahedron, and icosahedron), only the cube tiles ordinary space, in an obvious manner.

The classification of space fillers becomes even more difficult in higher dimensions. Not even the parallelotopes, which are the convex polytopes that tile by translation, have been completely enumerated for $d \geq 5$. Tilings by certain kinds of simplices have been studied, but it is still not known, even in three dimensions, which simplices tile space. There are several kinds of tetrahedra which do admit monohedral tilings of E^3, among them tetrahedra that are fundamental regions for discrete groups generated by reflections.

A more modest problem is the classification of all combinatorial types of space-filling convex polytopes in E^d. This problem is trivial for the plane, where triangles, quadrangles, pentagons, and hexagons are the only possible solutions. For dimensions $d \geq 3$ it is not even known if there are only finitely many combinatorial types of space-filling polytopes. The number of types would be finite if there was an upper bound on the number of facets of space-filling polytopes, but the existence of a general bound has not been established. The only general result available in the literature is the following theorem which provides an upper bound for the number of facets of stereohedra that admit isohedral face-to-face tilings:

Theorem 23. *If a stereohedron admits an isohedral face-to-face tiling of* E^d*, then its number of facets is bounded by* $2^d(h - \frac{1}{2}) - 2$*, where* h *is the index of the translation subgroup in the symmetry group of the tiling.*

The theorem gives a finite bound for the number of facets of d-dimensional stereohedra that admit an isohedral face-to-face tiling. In fact, the symmetry group of the tiling must be among the finitely many crystallographic groups in E^d, and so we know that the index h of the translation subgroup is uniformly bounded. In three dimensions, the maximum index is 48 and the bound for the number of facets is 378; it is likely that the true bound is considerably lower, possibly as low as 38.

The strong requirement of congruence of the tiles considerably restricts the various possibilities for designing monohedral tilings. If this requirement is relaxed to combinatorial equivalence, there is generally much freedom for choosing the metrical shape of the tiles to arrive at a tiling of the whole space. Call a tiling $\mathcal{T}$ of E^d by convex polytopes *monotypic* if each tile of $\mathcal{T}$ is combinatorially equivalent to a convex d-polytope T, the *combinatorial prototile* of $\mathcal{T}$. In a monotypic tiling, there generally are infinitely many different metrical shapes of tiles, but the tiles are all convex and combinatorially equivalent to a single combinatorial prototile. It is not difficult to see that the plane admits a monotypic face-to-face tiling $\mathcal{T}$ by convex n-gons for each $n \geq 3$. Figure 1 illustrates how such a tiling can be constructed for $n = 7$. It is a consequence of Euler's Theorem that these tilings cannot be normal if $n \geq 7$, and so infinitely many different shapes of n-gons are needed in the process.

Much less obvious are the following rather surprising results about monotypic tilings in E^3:

Theorem 24. *Every convex* 3*-polytope* T *is the combinatorial prototile of a monotypic tiling* $\mathcal{T}$ *of* E^3*. If all facets of* T *are triangles, then* $\mathcal{T}$ *can be made face-to-face.*

In other words, in three dimensions, every polytope tiles, as long as combinatorially equivalent (rather than congruent) copies are allowed. In general, these tilings will not be face-to-face. In fact, for each dimension $d \geq 3$, there are convex d-polytopes which cannot occur as combinatorial prototiles of monotypic face-to-face tilings of E^d.

VI. NONPERIODIC TILINGS

Tiling models are an important tool in the geometrical study of crystals. Crystal growth is a modular process: from a relatively tiny cluster (seed) of atoms, a crystal grows by the accretion of modules (atoms, molecules). In the geometric modeling of crystal structure, these modules are sometimes represented by space-filling polyhedra yielding a tiling of ordinary space. For nearly 200 years, until 1984, it had been an *axiom* of crystallography that the internal structure of a crystal was periodic. The presence of lattice structure in a crystal had been strongly supported by the geometry of the X-ray diffraction images of the crystal, but this "fundamental law" of crystal structure was overturned in 1984 when an alloy of aluminum and manganese was discovered that had diffraction images exhibiting icosahedral symmetry; pentagonal, and thus icosahedral, symmetry was known not to be compatible with lattice structure. Soon other crystal-like structures were found, and eventually the name "quasicrystals" emerged.

Since 1984, crystallography has gone through a process of redefining itself, as well as the objects it studies. In the world of crystals and quasicrystals, order is no longer synonymous with periodicity, but exactly how far one has to go beyond periodicity is still a big open problem. Tilings once again have become an important modeling tool, but now the interest is in nonperiodic tilings and in shapes that do not admit periodic tilings.

A. Aperiodicity

Aperiodicity is a fascinating phenomenon in tiling theory. Recall that a tiling $\mathcal{T}$ in Euclidean d-space E^d is called *nonperiodic* if it does not admit a nontrivial translational

symmetry. For example, the spiral tiling shown in Fig. 3 is nonperiodic. There are many shapes in E^d that admit both periodic tilings and nonperiodic tilings. For example, already the d-dimensional cube admits tilings whose symmetry group contains translational symmetries in any preassigned number k of independent directions, with $k = 1, \ldots, d$. In fact, if $\mathcal{S}$ is any finite set of prototiles in E^d which are convex polytopes, and if $\mathcal{S}$ admits a face-to-face tiling of E^d which possesses a nontrivial translational symmetry, then $\mathcal{S}$ also admits a tiling of E^d which is periodic (see Theorem 3).

A set $\mathcal{S}$ of prototiles in E^d is said to be *aperiodic* if $\mathcal{S}$ admits a tiling of E^d, but all such tilings are nonperiodic. In discussing aperiodic prototile sets it is convenient to generalize the notion of a tiling and allow decorations or markings on the tiles. This leads to *decorated tiles* and *decorated tilings*, respectively. Here we shall not investigate these concepts in full generality but restrict ourselves to applications in the theory of nonperiodic tilings. In a typical application in two dimensions, the tiles in a prototile set $\mathcal{S}$ are polygons with some corners colored or with orientations on some sides (that is, the colors and orientations are the decorations). The condition then is that, in constructing a tiling with the given set of decorated prototiles, we must place tile against tile in an edge-to-edge manner, such that colored corners are placed against colored corners with the same color, and oriented sides are placed against oriented sides with the same orientation; in short, the colors at corners and the orientations on sides must match. Figure 11 shows the Penrose aperiodic prototile set consisting of two decorated tiles known as *kite* and *dart*; here the corners are colored with two colors, black and white (say), as shown, but there are no orientations given to the sides. We elaborate on this example in the next subsection.

Decorated tiles and matching rules are the price we have to pay if we want tiles of simple geometric.
By altering the shape of the decorated tiles in a prototile set to reflect their decorations and the matching rules, we can often construct a prototile set with nondecorated tiles whose tiling properties are equivalent to those of the set of decorated tiles. However, the geometric shape of the nondecorated tiles is generally more complicated and less appealing than the underlying shape of the corresponding decorated tiles.

There is a close connection between aperiodicity and the Undecidability Theorem for tilings (see Theorem 1). In fact, the Undecidability Theorem was originally proved by Berger in 1966 by establishing the existence of an aperiodic set consisting of 20,426 so-called *Wang tiles*; these are square tiles with colored edges, which must be tiled in an edge-to-edge manner by translation only such that colors of adjacent tiles match. The existence of such a set is enough to ensure that no algorithm can exist which, for any given finite set $\mathcal{S}$ of prototiles, decides in a finite number of steps whether $\mathcal{S}$ admits a tiling or not. The number of tiles in an aperiodic set of Wang tiles has since then been reduced considerably.

It is still an open question whether there exists an aperiodic set in the plane consisting of a single decorated or nondecorated tile. Over the years, many examples of small aperiodic sets have been discovered, both in the plane and in higher dimensions. The most famous examples are the three Penrose aperiodic sets in the plane described in the next subsection; they have greatly influenced the study of aperiodicity in higher dimensional spaces. There is a pair of decorated aperiodic tiles in any dimension $d \geq 2$. There are also planar examples with only three nondecorated tiles (one hexagon and two pentagons) that force aperiodicity. In E^3, the aperiodic pair of *Penrose rhombs* depicted in Fig. 12 has been generalized to yield families of decorated (Ammann) rhombohedra which again only admit non-periodic tilings. There also exists an aperiodic set of only four decorated tetrahedral tiles in E^3 that admit tilings with global icosahedral symmetry.

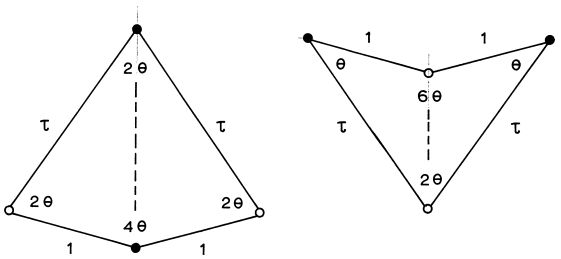

FIGURE 11 The Penrose kite and dart. The corners are colored black or white (solid or open circles, respectively), and the angles and side lengths are as indicated, with $\tau = (1+\sqrt{5})/2$ and $\theta = \pi/5$. [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

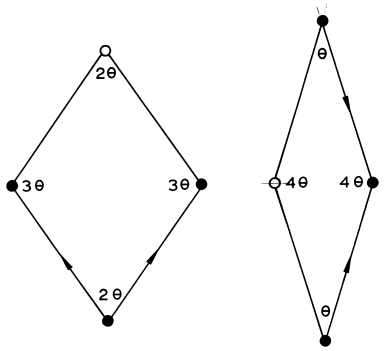

FIGURE 12 The Penrose rhombs. The rhombs have black and white corners (solid or open circles, respectively) and have orientations given to some of their sides; the angles are as indicated, with $\theta = \pi/5$. [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

A remarkable three-dimensional tile, known as the *Schmitt–Conway–Danzer tile*, has been discovered that is aperiodic when only direct congruent copies (that is, no mirror images) are allowed in tilings of E^3. The tile is a certain biprism with a cell-complex on its boundary, whose structure forces the tilings to have screw rotational symmetry through an irrational angle in one direction. The form of aperiodicity exhibited by this example is weaker than in the previous examples; in fact, although the tilings do not have translational symmetry, they still have a symmetry of infinite order.

B. The Penrose Tilings

A striking advance in tiling theory was Penrose's discovery in 1973 and 1974 of three aperiodic sets of decorated prototiles and matching rules in the plane, which are closely related to each other in that tilings with tiles from one set can be converted into tilings with tiles from another set. Two of these sets are depicted in Figs. 11 and 12; they are the Penrose kite and dart and the Penrose rhombs, both mentioned earlier. A *Penrose tiling* is a tiling of the entire plane that is constructed from any of the three sets by obeying the matching rules. Figure 13 shows a patch of a Penrose tiling by Penrose rhombs.

It is not difficult to make your own Penrose tiles from cardboard and build finite patches of tiles. However, even if you obey the matching rules, you will probably run into untileable regions at some stage, and you will have to remove or rearrange some tiles and try again. The decorations and matching rules are crucial in this process; in fact, the underlying geometric shapes do admit *periodic* tilings of the plane if the decorations and matching rules are ignored.

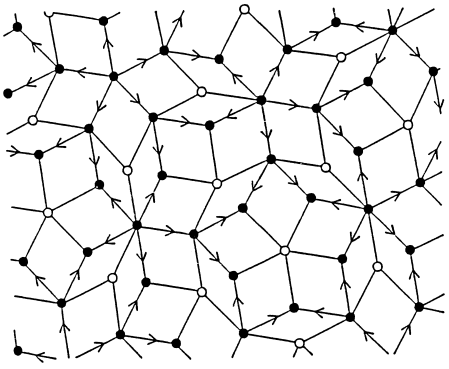

FIGURE 13 A Penrose tiling by Penrose rhombs. The tiling has been constructed according to the matching rule for Penrose tilings by Penrose rhombs (that is, the colors at corners and the orientations of sides of adjacent tiles must match). [From Grünbaum, B., and Shephard, G. C. (1986). *Tilings and Patterns*, Freeman & Co., San Francisco.]

The kite and dart of Fig. 11 have sides of two lengths in the ratio τ:1 (with $\tau = (1 + \sqrt{5})/2$ the golden ratio), and the angle θ is $\pi/5$. The corners are colored with two colors, black and white. The matching condition is that equal sides must be put together, so that the colors at the corners match. The two Penrose rhombs of Fig. 12 also have black and white corners and have orientations given to some of their sides; the angles are as indicated, where again $\theta = \pi/5$. The condition is that in constructing a tiling the colors of corners as well as lengths and orientations of sides must match.

Plane tilings by kites and darts can be transformed into plane tilings by rhombs, and vice versa. The transition from a kite and dart tiling to a rhomb tiling is illustrated in Fig. 14; the kites and darts are bisected, and the resulting triangles are merged into rhombs. The two tilings depicted in Fig. 14 are *mutually locally derivable*; that is, the tiles in either tiling can, through a process of decomposition into smaller tiles or regrouping with adjacent tiles, or a combination of both processes, form the tiles of the other. The concept of mutual local derivability links the tilings with one prototile set to those with another. Thus, characteristic properties of one prototile set translate into similar properties of the other set.

As for many other aperiodic prototile sets, the aperiodicity of the Penrose sets is based on two important transformations of tilings, namely *composition* and the corresponding inverse process of *decomposition*, which exhibit the existence of hierarchical structure. Figure 15 illustrates the composition process for a tiling by Penrose rhombs.

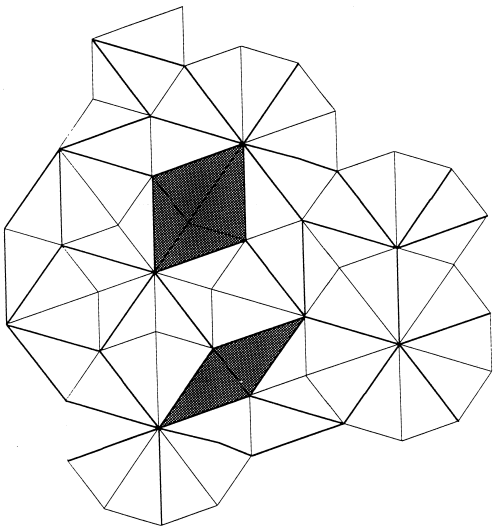

FIGURE 14 The transition from a Penrose kite and dart tiling to a Penrose rhomb tiling. The kites and darts of the original tiling are bisected, and the resulting triangles are merged into rhombs. [From Senechal, M. (1995). *Quasicrystals and Geometry*, Cambridge University Press. Cambridge.]

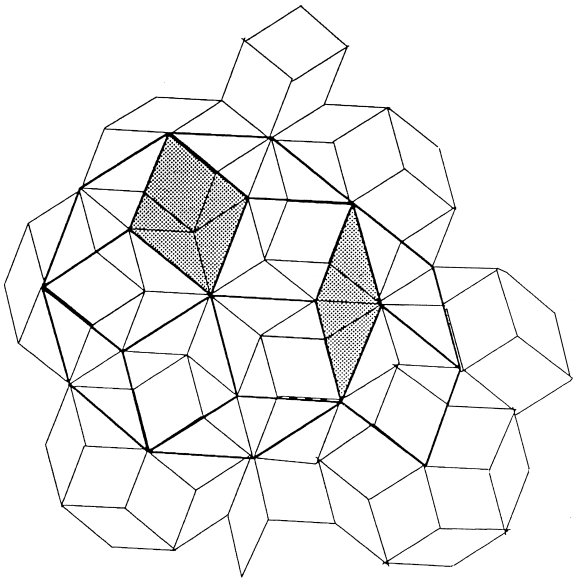

FIGURE 15 Composition for the Penrose rhombs. First, certain tiles of the original Penrose tiling are bisected to yield triangular tiles. Then, the triangular tiles and remaining rhombic tiles are regrouped with adjacent tiles to form the rhombic tiles of a new Penrose tiling of larger scale. [From Senechal, M. (1995). *Quasicrystals and Geometry*, Cambridge University Press. Cambridge.]

By composition we mean the process of taking unions of tiles (or pieces of tiles) to form larger tiles of basically the same shape as those of the original tiles, such that the decorations of the original tiles specify a matching condition equivalent to the original one. Decomposition is the basis for the process of *inflation* which, when iterated, can be used to generate arbitrarily large patches or even global tilings. Here inflation is the operation of, first, homothetically enlarging a given patch of tiles (in the case of the Penrose tiles, by some factor involving τ), and then decomposing it into tiles of the original size. Inflation and its inverse process, *deflation*, are characteristic features of many aperiodic sets and their tilings.

A tiling $\mathcal{T}$ in E^d is said to be *repetitive* if every bounded configuration of tiles appearing anywhere in $\mathcal{T}$ is repeated infinitely many times throughout $\mathcal{T}$; more precisely, for every bounded patch of $\mathcal{T}$ there exists an $r > 0$ such that every ball of radius r in E^d contains a congruent copy of the patch. Two tilings $\mathcal{T}_1$ and $\mathcal{T}_2$ are called *locally isomorphic* if for every bounded patch of $\mathcal{T}_1$ there exists a congruent copy of the patch in $\mathcal{T}_2$. The Penrose tilings of the plane are repetitive tilings, as are the nonperiodic tilings for many other aperiodic prototile sets. Furthermore, any two Penrose tilings with the same prototile set are locally isomorphic. So, for example, since there exist Penrose tilings of the plane with global (pentagonal) D_5-symmetry, there must be arbitrarily large finite patches with D_5-symmetry in any Penrose tiling with the same prototile set.

The remaining (but historically first) Penrose aperiodic set consists of six decorated prototiles and suitable matching rules.

C. The Projection Method

The projection method and its variants are important tools for the construction of nonperiodic tilings. These tilings are nondecorated.

In the *strip projection method*, the d-dimensional tilings are obtained as projection images of polyhedral surfaces that are embedded in a Euclidean "superspace" E^n. Let E be a d-dimensional linear subspace of E^n, and let $E^\perp$ be its orthogonal complement in E^n. Then, $\mathrm{E}^n = E \oplus E^\perp$. Let π and $\pi^\perp$ denote the orthogonal projections of E^n onto E or $E^\perp$, respectively. Recall that Z^n is the vertex set of the standard tessellation $\mathcal{C}$ of E^n by n-dimensional cubes, whose lower dimensional faces are also cubical. Let C denote the n-dimensional cube whose vertex set consists of all 0–1 vectors. A vector $t \in \mathrm{E}^n$ is said to be *regular* if the boundary of the *tube*,

$$E + C + t := \{x + c + t \mid x \in E,\ c \in C\}$$

does not have a point in common with Z^n; otherwise, z is *singular*. Note that the shape of the tube is determined by its cross-section with $E^\perp$, which is the projection image under $\pi^\perp$ of the cube $C + t$. If $d = n - 1$, the tube is a strip in E^n bounded by a pair of hyperplanes parallel to E.

Now, for every regular vector t, the d-dimensional faces of $\mathcal{C}$ that are fully contained in $E + C + t$ make up a d-dimensional polyhedral surface in E^n. This surface is tessellated by d-dimensional cubes and contains all i-dimensional faces of $\mathcal{C}$ contained in $E + C + t$, for $i = 0, \ldots, d$. When restricted to the surface, the projection π onto E is one-to-one and maps the cubical polyhedral complex on the surface onto a tiling $\mathcal{T}_t$ of E. Figure 16 illustrates the case $n = 2$ and $d = 1$, which yields tilings of the real line by projecting the staircase onto the line bounding the strip from below. The tiles of $\mathcal{T}_t$ are the projection images under π of the d-dimensional cubes on the surface; that is, the tiles are d-dimensional parallelopipeds. If $E \cap \mathrm{Z}^n = \{0\}$ (that is, if E is "totally irrational"), then the resulting tilings $\mathcal{T}_t$ with t regular are nonperiodic. The structure of these tilings depends on the parameter vector t (and the subspace E, of course), but any two such tilings (with the same E) are locally isomorphic. Note that the tilings are nondecorated.

The same tilings can also be obtained by the *canonical cut method* as follows. Let $e_1, \ldots, e_n$ denote the canonical basis of E^n, and let π and $\pi^\perp$ be as above. In applications, any d of the vectors $\pi(e_i)$ in E (or equivalently, any $n - d$ of the vectors $\pi^\perp(e_i)$ in $E^\perp$), with $i = 1, \ldots, n$, are linearly independent, and so we assume this from now on.

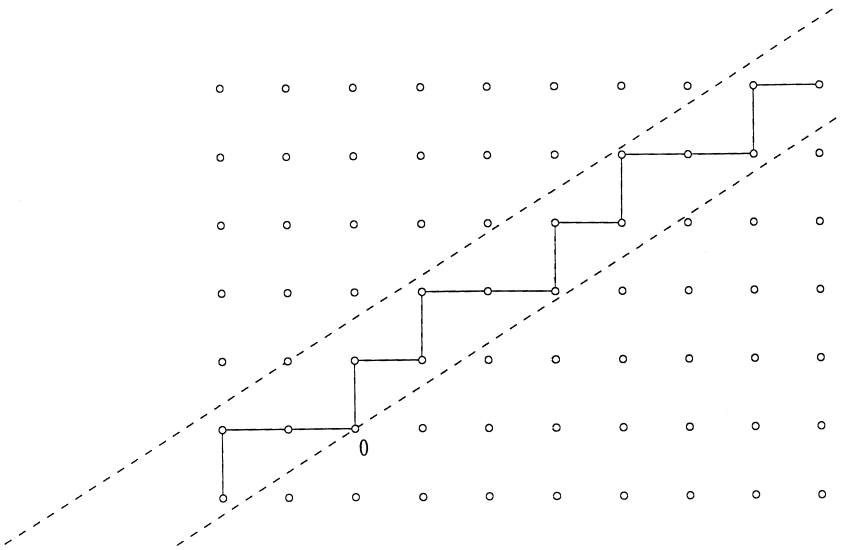

FIGURE 16 Illustration of the strip projection method for $n=2$ and $d=1$. The projection of the staircase onto the (totally irrational) line bounding the strip from below yields a nonperiodic tiling on the line by intervals of two sizes. These intervals are the projections of the horizontal or vertical line segments that are contained in the strip and connect two adjacent grid points. [From Senechal, M. (1995). *Quasicrystals and Geometry*, Cambridge University Press. Cambridge.]

We first construct a periodic tiling of E^n by prismatic tiles. For a d-element subset I of $\{1,\ldots,n\}$, let B_I and $B_I^\perp$, respectively, denote the parallelopipeds in E or $E^\perp$ that are generated by the sets of vectors $\{\pi(e_i) \mid i \in I\}$ and $\{-\pi^\perp(e_i) \mid i \notin I\}$ (the minus sign is significant). The convex n-polytope $P_I := B_I \oplus B_I^\perp$ is a "prism" with bases B_I in E and $B_I^\perp$ in $E^\perp$. Then the prisms $P_I + z$, with $z \in \mathrm{Z}^n$ and I a d-element subset of $\{1,\ldots,n\}$, are the tiles in a periodic tiling $\mathcal{O}$ of E^n called the *oblique tiling*.

The nonperiodic tilings now are obtained as sections of $\mathcal{O}$ with certain subspaces $E+t$. More precisely, if t is regular as before, then the intersection of the affine d-dimensional subspace $E+t$ with a tile P_I+z of $\mathcal{O}$ either is empty, or of the form B_I+y+z with y a relative interior point of $B_I^\perp$. Thus, the intersections of $E+t$ with the tiles of $\mathcal{O}$ yield the tiles in a tiling of $E+t$ by d-dimensional parallelopipeds. Then, via projection by π onto E, this gives a tiling of E by parallelopipeds. This is the same tiling $\mathcal{T}_t$ as before. Figure 17 illustrates the case $n=2$ and $d=1$; now $\mathcal{O}$ is a plane tiling with two kinds of square tiles (small and large), and nonperiodic tilings on the line are obtained by cutting $\mathcal{O}$ by a (regular) translate of E.

Further properties of these tilings generally depend on the particular choice of subspace E. For example, to obtain the *generalized Penrose tilings* of the plane, take $n=5$ and consider the group G of isometries of E^5 that permutes the coordinates like a cyclic group of order 5. Then G has three invariant subspaces, namely the line spanned by $e_1+\cdots+e_5$, and two planes, including the plane E spanned by the vectors:

$$x_1 = (4, \sqrt{5}-1, -\sqrt{5}-1, -\sqrt{5}-1, \sqrt{5}-1)$$
$$x_2 = (\sqrt{5}-1, 4, \sqrt{5}-1, -\sqrt{5}-1, -\sqrt{5}-1)$$

The resulting nondecorated plane tilings $\mathcal{T}_t$ in E have only two prototiles, namely the nondecorated Penrose rhombs. If the (regular) parameter vector t is contained in the invariant plane E' of G distinct from E (E' is a subspace of $E^\perp$), then we obtain an ordinary nondecorated Penrose tiling by rhombs (that is, a tiling obtained from a decorated Penrose tiling by rhombs by removing the decorations). The tilings $\mathcal{T}_t$ with $t \in E'$ have the property that every finite patch in any ordinary nondecorated Penrose tiling by rhombs already occurs in one of them. It is known that

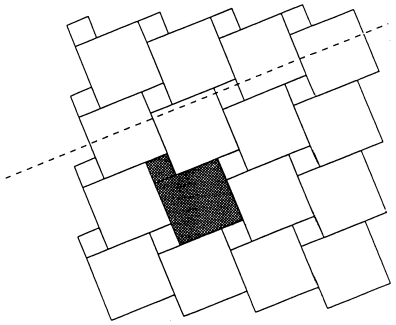

FIGURE 17 The oblique tiling $\mathcal{O}$ for $n=2$ and $d=1$. There are two kinds of square tiles in $\mathcal{O}$. A nonperiodic tiling on the line by two kinds of intervals is obtained by cutting $\mathcal{O}$ with the dotted line. [From Senechal, M. (1995). *Quasicrystals and Geometry*, Cambridge University Press. Cambridge.]

every ordinary nondecorated Penrose tiling by rhombs can be decorated by arrows in exactly one way to become an ordinary decorated Penrose tiling by rhombs.

GLOSSARY

Closure $\bar{A} = A \cup A'$ is called the closure of A, where A' is the set of all limit points of A.

Compact A topological space X is called compact if in each open covering of X there is a finite subcollection that covers X.

Connected A topological space is said to be connected if it cannot be written as the union of two disjoint nonempty open sets.

Continuous map A map f of a topological space X into a topological space Y is called continuous if for each open set Q of Y, $f^{-1}(Q) = \{x \in X : f(x) \in Q\}$ is open in X.

Covering A family $\{P_\alpha\}$ of sets is said to be a covering of $A \subset X$ if $A \subset \bigcup_\alpha A_\alpha$. If all P_α's are open, it is called an open covering.

Homeomorphism A continuous, open, and bijective map of a topological space X into a topological space Y is called a homeomorphism.

Limit point An element a is said to be a limit or accumulation point of a set A if each open set containing a contains at least one point of A other than a.

Metric d is said to define a metric for a set X if for all pairs (x, y), $x, y \in X$, $d(x, y)$ is a real number satisfying the following:

(i) $d(x, y) \geq 0$.
(ii) $d(x, y) = 0$, if $x = y$.
(iii) $d(x, y) = 0$ implies $x = y$.
(iv) $d(x, y) = d(y, x)$.
(v) $d(x, y) \leq d(x, z) + d(z, y)$ (triangle inequality).

Neighborhood A set U is a neighborhood of a point

a if there exists an open set P such that $a \in P \subset U$.

Open set Each member of a topology $\mathcal{T}$ on a set X is called an open set.

Set A collection of "distinguished" objects is called a set.

Topological group A group G endowed with a topology is called a topological group if the map $(x, y) \to xy^{-1}$ of $G \times G$ into G is continuous.

GENERAL TOPOLOGY is a branch of mathematics that deals with the study of topological spaces and maps, especially continuous maps. This subject is regarded as a natural extension of part of classical analysis (a major field of mathematics) insofar as the study of continuous maps is concerned. Classical analysis deals primarily with functions on the real line $\mathbb{R}$ or, more generally, n-dimensional Euclidean spaces $\mathbb{R}^n$, in which the notions of limit and continuity are very basic. With the help of topology, these concepts can be studied more generally in topological spaces. In short, the genesis of the subject general topology is rooted in the fundamental properties of $\mathbb{R}$ or $\mathbb{R}^n$ and functions thereon.

The reader is cautioned not to confuse "topology" with "topography" and "map" with a "map" of a country. For an explanation of basic set-theoretic concepts used herein, see Table I.

TABLE I Symbols and Set-Theoretic Notations

Set	A collection of distinguished objects: capital letters denote sets in the text
$\varnothing$	Null or empty set
$a \in A$	a is an element of the set A
$A \cup B$	Union of A and B
$A \cap B$	Intersection of A and B
$A \cap B = \varnothing$	A, B are disjoint
A^c	Complement of A
$A \backslash B$	The set of elements in A that are not in B
$\bigcup_{i=1}^{n} A_i$	(Finite) union of sets $A_1, A_2, \ldots, A_n$
$\bigcap_{i=1}^{n} A_i$	(Finite) intersection of sets $A_1, \ldots, A_n$
$\bigcup_{i=1}^{\infty} A_i$	Countable union of sets $\{A_1, A_2, \ldots\}$
$\bigcap_{i=1}^{\infty} A_i$	Countable intersection
$\bigcup_{\alpha\in\Gamma} A_\alpha$ or $\bigcup_\alpha A_\alpha$	(Arbitrary) union of a family $\{A_\alpha\}_{\alpha\in\Gamma}$ of sets
$\bigcap_{\alpha\in\Gamma} A_\alpha$ or $\bigcap_\alpha A_\alpha$	Arbitrary intersection
$f : X \to Y$	f is a map of X into Y
iff (or $\Leftrightarrow$)	If and only if (or implies and implied by)
$\mathbb{R}$ (or $\mathbb{C}$)	The set of all real (or complex) numbers
$\sum_{i=1}^{n} a_i$	$a_1 + a_2 + \cdots + a_n$
De Morgan's laws	$(\bigcup_\alpha A_\alpha)^c = \bigcap_\alpha A_\alpha^c$ and $(\bigcap_\alpha A_\alpha)^c = \bigcup_\alpha A_\alpha^c$

I. TOPOLOGY AND TOPOLOGICAL SPACES

A. Basic Notions of Topology and Examples

Let X be a set. A collection $\mathcal{T} = \{U_\alpha\}$ of subsets of X is said to define or is itself called a *topology* if the following axioms hold:

(i) $X, \varnothing$ belong to $\mathcal{T}$.
(ii) Finite intersections of elements in $\mathcal{T}$ are also in $\mathcal{T}$.
(iii) Arbitrary unions of elements in $\mathcal{T}$ are also in $\mathcal{T}$.

A set X endowed with a topology $\mathcal{T} = \{U_\alpha\}$ is called a *topological space* (TS) and is often denoted $(X, \mathcal{T})$. Each member of $\mathcal{T}$ is called an *open* set or $\mathcal{T}$*-open* (if the topology is to be emphasized). Thus, by definition the whole set X and the null set $\varnothing$ are open.

If the topology $\mathcal{T}$ consists of exactly two open sets $X, \varnothing$, then the topology is termed *indiscrete*. If, however, $\mathcal{T}$ consists of all subsets of X, it is called the *discrete* topology.

Let $\mathcal{T}, \mathcal{T}'$ be topologies on a set X. If each $\mathcal{T}'$-open set is also $\mathcal{T}$-open, then $\mathcal{T}$ is said to be *finer* than $\mathcal{T}'$ or, equivalently, $\mathcal{T}'$ is *coarser* than $\mathcal{T}$. Thus, the discrete topology is finer than the indiscrete one. Actually, the discrete topology is the *finest*, whereas the indiscrete one is the weakest or *coarsest* of all topologies on X.

A set C of a topological space $(X, \mathcal{T})$ is called *closed* or $\mathcal{T}$*-closed* (when the topology is to be emphasized) if the complement $C^c = X \backslash C$ of C is open. By De Morgan's laws (see Table I), arbitrary intersections and finite unions of closed sets are closed, since by definition finite intersections and arbitrary unions of open sets are open.

A subset P of a topological space $(X, \mathcal{T})$ is called a *neighborhood of a point* $x \in X$ if there is an open set U such that $x \in U \subset P$. If P itself is an open or a closed set, it is called an *open* or *closed neighborhood* of x. The collection $\mathcal{N}_x$ of all neighborhoods of x is called the *neighborhood system* at x. The following properties hold: $x \in U$ for all U in $\mathcal{N}_x$; for all U, V in $\mathcal{N}_x$, $U \cap V \in \mathcal{N}_x$; if W is any subset of X such that for some $U \in \mathcal{N}_x$, $U \subset W$, then $W \in \mathcal{N}_x$; and each U in $\mathcal{N}_x$ contains an open neighborhood of x.

Let A be a subset of a topological space $(X, \mathcal{T})$. The union of all open sets contained in A is called the *interior* of A and is denoted A^0. Clearly, $A^0 \subset A \cdot A = A^0$ iff (if and only if) A is open.

A point $x \in X$ is called a *limit* or *accumulation point* of a set $A \subset X$ if each neighborhood of x contains points of A other than x. The set of all limit points of a set A is usually denoted A' and is called the *derived set* of A. The set $\bar{A} = A \cup A'$ is called the *closure* of A. Closed sets can be characterized by closures as follows. A set A is closed iff

$A = \bar{A}$. In particular, each closed set contains all its limit points. In general, however, $A \subset \bar{A}$.

Properties of interior and closure operations are complementary and comparable: $A^0 \subset A$ (respectively, $A \subset \bar{A}$); $A^{00} = A^0$ (respectively, $\bar{\bar{A}} = \bar{A}$); and $A^0 \cap B^0 = (A \cap B)^0$ (respectively, $\bar{A} \cup \bar{B} = \overline{A \cup B}$).

The set $\partial A = \bar{A} \cap \overline{A^c}$ is called the *boundary* of A. It immediately follows that A is open (respectively, closed) iff $A \cap \partial A = \varnothing$ (respectively, $\partial A \subset A$).

A subset A of a topological space $(X, \mathcal{T})$ is said to be *dense* in X if $\bar{A} = X$. Since X is always closed, $\bar{X} = X$ implies that the whole space X is always a dense subset of itself. However, if the subset A is genuinely smaller than X, the topological space assumes some special features. A noteworthy case is the following. If A is a countable dense subset of X, then $(X, \mathcal{T})$ is called a *separable* topological space.

In practice, the collection of all open sets in a topological space is very huge. To cut it down to a smaller size without changing the topology, the notion of a base of a topology is useful. A subcollection $\mathcal{B}$ of open sets in a topological space $(X, \mathcal{T})$ is said to form a *base* of the topology if each open set of X is the union of sets from $\mathcal{B}$. To cut the size of $\mathcal{B}$ down even farther without changing the topology, one introduces the following concept. A subcollection $\mathcal{B}'$ of open sets in a topological space $(X, \mathcal{T})$ is said to form a *subbase* of the topology if the collection of all finite intersections of elements form $\mathcal{B}'$ forms a base of the topology. One notes the following facts. A collection $\mathcal{B}$ of open sets forms a base of the topology $\mathcal{T}$ iff for each $x \in X$ and each neighborhood U of x there is an element B in $\mathcal{B}$ such that $x \in B \subset U$. Furthermore, any nonempty family $\mathcal{B}'$ of subsets of a given set X such that $\mathcal{B}'$ covers X defines a unique topology on X or is a subbase of a unique topology.

If a topology $\mathcal{T}$ on X has a countable base, then $(X, \mathcal{T})$ is said to be a *second countable* (SC) space, but if each $x \in X$ has a *countable base* $\{U_n(x)\}$ of *neighborhoods*, that is, each neighborhood of x contains some $U_n(x)$, then the topological space is said to be a *first countable* (FC) space. It is clear that each second countable space is first countable, but the converse is not true. Moreover, each second countable space is separable. Again, the converse is not true. However, for a special class of topological spaces called metric space, which is introduced in Section V.A, the converse does hold. To ascertain the existence of limit points of certain subsets in a topological space, one has the following. Each uncountable subset of a second countable space has a limit point.

To make the above-mentioned abstract notions more concrete, we consider some examples. In the set $\mathbb{R}$ of all real numbers, for $a, b \in \mathbb{R}$, the subsets $(a, b) = \{x \in \mathbb{R} : a < x < b\}$ and $[a, b] = \{x \in \mathbb{R} : a \le x \le b\}$ are called open and closed intervals, respectively. A subset U of $\mathbb{R}$ is called open if for each $x \in U$ there is an open interval (a, b) such that $x \in (a, b) \subset U$. The collection of all open sets so designated defines a topology on $\mathbb{R}$, sometimes called the *natural* or *Euclidean topology* of $\mathbb{R}$. Clearly, each open (respectively, closed) interval of $\mathbb{R}$ is an open (respectively, closed) set. Thus, the collection of all open intervals forms a base of the natural topology of $\mathbb{R}$. Furthermore, it is easy to see that the collection of all half-open lines, $(a, \infty) = \{x \in \mathbb{R} : a < x\}$ and $(-\infty, b) = \{x \in \mathbb{R} : < b\}$, forms a subbase of the natural topology. If a, b run over rational numbers of $\mathbb{R}$, the collection $\{(a, b)\}$ of all these open intervals being a countable base of the natural topology of $\mathbb{R}$ makes $\mathbb{R}$ a second countable space. Since the set $\mathbb{Q}$ of rational numbers is a countable dense subset of $\mathbb{R}$, $\mathbb{R}$ is separable.

Apart from the natural topology of $\mathbb{R}$, as mentioned above, there are many other topologies, among which are the discrete and indiscrete. In the discrete case, each subset of $\mathbb{R}$ is open, in particular, each singleton (consisting of a single point) is open. Certainly, however, no singleton is open in the natural topology of $\mathbb{R}$. Thus, it follows that the discrete topology of $\mathbb{R}$ is strictly finer than the natural topology. $\mathbb{R}$ with the discrete topology is not separable and hence not second countable. Since for each x, $\{x\}$ forms a countable base of the neighborhood system at x, $\mathbb{R}$ with the discrete topology is first countable, but $\mathbb{R}$ with the indiscrete topology is trivial, because each singleton $\{x\}$ $(x \in \mathbb{R})$ is dense in $\mathbb{R}$.

Another important example of a useful topological space is the *n-dimensional* Euclidean real (or complex) space $\mathbb{R}^n$ (or $\mathbb{C}^n$) which is the set of all *n-tuples* $(x_1, x_2, \ldots, x_n)$ in which all $x_1, \ldots, x_n$ are real (respectively, complex) numbers. If $n = 1$, then $\mathbb{R}^1$ coincides with $\mathbb{R}$; for $n = 2$, $\mathbb{R}^2$ is called the *Euclidean plane*; for $n = 3$, $\mathbb{R}^3$ is called the *3-space*; and so on. The subsets defined by

$$B_\varepsilon(a_1, \ldots, a_n) = \{(x_1, \ldots, x_n) \in \mathbb{R}^n : (x_1 - a_1)^2 + \cdots + (x_n - a_n)^2 < \varepsilon^2\}$$

and

$$B'_\varepsilon(a_1, \ldots, a_n) = \{(x_1, \ldots, x_n) \in \mathbb{R}^n : (x_1 - a_1)^2 + \cdots + (x_n - a_n)^2 \le \varepsilon^2\}$$

are called *open* and *closed disks* of $\mathbb{R}^n$, respectively. A subset P of $\mathbb{R}^n$ is said to be open if for each $(x_1, \ldots, x_n) \in P$ there is a real number $\varepsilon > 0$ such that $(x_1, \ldots, x_n) \in B_\varepsilon(x_1, \ldots, x_n) \subset P$. Thus, the collection of all open disks forms the base of a topology called the *Euclidean topology* of $\mathbb{R}^n$. In this topology, each open (respectively, closed) disk is an open (respectively, closed) set. Like $\mathbb{R}$, $\mathbb{R}^n$ is second countable and hence

separable because the set of n-tuples $(x_1, \ldots, x_n)$ in which all $x_1, \ldots, x_n$ are rational numbers is a countable dense subset of $\mathbb{R}^n$. Here, too, the discrete topology is strictly finer than the Euclidean topology.

Another important property of $\mathbb{R}^n$ $(n \geq 1)$ that lends itself to abstraction is the following. A topological space $(X, \mathcal{T})$ is called *connected* if X cannot be written as the union of two disjoint, nonempty open sets of X. In other words, if $X = P \cup Q$ for some open sets P, Q such that $P \cap Q = \emptyset$, then one of P, Q must be a null set. $\mathbb{R}$ and $\mathbb{R}^n$ with their natural topology are connected, but not so in the discrete topology. $(X, \mathcal{T})$ is called *locally connected* if each neighborhood of each point of X contains a connected open neighborhood. Indeed, $\mathbb{R}^n$ $(n \geq 1)$ is locally connected.

A subset A of a topological space $(X, \mathcal{T})$ is called *connected* if it is so in the induced topology (see Section III.A). The closure of a connected set is connected. Moreover, an arbitrary union of connected subsets is connected provided that no two members of the collection are disjoint. A connected subset that is not properly contained in any other connected subset is called a *component*. Clearly, if a topological space $(X, \mathcal{T})$ is connected, it is its only component. Each component of the real numbers with the discrete topology consists of a singleton, whereas $\mathbb{R}$ with the natural topology is its only component.

B. Methods of Defining Topology

The method of defining topology by means of open sets is not the only one. There are several methods used in the mathematical literature. Four of them are given below.

1. Kuratowski Axioms

One can define topology by closure operations. This method was introduced by K. Kuratowski. Let X be a set and let $\mathcal{P}(X)$ denote the collection of all subsets of X (often called the *power set* of X). Let ϕ be an operation that to each subset A of X assigns a subset of X. In other words ϕ maps $\mathcal{P}(X)$ into itself. Suppose that ϕ satisfies the so-called Kuratowski axioms: $\phi(\emptyset) = \emptyset$; $A \subset \phi(A)$; $\phi(\phi(A)) = \phi(A)$; $\phi(A \cup B) = \phi(A) \cup \phi(B)$ for all A, B in $\mathcal{P}(X)$. Then there exists a unique topology $\mathcal{T}$ on X such that $\phi(A)$ becomes the closure $\bar{A}$ of A with respect to the topology $\mathcal{T}$. Specifically, a set A is called closed with respect to $\mathcal{T}$ if $\phi(A) = A$. Hence, the complement A^c of a closed set A will, as usual, be open, and the topology $\mathcal{T}$ is thus determined.

The reader will have noticed that Kuratowski axioms are satisfied by the closure operation defined in a topological space as shown in the preceding section.

2. Neighborhood Systems

The second method of defining topology is via neighborhood systems. Let X be a set. Suppose that for each $x \in X$ there is a collection $\mathcal{U}_x$ of subsets of X satisfying the following axioms. For each $x \in X$ and each U in $\mathcal{U}_x$, $x \in U$; if a subset W of X contains some $U \in \mathcal{U}_x$, then $W \in \mathcal{U}_x$; finite intersections of elements from $\mathcal{U}_x$ are also in $\mathcal{U}_x$; and for each U in $\mathcal{U}_x$ there is a V in $\mathcal{U}_x$ such that $V \subset U$ and $U \in \mathcal{U}_y$ for all $y \in V$. Then there exists a unique topology $\mathcal{T}$ on X such that for each $x \in X$, $\mathcal{U}_x$ becomes a neighborhood system at x with respect to the topology $\mathcal{T}$.

3. Nets

Another method of defining topology is by means of nets. The notion of net generalizes the concept of sequence, which is so useful and popular in the case of real numbers. To define *net* we first need some other notions.

Let Γ denote a nonempty set. Γ is called a partially ordered set if there is a binary relation ">" (or "<") defined for elements of Γ such that whenever $\alpha > \beta$ and $\beta > \gamma$ for $\alpha, \beta, \gamma \in \Gamma$, we have $\alpha > \gamma$. (Clearly, the set of all positive integers is a partially ordered set.) A partially ordered set Γ with the binary relation $>$ is called *directed* if for $\alpha, \beta \in \Gamma$ there is a $\gamma \in \Gamma$ such that $\gamma > \alpha$, $\gamma > \beta$. Γ is called linearly ordered if for all $\alpha, \beta \in \Gamma$ either $\alpha > \beta$ or $\beta > \alpha$ and $\alpha > \beta, \beta > \alpha \Rightarrow \alpha = \beta$. An element $\gamma \in \Gamma$ is called an *upper bound* of a subset $\Gamma' \subset \Gamma$ if $\gamma \geq \alpha$ for all $\alpha \in \Gamma'$. γ is called the *least upper bound* if γ is the smallest upper bound of Γ'.

A map ϕ of a directed partially ordered set Γ into a set X is called a *net*. If we write $\phi(\alpha) = x_\alpha \in X$ for all $\alpha \in \Gamma$, then often a net is denoted by its range $\{x_\alpha : \alpha \in \Gamma\}$ in X. In short, one denotes a net $\{x_\alpha\}$ instead of $\{x_\alpha : \alpha \in \Gamma\}$. Clearly, if we replace Γ by $\mathbb{N}$ (positive integers), then the net $\{x_n : n \geq 1\} = \{x_n\}$ is a sequence in X. Thus, a sequence is a particular case of a net.

A net $\{x_\alpha\}$ is called a *constant net* if $x_\alpha = x$ for all $\alpha \in \Gamma$. If $\{x_n\}$ is a sequence and $n_1 < n_2 < \cdots$ are infinitely many positive integers, then $\{x_{n_k}\} = \{x_{n_1}, x_{n_2}, \ldots\}$ is called a *subsequence* of $\{x_n\}$.

A net $\{x_\alpha\}$ in a topological space $(X, \mathcal{T})$ is said to *converge* to a point $x \in X$ if for each neighborhood U of x there exists $\alpha_0 \in \Gamma$ such that for $\alpha \geq \alpha_0$ $(\alpha \in \Gamma)$, $x_\alpha \in U$. Now the closure of a set A in X can be characterized by means of nets as follows: $x \in \bar{A}$ iff there is a net $\{x_\alpha\}$ in A converging to x. Clearly, a constant net is always convergent. Moreover, a subsequence of a convergent sequence is also convergent. Without going into finer details, let us say that nets can be used to define limit points and then closures of subsets leading to the definition of topology. For details the

interested reader is referred to any standard book on topology listed in the Bibliography.

4. Filters

Another method of defining a topology on a set is via filters. The notion of filters was introduced and popularized by French mathematicians, especially those belonging to the French group Bourbaki, named after a fictitious mathematician, Nicholas Bourbaki.

Let X be a nonempty set. A collection $\mathcal{F} = \{F_\alpha\}$ of subsets of X is called a *filter* if the following axioms hold. Each F_α is nonempty; for F_α, F_β in $\mathcal{F}$, $F_\alpha \cap F_\beta \in \mathcal{F}$; and if H is any subset of X such that $F_\alpha \subset H$ for some $F_\alpha \in \mathcal{F}$, then $H \in \mathcal{F}$. A collection $\mathcal{F} = \{F_\alpha\}$ of subsets F_α in X is called a *filter base* if each F_α is nonempty and if, for F_α, F_β in $\mathcal{F}$, there is F_γ in $\mathcal{F}$ such that $F_\gamma \subset F_\alpha \cap F_\beta$. Clearly, a filter base generates a filter consisting of all subsets of X, each containing a member of the filter base.

A neighborhood system $\mathcal{N}_x$ of x in a topological space $(X, \mathcal{T})$ is a filter called the *neighborhood filter*.

A filter $\mathcal{F} = \{F_\alpha\}$ in a topological space $(X, \mathcal{T})$ is said to *converge to* $x \in X$ if for each neighborhood U of x there exists $F_\alpha \in \mathcal{F}$ such that $F_\alpha \subset U$. An element $y \in X$ is called a *limit point* of a filter $\mathcal{F} = \{F_\alpha\}$ if $y \in \bar{F}_\alpha$ for all F_α in $\mathcal{F}$.

Theories of filters and nets are equivalent. Specifically, if $\{x_\alpha : \alpha \in \Gamma\}$ is a net, the collection of all $F_\alpha = \{x_\beta : \beta > \alpha, \beta \in \Gamma\}$ is a filter base. Conversely, given a filter $\mathcal{F} = \{F_\alpha\}$, it is possible to construct a net $\{x_\alpha\}$ by considering the set Γ of all pairs (x_α, F_α) in which $x_\alpha \in F_\alpha$, and by defining $(x_\alpha, F_\alpha) \leq (x_\beta, F_\beta) \Leftrightarrow F_\beta \subset F_\alpha$, we see that $\leq$ defines a partial ordering and Γ becomes a directed set because $\mathcal{F}$ is a filter. Now if we put $\phi(x_\alpha, F_\alpha) = x_\alpha$, we obtain a net $\{x_\alpha\}$. Details can be found in standard texts on topology. Thus, filters can be used to define a topology as nets do.

A filter can be contained in a *maximal* filter (one that is not a proper subcollection of a filter). A maximal filter is called an *ultrafilter*. (The existence of maximal filters is guaranteed by Zorn's lemma: Each partially ordered set in which each linearly ordered subset has a least upper bound has a maximal element.) A filter $\mathcal{F}$ in X is an ultrafilter iff for each subset A of X, one of the two sets A, A^c is in $\mathcal{F}$. Ultrafilters are useful for the study of extensions of topological spaces as well as compactness among others. We shall see one application of ultrafilters in Section V.B.

II. MAPS AND FUNCTIONS

Given two sets X and Y, if to each element x of X there corresponds a unique element y of Y, then this correspondence is called a *map* and often written as $f : X \to Y$, meaning that $y = f(x)$ for $x \in X$. X is called the *domain* of the map f, and $f(X) = \{y \in Y : y = f(x), x \in X\}$ the *range* of f. If $f(x) = f(x')$ implies that $x = x'$ for all $x, x' \in X$, then f is called *one to one* (or *injective*). If for each $y \in Y$ there is $x \in X$ such that $y = f(x)$, then f is called *onto* (or *surjective*). A map that is both injective and surjective is called *bijective*.

In particular cases when either $Y = \mathbb{R}$ (real numbers) or $X = Y = \mathbb{R}$, a map $f : X \to Y$ is often called a *real-valued function* or simply *function*.

The notion of map or function is very basic to understanding the physical phenomena of the universe, since each physical or other kind of event for a mathematical study must be expressed as a function. Indeed, the properties of real-valued functions studied in classical analysis are used in almost all scientific studies. Here we look at some special properties of maps between topological spaces.

A. Continuous, Open Maps and Homeomorphisms

Let $(X, \mathcal{T})$ and $(Y, \mathcal{T}')$ be two topological spaces. A map $f : X \to Y$ is said to be *continuous at a point* $x_0 \in X$ if for each neighborhood V of $f(x_0)$ in Y there exists a neighborhood U of x_0 in X such that $f(x) \in V$ for all $x \in U$. If f is continuous at each point of X, it is called *continuous*.

Indeed, each continuous map is continuous at each point of X by definition, but there are functions that are continuous at one point but not at another. For example, $f(x) = 1$ if $x \geq 0$ and $= 0$ if $x < 0$ is a real-valued function on $\mathbb{R}$ that is continuous at all $x \neq 0$ but not continuous at $x = 0$.

Since the continuity of a map depends on the topologies of the topological spaces concerned and since there are several methods of defining topologies, it is natural that the continuity of a map can be expressed in more than one way. Specifically, we have the following equivalent statements:

(i) f is continuous (see the above definition).
(ii) For each open set Q of Y, $f^{-1}(Q) = \{x \in X : f(x) \in Q\}$ is open in X.
(iii) For each net $\{x_\alpha\}$ in X converging to $x \in X$, $\{f(x_\alpha)\}$ converges to $f(x)$ in Y.
(iv) For each filter $\mathcal{F} = \{F_\alpha\}$ converging to $x \in X$, $\{f(F_\alpha)\}$ converges to $f(x) \in Y$.
(v) For each subset A of X, $f(\bar{A}) \subset \overline{f(A)}$.
(vi) For each subset B of Y, $f^{-1}(\overline{B}) \subset f^{-1}(\bar{B})$.

The continuity property is transitive in the following sense. If $f : X \to Y$ and $g : Y \to Z$ are continuous

maps, respectively, of topological spaces from $(X, \mathcal{T})$ into $(Y, \mathcal{T}')$ and from $(Y, \mathcal{T}')$ into $(Z, \mathcal{T}'')$, then the *composition map* $g \circ f : X \to Z$ defined by $g \circ f(x) = g(f(x))$, $x \in X$, is also continuous.

Although the continuity property of maps between topological spaces is the most popular and useful, there are other notions that complement or augment continuity.

A map f of a topological space $(X, \mathcal{T})$ into another topological space $(Y, \mathcal{T}')$ is called *open* if for each open set P of X, $f(P) = \{y = f(x) : x \in P\}$ is open in Y. It follows that f is open iff $[f(A)]^0 \subset f(A^0)$ for all subsets A of X. (Note that A^0 denotes the interior of A defined earlier.) A continuous map need not be open (e.g., $i : (\mathbb{R}, \mathcal{D}) \to (\mathbb{R}, \mathcal{T})$ in which $\mathcal{D}$ is the discrete topology and $\mathcal{T}$ the natural topology), or vice versa.

Similarly a map $f : (X, \mathcal{T}) \to (Y, \mathcal{T}')$ is called *closed* if for each closed set C of X, $f(C)$ is a closed set in Y. Here, too, we have a characterization: f is closed iff for each subset A of X, $\overline{f(A)} \subset f(\bar{A})$. Again, a continuous map need not be closed, nor is a closed map necessarily continuous.

A continuous, open, and bijective map of a topological space $(X, \mathcal{T})$ into another topological space $(Y, \mathcal{T}')$ is called a *homeomorphism*. If $f : (X, \mathcal{T}) \to (Y, \mathcal{T}')$ is a homeomorphism, then $(X, \mathcal{T})$ is said to be *homeomorphic* to $(Y, \mathcal{T}')$. In this case, there is no topological difference between the spaces $(X, \mathcal{T})$ and $(Y, \mathcal{T}')$, and hence they are sometimes called *topologically equivalent*.

It is one of the most important aspects of topological studies to discover conditions for homeomorphisms. For example, a simple result is that a bijective map between two discrete spaces is a homeomorphism. We present further examples of this kind in Section V.B.

Continuity can be used to define topology, thus adding one more method to those described earlier. Let X be a set, $(Y, \mathcal{T}')$ a topological space, and $f : X \to Y$ a map. We can endow X with a topology with respect to which f becomes continuous. Consider the collection $\mathcal{T} = \{f^{-1}(P) : P \in \mathcal{T}'\}$ of subsets of X in which $f^{-1}(P) = \{x \in X : f(x) \in P\}$ for an open set P in Y. It is routine to verify that this collection defines a topology $\mathcal{T}$ on X and f becomes continuous.

If $\{f_\alpha\}_{\alpha \in \Gamma}$ is a family of maps from a set X into a topological space $(X, \mathcal{T}')$, then the collection $\mathcal{T} = \{f_\alpha^{-1}(P) : P \in \mathcal{T}', \alpha \in \Gamma\}$ defines a topology $\mathcal{T}$ on X with respect to which each f_α becomes continuous.

B. Generalizations of Continuous Maps

If one cannot have the most desirable basic property of continuity of a map between topological spaces, one studies weaker notions to acquire more information about the maps. For this reason, a number of concepts weaker than continuity have been introduced and studied in the mathematical literature. Some of these are given here.

1. Almost Continuity

A map $f : (X, \mathcal{T}) \to (Y, \mathcal{T}')$ is said to be almost continuous at $x_0 \in X$ if for each neighborhood V of $f(x_0)$, in Y, $\overline{f^{-1}(V)}$ is a neighborhood of x_0 in X, f is called almost continuous if it is so at each point of X. (Elsewhere in the mathematical literature, what I have called an almost-continuous map is also called nearly continuous.)

Comparing the notion of almost continuity with that of continuity, we discover easily that each continuous map is almost continuous. The converse is not true, however, [e.g., $f : \mathbb{R} \to \mathbb{R}$ defined by $f(x) = 1$ or 0 according to whether x is a rational or irrational number.]

2. Closed Graphs

Let $(X, \mathcal{T}), (Y, \mathcal{T}')$ be two topological spaces. We put $X \times Y = \{(x, y) : x \in X, y \in Y\}$, which is the collection of all pairs (x, y) with first coordinate x and second coordinate y. $X \times Y$ is called the *Cartesian product* of X and Y. We endow $X \times Y$ with a topology $\mathcal{P}$, which has for a base the collection $\{U \times V\}$, in which U comes from $\mathcal{T}$ and V from $\mathcal{T}'$. The topology so defined is called the *product topology* on $X \times Y$ (see Section III.B).

If $f : X \to Y$ is a map, the subset $\{(x, y) : y = f(x), x \in X\}$ of $X \times Y$ is called the *graph of* f and is sometimes denoted G_f. If G_f is a closed subset of $X \times Y$ when the Cartesian product is endowed with the product topology, then f is said to have a *closed graph*.

Each continuous function $f : \mathbb{R} \to \mathbb{R}$ has a closed graph. However, the converse is not true [e.g., $f(x) = 1/x$ $(x \neq 0)$ and $= 0$ $(x = 0)$ has a closed graph but it is not continuous]. On the other hand, the identity map of any indiscrete space onto itself is continuous but does not have a closed graph. Thus, in general, the closed-graph property is not an exact generalization of continuity. It is true, however, if the continuous map is from a topological space into a Hausdorff space, which is introduced in Section IV.

Any result in which the closed-graph property of a map implies its continuity is called a closed-graph theorem.

3. Upper (or Lower) Semicontinuous Functions

A real-valued function f on a topological space $(X, \mathcal{T})$ is called upper (or lower) semicontinuous if for each real number α, the set $\{x \in X : f(x) < \alpha\}$ [respectively, $\{x \in X : f(x) > \alpha\}$] is an open subset of X. If we put $(-f)(x) = -f(x)$ for all $x \in X$, then f is lower semicontinuous iff $-f$ is upper semicontinuous. Indeed, each

continuous real-valued function on a topological space is upper and lower semicontinuous.

4. Right- and Left-Continuous Functions

Let X be an interval of $\mathbb{R}$ and $f: X \to \mathbb{R}$ a function. f is said to be right (or left) continuous at $x_0 \in X$ if for each arbitrary real number $\varepsilon > 0$, there is a real number $\delta > 0$ such that $|f(x) - f(x_0)| < \varepsilon$ whenever $x_0 < x < x_0 + \delta$ (respectively, $x_0 - \delta < x < x_0$). Clearly, f is continuous at x_0 iff it is right and left continuous at x_0. However, a right-continuous or left-continuous function may fail to be continuous [e.g., $f(x) = [x]$, the largest integer less than or equal to $x \in \mathbb{R}$; $[x]$ is called the *step function*, which is right continuous but not continuous at integers].

III. METHODS OF CONSTRUCTING NEW TOPOLOGICAL SPACES

There are a number of methods of constructing new topological spaces from old. In this section we present some of them.

A. Subspaces and Induced Topology

Let $(X, \mathcal{T})$ be a topological space. Any subset Y of X can be made into a topological space as follows. Consider the collection $\mathcal{T}' = \{P \cap Y : P \in \mathcal{T}\}$ of subsets of Y. Then it is easy to see that this collection defines a topology of Y called the *induced* or *relative topology*. In this topology, a subset Q of Y is *relatively open* iff there is an open set P in X such that $Q = P \cap Y$. If a subset E of Y is open in X, clearly E is relatively open. However, a relatively open subset of Y need not be open in X unless Y is itself an open subset of X. A subset Y of X endowed with the induced topology $\mathcal{T}'$ is called a *subspace* of X.

A topological space $(X, \mathcal{T})$ is said to have the *hereditary property* if each subspace of X satisfies the same property as does $(X, \mathcal{T})$ (see Table III for more information).

B. Products and Product Topology

There are two types of products: finite products and infinite products. Infinite products are of two kinds: countable products and arbitrary infinite products. By forming products of topological spaces we produce new topological spaces.

1. Finite Products

Let $(X_k, \mathcal{T}_k)$, $k = 1, 2, \ldots, n$, be n topological spaces with their respective topologies $\mathcal{T}_k$. By $\prod_{k=1}^{n} X_k = X_1 \times X_2 \times \cdots \times X_n$, we mean the set of all ordered n-tuples $(x_1, x_2, \ldots, x_n)$ in which $x_k \in X_k$, $k = 1, 2, \ldots, n$. Here, $\prod_{k=1}^{n} X_k$ is called the *finite Cartesian product* of $X_1, X_2, \ldots, X_n$. We topologize $\prod_{k=1}^{n} X_k$ as follows. The family $\mathcal{B} = \{U_1 \times U_2 \times \cdots \times U_n : U_k \text{ is open in } (X_k, \mathcal{T}_k), k = 1, \ldots, n\}$ forms a base of a topology, called the *product topology* on $\prod_{k=1}^{n} X_k$. In other words, a subset P of $\prod_{k=1}^{n} X_k$ is open in the product topology iff for each point $(x_1, \ldots, x_n) \in P$ there are open sets U_k in X_k for $k = 1, 2, \ldots, n$ with $x_k \in U_k$ such that $U_1 \times U_2 \times \cdots \times U_n \subset P$. We have already considered the special case when $n = 2$.

If $X = \prod_{k=1}^{n} X_k$ is a finite product with the product topology, the map $p_k(x_1, \ldots, x_n) = x_k$ is called the *kth projection* of X into X_k. Each p_k is continuous, open, and surjective. A finite product $\prod_{k=1}^{n} X_k$ is said to have the *productive property* if X satisfies the same property as does each X_k (see Table III).

2. Infinite Products

Let A be a nonempty indexing set. For each $\alpha \in A$, let $(X_\alpha, \mathcal{T}_\alpha)$ be a topological space with the topology $\mathcal{T}_\alpha$. By $\prod_{\alpha \in A} X_\alpha$, we mean the set of all maps $x: A \to \bigcup_{\alpha \in A} X_\alpha$ such that $x(\alpha) = x_\alpha \in X_\alpha$ for all $\alpha \in A$. The $\prod_{\alpha \in A} X_\alpha$ is called a *product*. If A is a finite set, then indeed $\prod_{\alpha \in A} X_\alpha$ is a finite product, as seen above. If A is countable (i.e., there is a one-to-one map between the elements of A and those of positive integers), then $\prod_{\alpha \in A} X_\alpha$ is called the *countable product* and is often written $\prod_{k=1}^{\infty} X_k$. If A is arbitrarily infinite and not countable, the product $\prod_{\alpha \in A} X_\alpha$ is called the *arbitrary infinite product* or simply *arbitrary product*. Here, again, the map $p_\alpha: \prod_{\alpha \in A} X_\alpha \to X_\alpha$ defined by $p_\alpha(x) = x_\alpha \in X_\alpha$ is called the αth projection.

To define a topology on $\prod_{\alpha \in A} X_\alpha$, we consider the family $\mathcal{B}$ of all subsets $P = \prod_{\alpha \in A} P_\alpha$ of $\prod_{\alpha \in A} X_\alpha$ in which P_α is an open subset of X_α for a finite number of α's, say, $\alpha_1, \alpha_2, \ldots, \alpha_n$ and $P_\alpha = X_\alpha$ for all $\alpha \neq \alpha_1, \alpha_2, \ldots, \alpha_n$. Then $\mathcal{B}$ forms a base of a topology of $\prod_{\alpha \in A} X_\alpha$, called the *product topology*. With the product topology on $\prod_{\alpha \in A} X_\alpha$, each αth projection becomes continuous and open.

The product topology on $\prod_{\alpha \in A} X_\alpha$ is very useful. For example, a map f of any topological space $(X, \mathcal{T})$ into $\prod_{\alpha \in A} X_\alpha$ is continuous iff each composition map $p_\alpha \circ f: X \to X_\alpha$ is continuous.

As for finite products, one can define productive property for infinite products (see Table III).

C. Quotient Topology

Let $(X, \mathcal{T})$ be a topological space, Y an arbitrary set, and $f: X \to Y$ a surjective map. We endow Y with a topology that will make f continuous. For this, we designate a

set Q of Y open whenever $f^{-1}(Q) = \{x \in X : f(x) \in Q\}$ is open in X. The collection of all such Q's defines a topology on Y, called the *quotient topology*. Clearly, if Y is endowed with the quotient topology, then $f : X \to Y$ becomes continuous.

Note that the quotient topology on Y depends on the topology of X and the map f. Indeed, one can always endow Y with the indiscrete topology to make f continuous. Among the topologies on Y that make f continuous, the quotient topology is the finest topology.

Like the product topology, the quotient topology is also very useful. For instance, suppose that Y is endowed with the quotient topology defined by $(X, \mathcal{T})$ and f. Let $(Z, \mathcal{T}')$ be a topological space and $g : Y \to Z$ a map. Then g is continuous iff $g \circ f : X \to Z$ is continuous.

IV. SEPARATION AXIOMS

The properties that appear to be obvious for real numbers are not easily available in general topological spaces. For instance, if a, b are two distinct real numbers, then for $\varepsilon = |a - b| > 0$, open intervals $A = \{x \in \mathbb{R} : |x - a| < \frac{1}{2}\varepsilon\}$ and $B = \{x \in \mathbb{R} : |x - b| < \frac{1}{2}\varepsilon\}$ are disjoint with $a \in A$ and $b \in B$. It is this kind of property that may not hold in general topological spaces. Such properties are termed *separation axioms*, also known as Alexandroff–Hopf Trennungaxioms.

One of the reasons separation axioms are necessary in the study of topological spaces is that they enable us to decide about the uniqueness of limits of convergent sequences or nets. This is not a trivial reason, for in an indiscrete space, no sequence or net has a unique limit. As a matter of fact, every sequence or net converges to every point of the indiscrete space. This abnormality makes the indiscrete spaces useless.

Now we consider the separation axioms.

A. T_0-Axiom

A topological space is said to satisfy the T_0-axiom or is called a *T_0-space* if at least one member of any pair of distinct points has an open neighborhood that does not contain the other. This axiom is not strong enough to yield any worthwhile results. Note that an indiscrete space containing more than one point is not a T_0-space.

B. T_1-Axiom

A topological space is said to satisfy the T_1-axiom or is called a T_1-space if each member of any pair of distinct points has an open neighborhood that does not contain the other. Although obviously better than the T_0-axiom, this axiom is not strong enough to guarantee the uniqueness of the limit of convergent sequences or nets. However, it does give us that each singleton (the set consisting of a single point) is a closed set and conversely (i.e., if each singleton is a closed set, the topological space must be a T_1-space). The class of T_1-spaces is hereditary and productive (see Table III).

C. T_2-Axiom

This is the most desirable separation axiom for the above-mentioned purpose and other reasons. A topological space is said to satisfy the T_2-axiom or is called a *T_2-space* or *Hausdorff space* (after F. Hausdorff) if both members of any pair of distinct points have disjoint open neighborhoods. This is indeed the weakest separation axiom that guarantees the uniqueness of the limit of a convergent sequence or net. As a matter of fact, a topological space is a Hausdorff space iff each convergent net or filter has the unique limit. The T_2-axiom is also equivalent to having the graph of the identity map closed. This class of spaces is also hereditary and productive.

There is another group of separation axioms that separate points from closed sets or closed sets from closed sets, as follows.

D. Regularity

A topological space is called regular (R) if for any closed set C and any point x not in C, there are disjoint open sets U and V such that $C \subset U$ and $x \in V$. Regularity is equivalent to the criterion that each point of the space have a base of closed neighborhoods. In general, regularity and the T_2-axiom have nothing in common. Therefore, to make them comparable, one defines *T_3-spaces* as those that are regular and satisfy the T_1-axiom. Now T_3-spaces are properly contained in the class of T_2-spaces and therefore satisfy the above-mentioned desirable property of uniqueness of limits of convergent nets in topological spaces as well. Moreover, they are hereditary and productive.

E. Complete Regularity

A topological space $(X, \mathcal{T})$ is said to be completely regular (CR) if for each closed set C of X and any point x not in C there is a continuous function $f : X \to [0, 1]$ such that $f(C) = 0$ and $f(x) = 1$. Complete regularity implies regularity but may fail to satisfy the T_2-axiom. However, if one joins the T_1-axiom with complete regularity, the resulting space does satisfy the T_2-axiom. A completely

regular T_1-space is generally known as a $T_{3\frac{1}{2}}$-space or *Tychonoff space* (after the Russian mathematician A. Tychonoff, who contributed a great deal to topology). Thus, each Tychonoff space is a Hausdorff space. The significance of Tychonoff spaces among others lies in the fact that on such spaces exist nonconstant continuous functions. Even on regular spaces there may not exist any nonconstant continuous function. Both classes of completely regular and Tychonoff spaces satisfy hereditary and productive properties.

F. Normality

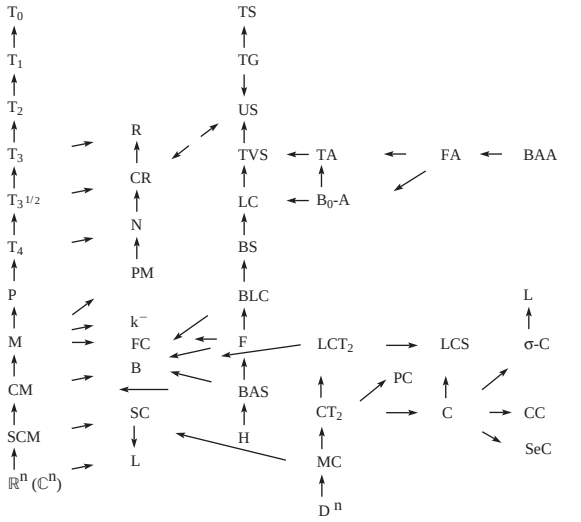
A topological space is said to be normal (N) if for any pair of disjoint closed subsets C_1, C_2 there are disjoint open sets U_1, U_2 such that $C_1 \subset U_1$ and $C_2 \subset U_2$. A useful characterization of normality is as follows. For each closed set C and open set U with $C \subset U$, there is an open set V such that $C \subset V \subset \bar{V} \subset U$. Even this apparently stronger separation axiom does not imply a Hausdorff space or the T_2-axiom, since singletons in a normal space need not be closed sets. Thus, to make it comparable with regularity and the T_2-axiom, one attaches the T_1-axiom to normality. A normal T_1-space is generally called a *T_4-space*. Now it is clear that each T_4-space is a T_3-space and hence Hausdorff, as shown earlier.

The axiom of complete regularity mentioned between those of regularity and normality apparently looks like an odd person out, but this is not the case, thanks to Urysohn's lemma: Let C_1, C_2 be any two disjoint closed subsets of a normal space $(X, \mathcal{T})$. Then there exists a continuous function $f : X \to [0, 1]$ such that $f(C_1) = 0$ and $f(C_2) = 1$. From this it follows that a T_4-space is a Tychonoff space, which in turn implies that it is a T_3-space and hence Hausdorff.

Extensions of functions from a subspace to the whole space play an important role in almost every aspect of mathematics. Thus, the question is which of the above axioms, if any, ensures extensions. We are indebted to H. Tietze for the so-called Tietze's extension theorem: If Y is a closed subspace of a T_4-space $(X, \mathcal{T})$ and $f : Y \to \mathbb{R}$ a continuous map, there exists a continuous map $\bar{f} : X \to \mathbb{R}$ such that $\bar{f}(x) = f(x)$ for all $x \in Y$.

There are other separation axioms finer or stronger than normality for which the reader is referred to texts on topology. However, normality is sufficient enough to carry out major parts of mathematical analysis. As noted in the preceding paragraphs, of the six separation axioms, T_0 is the weakest and T_4 the strongest. Consult Table II for a complete picture of these implications. For information about whether these six classes of spaces have hereditary or productive properties (or both), as mentioned in the preceding section, see Table III.

TABLE II Interconnection between Topological Spaces[a]



[a] A → B means that A is contained in B.

V. SPECIAL TOPOLOGICAL SPACES

In this section we consider some of the most useful topological spaces that are frequently mentioned and studied in topology and functional analysis (a modern branch of mathematics that deals simultaneously with abstract and concrete analysis).

A. Metric Spaces and Metrization

An important class of topological spaces that subsumes the classical spaces $\mathbb{R}^n$ or $\mathbb{C}^n$ is that of metric spaces.

Let X be a set. A function $d : X \times X \to \mathbb{R}$ is called a *metric* of X if d satisfies the following axioms:

(i) $d(x, y) \geq 0$ for all $x, y \in X$.
(ii) $d(x, y) = 0$ if $x = y$.
(iii) $d(x, y) = 0$ implies that $x = y$.
(iv) $d(x, y) = d(y, x)$.
(v) $d(x, y) \leq d(x, z) + d(z, y)$ (called the *triangle inequality*).

If d satisfies only (i), (ii), (iv), and (v), then d is called a *pseudometric* on X. A set X with a metric (or pseudometric) d is called a *metric* (or *pseudometric*) (M or PM, respectively) *space* and is sometimes denoted (X, d).

Each pseudometric (in particular, metric) space is indeed a topological space, for a set P in X is open if for each $x \in P$ there is a real number $r > 0$ such that the *open ball* $B_r(x) = \{y \in X : d(y, x) < r\}$ of radius r, centered at x,

TABLE III Hereditary and Productive Properties of Some Important Spaces[a]

Name	Hereditary		Productive properties		
	Arbitrary	Closed	Finite	Countable	Arbitrary
Topological spaces					
C (compact)	N	Y	Y	Y	Y
CM (compact metric)	N	Y	Y	Y	N
FC (first countable)	Y	Y	Y	Y	N
LCS (locally compact space)	N	Y	Y	N	N
M (metric)	Y	Y	Y	Y	N
P (paracompact)	N	Y	N	N	N
T_0	Y	Y	Y	Y	Y
T_1	Y	Y	Y	Y	Y
T_2	Y	Y	Y	Y	Y
T_3	Y	Y	Y	Y	Y
$T_{3^{1/2}}$	Y	Y	Y	Y	Y
T_4	N	Y	N	N	N
Topological vector spaces (vector subspaces)					
TVS (topological vector space)	Y	Y	Y	Y	Y
BAS (Banach space)	N	Y	Y	N	N
F (Fréchet)	N	Y	Y	Y	N
H (Hilbert)	N	Y	Y	N	N
Topological algebras (subalgebras)					
TA (topological algebra)	Y	Y	Y	Y	Y
BAA (Banach algebra)	N	Y	Y	N	N
B_0-A (B_0-algebra)	N	Y	Y	Y	N
FA (Fréchet algebra)	N	Y	Y	Y	N

[a] N (no) indicates that the property does not hold; Y (yes), that it does hold.

is completely contained in P; in symbols $x \in B_r(x) \subset P$. With this definition of open sets in a metric space (X, d), it is easily verified that the collection of all such open sets in X defines a topology called the *metric topology* of X and the collection of all open balls forms a base of the metric topology.

To see pseudometric or metric spaces from the separation-axiom point of view, note that each pseudometric (metric) space is normal (T_4-space), thus forming a telescopic chain of spaces from metric spaces up to T_0-spaces (see Table II).

If we consider the countable collection $\{B_{1/n}(x)\}$ of open balls of radius $1/n$ ($n \geq 1$, integer), centered at x, it follows that a metric space is first countable. A metric space is second countable iff it is separable.

Metric spaces enjoy an important place among topological spaces because, unlike general topological spaces, in metric spaces one can assign distances $d(x, y)$ between two points—a feature very noticeable in Euclidean spaces $\mathbb{R}^n$. Thus, one can study the notions of Cauchy sequences and uniformly continuous functions in metric spaces, which cannot be defined in general topological spaces.

A sequence $\{x_n\}$ in a metric space (X, d) is said to *converge* to $x \in X$ if for each arbitrary real number $\varepsilon > 0$ there is a positive integer n_0 such that $d(x_n, x) < \varepsilon$ whenever $n \geq n_0$. $\{x_n\}$ is called a *Cauchy sequence* if for each real number $\varepsilon > 0$ there is a positive integer n_0 such that $d(x_n, x_m) < \varepsilon$ whenever $n, m \geq n_0$.

Every convergent sequence is a Cauchy sequence, but the converse is not true. [For example, the sequence of rational numbers ≥ 1 and $< \sqrt{2}$, approximating $\sqrt{2}$, converges to $\sqrt{2}$ (which is not a rational number) and is a Cauchy sequence in the metric space of rational numbers.] A metric space (X, d) is called *complete* if every Cauchy sequence in it is convergent. (The set $\mathbb{R}$ of all real numbers is complete by the so-called Cauchy criterion for convergence of a real sequence.) We denote complete metric spaces CM and separable complete metric spaces SCM.

One can obtain topological information about closed sets by convergent sequences in a metric space (X, d) as follows. A subset C of X is closed iff for each sequence $\{x_n\}$ in C converging to x, it follows that $x \in C$. Since metric spaces, being T_4-spaces, are Hausdorff, the limits of convergent sequences are unique. Furthermore, metric spaces clearly enjoy the hereditary property but not the general productive property (see Table III). However, if (X_k, d_k), $k = 1, 2, \ldots$, is a countable family of metric

spaces, then the countable product $X = \prod_{k=1}^{\infty} X_k$ is a metric space with the metric

$$d(x, y) = \sum_{k=1}^{\infty} \frac{1}{2^k} \frac{d_k(x_k, y_k)}{1 + d_k(x_k, y_k)},$$

in which both $x = \{x_k\}$ and $y = \{y_k\}$ belong to X. In particular, the space ω of all real sequences is a metric space.

As pointed out above by the example of rational numbers, not every metric space is complete. However, there is a process, called the completion, by which an incomplete metric space can be completed. More precisely, if (X, d) is an incomplete metric space, there exists a unique complete metric space $(\hat{X}, \hat{d})$ containing a dense copy of $(X, d) \cdot (\hat{X}, \hat{d})$, called the *completion* of (X, d). For example, the set of all real numbers is the completion of the set of all rational numbers.

For metric spaces, the continuity of a map can be described as follows. Let (X, d) and (Y, d') be two metric spaces. A map $f : X \to Y$ is continuous at $x_0 \in X$ if and only if for each $\varepsilon > 0$ there is $\delta > 0$ such that for all $x \in X$, $d(x, x_0) < \delta$ implies that $d'(f(x), f(x_0)) < \varepsilon$. This is also equivalent to the so-called *sequential continuity* at x_0 : for all sequences $\{x_n\}$ in X converging to x_0, the sequence $\{f(x_n)\}$ converges to $f(x_0)$. A map $f : X \to Y$ is called *uniformly continuous* if for each $\varepsilon > 0$ there is $\delta > 0$ such that for all $x, y \in X$, $d(x, y) < \delta$ implies that $d'(f(x), f(y)) < \varepsilon$. If for all $x, y \in X$, $d'(f(x), f(y)) = d(x, y)$, then $f : X \to Y$ is called an *isometry* and thus f embeds X into Y in such a way that the metric induced from Y on $f(X)$ coincides with the metric of X. That is why it is sometimes called an *isometric embedding* of X into Y. An embedding need not be surjective. However, if $f(X) = Y$, then f is called an *isometric homeomorphism*. In this case, X and Y are set-theoretically and topologically the same.

A subset of a topological space is called an F_σ-set (respectively, G_δ-set) if it can be written as the countable union (respectively, countable intersection) of closed (respectively, open) sets. A subset A of a topological space is an F_σ-set (G_δ-set) iff its complement A^c is a G_δ-set (respectively, F_σ-set). Moreover, a countable union (countable intersection) of F_σ-sets (respectively, G_δ-sets) is an F_σ-set (respectively, G_δ-set). Also, a finite intersection (finite union) of F_σ-sets (respectively, G_δ-sets) is an F_σ-set (respectively, G_δ-set). Every closed (open) set of a metric space is a G_δ-set (respectively, F_σ-set). In particular, each closed (open) subset of $\mathbb{R}$ is a G_δ-set (respectively, an F_σ-set).

Since it is easier to grasp the topology of a metric space than that of general topological spaces, it is important to know when a topological space can be endowed with a metric topology. Indeed, indiscrete topology can never be defined by a metric, since a metric space is always Hausdorff, whereas the indiscrete space does not even satisfy the T_0-axiom. On the other hand, the discrete topology can be given by the trivial metric $d(x, y) = 1$ or 0 according to whether $x \neq y$ or $x = y$.

Whenever the topology of a topological space can be defined by a metric, the space is called *metrizable*. A nontrivial notable result in this regard is due to P. Urysohn, which goes by the name Urysohn's metrization theorem: Each second countable T_3-space is metrizable.

A separable complete metric space is called a *Polish space* and a metric space which is a continuous image of a Polish space is called a *Souslin space*. A closed subspace of a Polish (respectively, Souslin) space is also a Polish (respectively, Souslin) space. The same is true for countable products. Moreover, an open subset of a Polish space is also a Polish space. For example, $\mathbb{R}$ and the set of all irrational numbers endowed with the metric topology induced from $\mathbb{R}$ are Polish spaces. We give further properties of these spaces in the sequel.

B. Compactness and Compactifications

Another class of very important and useful topological spaces in topology as well as in analysis is that of compact spaces. Let $(X, \mathcal{T})$ be a topological space. A collection $\{P_\alpha\}$ of subsets of X is said to be a *covering* of a set $E \subset X$ if $E \subset \bigcup_\alpha P_\alpha$; in other words, each element of E belongs to some P_α. If $E = X$, then $\{P_\alpha\}$ is a covering of X if $X = \bigcup_\alpha P_\alpha$. If each member of the covering $\{P_\alpha\}$ of E is open, then $\{P_\alpha\}$ is called an *open covering* of E. If the number of sets in a covering is finite, it is called a *finite covering*.

1. Compact Spaces

A topological space $(X, \mathcal{T})$ is said to be compact (C) if from each open covering of X it is possible to extract a finite open covering of X. $(X, \mathcal{T})$ is called a *Lindelöf space* (L) if from each open covering $\{P_\alpha\}$ of X it is possible to extract a countable subcollection $\{P_{\alpha_i}, i \geq 1\}$ such that $X = \bigcup_{i=1}^{\infty} P_{\alpha_i}$. It is clear that each compact space is a Lindelöf space. However, the converse is not true (e.g., $\mathbb{R}$, with the natural topology). One of the celebrated theorems in analysis, called the Heine–Borel theorem, tells us that each closed bounded interval $[a, b]$, $-\infty < a \leq b < \infty$, of $\mathbb{R}$ is compact, but $\mathbb{R}$ itself is not. Similarly, each closed disk D^n in $\mathbb{R}^n$ is compact.

Compactness has several characterizations. Some of them are as follows. $(X, \mathcal{T})$ is compact $\Leftrightarrow$ for each family $\{C_\alpha\}$ of closed sets in X with the finite-intersection

property (i.e., for any finite subcollection $\{C_{\alpha_i}\}_{i=1}^n$ of $\{C_\alpha\}$, $\bigcap_{i=1}^n C_{\alpha_i} \neq \varnothing$), we have $\bigcap_a C_\alpha \neq \varnothing \Leftrightarrow$ each net or filter of X has a cluster point $\Leftrightarrow$ each ultrafilter in X is convergent.

Since the indiscrete space has only two open sets (actually only one nonempty open set), it is always compact, although not Hausdorff. On the other hand, a discrete space is compact iff it is a finite set. A Hausdorff compact space, however, is a T_4-space and so is normal.

With regard to the hereditary property, compact spaces do not have it (see Table III), but a closed subset of a compact space is compact. A far-reaching result for application purposes is concerned with the product of compact spaces and goes by the name of the *Tychonoff theorem*: If $(X_\alpha, \mathcal{T}_\alpha)$ $(\alpha \in A)$ is a family of compact spaces, the arbitrary product $\prod_{\alpha\in A} X_\alpha$ is also compact under the product topology. In addition, compact spaces are rich in other properties. For instance, the continuous image of a compact space is compact. Moreover, a continuous bijective map of a compact space onto a Hausdorff space is a homeomorphism. Every continuous real-valued function on a compact space is bounded; that is, there is $M > 0$ such that $|f(x)| \leq M$ for all $x \in X$.

Although a subspace of a compact space need not be compact, every subspace of a compact Hausdorff space is a Tychonoff space. This, among other properties, highlights the significance of a compact Hausdorff space. That is why it is sometimes called a *compactum*. Two esotoric examples of compacta are as follows.

a. Hilbert cube. Let $H^\omega = \{\{x_n\}, x_n \in \mathbb{R} : 0 \leq x_n \leq (1/n)\}$ with the metric $d(\{x_n\}, \{y_n\}) = \sqrt{\sum_{n=1}^\infty (x_n - y_n)^2}$. Then H^ω is a separable compact metric space, hence a second countable compactum and a Polish space. H^ω is called the Hilbert cube. It is a compact subset of the Hilbert space ℓ_2 (see Section VIII.B).

b. Cantor set. Let $A_0 = [0, 1]$, the closed unit interval. By removing the middle third of A_0 we obtain $A_1 = [0, 1/3] \cup [2/3, 1]$. Continuing this process, we obtain $A_n = [0, 1/3^n] \cup \ldots \cup [((3^n - 1)/3^n) - 1]$, $n = 0, 1, 2, \ldots$. Each A_n being a closed subset of the compact space A_0, we obtain a nonempty compact set $\mathfrak{C} = \bigcap_{n=0}^\infty A_n$, called the *Cantor set.* Alternatively, one can describe $\mathfrak{C}$ as follows: Let $E = \{0, 2\}$ be the two-point set and let E^ω be the countable product of E by itself, which is the set of all sequences with entries 0 or 2. For each $x = \{x_i\} \in E^\omega$, put $\varphi(x) = \sum_{i=1}^\infty (x_i/3^i)$. φ is an injective map of E^ω into $[0, 1]$. It can be shown that $\mathfrak{C} = \varphi(E^\omega)$, the Cantor set. $\mathfrak{C}$ is an uncountable compactum, has no isolated points, contains no interval of $\mathbb{R}$, and is perfect (i.e., closed and dense in itself).

2. Countably and Sequentially Compact Spaces

A topological space $(X, \mathcal{T})$ is called countably compact (CC) if from each countable open covering of X it is possible to extract a finite open covering. $(X, \mathcal{T})$ is called sequentially compact (SeC) if every sequence in it contains a convergent subsequence.

It is easily seen that each compact space is countably compact as well as sequentially compact, but a countably compact or a sequentially compact space may fail to be compact. In general, there is no connection between countable compactness and sequential compactness, although the two notions coincide on T_1-spaces. A metric space is compact iff countably compact iff sequentially compact. For hereditary and productive properties, see Table III.

3. σ-Compact Spaces

A topological space is called σ-compact if it is the countable union of compact spaces. Indeed, each compact space is σ-compact, but the converse is not true (e.g., $\mathbb{R}$).

Another frequently used notion of compactness in topology is as follows.

4. Locally Compact Spaces

A topological space $(X, \mathcal{T})$ is said to be locally compact (LCS) if each point of X has a neighborhood whose closure is compact.

Since a compact space is always a closed and compact neighborhood of each of its points, it follows that each compact space is locally compact, but the converse is not true (e.g., $\mathbb{R}$). In general, a locally compact space does not satisfy any separation axiom, but a Hausdorff locally compact space is a Tychonoff space and hence a T_3-space. Note that a Hausdorff locally compact space need not be normal.

Although locally compact spaces need not have the hereditary property, a closed subspace of a locally compact space is locally compact (see Table II). Moreover, a continuous, open, and surjective image of a locally compact space is locally, compact. Locally compact spaces are good for one-point compactifications (see below).

5. Hemicompact Spaces

A topological space $(X, \mathcal{T})$ is called hemicompact if there exists a countable family $\{K_n\}$ of compact subsets K_n of X such that $X = \bigcup_{n=1}^\infty K_n$ and each compact subset of X is contained in some K_n. ($K_n^>$s are said to form a fundamental system of compact subsets of X.) Each locally compact hemicompact space is σ-compact. Each locally compact

hemicompact (hence σ-compact) metrizable space is a Polish space.

6. MB Spaces

A metric space (X, d) is said to be an MB space if each closed bounded subset of X is compact. [Note that a subset B of X is bounded if the diameter $\delta(B) = \sup\{d(x, y) : x, y \in B\}$ is finite.] Clearly, each compact metric space is an MB space and each MB space is complete, separable, locally compact and σ-compact (hence hemicompact), and also a Lindelöf, Polish space. As examples, $\mathbb{R}^n$ (n-dimensional euclidean space) is an MB space, but the set of rational numbers with the induced metric from $\mathbb{R}$ is not.

Each continuous map of an MB space into a metric space carries bounded sets into bounded sets. A metric space (F, d') which is the continuous image of an MB space (E, d) such that the inverse image of a bounded set of F is bounded in E is an MB space. Indeed, a closed subset of an MB space is an MB space and, so, is the countable product of compact metric spaces.

7. Pseudocompact Spaces

A Hausdorff topological space $(X, \mathcal{T})$ is called pseudocompact (PC) if every continuous real-valued function on X is bounded (see Section V.B.1). Every Hausdorff compact or countably compact space is pseudocompact. The converse is not true, however. In particular, each closed bounded interval $[a, b]$ is pseudocompact. See Table III for other implications.

8. Paracompact Spaces

A Hausdorff topological space $(X, \mathcal{T})$ is called paracompact (P) if each open covering $\{P_\alpha\}$ of X has a *refinement* $\{Q_\beta\}$ (i.e., there exists another covering $\{Q_\beta\}$ of X such that each P_α contains some Q_β) such that $\{Q_\beta\}$ is *neighborhood finite* (i.e., for each $x \in X$ there is an open neighborhood U of x such that U intersects with only a finite number of Q_β's).

Since a finite open subcovering of an open covering is a refinement, each Hausdorff compact space is paracompact, but the converse is not true. Each paracompact space is a T_4-space (hence normal) and each metric space is paracompact. Now the significance of paracompact spaces becomes very notable. These spaces are useful for the extension of continuous functions from subspaces to the whole spaces, as well as for metrization. Paracompact spaces do not have the hereditary or productive properties, but a closed subspace of a paracompact space is paracompact.

9. Compactifications

A topological space $(\hat{X}, \hat{\mathcal{T}})$ is said to be a compactification of a topological space $(X, \mathcal{T})$ if $(\hat{X}, \hat{\mathcal{T}})$ is compact and contains a homeomorphic image of $(\hat{X}, \mathcal{T})$ that is dense in $(X, \hat{\mathcal{T}})$.

Among compactifications, two are significant for applications: one-point compactification and Stone-Čech compactification. The former is the smallest, whereas the latter is the largest in a certain sense. The former requires local compactness, whereas the latter needs complete regularity.

Let $(X, \mathcal{T})$ be a Hausdorff locally compact space. Let ω be any point outside X. Put $\hat{X} = X \cup \{\omega\}$ and endow $\hat{X}$ with the topology $\hat{\mathcal{T}}$ defined as follows. Each open subset of X is open in $\hat{X}$ (i.e., each $U \in \mathcal{T}$ is also in $\hat{\mathcal{T}}$) and any subset $\hat{U}$ of $\hat{X}$ that contains ω is in $\hat{\mathcal{T}}$ provided that $\hat{X} \setminus \hat{U}$ is compact in X. With this prescription of open sets, it is easy to verify that $\hat{\mathcal{T}}$ defines a topology such that $(\hat{X}, \hat{\mathcal{T}})$ is a Hausdorff compact space in which $(X, \mathcal{T})$ is dense. Moreover, $\hat{X} \setminus X = \{\omega\}$ consists of a single point. $(\hat{X}, \hat{\mathcal{T}})$ is called the *one-point compactification of* $(X, \mathcal{T})$.

As an example, $\mathbb{R}$ is a Hausdorff locally compact space. If we put $\hat{\mathbb{R}} = \mathbb{R} \cup \{\infty\}$, then $\hat{\mathbb{R}}$ is the one-point compactification of $\mathbb{R}$. It is easy to see that $\hat{\mathbb{R}}$ is homeomorphic with the circle: $\{(x, y) \in \mathbb{R}^2 : x^2 + y^2 = 1\}$.

For the Stone-Čech compactification, let $(X, \mathcal{T})$ be a Tychonoff space. Then the set $C(X)$ of all continuous functions from X into $[0, 1]$ contains nonconstant continuous functions, provided that X is not trivial (i.e., it consists of more than one point). If we put $I = [0, 1]$, then $I^{C(X)} = \prod_{f \in C(X)} I_f$, $(I_f = I)$, the infinite product is compact by the Tychonoff theorem (see Section V.B.1). If to each $x \in X$, we assign $(f(x))_{f \in C(X)} \in I^{C(X)}$, we get an injective map. The closure of this injective image, denoted βX, in the compact space $I^{C(X)}$ is also compact. βX is called the *Stone-Čech compactification* of X.

10. Perfect and Proper Maps

Let $(X, \mathcal{T})$ and $(Y, \mathcal{T}')$ be two topological spaces. A map $f : X \to Y$ is called *inversely compact* (or simply *compact*) if the inverse image $f^{-1}(\{y\})$ of each singleton $\{y\}$ in Y is compact in X. Note that a continuous map need not be compact, nor need a compact map be continuous, or closed, or open. A continuous, closed, compact, surjective map is called *perfect.*

Perfect maps transport a number of properties of their domains to their ranges. For instance, if $f : (X, \mathcal{T}) \to (Y, \mathcal{T}')$ is perfect and if X is Hausdorff or regular or completely regular or metrizable or second countable or compact or countably compact or Lindelöf or locally compact or paracompact, so is Y, respectively. Perfect maps are often used in category theory.

A map $f:(X,\mathcal{T})\to(Y,\mathcal{T}')$ is called *proper* (à la Bourbaki) if for each compact subset B of X, $f(B)$ is compact in Y, and for each compact subset C of Y, $f^{-1}(C)$ is compact in X. Each continuous map between compacta is proper and each continuous closed compact map of a T_2-space to a T_2-space is proper.

C. Baire Spaces and *k*-Spaces

Apart from those spaces dealt with in the preceding section, there are two more classes that are frequently used in topology and functional analysis. They are Baire spaces and *k*-spaces.

1. Baire Spaces

A subset A of a topological space $(X,\mathcal{T})$ is called *nondense* or *nowhere dense* if $(\bar{A})^0=\varnothing$ (i.e., the interior of the closure of A is empty). A countable union of nondense sets is called a *set of the first category* or *a meager* set. A set that is not of the first category is called a *set of the second category*. The complement of a set of the first category is called a *residual set*.

A topological space $(X,\mathcal{T})$ is called a *Baire space* (B) if for any countable collection of closed nondense sets $\{A_n\}$ such that $X=\bigcup_{n=1}^{\infty}A_n$, there is at least one n for which $A_n^0\neq\varnothing$. The class of all Baire spaces includes two of the important classes of topological spaces studied above, namely, the class of Hausdorff locally compact (hence, compact) spaces and the class of all complete metric spaces. The fact that each complete metric space is a Baire space is known as the *Baire category theorem*. Moreover, each Baire space is of the second category, and each open subset of a Baire space is a Baire space.

Let τ denote a cardinal number and let $D(\tau)$ be a set of real numbers of cardinality τ. Let $B_\tau=\{\{x_i\}:x_i\in D(\tau)\}$. For $x=\{x_i\}$, $y=\{y_i\}$ in B_τ, put $d(x,y)=1/k$, where k is the least integer i such that $x_i\neq y_i$. Then d is a metric on B_τ and the metric space (B_τ,d) is called a *Baire space* of *weight* τ. The metric topology of B_τ has a base of closed–open sets.

2. *k*-Spaces

A topological space $(X,\mathcal{T})$ is called a *k*-space if each subset C of X is closed whenever for each compact subset K of X, $C\cap K$ is closed.

All Hausdorff locally compact (hence, compact) spaces as well as metric spaces are included in the class of all *k*-spaces. However, a *k*-space need not be a Baire space. Although the class of *k*-spaces does not have the hereditary property, it is true that a closed subspace of a Hausdorff *k*-space is a *k*-space. Nor does the productive property hold in the class of *k*-spaces. A notable property for *k*-spaces is as follows. Each real-valued function on a *k*-space is continuous iff its restriction on each compact subset is continuous. Clearly, this generalizes the known fact about real-valued functions defined on the set of real numbers.

A completely regular T_2-space (i.e., a Tychonoff space) $(X,\mathcal{T})$ is called a k_r-space if each real-valued function on X whose restriction to each compact subset of X is continuous is indeed continuous on X. Each *k*-space is a k_r-space, but the converse is not true. For instance, the uncountable product $\mathbb{R}^\nu$ of $\mathbb{R}$, endowed with the product topology, is a k_r-space but not a *k*-space. One of the very useful properties of *k*-spaces is that each proper map between two *k*-spaces is continuous and closed.

D. Uniform Spaces and Uniformization

There are two important reasons for studying uniform spaces. One is to define uniform continuity, and the other is to define completeness for spaces more general than metric spaces. After a little thought, it becomes obvious to the reader that these two important concepts from classical analysis cannot be expressed in general topological spaces.

Let X be any set and $X^2=X\times X$, the Cartesian product of X by itself. Let $\mathcal{U}=\{U\}$ be a filter in X^2 satisfying the following:

(i) Each U in $\mathcal{U}$ contains the diagonal set $\{(x,y)\in X^2:x=y\}$.
(ii) For each U in $\mathcal{U}$, $U^{-1}=\{(y,x):(x,y)\in U\}$ is also in $\mathcal{U}$.
(iii) For each U and $\mathcal{U}$ there is a V in $\mathcal{U}$ such that $V\circ V\subset U$, in which $V\circ V=\{(x,y)\in X^2$: for some z both (x,z) and (z,y) are in $V\}$.

Then the filter $\mathcal{U}=\{U\}$ is called a *uniformity* and the pair $(X,\mathcal{U})$ is called a *uniform space* (US).

Each metric space (X,d) becomes a uniform space with the collection $\{U_\varepsilon\}$ of sets in X^2 as its uniformity, where $U_\varepsilon=\{(x,y)\in X^2:d(x,y)<\varepsilon\}$ for all real numbers $\varepsilon>0$.

Each uniform space $(X,\mathcal{U})$ can be endowed with a topology called the *uniform topology* defined as follows. A subset P of X is called open in the uniform topology if for each $x\in P$ there is U in $\mathcal{U}$ such that $\{y\in X:(x,y)\in U\}\subset P$. Each uniform space with the uniform topology is completely regular. Thus, if the uniform topology is Hausdorff, the uniform space becomes a Tychonoff space.

A map f of a uniform space $(X,\mathcal{U})$ into another uniform space $(Y,\mathcal{V})$ is called *uniformly continuous* if for each

V in $\mathcal{V}$ there exists U in $\mathcal{U}$ such that $(f(x), f(y)) \in V$ whenever $(x, y) \in U$. In particular, for metric spaces $(X, d), (Y, d')$, the uniform continuity of f has the following formulation. For each $\varepsilon > 0$ there exists $\delta > 0$ such that $d'(f(x), f(y)) < \varepsilon$ whenever $d(x, y) < \delta$.

Indeed, each uniformly continuous map is continuous. However, the converse is not true [e.g., $f : \mathbb{R} \to \mathbb{R}$ such that $f(x) = x^2$]. However, if $(X, \mathcal{T})$ is a compact uniform space, each real-valued continuous function on X is uniformly continuous. In particular, each continuous map $f : [a, b] \to \mathbb{R}$ is uniformly continuous.

A filter $\{F_\alpha\}$ (or net $\{x_\alpha\}$) in a uniform space $(X, \mathcal{U})$ is called a *Cauchy filter* (or *Cauchy net*) if for each U in $\mathcal{U}$ there exists F_α such that the set $\{(x, y) : x, y \in F_\alpha\} \subset U$ [or there exists α_0 such that for all $\alpha, \beta \geq \alpha_0$, $(x_0, x_\beta) \in U$]. Indeed, each convergent filter (or net) is a Cauchy filter (or net), but not conversely. Whenever the converse holds, the uniform space is said to be *complete*. As for metric spaces, each incomplete Hausdorff uniform space $(X, \mathcal{T})$ can be completed to a complete Hausdorff uniform space $(\tilde{X}, \tilde{\mathcal{T}})$. $(\tilde{X}, \tilde{\mathcal{T}})$ is called the *completion of* $(X, \mathcal{T})$.

The class of all complete Hausdorff uniform spaces includes all compact Hausdorff uniform spaces and is productive but not hereditary. However, a closed subset of a complete Hausdorff uniform space is complete.

A topological space $(X, \mathcal{T})$ is said to be *uniformizable* if there exists a uniformity $\mathcal{U}$ with respect to which $\mathcal{T}$ becomes the uniform topology. Indeed, each metric space is uniformizable, as shown above. An important characterization of uniformization is the following. A topological space $(X, \mathcal{T})$ is uniformizable iff it is completely regular iff $\mathcal{T}$ is defined by a family $\{d_\alpha\}$ of pseudometrics (see Sections II.A and V.A). A topological space whose topology is defined by a family of pseudometrics is called a *gauge space*.

E. Sequential Spaces

First, we note that a sequence $\{x_n\}$ in a nonmetric topological space $(X, \mathcal{T})$ is said to converge to a point $x \in X$ if for each neighborhood U of x there is a positive integer n_0, depending upon U, such that for all $n \geq n_0$, $x_n \in U$. Indeed, this definition is equivalent to the convergence of a sequence in a metric space given in Section V.A.

A topological space $(X, \mathcal{T})$ is called a *sequential space* if for any subset A of x, $A \neq \bar{A}$, there is a sequence $\{x_n\}$ in A converging to a point of $\bar{A} \backslash A$. Each metrizable space (in particular, $\mathbb{R}^n$) is a sequential space, but $\mathbb{R}^{\mathbb{R}}$ (see Section VII), the set of all real functions on $\mathbb{R}$ endowed with the product topology, is not.

For a subset A of a sequential space, the set of all points $x \in X$ for which there exists a sequence in A converging to x, is called the *sequential closure* of A and is denoted $\bar{A}^s$. It is easily seen that $\bar{\varnothing}^s = \varnothing$, $A \subset \bar{A}^s \subset \bar{A}$, and $\overline{A \cup B}^s = \bar{A}^s \cup \bar{B}^s$ for all subsets A, B of X. In general, however, $\overline{\bar{A}^s}^s \neq \bar{A}^s$, i.e., the sequential closure operation is not idempotent, unlike the topological closure, where we have $\bar{\bar{A}} = \bar{A}$.

A topological space $(X, \mathcal{T})$ is called a Fréchet–Urysohn space if $\bar{A}^s = \bar{A}$ for all subsets A of X. Clearly, each Fréchet–Urysohn space is a sequential space but the converse is not true. A useful characterization of a Fréchet–Urysohn space is: A topological space $(X, \mathcal{T})$ is a Fréchet–Urysohn space iff each subspace of $(X, \mathcal{T})$ is a sequential space. A first countable (hence metrizable) space is a Fréchet–Urysohn space. Each continuous map $f : (X, T) \to (Y, T')$ is sequentially continuous, but the converse is not true. However, if $(X, \mathcal{T})$ is a sequential space, then each sequential map of $(X, \mathcal{T})$ into $(Y, \mathcal{T}')$ is continuous. Indeed, on metric spaces, sequential continuity coincides with the usual concept of continuity as noted above (see Section V.A).

F. Proximity Spaces

Let $\mathcal{P}(X)$ denote the class of all subsets of a set X. Let δ define a binary relation on $\mathcal{P}(X)$. If $A \delta B$, then A is said to be *near* B for A, B in $\mathcal{P}(X)$ and $A \not\delta B$ ($\not\delta$, the negation of δ) means that A is *distant* from B. The pair (X, δ) is called a *proximity space* if the following axioms hold:

(i) $A \delta B \Leftrightarrow B \delta A$.
(ii) $\{x\} \delta \{x\}$.
(iii) $A \delta (B \cup C) \Leftrightarrow A \delta B$ or $A \delta C$.
(iv) $A \not\delta \varnothing$ for all $A \subseteq X$.
(v) $A \not\delta B \Rightarrow$ there is $C \in \mathcal{P}(X)$ such that $A \not\delta C$ and $B \not\delta (X \backslash C)$, where A, B, C are subsets of X and $x \in X$. δ is called a *proximity* for X.

A proximity δ for (X, δ) induces a topology, called the *proximity topology*, on X as follows. Let $\mathcal{T}_\delta$ denote the collection of all subsets P of X such that for each $x \in P$, $\{x\} \not\delta P^c$. The collection $\mathcal{T}_\delta$ satisfies all the properties of a topology and $(X, \mathcal{T}_\delta)$ becomes a completely regular topological space.

For a proximity space (X, δ), $d(A, B) = 0 \Leftrightarrow A \delta B$ gives a metric, where $d(A, B) = \inf\{d(a, b) : a \in A, b \in B\}$. On the other hand, if (X, d) is a metric space, then the relation defined by $A \delta_d B \Leftrightarrow d(A, B) = 0$ gives a proximity δ_d and (X, δ_d) becomes a proximity space. Moreover, the proximity topology induced by δ_d coincides with the original metric topology of (X, d). Thus each metric space is a proximity space.

Similarly, if $(X, \mathcal{U})$ is a Hausdorff uniform space, then the relation δ_u, defined by $A\delta_u B \Leftrightarrow$ for each $U \in \mathcal{U}$ there exists an element $a \in A$ and an element $b \in B$ such that $(a, b) \in U$ gives a proximity relation on X. On the other hand, for each proximity space (X, δ), let $U_{A,B} = [(A \times B) \cup (B \times A)]^c$. Then the collection $\mathcal{U}_\delta = \{U_{A,B} : A \not\delta B\}$ forms a subbase of a uniformity for X. Moreover, the proximity derived from this uniformity coincides with the given proximity δ. Thus each Hausdorff uniform space admits a proximity called the *uniform proximity*.

The collection of all proximities on a set X can be ordered by inclusion. A proximity δ_1 is larger than a proximity δ_2 if $A\delta_1 B \Rightarrow A\delta_2 B$ for all $A, B \in \mathcal{P}(X)$. Under this ordering, there is a largest proximity which can be described as follows: $A \not\delta B \Leftrightarrow A \cap B = \emptyset$. The largest proximity induces a discrete topology.

For any proximity space (X, δ), $\mathrm{Cl}_\delta A = \{x \in X : \{x\}\delta A\}$ defines a closure operation on X which gives the same proximity topology. Moreover, $A\delta B \Leftrightarrow \mathrm{Cl}_\delta A \delta \mathrm{Cl}_\delta B$. If (X, δ) is a compact proximity space, then $A\delta B \Leftrightarrow \mathrm{Cl}_\delta A \cap \mathrm{Cl}_\delta B \neq \emptyset$. Every Hausdorff proximity space (X, δ) is a dense subspace of a unique compact Hausdorff space αX such that $A\delta B$ in X iff $\mathrm{Cl}_\delta A \cap \mathrm{Cl}_\delta B \neq \emptyset$ where $\mathrm{Cl}_\delta A$ is taken in αX. αX is called the *Smirnov compactification* of X.

G. Connected and Locally Connected Spaces

For the definition of these spaces, see Section I.A. In addition to the properties of these spaces given in that section, we have the following.

A continuous map of a topological space into another carries connected sets into connected sets. A product of connected spaces is connected. If A is a connected subset of a topological space and B is any set such that $A \subset B \subset \bar{A}$, then B is connected. Any interval of $\mathbb{R}$, including $\mathbb{R}$ itself, is connected. Each convex subset of a real topological vector space (see Section VIII.B) is connected. An interesting characterization of connected spaces is: A topological space $(X, \mathcal{T})$ is connected if and only if every continuous map f of X into a discrete space Y is constant, i.e., $f(X) = \{y\}$, $y \in Y$.

A characterization of locally connected spaces is: A topological space is locally connected if and only if the components of its open sets are open. Local connectedness is preserved under closed maps.

A connected, metrizable compactum $(X, \mathcal{T})$ is sometimes called a *continuum*. Let $(X, \mathcal{T})$ be a continuum and $(Y, \mathcal{T}')$ a Hausdorff space. If $f : (X, \mathcal{T}) \to (Y, \mathcal{T}')$ is a continuous surjective map, then $(Y, \mathcal{T}')$ is also a continuum. Further, if $(Y, \mathcal{T}')$ is locally connected, so is $(Y, \mathcal{T}')$.

A topological space each of whose components consists of a singleton is called *totally disconnected*. For example, the set of integers is totally disconnected.

H. Extensions and Embeddings

Recall Tietz's extension theorem (Section IV), which states that each continuous function from a closed subset Y of a normal space $(X, \mathcal{T})$ into $[0, 1]$ can be extended to a continuous function of X into $[0, 1]$. It can be shown that $[0, 1]$ can be replaced by any interval $[a, b]$, $-\infty < a < b < \infty$. Actually, $[a, b]$ can be replaced by unit ball $B_n = \{(x_1, \ldots, x_n), x_i \in \mathbb{R} : \sum_{i=1}^n |x_i^2| \leq 1\}$ of $\mathbb{R}^n$. Furthermore, similarly, a continuous map $f : Y \to S^n = \{(x_1, \ldots, x_n), x_i \in \mathbb{R} : \sum_{i=1}^n |x_i^2| = 1\}$ (unit sphere of $\mathbb{R}^n$) extends to a continuous map on a neighborhood of Y.

We note that the given function $f : Y \to [0, 1]$ in Tietz's extension theorem is bounded. It is possible to replace $[0, 1]$ by $\mathbb{R}$, i.e., the theorem is true even for unbounded functions. Furthermore, normality of $(X, \mathcal{T})$ can be relaxed under certain conditions.

Let Y be a compact subset of a Tychonoff space $(X, \mathcal{T})$ (note that each normal T_1-space is a Tychonoff space) and $f : Y \to [0, 1]$ a continuous function, then there exists a continuous function $\tilde{f} : (X, \mathcal{T}) \to [0, 1]$ such that $\tilde{f}(x) = f(x)$ for all $x \in Y$. Further, each continuous bounded function on a Tychonoff space $(X, \mathcal{T})$ extends to its Stone-Čech compactification βX. In this result, the implicit assumption of the range of f being in $[a, b]$ can be weakened under suitable conditions. For instance, a continuous map f of a Tychonoff space $(X, \mathcal{T})$ to a compactum Y can be extended to a continuous map $\tilde{f} : \beta X \to Y$ such that $\tilde{f}(x) = f(x)$ for $x \in X$.

Let $(X, \mathcal{U})$ be a uniform space with its uniform topology induced by $\mathcal{U}$, and Y a dense subspace of X. Then each uniformly continuous map f of Y into a complete Hausdorff uniform space Z extends to a uniformly continuous map $\tilde{f} : X \to Z$ such that $\tilde{f}(x) = f(x)$ for all $x \in Y$.

Whenever there is a bijective map between two sets, they are deemed to be set-theoretically the same. If there is a surjective homeomorphism between two topological spaces, they are regarded to be the same set-theoretically as well as topologically. However, if a homeomorphism is into, i.e., if there is a continuous open injective map f of a topological space $(X, \mathcal{T})$ into $(Y, \mathcal{T}')$, then f is called an *embedding* of X into Y. In this case, $f(X)$ need not be equal to Y but X is homeomorphic to $f(X)$ (a subset of Y) with the topology induced from Y. Embeddings of abstract topological spaces into given or known topological spaces are of paramount importance and interests.

Simple examples of embeddings are as follows: Each metric space can be embedded into a complete metric space (its completion). In particular, the set of rational numbers is embedded into reals. Each Hausdorff uniform space can be embedded into a complete Hausdorff uniform space. Somewhat more sophisticated embeddings are as follows. Each second countable T_3-space can be embedded into the Hilbert cube. Furthermore, a Hausdorff space embeds into the Cantor perfect set if and only if it has a countable base of closed–open sets. A metric space (X, d) can be embedded into a Baire space $B(\tau)$ of weight τ if and only if X has a base $\mathcal{B}$ of closed–open sets such that the cardinality of $\mathcal{B}$ is less than or equal to τ. Each uniform space embeds in a product of pseudometric spaces and each Hausdorff uniform space embeds into a product of metric spaces.

Topological spaces having a base of closed–open sets are called *0-dimensional*. Every 0-dimensional T_0-space is completely regular. In a compact 0-dimensional space, two disjoint closed subsets can be separated by two disjoint open sets whose union is the whole space. Every locally compact totally disconnected space is 0-dimensional.

I. Topologies Defined by an Order

Let $(X, \leq)$ be a linearly ordered set, i.e., for $x, y \in X$, "$x \leq y$" means that "x is less than or equal to y," and for all $x, y \in X, x \neq y$, either $x < y$ or $y < x$. The notation $(x, y) = \{z \in X : x < z < y\}$ is called an "interval" in X. The collection of all such intervals forms a base of a topology on X, called the *order topology*, and $(X, \leq)$ endowed with the order topology is called an *ordered space*. $\mathbb{R}$ is an ordered space. An ordered space which is sequential is first countable. A discrete space is an ordered space. Unlike metric spaces, a separable ordered space need not be second countable.

$\mathbb{R}^2$ with the usual metric topology is not an ordered space. Let $I^2 = [0, 1] \times [0, 1]$ be the unit square in $\mathbb{R}^2$. We define the ordering in I^2 as follows: $(a_1, b_1) \leq (a_2, b_2)$ if and only if $a_1 < a_2$ or $a_1 = a_2$ and $b_1 < b_2$. This is called *dexicographic ordering* on I^2. Thus one obtains an order topology on I^2. It is possible to show from this example that a subspace of an ordered space need not be an ordered space.

We end this section with two diagrams indicating the interconnection of some spaces studied above. (As usual, $A \to B$ means that A is contained in B.)

$$\begin{array}{ccccc} & & \text{locally compact } T_2 & & \\ & \nearrow & & \searrow & \\ \text{Compact } T_2 & & & & \text{Baire} \to k\text{-space} \to k_r\text{-space.} \\ & \searrow & & \nearrow & \\ & & \text{complete metric} & & \end{array} \tag{1}$$

$$\begin{array}{ccccccc} \text{Metric compact} & \to \text{compact} \to & \left\{\begin{array}{l}\text{locally compact}\\ \sigma\text{-compact}\end{array}\right\} & \to & \text{paracompact} \\ \downarrow & & & & \downarrow \\ \begin{array}{l}\text{locally compact}\\ \text{2nd countable}\end{array} & \to \text{Polish} \to \text{Souslin} & & & \to \text{metric} \to \text{normal.} \end{array} \tag{2}$$

As pointed out above, a continuous function may not have a fixed point in general. However, if the space is restricted, one has a different situation. Specifically, if $D^n = \{(x_1, \ldots, x_n) \in \mathbb{R}^n : x_1^2 + \cdots + x_n^2 \leq 1\}$ is the closed n-dimensional disk, each continuous map $f : D^n \leftarrow D^n$ has a fixed point but not necessarily unique. This is known as the Brouwer fixed point theorem in the mathematical literature. This result has many extensions in functional analysis.

VI. FIXED POINTS

The information regarding those points that remain fixed under certain transformations is very useful. It can be put to work in many fields (e.g., differential equations and algebraic topology).

Let X be a set and $f : X \to X$ a self-map. $x \in X$ is called a *fixed point* of f if $f(x) = x$. Indeed, the identity map $i : X \to X, i(x) = x$, keeps every point of X fixed. On the other hand, $f : \mathbb{R} \to \mathbb{R}$ when $f(x) = e^x + 1$ has no fixed point. Neither of these extreme cases has useful applications. The case where there exists a unique fixed point is of utmost significance. The result that guarantees the existence and uniqueness of a fixed point is known as the contraction principle.

Let (X, d) be a metric space. A map $f : X \to X$ is called a *contraction* if there exists α, $0 \leq \alpha < 1$, such that for all $x, y \in X$ we have

$$d(f(x), f(y)) \leq \alpha d(x, y).$$

It is obvious that a contraction map is uniformly continuous (hence, continuous), but not conversely.

A. Contraction Principle

Each contraction map $f:(x,d)\to(X,d)$ of a complete metric space (X,d) has a unique fixed point.

Some important extensions are as follows: If C is a convex compact subset of a normed space (see Section VIII.B for the definitions), then a continuous map $f:C\to C$ has a fixed point (Banach–Schauder theorem). This is generalized by Tychonoff: Let C be a convex compact subset of a locally convex space (see Section VIII.B); then a continuous map $f:C\to C$ has a fixed point. An important contribution to fixed point theorems is due to Markov and Kakutani: Let C be a convex compact subset of a locally convex space. Let $\{f_\alpha:\ \alpha\in\Gamma\}$ be a family of continuous maps from C to C such that each f_α is *affine* [i.e., for all $x,y\in C$ and $0<t<1$, $f_\alpha(tx+(1-t)y)=tf_\alpha(x)+(1-t)f_\alpha(y)$] and the family is commuting [i.e., $f_\alpha\circ f_\beta(x)=f_\beta\circ f_\alpha(x)$ for all $x\in C$]. Then there is $x_0\in C$ such that $f_\alpha(x_0)=x_0$ for all $\alpha\in\Gamma$, i.e., the family $\{f_\alpha\}$ has a common fixed point.

VII. FUNCTION SPACES

So far we have been concerned with the properties of topological spaces and maps. In this section we want to topologize certain sets of functions. One might say that so far we have been working on the ground floor and now we want to move up to the first floor.

Let X,Y be two nonempty sets. Y^X denotes the set of *all* maps $f:X\to Y$. If X,Y are topological spaces, then $C(X,Y)$ denotes the set of all continuous maps of X into Y. Clearly, $C(X,Y)$ is a subset of Y^X. Both Y^X and $C(X,Y)$ with some appropriate topologies are called function spaces. Several topologies are very useful. Two of them are point-open topology and compact-open topology.

For each $x\in X$ and each open set V in Y, let $T(x,V)=\{f\in Y^X: f(x)\in V\}$. As x runs over X and V over all open subsets of Y, the collection $\{T(x,V)\}$ forms a subbase of a topology called the *point-open topology* and is denoted $\mathcal{T}_p$. Similarly, if K is a compact subset of X and V an open subset of Y, then

$$T(K,V)=\{f\in Y^X: f(x)\in V \text{ for all } x\in K\}.$$

The topology (denoted $\mathcal{T}_c$) having the collection $\{T(K,V)\}$ as a subbase is called the *compact-open topology*. Since each singleton is compact, it follows that $\mathcal{T}_c$ is finer than $\mathcal{T}_p$. Hence, the induced topology $\mathcal{T}_c$ on $C(X,Y)$ is finer than the induced topology $\mathcal{T}_p$. If Y is a Hausdorff space, both $(Y^X;\mathcal{T}_p/\mathcal{T}_c)$ and $(C(X,Y),\mathcal{T}_p/\mathcal{T}_c)$ are also Hausdorff spaces.

The following three cases are noteworthy. If (X,d) is a metric locally compact space and (Y,d') a complete metric space, then $(C(X,Y),\mathcal{T}_c)$ is a complete uniform space. If (X,d) is a compact metric space and (Y,d') a complete metric, then $(C(X,Y),\mathcal{T}_c)$ is a complete metric space with metric $d^+(f,g)=$ the least upper bound of $d'(f(x),g(x))$, $x\in X$ for $f,g\in C(X,Y)$. Thus, for a compact metric space (X,d), $C(X)=C(X,\mathbb{R})$ is a complete metric space. The same is true for $C[a,b]$.

Hereafter, both $C(X,\mathbb{R})$ and $C(X,\mathbb{C})$ are denoted $C(X)$, the space of all real- or complex-valued continuous functions on the topological space $(X,\mathcal{T})$. Indeed, if X is compact, then each $f\in C(X)$ is bounded and $\|f\|=$ the least upper bound of $\{|f(x)|, x\in X\}$ is finite. $\|f\|$ is called the *norm* of f and $d(f,g)=\|f-g\|$ gives a metric on $C(X)$ which is complete. For each fixed $x\in X$, $\varphi_x(f)=f(x)$, $f\in C(X)$, defines a map of $C(X)$ into $\mathbb{R}$ or $\mathbb{C}$. φ_x is called an *evaluation map*. The map φ_x is useful. We come back to it later.

In some particular cases, the topological space X can be embedded in $C(X)$. For instance, let (X,d) be a metric space and $C_b(X)$, the space of all continuous bounded functions on X. $C_b(X)$ is a metric space with the metric $d^+(f,g)=$ the least upper bound of $\{|f(x)-g(x)|: x\in X\}$, $f,g\in C_b(X)$. Now let $x_0\in X$ be a fixed element, and for each $y\in X$, set $f_y(x)=d(x,y)-d(x,x_0)$, $x\in X$. Then for each $y\in X$, $f_y\in C_b(X)$ and the map $y\to f_y$ of X into $C_b(X)$ is an isometry. Thus X can be isometrically embedded in $C_b(X)$. If X is compact, then $C_b(X)=C(X)$ and so each compact metric space can be isometrically embedded in $C(X)$.

If X,Y are topological spaces, then a continuous map $f:X\to Y$ induces a map $f^*:C(Y)\to C(X)$ by $f^*(g)=g\circ f$ (composition map). It is interesting to know what properties of f induce similar properties for f^*. An important scenario occurs when both X and Y are compact, viz., X,Y are homeomorphic if and only if $C(X),C(Y)$ are isometrically homeomorphic.

VIII. MARRIAGE OF TOPOLOGY AND ALGEBRA

Algebraic operations such as addition, subtraction, multiplication, and division play an important role in algebra. Topology, however, is not primarily concerned with them. When algebra and topology are married in the sense that a set with algebraic operations is endowed with a topology, new and interesting theories emerge. For instance, in the field of functional analysis (a major branch of mathematics), the topics of topological groups, topological vector

spaces, and topological algebras, among others, are the outcome of this marriage.

Among many topics in algebra, one specifically comes across the following algebraic structures: semigroups, groups, vector spaces, and algebras. By endowing them with topologies so that the underlying algebraic operations are continuous, one obtains interesting areas of mathematics.

A. Topological Semigroups and Groups

A set S with an associative binary operation [i.e., for all $x, y \in S$, $x \circ y \in S$ and $x \circ y \circ z = (x \circ y) \circ z = x \circ (y \circ z)$, in which "$\circ$" denotes the binary operation] is called a *semigroup*. A semigroup S with a topology $\mathcal{T}$ is called a *topological semigroup* (TS) if the map $(x, y) \to x \circ y$ of $S \times S$ into S is continuous.

A semigroup G is called a *group* if G has an *identity* $e (e \circ x = x \circ e = x$ for $x \in G)$ and each $x \in G$ has an *inverse* x^{-1} $(x^{-1} \circ x = x \circ x^{-1} = e)$. According to whether "$\circ$" is "$+$" or "$\times$," the group is called *additive* or *multiplicative*. If $x \circ y = y \circ x$, for all $x, y \in G$, the group G is called *Abelian* or *commutative*. A map f of a group G into a group H is called a *homomorphism* if $f(xy) = f(x) f(y)$. A bijective homomorphism of a group G into a group H is called an *isomorphism*.

A group G with a topology is called a *topological group* (TG) if the map $(x, y) \to xy^{-1}$ of $G \times G$ into G is continuous.

Each topological group is a uniform space, hence completely regular. If the topology satisfies the T_0-axiom, the topological group becomes a Tychonoff space, hence Hausdorff. A Hausdorff topological group is metrizable iff the neighborhood system at its identity has a countable base.

The class of all topological groups satisfies arbitrary productive properties. Moreover, the closure of each subgroup (i.e., a subset H of G such that H by its own right is a group under induced algebraic operations) is a topological group and each open subgroup is closed.

Let H be an invariant ($xH = Hx$ for all $x \in G$) subgroup of a group G. To each $x \in G$ we associate xH, called the *coset*. Let G/H denote the set of all cosets. With multiplication $(xH)(yH) = xyH$ and identity H, G/H becomes a group called the *quotient* or *factor* group. The map $\phi : x \to xH$ of G onto G/H is called the *quotient* or *canonical* map; ϕ is a homomorphism because $\phi(xy) = \phi(x)\phi(y)$. If G is a topological group, we can endow G/H with the quotient topology (see Section III), making ϕ continuous. It turns out that ϕ is a continuous, open, and surjective homomorphism of the topological group G into the topological group G/H. The quotient topology on G/H is Hausdorff iff H is closed.

1. Examples

$\mathbb{R}^n$ $(n \geq 1)$ with coordinatewise addition $(x_1, \ldots, x_n) + (y_1, \ldots, y_n) = (x_1 + y_1, \ldots, x_n + y_n)$ is an additive Abelian group and has identity $(0, \ldots, 0)$. With the euclidean topology defined in Section 1.A, $\mathbb{R}^n$ is an Abelian additive topological group. In particular, the set $\mathbb{R}$ of all real numbers is an Abelian additive topological group in which $\mathbb{Z}$, the subgroup of all integers, is a closed invariant subgroup. Thus, the quotient group $\mathbb{R}/\mathbb{Z}$ is a topological group. We denote $\mathbb{R}/\mathbb{Z}$ by $\mathbb{T}$. $\mathbb{T}$ is actually isomorphic with the circle group $\{e^{it} : 0 \leq t \leq 2\pi, i = \sqrt{-1}\}$. Hence, $\mathbb{T}$ is a compact Abelian topological group.

If G is an Abelian topological group, the set G' of all continuous homomorphisms $\phi : G \to \mathbb{T}$ is called the *dual group* of G. We can endow G' with the compact-open topology $\mathcal{T}_c$ (see Section VII). If G is a Hausdorff locally compact Abelian topological group, then $(G', \mathcal{T}_c)$ is also a Hausdorff locally compact Abelian topological group. Repeating the process, we see that G'' (the dual group of G') with the compact-open topology is also a locally compact Abelian topological group. A celebrated result called the Pontrjagin duality theorem tells us that G and G'' are isomorphic and homeomorphic. Furthermore, if G is compact (discrete), G' is discrete (compact).

If algebraic operations in a topological group with some additional structure are differentiable instead of being only continuous, it leads to the theory of Lie groups, which form an important branch of mathematics.

B. Topological Vector Spaces, Banach Spaces, and Hilbert Spaces

An algebraic system that is richer than groups is vector space. All scalars involved in this section are either real or complex numbers.

An Abelian additive group E is called a *real* or *complex* (depending on which scalars are used throughout) *linear* or *vector space* if for all $x \in E$ and scalar λ, $\lambda x \in E$ satisfies the following: $\lambda(x + y) = \lambda x + \lambda y$; $(\lambda + \mu)x = \lambda x + \mu x$; $\lambda(\mu x) = (\lambda\mu)x$ for all scalars λ, μ and all $x, y \in E$; $1x = x$ and $0x = 0$, the identity of the additive group E. If $F \subset E$ and F is a vector space in its own right over the same scalars as those of E, then F is called a *linear subspace* of E. A subset C of E is called *circled* if for scalars λ, $|\lambda| \leq 1$ and $x \in C$, $\lambda x \in C$. A subset C of a vector space E is called *convex* if for all $x, y \in C$ and $0 \leq \lambda \leq 1$, $\lambda x + (1 - \lambda)y \in C$. C is *absorbing* if for all $x \in E$ there is $\alpha_0 > 0$ such that for λ, $|\lambda| \geq \alpha_0$, $x \in \lambda C$.

A linear or vector space E endowed with a topology $\mathcal{T}$ is called a *topological linear* or *vector space* (TVS) if the maps $(x, y) \to x + y$ and $(\lambda, x) \to \lambda x$ of $E \times E$ into E and of $K \times E$ into E, respectively, are continuous, in

which the field K of real numbers or complex numbers is endowed with its natural topology. If there exists a base of convex neighborhoods of identity 0 in E, then E is called a *locally convex* (LC) space.

Clearly, each topological vector space is an Abelian additive topological group, hence it is a uniform space and, therefore, completely regular. Hence, a Hausdorff topological vector space is a Tychonoff space. As for topological groups, a Hausdorff topological vector space is metrizable iff the neighborhood system at 0 has a countable base. Among the metrizable topological vector spaces, there is a very distinguished and useful subclass of spaces called the normable spaces defined below.

Let E be a real (or complex) vector space. A map $p : E \to K$ is called a *functional*. If $p(x) \geq 0$ for all $x \in E$ such that $p(\lambda x) = |\lambda| p(x)$ and $p(x+y) \leq p(x) + p(y)$, then p is called a *seminorm*. If $p(x) = 0 \Leftrightarrow x = 0$, then p is called a *norm*, denoted $p(x) = \|x\|$. A seminorm p on a vector space E defines a pseudometric $d(x, y) = p(x - y)$. If p is a norm, d becomes a metric. If the topology of a topological vector space is induced by a *norm*, it is called a *normable* topological vector space. If a normable topological vector space is complete in its induced metric topology, it is called a *Banach space* (BAS). Each Banach space is a complete metric locally convex space called a *Fréchet space* (F). A Hausdorff locally convex space is called a *barreled space* (BS) if, in it, each *barrel* (convex, circled, absorbing, and closed set) is a neighborhood of 0. Each Baire locally convex (BLC) space is a barreled space, and each Fréchet space is a Baire space.

A map f of a vector space E into another vector space F is called *linear* if $f(\alpha x + \beta y) = \alpha f(x) + \beta f(y)$ for all $x, y \in E$ and scalars α, β. A functional f on a normed space E is called *bounded* if there is a real number $M > 0$ such that $|f(x)| \leq M\|x\|$ for all $x \in E$. An interesting but simple fact is that a linear functional on a normed space is bounded iff it is continuous.

To exhibit the richness that results from the marriage of topology and vector spaces, we cite a few prototypical results.

The first is the so-called Hahn–Banach extension theorem: Let F be a linear subspace of a vector space E. Let p be a seminorm on E, and f a linear functional on F such that $|f(x)| \leq p(x)$ for all $x \in F$. Then there exists a linear functional $\tilde{f}$ on E such that $\tilde{f}(x) = f(x)$ for all $x \in F$ and $|\tilde{f}(x)| \leq p(x)$ for all $x \in E$. It is worth comparing this result with Tietze's extension theorem given in Section IV.

The heart of functional analysis, especially that of topological vector spaces, lies in the so-called *twins* of functional analysis, popularly known as the open-mapping and closed-graph theorems.

1. Open-Mapping Theorem

Each continuous linear surjective map of a Fréchet (in particular, Banach) space onto a barreled (in particular, Fréchet or Banach) space is open.

2. Closed-Graph Theorem

Each linear map of a barreled (in particular, Fréchet or Banach) space into a Fréchet (or Banach) space with closed graph is continuous.

Another important result in topological vector spaces is as follows. If $\{f_n\}$ is a sequence of continuous linear functionals on a barreled (or Fréchet or Banach) space E such that $f(x) = \lim_n f_n(x)$, $x \in E$, then f is also linear and continuous. (This is called the Banach–Steinhaus theorem.)

If E is a real or complex topological vector space, the set E' of all continuous linear functionals on E is called the *dual* of E. If E is a normed space, so is E' with the norm $\|f\| =$ the least upper bound of $\{|f(x)| : \|x\| \leq 1\}$. Actually E' is a Banach space regardless of E being a complete or incomplete normed space. In special cases E' can be determined by the points of E, as shown below.

A normed space E is called a *pre-Hilbert* or *an inner product space* if the norm $\|\cdot\|$ satisfies the so-called *parallelogram law*: $\|x+y\|^2 + \|x-y\|^2 = 2(\|x\|^2 + \|y\|^2)$. The parallelogram law implies the existence of a bilinear functional $\langle , \rangle : E \times E \to K$ satisfying the following properties: $\langle x, x\rangle \geq 0$; $\langle x, x\rangle = 0 \Leftrightarrow x = 0$; $\langle x + y, z\rangle = \langle x, z\rangle + \langle y, z\rangle$; and $\langle x, y\rangle = \langle y, x\rangle$ (or $\overline{\langle y, x\rangle}$ for the complex scalars). We see that $\|x\| = +\sqrt{\langle x, x\rangle}$ gives a norm. If a pre-Hilbert space is complete, it is called a *Hilbert space* (H). For a Hilbert space H, its dual H' can be identified with the points of H as demonstrated by the so-called Riesz representation theorem: If H is a Hilbert space, then for each $f \in H'$ there exists a unique element $y_f \in H$ such that $f(x) = \langle x, y_f\rangle$, $x \in H$ with $\|y_f\| = \|f\|$. (See Table II for the interrelation of various topological spaces.)

Hereafter, we assume all topological vector spaces to be Hausdorff. For any vector space E over $\mathbb{R}$ or $\mathbb{C}$, E^* denotes the set of all real or complex linear functionals on E, called the *algebraic dual* of E. If E is a TVS, E' denotes the set of all continuous linear functionals on E, called the *topological dual* or simply the *dual* of E as mentioned above. If E is LC and $E \neq \{0\}$, then $E' \neq \{0\}$ and clearly $E' \subset E^* \subset \mathbb{R}^E$ (or $\mathbb{C}^E$), where $\mathbb{R}^E$ carries the pointwise convergence topology. The topology induced from $\mathbb{R}^E$ to E' is called the weak-star or w^*-*topology*. Under this topology all maps $f \to f(x)$ (for each fixed x, i.e., evaluation maps) are continuous.

Similarly, the coarsest topology on E which makes all the maps $x \to f(x)$ (for any fixed $f \in E'$) continuous

is called the *weak topology* $\sigma(E, E')$ on E, which is coarser than the initial topology of E. The space E with the weak topology $\sigma(E, E')$ becomes an *LC* space. The finest locally convex topology on E that gives the same dual E' of E is called the *Mackey topology* $\tau(E, E')$, which is finer than the initial topology $\mathcal{T}$ of E. Thus we have $\sigma(E, E') \subset \mathcal{T} \subset \tau(E, E')$. An *LC* space with the Mackey topology [i.e., $\mathcal{T} = \tau(E, E')$] is called a *Mackey space*. Every barreled (hence Fréchet, Banach, or Hilbert) space is a Mackey space. However, there exist Mackey spaces which are not Fréchet spaces. The weak, weak*, and Mackey topologies are extensively used in functional analysis. Here we list only a few samples of their usage.

Let E be a Banach space; then for each weakly compact subset A of E, the convex closure $\bar{c}_o(A)$ of A is also weakly compact, where $\bar{c}_o(A)$ is the intersection of all closed convex subsets of E containing A. Further, a weakly closed subset A of E is weakly sequentially compact if and only if A is weakly compact. This is known as the Eberlein theorem. Note that in general topological spaces sequential compactness is not equivalent to compactness. Furthermore, if A is a closed convex subset of E such that for each $f \in E'$ there is $x_f \in A$ with $|f(x_f)| =$ the least upper bound of $\{|f(x)| : x \in A\}$, then A is weakly compact. This is known as the James theorem.

As pointed out earlier, the dual E' of a normed space E is a Banach space with the norm $\|f\|$. The w^*-topology on E' is coarser than this norm topology. The unit ball $\{f \in E' : \|f\| \leq 1\}$ of E' is w^*-compact (Alaoglu's theorem) but not norm compact in general. *Actually*, the unit ball of a normed space E is norm compact iff E is finite-dimensional, i.e., E is homeomorphic to $\mathbb{R}^n$ (or $\mathbb{C}^n$) for some finite positive integer n.

Since the dual E' of a normed space E is a normed (actually Banach) space, we can consider the dual E'' of E'. E'' is called the *bidual* of E. Clearly E'' is also a Banach space. There is a natural embedding of E in E''. Put $x''(f) = f(x)$, $f \in E'$, for each $x \in E$. Then it can be verified that $x'' \in E''$ for each $x \in E$ and so $x \to x''$ gives a mapping of E into E'' such that $\|x''\| = \|x\|$. Thus E is embedded into E'' isometrically. In general this embedding is not surjective, i.e., $E \subset E''$, $E \neq E''$. Whenever $E = E''$, E is called *reflexive*. Since E'' is a Banach space, it follows that a reflexive normed space must be a Banach space. By virtue of the Riesz representation theorem, each Hilbert space is reflexive. Here are some examples of reflexive and nonreflexive spaces. Let $1 \leq p < \infty$ be a given real number. Let $\ell_p = \{\{a_i\} : \sum_{i=1}^{\infty} |a_i|^p < \infty\}$. Then ℓ_p is a Banach space with the norm $\|\{a_i\}\|_p = \{\sum_{i=1}^{\infty} |a_i|^p\}^{\frac{1}{p}}$. For all $p's$, $1 < p < \infty$, ℓ_p is a reflexive Banach space; note that ℓ_2, being a Hilbert space, is reflexive, but ℓ_1 is not reflexive. Note that for $1 < p < \infty$, $\ell_p' = \ell_q$, where $(1/p) + (1/q) = 1$ and $\ell_1' = \ell_\infty$, the space of all bounded sequences.

For a Tychonoff space $(X, \mathcal{T})$, $C(X) = (C(X), \mathcal{T}_c)$ denotes the set of all real or complex continuous functions on X, endowed with the compact-open topology $\mathcal{T}_c$ (see Section VII). One sees that $C(X)$ is an *LC* space. It is not, in general, a metrizable, or a complete, or a barreled or a Fréchet or a Banach space. As shown above, if X is compact, then $C(X)$ is a Banach space. Conversely, if $C(X)$ is a Banach space, then indeed X is compact. This immediately suggests an interplay of topological properties of X and $C(X)$.

To display this duet between X and $C(X)$ briefly, we need the following concept. Let $\mathcal{L} \in C'(X)$, the dual of $C(X)$. The smallest compact subset A of X such that for all $f \in C(X)$ with $f(A) = 0$ implies $\mathcal{L}(f) = 0$ is called the *support* of $\mathcal{L}$, denoted $\text{supp}\mathcal{L}$. If B' is a subset of $C'(X)$, then $\text{supp}B' = \text{Cl}\{\cup(\text{supp}\mathcal{L} : \mathcal{L} \in B')\}$ is the support of B'. Now we have the following:

- $C(X)$ is a Banach space iff X is compact.
- $C(X)$ is metrizable iff X is hemicompact.
- $C(X)$ is complete iff X is a k_r-space.
- $C(X)$ is a Fréchet space iff X is a hemicompact, k_r-space.
- $C(X)$ is a Mackey space iff $\text{supp}B'$ is compact for each convex circled w^*-compact subset B' of $C'(X)$.
- $C(X)$ is a barreled space iff X is a μ-space [i.e., for each w^*-bounded subset B' of $C'(X)$, $\text{supp}B'$ is compact].

C. Topological Algebras

An algebraic structure richer than vector spaces is what is known as algebra. A real or complex vector space A is called an *algebra* if there is some multiplication defined on A, that is, for all $x, y \in A$, $xy \in A$ satisfying the following axioms: $x(y + z) = xy + xz$; $(x + y)z = xz + yz$; $\lambda(xy) = (\lambda x)y = x(\lambda y)$; $x(yz) = (xy)z = xyz$ for all $x, y, z \in A$ and scalar λ. An algebra A is called *commutative* if $xy = yx$ for all $x, y \in A$. A has an identity e if $ex = xe = x$ for all $x \in A$. An element $x \in A$ is called *invertible* if there is $y \in A$ such that $xy = yx = e$. y is called the *inverse* of x and written $y = x^{-1}$. An algebra in which each nonzero element has an inverse is called a *division* algebra. An operation $^* : x \to x^*$ of A onto A is called an *involution* if $(x+y)^* = x^* + y^*$, $(\lambda x)^* = \bar{\lambda} x^*$, $(xy)^* = y^* x^*$, and $x^{**} = x$.

An algebra A with a topology $\mathcal{T}$ is called a *topological algebra* (TA) if the maps $(x, y) \to x + y$, $(\lambda, x) \to \lambda x$, and $(x, y) \to xy$ are continuous. It is clear that each topological algebra is a topological vector space. Hence, the results pertaining to topological vector spaces can be

used for topological algebras. If the topology is given by a norm on an algebra, it is called a *normed algebra*, provided that $\|xy\| \leq \|x\|\|y\|$. A complete normed algebra is called a *Banach algebra* (BAA). A Banach algebra with an involution * is called a B*-algebra if $\|xx^*\| = \|x\|^2$ for all x. We deal with these algebras in the next section.

If the topology of a topological algebra is locally convex, it is called a *locally convex algebra*. A complete metric locally convex algebra is called a *B_0-algebra* (B_0-A). Clearly, each Banach algebra is a B_0-algebra.

Examples of nonnormed algebras also abound in the literature. For example, for any Tychonoff space $(X, \mathcal{T})$, the set $C(X)$ of all continuous real or complex functions forms an algebra with pointwise operations, i.e.,

$$(f+g)(x) = f(x) + g(x), \qquad (\lambda f)(x) = \lambda f(x),$$
$$(fg)(x) = f(x)g(x),$$

where λ is a real or complex scalar. With the compact-open topology T_c, $C(X)$ is actually a locally convex algebra. Among many applications associated with $C(X)$, there is a celebrated result called the Stone–Weierstrass theorem: Let A be a subalgebra of $C(X)$ such that

(i) for all $x, y \in X$, $x \neq y$, there is $f \in A$ with $f(x) \neq f(y)$, (i.e., A separates points of X),
(ii) for each $x \in X$, there is $f \in A$ with $f(x) \neq 0$, and
(iii) for each $f \in A$, the complex conjugate $\bar{f}$ [i.e., $\bar{f}(x) = \overline{f(x)}$] is in A.

Then A is dense in $C(X)$ [i.e., $\bar{A} = C(X)$]. If, in addition, A is a closed subalgebra of $C(X)$, then $A = C(X)$. Note that condition (iii) is redundant for real algebras. From this theorem, one derives the classical Weierstrass theorem: Each continuous real function on $[a, b]$, $-\infty < a < b < \infty$, can be approximated by polynomials.

IX. BANACH ALGEBRAS

Banach algebras form an important subclass of topological algebras because they have a richer structure owing to the norm. Hence, they have more useful applications. The theory of Banach algebras can be used to advantage in mathematical analysis, Fourier series, representation theory, and other significant areas of mathematics.

An important result revealing a basic fact about Banach division algebra is the so-called Gelfand–Mazur theorem: A complex Banach division algebra is isomorphically homeomorphic with the algebra of complex numbers.

A functional f on an algebra A is called *multiplicative* if $f(xy) = f(x)f(y)$. A simple but beautiful result regarding multiplicative functionals is as follows. Each multiplicative linear functional on a Banach algebra is continuous. It is beautiful because an algebraic hypothesis (namely, linearity and multiplicativity) gives a topological conclusion (namely, the continuity). It is not known if this beautiful result is true for Fréchet algebras [i.e., those B_0-algebras whose topology is defined by a sequence of seminorms $\{p_n\}$ such that $p_n(xy) \leq p_n(x)p_n(y)$ for all $x, y \in A$].

If $\Delta(A)$ denotes the set of all nonzero multiplicative linear functionals on a commutative Banach algebra A, the above result says that $\Delta(A) \subset A'$, the dual of A. The set $\Delta(A)$ endowed with the $\mathcal{T}_p$ topology is called the *maximal ideal space* of A. $\Delta(A)$ is locally compact, but if the Banach algebra has identity, $\Delta(A)$ is a compact Hausdorff space.

Banach algebras are often grouped into three classes: function algebras, group algebras, and operator algebras. Function algebras are the targets of study in topology, whereas group algebras are studied in harmonic analysis and operator algebras in operator theory. The latter two constitute large fields of mathematics.

Here we consider only an instance of function algebras. Let $(X, \mathcal{T})$ be a compact Hausdorff space and $C(X)$ the set of all continuous complex-valued functions on X. With algebraic operations $(f+g)(x) = f(x) + g(x)$, $(\lambda f)(x) = \lambda f(x)$, $(fg)(x) = f(x)g(x)$, $C(X)$ becomes a complex algebra. If we put $\|f\| =$ the least upper bound of $\{|f(x)|, x \in X\}$, we have a norm on $C(X)$ with $\|fg\| \leq \|f\|\|g\|$. Using the last result in Section VII, $C(X)$ is complete in the norm topology. In other words, $C(X)$ is a Banach algebra. It is commutative and has identity $1(1(x) = 1)$. Moreover, there is an involution $f^*(x) = \overline{f(x)}$, complex conjugate. One can verify that $\|ff^*\| = \|f\|^2$. Thus, $C(X)$ is a B*-algebra. It was a crowning achievement of I. Gelfand and M. Naimark (Russian mathematicians) to show that each commutative B^*-algebra with identity is isometric (i.e., norm goes into norm) to $C(X)$ for some compact Hausdorff space X. Actually, it turns out that $X = \Delta(A)$, the maximal ideal space of A.

X. ALGEBRAIC TOPOLOGY

Certain properties of topological spaces, such as "invariance" and "congruence," can, under suitable conditions, be expressed in terms of groups—specifically homotopy and homology groups—associated with spaces. The study of this phenomenon constitutes part of an important field of mathematics called algebraic topology. Among many fascinating topics in this area, there are two noteworthy theories: homotopy and homology.

A. Homotopy

Let X, Y be two topological spaces and $I = [0, 1]$. Two maps $f, g: X \to Y$ are said to be *homotopic* (written $f \sim g$) if there exists a continuous map $\phi: X \times I \to Y$ such that $\phi(x, 0) = f(x)$ and $\phi(x, 1) = g(x)$ for $x \in X$. If g is a constant map [i.e., $g(x) = y_0 \in Y$ for all $x \in X$) and $f \sim g$, then f is called *null homotopic* and written $f \sim 0$.

In some cases each map is null homotopic. For instance, if $f: X \to \mathbb{R}^n$ or $g: \mathbb{R}^n \to Y$, then $f \sim 0$ and $g \sim 0$. However, it fails if we replace $\mathbb{R}^n$ by $S^{n-1} = \{(x_1, \ldots, x_n) \in \mathbb{R}^n : x_1^2 + \cdots + x_n^2 = 1\}$, the n-dimensional sphere.

The relation $f \sim g$ is an equivalence relation ($f \sim f$; $f \sim g \Rightarrow g \sim f$; $f \sim g$ and $g \sim h \Rightarrow f - h$). Thus, the homotopic relation decomposes $C(X, Y)$ into disjoint equivalence classes $\dot{f}$ ($g \in \dot{f} \Leftrightarrow f \sim g$) called the *homotopic classes*, which are denoted $[X, Y]$. If $\Psi: X \to Y$ is continuous, then for any topological space Z, there exists a map $\Psi^*: [Y, Z] \to [X, Z]$ defined by $\Psi^*(f) = f \circ \Psi$, $f \in [Y, Z]$. Thus, the topological properties of $\Psi: X \to Y$ can be studied by means of the properties of Ψ^*, and vice versa.

Homotopy is actually the study of the extension of maps, to which the reader has been introduced in previous sections. For $f \sim g$ iff the map $\phi: (X \times \{0\}) \cup (X \times \{1\}) \to Y$ defined by $\phi(x, 0) = f(x), \phi(x, 1) = g(x), x \in X$ can be extended to a continuous map $\tilde{\phi}$: $X \times I \to Y$. Such an extension in a particular case has a special name.

Two topological spaces X, Y are said to be *homotopic* if there exist continuous maps $f: X \to Y$ and $g: Y \to X$ such that the composition maps $f \circ g$ and $g \circ f$ are homotopic to the identity maps of Y and X, respectively. The symbol "$X \approx Y$" means that X is homotopic to Y.

It is easy to see that the relation of being homotopic is an equivalence relation on the class of all topological spaces. It follows easily that if X is homeomorphic with Y, then $X \approx Y$. But the converse need not be true. For example, $\mathbb{R}^n$ is homotopic to $\{0\}$ but is not homeomorphic.

The equivalence relation of being "homotopic" decomposes the class of all topological spaces into disjoint equivalence classes of homotopic spaces.

A property of a topological space is called a *topological* (respectively, *homotopic*) *invariant* if it remains *unaltered* under homeomorphisms (respectively, homotopic maps). Most topological invariants are not *homotopic invariants*. But some of them are.

A topological space (X, T) is called *pathwise connected* if for each pair $a, b \in X$, $a \neq b$, there is a path $f: I \to X$ such that $f(0) = a$, $f(1) = b$, $\mathbb{R}^n$, S^n (for $n \geq 1$) are pathwise connected. Pathwise connectedness is a homotopic invariant.

1. Retracts

A subset A of a topological space $(X, \mathcal{T})$ is said to be a retract of X if the identity map $i: A \to A (i(x) = x)$ can be extended to a continuous map $f: X \to A$ so that $f(x) = x$ for all $x \in A$. In this case f is called a *retract*.

Each retract of a Hausdorff topological space is closed. Each closed unit disk $D^n = \{(x_1, \ldots, x_n) \in \mathbb{R}^n : x_1^2 + \cdots + x_n^2 \leq 1\}$ is a retract of $\mathbb{R}^n$ and each sphere S^{n-1} is a retract of $\mathbb{R}^n \backslash \{0\}$.

A topological space Y is called an AR for *absolute retract* [or *AR* (*normal*)] if for any topological (respectively, normal) space X and a closed subjset $A \subset X$, each continuous map $A \to Y$ has a continuous extension to a map $X \to Y$. As shown in Tietze's extension theorem (Section IV), $\mathbb{R}$ is an AR (normal).

A subset E of a topological space $(X, \mathcal{T})$ is said to be *deformable* into a subset $F \subset X$ if the identity map $i: E \to E$ is homotopic in X to a map of E into F. Deformability is *topologically invariant*; that is, if $\phi: X \to Y$ is a homeomorphism, then $\phi(E)$ is deformable to $\phi(F)$ whenever E is deformable to F. For example, $\mathbb{R}^n \backslash \{0\}$ is deformable to S^{n-1}.

2. Degree

Another property of a map that is invariant under homotopy is the degree of a self-map of S^n. If $f: S^n \to S^n$ is a continuous map, there exists an integer $D(f)$ (positive, negative, or zero) called the *degree* of f. In the simple case of $n = 1$, the degree of $f: S^1 \to S^1$ (note that S^1 is the circle) represents the number of time and sense that the image point $f(x)$ rotates around S^1 when x rotates in one oriented direction of S^1. For example, the degree of $f(z) = z^n$ when f maps S^1 into S^1 is n. It follows that if $f, g: S^n \to S^n$, then $f \sim g \Leftrightarrow D(f) = D(g)$. From this or otherwise. Brouwer derived the fact that the identity map of S^n is not null homotopic. However, if $m < n$ and $f: S^m \to S^n$, then $f \sim 0$. If $m > n$, the situation is in general uncertain. However, if $n > 1$, then $f: S^n \to S^1$ is null homotopic. If $f: S^n \to S^n$ is *antipodal* [$f(-x) = -f(x)$], $n \geq 0$, then $D(f)$ is an odd number and hence f cannot be null homotopic.

3. Jordan Curves

To study further properties of $\mathbb{R}^n$, we say that a subset A of $\mathbb{R}^n$ *separates* $\mathbb{R}^n$ if $\mathbb{R}^n \backslash A$ is not connected (see Section I). For example, the circle S^1 separates the plane $\mathbb{R}^2$. Actually the *Jordan separation theorem* states that every homeomorphic image of S^{n-1} into $\mathbb{R}^n$ separates $\mathbb{R}^n$. Furthermore, it can be derived that if $m \neq n$, then $\mathbb{R}^n$ is not

homeomorphic with $\mathbb{R}^m$. (This is called the *invariance of dimension theorem.*) In the particular case of $\mathbb{R}^2$, every homeomorphic image of S^1 separates $\mathbb{R}^2$ in exactly two components. (This is the *Jordan curve theorem.*)

4. Paths and Loops

A continuous map p of $I=[0,1]$ into a topological space $(X,\mathcal{T})$ is called a *path* in X. $p(0)=a$ is called the *starting point* of p, and $p(1)=b$ the end point of p. If $p(0)=a=p(1)=b$, then p is called a *loop*. The set of all loops having their starting and end points at a is denoted $\mathcal{P}(X,a)$ and is called the *loop space*. Clearly, $\mathcal{P}(X,a)$ is a subset of $C(I,X)$ and so it can be given the compact-open topology $\mathcal{T}_c$, (see Section VIII). The study of loop spaces can be subsumed under a general structure called the H-structure.

5. H-Structures

A topological space X with a continuous map $\eta: X \times X \to X$ is said to have an H-structure if there exists a fixed point $a \in X$ making the maps $x \to \eta(x,a)$ and $x \to \eta(a,x)$ homotopic to the identity map of X. A topological space that carries an H-structure is called an *H-space*. For example, each topological group (see Section VIII.A) carries an H-structure, and so does a loop space $\mathcal{P}(X,a)$.

In general the point a in the H-structure is not unique. Let $P=\{a:$ the maps $x \to \eta(x,a)$ and $x \to \eta(a,x)$ are homotopic to the identity map of $X\}$. P is called a *path component* of X and is said to be the *principal component* of the H-space. If Comp X denotes the discrete space of all path components, it forms a group, called the *fundamental group*, of X at a. In general, the fundamental group is not Abelian. However, if X is *path-connected* [i.e., for all pairs $a, b, a \neq b$, in X, there is a path $p: I \to X$ with $p(0)=a$, $p(1)=b$], then the fundamental group is Abelian.

In modern algebraic topology, the study of H-structures can be subsumed under *fiber structure*.

6. Fiber Spaces

A triple (X, p, B), consisting of two topological spaces, X and B, and a continuous surjective map $p: X \to B$, is called a *fiber structure*. X is called a *total* (or *fibered*) space, B a *base* space, and p a projection. We say that (X, p, B) is a fiber structure over B, and for each $b \in B$, the set $p^{-1}(b)$ is called the *fiber* over b.

Let Y be a topological space and $f: Y \to B$ a continuous function. If there exists a continuous function $\tilde{f}: X \to B$ such that $p \circ \tilde{f} = f$, then $\tilde{f}$ is called the *lifting* or *covering* of f. In particular, a lifting of the identity $i: B \to B$ is called a *cross section*.

Let $\mathcal{A}$ be a class of topological spaces. A fiber structure (X, p, b) is called a *fiber space* (or *fibration*) for the class $\mathcal{A}$ if for each Y in $\mathcal{A}$, each continuous map $f: Y \times \{0\} \to X$, and each homotopy $\varphi: Y \times I \to B$ of $p \circ f$, there exists a homotopy $\tilde{\varphi}$ of f covering φ. A fiber space for the class of all topological spaces is called a Hurewicz *fibration*.

It can be shown that if both X and B are metric spaces and if (X, p, B) is a fibration for the class of all metric spaces, then (X, p, B) is a Hurewicz fibration.

For further details and application of these ideas, the interested reader can consult any appropriate book on algebraic topology; some relevant texts are listed in the Bibliography.

B. Homology

Homology can be studied in a more general way than we do here. We are concerned with the homology of polyhedra in $\mathbb{R}^n$. Usually such a study is part of the so-called combinatorial topology, which is a part of algebraic topology.

Let $A=\{a_0, a_1, \ldots, a_m\}$ be a set of $m+1$ $(m \leq n)$ points in $\mathbb{R}^n$ such that vectors $\{a_i - a_0 : 1 \leq i \leq m\}$ are linearly independent. ($\{x_0, \ldots, x_m\}$ are linearly independent if $\sum_{i=0}^m \lambda_i x_i = 0 \Rightarrow \lambda_i = 0$, for $i = 0, \ldots, m$.) The convex hull $\Delta_m = \{\sum_{i=0}^m \lambda_i a_i : \lambda_i \geq 0, \sum_{i=0}^m \lambda_i = 1\}$ of A is called an *m-dimensional simplex*. The points in A are called the *vertices* of Δ_m. If $m=1$, then Δ_1 is a *straight line segment*. If $m=2$, Δ_2 is a *triangle*, Δ_3 a *tetrahedron*, and so on.

If $r < m$, the simplex Δ_r with vertices $\{a_0, \ldots, a_{r-1}, a_{r+1}, \ldots, a_m\}$ is called the *r-face* of Δ_m.

A finite collection K of simplexes in $\mathbb{R}^n$ is called a *geometric complex* or just a *complex* if every face of each simplex is also in K and every two simplexes, if they intersect, intersect in a common face. If a complex K contains at least one m-dimensional simplex but not an $(m+1)$-dimensional one, then K is said to be an *m-complex*. The point set of a complex is called a *polyhedron*.

If one gives an ordering to the vertices of a simplex, the simplex is said to have an *orientation* and is called an *oriented simplex*.

Let $\Delta_m^1, \Delta_m^2, \ldots, \Delta_m^{k(m)}$ denote a set of arbitrarily oriented m-simplexes in a complex K. Then $C_m = \sum_{i=1}^{k(m)} g_i \Delta_m^i$ (where g_i are integers) is called an *m-chain*. The set of all m-chains forms an Abelian additive group. If Δ_{m+1} is an $(m+1)$-dimensional simplex, $\partial \Delta_{m+1}$ denotes the sum of all m-dimensional faces. The ∂ is called the boundary of Δ_{m+1}. One can verify that $\partial^2 = 0$. An m-chain C_m is called an *m-cycle* if $\partial C_m = 0$. Let Z_m denote the set of all m-cycles. Z_m is a subgroup of the group of m-chains. An m-cycle is called *homologous* to zero if it is the boundary of an $(m+1)$-chain. The set of all

m-cycles that are homologous to zero forms a subgroup of Z_m. The quotient or factor group $Z_m/H_m = B_m$ is called the *m-dimensional homology group or Betti group* of the complex K.

Betti groups are topologically invariant that is, if the two polyhedra K and K' are homeomorphic, their respective Betti groups are isomorphic.

Using group theory from modern algebra, it can be claimed that each Betti group has a finite number of generators. These generators are of two kinds: One kind gives an infinite cyclic group, and the other kind gives groups of finite order. The number of generators of the first kind is called the *rank* of the Betti group, whereas the order of each generator of the second kind is called the *torsion coefficient* of the Betti group. These numbers are related by the so-called *Euler–Poincaré formula*:

Let K be an n-complex. Let $k(m)$ denote the number of m-simplexes of K, and $p(m)$ the m-dimensional Betti number for $m = 0, \ldots, n$. Then $\sum_{m=0}^{n}(-1)^m k(m) = \sum_{m=0}^{n}(-1)^m p(m)$. The number $\chi(K) = \sum_{m=0}^{n}(-1)^m p(m)$ is called the *Euler characteristic* of the complex K.

1. Example

For Δ_2, the triangle joining the vertices $\{a_0, a_1, a_2\}$ in $\mathbb{R}^2$, $k(0) = 3$, $k(1) = 3$, $k(2) = 1$, and so $\chi(\Delta_2) = 3-3+1 = 1$.

There are a number of fascinating topics in algebraic topology that have not been touched here, for example, dimension theory, fiber bundles, and manifolds. The interested reader can consult the Bibliography.

GLOSSARY

Absolutely continuous Designates a continuous function on an interval which can be represented as the indefinite Lebesgue integral of its a.e. defined derivative.

a.e. Abbreviates "almost everywhere," meaning except for a set of Lebesgue measure zero.

Banach space A real linear space $\mathcal{Y}$ with a norm $\| \ \|$ that is complete in that if $y_n \in \mathcal{Y}$, $n = 1, 2, \ldots,$ then $\sum_{n=1}^{\infty} \|y_n\| < +\infty$ implies existence in $\mathcal{Y}$ of $\lim_{N\to\infty} \sum_{n=1}^{N} y_n$. Its *dual* $\mathcal{Y}^*$ is the linear space of all real valued norm continuous linear functions on $\mathcal{Y}$.

$\hat{\boldsymbol{C}}[\boldsymbol{a}, \boldsymbol{b}]$ Denotes the set of functions $\mathbf{y}$ on the compact interval $[a, b]$ that are $\hat{C}$ or *piecewise continuous* in that they have one-sided limits everywhere which agree except at a finite number of points.

$\hat{\boldsymbol{C}}^{\mathbf{1}}[\boldsymbol{a}, \boldsymbol{b}]$ Denotes the set of functions $\mathbf{y}$ on the compact interval $[a, b]$ that are $\hat{C}^1$ or *piecewise* C^1 in that they are continuous and have first derivatives $\mathbf{y}'$ from the left and from the right everywhere which agree except at a finite set of points called corner points.

$\boldsymbol{C^k}$ Abbreviates "k times continuously differentiable" for $k = 1, 2, \ldots$.

$\boldsymbol{C^k(S)}$ Denotes the class of functions that are C^k on a set S when S is either an open set or the closure of an open set in $\mathbb{R}^d$. (In the latter case, functions and their designated derivatives are assumed to have continuous extensions to ∂S, the boundary of S.)

div u Denotes the divergence of a vector valued function $\mathbf{u}$ with differentiable components $u_1, u_2, \ldots, u_d$ defined on a set in $\mathbb{R}^d$.

$\boldsymbol{f\,(x, y, y')}$ Indicates a real valued function of $2d + 1$ real variables. Insofar as they exist, the partial derivatives of f are denoted by subscripts f_x, $f_{\mathbf{y}}$, $f_{\mathbf{y}'}$, where the latter pair are vector valued.

inf Abbreviates "infimum," a synonym for "greatest lower bound."

Hilbert space A Banach space $\mathcal{Y}$ whose norm at y is given by $\|y\| = |(y, y)|^{1/2}$, where $(\cdot, \cdot)$ is a fixed inner product on $\mathcal{Y}$.

Homology The branch of algebraic topology which treats invariants that arise when objects of one class bound those of another in the sense that circles bound disks or other surfaces.

$L_p(S)$ The set of functions u on a set $S \subseteq \mathbb{R}^d$ for which $|u|^p$ is Lebesgue integrable over S $(p > 0)$.

Norm A real-valued function $\|\cdot\|$ on a linear space $\mathcal{Y}$ such that (i) $\|y\| \geq 0$ with equality *iff* $y = 0$; (ii) $\|cy\| = |c|\,\|y\|$ for all scalars c; (iii) $\|y + v\| \leq \|y\| + \|v\|$, for all $y, v \in \mathcal{Y}$. It topologizes $\mathcal{Y}$ through the distance assigning metric $\rho(y, v) = \|y - v\|$, $y, v \in \mathcal{Y}$.

sup Abbreviates "supremum," a synonym for "least upper bound."

∇u Denotes the gradient of a differentiable function u defined on a set in $\mathbb{R}^d$.

Vectors They are in $\mathbb{R}^d$ for some $d = 1, 2, \ldots$ and they are denoted by bold-faced letters, unless $d = 1$. $\mathbf{u} \cdot \mathbf{v}$ denotes the scalar product between vectors $\mathbf{u}$ and $\mathbf{v}$ so that $|\mathbf{u}| = (\mathbf{u} \cdot \mathbf{u})^{\frac{1}{2}}$ gives the length of $\mathbf{u}$.

VARIATIONAL CALCULUS is the branch of mathematics that treats optimization of functions of infinitely many variables through extensions of the concepts and techniques of ordinary calculus. Nearly as old as calculus, it too represents a continuation of ancient Greek efforts to provide idealized models for our universe. Already implicit in Greek geometry is the timeless conviction that a straight line supplies the shortest path between points. Moreover, by the first century, Zenodorus had proved geometrically that a circle encloses more area than isoperimetric polygons and conjectured that a sphere has maximal volume among solids with boundary surfaces of equal area. The belief that light travels optimal paths was incorporated by Heron four centuries later in his deduction of the principle of reflection.

I. HISTORICAL PERSPECTIVE

The modern chapter opened in 1686 with Newton's investigation of optimal design for projectiles of revolution. And a decade later, Johan Bernoulli challenged his fellow mathematicians, including Newton and Leibniz, to solve a problem in Galilean dynamics by finding the *brachistochrone*. This was the name he proposed to give the curve joining fixed points displaced horizontally and vertically along which a bead would fall from rest without friction in least time. (Fig. 1).

Some sixty years earlier, Galileo had conjectured that the optimal curve would be a circular arc, but Bernoulli and all fellow respondents discovered that it must lie on a cycloid, the curve traced by a point on the rim of a wheel as it rolls along a straight horizontal path. These early mathematicians used reasoning based on physical analogy and geometry that would be questioned today and all assumed tacitly that a minimizing curve exists. (However, Bernoulli subsequently tried to prove geometrically that the cycloidal arc does minimize the time of fall.) Most arguments employed were ad hoc but that of Bernoulli's older brother Jakob offered greater scope. In his solution, Jakob computed the time of fall along a curve which varied only slightly from an hypothesized brachistochrone. Then requiring that this exceed the time along the brachistochrone itself, he introduced a limiting argument to obtain parametric equations for the optimal curve. This variational approach was used to good effect on related problems by the Bernoullis and by Johan's outstanding disciple, Euler. As subsequently developed by Lagrange and his successors, the limiting argument became that of differentiating a parameter-dependent integral, and the method became known as the *calculus of variations*, or more succinctly, *variational calculus*.

This branch of analysis has remained active since its inception partly because the desire for optimal behavior continues to spur Western development. In particular, it provides the framework for extracting governing equations for a process, physical or mathematical, that

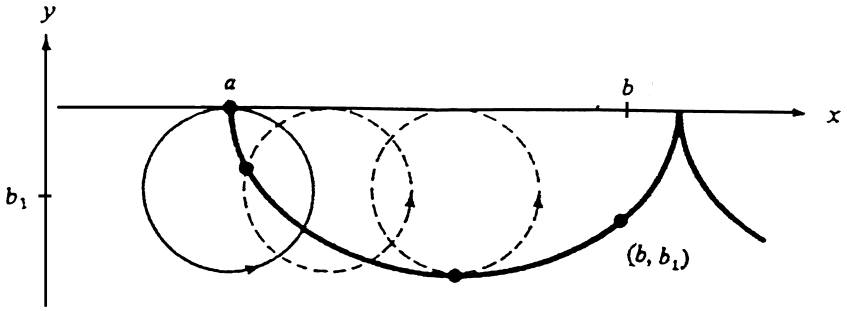

FIGURE 1 Bernoulli's brachistochrone problem.

is supposedly optimal relative to a class of competitors. Moreover, these equations can have nonoptimal solutions which suggests that other systems of equations may admit variational derivation. In previous centuries it was natural to employ variational methods when formulating and exploring principles of virtual work, least action, minimum potential energy, and under Hamilton, stationary action leading to Hamilton's equations of motion. There are also modern variational derivations of the equations of electrodynamics, relativity, and quantum mechanics.

Variational calculus together with the rest of mathematics experienced the 19th century transition from accepting intuitive conviction to demanding rigorous deduction in proofs. In lectures commencing around 1870, Weierstrass presented counterexamples to cherished claims of Gauss, Dirichlet, and Riemann concerning existence of minima in variational calculus. In modern terms, these minima were being confused with infima (greatest lower bounds), but the debacle of Dirichlet's Principle as it was called, generated issues that were only fully resolved a half century later through methods of functional analysis involving the Lebesgue integral. Even the subsequently developed tools of nonlinear functional analysis were tested and refined through application to problems in variational calculus. Consequently, it is now possible to give descriptive conditions that guarantee existence of an extremal solution to a problem in variational calculus. These conditions usually involve convexity which, expressed in various forms, lies at the heart of this subject.

Much recent activity concerns problems in optimal control that gained prominence during World War II from the need to steer a vehicle or projectile along a path deemed optimal relative to some targeted objective. Restricted versions of these problems are covered by standard variational methods and analysis of general problems led Pontrjagin and others to uncover a new principle of optimality. This principle is now invoked in disciplines as widely ranging as submarine navigation and economics, and it too has been incorporated in modern variational calculus.

Regardless of theoretical assurances, most problems in variational calculus or optimal control cannot be solved explicitly or exactly because of the nonlinearities involved. Consequently, the need for reliable methods of approximation has been apparent from the outset. In fact, Euler used piecewise linear approximations of an unknown extremal function to derive its governing equation. But serious consideration of approximation methods had to await improved understanding of convergence. Then in 1908, to approximate mode shapes of vibrating elastic plates, Ritz successfully modified earlier methods of Rayleigh and placed them in a Hilbert space setting. This approach, further modified by Galerkin and others, has been widely extended in a host of schemes formulated to take advantage of rapidly increasing computational strength.

II. ANALYTIC FOUNDATIONS

The basic problem of the variational calculus is to find or characterize a function $\mathbf{y}_0$ which optimizes (maximizes or minimizes) an integral of the form

$$F(\mathbf{y}) = \int_a^b f(x, \mathbf{y}(x), \mathbf{y}'(x))\, dx \tag{1}$$

on a set $\mathcal{D}$ of differentiable vector-valued functions $\mathbf{y}$ defined on the compact interval $[a, b]$. Here, f is a given real-valued function on a set $[a, b] \times D$ for a given domain D of $\mathbb{R}^{2d}$, and we assume that the composite $f[\mathbf{y}(x)] \stackrel{\text{def}}{=} f(x, \mathbf{y}(x), \mathbf{y}'(x))$ is Riemann integrable over $[a, b]$, for all $\mathbf{y}$ in $\mathcal{D}$. We also assume initially that the functions $\mathbf{y}$ in $\mathcal{D}$ meet fixed endpoint conditions of the form

$$\mathbf{y}(a) = \mathbf{a}, \qquad \mathbf{y}(b) = \mathbf{b}. \tag{2}$$

Since the maximum value of F on $\mathcal{D}$ would be given by a function $\mathbf{y}_0$ that minimizes $-F$ on $\mathcal{D}$, we can restrict attention to minimization issues.

For example, the minimum value of

$$L(\mathbf{y}) = \int_a^b |\mathbf{y}'(x)|\, dx \tag{3}$$

on

$$\mathcal{D} = \{\mathbf{y} \in C^1[a, b]\colon \mathbf{y}(a) = \mathbf{a}, \mathbf{y}(b) = \mathbf{b}\} \tag{4}$$

should provide the shortest length of a smooth curve joining points $\mathbf{a}$ and $\mathbf{b}$ in $\mathbb{R}^d$, when we suppose that a typical curve is parametrized by a continuously differentiable function $\mathbf{y}$ on the common interval $[a, b]$. We expect the minimum value to be $|\mathbf{a} - \mathbf{b}|$ which is given by the straight line path $\mathbf{y}_0$ joining the points.

On the other hand, in a formulation consistent with Fig. 1, Bernoulli's brachistochrone would be given by a function $\mathbf{y}_0$ that minimizes the integral

$$F(y) = \int_a^b y^{-\frac{1}{2}}(x)\sqrt{1 + y'(x)^2}\, dx \tag{5}$$

on

$$\mathcal{D} = \{y \in C^1[a, b]\colon y(a) = 0,\ y(b) = b_1 > 0,\ y(x) \geq 0\} \tag{6}$$

Here, $f(x, y, y') = y^{-\frac{1}{2}}\sqrt{1 + y'^2}$, where y' designates a real variable, but it is not evident that a minimizing function exists, nor how to find one, if it does.

When a C^1 function $\mathbf{y}_0$ minimizes F on $\mathcal{D}$ of Eq. (4) it usually minimizes F on the larger class $\hat{\mathcal{D}}$ of piecewise C^1 functions with the same endpoint values, since each such function is almost C^1. However, it is possible that

only a $\hat{C}^1$ function can minimize F on $\hat{\mathcal{D}}$. This is illustrated by an integral of Weierstrass

$$F(y) = \int_{-1}^{1} y^2(1 - y')^2 \, dx \tag{7}$$

which is zero for the piecewise C^1 function $y_0(x) = \max(x, 0)$, but is positive for any other function in

$$\hat{\mathcal{D}} = \{y \in \hat{C}^1[-1, 1]\colon y(-1) = 0, \quad y(1) = 1\}. \tag{8}$$

Thus, in variational calculus even a simple problem need not have a solution in the class of functions of interest. As classical theory developed, functions were routinely assigned as much differentiability as desired, and smooth solutions to many problems were obtained through methods to be discussed presently. Modern theory has focused on eliminating as much differentiability/continuity as possible in order to extend the search to a class of objects large enough to guarantee existence of a minimizer. Whether the resulting object itself has practical utility is a matter of debate, but it can often be usefully approximated by one that does.

A. Necessary Conditions

If $\mathbf{y}_0$ minimizes

$$F(\mathbf{y}) = \int_a^b f[\mathbf{y}(x)] \, dx = \int_a^b f(x, \mathbf{y}(x), \mathbf{y}'(x)) \, dx \tag{9}$$

on

$$\mathcal{D} = \{\mathbf{y} \in C^1[a, b]\colon y(a) = \mathbf{a}, \quad y(b) = \mathbf{b}\} \tag{10}$$

then the *Gâteaux variation*

$$\delta F(\mathbf{y}_0; \mathbf{v}) \stackrel{\text{def}}{=} \lim_{\varepsilon \to 0} \varepsilon^{-1}\big[F(\mathbf{y}_0 + \varepsilon \mathbf{v}) - F(\mathbf{y}_0)\big] = 0 \tag{11}$$

in each "direction" $\mathbf{v}$ in $C^1[a, b]$ for which $\mathbf{y}_0 + \varepsilon \mathbf{v}$ is in $\mathcal{D}$ when ε is a sufficiently small real number, and the limit exists.

When f is continuous together with each component of its partial gradients $f_{\mathbf{y}}$ and $f_{\mathbf{y}'}$, then in general

$$\delta F(\mathbf{y}_0; \mathbf{v}) = \int_a^b \{f_{\mathbf{y}}[\mathbf{y}_0(x)] \cdot \mathbf{v}(x) + f_{\mathbf{y}'}[\mathbf{y}_0(x)] \cdot \mathbf{v}'(x)\} \, dx \tag{12}$$

and $\mathbf{y}_0 + \varepsilon \mathbf{v}$ is in $\mathcal{D}$ for small ε when $\mathbf{v}(a) = \mathbf{v}(b) = \mathbf{0}$.

Finally, $\delta F(\mathbf{y}_0\,; \mathbf{v}) = 0$ for all such $\mathbf{v}$ if and only if $\mathbf{y}_0$ is a solution of the first E-L (Euler-Lagrange) equation

$$\frac{d}{dx} f_{\mathbf{y}'}[\mathbf{y}_0(x)] = f_{\mathbf{y}}[\mathbf{y}_0(x)] \tag{13}$$

(interpreted componentwise).

[If Eq. (13) holds, then indeed from Eq. (12):

$$\delta F(\mathbf{y}_0; \mathbf{v}) = f_{\mathbf{y}'}[\mathbf{y}_0(x)] \cdot \mathbf{v}(x) \,|_a^b = 0 \text{ when } \mathbf{v}(a) = \mathbf{v}(b) = \mathbf{0}, \tag{14}$$

and the converse assertion follows by showing that the continuous function

$$\mathbf{g}(x) \stackrel{\text{def}}{=} f_{\mathbf{y}'}[\mathbf{y}_0(x)] - \int_a^x f_{\mathbf{y}}[\mathbf{y}_0(t)] \, dt \tag{15}$$

is constant.]

Now Eq. (13) is usually a second-order system of nonlinear differential equations for an unknown minimizing function $\mathbf{y}_0$. This system need not have any solutions on a given interval $[a, b]$ with prescribed endpoint values, and even if it does, finding an explicit solution is quite challenging. However, when f is continuously differentiable the system for a minimizing $\mathbf{y}_0$ does have a useful first integral. Then

$$\begin{aligned} h(x) &\stackrel{\text{def}}{=} f[\mathbf{y}_0(x)] - f_{\mathbf{y}'}[\mathbf{y}_0(x)] \cdot \mathbf{y}'_0(x) \\ &= \int_a^x f_x[\mathbf{y}_0(t)] \, dt + \text{const.} \end{aligned} \tag{16}$$

which gives the second E-L equation,

$$\frac{d}{dx} h(x) = f_x[\mathbf{y}_0(x)], \quad x \in (a, b). \tag{17}$$

Note that unlike Eq. (13), this second equation is real-valued; indeed, it represents a residual effect of variations with respect to the independent variable x.

When a piecewise C^1 function $\mathbf{y}_0$ minimizes F on the corresponding set

$$\hat{\mathcal{D}} = \{\mathbf{y} \in \hat{C}^1[a, b]\colon \mathbf{y}(a) = \mathbf{a}, \mathbf{y}(b) = \mathbf{b}\} \tag{18}$$

then although $\mathbf{g}$ of Eq. (15) remains constant, we cannot conclude that Eq. (13) follows. Instead, as was shown independently by Weierstrass and Erdmann, we can say that Eq. (13) holds on each interval that excludes corner points of $\mathbf{y}_0$ which can occur only at x values c where $\mathbf{y}'_0(c+) \neq \mathbf{y}'_0(c-)$ and

$$f_{\mathbf{y}'}[\mathbf{y}_0(c+)] = f_{\mathbf{y}'}[\mathbf{y}_0(c-)]. \tag{19}$$

Similarly, when f is C^1, Eq. (17) holds on each interval that excludes corner points of $\mathbf{y}_0$ which can occur only at values c where in addition

$$(f - \mathbf{y}' \cdot f_{\mathbf{y}'})[\mathbf{y}_0(c+)] = (f - \mathbf{y}' \cdot f_{\mathbf{y}'})[\mathbf{y}_0(c-)]. \tag{20}$$

Equations (19) and (20) are known, respectively, as the first and second W-E (Weierstrass-Erdmann) corner conditions. [A $\mathbf{y}_0$ that minimizes F only on a sufficiently restricted subset of $\hat{\mathcal{D}}$ in Eq. (18) can have a corner point where Eq. (19) holds but Eq. (20) does not.]

For the Weierstrass example of Eq. (7), these conditions limit the location of a possible corner point $(c, y_0(c))$ of a minimizing y_0 to values where $y_0^2(c)(1 - y'_0(c+)) = y_0^2(c)(1 - y'_0(c-))$, and since $y'_0(c+) \neq y'_0(c-)$: $y_0(c) = 0$. Moreover from Eq. (17), we see that $h(x) = y_0^2(1 - y_0'^2)(x)$ is constant so that it too is

zero. Thus, on an interval excluding corner points, either $y_0(x) = 0$ or $y_0'(x) = \pm 1$. Assembling these facts we arrive at $y_0(x) = \max(x, 0)$ as the only candidate in $\hat{\mathcal{D}}$ of Eq. (8).

If we replace f by $-f$ in Eq. (9), then all necessary conditions obtained so far are unaffected; thus they would also hold for a $\mathbf{y}_0$ that maximizes F on $\mathcal{D}$ (or on $\hat{\mathcal{D}}$). To derive a condition that arises only for a minimizer, Weierstrass employed a small variation whose derivative at a single point remains constant as the variation diminishes in magnitude to zero. He found that if $\mathbf{y}_0$ minimizes F on $\mathcal{D}$ then for each $x \in [a, b]$:

$$f(x, \mathbf{y}_0(x), \mathbf{y}') - f(x, \mathbf{y}_0(x), \mathbf{y}_0'(x)) \geq f_{\mathbf{y}'}[\mathbf{y}_0(x)] \cdot (\mathbf{y}' - \mathbf{y}_0'(x)) \tag{21}$$

for all vectors $\mathbf{y}'$ of interest. [If $\mathbf{y}_0$ minimizes F on $\hat{\mathcal{D}}$ then this inequality holds at a corner point $(c, \mathbf{y}_0(c))$ when $\mathbf{y}_0'(x)$ is replaced by either $\mathbf{y}_0'(c+)$ or $\mathbf{y}_0'(c-)$.] Assuming enough continuity it follows that the matrix having elements $f_{y_i' y_j'}(x, \mathbf{y}_0(x), \mathbf{y}_0'(x))$ arranged in natural order is positive semidefinite. When it is positive definite, Hilbert showed that a C^1 solution $\mathbf{y}_0$ of Eq. (13) is necessarily C^2.

B. Stationarity

Condition (11), $\delta F(\mathbf{y}_0; \mathbf{v}) = 0$ for all $\mathbf{v}$ with $\mathbf{v}(\boldsymbol{a}) = \mathbf{v}(\boldsymbol{b}) = \mathbf{0}$, is not sufficient to infer that $\mathbf{y}_0$ is an extremum for F on $\mathcal{D}$. It would also hold when $\mathbf{y}_0$ is only a local extremum, that is, an extremum in an appropriately defined neighborhood of $\mathbf{y}_0$. (In particular, $\mathbf{y}_0$ could be a *strong* local extremum relative to a neighborhood in which $|\mathbf{y} - \mathbf{y}_0|$ is uniformly small, or a *weak* local extremum relative to a neighborhood in which $|\mathbf{y}' - \mathbf{y}_0'|$ is also uniformly small.) But condition (11) alone cannot be used to infer extremal behavior in any direction $\mathbf{v}$. Instead, it characterizes F as having stationary behavior at $\mathbf{y}_0$ in that at $\mathbf{y}_0$, F exhibits no predisposition to either increase or decrease in any associated direction $\mathbf{v}$. For the same reason, solutions of the E-L system [Eq. (13)] are sometimes called *stationary functions*, although the misleading terms *extremal function* or *extremal* are common in the literature.

C. Sufficient Conditions; Convexity

It is obvious graphically that a real-valued function f of a single real variable t has a minimum value at a point where its derivative is zero provided that its graph resembles an arc of an upward directed parabola. Such functions are now said to be convex, a condition that can be inferred if f has a nonnegative second derivative. However, this implies a weaker property, that for all t, t_0 of interest:

$$f(t) - f(t_0) \geq f'(t_0)(t - t_0), \tag{22}$$

which indicates that the graph of f lies above (or on) each of its tangent lines. Finally, (22) implies that on each interval $[t_0, t_1]$ of definition, the graph of f lies below the chordal line joining the endpoints, so that

$$f((1-s)t_0 + st_1) \leq (1-s) f(t_0) + s f(t_1), \quad 0 \leq s \leq 1. \tag{23}$$

The last condition is purely geometrical and does not require differentiability or even continuity of f, although the latter can be deduced when f is bounded. But for our immediate purposes, (22) is more natural; indeed, we already encountered one version of it in (21).

Accordingly, we say that the function $f(x, \mathbf{y}, \mathbf{y}')$ is *convex in* $\mathbf{y}$ *and* $\mathbf{y}'$ when for each fixed x,

$$f(x, \mathbf{y}, \mathbf{y}') - f(x, \mathbf{y}_0, \mathbf{y}_0') \geq f_{\mathbf{y}}(x, \mathbf{y}_0, \mathbf{y}_0') \cdot (\mathbf{y} - \mathbf{y}_0) + f_{\mathbf{y}'}(x, \mathbf{y}_0, \mathbf{y}_0') \cdot (\mathbf{y}' - \mathbf{y}_0') \tag{24}$$

for all vectors $\mathbf{y}$, $\mathbf{y}'$, $\mathbf{y}_0$, and $\mathbf{y}_0'$ of interest. In this case, from Eqs. (9) and (12), it follows that

$$F(\mathbf{y}) - F(\mathbf{y}_0) \geq \delta F(\mathbf{y}_0; \mathbf{v}) \qquad \text{for} \quad \mathbf{v} = \mathbf{y} - \mathbf{y}_0,$$

which ascribes a directional convexity to F.

In particular, when $\mathbf{y_0}$ in $\mathcal{D}$ of (10) is a solution of Eq. (13), then from Eq. (14), $\delta F(\mathbf{y}_0; \mathbf{v})$ is zero for $\mathbf{y}$ in $\mathcal{D}$, so that $\mathbf{y}_0$ minimizes F on $\mathcal{D}$. If $\mathbf{y}_0$ is in $\hat{\mathcal{D}}$ of (18) and satisfies the E-L system [Eq. (13)] on intervals between corner points, at each of which it meets the first W-E condition [or equivalently, $\mathbf{g}(x)$ of Eq. (15) is constant] then under (24), $\mathbf{y}_0$ minimizes F on $\hat{\mathcal{D}}$. Moreover, under a slightly stronger version of (24) there is at most one such $\mathbf{y}_0$ in $\hat{\mathcal{D}}$.

Most functions f do not exhibit the full convexity of (24) but many do, including the one-dimensional examples, $f(x, y, y') = \sqrt{1 + y'^2}$, $\sqrt{y'^2 + y^{-2}}$ and $e^x \sqrt{1 + y'^2} + (\sin x) y$. Even when the integrand f is not sufficiently convex, it is possible that an invertible change of dependent variables of the form $\mathbf{y} = \boldsymbol{\varphi}(\boldsymbol{\eta})$ results in a new integrand that is suitably convex. Although the brachistochrone integrand $f(x, y, y') = \sqrt{(1 + y'^2) y^{-1}}$ of Eq. (5) does not satisfy (24), the transformation $y = \eta^2/2$ (so $y' = \eta\eta'$) results in the new integrand $\tilde{f}(x, \eta, \eta') = \sqrt{2(\eta'^2 + \eta^{-2})}$ which does, and this gives an elementary means of proving that the cycloidal arc is the brachistochrone. If usable convexifying transformations in $\mathbf{y}$ cannot be found, it may be possible to recast a problem so that a new integrand is convex, but it is an open question whether every problem with a known minimum can be transformed into one that has an integrand satisfying (24).

In fact, explorations of (24) are of surprisingly recent origin. Sufficiency was first considered by Legendre who in 1786 attempted to establish local minimization of F at $\mathbf{y}_0$ by requiring in effect, the positivity of $\delta^2 F(\mathbf{y}_0; \mathbf{v})$, the second variation of F. In the one-dimensional case

when $\mathbf{y} = y$ and f are C^2, using Eqs. (11) and (12) it is straightforward to show that

$$\delta^2 F(y_0; v) = \int_a^b \left(f_{yy} v^2 + 2 f_{yy'} v v' + f_{y'y'} v'^2 \right) dx \quad (25)$$

where the partial derivatives of f are evaluated at $(x, y_0(x), y_0'(x))$. Assuming that $\delta F(y_0; v) = 0$, it is true that having $\delta^2 F(y_0; v) > 0$ ensures local minimization of F at y_0 *in the direction* v, but flaws in Legendre's efforts to infer positivity of $\delta^2 F(y_0; v)$ from that of $f_{y'y'}(x, y_0(x), y_0'(x))$ impeded progress with this approach. Then, in 1836 Jacobi carefully examined Legendre's analysis and showed that local minimization can be established when f is C^4, provided that a positive solution u is available for the linear differential equation

$$(f_{yy'} u + f_{y'y'} u')' = f_{yy} u + f_{yy'} u' \quad (26)$$

now known as *Jacobi's equation*. Moreover, Jacobi proved that this new condition is essential for minimization, even when $f_{y'y'}$ is positive.

In these early works, convexity manifested itself through positivity of second derivatives, but the next wave of investigations, launched by Weierstrass in lectures around 1879, brought a new formulation. After recognizing that (21) was a necessary condition for minimization, Weierstrass began to study integrand functions $f(x, \mathbf{y}, \mathbf{y}')$ that satisfy the related inequality

$$f(x, \mathbf{y}_0, \mathbf{y}') - f(x, \mathbf{y}_0, \mathbf{y}_0') \geq f_{\mathbf{y}'}(x, \mathbf{y}_0, \mathbf{y}_0') \cdot (\mathbf{y}' - \mathbf{y}_0') \quad (27)$$

for all vectors $\mathbf{y}_0'$ and $\mathbf{y}'$ of interest. (In modern terminology, such functions are convex in $\mathbf{y}'$ only.) In subsequent work extended substantially by Hilbert (1900), it was shown that under (27), a solution $\mathbf{y}_0$ of E-L (13) in $\mathcal{D}$ of (10) does minimize F on $\hat{\mathcal{D}}$ of (18) when $\mathbf{y}_0$ can be embedded in a suitable family (a field) of other solutions to Eq. (13). The resulting Weierstrass-Hilbert field theory of sufficiency dominated subsequent development, although it can be rather difficult to find a usable field. Indeed, in order to guarantee theoretically that a given solution $\mathbf{y}_0$ can be embedded in a field large enough to ensure local minimization for a C^3 f, one must prove that an auxiliary linear system has solutions that remain linearly independent on the interval (a, b). In the simple case where $\mathbf{y}$ is real-valued, this condition requires a positive solution u of the Jacobi equation (26). On the other hand, condition (24) is effective only on a fixed interval while field theory methods are in principle more adaptable.

III. CONSTRAINTS

The fixed endpoint conditions $\mathbf{y}(a) = \mathbf{a}$, $\mathbf{y}(b) = \mathbf{b}$ considered previously represent constraints on the admissible functions. When other constraints are imposed the results must be modified.

For example, if we require only $\mathbf{y}(a) = \mathbf{a}$, then at b a minimizing function $\mathbf{y}_0$ must necessarily satisfy the natural boundary conditions

$$f_{\mathbf{y}'}[\mathbf{y}_0(b)] = \mathbf{0} \quad (28)$$

whose relevance is visible in Eq. (14). [Conversely, under the convexity of (24), any solution $\mathbf{y}_0$ of E-L on (a, b) with $\mathbf{y}_0(a) = \mathbf{a}$, that satisfies Eq. (28) must minimize.] Requiring only $\mathbf{y}(a) = \mathbf{a}$ constrains the right endpoint of the graphs of the admissible functions to lie on the (hyper)plane $x = b$ in $\mathbb{R}^{d+1}$. When this plane is replaced by a smooth transversal surface T with equation $\tau(x, \mathbf{y}) = 0$, then b is not fixed and the corresponding natural boundary condition at T is

$$[h\tau_{\mathbf{y}} - \tau_x f_{\mathbf{y}'}]_T = \mathbf{0}, \quad (29)$$

where h is given in Eq.(16). In the so-called infinite horizon case where T reduces to the line $\mathbf{y} = \mathbf{b}$ so that $\tau(x, \mathbf{y}) = \mathbf{y} - \mathbf{b}$, then for minimization b must be selected to make $h(b, \mathbf{b}) = 0$. Of course, similar constraints at the left endpoint result in corresponding natural boundary conditions, and under (27) Weierstrass-Hilbert field theory of sufficiency can in principle be modified to accommodate any of these endpoint conditions. For other types of constraints, it is usually necessary to modify the integrand.

A. Isoperimetric Constraints

Variational methods can be used to examine the Zenodorus conjecture concerning the maximal planar area enclosable by isoperimetric curves (those having the same length). The most natural approach involves optimizing one integral function (the area) while holding constant the values of another (the length). Constraints of this type, first investigated by Euler, are termed *isoperimetric* as are optimization problems involving only a finite number of such constraints. Suppose we wish to minimize F of Eq. (9) on $\mathcal{D}$ of Eq. (10) under the *isoperimetric* constraints

$$\mathbf{G}(\mathbf{y}) \stackrel{\text{def}}{=} \int_a^b \mathbf{g}(x, \mathbf{y}, \mathbf{y}')\, dx = \boldsymbol{\ell}, \text{ a constant vector}, \quad (30)$$

where $\mathbf{g}$ is a given vector-valued function. To do so, we introduce a Lagrangian multiplier vector $\boldsymbol{\lambda}$ and seek instead a $\mathbf{y}_0$ in $\mathcal{D}$ that minimizes

$$\tilde{F}(\mathbf{y}) = F(\mathbf{y}) + \boldsymbol{\lambda} \cdot \mathbf{G}(\mathbf{y}) \quad (31)$$

on $\mathcal{D}$. Clearly, any such $\boldsymbol{\lambda}$-dependent $\mathbf{y}_0$ also minimizes F on the subset of $\mathcal{D}$ where $\mathbf{G}(y) = \mathbf{G}(\mathbf{y}_0)$, so that if now $\boldsymbol{\lambda}$ can be selected to make $\mathbf{G}(\mathbf{y}_0) = \boldsymbol{\ell}$, an associated $\mathbf{y}_0$ would supply a minimizer. It can also be shown that if a

minimizing $\mathbf{y}_0$ for this isoperimetric problem exists, then in principle so must an associated $\boldsymbol{\lambda}$ unless the determinant with elements $\delta G_i(\mathbf{y}_0\,;\mathbf{v}_j)$ vanishes for all choices of $\mathbf{v}_j$ with $\mathbf{v}_j(a)=\mathbf{v}_j(b)=\mathbf{0}$. Here G_i is the ith component of $\mathbf{G}$.

Note that if $\mathbf{y}_0$ minimizes $\tilde{F}$ of Eq. (31) on $\mathcal{D}$, then it also minimizes F on $\mathcal{D}$ under the corresponding inequality constraint

$$\boldsymbol{\lambda}\cdot\mathbf{G}(\mathbf{y})\le\boldsymbol{\lambda}\cdot\mathbf{G}(\mathbf{y}_0)=\boldsymbol{\lambda}\cdot\boldsymbol{\ell} \tag{32}$$

which can be realized through inequalities involving the signs of the components of $\boldsymbol{\lambda}$ and $\mathbf{G}$.

In practice, we seek a minimizing $\mathbf{y}_0$ for $\tilde{F}$ on $\mathcal{D}$ among solutions of the E-L equation (13) for $\tilde{f}=f+\boldsymbol{\lambda}\cdot\mathbf{g}$, the integrand of $\tilde{F}$. Then we select those $\boldsymbol{\lambda}$ for which $G(\mathbf{y}_0)=\boldsymbol{\ell}$, and try to establish minimization perhaps by appeal to convexity of the resulting $\tilde{f}$. To illustrate this procedure, consider the simple but nontrivial problem of minimizing

$$F(y)\overset{\text{def}}{=}\int_0^1 4y(x)\,dx \qquad \text{on}$$

$$\mathcal{D}=\{y\in C^1[0,1]\colon y(0)=0,\,y(1)=1\} \tag{33}$$

under the isoperimetric constraint

$$G(y)\overset{\text{def}}{=}\int_0^1 y'(x)^2\,dx=4/3. \tag{34}$$

Here, $\tilde{f}(x,y,y')=4y+\lambda y'^2$ provides the E-L equation $\frac{d}{dx}(2\lambda y')=4$ with solution $y_0(x)=(x^2+(\lambda-1)x)/\lambda$ in $\mathcal{D}$. Moreover $G(y_0)=1+(3\lambda^2)^{-1}$, and this equals $4/3$ when $\lambda=\pm1$. Now $\tilde{f}=4y+(1)y'^2$ is convex in the sense of (24) so that $y_0(x)=x^2$ solves our problem. [The other choice, $\lambda=-1$, gives a y_0 which in fact *maximizes* F on $\mathcal{D}$ under (34) since with it, $-\tilde{f}=-4y+y'^2$ is again convex in the sense of (24).]

If we replace $\mathcal{D}$ of Eq. (33) by $\mathcal{D}_1=\{y\in C^1[0,1]\colon y(0)=0\}$ then minimization of $\tilde{F}$ on $\mathcal{D}_1$ requires a y_1 that satisfies the natural boundary condition of Eq. (28), $\tilde{f}_{y'}[y_1(1)]=0$ or $y_1'(1)=0$; this gives the minimizing function $y_1(x)=x^2-2x$. Finally we see that the same y_0 or y_1 minimizes F on $\mathcal{D}$ or $\mathcal{D}_1$, respectively, under the inequality constraint $G(y)\le 4/3$.

B. Eigenvalue Problems

A nonuniform string of linear density $\rho=\rho(x)$ and local tensile resistance $\tau=\tau(x)$ stretched between fixed supports a distance l apart can be shown to vibrate freely with small deflection in mode shapes $y_n=y_n(x)$ at natural frequency ω_n for $n=1,2,\ldots$. Furthermore $\lambda_n\overset{\text{def}}{=}\omega_n^2=\min\{\int_0^1\tau y'^2\,dx\colon y\in\mathcal{D}_n\}$ where $\mathcal{D}_1=\{y\in C^1[0,l]\colon y(0)=y(l)=0;\ \int_0^1\rho y^2dx=1\}$ and for $n>1$: $\mathcal{D}_n=\{y\in\mathcal{D}_1\colon\int_0^1\rho y y_k\,dx=0,k=1,2\ldots n-1\}$ assuming successive identification of modal functions y_k is possible. (For a uniform string, τ and ρ are positive constants; then $y_n(x)=\sin(n\pi x/l)$ and $\omega_n=n\omega_1$ for $n=1,2\ldots$, where $\omega_1^2=\tau\pi^2/\rho l^2$.) In 1873 Lord Rayleigh showed how to estimate a few lower frequencies ω_n using approximations of associated modal functions y_n. Then Weyl, Courant, and others found alternate characterizations for eigenvalues λ_n that replace use of eigenfunctions y_n with more general assessments involving maxima of minima (or minima of maxima) of values of F on subfamilies of $\mathcal{D}$. For example, when $\rho=1$, λ_n is the *maximum* (over all sets of continuous functions $\varphi_1,\varphi_2,\ldots,\varphi_{n-1}$) of the *minimum* value of $F(y)$ for all y in $\mathcal{D}_1$ for which $\int_0^1 y\varphi_j\,dx=0$, $j<n$.

Here, the λ_n are the eigenvalues of an associated Sturm-Liouville system, and this variational approach extends to characterizing eigenvalues of other linear operators on Hilbert spaces.

C. Lagrangian Constraints

Certain applications require minimizing F of Eq. (9) on $\mathcal{D}$ of Eq. (10) under interval constraints of the form

$$\mathbf{g}[\mathbf{y}(x)]=\mathbf{g}(x,\mathbf{y}(x),\mathbf{y}'(x))=\mathbf{0},\quad a\le x\le b \tag{35}$$

first considered by Lagrange. Again $\mathbf{g}$ is a given vector-valued function. Upon introducing a corresponding multiplier function $\boldsymbol{\lambda}(x)$, we see that a $\mathbf{y}_0$ in $\mathcal{D}$ for which $g[\mathbf{y}_0(x)]\equiv 0$ will solve this problem provided that for some $\boldsymbol{\lambda}$, $\mathbf{y}_0$ minimizes

$$\tilde{F}(\mathbf{y})=F(\mathbf{y})+\int_a^b\boldsymbol{\lambda}(x)\cdot\mathbf{g}[\mathbf{y}(x)]\,dx \tag{36}$$

on $\mathcal{D}$. Moreover this $\mathbf{y}_0$ will also minimize F on $\mathcal{D}$ under the Lagrangian inequality constraint

$$\boldsymbol{\lambda}(x)\cdot\mathbf{g}[\mathbf{y}(x)]\le 0 \tag{37}$$

which can be realized through inequalities involving the components of $\boldsymbol{\lambda}$ and $\mathbf{g}$. Thus we would seek $\mathbf{y}_0$ in $\mathcal{D}$ and a function $\boldsymbol{\lambda}$ on $[a,b]$ that satisfy the differential system

$$\frac{d}{dx}\tilde{f}_{\mathbf{y}'}[\mathbf{y}_0(x)]=\tilde{f}_{\mathbf{y}}[\mathbf{y}_0(x)] \tag{38}$$

$$\mathbf{g}[\mathbf{y}_0(x)]=\mathbf{0} \tag{39}$$

where $\tilde{f}=f+\boldsymbol{\lambda}\cdot\mathbf{g}$. If for some resulting $\boldsymbol{\lambda}$, $\tilde{f}$ is, say, convex in the sense of (24), then an associated $\mathbf{y}_0$ would solve the problem. Note that Eq. (38) usually involves the derivatives of the multiplier functions $\boldsymbol{\lambda}$.

For problems with Lagrangian constraints, the presence of multiplier functions is unavoidable. If $\mathbf{y}_0$ minimizes F on $\mathcal{D}$ under (35), then in general it can be shown that there exists a $\boldsymbol{\lambda}_0$ (either 0 or 1) and a multiplier function $\boldsymbol{\lambda}$ satisfying Eq. (38) when

$$\tilde{f} = \lambda_0 f + \boldsymbol{\lambda} \cdot \mathbf{g}.$$

Moreover, if $\mathbf{y}_0$ minimizes F on $\mathcal{D}$ under the corresponding inequality constraint

$$\mathbf{g}[\mathbf{y}(x)] \leq \mathbf{0} \quad \text{(interpreted componentwise)} \tag{40}$$

then in the same sense, the multiplier functions meet the Karush-Kuhn-Tucker conditions $\boldsymbol{\lambda}(x) \geq \mathbf{0}$. A component constraint g_i is said to be active at points x where its associated multiplier $\lambda_i(x)$ is nonzero and inactive otherwise.

D. Problem Conversions; Higher Derivatives

Lagrangian constraints can be introduced to replace constraints of other types and to unify the theoretical appearance of problems in variational calculus. For example, the isoperimetric problem of Eqs. (33) and (34) can be replaced by one of finding a vector function $\mathbf{y} = (y, y_1, y_2)$ with components in $C^1[0, 1]$ that has minimum last coordinate value $y_2(1)$ among those that satisfy the Lagrangian system

$$y_1' = g(x, y, y') = y'^2$$
$$y_2' = f(x, y, y') = 4y$$

with $\mathbf{y}(0) = \mathbf{0}$ and $y(1) = 1$, $y_1(1) = 4/3$. This approach, attributed to Maier, has proved useful in the development of optimal control theory.

Lagrangian constraints also provide a straightforward means of extending the basic problems in the variational calculus to functions involving higher derivatives. For example, to minimize

$$F^*(y) = \int_a^b f^*(x, y, y', y'')\, dx$$

on $\mathcal{D}^* = \{y \in C^2[a, b]: y(a) = 0, y'(a) = 1, y(b) = 2\}$ we could seek a pair $\mathbf{y} = (y, y_1)$ that minimizes the integral

$$F(\mathbf{y}) = \int_a^b f(x, \mathbf{y}, \mathbf{y}')\, dx$$

on $\mathcal{D} = \{\mathbf{y} \in C^1[a, b]: \mathbf{y}(a) = (0, 1), y(b) = 2\}$ under the Lagrangian constraint

$$y' - y_1 = 0.$$

Here $f(x, \mathbf{y}, \mathbf{y}') = f^*(x, y, y_1, y_1')$, and it is readily seen how to extend this approach to integrals involving even higher derivatives, or, as in the previous example, to replace the integral itself.

Since each new Lagrangian constraint introduces an additional unknown multiplier function, the advisability of using these transformations in a specific application is a matter of taste and experience. However, it is important to be aware that a given problem may be replaced by one more amenable to either theoretical or practical analysis.

IV. OPTIMAL CONTROL PROBLEMS

We operate a land vehicle by applying controls (steering wheel, throttle, brakes, etc.) to alter its state (position, temperature, etc.) over a time interval to achieve some overall purpose, often conceived of in optimal terms. Restrictions are imposed on state variables, controls, and goals.

Assume that the state $\mathbf{y}(t) \in \mathbb{R}^d$ of a controllable dynamical system at time t evolves in time under laws expressed through a given system of differential equations in the form

$$\dot{\mathbf{y}}(t) = \mathbf{G}(t, \mathbf{y}(t), \mathbf{u}(t)), \quad 0 \leq t \leq T \tag{41}$$

where $\mathbf{u}(t)$ represents the values of the control variables at time t assumed to lie in a fixed control region U of $\mathbb{R}^k$.

Suppose we wish to operate this system from a fixed initial state $\mathbf{y}(0) = \mathbf{a}$, over the time interval $[0, T]$ so as to optimize a performance criterion that can be assessed by an integral of the form

$$F(\mathbf{y}, \mathbf{u}, T) = \int_0^T f(t, \mathbf{y}(t), \mathbf{u}(t))\, dt. \tag{42}$$

For example, the choice of $f \equiv 1$, results in optimizing the time-of-travel, T. The problem is said to be autonomous when neither f nor $\mathbf{G}$ depend explicitly on t. It is usually assumed that the control function $\mathbf{u}$ is piecewise continuous.

When the target time T is fixed, we can use convexity to suggest a method of attack. For simplicity, consider only the problem of minimizing

$$F(y, u) = \int_0^T f(t, y(t), u(t))\, dt$$

on

$$\mathcal{D} = \{y \in \hat{C}^1[0, T], u \in \hat{C}[0, T]: y(0) = a_1; y(T) = b_1\}$$

under the state law

$$\dot{y}(t) = g(t, y(t), u(t)). \tag{43}$$

To do so, we introduce the auxiliary function

$$h = f + pg \tag{44}$$

expressed in terms of an unspecified multiplier function $p = p(t)$ (also called the costate or adjoint function). Then, following the analysis in Section III.C, we see that on $\mathcal{D}$, admissible state and control functions y_0 and u_0, respectively, that minimize

$$\tilde{F}(y, u) = \int_0^T [h(t, y(t), u(t)) - p(t)\dot{y}(t)]\, dt \tag{45}$$

must minimize F under Eq. (43).

Moreover, they will minimize $\tilde{F}$ on $\mathcal{D}$ provided that h is convex in y and u, and that they satisfy the appropriate E-L equations (13) together with the Weierstrass-Erdmann

conditions (19), (20) for $\tilde{f}$, the integrand function of $\tilde{F}$. These take the forms

$$-\dot{p} = h_y = f_y + pg_y \tag{46}$$

with continuity of p and $h_0(t) = h(t, y_0(t), u_0(t))$ and

$$h_u(t, y_0(t), u_0(t)) = 0, \tag{47}$$

the latter requiring that the control set U be open. Since at each t, $h(t, y_0(t), u)$ is supposed convex in u, we see that the optimal control $u_0(t)$ *minimizes* this function. In fact, when the control set U is itself convex (an interval), we can replace Eq. (47) by requiring that at each t

$$h(t, y_0(t), u_0(t)) = \min_{u \in U} h(t, y_0(t), u) \tag{48}$$

Thus, to attack our problem, we should seek solutions y_0, u_0, p to the *adjoint equation* (46) that have the minimizing property (48). The underlying principle, first announced in little-read work of Hestenes in 1950, gained wide acceptance only when it was rediscovered by Russian mathematicians. It is usually credited to their leader, and with the replacement of h by $-h$, is known as the "Pontrjagin Maximal Principle." These mathematicians also proved that related conditions are necessary for solution of optimal control problems under even more general target conditions and obtained corresponding natural boundary conditions that characterize optimal targets. Similar results can be obtained to characterize optimal controls in the presence of inequality restrictions on the state and control variables, expressed in the form of Karush-Kuhn-Tucker type conditions.

Although this approach to optimal control emphasizes its relationship to variational calculus, other treatments have proved beneficial, including those of Young, Bellman, and Leitmann. Each has advantages in certain applications, but none makes the solution of control problems elementary. Moreover, an optimal control need not be unique, and even if it is, it can change dramatically with slight changes in initial conditions. In particular, numerical approximations to solutions can behave quite erratically. Finally, as with any extremal problem, optimal controls need not exist—at least within the family of admissible competitors being considered. Some of these difficulties are ameliorated through the probabilistic view taken in the stochastic version of control theory.

V. MINIMIZATION THEORY

Solution of a problem in variational calculus or optimal control can usually be reduced to the search for an element y_0 of a set $\mathcal{S}$ that minimizes the value of a function F defined on $\mathcal{S}$ with values in $(-\infty, \infty]$. $\mathcal{S}$ is usually a subset of a linear space of functions, $\mathcal{Y}$, but F must exhibit some continuity with respect to a topology on $\mathcal{Y}$ (or at least a topology on $\mathcal{S}$) in order to develop a theory. In the century just concluded many candidates for spaces $\mathcal{Y}$ and related topologies have been examined, in particular, those made possible by Lebesgue's extension of the integral in 1902, together with the development of functional analysis to explore the consequences.

What would guarantee existence of a minimizer y_0 is assurance that from a sequence $y_n \in \mathcal{S}$, $n = 1, 2, \ldots$, with values $F(y_n) \searrow \mu = \inf_{y \in \mathcal{S}} F(y)$ we can extract a subsequence $\{y_{n_k}\}$ with a "limit" y_0 in $\mathcal{S}$, for which $F(y_0) \le \lim_{k \to \infty} F(y_{n_k}) = \mu$. Thus F must be *lower semicontinuous* on $\mathcal{S}$ with respect to a topology that gives the sequence $\{y_n\}$ *sequentially compact closure* in $\mathcal{S}$. In work begun in 1915 Tonelli and his successors generalized earlier results of Hilbert (from 1901). They showed that an integral function

$$F(y) = \int_a^b f(x, y, y')\, dx \tag{49}$$

would have these properties on the subset $\mathcal{S}$ of absolutely continuous functions y on $[a, b]$ with $y(a)$ bounded, when for some fixed $p \in (1, +\infty)$

(i) The almost everywhere defined derivatives of y lie in the Lebesgue space $L_p[a, b]$.
(ii) $f(x, y, y') \ge A|y'|^p$ for some positive constant A.
(iii) $f(x, y, y')$ is convex in y'. (50)

These conditions can be relaxed somewhat. For example, the classical convexity of (iii) can be replaced by geometrical convexity as in (23). Moreover, similar results hold when $p = 1$, provided that (ii) is replaced by the coercive requirement $f(x, y, y') \ge |y'|\varphi(|y'|) > 0$ where φ is a continuous function on $[0, +\infty)$ with infinite limit at infinity. Finally, there are corresponding vector-valued versions, even for certain nonconvex f. However, the innocent-looking problem of finding an absolutely continuous function on $[0, 1]$ that minimizes the *positive* integral

$$F(y) = \int_0^1 [(y'^2 - 1)^2 + y^2]\, dx \tag{51}$$

among those with zero endpoint values has no solution, because for small sawtooth functions y with slopes ± 1 except at a finite set of points, $F(y) = \int_0^1 y^2\, dx$ is correspondingly small. And there is a similar integral problem with an absolutely continuous minimizer y_0 that cannot be approximated by smoother functions that almost minimize (the Lavrientiev phenomenon).

Despite this, Ekeland has shown recently that when F is lower semicontinuous and bounded below on a closed set

$\mathcal{S}$ of a Banach space $\mathcal{Y}$, then $\mathcal{S}$ does contain a minimizer for the slightly modified function $\tilde{F}(y) = F(y) + \varepsilon\|y - y_1\|$ with an appropriate choice of $\varepsilon > 0$ and $y_1 \in \mathcal{S}$.

In specific cases, it may be feasible to approximate an unknown but theoretically existent minimizer y_0 through elements y_n of a computationally accessible sequence. Many schemes have been proposed to do so including those based on a Ritz-Galerkin type procedure for selecting a y_n that minimizes F on an n-dimensional closed subset $\mathcal{S}_n$ with known basis for which $\mathcal{S}_n \subseteq \mathcal{S}_{n+1}$ and $\mathcal{S} = \cup_n \mathcal{S}_n$. Then $F(y_n) \geq F(y_{n+1}) \geq F(y_0)$ and under reasonable conditions $F(y_0) = \lim_{n\to\infty} F(y_n)$. Thus $F(y_n)$ approximates $F(y_0)$ from above, but it is much more difficult to arrange that y_n approximates y_0 in any usable sense.

Now, in general, conditions which guarantee existence of a minimizer y_0 for a function F do not permit us to further characterize it. Indeed, Ball and Mizel have produced an integral function F with polynomial integrand similar to that in (51) with an absolutely continuous minimizer y_0 which does not satisfy Eq. (13) even in distributional form. To mirror the classical development we need some means of differentiating F. We have already seen the utility of the Gâteaux variations $\delta F(y_0; v)$ of Eq. (11) when they exist. They must exist if y_0 is in a Banach space $\mathcal{Y}$ where F has the *Fréchet derivative* $F'(y_0)$, the unique continuous linear functional L on $\mathcal{Y}$ such that for all $v \in \mathcal{Y}$ with small norm $\|v\|$: $F(y_0 + v) = F(y_0) + Lv + \|v\|\mathcal{Z}(v)$; here, $\mathcal{Z}$ denotes a function with zero limit as $\|v\| \to 0$. Indeed, then $\delta F(y_0; v) = F'(y_0)v$.

When this occurs at an interior point y_0 of $\mathcal{S}$ where F is minimized, then $F'(y_0) = 0$. Moreover, if F is convex on $\mathcal{S}$ in that

$$F(y) - F(y_0) \geq F'(y_0)(y - y_0); \quad y, y_0 \in \mathcal{S} \tag{52}$$

then having $F'(y_0) = 0$ guarantees minimization at y_0 even when y_0 is a boundary point of $\mathcal{S}$. However, in the latter case $F'(y_0)$ need not be zero as is evident for the convex function $F_1(y) = y^2$ on the interval $\mathcal{S} = [2, 3)$ where $y_0 = 2$. In this example we do see that the line through the point $(2, 2^2)$ with slope zero lies below the graph of F_1, and in 1954, Rockafellar proved more generally, that when y_0 is a minimizer for a convex function F on a closed convex set $\mathcal{S}$, then the zero functional is in the set $\partial(F + \delta_{\mathcal{S}})(y_0) = \partial F(y_0) + \partial\delta_{\mathcal{S}}(y_0)$. Here $\delta_{\mathcal{S}}$, the convex indicator function for $\mathcal{S}$, has values 1 on $\mathcal{S}$, $+\infty$ otherwise, and $\partial F(y_0) = \{y^* \in \mathcal{Y}^*: F(y) - F(y_0) \geq y^*(y - y_0)\}$ defines the *subdifferential* of F at y_0 as a subset of linear functionals in the dual space $\mathcal{Y}^*$. The subdifferential represents one of the more successful efforts to extend the concept of differentiability. It is the basis of nonsmooth analysis, where the derivative of a function is a multifunction, a set-valued mapping. The usual linearity properties of derivatives have set-valued correspondents, and in some cases, integrals of multifunctions can be defined. But it is less evident how to differentiate such objects, and at present several candidates are being considered. What is significant is that nonsmooth extensions characterizing existence, necessary conditions, and sufficient conditions for minimization have been obtained for a large class of problems in the variational calculus. For example, the nonsmooth version of the Euler-Lagrange equation (13) for an absolutely continuous y_0 takes the form of a *differential inclusion*: There exists an absolutely continuous function p on $[a, b]$ such that for a.e. x, the pair $(p'(x), p(x))$ in $\mathbb{R}^2$ lies in the subgradient of $f(x, y, z)$ with respect to y and z at the point $(x, y_0(x), y_0'(x))$. Were f continuously differentiable, this subgradient would reduce to the ordinary partial derivatives of f at the point, so that $p = f_{y'}$, and its derivative is f_y, recapturing Eq. (13). In this way, differential inclusions provide nonsmooth extensions of differential equations. There are also nonsmooth approaches to minimizing a globally defined F restricted to a subset S, including use of a (nonsmooth) penalty function P whose value at y assigns a distance from y to S so large that minima for $F + P$ can only be found in S (where P vanishes).

VI. HAMILTONIAN CONTRIBUTIONS

The universe should operate efficiently. That conviction part philosophical, part religious, has been expressed in various terminology for centuries and the assessment of efficiency has received many formulations. For scientific purposes, the most fruitful has proved to be that of Hamilton (1834) which with some refinements has survived transition in modern physics to both relativity and quantum mechanics. In this model, we envisage the universe as a large but finite number N of particles with individual masses, positions $\mathbf{y}$ and velocities $\dot{\mathbf{y}} = \frac{d}{dt}\mathbf{y}$ giving rise to system kinetic energy T and potential energy V, at each time t. Then we postulate that between fixed times a and b at which positions are specified, the universe moves in a manner that makes stationary the *action integral*

$$F(y) = \int_a^b L(t, \mathbf{y}, \dot{\mathbf{y}})\, dt \tag{53}$$

expressed in terms of the Lagrangian

$$L = T - V. \tag{54}$$

Assuming that no further constraints are present, this would result in the E-L system (13)

$$\frac{d}{dt} L_{\dot{\mathbf{y}}} = L_{\mathbf{y}} \tag{55}$$

which are in fact Newton's equations of motion in the form already obtained by Lagrange (1762). (To permit certain constraints, Lagrange replaced the natural variables $\mathbf{y}$ by

so-called generalized coordinates $\mathbf{q}$ which are independent and meet these constraints.)

In order to attack the second-order system (55) Hamilton and his successors (notably Jacobi) effectively assumed that for fixed t and $\mathbf{y}$, the momentum vector system $\mathbf{p} = L_{\dot{\mathbf{y}}}(t, \mathbf{y}, \dot{\mathbf{y}})$ could be solved to express the variable(s) $\dot{\mathbf{y}}$ in terms of t, $\mathbf{y}$ and $\mathbf{p}$. Then through the chain rule, equations (55) become the first-order system in normal form

$$\dot{\mathbf{p}} = -H_{\mathbf{y}} \qquad \dot{\mathbf{y}} = H_{\mathbf{p}} \tag{56}$$

where the Hamiltonian H is defined by

$$H = H(t, \mathbf{y}, \mathbf{p} = \mathbf{p} \cdot \dot{\mathbf{y}} - L(t, \mathbf{y}, \dot{\mathbf{y}}) \tag{57}$$

assuming $\dot{\mathbf{y}} = \dot{\mathbf{y}}(t, \mathbf{y}, \mathbf{p})$ in the last equation. (These substitutions are now referred to collectively as the Legendre transformation.) In the classical case considered by Hamilton, L is independent of t, and $H = T + V$ is constant so that particles move on paths which preserve the total energy of the system. In general, Hamilton's equations (56) are analytically preferable to those of Lagrange (55). For example, their solutions are amenable to numerical approximation because they depend stably and uniquely on initial data.

Of course, the Legendre transformation can, in principle, be employed to replace the general E-L system (13) by an equivalent first order system in Hamiltonian form

$$\mathbf{p}' = -H_{\mathbf{y}} \qquad \mathbf{y}' = H_{\mathbf{p}} \tag{58}$$

where now $\mathbf{p} = f_{\mathbf{y}'}(x, \mathbf{y}, \mathbf{y}')$ is solved for $\mathbf{y}'$ and

$$H = H(x, \mathbf{y}, \mathbf{p}) = \mathbf{p} \cdot \mathbf{y}' - f(x, \mathbf{y}, \mathbf{y}') \tag{59}$$

in the resulting variables.

It is not difficult to show that for fixed x, f will be convex in $\mathbf{y}$ and $\mathbf{y}'$ in the sense of (24) precisely when H is convex in $\mathbf{p}$ for fixed $\mathbf{y}$ and $-H$ is convex in $\mathbf{y}$ for fixed $\mathbf{p}$. Such functions, among them $H(x, \mathbf{y}, \mathbf{p}) = |\mathbf{p}|^2 - |\mathbf{y}|^2$, are said to have saddle behavior.

Now, when f is just convex in $\mathbf{y}'$, then for fixed x, $\mathbf{y}$, $\mathbf{p}$, the $\mathbf{z}$ which makes $\mathbf{p} = f_{\mathbf{y}'}(x, \mathbf{y}, \mathbf{z})$ is that which maximizes $\mathbf{p} \cdot \mathbf{z} - f(x, \mathbf{y}, \mathbf{z})$. This suggests that when $f > -\infty$, the Hamiltonian should be given by

$$H(x, \mathbf{y}, \mathbf{p}) = \sup_{\mathbf{z}} [\mathbf{p} \cdot \mathbf{z} - f(x, \mathbf{y}, \mathbf{z})], \tag{60}$$

a definition that presupposes neither differentiability of f nor solvability of an auxiliary system. Note that $\mathbf{p} \cdot \mathbf{z}$ can be regarded as the value assigned at $\mathbf{z}$ to the linear functional $\mathbf{p}$ in the euclidean space considered as dual to that of $\mathbf{z}$. Building on earlier work of Fenchel (in euclidean spaces) and Moreau (in locally convex spaces), Rockafellar has used duality to study this Hamiltonian in a nonsmooth analytic setting where Hamiltonian inclusions replace Eqs. (58). He has also investigated the more general expression where the supremum is taken on $\mathbf{q} \cdot \mathbf{y} + \mathbf{p} \cdot \mathbf{z} - f(\mathbf{x}, \mathbf{y}, \mathbf{z})$ for fixed $\mathbf{x}, \mathbf{p}, \mathbf{q}$, which he conjectures may be the true Hamiltonian for mathematical purposes.

VII. MULTIDIMENSIONAL INTEGRAL PROBLEMS

Heretofore we have considered minimization of a real-valued function F on a set of functions defined over an interval $[a, b]$. When this interval is replaced by $\bar{D}$, the closure of a bounded domain D of $\mathbb{R}^d$ for $d > 1$, the analysis is more complicated, but basic ingredients remain in evidence.

In particular, when ∇u denotes the gradient of the real-valued C^1-function $u = u(\mathbf{x})$, the appropriate E-L equation for a C^2-function $f = f(\mathbf{x}, u, \nabla u)$, is

$$\mathbf{div}\, f_{\nabla u} = f_u, \quad \mathbf{x} \in D. \tag{61}$$

(This equation governs each component u of a vector-valued $\mathbf{u}$.)

Only solutions u_0 of this partial differential equation could minimize the integral function

$$F(u) = \int_{\bar{D}} f(\mathbf{x}, u(\mathbf{x}), \nabla u(\mathbf{x}))\, d\mathbf{x} \tag{62}$$

on the set

$$\mathcal{D} = \{u \in C^2(\bar{D}) \colon u|_S = \gamma\} \tag{63}$$

where γ is a given continuous real-valued function on S, the boundary of a fixed domain D. Here $d\mathbf{x}$ denotes the volume element in $\mathbb{R}^d$, and we suppose initially that S is so regular that the Riemann integral over $\bar{D} = D \cup S$ is defined and Green's Theorem holds.

Conversely, when f is convex in the variables u and ∇u, then each $u_0 \in \mathcal{D}$ that satisfies Eq. (61) must minimize F on $\mathcal{D}$. [However, in the multidimensional case, minimization does not imply a Weierstrass convexity in ∇u analogous to that in (21).]

A. Dirichlet's Principle

For example, $f(\mathbf{x}, u, \nabla u) = f(\nabla u) = |\nabla u|^2$ is convex in this sense and $f_{\nabla_u} = 2\nabla u$, so that each solution $u_0 \in \mathcal{D}$ of *Laplace's equation* $\mathbf{div}\,(\nabla u_0) = 0$ in D minimizes the Dirichlet integral

$$F(u) = \int_{\bar{D}} |\nabla u|^2\, d\mathbf{x} \tag{64}$$

on $\mathcal{D}$. Solutions of Laplace's equation are called *harmonic functions*. It is not difficult to show that in this case there

is at most one such minimizing function, but even here, it is far from evident that a minimizing harmonic function exists. Indeed, the assertion that it must (Dirichlet's Principle) applied uncritically by Riemann (1851), then challenged by Weierstrass, spurred the development of much subsequent analysis including the so-called direct methods of variational calculus pioneered by Hilbert in 1901. Moreover, on the disk $D = \{(r, \theta): r < 1\}$, the harmonic function $u_1(r, \theta) = \sum_{n=1}^{\infty} n^{-2} r^{n!} \cos(n!\theta)$ (in polar coordinates) extends continuously to $\bar{D}$, but its Dirichlet integral is infinite. Here, the highly irregular boundary values $\gamma = \gamma_1$ of u_1 determine a $\mathcal{D}$ of Eq. (63) that is empty, but for less pathological γ, Dirichlet's Principle has been established through functional analytic methods on much more general domains.

Again the basic procedure is to use convexity in ∇u and coercivity [(50) (ii) and (iii)] to prove existence of a minimizer u_0 in a Sobolev space of functions whose derivatives are in a set of Lebesgue integrable functions. Then one tries to show that u_0 is regular (smooth) enough to satisfy Laplace's equation in some sense. In fact, satisfaction in the distributional sense guarantees that u_0 is equal to a C^2 harmonic function almost everywhere (Weyl's Lemma).

Finding harmonic functions in D that extend continuously to assume prescribed values γ on ∂D is known as the *Dirichlet problem* for D. It is comparatively easy to show that there is at most one solution, and this boundary value problem is of independent interest because its solution u_0, if any, describes various physical situations. For example, if D is a domain in $\mathbb{R}^3$, then u_0 represents the steady-state temperature distribution within a homogenous medium (D) resulting from prescribed surface temperatures γ. However, as first noted by Lebesgue, we cannot expect a solution even on physical grounds: If γ is zero except on the surface of a sufficiently sharp thorn directed inward, then the temperature in D need not rise continuously to assume a prescribed maximum value of 100° at the tip of the thorn. For such domains, Dirichlet's Principle cannot hold—at least in its classical formulation. There is a "minimizing" harmonic function, but it does not assume the boundary values. The full study of related questions especially by Kellog and F. Riesz, resulted in the development of modern potential theory and its extension to solutions of other elliptic partial differential equations.

B. Plateau's Problem

Success in understanding, legitimizing, and extending Dirichlet's Principle encouraged examination of the related but much more difficult minimal surface problem. Although first considered by Lagrange in 1760, this problem is now attributed to Plateau, the Belgian physicist, whose mid-nineteenth century experiments helped define

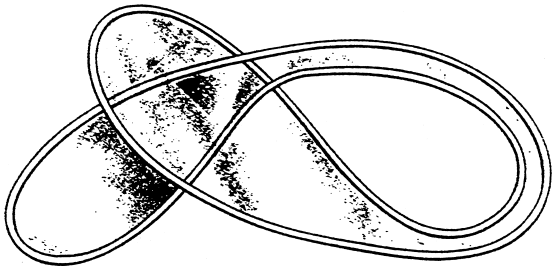

FIGURE 2 Soap film generated by a wire loop.

it. He conjectured that surface tension causes the actual shapes taken by soap films supported by wire loops withdrawn from a glycerine solution to be those that possess minimum area among competing surfaces with the same boundaries. However, Fig. 2 shows how difficult it can be to describe the possibly re-entrant competing surfaces in order to assign their areas, even for a single loop.

If we restrict attention to smooth surfaces that can be parametrized by a vector-valued mapping from a fixed planar region D, then their areas are given by an integral function similar to Eq. (62), and through Eq. (61) applied componentwise it can be shown that any smooth minimal surface must have zero mean curvature. Such surfaces can, in turn, be studied with the help of Dirichlet's Principle. Around 1931 this program led Douglas and Rado to produce independently the first major result: Among all continuous mappings of a closed base disk D into $\mathbb{R}^3$ whose boundary is mapped one-to-one onto a closed curve C (representing a single wire loop) there is one whose smooth image surface (the soap film) has minimum area. However, it was shown subsequently that some curves C admit spanning surfaces described by mappings from other base regions (disks with handles) that have less area. Moreover actual soap films which need not touch the entire bounding curve C could obviously have less area. Finally, multiple bounding curves C representing separate wire loops further complicate the descriptive picture, and their soap films can have smooth surface pieces that do not terminate on C. Indeed, the parallel circular rings of Fig. 3a can generate the soap film indicated having the shaded internal disk with a singular bounding circle in addition to those of the smooth surface of revolution and the pair of shaded disjoint circular disks of Fig. 3b and 3c.

What is needed is mathematics that can describe and assign size to such objects. For this purpose, Weierstrass introduced so-called *parametric* integrals whose values like those in Eq. (3) are unaffected by reparametrization and considered their minimization in his lectures. To handle other anomalies, several tools, both analytic and topological, were developed during the past century including

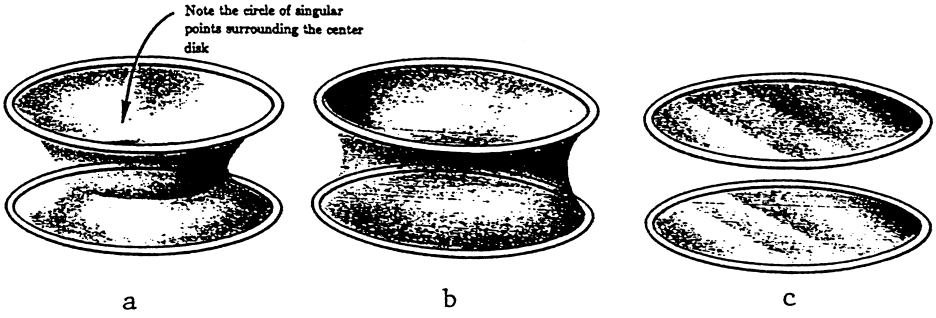

FIGURE 3 Soap films generated by a pair of rings.

Hausdorff measure of m-dimensional sets in higher dimensional space, varifolds, and integral currents. These provide the principle components of geometric measure theory formulated around 1960 by Almgren, Federer, and Fleming among others, and used to attack other extremal problems in higher dimensions that require intrinsic description. In particular, these methods have given new impetus to the study of minimal surface problems in $\mathbb{R}^d$ for $d > 3$ that was initiated in Douglas' work of 1931. Moreover, in $\mathbb{R}^3$ a few significant results have been obtained recently concerning surfaces with constant nonzero mean curvature that can represent closed soap bubbles.

Despite these efforts, many questions remain unanswered, especially in regard to multiply connected regions. In particular, in $\mathbb{R}^3$, it is still not known which surfaces of zero mean curvature (unfortunately referred to as *minimal surfaces*) have minimal area—at least among nearby competitors—thereby possessing the stability required of actual soap films. In certain cases, mathematical existence of unstable surfaces can be established, but just how many different surfaces are permitted by some boundary loop configurations and which of these will have singular sets is yet to be determined. However, the methods used to attack these questions have found other physical applications that range from characterizing types of crystalline structures in physical chemistry to establishing existence of black holes in relativistic analysis.

VIII. VARIATIONAL CALCULUS IN THE LARGE

Concern with unstable surfaces represents a modern trend in variational calculus, namely, consideration of *all* critical points of an integral function F, not just those that give local extremals. At each such point the Fréchet derivative F' vanishes, and just as in the case of ordinary functions of several variables, F can have directions of local maximal behavior as well as those of local minimal behavior, distinguished by signs of the second variations in these directions [recall Eq. (25)]. Thus, we are led to think of the graph of F as a "surface" lying over its domain $\mathcal{D}$ of functions. (Fig. 4).

Viewed in this light, we see that between a pair of isolated local minimum points there should be a region of $\mathcal{D}$ over which the graph of F resembles a range of mountains. Across this range, there should be at least one route connecting these points with lowest high point (a mountain pass), at which there are directions down as well as directions up the mountain. But this would correspond to a critical saddle point of F that is not a local extremal, and with care, this suggestive "mountain pass" terminology can be converted into a mathematically rigorous existence argument. It was first used successfully around 1940 by Courant to establish existence of unstable minimal surfaces, and it has since become an important technique in variational considerations.

However, the most remarkable consequence of regarding F over $\mathcal{D}$ as a whole, is the recognition that a deep relationship exists between the algebraic topological character of a space $\mathcal{D}$ and the variational functions F defined on it. Although first used by Birkhoff in 1917, this relationship was set forth around 1930 in works of Morse in America and, from a different viewpoint, Liusternik and Schnirelman in Russia. As a fundamental principle of nonlinear functional analysis, it now supplies an important source of results and insight in both variational calculus and nonlinear partial differential equations.

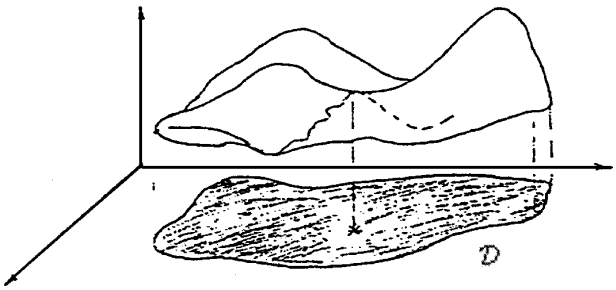

FIGURE 4 A mountain pass.

In its simplest form, Morse theory presupposes that F has only isolated non-degenerate critical points, and establishes a lower bound for their number based on numbers of homology classes of $\mathcal{D}$. This is achieved through recognition that the homology of the sublevel sets of F changes only at a critical point, and then only in a manner commensurate with the character of the critical point as reflected in that of the quadratic form of its second variation. In principle, Morse's theory even offers lower estimates of each type of critical point, but skill is required to assign a topology to the underlying function space $\mathcal{D}$ that has usable homology. Nevertheless, this theory was employed to establish existence of unstable minimal surfaces in 1939, and it has been extended to infinite dimensional Hilbert manifolds by Milnor, Palais, and Smale, and recently even to more general structures.

A simple version of Liusternik-Schnirelman theory provides lower estimates for the size of the critical set of a differentiable even function F (one for which $F(-u) = F(u)$) restricted to the surface $\mathcal{S}$ of the unit ball in a Banach space. In fact, the associated critical values of F at such points can be assessed through maximin estimates similar to those in Section III.B involving values of F on families of sets dependent on the topology of $\mathcal{S}$. This approach was used to prove existence of three non-self-intersecting closed geodesics (surface curves of stationary length) on any closed surface in $\mathbb{R}^3$ that smoothly resembles the surface of a sphere. Because this theory does not require assumptions about the critical set, it has had wide extensions and applications.

IX. CONCLUSION

Variational calculus supplies the analytic bridge linking ancient conjectures concerning an ideal universe with modern demands for optimal control of operating systems. It was instrumental in formulating variational principles of mechanics and physics and continues to supply insight into the relationship between these principles and their Euler-Lagrange systems of differential equations. Finally, it furnishes a wealth of nonlinear problems, many of physical origin, that appear simple but have consequences that are not. These problems have provided a motivating force in the creation of functional analysis, both linear and nonlinear as well as geometric measure theory.

GLOSSARY

Cascade algorithm This algorithm gives a constructive and efficient way to compute approximate values for the scaling function with arbitrarily high precision.

Discrete wavelet transform The discrete wavelet transform calculates the coefficients of the wavelet series approximation for a discrete signal.

Multiresolution analysis A multiresolution analysis of $L_2(R)$ consists of a scaling function and a nested sequence of closed subspaces for approximating $L_2(R)$ functions. Subspaces in this nested sequence correspond to different resolution levels from coarser to finer scales.

Thresholding Many of the coefficients of a wavelet series are often close to or equal to zero. The thresholding method sets these small wavelet coefficients to zero so that the sequence of wavelet coefficients contains long strings of zeros. It can be used for data compression or for noise removal. There are some different thresholding rules in wavelet shrinkage motivated from statistical theory.

Wavelet packets Wavelet packet functions consist of a rich family of building block functions. Mixtures of orthogonal quadrature filters may be applied to scaling functions and wavelets to get new building block functions. Families of new orthonormal basis functions so produced are called wavelet packets. Wavelet packet functions are more flexible than wavelets in representing different types of signals.

Wavelets Wavelets are waveform-like functions with fast tail decay and are oscillatory and localized. They comprise the family of translations and dilations of a single function. They are versatile building blocks for representing functions or signals in various functional classes.

Wavelet shrinkage A methodology for denoising by shrinking the empirical wavelet coefficients toward zero.

Wavelet shrinkage—Bayesian approach A methodology for denoising by combining the wavelet shrinkage and Bayesian formulation.

I. INTRODUCTION: WHY WAVELETS?

Wavelets and multiresolution analysis are a very popular subject in mathematical science and engineering. Wavelets are waveform-like functions with fast tail decay, and they are oscillatory and localized. They comprise the family of translations and dilations of a single function. They are versatile building blocks for representing functions or signals in various functional classes.

The wavelet transform is the set of inner products of all dilated and translated wavelets with an analyzed function. The range of this linear map is characterized by a reproducing kernel Hilbert space, and this linear map is isometric. The wavelet transform is a time–frequency analysis tool that decomposes the analysed function into different frequency components. Each frequency component is matched with a resolution scale. The wavelet transform of a signal depends on two variables, frequency and time (or scale and space). It provides localized time–frequency information of the analysed function.

To study the spectral behavior of a function or a signal, the classical Fourier transform requires full knowledge of the signal in the time domain. A signal change in a small interval of time will affect the entire spectral behavior. In contrast, wavelets can provide good localization in both time and frequency domains. The short-time Fourier transform can also correct the deficiency of the Fourier transform by placing a window function around a certain time point of interest before taking the Fourier transform, and it has the effect of restricting the spectral information of the signal to the domain of influence of the window function. However, the short-time Fourier transform cuts up the signal (in the time domain) into slices of fixed length determined by the time window width. Slices of the same length in time domain are used to resolve all frequency components high or low, which results in redundant information for high-frequency components and inadequate information for low-frequency components. However, the wavelet transform provides ideal and adaptive time–frequency localization. It cuts up the signal with different time window widths to adapt to different frequency components. Lower frequency components are analyzed through a time interval of wider width and higher frequency components are analyzed through a time interval of shorter width.

An arbitrary function in $L_2(R)$ can be represented by wavelet series. The computational aspects of wavelet series are very attractive with fast algorithm and low complexity. Wavelet coefficients of lower scales can be obtained from coefficients of higher scales using the fast algorithm. In the reverse direction, coefficients of higher scales can be recovered from coefficients of lower scales, again using the fast algorithm.

In all, the wavelet analysis has good time–frequency localization and good adaptivity to local features of a signal. These advantages together with the fast algorithm make wavelets a very popular analysis tool for a wide range of applications, including signal and image processing, data compression, statistical estimation, and denoising.

II. WAVELETS AND CONTINUOUS WAVELET TRANSFORMS

Let $\{\psi_{a,b}(x)\}$, with $a, b \in R$ and $a \neq 0$, be a family of functions obtained from a single function $\psi(x) \in L_2(R)$ by dilation and translation:

$$\psi_{a,b}(x) = \frac{1}{\sqrt{|a|}}\psi\left(\frac{x-b}{a}\right)$$

Further, ψ satisfies conditions $\int_{-\infty}^{\infty}\psi(x)\,dx = 0$ and $\int_{-\infty}^{\infty}\psi^2(x)\,dx = 1$ and also the admissibility condition

$$C_\psi = 2\pi\int_{-\infty}^{\infty}\frac{|\hat{\psi}(\omega)|^2}{|\omega|}\,d\omega < \infty$$

where

$$\hat{\psi}(\omega) = (\sqrt{2\pi})^{-1}\int_{-\infty}^{\infty}\psi(x)e^{-i\omega x}\,dx$$

is the Fourier transform of $\psi(x)$. The function $\psi(x)$ is called the mother wavelet function and $\psi_{a,b}(x)$ are called wavelets. The name "wavelet" comes from the fact that $\psi(x)$ is well localized and, as $\int_{-\infty}^{\infty}\psi(x)\,dx = 0$, its shape resembles small waves. The localization of wavelets can be made arbitrarily fine by appropriate rescaling.

For any function $f \in L_2(R)$, the continuous wavelet transform is defined as a bivariate function

$$\mathcal{T}f(a,b) = \int_{-\infty}^{\infty} f(x)\overline{\psi_{a,b}(x)}\,dx$$

The value of $\mathcal{T}f(a,b)$ is called the scale-space wavelet coefficient. Notice that $|\mathcal{T}f(a,b)| \leq \|f\|_2$.

A. Time–Frequency Analysis

The function $f(x)$ is analyzed by the continuous wavelet transform based on dilations and translations of one single wavelet function $\psi(x)$. The continuous wavelet transform can serve as a window function extracting local information around certain time-frequency span. We say a function

$w(x) \in L_2(R)$ is a window function if $xw(x)$ is in $L_2(R)$. The center c_w and the radius Δ_w of a window function $w(x)$ are defined by

$$c_w = \frac{1}{\|w\|_2^2} \int_{-\infty}^{\infty} x|w(x)|^2\,dx$$

and

$$\Delta_w = \frac{1}{\|w\|_2^2} \left\{ \int_{-\infty}^{\infty} (x - c_w)^2 |w(x)|^2\,dx \right\}^{1/2}$$

Suppose that $\psi(x)$ and $\hat{\psi}(\omega)$ are window functions. Denote their centers and radii by c_ψ, Δ_ψ, and $c_{\hat{\psi}}$, $\Delta_{\hat{\psi}}$, respectively.

The continuous wavelet transform by $\psi_{a,b}(x)$ localizes the signal $f(x)$ with a "time window" centered at $ac_\psi + b$ and with width $2a\Delta_\psi$. On the other hand, $\hat{\psi}_{a,b}(\omega)$ can serve as a window function, which localizes the spectral information of $\hat{f}(\omega)$ with a "frequency window" centered at $c_{\hat{\psi}}/a$ and with width $2\Delta_{\hat{\psi}}/a$. Notice that, by the Parseval identity, the continuous wavelet transform can be expressed as

$$\begin{aligned} \mathcal{T}_\psi f(a,b) &= \int_{-\infty}^{\infty} f(x)\overline{\psi_{a,b}(x)}\,dx \\ &= \int_{-\infty}^{\infty} \hat{f}(\omega)\overline{\hat{\psi}_{a,b}(\omega)}\,d\omega \end{aligned}$$

Notation $\mathcal{T}_\psi$ is used to indicate that the transform is wavelet dependent. For simplicity, we may suppress the subscript and use notation $\mathcal{T}$ instead, if no confusion. The continuous wavelet transform $\mathcal{T}f(a,b)$ localizes both the time and frequency information of the signal f. The window widths for time and frequency are $2a\Delta_\psi$ and $2\Delta_{\hat{\psi}}/a$, respectively. That is, the continuous wavelet transform $\mathcal{T}f(a,b)$ can serve as a time–frequency window with shorter time-window width for higher frequency and wider time-window width for lower frequency.

B. Regularity

A wavelet function $\psi(x)$ is called r-regular ($r \in N$) if it satisfies the condition

$$\left|\psi^{(\alpha)}(x)\right| \le C_m(1 + |x|)^{-m}$$

for each integer $m \in N$ and for every $\alpha = 0, 1, \ldots, r$.

C. Localization

In order to have good time-domain resolution, it is necessary that wavelets be localized in time. Such time localization may be quantified by the index γ:

$$|\psi(x)| \le c(1 + |x|^2)^{-\gamma/2}, \quad c > 0,\ \gamma > 1$$

The larger γ is, the better the localization is. In the same way the frequency localization can be quantified by the index $\tilde{\gamma}$:

$$|\hat{\psi}(\omega)| \le c(1 + |\omega|^2)^{-\tilde{\gamma}/2}, \quad c > 0,\ \tilde{\gamma} > 0$$

Again, the larger $\tilde{\gamma}$ is, the better the frequency localization is.

D. Vanishing Moments (or Oscillation Condition)

The wavelet function has at least the 0th degree moment vanished. This phenomenon can be extended to require that some more consecutive moments vanish

$$\int_{-\infty}^{\infty} \psi(x)x^k\,dx = 0, \quad k = 0, 1, \ldots, \ell \qquad (1)$$

assuming that $\psi(x)$ is sufficiently localized. We say that the wavelet $\psi(x)$ has vanishing moments of order m (or of degree $m-1$) if and only if

$$\int_{-\infty}^{\infty} \psi(x)x^k\,dx = 0, \quad k = 0, \ldots, m-1,$$

and

$$\int_{-\infty}^{\infty} \psi(x)x^m\,dx \neq 0$$

Condition (1) is equivalent to

$$\hat{\psi}(\omega) = o(\omega^\ell), \quad (\omega \to 0)$$

whenever $\psi(x) \in L_1(R)$ and $x^\ell\psi(x) \in L_1(R)$. Notice that an r-regular wavelet function has at least up to rth degree vanishing moments. Usually the degree of vanishing moments is much higher than the degree of regularity.

E. Resolution of Identity

If $f, g \in L_2(R)$, then the following resolution of the identity formula holds:

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathcal{T}f(a,b)\overline{\mathcal{T}g(a,b)}\frac{1}{a^2}\,da\,db = C_\psi\langle f, g\rangle$$

where ψ satisfies the admissibility condition. A function can be reconstructed from its wavelet transform:

$$f(x) = \frac{1}{C_\psi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathcal{T}f(a,b)\psi_{a,b}(x)\frac{1}{a^2}\,da\,db$$

by means of the resolution of the identity. The preceding equality is meant in the L_2-sense, not in the pointwise sense. Furthermore, by taking $f = g$ in the resolution of the identity formula, we obtain

$$C_\psi^{-1}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}|\mathcal{T}f(a,b)|^2a^{-2}\,da\,db=\int_{-\infty}^{\infty}|f(x)|^2\,dx$$

That is, the continuous wavelet transform $\mathcal{T}_\psi$ maps $L_2(R,dx)$ isometrically into $L_2(R^2,a^{-2}C_\psi^{-1}\,da\,db)$.

F. The Associated Reproducing Kernel Hilbert Spaces

Denote the set of images of the wavelet transform $\{\mathcal{T}f\colon f\in L_2(R)\}$ by $\mathcal{H}$, which is a subspace of $L_2(R^2,a^{-2}C_\psi^{-1}\,da\,db)$. Then $\mathcal{H}$ is a reproducing kernel Hilbert space with the reproducing kernel

$$\mathcal{K}(u,v;a,b)=\int_{-\infty}^{\infty}\psi_{u,v}(x)\overline{\psi_{a,b}(x)}\,dx$$

and the following identity holds

$$C_\psi^{-1}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\mathcal{K}(u,v;a,b)\mathcal{T}f(u,v)u^{-2}\,du\,dv=\mathcal{T}f(a,b)$$

G. Shifting and Scaling Properties

Let $g(x)=f(x-x_0)$ and $h(x)=\sqrt{s}f(sx)$, then

$$\mathcal{T}g(a,b)=\mathcal{T}f(a,b-x_0)\text{ and }\mathcal{T}h(a,b)=\mathcal{T}f(sa,sb)$$

H. Function Regularity and the Order of Magnitude of Wavelet Coefficients

As we will see, a local regularity of the analyzed function implies a local decrease of the scale-space wavelet coefficients at fine resolutions.

We say that a funcation f is of local Hölder regularity α at x_0, if and only if f can be written as $f(x+x_0)=P_n(x)+\delta(x)$, where $n<\alpha\le n+1$, P_n is a polynomial of degree at most n and $\delta(x)=O(|x|^\alpha)$ as $x\to 0$. Suppose that the wavelet $\psi(x)$ has vanishing moments of order at least $n+1$ and that $x^\alpha\psi(x)\in L_1(R)$. If f is of local Hölder regularity of degree α at a point x_0, then

$$\mathcal{T}f(a,b+x_0)=O(|a|^{\alpha+1/2}+|a|^{1/2}|b|^\alpha),\quad a\neq 0 \tag{2}$$

as $a,b\to 0$. The asymptotic behavior (2) of $\mathcal{T}f(a,b+x_0)$ for a and b approaching zero implies that, for every fixed (a,b),

$$\mathcal{T}f(\lambda a,\lambda b+x_0)=O(|\lambda|^{\alpha+1/2})$$

as $\lambda\to 0$. In other words, the local Hölder regularity of degree α for f at a point x_0 is mirrored by a decrease of order $|\lambda|^{\alpha+1/2}$ along every straight line $\{(\lambda a,\lambda b+x_0)\colon \lambda\in R\}$ in the plane.

III. MULTIRESOLUTION ANALYSIS

Wavelets can be used as an analysis tool to describe mathematically the increment in information needed to go from a coarser approximation to a higher resolution approximation. This insight was put into the framework of multiresolution analysis by Mallat (1989).

A multiresolution analysis of $L_2(R)$ consists of a nested sequence of closed subspaces $\cdots V_{j-1}\subset V_j\subset V_{j+1}\cdots$ for approximating $L_2(R)$ functions. The multiresolution analysis satisfies the following conditions:

1. $\bigcup_{j=-\infty}^{\infty}V_j$ is dense in $L_2(R)$.
2. $\bigcap_{j=-\infty}^{\infty}V_j=\{0\}$.
3. $f(x)\in V_j$ if and only if $f(2x)\in V_{j+1},\ \forall j\in Z$.
4. There exists a function $f(x)$ such that $\{f(x-k)\colon k\in Z\}$ forms an unconditional basis (also known as Riesz basis) for V_0.

Notice that $\{f(2^jx-k)\colon k\in Z\}$ is an unconditional basis for V_j.

Given this translation-invariant unconditional basis, we are seeking whether a translation-invariant orthonormal basis exists. The answer is affirmative. There exists a function $\phi(x)$ such that $\int_{-\infty}^{\infty}\phi(x)\,dx=1$ and that $\{\phi(x-k)\}_{k\in Z}$ forms an orthonormal basis for V_0. The function $\phi(x)$ is called a wavelet scaling function or the father wavelet.

The following is a brief description of construction of $\phi(x)$ from the unconditional basis $\{f(x-k)\}_{k\in Z}$ based on the Fourier method.

The family of integral translates of one single function $\phi^{(o.n.)}(x)\in L_1(R)\cap L_2(R)$ is an orthonormal set if and only if

$$\sum_{k\in Z}\left|\hat{\phi}^{(o.n.)}(\omega+2\pi k)\right|^2=\frac{1}{2\pi} \tag{3}$$

for all $\omega\in R$. Given the unconditional basis $\{f(x-k)\colon k\in Z\}$, let

$$M(\omega)=\left(2\pi\sum_{k=-\infty}^{\infty}|\hat{f}(\omega+2k\pi)|^2\right)^{-1/2}$$

and let $\phi(x)$ be given by

$$\hat{\phi}(\omega)=M(\omega)\hat{f}(\omega)$$

It can be easily checked that $\phi(x)$ satisfies (3). Thus $\{\phi(x-k)\}_{k\in Z}$ forms an orthonormal basis for V_0. Notice that $\{\phi_{j,k}(x)=\sqrt{2^j}\phi(2^jx-k)\colon k\in Z\}$ is then an orthonormal basis for V_j. Since $V_0\subset V_1$, the scaling function $\phi(x)$ can be represented as a linear combination of functions $\phi_{1,k}(x)$:

$$\phi(x) = \sum_{k\in Z} h_k \phi_{1,k}(x) \tag{4}$$

for some coefficients $h_k, k \in Z$. The preceding equation is called the two-scale equation or the scaling equation. The sequence of coefficients $\{h_k : k \in Z\}$ has the properties

$$\sum_{k\in Z} h_k = \sqrt{2} \qquad \text{and} \qquad \sum_{k\in Z} h_k^2 = 1$$

The two-scale equation (4) can be rewritten in terms of Fourier transform as

$$\hat{\varphi}(\omega) = \sum_{k\in Z} h_k \hat{\varphi}_{1,k}(\omega) = m_0(\omega/2)\hat{\varphi}(\omega/2) \tag{5}$$

where

$$m_0(\omega) = \frac{1}{\sqrt{2}} \sum_{k\in Z} h_k e^{-ik\omega}$$

Orthogonality of these $\phi(x-k)$ implies that

$$|m_0(\omega)|^2 + |m_0(\omega+\pi)|^2 = 1$$

By iterating (5), we have

$$\hat{\varphi}(\omega) = \hat{\phi}(0) \prod_{j=1}^{\infty} m_0\left(\frac{\omega}{2^j}\right) = \frac{1}{\sqrt{2\pi}} \prod_{j=1}^{\infty} m_0\left(\frac{\omega}{2^j}\right)$$

Define the orthogonal complementary subspaces $W_j = V_{j+1} - V_j$ so that $V_{j+1} = V_j \oplus W_j$, where $\oplus$ is an orthogonal direct sum. Then the space $L_2(R)$ can be decomposed as

$$L_2(R) = \bigoplus_{j\in Z} W_j$$

For an arbitrary multiresolution analysis of $L_2(R)$, there exists a function $\psi(x)$ such that $\{\psi_{j,k}(x) = \sqrt{2^j}\,\psi(2^j x - k) : k \in Z\}$ forms an orthonormal basis of the difference space W_j. Thus, $\{\psi_{j,k}(x) : j, k \in Z\}$ forms an orthonormal basis for $L_2(R)$. The function $\psi(x)$ is called a wavelet function or the mother wavelet. Since $\psi(x) \in W_0 \subset V_1$, it can be represented as

$$\psi(x) = \sum_{k\in Z} g_k\, \phi_{1,k}(x) \tag{6}$$

for some coefficients g_k, $k \in Z$. One possibility for the choice of these coefficients may be set to relate to h_k by

$$g_k = (-1)^k \bar{h}_{1-k}$$

That is, essentially only one two-scale sequence h governs the multiresolution analysis and its wavelet decomposition. The two-scale equation (6) can be rewritten in terms of Fourier transform as

$$\hat{\psi}(\omega) = m_1(\omega/2)\hat{\varphi}(\omega/2) \tag{7}$$

where

$$m_1(\omega) = \frac{1}{\sqrt{2}} \sum_{k\in Z} g_k e^{-ik\omega} = -e^{-i\omega}\,\overline{m_0(\omega+\pi)}$$

The sequence of coefficients $\{g_k : k \in Z\}$ has the properties

$$\sum_{k\in Z} g_k = 0 \qquad \text{and} \qquad \sum_{k\in Z} g_k^2 = 1$$

A multiresolution analysis $\{V_j : j \in Z\}$ of $L_2(R)$ is called r-regular, if the scaling function $\phi(x)$ (or the wavelet $\psi(x)$) can be so chosen to satisfy the condition

$$\left|\phi^{(\alpha)}(x)\right| \le C_m (1+|x|)^{-m}$$

for each integer $m \in N$ and for every $\alpha = 0, 1, \ldots, r$.

For the rest of this section, the multiresolution analysis $\{V_j : j \in Z\}$ is assumed r-regular, unless otherwise specified.

Let

$$\mathcal{V}(x,y) = \sum_{k\in Z} \phi(x-k)\overline{\phi(y-k)}$$

$$\mathcal{V}_j(x,y) = \sum_{k\in Z} 2^j \phi(2^j x - k)\overline{\phi(2^j y - k)}$$

$$\mathcal{W}(x,y) = \sum_{k\in Z} \psi(x-k)\overline{\psi(y-k)}$$

$$\mathcal{W}_j(x,y) = \sum_{k\in Z} 2^j \psi(2^j x - k)\overline{\psi(2^j y - k)}$$

By the r-regularity property, we immediately deduce that

$$\left|\partial_x^\alpha \partial_y^\beta\, \mathcal{V}(x,y)\right| \le C_m (1+|x-y|)^{-m}$$

for each integer $m \in N$ and for every $\alpha = 0, 1, \ldots, r$, and $\beta = 0, 1, \ldots, r$.

The wavelet subspaces V_j and W_j are reproducing kernel Hilbert spaces with the reproducing kernels $\mathcal{V}_j(x,y)$ and $\mathcal{W}_j(x,y)$, respectively. The orthogonal projection of $f \in L_2(R)$ onto the subspaces V_j and W_j can be written respectively as

$$\mathcal{P}_{V_j} f(x) = \int_{-\infty}^{\infty} \mathcal{V}_j(x,y) f(y)\, dy$$

and

$$\mathcal{P}_{W_j} f(x) = \int_{-\infty}^{\infty} \mathcal{W}_j(x,y) f(y)\, dy$$

For an r-regular multiresolution analysis, we have

$$\int_{-\infty}^{\infty} \mathcal{V}_j(x,y) y^k\, dy = x^k$$

and

$$\int_{-\infty}^{\infty} \mathcal{W}_j(x,y) y^k\, dy = 0$$

for every $j \in Z$ and $k = 0, 1, \ldots, r$.

A kernel $\mathcal{V}(x,y)$ is said to be of order m if and only if it satisfies the moment conditions

$$\int_{-\infty}^{\infty} \mathcal{V}(x,y) y^k\, dy = \begin{cases} 1, & k = 0 \\ x^k, & k = 1, \ldots, m-1 \\ \alpha(x) \ne x^m, & k = m \end{cases}$$

A projection kernel $\mathcal{V}(x, y)$ arising from a multiresolution analysis is of order m if and only if the associated wavelet $\psi(x)$ has vanishing moments of order m. Usually the order of vanishing moments is much higher than the degree of regularity.

For a multiresolution analysis, one may be interested in knowing the wellness of the projection approximation $\mathcal{P}_{V_j} f$ to f. The answer depends on the regularity of f and the regularity of functions in V_j. The higher these regularities are, the better the projection approximation is.

Theorem 1 *Suppose that the multiresolution analysis has regularity r. Then $f(x)$ is in the Sobolev space $W_2^s(R)$, $0 \le s \le r$, if and only if*

$$\limsup_{j\to\infty} 2^{js} \left\| f - \mathcal{P}_{V_j} f \right\|_2 < \infty$$

This theorem reveals the approximation order of the projection $\mathcal{P}_{V_j}$ in L_2-norm. It also characterizes the function space of $W_2^s(R)$.

To look further into the pointwise behavior of the projection $\mathcal{P}_{V_j}$, assume that $f(x)$ belongs to $C^{m,\alpha}(R) \cap L_2(R)$ for some $0 < \alpha \le 1$, where

$$C^{m,\alpha}(R) = \left\{ f \in C^m(R) : \left| f^{(m)}(x) - f^{(m)}(y) \right| \le A|x - y|^\alpha,\ A > 0 \right\}.$$

Suppose that $\mathcal{V}(x, y)$ is of order m. Define

$$b_m(x) = x^m - \int_{-\infty}^{\infty} \mathcal{V}(x, y) y^m \, dy$$

Notice that the function $b_m(x)$ is a continuous periodic function with period one. Assume that the kernel $\mathcal{V}(x, y)$, or $\phi(x)$ or $\psi(x)$, is sufficiently localized so that

$$\int_{-\infty}^{\infty} |\mathcal{V}(x, y)(y - x)^{m+\alpha}| \, dy < \infty$$

Then

$$f(x) - \mathcal{P}_{V_j} f(x) = \frac{1}{2^{jm}\, m!} f^{(m)}(x) b_m(2^j x) + O\left(2^{-j(m+\alpha)}\right) \tag{8}$$

A multiresolution analysis $\{V_j : j \in Z\}$ is said to be symmetric if the projection kernel satisfies the condition $\mathcal{V}(-x, y) = \mathcal{V}(x, -y)$. Notice that $\mathcal{V}(-x, y)$ is a time-reversed kernel, and $\int_{-\infty}^{\infty} \mathcal{V}(x, -y) f(y) \, dy$ corresponds to the transform of time-reversed signal f. If the multiresolution analysis is symmetric, then $b_m(-x) = (-1)^m b_m(x)$. When m is even, $b_m(x)$ is symmetric about zero. Since $b_m(x)$ is periodic with period one, $b_m(x)$ is also symmetric about all the points $x = k/2, k \in Z$. When m is odd $b_m(x)$ is antisymmetric about zero and hence antisymmetric about all the points $x = k/2, k \in Z$.

IV. DISCRETE WAVELET TRANSFORMS

In the continuous wavelet transform, we consider the family of wavelets

$$\psi_{a,b}(x) = \frac{1}{\sqrt{|a|}} \psi\left(\frac{x - b}{a}\right)$$

where $a, b \in R$, $a \ne 0$ and $\psi(x)$ is admissible. In the multiresolution analysis, there exist such functions $\phi(x)$ and $\psi(x)$ that $\{\phi_{j,k}(x) : k \in Z\}$ constitutes an orthonormal basis for V_j and $\{\psi_{j,k}(x) : k \in Z\}$ constitutes an orthonormal basis for W_j. Thus, sampling information of $f(x)$ on the lattice points,

$$a = 2^j, \quad b \in 2^j Z \quad \text{for } j \in Z$$

is enough to gain full knowledge of f. In the discretization, we restrict a and b to the above lattice points. For every $f(x) \in L_2(R)$, $f(x)$ can be represented in terms of orthonormal wavelet series

$$f(x) = \sum_{k\in Z} c_{j,k} \phi_{j,k}(x) + \sum_{\ell \ge j} \sum_{k\in Z} d_{\ell,k} \psi_{\ell,k}(x)$$

or

$$f(x) = \sum_{\ell\in Z} \sum_{k\in Z} d_{\ell,k} \psi_{\ell,k}(x)$$

where

$$c_{j,k} = \langle f, \phi_{j,k} \rangle, \qquad d_{\ell,k} = \langle f, \psi_{\ell,k} \rangle$$

with $\langle \cdot, \cdot \rangle$ the inner product in L_2. By the two-scale equations (4) and (6), we have

$$\phi_{j-1,k}(x) = \sum_{\ell\in Z} h_{\ell-2k} \phi_{j,\ell}(x) \tag{9}$$

and

$$\psi_{j-1,k}(x) = \sum_{\ell\in Z} g_{\ell-2k} \phi_{j,\ell}(x) \tag{10}$$

By (9), (10), and the orthogonality property of wavelets, we obtain

$$c_{j-1,k} = \langle f, \phi_{j-1,k} \rangle = \left\langle f, \sum_{\ell\in Z} h_{\ell-2k} \phi_{j,\ell} \right\rangle = \sum_{\ell\in Z} h_{\ell-2k} c_{j,\ell}$$

Similarly,

$$d_{j-1,k} = \langle f, \psi_{j-1,k} \rangle = \left\langle f, \sum_{\ell\in Z} g_{\ell-2k}\ \phi_{j,\ell} \right\rangle = \sum_{\ell\in Z} g_{\ell-2k} c_{j,\ell}$$

In the reverse direction, coefficients in the finer resolution scale can be obtained from coefficients in the coarser resolution scale:

$$c_{j,k} = \langle f, \phi_{j,k}\rangle = \sum_\ell c_{j-1,\ell}\langle \phi_{j-1,\ell}, \phi_{j,k}\rangle + \sum_\ell d_{j-1,\ell}\langle \psi_{j-1,\ell}, \phi_{j,k}\rangle = \sum_\ell c_{j-1,\ell} h_{k-2\ell} + \sum_\ell d_{j-1,\ell} g_{k-2\ell}$$

In summary, we have the following fast wavelet algorithm.

Wavelet decomposition: $\begin{cases} c_{j-1,k} = \sum_{\ell\in Z} h_{\ell-2k} c_{j,\ell}, \\ d_{j-1,k} = \sum_{\ell\in Z} g_{\ell-2k} c_{j,\ell}, \end{cases}$

Wavelet reconstruction:

$$c_{j,k} = \sum_{\ell\in Z} h_{k-2\ell} c_{j-1,\ell} + \sum_{\ell\in Z} g_{k-2\ell} d_{j-1,\ell}$$

The preceding formulas give the so-called cascade algorithm. The algorithm gives a constructive and efficient way to compute approximate values of the scaling function $\phi(x)$ with arbitrarily high precision, provided that $\phi(x)$ has compact support. Use the notation $c_j = (\ldots, c_{j,-1}, c_{j,0}, c_{j,1}, \ldots)$ to denote the low-pass sequence and $d_j = (\ldots, d_{j,-1}, d_{j,0}, d_{j,1}, \ldots)$ to denote the high-pass sequence. Following is the cascade algorithm for approximate values of the scaling function.

1. We start with a low-pass sequence c_0, with $c_{0,0} = 1$ and $c_{0,k} = 0$ for $k \neq 0$, and a high-pass sequence $d_0 = 0$.
2. Set $j = j + 1$. Compute c_j based on c_{j-1} and $d_{j-1} = 0$ using the reconstruction formula. At each step of this cascade algorithm, twice as many values are computed. Values at "even points" $c_{j,2k}$ are refined from the previous iteration

$$c_{j,2k} = \sum_{\ell\in Z} h_{2(k-\ell)} c_{j-1,\ell}$$

and values at "odd points" $c_{j,2k+1}$ are computed by

$$c_{j,2k+1} = \sum_{\ell\in Z} h_{2(k-\ell)+1} c_{j-1,\ell}$$

3. Go to step 2, if $j < J$; otherwise, terminate the iteration and go to step 4 for approximate values of $\phi(x)$.
4. Set $\eta_J(2^{-J}k) = c_{J,k}$. Linearly interpolate the values $\eta_J(2^{-J}k)$ to obtain $\eta_J(x)$ for nondyadic x. This function $\eta_J(x)$ is used to approximate $\phi(x)$.

The error order of this approximation is given by

$$\|\phi - \eta_J\|_\infty = O(2^{-J\alpha})$$

where $\phi(x)$ is assumed to be Hölder continuous with exponent α. Thus, by letting the number of iterations $J \to \infty$, the approximation to $\phi(x)$ can be made with arbitrarily high accuracy. An attractive feature of the cascade algorithm is that it allows one to zoom in on particular features of $\phi(x)$.

For a discrete signal of finite extent $f = (f_1, \ldots, f_n)$, the discrete wavelet transform calculates the coefficients of its wavelet transform approximation. This transformation maps the vector f to a vector of n wavelet coefficients. The discrete wavelet transform can be obtained as $w = Wf$, where W is an orthogonal matrix corresponding to the discrete wavelet transform. To get the wavelet coefficients w, we do not actually perform the matrix multiplication. Instead we use the fast algorithm with complexity $O(n)$.

Functions in the space $L_2(R)$ can be represented by orthonormal wavelet series. We shall notice that wavelet series are just as effective in the analysis of other spaces, such as $L_p(R)$ for $1 < p < \infty$, Sobolev spaces, Hölder spaces, Hardy spaces, and Besov spaces.

Suppose that the mother wavelet $\psi(x)$ arising from a multiresolution analysis of $L_2(R)$ has regularity of degree $r \geq 1$. Then the set $\{\psi_{j,k}(x): j, k \in Z\}$ constitutes an unconditional basis for $L_p(R)$, $1 < p < \infty$. It clearly does not apply to the spaces $L_1(R)$ and $L_\infty(R)$, which have no unconditional bases. Moreover, a wavelet series $f(x) = \sum_{j,k\in Z}\langle f, \psi_{j,k}\rangle\psi_{j,k}(x)$ belongs to $L_p(R)$ if and only if

$$\left(\sum_{j,k\in Z}\langle f, \psi_{j,k}\rangle^2 \psi_{j,k}^2(x)\right)^{1/2} \in L_p(R)$$

if and only if

$$\left(\sum_{j,k\in Z}\langle f, \psi_{j,k}\rangle^2 I(2^{-j}k \leq x \leq 2^{-j}(k+1))\right)^{1/2} \in L_p(R)$$

where I is the indicator function.

Similarly, wavelets provide unconditional bases and characterizations for Sobolev spaces $W_2^s(R)$, $s \geq 0$. The Sobolev spaces $W_2^s(R)$ are defined by

$$W_2^s(R) = \left\{ f \in L_p(R): \int_{-\infty}^{\infty} (1 + |\omega|^2)^s |\hat{f}(\omega)|^2 \, d\omega < \infty \right\}$$

The set $\{\psi_{j,k}(x): j, k \in Z\}$ constitutes an unconditional basis for $W_2^s(R)$ for $0 \leq s < r$. A wavelet series $f(x) = \sum_{j,k\in Z}\langle f, \psi_{j,k}\rangle\psi_{j,k}(x)$ belongs to $W_2^s(R)$ if and only if

$$\sum_{j,k\in Z}\langle f, \psi_{j,k}\rangle^2 (1 + 2^{2js}) < \infty$$

V. FILTERS AND QUADRATURE FILTERS

The discrete wavelet analysis and the associated fast algorithm can be conveniently put into the framework of filtering. Consider a discrete signal $f = \{f_n\}$, which could be finite or infinite. If not otherwise specified, we assume

that the sequence is doubly infinite, i.e., the index n goes from $-\infty$ to $+\infty$.

We use the term filter to denote a convolution operator. Suppose that h and f are both in $\ell_1(Z)$. The filter operator H acting on f is given by

$$(Hf)_n = \sum_{k\in Z} h_{n-k} f_k$$

If the filter sequence h_k is finitely supported, we have a finite impulse response (FIR) filter; otherwise, we have an infinite impulse response (IIR) filter.

We use the term quadrature filter (QF) to denote a linear operator that convolves and decimates. Define a convolution–decimation QF operator H_Q and its adjoint H_Q^* by the following formulas:

$$(H_Q f)_k = \sum_{\ell\in Z} h_{\ell-2k} f_\ell, \quad k \in Z$$

and

$$\left(H_Q^* f\right)_k = \sum_{\ell\in Z} \bar{h}_{k-2\ell} f_\ell, \quad k \in Z$$

An individual quadrature filter is not invertible, as it loses information in the decimation step. However, it is possible to find a pair of QFs so that each preserves the information lost by the other. Such a pair of QFs can be combined into an invertible operator. For convenience, we may suppress the subscript Q for notation of quadrature filters, if there is no confusion.

A pair of QFs H and G satisfying

$$g_k = (-1)^k \bar{h}_{1-k}$$

is called a set of quadrature mirror filters (QMFs). A pair of QFs H and G is called a set of orthogonal QFs, if the following conditions hold:

$$HH^* = GG^* = I$$
$$GH^* = HG^* = 0$$
$$H^*H + G^*G = I$$
$$H\mathbf{1} = \sqrt{2}\,\mathbf{1},\ \mathbf{1} = (\ldots, 1, 1, 1, \ldots)^T$$

There are no symmetric orthogonal exact reconstruction FIR QMFs. The orthogonal QF conditions just given imply that

$$H^*\mathbf{1} = \frac{1}{\sqrt{2}}\mathbf{1}, \qquad G\mathbf{1} = 0, \qquad |G^*\mathbf{1}| = \frac{1}{\sqrt{2}}\mathbf{1}$$

where the absolute value in $|G^*\mathbf{1}|$ is meant entrywise.

Associated with the filter H, define

$$H(\omega) = \sum_{k\in Z} h_k e^{-ik\omega}$$

The filter H is said to be low-pass if the support of $H(\omega)$ contains 0; otherwise, it is said to be high-pass.

The fast wavelet algorithm can be represented through QFs:

Wavelet decomposition: $c_{j-1} = Hc_j,\ d_{j-1} = Gc_j$

Wavelet reconstruction: $c_j = H^*c_{j-1} + G^*d_{j-1}$

VI. SOME EXAMPLES OF WAVELETS

A. Haar Wavelets

The scaling function is

$$\phi(x) = I(0 \le x < 1), \text{ where } I \text{ is the indicator function}$$

The wavelet is

$$\psi(x) = I(0 \le x < 1/2) - I(1/2 \le x < 1)$$

The associated orthogonal QF coefficients are

$$h_0 = h_1 = \frac{1}{\sqrt{2}}, \qquad g_0 = \frac{1}{\sqrt{2}}, \qquad g_1 = -\frac{1}{\sqrt{2}}$$

The Haar wavelet is extremely localized in time, but it has poor regularity (not even continuous). Its Fourier transform satisfies the condition

$$|\hat{\psi}(\omega)| = O(|\omega|^{-1}), \quad |\omega| \to \infty$$

That is, the Haar wavelet has poor localization in the frequency domain.

B. Littlewood–Paley Wavelets or Shannon's Wavelets

The Haar wavelets have very good time localization but poor frequency localization. The other extreme is the Shannon wavelets, also known as the Littlewood–Paley analysis. They have very good frequency localization but poor time localization. They are time-scale mirror images of Haar wavelets.

A function $f \in L_2(R)$ is called bandlimited if its Fourier transform $\hat{f}(\omega)$ has compact support. For simplicity, we assume the support is on $[-\pi, \pi]$. Then $\hat{f}(\omega)$ can be represented by its Fourier series

$$\hat{f}(\omega) = \sum_{k\in Z} f(n)\frac{e^{-ik\omega}}{\sqrt{2\pi}}, \quad \omega \in [-\pi, \pi]$$

It follows that

$$f(x) = \frac{1}{\sqrt{2\pi}} \int_{-\pi}^{\pi} \hat{f}(\omega) e^{i\omega x}\, d\omega = \sum_{k\in Z} f(k)\, \frac{\sin \pi(x-k)}{\pi(x-k)}$$

Let $V_j \subset L_2(R)$ be the space of bandlimited functions $f(x)$ whose Fourier transform is supported on $[-2^j\pi, 2^j\pi]$. It can be shown that $\{V_j : j \in Z\}$ constitutes

a multiresolution analysis of $L_2(R)$. The scaling function and its Fourier transform are given by

$$\phi(x) = \frac{\sin(\pi x)}{\pi x}$$

and

$$\hat{\phi}(\omega) = \frac{1}{\sqrt{2\pi}}\, I(-\pi \le \omega < \pi)$$

The set $\{\phi(x-k): k \in Z\}$ forms an orthonormal basis for V_0. It is easy to see that

$$m_0(\omega) = \sum_{k \in Z} I(-\pi/2 + 2k\pi \le \omega < \pi/2 + 2k\pi)$$

Notice that the filter coefficients h_k are given by $H(\omega) = \sqrt{2}\, m_0(\omega)$ for $\omega \in [-\pi, \pi]$. Thus,

$$h_k = \frac{\sqrt{2}}{2\pi} \int_{-\pi}^{\pi} m_0(\omega) e^{i\omega k}\, d\omega = \frac{1}{\sqrt{2}} \frac{\sin(\pi k/2)}{(\pi k)/2}$$

for $k \in Z$. The Shannon filter sequence h_k does not have finite support. It has not quite fast enough decay, $h_k = O(|k|^{-1})$ as $|k| \to \infty$, for absolute summability. Though the filter has poor time localization, it has very good frequency localization property.

By some straightforward calculation, we get the Shannon wavelet function and its Fourier transform given by

$$\psi(x) = \frac{\sin \pi(x - 1/2) - \sin 2\pi(x - 1/2)}{\pi(x - 1/2)}$$

and

$$\hat{\psi}(\omega) = \frac{-e^{-i\omega/2}}{\sqrt{2\pi}}\, I(-2\pi \le \omega < -\pi, \quad \pi \le \omega < 2\pi)$$

C. Daubechies' Wavelets

Daubechies was first to construct compactly supported orthogonal wavelets with a preassigned order, denoted by N, of vanishing moments. It is also of interest to make $\phi(x)$ and $\psi(x)$ reasonably regular.

Start with $m_0(\omega)$ of the form

$$m_0(\omega) = \left(\frac{1 + e^{-i\omega}}{2}\right)^N \mathcal{L}(\omega), \quad N \ge 1 \qquad (11)$$

where $\mathcal{L}(\omega)$ is a trigonometric polynomial. A trigonometric polynomial m_0 of the form (11) satisfies the condition

$$|m_0(\omega)|^2 + |m_0(\omega + \pi)|^2 = 1 \qquad (12)$$

if and only if the function $L(\omega) = |\mathcal{L}(\omega)|^2$ can be written as

$$L(\omega) = P\left(\sin^2 \frac{\omega}{2}\right) \qquad (13)$$

where

$$P(y) = \sum_{k=0}^{N-1} \binom{N + k - 1}{k} y^k + y^N R(1/2 - y) \qquad (14)$$

with $R(y)$ an odd polynomial so chosen that $P(y) \ge 0$ for $y \in [0, 1]$.

To get the function $m_0(\omega)$, we need to extract the square root from $L(\omega)$ using the spectral factorization. The solution is not unique. We can get all possible constructions of $m_0(\omega)$ of the form (11) that satisfy the condition $|m_0(\omega)|^2 + |m_0(\omega + \pi)|^2 = 1$. However, it is not yet sufficient to ensure that such m_0 lead to an orthonormal wavelet basis.

The following theorem gives a necessary and sufficient condition for orthonormality.

Theorem 2 *Suppose* $m_0(\omega) = \frac{1}{\sqrt{2}} \sum_{k=0}^{n} h_k e^{-ik\omega}$ *is a trigonometric polynomial such that* (12) *holds and* $m_0(0) = 1$. *Define* ϕ *and* ψ *by*

$$\hat{\phi}(\omega) = \frac{1}{\sqrt{2\pi}} \prod_{j=1}^{\infty} m_0(2^{-j}\omega)$$

$$\hat{\psi}(\omega) = -e^{-i\omega/2} \hat{\phi}(\omega/2) \overline{m_0(\omega/2 + \pi)}$$

Then ϕ *and* ψ *are compactly supported functions in* $L_2(R)$, *satisfying*

$$\phi(x) = \sqrt{2} \sum_{k=0}^{n} h_k \phi(2x - k)$$

$$\psi(x) = \sqrt{2} \sum_{k=0}^{n} (-1)^k h_{1-k} \phi(2x - k)$$

Moreover, the set of functions $\{\psi_{j,k}(x): j, k \in Z\}$ *constitutes an orthonormal basis for* $L_2(R)$ *if and only if the eigenvalue* 1 *of the* $(2n - 1) \times (2n - 1)$ *matrix* A *given by*

$$A(i, j) = \sum_{k=0}^{n} h_k \overline{h_{j-2i+k}}$$

is nondegenerate.

A family of wavelets corresponding to $m_0(\omega)$ satisfying (11) to (14) with $R \equiv 0$ was first constructed by Daubechies. For each N, the ${}_N m_0$ has $2N$ nonvanishing coefficients; we can choose the phrase of ${}_N m_0$ so that ${}_N m_0(\omega) = \frac{1}{\sqrt{2}} \sum_{k=0}^{2N-1} {}_N h_k e^{-ik\omega}$. Lists of low-pass filter coefficients ${}_N h_k$ for $N = 2, 3, \ldots, 10$ of Daubechies wavelets can be found in Daubechies (1992). However, there are no explicit expressions for the scaling function ${}_N\phi(x)$ and the wavelet ${}_N\psi(x)$. They are computed via the cascade algorithm. These functions ${}_N\phi(x)$ and ${}_N\psi(x)$, referred to as the extremal phase family, are not symmetric.

D. Symmlets

There are no symmetric orthonormal wavelets with compact support. However, it is possible to construct wavelets with compact support that are "more symmetric." The symmlets were also constructed by Daubechies. They were constructed to be as nearly symmetric as possible. Symmlets are also called the least asymmetric Daubechies wavelets. Low-pass filter coefficients for symmlets with vanishing moments of order N, for $N = 4, 5, \ldots, 10$, can be found in Daubechies (1992).

E. Spline Wavelets

The spline wavelets are associated with multiresolution analysis ladders consisting of spline function spaces. A cardinal spline of order m is a function in C^{m-2} such that the restriction of the function to any interval $[k, k+1)$, $k \in Z$, is an order m (or degree less than or equal to $m-1$) polynomial. We take V_0 the $L_2(R)$ subspace of cardinal splines of order m and $V_j = \{f(2^j x)\colon f(x) \in V_0\}$.

If we choose $\phi(x)$ to be the piecewise constant spline,

$$\phi(x) = I(0 \le x < 1)$$

then we end up with the Haar wavelet.

The next example is the piecewise linear spline. The linear cardinal B-spline with support on $[-1, 1]$ is given by

$$B(x) = \begin{cases} 1-x & x \in [0,1] \\ 1+x & x \in [-1,0] \\ 0 & \text{otherwise} \end{cases} \tag{15}$$

$$B(x) = (1-|x|)I(0 \le |x| \le 1)$$

The set of B-splines $\{B(x-k)\colon k \in Z\}$ forms an unconditional basis for the $L_2(R)$ subspace V_0 consisting of cardinal splines of order 2. Define

$$H(x) = \sum_{k=-\infty}^{\infty} B(x-k) c_1 r_1^{|k|}$$

where $r_1 = -2+\sqrt{3}$ and $c_1 = \sqrt{3}$. Notice that for a fixed x the above sum is actually a finite sum of two terms. Let

$$\phi(x) = \frac{3+\sqrt{3}}{6} H(x) + \frac{3-\sqrt{3}}{6} H(x-1) \tag{16}$$

Then $\{\phi(x-k)\}_{k \in Z}$ constitutes an orthonormal basis for V_0. The scaling function $\phi(x)$ has exponential decay. Its Fourier transform satisfies the condition

$$\hat{\phi}(\omega) = O(|\omega|^{-2}), \quad |\omega| \to \infty$$

The associated low-pass and high-pass filter coefficients can be computed using the explicit expression (16): $h_k = \langle \phi, \phi_{1,k} \rangle$ and $g_k = (-1)^k h_{1-k}$.

For spline wavelets, they can be chosen in C^k. The decay rate is exponential order in the time domain and polynomial order $k+2$ in the frequency domain.

F. Coiflets

Coiflets are wavelets that both the wavelet $\psi(x)$ and the scaling function $\phi(x)$ have vanishing moments of order N, i.e.,

$$\int_{-\infty}^{\infty} x^k \phi(x)\, dx = 0, \quad k = 1, \ldots, N-1$$

$$\int_{-\infty}^{\infty} x^k \psi(x)\, dx = 0, \quad k = 0, \ldots, N-1$$

If $f(x)$ is smooth enough, the following formulas are accurate up to error of order N:

$$\int_{-\infty}^{\infty} f(x) \frac{1}{h} \phi\left(\frac{x-x_0}{h}\right) dx = f(x_0) + O(h^N), \quad h \to 0$$

and

$$\int_{-\infty}^{\infty} f(x) \frac{1}{h} \psi\left(\frac{x-x_0}{h}\right) dx = O(h^N), \quad h \to 0$$

Thus, the wavelet series expansion for $f(x)$ is

$$f(x) = \sum_k f(2^{-j}k)\phi(2^j x - k) + O(2^{-jN})$$

provided that $f \in C^N(R) \cap L_2(R)$ and $\|f^{(N)}\|_\infty < \infty$. The function

$$\sum_k f(2^{-j}k)\phi(2^j x - k)$$

can be intepreted as a "blurred version" of f.

Coiflets are almost symmetric. The price to pay for this additional symmetry is a larger support. The length of the support for coiflets is $3N-1$ compared to $2N-1$ for the standard Daubechies family. The filter coefficients for the coiflets with $N = 2, 4, 6, 8, 10$ can be found in Daubechies (1992).

VII. WAVELET PACKETS

Wavelet packet functions consist of a rich family of building block functions. Mixtures of H and G may be applied to functions $\phi(x)$ and $\psi(x)$ to get new building block functions. Families of new orthonormal basis functions so produced are called wavelet packets. Wavelet packet functions are more flexible than wavelets in representing different types of signals. In particular, they are better at representing signals that exhibit oscillatory or periodic behavior.

A. Unit-Scale Wavelet Packets

Let us use the notation

$$\begin{cases}\mu_0(x)=\phi(x)\\ \mu_1(x)=\psi(x)\end{cases}$$

Define the following sequence of functions:

$$\begin{cases}\mu_{2m}(x) &= \sum_{\ell\in Z} h_\ell\sqrt{2}\,\mu_m(2x-\ell)\\ \mu_{2m+1}(x) &= \sum_{\ell\in Z} g_\ell\sqrt{2}\,\mu_m(2x-\ell)\end{cases} \tag{17}$$

Functions $\{\mu_n(x-k): n\in Z_+, k\in Z\}$ are called wavelet packets associated to H and G (or to ϕ and ψ). Notice that the scaling equations (17) can be rewritten as

$$\begin{cases}\mu_{2m}(x-k) &= \sum_{\ell\in Z} h_{\ell-2k}\sqrt{2}\,\mu_m(2x-\ell)\\ \mu_{2m+1}(x-k) &= \sum_{\ell\in Z} g_{\ell-2k}\sqrt{2}\,\mu_m(2x-\ell)\end{cases} \tag{18}$$

Theorem 3 *If H and G are orthogonal QFs, then $\{\mu_n(x-k): n\in Z_+, k\in Z\}$ forms an orthonormal basis for $L_2(R)$.*

Let Λ_n be the closed linear subspace of $L_2(R)$ spanned by $\{\mu_n(x-k): k\in Z\}$. If H and G are orthogonal QFs, then $\{\Lambda_n: n\ge 0\}$ is an orthogonal decomposition of $L_2(R)$ into subspaces of unit-scale functions of different frequencies.

B. Multiscale Wavelet Packets

A wavelet packet of scale index s, frequency index n, and translation index k is given by

$$\mu_{snk}(x) = 2^{s/2}\mu_n(2^s x-k)$$

Denote by Λ_{sn} the closed linear subspace of $L_2(R)$ spanned by $\{\mu_{snk}(x): k\in Z\}$. Define a dyadic interval I_{sn} by

$$I_{sn} = [2^s n, 2^s(n+1))$$

Notice that for any two dyadic intervals, either they are disjoint or one contains the other. There is a natural one-to-one correspondence between the dyadic interval I_{sn} and the subspace Λ_{sn}. Thus, the dyadic intervals can be used to keep track of multiscale wavelet packets.

Lemma 1 *Suppose H and G are orthogonal QFs. Functions $\mu_{snk}(x)$ and $\mu_{s'n'k'}(x)$ are orthogonal to each other if I_{sn} and $I_{s'n'}$ are disjoint, or if I_{sn} and $I_{s'n'}$ are identical but $k\ne k'$.*

Denote an arbitrary collection of disjoint dyadic intervals by $\mathcal{I}$ and its corresponding subspace by $\Lambda_{\mathcal{I}}$, where

$$\Lambda_{\mathcal{I}} = \overline{\cup_{I_{sn}\in\mathcal{I}}\Lambda_{sn}}\,.$$

If two collections of dyadic intervals $\mathcal{I}_1$ and $\mathcal{I}_2$ are disjoint, then $\Lambda_{\mathcal{I}_1}$ and $\Lambda_{\mathcal{I}_2}$ are linearly independent. If $\mathcal{I}$ covers R^+, then $\Lambda_{\mathcal{I}} = L_2(R)$ and the space $L_2(R)$ can be decomposed via dyadic intervals in $\mathcal{I}$:

$$L_2(R) = \sum_{I_{sn}\in\mathcal{I}} \Lambda_{sn}$$

Theorem 4 *If H and G are orthogonal QFs and $\mathcal{I}$ is a disjoint dyadic covering of R^+, then $\{\mu_{snk}(x): k\in Z, I_{sn}\in\mathcal{I}\}$ forms a complete orthonormal basis for $L_2(R)$.*

The above theorem may be called graph theorem because disjoint dyadic coverings can be viewed as graphs from partitions of R^+ to bases for $L_2(R)$. The orthonormal basis associated with each disjoint dyadic covering is called orthonormal graph basis. Graph bases provide a large library of bases. Some examples of wavelet packet graph bases are

Walsh-type basis:	$\Lambda_0\oplus\Lambda_1\oplus\cdots\Lambda_n\oplus\cdots$	$n\in N$
subband basis:	$\Lambda_{s0}\oplus\Lambda_{s1}\oplus\cdots\Lambda_{sn}\oplus\cdots$	$n\in N$
wavelet basis:	$\cdots\oplus\Lambda_{-1,1}\oplus\Lambda_{0,1}\oplus\cdots\oplus\Lambda_{s1}\cdots$	$s\in Z$

For any disjoint dyadic covering $\mathcal{I}$ of R^+, every function $f\in L_2(R)$ can be represented by wavelet packets as

$$f(x) = \sum_{I_{sn}\in\mathcal{I},k\in Z} \langle f,\mu_{snk}\rangle\,\mu_{snk}(x)$$

Example 1 (Haar–Walsh wavelet packets) *Consider the scaling function $\phi(x)=I(0\le x<1)$ and the wavelet $\psi(x)=I(0\le x<1/2)-I(1/2\le x<1)$ from the Haar basis. Define a system of functions in a recursive manner as*

$$\begin{cases}\mu_0(x)=\phi(x)\\ \mu_{2m+1}(x)=\mu_m(2x)-\mu_m(2x-1), & m\ge 0\\ \mu_{2m}(x)=\mu_m(2x)+\mu_m(2x-1), & m\ge 1\end{cases}$$

The set of functions

$$\{\mu_n(x-k): n\in Z_+, k\in Z\}$$

forms an orthonormal basis for $L_2(R)$, called the Haar–Walsh basis, and the set of functions

$$\{\mu_{2^m}(x-k), \mu_{2^m+1}(x-k), \ldots, \mu_{2^{m+1}-1}(x-k): k\in Z\}$$

forms an orthonormal basis for the wavelet subspace W_m. The scaled functions $\mu_{snk}(x)=2^{s/2}\mu_n(2^s x-k)$ are called Haar–Walsh wavelet packets.

Like the discrete wavelet transform, wavelet packet coefficients can be calculated in an efficient way. The fast algorithm for discrete wavelet transform extends in a straightforward manner to wavelet packet analysis. For a given function $f\in L_2(R)$, define

$$\lambda_{snk} = \langle f,\mu_{snk}\rangle = \int_{-\infty}^{\infty} f(x)\overline{\mu_{snk}(x)}\,dx$$

Let $\lambda_{sn} = \{\lambda_{snk} : k \in Z\}$ be a sequence of numbers. Then we have

$$\begin{aligned}(H\lambda_{sn})_k &= \sum_{\ell \in Z} h_{\ell-2k}\lambda_{sn\ell} \\ &= \sum_{\ell \in Z} h_{\ell-2k} \int_{-\infty}^{\infty} f(x)\overline{2^{s/2}\mu_n(2^s x - \ell)}\,dx \\ &= \int_{-\infty}^{\infty} f(x)\left(\sum_{\ell \in Z} h_{\ell-2k}\overline{2^{s/2}\mu_n(2^s x - \ell)}\right)dx \\ &= \int_{-\infty}^{\infty} f(x)\overline{2^{(s-1)/2}\mu_{2n}(2^{s-1}x - k)}\,dx \\ &= \lambda_{s-1,2n,k}\end{aligned}$$

Similarly, we have

$$(G\lambda_{sn})_k = \sum_{\ell \in Z} g_{\ell-2k}\lambda_{sn\ell} = \lambda_{s-1,2n+1,k}$$

To obtain the wavelet packet analysis of a function, we first find its coefficient sequence in the root subspace; then H or G is applied down the branches of wavelet packet coefficient tree:

$$H\lambda_{sn} = \lambda_{s-1,2n} \qquad \text{and} \qquad G\lambda_{sn} = \lambda_{s-1,2n+1}$$

The wavelet packet analysis gives a decomposition of the function into the whole collection of its wavelet packet components, which are more than a basis set. A basis subset can be chosen by checking that its associated dyadic intervals form a disjoint covering of R^+.

In the reverse direction, we can synthesize the root coefficients via the adjoints H^* and G^* in the following way:

$$\lambda_{sn} = H^*\lambda_{s-1,2n} + G^*\lambda_{s-1,2n+1}$$

VIII. BEST BASIS SELECTION IN WAVELET PACKET ANALYSIS

The wavelet packet components of a funciton contain redundant information. To select among wavelet packet bases, we first have to define cost criteria for judging the bases.

Let $\mathcal{L}$ be a library of bases (the collection of wavelet packets is an example). Let $\mathcal{B} \subset \mathcal{L}$ be a basis. Given the data $x = (x_1, \ldots, x_n)$, let the cost of the basis $\mathcal{B}$ for representation of x be denoted by $C(\mathcal{B}x)$. There are some papular cost measures:

- The entropy cost: $C(y) = -\sum_{i=1}^n p_i \log p_i$, where $p_i = |y_i|^2/\|y\|_2^2$.
- The threshold cost: $C(y) = \sum_{i=1}^n I(|y_i| \geq \delta)$, $\delta > 0$.
- The ℓ_p-norm cost: $C(y) = (\sum_{i=1}^n |y_i|^p)^{1/p}$ for $0 < p < 2$. (Since orthogonal transform preserves the ℓ_2-norm, the costs for $p = 2$ are the same for all bases.)
- The SURE (Stein's unbiased risk estimate) cost:

$$C(y) = \sigma^2\left(n - 2\sum_{i=1}^n I(|y_i| \leq \sigma\delta) + \sum_{i=1}^n \min\{(y_i/\sigma)^2, \delta^2\}\right)$$

where $\delta = \sqrt{2\log_e(n\log_2 n)}$ and σ is the noise level of data.

Suppose that the data is of length 2^J and the height of the packet tree is J. Recall that λ_{sn} has two children $\lambda_{s-1\ 2n}$ and $\lambda_{s-1\ 2n+1}$. The algorithm leading to the selection of best basis is briefly described as follows.

0. Let $\lambda_{00} = (\lambda_{000}, \ldots, \lambda_{00\ 2^J-1})$ come from data. Order the wavelet packet components $\lambda_{sn} = (\lambda_{sn0}, \ldots, \lambda_{sn\ 2^{j_0+s}-1})$ into a tree, where the resolution scale ranges over $s = 0, -1, \ldots, -J$, and $n = 0, \ldots, 2^{|s|} - 1$. The top of the tree is λ_{00}, the second row is $\lambda_{-1,0}$ and $\lambda_{-1\ 1}$, and the bottom of the tree is $\lambda_{-J\ 0}, \lambda_{-J\ 1}, \ldots, \lambda_{-J+1\ 2^J-1}$. Put all these components into the library $\mathcal{L}$. Start with $\mathcal{B}$, an empty set, as a candidate set of best basis.

1. Consider the current wavelet packet component $\lambda_{sn} \in \mathcal{L}$ in the wavelet packet tree as a candidate component for inclusion into $\mathcal{B}$.

2. If $s = -J$ (the coarsest resolution level) or if

$$C(\lambda_{sn}) \leq C(\lambda_{s-1\ 2n}) + C(\lambda_{s-1\ 2n+1})$$

then go to the next step. Else discard λ_{sn} from $\mathcal{L}$ and return to step 1.

3. Move λ_{sn} to $\mathcal{B}$. Remove λ_{sn} and all its descendants from $\mathcal{L}$. Stop if $\mathcal{L}$ is empty, otherwise return to step 1.

IX. WAVELETS IN STATISTICAL ESTIMATION

With the basic introduction to wavelets, we now turn to their application to nonparametric statistical estimation.

A. Wavelet Density Estimation

Let $X_1, \ldots, X_n$ be independently and identically distributed random variables from a distribution with probability density function $f(x)$. Consider the problem of estimating $f(x)$ assuming that $f(x)$ lies a priori in a functional class with certain regularity conditions.

Represent $f(x)$ in terms of wavelet expansion

$$f(x) = \sum_{k\in Z} c_{j,k}\phi_{j,k}(x) + \sum_{\ell\geq j}\sum_{k\in Z} d_{\ell,k}\psi_{\ell,k}(x)$$

The coefficients $c_{j,k}$ and $d_{\ell,k}$ can be estimated by

$$\hat{c}_{j,k} = \frac{1}{n}\sum_{i=1}^{n}\phi_{j,k}(X_i) \qquad \text{and} \qquad \hat{d}_{\ell,k} = \frac{1}{n}\sum_{i=1}^{n}\psi_{\ell,k}(X_i)$$

These estimates $\hat{c}_{j,k}$ and $\hat{d}_{\ell,k}$ are called empirical wavelet coefficients. Notice that the empirical wavelet coefficients are unbiased; that is,

$$E\hat{c}_{j,k} = E\phi_{j,k}(X) = c_{j,k}$$

and

$$E\hat{d}_{\ell,k} = E\psi_{\ell,k}(X) = d_{\ell,k}$$

Also notice that

$$Var(\hat{c}_{j,k}) = \frac{1}{n}\int_{-\infty}^{\infty}\phi_{j,k}^2(x)f(x)\,dx = O\left(\frac{2^j}{n}\right)$$

and

$$Var(\hat{d}_{\ell,k}) = \frac{1}{n}\int_{-\infty}^{\infty}\psi_{\ell,k}^2(x)f(x)\,dx = O\left(\frac{2^\ell}{n}\right)$$

To estimate $f(x)$, we have to truncate at a certain resolution level, say, J, and get

$$\hat{f}(x) = \sum_{k\in Z}\hat{c}_{j,k}\phi_{j,k}(x) + \sum_{\ell=j}^{J-1}\sum_{k\in Z}\hat{d}_{\ell,k}\psi_{\ell,k}(x) \qquad (19)$$

which is equivalent to

$$\hat{f}(x) = \sum_{k\in Z}\hat{c}_{J,k}\phi_{J,k}(x) \qquad (20)$$

For compactly supported $\phi(x)$ and $\psi(x)$, the above summations $\sum_{k\in Z}$ in (19) and (20) are finite sums. For other infinitely supported wavelets with rapid decay

$$|\psi(x)| \leq c(1+|x|)^{\gamma}, \quad c>0,\ \gamma>1$$

the summations $\sum_{k\in Z}$ just given can be truncated to finite sums with arbitrary prescribed precision.

The linear estimator (19), or equivalently (20), can be written as a projection type kernel estimator. As seen previously, the projection of a function $f(x)\in L_2(R)$ onto the subspace V_J is given by $\mathcal{P}_{V_J}f(x) = \int_{-\infty}^{\infty}\mathcal{V}_J(x,y)f(y)\,dy$. Notice that

$$\mathcal{V}_J(x,y) = 2^J\mathcal{V}(2^Jx, 2^Jy)$$

Instead of dyadic bandwidths, we may also consider kernels with continuously varying bandwidths

$$\mathcal{V}_h(x,y) = \frac{1}{h}\mathcal{V}\left(\frac{x}{h},\frac{y}{h}\right)$$

A density estimator based on the projection kernel $\mathcal{V}_h(x,y)$ is given by

$$\hat{f}(x) = \frac{1}{n}\sum_{i=1}^{n}\mathcal{V}_h(x,X_i) = \frac{1}{nh}\sum_{i=1}^{n}\mathcal{V}\left(\frac{x}{h},\frac{X_i}{h}\right) \qquad (21)$$

The asymptotic bias and variance of the linear wavelet density estimator (21) are discussed here after. Suppose that $\mathcal{V}(x,y)$ is of order m. Recall that

$$b_m(x) = x^m - \int_{-\infty}^{\infty}\mathcal{V}(x,y)y^m\,dy \qquad (22)$$

For $h>0$, we have

$$x^m - \int_{-\infty}^{\infty}\mathcal{V}_h(x,y)y^m\,dy = h^m b_m\left(\frac{x}{h}\right)$$

Theorem 5 *Assume that $f(x)\in C^{m,\alpha}(R)\cap L_2(R)$, for some $0<\alpha\leq 1$, that $\int_{-\infty}^{\infty}|\mathcal{V}(x,y)(y-x)^{m+\alpha}|\,dy<\infty$, and that $h\to 0$, $nh\to\infty$, as $n\to\infty$. Then for a fixed x, we have the following pointwise asymptotic bias*:

$$E\hat{f}(x) - f(x) = \frac{-1}{m!}f^{(m)}(x)b_m\left(\frac{x}{h}\right)h^m + O(h^{m+\alpha})$$

Moreover, if $f^{(m)}$ is in $L_2(R)$, then the integrated squared bias is

$$\|E\hat{f} - f\|_2^2 = \frac{b_{2m}}{(2m)!}\|f^{(m)}\|_2^2 h^{2m} + O\left(h^{2(m+\alpha)}\right)$$

where

$$b_{2m} = (2m)!(m!)^{-2}\int_0^1 b_m^2(x)\,dx$$

Example 2 (Spline wavelets) *Consider a density estimator using spline wavelets of order m. Then we have*

$$b_m(x) = B_m(x) \text{ for } x\in(0,1) \text{ and } b_{2m} = |B_{2m}|$$

where $B_m(x)$ is the mth Bernoulli polynomial and B_{2m} is the $2m$th Bernoulli number.

Example 3 (Daubechies' wavelets) *Consider a density estimator using ${}_N\phi(x)$. An expression for the bias $b_N(x)$ is*

$$b_N(x) = x^N - \sum_{\ell=0}^{N}C(N,\ell)\,a_N^{\ell}\,\Phi_N^{N-\ell}(x)$$

where $C(N,\ell) = N!/\ell!(N-\ell)!$ and

$$a_N^{\ell} = \int_0^{2N-1}{}_N\phi(x)x^{\ell}\,dx,$$

$$\Phi_N^{N-\ell}(x) = \sum_{k=-2N+2}^{0}k^{N-\ell}\,{}_N\phi(x-k)$$

Theorem 6 *Suppose that $f(x)\in C^1(R)$ and that $f(x)$ and $f'(x)$ are uniformly bounded. For a fixed x, we have*

$$\text{Var }\hat{f}(x) = \frac{1}{n}f(x)v_h(x) + O\left(\frac{1}{n}\right)$$

where

$$v_h(x) = \int_{-\infty}^{\infty} \mathcal{V}_h^2(x, y)\, dy = \frac{1}{h}\mathcal{V}\left(\frac{x}{h}, \frac{x}{h}\right) \tag{23}$$

Moreover, the integrated variance is given by

$$\int_{-\infty}^{\infty} \mathrm{Var}\ \hat{f}(x)\, dx = \frac{1}{nh} + O\left(\frac{1}{n}\right)$$

In a wavelet method, the bandwidth selection problem is often considered in a discrete manner, i.e., $h = 2^{-j}$. However, from the kernel point of view, bandwidths can be chosen in a continuous manner. Any automatic bandwidth selector for a convolution type kernel estimator can be tried out for estimator (21). Theoretical optimal bandwidth can be obtained by minimizing the asymptotic IMSE

$$\mathrm{IMSE} = E\|\hat{f} - f\|_2 \simeq \frac{b_{2m}}{(2m)!}\left\|f^{(m)}\right\|_2^2 h^{2m} + \frac{v}{nh} \tag{24}$$

The optimal bandwidth is

$$h_{\mathrm{opt}} = \left(\left\|f^{(m)}\right\|_2^2\right)^{-1/(2m+1)} \left(\frac{(2m-1)!v}{b_{2m}}\right)^{1/(2m+1)} \times n^{-1/(2m+1)} \tag{25}$$

This optimal bandwidth suggests that the resolution level J should be chosen to satisfy the order

$$2^J = O\left(n^{1/(2m+1)}\right)$$

The preceding formulas (24) and (25) are valid for a convolution type kernel $\mathcal{V}(x)$ with $v = \int_{-\infty}^{\infty} \mathcal{V}^2(x)\, dx$ and $b_{2m} = (2m)!(m!)^{-2}(\int_{-\infty}^{\infty} \mathcal{V}(x)x^m\, dx)^2$. Plugging h_{opt} into (24), we have

$$\mathrm{IMSE}_{\mathrm{opt}} \simeq \frac{2m+1}{2m}\left(\frac{b_{2m}}{(2m-1)!}\right)^{1/2m+1} \times \left\|f^{(m)}\right\|_2^{2/2m+1}\left(\frac{v}{n}\right)^{2m/2m+1} \tag{26}$$

Let $C_m(\mathcal{V}) = b_{2m}^{1/2m+1} v^{2m/2m+1}$. The relative efficiency of two kernels $\mathcal{V}^\star$ to $\mathcal{V}$ is defined as

$$\text{rel eff} = \{C_m(\mathcal{V})/C_m(\mathcal{V}^\star)\}^{(2m+1)/2m} \tag{27}$$

Wavelet estimators have good asymptotic behavior not only in the L_2 norm, but also in general L_p norms, and not only for Hölder continuous functions, but also for functions in the Besov class. In the following theorem, wavelet estimators can attain the minimax convergence rate judged by $E\|\hat{f} - f\|_p$ on the Besov class.

Theorem 7 *Suppose that the underlying density f is in $F_p^{sq}(M) = \{f \in B_p^{sq}: \|f\|_{B_p^{sq}} \le M\}$, $s > 0$, $2 \le p < \infty$, $1 \le q < \infty$, and that the multiresolution analysis has regularity $r > s$. Then, taking the resolution level J so that $2^J = O(n^{1/(2s+1)})$, the estimator $\hat{f}$ in (20) has the upper bound of convergence rate*

$$\sup_{f \in F_p^{sq}(M)} E\|\hat{f} - f\|_p^p \le c_1\, n^{-sp/(2s+1)},$$

for some constant $c_1 > 0$

This upper bound is still true for $1 < p < 2$ if one requires in addition that $f(x) < w(x)$, $x \in R$, for some symmetric unimodal function $w(x) \in L_{p/2}(R)$.

The rate $O(n^{-sp/(2s+1)})$ is also known to be the minimax rate on Besov class in the sense that

$$\inf_{\hat{f} \in F^*} \sup_{f \in F_p^{sq}(M)} E\|\hat{f} - f\|_p^p \ge c_2\, n^{-sp/(2s+1)},$$

for some constant $c_2 > 0$

where F^* is the set of estimators taking their values in a class containing $F_p^{sq}(M)$. Thus, linear wavelet estimators can attain the minimax rate on Besov class.

Instead of linear estimators, we may consider nonlinear estimators to allow wavelets to perform innate adaptive fit by shrinking the wavelet coefficients toward zero.

B. Wavelet Shrinkage

In the density estimation setting, we first compute the empirical wavelet coefficients $\hat{c}_{j,k}$ and $\hat{d}_{\ell,k}$ for $\ell = j$, $j+1, \ldots, J-1$, and $k \in Z$. Let $\Delta(\cdot, \delta)$ be a shrinkage/thresholding rule. Examples of $\Delta(\cdot, \delta)$ include

Hard threshold: $\Delta^H(d, \delta) = dI(|d| \ge \delta)$

Soft threshold: $\Delta^S(d, \delta) = sign(d)(|d| - \delta)I(|d| \ge \delta)$

Diagonal shrinkage: $\Delta^D(d, \delta) = \left(1 - \dfrac{\delta^2}{d^2}\right) dI(d^2 \ge \delta^2)$

A nonlinear wavelet density estimator of $f(x)$ can be obtained via a certain shrinkage/thresholding rule Δ:

$$\hat{f}(x) = \sum_k \hat{c}_{j,k}\phi_{j,k}(x) + \sum_{\ell=j}^{J-1}\sum_k \Delta(\hat{d}_{\ell,k}, \delta)\psi_{\ell,k}(x)$$

A suggested choice for the finest resolution level is $J = [\log_2 n]$, where $[t]$ is the greatest integer less than or equal to t. For simplicity, we may assume that the data size is $n = 2^J$.

The wavelet shrinkage estimation is particularly useful for regression function estimation and denoising. Consider a nonparametric regression problem with observations y_i arising from the following regression model:

$$y_i = f(x_i) + \sigma\epsilon_i, \quad i = 1, \ldots, n, x_i \in [0, 1] \tag{28}$$

where $x_1, \ldots, x_n$ are equally spaced design points, $\sigma > 0$ is a noise level, and ϵ_i are independently and identically distributed $N(0, 1)$ random errors. In vector form, the model (28) can be written as

$$y = f + \sigma\epsilon$$

where $y=(y_1,\ldots,y_n)$, $f=(f(x_1),\ldots,f(x_n))$, and $\epsilon=(\epsilon_1,\ldots,\epsilon_n)$. The goal is to estimate the regression function $f(x)$ based on the observations y.

Represent f in terms of wavelet expansion

$$f(x)=\sum_k c_{j,k}\phi_{j,k}(x)+\sum_{\ell\geq j}\sum_k d_{\ell,k}\psi_{\ell,k}(x)$$

The empirical wavelet coefficients are given by

$$\hat{c}_{j,k}=\frac{1}{n}\sum_{i=1}^{n}\phi_{j,k}(x_i)y_i \quad \text{and} \quad \hat{d}_{\ell,k}=\frac{1}{n}\sum_{i=1}^{n}\psi_{\ell,k}(x_i)y_i$$

Order these empirical wavelet coefficients into a vector form

$$w=\sqrt{n}(\hat{c}_{j,1},\ldots,\hat{c}_{j,2^j},\hat{d}_{j,1},\ldots,\hat{d}_{J-1,2^{J-1}}) \qquad (29)$$

and w is indexed as

$$w_{j,k}=\sqrt{n}\,c_{j,k}, \qquad w_{\ell+1,k}=\sqrt{n}\,d_{\ell,k}$$

The vector w can be obtained by an orthogonal transform of data $w=Wy$, where W is the orthogonal matrix corresponding to the discrete wavelet transform. Represent w as

$$w=\theta+\sigma e, \quad \text{where } \theta=Wf \text{ and } e\sim N(0,I) \quad (30)$$

Now θ is the object of interest and we wish to estimate it with ℓ_2 loss. Define the risk measure

$$R(\hat{\theta},\theta)=E\|\hat{\theta}-\theta\|_{\ell_2}^2$$

Suppose that we had available an oracle that would supply for us the ideal coefficients $I(|\theta_i|\geq\sigma)$ optimal for use in the keep-or-kill scheme. The ideal scheme consists in estimating only those θ_i larger than the noise level. The ideal estimate of θ is then given by

$$\hat{\theta}_{\ell,k}=w_{\ell,k}I(|\theta_{\ell,k}|\geq\sigma), \quad k=1,\ldots,2^\ell,\ \ell=j,\ldots,2^J$$

The ideal risk is

$$R_{\text{ideal}}(\hat{\theta},\theta)=\sum_{\ell,k}\min\{\theta_{\ell,k}^2,\sigma^2\}$$

In general, the ideal risk can not be attained by any estimator, linear or nonlinear. However, simple estimates do come remarkably close. The shrinkage rules Δ^H, Δ^S, and Δ^D had been known in statistics before the discovery of wavelets. They can apply to the scaling and wavelet coefficients simultaneously, or apply only to wavelet coefficients and retain the scaling coefficients unchanged.

The preceding shrinkage rules retain only data that exceed a certain amount of the noise level. There are several methods for setting up the threshold parameter δ.

The universal threshold. The threshold parameter is set to

$$\delta=\sigma\sqrt{2\log n}$$

The minimax threshold. It minimizes a theoretical upper bound on the asymptotic risk. They are always smaller than the universal threshold for a given sample size, and thus results in less smoothing. Values of the minimax threshold for various sample sizes are computed and listed in Table 2 of Donoho and Johnstone (1994).

SURE. It is based on the principle of minimizing the Stein unbiased risk estimate at each resolution level. The level-dependent threshold value at resolution level ℓ is given by

$$\delta_\ell^{\text{SURE}}=\sigma\left(\arg\min_{0\leq\delta\leq\sqrt{2\log n_\ell}}\text{SURE}(\sigma^{-1}w_\ell,\delta)\right)$$

where

$$\text{SURE}(\sigma^{-1}w_\ell,\delta)=n_\ell-2\sum_{k=1}^{n_\ell}I(\sigma^{-1}|w_{\ell,k}|\leq\delta)+\sum_{k=1}^{n_\ell}\min\{\sigma^{-2}w_{\ell,k}^2,\delta^2\}$$

with n_ℓ is the number of coefficients in the resolution level. In this article, $n_\ell=2^\ell$.

The SURE threshold should only be used with the soft shrinkage. The SURE threshold can perform poorly if the coefficients are very sparse. Define

$$s_\ell^2=\frac{1}{n_\ell}\sum_{k=1}^{n_\ell}(w_{\ell,k}^2-1) \qquad \text{and} \qquad \gamma_\ell=\frac{(\log_2 n_\ell)^{3/2}}{\sqrt{n_\ell}}$$

Wavelet coefficients at a level ℓ are considered sparse if $s_\ell^2\leq\gamma_\ell$. To correct the drawback in situations of sparse wavelet coefficients, the following hybrid rule combining SURE and universal threshold is suggested. When the coefficients are not sparse, use the SURE threshold; otherwise, use the universal threshold. This hybrid method is proposed by Donoho and Johnstone (1995). It works as follows. At a resolution ℓ,

$$\hat{\theta}_{\ell,k}=\begin{cases}\Delta^S(w_{\ell,k},\delta_\ell^{\text{SURE}}), & s_\ell^2>\gamma_\ell\\ \Delta^S(w_{\ell,k},\sigma\sqrt{2\log n}), & s_\ell^2\leq\gamma_\ell\end{cases}$$

C. Bayesian Wavelet Shrinkage

Consider still the nonparametric regression setting (28) on an finite interval; without loss of generality, $x\in[0,1]$. The main objective of this section is to study the wavelet estimation from a Bayesian viewpoint. The Bayesian formulation here is inspired by models of smoothing splines.

1. The Prior Model

The underlying function of interest, $f(x)$, has the wavelet series representation

$$f(x) = \sum_{k=1}^{2^j} c_{j,k}\phi_{j,k}(x) + \sum_{\ell \geq j}\sum_{k=1}^{2^\ell} d_{\ell,k}\psi_{\ell,k}(x), \quad x \in [0,1] \tag{31}$$

where $\phi_{j,k}(x)$ and $\psi_{\ell,k}(x)$ are scaling functions and wavelets on the interval $[0, 1]$. These scaling functions and wavelets are assumed to retain orthonormality. It is also assumed that this system is with regularity $r > 0$ and $\psi(x)$ has vanishing moments of order $N > r$. The properties of regularity and vanishing moments ensure that these ϕs and ψs form an unconditional basis for Besov spaces $B^s_{p,q}$ for $0 < s < r$ and $1 \leq p, q \leq \infty$. The construction of wavelets on an interval can be found in Cohen *et al.* (1993a,b).

The scaling coefficients $c_{j,k}$ in (31) are assume fixed but unknown and the wavelet coefficients $d_{\ell,k}$ are assumed uncorrelated random variables with zero mean and a common variance σ^2. Such model is a nonparametric mixed-effects model.

We briefly summarize the definition of Besov space. For $0 < b \leq 1$ and $1 \leq p, q \leq \infty$, $J^b_{p,q}$ is defined by

$$J^b_{p,q}(f) = \begin{cases} \left(\int_{h=0}^{1/(1+[b])} h^{-qb-1} \left\|\Delta_h^{1+[b]} f\right\|^q_{L_p[0,1-(1+[b])h]}\, dh\right)^{1/q}, & q < \infty \\ \sup_{h\in[0,1/(1+[b])]} h^{-b} \left\|\Delta_h^{1+[b]} f\right\|_{L_p[0,1-(1+[b])h]}, & q = \infty \end{cases}$$

where Δ_h^k is the kth-order difference and $[b]$ is the greatest integer less than or equal to b. When $s > 0$ with $s = a + b$ for a positive integer a and $0 < b \leq 1$, the Besov space $B^s_{p,q}$ is the collection of functions f such that $f, f^{(1)}, \ldots, f^{(a)} \in L_p[0, 1]$ and $J^b_{p,q}(f^{(a)}) < \infty$. This space $B^s_{p,q}$ is equipped with the norm $\|f\|_{B^s_{p,q}} = \|f\|_{L_p} + \sum_{k=1}^a J^b_{p,q}(f^{(k)})$.

Expand $f(x)$ in terms of the wavelet basis:

$$f(x) = \sum_k c_{j,k}\phi_{j,k}(x) + \sum_{\ell\geq j}\sum_k d_{\ell,k}\psi_{\ell,k}(x)$$

Let $\|c_j\|_{\ell_p} = (\sum_k c^p_{j,k})^{1/p}$ and $\|d_\ell\|_{\ell_p} = (\sum_k d^p_{\ell,k})^{1/p}$ with the usual modification for $p = \infty$. The above norm $\|f\|_{B^s_{p,q}}$ is equivalent to the sequence norm

$$\|c_j\|_{\ell_p} + \left\{\sum_{\ell\geq j}\left(2^{\ell(s+1/2-1/p)}\|d_\ell\|_{\ell_p}\right)^q\right\}^{1/q}$$

with the usual modification for $q = \infty$. Note that $B^s_{2,2} = W^s_2$ for $s > 0$.

The relation between the prior parameters and the Besov spaces can be characterized as follows. For $1 \leq p \leq \infty$, the prior sample path of $f(t)$ is in $B^{s-1/2}_{p,\infty}$ $a.s.$ if and only if $\lambda_\ell = O(2^{-2\ell s})$, where $s > 1/2$.

Consider the functional class consisting of sample paths of prior model (31) with a common upper bound $\limsup_{\ell\to\infty} 2^{2\ell s}\lambda_\ell \leq C$ imposed upon prior parameters. Let π denote the induced prior probability measure. We have that $\|f\|_{B^{s-1/2}_{p,\infty}} \leq C$ almost surely. That is, $\pi\{\|f\|_{B^{s-1/2}_{p,\infty}} \leq C\} = 1$. It indicates that we are working over a compact prior functional class.

2. The Bayesian and Empirical Bayesian Approach

The posterior mean of $f(x)$ given the observations y can be calculated in a straightforward manner:

$$E(f(x)|y) = \mu(x) + \sigma^{-2}w^T(x)\, M^{-1}(y - \mu) \tag{32}$$

where $\mu(x) = \sum_{k=1}^{2^j} c_{j,k}\phi_{j,k}(x)$, $\mu = [\mu(x_1), \ldots, \mu(x_n)]^T$, $w(x) = [\mathcal{W}(x, x_1), \ldots, \mathcal{W}(x, x_n)]^T$ with $\mathcal{W}(x, s) = \sum_{\ell=j}^{J-1}\sum_k \lambda_\ell\psi_{\ell,k}(x)\psi_{\ell,k}(s)$, $M = R + \sigma^{-2}W$, and W is an $n \times n$ matrix with the (i, j)th entry given by $\mathcal{W}(x_i, x_j)$. The foregoing posterior mean (32) is the Bayes rule under the squared error loss.

If the coefficients c are not known, one needs to estimate them from the data y. This is known as the empirical Bayes approach. A generalized least squares estimate is proposed to estimate c here, which is

$$\hat{c} = (X^T M^{-1} X)^{-1} X^T M^{-1} y \tag{33}$$

where X is the design matrix for fixed effects. The empirical Bayes estimator becomes

$$\hat{f}(x) = \hat{\mu}(x) + \sigma^{-2}w^T(x)M^{-1}(y - \hat{\mu}) \tag{34}$$

where $\hat{\mu}(x) = \sum_{k=1}^{2^j} \hat{c}_{j,k}\,\phi_{j,k}(x)$ and $\hat{\mu} = [\hat{\mu}(x_1), \ldots, \hat{\mu}(x_n)]^T$.

The preceding empirical Bayes estimator has an asymptotic expression as

$$\hat{f}(x) \approx \hat{f}_L(x) + \hat{f}_{res,DS}(x), \quad x \in [0, 1] \tag{35}$$

where

$$\hat{f}_L(x) = \sum_{k=1}^{2^j} \hat{c}_{j,k}\,\phi_{j,k}(x),$$

$$\hat{f}_{res,DS}(x) = \sum_{\ell=j}^{J-1}\sum_{k=1}^{2^\ell} \frac{\lambda_\ell}{\lambda_\ell + \sigma^2/n}\,\hat{d}_{\ell,k}\psi_{\ell,k}(x)$$

and $\hat{c}_{j,k}$ and $\hat{d}_{\ell,k}$ are empirical wavelet coefficients, which can be obtained by the fast algorithm of discrete wavelet transform.

When the parameter values for σ and λ_ℓ are not available, adaptive estimates are necessary. Since

$$E\left(\hat{d}_{\ell,k}^2\right) \approx \lambda_\ell + \frac{\sigma^2}{n}$$

an alternative estimate using diagonal shrinkage rule is given by

$$\begin{aligned}\hat{f}(x) &= \sum_{k=1}^{2^j} \hat{c}_{j,k}\,\phi_{j,k}(x) \\ &\quad + \sum_{\ell=j}^{J-1}\sum_{k=1}^{2^\ell}\left(1-\frac{\sigma^2/n}{\hat{d}_{\ell,k}^2}\right)_+ \hat{d}_{\ell,k}\psi_{\ell,k}(x) \\ &= \sum_{k=1}^{2^j} \hat{c}_{j,k}\,\phi_{j,k}(x) + \sum_{\ell=j}^{J-1}\sum_{k=1}^{2^\ell}\Delta^D\left(d_{\ell,k},\sigma^2/n\right)\psi_{\ell,k}(x)\end{aligned} \tag{36}$$

Often σ^2 is not known, the threshold value can be chosen by generalized cross validation:

$$\hat{f}(x) = \sum_{k=1}^{2^j} \hat{c}_{j,k}\phi_{j,k}(x) + \sum_{\ell=j}^{J-1}\sum_{k=1}^{2^\ell}\Delta^D(d_{\ell,k},\delta_{\mathrm{GCV}})\psi_{\ell,k}(x) \tag{37}$$

3. The BLUP

The estimator (34) turns out to be the unique BLUP in the following sense.

Definition *A predictor $\hat{f}(x)$ is the best linear unbiased prediction (BLUP) for $f(x)$ if and only if (i) $\hat{f}(x)$ is linear in y, (ii) $\hat{f}(x)$ is unbiased in the sense that $E\hat{f}(x) = Ef(x) = \sum_{k=1}^{2^j} c_k\phi_{j,k}(x)$ for all $x \in [0,1]$ and all $c \in R^{2^j}$, (iii) $\hat{f}(x)$ has the minimum mean squared error, among all linear unbiased estimators $\tilde{f}(x)$, i.e., $E(\hat{f}(x)-f(x))^2 \le E(\tilde{f}(x)-f(x))^2$ for all $x \in [0,1]$ and all $c \in R^m$.*

The empirical Bayes estimator $\hat{f}(x)$ is a shrinkage estimator toward $\hat{\mu}(x)$, where $\hat{\mu}(x)$ is the generalized least squares fit of data to the low dimensional subspace H_0 spanned by $\{\phi_{j,k}(x): k = 1,\ldots,2^j\}$. Let $H_{\mathcal{W}}$ be the closure (not the L_2 closure, but rather the closure with respect to the norm given below) of linear space spanned by $\{\psi_{\ell,k}(x): k = 1,\ldots,2^\ell;\ \ell \ge j\}$. The norm in $H_{\mathcal{W}}$ is defined by

$$\left\|\sum_{\ell\ge j}\sum_{k=1}^{2^\ell} d_{\ell,k}\psi_{\ell,k}\right\|_{H_{\mathcal{W}}}^2 = \sum_{\ell\ge j}\sum_{k\in\mathcal{J}_\ell} d_{\ell,k}^2/\lambda_\ell$$

where $0/0$ is defined to be zero. The BLUP (34) can be obtained as a penalized least squares estimate.

Theorem 8 *The empirical Bayes estimator $\hat{f}(x)$ in (34) can be also obtained as the solution to the following minimization problem*:

$$\min_{f\in H_0\oplus H_{\mathcal{W}}} n^{-1}(y-f)^T R^{-1}(y-f) + \lambda\|f\|_{H_{\mathcal{W}}}^2 \text{ with } \lambda = \frac{\sigma^2}{n} \tag{38}$$

and $f = (f(x_1),\ldots,f(x_n))^T$.

The penalized least squares estimate in (38) is a method of regularization based on the Sobolev norm $\|\cdot\|_{H_{\mathcal{W}}}$. By choosing the order for λ_ℓ, we can control the degree of global smoothness of the estimator $\hat{f}$. When λ_ℓ is of order $O(2^{-2\ell s})$ as $\ell \to \infty$, the posterior space $H_0 \oplus H_{\mathcal{W}}$ is simply $W_2^s[0,1]$, i.e., $\hat{f}$ is in $W_2^s[0,1]$.

The method of regularization in (38) penalizes on random effects. The penalty on random effects is magnified more and more as the resolution level goes finer and finer. Such penalty highly discourages high-frequency wavelet coefficients and hence diminishes high-frequency fluctuation to get smoother posterior curves than the prior curves.

The empirical Bayes estimator $\hat{f}(x)$ (34), or equivalently (38), is the minimax linear estimator of $f(x)$ under mean squared error for f in the functional class

$$W_2^s(\delta) = \left\{f \in W_2^s[0,1], s > 0, \text{ and } \|f\|_{H_{\mathcal{W}}}^2 \le 1\right\}$$

D. Cycle Spinning

In view of expressions (22) and (23), the pointwise asymptotic bias and variance depend on their positions relative to grid points, or dyadic points in multiresolution analysis. The oscillatory effects appearing in bias and variance can be removed or lessened by shifting the grid points and then averaging over the shifts.

Consider an averaged shifted kernel

$$\mathcal{V}_h^{(q)}(x,y) = \frac{1}{q}\sum_{\ell=0}^{q-1}\mathcal{V}_h\left(x+\frac{\ell h}{q}, y+\frac{\ell h}{q}\right) \tag{39}$$

The kernel $\mathcal{V}_h^{(q)}(x,y)$ has the same order as the original kernel $\mathcal{V}_h(x,y)$. An estimator based on the averaged shifted kernel is given by

$$\hat{f}_{ASKE,q}(x) = \frac{1}{n}\sum_{i=1}^n \mathcal{V}_h^{(q)}(x,X_i)$$

for density estimation

$$\hat{f}_{ASKE,q}(x) = \frac{1}{n}\sum_{i=1}^n \mathcal{V}_h^{(q)}(x,x_i)y_i$$

for regression estimation

Assume that $f(x) \in C^{m,\alpha}(R) \cap L_2(R)$, for some $0 < \alpha \le 1$, and that $\int_{-\infty}^{\infty}|\mathcal{V}(x,y)(y-x)^{m+\alpha}|\,dy < \infty$. We have, as $h \to 0$ and $n \to \infty$,

$$E\,\hat{f}_{ASKE,q}(x) - f(x) = \frac{-f^{(m)}(x)}{m!}\,\frac{1}{q}\left(\sum_{\ell=0}^{q-1} b_m\left(\frac{x}{h}+\frac{\ell}{q}\right)\right)h^m + O(h^{m+\alpha})$$

where $O(h^{m+\alpha})$ is uniform in q. Notice that the number of cycles q can be chosen independently of n and h. By letting $q \to \infty$, we have

$$\frac{1}{q}\left(\sum_{\ell=0}^{q-1} b_m\left(\frac{x}{h}+\frac{\ell}{q}\right)\right) \to \int_0^1 b_m\left(\frac{x}{h}+t\right)dt = 0$$

That is, the asymptotic bias tends to order $O(h^{m+\alpha})$ as the number of cycles q goes to infinity.

As for the variance part, we have

$$\mathcal{V}^{(q)}\left(\frac{x}{h},\frac{x}{h}\right) \to \int_0^1 \mathcal{V}(x,x)\,dx = 1$$

The variance is getting more and more stable in the sense that

$$\sup_{x\in R}\left|\mathcal{V}^{(q)}(x,x)-1\right| \to 0, \quad \text{as } q \to \infty$$

Therefore, we get

$$\text{Var}\ \hat{f}_{ASKE,q}(x) \le \frac{1}{nh} f(x) K_0^{(q)}\left(\frac{x}{h},\frac{x}{h}\right) + O\left(\frac{1}{n}\right)$$

where $O(n^{-1})$ is uniform in q.

The action of shift-and-average is a smoothing operation on the grid points rather than on the data points. It is well known that when a smoothing operation is applied to the data points, there is a trade-off between bias and variance. However, this is not the case for a smoothing operation applied to grid points. This operation results in bias reduction and is variance stable.

X. TWO-DIMENSIONAL WAVELET ALGORITHM AND IMAGE PROCESSING

Suppose $\{V_j : j \in Z\}$ is a multiresolution analysis of $L_2(R)$ and $\phi(x)$ and $\psi(x)$ are the associated orthonormal scaling function and wavelet. Then the tensor product $\{V_j \otimes V_j : j \in Z\}$ forms a multiresolution analysis of $L_2(R^2)$. The set of functions

$$\{\phi(x-k)\phi(y-k') : k, k' \in Z\}$$

is an orthonormal basis for $V_0 \otimes V_0$. Moreover, the spaces $V_j \otimes V_j$, $V_j \otimes W_j$, $W_j \otimes V_j$ and $W_j \otimes W_j$ have as bases the sets of functions

$$\{\phi_{j,k}(x)\phi_{j,k'}(y) : k, k' \in Z\}$$
$$\{\phi_{j,k}(x)\psi_{j,k'}(y) : k, k' \in Z\}$$
$$\{\psi_{j,k}(x)\phi_{j,k'}(y) : k, k' \in Z\}$$
$$\{\psi_{j,k}(x)\psi_{j,k'}(y) : k, k' \in Z\}$$

respectively. The two-dimensional fast algorithm can be easily formulated from its one-dimensional counterpart. Subscripts H, V, D stand for horizontal, vertical, and diagonal, as the subspaces $V_j \otimes W_j$, $W_j \otimes V_j$, and $W_j \otimes W_j$ tend to emphasize horizontal, vertical, and diagonal features of a two-dimensional image.

The decomposition formula is

$$\begin{aligned} c^{j-1} &= H_c H_r c^j \\ d_H^{j-1} &= G_c H_r c^j \\ d_V^{j-1} &= H_c G_r c^j \\ d_D^{j-1} &= G_c G_r c^j \end{aligned}$$

where $H_r = H$ and $G_r = G$ are quadrature filters acting on each row of the underlying array; similarly, $H_c = H$ and $G_c = G$ are quadrature filters acting on each column of the underlying array. That is,

$$\begin{aligned} \left(H_c H_r c^{j-1}\right)_{m,n} &= \sum_{k\in Z} h_{k-2m}\left(H_r c^j\right)_{k,n} \\ &= \sum_{k\in Z}\sum_{\ell\in Z} h_{k-2m} h_{\ell-2n} c^j_{k,\ell} \\ \left(G_c H_r c^{j-1}\right)_{m,n} &= \sum_{k\in Z} g_{k-2m}\left(H_r c^j\right)_{k,n} \\ &= \sum_{k\in Z}\sum_{\ell\in Z} g_{k-2m} h_{\ell-2n} c^j_{k,\ell} \\ \left(H_c G_r c^{j-1}\right)_{m,n} &= \sum_{k\in Z} h_{k-2m}\left(G_r c^j\right)_{k,n} \\ &= \sum_{k\in Z}\sum_{\ell\in Z} h_{k-2m} g_{\ell-2n} c^j_{k,\ell} \\ \left(G_c G_r c^{j-1}\right)_{m,n} &= \sum_{k\in Z} g_{k-2m}\left(G_r c^j\right)_{k,n} \\ &= \sum_{k\in Z}\sum_{\ell\in Z} g_{k-2m} g_{\ell-2n} c^j_{k,\ell} \end{aligned}$$

The reconstruction formula is

$$c^j = H_c^* H_r^* c^{j-1} + G_c^* H_r^* d_H^{j-1} + H_c^* G_r^* d_V^{j-1} + G_c^* G_r^* d_D^{j-1}$$

where H^* and G^* are adjoint operators and the subscripts c and r indicate respectively the operators acting on each column and each row.

Let $c^0 = (c^0_{m,n})_{r\times c}$ be an $r \times c$ matrix representing a discretized image intensity. The entries $c^0_{m,n}$ are called the pixel values or gray-scale levels. In practice these pixel values are in a finite range. Typical values are $0, 1, \ldots, 255$ (eight bits per pixel).

To compress an image, the image can first be decomposed into wavelet coefficients, then coefficients smaller

than a certain threshold value can be thrown away, and finally the image can be reconstructed with new coefficients.

GLOSSARY

Compression Manipulating data so it can be stored in a smaller amount of space.

Daubechies wavelets Smooth, orthogonal wavelets, with compact support, that can be used to decompose and recompose polynomial functions with no error.

Detail coefficients Numbers generated from applying a high-pass filter.

Differencing Computing certain linear combinations of components in a signal to create detail coefficients.

Dilation equation An equation relating the father wavelet (scaling function) or mother wavelet to translates and dilations of the father wavelet. Dilation equations generate the coefficients of filters.

Filter Operators on signals that act via averaging and differencing to produce new signals.

Multiresolution analysis A nested sequence of inner product spaces satisfying certain properties. Members of a wavelet family form bases for the spaces in a multiresolution analysis.

Refinement coefficients Coefficients found in a dilation equation.

Thresholding A process in which certain wavelet coefficients are modified in order to achieve an application (e.g., compression or denoising) while preserving the essential structure of a signal.

Wavelets Special functions, consisting of the father wavelet and other functions generated by scalings and translations of a basic function called the mother wavelet.

THE FUNDAMENTAL problem in wavelet research and applications is to find or create a set of basis functions

that will capture, in some efficient manner, the essential information contained in a signal or function. Beginning with a *scaling function* ϕ, we define a *mother wavelet*, ψ, and then *wavelets* $\psi_{m,k}(t) = \psi(2^m t - k)$ generated by scalings and translations of the mother wavelet. The scaling function may be chosen based on many requirements, e.g., regularity, depending on the application. These functions form a basis that provides information about a signal or a function on both a local and global scale. Key ideas in this subject—multiresolution, localization, and adaptability to specific requirements—have made wavelets an important tool in many areas of science.

I. INTRODUCTION

Information surrounds us. Technology has made it easy to collect tremendous amounts of data. The sheer size of the available data makes it difficult to analyze, store, retrieve, and disseminate it. To cope with these challenges, more and more people are using *wavelets*.

As an example, the FBI has more than 25 million cards containing fingerprints. On each card is stored 10 rolled fingerprint impressions, producing about 10 megabytes of data per card. It requires an enormous amount of space just to store all of this information. Without some sort of image compression, a sortable and searchable electronic fingerprint database would be next to impossible. For this purpose, the FBI has adopted a wavelet compression standard for fingerprint digitization. Using this standard, they are able to obtain a compression ratio of about 20:1, without sacrificing the necessary detail required by law.

The history of wavelets began with the development of Fourier analysis. In the early 1800s, Joseph Fourier showed that any periodic function (one that repeats itself like a sine wave) can be represented as an infinite sum of sines and cosines. Within this process, it is possible to approximate such a periodic function as closely as one likes with a finite sum of sines and cosines. To do this, it is necessary to determine the coefficients (amplitudes) of the sines and cosines, along with appropriate translations, in order to "fit" the function being approximated. The ideas of Fourier analysis are used today in many applications.

Although Fourier analysis is a useful and powerful tool, it does have its limitations. The major drawback to Fourier methods is that the basis functions (the sines and cosines) are periodic on the entire real line. As a result, Fourier methods supply global information (i.e., the "big picture") about functions, but not local information (or details). The desire for analytic techniques that provide simultaneous information on both the large and small scale led to the development of wavelets.

The roots of this subject are many. Researchers in different areas such as optics, quantum physics, geology, speech, computer science, and electrical engineering developed wavelet tools to attack problems as diverse as modeling human vision and predicting earthquakes. The main idea was to find basis functions that would allow one to analyze information at both coarse and fine resolutions, leading ultimately to the notion of a *multiresolution analysis*. Work in this area can be traced back to the 1930s. Because of the lack of communication between scientists working in these disparate fields, the tools that were developed in the early years were not seen as being related.

The formal field of wavelets is said to have been introduced in the early 1980s when the geophysicist Jean Morlet developed wavelets as a tool used in oil prospecting. Morlet sought assistance with his work from the physicist Alexander Grossmann, and together the two broadly defined wavelets based in a physical context. In the mid-1980s, Stéphane Mallat and Yves Meyer further developed the field of wavelets by piecing together a broader framework for the theory and constructing the first nontrivial wavelets. In 1987, Ingrid Daubechies used Mallat's work to construct a family of wavelets that satisfied certain conditions (smooth, orthogonal, with compact support) that have become the foundation for current applications of wavelets.

Examples of applications of wavelets today can be found in medical imaging, astronomy, sound and image compression and recognition, and in the studies of turbulence in systems, understanding human vision, and eliminating noise from data.

II. BASIC TECHNIQUES

In this section we will introduce wavelets and discuss how they can be used to process data. The Haar wavelets will be used to illustrate the process.

Any ordered collection of data will be called a *signal*. To obtain an example of a signal, we will collect output from the damped oscillation $\cos(3t)e^{-t}$ on the interval [0,5] at 32 evenly spaced points. This results in the signal

$$\begin{aligned}\mathbf{s} = [&0.763, 0.433, 0.103, -0.160, -0.320, -0.371,\\ &-0.332, -0.235, -0.116, -0.005, 0.077, 0.121,\\ &0.129, 0.108, 0.070, 0.029, -0.008, -0.033,\\ &-0.045, -0.044, -0.034, -0.020, -0.006, 0.006,\\ &0.013, 0.016, 0.015, 0.011, 0.006, 0.001, -0.003,\\ &-0.005].\end{aligned}$$

Note: To save space, all data will be rounded to three decimal places.

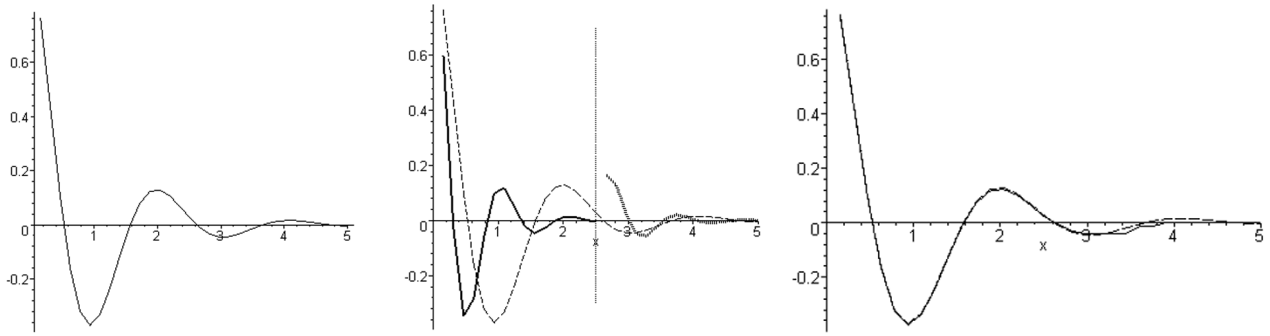

FIGURE 1 (*Left*) Plot of original data. (*Center*) Result of low- and high-pass filters. The plot of the original signal is dashed, the result of the low-pass filter is solid, and the result of the high-pass filter is dotted. (*Right*) Reconstruction of signal after thresholding. The plot of the original signal is dashed; the reconstructed signal is solid.

To graph this signal, we plot t values along the horizonal axis and the corresponding sample values along the vertical axis. We then connect the resulting points with line segments. A plot of this data is shown in Fig. 1.

To process a signal with wavelets, we use *filters* that are determined by the wavelets. There are two components to each filter—a low-pass filter and a high-pass filter. These filters come from what are called the *father* and *mother wavelets* that define a family of wavelets. Each family of wavelets gives us different filters. We will use the Haar wavelets to illustrate.

The *Haar father wavelet*, ϕ, and *Haar mother wavelet*, ψ, are defined by

$$\phi(t) = \begin{cases} 1, & \text{if } 0 \le t < 1 \\ 0, & \text{otherwise} \end{cases} \quad \text{and}$$
$$\psi(t) = \begin{cases} 1, & \text{if } 0 \le t < \frac{1}{2} \\ -1, & \text{if } \frac{1}{2} \le t < 1 \\ 0, & \text{otherwise} \end{cases} \tag{1}$$

The father wavelet is also called the *scaling function*. Note that the father and mother wavelets are related by

$$\begin{aligned} \phi(t) &= \phi(2t) + \phi(2t-1) \quad \text{and} \\ \psi(t) &= \phi(2t) - \phi(2t-1). \end{aligned} \tag{2}$$

The low-pass filter is determined by the father wavelet. This filter uses the coefficients from (2) to perform an averaging of values of a signal. For the Haar wavelets, the two coefficients (1 and 1) are divided by 2 and then used to compute linear combinations of pairs of elements in the signal (later we will see from where the factor of 2 comes). This results in computing an average of pairs of elements. For example, the average of the first pair of data points in our sample is $(0.763 + 0.433)/2 = 0.598$, the average of the second pair of sample points is $(0.103 - 0.161)/2 = -0.029$, and so on. The result is a new signal half the length of the old one. In particular, the result of applying the low-pass filter to our original signal is

$$\begin{aligned} \mathbf{s}_l = [&0.598, -0.029, -0.346, -0.284, -0.061, \\ &0.099, 0.119, 0.050, -0.021, -0.045, -0.027, \\ &0, 0.015, 0.013, 0.004, -0.004] \end{aligned}$$

The high-pass filter is determined by the mother wavelet. This time, instead of adding the data in pairs and dividing by 2, we subtract and divide by 2. This is called *differencing*. For example, using the first two components of $\mathbf{s}$ we obtain $0.763/2 - 0.433/2 = 0.165$, the second pair yields $0.103/2 - 0.161/2 = 0.132$, and so on. When the high-pass filter is applied to the original signal we obtain

$$\begin{aligned} \mathbf{s}_h = [&0.165, 0.132, 0.026, -0.049, -0.056, -0.022, \\ &0.011, 0.021, 0.013, -0.001, -0.007, -0.006, \\ &-0.002, 0.002, 0.003, 0.001] \end{aligned}$$

Note that both $\mathbf{s}_l$ and $\mathbf{s}_h$ are half the length of the original signal. We can think of these shorter signals as signals of length 32 by appending zeros at either the beginning or the end of the signals. In particular, we can identify $\mathbf{s}_l$ with a signal $\mathbf{s}'_l$ of length 32 by attaching 16 zeros to the end of the signal. Similarly, we will view $\mathbf{s}_h$ as a signal $\mathbf{s}'_h$ of length 32 by adding 16 zeros to the beginning of the signal. We attach the zeros in this way so that we can view the result of applying the low- and high-pass filters to $\mathbf{s}$ as $\mathbf{s}' = \mathbf{s}'_l + \mathbf{s}'_h$. We can then plot the signal $\mathbf{s}'$ against the signal $\mathbf{s}$ and compare. A graph is shown in Fig. 1. The result of the low-pass filter is seen on the interval [0,2.5]; the output from the high-pass filter appears on [2.5,5]. We see that the low-pass filter, or the averaging, makes a copy of the original signal but on half scale.

The high-pass filter, or the differencing, keeps track of the detail lost by the low-pass filter. The entries in the signal $\mathbf{s}_h$ obtained from the high-pass filter are called *detail coefficients*.

To see how these coefficients keep track of the details, it is only necessary to see how they are used to recover the original signal. Note that if we have an average $A = \frac{a}{2} + \frac{b}{2}$ of data points a and b and we know the corresponding detail coefficient $C = \frac{a}{2} - \frac{b}{2}$, then we can recover both a and b via $a = A + C$ and $b = A - C$. In this way, the process of applying the low- and high-pass filters is completely reversible.

By applying the low-pass filter, a copy of the original signal $\mathbf{s}_l$ at half scale is created. We now apply the low- and high-pass filters to this new copy to obtain another reduced copy of the original signal at one-quarter scale, plus more detail coefficients. This gives us another new copy of the original signal at one-quarter scale:

$$\mathbf{s}_{ll} = [0.285, -0.315, 0.019, 0.085, -0.033, -0.014, 0.014, 0]$$

plus corresponding detail coefficients

$$\mathbf{s}_{lh} = [0.314, -0.031, -0.080, 0.035, 0.012, -0.014, 0.001, 0.004].$$

Again, we can attach 0's at appropriate ends of these signals to produce a signal

$$\mathbf{s}'_{ll} + \mathbf{s}'_{lh} + \mathbf{s}'_h$$

of length 32.

We can continue with this process until we obtain one number that contains a copy of the original signal at the smallest possible scale. Through this process we have constructed a new signal consisting of the average of all the elements of the original signal, plus all of the detail coefficients. In our example, this new signal is

$$\mathbf{s}_{new} = [0.005, 0.014, -0.034, -0.016, 0.300, -0.033, -0.010, 0.007, 0.314, -0.031, -0.080, 0.035, 0.012, 0.014, 0.001, 0.004, 0.165, 0.132, 0.026, -0.049, -0.056, -0.022, 0.011, 0.021, 0.013, -0.001, -0.007, -0.006, -0.002, 0.002, 0.003, 0.001].$$

This new signal has the same length as the original and contains all of the information the original signal does. In fact, as we discussed above, each step in this processing can be reversed to recover the original signal from this new one. Since no information is lost as a result of applying these filters, this process is called *lossless*. The entries in $\mathbf{s}_{new}$ obtained in this way are called *wavelet coefficients*.

III. TWO APPLICATIONS

A. Thresholding and Compression

Although the preceding process shows a new way to store a signal, it is important to see what benefits this provides. Recall that the detail coefficients are obtained by averaging the differences of pairs of data points. Notice that the data points collected from our damped oscillation are close together in value near the end of the graph. When we process with our high-pass filter, the differencing generates values that are close to 0 in our signal, $\mathbf{s}_{new}$. When the detail coefficients are near 0, there is not much detail in certain parts of the original signal, that is, the signal has fairly constant values there. If we replace all of the detail coefficients that are close to 0 with 0, then reverse the processing with the low- and high-pass filters, we should obtain a signal that is reasonably close to the original. In other words, when the data is similar in small groups like this, we will lose little information in the signal if we replace all of these values that are "close together" with the same value.

Returning to our example, let us assume that "close" to 0 means within 0.01. In other words, replace all of the entries in the processed signal that are closer to 0 than 0.01 with a value of 0. This is called *hard thresholding*. After hard thresholding we obtain the processed signal

$$[0, 0.014, -0.034, -0.016, 0.300, -0.033, 0, 0, 0.314, -0.031, -0.080, 0.035, 0.012, -0.014, 0, 0, 0.165, 0.132, 0.026, -0.049, -0.056, -0.022, 0.011, 0.021, 0.013, 0, 0, 0, 0, 0, 0, 0]$$

To reverse the processing, the first step is to use the final average, 0, along with the final detail coefficient, 0.014, to recover the signal on $\frac{1}{32}$ scale. Note that we introduce some error in this process by rounding. However, we will tolerate this in the interest of saving space in the discussion. This gives us $[0 + 0.014, 0 - 0.014] = [0.014, -0.014]$. The result of our first step in deprocessing the signal is

$$[0.014, -0.014, -0.034, -0.016, 0.300, -0.033, 0, 0, 0.314, -0.031, -0.080, 0.035, 0.012, -0.014, 0, 0, 0.165, 0.132, 0.026, -0.049, -0.056, -0.022, 0.011, 0.021, 0.013, 0, 0, 0, 0, 0, 0, 0]$$

Continuing in this manner, we reconstruct an imperfect copy of the original signal on full scale:

$$[0.759, 0.429, 0.098, -0.166, -0.325, -0.377, -0.338, -0.240, -0.121, -0.009, 0.073, 0.117, 0.127, 0.105, 0.067, 0.025, -0.005, -0.031, -0.042, -0.042, -0.044, -0.044, -0.016, -0.016, 0.002, 0.002, 0.002, 0.002, 0.002, 0.002, 0.002, 0.002]$$

If we plot the original data and this reconstructed data after thresholding on the same set of axes, we get the picture in Fig. 1. Notice that it is difficult to tell the two plots apart.

What is the point of thresholding? One important use of wavelets is in the compression of data. If we simply compute wavelet coefficients, we lose no information from our signal, but we usually gain little in the way of storage space. However, if through thresholding we are able to introduce long strings of zeros in our signal, this allows us to store the information in a smaller amount of space. Instead of storing each 0 individually, we set a flag to tell us that we have a string of zeros, then follow that flag with the number of zeros in the string. So instead of storing, say, a string of 10 separate zeros, we only need to use two storage spaces, one for the flag, and one for the number of zeros in the string. In this way, we can reduce the amount of storage space from 10 bytes to 2 bytes. If we are willing to sacrifice some of the original signal, impressive compression results can be obtained through processing and thresholding. Since we lose some information through thresholding, we call this a *lossy* process. It should be noted that hard thresholding is only one of many different thresholding techniques.

B. Noise Removal

Noise, which is unwanted and irrelevant data, often creeps into data sets during collection. A few of the most common types of noise are random noise (which occurs through a signal), localized random noise (which appears in small intervals in the signal), and other noise (for example, pops that occur in old phonograph recordings).

As we have seen, the detail coefficients indicate where important details are located in a data set. If some of these coefficients are very small in relation to others, eliminating them may not substantially alter the original data set. In this manner, wavelets can be used to filter out unwanted noise from a data set. This process is called *denoising*.

In this process we are making the assumption that data we collect is of the form $\mathbf{q} = \mathbf{s} + noise$, where $\mathbf{q}$ is the received signal that is contaminated with noise and $\mathbf{s}$ is the actual signal. We also assume that *noise* is random and that $|noise| < c$ for some constant c. In other words, the noise is uniformly bounded on both sides of the actual signal. Our goal is to recover the signal $\mathbf{s}$.

As an example, we have artificially introduced noise onto the piecewise constant function f, with values of 2 on (0,1], 4 on (1,2], and 2 on (2,3], and then sampled at 1024 points to obtain a signal $\mathbf{s}$. (Note: The "noise" introduced here is defined as $0.01t\sin(150t)$ on (0,1], $0.01\sin(150t)$ on (1,2], and $0.01(t-2.5)^2\sin(150t)$ on (2,3].) The data is shown in Fig. 2.

We process this signal to obtain the signal $\mathbf{s}_{new}$, which consists of wavelet coefficients. A plot of $\mathbf{s}_{new}$ is shown in Fig. 2. The vertical axis in this figure is scaled so that the noise can be clearly seen. Other detail coefficients do not completely fit in this window.

Since the actual signal $\mathbf{s}$ is mostly constant, we should expect the majority of detail coefficients to be 0. However, the added noise makes many of these entries small, but nonzero. If we apply thresholding to eliminate what appears to be the added noise, we should be able to recover the signal $\mathbf{s}$. After applying hard thresholding with a tolerance $\lambda = 0.0075$ and reversing the processing, we obtain the "denoised" data shown in Fig. 2.

Similar ideas may be used to restore damaged video, photographs, or recordings, or to detect corrosion in metallic equipment. This approach has also been used in the correction of seismic data in Japan. However, it should be noted here that the Haar wavelets were effective in denoising the signal in this section because of the piecewise constant nature of the signal. Later we will see examples of other types of wavelets that are better choices for the applications mentioned here.

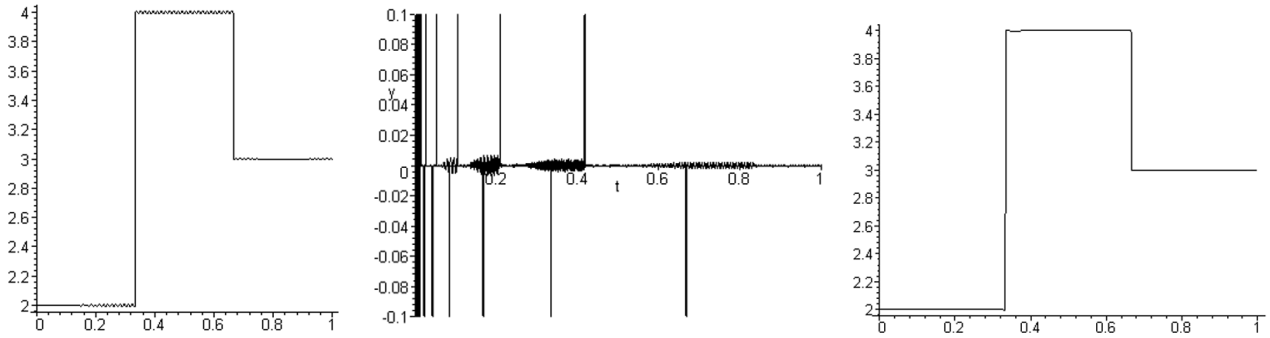

FIGURE 2 (*Left*) Piecewise constant signal with added noise. (*Center*) Wavelet coefficients of noisy data. (*Right*) Reconstructed piecewise constant signal after thresholding.

IV. SIGNALS AS FUNCTIONS

When working with wavelets it is convenient to describe our data in terms of functions. There is a simple way to do this, which we describe in this section.

In the previous section we began with an initial signal, **s**, of length 32 or 2^5. Note that this is only one of infinitely many signals of length 32. For convenience, we will denote the collection of all signals of length 2^n by $\mathbb{R}^{2^n}$ and write $\mathbf{s} \in \mathbb{R}^{32}$.

There is a natural connection between the space $\mathbb{R}^{2^n}$ of signals and the space of real-valued functions. We can think of each signal in $\mathbb{R}^{2^n}$ as representing a piecewise defined function on the interval [0,1] as follows. Break the interval into 2^n subintervals of equal length. The function identified with the signal has constant values on each subinterval, with the value of the function on the ith subinterval given by the ith entry of the signal. For example, the signal [1,2,3,4] in $\mathbb{R}^4$ corresponds to the function f that has values of 1 on $[0, \frac{1}{4})$, 2 on $[\frac{1}{4}, \frac{1}{2})$, 3 $[\frac{1}{2}, \frac{3}{4})$, 4 on $[\frac{3}{4}, 1)$, and 0 elsewhere.

We will denote the collection of all piecewise constant functions on such intervals of length $\frac{1}{2^n}$ by V_n. Our signal from the first section is then viewed as a function in V_5. Similarly, the father and mother Haar wavelets (1) can be viewed as functions in V_2 and identified with the vectors [1,1,1,1] and [1,1,−1,−1] in $\mathbb{R}^4$.

It is important to make the connection between the standard basis for $\mathbb{R}^{2^n}$ and the corresponding basis for V_n. Since V_0 consists of the constant functions on the interval [0,1], the father wavelet, $\phi(t)$, will span V_0. In V_1, we consider functions that are piecewise constant on the intervals $[0, \frac{1}{2})$ and $[\frac{1}{2}, 1)$. The standard basis for V_1 is then $\{\phi(2t), \phi(2t-1)\}$. In general, we can see that the set $S_n = \{\phi(2^n t - k) : 0 \le k < 2^n - 1\}$ will be a basis for V_n corresponding to the standard basis for $\mathbb{R}^{2^n}$.

V. THE HAAR FAMILY OF WAVELETS

In the previous sections we defined the father and mother Haar wavelets and saw how these wavelets were used to define two filters that we used to process data. In this section we will introduce the Haar family of wavelets and explain how the functional view of data discussed in the previous section actually determines the filters.

The function setting is the natural one in which to study wavelets. To see why, we must view each of the sets V_n as defined in the previous section as an *inner product space*.

Definition Let V be a vector space. An *inner product* on V is a function that assigns to each pair of vectors $\mathbf{u}$, $\mathbf{v}$ in V a real number, denoted $\langle \mathbf{u}, \mathbf{v} \rangle$, satisfying the following:

1. $\langle \mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{v}, \mathbf{u} \rangle$ for all $\mathbf{u}, \mathbf{v} \in V$.
2. $\langle k\mathbf{u}, \mathbf{v} \rangle = k\langle \mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{u}, k\mathbf{v} \rangle$ for all $\mathbf{u}, \mathbf{v} \in V$ and $k \in \mathbb{R}$.
3. $\langle \mathbf{u} + \mathbf{v}, \mathbf{w} \rangle = \langle \mathbf{u}, \mathbf{w} \rangle + \langle \mathbf{v}, \mathbf{w} \rangle$ for all $\mathbf{u}, \mathbf{v}, \mathbf{w} \in V$.
4. $\langle \mathbf{v}, \mathbf{v} \rangle \ge 0$ for all $\mathbf{v} \in V$ with equality if and only if $\mathbf{v} = 0$.

If V is a vector space on which an inner product, $\langle , \rangle$, is defined, we call the pair $(V, \langle , \rangle)$, an *inner product space*. A familiar example of an inner product space is $\mathbb{R}^n$ with the dot product as inner product.

Each V_n can be considered an inner product space using the inner product $\langle f, g \rangle = \int_{-\infty}^{\infty} f(t)g(t)\,dt$.

It is important to notice that signals and Haar wavelets have values of 0 outside the interval [0,1]. (Functions that are 0 outside of a closed and bounded interval are said to have *compact support*.) Each finite signal **s** corresponds to a function $f_{\mathbf{s}}$ satisfying $\int_{-\infty}^{\infty} f_{\mathbf{s}}(t)^2\,dt < \infty$. So, each V_n is a subspace of the larger inner product space $L^2(\mathbb{R})$, which consists of those functions $f : \mathbb{R} \to \mathbb{R}$ whose *norm*

$$\| f \| = \langle f, f \rangle^{1/2} = \left(\int_{-\infty}^{\infty} f(t)^2\,dt \right)^{1/2} \tag{3}$$

is finite.

Inner product spaces are useful in that we can measure lengths of vectors and angles between vectors in these spaces. We measure lengths of functions in V_n using the norm given in (3). Although we are not usually interested in angles between functions, we are interested in *orthogonality*. Recall that in the inner product space $\mathbb{R}^n$, using the dot product as inner product, two vectors **u** and **v** are perpendicular if $\mathbf{u} \cdot \mathbf{v} = 0$. Orthogonality is a generalization of this idea. In an inner product space V, two vectors **u** and **v** are *orthogonal* if $\langle \mathbf{u}, \mathbf{v} \rangle = 0$. As we will see, orthogonality is a very useful tool when computing projections.

Now we return to wavelets. Recall that we defined the father and mother wavelets by the equations in (1). As the terminology suggests, the father and mother generate "children." These children are determined by *scalings* and *translations* of the parents. In general, the nth-*generation children* are defined by

$$\psi_{n,k}(t) = \psi(2^n t - k), \quad 0 \le k \le 2^n - 1 \tag{4}$$

Note that there are 2^n children in the nth generation. The graphs of each of these children look like compressed and translated copies of the mother wavelet.

In the previous section we saw that there is a correspondence between the vector spaces V_n and $\mathbb{R}^{2^n}$. Consequently, the dimension of V_n is 2^n. In fact, we saw earlier that S_n is the "standard" basis for V_n. Another useful basis for V_n is

$$B_n = \left\{ \phi, \psi, \psi_{m,k} : 0 \le k \le 2^m - 1, 1 \le m \le n - 1 \right\}$$

which consists of father, mother, and children wavelets. The basis B_n is important in the world of wavelets precisely because the elements in B_n *are* the wavelets. The basis B_n also has the property that $\langle f, g\rangle = \int_{-\infty}^{\infty} f(t)g(t)\,dt = 0$ for any $f, g \in B_n$, with $f \neq g$. In other words, B_n is an *orthogonal basis* for V_n.

Any time we have an orthogonal basis for a subspace of an inner product space, we can *project* any vector in the space onto the subspace. What is more, there is an elegant way to do this given by the *orthogonal decomposition theorem*.

The orthogonal decomposition theorem If $\{\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_k\}$ is an orthogonal basis for a finite-dimensional subspace W of an inner product space V, then any $\mathbf{v} \in V$ can be written uniquely as $\mathbf{v} = \mathbf{w} + \mathbf{w}_\perp$, with $\mathbf{w} \in W$. Moreover,

$$\mathbf{w} = \frac{\langle \mathbf{v}, \mathbf{w}_1\rangle}{\langle \mathbf{w}_1, \mathbf{w}_1\rangle}\mathbf{w}_1 + \cdots + \frac{\langle \mathbf{v}, \mathbf{w}_k\rangle}{\langle \mathbf{w}_k, \mathbf{w}_k\rangle}\mathbf{w}_k = \sum_{i=1}^{k} \frac{\langle \mathbf{v}, \mathbf{w}_i\rangle}{\langle \mathbf{w}_i, \mathbf{w}_i\rangle}\mathbf{w}_i$$

and $\mathbf{w}_\perp = \mathbf{v} - \mathbf{w}$. The vector $\mathbf{w}$ in the orthogonal decomposition theorem is called the *projection of* $\mathbf{v}$ *onto* W.

This theorem is important in many respects. One way to use this theorem is for approximations. The vector $\mathbf{w}$ determined by the theorem is the "best" approximation to the vector $\mathbf{v}$ by a vector in W, in the sense that $\mathbf{w}_\perp$ is orthogonal to W. In fact, $\mathbf{w}_\perp$ is orthogonal to every vector in W. The collection of all vectors in V that are orthogonal to every vector in W is a subspace of V. This subspace is called the *orthogonal complement of* W *in* V and is denoted $W^\perp$. We then represent the result of the orthogonal decomposition theorem as $V = W \oplus W^\perp$.

To see how this applies to wavelets, let us return to our earlier example:

$$\begin{aligned}\mathbf{s} = [&0.763, 0.433, 0.103, -0.160, -0.320, -0.371,\\ &-0.332, -0.235, -0.116, -0.005, 0.077, 0.121,\\ &0.129, 0.108, 0.070, 0.029, -0.008, -0.033,\\ &-0.045, -0.044, -0.034, -0.020, -0.006, 0.006,\\ &0.013, 0.016, 0.015, 0.011, 0.006, 0.001, -0.003,\\ &-0.005]\end{aligned}$$

Recall that $\mathbf{s}$ is an element of V_5. Consider the subspace of V_5 spanned by the set $C_4 = \{\psi_{4,k} : 0 \le k \le 2^4 - 1\}$. Now C_4 is an orthogonal basis for the space it spans. Let W_4 be the span of C_4. Using this subspace W_4, let us compute the projection of $\mathbf{s}$ onto the space W_4 as described in the orthogonal decomposition theorem. Call this vector $\mathbf{w}$. First, note that $\langle \psi_{4,k}, \psi_{4,k}\rangle = \frac{1}{2^4}$ for any value of k. Let $\mathbf{s}_i$ denote the ith component of $\mathbf{s}$. Now notice that $\langle \mathbf{s}, \psi_{4,k}\rangle = (\mathbf{s}_{2k+2} - \mathbf{s}_{2k+1})/2^5$ for each k. Then the coefficient of $\psi_{4,k}$ in the orthogonal decomposition theorem is

$$\frac{\langle \mathbf{s}, \psi_{4,k}\rangle}{\langle \psi_{4,k}, \psi_{4,k}\rangle} = \frac{\frac{\mathbf{s}_{2k+1} - \mathbf{s}_{2k+2}}{2^5}}{\frac{1}{2^4}} = \frac{\mathbf{s}_{2k+1} - \mathbf{s}_{2k+2}}{2}$$

which is a detail coefficient as described earlier. The factor of 2 occurs naturally as a result of the squares of the norms of our basis vectors. Let $a_{4,k}$ represent the coefficient of $\psi_{4,k}$ in $\mathbf{w}$, so that $a_{4,k} = (\mathbf{s}_{2k+2} - \mathbf{s}_{2+1})/2$. We then have

$$\mathbf{w} = \sum_{k=0}^{15} a_{4,k}\psi_{4,k} \tag{5}$$

We must treat this projection with caution. Notice that we have only 16 coefficients in (5). As a result, we can treat $\mathbf{w}$ as a signal in $\mathbb{R}^{16}$. In this sense, the coefficients we calculated when projecting $\mathbf{s}$ onto W_4 are exactly those we obtained from applying the high-pass filter in the first section. In other words, we can say $\mathbf{w} = \mathbf{s}_h$. When using the orthogonal decomposition theorem, however, we must view this projection as an element of the larger space, or V_5 in this case. To do this, recall that the nonzero components of the vectors in $\mathbb{R}^{32}$ that correspond to $\psi_{4,k} \in V_5$ are 1 and -1. When viewed in this way, the vector in $\mathbb{R}^{32}$ corresponding to $\mathbf{w}$ (from (5)) will have components

$$[a_{4,0}, -a_{4,0}, a_{4,1}, -a_{4,1}, \ldots, a_{4,15}, -a_{4,15}]$$

This will be important when we compute $\mathbf{w}_\perp$. (This is different from how we earlier extended $\mathbf{s}_h \in \mathbb{R}^{16}$ to a signal in $\mathbb{R}^{32}$. In that situation, we were interested in interpreting our results graphically. In this case, we are guided by the orthogonal decomposition theorem.)

Now let us compute $\mathbf{w}_\perp = \mathbf{s} - \mathbf{w}$. Computing the first two components of $\mathbf{w}_\perp$ yields

$$\mathbf{s}_1 - \mathbf{w}_1 = \mathbf{s}_1 - a_{4,0}\psi_{4,0}(t) = \mathbf{s}_1 - \left(\frac{\mathbf{s}_1 - \mathbf{s}_2}{2}\right) = \frac{\mathbf{s}_1 + \mathbf{s}_2}{2}$$

and

$$\mathbf{s}_2 - \mathbf{w}_2 = \mathbf{s}_2 + a_{4,0}\psi_{4,0}(t) = \mathbf{s}_2 + \left(\frac{\mathbf{s}_1 - \mathbf{s}_2}{2}\right) = \frac{\mathbf{s}_1 + \mathbf{s}_2}{2}$$

The remaining components can be computed in a similar manner. Looking at the result componentwise, we identify $\mathbf{w}_\perp$ with the signal

$$\left[\frac{\mathbf{s}_1 + \mathbf{s}_2}{2}, \frac{\mathbf{s}_1 + \mathbf{s}_2}{2}, \frac{\mathbf{s}_3 + \mathbf{s}_4}{2}, \frac{\mathbf{s}_3 + \mathbf{s}_4}{2}, \ldots, \frac{\mathbf{s}_{31} + \mathbf{s}_{32}}{2}, \frac{\mathbf{s}_{31} + \mathbf{s}_{32}}{2}\right]$$

In other words, if we ignore the duplication, we can view $\mathbf{w}_\perp$ as the result of applying the low-pass filter to the signal.

Recall that the averaging process (the low-pass filter) produces a copy of the original signal on half scale. So we can consider the copy, $\mathbf{s}_l$, of our signal as a function in V_4. It can be shown that each basis element in B_4 is orthogonal

to the functions in V_4. Consequently, every function in W_4 is orthogonal to every function in V_4. So V_4 and W_4 are orthogonal complements in V_5. In other words, $W_4 = V_4^{\perp}$ and $V_5 = V_4 \oplus V_4^{\perp}$.

The next step in processing is to decompose the new signal $\mathbf{s}_l$ in V_4. When we apply the orthogonal decomposition theorem to $\mathbf{s}_l$, we decompose it into two pieces, one in V_3 and one in $V_3^{\perp}$ as subspaces of V_4. This gives us another decomposition of $\mathbf{s}$ in $V_3 \oplus V_3^{\perp} \oplus V_4^{\perp}$. Again, this decomposition uses the idea that we are identifying V_3 as subspace of V_4, which is a subspace of V_5.

This process continues until we have obtained a vector in

$$V_0 \oplus V_0^{\perp} \oplus V_1^{\perp} \oplus V_2^{\perp} \oplus V_3^{\perp} \oplus V_4^{\perp}$$

In our earlier work, this was the signal $\mathbf{s}_{new}$. Since the coefficients that are determined in this process are multipliers on wavelets, we can see why they are called wavelet coefficients. We should note here that the process described in the previous sections of constructing new signals through averaging and differencing has involved successively producing versions of the original signal on half scales. Since we continually reduce the scale by half, the process can only be applied to signals of length 2^n some integer n.

VI. DILATION EQUATIONS AND OPERATORS

In this section we will see how wavelet processing can be viewed as *operators* that arise from *dilation equations*. Again, we use the Haar wavelets to motivate the discussion.

The processing we have done has depended only on the equations (2). These equations are called *dilation, equations*, and they completely determine the process through which the wavelet coefficients are found. In many situations, the properties that we desire our wavelets to have determine the dilation equations for the wavelets.

Once we have dilation equations for a family of wavelets, we can use them to describe low- and high-pass filters for that family. To make computations more efficient, however, we *normalize* the functions in equations (2). Recall that a vector is a *normal vector* if its norm or length is 1. In the case of our wavelets, we use the $L^2(\mathbb{R})$ integral norm defined in (3). A simple integration by substitution shows us that $\|\phi(2t)\| = \sqrt{2} = \|\phi(2t-1)\|$.

Multiplying $\phi(2t)$ and $\phi(2t-1)$ in the original dilation equations by $\sqrt{2}$ to normalize them produces the dilation equations

$$\begin{aligned} \phi(t) &= h_0\sqrt{2}\phi(2t) + h_1\sqrt{2}\phi(2t-1) \quad \text{and} \\ \psi(t) &= g_0\sqrt{2}\phi(2t) - g_1\sqrt{2}\phi(2t-1) \end{aligned} \tag{6}$$

where $h_0 = h_1 = \frac{1}{\sqrt{2}}$, and $g_0 = \frac{1}{\sqrt{2}}$ and $g_1 = -\frac{1}{\sqrt{2}}$ for the Haar wavelets.

Suppose we have a signal $\mathbf{s} = [\mathbf{s}_0, \mathbf{s}_1, \ldots, \mathbf{s}_{2^n-1}]$ of length 2^n. The low- and high-pass filters can then be described in general by two *operators*, H (the low-pass operator) and G (the high-pass operator), defined by

$$(H\mathbf{s})_k = \sum_{j\in\mathbb{Z}} h_{j-2k}\mathbf{s}_j \quad \text{and} \quad (G\mathbf{s})_k = \sum_{j\in\mathbb{Z}} g_{j-2k}\mathbf{s}_j \tag{7}$$

The coefficients h_i and g_i in these sums are called *filter coefficients*. There are two items to be aware of here:

- Note the translation in the subscripts of h and g by $2k$. If we do a standard convolution (translate by k), the entries we want occur in every other component. We saw this happen earlier when we used the orthogonal decomposition theorem. Hence, we *downsample* at $2k$.
- It might seem natural that the high-pass operator should be denoted by H, but the convention is to use G instead.

Notice that for the Haar wavelets these operators give us exactly the results (up to a factor of $\sqrt{2}$) that we obtained in the previous section. The importance of this operator approach is that to process signals with wavelets we only need to know the coefficients in the dilation equations. As we will see later, other wavelet families have dilation equations whose coefficients are different from those of the Haar wavelets. However, the method of processing signals with these wavelet families is the same.

To undo the processing with H and G, we define the *dual operators* denoted H^* and G^*. The dual operators are defined by

$$(H^*\mathbf{s}^*)_k = \sum_{j\in\mathbb{Z}} h_{k-2j}\mathbf{s}_j^* \quad \text{and} \quad (G^*\mathbf{s}^*)_k = \sum_{j\in\mathbb{Z}} g_{k-2j}\mathbf{s}_j^* \tag{8}$$

Note the change in indices from the definitions of H and G.

It is not difficult to see that $H^*(H\mathbf{s}) + G^*(G\mathbf{s}) = \mathbf{s}$ for any signal $\mathbf{s}$ of length 2^n using the Haar wavelets. However, the orthogonality plays a critical role in this process (recall how orthogonality arose in the projections onto the subspaces V_n and $V_n^{\perp}$), so these operators will not perform in the same way if the wavelets we use are not orthogonal. Also, the operators defined by (7) are designed to process signals of infinite length, so there may be difficulties in recomposing a finite signal at either end if the number of nonzero coefficients in the dilation equations is different from 2. This is called a *boundary problem*, and there are several methods to cope with such difficulties. We will discuss three such methods in a later section.

VII. LOCALIZATION

Another important property of wavelets is their ability to identify important information on small scale. This is called *localization*.

In (4) we defined the nth-generation children wavelets as contractions and translations of the mother wavelet. By selecting a large enough value of n, we are able to analyze our data on very small intervals. There is, however, no reason to restrict ourselves to small intervals. In fact, the beauty and power of wavelets lies in their ability to perform analysis on both large and small scales simultaneously. To see how this works, we extend the definitions of the previously defined sets V_n to include negative values of n as well as to cover functions defined (and nonzero) outside of [0,1].

Recall that for nonnegative integer values of n, V_n consists of the functions that are piecewise constant on intervals of length $1/2^n$ within the interval [0,1]. If we allow for translations outside of the interval [0,1], then we can extend the definition of each V_n. We will need to be careful, however, to insist that each of our functions remains in $L^2(\mathbb{R})$. With this in mind, V_0 will be the space of all functions in $L^2(\mathbb{R})$ that are piecewise constant on intervals of length 1 with integer end points. The space V_0 will be generated by translations of the father wavelet of the form $\phi(t-k)$ for $k \in \mathbb{Z}$. Next, V_1 will include all functions in $L^2(\mathbb{R})$ that are piecewise constant on intervals of length $\frac{1}{2}$ with possible breaks at integer points or at points of the form $(2n+1)/2$ from some integer n. We can generate functions in V_1 with the collection $\{\phi(2t-k): k \in \mathbb{Z}\}$. Similarly, V_2 will be spanned by $\{\phi(2^2t-k): k \in \mathbb{Z}\}$ and will contain all functions with possible breaks at rational points with denominators of $4 = 2^2$, and so on.

This perspective allows us to define V_n for negative values of n as well. In these cases, instead of contracting the intervals on which our functions are constant, we expand them. For example, V_{-1} will consist of all functions in $L^2(\mathbb{R})$ that are piecewise constant on intervals of length 2, with integer end points. More generally, V_n will contain piecewise constant functions in $L^2(\mathbb{R})$ with possible jumps at points of the form $m \times 2^{-n}$ for any integer n. The set $\{\phi(2^n t-k): k \in \mathbb{Z}\}$ will generate V_n. An advantage to this approach is that we can now work with data that is defined on intervals other than [0,1].

To illustrate this advantage, consider the methods of Fourier analysis, which were discussed in the Introduction. As was previously stated, one disadvantage of Fourier methods is that they produce *global* information about signals, but not *local* information. For instance, if a low-pass filter, based on Fourier analysis, is applied to a signal, then high frequencies are eliminated throughout the whole signal, which may not be desired. The global approach of Fourier methods can also be seen in the formula for the discrete Fourier transform, where *every* data point contributes to *every* Fourier coefficient.

A wavelet analysis of a signal will bring out local information. As an example, consider the signal represented on the left in Fig. 3. The key behavior of this signal can be found on the intervals $[-4, -2]$ and $[1, 1.5]$. If we analyze this signal with wavelets, then specific wavelets will pick up the information on specific intervals. For instance, wavelet coefficients corresponding to the Haar wavelet $\psi(2^{-1}t+2) \in V_0$, along with scalings of this wavelet that are in $V_1, V_2, \ldots$, will be nonzero, because of the impulse on the interval $[-4, -2]$. Similarly, $\psi(2t-1) \in V_2$ and its scalings in $V_3, V_4, \ldots$ will notice the impulse on the other interval. All other wavelet coefficients will be zero.

Consequently, translations of ψ can be used to find specific time intervals of interest, and the scalings of these translations will reveal finer and finer details. This idea is represented on the right in Fig. 3. There, the shaded regions correspond to the wavelets we can use to analyze this function.

VIII. MULTIRESOLUTION ANALYSIS

In this section we will introduce the idea of a *multiresolution analysis* within the context of the Haar wavelets.

Let us return to our example processing a signal. There we applied the low- and high-pass filters to our original

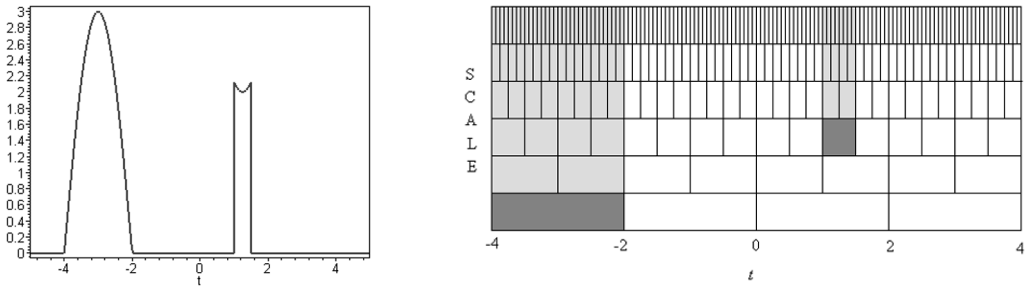

FIGURE 3 (*Left*) A signal with two short impulses. (*Right*) Selecting wavelets of different scales to analyze a signal.

signal **s** to obtain two new signals, $\mathbf{s}_l$ and $\mathbf{s}_h$, each in $\mathbb{R}^{16}$. They (or, consequently, the corresponding functions in V_4) can be thought of in at least two different ways as belonging to $\mathbb{R}^{32}$ (or V_5). With such inclusions, we can say that $\mathbb{R}^{16}$ is a subset of $\mathbb{R}^{32}$ ($\mathbb{R}^{16} \subset \mathbb{R}^{32}$) or, in the function setting, V_4 is a subset of V_5 ($V_4 \subset V_5$). After the first round of processing with the Haar wavelets, the original signal **s** in $\mathbb{R}^{32}$ is decomposed into two signals in $\mathbb{R}^{32}$.

The second round of processing consists of applying the low- and high-pass filters to $\mathbf{s}_l$, which yields two new signals $\mathbf{s}_{ll}$ and $\mathbf{s}_{lh}$ in $\mathbb{R}^8$. Again, each of these signals can be identified with signals in $\mathbb{R}^{16}$ and $\mathbb{R}^{32}$ by an appropriate extension. At each stage of the processing, new signals on half scale are obtained. The processing ends when we are reduced to a single number, a signal in $\mathbb{R}$.

In the function setting, when we process the signal with the low-pass filter, a copy of the corresponding function from V_5 is produced on half scale in V_4. Continued processing constructs additional copies on smaller scales in V_3, then V_2, and so on until V_0 is reached. In other words, we are reproducing our function in a nested sequence of spaces,

$$V_0 \subset V_1 \subset V_2 \subset V_3 \subset V_4 \subset V_5$$

Of course, there is no reason to restrict ourselves to signals of a given length. We can expand this idea to build a nested collection of sets

$$\cdots \subset V_{-2} \subset V_{-1} \subset V_0 \subset V_1 \subset V_2 \subset V_3 \subset V_4 \cdots$$

that continues for as long as we need in either direction. It can also be shown that the set $\{\phi(t-k)\}_{k\in\mathbb{Z}}$ forms an orthogonal basis for V_0. These are the basic ideas behind *multiresolution analysis*.

We have so far only encountered the Haar wavelets, but there are many other families of wavelets. Wavelets that are typically used in applications are constructed to satisfy certain criteria. The standard approach is to first build a multiresolution analysis (MRA) and then construct the wavelet family with the desired criteria from the MRA. All of the features of the Haar wavelets can be seen in the following definition.

Definition A *multiresolution analysis* (MRA) is a nested sequence

$$\cdots \subset V_{-1} \subset V_0 \subset V_1 \subset V_2 \subset \cdots$$

of subspaces of $L^2(\mathbb{R})$ with a scaling function ϕ such that

1. $\bigcup_{n\in\mathbb{Z}} V_n$ is dense in $L^2(\mathbb{R})$
2. $\bigcap_{n\in\mathbb{Z}} V_n = \{0\}$
3. $f(t) \in V_n$ if and only if $f(2^{-n}) \in V_0$
4. $\{\phi(t-k)\}_{k\in\mathbb{Z}}$ is an orthonormal basis for V_0 (that is, $\{\phi(t-k)\}_{k\in\mathbb{Z}}$ is an orthogonal basis for V_0 in which $\|\phi(t-k)\| = 1$ for each $k \in \mathbb{Z}$)

In every multiresolution analysis there is a *dilation equation* of the form

$$\phi(t) = \sum_k c_k \phi(2t-k) \tag{9}$$

The constants c_k in a dilation equation are called *refinement coefficients*. Equations (2) are examples of dilation equations. As we will see later, dilation equations allow us to construct a wide variety of different types of wavelets.

IX. DAUBECHIES WAVELETS

A. Dilation Equation for Daubechies Wavelets

The idea of a scaling function having compact support is featured in a type of wavelet family that is named after Ingrid Daubechies, who pioneered their development. The scaling functions for *Daubechies wavelets* have compact support and, more importantly, can be used to accurately decompose and recompose polynomial functions. This property of Daubechies wavelets is called the *regularity property*, and it is what makes these wavelets special.

There is more than one family of Daubechies wavelets, and one of the simplest families is generated by the scaling function called D_4. This function has compact support $[0,3]$, and because of this compact support, only four of the refinement coefficients are nonzero (hence the subscript 4). In other words, we can write

$$D_4(t) = c_0 D_4(2t) + c_1 D_4(2t-1) + c_2 D_4(2t-2) + c_3 D_4(2t-3) \tag{10}$$

The values of the four refinement coefficients are determined by using the fourth property of MRAs, an averaging condition for the scaling function, and a regularity condition. The orthogonality of the translates of D_4 yields the following two equations:

$$c_0^2 + c_1^2 + c_2^2 + c_3^2 = 2 \quad \text{and} \quad c_0 c_2 + c_1 c_3 = 0 \tag{11}$$

The *averaging condition* for the scaling function is simply that its average value over the real line is 1. This leads to the equation

$$c_0 + c_1 + c_2 + c_3 = 2 \tag{12}$$

The regularity condition for D_4 will lead to two more equations. The condition states that constant and linear functions can be reproduced by D_4 and its translates. More specifically, for any real numbers α and β, there exists a sequence of coefficients $\{a_k\}$ such that $\alpha t + \beta = \sum_k a_k D_4(t-k)$. This ability to reproduce polynomials

is referred to as *regularity* or *smoothness*, and it distinguishes the different families of Daubechies wavelets. For instance, the regularity condition for D_6, Daubechies scaling function with six refinement coefficients, is that constant, linear, and quadratic functions can be perfectly reproduced.

In some places in the literature, the regularity condition is presented in terms of the mother wavelet ψ that corresponds with D_4, and the following *vanishing moment conditions* are stated instead: $\int_{-\infty}^{\infty} \psi(t)\,dt = 0$ and $\int_{-\infty}^{\infty} t\psi(t)\,dt = 0$. It should be clear that for the family that is generated by D_6, there is a third moment condition to be included: $\int_{-\infty}^{\infty} t^2\psi(t)\,dt = 0$.

Regularity is important for several reasons. First, in image processing, smooth images, where colors and shades change gradually rather than suddenly, are better analyzed with smoother wavelets, as edge effects and other errors are avoided. Also, smoother wavelets lead to a cleaner separation of signals into low-pass and high-pass pieces. Finally, numerical methods such as the fast wavelet transform have been found to work more efficiently with wavelets that are more regular.

The regularity condition for D_4 leads to these two equations:

$$-c_0 + c_1 - c_2 + c_3 = 0 \quad \text{and} \quad -c_1 + 2c_2 - 3c_3 = 0 \tag{13}$$

The system of equations (11), (12), and (13) has two solutions. By convention, we use the solution that gives this dilation equation:

$$D_4(t) = \frac{1+\sqrt{3}}{4} D_4(2t) + \frac{3+\sqrt{3}}{4} D_4(2t-1) + \frac{3-\sqrt{3}}{4} D_4(2t-2) + \frac{1-\sqrt{3}}{4} D_4(2t-3) \tag{14}$$

See Fig. 4 for a graph of D_4. The other solution of the system of equations leads to a function whose graph is a mirror image of this graph, which is why we can ignore it.

The scaling function D_4 has a distinctive jagged shape. Although it may be difficult to label D_4 as *smooth*, it is continuous, and given the regularity condition, it should not come as a surprise that as n gets larger, D_n itself looks smoother and smoother. The method used to create this graph is described in the next section.

B. The Cascade Algorithm

The Haar wavelets are the simplest, and least regular, type of Daubechies wavelets, reproducing constant functions only. Also, the Haar scaling function is the only Daubechies scaling function that can represented with a simple formula. For other Daubechies wavelets families, the scaling functions are generated from the dilation equation using the *cascade algorithm*.

The cascade algorithm is based on the dyadic scaling and dilation equations (9) that are at the heart of an MRA. The equation (14) is another dilation equation. These equations can be used to determine function values at smaller scales, if function values at larger scales are known. For instance, if ϕ is known at all multiples of $\frac{1}{2}$, then (9) can be used to determine the value of ϕ at all multiples of $\frac{1}{4}$.

The cascade algorithm is a fixed-point method. Assuming the refinement coefficients are known, we can define a mapping from functions to functions by

$$F(u(t)) = \sum_k c_k u(2t-k). \tag{15}$$

Fixed points of F will satisfy (9), and it is possible to find these fixed points through an iterative process.

We will demonstrate how this works on (14), and consequently generate D_4. To begin, create an "initial guess" for a fixed point of (15), called u_0, defined only on the integers. Let u_0 be this guess: The function is zero on all of the integers except that $u_0(0) = 1$. Then, to get a good picture, connect these points with line segments, as is done is Fig. 5. (This is a reasonable first guess for D_4, as we know the scaling function has compact support and reaches some sort of maximum on the interval $[0,3]$. Connecting the

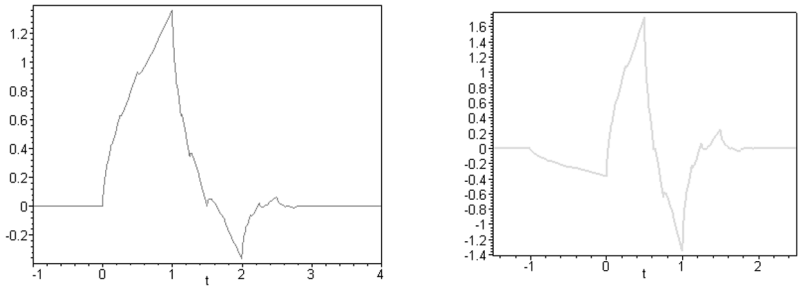

FIGURE 4 (*Left*) Scaling function D_4 of Daubechies. (*Right*) Daubechies' mother wavelet.

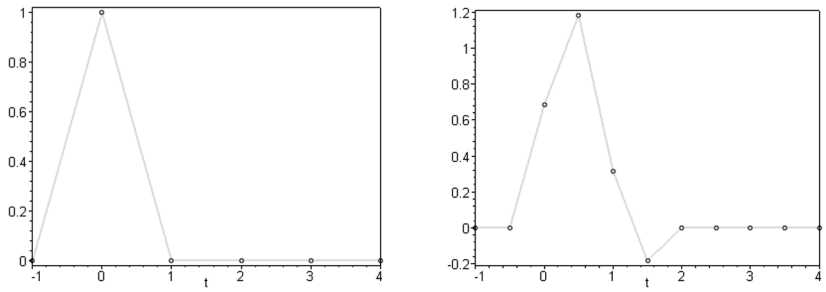

FIGURE 5 (*Left*) Initial guess for the cascade algorithm. (*Right*) First iteration of the cascade algorithm.

points is not necessary, except to get good images of the iterates. Also, for normalization reasons, it is important that the values of u_0 sum to 1.)

Next, use (14) to compute $u_1 = F(u_0)$ on all multiples of $\frac{1}{2}$, including the integers. For example,

$$u_1\left(\frac{3}{2}\right) = \frac{1+\sqrt{3}}{4}u_0(3) + \frac{3+\sqrt{3}}{4}u_0(2) + \frac{3-\sqrt{3}}{4}u_0(1) + \frac{1-\sqrt{3}}{4}u_0(0) = \frac{1-\sqrt{3}}{4}$$

Once the values on the multiples of $\frac{1}{2}$ are determined, connect the points to create Fig. 5.

A second iteration will yield u_2, defined on multiples of $\frac{1}{4}$. Graphs of the function u_2 and other iterates, demonstrating convergence to D_4, are found in Fig. 6. Of note is that, at convergence, the scaling function equals zero on all of the integers, except that $D_4(1) = (1+\sqrt{3})/2$ and $D_4(2) = (1-\sqrt{3})/2$.

As can be seen from this example, two important actions are occuring simultaneously in the cascade algorithm. First, each iterate is being defined on a finer scale that the previous one, so the algorithm can be run until a desired level of refinement is reached. Second, the iterates are converging to the scaling function. For the types of dilation equations described in this article, the cascade algorithm will converge, and proofs of this convergence can be found in the literature.

As in the case of the Haar wavelets, we can create a mother wavelet that corresponds with D_4. The key is the well-known relationship between the filter coefficients of the low-pass operator H and the high-pass operator G, and the relationship between the filter coefficients of H and the refinement coefficients in (9):

$$g_k = (-1)^k h_{1-k} \quad \text{and} \quad h_k = \frac{c_k}{\sqrt{2}} \tag{16}$$

These identities were demonstrated for the Haar wavelets in (6).

Since we know the values of c_k for D_4, we can determine h_k, and then g_k, and finally an equation as in (2) that relates D_4 to its mother wavelet:

$$\psi(t) = \frac{1-\sqrt{3}}{4}D_4(2t+2) - \frac{3-\sqrt{3}}{4}D_4(2t+1) + \frac{3+\sqrt{3}}{4}D_4(2t) - \frac{1+\sqrt{3}}{4}D_4(2t-1) \tag{17}$$

See Fig. 4 for a graph of ψ. This function is often referred to as simply the "Daubechies wavelet."

Refinement coefficients for other Daubechies scaling functions (e.g, D_6, D_8) can also be found in the literature. The cascade algorithm can be used to generate these functions, and equations such as (17) can be used to create the corresponding mother wavelets.

C. Analysis of Polynomials by Daubechies Wavelets

Constant and linear functions can be reproduced exactly by the Daubechies scaling function D_4 and its translates.

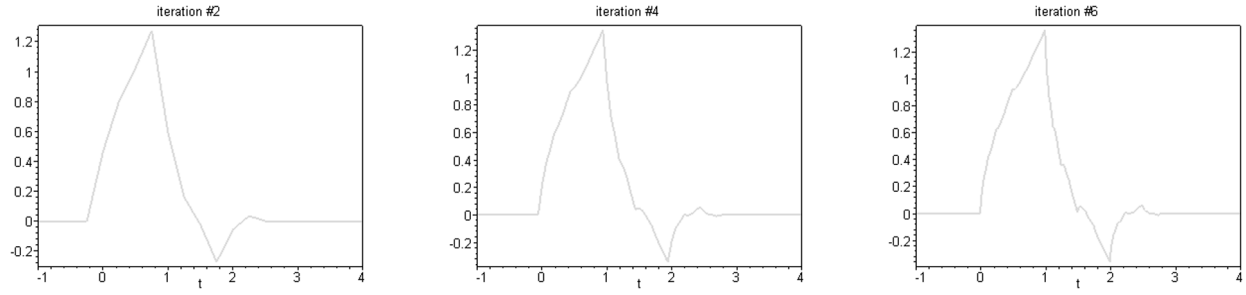

FIGURE 6 Selected iterations of the cascade algorithm.

This is surprising, as D_4 has a rather jagged shape. However, we will demonstrate how a linear function g can be written as a linear combination of D_4 and its translates. That is, we will show how to determine the values of a_k that satisfy

$$g(t) = \sum_k a_k D_4(t-k) \tag{18}$$

To find the coefficients in the linear combination, the orthogonal decomposition theorem can be used. For example, according to the theorem, a_{-2}, the coefficient that goes with $D_4(t+2)$, is defined by

$$a_{-2} = \frac{\langle g(t),\, D_4(t+2)\rangle}{\langle D_4(t+2),\, D_4(t+2)\rangle}$$

The denominator is 1 because the basis is orthonormal, so the coefficient that goes with $D_4(t+2)$ is

$$a_{-2} = \int_{-\infty}^{\infty} g(t) D_4(t+2)\, dt$$

Since the compact support of D_4 is $[0,3]$, this integral can be written as

$$a_{-2} = \int_{-2}^{1} g(t) D_4(t+2)\, dt \tag{19}$$

As discussed earlier, there is no simple formula for D_4, as it is simply defined through its dilation equation, so integrals such as (19) must be computed numerically to as much accuracy as desired.

A second approach to determining a_k begins by applying a simple change of variables to (18) to get

$$g(t) = \sum_j a_{t-j} D_4(j)$$

Using the values of D_4 on the integers yields

$$\begin{aligned} g(t) &= a_{t-1} D_4(1) + a_{t-2} D_4(2) \\ &= a_{t-1}\frac{1+\sqrt{3}}{2} + a_{t-2}\frac{1-\sqrt{3}}{2} \end{aligned} \tag{20}$$

If we think of a_k as a function in k, then it can be proved that a_k is a polynomial with the same degree as g.

We will use this fact to investigate what happens in the cases where g is the constant function 1, and where g is the linear function t. If g is constant, then a_k is the same constant for all k, which we will label a. Then (20) becomes

$$1 = a\frac{1+\sqrt{3}}{2} + a\frac{1-\sqrt{3}}{2} = a$$

So, $a_k = 1$ for all values of k, and

$$1 = \sum_k D_4(t-k) \tag{21}$$

If g is the linear function t, then $a_k = \gamma k + \delta$ for some constants γ and δ, and (20) is

$$t = (\gamma(t-1)+\delta)\frac{1+\sqrt{3}}{2} + (\gamma(t-2)+\delta)\frac{1-\sqrt{3}}{2}$$

which simplifies to

$$t = \gamma t + \left(\delta - \gamma\left(\frac{3-\sqrt{3}}{2}\right)\right)$$

Therefore, $\gamma = 1$, $\delta = (3-\sqrt{3})/2$, and we have the identity

$$t = \sum_k \left(k + \frac{3-\sqrt{3}}{2}\right) D_4(t-k) \tag{22}$$

We now apply this analysis to the specific case of $g = 3t+4$. Combining the identities (21) and (22) leads to

$$3t+4 = \sum_k \left(3k + \frac{17-3\sqrt{3}}{2}\right) D_4(t-k) \tag{23}$$

Although this sum is infinite, we can illustrate this identity on a finite interval. (It is tempting to conclude that $g = 3t+4$ is an element of V_0 for this wavelet family, as it is a linear combination of the translates of D_4. However, $V_0 \subset L^2(\mathbb{R})$, but g is not in $L^2(\mathbb{R})$. So, while any function in V_0 can be written uniquely as a linear combination of D_4 and its translates, not every linear combination is in V_0. The counterexamples are *infinite* sums where $\{a_k\} \notin l^2(\mathbb{R})$.) Here is the sum, using k from -1 to 1, with the coefficients evaluated to three decimal places:

$$2.902 D_4(t+1) + 5.902 D_4(t) + 8.902 D_4(t-1)$$

The graph of this linear combination is in Fig. 7. Note that it reproduces $3t+4$ exactly on the interval $[0,2]$, but not outside this interval.

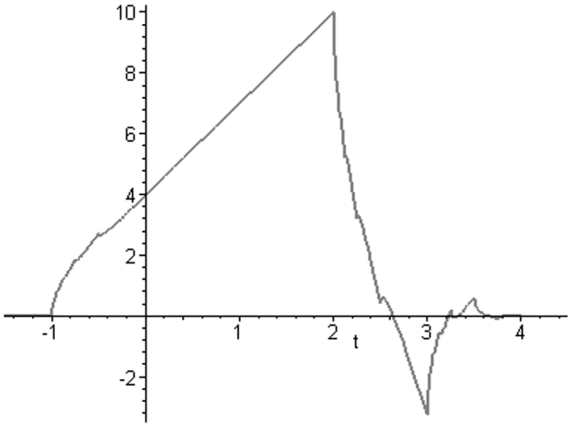

FIGURE 7 A truncated linear combination of the translates of D_4 reproduces a linear function on the interval [0,2].

D. Filters Based on Daubechies Wavelets

We now return to a discrete situation, where we wish to process a signal $\mathbf{s}$, rather than analyze a linear function g, with Daubechies wavelets. Two cases will be discussed: an infinite signal and a finite signal.

The low-pass and high-pass operators, H and G, defined by (7), will be used to process signals. For wavelets based on D_4, the values of the coefficients in the filter come from dividing the coefficients in (14) and (17) by $\sqrt{2}$, giving us

$$h_0 = \frac{1+\sqrt{3}}{4\sqrt{2}} \approx 0.48296 \quad h_1 = \frac{3+\sqrt{3}}{4\sqrt{2}} \approx 0.83652$$

$$h_2 = \frac{3-\sqrt{3}}{4\sqrt{2}} \approx 0.22414 \quad h_3 = \frac{1-\sqrt{3}}{4\sqrt{2}} \approx -0.12941$$

$$g_{-2} = \frac{1-\sqrt{3}}{4\sqrt{2}} \approx -0.12941$$

$$g_{-1} = -\frac{3-\sqrt{3}}{4\sqrt{2}} \approx -0.22414$$

$$g_0 = \frac{3+\sqrt{3}}{4\sqrt{2}} \approx 0.83652$$

$$g_1 = -\frac{1+\sqrt{3}}{4\sqrt{2}} \approx -0.48296$$

Since these are the only filter coefficients that are non-zero, the equations in (7) become

$$(H\mathbf{s})_k = h_0\mathbf{s}_{2k} + h_1\mathbf{s}_{2k+1} + h_2\mathbf{s}_{2k+2} + h_3\mathbf{s}_{2k+3} \qquad (24)$$

and

$$(G\mathbf{s})_k = g_{-2}\mathbf{s}_{2k-2} + g_{-1}\mathbf{s}_{2k-1} + g_0\mathbf{s}_{2k} + g_1\mathbf{s}_{2k+1} \qquad (25)$$

For example, consider the infinite signal that is analogous to the example in the previous section, $g = 3t + 4$. For all j, let $\mathbf{s}_j = 3j + 4$. Then, (24) and (25) become

$$(H\mathbf{s})_k = h_0(6k+4) + h_1(6k+7) + h_2(6k+10) + h_3(6k+13) = \sqrt{2}\left(6k + \frac{17-3\sqrt{3}}{2}\right)$$

and

$$(G\mathbf{s})_k = g_{-2}(6k-2) + g_{-1}(6k+1) + g_0(6k+4) + g_1(6k+7) = 0$$

There are many observations to make about these results. The output of the low-pass operator is, as in the case of the Haar wavelets, an average, but this time it is a weighted average, using the four weights h_0, h_1, h_2, and h_3. Those specific weights are important because then the high-pass operator G will filter the linear signal completely, leaving an output of zero. In other words, the details that are critical here are the ones that deviate from a linear trend, and, in this case, there are no details. *This is why the Daubechies wavelets are important.*

Also of note is that the output of the low-pass operator is similar to the coefficients in (23). Integrals such as (19) also compute weighted averages, but this time in the continuous domain, so it is reasonable that the results would be quite similar. The different coefficient on k is due to normalization and downsampling.

E. Analysis of Finite Signals

In reality, signals that require processing are finite, which presents a problem at the ends of the signal. If a signal $\mathbf{s} = [\mathbf{s}_0, \mathbf{s}_1, \ldots, \mathbf{s}_7]$ has length 8, then we can compute $(H\mathbf{s})_k$ only for $k = 0, 1$, and 2. Similarly, we can compute $(G\mathbf{s})_k$ only for $k = 1, 2$, and 3. If we are ever going to have any hope of reconstructing the original signal from average and detail coefficients, then we will need at least eight of them. There are many ways of addressing this issue, all of which involve concatenating infinite strings on both ends of $\mathbf{s}$, giving us an infinite signal that we can process as we did earlier. Then, we can generate as many average and detail coefficients as we need.

One approach is called *zero padding*, and we simply add infinite strings of zeros to both ends of $\mathbf{s}$, giving us

$$\ldots, 0, 0, 0, \mathbf{s}_0, \mathbf{s}_1, \mathbf{s}_2, \mathbf{s}_3, \mathbf{s}_4, \mathbf{s}_5, \mathbf{s}_6, \mathbf{s}_7, 0, 0, 0, \ldots$$

A second approach is called the *periodic method*, where we repeat $\mathbf{s}$ as if it were periodic, yielding

$$\ldots, \mathbf{s}_5, \mathbf{s}_6, \mathbf{s}_7, \mathbf{s}_0, \mathbf{s}_1, \mathbf{s}_2, \mathbf{s}_3, \mathbf{s}_4, \mathbf{s}_5, \mathbf{s}_6, \mathbf{s}_7, \mathbf{s}_0, \mathbf{s}_1, \mathbf{s}_2, \ldots$$

A third way is called the *symmetric extension method*, where we create symmetry in the string by concatenating the the reverse of $\mathbf{s}$ and repeating, leading to

$$\ldots, \mathbf{s}_2, \mathbf{s}_1, \mathbf{s}_0, \mathbf{s}_0, \mathbf{s}_1, \mathbf{s}_2, \mathbf{s}_3, \mathbf{s}_4, \mathbf{s}_5, \mathbf{s}_6, \mathbf{s}_7, \mathbf{s}_7, \mathbf{s}_6, \mathbf{s}_5, \ldots$$

Each method has its advantages. Zero padding is easy to implement. The periodic method leads to periodic output from the filters. Symmetric extension is popular because it does not introduce a sudden change in the signal as the other two do. It is important to observe that each method described here will lead to different results when applying H and G to the extended signals.

For the filters based on D_4, there is an overlapping dependence of filter values on data points. For this reason, we must use one of these boundary methods. This is not a problem with the Haar wavelets, however, so signals being processed with the Haar filters do not need to be extended. Finally, the shortest signal that can be processsed

by a filter is a concern. The Haar filters can be applied to signals of length 2, but the shortest possible signal for the D_4 filters has length 4.

F. A Final Example

At the beginning of this article, we investigated the analysis of a finite signal using the Haar wavelets. In this section, the filters based on D_4 will be used to analyze a signal that has a linear trend, along with some random noise. Through this example, the various ideas discussed in this article will come into play.

The following string is a truncated version of the infinite string from earlier, $3j + 4$, with some added random noise (see Fig. 8):

$$\mathbf{s}_{init} = [4.03, 7.82, 9.66, 12.45, 16.03, 15.97, 22, 27.11, 28.58, 31.98, 34, 36.99, 40, 44.1, 44.87, 49.13]$$

We will apply the periodic boundary method to create a new signal that we can filter. This signal would be

$$\tilde{\mathbf{s}} = [\ldots, 34, 36.99, 40, 44.1, 44.87, 49.13, \mathbf{4.03}, \mathbf{7.82}, \mathbf{9.66}, \mathbf{12.45}, \mathbf{16.03}, \mathbf{15.97}, \mathbf{22}, \mathbf{27.11}, \mathbf{28.58}, \mathbf{31.98}, \mathbf{34}, \mathbf{36.99}, \mathbf{40}, \mathbf{44.1}, \mathbf{44.87}, \mathbf{49.13}, 4.03, 7.82, 9.66, 12.45, 16.03, 15.97, \ldots]$$

where the periodic "core" of this signal is in bold. Applying (24) and (25) to this signal yields

$$\tilde{\mathbf{s}}_l = [9.042, 16.606, 22.524, 35.571, 43.389, 50.622, 59.908, 62.660]$$

and

$$\tilde{\mathbf{s}}_h = [-17.224, -0.206, 1.656, -0.344, -0.461, -0.290, -0.529, -1.254]$$

We observe that the low-pass filter H is computing weighted averages of the values in the signal, while the high-pass filter G captures the deviation from a linear sequence, which, in this case, is the noise. (The Haar filters capture the deviation from a constant sequence.) Unlike the earlier example, the detail coefficients are not zero because noise is detected. Also, because the linear trend in the data is broken at the periodic extension (from $\tilde{\mathbf{s}}_{-1}$ to $\tilde{\mathbf{s}}_0$, for instance) there is a detail coefficient, -17.224, that is not very close to zero.

As we did at the beginning of this article, we can apply the filters to $\tilde{\mathbf{s}}_l$, extended periodically, to perform a second level of processing. Applying (24) and (25) produces

$$\tilde{\mathbf{s}}_{ll} = [18.704, 43.808, 68.620, 81.227]$$

and

$$\tilde{\mathbf{s}}_{lh} = [-22.254, -3.230, .960, 2.891]$$

We can apply the filters one more time to $\tilde{\mathbf{s}}_{ll}$, which has period 4 (the minimum length for the D_4 filters). This will give us:

$$\tilde{\mathbf{s}}_{lll} = [50.548, 99.612] \quad \text{and} \quad \tilde{\mathbf{s}}_{llh} = [-32.598, 5.933]$$

Combining $\tilde{\mathbf{s}}_{lll}$ and $\tilde{\mathbf{s}}_{llh}$ with the detail coefficients given previously, we create the new signal

$$\tilde{\mathbf{s}}_{new} = [50.548, 99.612, -32.598, 5.933, -22.254, -3.230, .960, 2.891, -17.224, -.206, 1.656, -.344, -.461, -.290, -.529, -1.254]$$

This signal, $\tilde{\mathbf{s}}_{new}$, of length 16 contains all of the information needed to reproduce $\mathbf{s}_{init}$.

The next step in processing this signal is to apply thresholding as a way to remove the noise. Applying a tolerance of 1.8 to $\mathbf{s}_{new}$ to eliminate some of the detail coefficients produces

$$\hat{\mathbf{s}} = [50.548, 99.612, -32.598, 5.933, -22.254, -3.230, 0, 2.891, -17.224, 0, 0, 0, 0, 0, 0, 0]$$

Finally, we apply the dual operators (8) to $\hat{\mathbf{s}}$ and compare our results with $\mathbf{s}_{init}$. Reconstructing the original signal requires applying the dual operators three times. The first time, we calculate $H^*(\tilde{\mathbf{s}}_{lll}) + G^*(\tilde{\mathbf{s}}_{llh})$, creating

$$[18.704, 43.808, 68.620, 81.227]$$

Continuing this process ultimately yields

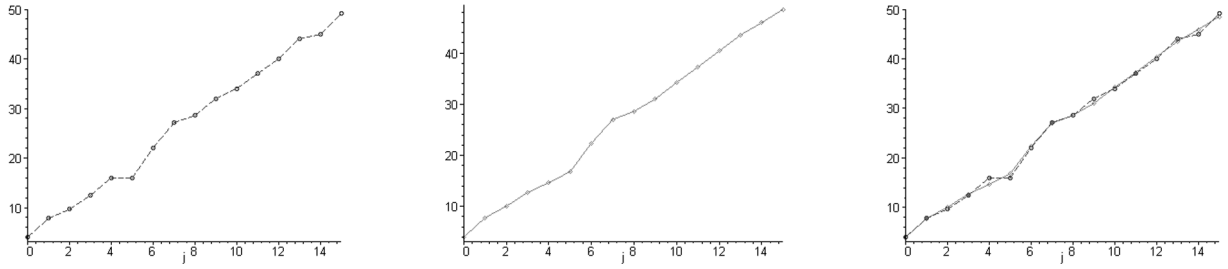

FIGURE 8 (*Left*) The original signal—a linear trend, but with noise. (*Center*) The smoother processed signal. (*Right*) Both signals together.

[4.003, 7.773, 10.046, 12.721, 14.660, 16.796,
22.359, 27.004, 28.588, 30.993, 34.217, 37.223,
40.383, 43.503, 45.919, 48.524]

The original signal and the new signal are compared in Fig. 8. Notice that the effect of processing with thresholding is to smooth the original signal and make it more linear. If we had wished to denoise only the second half of the original signal, then we would have altered only the detail coefficients that are based on that part of the signal.

This example demonstrates many of the ideas discussed in this article. The filters based on D_4 were well suited for this example, as the original signal had a linear trend, and the filters effectively separated the linear part of the signal from the noise. Each detail coefficient indicated the extent of the noise in a specific part of the signal. We then reduced the noise through thresholding, in effect smoothing the original signal. In this process, we applied filters at three different resolutions, until the output of the low-pass filter was too short to continue.

X. CONCLUSION

Our discussion in this article has focused on the Haar and Daubechies wavelets and their application to one-dimensional signal processing. As we have seen, the main goal in wavelet research and applications is to find or create a set of basis functions that will capture, in some efficient manner, the essential information contained in a signal or function. Recent work in wavelets by Donoho, Johnson, Coifman, and others has shown that wavelet systems have inherent characteristics that make them almost ideal for a wide range of problems of this type. This article has addressed just the basic ideas behind wavelets. Additional topics for an interested reader include frames, multiwavelets, wavelet packets, biorthogonal wavelets, and filter banks, to name only a few.

Many results in wavelet theory (the important relationship in (16), for example) are generally derived through Fourier analysis. The lack of space and the expository nature of an encyclopedia article motivates the decision to omit such discussion. However, there is such a close relationship between Fourier analysis and wavelets that it is impossible to thoroughly understand the latter without some knowledge of the former.

Wavelets have become an important tool in many disciplines of science. In areas as diverse as radiology, electrical engineering, materials science, seismology, statistics, and speech analysis, scientists have found the key ideas in this subject—multiresolution, localization, and adaptability to specific requirements—to be very important and useful in their work.
