GLOSSARY

Binary relation Set of ordered pairs (a, b), where a, b belong to given sets A, B; as the set of ordered pairs of real numbers (x, y) such that $x > y$.

Equivalence relation Binary relation on a set S often written $x \sim y$ if (x, y) is in the relation such that (1) $x \sim x$; (2) if $x \sim y$ then $y \sim x$; and (3) if $x \sim y$ and $y \sim z$ then $x \sim z$ for all x, y, z in S.

Field Structure having operations of commutative, associative distributive addition and multiplication with additive and multiplicative identities and inverses of nonzero elements, as the real or rational numbers.

Function Binary relation from a set A to a set B that to every a in A associates a unique b in B such that (a, b) is in the (binary) relation, as a polynomial associates its value to a given x.

Group Structure having one associative operation with identity and inverses.

Homomorphism Function f from one structure S to another structure T such that, for every operation $*$ and all x, y in S, $f(x * y) = f(x) * f(y)$.

Ideal Subset $\Im$ of a ring containing the sum and difference of any two elements of $\Im$, and the product of any element of $\Im$ with any element of the ring.

Identity Element e such that, for all x for a given operation $*$, $e * x = x * e = x$.

Incline Structure having two associative and commutative operations $+$ and $\times$, satisfying the distributive law and (1) $x + x = x$ and (2) $x + (x \times y) = x$.

Isomorphism Homomorphism f from a set S to a set T such that the inverse mapping g from T to S where $g(y) = x$ if and only if $f(x) = y$ is also a homomorphism.

Partial order Binary relation R on a set S such that for all x, y, z in S (1) (x, x) is in R; (2) if (x, y) and (y, x) are both in R, then $x = y$; and (3) if (x, y) and (y, z) are in R, so is (x, z).

Quadratic form A function defined on a ring $\Re$ by $\Sigma a_{ij} x_i x_j$.

Quotient group For a normal subgroup N of a group G, the group formed by equivalence classes $\bar{x}$ under the relation that $x \sim y$ if xy^{-1} in N, with multiplication given by $\bar{x}\bar{y} = \overline{xy}$.

Ring Structure having one associative and commutative operation with identity and inverses, and a second operation associative and distributive with the first.

Semigroup Structure having an associative operation.

Simple Structure S such that, for every homomorphism f to another structure, either $f(x) = f(y)$ for all x, y in S or $f(x) \neq f(y)$ for all $x \neq y$ in S.

Subgroup Subset S of a group G containing the product and inverse of any of its elements. It is called normal if, for every g in G, s in S, the element gsg^{-1} is in S.

ABSTRACT ALGEBRA is the study of laws of operations and relations such as those valid for the real numbers and similar laws for new systems. It studies the class of all possible systems having given laws, for example, associativity. There is no standard object that it studies such as the real numbers in analysis. Two systems are isomorphic in abstract algebra if there is a one-to-one (1–1 for short) correspondence between their elements such that relations and operations agree in the two systems.

I. SETS AND RELATIONS

A. Sets

A set is any precisely defined collection of objects. The objects in a set are called elements (or members) of the set. The set $A = \{1, 2, x, y\}$ has elements $1, 2, x, y$ and we write $1 \in A$, $2 \in A$, $x \in A$, and $y \in A$. There is no set of all sets, but given any set we can obtain other sets by operations listed below, and for any set A and property $P(x)$ we have a set $\{x \in A : P(x)\}$ of all elements of A having the property. Things such as "all sets" are called classes rather than sets. There is a set of all real numbers and one of all isosceles triangles in three-dimensional space.

We say that A is a subset of B if all elements of A are in B. This is written $A \subset B$, or $B \supset A$. The set is called a proper subset if $A \neq B$; otherwise it is called an improper subset. For finite sets, a subset is proper if and only if it has strictly fewer elements. The empty set $\emptyset$ is the set with no elements.

If $A \subset B$ and $B \subset A$, then $A = B$. The union $\cup_{\mathfrak{F}} A$ of a family $\mathfrak{F}$ of sets is the set whose elements are all things that belong to at least one set $A \in \mathfrak{F}$. The intersection $\cap_{\mathfrak{F}} A$ is the set of all elements lying in every set A in $\mathfrak{F}$.

The power set $\mathfrak{P}(A)$ is the set of all subsets of A. The relative complement $B \backslash A$ (or $B - A$) is the set of all elements in B but not in A. For fixed set $B \supset A$, this is called the complement of A in B.

The Cartesian product $A_1 \times A_2 \times \cdots \times A_n$ of n sets $A_1, A_2, \ldots, A_n$ is the set of all n-tuples $(a_1, a_2, \ldots, a_n)$ such that $a_i \in A_i$ for all $i = 1, 2, \ldots, n$. Infinite Cartesian products can be similarly defined with i ranging over any index set **I**.

B. Binary Relations

The truth or falsity of any mathematical statement about a relationship $x\,R\,y$, for instance, $x^2 + y^2 = 1$, can be determined from the set of ordered pairs (x, y) such that $x\,R\,y$. In fact, R is equivalent to the relationship that $(x, y) \in \{(x, y) \in A \times B : x\,R\,y\}$, where A and B are sets containing x and y.

The set of ordered pairs then represents the relationship and is called a binary relation. In general, a binary relation from A to B is a subset of $A \times B$, that is, a set of ordered pairs.

The union, intersection, and complement of binary relations from A to B are defined on them as subsets of $A \times B$. Another operation is composition. If R is a binary relation from A to B and S is a binary relation from B to C, then $R \circ S$ is $\{(x, z) \in A \times C : (x, y) \in R$ and $(y, z) \in S$ for some $y \in B\}$. Composition is distributive over union. For R, R_1, S, S_1, T, from A to B, A to B, B to C, B to C, C to D, we have $(R \cup R_1) \circ S = (R \circ S) \cup (R_1 \circ S)$ and $R \circ (S \cup S_1) = (R \circ S) \cup (R \circ S_1)$. It is associative; we have $(x, w) \in (R \circ S) \circ T$ if and only if for some $y \in B$ and $z \in C$, $(x, y) \in R$, $(y, z) \in S$, and $(z, w) \in T$. The same condition is obtained for $R \circ (S \circ T)$.

The identity relation 1_A is $\{(a, a) : a \in A\}$. This relation acts as an identity on either side for $R \subset A \times B$, $S \subset B \times C$; that is, $R \circ 1_B = R$, and $1_B \circ S = S$.

The transpose R^{T} of a binary relation R from A to B is $\{(b, a) \in B \times A : (a, b) \in R\}$. It is also called converse and inverse.

C. Functions

A partial function from a set A to a set B is a relation f from A to B such that if $(x, y) \in f$, $(x, z) \in f$ then $y = z$. If $(x, y) \in f$, we write $y = f(x)$ since this condition means y is unique. A partial function is a function defined on a subset of a set considered. Its domain is $\{a \in A : (a, b) \in f$ for some $b \in B\}$.

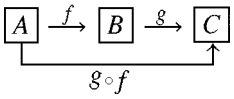
A function is a partial function such that for all $x \in A$ there exists $y \in B$ with $(x, y) \in f$.

A function is 1–1 if and only if whenever $(x, z) \in f$, $(y, z) \in f$ we have $x = y$. This is the transpose of the definition of a partial function. Functions and partial functions are thought of in several ways. A function may be

considered the output of a process in which x is an input, as $x^2 + x + 1$ adds a number to its square and 1. We may consider it as assigning an element of B to any element of A. Or we may consider it to be a map of A into the set B in which the point $x \in A$ is represented by $f(x) \in B$. Then $f(x)$ is called the image of x. Also for a subset $C \subset A$ the image $f(C)$ is $\{f(x) : x \in C\}$ the set of images of points of C. We may also consider it to be a transformation. Strictly, however, the term *transformation* is sometimes reserved for functions from a set to itself.

A 1–1 function sends distinct values of A to distinct points. For a 1–1 function on a finite set C, $f(C)$ will have exactly as many elements as C.

The composition of functions $f : A \to B$ and $g : B \to C$ is given by $g(f(x))$. It is written $g \circ f$. Composition is associative since it is a special case of composition of binary relations except that the order is reversed. The identity relation on a set is also called the identity function. A composition of partial (1–1) functions is respectively a partial (1–1) function.



A function $f : A \to B$ is *onto* if $f(A) = B$, that is, if every $y \in B$ is the image of some x. A composition of onto functions is onto. A 1–1 onto function is called a 1–1 correspondence. For a 1–1 onto function f, the inverse (converse) of f is defined by $f^{-1} = \{(y, x) : (x, y) \in f\}$ or $x = f^{-1}(y)$ if and only if $y = f(x)$. It is characterized by $f \circ f^{-1} = 1_B$, $f^{-1} \circ f = 1_A$. Moreover, for any binary relations R, S if $R \circ S = 1_B$, $S \circ R = 1_A$ both R and S must be 1–1 correspondences and S must be R^{T}. A 1–1 correspondence from a finite set to itself is called a permutation.

D. Order Relations

That a binary relation R from a set A to itself is (OR-1) reflexive means $(x, x) \in R$ for all $x \in A$; (OR-2) symmetric means if $(x, y) \in R$, then $(y, x) \in R$; and (OR-3) transitive means if $(x, y) \in R$ and $(y, z) \in R$, then $(x, z) \in R$. Frequently $x\, R\, y$ is written for $(x, y) \in R$, so that transitivity means if $x\, R\, y$ and $y\, R\, z$, then $x\, R\, z$. For instance, if $x \geq y$ and $y \geq z$, then $x \geq z$. So $x \geq y$ is transitive, but $x \neq y$ is not transitive.

The following relations are reflexive, symmetric, and transitive on the set of geometric figures: $x = y$ (same point set), $x \simeq y$ (congruence), $x \sim y$ (similarity), x has the same area as y. A reflexive, symmetric, transitive relation is called an equivalence relation. For any function f from A to B the relation $\{(x, y) \in A \times A : f(x) = f(y)\}$ is an equivalence relation.

The set $\bar{x} = \{y \in A : x\, R\, y\}$ is called the equivalence class of x (the set of all elements equivalent to the same element x). The set of equivalence classes $\bar{x}$ is called the quotient set A/R. The function $f(x) = \bar{x}$ is called the quotient map $A \to A/R$. The relation $\{(x, y) \in A \times A : f(x) = f(y)\}$ is precisely R.

Any two equivalence classes are disjoint or equal: If $x\, R\, z$ and $y\, R\, z$, by symmetry $z\, R\, y$ and by transitivity $x\, R\, y$. Any element belongs in the equivalence class of itself. A family $\mathfrak{F}$ of nonempty subsets of a set S is called a partition if (1) whenever $C \neq D$ in $\mathfrak{F}$, we have $C \cap D = \emptyset$; (2) $\cup_{\mathfrak{F}}\, C = S$. Therefore, the set of equivalence classes always forms a partition. Conversely, every partition $\mathfrak{F}$ arises from the equivalence relation $\{(x, y) \in A \times A$: for some $C \in \mathfrak{F}$, $x \in C$ and $y \in C\}$.

An important equivalence is congruence modulo m of integers. We say $x \equiv y (\mathrm{mod}\ m)$ for integers x, y, m if there exists an integer h such that $x - y = hm$, that is, if m divides $x - y$. If $x - y = hm$ and $y - z = km$, then $x - z = x - y + y - z = hm + km$. So if $x \equiv y (\mathrm{mod}\, m)$ and $y \equiv z (\mathrm{mod}\, m)$, then $x \equiv z (\mathrm{mod}\ m)$. This proves transitivity.

A relation that is reflexive and transitive is called a quasiorder. If it satisfies also (OR-4) antisymmetry if $(x, y) \in R$ and $(y, x) \in R$ then $x = y$, it is called a partial order. If a partial order satisfies (OR-5) completeness for all $x, y \in A$ either $(x, y) \in R$ or $(y, x) \in R$, it is called a total order, or a linear order.

For every total order on a finite set A, the elements of A can be labeled $a_1, a_2, \ldots, a_n$ in such a way that $a_i\, R\, a_j$ if $i < j$. An isomorphism between a binary relation R_1 on a set A_1 and R_2 on A_2 is a 1–1 correspondence $f : A_1 \to A_2$ such that $(x, y) \in R_1$ if and only if $(f(x), f(y)) \in R_2$. Therefore, every total order on a finite set is isomorphic to the standard order on $\{1, 2, \ldots, n\}$.

There are many nonisomorphic infinite total orders on the same set and many nonisomorphic partial orders on finite sets of n elements. The structure of quasiorders can be reduced to that of partial orders. For every quasiorder R on any set A, the relation $\{(x, y) : (x, y) \in R$ and $(y, x) \in R\}$ is an equivalence relation. The quasiorder gives a partial order on the set of equivalence classes of R and $(x, y) \in R$ if and only if $(\bar{x}, \bar{y}) \in R_1$.

The structure of partial orders on small sets can be described by diagrams known as Hasse diagrams. An element x of a partial order is called minimal (maximal) if for no $y \neq x$ does $(y, x) \in R$ ($(x, y) \in R$) where $(x, y) \in R$ is taken as $x \leq y$ in the order. Every partial order on a finite set has at least one minimal and at least one maximal element. Represent all minimal elements of the partial order as points at the same horizontal level of the bottom of the diagram. From then on, the ith level consists of elements z not in previous levels but such that for at least one y on

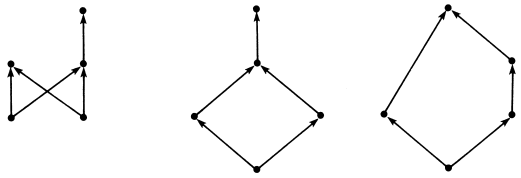


FIGURE 1 Hasse diagrams of partially ordered sets.

a previous level $y < z$ and for no x is $y < x < z$. That is, z is the very next element greater than y. For all such z, y draw a line segment from z to y. Figure 1 gives the Hasse diagrams of three partially ordered sets (posets for short).

A poset is called a lattice if every pair of elements in it have a least upper bound and a greatest lower bound. An upper (lower) bound on a set S is an element x such that $y \geq x$ ($y \leq x$) for all $y \in S$. Every linearly ordered set is a lattice, and any family of subsets of a set containing the union and intersection of any two of its members. These lattices are distributive: If $\wedge$, $\vee$ denote greatest lower bound, least upper bound, respectively, then $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$ and $x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z)$. A lattice is called modular if these laws hold whenever two of x, y, z are comparable [two elements a, b are comparable for R if $(a, b) \in R$ or $(b, a) \in R$]. There exist nonmodular lattices, as the last diagram of Fig. 1.

A binary relation R is called a strict partial order if it is transitive and (OR-6) irreflexive, for no x does $(x, x) \in R$. There is a 1–1 correspondence between partial orders R (as $x \leq y$) on A and strict partial orders ($x < y$) obtained as $R \backslash \{(a, a) : a \in A\}$. An irreflexive binary relation R on A is called a semiorder if for all $x, y, z, w \in A$, (1) if $(x, y) \in R$ and $(z, w) \in R$, then either $(x, w) \in R$ or $(z, y) \in R$; (2) if $(x, y) \in R$ and $(y, z) \in R$, then either $(w, z) \in R$ or $(x, w) \in R$. Semiorders can be represented always as $\{(x, y) : f(x) > f(y) + \delta\}$ for some real valued function f and number δ, and are strict partial orders. Figure 2 shows the relationship of many of the relations taken up here.

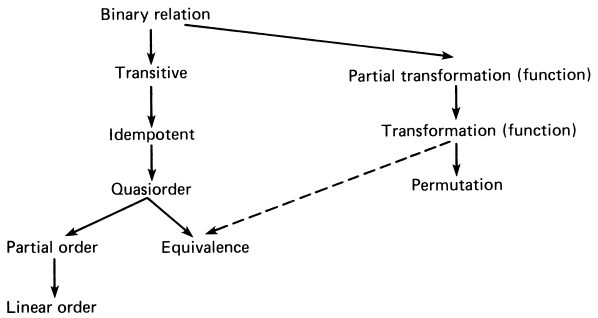

FIGURE 2 Classification of binary operations.

E. Boolean Matrices and Graphs

The Boolean algebra $\mathfrak{B}$ has elements $\{0, 1\}$ and operations $+, \cdot, ^c$ given by $0+0=0, 0+1=1+0=1+1=1, 0 \cdot 0 = 1 \cdot 0 = 0 \cdot 1 = 0, 1 \cdot 1 = 1, 0^c = 1, 1^c = 0$. There are many interpretations and uses of the Boolean algebra $\mathfrak{B}$: (1) propositional logic where 0 is false, 1 is true, $+$ is "or," $\cdot$ is "and," ^{c} is "not," (2) switching circuits where 0 means no current flows, 1 means current flows; and (3) $\mathfrak{B} \times \mathfrak{B} \times \cdots \times \mathfrak{B}$ can be taken as the set of subsets of an n-element set $\{y_i\}$, where $(x_1, x_2, \ldots, x_n)$ corresponds to the subset $\{y_i : x_i = 1\}$; (4) 0 means zero in $\mathbf{R}$, 1 means some positive number in $\mathbf{R}$, where $\mathbf{R}$ denotes the set of all real numbers. The algebra $\mathfrak{B}$ satisfies the same laws as the algebra of sets under $\cup, \cap, \sim$ where $\sim$ denotes the complementation since it is a Boolean algebra.

An $n \times m$ Boolean matrix $A = (a_{ij})$ is an $n \times m$ rectangle of elements of $\mathfrak{B}$. The entry in row (horizontal) i and column (vertical) j is denoted a_{ij}. To every binary relation R from a set $X = \{x_1, x_2, \ldots, x_n\}$ to set $Y = \{y_1, y_2, \ldots, y_m\}$ we can assign a Boolean matrix $M = (m_{ij})$, where m_{ij} is 0 or 1 according to whether (x_i, y_j) does or does not lie in R. This gives a 1–1 onto correspondence from binary relations from X to Y to $n \times m$ Boolean matrices. Many questions can be dealt with simply in the Boolean matrix form. Boolean matrices are multiplied and added by the same formulas as for ordinary matrices, except that operations are Boolean. Composition (union) of binary relations corresponds to product (sum) of Boolean matrices.

A directed graph (digraph for short) consists of a set V of elements called vertices (represented by points) and a set E or ordered pairs of V known as edges. Each ordered pair (x, y) is represented by a segment with an arrow going from point x to point y. Thus digraphs are essentially the same as binary relations from a set to itself. Any $n \times n$ (n-square) Boolean matrix or binary relation on a labeled set can be represented as a digraph, and conversely. Figure 3 shows the Boolean matrix and graph of a binary relation on {1, 2, 3, 4}.

F. Blockmodels

Often binary relations are empirically obtained. Such binary relations can frequently be simplified by blocking the Boolean matrices: dividing the set of indices into disjoint subsets, relabeling to get members of the same subset adjacent, and dividing the matrix into blocks. Each nonzero block is replaced by a single 1 entry and each zero block by a single 0 entry. Many techniques called clustering exist for dividing the total set into subsets. One (CONCOR) is to take iterated correlation matrices of the rows.

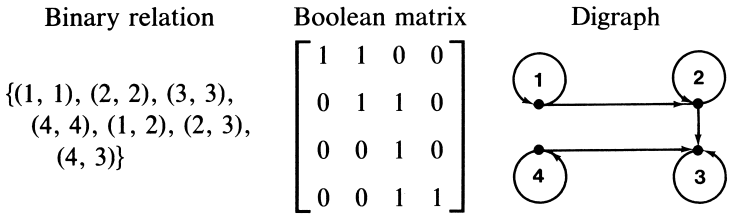

FIGURE 3 Matrix and graph of a relation.

Provided that every nonzero block has at least one 1 in each row the replacement of blocks by single entries will preserve all Boolean sums and products.

G. General Relational Structures

A general finite relational structure on a set S is an indexed family R_α of subsets of $S \cup (S \times S) \cup (S \times S \times S) \cup \cdots$. Such structures include order structures and operational structures such as multiplicative ones as subsets $\{(x, y, z) \in S \times S \times S : x * y = z\}$. A homomorphism of relational structures (index the same way) R_α on S_1 to T_α on S_2 consists of a function $f : S_1 \to S_2$ such that if g is the mapping $S_1 \cup (S_1 \times S_1) \cup (S_1 \times S_1 \times S_1) \cup \cdots$ to $S_2 \cup (S_2 \times S_2) \cup (S_2 \times S_2 \times S_2) \cup \cdots$ which is f on each coordinate then $g(R_\alpha) \subset T_\alpha$ for each α. An isomorphism of relational structures is a 1–1 onto homomorphism such that $g(R_\alpha) = T_\alpha$ for each α. The quotient structure of R_α on S associated with an equivalence relation E on S is the structure $T_\alpha = g(R_\alpha)$, for f the mapping $S \to S/E$ assigning to each element its equivalence class.

H. Arithmetic of Residue Classes

Let $\mathbf{Z}$ denote the set of all integers. Let E_m be the equivalence relation $\{(x, y) : \mathbf{Z} \times \mathbf{Z} : x - y = km$ for some $k \in \mathbf{Z}\}$. This is denoted $x \equiv y (\mathrm{mod}\, m)$. We have previously noted that it is an equivalence relation.

It divides the integers into exactly m equivalence classes, for $m \neq 0$. For $m = 3$, the classes are $\bar{0} = \{\ldots, -9, -6, -3, 0, 3, 6, 9, \ldots\}$, $\bar{1} = \{\ldots, -8, -5, -2, 1, 4, 7, 10, \ldots\}$, $\bar{2} = \{\ldots, -7, -4, -1, 2, 5, 8, 11, \ldots\}$. Any two members of the same class are equivalent (3 divides their difference).

This relation has the property that if $x \equiv y (\mathrm{mod}\, m)$ then, for any $z \in \mathbf{Z}$, $x + z \equiv y + z$ since m divides $x + z - (y + z) = x - y$ and $xz \equiv yz$. Such a relation in general is called a congruence. For any congruence, we can define operations on the classes by $\overline{x + y} = \bar{x} + \bar{y}$, and $\overline{xy} = \bar{x}\bar{y}$.

Let $\mathbf{Z_m}$ be the set of equivalence classes of $\mathbf{Z}$ under congruence module $\mathbf{m}$ and under $+, \times$ quotient operators.

Operations in $\mathbf{Z_5}$ are given in Fig. 4.

II. SEMIGROUPS

A. Generators and Relations

A binary operation is a function that given two entries from a set S produces some element of a set T. Therefore, it is a function from the set $S \times S$ of ordered pairs (a, b) to T. The value is frequently denoted multiplicatively as $a * b$, $a \circ b$, or ab. Addition, subtraction, multiplication, and division are binary operations.

The set S is said to be closed under the operation if the product always lies in S itself. The positive integers are not closed under subtraction or division.

The operation is called associative if we always have $(a \circ b) \circ c = a \circ (b \circ c)$. We have noted that this always holds for composition of functions or binary relations. Conversely, if closure and associatively hold, the set can always be represented by a set of functions under composition.

A set with a binary operation satisfying associativity and closure is called a semigroup. The positive integers form a semigroup under multiplication or addition. An element e is called a left (right) identity in a semigroup S if for all $x \in S$, $ex = x (xe = x)$. A semigroup with two-sided identity is called a monoid. To represent a semigroup as a set of functions under composition, first add a two-sided identity element e to obtain a monoid M. Then for each x in M define a function $f_x : M \to M$ by $f_x(y) = x \circ y$.

The set generated by a subset $G \subset S$ is the set of all finite products $\{x_1 x_2 \cdots x_n : n \in \mathbf{Z^+}, x_i \in G\}$, where $\mathbf{Z^+}$ denotes the set of all positive integers. The set satisfies

$+$	$\bar{0}$	$\bar{1}$	$\bar{2}$	$\bar{3}$	$\bar{4}$
$\bar{0}$	$\bar{0}$	$\bar{1}$	$\bar{2}$	$\bar{3}$	$\bar{4}$
$\bar{1}$	$\bar{1}$	$\bar{2}$	$\bar{3}$	$\bar{4}$	$\bar{0}$
$\bar{2}$	$\bar{2}$	$\bar{3}$	$\bar{4}$	$\bar{0}$	$\bar{1}$
$\bar{3}$	$\bar{3}$	$\bar{4}$	$\bar{0}$	$\bar{1}$	$\bar{2}$
$\bar{4}$	$\bar{4}$	$\bar{0}$	$\bar{1}$	$\bar{2}$	$\bar{3}$

$\cdot$	$\bar{0}$	$\bar{1}$	$\bar{2}$	$\bar{3}$	$\bar{4}$
$\bar{0}$	$\bar{0}$	$\bar{0}$	$\bar{0}$	$\bar{0}$	$\bar{0}$
$\bar{1}$	$\bar{0}$	$\bar{1}$	$\bar{2}$	$\bar{3}$	$\bar{4}$
$\bar{2}$	$\bar{0}$	$\bar{2}$	$\bar{4}$	$\bar{1}$	$\bar{3}$
$\bar{3}$	$\bar{0}$	$\bar{3}$	$\bar{1}$	$\bar{4}$	$\bar{2}$
$\bar{4}$	$\bar{0}$	$\bar{4}$	$\bar{3}$	$\bar{2}$	$\bar{1}$

FIGURE 4 Addition and multiplication of module 4 residue classes.

closure since $(x_1x_2\cdots x_n)(y_1y_2\cdots y_n)$ has agian the form required. A subset of a semigroup satisfying closure is itself a semigroup and is called a subsemigroup. The set G is called a set of generators for S if G generates the entire semigroup.

For a given set G of generators of S, a relation is an equation $x_1x_2\cdots x_n = y_1y_2\cdots y_n$, where $x_i, y_i \in G$.

A homomorphism of semigroups is a mapping $f: S_1 \to S_2$ such that $f(x \circ y) = f(x)f(y)$ for all $x, y \in S_1$. For example, e^z is a homomorphism from the additive semigroup of real numbers $(\mathbf{R}, +)$ to the multiplicative semigroup of complex numbers $(\mathbf{C}, \times)$, since $e^{x+y} = (e^x)(e^y)$. Here $\mathbf{C}$ denotes the set of all complex numbers. The trace and determinant of n-square matrices are homomorphisms, respectively, from the additive and multiplicative semigroups of n-square matrices to the additive and multiplicative semigroups of real numbers.

An isomorphism of semigroups is a 1–1 onto homomorphism. The inverse function will then also be an isomorphism. Isomorphic semigroups are structurally identical.

Two semigroups having the same generating set G and the same relations are isomorphic, since the mapping $f(x_1 \circ x_2 \circ \cdots \circ x_n) = x_1 * x_2 * \cdots * x_n$ will be a homomorphism where $\circ, *$ denote the two operations. The identity of the sets of relations guarantees that this is well defined, that is, if $x_1 \circ x_2 \circ \cdots \circ x_m = y_1 \circ y_2 \circ \cdots \circ y_n$, then $f(x_1 \circ x_2 \circ \cdots \circ x_m) = f(y_1 \circ y_2 \circ \cdots \circ y_n)$.

For any set of generators G and set R of relations, a semigroup S can be produced having these generators and satisfying the relations such that if $f(G) \to T$ is any function such that for every relation $x_1 \circ x_2 \circ \cdots \circ x_m = y_1 \circ y_2 \circ \cdots \circ y_n$ the relation $f(x_1) * f(x_2) * \cdots * f(x_m) = f(y_1) * f(y_2) * \cdots * f(y_n)$ holds then f extends to a homomorphism $S \to T$.

To produce S we take the set of all "words" $x_1x_2\cdots x_m$ in G, that is, sequences of elements in G. Two "words" are multiplied by writing one after the other $x_1x_2\cdots x_my_1y_2\cdots y_n$. We define an equivalence relation on words by $w_1 \sim w_2$ if w_2 can be obtained from w_1 by a series of replacments of a $x_1x_2\cdots x_nb$ by $ay_1y_2\cdots y_mb$, where a, b are words (or are empty) and $x_1x_2\cdots x_n = y_1y_2\cdots y_m$ is a relation in R. Then S is the set of equivalence classes of words.

The semigroup S is called the semigroup with generators S and defining relations R. The fact that multiplication is well defined in S follows from the fact that $a \sim b$ is a congruence. This means that if $a \sim b$ then for all words x, $ax \sim bx$ and $xa \sim xb$, and that $\sim$ is an equivalence relation.

For all semigroup homomorphisms $f: S \to T$ the relation $f(x) = f(y)$ is a congruence. Conversely any congruence gives rise to a homomorphism from S to the set of equivalent classes.

B. Green's Relations

For analyzing the structure of semigroups in many cases it is best to decompose it into a family of equivalence classes.

Let S be a semigroup and let M be S with an identity element if S lacks one. Let $\mathcal{R}$ be the relation for $x, y \in S$ that for some $a, b \in M$, $xa = y$, $yb = x$. Let $\mathcal{L}$ be the relation for some $a, b \in M$, $ax = y$, $by = x$. Let $\mathcal{J}$ be the relation that for some $a, b, c, d \in M$, $axc = y$, $byd = x$. What these equations express is a kind of divisibility, that either x, y can be a factor of the other. For example, in $\mathbf{Z}^+$ under multiplication $(2, 5) \notin \mathcal{J}$ because 2 is not a factor of 5.

There are two other important relations: $\mathcal{H} = \mathcal{L} \cap \mathcal{R} = \{(x, y) : x \mathcal{L} y \text{ and } x \mathcal{R} y\}$ and $\mathcal{D} = \mathcal{L} \circ \mathcal{R} = \mathcal{R} \circ \mathcal{L}$. These are both equivalence relations also and are known as Green's relations.

For the semigroup of transformations on a finite set T, $f \mathcal{L} g$ if and only if the partitions given by the equivalence relations $\{(x, y) \in T \times T : f(x) = f(y)\}$, $\{(x, y) \in T \times T : g(x) = g(y)\}$ coincide, $f \mathcal{D} g$ if and only if $f \mathcal{J} g$ if and only if f, g have the same number of image elements, and $f \mathcal{R} g$ if and only if their images are the same.

In a finite semigroup, $\mathcal{J} = \mathcal{D}$. The entire semigroup is always broken into $\mathcal{J}$-classes, which are partially ordered by divisibility. The $\mathcal{D}$-classes, which are in these, are broken into $\mathcal{H}$-classes $H_{ij} = R_i \cap L_j$, where R_i, L_i are the $\mathcal{R}, \mathcal{L}$-classes in a given $\mathcal{D}$-class.

The $\mathcal{H}$-classes can be laid out in a matrix (H_{ij}) called the eggbox picture of a semigroup. There exists a 1–1 correspondence between any two $\mathcal{H}$-classes.

A left ideal in a semigroup S is a set $\mathcal{I} \subset S$ such that for all $x \in S$, $y \in \mathcal{I}$ the element $xy \in \mathcal{I}$. Right and two-sided ideals are similarly defined by $yx \in \mathcal{I}$, $yxz \in \mathcal{I}$ for all $y, z \in S$, respectively. An element x generates the principal left, right two-sided ideals $Sx = \{yx : y \in S\}$, $xS = \{xy : y \in S\}$, $SxS = \{yxz : y, z \in S\}$. Two elements are $\mathcal{L}$-, $\mathcal{R}$-, $\mathcal{J}$-equivalent (assuming S has an identity, otherwise add one) if and only if they generate the same left, right, or two-sided ideals, respectively.

C. Binary Relations and Boolean Matrices

The set of binary relations on an n-element set under composition forms a semigroup that is isomorphic to B_n, the semigroup of n-square Boolean matrices under Boolean matrix multiplication. A $1 \times n (n \times 1)$ Boolean matrix is called a row (column) vector. Two vectors are added or multiplied by a constant (0 or 1) as matrices: $(1, 0, 1) + (0, 1, 0) = (1, 1, 1)$, $0v = 0$, and $1v = v$. A set of Boolean vectors is called a subspace if it is closed under sums and contains 0. The span of a set W of Boolean vectors is the set of all finite sums of elements of W, including 0.

The row (column) space of a Boolean matrix is the space spanned by its row (column) vectors. Two Boolean matrices are $\mathcal{J}$- (also $\mathcal{D}$-) equivalent if and only if their row spaces are isomorphic. The basis for a space of Boolean vectors spanned by S is $\{x \in S : x \neq 0$ and x is not in the span of $S\backslash\{x\}\}$. Two subspaces are identical if and only if their bases are the same. Bases for the row, column spaces of a Boolean matrix are called row, column bases. Two Boolean matrices are $\mathcal{L}$- ($\mathcal{R}$-) equivalent if and only if their row (column) bases (and so spaces) coincide.

A semigroup of the form $\{x^n\}$ is called cyclic. Every cyclic semigroup is determined by the index $k = \inf\{k \in \mathbf{Z}^+ : x^{k+m} = x^k$ for some $m \in \mathbf{Z}^+\}$, and the period $d = \inf\{d \in \mathbf{Z}^+ : x^{k+d} = x^k\}$. The set of powers $k, k+1, \ldots$ repeat with period d. If an n-square Boolean matrix A is reflexive ($A \geq I$), then $A = AI \leq A^2 \leq A^3 \leq \cdots \leq A^{n-1} = A^n$, an idempotent. Here I denotes the identity matrix. Also if A is fully indecomposable, meaning that there exists no nonempty $K, L \subset \{1, 2, \ldots, n\}$ with $|K| + |L| = n$, where $|S|$ denotes the cardinality of a set S, and $a_{ij} = 0$ for $i \in K$, $j \in L$, then $A^{n-1} = J$ and so A has period 1 and index at most $n-1$. Here J is the Boolean matrix all entries of which are 1.

In general, an n-square Boolean matrix has period equal to the period of some permutation on $\{1, 2, \ldots, n\}$ and index at most $(n-1)^2 + 1$.

D. Regularity and Inverses

An element x of a semigroup S is said to be a group inverse of y if S has a two-sided identity e and $xy = yx = e$. A semigroup in which every element has a group inverse is called a group. In most semigroups, few elements are invertible in this sense. A function is invertible if and only if it is 1–1 onto. A Boolean matrix in invertible if and only if it is the matrix of a permutation (permutation matrix).

There are many weaker ideas of inverse. The two most important are regularity $yxy = y$ and Thierrin–Vagner inverse $yxy = y$ and $xyx = x$. An element y has a Thierrin–Vagner inverse if and only if it is regular: If $yxy = y$ then xyx is a Thierrin–Vagner inverse. A semigroup in which all elements are regular is called a regular semigroup. The semigroups of partial transformation, transformations, and n-square matrices over a field are regular. In the semigroup of n-square Boolean matrices, an element is regular if and only if its row space forms a distributive lattice as a poset.

An idempotent is an element x such that $xx = x$. An element x is regular if and only if its $\mathcal{L}$-equivalence class contains an idempotent: if $xyx = x$ then xy is idempotent. The same holds for $\mathcal{R}$-equivalence classes. Therefore, if two elements are $\mathcal{L}$ or $\mathcal{R}$-equivalent (therfore $\mathcal{D}$-equivalent), one is regular if and only if the other is.

If an $\mathcal{H}$-class contains an idempotent, then it will be closed under multiplication, and multiplication by any of its elements gives a 1–1 onto mapping from it to itself. Therefore, it forms a group. Conversely any group in a semigroup lies in a single $\mathcal{H}$-class since under multiplication any two elements are $\mathcal{L}$-equivalent and $\mathcal{R}$-equivalent.

E. Finite State Machines

The theory of automata deals with different classes of theoretical machines representing robots, calculators, and similar devices. The simplest are the finite state machines. There are two essentially equivalent varieties: Mealy machines and Moore machines.

A Mealy machine is a 5-tuple (S, X, Z, ν, μ), where S, X, Z are sets, ν a function $S \times X$ to S, and μ a function $S \times X$ to Z. The same definition holds for Moore machines except that μ is a function S to Z.

Here S is the set of internal states of the machine. For a computer this could include all posibilities as to which circuit elements are on or off. The set X is the set of inputs, which could include a program and data. The set Z is the set of outputs, that is, the desired response. The function μ gives the particular output from a given internal state and input. The function ν gives the next internal state resulting from a given state and input. For a computer this is determined by the circuitry. For example, a flip-flop will change its internal state if it receives an input of 1; otherwise the internal state will remain unchanged.

A Mealy machine to add two n-digit binary numbers, a, b can be constructed as follows. Let the ith digits of a_i, b_i be inputs, so $X = \{0, 1\} \times \{0, 1\}$. Let the carry from the $i-1$ digit be c_i. It is an internal state, so $S = \{0, 1\}$. The output is the ith digit of the answer, so $Z = \{0, 1\}$. The function ν gives the next carry. It is 1 if and only if $a_i + b_i + c_i > 1$. The function μ gives the output. It is 1 if and only if $a_i + b_i + c_i$ is odd. Figure 5 gives the values of ν and μ.

With a finite state machine is associated a semigroup of transformations, the transformations $f_x(s) = \nu(s, x)$ of

X		S	ν	μ
0	0	0	0	0
0	1	0	0	1
1	0	0	0	1
1	1	0	1	0
0	0	1	0	1
0	1	1	1	0
1	0	1	1	0
1	1	1	1	1

FIGURE 5 Machine to add two binary numbers.

the state space, and all compositions of them $f_{x_1x_2\cdots x_n}(s) = f_{x_1}(f_{x_2}\cdots f_{x_n}(s))$. This is called the semigroup of the machine.

Two machines are said to have the same behavior if there exists a binary relation R from the initial states of one machine to the intial state of the other such that if $(s, t) \in S$ then for any sequence $x_1, x_2, \ldots, x_k$ of inputs machine 1 in state s gives the same sequence of outputs as machine 2. A machine M_1 equivalent to a given machine M having a minimal number of states can be constructed as follows. Call two states of M equivalent if, for any sequence of inputs, the same sequence of outputs is obtained. This gives an equivalence relation on states. Then let the states of M_1 be the equivalence classes of states of M.

No finite state machine M can multiply, as the above machine adds binary number of arbitrary length. Suppose such a machine has n states. Then suppose we multiply the number 2^k by itself in binary notation (adding zeros in front until the correct number of digits in the answer is achieved). Let f_x be the transformation of the state space given by inputs of 0, 0 and let a be the state after the inputs 1, 1. The inputs 0, 0 applied to state $f_x^i(a)$ give output 0 for $i = 0, 1, 2, \ldots, k-2$ but output 1 for $i = k-1$. Yet the transformation f on a set of n elements will have index at most n. Therefore, if $k > n$ then $f_x^{k-1}(a)$ will coincide with $f_x^j(a)$ for some $j < k-1$. This is a contradiction since one yields 0 output, the other 1 output. It follows that no such machine can exist.

F. Mathematical Linguistics

We start with a set W of basic units considered words. Mathematical linguistics is concerned with the formal theory of sentences, that is, sequences of words that are grammatically allowed and the grammatical structure of sentences (or longer units). This is syntax. Meaning (semantics) is usually not dealt with.

For a set X, let X^* be the set of finite sequences from X including the empty sequence e. For instance, if X is $\{0, 1\}$, then X^* is $\{e, 0, 1, 00, 01, 10, 11, 000\cdots\}$. For a more important example, we can consider the family of all sequences of logical variables p, q, r, and $\vee$ (or), $\wedge$ (and), (,) (parentheses), $\rightarrow$ (if then), $\sim$ (not). The set of logical formulas will be a subset of this.

A phrase structure grammar is a quadruple (N, W, ρ, ψ), where W (set of words) is nonempty and finite, N (nonterminals) is a finite set disjoint from W, $\psi \in N$, and ρ is a finite subset of $((N \cup W)^* \setminus W^*) \times (N \cup W)^*$. The set N is a set of valid grammatical forms involving abstract concepts such as ψ (sentence) or subject, predicate, object. The set ρ (productions) is a set of ways we can substitute into a valid grammatical form to obtain another, more specific one. The element ψ is called the starting symbol. If $(x, y) \in \rho$, we are allowed to change any occurrence of x with y. Members of W are called terminals.

Consider logical formulas involving operations $\vee, \sim$ and variables p, q, r. Let $W = \{p, q, r, \vee, (,), \sim\}$, $N = \{\psi\}$. We derive formulas by successive substitution, as ψ, $(\psi \vee \psi)$, $((\psi \vee \psi) \vee \psi)$, $((\psi \vee \psi) \vee \sim \psi)$, $((p \vee \psi) \vee \sim \psi)$, $((p \vee q) \vee \sim \psi)$, $((p \vee q) \vee \sim r)$.

An element $y \in (N \cup W)^*$ is said to be directly derived from $x \in (N \cup W)^*$ if $x = azb$, $y = awb$ for some $(z, w) \in \rho$, $a, b \in (N \cup W)^*$. An indirect derivation is a sequence of direct derivations. Here $\rho = \{(\psi, p), (\psi, q), (\psi, r), (\psi, \sim\psi), (\psi, (\psi \vee \psi))\}$.

The language determined by a phrase structure grammar is the set of all $a \in W^*$ that can be derived from ψ.

A grammar is called context free if and only if for all $(a, b) \in \rho$, $a \in N$, $b \neq e_0$. This means that what items can be substituted for a given grammatical element do not depend on other grammatical elements. The grammar above is context free.

A grammar is called regular if for all $(a, b) \in \rho$ we have $a \in N$, $b = tn$, where $t \in W$, $n \in N$, or $n = e_0$. This means at each derivation we go from $t_1t_2\cdots t_r n$ to $t_1t_2\cdots t_r t_{r+1}m$, where t_i are terminals, n, m nonterminals, $(n, t_{r+1}m) \in \rho$. So we fill in one terminal at each step, going from left to right. The grammar mentioned above is not regular.

To recognize a grammar is to be able to tell whether or not a sequence from W^* is in the language. A grammar is regular if and only if some finite state machine recognizes it. The elements of W are input 1 at a time and outputs are "yes, no," meaning all symbols up to the present are or are not in the language. Let the internal states of the machine be in 1–1 correspondence with all subsets of N, and let the initial state be ψ. For a set S_1 of nonterminals and input x let the next state be the set S_2 of all nonterminals z such that for some $u \in S_1$, (u, xz) is a production. Then at any time the state consists of all nonterminals that could occur after the given seqence of inputs. Let the output be "yes" if and only if for some $u \in N$, $(u, x) \in \rho$. This is if and only if the previous inputs together with the current input form a word in the language.

For the converse, if a finite state machine can recognize a language, let W be as in the language, N be the set of internal states, ψ the initial state, the productions the set of pairs (n_1, xn_2) such that if the machine is in state n_1 and x is input, state n_2 is the next state, and the set of pairs (n_1, x) such that in state n_1 after input x the machine answers "yes."

A further characterization of regular language is the Myhill–Nerode theorem. Let W^* be considered a semigroup of words. Then a language $L \subset W^*$ is regular if and only if the congruence $\{(x, y) \in W^* \times W^* : axb \in L$ if and only if $ayb \in L$ for all $a, b \in L\}$ has finitely many equivalence classes. This is if and only if there exists a

finite semigroup H, a homomorphism $h: W^* \to H$ is onto, and a subset $S \subset H$ such that $L = h^{-1}(S)$.

III. GROUPS

A. Examples of Groups

A group is a set G together with a binary operation here denoted $\circ$ such that (1) $\circ$ is a function $G \times G \to G$ (closure); (2) $\circ$ is associative, for example, $(x \circ y) \circ z = x \circ (y \circ z)$; (3) there exists a two-sided identity e such that $e \circ x = x \circ e = x$ for all $x \in G$; (4) for all $x \in G$ there exists $y \in G$ with $x \circ y = y \circ x = e$. Here y is known as an inverse of x. From now on we suppress $\circ$.

For any semigroup S with a two-sided identity e, let $S^* = \{x \in S : xy = yx = e \text{ for some } y \in S\}$, the set of invertible elements. The element $y = x^{-1}$ is unique since if $y_1 x = e$, $xy_2 = e$ then $y_1 = y_1 x y_2 = y_2$. Then S^* satisfies closure since $(ab)^{-1} = b^{-1}a^{-1}$ and is a group where a^{-1} is an inverse of a.

A group with a finite number of elements is called a finite group; otherwise, it is called an infinite group. If a group G is finite, and G contains n elements, we say that the order of G is n and we write $|G| = n$. If G is infinite, we write $|G| = \infty$. In general, $|G|$ denotes the cardinality of a set G.

The group of all permutations of $\{1, 2, \ldots, n\}$ is called $\mathcal{S}_n$, the symmetric group of degree n. The degree is the number of elements in the domain (and range) of a permutation. Therefore, $\mathcal{S}_n$ has degree n, order $n!$. A subgroup of $\mathcal{S}_n$ is formed by the set of all transformation of the form $1 \to k+1, 2 \to k+2, \ldots, n-k \to n, n-k+1 \to 1, \ldots, n \to k$.

For any set P of subsets of n-dimensional Euclidean space $\mathbf{E}^n$, let T be the union of the subsets of P. A symmetry of P is a mapping $f: T \to T$ such that (S–1) for $x, y \in T$, $d(x, y) = d(f(x), f(y))$, where $d(x, y)$ denotes the distance from x to y; and (S–2) for $A \subset T$, $A \in P$ if and only if $f(A) \in P$. That is, f preserves distances and sends the subsets C of P, for example, points and lines, so other subsets of P. The inverse off is its inverse function, which also satisfies (S–1) and (S–2).

The sets $\mathbf{R}$, $\mathbf{Z}$, $\mathbf{Z_m}$ under addition are all groups. The group $\mathbf{Z_m}$, the group of permutations $\{1 \to k+1, 2 \to k+2, \ldots, n \to k\}$, and the group of rotational symmetries of an n-sided regular polygon are isomorphic. That is, there exists a 1–1 correspondence f between any two such that $f(xy) = f(x)f(y)$ for all x, y in the domain. A group isomorphic to any of these is called a cyclic group of order m.

The group of all symmetries of a regular n-sided polygon has order $2n$ and is called the dihedral group of order n. It is isomorphic to the group of functions $\mathbf{Z_n} \to \mathbf{Z_n}$ of the form $f(x) = \pm x + k$. Its multiplication table is given in Fig. 6, where x_i is $x + i - 1$ if $i > n+1$, $-x + i - n - 1$ if $i > n$.

	x_1x_2	$\cdots$	x_n	$x_{n+1}x_{n+2}$	$\cdots$	x_{2n}
x_1	x_1x_2	$\cdots$	x_n	$x_{n+1}x_{n+2}$	$\cdots$	x_{2n}
x_2	x_2x_3	$\cdots$	x_1	$x_{n+2}x_{n+3}$	$\cdots$	x_{n+1}
$\vdots$		$\cdots$				
x_n	x_nx_1	$\cdots$	x_{n-1}	$x_{2n}x_{n+1}$	$\cdots$	x_{2n-1}
x_{n+1}	$x_{n+1}x_{2n}$	$\cdots$	x_{n+2}	x_1x_n	$\cdots$	x_2
$\vdots$		$\cdots$			$\cdots$	
x_{2n}	$x_{2n}x_{2n-1}$	$\cdots$	x_{n+1}	x_nx_{n-1}	$\cdots$	x_1

FIGURE 6 Multiplication table of the dihedral group.

B. Fundamental Homomorphism Theorems

A group homomorphism is a function $f: G \to H$ satisfying $f(xy) = f(x)f(y)$ for all x, y in G. If f is 1–1 and onto it is called an isomorphism. For any group G of order n there is a 1–1 homomorphism $G \to \mathcal{S}_n$; label the elements of G as $x_1, x_2, \ldots, x_n$. For any x in G, the mapping $a \to xa$ gives a 1–1 onto function $G \to G$, so there exists a permutation π with $xx_i = x_{\pi(i)}$. This is a homomorphism since if x, y are sent to π, ϕ, we have $yxx_i = yx_{\pi(i)} = x_{\phi(\pi(i))}$. There is an isomorphism from $\mathcal{S}_n$ to the set of n-square permutation matrices (either over $\mathbf{R}$ or a Boolean algebra), and it follows that any finite group can be represented as a group of permutations or of invetible matrices.

Groups can be simplified by homomorphisms in many cases. The determinant represents the group of nonsingular n-square matrices in the multiplicative group of nonzero real numbers (it is not 1–1). For a bounded function g, $\int gf\,dx$ is a homomorphism from the additive group of integrable functions f to the additive $\mathbf{R}$.

The kernel of a homomorphism $f: G \to H$ is $\{x : f(x) = e\}$. Every homomorphism sends the identity to the identity and inverses to inverses. Existence of inverses means we can cancel on either side in groups: If $ax = ay$ then $a^{-1}ax = a^{-1}ay$, $ex = ey$, $x = y$. Therefore, the identity is the unique elements satisfying $ee = e$. Under a homomorphism $f(e) = f(ee) = f(e)f(e)$ so $f(e)$ is an identity. So e is in the kernel. A homomorphism is 1–1 if and only if e is its only element: If $f(x) = f(y)$, then $f(xy^{-1}) = f(x)f(y^{-1}) = f(x)f(y)^{-1} = f(x)f(x)^{-1} = e$.

If x, y are in the kernel, so is xy since $f(xy) = f(x)f(y) = ee = e$. If x is in the kernel, so is x^{-1}. Any

subset of group that is closed under products and inverses is a subgroup. Both the kernel and image of a homomorphism are subgroups.

The mapping $c_g : G \to G$ defined by $c_g(x) = gxg^{-1}$ is called a conjugation. An isomorphism from a group (or other structure) to itself is called an automorphism. Since $c_g(xy) = gxyg^{-1} = gxg^{-1}gyg^{-1}$, c_g is a homomorphism. If $h = g^{-1}$, then c_g is the inverse of c_h. Therefore, the mappings c_g are automorphisms of a group. They are called the inner automorphisms. This gives a homomorphism of any group to its automorphisms, which also form a group, the automorphism group. A subgroup N is normal if $c_g(x) \in N$ for all $x \in N$ and $g \in G$. The kernel is always a normal subgroup.

If $f : G \to H$ has kernel K and is onto, the group G is said to be an extension of K by H. Whenever there exists a homomorphism f from K to Aut(H) for any groups K, H, a particular extension exists called the semidirect product. Here Aut(H) denotes the automorphism group of H. This has as its set $K \times H$ and products are defined by $(k_1, h_1)(k_2, h_2) = [k_1k_2,\ f(k_2)(h_1)(h_2)]$, $k_1, k_2 \in K$ and $h_1, h_2 \in H$. The dihedral group is a semidirect product of $\mathbf{Z_2}$ and $\mathbf{Z_m}$.

The groups K, H will generally be simpler than G. A theory exists classifying extensions. If a group has no normal subgroups except itself and $\{e\}$, it is called simple. The alternating group, the group of permutations in $\mathcal{S}_n$ whose matrices have positive determinant, is simple for $n > 4$. Its order is $n!/2$. For n odd, the group of n-square real-valued invertible matrices of determinant 1 is simple. For n even a homomorphic image of $\mathcal{S}_n$ with kernel $\{I, -I\}$ is simple, where I is an identity matrix. All finite and finite-dimensional differentiable, connected simple groups are known and most are constructed from groups of matrices.

For any subgroup H of a group G there exist equivalence relations defined by $x \sim y$ if $xy^{-1} \in H (y^{-1}x \in H)$. These equivalence classes are called left (right) cosets. The left (right) coset of a is $Ha = \{ha : h \in H\}$ ($aH = \{ah : h \in H\}$). There exists a 1–1 correspondence $H \to Ha$ given by $x \to xa$ ($x \to ax$ for right cosets). Therefore, all cosets have the same cardinality as H. If $[G : H]$ denotes the number of right (or left) cosets, then $|G| = |H|[G : H]$, which is known as Lagrange's theorem. So the order of a subgroup of a finite group must divide the order of the group. If G is a group of prime order p, let $x \in G$, $x \neq e$. Then $\{x^n\}$ forms a subgroup whose order divides and must therefore equal p. So $G = \{x^n\}$.

If N is a normal subgroup and $x \sim y$, for all $g \in G$ then $gx \sim gy$ and $xg \sim yg$ since $gxy^{-1}g^{-1}$ and xy^{-1} are in N if xy^{-1} in N. It follows that if $a \sim b$ and $c \sim d$, then $ac \sim bd$. Therefore, the equivalence classes form a group G/N called the quotient group. Its order is $|G|/|N|$.

For any homomorphism $f : G \to H$ with kernel K, image M every equivalence class of K is sent to a single element. That is, f gives a mapping $G/K \to M$. This mapping is an isomorphism.

If A, B are normal in a group G, and B is a subgroup of A, then

$$\frac{G/B}{A/B} = G/A$$

If A is a normal subgroup and B is any subgroup of G, and $AB = \{ab : a \in A, b \in B\}$ then,

$$\frac{AB}{A} = \frac{B}{A \cap B}$$

C. Cyclic Groups

Let G be a group. If there exists $a \in G$ such that $G = \{a^k : k \in \mathbf{Z}\}$, then G is called a cyclic group generated by a, and a is called a generator of G. For addition, the definition becomes:
There exists $a \in G$ such that for each $g \in G$ there exists $k \in \mathbf{Z}$ such that $g = ka$.

A group G is said to be commutative when $xy = yx$ for all x, y in G. Commutative groups are also called Abelian. In a commutative group, $gxg^{-1} = x$ for all $g \in G$. Therefore, every subgroup of a commutative group is normal. Let $\mathbf{R^n}$ denote the set of all n-tuples of real numbers. Then ($\mathbf{R^n}$, $+$) is a commutative group. For any groups $G_1, G_2, \ldots, G_n$, the set $G_1 \times G_2 \times \cdots \times G_n$ under componentwise multiplication $(x_1, \ldots, x_n) \times (y_1, \ldots, y_n) = (x_1y_1, \ldots, x_ny_n)$ is a group called the Cartesian or direct product of $G_1, G_2, \ldots, G_n$. If all G_i are commutative, so is the direct product. For any indexed family G_α of groups, coordinatewise multiplication makes the Cartesian product a group $\times\alpha G_\alpha$. The subset of elements (x_α) such that $\{\alpha : x_\alpha = e\}$ is finite is also a group sometimes called the direct sum.

A set $G_0 \subset G$ is said to generate the set $\{x_1x_2 \cdots x_n : x_i \in G_0$ or $x_i^{-1} \in G_0$ for all i and $n \in \mathbf{Z}\}$. Every finitely generated Abelian group is isomorphic to a direct product of cyclic (1 generator) groups.

A group of words on any set X is defined as the set of finite sequences (with e) $x_1^{a(1)}x_2^{a(2)} \cdots x_n^{a(n)}$, $x_i \in X$, $a(n) \in \mathbf{Z}$. We can reduce such words until $a(i) \neq 0$, $x_i \neq x_{i+1}$ by adding exponents if and only if they have the same reduced form. Equivalence classes of words form a group F.

Relations among generators in a group can be written in the form $x_1^{a(1)}x_2^{a(2)} \cdots x_n^{a(n)} = e$. For any set G_0 and set of relations R in the elements of G_0, there exists a group G defined by these relations such that any mapping $f : G_0 \to H$ extends to a unique homomorphism $g : G \to H$ if the relations hold in H. The group G is

defined to be F/N, where N is the subgroup generated by $\{yx_1^{a(1)}x_2^{a(2)}\cdots x_n^{a(n)}y^{-1} : x_1^{a(1)}x_2^{a(2)}\cdots x_n^{a(n)} = e$ is a relation of R, $y \in F\}$.

The dihedral group has generators, x, y and defining relations $x^m = e$, $y^2 = e$, $yx = x^{-1}y$.

The word problem for a group G with given sets of generators and defining relations is to find an algorithm which for any product $x_1^{a(1)}x_2^{a(2)}\ldots x_n^{a(n)}$ will determine (in a finite number of steps) whether this product is e. For general groups with finite G_0, R, the word problem is unsolvable; that is, no algorithm exists.

If a cyclic group $\{x^m\}$ has two powers equal, then some power is e. Let d be the least positive power equal to e. Then $x^0, x^1, x^2, \ldots, x^{d-1}$ are distinct and for any m if $m = qd + r$ then $x^m = (x^d)^q x^r = e^q x^r = x^r$. It follows that the group is isomorphic to $\mathbf{Z_m}$ under addition. If no two powers are equal, then $f(x^m) = m$ defines an isomorphism to $\mathbf{Z}$ under addition.

The multiplicative groups $\mathbf{Z_m^*} = \mathbf{Z_m}\backslash\{\bar{0}\}$ must be distinguished from $\mathbf{Z_m}$. For m prime we will later prove $\mathbf{Z_m^*}$ is cyclic (of order $m-1$). For $m = 8$, $S = \{\bar{1}, \bar{3}, \bar{5}, \bar{7}\} \subset \mathbf{Z_8^*}$ with multiplication $\bar{1} = e$, $\bar{3}^2 = \bar{5}^2 = \bar{7}^2 = \bar{1}$, $\bar{3}\bar{5} = \bar{7}$. It is isomorphic to $\mathbf{Z_2} \times \mathbf{Z_2}$, is not cyclic, and is the noncyclic group of smallest order.

D. Permutation Groups

In the symmetric group $\mathcal{S}_n$ of all permutations of $\{1, 2, \ldots, n\}$ elements are written in two standard ways. The notation

$$\begin{pmatrix} 1 & 2 & 3 & \ldots & n \\ a_1 & a_2 & a_3 & \ldots & a_n \end{pmatrix}$$

denotes the function $f(1) = a_1$, $f(2) = a_2$, $f(3) = a_3, \ldots, f(n) = a_n$. It is convenient to compose permutations written in this notation. To find

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 5 & 4 & 3 & 2 & 1 \end{pmatrix} \circ \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 3 & 5 & 4 & 2 & 1 \end{pmatrix}$$

as functions, on the right go through 1 to 5 on top. For each number find its image below; then locate that image on the upper left. Below it is the final image.

$$\begin{array}{l} 1{-}5{-}1 \\ 2{-}4{-}2 \\ 3{-}3{-}4 \\ 4{-}2{-}5 \\ 5{-}1{-}3 \end{array} \longrightarrow \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 1 & 2 & 4 & 5 & 3 \end{pmatrix}$$

The inverse of an element is obtained by looking up i on the bottom and taking the element above it, $i = 1$ to 5.

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 4 & 5 & 1 & 2 & 3 \end{pmatrix}^{-1} = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 3 & 4 & 5 & 1 & 2 \end{pmatrix}$$

In computer work, permutations can be stored as arrays $F(N)$, $G(N)$ with composition $F(G(N))$ [or $u = G(x)$: $y = F(u)$].

The second standard notation is cyclic notation. A k-cycle $(x_1x_2\cdots x_k)$ is the permutation f such that $f(x_1) = x_2$, $f(x_2) = x_3, \ldots, f(x_k) = x_1$, and $f(y) = y$ for $y \neq x_i$. If for $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, k$, $x_i \neq y_j$, then $(x_1x_2\cdots x_m)$ and $(y_1y_2\ldots y_k)$ commute.

Any permutation ρ can be written uniquely as a product of disjoint cycles of length greater than 1. In such a representation x, y will lie in the same cycle if and only if $\rho(x) \neq x$, $\rho(y) \neq y$ and $\rho^k(x) = y$ for some $k \in \mathbf{Z}$. This defines an equivalence relation, so take the sets of cycles to be the equivalence classes. In each equivalence class, choose an element x, and the cycle if it has size d must be $(x\rho(x)\rho^2(x)\cdots\rho^{d-1}(x))$.

Two permutations are conjugate if and only if they have the same number of cycles of each length. The order of a group element x is the order of the cyclic subgroup it generates, that is, the least m such that $x^m = e$. If $x = z_1z_2\cdots z_k$ in cycle form, then since $z_iz_j = z_jz_i$, $x^m = z_1^m z_2^m \cdots z_k^m$ and $x^m = e$ if and only if all $z_i^m = e$. Therefore, the order of x is the least common multiple of the lengths of its cycles.

A permutation ρ acts on the expression $\Pi_{i<j}(x_1 - x_j)$ by taking it to $\Pi_{i<j}(x_{\rho(i)} - x_{\rho(j)})$. Since each pair $\{i, j\}$ is sent to $\{\rho(i), \rho(j)\}$ in a 1–1 fashion, each factor goes to plus or minus another factor in the same expression. The sign of a permutation is defined to be $+1$ or -1 according as the whole expression goes to $+$ or $-$ itself. This is a group homomorphism. Permutations of sign $+1$ (-1) are called even (odd). Those of sign $+1$ form the kernel of the homomorphism, the alternating group $\mathcal{A}_n$. Any 2-cycle (transposition) is odd. A k-cycle $(x_1x_2\cdots x_k)$ is a product of $(k-1)$ transpositions $(x_kx_{k-1})(x_{k-1}x_{k-2})\cdots(x_2x_1)$ so it has sign $(-1)^{k-1}$. The symmetric group is generated by any transposition $t = (ab)$ and any n-cycle of the form $z = (ab\cdots)$. By conjugation $z^n t z^{-n}$ we obtain a family of transpositions t_i. Products of these give a new family of elements w_i. Conjugation of t_i by w_j give all transpositions. Products of these give all cycles. Products of cycles give all permutations.

E. Orbits

A group G of permutations of a set S is also said to be a group acting on a set. The function evaluation $g(s)$ defines a function $G \times S \to S$ such that $g(h(s)) = (g \circ h)(s)$. The relation on S; $\{(s, t) : g(s) = t$ for some $g \in G\}$ is an equivalence relation. If $g(s) = t$ and $h(t) = u$, then $h(g(s)) = u$,

so it is transitive. Its equivalence classes are called orbits. For cyclic groups, the orbits are the underlying sets of the cycles.

A permutation group is said to be transitive if S has a single orbit. This will be true if and only if G does not lie in a conjugate of some $S(n_1) \times S(n_2) \times \cdots \times S(n_k) \subset S(n)$, where $n_i > 0, k > 1, \Sigma n_i = n$, and $S(n_i)$ acts on $n_1 + n_2 + \cdots + n_{i-1} + 1, n_1 + n_2 + \cdots + n_{i-1} + 2, \ldots, n_1 + n_2 + \cdots + n_{i-1} + n_i$. Otherwise, it is called intransitive. For any element x, the isotropy subgroup of x is $H = \{g \in G : gx = x\}$. Then for any a, the coset aH maps x to a single element ax. Different cosets give different elements. Therefore, there is a 1–1 correspondence between cosets and elements of the orbit of x. So $[G : H]$ is the cardinality of the orbits of x.

Any group acts on itself by conjugation. The orbits are the equivalence classes under the relation for some g in G, $x = gyg^{-1}$, and are called conjugacy classes. Their size, since they are orbits, divides $|G|$.

Let G be a group of order p^n, p prime, $n \in \mathbf{Z}^+$. Suppose the identity e was the only conjugacy class containing only one element. Then all other conjugacy classes have order $p^i, i > 0$. So G has $kp + 1$ elements for some k. This is false. If every element of G has an order power of p, then G is called a p-group. Therefore, for any p-group G the set $C = \{c : cg = gc \text{ for all } g \in G\}$ has size larger than 1. For any group C so defined is a normal subgroup and is commutative, called the center.

F. Symmetry

An algebraic structure on a set S is a family of subsets $\mathfrak{F}_\alpha$ indexed on $\alpha \in \mathbf{I}$ of $S_1 = S \cup (S \times S) \cup (S \times S \times S) \cup \cdots$. An automorphism of this structure is a 1–1 onto mapping $f : S \to S$ such that for all $\alpha \in \mathbf{I}$, $T \in \mathfrak{F}_\alpha$ if and only if $f(T) \in \mathfrak{F}_\alpha$. For operational structures, this is any 1–1 mapping that is a homomorphism: $f(xy) = f(x) f(y)$. The complex number system has the automorphism $a + bi \to a - bi$. The additive real numbers has the automorphism $x \to -x$.

Especially in a geometric setting, automorphisms are called symmetries. A metric symmetry of a geometric figure is an isometry (distance-preserving map) on its points, which also gives a 1–1 correspondence on its lines and other distinguished subsets. Finite groups of isometries in three-dimensional space include the isometry groups of a regular n-gon (dihedral), cube and octahedron (extension of $\mathbf{Z_2}$ by $\mathcal{S}_4$), icosahedron and dodecahedron (extension of $\mathbf{Z_2}$ by $\mathcal{A}_5$).

The possible isomorphism types of n-dimensional symmetric groups, finite or continuous, are limited. One of the principal applications of group theory is to make use of exact or approximate symmetries of a system in studying it.

G. Enumeration

The equation $|O_X| = |G|/|H|$, where O_X is the orbit of X, G a group, and H the isotropy subgroup of X, simplifies a number of enumeration problems.

Another problem is to count the number of orbits. A lemma of Burnside states that for a group G acting on a set X the number of orbits is $|G|^{-1} \Sigma_{g \in G} f_g$, where f_g is the number of elements fixed by g, that is, $|\{x : gx = x\}|$. This is proved by counting the set $S = \{(x, g) : g(x) = x\}$ first over each g (yielding Σf_g) and then over each x (yielding $\Sigma |G|/|O_x|$).

Polya's theory of counting was motivated partly by a desire to count the number of distinct structures of a chemical compound with known numbers of elements and known graph but unknown locations of elements within the diagram. Suppose we have a hexagonal compound containing four carbon and two silicon atoms (Fig. 7; the reality of such a compound is not considered here). In how many distinct ways can the atoms be arranged? The symmetry group of a hexagon is the dihedral group of order 12.

In the Redfield–Polya theory, we first obtain a polynomial

$$P_G(x_1, x_2, \ldots, x_k) = \frac{1}{|G|} \sum_{g \in G} x_1^{c_1(g)} x_2^{c_2(g)} \cdots x_k^{c_k(g)}$$

where $c_i(g)$ is the number of cycles of g of length i and k is the maximum length of any cycle. The dihedral group breaks down as shown in Table I. Then

$$P_G(x_1, x_2, \ldots, x_n) = \tfrac{1}{12}\left(x_1^6 + 2x_6^1 + 2x_3^2 + x_2^3 + 3x_2^2 x_1^2 + 3x_2^3\right)$$

For instance, e having six 1-cycles yields term x_1^6. Redfield and Polya computed the number of labelings of X by labels $\theta_1, \theta_2, \ldots, \theta_m$ such that θ_i occurs exactly n_i times. They proved that this is the coefficient of $\theta_1^{n_1} \theta_2^{n_2} \cdots \theta_m^{n_m}$ in

$$P_G\left(\theta_1 + \theta_2 + \cdots + \theta_m, \theta_1^2 + \theta_2^2 + \cdots + \theta_m^2, \ldots, \theta_1^k + \theta_2^k + \cdots + \theta_m^k\right)$$

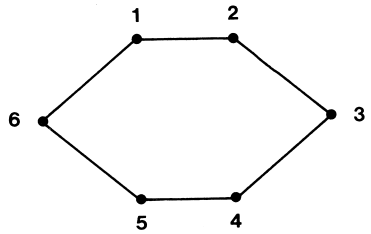

FIGURE 7 Hexagonal molecule.

TABLE I Cycle Structure of Hexagonal Symmetries

Rotations			Reflections		
e	6 1-cycles	$c_1 = 6$	—	—	—
(123456) (654321)	1 6-cycle	$c_6 = 1$	About 2 vertices (26) (35) (13) (46) (15) (24)	2 2-cycles	$c_1 = c_2 = 2$
(135) (246) (153) (246)	2 3-cycles	$c_3 = 2$	—	—	—
(14) (25) (36)	3 2-cycles	$c_2 = 3$	About an edge center (12) (36) (45) (23) (14) (65) (16) (25) (34)	3 2-cycles	$c_2 = 3$

In the problem above this yields the coefficient of $\theta_1^2\theta_2^4$ in

$$\tfrac{1}{12}\Big[(\theta_1+\theta_2)^6 + 2\big(\theta_1^6+\theta_2^6\big) + \big(\theta_1^3+\theta_2^3\big)^2 + 4\big(\theta_1^2+\theta_2^2\big)^3 + 3\big(\theta_1^2+\theta_2^2\big)^2(\theta_1+\theta_2)^2\Big]$$

That coefficient is

$$\frac{1}{12}\left(\binom{6}{2} + 4\binom{3}{1} + 3(3)\right) = \frac{1}{12}(15+12+9) = 3$$

IV. VECTOR SPACES

A. Vector Space Axioms

A vector space is a set having a commutative group addition, and a multiplication by another set of quantities (magnitudes) called a field. A field is a set $\mathbf{F}$ such as $\mathbf{R}$ or $\mathbf{C}$ having addition and multiplication $\mathbf{F}\times\mathbf{F}\to\mathbf{F}$ such that the axioms in Table II hold for all x, y, z and some 0, 1 in $\mathbf{F}$.

The standard example of a vector space is the set $\mathbf{v_n}$ of n-tuples of members of $\mathbf{F}$. Let $(x_1, x_2, \ldots, x_n), (y_1, y_2, \ldots, y_n) \in \mathbf{v_n}$. The $(x_1, x_2, \ldots, x_n) + (y_1, y_2, \ldots, y_n) = (x_1+y_1, x_2+y_2, \ldots, x_n+y_n)$ and multiplication by c is given by $c(x_1, x_2, \ldots, x_n) = (cx_1, cx_2, \ldots, cx_n)$ where $c \in \mathbf{F}$. For $\mathbf{F} = \mathbf{R}$, $\mathbf{v_3}$ is the set of vectors consideered in physics. These can be regarded as positions (displacement), velocities, or forces: Each adds in the prescribed way.

TABLE II Field Axioms

Property	Operation: Addition	Operation: Multiplication
Commutative	$x+y=y+x$	$xy=yx$
Associative	$(x+y)+z=x+(y+z)$	$(xy)z=x(yz)$
Identity	For all $x\in\mathbf{F}$, $x+0=0$	For all $x\in\mathbf{F}$, $x1=x$
Inverse	For all $x\in\mathbf{F}$, there exists $-x$ such that $x+(-x)=0$	For all $x\in\mathbf{F}$ $(x\neq 0)$, there exists x^{-1} such that $xx^{-1}=1$
Distributive	$x(y+z)=xy+xz$	

A general vector space is a set $\mathbf{v}$ having an addition $\mathbf{v}\times\mathbf{v}\to\mathbf{v}$ and a scalar multiplication $\mathbf{F}\times\mathbf{v}\to\mathbf{v}$ such that $(\mathbf{v}, +)$ is a commutative group and for all $a, b\in\mathbf{F}$, v, $w\in\mathbf{v}$; $a(v+w)=av+aw$, $(a+b)v=av+bv$, $(ab)v=a(bv)$, and $cv=v$, where $c=1\in\mathbf{F}$. Incidentally, $\mathbf{F}$ is called the field of scalars, and multiplication by its elements scalar multiplication.

B. Basis and Dimension

The span $\langle S\rangle$ of a subset $S\subset\mathbf{v}$ is $\{a_1s_1+a_2s_2+\cdots+a_ns_n : n\in\mathbf{Z}^+, s_i\in S, a_i\in\mathbf{F}\}\cup\{0\}$. The elements $a_1s_1+a_2s_2+\cdots+a_ns_n$ are called linear combinations of $s_1, s_2, \ldots, s_n$. A sum of two linear combinations is a linear combination and a multiple by $c\in\mathbf{F}$ of a linear combination is a linear combination. A subset of a vector space closed under addition and scalar multiplication is called a subspace. Therefore, the span of any set is a subspace.

A subspace is a vector space in itself. Its span is itself. It follows that $\langle S\rangle$ lies in any subspace containing S.

An indexed family t_α, $\alpha\in\mathbf{I}$ of vectors is said to be linearly independent if t_γ is not a linear combination of t_α, $\alpha\neq\gamma$ and no $t_\gamma=0$ for all γ. Otherwise, it is called linearly dependent. A set of vectors W is likewise said to be linearly independent if for all $x\in W$, $x\notin\langle W\backslash\{x\}\rangle$.

A basis for a vector space is a linearly independent spanning set for the vector space. A chain in a poset is a subset that is linearly ordered by the partial order. Zorn's lemma states that in a poset X in which every chain has a maximal element there is a maximal element of X. Take X to be the family of linearly independent sets in $\mathbf{v}$. Every chain has its union as an upper bound. A maximal linearly independent set therefore exists. It is a basis. Therefore, every vector space has a basis.

A linearly ordered set is well ordered if every nonempty subset has a least element. Using Zorn's lemma it can be shown that every set can be well ordered. From every set $\{x_\alpha\}$ of vectors where the index set is well ordered we can pick a subset $\{x_\gamma\}$ that is linearly independent and spans the same set. Let $B = \{x_\gamma : x_\gamma \notin \langle\{x_\alpha : \alpha < \gamma\}\rangle\}$. Then no element of B is linearly dependent on previous vectors. But if some element of B were linearly dependent, let $y = \Sigma a_i x_i$, $a_i \neq 0$. Let x_n be the last of the x_i in the ordering. Then $x_n = (1/a_n)(y - \Sigma_{i\neq n} a_i x_i)$ is linearly dependent on previous vectors. This is a contradiction.

Two bases for a vector space have the same cardinal number. For finite bases $u_1, u_2, \ldots, u_n, v_1, v_2, \ldots, v_m$ let $m < n$. Expressions $u_i = \Sigma a_{ij} v_j$ exist since $\langle\{v_i\}\rangle = \langle\{u_i\}\rangle$. Since $m < n$, we can find a nonzero solution of the m linear equations $\Sigma_i w_i a_{ij} = 0$, $j = 1$ to m in n variables w_i. Then $\Sigma w_i u_i = 0$, not all $w_i = 0$. This contradicts linear independence of the u_i.

The cardinality of a basis for a vector space is called the dimension of the vector space.

For vector spaces $\mathbf{v}$, $\mathbf{w}$ a homomorphism (isomorphism) is a (1–1 and onto) function $f : \mathbf{v} \to \mathbf{w}$ such that $f(x + y) = f(x) + f(y)$ and $f(cx) = cf(x)$ for all $x, y \in \mathbf{v}$, $c \in \mathbf{F}$. If two vector spaces over $\mathbf{F}$ have the same dimension, choose bases u_α, v_α for them. Every element of $\mathbf{v}$ has a unique expression $\Sigma a_i u_i$, $u_i \in \{u_\alpha\}$, and every element of $\mathbf{w}$ has a unique expression $\Sigma a_i v_i$, $v_i \in \{v_\alpha\}$. Therefore, $f(\Sigma a_i u_i) = \Sigma a_i v_i$ defines an isomorphism $\mathbf{v}$ to $\mathbf{w}$. Conversely if two vector spaces are isomorphic, their dimensions must be equal since if $\{u_\alpha\}$ is a linearly independent (spanning) set for $\mathbf{v}$, $\{f(u_\alpha)\}$ will be a linearly independent (spanning) set for $\mathbf{w}$.

C. Linear Transformations

A linear transformation is another phrase for homomorphism of vector spaces. To every subspace $\mathbf{w}$ of a vector space $\mathbf{v}$ is associated the quotient space $\mathbf{v}/\mathbf{w}$. This is the set of equivalence classes of the equivalence relation $x - y \in \mathbf{w}$. Transitivity follows from $(x - y) + (y - z) = x - z \in \mathbf{w}$ if $x - y$, $y - z$ do. If $x - y \in \mathbf{w}$, $u - v \in \mathbf{w}$, then $(x + u) - (y + v) \in \mathbf{w}$. So addition of equivalence classes is well defined; so is scalar multiplication since $a(x - y) \in \mathbf{w}$ if $x - y$ does.

The quotient space, additively, is the same as the quotient group. Let $\{s_\sigma\}$ be a basis for $\mathbf{w}$. We can find a basis for $\mathbf{v}$ of the form $\{s_\sigma\} \cup \{t_\tau\}$, where $\{s_\sigma\} \cap \{t_\tau\} = \emptyset$. Let q_γ be a well-ordered basis for $\mathbf{v}$. Delete each q_α that is linearly dependent on prior q_γ together with the s_σ. The remaining set with s_σ is a spanning set and is linearly independent. This is a basis for $\mathbf{v}$, which contains a basis for $\mathbf{w}$.

Let $\{s_\sigma\} \cup \{t_\tau\}$ denote the resulting basis. Since every element of $\mathbf{w}$ has the form $\Sigma a_i s_i + \Sigma b_i t_i$ it will be equivalent to $\Sigma b_i t_i$. No two distinct sums $\Sigma b_i t_i$ can have difference a nonzero sum $\Sigma a_i s_i$ so the classes of t_i are linearly independent in $\mathbf{v}/\mathbf{w}$. Therefore $\bar{t}_\tau$ gives a basis for $\mathbf{v}/\mathbf{w}$.

The external direct sum of two vector spaces $\mathbf{v}$, $\mathbf{w}$ is $\mathbf{v} \times \mathbf{w}$ with operations $(v_1, w_1) + (v_2, w_2) = (v + v_2, w_1 + w_2)$, and $c(v, w) = (cv, cw)$. It has as basis the disjoint union of any bases for $\mathbf{v}$, $\mathbf{w}$. It is denoted $\mathbf{v} \oplus \mathbf{w}$. Therefore, if $\mathbf{w} \subset \mathbf{v}$, $\mathbf{v}$ is isomorphic to $\mathbf{w} \otimes \mathbf{v}/\mathbf{w}$. Moreover, $\dim(\mathbf{w}) + \dim(\mathbf{v}/\mathbf{w}) = \dim(\mathbf{v})$, where $\dim(\mathbf{v})$ denotes the dimension of $\mathbf{v}$.

A complement to a subspace $\mathbf{w} \subset \mathbf{v}$ is a subspace $\mathbf{u} \subset \mathbf{v}$ such that $\mathbf{u} \cap \mathbf{w} = \{0\}$, $\mathbf{u} + \mathbf{w} = \mathbf{v}$, where $\mathbf{u} + \mathbf{w} = \{u + w : u \in \mathbf{u}, w \in \mathbf{w}\}$. Every subspace has a complement by the construction above with $\mathbf{u} = \langle\{t_\alpha\}\rangle$. The mapping $\Sigma a_i t_i \to \Sigma a_i \bar{t}_i$ gives an isomorphism $\mathbf{u} \to \mathbf{v}/\mathbf{w}$.

For a linear transformation $f : \mathbf{v} \to \mathbf{w}$, the image set $\mathrm{Im}(f)$ and the null space (kernel) $\mathrm{Nu}(f) = \{v \in \mathbf{v} : f(v) = 0\}$ are both subspaces. Results on group homomorphism imply that f gives an isomorphism $\bar{f} : \mathbf{v}/\mathrm{Nu}(f) \to \mathrm{Im}(f)$.

A linear transformation is 1–1 (onto) if and only if $\mathrm{Nu}(f) = 0$ ($\mathrm{Im}(f) = \mathbf{w}$). The dimension of $\mathrm{Im}(f)$ is called the rank of f.

Choose bases x_i, y_i, z_i for vectors spaces $\mathbf{u}$, $\mathbf{v}$, $\mathbf{w}$. Let f be a homomorphism from $\mathbf{u}$ to $\mathbf{v}$ and g a homomorphism $\mathbf{v}$ to $\mathbf{w}$. There exist unique coefficients a_{ij}, b_{ij} such that $f(x_i) = \Sigma a_{ij} y_i$ and $g(y_i) = \Sigma b_{ij} z_j$. Then $g(f(x_i)) = g(\Sigma a_{ij} y_j) = \Sigma a_{ij} g(y_j) = \Sigma a_{ij} \Sigma b_{jk} z_k$. Therefore, the composition $g \circ f$ sends x_i to $\Sigma_{j,k} a_{ij} b_{jk} z_k$. This rule defines a product on nm-tuples a_{ij}, which must be associative since composition of functions is. It is distributive since $f(g(x) + h(x)) = f(g(x)) + f(h(x))$ and $(g + h)(f(x)) = g(f(x)) + h(f(x))$.

D. Matrices and Determinants

An $n \times m$ matrix A is an nm-tuple (a_{ij}) indexed on $i = 1, 2, \ldots, n$, and $j = 1, 2, \ldots, m$. Matrices are represented as rectangles of elements where a_{ij} is placed in horizontal line i (row i) and vertical line j (column j).

Addition is entrywise. The entries of both matrices in location (i, j) are added to form the (i, j)-entry of the sum. The (i, j)-entry of the product is formed by multiplying row i of the first factor by column j of the second factor entry by entry and adding all these products. For example,

$$\begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix} = \begin{bmatrix} a_{11}b_{11} + a_{12}b_{21} & a_{11}b_{12} + a_{12}b_{22} \\ a_{21}b_{11} + a_{22}b_{21} & a_{21}b_{12} + a_{22}b_{22} \end{bmatrix}$$

This is the same as the operation defined at the end of the last section. To multiply two n-square matrices by the

formula requires n^3 multiplications and $n^2(n-1)$ additions. There does exist a slightly improved computer method known as fast matrix multiplication.

Matrices obey the following laws: (1) $A+B=B+A$, (2) $(A+B)+C=A+(B+C)$, (3) $(AB)C=A(BC)$, (4) $A(B+C)=AB+AC$, and (5) $0+A=A$. Here 0 denotes the zero matrix all the entries of which are 0. It is an additive identity.

There is a 1–1 correspondence from the set of linear transformations from an n-dimensional vector space to an m-dimensional vector space to the set of $n \times m$ matrices, given bases in these. As in the last subsection (a_{ij}) corresponds to f such that $f(x_i)=\Sigma a_{ij}y_j$.

Consider linear transformations from a vector space with basis $\{x_i\}$ to itself. Let f be represented as (a_{ij}). Let $\{w_j\}$ be another basis, where $x_i=\Sigma b_{ij}w_j$, $w_j=\Sigma c_{ji}x_i$. Then $f(w_j)=\Sigma c_{ji}f(x_i)=\Sigma c_{ji}a_{ik}x_k=\Sigma c_{ji}a_{ik}b_{km}w_m$. From $w_j=\Sigma c_{ji}x_i=\Sigma c_{ji}b_{ik}w_k$ it follows that $CB=I$, where I is the matrix

$$\begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ 0 & 1 & 0 & \cdots & 0 \\ & & \cdots\cdots & & \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix}$$

is known as a (multiplicative) identity. It acts as a two-sided identity $IA=AI=A$. We also have $x_i=\Sigma b_{ij}w_j=\Sigma b_{ij}c_{jk}x_k$ so $BC=I$. Therefore, $B=C^{-1}$. Here C^{-1} denotes the (multiplicative) inverse of C. Then, expressed in terms of w_j, f is $CAB=CAC^{-1}$. Two matrices X, YXY^{-1} are said to be similar.

A linear transformation $\mathfrak{T}$ represented as (a_{ij}) sends $\Sigma c_i x_i$ to $\Sigma c_i a_{ij} y_j$. The matrix product $(c_i)(a_{ij})$ is $(\Sigma c_i a_{ij})$. A row (column) vector is an $1 \times n (n \times 1)$ matrix. So the linear transformation $\mathfrak{T}$ is equivalent to that given by matrix multiplication on row vectors. Matrices also act as linear transformation on column vectors.

The rank of a matrix is its rank as a linear transformation on row vectors. Taking column vectors gives the same number.

The image space is spanned by the rows of the matrix since $(\Sigma_i c_i a_{ij})$ is the sum of c_i times the ith row of A. Therefore, the row rank is the maximum size of a set of linearly independent rows. The ith row (column) of A is denoted $A_{i*}(A_{*i})$.

In general, an n-square matrix X is invertible if there exists Y with $XY=I$ or $YX=I$. Either equation implies the other and is equivalent to the rank of the matrix being n.

The determinant of a matrix A is defined to be

$$\det(A)=\sum_{\pi\in\mathcal{S}_n}\operatorname{sgn}(\pi)a_{1\pi(1)}a_{2\pi(2)}\cdots a_{n\pi(n)}$$

where the summation is over all permutations π, and $\operatorname{sgn}(\pi)$ denotes the sign of π and so $\operatorname{sgn}(\pi)$ is ± 1 according to whether π is even or odd. As before, a permutation is even or odd according to whether it is the product of an odd or even number of transpositions. It has the following properties, which can be proved in turn. Let $(a_{ij})^{\mathrm{T}}$ denote (a_{ji}), called the transpose of A. This operation changes rows into columns and columns into rows.

(D-1) Since $\operatorname{sgn}(\sigma)=\operatorname{sgn}(\sigma^{-1})$, $\det(A)=\det(A^{\mathrm{T}})$, $\sigma\in\mathcal{S}_n$.
(D-2) If $A_{i*}=B_{i*}=C_{i*}$ for $i\neq k$ and $C_{k*}=A_{k*}+B_{k*}$, then $\det(C)=\det(A)+\det(B)$.
(D-3) If the rows of A are permuted by a permutation π, the determinant of A is multiplied by $\operatorname{sgn}(\pi)$.
(D-4) If two rows (columns) of A are equal, then $\det(A)=0$.
(D-5) If any row is multiplied by k, then the determinant is multiplied by k.
(D-6) If A_{i*} is replaced by $A_{i*}-kA_{j*}$, $i\neq j$, then the determinant is unchanged.
(D-7) If $a_{ij}=0$ for $i>j$, then $\det(A)=a_{11}a_{22}\cdots a_{nn}$.
(D-8) $\det(AB)=\det(A)\det(B)$.
(D-9) $\det(A)\neq 0$ if and only if A has an inverse.
(D-10) Let $A[i\,|\,j]$ the submatrix of A obtained by deleting row i and column j. The $(i,\,j)$th-cofactor of a_{ij} is $(-1)^{i+j}$ $\det A[i\,|\,j]$ and it is denoted as $C[i\,|\,j]$:

$$\det(A)=\sum_{j=1}^{n}a_{rj}C[r\,|\,j]=\sum_{i=1}^{n}a_{is}C[i\,|\,s]$$

Property (D-1) ensures that for properties of determinants stated in terms of their rows, equivalent properties can be stated in terms of columns. These sometimes will not be explicitly mentioned.

If follows from (D-4), (D-9), and (D-10) that if A has an inverse

$$A^{-1}=\frac{1}{\det(A)}(C[i\,|\,j]^{\mathrm{T}})$$

From (D-7) and (D-8), $\det(I)=1$, $\det(A^{-1})=1/\det(A)$.

E. Boolean Vectors and Matrices

Most of the theory of the last section holds in the case of Boolean matrices. Boolean row (column) vectors are $1\times n(n\times 1)$ Boolean matrices. The set V_n is the set of all Boolean n-tuples, and additive homomorphisms preserving 0 from V_n to V_m are in 1–1 correspondence with Boolean matrices.

Matrices over a Boolean algebra or field can be multiplied or added in blocks using the same formulas as

for individual entries $(A_{ij})+(B_{ij})=(A_{ij}+B_{ij})$, and $(A_{ij})(B_{ij})=(\Sigma A_{ik}B_{kj})$. Here the set of all indices has been partitioned into r subsets $S_1, S_2, \ldots, S_r$ and A_{ij} is the submatrix consisting of all a_{km} such that $(k, m) \in S_i \times S_j$. Usually the numbers in each S_t are assumed adjacent. For example,

$$\left[\begin{array}{cc|cc} 1 & 2 & 5 & 6 \\ 3 & 4 & 7 & 8 \\ \hline 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 \end{array}\right]\left[\begin{array}{cc|cc} 1 & 2 & 5 & 6 \\ 3 & 4 & 7 & 8 \\ \hline 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 \end{array}\right]$$

$$= \left[\begin{array}{cc} \begin{bmatrix}1&2\\3&4\end{bmatrix}\begin{bmatrix}1&2\\3&4\end{bmatrix}+\begin{bmatrix}5&6\\7&8\end{bmatrix}\begin{bmatrix}0&1\\1&0\end{bmatrix} & \begin{bmatrix}1&2\\3&4\end{bmatrix}\begin{bmatrix}5&6\\7&8\end{bmatrix}+\begin{bmatrix}5&6\\7&8\end{bmatrix}\begin{bmatrix}1&1\\1&1\end{bmatrix} \\ \begin{bmatrix}0&1\\1&0\end{bmatrix}\begin{bmatrix}1&2\\3&4\end{bmatrix}+\begin{bmatrix}1&1\\1&1\end{bmatrix}\begin{bmatrix}0&1\\1&0\end{bmatrix} & \begin{bmatrix}0&1\\1&0\end{bmatrix}\begin{bmatrix}5&6\\7&8\end{bmatrix}+\begin{bmatrix}1&1\\1&1\end{bmatrix}\begin{bmatrix}1&1\\1&1\end{bmatrix} \end{array}\right]$$

A block lower triangular form is one such that $A_{ij}=0$ for $i<j$. Every Boolean matrix can be put uniquely into a block triangular form such that main diagonal blocks A_{ii} are indecomposable or zero. This means $\Sigma_{n=0}^{\infty}A_{ii}^{n}=J$, the matrix consisting entirely of 1 for each i.

If the Boolean matrix is idempotent, every block in this block triangular form consists identically of 0 or of 1.

A Boolean matrix is invertible if and only if it is the matrix of a permutation. The row (column) rank of a Boolean matrix is the number of vectors in row (column) basis. An n-square Boolean matrix is nonsingular if it has row and column rank n and it is regular. Incidentally, the row and column rank of a Boolean matrix are not necessarily equal when $n \geq 4$. For a nonsingular Boolean matrix, there exists an analog of the formula for inverses. The permanent of a Boolean matrix A is

$$\operatorname{per}(A)=\sum_{\pi\in\mathcal{S}_n} a_{1\pi(1)}a_{2\pi(2)}\cdots a_{n\pi(n)}$$

A nonsingular Boolean matrix A has a unique Thierrin–Vagner inverse given by $\operatorname{per}(A[i|j])^{\mathrm{T}}$. The theories of Boolean matrices and semirings found more and more applications related to computers in the 1990s such as communication complexity and Schein rank, image processing, and the study of parallel computation.

F. Characteristic Polynomials

The linear transformations on a vector space are isomorphic (as binary relations) by an isomorphism of the vector space if and only if their matrices are similar. Similarity is an equivalence relation. To describe it completely we need a set of similarity invariants that distinguish any two nonsimilar matrices.

The most important similarity invariant is the characteristic polynomial defined by $p(\lambda)=\det(\lambda I-A)$. If $B=XAX^{-1}$, then

$$\begin{aligned}\det(\lambda I-XAX^{-1}) &= \det(X(\lambda I-A)X^{-1}) \\ &= \det(X)p(\lambda)(\det(X))^{-1} \\ &= p(\lambda)\end{aligned}$$

Therefore, it is a similarity invariant. Its roots are called eigenvalues (characteristic values, latent values).

The matrix A itself satisfies $p(A)=0$. The coefficient of λ^{n-1} is minus Σa_{ii}. This quantity is called the trace of A and it is denoted by $\operatorname{Tr}(A)$. We have $\operatorname{Tr}(AB)=\operatorname{Tr}(BA)$ and the trace is an additive homomorphism. The last coefficient is $(-1)^n\det(A)$.

An eigenvector (characteristic vector, latent vector) v of an n-square matrix is a vector such that $vA=\lambda v$ for some λ. There exists an eigenvector for λ if and only if $v(A-\lambda I)=0$ if and only if $A-\lambda I$ has rank less than n if and only if $p(\lambda)=0$. That is, λ must be an eigenvalue.

V. RINGS

A. Ring of Integers

The ring of integers satisfies the following algebraic axioms: Let $x, y, z \in \mathbf{Z}$. (R-1) $x+y=y+x$; (R-2) $(x+y)+z=x+(y+z)$; (R-3) $x(y+z)=xy+xz$; (R-4) $(y+z)x=yx+zx$; (R-5) $(xy)z=x(yz)$ (R-6) there exists 0 such that $0+x=x$ for all x; (R-7) for all x there exists $-x$ such that $x+(-x)=0$; (R-8) $xy=yx$; (R-9) if $xz=yz$, then $x=y$ or $z=0$; (R-10) there exists 1 such that $1\cdot x=x$ for all x.

Any structure of a set with two binary operations satisfying (R-1) to (R-7) is called a ring. If (R-8) holds, it is called a commutative ring. The sets of n-square matrices over $\mathbf{Z}$, $\mathbf{Q}$, $\mathbf{R}$, $\mathbf{C}$ satisfy (R-1) to (R-7) and (R-10) but not (R-8) and (R-9). Here $\mathbf{Q}$ denotes the set of all rational numbers. A ring satisfying (R-10) is called a ring with unit. A ring satisfying (R-1) to (R-10) is called an integral domain.

In addition the integers satisfy the properties that there exists a set $\mathbf{P}\subset\mathbf{Z}$ called the positive integers such that (R-11) $\mathbf{P}$ is closed under addition, (R-12) $\mathbf{P}$ is closed under multiplication, and (R-13) for all integers exactly one of these holds: $x=0$, $x\in\mathbf{P}$, $-x\in\mathbf{P}$. (Obviously, $\mathbf{P}=\mathbf{Z}^{+}$.) A ring satisfying these is called an ordered ring. $\mathbf{R}$ but not $\mathbf{C}$ is an ordered ring.

The final axiom is the induction property (R-14): If a nonempty set S is contained in $\mathbf{P}$ and $1 \in S$ and $1 + x \in S$ whenever $x \in S$, then $S = \mathbf{P}$.

The ordinary rules of algebra follow from these axioms, as $(1 + (-1) + 1) \cdot (-1) = (0 + 1) \cdot (-1) = 1 \cdot (-1) = -1$. Therefore, $-1 + (-1)(-1) + (-1) = -1$, $1 + (-1) + (-1)(-1) + (-1) + 1 = 1 + (-1) + 1$, and $(-1)(-1) = 1$.

B. Euclidean Domains

Many properties of $\mathbf{Z}$ are shared by the ring of polynomials over any field, and the rings $\{a + bi : a, b \in \mathbf{Z}\}$ and $\{a + b[(1 + \sqrt{3})/2]i : a, b \in \mathbf{Z}\}$. To deal with these we define Euclidean domains. A Euclidean domain is a ring $\mathfrak{E}$ satisfying (R-1) to (R-10) provided with a function $\omega(x)$ defined from nonzero elements of $\mathfrak{E}$ into $\mathbf{Z}$ such that (R-15) $\omega(xy) \geq \omega(x)$; (R-16) for all $x, y \in \mathfrak{E}$ there exist $q, r \in \mathfrak{E}$ such that $x = qy + r$, and either $\omega(r) < \omega(y)$ or $r = 0$; and (R-17) $\omega(x) \geq 0$. For polynomials, let ω be the degree. For other cases, let it be $|x|$.

In any ring with unit $\mathfrak{R}$, the relation $x|y$ can be defined by there exists $z \in \mathfrak{R}$ with $zx = y$. This relation is transitive. If $x|y$, $x|z$, then $x|y + z$ since $y = ax$, $z = bx$, $y + z = (a + b)x$ for some a, b. If $x|y$ then $xa|ya$ for any a. Since $1x = x$, it is a quasiorder. It is called (right) divisibility.

In an integral domain, suppose $y|x$ and $x|y$. Then $x = ry$, $y = sx$ for some r, s. If either is zero then both are. Otherwise $rsx = ry = x = 1x$ and $rs = 1$ by (R-9). So r, s are invertible.

A greatest common divisor (g.c.d.) of a set $S \subset \mathfrak{E}$ is an element $g \in \mathfrak{E}$ such that $g|x$ for all $x \in S$ and if $y|x$ for all $x \in S$ then $y|g$. Any two g.c.d.'s of the same set must be multiples of one another, and so multiples by an invertible element. Let g be a g.c.d. of S and h be a g.c.d. of a set T and m be a g.c.d. of $\{g, h\}$. Then m is a g.c.d. of $S \cup T$. The g.c.d. is a greatest lower bound in the partial order of the set of equivalence classes of elements of $\mathfrak{E}$ under the relation $x \sim ay$ if a is invertible.

In a Euclidean domain, the Euclidean algorithm is an efficient way to calculate the g.c.d. of two elements x, y. Assume $\omega(x) \geq \omega(y)$. Let $d_0 = x$, $d_1 = y$. Choose a sequence d_i, q_i for $i > 0$ by $d_i = q_{i+1}d_{i+1} + d_{i+2}$, where $\omega(d_{i+2}) < \omega(d_{i+1})$. The process terminates since $\omega(x)$ is always a nonnegative integer, and in the last stage we have a remainder $d_{k+2} = 0$. Then $d_{k+1}|d_k$. By induction using the equations $d_i = q_{i+1}d_{i+1} + d_{i+2}$ it will divide the right side and therefore the left side. So it divides all d_i. Also $d_{i+2} = d_i - q_{i+1}d_{i+1}$ is a linear combination of d_i, d_{i+1} so by induction d_{k+1} is a linear combination of a, b. Therefore, if x divides a, b, it divides d_{k+2}. Therefore, the element $d_{k+1} = ra + sb$ is a g.c.d. of a, b.

When an argument is made by induction, it is understood that a statement $P(n)$ holds for $n = 1$ and that there is an argument showing that if $P(1), P(2), \ldots, P(n-1)$ hold so does $P(n)$. Let $S = \{n \in P : P(n) \text{ is true}\}$. Then by the induction axiom (R-14), S is all of P. Arguments by induction are especially common in the theory of $\mathbf{Z}$.

The following is an example of the Euclidean algorithm for polynomials:

$$x^3 + 1 = x(x^2 + 1) + (-x + 1)$$
$$x^2 + 1 = (-x + 1)(-x - 1) + 2$$
$$-x - 1 = 2\left(\frac{-x - 1}{2}\right)$$

Therefore, 2 (equivalently 1) is a g.c.d. of $x^2 + 1$, $x^3 + 1$. We can now express it in terms of them:

$$2 = (x^2 + 1) - (-x + 1)(-x - 1)$$
$$= (x^2 + 1) - (-x + 1)(x + 1)$$
$$2 = (x^2 + 1) + ((x^3 + 1) - x(x^2 + 1))(x + 1)$$
$$2 = (x^2 + 1) + (x + 1)(x^3 + 1) - x(x + 1)(x^2 + 1)$$
$$2 = (1 - x - x^2)(x^2 + 1) + (x + 1)(x^3 + 1)$$

In the second step, we substituted $x^3 + 1 - x(x^2 + 1)$ for $-x + 1$.

By induction there is a g.c.d. of $x_1, x_2, \ldots, x_k$ that is linear combination $s_1x_1 + s_2x_2 + \cdots + s_kx_k$ of them. If we multiply by invertible elements, we obtain such an expression for any g.c.d.

If a is invertible, then $\omega(ab) \leq \omega(b)$ and $\omega(a^{-1}ab) \leq \omega(ab)$, so the two are equal. Conversely, if $\omega(ab) = \omega(b)$, $b \neq 0$, $b \in \mathfrak{E}$, then a is a unit [divide b by ab; if $\omega(r) < \omega(ab) = \omega(b)$ we have a contradiction].

From this we can establish the basic facts of prime factorizations. An element $p \in \mathfrak{E}$ is called prime if it is not invertible but whenever $p = xy$ one of x, y is invertible. It follows that for any a if $p|a$ then the g.c.d. of p, a is invertible.

Suppose 1 is a g.c.d. of c, a. Let $1 = ar + cs$. If $c|ab$, then $c|abr + cbs = b$. Therefore, if p, a prime, divides xy, it divides x or y. To factor an element y of $\mathfrak{E}$ into primes choose a divisor x that has minimal $\omega(x)$ among nonivertible elements. If $x = ut$ and u is not invertible then $\omega(u) = \omega(x)$ and so t is invertible and so x is prime. Since x is not invertible, $\omega(y/x) < \omega(y)$. So after a finite number of prime factors the process ends.

By induction we can show that if p is a prime and divides $y_1y_2 \cdots y_k$, then p divides some y_i. From this it can be proved that if $a = p_1p_2 \cdots p_m = q_1q_2 \cdots q_n$, where p_i, q_i are primes, then $n = m$ and the q_i can be renumbered so that $p_i = u_iq_i$, where u_i is invertible. Since $p_i|q_1q_2 \cdots q_n$, p_1 divides some q_i. Label it q_1. Since both are primes,

$p_1 = q_1$. This reduces n, m by 1 and the process can be repeated.

C. Ideals and Congruences

A ring homomorphism is a function $f : \mathfrak{R} \to \mathfrak{S}$ satisfying $f(x+y) = f(x) + f(y)$ and $f(xy) = f(x)f(y)$. That is, it is a semigroup homomorphism for multiplication and a group homomorphism for addition.

The following are examples of ring homomorphisms. (1) The mapping from n-square matrices to m-square matrices for $m > n$, which adds to a matrix $m-n$ rows and columns of zero. (2) The mapping $f : \mathbf{Z} \to \mathbf{Z_m}$, $f(x) = \bar{x}$. For any two rings $\mathfrak{R}$, $\mathfrak{S}$ a product ring $\mathfrak{R} \times \mathfrak{S}$ is defined by operations $(a, b) + (c, d) = (a + c, b + d)$, $(a, b)(c, d) = (ac, bd)$. (3) The mapping $\mathfrak{R} \times \mathfrak{S} \to \mathfrak{R}$ sending (a, b) to a (or b) is a ring homomorphism. (4) For any complex number c, the evaluation $f(c)$ is a homomorphism from the ring of all functions $f : \mathbf{C} \to \mathbf{C}$ into $\mathbf{C}$ itself.

A subring of a ring is a subset closed under addition, subtraction, and multiplication. An ideal is a subset S of a ring $\mathfrak{R}$ closed under addition and subtraction (if $x, y \in S$, then $x - y \in S$) and such that if $z \in \mathfrak{R}$, $x \in S$, then $xz, zx \in S$. The set of even integers is an ideal in the set of intergers.

A congruence on a ring $\mathfrak{R}$ is an equivalence relation $x \sim y$ such that for all $a \in \mathfrak{R}$ if $x \sim y$ then $x + a \sim y + a$, $xa \sim ya$, and $ax \sim ay$. For any congruence $\mathfrak{R}$ if $x \sim y$, $z \sim w$ then $x + z \sim y + z \sim y + w$ and $xz \sim yw$. Then addition and multiplication of equivalence classes $\bar{x} + \bar{y} = \overline{x+y}$, $\bar{x}\bar{y} = \overline{xy}$ are well defined and give a ring called the quotient ring. The function $x \to \bar{x}$ is a homomorphism.

There is a 1–1 correspondence between ideals and congruences. To a congruence associate the set $x \sim 0$, which is an ideal $\mathfrak{I}$. Then the congruence is defined by $x \sim y$ if and only if $x + (-y) \sim y + (-y) = 0$. Therefore, $x \sim y$ if and only if $x - y \in \mathfrak{I}$. Every ideal in this way determines a congruence.

The equivalence classes have the form $x + \mathfrak{I} = \{x + m : m \in \mathfrak{I}\}$. The quotient ring is denoted $\mathfrak{R}/\mathfrak{I}$.

All ideals in the integers—in fact, all subgroups—have the form $m\mathbf{Z} = \{mx : x \in \mathbf{Z}\}$. The congruence associated with these is $a \equiv b (\mathrm{mod}\ m)$ if and only if $a - b = km$ for some k. By the general theory, such congruences can be added, subtracted, multiplied, or raised to a power. Congruences can sometimes decide whether or not equations are solvable in whole numbers. For example, $x^2 + y^2 + z^2 = w$ is not possible if $w \equiv 7 (\mathrm{mod}\ 8)$. To prove this it can first be noted that $x^2 \equiv K (\mathrm{mod}\ 8)$ where $k = 0, 1, 4$, and no three elements of {0, 1, 4} add to 7(mod 8). The ring of all polynomials in a variable x having coefficients in a field $\mathbf{K}$ is denoted $\mathbf{K}[x]$. As a set it is a subset of a Cartesian product of countably many copies of $\mathbf{K}$, sequences $(a_0, a_1, \ldots)$ such that only finitely many a_i are nonzero. The a_i are the coefficients of the polynomial and multiplication can be defined by $(a_n)(b_n) = (\Sigma_r a_r b_{n-r})$.

In it or any Euclidean domain, all ideals have the form $\{f(x)y : y \in \mathbf{K}[x]\}$ for some polynomial $f(x)$. Given an ideal $\mathfrak{I}$, take a nonzero element $f(x)$ in it such that $\omega(f(x))$, the degree, is minimal.

If $f(x)$ is another element of the ideal, choose $q(x), r(x)$ such that $r(x) = 0$ or $\omega(r(x)) < \omega(f(x))$ for $g(x) = f(x)q(x) + r(x)$. Then $r(x) = g(x) - f(x)q(x) \in \mathfrak{I}$ since $g(x), f(x)$ do. So $\omega(r(x)) < \omega(f(x))$ contradicts minimality of $\omega(f(x))$. So $r(x) = 0$. So every element in $\mathfrak{I}$ is a multiple of $f(x)$. Conversely multiples of $f(x)$ belong in $\mathfrak{I}$ since it is an ideal.

Ideals of the form $a\mathfrak{R} = \{ax : x \in \mathfrak{R}\}$ are called principal, and a is said to be a generator. Therefore, Euclidean domains are principal ideal domains, that is, integral domains in which all ideals are principal.

In all principal ideal domains, all elements can be uniquely factored in terms of primes and invertible elements. Let $\mathfrak{R}_m$ where $m \in \mathbf{Z}$ is not divisible by the square of a prime denote $\{a + [b(1 + \sqrt{m})/2] : a, b \in \mathbf{Z}\}$ or $\{a + b\sqrt{m} : a, b \in \mathbf{Z}\}$ according to whether $m \equiv 1 (\mathrm{mod}\ 4)$ or not. If $0 < m < 25$, then $\mathfrak{R}_m$ is a principal ideal domain if and only if $m \neq 10, 15$. If $-130 < m < 0$, then $\mathfrak{R}_m$ is a principal ideal domain if $m = -1, -2, -3, -7, -11, -19, -43, -67$. (This is a result proved by techniques of algebraic number theory.) Unique factorization does not hold in $\mathfrak{R}_m$ if it is not a principal ideal domain.

For noncommutative rings, there are separate concepts of right and left ideals. A subset S of a ring $\mathfrak{R}$ closed under addition and subtraction is a left (right) ideal if and only if $ax \in S$ ($xa \in S$) for all $x \in S$, $a \in \mathfrak{R}$. The ring of n-square matrices has no (two-sided) ideals except itself and zero but for any subspace $\mathbf{W}$, $\mathfrak{I} = \{M \in M_n(\mathbf{F}) : vM \in \mathbf{W}\}$ is a right ideal. A proper ideal is an ideal that is a proper subset. The trivial ideal is {0}.

Suppose a ring $\mathfrak{R}$ has not all products zero and has no proper nontrivial right ideals. If $ab \neq 0$ for some b, then $\{x : ax = 0\}$ is a proper right ideal and is therefore zero. The set $\{ax\}$ is a nonzero right ideal and is therefore $\mathfrak{R}$. So multiplication on the left by a is 1–1 and onto.

Let $\mathfrak{I} = \{a : ab = 0 \text{ for all } b \in \mathfrak{R}\}$. Then $\mathfrak{I}$ is a proper right ideal and is therefore 0. So for all $a \neq 0$ left multiplication by a is 1–1 and onto. So if $ab = 0$, then $a = 0$ or $b = 0$.

For any $a \neq 0$ since $\{ax\} = \mathfrak{R}$, there exist e, a^{-1} such that $ae = a$, $aa^{-1} = e$. Then for any $x \in \mathfrak{R}$, $aex = ax$. So $ex = x$ since left multiplication is 1–1. From $ab \neq 0$ for $a \neq 0$, $b \neq 0$, it follows that right multiplication is also 1–1. Since $xexe = xx$ and $xe = x$, e is an identity. From $aa^{-1}a = ea = a = ae$, it follows that a^{-1} is an inverse of a. Therefore, in $\mathfrak{R}$, all nonzero elements have inverses.

A ring with unit in which all nonzero elements have inverses is called a division algebra. The best known division algebra that is not a field is the ring of quaternions. As a set, it is $\mathbf{R}\times\mathbf{R}\times\mathbf{R}\times\mathbf{R}$. Elements are written as $a+b\,\imath+c\,\jmath+d\,\ell$. Expressions are multiplied by expanding and using the rules $\imath^2=\jmath^2=\ell^2=-1$, $\imath\jmath=\ell$, $\jmath\ell=\imath$, $\ell\imath=\jmath$, $\jmath\imath=-\ell$, $\ell\jmath=-\imath$, $\imath\ell=-\jmath$. Any multiplication defined from a basis by expanding terms is distributive. The multiplication on basis elements and their negative $\pm1, \pm\imath, \pm\jmath, \pm\ell$ is a finite group of order 8. This implies associativity.

D. Structure of $\mathbf{Z_n}$

The ring $\mathbf{Z_n}$ is the ring of congruence classes modulo n. It is the quotient ring $\mathbf{Z}/\Im_n$, where $\Im_n=\{nx : x\in\mathbf{Z}\}$. For any quotient ring $\Re/\Im$, ideals of the quotient ring are in 1–1 correspondance with ideals of $\Re$ containing $\Im$. An ideal $\Im_m\supset\Im_n$ if and only if $m|n$. So the ideals of $\mathbf{Z_n}$ are in 1–1 correspondence with positive integers m dividing n. The ring $\mathbf{Z_n}$ has exactly n elements, since each integer x can be expressed as $nk+r$ for a unique $r\in\{0,1,\ldots,n-1\}$, and then $x\equiv r(\mathrm{mod}\ n)$. It has a unit and is commutative.

Two elements of an integral domain are called relatively prime if 1 is a g.c.d. of them. If x, n are relatively prime, then $rx+sn=1$ for some r and s. Thus, $\bar r\bar x=1$ so $\bar x$ is invertible. Conversely, if $\bar r\bar x=1$, then $rx-1=sn$ for some s, and 1 is a g.c.d. of x and n. Thus, the number of invertible elements equals $\Phi(n)$, the number of positive integers $m<n$ that are relatively prime to n.

The Chinese remainder theorem asserts that if all pairs of $n_1, n_2, \ldots, n_m$ are relatively prime and $a_i\in\mathbf{Z}$, $i=1$ to m, then there exists $x\in\mathbf{Z}$ and $x\equiv a_i(\mathrm{mod}\ n_i)$ for $i=1$ to m. Any two such x are congruent modulo $n_1n_2\cdots n_m$.

The set of invertible elements is closed under products since $(xy)^{-1}=y^{-1}x^{-1}$ and contains inverses and identity, so it forms a group for any ring. Here it is a finite group. For any invertible element x, the elements $1, x, \ldots, x^{k-1}$ form a subgroup if k is the order of x. By the Lagrange's theorem, the order of any subgroup of a group divides the order of the group. Therefore, $k|\Phi(n)$. From $x^k=1$, follows $x^{\Phi(n)}=1$. This proves a theorem of Euler and Fermat. For any $x\in\mathbf{Z_n}$, if x is invertible, then $x^{\Phi(n)}=1$.

If p is prime, then $1, 2, \ldots, p-1$ are all relatively prime to p, so $\Phi(p)=p-1$, and $x^{p-1}\equiv1(\mathrm{mod}\ p)$ if $x\not\equiv0$). Then $x^p\equiv x(\mathrm{mod}\ p)$ for all $x\in\mathbf{Z_p}$. Assume p is prime for the rest of this section.

The multiplicative group $\mathbf{Z_p^*}=\{\bar x\not\equiv\bar0 : \bar x\in\mathbf{Z_p}\}$ is a commutative group of order $p-1$. The ring $\mathbf{Z_p}$ is a field since $\mathbf{Z_p^*}$ is a group. Polynomials over $\mathbf{Z_p}$ can be uniquely factored into primes.

Over any field $\mathbf{K}$, if a polynomial $p(x)$ satisfies $p(k)=0$, where $k\in\mathbf{K}$, then let $p(x)=(x-k)q(x)+r$. By substitution $x=k$ we find $r=0$. So if $p(k)=0$, then $(x-k)|p(x)$. Thus, a polynomial of order n cannot have more than n distinct roots since each root gives a degree 1 factor $(x-k)$.

The polynomial $x^{p-1}-1$ has exactly $p-1$ roots in $\mathbf{Z_p}$, that is, $1, 2, \ldots, p-1$. Thus, it factors as $c(x-1)\cdots(x-(p-1))$. Since the, coefficient of x^{p-1} is 1, we have $c=1$. The polynomial x^r-1 divides $x^{p-1}-1$ for $r|p-1$, so by unique factorization it factors into linear factors and has exactly r roots. For any prime power r^t dividing $p-1$ take a root y_r of $x^{r^t}=1$, which is not a root of $x^{r^{t-1}}=1$. Then y_r has order precisely r^t. Take t maximal. The product u of all y_r will have order the least common multiple of r^t, which is $p-1$. Therefore, $u, u^2, \ldots, u^{p-1}$ are distinct and are all of $\mathbf{Z_p^*}$ since it has exactly $p-1$ elements. This proves $\mathbf{Z_p^*}$ is cyclic. Therefore, it is isomorphic to $(\mathbf{Z_{p-1}}, +)$.

In $\mathbf{Z_n}$ for $m|n$, an element y is a multiple of m if and only if $(n/m)y\equiv0$. Therefore, in $\mathbf{Z_p^*}$, an element y is an mth power for $m|p-1$ if and only if $y^{(p-1)/m}\equiv1(\mathrm{mod}\ p)$. The mth powers form a multiplicative subgroup of order $(p-1)/m$.

E. Simple and Semisimple Rings

A ring is called simple if it has no proper nontrivial (two-sided) ideals. A commutative simple ring is a field. It is simplest to treat the case of finite dimensional algebras. An algebra over a field $\mathbf{F}$ is a ring $\Re$ provided with a multiplication $\mathbf{F}\times\Re\to\Re$ such that (1) $(ax)y=a(xy)=x(ay)$ for all $a\in\mathbf{F}$, $x, y\in\Re$; and (2) $\Re$ is a vector space over $\mathbf{F}$. The quaternions, the complex numbers, and the ring of all functions $\mathbf{R}$ to $\mathbf{R}$ are all algebras over $\mathbf{R}$.

A division algebra is an algebra that is a division ring. Division algebras can be classified in terms of fields. A field $\mathbf{F}$ is called algebraically closed if every nonzero polynomial $p(x)=a_0x^n+a_1x^{n-1}+\cdots+a_nx^0$, $a_i\in\mathbf{F}$, $a_0\neq0$, $n\neq0$ has a root $r\in\mathbf{F}$. Suppose we have a division algebra $\mathfrak{D}$ over an algebraically closed field $\mathbf{F}$ of finite dimension n. Let $a\in\mathfrak{D}$. Then $1, a, \ldots, a^n$ are $n+1$ elements in an n-dimensional vector space so they cannot be linearly independent (they could be extended to a basis). So some combination $p(a)=c_0+c_1a+\cdots+c_na^n=0$. Choose the degree of p minimal. Let $\deg(p)$ denote the degree of p. If $\mathrm{Deg}(p)>1$, then p can be factored over $\mathbf{F}$. Each factor is nonzero evaluated at a, but their product is zero. This is impossible in a division algebra where nonzero elements are invertible. Therefore, $\mathrm{Deg}(p)=1$, so $c_0+c_1a=0$, as $a\in\mathbf{F}$. So $\mathfrak{D}=\mathbf{F}$. Any such division algebra coincides with $\mathbf{F}$. This applies to $\mathbf{F}=\mathbf{C}$.

A finite dimensional $\mathbf{F}$-algebra is simple if and only if it is isomorphic to the ring $M_n(\mathfrak{D})$ of n-square matrices over $\mathfrak{D}$. More generally, every ring having no infinite strictly

decreasing sequence of distinct left ideals (Artinian ring) that is simple is an $M_n(\mathfrak{D})$.

A finite dimensional **F**-algebra $\mathfrak{A}$ is called semisimple if as a vector space it is an internal direct sum of minimal right ideals $\mathfrak{R}_i$. This means every $x \in \mathfrak{A}$ can be uniquely expressed as Σx_i, $x_i \in \mathfrak{R}_i$. Left ideals can equivalently be used.

This is equivalent to any of the following conditions. (1) The multiplicative semigroup of $\mathfrak{R}$ is regular; (2) every left ideal of $\mathfrak{A}$ is generated by an idempotent; and (3) $\mathfrak{A}$ has no two-sided ideals $\mathfrak{I}$ such that $\mathfrak{I}^m = \{x_1 x_2 \cdots x_m : x_i \in \mathfrak{I}\}$ is zero for some m. Ideals $\mathfrak{I}$ such that $\mathfrak{I}^m = 0$ are called nilpotent.

A finite dimensional semisipmle **F**-algebra is isomorphic to a direct sum of rings $M_n(\mathfrak{D})$.

If $\mathfrak{I}$ and $\mathfrak{J}$ are nilpotent two-sided ideals, so is $\mathfrak{I} + \mathfrak{J}$ since $(\mathfrak{I} + \mathfrak{J})^{2^n} \subset \mathfrak{I}^n + \mathfrak{J}^n$. This implies that every finite dimensional algebra has a maximal two-sided nilpotent ideal, the Jacobson radical, and its quotient ring by this ideal is semisimple.

All finite division rings are fields.

F. Group Rings and Group Representations

A group ring of a group G over a ring $\mathfrak{R}$ is formally the set of all functions $f : G \to \mathfrak{R}$ such that $|\{g : f(g) \neq 0\}|$ is finite. Multiplication is given by $(fh)(x) = \Sigma_{yz=x} f(y)h(z)$ and addition is the usual sum of functions. Distributivity follows from the linear form of this expression. Associativity follows from $\{(u, v, w) : uv = y \text{ and } yw = x \text{ for some } y\} = \{(u, v, w) : vw = z, uz = x \text{ for some } z\}$. In fact, semigroups also have semigroup rings.

The group ring can be thought of as the set of all sums $r_1 g_1 + r_2 g_2 + \cdots + r_n g_n$ of group elements with coefficients in $\mathfrak{R}$. For coefficients in **Z**, we have, for instance, $(2g + e)(3e - 2g) = 3e - 2g + 6g - 4g^2 = 3e + 4g - 4g^2$.

A representation of a group G is a homomorphism h from G into the ring $M_n(\mathbf{F})$ of n-square matrices over **F**. Two representations f, h are called equivalent if there exists an invertible matrix $M \in M_n(\mathbf{F})$ with $f(g) = Mh(g)M^{-1}$ for all $g \in G$. This is an equivalence relation.

Every representation f of a group G defines a ring homomorphism $h : F(G) \to M_n(\mathbf{F})$ by $h(\Sigma r_i g_i) = \Sigma r_i h(g_i)$ such that $h(1) = I$ where I is an n-square identity matrix. This is a 1–1 correspondence since if h is a ring homomorphism $h(g)$ gives a group representation.

For $\mathbf{F} = \mathbf{C}$, every group representation is equivalent to a unitary representation, that is, one in which every matrix $f(g)$ satisfies $f(g)f(g)^{*\mathrm{T}} = I$. Here * is complex conjugation. Define a modified inner product on row vectors by $b(x, y) = \Sigma_g x f(g)(y f(g))^{*\mathrm{T}}$. Then $b(x, y) = b(x f(h), y f(h))$ for $h \in G$ since multiplication by h permutes the group elements g and so permutes the terms in the sum. We have $b(x, x) \geq 0$ and $b(x, x) = 0$ only if $x = 0$ since each term will be a vector $vv^{*\mathrm{T}} = \Sigma |v_i^2|$. We can inductively choose a basis u_i for row vectors such that $b(u_i, u_i) = 1$, $b(u_i, u_j) = 0$ if $i \neq j$. In this basis, let $u_i f(g) = \Sigma u_k a_{ki}$. Then $b(u_i, u_j) = b(\Sigma u_k a_{ki}, \Sigma u_k a_{kj}) = \Sigma a_{kj}^* a_{ki} b(u_k, u_k)$. So $\Sigma a_{kj}^* a_{ki} = 1, 0$ according to whether $i = j$ or $i \neq j$. This proves the matrix is now unitary.

For $\mathbf{F} = \mathbf{R}$, essentially the same can be done. A real unitary matrix is called orthogonal. Orthogonal matrices are geometrically products of rotations and reflections.

G. Modules

A module differs from a vector space only in that the ring involved may not be a field. A left (right) $\mathfrak{R}$-module is a set $\mathfrak{M}$ provided with a binary operation denoted as addition and a multiplication $\mathfrak{R} \times \mathfrak{M} \to \mathfrak{M}$ ($\mathfrak{M} \times \mathfrak{R} \to \mathfrak{M}$), where $\mathfrak{R}$ is a ring such that the axioms in Table III hold for all $x, y \in \mathfrak{M}$, $r, s \in \mathfrak{R}$, and some $0 \in \mathfrak{M}$.

For group representations, we consider only unitary modules, those in which $1x = x$ for all $x \in \mathfrak{M}$. Henceforth, we consider left modules.

A homomorphism of modules is a mapping $f : \mathfrak{M} \to \mathfrak{R}$ such that $f(x + y) = f(x) + f(y)$ and $f(rx) = rf(x)$ for all $x, y \in \mathfrak{M}$, and $r \in \mathfrak{R}$. A submodule of $\mathfrak{M}$ is a subset closed under addition, subtraction, and multiplication by elements of $\mathfrak{R}$. For any submodule $\mathfrak{N} \subset \mathfrak{M}$, the equivalence relation $x \sim y$ if and only if $x - y \in \mathfrak{N}$ is a module congruence, that is, $x + z \sim y + z$, $rx \sim ry$ for all $z \in \mathfrak{M}$, $r \in \mathfrak{R}$. Then the equivalence classes form a new module called the quotient module.

Modules are a type of algebraic action, that is, a mapping $G \times S \to S$ for a structure G and set S. Figure 8 classifies some of these.

Direct sums of modules are defined as for vector spaces. Unlike the vector space case not every finite dimensional module over a general algebra is isomorphic to a direct sum $\mathfrak{R} \oplus \mathfrak{R} \oplus \cdots \oplus \mathfrak{R}$ of copies of $\mathfrak{R}$ (with operations from $\mathfrak{R}$). If a ring is an **F**-algebra, all modules over it are vector spaces and this determines their dimension.

TABLE III Module Axioms

Left module	Right module
$(x + y) + z = x + (y + z)$	$(x + y) + z = x + (y + z)$
$x + 0 = x$	$0 + x = x$
$0x = 0$	$x0 = 0$
There exists $-x$ such that $x + (-x) = 0$ for all x	There exists $-x$ such that $x + (-x) = 0$ for all x
$r(x + y) = rx + ry$	$(x + y)r = xr + yr$
$(r + s)x = rx + sx$	$x(r + s) = xr + xs$
$r(sx) = (rs)x$	$(xs)r = x(sr)$

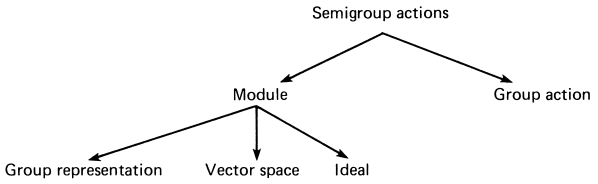

FIGURE 8 Algebraic actions.

There is a 1–1 correspondence between equivalence classes of representations in $M_n(\mathbf{F})$ and isomorphism classes of modules over $\mathbf{F}(G)$ of dimension n, where $\mathbf{F}(g)$ is the group ring of G over $\mathbf{F}$. For any group representation, the set of column vectors is a left module over $\mathbf{F}(G)$ with action given by $(\Sigma c_i g_i)v = \Sigma c_i h(g_i)v$. For any module of dimension n, the group action gives a set of linear transformations of a vector space. If we choose a basis, the matrices of these linear transformations give a group representation.

H. Irreducible Representations

A module is called irreducible if it has no proper nonzero submodules. Suppose $\mathfrak{N} \subset \mathfrak{M}$, where $\mathfrak{M}$, $\mathfrak{N}$ are finite dimensional $\mathbf{F}(G)$-modules. Then there exists a vector space complement $\mathbf{V}$ of $\mathfrak{M}$ in $\mathfrak{N}$. Then there is a natural isomorphism $f : \mathbf{V} \to \mathfrak{M}/\mathfrak{N}$ of vector spaces. Consider $f^{-1} : \mathfrak{M}/\mathfrak{N} \to \mathbf{V} \subset \mathfrak{M}$. Assume $|G| \neq 0$ in $\mathbf{F}$ (if $\mathbf{F}$ is $\mathbf{R}$ or $\mathbf{C}$, for instance). Let

$$h(x) = \frac{1}{|G|} \sum g^{-1} f^{-1}(gx)$$

Then $h(gx) = gh(x)$, so h is a module homomorphism. If we let h_1 be $h : \mathfrak{M}/\mathfrak{N} \to \mathfrak{M}$ composed with the quotient mapping $\mathfrak{M} \to \mathfrak{M}/\mathfrak{N}$, h_1 is the identity since the summand $g^{-1} f^{-1}(gx) = f^{-1}(x)$ because we have a module isomorphism. So h is 1–1. Its image has dimension Dim($\mathbf{V}$) and intersection $\{0\}$ with $\mathfrak{N}$ since h_1 is 1–1. Thus the image of h gives a module isomorphic to $\mathfrak{M}/\mathfrak{N}$ whose intersection with $\mathfrak{N}$ is $\{0\}$. Then $\mathfrak{M} \simeq \mathfrak{N} \oplus \mathrm{Im}(h)$, where Im($h$) is the image of h.

Therefore, all representations are direct sums of irreducible modules since we can repeatedly express a module as a direct sum.

If we regard right ideals as modules, the group ring is then a direct sum of irreducible left ideals. These ideals are minimal. Their number is at most the dimension of $\mathfrak{R}(G)$. Therefore, $\mathfrak{R}(G)$ is semisimple and is isomorphic to a direct sum of matrix rings $M_n(\mathfrak{D})$. If $\mathbf{F} = \mathbf{C}$, then $\mathfrak{D} = \mathbf{C}$ so it is isomorphic to a direct sum of rings $M_n(\mathbf{C})$.

For any irreducible module $\mathfrak{N}$, let $0 \neq x \in \mathfrak{N}$. The mapping $\Sigma c_i g_i \to \Sigma c_i g_i$ gives a mapping $\mathfrak{R}(G)$ to $\mathfrak{N}$. This must be nonzero on some left ideal $\mathfrak{M}$ in a given direct sum decomposition $\mathfrak{R}(G) = \oplus \mathfrak{M}_i$. The mapping $\mathfrak{M} \to \mathfrak{N}$ has kernel a proper submodule and image a nontrivial submodule. So by irreducibility it has kernel zero and image $\mathfrak{N}$. Therefore, every irreducible module is isomorphic to a member of the finite set $\{\mathfrak{M}_i\}$.

Further use of these facts gives the basic facts about group representations such as orthogonality for group characters. The character of a representation is the function assigning to each group element g the trace of the matrix $h(g)$.

VI. FIELDS

A. Integral Domains

An integral domain is a commutative ring with unit having cancellation. Any subring of a field must be an integral domain.

Conversely, let $\mathfrak{R}$ be an integral domain. We construct a field, the field of fractions containing $\mathfrak{R}$. Let $S = \mathfrak{R} \times (\mathfrak{R} \setminus \{0\})$. We consider $(a, b) \in S$ as a/b. Therefore, since $a/b = c/d$ if $ad = bc$, we define an equivalence relation by $(a, b) \sim (c, d)$ if and only if $ad = bc$. Transitivity follows for $(a, b) \sim (c, d) \sim (e, f)$ since we have $ad = bc$, $cf = de$; therefore, $adf = bcf = bde$. By cancellation of $d \neq 0$, $af = be$. The relation is a multiplicative congruence if we define products by $(a, b)(c, d) = (ac, bd)$. This shows that equivalence classes can be multiplied under this definition.

Addition is defined by $(a, b) + (c, d) = (ad + bc, bd)$ by analog with ordinary fractions. A computation shows that the equivalence relation is also a congruence with respect to addition and that associativity and distributivity hold. The elements (0, 1) and (1, 1) are additive and multiplicative identities. A nonzero element (a, b) has the additive inverse $(-a, b)$ and the multiplicative invese (b, a). Therefore, the set of equivalence classes is a field.

If $\mathfrak{R}$ is the ring of polynomials over a field $\mathbf{K}$ in one variable, then the field is the field of rational functions.

B. Fields and Extensions

Let $(\mathbf{F_1}, *, \square)$ be a field. A subset $\mathbf{F_2}$ of $\mathbf{F_1}$ is a called a subfield $\mathbf{F_1}$ if the elements of $\mathbf{F_2}$ form a field under $*$ and $\square$.

The rings $(\mathbf{Z_p}, +, \cdot)$, where $\mathbf{p}$ is a prime number and $(\mathbf{Q}, +, \cdot)$ are fields. Let $\mathbf{F}$ be any field. If no sum of $n1 = (1 + 1 + \cdots + 1)$ is zero, then $\mathbf{Q}$ is isomorphic to the subfield $\{n1/m1 : m \neq 0\}$ of $\mathbf{F}$. If $n1 = 0$ where n is minimal, n must be a prime p; else we would have zero divisors $(p1)(q1) = 0$. Then $\mathbf{Z_p} = \{n1\}$ is a subfield of $\mathbf{F}$.

Let $\mathbf{E}$, $\mathbf{F}$ be fields. If $\mathbf{F} \subset \mathbf{E}$, then $\mathbf{E}$ is called an extension of $\mathbf{F}$. All fields are extensions of $\mathbf{Q}$ or $\mathbf{Z_p}$. The field $\mathbf{E}$ is a

vector space over $\mathbf{F}$. The dimension of $\mathbf{E}$ over $\mathbf{F}$ is denoted $[\mathbf{E} : \mathbf{F}]$ and is called the degree of the extension.

Suppose $\mathbf{F} \subset \mathbf{E} \subset \mathbf{D}$. Let x_i be a basis for $\mathbf{E}$ over $\mathbf{F}$ and y_i a basis for $\mathbf{D}$ over $\mathbf{E}$. Then every element of $\mathbf{D}$ can be written uniquely as $\Sigma c_i y_i$, $c_i \in \mathbf{E}$, and in turn this can be written uniquely as $\Sigma(f_{ij}x_j)y_i$, $f_{ij} \in \mathbf{F}$. So $x_j y_i$ are a basis and $[\mathbf{E}:\mathbf{F}][\mathbf{D}:\mathbf{E}] = [\mathbf{D}:\mathbf{F}]$.

Let $\mathbf{E}$ be an extension of $\mathbf{F}$ and let $t \in \mathbf{E}$. Then $\mathbf{F}(t)$ denotes the subfield of $\mathbf{E}$ generated by $\mathbf{F}$, that is, all elements of $\mathbf{E}$ that can be obtained from elements of $\mathbf{F}$, t by adding, multiplying, subtracting, and dividing.

Suppose $\mathbf{E}$ is a finite dimensional extension of degree n. Let x denote an indeterminate. Then the elements $1, t, t^2, \ldots, t^n$ are $n+1$ elements and so are linearly dependent. Then some sum $\Sigma_{i=0}^{n} a_i t^i = 0$. We can choose n minimal and assume by dividing by a_n that $a_n = 1$. If $a_n = 1$, we say that a polynomial is monic. We then get a polynomial $p(t) = 0$ of minimal degree called the minimal polynomial of t. If $f(t) = 0$ for any other polynomial $f(x)$, divide $p(x)$ into $f(x)$. Then $r(t) = f(t) - q(t)p(t) = 0$. If $r(x) \neq 0$ it would have lower degree than $p(x)$ by minimality. Therefore, $p(x)$ divides every other polynomial $f(x)$ such that $f(t) = 0$. Also by minimality $1, t, t^2, \ldots, t^{n-1}$ are linearly independent. The polynomial $p(x)$ must also be prime; else if $p(x) = r(x)s(x)$ then one of $r(t), s(t) = 0$. Prime polynomials are called irreducible.

We next show that $1, t, t^2, \ldots, t^{n-1}$ are a basis for $\mathbf{F}(t)$. They are linearly independent. Since $t^n = \Sigma_{i=0}^{n-1} a_i t^n$, $t^{n+j} = \Sigma_{i=0}^{n-1} a_i t^{i+j}$, every power of t can be expressed as a linear combination of $1, t, t^2, \ldots, t^{n-1}$. Therefore, their span is a subring. Suppose $f(t) \neq 0$. Then $p(x)$ does not divide $f(x)$. Since $p(x)$ is prime, 1 is a g.c.d. of $p(x)$, $f(x)$. For some $r(x), s(x)$, $r(x)p(x) + s(x)f(x) = 1$. So $s(t)f(t) = 1$ and $s(t)$ is an inverse of $f(t)$. Therefore, the span of $1, t, t^2, \ldots, t^{n-1}$ is closed under division and is a field. So it must be the field $\mathbf{F}(t)$ generated by t.

There exists a homomorphism h from the ring of polynomials $\mathbf{F}[x]$ to $\mathbf{F}(t)$ defined by $h(f(x)) = f(t)$. From the usual laws of algebra it is a ring homomorphism that is also onto.

The kernel is the set of polynomials $f(x)$ such that $f(t) = 0$. We have already shown that this is the set of polynomials divisible by $p(x)$, or the ideal $p(x)\mathbf{F}(x)$ generated by $p(x)$.

Therefore, in summary of these results, let $p(x)$ be the minimum polynomial, of degree n, of t. Then $[\mathbf{F}(t):\mathbf{F}] = n$ with basis $1, t, t^2, \ldots, t^{n-1}$. The field $\mathbf{F}(t)$ is isomorphic to the quotient ring $\mathbf{F}[x]/p(x)\mathbf{F}[x]$, where $\mathbf{F}[x]$ is the ring of all polynomials in an indeterminate x.

Conversely, let $p(x)$ be a monic irreducible polynomial. Then we will show that $\mathbf{F}[x]/p(x)\mathbf{F}[x]$ is an extension field of $\mathbf{F}$ in which $t = \bar{x}$ has minimum polynomial $p(x)$. For any $f(x)$ such that $f(\bar{x}) \neq 0$, there will exist $r(x), s(x)$ such that $r(x)f(x) + s(x)p(x) = 1$ since f, p have g.c.d. 1. So $f(t)$ has an inverse $r(t)$ and the quotient ring is a field.

C. Applications to Solvability and Constructibility

The problem of solving quadratic equations goes at least back to the Babylonians. In the ninth century, the Muslim mathematician Al-Khwarismi gave a version of the modern quadratic formula. In the mid-sixteenth century, Italian mathematicians reduced the solution of a cubic equation to the form

$$x^3 + mx = n$$

by dividing it by the coefficient of x^3 and making a substitution replacing x by some $x - c$. They then solved it as

$$x = a - b$$

$$a = \sqrt[3]{(n/2) + \sqrt{(n/2)^2 + (m/3)^3}}$$

$$b = \sqrt[3]{-(n/2) + \sqrt{(n/2)^2 + (m/3)^3}}.$$

They proceeded to solve quartic equations by reducing them to cubics. But no one was able to solve the general quintic using nth roots and in 1824 N.H. Abel proved this is impossible. E. Galois in his brief life proved this also, as part of a general theory that applies to all polynomials. This is based on field theory, and we describe it next.

In the extensions $\mathbf{F}(t)$, one root of a polynomial $p(t)$ has been added, or adjoined, to $\mathbf{F}$. Extensions obtained by adding all roots of a polynomial are called normal extensions. The roots can be added one at a time in any order.

Finite dimensional normal extensions can be studied by finite groups called Galois groups. The Galois group of a normal extension $\mathbf{F} \subset \mathbf{E}$ is the group of all field automorphisms of $\mathbf{E}$ that are the identity on $\mathbf{F}$. It will, in effect, permute the roots of a polynomial whose roots generate the extension. For example, let $\mathbf{F} = \mathbf{Q}(\xi)$ and let $\mathbf{E} = \mathbf{F}(\sqrt[3]{2})$, where $\xi = (-1 + i\sqrt{3})/2$. Then an automorphism of $\mathbf{E}$ exists taking $\sqrt[3]{2} \to \xi\sqrt[3]{2}$, $\xi\sqrt[3]{2} \to \xi^2(\sqrt[3]{2})$, $\xi^2(\sqrt[3]{2}) \to \sqrt[3]{2}$. The Galois group is cyclic of order 3, generated by this automorphism. Since the ratio ξ of two roots goes to itself, it is the identity on $\mathbf{Q}(\xi)$.

The order of the Galois group equals the degree of a normal extension. Moreover, there is a 1–1 correspondence between subfields $\mathbf{F} \subset \mathbf{K} \subset \mathbf{E}$ and subgroups of $H \subset G$, the Galois group of $\mathbf{E}$ over $\mathbf{F}$. To a subgroup H is associated the field $\mathbf{K} = \{x \in \mathbf{E} : f(x) = x \text{ for all } f \in \mathbf{K}\}$.

A splitting field of a polynomial p over a field $\mathbf{F}$ is a minimal extension of $\mathbf{F}$ over which p factors into factors

of degree 1. It is a normal extension and any two splitting fields are isomorphic.

Suppose a polynomial p is solvable by radicals over $\mathbf{Q}$. Let $\mathbf{E}$ be the splitting field of p over $\mathbf{Q}$. Each time we extract a radical the roots of the radical generate a normal extension $\mathbf{F_1}$ of a previous field $\mathbf{F_2}$. Let $\mathbf{E_i} = \mathbf{F_i} \cap \mathbf{E}$. Then $\mathbf{F_2}$ over $\mathbf{F_1}$ has cyclic Galois group, so $\mathbf{E_2}$ over $\mathbf{E_1}$ does also.

It follows that there exist a series of extensions $\mathbf{Q} = \mathbf{D_0} \subset \mathbf{D_1} \subset \cdots \subset \mathbf{D_n} = \mathbf{E}$ each normal over the preceding such that the Galois group of each over the other is cyclic. It follows that the Galois group G has a series of subgroups $G_n = \{e\} \subset G_{n-1} \subset \cdots \subset G_0 = G$ such that g_i is a normal subroup of G_{i-1} with cyclic quotient group. Such a group is called solvable.

The symmetric group of degree 5 has as its only nontrivial proper normal subgroup the alternating group which is simple. Therefore, it is not solvable. If $\mathbf{F}(x)$ is a degree 5 irreducible polynomial over $\mathbf{Q}$ with exactly two nonreal roots, there exists an order 5 element in its Galois group just because 5 divides the degree of the splitting field. Complex conjugation gives a transposition. Therefore, the Galois group is $\mathcal{S}_5$. So polynomials of degree 5 cannot in general be solved by radicals.

Conversely, it is true that every normal extension $\mathbf{E} \subset \mathbf{F}$ with cyclic Galois group can be generated by radicals. It can be shown that there is a single element θ such that $\mathbf{E} = \mathbf{F}(\theta)$ (consider all linear combinations θ of a basis for $\mathbf{E}$ over $\mathbf{F}$, and there being a finite number of intermediate fields).

Let the extension be cyclic of order n and let τ be such that $\tau^n = 1$ but no lower power. Let the automorphism g generate the Galois group. Let $t = \theta + \tau g(\theta) + \cdots + \tau^{n-1} g^{n-1}(\theta)$. Then t has n distinct conjugates (assuming $\tau \in \mathbf{F}$) $g^i(\theta) + \tau g^{i+1}(\theta) + \cdots + \tau^{n-1} g^{n-1+i}(\theta)$ and so its minimum polynomial has degree n. Since $g(t) = \tau^{-1}(t)$, the element $t^n = a$ is invariant under the Galois group and lies in $\mathbf{F}$. So $\theta, g(\theta), \ldots, g^{n-1}(\theta)$ lie in the splitting field of $x^n = a$, which must be $\mathbf{E}$.

Geometric constructions provide an application of field theory. Suppose we are given a unit line segment. What figures can be constructed from it by ruler and compass? Let the segment be taken as a unit length or the x axis. Wherever we construct a new point from existing ones by ruler and compass it is an intersection of a line or circle with a line or circle. Such intersections lead to quadratic equations. Therefore, if a point P is constructible, each coordinate must be obtained from rational numbers by adding, subtracting, multiplying, dividing, or taking square roots. Such quantities lie in an extension field of $\mathbf{E} \subset \mathbf{Q}$ such that there exist fields $\mathbf{E_0} = \mathbf{Q} \subset \mathbf{E_1} \subset \cdots \subset \mathbf{E_k} = \mathbf{E}$ and $\mathbf{E_n} = \mathbf{E_{n-1}}(\sqrt{a})$ for $a \in \mathbf{E_{n-1}}$. The degree of $[\mathbf{E} : \mathbf{Q}] = [\mathbf{E_n} : \mathbf{E_{n-1}}] \cdots [\mathbf{E_1} : \mathbf{E_0}]$ is a power of 2.

Therefore, if x is a coordinate of a constructible point, x lies in an extension of degree 2^n, in fact a normal extension of degree 2^n. But if $[\mathbf{Q}(x) : \mathbf{Q}]$ has degree not a power of 2, this is impossible since $[\mathbf{E} : \mathbf{Q}] = [\mathbf{E} : \mathbf{Q}(x)][\mathbf{Q}(x) : \mathbf{Q}]$.

In particular, duplicating a cube (providing a cube of volume precisely 2) and trisecting an angle of 60° lead to roots of irreducible cubics $x^3 - 2 = 0$ and $4\cos^3\theta - 3\cos\theta - \cos 60^\circ = 0$ and cannot be performed. Since π does not satisfy any monic polynomial with coefficients in $\mathbf{Q}$, the circle cannot be squared.

D. Finite Fields

The fields $\mathbf{Z_p}$ where p is a prime number are fields with a finite number of elements. All finite fiels have $n1 = 0$ for some n and are therefore extension fields of some $\mathbf{Z_p}$. If $\mathbf{Z_p} \subset \mathbf{E}$, then $\mathbf{E}$ is a vector space over $\mathbf{Z_p}$. Let $x_1, x_2, \ldots, x_n$ be a basis. Then all elements of $\mathbf{E}$ can be uniquely expressed as linear combinations $\Sigma c_i x_i$, where $c_i \in \mathbf{Z_p}$. This set has cardinality $|\{(c_1, c_2, \ldots, c_n)\}| = |\mathbf{Z_p^n}| = p^n$. So $|\mathbf{E}| = p^n$ if $[\mathbf{E} : \mathbf{Z_p}] = n$.

Let $\mathbf{E}$ have order p^n. Then the multiplicative group $\mathbf{E}^*$ has order $p^n - 1$. So every element has order dividing $p^n - 1$. So if $r \neq 0, r^{p^n - 1} = 1$. So for all $r \in \mathbf{E}$, $r^{p^n} = r$. Then for all $r \in \mathbf{E}$, $x - r$ divides the polynomial $x^{p^n} - x$. Therefore $x^{p^n} - x$ factors as precisely the product of $x - r$ for all $r \in \mathbf{E}$. Therefore, if m is a divisor of $p^n - 1$, the equation $x^m - 1$ divides $x^{p^n - 1} - 1$ and splits into linear factors. As with $\mathbf{Z_p}$ this means we can get an element u_i of order a maximum power of each prime dividing $p^n - 1$ and their product will have order $p^n - 1$ and generate the group. So $\mathbf{E}^*$ is cyclic.

Since $p | p!$ but not $r!$ for $r < p$, p prime we have $p | \binom{p}{r}$. In $\mathbf{E}$ since $p1 = 0$, every element satisfies $x + x + \cdots + x = px = 0$. So $(x + y)^n = \Sigma \binom{n}{r} x^r y^{n-r}$ by the binomial theorem, which holds in all commutative rings. In $\mathbf{E}^*$, $(x+y)^p = x^p + y^p$ since other terms are divisible by p. This implies by induction, $(x + y)^{p^r} = x^{p^r} + y^{p^r}$. Therefore, x^{p^r} is an automorphism of $\mathbf{E}$.

This gives a cyclic group of order n of automorphisms of $\mathbf{E}$ since if y generates the cyclic group then $y^{p^i} \neq y$ for $i < n$. This is the complete automorphism group of $\mathbf{E}$.

If an element z lies in a proper subfield $\mathbf{F}$ of $\mathbf{E}$, then $\mathbf{F}$ has order p^k and $k | n$ and $z^{p^k} = z$. Conversely, the set of $\{z : z^{p^k} = z\}$ is closed under sums and products and multiplicative inverses so it is a proper subfield. So if $z^{p^k} = z$ then z lies in a proper subfield.

For any irreducible polynomial $p(x)$ of degree k over $\mathbf{Z_p}$, there exists a field $\mathbf{H} = \mathbf{Z_p}[x]/p(x)\mathbf{Z_p}[x]$. It has degree k and so order p^k. If $t = \bar{x}$, then it is $\mathbf{Z_p}(t)$ where $p(t) = 0$ is the minimum polynomial of t. Since $t^{p^k} - t = 0$, we have $p(x) | x^{p^k} - x$, and if $k | n$, then $p(x) | x^{p^k} - x | x^{p^n} - x$.

Suppose $p(x)|x^{p^n}-x$ and is irreducible of degree k, $k \not| n$. Then in $\mathbf{Z_p}(t)$ of degree k we would have $t^{p^n}=t$ and so for all r in the field $r^{p^n}=r$. This is false. So an irreducible polynomial divides $x^{p^n}-x$ if and only if its degree divides n.

The derivative can be defined for polynomials in $\mathbf{Z_p}[x]$ and satisfies the usual sum, product, power rules. If $x^{p^n}-x=q(x)(p(x))^2$, then $(d/dx)(x^{p^n}-x)=-1=q'(x)(p(x))^2+2q(x)p(x)p'(x)$. So $p(x)$ divides -1. For p of degree greater than zero, this is false. Therefore, $x^{p^n}-x$ has each irreducible polynomial of degree k dividing n exactly once as a factor.

Suppose $x^{p^n}-x$ has no irreducible factors of degree n. Then all its factors divide $x^{p^k}-x$, $k<n$. So $x^{p^n}-x|(x^{p^{n-1}}-x)\cdots(x^p-x)$. Since $x^{p^n}-x$ has higher degree this is false. So $x^{p^n}-x$ has an irreducible factor $g(x)$ of degree n. Therefore, a field $\mathbf{H}$ exists of order exactly p^n.

Any field $\mathbf{F}$ of order p^n has an element r such that $x-r|g(x)|x^{p^n}-x$ since $x^{p^n}-x$ factors into linear factors. Then r has minimum polynomial $g(x)$. It follows that $\mathbf{Z_p}(r)$ has degree n and equals $\mathbf{F}$. And $\mathbf{F}$ is isomorphic to $\mathbf{H}$. So any two fields of order p^n are isomorphic.

E. Codes

Coding theory is concerned with the following problem. Consider information in the form of sequences $a_1a_2\cdots a_m$ over a q-element set assumed to be a finite field $\mathbf{F}$ of order q. We wish to find a function f encoding $a_1a_2\cdots a_m$ as another sequence $b_1b_2\cdots b_n$ such that, if an error of specified type occurs in the sequence (b_i), the sequence (a_i) can still be recovered. There should also be a readily computable function g giving $a_1a_2\cdots a_m$ from $b_1b_2\cdots b_n$ with possible errors. We assume any t or fewer errors could occur in (b_i).

We consider $a_1a_2\cdots a_m$ as an m-dimensional vector $(a_1, a_2, \ldots, a_m)$ over $\mathbf{F}$, that is, $a\in\mathbf{V_m}$ and (b_i) as a vector $b\in\mathbf{V_n}$. Therefore, a coding function is a function $\mathrm{f}:\mathbf{V_m}\to\mathbf{V_n}$. The resulting code is its image of C where $C\subset\mathbf{V_n}$.

Suppose two vectors v, w in a code differ in at most $2t$ places. Then let z agree with v in half these, w the other half, and agree with v and w where they agree. Then z could have been either v or w. Error correction is impossible.

Conversely, if two vectors v, w could give rise to the same vector z by at most t errors each, then they differ in at most $2t$ places.

Therefore, a code can correct t errors if and only if every pair of vectors differ in at least $2t+1$ places.

For such a code, $q^n\geq q^m(\binom{n}{0}+(q-1)\binom{n}{1}+\cdots+(q-1)^t\binom{n}{t})$ since the kth term on the right is the number of vectors that differ from a code vector on exactly r places, and for $r\leq t$ all these are distinct.

A perfect code is one such that equality holds. A linear code is one that is a subspace of $\mathbf{V_n}$. A cyclic code is a linear code in which each cyclic rearrangement $b_1b_2\cdots b_n\to b_nb_1\cdots b_{n-1}$ of a code vector is a code vector.

Let $\mathbf{V_n}$ be considered as the set of polynomials of degree less than n in x. Then cyclic rearrangement is multiplication by x if we set $x^n=1$. Therefore, cyclic codes are subspaces closed by multiplication by x in

$$\frac{\mathbf{F}[x]}{(x^n-1)\mathbf{F}[x]}$$

and are therefore ideals.

Such an ideal is generated by a unique monic irreducible polynomial $g(x)$. Let γ be an element of an extension field of $\mathbf{F}$ such that $\gamma^n=1$ but no lower power is 1. Let $g(x)$ be the least common multiple of the minimum polynomials of $\gamma^1, \gamma^2, \ldots, \gamma^{d-1}$, where $d\leq n$, d is relatively prime to n. Then $g(x)|x^n-1$ since all powers of γ are roots of x^n-1. By a computation involving determinants no element of the ideal of $g(x)$ can have fewer than d nonzero coefficients. So $t=(d-1)/2$ errors can be corrected. The number m is n minus the degree of $g(x)$. These are called the BCH (Bose–Chaudhuri–Hoquenghem) codes and if $n=q-1$ Reed–Solomon codes.

F. Applications to Latin Squares

An $n\times n$ Latin square is a matrix whose entries are elements of an n-element set such that each number occurs exactly once in every row and column. The following cyclic Latin square occurs for all n:

$$\begin{bmatrix} 1 & 2 & \cdots & n \\ 2 & 3 & \cdots & 1 \\ \cdots & \cdots & & \\ n & 1 & \cdots & n-1 \end{bmatrix}$$

Two Latin squares (a_{ij}), (b_{ij}) are orthogonal if for all i, j, the ordered pairs (a_{ij}, b_{ij}) are distinct.

Orthogonal Latin squares are used in experiments in which several factors are tested simultaneously. In particular, suppose we want to test 5 fertilizers, 5 soil types, 5 amounts of heat, and 5 plant varieties. Choose 5×5 orthogonal Latin squares. Take an experiment with variety i, heat amount j, soil type a_{ij}, fertilizer b_{ij} for all i, j, and n^2 experiments. Then for any two factors, each variation on one factor occurs in combination with each for the other factor exactly once. If we have k mutually orthogonal Latin squares we can test $k+2$ factors.

Suppose $n=p_1^{n_1}p_2^{n_2}\cdots p_r^{n_r}$, where p_i is a prime number. Let R be the direct product of fields of order $p_i^{n_i}$. Let $k=\inf\{p_i^{n_i}-1\}$. Choose k invertible elements from each field, $x_{ij}: i=1,2,\ldots,k;\ j=1,2,\ldots,r$. Then the

elements $z_i = (x_{i1}, x_{i2}, \ldots, x_{ir})$ are invertible and the difference of any two is invertible.

Define r, $n \times n$ Latin squares $M\langle s\rangle$ by $m\langle s\rangle_{ij} = z_s y_i + y_j$, where y_i, y_j run through all elements of R. Then this function is 1–1 in y_j. Since z_r is invertible, it is 1–1 in y_i. From the fact that $z_s - z_t$ is invertible, it follows that $(m\langle s\rangle_{ij}, m\langle t\rangle_{ij}) \neq (m\langle s\rangle_{hk}, m\langle t\rangle_{hk})$ unless $i = h$ and $j = k$. So all the square are orthogonal. If n is a prime power, then $n-1$ is the maximum number of orthogonal $n \times n$ Latin squares. However, there exists a pair of orthogonal $n \times n$ Latin squares for all $n \neq 2$, 6 constructed by R. C. Bose, S. S. Shrikhande, and E. T. Parker in 1958. The existence of 10×10 Latin squares disproved a long-standing conjecture of Euler.

A $k \times m$ orthogonal array is a $k \times m$ matrix (a_{ij}) such that for any $i \neq j$ the ordered pairs a_{is}, a_{js} are distinct for $s = 1$ to m.

An $(m+2) \times n^2$ orthogonal array with entries from an n-element set yields m mutually orthogonal Latin squares. The first two rows run through all pairs (i, j) so let $m\langle r\rangle_{ij}$ be the entry in row $r+2$ such that rows 1, 2 have entries (i, j) in that place.

For n a prime power congruent to 3 modulo 4, an orthogonal $4 \times n^2$ array can be constructed. Let $\mathbf{F}$ be a field of order n and let g generate $\mathbf{F}^*$ its multiplicative group. Because of the congruence condition -1 will not be a square in $\mathbf{F}$. Let $y_1, y_2, \ldots, y_k$, $k = \frac{1}{2}(n-1)$, be distinct symbols not in $\mathbf{F}$. Take as columns of the array all columns of the types shown in Table IV, where x ranges through $\mathbf{F}$, and i independently varies from $1, 2, \ldots, \frac{1}{2}(n-1)$, together with n columns

$$\begin{bmatrix} x \\ x \\ x \\ x \end{bmatrix}, \qquad x \in \mathbf{F}$$

and $(n-1)^2/4$ columns corresponding to a pair of orthogonal Latin squares of size $(n-1)/2 \times (n-1)/2$ with entries $y_1, y_2, \ldots, y_k$. This gives an orthogonal array yielding, for example, two 10×10 orthogonal Latin squares.

G. Applications to Projective Planes

A projective plane is a mathematical system with a binary relation called incidence (lying on) from a set P called the set of points to a set L called the set of lines, satisfying three axioms: (1) Exactly one line is determined by two distinct points; (2) two lines intersect in exactly one point; and (3) there exist four points no three of which are collinear. The last axiom is only to guarantee that the system does not reduce to various special cases.

TABLE IV Columns Used to Construct Two Orthogonal Latin Squares

y_i	$g^{2i}(g+1)+x$	$g^{2i}+x$	x
x	y_i	$g^{2i}(g+1)+x$	$g^{2i}+x$
$g^{2i}+x$	x	y_i	$g^{2i}(g+1)+x$
$g^{2i}(g+1)+x$	$g^{2i}+x$	x	y_i

Let $\mathfrak{D}$ be any division ring. Left modules over $\mathfrak{D}$ have many of the properties of vector spaces. Let $\mathfrak{S} = \mathfrak{D} \times \mathfrak{D} \times \mathfrak{D}$ as a left module. Let $\mathfrak{P}$ be the set of submodules of the form $\mathfrak{D}x$, $x \in \mathfrak{S}$. Let $\mathfrak{L}$ be the set of submodules of the form $\mathfrak{D}x + \mathfrak{D}y$, $x, y \in \mathfrak{S}$, where $x \neq dy$ for any $d \in \mathfrak{D}$. Then $\mathfrak{P}$ and $\mathfrak{L}$ are essentially one- and two-dimensional subspaces of $\mathfrak{S}$. Let incidence be the relation $U \subset V$. Then we have a projective plane. A choice of $\mathfrak{P} = \mathbf{R}$ gives the standard geometric projective plane. This type of projective plane is characterized by the validity of the theorem of Desargues.

Many more general systems also give rise to projective planes. A ternary ring (or groupoid) is a set $\mathbf{R}$ with an operation $\mathbf{R} \times \mathbf{R} \times \mathbf{R}$ to $\mathbf{R}$ denoted $x \circ m * b$. Every projective plane can be realized with $\mathfrak{P}$ the set $\mathbf{R} \times \mathbf{R} \cup \mathbf{R} \cup \{\infty\}$, where $\mathbf{R} \times \mathbf{R}$ is considered as a plane for the ternary ring, $\mathbf{R} \cup \{\infty\}$ the points on a line at infinity. Incidence is interpreted set theoretically by membership, and lines consist of sets $y = x \circ m * b$ together with a line at infinity. Necessary and sufficient conditions that the ternary ring give a projective plane are that for some $0, 1 \in \mathbf{R}$, for all $x, m, b, y, k \in \mathbf{R}$: (TR-1) $0 \circ m * b = x \circ 0 * b = b$; (TR-2) $1 \circ m * 0 = m \circ 1 * 0 = m$; (TR-3) there exists a unique z such that $a \circ m * z = b$; (TR-4) there exists a unique z such that $z \circ m * b = z \circ k * a$ if $k \neq m$; and (TR-5) there exist unique z, w such that $a \circ z * w = x$ and $b \circ z * w = y$ if $a \neq b$.

Finite fields give ternary rings $xm + b$ of all prime power orders. It is unknown whether ternary rings (TR-1) to (TR-5) exist not of prime power order. If $|\mathbf{R}| = m$, then $|\mathfrak{P}| = |\mathfrak{L}| = m^2 + m + 1$.

Projective planes are essentially a special case of block designs. A balanced incomplete block design of type (b, v, r, k, λ) consists of a family B_i, $i = 1$ to b of subsets of a set V having v elements such that (1) $|B_i| = k > \lambda$ for all i; (2) $|\{i : x \in B_i\}| = r$ for all $x \in V$; and (3) $|\{i : x \in B_i$ and $y \in B_i\}| = \lambda$ for all $x \in V$, $x \neq y$. These are also used in design of experiments where B_i is the ith set of experiments and V the set of varieties tested.

Let $A = (a_{ij})$ be the matrix such that $a_{ij} = 1$ if and only if the ith element of V occurs in B_i. Then $AA^{\mathrm{T}} = \lambda J + (r-\lambda)I$ and all column sums of A are k, where J is a matrix all of whose entries are 1. Moreover, these properties characterize balanced incomplete block designs. For $k = 3$, $\lambda = 1$, designs are called Steiner triple systems.

A permutation group G acting on a set S is called doubly transitive if for all $x \neq y, u \neq v$ in S there exists g in G with

$gx = u$ and $gy = v$. If $T \subset S$, then the family of subsets $\{B_i\} = \{g(T)\}$ forms a balanced incomplete block design.

VII. OTHER ALGEBRAIC STRUCTURES

A. Groupoids

As mentioned before, a groupoid is a set having one binary operation satisfying only closure. For instance, in a finite group, the operation $aba^{-1}b^{-1}$ called the commutator gives a groupoid. Congruences and homomorphism on groupoids are defined in the same way as for semigroups, and for every congruence there is a quotient groupoid. Sometimes as in topology, groupoids are used to construct quotient groupoids which are groups.

Groupoids are also used in combinatorics. For example, any $n \times n$ Latin square, its entries labeled $1, 2, \ldots, n$ is equivalent to a groupoid satisfying (q) any two of a, b, c determines the third uniquely in $ab = c$. A groupoid satisfying (q) is called a quasigroup. A loop is a quasigroup with two-sided identity. Figure 9 classifies some one-operation structures.

B. Semirings

A semiring is a system in which addition and multiplication are semigroups with distributivity on both sides. Any Boolean algebra and any subset of a ring closed under addition and multiplication as the nonnegative elements in **Z** or **R** are semirings. The set of matrices over a semiring with 0, 1 comprises a semiring with additive and multiplicative identity.

A homomorphism of semirings is a function f from $\mathfrak{R}$ to $\mathfrak{S}$ such that $f(x+y) = f(x) + f(y)$, and $f(xy) = f(x)f(y)$ for all $x, y \in \mathfrak{R}$. The equivalence relation $\{(x, y) : f(x) = f(y)\}$ is a congruence. This means that, if $x \sim y$, then $x + z \sim y + z$, $xz \sim yz$, and $zx \sim yz$ for all $z \in \mathfrak{R}$. Conversely, for every congruence there is a quotient semiring and a homomorphism to the quotient semiring $x \to \bar{x}$.

If the semiring is partially ordered, so are the semirings of n-square matrices over it.

Just as Boolean matrices represent binary relations, so matrices over semirings on $[0, 1]$ can represent relations in which there is a concept of degree of relationship. One widely used semiring is the fuzzy algebra in which the operations are $\sup\{x, y\}$, $\inf\{x, y\}$, giving a distributive lattice. Fuzzy matrices have applications in clustering theory, where objects are partitioned into a hierarchy of subsets on the basis of a matrix $C = (c_{ij})$ giving the similarity between objects i and j. Applications of fuzzy matrices are also found in cybernetics.

Inclines are a more general class of semirings. An incline is a semiring satisfying $x + x = x$, $xy \leq x$, and $xy \leq y$ for all x, y. The set of two-sided ideals in any ring or semigroup forms an incline. The additive operation in an incline makes it a semilattice and, under weak restrictions such as compactness of intervals, a lattice. In a finitely generated incline for every sequence (a_i), $i \in \mathbf{Z}^+$, there exist $i < j$ with $a_i \geq a_j$. The set of n-square matrices over an incline is not an incline under matrix multiplication but is one under the elementwise product given by $(a_{ij}) \odot (b_{ij}) = (a_{ij} b_{ij})$. Inclines can be used to study optimization problems related to dynamic programming.

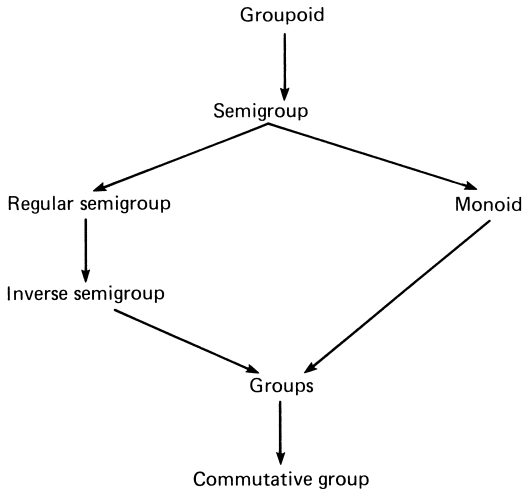

FIGURE 9 Classification of one-operation structures.

C. Nonassociative Algebras and Higher Order Algebras

A nonassociative ring is a system having two binary operations satisfying all the axioms for a ring except associativity of multiplication. A nonassociative algebra $\mathfrak{A}$ over a field **F** in addition is a vector space over the field satisfying the algebra property $a(bc) = b(ac) = (ab)c$ for all $a \in \mathbf{F}$, $b, c \in \mathfrak{A}$. There exists a nonassociative eight-dimensional division algebra over the real numbers called the Cayley numbers. It is an alternative ring, that is, $(yy)x = y(yx)$, and $(yx)x = y(xx)$ for all x, y. It has applications in topology and to projective planes.

A Lie algebra is an algebra in which for all a, b, c the product denoted $[a, b]$ satisfies (L-1) $[a, a] = 0$; (L-2) $[a, b] + [b, a] = 0$; and (L-3) $[[a, b], c] + [[b, c], a] + [[c, a], b] = 0$. In any associative algebra, the commutators $[a, b] = ab - ba$ define a Lie algebra. Conversely, for any Lie algebra an associative algebra called the universal enveloping algebra can be defined such that the Lie algebra is a subalgebra of its algebra of commutators. In many topological groups, for every element a there exists

a parametrized family $b(t), t \in \mathbf{R}$ of elements such that $b(1)=a$, $b(t+s)=b(t)b(s)=b(s)b(t)$. The operation $b(t)c(t)$ is commutative up to first order in t as $t \to 0$ and defines a real vector space. The operation $b(t)c(t)b^{-1}(t)c^{-1}(t)$ taken to second order in t then defines a Lie algebra. All finite dimensional connected, locally connected continuous topological groups can be classified using Lie algebras.

For any group G, let $\Gamma_i(G)$ denote the subgroup generated by all products of i elements under the operation of group commutator $xyx^{-1}y^{-1}$. Then $\Gamma_i(G)$ is a normal subgroup and $\Gamma_i(G)/\Gamma_{i+1}(G)$ is an Abelian group. Commutators give a product from $\Gamma_i(G)/\Gamma_{i+1}(G) \times \Gamma_j(G)/\Gamma_{j+1}(G)$ to $\Gamma_{i+j}(G)/\Gamma_{i+j+1}(G)$ satisfying (L-1) to (L-3). Such a structure is called a Lie ring. The sequence of normal subgroups $\Gamma_i(G)$ is called the lower central series.

A (noncommutative) Jordan algebra is a nonassociative algebra such that $(x^2y)x = x^2(yx)$, and $(xy)x = x(yx)$. Commutative Jordan algebras are used in constructing exceptional Lie algebras. For any associative algebra, the product $xy + yx$ defines a commutative Jordan algebra. They also are used in physics.

A median algebra is a set S with ternary product xyz such that (1) xyz is unchanged under any permutation of x, y, z; (2) $(x(xyz)w) = (xy(xzw))$; and (3) $xyy = y$ for all x, y, z, w. The product in any two factors is then a semilattice. The set of n-diemensional Boolean vectors is a median algebra under the componentwise product that xyz equals whichever of x, y, z is in the majority. The set of linear orders on n elements is a median algebra under the same operation.

D. Varieties

As mentioned earlier an algebraic operation on a set S is a function $S^n = S \times S \times \cdots \times S$ to S for some positive integer n. An operational structure is any labeled collection of operations on a set S. A substructure is a subset closed under all operations. A congruence is an equivalence relation such that for each operation if $x_i = y_i$ for $i \neq j$ and $x_j \sim y_j$, then $f(x_1, x_2, \ldots, x_n) \sim f(y_1, y_2, \ldots, y_n)$. Multiplication is then uniquely defined on equivalence classes, which form a quotient structure. A homomorphism is a function h such that for each operation f and all $x_1, x_2, \ldots, x_n$ in the domain $h[f(x_1, x_2, \ldots, x_n)] = f[h(x_1), h(x_2), \ldots, h(x_n)]$. Its image will be a substructure of the structure into which f is defined. An isomorphism is a 1–1 onto homomorphism. The direct product of algebraic structures with operations of the same type is the product set with componentwise operations.

A law for an algebraic structures S is a relation which holds identically for all elements of the structure. That is, it asserts that a certain composition of operations applied $x_1, x_2, \ldots, x_n$ equals a certain other composition for all $x_1, x_2, \ldots, x_n$ in the set. The commutative, associative, and distributive laws for commutative rings form an example. A variety is the class of all structures satisfying given laws. Any law valid for a class of structures will also hold for their substructures, homomorphic images, and direct products of them. Conversely, suppose a class $\mathfrak{S}$ of structures is closed under taking of substructures, product structures, and homomorphic images. For any set of generators $\mathcal{g}$ we can construct an element of $\mathfrak{S}$ whose only relations are those implied by the general laws of $\mathfrak{S}$.

To do this we take one copy of each isomorphism class S_α of structues in $\mathfrak{S}$ that are either finite or have the same cardinality at most $|\mathcal{g}|$. Replicate these copies until we have one copy $S_{\alpha\beta}$ for every map $f_{\alpha\beta} : \mathcal{g} \to S_\alpha$. Take the direct product $\times S_{\alpha\beta}$ and the substructure $\mathbf{F}(\mathcal{g})$ generated by the image of $\mathcal{g}$ under each. Then by construction any relation among these generators must hold identically in all the S_α and thus be a law. It follows that the relations of $\mathcal{g}$ conicide with laws of $\mathfrak{S}$.

If S is any structure in which the laws hold with $|S| = \mathcal{g}$, then the the relations of $\mathbf{F}(\mathcal{g})$, being laws of $\mathfrak{S}$, hold is S. In particular, there will then be an onto homomorphism from $\mathbf{F}(\mathcal{g})$ to S. This proves that a class is a variety if and only if it is closed under taking substructures, product structures, and homomorphic images. Much work has been done on classifying varieties, especially groups.

Quasivarieties of relational structures on a set S also exist but must be defined a little differently, as classes closed under isomorphism, structures induced on subsets, and product structures. Laws are of three types. For a collection of variables $x_1, x_2, \ldots, x_n$ take a collection T_α of m-tuples from $x_1, x_2, \ldots, x_n$ for each m-ary relation R. For all replacements of x_i by elements of the set T either (1) if for all α, all members of T_α belong in R, then $(x_{i(1)}, x_{i(2)}, \ldots, x_{i(k)}) \in R$, where $i(1), i(2), \ldots, i(n) \in \mathbf{Z}^+$; (2) if for all α, all members of T_α belong in R, then $(x_{i(1)}, x_{i(2)}, \ldots, x_{i(k)}) \notin R$; or (3) if for all α, all members of T_α belong in R, then $x_{i(1)} = x_{i(2)}$ for some $i(1), i(2) \in \mathbf{Z}^+$. The classes of reflexive, irreflexive, symmetric, and transitive binary relations are all quasivarieties.

E. Categories and Topoi

If we take algebraic structures of a given type and ignore the internal structure but consider only the homomorphisms that exist between them, then we have assentially a category. To be precise, a category consists of (1) a class $\mathfrak{S}$ called the class of objects together with (2) a set $\mathrm{Hom}(x, y)$ for all $x, y \in \mathfrak{S}$ called the set of morphisms from x to y; (3) a special morphism 1_x for each x in $\mathfrak{S}$ called the identity morphism; and (4) an operation from $\mathrm{Hom}(x, y) \times \mathrm{Hom}(y, z)$ to $\mathrm{Hom}(x, z)$ called composition

of morphisms. It is required that composition be associative when defined and that 1_x act as the identity element whenever composition with it is defined. The most fundamental category consists of all sets and all functions, between sets. Sets and binary relations form a category. There are categories in which $\mathrm{Hom}(x, y)$ does not consist of functions, for example, let C be a poset and let $\mathrm{Hom}(x, y) = (x, y)$ if $x \leq y$ and $\mathrm{Hom}(x, y) = \emptyset$ otherwise.

The category of all modules over a ring is an additive category: Morphisms can be added in a natural way.

The direct product of objects $K_1 \times K_2$ can be described in terms of categories by its universal property. This is that there exist mappings $\pi_i : K_1 \times K_2$ to K_i such that for any object A and any mappings $f_i : A$ to K_i there exists a unique mapping $h : A \to K_1 \times K_2$ such that $\pi_i(h(x)) = f_i(x)$. There exists a dual concept of direct sum, an object $K_1 \times K_2$ with mapping $g_j : K_j \to K_1 \times K_2$ such that for any object A and any mappings $f_j : K_j$ to A there exists a unique mapping $h : K_1 \times K_2 \to A$ such that $h(g_j(x)) = f_j(x)$.

More generally, in category theory, one works with finite diagrams, or graphs, in which each vertex is an object and each arrow a morphism. The limit of a diagram cosists of an object A and a mapping g_j from each object a_j of the diagram to A such that if there is an arrow $f : a_k \to a_j$, then $g_j(f(x)) = g_k(x)$ and for any other object H and mappings m_j with the same properties there exists a unqiue mapping $h : A \to H$ such that $h(g_j(x)) = m_j(x)$ for all j. A colimit is the dual concept. Any variety of relational structures, as the variety of commutative rings, has products, coproducts, limits, and colimits. Moreover, there is the trivial structure $\{0\}$ where any set of operations on zero gives zero. Any object has a unique mapping to zero.

A topos is a category with limits, colimits, products, coproducts, and a few additional properties: There exists an exponential object X^Y for any objects X, Y such that for any object X there is a natural isomorphism from $\mathrm{Hom}(Z, X^Y)$ to $\mathrm{Hom}(Z \times Y, X)$. In addition, there exists a subobject classifier, that is, an object Ω and a mapping called true from a point p to Ω such that there is a 1–1 correspondence between substructures of any object X and mappings $X \to \Omega$. The category of sets acted on the left by a fixed monoid M is a topos. In the category of sets itself $\Omega = \{0, 1\}$, where subsets T of a set S are in 1–1 correspondence with mappings $f : S \to \{0, 1\}$ such that $f(x) = 1$ if x is in T and $x = 0$ if $x \notin T$. Topoi have important applications to models in mathematical logic such as in Boolean-valued models used to show the independence of the continuum hypothesis in Zermelo–Frankel set theory.

A functor from one category C_1 to another category C_2 consists of an assignment of a unique object of C_2 to each object of C_1, a unique morphism of C_2 to each morphism of C_1 such that the objects involved correspond, the mappings 1_x go to identities, and composition is preserved. Group rings over a fixed ring give a functor from the category of groups to the category of rings.

F. Algebraic Topology

Algebraic topology is the study of functors from subcategories (subsets of the sets and morphisms of a category forming a category under the same operations) of the category of topological spaces and continuous mappings to categories of algebraic structures. These functors often allow one to deduce the nonexistence or existence of possible topological spaces or continuous mappings. If for some functor F and two topological spaces X, Y, $F(X)$ is not isomorphic to $F(Y)$, then X, Y cannot be topologically equivalent. In topology, any mapping between spaces is meant to be a continuous mapping.

Let $A(B)$ be a subset of the topological space $X(Y)$. A mapping from X, A to Y, B is a mapping $f : X \to Y$ such that $f(A) \subset B$. Two mapings f and $g : X, A \to Y$, B are called homotopic if there exists a mapping $h : \mathfrak{U} \times X, \mathfrak{U} \times A \to Y, B$ where $\mathfrak{U} = [0, 1]$ such that $h(0, x) = f(x)$, and $h(1, x) = g(x)$. This is an equivalence relation. Equivalence classes of mappings under homotopy form a new category called the homotopy category.

The first important functor from a category associated to the category of topological spaces to the category of groups is the fundamental group. Let x_0 denote any point of X. Homotopy classes of mappings f, g from $\mathfrak{U}, \mathfrak{V}$ (where $\mathfrak{V} = \{0, 1\}$) to X, x_0 can be multiplied by defining $f * g = h$ such that $h(t) = g(2t)$ for $0 \leq t \leq 0.5$ and $h(t) = g(2t - 1)$ for $0.5 \leq t \leq 1$. The product depends only on homotopy classes, and on homotopy classes is a group, where $f(1 - t)$ is the inverse of $f(t)$.

Every group is the fundamental group of some topological space, and every group homomorphism can be realized by a continuous mapping of some topological spaces.

Higher homotopy groups are defined in a similar way using an n-cube and its boundary in place of $\mathfrak{U}, \mathfrak{V}$.

Suppose a space Y is a topological groupoid; that is, there exists a continuous mapping $Y \times Y \to Y$. Then the set $[X : Y]$ of homotopy classes of mappings from X to Y is a groupoid for any topological space Y. If we let Y be a topological space whose only nonzero homotopy group is an Abelian group G in dimension n, called an Eilenberg–MacLane space, then $[X; Y]$ is a group called the nth cohomology group of X. All the cohomology groups together form a ring. From the cohomology groups of Eilenberg–MacLane spaces themselves can be obtained cohomology operations, that is, mappings from one cohomology group to another preserved by continous mappings.

A vector bundle over a topological space X is a vector space associated to each point of X such that the union of the vector spaces forms a topological space. An example is the tangent vectors to a surface. The K-theory of a topological space is essentially a quotient of the semigroup of vector bundles over X under the operation of direct sum of vector spaces. The equivalence class of a vector bundle V is the set of vector bundles W such that $U \oplus V$ is equivalent to $U \oplus W$ for some vector bundle U. K-Theory of X also equals $[X; Y]$ for a space Y which can be constructed from quotient groups of groups of n-square matrices.

By analogy-with topological constructions, researchers have defined homology and K-theory for rings and modules.

G. Inclines and Antiinclines

We have defined incline above as a semiring satisfying the incline inequality. The set of two-sided ideals in a ring (semigroup) for example forms an incline under $I + J(I \cap J)$ and IJ. Many results on Boolean and fuzzy matrices generalize to inclines. Green's relation $\mathcal{L}$- ($\mathcal{R}$-) classes in the semiring of matrices over an incline are characterized by equality of row, column spaces. In many cases the row, column spaces will have a unique basis. For the fuzzy algebra $[0, 1]$ under $\sup\{x, y\}$, $\inf\{x, y\}$, it is necessary to add the condition that if $c_i = \Sigma a_{ij} c_j$, $\{c_i\}$ the basis, then $a_{ii} c_i = c_i$. Matrices will have computable maximal subinverses $A \times A \leq A$, giving a way to test regularity.

In any finitely generated incline, no chain has an infinite nondecreasing subchain. Eigenvectors and eigenvalues can be described in terms of a power of a matrix. A particularly interesting incline is $[0, 1]$ under $\sup\{x, y\}$ and xy (ordinary multiplication).

The asymptotic forms of finite matrices can be described by the existence of positive integers k, d, and a matrix C such that

$$A^{k+nd} = A \odot C \odot \cdots \odot C$$

where $\odot$ denotes entrywise product.

Antiinclines are defined by the reverse inequalities $xy \geq x$ and $yx \geq x$. They have the dual nonascending chain property.

H. Quadratic Forms

A *quadratic form* over a ring $\mathcal{R}$ is a function $f(x) = \Sigma a_{ij} x_i x_j$, $a_{ij} \in \mathcal{R}$ from $\mathcal{R}^n \times \mathcal{R}^n$ to $\mathcal{R}$. Quadratic forms occur often in statistics and optimization and as the first nonlinear term in a power series, as well as in pure mathematics.

Two quadratic forms are *isomorphic* if they become identical after a linear invertible change of variables. A form is *isotropic* if nonzero x gives $f(x) = 0$. It is defined to be *totally isotropic* if $f(x) = 0$ identically, *hyperbolic* if it is isomorphic to a direct sum of forms $f(x) = x_1 x_2$ over $\mathcal{R}^2$, and *anisotropic* if it is not isotropic.

Over a field every quadratic form is uniquely expressible as the direct sum of an anisotropic form, a hyperbolic form, and a totally isotropic form up to equivalence. Cancellation holds for direct sum: if $h(x) \oplus f(x)$ is isomorphic to $h(x) \oplus g(x)$ then $f(x)$ is isomorphic to $g(x)$. It is then convenient to work with a ring of isomorphism classes of forms and their additive inverses called the *Witt-Grothendieck ring* $\hat{\mathcal{W}}$. The *Witt ring* $\mathcal{W}$ is generated by $\langle a \rangle$, the class of ax_{ij}^2 has operations induced by direct sum and tensor product, and is defined by relations $\langle 1 \rangle = 1$ $\langle a \rangle \langle b \rangle = \langle ab \rangle$, $\langle a \rangle + \langle b \rangle = \langle a + b \rangle (1 + \langle ab \rangle)$. Here $\hat{\mathcal{W}}$ is defined as $\hat{\mathcal{W}}/H$ where H is the ideal of hyperbolic forms. It is studied in terms of the filtration by powers of the ideal I generated by $\langle a \rangle - 1$.

Over the real numbers, rank [of the matrix (a_{ij})] and signature (the number of its positive eigenvalues, given $a_{ij} = a_{ji}$) are complete isomorphism invariants. Over the rational numbers the *strong Hasse principle* asserts that two forms are isomorphic if and only if they are isomorphic over each completion (real and p-adic) of the rationals. The *weak Hasse principle* asserts that a form is isotropic if and only if it is isotropic over each completion. A *complete set of invariants of nonsingular forms* is given by determinant $\det[(a_{ij})]$ and Hasse invariants at each prime. The Hasse invariant of a *quadratic form* $\Sigma a_{ii} x_i^2$ can be defined as

$$\prod_{i \leq j} (a_{ii}, a_{ij})$$

where $(a_{ii}, a_{jj}) = \pm 1$ according as $a_{ii} x^2 + a_{jj} y^2 = 1$ has a solution or not, over the p-adic numbers. The determinant, taken modulo squares is called the *discriminant*.

Milnor's theorem gives a description of the Witt ring of $\mathcal{K}(x)$, x transcendental in terms of the Witt ring of $\mathcal{K}$. The Tsen–Lang theorem asserts that if $\mathcal{K}$ has transcendance degree n over $\mathbf{C}$ then every quadratic form of dimension greater than 2^n is isotropic. The theory of quadratic forms is also related to that of division algebra.

I. Current and Recent Research

The greatest achievement in algebra itself since 1950 has been the classification of finite simple groups. Proofs are very lengthy and due to many researchers. Much progress has been made on decidability of algebraic problems, for example, the result that the word problem is unsolvable in general groups having a finite number of generators and

the solution of Hilbert's problem showing that polynomial equations in n variables over $\mathbf{Z}$ (Diophantine equation) are in general undecidable by Turning machines. The proof of Mordell's conjecture gives a positive step for equations of degree n in two variables over $\mathbf{Q}$. Another result in group theory was the construction of an infinite but finitely generated group G such that $x^m = e$ for all x in G and for a fixed m in $\mathbf{Z}^+$.

In algebraic geometry, a remarkable theory has been created leading to the proof of the Weil conjectures. This theory made it possible to prove that, for any Diophantine equation, it is decidable whether for every prime number p it has a solution modulo p. Much has been done with algebraic groups.

In coding theory, all perfect codes have been found. A pair of $n \times n$ orthogonal Latin squares have been constructed for all n except 2 and 6.

The entire subjects of homological algebra and algebraic K-theory have been developed. For a ring $\mathfrak{R}$, the following sequence

$$M_1 \xrightarrow{f_1} M_2 \xrightarrow{f_2} \cdots \xrightarrow{f_n} M_n$$

is called exact if $\mathrm{Im}(f_i) = \mathrm{Ker}(f_{i+1})$, where $\mathrm{Ker}(f)$ denotes the kernel of f. A free resolution of a module $\mathfrak{M}$ is an exact sequence $\cdots \to \mathfrak{C}_n \to \mathfrak{C}_{n-1} \to \cdots \mathfrak{C}_0 \to \mathfrak{M}$, where each $\mathfrak{C}_i$ is a free module. Another module $\mathfrak{N}$, gives a sequence

$$\cdots \leftarrow \mathrm{Hom}(\mathfrak{C}_n, \mathfrak{N}) \xleftarrow{g_n} \mathrm{Hom}(\mathfrak{C}_{n-1}, \mathfrak{N}) \xleftarrow{g_{n-1}} \cdots \xleftarrow{g_0} \mathrm{Hom}(\mathfrak{C}_0, \mathfrak{N})$$

The quotients $\mathrm{Ker}(g_{n+1})/\mathrm{Im}(g_n)$ are independent of the particular free resolution and are called $\mathrm{Ext}^n(\mathfrak{M}, \mathfrak{N})$. Whitehead's problem is whether if $\mathrm{Ext}^1(A, \mathbf{Z}) = 0$, then A is a direct sum of copies of $\mathbf{Z}$. S. Shelah proved this is independent of the axioms of Zermelo–Frankel set theory.

Considerable research has been done on order structures and on ordered algebraic structures in lattice theory and general algebra. Finite posets can be studied in ways similar to topological spaces, because they are equivalent to finite topological spaces. The theory of Boolean and fuzzy matrices has been developed with the advent of Green's relations classes. Inclines, semirings $(\mathfrak{R}, \circ, *)$ satisfying $x \circ x = x$, $x \circ (x * y) \circ (y * x) = x$ are a further generalization. The algebraic structure of semigroups, especially regular semigroups, has become well understood. In matrix theory and algebraic number theory, there have been numerous important developments such as the proof of the van der Waerden conjecture.

Mathematical linguistics and automata theory have become well-developed subjects.

Research is actively continuing in most of these areas as well as in category theory and the theory of varieties and combinatorial aspects of algebra.

In the 1990s quantum algebras has become a very active field. This deals with structures related to traditional algebraic structures in the way quantum physics is related to classical physics. In particular, a quantum group is a kind of Hopf algebra.

A somewhat related and active area is noncommutative algebraic geometry, in which a prominent place is occupied by the K-theoretic ideas of A. Connes.

GLOSSARY

Affine space The space of n-tuples with coordinates in a field K.
Algebraic set The set of solutions to a collection of polynomial equations in affine or projective space.
Coordinate ring Ring of polynomial functions on an algebraic set.
Curve An algebraic variety of dimension one.
Genus The fundamental invariant of curves, equal to the dimension of the space of regular 1-forms.
Moduli space A topological space (usually an algebraic variety itself) whose points represent algebraic varieties of a specific type.
Projective space The space of $(n+1)$-tuples with coordinates in a field K, not all zero, up to scalar factor. The natural compactification of affine space, which includes points at infinity.
Quadric An algebraic variety defined by a single quadratic equation.
Rational function A ratio of polynomial functions defined on an algebraic set in affine or projective space.
Regular function A rational function whose denominator does not vanish at a subset of an algebraic set.

ALGEBRAIC GEOMETRY is, broadly speaking, the study of the solutions of polynomial equations. Since polynomials are ubiquitous in mathematics, algebraic geometry has played a central role in the development and study of many mathematical ideas. Its origins can be traced to ancient Greek mathematics, when the study of lines and conics in the plane began. From these relatively simple beginnings, modern algebraic geometry has grown into a subject which draws on and informs nearly every other discipline in mathematics, and modern practitioners develop and use some of the most sophisticated "mathematical machinery" (including sheaves, cohomology, etc.) available. However, the subject is still rooted in fundamental questions about systems of polynomial equations; the complexity and apparent abstraction of some of the modern tools of practicing algebraic geometers should not be confused with a lack of concern for basic and accessible problems.

I. BASIC DEFINITIONS OF AFFINE GEOMETRY

A. Affine Space

To be more precise about solutions to polynomial equations, one first specifies a field k of numbers where the

coefficients of the polynomials lie, and where one looks for solutions. A field is a set with two binary operations (addition and multiplication) in which all of the usual rules of arithmetic hold, including subtraction and division (by nonzero numbers). The main examples of interest are the field $\mathbb{Q}$ of rational numbers, the field $\mathbb{R}$ of real numbers, and the field $\mathbb{C}$ of complex numbers. Another is the finite field $\mathbb{Z}/p$ of the integers $\{0, 1, \ldots, p-1\}$ under addition and multiplication modulo a prime p.

Solutions to polynomials in n variables would naturally be n-tuples of elements of the field. If we denote the field in question by K, the natural place to find solutions is affine n-space over K, denoted by K^n, $\mathbb{A}^n_K$, or simply $\mathbb{A}^n$:

$$\mathbb{A}^n = \{\underline{\mathbf{z}} = (z_1, z_2, \ldots, z_n) \mid z_i \in K\}.$$

When $n = 1$ we have the affine line, if $n = 2$ we have the affine plane, and so forth.

B. Affine Algebraic Sets

Let $f(\underline{\mathbf{x}}) = f(x_1, \ldots, x_n)$ be a polynomial in n variables with coefficients in K. The zeros of f are denoted by $Z(f)$:

$$Z(f) = \{\underline{\mathbf{z}} \in \mathbb{A}^n \mid f(\underline{\mathbf{z}}) = 0\}.$$

For example, $Z(y - x^2)$ is a parabola in the plane, and $Z(x^2 - y^2 - z^2 - 4)$ is a hyperboloid in 3-space.

More complicated geometric objects in affine space must be defined by more than one polynomial. Let $\mathcal{S}$ be a set of polynomials (not necessarily finite) all having coefficients in the field K. The common zeros of all the polynomials in the set $\mathcal{S}$ is denoted by $Z(\mathcal{S})$:

$$Z(\mathcal{S}) = \{\underline{\mathbf{z}} \in \mathbb{A}^n \mid f(\underline{\mathbf{z}}) = 0 \quad \text{for all } f \in \mathcal{S}\}.$$

An algebraic set in $\mathbb{A}^n$, or simply an affine algebraic set, is a subset of $\mathbb{A}^n$ of the form $Z(\mathcal{S})$ for some set of polynomials $\mathcal{S}$ in n variables. That is, an affine algebraic set is a set which is exactly the set of common zeros of a collection of polynomials. Affine algebraic sets are the fundamental objects of study in affine algebraic geometry.

The empty set is an affine algebraic set [it is $Z(1)$] and so is all of affine space [it is $Z(0)$]. The intersection of an arbitrary collection of algebraic sets is an algebraic set. The union of a finite number of algebraic sets is also an algebraic set. Therefore the algebraic sets in affine space form the closed sets in a topology; this topology is called the Zariski topology.

C. Ideals Defining Algebraic Sets

The "algebraic" part of algebraic geometry involves the use of the tools of modern algebra to study algebraic sets. Algebra is the study of sets with operations on them, and the most common algebraic structure is the ring, which is a set with addition and multiplication, but not necessarily division. The ring of importance in affine algebraic geometry is the ring $K[\underline{\mathbf{x}}] = K[x_1, x_2, \ldots, x_n]$ of polynomials in the n variables $\underline{\mathbf{x}} = (x_1, \ldots, x_n)$. Sometimes this is called the affine coordinate ring, since it is generated by the coordinate functions x_i. It is from this ring that we draw the subset $\mathcal{S} \subset K[\underline{\mathbf{x}}]$ of polynomials whose zeros we want to study.

An ideal J in a ring R (like $K[\underline{\mathbf{x}}]$) is a subset of the ring R with the special properties that it is closed under addition and "outside multiplication": if f and g are in J then $f + g$ is in J, and if g is in J then fg is in J for any f in the ring. An example of an ideal is the collection of all polynomials that vanish at a particular point $p \in \mathbb{A}^n$.

If $\mathcal{S}$ is a subset of the ring, the ideal generated by $\mathcal{S}$ is the set of all finite "linear combinations" $\sum_i h_i f_i$ where the h_i's are in the ring and the f_i's are in the given subset $\mathcal{S}$. The reader may check that this set, denoted by $\langle \mathcal{S} \rangle$, is closed under addition and outside multiplication, and so is always an ideal.

Returning to the setting of algebraic sets, one can easily see that if $\mathcal{S}$ is any collection of polynomials in $K[\underline{\mathbf{x}}]$, and $J = \langle \mathcal{S} \rangle$ is the ideal in $K[\underline{\mathbf{x}}]$ generated by $\mathcal{S}$, then $\mathcal{S} \subset J$ and $Z(\mathcal{S}) = Z(J)$: the set $\mathcal{S}$ and the ideal J have exactly the same set of common zeros. This allows algebraic geometers to focus only on the zeros of ideals of polynomials: every algebraic set is of the form $Z(J)$ for an ideal $J \subset K[\underline{\mathbf{x}}]$. It is not the case that the ideal defining the algebraic set is unique, however: it is possible that two different ideals J_1 and J_2 have the same set of common zeros, so that $Z(J_1) = Z(J_2)$.

D. Algebraic Sets Defining Ideals

We saw in the last paragraph that ideals may be used to define all algebraic sets, but that the defining ideal is not unique. In the construction of algebraic sets, we look at a collection of polynomials and take their common zeros, which is a set of points in $\mathbb{A}^n$. Now we turn this around, and look instead at a subset $X \subset \mathbb{A}^n_K$ of points in affine space, and consider all the polynomials that vanish on X. We denote this by $I(X)$:

$$I(X) = \{f \in K[\underline{\mathbf{x}}] \mid f(\underline{\mathbf{z}}) = 0 \quad \text{for all } \underline{\mathbf{z}} \in X\}.$$

No matter what kind of subset X we start with, this is always an ideal of polynomials. Again there is the same possibility of non-uniqueness: it may be that two different subsets X and Y of $\mathbb{A}^n$ have the same ideal, so that $I(X) = I(Y)$. This would happen if every polynomial that vanished on X also vanished on Y and vice versa.

The ideal $I(X)$ for a subset $X \subset \mathbb{A}^n$ has a special property not shared by all ideals: it is closed under roots. That is, if f is a polynomial, and f^m vanishes on all the points of X, then it must be the case that f itself vanishes. This means that if $f^m \in I(X)$, then $f \in I(X)$. An ideal with this special property is called a radical ideal.

E. The *Z–I* Correspondence

The two operations of taking an ideal of polynomials and using Z to get a subset of affine space, and taking a subset of affine space and using I to get an ideal of polynomials form the theoretical foundation of affine algebraic geometry. We have the following basic facts:

- If $J_1 \subset J_2 \subset K[\underline{\mathbf{x}}]$ are ideals, then $Z(J_1) \supset Z(J_2)$.
- If $X_1 \subset X_2 \subset \mathbb{A}^n$, then $I(X_1) \supset I(X_2)$.
- If $J \subset K[\underline{\mathbf{x}}]$ is an ideal, then $I(Z(J)) \supset J$.
- If $X \subset \mathbb{A}^n$, then $Z(I(X)) \supset X$.

This last statement can be sharpened to give a criterion for when a subset of $\mathbb{A}^n$ is algebraic, as follows. If X is algebraic, equal to $Z(J)$ for some ideal J, then $I(X) = I(Z(J)) \supset J$, so that $Z(I(X)) = Z(I(Z(J))) \subset Z(J) = X$, which forces $Z(I(X)) = X$. Conversely if $Z(I(X)) = X$, then X is obviously algebraic. Hence,

X is an algebraic subset of $\mathbb{A}^n$ if and only if $Z(I(X)) = X$.

This statement addresses the question of which points are additional zeros of all the polynomials which vanish on X, stating that if X is algebraic there are no additional such points.

F. The Nullstellensatz and the Basis Theorem

The Nullstellensatz turns the previous question around and asks which additional polynomials always vanish at the points which are common zeros of a given ideal of polynomials. This is a much more subtle question, and the answer is the fundamental theorem in elementary affine geometry. It uses the concept of the radical of an ideal J, $\mathrm{rad}(J)$, which is the set of all polynomials for which some power is in J:

$$\mathrm{rad}(J) = \{f \in K[\underline{\mathbf{x}}] \mid f^m \in J \quad \text{for some } m \geq 1\}.$$

It is always the case that $\mathrm{rad}(J) \supset J$, and that $\mathrm{rad}(J)$ is a radical ideal. Clearly $I(Z(J)) \supset \mathrm{rad}(J)$: if $f^m \in J$, then f will certainly vanish wherever everything in J (in particular wherever f^m) vanishes.

An algebraically closed field is a field that contains all roots of all polynomials in one variable. The field $\mathbb{C}$ of complex numbers is algebraically closed; the field $\mathbb{Q}$ of rational numbers, the field $\mathbb{R}$ of real numbers, and all finite fields are not algebraically closed.

Theorem 1 (Hilbert's Nullstellensatz). *If K is an algebraically closed field, then for any ideal $J \subset K[\underline{\mathbf{x}}]$, $I(Z(J)) = \mathrm{rad}(J)$.*

The power of the Nullstellensatz occurs because in many applications one has access to a polynomial f which is known to be zero when other polynomials $g_1, \ldots, g_k$ are. The conclusion is then that f is in the radical of the ideal generated by the g_i's. Therefore there is a power of f which is a linear combination of the g_i's, and so there is an explicit equation of the form

$$f^m = \sum_i h_i g_i.$$

The Nullstellensatz permits a more detailed correspondence of properties between the algebraic set X and its ideal $I(X)$. Typical statements when K is algebraically closed are as follows:

- There is a one-to-one correspondence between algebraic subsets of $\mathbb{A}^n$ and radical ideals in $K[\underline{\mathbf{x}}]$.
- X is empty if and only if $I(X) = K[\underline{\mathbf{x}}]$.
- $X = \mathbb{A}^n$ if and only if $I(X) = \{0\}$.
- X consists of a single point if and only if $I(X)$ is a maximal ideal.
- X is an irreducible algebraic set (that is, it is not a union of two proper algebraic subsets) if and only if $I(X)$ is a prime ideal [that is, $I(X)$ has the property that if $fg \in I(X)$ then either $f \in I(X)$ or $g \in I(X)$].

All these statements relate geometric properties of the algebraic set X to algebraic properties of the ideal $I(X)$. This is the basic theme of algebraic geometry in general.

The other main theorem concerning these general ideas is the basis theorem, which addresses the question of the finiteness of the set of equations which may define an algebraic set:

Theorem 2 (Hilbert's basis theorem). *Every ideal J in the ring of polynomials $K[\underline{\mathbf{x}}]$ is finitely generated: there is a finite set $\mathcal{S}$ of polynomials such that $J = \langle \mathcal{S} \rangle$. As a consequence, every algebraic set $X \subset \mathbb{A}^n$ may be defined as the set of common zeros of a finite set of polynomials.*

G. Regular and Rational Functions

Any polynomial $f \in K[\underline{\mathbf{x}}]$ can be considered as a K-valued function on affine space $\mathbb{A}^n$. If $X \subset \mathbb{A}^n$ is an algebraic set, such a polynomial may be restricted to X

to obtain a function on X. Functions on X which are restrictions of polynomial functions are called polynomial functions. The polynomial functions on X form a ring, denoted by $K[X]$ and called the affine coordinate ring of X. For example, the affine coordinate ring of affine space is the entire polynomial ring: $K[\mathbb{A}^n] = K[\underline{\mathbf{x}}]$.

There is an onto ring homomorphism (restriction) from $K[\underline{\mathbf{x}}]$ to $K[X]$, whose kernel is the ideal $I(X)$. Therefore $K[X]$ is isomorphic as a ring to the quotient ring $K[\underline{\mathbf{x}}]/I(X)$.

Irreducible algebraic sets are often referred to as algebraic varieties. If X is an algebraic variety, then $I(X)$ is a prime ideal, so that the coordinate ring $K[X]$ is an integral domain (if $fg = 0$ then either $f = 0$ or $g = 0$). The field of fractions of $K[X]$, denoted by $K(X)$, represent rational functions on the variety X. Rational functions are more useful than polynomial functions, but they have the drawback that any given rational function may not be defined on all of X (where the denominator vanishes). If a rational function is defined at a point p, one says that the function is regular at p.

The rational function field $K(X)$ of an algebraic variety X is an extension field of the base field K, and as such has a transcendence degree over K: this is the largest number of algebraically independent rational functions. This transcendence degree is the dimension of the variety X. Points have dimension zero, curves have dimension one, surfaces have dimension two, and so forth.

Polynomial and rational functions are used to define maps between algebraic sets. In particular, maps between two affine spaces are simply given by a vector of functions. Maps between affine algebraic sets are given by restriction of such a vector of functions. Depending on the type of functions used, such maps are called polynomial or rational maps. Again, rational maps have the property that they may not be defined everywhere. A map is called regular if it is given by rational functions but is defined everywhere.

H. Examples

The most common example of an affine algebraic variety is an affine subspace: this is an algebraic set given by linear equations. Such a set can always be defined by an $m \times n$ matrix A, and an m-vector $\underline{\mathbf{b}}$, as the vanishing of the set of m equations given in matrix form by $A\underline{\mathbf{x}} = \underline{\mathbf{b}}$. This gives the geometric viewpoint on linear algebra. One consequence of the geometric point of view is a deeper understanding of parallelism for linear spaces: geometrically, one begins to believe that parallel lines might be made to intersect "at infinity." This is the germ of the development of projective geometry.

No doubt the first nonlinear algebraic sets to be studied were the conics. These are the algebraic sets given by a single quadratic equation in two variables, and they define a curve in the affine plane. The classification and study of conics date to antiquity. Most familiar is the classification of nonempty irreducible conics over the real numbers $\mathbb{R}$: we have either an ellipse, a parabola, or a hyperbola. Again an appreciation of the points "at infinity" sheds light on this classification: an ellipse has no real points at infinity, a parabola has one real point at infinity, and a hyperbola has two real points at infinity.

Over any field, if an irreducible conic C [given by $f(x, y) = 0$] is nonempty, then it may be parametrized using a rational function of one variable. This is done by choosing a point $p = (x_0, y_0)$ on C, writing the line L_t through p with slope t [given by $y - y_0 = t(x - x_0)$], and intersecting L_t with C. This intersection will consist of the point p and one other point p_t which depends on t. One may solve easily for the coordinates of p_t as rational functions of t, giving a rational parametrization for the conic C. From the point of view of maps, this gives a rational map $\phi : \mathbb{A}^1 \to C$ which has an inverse: for any point (x, y) on C, the t-value is $t = (y - y_0)/(x - x_0)$. Invertible rational maps are called birational, and most of the classification efforts of algebraic geometry are classifications up to birational maps.

Applying this procedure to the unit circle C (defined by $x^2 + y^2 = 1$) and choosing the point p to be the point $(-1, 0)$, one finds the parametrization

$$p_t = \left(\frac{1 - t^2}{1 + t^2}, \frac{2t}{1 + t^2} \right).$$

We see here the origins of algebraic number theory, in particular the formulas for the Pythagorean triples. If we look at the case when $t = p/q$ is a rational number, we find (clearing the denominator q) that $((q^2 - p^2)/(q^2 + p^2), 2pq/(q^2 + p^2))$ is a point on the unit circle. Again clearing the denominator $q^2 + p^2$, we see that this means

$$(q^2 - p^2)^2 + (2pq)^2 = (q^2 + p^2)^2,$$

which gives the standard parametrization of Pythagorean triples. This style of argument in elementary number theory dates the ancient Greeks, in particular to Appollonius and Diophantus.

In higher dimensions, an algebraic variety given by a single quadratic equation is called a quadric. Although the classification of affine quadrics is not difficult, it becomes clearer that the use of projective techniques simplifies the matter considerably.

Algebraic varieties defined by either more equations or equations of degree larger than two present a much greater challenge. Even the study of cubic curves in the plane [given by a single equation $f(x, y) = 0$ where f

has degree three] is still a subject of modern research, especially over number fields.

I. Affine Schemes

The theory exposed above was developed in the hundred years ending in the middle of the twentieth century. In the second half of the twentieth century a different foundation to algebraic geometry was developed, which more closely follows the algebra of the rings and ideals in question. Recall that there is a correspondence between algebraic subsets of affine space and radical ideals in the polynomial ring $K[\underline{\mathbf{x}}]$. If the ground field K is algebraically closed, points correspond to maximal ideals, and irreducible algebraic sets to prime ideals. The ring of polynomial functions on X is naturally the ring $K[\underline{\mathbf{x}}]/I(X)$. This ring is a finitely generated K-algebra, with no nilpotent elements (elements $f \neq 0$ such that $f^k = 0$ for some k). From this ring one can recover X, as the set of maximal ideals.

The idea of affine schemes is to start with an arbitrary ring R and to construct a geometric object X having R as its natural ring of functions. Grothendieck's theory, developed in the 1950s and 1960s, uses $\mathrm{Spec}(R)$, the set of prime ideals of R, as the set X. This gives the notion of an affine scheme.

II. PROJECTIVE GEOMETRY

A. Infinity

Consider the affine line $\mathbb{A}^1$, which is simply the ground field K as a set. What should it mean to approach infinity in $\mathbb{A}^1$? Consider a ratio $x/y \in K$; if $y \neq 0$ this is an element of K, but as y approaches zero for fixed x, this element will "approach infinity." However, we cannot let y equal zero in this ratio, since one cannot divide by zero in a field. It makes sense then to separate the numerator and denominator in this ratio and consider the ordered pair: let us write $[y : x]$ for this. Since we are thinking of this ordered pair as representing a ratio, we should maintain that $[y : x] = [ay : ax]$ for any nonzero $a \in K$. The ordered pair $[1 : x]$ will represent the number $x \in K$; the ordered pair $[0 : 1]$ will represent a new point, at infinity. We remove the ordered pair $[0 : 0]$ from the discussion, since this would represent an undefined ratio.

B. Projective Space

The construction above generalizes to n-dimensional affine space $\mathbb{A}^n$, as follows. Let us define projective space $\mathbb{P}^n$ to be the set of all ordered $(n+1)$-tuples $[x_0 : x_1 : \ldots : x_n]$, with each $x_i \in K$, not all equal to zero, subject to the equivalence relation that

$$[x_0 : x_1 : \ldots : x_n] = [\lambda x_0 : \lambda x_1 : \ldots : \lambda x_n]$$

for any nonzero $\lambda \in K$. The x_i's are called the homogeneous coordinates of the point $[\underline{\mathbf{x}}]$; note that they are not individually well-defined, because of the scaling condition. However, it does make sense to say whether $x_i = 0$ or not.

If $x_0 \neq 0$, we can scale by $\lambda = 1/x_0$ and assume $x_0 = 1$; then all the other n coordinates are well-defined and correspond to a unique point in affine n-space $\mathbb{A}^n$:

$$p = (x_1, \ldots, x_n) \in \mathbb{A}^n \text{ corresponds to}$$
$$[1 : x_1 : \ldots : x_n] \in \mathbb{P}^n.$$

However, we have a host of new points where $x_0 = 0$ in $\mathbb{P}^n$; these are to be thought of as points "at infinity" of $\mathbb{A}^n$. In this way the points at infinity are brought into view and in fact become no different than any other point, in projective space.

C. Projective Algebraic Sets

Let $K[\underline{\mathbf{x}}] = K[x_0, x_1, \ldots, x_n]$ be the polynomial ring generated by the homogeneous coordinates. We can no longer view these polynomials as functions since (because of the scaling issue) even the coordinates themselves do not have well-defined values. However, suppose that a polynomial $F(\underline{\mathbf{x}})$ is homogeneous; that is, every term of F has the same degree d. Then $F(\lambda\underline{\mathbf{x}}) = \lambda^d F(\underline{\mathbf{x}})$ for any nonzero λ, and hence whether $F = 0$ or not at a point $[\underline{\mathbf{x}}] \in \mathbb{P}^n$ is well-defined.

We therefore define a projective algebraic set to be the set of common zeros of a collection $\mathcal{S}$ of homogeneous polynomials:

$$Z(\mathcal{S}) = \{[\underline{\mathbf{x}}] \in \mathbb{P}^n \mid F(\underline{\mathbf{x}}) = 0 \quad \text{for all } F \in \mathcal{S}\}.$$

Correspondingly, given a subset $X \subset \mathbb{P}^n$, we define the homogeneous ideal of X, $I(X)$, to be the ideal in $K[\underline{\mathbf{x}}]$ generated by all homogeneous polynomials F which vanish at all points of X:

$$I(X) = \langle \{\text{homogeneous } F \in K[\underline{\mathbf{x}}] \mid F|_X = 0\} \rangle.$$

The reader will see the possibility of developing exactly the same type of theory, complete with a $Z-I$ correspondence, a basis theorem, and a projective version of the Nullstellensatz, all properly interpreted with the extra attention paid to the homogeneity conditions at every turn. This is in fact what happens, and projective geometry attains an algebraic foundation as solid as that of affine geometry.

D. Regular and Rational Functions

In the context of projective geometry, the polynomial ring $K[\underline{\mathbf{x}}]$ is called the homogeneous coordinate ring. It is a graded ring, graded by degree: $K[\underline{\mathbf{x}}] = \oplus_{d\geq 0} V_d$ where V_d is the vector space of homogeneous polynomials in $\underline{\mathbf{x}}$ of degree exactly d. If $X \subset \mathbb{P}^n$ is a projective algebraic set, the homogeneous ideal $I(X)$ is also graded: $I(X) = \oplus_d I_d$, and the graded quotient ring $K[X] = K[\underline{\mathbf{x}}]/I(X)$ is called the homogeneous coordinate ring of X.

As we have noted above, a polynomial (even a homogeneous one) F does not have well-defined values at points of projective space. However, a ratio of polynomials $r = F/G$ will have a well-defined value at a point p if both F and G are homogeneous of the same degree, and $G(p) \neq 0$. Such a ratio is called a rational function of degree zero, and these functions form the foundation of the function theory on projective algebraic sets. A rational function whose denominator does not vanish at p is said to be regular at p.

E. Homogenization

Let us suppose now that we have an affine algebraic set, given by the vanishing of a polynomial $f(x_1, \ldots, x_n)$. We want to investigate how this algebraic set looks at infinity, in projective space. Let d be the largest degree of terms of f. To each term of f, we multiply in the appropriate power of the new variable x_0 to make the term have degree exactly d. This produces a homogeneous polynomial $F(x_0, x_1, \ldots, x_n)$, which for $x_0 = 1$ has the same zeros as the original polynomial f. However, now for $x_0 = 0$ we have new zeros, at infinity, in projective space.

For a general affine algebraic set X defined by more than one equation, we do this process for every polynomial in $I(X)$, producing a collection of homogeneous polynomials $\mathcal{S}$. Then $Z(\mathcal{S}) \subset \mathbb{P}^n$ is the projective closure $\bar{X}$ of X and exactly adds the minimal set of points at infinity to X to produce a projective algebraic set.

For example, let us consider the hyperbola in the affine plane defined by $f(x, y) = x^2 - y^2 - 1 = 0$. We homogenize this to $F(z, x, y) = x^2 - y^2 - z^2$, a homogeneous polynomial of degree two. For $z = 0$, we recover the two points $[0:1:1]$ and $[0:1:-1]$ at infinity (where $x^2 - y^2 = 0$), up to scalar factors.

F. Bezout's Theorem

One of the consequences of adding in the points at infinity to form projective space is that algebraic sets which did not intersect in affine space now tend to intersect, at infinity, in projective space. The classic example is that of two parallel lines in the affine plane: these intersect at one point at infinity in the projective plane.

In general, one expects that each time one adds a new equation that must vanish, the dimension of the set of zeros goes down by one. Therefore, in projective space $\mathbb{P}^n$, which has dimension n, one expects that the projective algebraic set defined by exactly n homogeneous polynomials $F_1 = F_2 = \cdots = F_n = 0$ will have dimension zero; this means that it should be a finite set of points.

Bezout's theorem deals with the number of such intersections. It may happen that a point of intersection is counted with multiplicity; this is the same phenomenon as when a polynomial in one variable has a double root: it counts for two when the number of roots is being enumerated. In more than one variable, there is a corresponding notion of multiplicity; this is always an integer at least one (for a common isolated root).

Theorem 3 (Bezout's theorem). Suppose the ground field K is algebraically closed. Let F_i, $i = 1, \ldots, n$, be homogeneous polynomials in the $n+1$ homogeneous variables of projective n-space $\mathbb{P}^n$. Suppose that F_i has degree d_i. Then,

(a) *The common zero locus $X = Z(\{F_1, \ldots, F_n\})$ is nonempty.*
(b) *If X is finite, the cardinality of X is at most the product of the degrees $d_1 d_2 \cdots d_n$.*
(c) *If each point of X is counted according to its multiplicity, the sum of the multiplicities is exactly the product of the degrees $d_1 d_2 \cdots d_n$.*

For example, three quadrics (each of degree two) in $\mathbb{P}^3$ always intersect. If the intersection is finite, it is at most eight points; if the points are counted according to their multiplicity, the sum is exactly eight.

As another example, a line and a cubic in the plane will intersect three times, counted with multiplicity. This is the basis for the famous "group law" on a plane projective cubic curve X: given two points p and q on X, the line joining p and q will intersect the curve X in a third point, and this operation forms the basis for a group structure on X.

III. CURVES AND SURFACES

A. Singularities

Let X be an irreducible algebraic variety, of codimension r, in $\mathbb{A}^n$. If x_i are local affine variables at a point $p \in X$, and the ideal of X is generated near p by polynomials $f_1, \ldots, f_k$, then the Jacobian matrix $J = (\partial f_i/\partial x_j)$ will have rank at most r at every point of X and will have maximal rank r at all points of X away from a subalgebraic set $\mathrm{Sing}(X)$. At points of $X - \mathrm{Sing}(X)$, the variety

is said to be nonsingular, or smooth; at points of Sing(X), the variety is said to be singular, and Sing(X) is called the singular locus of X. Over the complex numbers, the nonsingular points are those points of X where X is a complex manifold, locally analytically isomorphic to an open set in $\mathbb{C}^d$, where d is the dimension of X. A common situation is when Sing(X) is empty; then the variety is said to be smooth. At smooth points of algebraic varieties, there are local "analytic" coordinates $y_1, \ldots, y_d$ equal in number to the dimension of the variety.

B. 1-Forms

A 1-form on a smooth algebraic variety is a collection of local expressions of the form $\sum_i f_i(\mathbf{y})\, dy_i$, where $\{y_i\}$ are local coordinates on the variety and the f_i's are rational functions; this collection of expressions must be all equal under changes of coordinates, and at every point of the variety at least one of the expressions must be valid. For a curve, where there is only one local coordinate y, a local 1-form expression has the simple form $f(y)\, dy$. The set of 1-forms on a variety form a vector space.

C. The Genus of a Curve

Let X be a smooth projective curve. Let ω be a 1-form on X. If at every point of X there is a local expression for ω of the form $f(y)\, dy$ where y is a local coordinate and f is a regular function, then we say that ω is a regular 1-form. The set of regular 1-forms on a smooth projective curve form a finite-dimensional vector space over K, and the number of linearly independent regular 1-forms, which is the dimension of this vector space, is the most important invariant of the curve, called the genus.

If K is the complex numbers, the genus has a topological interpretation also. A smooth projective curve is a compact complex manifold of dimension one, which is therefore a compact orientable real manifold of dimension two. As such, it is topologically homeomorphic to a sphere with g handles attached; this g is the topological genus, which is equal to the genus. If $g = 0$, the curve is topologically a sphere; if $g = 1$, the curve is topologically a torus; if $g \geq 2$, the curve is topologically a g-holed torus.

The simplest smooth projective curve is the projective line itself, $\mathbb{P}^1$. It has genus zero.

D. Plane Curves and Plücker's Formula

The most common projective curves studied over the centuries are the plane curves, which are defined by a single irreducible polynomial $f(x, y) = 0$ in affine 2-space, and then closed up with points at infinity to a projective curve defined by the homogenization $F(x, y, z) = 0$ in the projective plane. Plücker's formula addresses the question of the genus of this curve in relation to the degree of the polynomial F:

Theorem 4 (Plücker's formula). Suppose X is a smooth projective plane curve defined by an irreducible polynomial $F(x, y, z)$ of degree d. Then the genus of X is equal to $(d-1)(d-2)/2$.

Plücker's formula has been generalized to curves with singularities, in particular with simple singularities like nodes (locally like $xy = 0$ or $y^2 = x^2$) and cusps (locally like $y^2 = x^3$). Then the formula gives the genus of the desingularization of the curve: if a plane projective curve of degree d has a finite number of singularities which are all either nodes or cusps, and there are ν nodes and κ cusps, then the genus of the desingularization is

$$g = \frac{(d-1)(d-2)}{2} - \nu - \kappa.$$

E. Elliptic and Hyperelliptic Curves

Using Plücker's formula, we see that smooth plane projective curves of degree one or two have genus zero. We have in fact seen above that conics may be parametrized by lines, and this is possible precisely because they have the same genus. Smooth projective plane cubic curves have genus one, and they cannot be parametrized by lines. Every smooth projective plane curve over $\mathbb{C}$ has exactly nine inflection points, and if an inflection point is put at the projective point $[0:1:0]$, and if the line of inflection is the line at infinity, the affine equation of the cubic curve can be brought into Weierstrass form

$$y^2 = x^3 + Ax + B$$

for complex numbers A and B, such that $4A^3 + 27B^2 \neq 0$ (this is the smoothness condition). The form of this equation shows that a cubic curve is also representable as a double cover of the x-line: for every x-value there are two y-values each giving points of the curve.

In general, there are curves of every genus representable as double covers, using similar affine equations of the form

$$y^2 = f_d(x),$$

where f_d is a polynomial with distinct roots of degree d. Such a curve is called hyperelliptic and has genus $g = [(d-1)/2]$. In particular these constructions show the existence of curves of any genus $g \geq 0$.

Higher-degree coverings of the projective line, such as a curve given by an equation of the form $y^3 = f(x)$, are also important in the classification of curves. Coverings of degree three are called trigonal curves, tetragonal curves are covers of degree four, and so forth.

F. Rational Functions, Forms, and the Riemann-Roch Theorem

The most celebrated theorem in the theory of curves is the theorem of Riemann-Roch, which gives precise information about the rational functions on a smooth projective curve X. The space of rational functions $K(X)$ on X forms a field of transcendence degree one over K, and as such is an infinite-dimensional vector space over K. In order to organize these functions, we concentrate our attention on the zeros (where the numerator vanishes) and the poles (where the denominator vanishes). Specifically, given a point $p \in X$ and a positive integer m, we may look at all the rational functions on X with a zero at p, no zero or pole at p, or a pole at p of order at most m. We denote this space by $\mathcal{L}(mp)$. If $m = -n$ is a negative integer, we define $\mathcal{L}(mp) = \mathcal{L}(-np)$ to be the space of rational functions with a zero at p of order at least n.

A divisor on X is a function from the points of X to the group of integers $\mathbb{Z}$, such that all but finitely many values are zero. For any divisor D, we define the vector space $L(D)$ to be the space $L(D) = \cap_{x \in X} \mathcal{L}(D(x) \cdot x)$. In plain English this is the space of rational functions with restricted poles (to the set of points with positive D-values) and prescribed zeros (as the set of points with negative D-values). Part of the Riemann-Roch theorem is that these spaces are finite-dimensional.

We can make the same construction with rational 1-forms also. Let us recall that a rational 1-form has local expression $f(y)\,dy$ and use the function part f to define the zeros and poles. Given a divisor E, we may then consider the space $\Omega^1(E)$ of rational 1-forms with restricted poles and prescribed zeros as E indicates. Again, this is a finite-dimensional space of forms.

Theorem 5 (Riemann-Roch). Let X be a smooth projective curve of genus g. Let D be a divisor on X, and denote by d the sum of the values of D: $d = \sum_x D(x)$. Then,

$$\dim(L(D)) = d + 1 - g + \dim(\Omega^1(-D)).$$

The inequality $\dim(L(D)) \geq d + 1 - g$ was proved by Riemann; Roch supplied the "correction term" related to 1-forms. One of the main uses of the Riemann-Roch theorem is to guarantee the existence of rational functions with prescribed zeros and poles, in order to intelligently embed the curve in projective space: given rational functions $f_0, \ldots, f_n$ on a curve X, the mapping sending $x \in X$ to the point $[f_0(x), f_1(x), \ldots, f_n(x)]$ will always be well-defined on all of X and under certain circumstances will embed X as a subvariety of $\mathbb{P}^n$.

Using this technique, we can show for example that (a) all curves of genus zero are isomorphic to the projective line $\mathbb{P}^1$; (b) all curves of genus one are isomorphic to smooth plane cubic curves; (c) all curves of genus two are hyperelliptic, given by an equation of the form $y^2 = f_6(x)$, where f_6 is a sextic polynomial; (d) all curves of genus three are either hyperelliptic or smooth plane quartic curves; (e) all curves of genus four are either hyperelliptic or the intersection of a quadric surface and a cubic surface in $\mathbb{P}^3$; and (f) all curves of genus five are hyperelliptic, trigonal, or the intersection of three quadric threefolds in $\mathbb{P}^4$. Of special interest is the so-called canonical embedding of a smooth curve, which shows that a curve of genus g either is hyperelliptic or can be embedded as a curve of degree $2g - 2$ in $\mathbb{P}^{g-1}$.

G. The Moduli Space M_g

Much of the research in algebraic geometry since 1960 has focused on the study of the moduli spaces for algebraic varieties. In general, a moduli space is a topological space M whose points represent particular geometric objects; the topology on M is such that points which are close in M represent geometric objects which are also "close" to each other. Of particular interest has been the moduli space $\mathcal{M}_g$ for smooth projective curves of genus g. For example, since every curve of genus zero is isomorphic to the projective line, $\mathcal{M}_0$ consists of a single point. The moduli space $\mathcal{M}_1$ classifying curves of genus one is isomorphic to the affine line $\mathbb{A}^1$: the famous j-invariant of elliptic curves classifies curves of genus one by a single number. [For a plane cubic curve of genus one in Weierstrass form $y^2 = x^3 + Ax + B$, $j = 4A^3/(4A^3 + 27B^2)$.] For $g \geq 2$, $\mathcal{M}_g$ is itself an algebraic variety of dimension $3g - 3$.

Of particular interest has been the construction and study of meaningful compactifications of various moduli spaces. For $\mathcal{M}_g$, the most natural compactification $\overline{\mathcal{M}_g}$ was constructed by Deligne and Mumford and the additional points represent stable curves of genus g, which are curves without continuous families of automorphisms, and having only nodes as singularities. Even today the construction and elementary properties of moduli spaces for higher-dimensional algebraic varieties (e.g., surfaces) is a challenge. More recently attention has turned to moduli spaces for maps between algebraic varieties, and it is an area of very active research today to compactify and understand such spaces of maps.

H. Surfaces and Higher Dimensions

The construction and understanding of the moduli spaces $\mathcal{M}_g$ for smooth curves is tantamount to the successful classification of curves and their properties. The classification of higher-dimensional varieties is not anywhere near as

complete. Even surfaces, for which a fairly satisfactory classification exists due to Enriques, Kodaira, and others, presents many open problems.

The Enriques classification of smooth surfaces essentially breaks up all surfaces into four categories. The first category consists of those surfaces with a family of genus zero curves on them. Since genus zero curves are all isomorphic to lines, such surfaces are known as ruled surfaces, and a detailed understanding of them is possible. The prototype is a product surface $X \times \mathbb{P}^1$ for a curve X. The second category consists of surfaces with a nowhere-vanishing regular 2-form, or finite quotients of such surfaces. These are the so-called abelian surfaces, $K3$ surfaces, Enriques surfaces, and hyperelliptic surfaces. The third category consists of surfaces with a family of genus one curves on them. Some techniques similar to those used in the study of ruled surfaces are possible, and since genus one curves are very well understood, again a rather detailed description of these surfaces, called elliptic surfaces, is available. The last category is the surfaces of general type, and most surfaces are in this category. Moduli spaces have been constructed, and many elementary invariants are known, but there is still a lot of work to do to understand general-type surfaces. An exciting current application area has to do with the connection of algebraic surfaces (which over the complex numbers are real four-dimensional objects) and the study and classification of 4-manifolds.

For varieties of dimension three or more, there are essentially no areas of complete classification. Basic techniques available for curves and surfaces begin to break down for threefolds, in particular because several fundamental constructions lead immediately to singular varieties, which are much more difficult to handle. However, since the 1980s, starting with the groundbreaking work of Mori, steady progress has been made on fundamental classification constructions.

IV. APPLICATIONS

The origins of algebraic geometry, and the development of projective geometry in the Renaissance, were driven in large part by applications (of the theory of multivariable polynomials) to a variety of problems in geography, art, number theory, and so forth. Later, in the 1800s, newer problems in differential equations, fluid flows, and the study of integrals were driving development in algebraic geometry. In the 1900s the invention of algebra as we know it today caused a rethinking in the foundations of algebraic geometry, and the energies of working researchers were somewhat siphoned into the development of new structures and techniques: these have culminated in the widespread use of general schemes, sheaves, and homological algebra, as well as slightly more general notions of algebraic spaces and stacks.

After this period of partial introspection, a vigorous return to application areas in algebraic geometry began in the 1980s. We will close this article with brief discussions of a sampling of these.

A. Enumeration

One of the fundamental questions of geometry, and of many other subjects in mathematics, is the "how many" question: in algebraic geometry, this expresses itself in counting the number of geometric objects with a given property. In contrast to pure combinatorics, often the geometric approach involves counting objects with multiplicity (e.g., roots of a polynomial).

Typical enumerative questions (and answers) ask for the number of flexes on a smooth cubic curve (9); the number of lines on a smooth cubic surface (27); the number of conics tangent to five given conics (3264); and the number of lines on a smooth quintic threefold (2875).

Recent breakthrough developments in intersection theory have enabled algebraic geometers to compute such numbers of enumerative interest which have stumped prior generations. New excitement has been brought by totally unexpected relationships with string theory in theoretical physics, where the work of Witten and others has found surprising connections between computations relating elementary particles and generating functions for enumerative problems of the above sort in algebraic geometry.

B. Computation

Computation with polynomials is a fundamentally algorithmic process which permits in many cases the design of explicit algorithms for calculating a multitude of quantities of interest to algebraic geometers. Usually these quantities either are related to enumerative questions such as those mentioned above or are the dimensions of vector spaces (typically of functions or forms) arising naturally either in elementary settings or as cohomology spaces.

With the advent of sufficient computing power as represented by modern computers and computer algebra software packages, it has become more possible to actually perform these types of computations by means of computer. This has led to an explosion of activity in designing efficient and effective algorithms for the computations of interest. These algorithms usually rely in some way on the theory of Gröbner bases, which build on a multivariable version of the division algorithm for polynomials.

Software is now widely available to execute many calculations, and it is typically user-customizable, which has enabled researchers around the world to make

fundamental contributions. Software packages which are widely used include Macaulay, CoCoA, and Schubert.

C. Mechanics

Many problems in mechanical engineering and construction involve the precise understanding of the position of various machine parts when the machine is in motion. Robotic analysis is especially concerned with the position and velocity of robot extremities given various parameters for joint motion and extension. There are a few basic motions for machine joints, and these are all describable by simple polynomials [e.g., circular motion of radius r occurs on the circle $(x^2 + y^2 = r^2)$]. It is not difficult to see therefore that in suitable coordinate systems, virtually all such problems can be formulated by polynomial systems.

However, mechanical devices with many joints can correspond to algebraic sets in affine spaces with many variables and many equations, which makes the geometric analysis rather complicated. It is therefore useful to be able to apply more sophisticated techniques of the theory to reduce the complexity of the problem, and this is where the power of algebraic geometry can come into play.

A specific example of the type of problem is the following so-called n-bar configuration. Let us consider a cyclical arrangement of n stiff rods, joined at the ends by joints that can actuate only in a planar way locally. For what initial positions of this arrangement does the configuration actually move and flex? In how many different ways can it be made to flex? When $n = 3$, the configuration must lie in a plane, and no flexing or motion is possible; for $n = 4$, the flexing configurations, although known, have not been completely analyzed.

D. Coding Theory

A code is a collection of vectors in K^n for some n, where K is a field; each vector in the collection is a code word. The Hamming distance between two code words is the number of positions where the code words differ. If each code word is intended to represent some piece of irreducible information, then desirable properties of a code are as follows:

(a) *Size*: There should be many code words so that a large amount of information can be represented.
(b) *Distinctness*: The Hamming distance between any two code words should be large, so that if a code word is corrupted in some way, the original code word can be recovered by changing the corrupted code word in a small number of positions.
(c) *Efficiency*: The ambient dimension n, which is the number of positions, should be as small as possible.

These three properties tend to act against one another, and the theory of error-correcting codes is directed toward the classification and analysis of possible codes and coding schemes.

Algebraic geometry has found an application in this area, by taking the field K to be a finite field, and taking the code to be certain natural spaces of functions or forms on an algebraic variety. Most successful have been attempts to use algebraic curves; this was initiated by Goppa and has been successful in producing codes with desirable properties and in aiding in the classification and uniform treatment of several families of previously known codes.

E. Automatic Theorem Proving

It is often the case, especially in elementary geometry, that geometric statements can be expressed by having some polynomial vanish. For example, three points (x_1, y_1), (x_2, y_2), and (x_3, y_3) in the plane are collinear if and only if the determinant of the matrix

$$\begin{pmatrix} 1 & 1 & 1 \\ x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \end{pmatrix},$$

which is the polynomial $x_2y_3 - x_3y_2 - x_1y_3 + x_3y_1 + x_1y_2 - x_2y_1$, is zero.

A typical theorem therefore might be viewed as a collection of hypothesis polynomials $h_1, \ldots, h_k$, and a conclusion polynomial g. The truth of the theorem would be equivalent to saying that wherever the hypothesis polynomials all vanish, the conclusion polynomial is also zero. This exactly says that $g \in I(Z(\{h_1, \ldots, h_k\}))$, using the language of the $Z-I$ correspondence of affine algebraic geometry.

If the field is algebraically closed, the Nullstellensatz says that the conclusion polynomial g is in this ideal if and only if some power of g is a linear combination of the h_i's; that is, there is some equation of the form

$$g^r = \sum_i f_i h_i,$$

where f_i are other polynomials. A "proof" of the theorem would be given by an explicit collection of polynomials f_i, which exhibited the equation above for some r, and this can be easily checked by a computer. Indeed, algorithms exist which check for the existence of such an expression for g and are therefore effective in determining the truth of a given proposed theorem.

F. Interpolation

A general problem in approximation theory is to construct easy-to-evaluate functions with specified behavior.

Typically this behavior involves the values of the function at prescribed loci, the values of the derivatives of the functions, or both. Polynomial interpolation is the method whereby polynomial functions are used in this manner, and algebraic geometry has found recent applications and new problems of interest in this field in recent decades.

Lagrange interpolation involves finding polynomial functions with specified values c_k at a specified set of points $p_k \in \mathbb{A}^n$. In one variable, there is a relatively easy formula for writing down the desired polynomial, and this is taught in most first-year calculus courses. In higher dimensions, no such formula exists. However, the problem is a linear problem, and so it is a straightforward application of linear algebra techniques.

Hermite interpolation involves finding polynomial functions with specified derivative values. This is a significantly more complicated generalization, and open questions exist even for polynomials in two variables.

Spline interpolation involves finding piecewise polynomial functions, which stitch together to have a certain degree of global smoothness, but which also have specified behavior at given points. Cubic splines are the most popular in one variable, and with the advent of computer graphics, two- and three-variable splines are becoming more widely known and used in elementary applications.

In all these settings, techniques of algebraic geometry are brought to bear in order to determine the dimension of the space of suitable interpolating functions. Usually it is a simple matter to find a lower bound for such dimensions, and the more difficult problem is to find sharp upper bounds.

G. Graphics

The origins of projective geometry lie in the early Renaissance, when artists and architects began to be interested in accurately portraying objects in perspective. The correct treatment of horizon lines and vanishing points in artwork of the period led directly to a new appreciation of points at infinity and eventually to a mathematically sound theory of projective geometry.

With the recent explosion of capabilities in computer speed, resolution of displays, and amount and interest of visualizing data, an appreciation of projective geometry, homogeneous coordinates, and projective transformations has lately become standard fare for computer graphics specialists and novices alike.

Although initially the application of the ideas of projective geometry were rather elementary, more sophisticated techniques are now being brought to bear, especially those involving problems in computer vision and pattern recognition. In particular it now seems feasible to use subtle projective invariants to discriminate between scene objects of either different types at the same perspective or the same type at different perspectives.

GLOSSARY

Center Let A be a bounded set in a normed linear space X. An element x_0 in X is called a center (or Chebyshev center) of A if $\sup\{\|x_0 - y\| : y \in A\} = \inf_{x \in X} \sup\{\|x - y\| : y \in A\}$.

***L* Summand** A closed subspace S of a Banach space X is said to be an L summand (or L ideal) if there exists a closed subspace T of X such that $X = S \otimes T$ and $\|x + y\| = \|x\| + \|y\|$ for all $x \in S$ and $y \in T$.

***M* Ideal** A closed subspace S of a Banach space X is called an M ideal in X if its annihilator $S^{\perp}$ is an L summand of the dual space X^*.

Modulus of smoothness Let f be in $L_p[0, 1]$, $1 \leq p \leq \infty$, and $\Delta_t^r f$ denote the rth forward difference of f with step size t, where $rt \leq 1$. The L_p rth modulus of smoothness of f is defined by $w_r(f, h)_p = \sup\{\|\Delta_t^r f\|_p : 0 < t < h\}$, where the L_p norm is taken over all of $[0, 1]$ for the periodic case and over $[0, 1 - rt]$ for the nonperiodic setting. Also, denote $w(f, h)_p = w_1(f, h)_p$.

Natural spline Let $a = t_0 < \cdots < t_{n+1} = b$. A function s in $C^{2k-2}[a, b]$ is called a natural (polynomial) spline of order $2k$ and with knots at $t_1, \ldots, t_n$, if the restriction of s to each $[t_i, t_{i+1}]$ is a polynomial of degree $2k - 1$ for $i = 1, \ldots, n - 1$, and a polynomial of degree $k - 1$ on each of the intervals $[a, t_1]$ and $[t_n, b]$.

Normalized *B* spline Let $t_i \leq \cdots \leq t_{i+k}$ with $t_i < t_{i+k}$. The ith normalized B spline of order k and with knots at $t_i, \ldots, t_{i+k}$, is defined by $N_{i,k}(x) = (t_{i+k} - t_i)[t_i, \ldots, t_{i+k}](\cdot - x)_+^{k-1}$, where the kth order divided difference of the truncated $(k - 1)$st power is taken at $t_i, \ldots, t_{i+1}$.

***n* Widths** Let A be a subset of a normed linear space X. The Kolmogorov n width of A in X is the quantity $d_n(A; X) = \inf_{X_n} \sup_{x \in A} \inf_{y \in X_n} \|x - y\|$, where X_n is any subspace of X with dimension at most n. The linear

n width of A in X is the quantity $\delta_n(A; X) = \inf_{P_n} \sup_{x \in A} \|x - P_n x\|$, where P_n is any set of continuous linear operators of X into itself of rank at most n. The Gel'fand n width of A in X is the quantity $d^n(A; X) = \inf_{L_n} \sup_{x \in A_n \cap L_n} \|x\|$, where L_n is any closed subspace of X with codimension at most n. The Bernstein n width of A in X is the quantity $b_n(A; X) = \sup_{X_{n+1}} \sup\{t : t B(X_{n+1}) \subseteq A\}$, where X_{n+1} is any subspace of X with dimension at least $n+1$ and $B(X_{n+1})$ is the unit ball $\{x \in X_{n+1} : \|x\| \leq 1\}$ in X_{n+1}.

Padé approximants The $[m, n]$ Padé approximant of a formal power series $c_0 + c_1 z + c_2 z^2 + \cdots$ is the (unique) rational function p_m/q_n, where $p_m(z) = a_0 + \cdots + a_m z^m$ and $q_n(z) = b_0 + \cdots + b_n z^n$ are determined by the algebraic quantity $(c_0 + c_1 z + c_2 z^2 + \cdots)(b_0 + \cdots + b_n z^n) - (a_0 + \cdots + a_m z^m) = d_1 z^{m+n+1} + d_2 z^{m+n+2} + \cdots$ for some $d_1, d_2, \ldots$.

Total positivity An $n \times n$ square matrix $A = [a_{ij}]$ is said to be totally positive (TP) if the determinant of $[a_{i_m j_n}]$ is nonnegative for all choices of integers $1 \leq i_1 < \cdots < i_k \leq n$ and $1 \leq j_1 < \cdots < j_k \leq n$ and any integer $k = 1, \ldots, n$. It is said to be strictly totally positive (STP) if each of the above determinants is positive. A kernel $K(x, y)$, where $a \leq x \leq b$ and $c \leq y \leq d$, is TP or STP if the matrices $K(x_i, y_j)$ are TP or STP, respectively, for all choices of x_i and y_j with $a \leq x_1 < \cdots < x_m \leq b$ and $c \leq y_1 < \cdots < y_m \leq d$, and all $m = 1, 2, \ldots$.

Wavelets A function, with sufficiently fast decay at infinity, can be used as a wavelet to define the wavelet transform, if its Fourier transform vanishes at the origin.

APPROXIMATION of discrete data, complicated functions, solutions of certain equations, and soon by functions from a simple and usually finite dimensional space is often done in every field of science and technology. Approximation theory, also known as approximations and expansions, serves as an important bridge between pure and applied mathematics and is intimately related to numerical analysis. This field has no well-defined boundary and overlaps with various branches of mathematics. Among the most important areas of study are possibility of approximation, quality of approximation, optimal approximation, families of approximants, approximation schemes, and computational algorithms. Approximation of bounded operators by compact operators on a Banach space and factorization of biinfinite matrices are also important areas in the field of approximation theory. Recent development of approximation theory includes computer-aided geometric design (CAGD) and wavelets.

I. BACKGROUND

Approximation theory, which is often classified as approximations and expansions, is a subject that serves as an important bridge between pure and applied mathematics. Although its origin is traced back to the fundamental work of Bernstein, Chebyshev, Haar, Hermite, Kolmogorov, Lagrange, Markov, and others, this branch of mathematics was not fully established until the founding of the *Journal of Approximation Theory* in 1968. Now with the rapid advance of digital computers, approximation theory has become a very important branch of mathematics. Two other journals on this subject, *Approximation Theory and Its Applications and Constructive Approximation,* were founded in late 1984.

There is no well-defined boundary of the field of approximation theory. In fact, it overlaps with both classical and modern analysis, as well as numerical analysis, linear algebra, and even various branches of applied mathematics. We may nevertheless divide it into five areas: (1) possibility of approximation, (2) quality of approximation, (3) optimal approximation, (4) families of approximants, and (5) approximation schemes and computational algorithms. The first area is mainly concerned with density and completeness problems. The typical classical results in this area are the theorems of Stone-Weierstrass, Müntz-Szasz, Mergelian, Korovkin, and others. The subject of qualitative approximation includes mainly the study of degrees of approximations and inverse theorems. Jackson's theorems and the so-called saturation theorems are typical results in this area. Optimal approximation is probably the backbone of the field of approximation theory. The typical problems posed in this area are existence, uniqueness, characterization, and computation of best approximants, and the most basic result is probably the so-called alternation theorem. This area of mathematics is extremely important and includes the subjects of least-squares methods, minimal projections, orthogonal polynomials, optimal estimation, and Kalman filtering. Depending on the mathematical models or the nature of the approximation problems, certain families of approximants are to be used. The most familiar families of approximants are algebraic polynomials, trigonometric polynomials, rational functions, and spline functions. In this direction, there is a vast amount of literature, including, in particular, the study of total positivity. Unfortunately, most of the beautiful properties of these classical families of approximants do not carry over to the two- and higher-dimensional settings. The important subject of multivariate spline functions, for instance, has been a very active field of research in recent years. Again depending on the approximation problems, appropriate schemes of approximation are used. Computational algorithms are very important for the purpose of

yielding good approximations efficiently. This area of approximation theory includes the subjects of interpolation, least-squares methods, and approximate quadratures.

It must be noted that the separation of the field of approximation theory into five areas should not be taken very strictly since these areas obviously have to overlap. For instance, the elementary and yet important method of least-squares is an approximation scheme with efficient computational algorithms and yields an optimal approximation. In addition, many mathematicians and practitioners may give a broader or even different definition of approximation theory. Hence, only selected topics of this field are treated in this article and the selection of topics and statements of results has to be subjective. In addition, many interesting areas, such as approximation theory in the complex domain, trigonometric approximation and interpolation, numerical approximation and algorithms, inequalities, orthogonal polynomials, and asymptotic approximation, are not included.

II. BEST APPROXIMATION

Approximation theory is built on the theory of best approximation. Suppose that we are given a sequence of subsets $P_1 \subset P_2 \subset \cdots$ in a normed linear space X of functions with norm $\| \ \|$. For each function f in X, consider the distance

$$E_n(f) = \inf\{\| f - g\| : g \in P_n\}$$

of f from P_n. If there exists a function p_n in P_n such that $\| f - p_n\| = E_n(f)$, we say that p_n is a best approximant of f in X from P_n. Existence of best approximants is the first basic question in the theory of best approximation. Compactness of P_n, for instance, guarantees their existence. The second basic question is uniqueness, and another basic problem is to characterize them. Characterization is fundamental to developing algorithms for the construction of best approximants.

Suppose that the function f that we wish to approximate lies in some subset G of X. Let B be the unit ball of all f in G (with $\| f\| \leq 1$). Then the quantity

$$E_n(B) = \sup\{E_n(f) : f \in B\}$$

is called the order of approximation of functions in G from P_n. Knowing if, and if so how fast, $E_n(B)$ tends to zero is also one of the most basic problems in best approximation.

A. Polynomial and Rational Approximation

Consider the Banach space $C[0, 1]$ with the uniform (or supremum) norm. Let π_n be the space of all polynomials of degree at most n. Although π_n is not compact, a compactness argument still applies to yield the existence of a best approximant to each f in $C[0, 1]$ from π_n. It is also well known that best approximation from π_n has a unique solution. This can be proved by using the following characterization theorem, which is better known as the alternation theorem.

Theorem 1. p_n is a best approximant of f in $C[0, 1]$ from π_n if and only if there exist points

$$0 \leq x_1 < \cdots < x_{n+2} \leq 1$$

such that $(f - p_n)(x_i) = a(-1)^i \| f - p_n\|$ for $i = 1, \ldots, n + 2$, where $a = 1$ or -1.

More can be said about the uniqueness of best approximants as stated in the following so-called strong unicity theorem.

Theorem 2. Let f be in $C[0, 1]$ and p_n its best approximant from π_n. Then there exists a constant C_f such that

$$\| f - g\| \geq E_n(f) + C_f \| p_n - g\|$$

for all g in π_n.

There are results concerning the behavior of the constant C_f in the literature. All the above results on approximation by algebraic polynomials are also valid for any Chebyshev system.

Results on the orders (or degrees) of approximation by algebraic or trigonometric polynomials are called Jackson's theorems. Favard also gave sharp constants for best trigonometric polynomial approximation.

Although rational functions do not form a linear space, analogous results on existence, uniqueness, and characterization still hold. Let $R_{m,n}$ be the collection of all functions p/q, where $p \in \pi_m$ and $q \in \pi_n$, such that p and q are relatively prime and $q(x) > 0$ for all x on $[0, 1]$. The last condition is not restrictive since, for approximation purposes, p/q must be finite on $[0, 1]$. A more careful compactness argument shows that every function in $C[0, 1]$ has at least one best rational approximant from $R_{m,n}$. The following alternation theorem characterizes best rational approximants. We will use the notation $d(p)$ to denote the degree of a polynomial p.

Theorem 3. p_m/q_n is a best approximant of f from $R_{m,n}$ if and only if there exist points

$$0 \leq x_1 < \cdots < x_r \leq 1$$

where $r = 2 + \max\{m + d(q_n), n + d(p_m)\}$ such that $(f - p_m/q_n)(x_i) = a(-1)^i \| f - p_m/q_n\|$ for $i = 1, \ldots, r$, where $a = 1$ or -1.

Again uniqueness of best rational approximants can be shown using the alternation theorem, and in fact an analogous strong unicity result can be obtained. Unfortunately, although rational functions form a larger class than polynomials, they do not improve the orders of approximation in general. For instance, the approximation order of the class of all lip α functions by R_{nn} is $O(1/n^{\alpha})$, which is the same as the order of approximation from π_n. However, while best approximation from π_n is saturated [e.g., $E_n(f) = O(1/n^{\alpha})$ for $0 < \alpha < 1$ if and only if $f \in \text{lip } \alpha$, and $E_n(f) = O(1/n)$ if and only if f is in the Zygmund class], this is certainly not the case in rational approximation. A typical example is that the order of best approximation of the important function $|x - \frac{1}{2}|$ from R_{nn} is $O(e^{-\sqrt{n}})$, which is much better than $O(1/n)$.

B. Best Local Approximation

Because of the alternation properties of best polynomial and rational approximants, these approximants are believed to behave like Taylor polynomials and Padé approximants, respectively, when the interval of best approximation is small. This leads to the study of best local approximation.

Suppose we are given a set of discrete data $\{a_{jk}\}$, which are the values of some (unknown) function f and its derivatives at the sample points $x_1, \ldots, x_n$, say

$$a_{jk} = f^{(j)}(x_k), \qquad k = 1, \ldots, n$$

The problem is to give a "best" approximation of f using the available discrete data from some class P of functions (π_n, R_{mn}, etc.).

Let us assume, for the time being, that f is known in a neighborhood of the sample points. It will be clear that the best local approximant of f (or more precisely of the data $\{a_{jk}\}$) does not depend on f, except on its interpolatory conditions mentioned above. For each $k = 1, \ldots, n$, let $V_k = x_k + \varepsilon_k A_k$, where $\varepsilon_k = \varepsilon_k(\delta) > 0$ and tends to zero as $\delta \to 0$ and $A_k = A_k(\delta)$, be uniformly bounded measurable sets with unit measure, and let $V(\delta)$ be the union of $V_1, \ldots, V_n$. Now, for each δ, let $g_\delta = g_{\delta,p}$ be a best approximant of f from P in $L_p[V(\delta)]$, where $1 \le p \le \infty$ (and L_∞ will be replaced by C, as usual). Then if $g_\delta \to g_0$ as $\delta \to 0$, we say that g_0 is a best L_p local approximant of f or of the data $\{a_{jk}\}$.

We will discuss only the one-variable setting, although some of these results have multivariate extensions. We will also say that an n tuple $(i_1, \ldots, i_n)$ of integers is p-balanced (or simply balanced), if for each j with $i_j > 0$,

$$\sum_{k=1}^{n} \varepsilon_k^{i_k + 1/p} = O\left(\varepsilon_j^{i_j - 1 + 1/p}\right)$$

as $\delta \to 0$. If this n tuple is balanced, then their sum is called a balanced integer. There is an algorithm to generate all balanced integers.

Theorem 4. Let $(i_1, \ldots, i_n)$ be balanced, N its sum, and P_N a fully interpolating set of functions in $L_p[V(\delta)]$, in the sense that, for any discrete data $\{a_{jk}\}$, there exists a unique g in P_n such that

$$g^{(j)}(x_k) = a_{jk}$$

for $j = 0, \ldots, i_k - 1$ and $k = 1, \ldots, n$. Then for any f that is i_k-times differentiable around x_k, $k = 1, \ldots, n$, the best local L_p approximant of f from P_N exists and is the unique function g_0 that satisfies the Hermite interpolation condition

$$(f - g_0)^{(j)}(x_k) = 0$$

for $j = 0, \ldots, i_k - 1$ and $k = 1, \ldots, n$. Conversely, to any n tuple of positive integers $(c_1, \ldots, c_n)$ with sum M, there is some scaling $\varepsilon_k'(\delta) > 0$ such that this n tuple is balanced with respect to $\{\varepsilon_k'(\delta)\}$, $k = 1, \ldots, n$; consequently, any Hermite interpolation is a best L_p local approximation scheme.

The general case where $(i_1, \ldots, i_n)$ is not balanced is much more delicate, and the best result in this direction in the literature is stated as follows:

Theorem 5. Suppose $(i_1, \ldots, i_n)$ is not balanced and N is its sum. Assume that each A_k is either an interval for each δ or is independent of δ. Also assume that

$$\varepsilon_k(\delta)^{i_k' + 1/p} \left[\sum_{j=1}^{n} \varepsilon_j(\delta)^{i_j' + 1/p} \right]^{-1} = e_k + o(1)$$

as $\delta \to 0$, where $i_1' + \cdots + i_n'$ is the largest balanced integer that does not exceed N. Let $J_A(i, p)$ denote the minimum L_p norm on a measurable set A of the polynomial in π_i with unit leading coefficient. Suppose that f is i_k'-times differentiable around x_k for $k = 1, \ldots, n$ and $1 < p \le \infty$. Then the best L_p local approximant of f exists and is the unique solution of the constrained l_p minimization problem:

$$\min_{g \in P_N} \left\| \left\{ e_k J_{A_k}(i_k', p)(f - g)^{(i_k')}(x_k) i_k! \right\} \right\|_{l_p}$$

$$\text{subject to } \begin{cases} (f - g)^{(j)}(x_k) = 0 \\ j = 0, \ldots, i_k' - 1; \qquad k = 1, \ldots, n \end{cases}$$

We remark that if A_k is an interval, then the subscript A_k of J can be replaced by $[0, 1]$ and that for $p = 1$, the l_1 minimization may not have a unique solution, but if it does, it is the best L_1 local approximant of f.

In the special case when there is only one sample point, say the origin, then the best L_∞ local approximant to a

sufficiently smooth function f from R_{mn} is the $[m, n]$ Padé approximant of f. We remark, however, that the convergence of the net of best uniform approximants on small intervals to the Padé approximant is in general not uniform, but only in measure.

C. Padé Approximants

As just mentioned, Padé approximants are best local approximants and include Taylor polynomials, which are just $[m, 0]$ approximants. What is interesting is that Padé approximants to a formal power series are defined algebraically, so that they are certainly well defined even if the series has zero radius of convergence. In this case, taking suitable limits of the approximants on the Padé table can be considered a summability scheme of the divergent series. The most interesting example is, perhaps, the Stieltjes series,

$$a_0 + a_1 z + a_2 z^2 + \cdots$$

where

$$a_n = \int_0^\infty t^n \, d\mu$$

with μ being a positive measure on $[0, \infty)$. It has been shown that the diagonal Padé approximants $[n + j, n]$, where j is fixed, converge uniformly, in each compact set in the complex plane that does not intersect the interval $[0, \infty)$, to the Stieltjes integral

$$\int_0^\infty \frac{d\mu}{1 - zt}$$

provided that the coefficients a_n do not tend to infinity too fast, say

$$a_n = O[(2n + 1)! R^{2n}]$$

for some $R > 0$. A simple example is $a_n = n!$, where

$$d\mu = e^{-t} \, dt.$$

It has been proved, however, that the Padé approximants to a Stieltjes series diverge along any ray of the Padé table that is not parallel to the diagonal.

It is also interesting that, while Padé approximants along the diagonals behave so nicely for Stieltjes series, they do not necessarily converge even for some entire functions. One reason is that the distribution of the poles of the approximants cannot be controlled. Suppose that

$$f(z) = a_0 + a_1 z + \cdots$$

is actually a meromorphic function. Then along each row of the Padé table, where the denominators of the approximants have a fixed degree n, the poles of f usually attract as many poles of the approximants as possible. Results of this type are related to a classical theorem of de Montessus de Ballore. The following inverse result has been obtained. Let q_{mn} denote the denominator of the $[m, n]$ Padé approximant of f. Since n is fixed, we use any norm that is equivalent to a norm of the $(n + 1)$-dimensional space π_n.

Theorem 6. Suppose that there exist nonzero complex numbers z_i and positive integers p_i with $p_1 + \cdots + p_k = n$, such that

$$\lim_{m \to \infty} \sup \left\| q_{mn}(z) - \prod_{j=1}^{k} (z - z_i)^{p_i} \right\|^{1/m} = r < 1$$

Then f is analytic in

$$|z| < r^{-1} \max\{|z_j| : j + 1, \ldots, k\}$$

with an exception of the poles at $z_1, \ldots, z_k$ with multiplicities $p_1, \ldots, p_k$, respectively.

Without the geometric convergence assumed in Theorem 6, the following inverse result still holds.

Theorem 7. Suppose that

$$\lim_{m \to \infty} q_{mn}(z) = \prod_{j=1}^{n} (z - z_i)$$

where $0 < |z_1| \leq \cdots \leq |z_{n-1}| < |z_n|$. Then f is analytic in $|z| < |z_n|$ with an exception of the poles at $z_1, \ldots, z_{n-1}$, counting multiplicities, and has a singular point at z_n.

Let us return to the diagonal approximants. In particular, consider the main diagonal of the Padé table: $r_n = p_n / q_n$. Since there exist entire functions whose diagonal Padé approximants r_n diverge everywhere in the complex plane except at the origin, it is interesting to investigate the possibility of convergence when the poles of r_n can be controlled. In this direction, the following result has been obtained.

Theorem 8. Let $f(z) - r_n(z) = bz^{2n+1} + \cdots$ for each $n = 1, 2, \ldots$. Suppose that r_n is analytic in $|z| < R$ for all sufficiently large n. Then $\{r_n\}$ converges uniformly on every compact subset of $|z| < R$ to f, so that f is analytic in $|z| < R$.

It should be noted that no *a priori* analytic assumption was made on f. This shows that, once the location of the poles of the Padé approximants can be estimated, we can make a conclusion about the analyticity of the formal power series. This result actually holds for a much more general domain in the complex plane.

D. Incomplete Polynomials

Loosely speaking, if certain terms in an algebraic polynomial do not appear, it is an incomplete polynomial. We

shall discuss best approximations by incomplete polynomials. in $C[0, 1]$. Let H be a finite set of nonnegative integers, and consider the best approximation problem

$$E(f, H) = \inf_{c_i} \left\| f - \sum_{i \in H} c_i x^i \right\|$$

Note that $E(f, H) = E_n(f)$ if $H = \{0, \ldots, n\}$. We also denote

$$E_n^k(f) = E(f, \{0, \ldots, k-1, k+1, \ldots, n\})$$

for any $0 \le k \le n$. The following result has been obtained:

Theorem 9. Let $0 < c < 1$. There exists a positive constant M_k independent of n such that, if f is in $C^k[0, 1]$ and $f^{(k)}(c) \ne 0$, then

$$E_n^k(f) \ge M_k n^{-k}[|f^{(k)}(c)| + o(1)]$$

as $n \to \infty$.

Hence, since $E_n(f)$ is of order

$$O\left[n^{-k} E_n(f^{(k)})\right] = o(n^{-k})$$

we have $E_n^k(f)/E_n(f) \to \infty$ for each f in $C^k[0, 1]$ whose kth derivative does not vanish identically in $[0, 1]$. So even one term makes some difference in studying the order of approximation.

If only finitely many terms are allowed, the natural question is which are the optimal ones. Let $0 < n < N$ and $H_n + \{t_1, \ldots, t_n\}$ be a set of integers with $0 \le t_1 < \cdots < t_n < N$. The problem is to find a set H_n, which we call an optimal set, denoted by H_n^*, such that

$$E\left(f, H_n^*\right) = \inf\{E(f, H_n) : H_n\}$$

An analogous problem for trigonometric approximation has interesting applications to antenna design where certain frequencies are to be received by using a specified number of antennas. Unfortunately, the general problem is unsolved. We have the following result:

Theorem 10. For $f(x) = x^M$, where $M \ge N$, $H_n^* = \{N - n, \ldots, N - 1\}$ and is unique.

This result can be generalized to a Descartes system and even holds for any Banach function space with monotone norm. In a different direction, the analogous problem of approximating a given incomplete polynomial by a monomial has also been studied.

Next, consider $H_n = \{0, t_1, \ldots, t_n\}$, where $0 < t_1 < t_2 <, \ldots$ with

$$\sum_{i=1}^{\infty} \frac{1}{t_i} = \infty$$

and set $E_n(f) = E(f, H_n)$. The so-called Müntz–Szasz's theorem guarantees that $E_n(f) \to 0$ for every f in $C[0, 1]$. Hence, the order of approximation is of interest. Results in this area are called Müntz–Jackson theorems.

We end our discussion of incomplete polynomials by considering the density of the polynomials.

$$p_{n,a}(x) = \sum_{k=m(a)}^{n} c_k x^k, \qquad m(a) \ge na$$

where $0 < a < 1$.

Theorem 11. If $\|p_{n,a}\|$ is uniformly bounded, then

$$\lim_{n \to \infty} p_{n,a}(x) = 0, \qquad 0 \le x < a^2$$

and the convergence is uniform on every interval $[0, r]$, where $r < a^2$.

Thus, the best we can do is to consider approximation on $[a^2, 1]$:

Theorem 12. Let $f \in C(a^2, 1)$. Then there exists a sequence of polynomials $p_{n,a}$ such that

$$\lim_{n \to \infty} p_{n,a}(x) = f(x)$$

uniformly on $[r, 1]$ for any $r > a^2$.

E. Chebyshev Center

Suppose that, instead of approximating a single function f in a normed linear space X from a subset P of X, we are interested in approximating a bounded set A of functions in X simultaneously from P. Then the order of approximation is the quantity

$$r_P(A) = \inf\left\{ \sup_{f \in A} \|f - g\| : g \in P \right\}$$

Of course, if $P = P_n$ and A is a singleton $\{f\}$, then $r_P(A)$ reduces to $E_n(f)$, introduced at the beginning of this section. In general, $r_P(A)$ is called the Chebyshev radius of A with respect to P. A best simultaneous approximant x_0 of A from P, defined by

$$\sup_{f \in A} \|f - x_0\| = r_P(A)$$

is called a Chebyshev center (or simply center) of A with respect to P. We denote the (possibly empty) set of such x_0 by $c_P(A)$. In particular, we usually drop the indices if $P = X$; that is,

$$r(A) = r_X(A) \qquad \text{and} \qquad c(A) = c_X(A)$$

which are simply called the Chebyshev radius and the set of centers of A, respectively.

Most of the literature in this area is concerned with the existence problem; namely, $c_P(A)$ is nonempty. If $c_P(A) \ne \emptyset$ for all bounded nonempty sets A in X, we

say that P admits centers. A classical result is that if X is the range of a norm-one projection defined on its second dual, then X admits centers. In addition, if X admits centers and P is a norm-one complemented subspace, then P also admits centers. An interesting example is the Banach space of real-valued continuous functions on a paracompact space. Not only does it admit centers; the set of centers of any bounded nonempty set A of functions in this space is also relatively easy to describe in terms of A. If X is a uniformly rotund Banach space, then we even have unique best approximants in the sense that $c(A)$ is a singleton for any bounded nonempty set A in X. The following result has been obtained:

Theorem 13. Let X be a Banach lattice such that the norm is additive on the positive cone, and Q be a positive linear nonexpansive mapping of X into itself. Then the set of fixed points of Q admits centers.

The proof of this result depends on the fact that the Banach lattice X described here admits centers itself.

Now suppose that X is a Hilbert space and B its unit ball. Then a hypercircle in X is the (nonempty) intersection of some translate of a closed linear subspace of X with rB for some $r > 0$.

Theorem 14. The Chebyshev center of any hypercircle in a Hilbert space is the unique element of minimum norm.

This result is basic in the study of optimal estimation.

F. Optimal Estimation and Recovery

Suppose that a physical object u is assumed to be adequately modeled by an unknown element x_u of some normed linear space X, and observations or measurements are taken of u that give a limited amount of information about x_u. The data accumulated, however, are inadequate to determine x_u completely. The optimal estimation problem is to approximate x_u from the given data in some optimal sense. Let us assume that the data describe some subset A of X. Then the maximum error in estimating x_u from A is

$$\sup_{f \in A} \| f - x_u \|$$

In order for this quantity to be finite it is necessary and sufficient that A is a bounded subset of X, and we shall make that assumption. To optimize our estimate with only the additional knowledge that x_u must lie in some subset P of X we minimize the error, and this leads to the Chebyshev radius

$$r_P(A) = \inf\left\{ \sup_{f \in A} \| f - x \| : x \in P \right\}$$

of A with respect to the "model" set P. A (Chebyshev) center, if it exists, is an optimal estimation of x_u.

A related but somewhat different problem in best approximation is optimal recovery. Let x be in a normed linear space X, and U an operator from X into another normed linear space Z. The problem is to recover Ux from a limited amount of information about x. Let I be the information operator mapping X into another normed linear space Y. Suppose Ix is known. To estimate Ux, we need an operator A from Y to Z, so that AIx approximates Ux. A is called an algorithm.

Usually, we assume that x is restricted to a balanced convex subset K of X. Here, K is said to be balanced if $v \in K$ implies that $-v \in K$. If the information Ix of x may not be precise, say with some tolerance $\varepsilon \geq 0$, then an algorithm A that is used to recover Ux has the maximum error

$$E(A) = \sup\{ \| Ux - Ay \| : x \in K,\ \| Ix - y \| \leq \varepsilon \}$$

Hence, to recover Ux optimally we have to determine an algorithm A^*, called an optimal algorithm, such that

$$E(A^*) = \inf_A E(A)$$

It should be remarked that an optimal algorithm may be nonlinear, although linear optimal algorithms exist in a fairly general situation. A lower bound of $E(A^*)$ usually helps, and it can be found in

$$E(A^*) \geq \sup\{ \| Ux \| : x \in K, \| Ix \| \leq \varepsilon \}$$

There has been some progress in optimal recovery of nonlinear operators, and results on the Hardy spaces have also been obtained. It is not surprising that (finite) Blaschke products play an essential role here in the H^p problems.

G. *n* Widths

Let A be a set in a normed linear space X that we wish to approximate from an n-dimensional subspace X_n of X. Then the maximum error (or order of approximation if A is the unit ball) is the quantity

$$E(A, X_n) = \sup_{x \in A} \inf\{ \| x - y \| : y \in X_n \}$$

It was Kolmogorov who proposed finding an optimal n-dimensional subspace $\bar{X}_n$ of X. By this, we mean

$$E(A, \bar{X}_n) = \inf_{X_n} E(A, X_n)$$

where the infimum is taken over all subspaces X_n of X with dimension at most n. This optimal quantity is called the Kolmogorov n width of A and is denoted by

$d_n(A) = d_n(A; X)$. Knowing the value of $d_n(A)$ is important in identifying an optimal (or extremal) approximating subspace $\bar{X}_n$ of X.

Replacing the distance of $x \in A$ from X_n in Kolmogorov's definition by the distance of x from its image under a continuous linear operator P_n of rank at most n of X into itself yields the notion of the linear n width of A in X, defined by

$$\delta_n(A) = \delta_n(A; X) = \inf_{P_n} \sup_{x \in A} \|x - P_n x\|$$

It is clear from the two definitions that $\delta_n(A) \geq d_n(A)$.

A dual to the Kolmogorov n width is the Gel'fand n width defined by

$$d^n(A) = d^n(A; X) = \inf_{L_n} \sup_{x \in A \cap L_n} \|x\|$$

where L_n is a closed subspace of X with codimension at most n. It has also been shown that $d^n(A)$ is also bounded above by the linear n width $\delta_n(A)$. To provide a lower bound for both $d_n(A)$ and $d^n(A)$, the Bernstein n width defined by

$$b_n(A) = b_n(A; X) = \sup_{X_{n+1}} \sup\{t : tB(X_{n+1}) \subseteq A\}$$

could be used. Here, X_{n+1} is a subspace of X with dimension at least $n+1$, and $B(X_{n+1})$ is the unit ball in X_{n+1}.

An important setting is that A is the image of the unit ball in a normed linear space Y under some $T \in L(Y, X)$, the class of all continuous linear operators from Y to X. Although the set A is *not* TY, the commonly used notations in this case are $d_n(TY; X)$, $\delta_n(TY; X)$, $d^n(TY; X)$, and $b_n(TY; X)$. Let $C(Y, X)$ be the class of all compact operators in $L(Y, X)$. Then the duality between d_n and d^n can be seen in the following theorem:

Theorem 15. Let $T \in L(Y, X)$ and $T^* \in L(X^*, Y^*)$ be its adjoint. Suppose that $T \in C(Y, X)$ or that X is a reflexive Banach space. Then

$$d_n(TY; X) = d^n(T^*X^*; Y^*)$$

and

$$\delta_n(TY; x) = \delta_n(T^*X^*; Y^*)$$

Let us now consider some important examples. First, let A be the unit ball B_p^k of functions in the Sobolev space $H_p^k = H_p^k[0, 1]$ with $\|f^{(k)}\|_p \leq 1$, where $1 \leq p \leq \infty$. Also, let q be the conjugate of p. The following result describes the asymptotic estimates of d_n, d^n and δ_n. We shall use the notation $d_n \approx n^s$ to mean $C_1 n^s \leq d_n \leq C_2 n^s$ for some positive constants C_1 and C_2 independent of n.

Theorem 16. Let $k \geq 2$. Then

$$d_n(B_p^k; L_r) \approx \begin{cases} n^{-k}, & 1 \leq r \leq p \leq \infty \\ & \text{or} \quad 2 \leq p \leq r \leq \infty \\ n^{-k+1/p-1/2}, & 1 \leq p \leq 2 \leq r \leq \infty \\ n^{-k+1/p-1/r}, & 1 \leq p \leq r \leq 2 \end{cases}$$

$$d^n(B_p^k; L_r) \approx \begin{cases} n^{-k}, & 1 \leq r \leq p \leq \infty \\ & \text{or} \quad 1 \leq p \leq r \leq 2 \\ n^{-k+1/2-1/r}, & 1 \leq p \leq 2 \leq r \leq \infty \\ n^{-k+1/p-1/r}, & 2 \leq p \leq r \leq \infty \end{cases}$$

and

$$\delta_n(B_p^k; L_r) \approx \begin{cases} n^{-k}, & 1 \leq r \leq p \leq \infty \\ n^{-k+1/p-1/r} & 1 \leq p \leq r \leq 2 \\ & \text{or} \quad 2 \leq p \leq r \leq \infty \\ n^{-k+1/p-1/2}, & 1 \leq p \leq 2 \leq r \leq \infty \\ & \text{and} \quad q \geq r \\ n^{-k+1/2-1/r}, & 1 \leq p \leq 2 \leq r \leq \infty \\ & \text{and} \quad q \leq r \end{cases}$$

For the discrete case R^m, let B_p denote the unit ball using the $l_p(R^m)$ norm, and set $X = l_\infty(R^m)$. The following estimates have been obtained:

Theorem 17. There exist constants C and C_a independent of m and n such that

$$d_n(B_1; X) \leq C_m^{1/2} \Big/ n \tag{1}$$

$$d_n(B_1; X) \leq 2[(\ln m)/n]^{1/2} \tag{2}$$

$$d_n(B_1; X) \leq C_a n^{-1/2} \qquad \text{if} \qquad n < m < n^a \tag{3}$$

$$d_n(B_1; X) \leq C\left[\left(1 + \ln \frac{n}{m}\right) \Big/ n\right]^{1/2} \tag{4}$$

$$d_n(B_1; X) \leq 8\left(\frac{\ln m}{\ln n}\right) \Big/ n^{1/2} \tag{5}$$

$$d_n(B_1; X) \geq \left(1 + \frac{(m-1)n}{m-n}\right)^{-1/2} \tag{6}$$

$$d_n(B_2; X) \leq C\left(1 + \ln \frac{m}{n}\right)^{3/2} \Big/ n^{1/2} \tag{7}$$

III. BIVARIATE SPLINE FUNCTIONS

Spline functions in one variable have proved to be very rich in theory and extremely useful in applications. However, not much was done in the multivariable setting until the 1980s, and at this writing, many basic questions concerning dimensions, bases, minimum supported elements, interpolation, approximation order, shape-prescribed or

shape-preserving approximation schemes, computational algorithms, and so on are still unanswered. In fact, many of the very fundamental problems do not seem to have satisfactory solutions. This is an area in approximation theory that requires much research effort. In this section we discuss only some selected basic results in the two-variable setting, although most of the results here could be obtained in higher dimensions. A different aspect of the multivariable theory is discussed in Section VIII.

Since spline functions in one variable (or univariate splines) are piecewise polynomials separated by points, spline functions in two variables (of bivariate splines) are piecewise polynomials separated by curves. If the bivariate splines are to be continuous, these curves, which we call grids, are necessarily algebraic. In fact, if the restrictions of s to D_1 and D_2 are polynomials p_1 and p_2, respectively, and D_1, D_2 are separated by an (algebraic) curve C represented by an irreducible polynomial equation $l(x, y) = 0$, then a necessary and sufficient condition that s is in C^k on $D_1 \cup C \cup D_2$ is the existence of a polynomial q_{12} with $p_1 - p_2 = q_{12} l^{k+1}$. Since the factor l^{k+1} determines the smoothing condition of the bivariate spline s, it is called the smoothing factor of s across C, and the polynomial q_{12} is called a smoothing cofactor of s. Note that $q_{21} = -q_{12}$ and q_{12} uniquely determines s on D_2 if s is already known on D_1. If $C_1, \ldots, C_n$ are algebraic curves with a common point of intersection A, called a vertex, and separate the domains $D_1, \ldots, D_n$, and if the restriction of a C^k bivariate spline s on D_j is a polynomial p_j, then the smoothing cofactors of s across $C_1, \ldots, C_n$ must satisfy the following conformality condition.

$$q_{12}(l_1)^{k+1} + \cdots + q_{n-1,n}(l_{n-1})^{k+1} + q_{n,1}(l_n)^{k+1} = 0$$

where $l_j(x, y) = 0$ is an irreducible polynomial equation of C_j. Hence, a bivariate spline s on a region D in R^2 that is partitioned by algebraic curves is uniquely determined by all smoothing cofactors that satisfy the conformality conditions around each interior vertex as long as one polynomial piece is prescribed. This simple observation allows us to study the dimensions of bivariate spline spaces and to construct basis elements, particularly locally supported bivariate splines. However, even the dimension on a very simple grid partition is "unstable" in the sense that a perturbation would change the dimension. Among the "stable" bivariate spline spaces are those with ray (or quasi-cross-cut) partitions. Let D be a simply connected domain in R^2. A ray partition Δ of D is one that each (polynomial) curve C must have at least one end point that lies on the boundary of D. The other end point must either be an interior vertex or also lie on the boundary of D. In the latter case, C is called a cross-cuts of D. Suppose that there are m cross-cuts with (irreducible) degrees $d_1, \ldots, d_m$ and n interior vertices $A_1, \ldots, A_n$, such that the rays through A_i are represented by irreducible polynomials $l_{i,1}, \ldots, l_{i,n_i}$ with degrees $f_{i,1}, \ldots, f_{i,n_i}$, respectively. Then we have the following result on the dimension of the space S_d^k of all C^k bivariate splines on D with degree d and grid partition Δ.

Theorem 18.

$$\dim S_d^k = \binom{d+2}{2} + \sum_{j=1}^{m} \binom{d-(k+1)d_j+2}{2}_+ + \sum_{j=1}^{n} b_j$$

where $b_j = \dim V_j$ and

$$V_j = \left\{ (q_1, \ldots, q_{n_j}) : q_i \in \pi_{d-(k+1)f_{j,i}}, \sum_{i=1}^{n_j} q_i (l_{j,i})^{k+1} = 0 \right\}$$

However, the dimension b_j is difficult to determine in general. In the particular case where all $f_{j,i}$'s are equal to 1, then we have, using the notation $N = n_j$,

$$b_j = \dim V_j = \frac{1}{2}\left[d - k - \left[\frac{k+1}{N-1} \right] \right]_+ \times \left[(N-1)d - (N+1)k + (N-3) + (N-1)\left[\frac{k+1}{N-1} \right] \right]$$

with $[x]$ denoting the integral part of x.

A basis of the above bivariate spline space can be constructed, but there may not be any locally supported functions in general. Much work has been done in the three and four-directional meshes. Let us assume that two of the directions in each case are parallel to the x and y axes, and to be more specific let the horizontal and vertical grids be $x = i$ and $y = i$ with $i \in Z$. Then a three-directional mesh is a unidiagonal triangulation and a four-directional mesh is a crisscross triangulation of a uniform rectangular partition. They are also called type I and type II triangulations, respectively. Even in these special cases many interesting and unexpected results have been obtained. For instance, minimum-supported splines may be linearly dependent, some functions in S_d^k cannot be locally reproduced, and even the optimal approximation orders are somewhat unexpected.

We discuss only the three-directional mesh here. The approximation order of S_d^k is an integer m such that dist $(f, S_h) = O(h^m)$ for all sufficiently smooth functions f and dist$(g, S_h) \neq o(h^m)$ for some C^∞ function g. Here, S_h is simply the space of all $s_h(x, y) = s(x/h, y/h)$, where

$s \in S_d^k$. Let $m(d) = \min\{2(d-K), d+1\}$. It is known that, if $k \le (2d-2)/3$, then $m(d) - 2 \le m \le m(d)$. For instance, for S_3^1, $m(d) = 4$ and m is known to be 3. It is also known that if $k > (2d-2)/3$, then $m = 0$. These results were proved using box splines, which are discussed in Section VIII.

While the exact value of m is still unknown even for the three-directional mesh that we discuss here, the controlled approximation order with respect to box splines has been determined. Let $\{B^1, \ldots, B^N\}$ be the collection of all box splines in S_d^k. Then the controlled approximation order of S_h with respect to box splines is the largest integer n such that

$$\left\| f - \sum_{i=1}^{N} \sum_{z \in Z^2} w_i^h(j) B^i\left(\frac{\cdot}{h} - j\right) \right\|_\infty \le C h^n \| D^n f \|_\infty$$

for some sequence $w_i^h(j)$ satisfying

$$\left\| w_i^h(\cdot) \right\|_{l_\infty} \le C \| f \|_\infty, \qquad i = 1, \ldots, N$$

where C is an absolute constant, and f and C^∞ function. In Section VIII, it will be seen that ∞ can be replaced by any p, $1 \le p \le \infty$, even when the controlled condition on the weights is replaced by a "local" one.

Theorem 19. Let S_h be the scaled three-directional mesh of S_d^k. Then the controlled approximation order of S_h with respect to all box splines of S_d^k is

$$2d - 2k \quad \text{for} \quad 2d - 3k = 2 \tag{1}$$

$$2d - 2k - 1 \quad \text{for} \quad 2d - 3k = 3 \quad \text{or} \quad 4 \tag{2}$$

$$d + 1 \quad \text{for} \quad k = 0 \tag{3}$$

$$\min\{2d - 2k - 2, d\} \quad \text{for} \quad k \ge 1 \quad \text{and} \quad 2d - 3k \ge 5 \tag{4}$$

However, the controlled approximation order of S_h with respect to all minimum-supported splines is still unknown.

When the rectangular partitions are nonuniform, the unidiagonal and crisscross triangulations are no longer three- and four-directional meshes. The dimensions of these spaces are still unknown except for the cases when $d - k$ is sufficiently large or when $k = 1, 2$. It is also known that, while the support of the S_2^1 minimum-supported bivariate splines on the crisscross triangulation is independent of the uniformity of the rectangular partition, the corresponding statement for S_3^1 on the unidiagonal triangulation is false. In fact, even the support of the box splines, which are larger in this case, is not preserved under nonuniform perturbation of the rectangular partition, and if one minimum-supported spline in the perturbed case here is used, the totality of all its "translates" does not necessarily produce constants. There is still no general result in the nonuniform setting.

When a triangular grid partition is considered, it is usually more convenient to use Bézier (or Bernstein) representations of the polynomial pieces. Smoothing conditions on the adjacent polynomial pieces are expressed in terms of certain relations on the Bézier coefficients. Many interesting formulas have been recently obtained. These formulas have applications to constructing Hermite interpolants and quasi interpolants to scattered data and also have nice applications to computer-aided geometric designs.

IV. COMPACT OPERATORS AND *M* IDEALS

Since the mid-1970s, a branch of approximation theory called operator approximation has come into vogue. This area is concerned with the approximation of an operator from a family of operators with some nice structures, namely, positive operators, self-adjoint operators, normal operators, compact operators, or operators with more than one of these properties. Since the majority of the research papers in this area have been concerned with compact operator approximation, we limit ourselves to the discussion of this topic. Let $B(X)$ denote the class of bounded linear operators on a Banach space X, and $C(X)$ the subcollection of compact operators on X. The general question of interest is the existence of a best approximant to a given operator T in $B(X)$ from $C(X)$. If every T in $B(X)$ has at least one best approximant from $C(X)$, we say that $C(X)$ is proximal in $B(X)$. It is well known that, if X is a Hilbert space, then $C(X)$ is proximinal in $B(X)$. The following result on Banach spaces is worth stating:

Theorem 20. Let $1 < p < \infty$. Then $C(l_p)$ is proximinal in $B(l_p)$. However, $C(X)$ is not proximinal in $B(X)$ for $X = C[0, 1]$ or $X = L_p[0, 1]$, $1 < p < \infty$, $p \ne 2$.

Nevertheless, certain bounded linear operators in $B(L_p)$ may still have best compact approximants. Let $B_1(L_p)$ be the collection of T in $B(L_p)$ such that $\|Tx_n\|_p \to 0$ for every uniformly bounded weakly null sequence $\{x_n\}$ in L_p. Also, let $B_2(L_p)$ be the integral operators in $B_1(L_p)$. The following result holds:

Theorem 21. $C(L_p)$ is proximinal in $B_1(L_p)$ for $2 < p < \infty$ and is proximinal in $B_2(L_p)$ for $1 < p < \infty$.

If H is a Hilbert space, every Hankel operator in $B(H)$ has a best compact Hankel approximant. Using some function theoretic arguments, the following result can then be obtained. Here, H^∞ will denote the Hardy space of bounded analytic functions and C the space of continuous functions.

Theorem 22. $H^\infty + C$ is a proximinal subspace in L^∞.

It should be remarked that, although this theorem does not seem to be a result in operator approximation, it is indeed related to best approximation by compact Hankel operators. For the l_p spaces, if we let P_n be the norm-one projection of l_p onto the first n coordinate vectors, the following distance formula is obtained:

Theorem 23. Let T be in $B(l_p)$, where $1 < p < \infty$. Then $\|P_n^\perp T P_n^\perp\| \to \text{dist}[T, C(l_p]$ as n tends to infinity.

For $p = 2$, P_n could be chosen as a norm-one projection onto the first n vectors of any orthonormal basis. It is important to remark, however, that nothing has been mentioned about uniqueness. In fact, if T is a noncompact bounded linear operator in l_p, where $1 < p < \infty$, T has "many" compact best approximants. This observation follows from the fact that $C(l_p)$ is an M ideal in $B(l_p)$.

The notion of an M ideal in a Banach space was introduced in the early 1970s. A closed subspace Y of a Banach space X is an M ideal in X if its annihilator $Y^\perp$ is an L summand of the dual space X^*. This in turn means that $Y^\perp$ is the range of an L projection defined on X^*, that is, a projection $Q : X^* \to Y^\perp$ with the property that $\|f\| = \|Qf\| + \|f + Qf\|$ for every f in X^*. The importance of M ideals in approximation theory is that M ideals are proximinal subspaces with certain special approximation properties. For instance, (1) the metric projection P_Y onto Y satisfies the Lipschitz condition $d_H[P_Y(x), P_Y(y)] \le 2\|x - y\|$ for all x, y in X, where d_H denotes the Hausdorff distance, and (2) there exists a continuous homogeneous selection for the metric projection P_Y. Perhaps the most remarkable approximation characteristic of M ideals is the following result:

Theorem 24. Let Y be an M ideal in a Banach space X and x be in $X \backslash Y$. Then $P_Y(x)$ algebraically spans Y.

We have already seen in Theorem 20 that $C(l_p)$ is proximinal in $B(l_p)$, where $1 < p < \infty$. It is also known that $C(l_p)$ is an M ideal in $B(l_p)$, $1 < p < \infty$. In fact, $C(l_p)$ is the only M ideal in $B(l_p)$.

Theorem 25. Let Z be a subspace of l_p, where $1 < p < \infty$. Then the compact operators on Z form an M ideal in the space of bounded operators on Z if and only if Z has the compact approximation property.

In the same direction as Theorem 22, the following result can be proved:

Theorem 26. The compact Hankel operators form an M ideal in the space of Hankel operators on a Hilbert space.

M Ideals have other important structures. For instance, an M ideal of a Banach algebra must be an algebra, and if Ω is a compact Hausdorff space and A a function algebra contained in $C(\Omega)$, then the M ideals of A are precisely the closed ideals with a bounded approximate identity. If, in particular, A is the disc algebra, then the M ideals of A are exactly the two-sided ideals with norm-one approximate identity. In addition, the following interpolation result has been obtained:

Theorem 27. Let f be in the disc algebra A and for each $n = 1, 2, \ldots$, E_n be a closed subset of the unit circle with linear measure zero such that $\gamma_n = \log(\|f\| T^{/} \|f\|_{E_n}) \to 0$. Then there exist minimal norm interpolants s_n of f satisfying $(f - s_n) \in Y_n = \{g \in A : g(E_n) = 0\}$ such that $\|f - s_n\| = O(\gamma_n)$. Furthermore, the rate of convergence $O(\gamma_n)$ cannot be replaced by $o(\gamma_n)$ in general.

V. CONSTRAINED APPROXIMATIONS

In many approximation and interpolation problems, the approximants, which may also be interpolants, are required to satisfy certain constraints. The constraints may be explicit conditions imposed on the approximation problems, or they may be certain specific properties of the mathematical model or data the approximants are supposed to preserve. In general, constrained approximation problems are nonlinear, and some important problems do not even have analytic solutions. We mention a few such problems. The examples we have chosen should not be construed as the most important work in this area but should be thought of as illustrating the results of the subject.

We first limit ourselves to approximation by polynomials and splines in one variable. For polynomial approximation in the uniform (or supremum) norm $\|\ \|_\infty$, the following result is known:

Theorem 28. Let k be any nonnegative integer. Then there exists a constant C such that for any function f in $C^k[0, 1]$ satisfying $f' \ge 0$ and any integer $n \ge k + 1$

$$\inf\{\|f - p\|_\infty : p' \ge 0,\ p \text{ a polynomial of degree} \le n\} \le Cn^{-k} w\left(f^{(k)}, n^{-1}\right)_\infty$$

where $w(\cdot,\ n^{-1})_\infty$ denotes, as usual, the modulus of continuity in the uniform norm.

This result essentially says that monotone approximation by polynomials retains the same order of approximation as unconstrained approximation. For spline approximation, an analogous result has been obtained, and this

result holds even in the L_p setting. Let $S^*_{k,N}$ denote the space of all kth-order splines s with knots at i/N, $i=0, \ldots, N$, such that $s' \geq 0$. We have the following result:

Theorem 29. Let $1 \leq p \leq \infty$ and k be a nonnegative integer. Then there exists a positive constant C such that for any monotonically nondecreasing function f with $f^{(j)} \in L_p[0, 1]$, if $1 \leq p > \infty$, or $f^{(j)} \in C[0, 1]$, if $p = \infty$, where $0 \leq j \leq k-1$, and for any $N = 1, 2, \ldots$

$$\inf\{\|f - s\|_p : s \in S^*_{k,N}\} \leq CN^{-j} w\big(f^{(j)}, N^{-1}\big)_p$$

We now turn to the interpolation problem but concentrate only on spline interpolation. Let $0 = t_0 \leq t_1 \leq \cdots t_n \leq t_{n+1} = 1$. Defining t_j for $j < 0$ and $j > n+1$ arbitrarily as long as $t_j < t_{j+k}$ for all j, we can use $\{t_j\}$ as the knot sequence of the normalized B splines $N_{j,k}$ of order k. Let $H^k_p = H^k_p[0, 1]$ denote, as usual, the Sobolev space of functions f in $C^{k-1}[0, 1]$ with $f^{(k-1)}$ absolutely continuous and $f^{(k)}$ in $L_p[0, 1]$. The "optimal" interpolation problem can be posed as follows. Let $\{g_i\}$, $i = 1, \ldots, n$, and

$$\|s^{(k)}\|_p = \inf\{\|f^{(k)}\|_p : f \in H^k_p,\ f(t_i) = g_i,\ i = 1, \ldots, n\}$$

if $1 < p < \infty$, s always exists, and if $1 < p < \infty$ and $n \geq k$, s is also unique. It is also known that, for $1 < p < \infty$ and $n \geq k$,

$$s^{(k)} = |h|^{q-1} \operatorname{sgn} h$$

where h is some linear combination of the normalized B splines $N_{i,k}$ and q the conjugate of the index p. Suppose that the data $\{g_i\}$ are taken from some function g in $C^k[0, 1]$. Then the constrained version of the above problem is determining an s in H^k_p such that $s(t_i) = g(t_i)$ for $i = 1, \ldots, n$, $s^{(k)} \geq 0$, and

$$\|s^{(k)}\|_p = \inf\{\|f^{(k)}\|_p : f \in H^k_p,\ f(t_i) = g(t_i),\ f^{(k)} \geq 0\}$$

Again for $1 < p < \infty$ and $n \geq k$, s exists and is unique. In fact, the following result is known. To formulate the result, we set

$$d_i = [t_i, \ldots, t_{i+k}]g$$

where the divided difference notation has been used. Also, let χ_A denote the characteristic function of a set A.

Theorem 30. The unique function s described above is characterized by

$$\int_0^1 s^{(k)} N_{i,k} = d_i$$

for $i = 1, \ldots, n-k$, and

$$s^{(k)} = \left(\sum_{j=1}^{n-k} \alpha_j N_{j,k}\right)_+^{q-1} \chi_A$$

where q is the conjugate of p and

$$A = [0, 1] \Big\backslash \bigcup_{j=1}^{n-k} \{(t_j, t_{j+k}) : d_j = 0\}$$

We observe that if $p = 2$, so that $q - 1 = 1$, then s is in C^{k-1} and is a piecewise polynomial of order $2k$. Recently, an analog to the perfect spline solution of the unconstrained problem has been obtained for case $p = \infty$. However, with the exception of some simple cases, no numerical algorithm to determine s is known.

To describe computational methods for shape-prescribed splines, it is easier to discuss quadratic spline interpolation. It should be clear from the above result that extra knots are necessary. Let these knots be $x_1, \ldots, x_{n-1}$ with $t_i < x_i < t_{i+1}$ and let $\{y_i, m_i\}$, $i = 1, \ldots, n$, be a given Hermite data set. Then a quadratic spline s with knots at $\{t_1, \ldots, t_n, x_1, \ldots, x_{n-1}\}$ is uniquely determined by the interpolation conditions $s(t_i) = y_i$ and $s'(t_i) = m_i$ for $i = 1, \ldots, m$. The slopes of s at the knots x_i can be shown to be

$$s'(x_i) = \frac{2(y_{i+1} - y_i) - (x_i - t_i)m_i - (t_{i+1} - x_i)m_{i+1}}{t_{i+1} - t_i}$$

for $i = 1, \ldots, n-1$. Hence, the knot x_i is not active if and only if

$$\frac{m_{i+1} + m_i}{2} = \frac{y_{i+1} - y_i}{t_{i+1} - t_i}$$

In general, the slopes m_i are not given and can be considered parameters to ensure certain shape. For instance, if $m_i m_{i+1} \geq 0$, a necessary and sufficient condition that $m_i s'_{(t)} \geq 0$ for $t_i \leq t \leq t_{i+1}$ is $|(x_i - t_i)m_i + (t_{i+1} - x_i)m_{i+1}| \leq 2\,|y_{i+1} - y_i|$.

Similar conditions can be obtained for comonotonicity and convexity preservation. For practical purposes, the slopes m_i could be selected as a weighted central difference formula for $2 \leq i \leq n-1$ and a weighted noncentral formula for $i = 1$ and n, so that the artificial knots x_i can be determined using the corresponding necessary and sufficient condition such as the inequality mentioned above. Such an algorithm has the advantage of being one-pass.

Cubic splines could be easily used for monotone approximation. In fact, if $n \geq 2$, there is a uique function s such that s'' satisfies $s' \geq 0$, $s(t_i) = g_i$, and

$$\|s''\|_2 = \inf\{\|f''\|_2 : f \in H^2_2,\ f(t_i) = g_i,\ f' \geq 0\}$$

The unique solution s is a natural cubic spline with at most $2[n/2] + 2$ extra knots in addition to the knots at $t_i, \ldots, t_n$.

Much more can be said when the Hilbert space H^k_2 is considered. For instance, let C be a closed convex subset of H^k_2. This may be a set of functions that are positive, monotone, convex, and so on. The following result has been obtained:

Theorem 31. Let $g \in C \subset H_2^k$ and $n \geq k+1$. Then there is a unique function s_n in C such that $s_n(t_i) = g(t_i)$ for $i = 1, \ldots, n$, and

$$\left\|s^{(k)}\right\|_2 = \inf\left\{\left\|f^{(k)}\right\|_2 : f \in H_2^k,\ f(t_i) = g(t_i),\ f \in C\right\}$$

Furthermore, s_n is a piecewise polynomial of order $2k$, and if s_n^* denotes the (unconstrained) natural spline of order $2k$ interpolating the same data, then

$$\left\|(s_n - g)^{(k)}\right\|_2 \leq \left\|\left(s_n^* - g\right)^{(k)}\right\|_2$$

Consequently, the rate of convergence of the constrained interpolants s_n to g is established. Another consequence is that the convergence rate for splines interpolating derivatives at the end points remains the same as the unconstrained ones.

We now give a brief account of the multivariable setting. Minimizing the L_2 norm over the whole space R^s of certain partial derivatives gives the so-called thin-plate splines. So far, the only attempt to preserve shape has been preserving the positivity of the data. Since the notation has to be quite involved, we do not go into details but remark that the convergence rate does not differ from the unconstrained thin-plate spline interpolation. It must be mentioned, however, that thin-plate splines are not piecewise polynomials. Piecewise polynomials satisfying certain smoothness joining conditions are discussed in the sections of bivariate splines for two variables and multivariate polyhedral splines for the general n-dimensional setting. Results on monotone and convex approximation by piecewise polynomials, however, are not quite complete and certainly not yet published.

VI. FACTORIZATION OF BIINFINITE MATRICES

There has been much interest in biinfinite matrices. We will discuss this topic only from the view of an approximation theorist, although biinfinite matrices have also important applications to signal processing, time series, and so on. The importance of biinfinite matrices in approximation theory can best be explained via the following (polynomial) spline interpolation problem.

Let $\mathbf{t}: \cdots < t_i < t_{i+1} < \cdots$ be a knot sequence and $\mathbf{x}: \cdots < x_i < x_{i+1} < \cdots$ a sequence of sample points. If a certain sequence of data $\{(x_i, y_i)\}$ is given where $\{y_i\} \in l_\infty$, we would like to know the existence and uniqueness of a kth-order spline s with knots at $\mathbf{t}$ such that $s(x_i) = y_i$ for all i and $s \in L_\infty$. If we write s as a linear combination of the normalized B splines $N_j = N_{j,k,t}$, the interpolation problem can be expressed as a biinfinite linear system $A\alpha = \mathbf{y}$ where $\mathbf{y} = [\cdots y_i, y_{i+1}, \ldots]^T$ and $A = [a_{ij}]$, with $a_{ij} = N_j(x_i)$. Hence, the biinfinite (coefficient) matrix A can be considered an operator from l_∞ into itself. If A is surjective, then a bounded spline interpolant s exists, and if A is injective, then s is uniquely determined by the interpolation condition $s(x_i) = y + i$, where $i = \ldots 0, 1, \ldots$. It is clear that A cannot be invertible unless it is banded, and using the properties of B splines, it can be shown that A is totally positive.

Generally, certain biinfinite matrices $A = [a_{ij}]$ can be considered as operators on l_p as follows. Let $A\{x_i\} = \{Ax_i\}$, with $Ax_i = \sum_j a_{ij}x_j$, where $\{x_j\}$ is a finitely supported sequence. Then the definiton can be extended to all of l_p using the density of finitely supported sequences. If the extension is unique, we denote the operator also by A and use the usual operator norm $\|A\|_p$. Let $\{\mathbf{e}_j\}$ be the natural basis sequence with $e_j(i) = \delta_{ij}$, and denote by P_n the projection defined by $P_n\mathbf{e}_j = \mathbf{e}_j$ for $|j| \leq n$ and zero otherwise. Therefore, the biinfinite matrix representation of P_n is $[p_{ij}]$, where $p_{ij} = \delta_{ij}$ for $|j| \leq n$ and zero otherwise. For any biinfinite matrix A, we can consider its truncation $A_n = P_nAP_n$. Also, let S be the shift operator defined by $S\mathbf{e}_j = \mathbf{e}_{j+1}$. Then $(S^rA)_n(i, j) = 0$ if $|i| > n$ or $|j| > n$ and $= a_{i-rj}$ otherwise. That is, S^r shifts the diagonals of A down by r units.

We use the notation $A \in B(l_p)$ if A, considered an operator on l_p, is a bounded operator. We also say that A is boundedly invertible if, as an operator on l_p, A is both injective and surjective. In order to extend the important results in finite matrices, it is important to be able to identifya "main diagonal" of A. Perhaps the following is a good definition of such diagonal. The rth diagonal of A is main if

$$\limsup\left\|(S^rA)_n^{-1}\right\|_p < \infty$$

Clearly, the zeroth (or central) diagonal of the identity operator I on l_p is main, and in fact if both $I + K$ and its inverse are in $B(l_p)$, the zeroth diagonal is also main. Another example is that, if $\|K\|_p < 1$, then the zeroth diagonal of $I + K$ is a main diagonal. For the Hilbert space l_2, in particular, it can be verified that, if A is a positive definite symmetric matrix such that both A and A^{-1} are in $B(l_2)$, then the zeroth diagonal of A is main. For l_1, if A is column diagonally dominant such that A and A^{-1} are in $B(l_1)$, then again the zeroth diagonal of A is a main diagonal.

The following result is important in spline interpolation:

Theorem 32. Any totally positive biinfinite matrix A such that both A and A^{-1} are in $B(l_\infty)$ has a unique main diagonal.

This theorem allows us to conclude that A^{-1} is checkerboard with the main diagonal containing only positive entries, so that a bound on the local mesh ratio in spline

interpolation can be obtained in terms of the norm of A^{-1}. We remark that there are many other possible and plausible definitions for a main diagonal of a biinfinite matrix.

In solving a biinfinite linear system as discussed earlier, a Gauss elimination procedure quite often factors the coefficient matrix A as $A = LU$, where L is a unit lower triangular matrix with the zeroth diagonal as its rightmost (nontrivial) band, and U is an upper triangular matrix. This is called an LU factorization of A. We say that an LU factorization is invertible if each factor is bounded and boundedly invertible, with L^{-1} and U^{-1} being again lower and upper triangular, respectively.

Theorem 33. Let A be totally positive with both A and A^{-1} in $B(l_\infty)$. Then there exists a unique r such that $S^r A = LU$, where L, L^{-1}, U, U^{-1} are in $B(l_\infty)$, L, L^{-1} being unit lower triangular and U, U^{-1} being upper triangular biinfinite matrices. Furthermore, if we write

$$(S^r A)_n = L_n U_n$$

for each n, then $L_n \to L$ and $U_n \to U$ entrywise.

It is clear that the LU factorization above is unique. However, it would be even better if U were the transpose of L. Such a factorization is called a Cholesky decomposition. We have the following result:

Theorem 34. Let A be a positive definite symmetric matrix with A and A^{-1} in $B(l_2)$. Then A has a unique Cholesky decomposition; that is, $A = LL^T$, where L and L^{-1} are lower triangular biinfinite matrices in $B(l_2)$ with $l_{ii} > 0$. Furthermore, L is unique, and writing $A_n = L_n L_n^T$, we have $L_n \to L$ and $n \to \infty$.

The following result for l_1 is also of some interest.

Theorem 35. Let A be a column diagonally dominant biinfinite matrix with A and A^{-1} in $B(l_1)$. Then there is a unique factorization $A = LU$, where L, L^{-1} are $B(l^1)$ unit lower triangular, and U, U^{-1} are $B(l^1)$ upper triangular. Furthermore, writing $A_n = L_n U_n$, we have $L_n x \to Lx$ and $U_n x \to Ux$ for all $x \in l_1$.

Certain biinfinite matrices have more refined factorizations. We will call a one-banded biinfinite matrix $R = [r_{ij}]$ elementary if $r_{ii} = 1$ and $r_{ij} = 0$ for all i and j with $j \le i - 2$ or $j > i$.

Theorem 36. Any strictly m-banded totally positive unit lower triangular biinfinite matrix A has a factorization $A = R_1 \cdots R_m$ where each R_i, $i = 1, \ldots, m$, is elementary.

Hence, if A is not necessarily unit but is m-banded totally positive and lower triangular, then $A = R_1 \cdots R_m B$, where B is a diagonal matrix with positive diagonal entries.

We conclude this section by stating a factorization result of block Toeplitz matrices.

Theorem 37. Let A be totally positive biinfinite block Toeplitz, with block size at least 2, and unit lower triangular. Write $A = [A_{ij}]$, where $A_{ij} = A_k$ for all i and j with $i = j + k$, and denote

$$A(z) = \sum_{k=0}^{\infty} A_k z^k$$

Then

$$A(z) = \prod_{k=1}^{\infty} [I + a_k(z)] c(z) \left(\prod_{k=1}^{\infty} [I - b_k(z)] \right)^{-1}$$

where $I + a_k(z)$ and $I - b_k(z)$ are the symbols of one-banded block Toeplitz matrices with $a_k(1)$, $b_k(1) \ge 0$ and $\sum [a_k(1) + b_k(1)] < \infty$. Furthermore, $c(z)$ is the symbol of a totally positive block Toeplitz matrix with $c(z)$ and $c^{-1}(z)$ entire, and $\det c(z) = 1$.

VII. INTERPOLATION

The theory and methods of interpolation play a central role in approximation theory and numerical analysis. This branch of approximation theory was initiated by Newton and Lagrange. Lagrange interpolation polynomials, formulated as early as 1775, are still used in many applications. To be more explicit, let

$$\Delta_n : -1 \le t_{n-1} < \cdots t_{nn} \le 1$$

be a set of interpolation nodes (or sample points) and

$$l_{nk}(t) = \prod_{i \ne k} (t - t_{ni}) / (t_{nk} - t_{ni})$$

Then for an given set of data $Y = \{y_i, \ldots, y_n\}$, the polynomial

$$p_n(t) = p_n(t; Y, \Delta_n) = \sum_{k=1}^{n} y_k l_{nk}(t)$$

interpolates the data Y on Δ_n. It is interesting that, even for uniformly spaced Δ_n, there exists a continuous function g on $[-1, 1]$ such that the (Lagrange) interpolating polynomials $p_n(t)$ to $y_i = g(t_{ni})$, $i = 1, \ldots, n$, do not converge uniformly to $g(t)$ on $[-1, 1]$. This leads to the study of the Lebesgue function and constant defined, respectively, by

$$l_n(t) = l_n(t; \Delta_n) = \sum_{k=1}^{n} |l_{nk}(t)|$$

and

$$l_n = l_n(\Delta_n) = \max\{l_n(t) : -1 \le t \le 1\}$$

The following result indicates the divergence property of $l_n(t)$:

Theorem 38. There exists a positive constant C such that, for any sequence of positive numbers e_n and any Δ_n, there is a set $H_n(e_n, \Delta_n)$ of measure no greater than e_n with

$$l_n(t) > Ce_n \ln n$$

for $t \in [-1, 1]\backslash H_n(e_n, \Delta_n)$ and all $n = 1, 2, \ldots$.

Hence, $l_n = O(\ln n)$ is the best we can expect for various choices of Δ_n. A natural (and almost best) choice of Δ_n is the set

$$T_n = \left\{ \cos\frac{(2k-1)\pi}{2n} : k = 1, \ldots, n \right\}$$

of roots of the nth-degree Chebyshev polynomial of the first kind. In this case, the asymptotic expression of the Lebesgue constant is given in the following expression:

Theorem 39.

$$l_n(T_n) - \frac{2}{\pi}\left(\ln n + \gamma + \ln\frac{8}{\pi}\right) \sim \frac{8}{\pi}\sum_{s=1}^{\infty}(-1)^{s-1} \times (2^{2s-1}-1)^2\,\pi^{2s}B_{2s}^2/(2s)!(2s)(2n)^{2s}$$

where γ is the Euler constant and B_{2s} are the Bernoulli numbers.

The best choice of Δ_n could be defined by Δ_n^*, where

$$l_n(\Delta_n^*) = \inf\{l_n(\Delta_n) : \Delta_n\}$$

and we set $l_n^* = l_n(\Delta_n^*)$. It is known that Δ_n^* exists and is unique. In fact, it is characterized by the localization condition

$$\max\{l_n(t; \Delta_n) : t_{n,i} \le t \le t_{n,i+1}\} = l_n(\Delta_n)$$

for $i = 1, \ldots, n-1$. Let us denote the above localized maximum by $l_{ni}(\Delta_n)$. Then the (modified) roots of the nth-degree Chebyshev polynomials are known to satisfy

$$\max_i l_{ni}(\hat{T}_n) - \min_i l_{ni}(\hat{T}_n) < 0.0196$$

for all $n \ge 70$, where the modification is just a linear scaling, mapping the largest and smallest roots to the end points of $[-1, 1]$; namely,

$$T_n = \left(\cos\frac{\pi}{2n}\right)\hat{T}_n$$

This is the reason that modified roots of the Chebyshev polynomials are believed to be an "almost best" choice of Δ_n.

For each choice of Δ_n, there is some continuous function f such that the corresponding Lagrange polynomial interpolation to f does not even converge in L_p. Some extra interpolating conditions are required to increase the chance of convergence. We first discuss interpolation at the roots $x_{nk} = x_{nk}(w)$ of the (generalized) Jacobi orthogonal polynomials corresponding to a "smooth" weight w. Let $x_{no} = -1$, $x_{n,n+1} = 1$, and

$$L_n = L_n^{(r,s)}(\cdot, f) = L_n^{(r,s)}(w, f, \{x_{nk}\})$$

denote the interpolating polynomial of f satisfying the interpolating conditions

$$L_n(x_{nk}) = f(x_{nk}), \qquad k = 0, \ldots, n+1$$
$$D^l L_n(1) = 0, \qquad l = 1, \ldots, r-1$$

and

$$D^l L_n(-1) = 0, \qquad l = 1, \ldots, s-1$$

Theorem 40. Let u be a nonnegative function not identically equal to zero on $[-1, 1]$ and be in $(L\log^+ L)_p$, where $0 < p < \infty$. Then

$$\lim_{n\to\infty} \left\| \left[L_n^{(r,s)}(\cdot, f) - f(\cdot)\right]u(\cdot)\right\|_p = 0$$

for all f in $C[-1, 1]$ if and only if both

$$(1-x)^{-r+1/4}(1+x)^{-s+1/4}[w(x)]^{1/2}$$

is in L_1 and

$$u(x)(1-x)^{r-1/4}(1+x)^{s-1/4}[w(x)]^{-1/2}$$

is in L_p. Furthermore, the condition that u is in $(L\log^+ L)_p$ cannot be replaced by $u \in L_p$.

It should be mentioned, however, that to every continuous function f there exists a sequence of interpolation nodes Δ_n such that the Lagrange interpolation polynomials of f at Δ_n converge uniformly to f on $[-1, 1]$. Fejér arranged the interpolation nodes for Hermite interpolation and gave an easy proof of the Weierstrass theorem. His polynomials, which are usually called Hermite–Fejér interpolation polynomials, are defined by the interpolation condition $H_n(x_{nk}, f) = f(x_{nk})$ and $DH_n(x_{nk}, f) = 0$ for $k = 1, \ldots, n$, where $\{x_{nk}\} = T_n$ are the roots of the nth-degree Chebyshev polynomial. Later, other choices of Δ_n were also studied, and results on approximation orders, asymptotic expansions, and so on were obtained. For instance, the following result is of some interest:

Theorem 41. Let C_n denote the nth-degree Chebyshev polynomial of the first kind and $H_n(\cdot, f)$

denote the Hermite-Fejér interpolation polynomial of a continuous function f at the roots T_n of C_n. Then

$$|H_n(x, f) - f(x)| = O(1)\left\{ \sum_{i=1}^{n} \frac{1}{i^2} w\left[f, \frac{i}{n}(1-x^2)^{1/2} \times |C_n(x)| \right] + \sum_{i=1}^{n} \frac{1}{i^2} w\left[f, \left(\frac{i}{n}\right)^2 |xC_n(x)| \right] \right\}$$

and

$$|H_n(x, f) - f(x)| = O(1)\left\{ \frac{1}{n} \sum_{i=1}^{n} w\left[f, \frac{1}{i}(1-x^2)^{1/2} \times |C_n(x)| + i^{-2}|xC_n(x)| \right] \right\}$$

There has been much interest in the so-called Birkhoff polynomial interpolation problem. The interpolation conditions here are governed by an incidence matrix $E = [e_{ij}]$, where $e_{ij} = 1$ or 0, namely,

$$D^j p(x_i) = y_{ij} \qquad \text{if} \qquad e_{ij} = 1$$

We now study interpolation by spline functions. Spline interpolation is much more useful than polynomial interpolation. In the first place there is no need to worry about convergence. Another great advantage is that a spline interpolation curve does not unnecessarily oscillate as a polynomial interpolation curve does when a large number of nodes are considered. The most commonly used is a cubic spline. If interpolation data are given at the nodes $\Delta_m : 0 = x_0 < \cdots < x_m = 1$, the interior nodes can be used as knots of the cubic spline. When the first derivatives are prescribed at the end points, the corresponding interpolation cubic spline, called a complete cubic spline, is uniquely determined. If no derivative values at the end points are given, a natural cubic spline with zero second derivatives at the end points could be used. Spline functions can also adjust to certain shapes. This topic is discussed in Section V on constrained approximation. There is a vast amount of literature on various results on spline interpolations: existence, uniqueness, error estimates, asymptotics, variable knots, and so on. We shall discuss only the following general interpolation problem:

Let $E = [e_{ij}]$ and $F = [f_{ij}]$ be $m \times n$ incidence matrices and Δ_n be a partition of [0, 1] as defined above. We denote by $S_n(F, \Delta_m)$ the space of all piecewise polynomial functions f of degree n with the partition points x_i of Δ_m as break points such that $D^{n-j} f(x_i^-) = D^{n-j} f(x_i^+)$ for all pairs (i, j) with $f_{ij} = 0$, where $0 < i < m$. The following problem is called an interpolation problem, I.P.(E, F, Δ_m):

Given a set of data $\{y_{ij} : e_{ij} = 1\}$, find an f in $S_n(F, \Delta_m)$ satisfying $D^j f(x_i) = y_{ij}$, where $e_{ij} = 1$ and $D^j f(x_i) = \frac{1}{2}[D^j f(x_i^-) + D^j f(x_i^+)]$.

The problem I.P.(E, F, Δ_m) posed here is said to be poised if it has a unique solution for any given data set. It is known that I.P.(E, F, Δ_m) is poised if and only if I.P.(E, F, Δ_m) is poised. By using the Pólya conditions on (E, F) and the Budan–Fourier theorem, the following result can be shown. We say that E is quasi Hermite if for each $i = 1, \ldots, m-1$, there exists an M_i such that $e_{ij} = 1$ if and only if $j < M_i$.

Theorem 42. Suppose that (E, F) satisfies the Pólya conditions and the $e_{ij} = 1$ implies $f_{i,n-j} = 0$ for all (i, j). Suppose further that one of the matrices E and F is quasi Hermite and the other has no supported odd blocks. Then the problem I.P.(E, F, Δ_m) is poised for any Δ_m.

For cardinal interpolation, we impose the extra conditions $e_{0j} = e_{mj}$ and $f_{0j} = f_{mj}$ for $j = 0, \ldots, m$ on the incidence matrices. Of course, $S_n(F, \Delta_m)$ has to be extended to be piecewise polynomial functions f of degree n with break points at $q + x_1$, where $i = 1, \ldots, m$ and $q = \cdots 0, 1, \ldots$, such that

$$D^{n-j} f\left(q + x_i^-\right) = D^{n-j} f\left(q + x_i^+\right)$$

for all q and (i, j) with $f_{ij} = 0$. The following problem will be called a cardinal interpolation problem, C.I.P.(E, F, Δ_m):

Given a set of data $\{y_{ijq}\}$, for any $0 \le i < m$ and $e_{ij} = 1$, find an f in $S_n(F, \Delta_m)$ satisfying $D^j f(q + x_i) = y_{ijq}$, where $D^j f(q + x_i)$ is the average of $D^j f(q\ x_i^-)$ and $D^j f(q + x_i^+)$.

The problem C.I.P.(E, F, Δ_m) is said to be poised if whenever y_{ijq} is arbitrarily given and satisfies $y_{ijq} = O(|q|^p)$ for some p, as $q \to \pm\infty$, for all (i, j), the problem C.I.P.(E, F, Δ_m) has a unique solution f satisfying $f(x) = O(|x|^p)$ as $x \to \pm\infty$. Let C_o denote the space of all solutions of C.I.P.(E, F, Δ_m) with $y_{ijq} = 0$ and denote its dimension by d. A function f in C_o is called an eigenspline with eigenvalue λ if $f(x+1) = \lambda f(x)$ for all x. The following results have been obtained:

Theorem 43. The C.I.P.(E, F, Δ_m) has eigenvalue Λ if and only if the C.I.P.(E, F, Δ_m) has eigenvalue λ^{-1}.

Theorem 44. Let the C.I.P.(E, F, Δ_m) have d distinct eigenvalues. Then the problem is poised if and only if none of the eigenvalues lies on the unit circle.

Error estimates on interpolation by these splines have also been obtained.

We next discuss multivariate interpolation. First it should be mentioned that not every choice of nodes in R^s,

$s \geq 2$, admits a unique Lagrange interpolation. Hence, it is important to classify such nodes. We will use the notation

$$N_n(s) = \binom{n+s}{s}$$

The following result gives such a criterion, which can be used inductively to give an admissible choice of nodes in any dimension:

Theorem 45. Let $\Delta_n = \{x^i\}_{1,\ldots,N_n(s)}$ be a set of nodes in R^s. If there exists $n+1$ distinct hyperplanes $S_0, \ldots, S_n$ in R^s and $n+1$ pairwise disjoint subsets $A_0, \ldots, A_n$ of the set of nodes Δ_n such that for each $j = 0, \ldots, n$, A_j is a subset of $S_j \backslash \{S_{j+1} \cup \cdots \cup S_n\}$, has cardinality $N_j(s-1)$, and admits a unique Lagrange polynomial interpolation of degree j in $(s-1)$ variables, then Δ_n admits a unique Lagrange polynomial interpolation of degree n in R^s.

On the other hand, we remark that an arbitrary choice of n nodes in R^s admits an interpolation from some n-dimensional incomplete polynomial space if we neglect the degree of the polynomials.

We next discuss a Birkhoff-type interpolation problem by polynomials in two variables. It will be clear that an analogous problem can be posed in any dimension. Let S be a lower set of a finite number of pairs of integers; that is, whenever $i' \leq i$, $j' \leq j$ and $(i, j) \in S$, then $(i', j') \in S$. Denote by P_S the space of all polynomials $\sum a_{ij} x^i y^j$, where $a_{ij} = 0$ if $(i, j) \notin S$. Note that the dimension of P_S is simply $|S|$, the cardinality of S. Let $E = [e_{qik}]$ be a set of 0 and 1 defined for $q = 1, \ldots, m$ and $(i, k) \in S$. We shall call E an interpolation matrix. The interpolation problem we discuss here is to find a polynomial p in P_S such that

$$\frac{\partial^{i+k}}{\partial x^i \partial y^k} p(z_q) = c_{qik}$$

for all q, i, k with $e_{qik} = 1$, where $Z = \{z_1, \ldots, z_m\}$ is a given set of nodes in R^2 and $C = \{c_{qik}\}$ is a given set of data values.

An interpolation matrix E is said to be regular if for any sets Z and C the above interpolation problem is solvable. It is said to be an Abel matrix if, for each pair (i, k) in S, there is one and only one q for which $e_{qik} = 1$. The following result has been obtained:

Theorem 46. Let $E = [e_{qik}]$ be a normal interpolation matrix with respect to a lower index set S; that is,

$$\sum_{q=1}^{m} \sum_{(i,k) \in S} e_{qik} = |S|$$

Then E is regular if and only if it is an Abel matrix.

We now consider the problem of Lebesgue constants in the multivariate setting. Let V_i, $i = 1, \ldots, s+1$, be the vertices of a simplex T^s in R^s, and for each x in T^s let $(u_1, \ldots, u_{s+1})$ be its barycentric coordinate; that is,

$$x = \sum_{i=1}^{s+1} u_i V_i; \qquad \sum_{i=1}^{s+1} u_i = 1, \qquad u_i \geq 0$$

Let $a = (a_1, \ldots, a_{s+1})$, where $a_1, \ldots, a_{s+1}$ are nonnegative integers such that $|a| = a_1 + \cdots + a_{s+1} \leq n$. It is known that the set of equally spaced nodes $\{x_a\}$, $|a| \leq n$, where $x_a = (a_1 n^{-1}, \ldots, a_{s+1} n^{-1})$, admits a unique Lagrange interpolation. For this set of equally spaced knots $\{x_a\}$, we define

$$l_a(x) = n^n \prod_{i=1}^{s+1} \prod_{j=0}^{a_i - 1} \left(u_i - \frac{j}{n}\right) \Bigg/ \prod_{k=1}^{s+1} a_k!$$

$$L_n(x) = \sum_{|a| \leq n} |l_a(x)|$$

and

$$L_n = \max\{L(x) : x \in T^s\}$$

$L_n(x)$ and L_n are called the Lebesgue function and Lebesgue constant, respectively, corresponding to the knots $\{x_a\}$. The following estimate of the Lebesgue constant is known:

Theorem 47. For the above equally spaced nodes $\{x_a\}$, the Lebesgue constant satisfies

$$L_n \leq \binom{2n-1}{n}$$

for each $n = 1, 2, \ldots$. Furthermore,

$$L_n \to \binom{2n-1}{n}$$

as the dimension s tends to infinity.

Another problem in Lebesgue constants is concerned with optimality of the nodes. However, not much is known about this subject. We simply quote a result on its growth order, which again turns out to be logarithmic as expected. Let

$$n = \prod_{i=1}^{s} (n_i + 1)$$

and $E_n = \{x^1, \ldots, x^n\}$ be an admissible set of nodes in the unit cube I^s in the sense that for each function f in $C(I^s)$ there exists a unique polynomial

$$p_n(x, f) = \sum_{\substack{0 \leq k_i \leq n_i \\ i=1,\ldots,s}} b_k x^k$$

where $k = (k_1, \ldots, k_s)$, such that $p_n(x^i, f) = f(x^i)$, $i = 1, \ldots, n$. We define the "optimal" Lebesgue constant Λ_n by

$$\Lambda_n = \inf_{E_n \subset I^s} \sup_{f \in C(I^s)} \frac{\|p(\cdot, f)\|}{\|f\|}$$

where the supremum norm is being used. The following result has been obtained:

Theorem 48. There exist constants A_s and B_s depending only on the dimension s, such that

$$A_s \prod_{i=1}^{s} \ln(n_i + 2) \le \Lambda_n \le B_s \prod_{i=1}^{s} \ln(n_i + 2)$$

VIII. MULTIVARIATE POLYHEDRAL SPLINES

Spline functions in one variable can be considered linear combinations of B splines. Let $X = \{t_0, \ldots, t_n\}$, where $t_0 \le \cdots \le t_n$ with $t_0 < t_n$. Then the univariate B spline, with X as its set of knots and order n, is defined by

$$M(x, X) = n[t_0, \ldots, t_n](\cdot - x)_+^{n-1}$$

An application of the Hermite–Gennochi formula for divided differences gives the interesting relation

$$\int_R M(x, X)g(x)\,dx = n! \int_{S^n} g(u_0 t_0 + \cdots + u_n t_n)\,du_1 \cdots du_n$$

for any continuous function g, where S^n is the n simplex

$$\sum_{i=0}^{n} u_i = 1, \qquad u_i \ge 0$$

The development of multivariate polyhedral splines is based on a certain geometric interpretation of this relation. First, by simply replacing the knots $\{t_0, \ldots, t_n\}$ by a set $X = \{t^0, \ldots, t^n\}$ of $n+1$ points (which are not necessarily distinct) in R^s such that the algebraic span of X, denoted by $\langle X \rangle$, is all of R^s, we arrive at the formula

$$\int_{R^s} S(x, X)g(x)\,dx = n! \int_{S^n} g\left(u_0 t^0 + \cdots + u_n t^n\right) du_1 \cdots du_n$$

for any test function g in C_0, the class of all continuous functions in R^s with compact supports. The function $S(\cdot, X)$, called the simplicial spline with X as its set of knots, has a very nice geometric interpretation. Let $y^0, \ldots, y^n$ be in R^n such that the set

$$\sigma = \left\{ \sum_{i=0}^{n} u_i y^i : u_0 + \cdots + u_n = 1;\ u_0, \ldots, u_n \ge 0 \right\}$$

has positive volume and $Py^i = t^i$, $i = 0, \ldots, n$, where P is the projection of any y in R^s onto an x in R^s consisting of its first s coordinates. Then for each x in R^s, we have

$$S(x, X) = \mathrm{vol}_{n-s}\{y \in \sigma : Py = x\}/\mathrm{vol}_n \sigma$$

Next, let $X_n = \{x^1, \ldots, x^n\}$, where each x^i is a nonzero vector in R^s such that $\langle X_n \rangle = R^s$. Suppose that $I = [0, 1]$ and $B(\cdot, X_n)$ is defined, again in the distribution sense, by

$$\int_{R^s} B(x, X_n)g(x)\,dx = \int_{I^n} g\left(u_1 x^1 + \cdots + u_n x^n\right) du_1 \cdots du_n$$

for all test functions g in C_0. We call $B(\cdot, X_n)$ a box spline with directions $X_n = \{x^1, \ldots, x^n\}$. Box splines also have a nice geometric interpretation. Let

$$\eta = \left\{ \sum_{i=1}^{n} u_i y^i : 0 \le u_i \le 1,\ Py^i = x^i \right\}$$

where, and hereafter, P denotes an arbitrary orthogonal projection from R^n onto R^s. Then we can write

$$B(x, X_n) = \mathrm{vol}_{n-s}\{y \in \eta : Py = x\}/\mathrm{vol}_n \eta$$

If we consider the formula

$$\int_{R^s} C(x, X_n)g(x)\,dx = \int_{R_+^n} g\left(u_1 x^1 + \cdots + u_n x^n\right) du_1 \cdots du_n$$

for all g in C_0, we arrive at a truncated power (or cone) spline.

Box splines can be derived from truncated power splines, and conversely truncated power splines can be expressed in terms of box splines. Let

$$\Delta_y f(\cdot) = f(\cdot) - f(\cdot - y) \qquad \text{for any} \qquad y \text{ in } R^s$$

and

$$\Delta_{X_n} = \prod_{y \in X_n} \Delta_y$$

In addition, let $[X_n]$ be the $n \times n$ matrix whose ith column is x^i, and let

$$L(X_n) = \left\{ [X_n]b : b \in Z^n \right\}$$

and $t(a, X_n)$ denote the number of different solutions $b \in Z_+^n$ to $a = [X_n]b$. Here, Z and Z_+ denote, as usual, the set of all integers and nonnegative integers, respectively. Then we have the following relationships:

Theorem 49.

$$B(\cdot, X_n) = \Delta_{X_n} C(\cdot, X_n)$$

and

$$C(\cdot, X_n) = \sum_{a \in L(X_n)} t(a, X_n) B(\cdot - a, X_n)$$

A more general notion is the so-called multivariate polyhedral spline (or P shadow) $M_B(\cdot, P)$, where B is an arbitrary convex polyhedral body in R^n, defined in the distribution sense by

$$\int_{R^s} M_B(x, P) g(x)\, dx = \int_B g(Pu)\, du$$

for all g in C_0. Some important properties are included in the following two theorems. Let

$$D_y = \sum_{i=1}^{n} y_i \frac{\partial}{\partial x_i}$$

where $y = (y_1, \ldots, y_n)$, and if B is a polyhedral body in R^n, then B_i will denote an $(n-1)$-dimensional flat of B with unit outer normal n_i.

Theorem 50. For each z in R^n,

$$D_{Pz} M_B(\cdot, P) = -\sum_i z \cdot n_i M_{B_i}(\cdot, P) \tag{1}$$

$$M_B(Pz, P) = \frac{1}{n-s} \sum_i (b_i - z) \cdot n_i M_{B_i}(Pz, P) \tag{2}$$

$$D_x M_B(x, P) = (n-m) M_B(x, P) - \sum_i b_i \cdot n_i M_{B_i}(x, P) \tag{3}$$

where b_i lies on B_i.

Theorem 51. Let $n \geq m \geq s$, and P and Q be any orthogonal projections of R^n and R^m, respectively, onto R^s. If B and C are any two proper convex polyhedral bodies in R^n and R^m respectively, then

$$\int_{R^s} M_B(x - y, P) M_C(y, Q)\, dy = M_{B \times C}(x, P \otimes Q) \tag{1}$$

$$\int_{R^s} M_B(x, P) M_C(x, Q)\, dx = \frac{1}{n+m-s} \times \left\{ \sum_i (b_i - z) \cdot n_i \int_{R^s} M_{B_i}(x) M_C(x)\, ds + \sum_i (c_i - z') \cdot m_i \int_{R^s} M_B(x) M_{C_i}(x)\, dx \right\} \tag{2}$$

where b_i and c_i lie on B_i and C_i, respectively, z in R^n, with z' in R^m consisting of the first m components of z.

It is obvious that $M_B(\cdot, P)$ is nonnegative and vanishes outside PB. From the recurrence relations, it is also clear that it is a piecewise polynomial of degree $n-s$. Let us now specialize on box splines $B(\cdot, X_n)$. In addition to being a piecewise polynomial of degree $n-s$, it is in $C^{d-1}(R^s)$, where

$$d = d(X_n) = \max\{m : |Y| = m, Y \subset X_n, \langle X_n \backslash Y \rangle = R^s\}$$

The Fourier transform of $B(\cdot, X_n)$ is particularly simple, being

$$\hat{B}(x, X_n) = \prod_{y \in X_n} \frac{1 - e^{-ix \cdot y}}{ix \cdot y}$$

This immediately yields the following result, which is a special case of the above theorem:

$$B(\cdot, X_n \cup Y_m) = B(\cdot, X_n) * B(\cdot, Y_m)$$

Let $S(B)$ denote the linear span

$$\sum_{a \in L(X_n)} c_a B(\cdot - a, X_n)$$

of the translates of $B(\cdot, X_n)$. We first state the following result:

Theorem 52. Let Y be a subset of X_n with $\langle Y \rangle = R^s$. Then

$$\sum_{b \in Z^s} B(\cdot - Yb, X_n) = \frac{1}{|\det Y|}$$

Hence, appropriate translates of box splines form a partition of unity, so that $S(B)$ can at least approximate continuous functions. More important is the following result on linear independence of translates of a box spline.

Theorem 53. Let $X_n \subset Z^s \backslash \{0\}$. Then

$$\{B(\cdot - a, X_n) : a \in L(X_n)\}$$

is linearly independent if and only if

$$|\det Y| = 1$$

for all $Y \subset X_n$ with $\langle Y \rangle = R^s$.

As usual, let π_k denote the space of all polynomials in R^s with total degree at most k. Then the following result is obtained:

Theorem 54. Let $X_n \subset Z^s \backslash \{0\}$ and $d = d(X_n)$. Then there exists a linear functional λ on π_d such that

$$p(x) = \sum_{a \in Z^s} \lambda[p(\cdot + a)] B(x - a, X_n)$$

for all $p \in \pi_d$.

In fact, if we write

$$[\hat{B}(x, X_n)]^{-1} = \sum_j a_j x^j$$

where $j = (j_1, \ldots, j_s)$, and $x^j = x_1^{j_1} \cdots x_s^{j_s}$ then, using the notation

$$D^j = \left(\frac{\partial}{\partial x_1}\right)^{J_1} \cdots \left(\frac{\partial}{\partial x_s}\right)^{j_s}$$

we have

$$\lambda(p) = \sum_j a_j (-1)^{|j|} D^j p(0)$$

Let F be an extension of the linear functional $\lambda(p)$ on $C(R^s)$, such that,

$$|F(f)| \le \|F\| \|f\|, \qquad f \in C(R^s)$$

and $F(p) = \lambda(p)$ for any polynomial p. For any $h > 0$, define

$$(Q_h f)(x) = \sum_a F\{f[h(\cdot + a)]\} B\left(h^{-1}x - a, X_n\right)$$

Then the following estimate is established:

Theorem 55. There exist absolute constants C and r such that

$$|f(x) - (Q_h f)(x)| \le C h^{d+1-s/p} \sum_{|j|=d+1} \|D^j f\|_{LP(A_{x,h})}$$

for all $x \in R^s$ and $f \in H_p^d(R^s)$, where $d = d(X_n)$, and

$$A_{x,h} = x + rh[-1, 1]^s$$

At least for $p = \infty$, the order $O(h^{d+1})$ cannot be improved. Let us now replace B by a finite collection Φ of locally supported splines ϕ_i on R^s. Hence, $S(\Phi)$ will denote the linear span of the translates $\phi_i(\cdot, -a)$, $a \in Z^s$, where $i = 1, \ldots, N$, say. Let $H_{p,c}^m$ be the subspace of the Sobolev space H_p^m of compactly supported functions f with norm

$$\|f\|_{p,m} = \left\{ \sum_{|j| \le m} \|D^j f\|_p^p \right\}^{1/p}$$

We say that $S(\Phi)$ provides local L_p approximation of order k, or $S(\Phi) \in A_{p,k}$, if for any $f \in H_{p,c}^m$, there exist weights $w_{i,a}^h$ such that

$$\left\| f - \sum_{i=1}^N \sum_{a \in \mathbf{Z}^s} w_{i,a}^h \phi_i\left(\frac{\cdot}{h} - a\right) \right\|_p \le C h^k \|f\|_{p,m}$$

and $w_{i,a}^h = 0$ whenever $\operatorname{dist}(ah, \operatorname{supp} f) > r$ holds, where C and r are positive constants independent of h and f.

Theorem 56. The following statements are equivalent:

1. There exists a sequence $\{\psi_a\}$, $|a| < k$, in $S(\Phi)$ that satisfies

$$\hat{\psi}_0(a) = \delta_{0,a}, \qquad a \in 2\pi Z^s$$

and

$$\sum_{c \le b} \frac{(-i)^{|c|}}{c!} D^c \hat{\psi}_{b-c}(a) = 0$$

for $a \in 2\pi Z^s \backslash \{0\}$ and $1 \le |b| < k$.

2. There exists a sequence $\{\psi_a\}$, $|a| < k$, in $S(\Phi)$ such that

$$\frac{x^b}{b!} - \sum_{c \le b} \sum_{a \in Z^s} \psi_{b-c}(x - a) \frac{a^c}{c!}$$

is in $\pi_{|b|-1}$ for $|b| < k$.

3. There exist some finitely supported $w_{i,a}$ so that

$$\psi = \sum_{i=1}^N \sum_{a \in Z^s} w_{i,a} \phi_i(\cdot - a)$$

satisfies

$$\frac{x^b}{b!} - \sum_{a \in Z^s} \psi(x - a) \frac{a^b}{b!}$$

is in $\pi_{|b|-1}$ for $|b| < k$.

4. $S(\Phi) \in A_{p,k}$ for all p, $1 \le p \le \infty$.

5. $S(\Phi) \in A_{\infty,k}$.

In the two-dimensional setting, and particularly the three-directional mesh, the approximation order of $S(\Phi)$, where Φ is a collection of box splines, has been extensively studied. It is interesting that, although C^1 cubics locally reproduce all cubic polynomials, the optimal approximation rate is only $O(h^3)$. However, not much is known on the approximation order of $S(\Phi)$ for R^s with $s > 2$.

Although multivariate polyhedral splines are defined in the distributional setting, they can be computed by using the recurrence relations. The computational schemes, however, are usually very complicated. For R^2, there is an efficient algorithm that gives the Bézier coefficients for each polynomial piece of a box spline. In general, one could apply the subdivision algorithms, which are based on discrete box splines. Under certain mild assumptions, the convergence rate could be shown to be quadratic.

IX. QUADRATURES

This section is devoted to approximation of integrals. Let D be a region in R^s and $C(D)$ the space of all continuous

functions on D. The approximation scheme is to find linear functionals L_{nk}, $k = 1, \ldots, n$, on $C(D)$ such that the error functional r_n, defined by

$$\int_D f(x)w(x)\,dx = \sum_{k=1}^{n} L_{nk} f + r_n(f) = Q_n(f) + r_n(f)$$

where $w(\cdot)$ is some positive weight function, satisfying $r_n(f) \to 0$ as $n \to \infty$ for all f in $C(D)$. In one dimension, the above formula is called an integration quadrature formula. Multivariable quadrature formulas are sometimes called cubature formulas. There is a vast amount of literature on this subject. The most well-known quadrature formulas are, perhaps the trapezoidal and Simpson rules. These rules are obtained using certain interpolatory linear functionals L_{nk}. In addition to various other interpolatory-type formulas, there are automatic quadrature, Gauss-type quadrature, and integral formulas obtained by the adaptive Simpson (or Romberg) method. Of course, error analysis is very important. There is literature on algebraic precision, optimal quadrature, asymptotic expansion, and so on. In one variable, the most commonly used weights are perhaps 1, $(1-x)^\alpha x^\beta$, $\log(1/x)$ for the interval $[0, 1]$, e^{-x} for $[0, \infty)$ and e^{-x^2} for R. It is impossible to discuss many important results on this subject in a short section. We give only a brief description of three approaches in the one-variable setting and briefly discuss optimal and multivariable quadratures at the end of the section. For simplicity we will assume that $D = [-1, 1]$ in the following discussion.

A. Automatic Quadratures

An integration method that can be applied in a digital computer to evaluate definite integrals automatically within a tolerable error is called an automatic quadrature. The trapezoidal, Simpson, and adaptive Simpson rules are typical examples. We may say that an automatic quadrature is based on interpolatory-type formulas. An ideal interpolatory quadrature is one whose linear functionals L_{nk} are defined by $L_{nk} f = A_k^n(x_k)$, $k = 1, \ldots, n$, where $-1 \le x_1 < \cdots < x_n \le 1$, such that $A_k^n > 0$, the function values $f(x_k)$, can be used again in future computation (i.e., for $n+1, n+2, \ldots$), and that the quadrature has algebraic precision of degree $n-1$ [i.e., $r_n(f) = 0$ for $f(x) = 1, \ldots, x^{n-1}$]. Using Lagrange interpolation by polynomials of degree $n-1$ guarantees the algebraic precision. Here, we have

$$A_k^n = \int_{-1}^{1} \prod_{i \ne k} (x - x_i)/(x_k - x_i)\,dx$$

and the quadrature is sometimes attributed to Newton. However, the sequence $\{A_k^n\}$, $k = 1, \ldots, n$, is usually quite oscillatory. Since it is known that $r_n(F) \to 0$ for all $f \in C[-1, 1]$ if and only if

$$\sum_{k=1}^{n} |A_k^n| \le M < \infty$$

for all n, the sample points x_k should be chosen very carefully. For instance, equally spaced sample points yield

$$\sum_{k=1}^{n} |A_k^n| \to \infty$$

The following scheme is quite efficient. Let $t_1 = \frac{1}{4}$, $t_{2i} = t_i/2, t_{2i+1} = t_{2i} + \frac{1}{2}, i = 1, 2, \ldots,$ and $x_k = \cos 2\pi t_k, k = 1, 2, \ldots$. Fix an $N = 2^m$ for some $m > 0$, and let $T_k(x)$ and $U_k(x)$ denote the Chebyshev polynomials of the first and second kinds, respectively. Consider the polynomial

$$p_n(x) = \sum_{k=1}^{N-1} b_{0k} U_{k-1}(x) + \sum_{i=1}^{n} w_i [T_N(x)] {\sum_{k=0}^{N-1}}' b_{ik} T_k(x)$$

where $\sum'$ indicates that the first term under this summation is halved, and

$$w_m(x) = 2^m \prod_{k=1}^{m} (x - x_k)$$

For each f in $C[-1, 1]$, the polynomial $p_n(x)$ is then uniquely determined by the interpolation conditions $p_n(x_i) = f(x_i)$ for $i = 1, \ldots, (n+1)N - 1$. Write $b_{ik} = b_{ik}(f)$ for this interpolation polynomial. We then arrive at the quadrature

$$Q_{(n+1)N-1}(f) = \sum_{k=1}^{N-1} A_{0k} b_{0k}(f) + \sum_{i=1}^{n} \sum_{k=0}^{N-1} A_{ik} b_{ik}(f)$$

where

$$A_{0k} = \int_{-1}^{1} U_{k-1}(x)\,dx$$

and

$$A_{1k} = \int_{-1}^{1} w_i [T_N(x)] T_k(x)\,dx$$

for $i = 1, \ldots, n$. It is important to point out that $b_{ik}(f)$ and A_{ik} are independent of n and that to proceed from $Q_{(n+1)N-1}(f)$ to $Q_{(n+2)N-1}(f)$ we need only the extra terms $b_{n+1,k}(F)$ and $A_{n+1,k}$, for $k = 1, \ldots, N$, and their recurrence relations are available.

B. Gauss Quadrature

Let us return to the integration quadrature formula

$$\int_{-1}^{1} f(x)w(x)\,dx = Q_n(f) + r_n(f)$$

where

$$Q_n(f) = \sum_{k=1}^{n} A_k^n f(x_{nk})$$

with $-1 \le x_{n1} < \cdots < x_{nn} \le 1$. Gauss approached this problem by requiring $r_n(f) = 0$ for as many polynomials f with degrees as high as possible and proved that the highest degree is $2n-1$. In fact, this polynomial precision condition uniquely determines x_{nk} and the coefficients A_k^n. We call this $Q_n(f)$ a Gauss quadrature formula. The points x_{nk} turn out to be the roots of the orthonormal polynomials p_n with respect to the weight function w, and the coefficients A_k^n, known as Christoffel numbers, are

$$A_k^n = \left(\sum_{j=0}^{n-1} p_j^2(x_{nk}) \right)^{-1}$$

If $w(x) = 1$, then the polynomials p_n are the Legendre polynomials, and if $w(x) = (1-x^2)^{-1/2}$, the p_n's are (constant multiples of) Chebyshev polynomials of the first kind. The corresponding quadrature formulas are called Gauss–Legendre and Gauss–Chebyshev quadratures. The following estimate has been obtained:

Theorem 57. Let $1 \le s < 2n$ and $(1-x^2)^s f^{(s)}(x)$ be integrable on $[-1, 1]$. Then the error $r_n(f)$ of the Gauss–Legendre quadrature of f satisfies

$$|r_n(f)| \le C_s \int_{-1}^{1} \left| f^{(s)}(x) \right| \min\{(1-x^2)^{s/2}/n^s, (1-x^2)^s\}\, dx$$

where the constant C_s is independent of n and f.

Several generalizations of the Gauss quadrature have been considered. For instance, requiring the weaker polynomial precision condition $r_n(f) = 0$ for all f in π_{2n-m-1} gives a so-called $[2n-m-1,\ n,\ w(x)]$ quadrature. The following result gives a characterization of this quadrature. We denote by P_n the polynomials in π_n the polynomials in π_n with leading coefficient equal to 1 that are orthogonal on the unit circle with respect to the weight function

$$w(\cos\theta)|\sin\theta|$$

Theorem 58. Let $0 < m \le n$. Then $a[2n-m-1,\ n,\ w(x)]$ quadrature with nodes x_i in $[-1, 1]$ has $n-l$ positive coefficients and l negative coefficients if and only if there exists a polynomial q_m in π_m with leading coefficient equal to 1 and real coefficients such that

$$2^{-n+1} \mathrm{Re}\left\{ z^{-n+1} q_m(z) P_{2n-m-1}(z) \right\} = \prod_{j=1}^{n} (x - x_j)$$

where $x = \cos\theta$ and $z = e^{i\theta}$, $\theta \in [0, \pi]$, and q_m has $m-2l$ zeros inside and $2l$ zeros outside the unit circle.

Another generalization is the quadrature

$$\int_{-1}^{1} f(x) w(x)\, dx = \sum_{j=1}^{n} \sum_{i=1}^{n_j} c_{ji} f^{(i-1)}(x_j) + \sum_{j=1}^{m} \sum_{i=1}^{m_j} d_{ji} f^{(i-1)}(y_j) + r_N(f)$$

where $N = m_1 + \cdots + m_m + n_1 + \cdots + n_n$ and $y_1, \ldots, y_m$ are prescribed. It is well known that the polynomial precision requirement $r_N(f) = 0$ for all f in π_{N+n} completely characterizes the nodes $x_1, \ldots, x_n$. In fact, they are determined by the n equations

$$\int_{-1}^{1} w(x) x^k \prod_{j=1}^{m} (x - y_j)^{m_j} \prod_{j=1}^{m} (x - x_j)^{n_j}\, dx = 0 \qquad k = 0, \ldots, n-1.$$

There are methods for computing the nodes x_j and coefficients c_{ji} and d_{ji}. In fact, by establishing a relation between these coefficients and the eigenvectors of the Jacobi matrix corresponding to the weight function $w(\cdot)$, one can obtain a stable and efficient algorithm to evaluate these nodes and coefficients.

C. Chebyshev Quadratures

It is easy to see that all the Christoffel numbers of the Gauss–Chebyshev quadrature are the same. This leads to the problem of determining the weight functions for which the constants in the corresponding quadratures are independent of the summation index. More precisely, a quadrature formula

$$\int_{-1}^{1} f(x) w(x)\, dx = A_n \sum_{k=1}^{n} f(x_{nk}) + r_n(f)$$

$-1 \le x_{n1} < \cdots < x_{nn} \le 1$, that satisfies $r_n(f) = 0$ for all f in π_{n-1} is called a Chebyshev quadrature formula. Bernstein proved that $w(x) = 1$ does not give a Chebyshev quadrature for $n = 8$ or $n \ge 10$. It has been shown that the weights

$$w(x, p) = (2p + 1 + x)^{-1} (1 - x^2)^{-1/2}$$

where $p \ge 1$, give Chebyshev quadratures for all $n \ge 1$. This means, of course, that $A_n = A_n(p)$ and $x_{nk} = x_{nk}(p)$ exist such that the quadrature formulas are $(n-1)$st degree polynomial precise.

Finally, we discuss multivariable quadrature (or cubature) formulas very briefly. With the exception of very special regions (balls, spheres, cones, etc.), nontensor-product

cubatures are very difficult to obtain. Some of the reasons are that multivariate interpolation may not be unisolvent and that orthogonal polynomials are difficult to find on an arbitrary region D and R^s. There are, however, other methods, including, Monte Carlo, quasi Monte Carlo, and number-theoretic methods. On the other hand, many of the one-variable results can be generalized to Cartesian product regions. For instance, let us study optimal quadratures.

Let $H_p^r(I)$ denote the Sobolev spaces on $I=[-1, 1]$, and $W_{r,p}$ the unit ball of f in $H_p^r(I)$; that is

$$\left\| f^{(r)} \right\|_p \le 1$$

To extend to two variables, for instance, let $V_{r,s;p}(M)$ be the set of all functions $g(\cdot\,,\cdot)$ in the Sobolev space $H_p^{(r,s)}(I^2)$ such that

$$\left\| g^{(r,s)}(\cdot\,,\cdot) \right\|_p \le M$$

where M is a fixed positive constant. Now, in the one-variable setting, if

$$r_m(f) = \int_{-1}^{1} f(x)\,dx - \sum_{k=1}^{m} A_k^m f(x_{mk})$$

and

$$r_m(W_{r,p}) = \sup\{|r_m(f)| : f \in W_{r,p}\}$$

it is known that $r_m(W_{r,p})$ attains its minimum at some set of nodes $\bar{x}_{m1}, \ldots, \bar{x}_{mm}$ in I and some coefficients $\bar{A}_1^m, \ldots, \bar{A}_m^m$. The resulting quadrature formula,

$$\int_{-1}^{1} f(x)\,dx = \sum_{k=1}^{m} \bar{A}_k^m f(\bar{x}_{mk}) + \bar{r}_{m,r}(f)$$

is called an optimal quadrature formula for $W_{r,p}$. Let

$$\int_{-1}^{1} f(x)\,dx = \sum_{k=1}^{n} \bar{B}_k^n f(\bar{y}_{nk}) + \bar{r}_{n,s}(f)$$

be an optimal quadrature formula for $W_{s,p}$. The following result has been obtained:

Theorem 59. Let $1 < p \le \infty$. Then the formula

$$\int_{I^2} g(x, y)\,dx\,dy = \sum_{k=1}^{m} \bar{A}_k^m \int_I g(\bar{x}_{mk}, y)\,dy + \sum_{j=1}^{n} \bar{B}_j^n \int_I g(x, \bar{y}_{nj})\,dx - \sum_{k=1}^{m}\sum_{j=1}^{n} \bar{A}_k^m \bar{B}_j^n g(\bar{x}_{mk}, \bar{y}_{nj}) + r_{mn}^*(g)$$

is optimal in the sense that $r_{mn}^*[V_{r,s;p}(M)]$, defined to be

$$\sup\left\{\left|r_{mn}^*(g)\right| : g \in V_{r,s;p}(M)\right\}$$

does not exceed $r_{m,n}[V_{r,s;p}(M)]$, defined analogously, where $r_{mn}(g)$ has the same form as $r_{mn}^*(g)$ with arbitrary nodes x_k and y_j in I and arbitrary coefficients A_j, B_k, and C_{kj}. Furthermore

$$r_{mn}^*[V_{r,s;p}(M)] = M\bar{r}_{r,p}(W_{r,p})\bar{r}_{n,s}(W_{s,p})$$

X. SMOOTHING BY SPLINE FUNCTIONS

Not only are spline functions useful in interpolation and approximation; they are natural data-smoothing functions, especially when the data are contaminated with noise. We first discuss the one-variable setting.

Let $0 = t_0 < \cdots < t_{n+1} = 1$ and $H_2^k = H_2^k[0, 1]$ be the Sobolev space of functions f such that $f, \ldots, f^{(k)}$ are in $L_2 = L_2[0, 1]$, where $k \le n - 1$. For any given data $Z = [z_1, \ldots, z_n]^T$, it can be shown that there is a unique function $s_{k,p} = s_{k,p}(\cdot;\ Z)$, which minimizes the functional

$$J_{k,p}(u; Z) = p\int_0^1 [D^k u]^2 + \frac{1}{n}\sum_{i=1}^{n}[u(t_i) - z_i]^2$$

over all functions u in H_2^k. In fact, the extremal function $s_{k,p}$ is a natural spline of order $2k$ having its knots at $t_1, \ldots, t_n$. The parameter $p > 0$, called the smoothing parameter, controls the "trade-off" between the smoothness of $s_{k,p}$ and its approximation to the data Z. Let $s_{k,p}(t_i) = y_i$ and $Y = [y_1, \ldots, y_n]^T$. Then $Y = A_k(p)Z$, where the $n \times n$ matrix $A_k(p)$ is called the influence matrix. Determining $s_{k,p}$ is equivalent to determining Y. Hence, the influence matrix is importtant. It can be shown that $A_k(p) = (I_n + npB_k)^{-1}$, where B_k is an $n \times n$ nonnegative definite symmetric matrix with exactly k zero eigen-values. The other $n - k$ eigenvalues of B_n are positive and simple, regardless the location of the t_i. Let these eigenvalues be $d_i = d_{ni}$ arranged in nondecreasing order as follows: $0 = d_1 = \cdots = d_k < d_{k+1} < \cdots < d_n$. It is clear that if Q is the unitary matrix that diagonalizes B_k in the sense that $B_k = Q^* D_k Q$, where $D_k = \mathrm{diag}[d_1 \cdots d_n]$, then setting $\hat{Y} = Q^*Y$ and $\hat{Z} = Q^*Z$, we have

$$\hat{y}_i = \frac{1}{1 + npd_i}\hat{z}_i$$

where $\hat{Y} = [\hat{y}_1 \cdots \hat{y}_n]^T$ and $\hat{Z} = [\hat{z}_1 \cdots \hat{z}_n]^T$ could be viewed as the Fourier transforms of Y and Z, respectively.

Theorem 60. Let $\{t_i\}$ be quasi-uniformly distributed; that is

$$\max(t_{i+1} - t_i) \le c \min(t_{t+1} - t_i)$$

where c is independent of n as $n \to \infty$. Then there exist positive constants c_1 and c_2 such that

$$c_1 i^{2k} \le n d_{ni} \le c_2 i^{2k}$$

for $i = k+1, \ldots, n$ and $n = 1, 2, \ldots$.

Hence, for quasi-uniformly distributed $\{t_i\}$, we have the following asymptotic behavior of $\hat{y}_i$, $i = k+1, \ldots, n$:

$$\hat{y}_1 \sim \frac{1}{1 + (p^{1/2k} r i)^{2k}} \hat{z}_i \sim b_k(p^{1/2k} r i)\hat{z}_i$$

as $n \to \infty$, where r is a positive constant and b_k a Butterworth-type low-pass filter with the inflection point as its cutoff frequency $i_c = (r p^{1/2k})^{-1}$. The size of the window of this filter decreases monotonically as the smoothing parameter p increases. In the limiting cases as $p \to \infty$, we have

$$\lim_{p\to\infty} \hat{y}_i = \begin{cases} \hat{z}_i & \text{if } i = 1, \ldots, k \\ 0 & \text{if } i = k+1, \ldots, n \end{cases}$$

In this case, the smoothing spline $s_{k,\infty}(\cdot;\ Z)$ is simply the least-squares polynomial of degree $k-1$. On the other hand, as $p \to 0$, we have

$$\lim_{p\to 0} \hat{y}_i = \hat{z}_i, \qquad i = 1, \ldots, n$$

so that $s_{k,0}(\cdot;\ Z)$ is the natural spline of order $2k$ interpolating the data Z.

Suppose that the data are contaminated with noise, say $z_i = g(t_i) + e_i$, where $g \in H_2^k$ and $e_1, \ldots, e_n$ are independent random variables with zero mean and positive standard deviation. A popular procedure for controlling the smoothing parameter p is the method of generalized cross-validation (GCV). We will not go into details but will remark that it is a predictor–corrector procedure.

The idea of a smoothing spline in one dimension has a natural generalization to the multivatiate setting. Unfortunately not much is known for an arbitrary domain D in R^s. In the following, the L_2 norm $\| \ \|_2$ will be taken over all of R^s, and this accounts for the terminology of "thin-plate splines." Again let $p > 0$ be the smoothing parameter and $k > s/2$. Then for every set of data $\{Z_1, \ldots, Z_n\}$ in R and a scattered set of sample points $\{t_1, \ldots, t_n\}$ in R^s, the thin-plate smoothing spline of order $2k$ and with smoothing parameter p is the (unique) solution of the minimization problem,

$$\inf_{u \in D^{-k}L^2(R^s)} \left\{ p|u|_k^2 + \frac{1}{n}\sum_{i=1}^{n} [u(t_i) - z_i]^2 \right\}$$

where

$$|u|_k^2 = \sum_{i_1,\ldots,i_k=1}^{s} \left\| \frac{\partial^k}{\partial x_{i_1} \cdots \partial x_{i_k}} u \right\|_2^2$$

and

$$D^{-k}L^2(R^s) = \{u \in D'(R^s) : D^a u \in L^2(R^s),\ |a| = k\}$$

with $D'(R^s)$ denoting the space of Schwartz distributions on R^s and

$$D^a = \frac{\partial^{|a|}}{\partial x_1^{a_1} \cdots \partial x_s^{a_s}}$$

Of course, all derivatives are taken in the distributional sense. Since $K > s/2$, the elements in $D^{-k}L^2(R^s)$ are continuous functions.

Theorem 61. The smoothing spline $s_{k,p} = s_{k,p}(\cdot;\ Z)$ that minimizes the above optimization problem exists and is unique and satisfies the distributional equation

$$(-1)^k \Delta^k S_{k,p} = \frac{1}{np} \sum_{i=1}^{n} c_i \delta_{t_i}$$

where δ_t is the Dirac distribution and $c_i = z_i - s_{k,p}(t_i;\ Z)$, $i = 1, \ldots, n$. Furthermore, $\Delta^k s_{k,p}$ is orthogonal to the collection π_{k-1} of polynomials of total degree $k-1$ in the sense that

$$\langle \Delta^k s_{k,p},\ p \rangle = \sum_{i=1}^{n} c_i P(t_i) = 0$$

for all P in π_{k-1}.

Let K_k be the elementary solution of the k-times-iterated Laplacean:

$$\Delta^k K_k = \delta_0$$

Then it is well known that

$$K_k(t) = \begin{cases} c_k |t|^{2k-s} & \text{if } s \text{ is odd} \\ c_k |t|^{2k-s} \log |t| & \text{if } s \text{ is even} \end{cases}$$

where $c_k = (-1)^k 2\pi [2^{k-1}(k-1)!]^2$. Also, if m is a measure with compact support orthogonal to π_{k-1}, then $m * K_k$ is an element of $D^{-k}L^2(R^s)$. Applying this result to $\Delta^k s_{k,p}$, we have

$$(-1)^k \Delta^k s_{k,p} * K_k = \frac{1}{np} \sum_{i=1}^{n} c_i K_k(t - t_i)$$

and

$$\begin{aligned} \Delta^k \big((-1)^k \Delta^k s_{k,p} * K_k \big) &= (-1)^k \big(\Delta^k s_{k,p} \big) * \big(\Delta^k K_k \big) \\ &= (-1)^k \big(\Delta^k s_{k,p} \big) * \delta_0 \\ &= (-1)^k \Delta^k s_{k,p} \end{aligned}$$

This yields

$$s_{k,p} - (-1)^k \Delta^k s_{k,p} * K_k \in \pi_{k-1}$$

Theorem 62. The smoothing spline $s_{k,p}$ satisfies

$$s_{k,p}(t) = (-1)^k \sum_{i=1}^{n} d_i K_k(t - t_i) + P(t)$$

where $P \in \pi_{k-1}$. Furthermore, the polynomial P and the coefficients $d_1, \ldots, d_n$ are uniquely determined by the equations:

$$(-1)^k \frac{1}{np} d_i + s_{k,p}(t_i) - z_i = 0, \qquad i = 1, \ldots, n$$

and

$$d_1 Q(t_1) + \cdots + d_n Q(t_n) = 0, \qquad Q \in \pi_{k-1}$$

Hence, if the values $y_i = s_{k,p}(t_i; Z)$, $i = 1, \ldots, n$, are known, the smoothing spline $s_{k,p}$ is also determined. Writing $Y = A_k(p)Z$, where $Y = [y_1, \ldots, y_n]^T$, it is important to study the influence matrix $A_k(p)$ as in the one-variable setting. Again it is possible to write

$$A_k(p) = (I + npB_k)^{-1}$$

Let $\{t_1, \ldots, t_n\}$ lie in a bounded domain D and R^s. We say that $\{t_i\}$ is asymptotically quasi-uniformly distributed in D if for all large n,

$$\sup_{t \in D} \min_{1 \le i \le n} |t - t_i| \le c \min_{1 \le i < j \le n} |t_1 - t_j|$$

where c is some positive constant, depending only on D.

Theorem 63. Let D satisfy a uniform cone condition and have Lipschitz boundary and $\{t_1, \ldots, t_n\}$ be asymptotically quasi-uniformly distributed in D. Then there exists a positive constant C such that the eigenvalues $d_{n1}, \ldots, d_{nn}$ of B_k satisfy $0 = d_{n1} = \cdots = d_{nk} < d_{n,k+1} < \cdots < d_{nn}$ and

$$i^{2k/s} \le n d_{ni} \le C i^{2k/s}, \qquad i = N+1, \ldots, n$$

for all n, where

$$N = \dim \pi_{k-1} = \binom{k+s-1}{s}$$

Thus, if we study the effect of thin-plate spline smoothing in the "frequency domain" as before by writing

$$\hat{Y} = Q^* Y; \qquad \hat{Z} = Q^* Z$$

where Q is unitary with $QB_kQ^* = \operatorname{diag}[d_{n1} \cdots d_{nn}]$, we obtain

$$\hat{y}_i = \frac{1}{1 + p d_{ni}} \hat{z}_i \sim b_k(p^{1/2k} r i) \hat{z}_i$$

where, again, b_k is a Butterworth-type low-pass filter with cutoff frequency at $(rp^{s/2k})^{-1}$. Similar conclusions can be drawn on the limiting cases as $p \to \infty$ and $p \to 0$, and again the method of GCV is commonly used to choose the smoothing parameter p. It is a predictor–corrector procedure and amounts to choosing p as the minimizer of the GCV function:

$$\frac{1}{n} \sum_{i=1}^{n} [s_{k,p}(t_i; Z) - z_i]^2 \Bigg/ \left[1 - \frac{1}{n} tr\, A_k(p)\right]^2$$

Of course, $s_{k,p}(t_i; Z) = y_i$ and determining $\{y_i\}$ is equivalent to determining $s_{k,p}$ itself.

In a more general setting, let X, H, K be three Hilbert spaces and T, A be linear operators mapping X onto H and K and having null spaces $N(T)$, $N(A)$, respectively. Let $p > 0$ be the smoothing parameter in the functional

$$J_{k,p}(u, Z) = p\|Tu\|_H^2 + \|Au - Z\|_K^2$$

where Z is the given "data" vector in K and $u \in X$.

Theorem 64. If $N(T) + N(A)$ is closed in X with $N(T) \cap N(A) = \{0\}$, there exists a unique function s_p in X satisfying

$$J_{k,p}(s_p, Z) = \inf\{J_{k,p}(u, Z) : u \in X\}$$

Moreover, if S denotes the space of all "spline" functions defined by

$$S = \{s \in X : T^*Ts \text{ is in the range of } A^*\}$$

where T^*, A^* denote the adjoints of T and A, respectively, then s_p satisfies $s_p \in S$ and

$$T^*Ts_p = p^{-1} A^*(Z - As_p)$$

As a corollary, it is clear that $s_p \in X$ is the smoothing spline function if and only if

$$\langle Ts_p, Tx \rangle_H = p^{-1} \langle Z - As_p, Ax \rangle_K$$

for all $x \in X$.

An interesting special case is $X = H_2^k(D)$, where D is a bounded open set in R^s with Lipschitz boundary and satisfying a uniform cone condition. If $k > s/2$, then the evaluation functional δ_t is continuous. Let $t_i, \ldots, t_n \in D$ and set $K = R^n$ and $H = [L_2(D)]^N$, where $N = s^k$. Also, define

$$Au = \left[\delta_{t_1} u \cdots \delta_{t_n} u\right]^T$$

and

$$T = \frac{\partial^k}{\partial x_{i_1} \cdots \partial x_{i_k}}$$

where $i_1 = 1, \ldots, s$ and $i_k = 1, \ldots, s$, and equip H with the norm $\| \ \|_H$, where

$$\|v\|_H^2 = \sum_{t_1, \ldots, i_k = 1}^{d} \left\| v_{i_{i_1 \cdots i_k}} \right\|_{L_2}^2 (D)$$

Then using Theorem 64 and the fact that $\{t_1, \ldots, t_n\}$ is a π_{k-1} unisolvent set, the following result can be proved:

Theorem 65. There exists a unique s_p in $H_2^k(D)$ that minimizes $J_{k,p}(u, Z)$ for all u in $H_2^k(D)$. Furthermore, s_p satisfies the distributional partial differential equation.

$$(-1)^k \Delta^k s_p = \frac{1}{p} \sum_{i=1}^{n} [z_i - s_p(t_i)] \delta_{t_i}$$

In fact, the following estimate has also been obtained for noisy data:

Theorem 66. Let $z_i = g(t_i) + e_i, \quad i = 1, \ldots, n$, where g is in $H_2^k(D)$, and let $e_1, \ldots, e_n$ be independent identically distributed random variables with variance V. If the points t_i satisfy a quasiuniform distribution condition in D, then there exist positive constants c_1 and c_2, independent of n, such that for $0 \le p \le 1$,

$$E\left[|s_p(\cdot\,; Z) - g|_j^2\right] \le c_1 p^{(k-j)/k} + \frac{1}{n} c_2 V p^{-(2j+s)/2k}$$

for $n^{-2nk/s} \le p \le 1$, where $1 \le j \le k$.

However, no general result on asymptotic optimality of cross-validation is available at the time of this writing.

XI. WAVELETS

The Fourier transform $\hat{f}(w)$ of a function $f(t)$ represents the spectral behavior of $f(t)$ in the frequency domain. This representation, however, does not reflect time-evolution of frequencies. A classical method, known as short-time Fourier transform (STFT), is to window the Fourier integral, so that, by the Plancherel identity, the inverse Fourier integral is also windowed. This procedure is called time-frequency localization. This method is not very efficient, however, because a window of the same size must be used for both low and high frequencies. The integral wavelet transform (IWT), defined by

$$(W_\psi f)(b, a) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} f(t) \overline{\psi\left(\frac{t-b}{a}\right)}\, dt,$$

on the other hand, has the property that the time-window narrows at high frequency and widens at low frequency. This is seen by observing that, for real f and ψ,

$$(W_\psi f)(b, a) = Re \frac{\sqrt{a}}{\pi} \int_0^{\infty} e^{-ib\omega} \hat{f}(\omega) \overline{g\left(a\left(\omega - \frac{\omega_0}{a}\right)\right)}\, d\omega;$$

where $g(\omega) := \hat{\psi}(\omega + \omega_0)$, and ω_0 is the center of the frequency window function $\hat{\psi}(\omega)$. More precisely, the window in the time-frequency domain may be defined by

$$[b - a\Delta_\psi, b + a\Delta_\psi] \times \left[\frac{\omega_0}{a} - \frac{1}{a}\Delta_{\hat{\psi}}, \frac{\omega_0}{a} + \frac{1}{a}\Delta_{\hat{\psi}}\right],$$

where Δ_ψ and $\Delta_{\hat{\psi}}$ denote the standard deviations of ψ and $\hat{\psi}$, respectively, and we have identified the frequency by a constant multiple of a^{-1}. Hence, the IWT has the zoom-in and zoom-out capability.

This localization of time and frequency of a signal function $f(t)$, say, not only makes it possible for filtering, detection, enhancement, etc., but also facilitates tremendously the procedure of data reduction for the purpose of storage or transmittance. The modified signal, however, must be reconstructed, and the best method for this reconstruction is by means of a wavelet series. To explain what a wavelet series is, we rely on the notion of multiresolution analysis as follows: Let $\{V_n\}$ be a nested sequence of closed subspaces of $L^2 = L^2(\mathbb{R})$, such that the intersection of all V_n is the zero function and the union of all V_n is dense in L^2. Then we say that $\{V_n\}$ constitutes a multiresolution analysis of L^2 if for each $n \in \mathbb{Z}$, we have $f \in V_n \Leftrightarrow f(2\cdot) \in V_{n+1}$ and if there exists some $\phi \in V_0$ such that the integer translates of ϕ yields an unconditional basis of V_0. We will also say that ϕ generates a multiresolution analysis of L^2. Examples of ϕ are B-splines of arbitrary order and with $\mathbb{Z}$ as the knot sequence. Next, for each $k \in \mathbb{Z}$, let W_k be the orthogonal complementary subspace of V_{k+1} relative to V_k. Then it is clear that the sequence of subspaces $\{W_k\}$ is mutually orthogonal, and the orthogonal sum is all of L^2. Consequently, every $f \in L^2$ can be decomposed as an orthogonal sum of functions $g_k \in W_k, k \in \mathbb{Z}$. It can be proved that there exists some function ψ whose integer translates form an unconditional basis of L^2. If this ψ, called a *wavelet*, is used as the window function in the IWT, then the "modified" signal $f(t)$ can be reconstructed from IWT at dyadic values by means of a wavelet series.

Let us first introduce the dual $\tilde{\psi} \in W_0$ of ψ defined (uniquely) by

$$\langle \tilde{\psi}, \psi(\cdot - n) \rangle = \delta_{n,0}, \qquad n \in \mathbb{Z}.$$

Then, by using the notation

$$\psi_{k,j}(t) = \psi(2^k t - j)$$

where $j, k \in \mathbb{Z}$, and the same notation for $\tilde{\psi}_{k,j}$, we have the following.

Theorem 67. For every $f \in L^2$, then

$$f(t) = \sum_{k,j \in Z} 2^{k/2} (W_\psi f)(j2^{-k}, 2^{-k}) \tilde{\psi}_{k,j}(t) = \sum_{k,j \in Z} 2^{k/2} (W_{\hat{\psi}} f)(j2^{-k}, 2^{-k}) \psi_{k,j}(t).$$

Algorithms are available to find the coefficients of the partial sums of this series and to sum the series using values of the coefficients. Since these coefficients are $2^{k/2}$ multiples of the IWT at $(j2^{-k}, 2^{-k})$ in the time-scale plane,

these algorithms determine the IWT efficiently without integration and reconstruct $f(t)$ efficiently without summing at every t. Based on two pairs of sequences (p_n, q_n) and (a_n, b_n), which are known as reconstruction and decomposition sequences, respectively, a pyramid algorithm is realizable. Here, $\{p_n\}$ defines the ϕ that generates the multiresolution analysis, namely:

$$\phi(t) = \sum_{n\in\mathbb{Z}} p_n \phi(2t - n)$$

and $\{q_n\}$ relates ψ to ϕ by:

$$\psi(t) \sum_{n\in\mathbb{Z}} q_n \phi(2t - n).$$

In addition, $\{a_n\}$ and $\{b_n\}$ determine the decomposition $V_1 = V_0 \oplus W_0$ by

$$\phi(2t - \ell) = \sum_{n\in\mathbb{Z}} a_{\ell-2n}\phi(t - n) + \sum_{n\in\mathbb{Z}} b_{\ell-2n}\psi(t - n),$$

for all $\ell \in \mathbb{Z}$.

If $\phi(t) = N_m(t)$ is the mth order B-spline with integer knots and supp $N_m = [0, m]$, then we have the following result.

Theorem 68. For each positive integer m, the minimally supported wavelet ψ_m corresponding to $N_m(t)$ is given by

$$\psi_m(t) = \frac{1}{2^{m-1}} \sum_{j=0}^{2m-2} (-1)^j N_{2m}(j + 1) \times \sum_{\ell=0}^{m} (-1)^\ell \binom{m}{\ell} N_m(2t - j - \ell).$$

Furthermore, the reconstruction sequence pair is given by:

$$p_n = s^{-m+1}\binom{m}{n}$$

and

$$q_n = \frac{(-1)^n}{2^{m-1}} \sum_{j=0}^{m} \binom{m}{j} N_{2m}(n - j + 1),$$

with supp$\{p_n\} = [0, m]$ and supp$\{q_n\} = [0, 3m - 2]$.

To describe the pair of decomposition sequences, we need the "Euler–Forbenius" polynomial

$$\prod\nolimits_m(z) := \sum_{n=0}^{2m-2} N_{2m}(n + 1)z^n,$$

Where we have omitted the multiple of $[(2m - 1)!]^{-1}$ for convenience. Then $\{a_n\}$ and $\{b_n\}$ are determined by the Laurent series:

$$G(z) = \frac{1}{2^m}(1 + z)^m \frac{\prod_m(z)}{z\prod_m(z^2)} = \sum_{n\in\mathbb{Z}} a_n z^{-n}$$

$$H(z) = -\frac{1}{2^m}(1 - z)^m \frac{1}{z\prod(z^2)} = \sum_{n\in\mathbb{Z}} b_n z^{-n}.$$

The duals $\tilde{N}_m$ of N_m and $\tilde{\psi}_m$ of ψ can be computed by using the following formulas:

$$\tilde{N}_m(t) = \sum_{n\in\mathbb{Z}} 2a_m \tilde{N}_m(2t - n)$$

$$\tilde{\psi}_m(t) = \sum_{n\in\mathbb{Z}} 2b_n \tilde{N}_m(2t - n).$$

Boolean Algebra

Raymond Balbes
University of Missouri-St. Louis

GLOSSARY

Atom Minimal nonzero element of a Boolean algebra.
Boolean homomorphism Function from one Boolean algebra to another that preserves the operations.
Boolean subalgebra Subset of a Boolean algebra that is itself a Boolean algebra under the original operations.
Complement In a lattice with least and greatest elements, two elements are complemented if their least upper bound is the greatest element and their greatest lower bound is the least element of the lattice.
Complete Pertaining to a Boolean algebra in which every subset has a greatest lower bound and a least upper bound.
Field of sets Family of sets that is closed under finite unions, intersections, and complements and also contains the empty set.
Greatest lower bound In a partially ordered set, the largest of all of the elements that are less than or equal to all of the elements in a given set.
Ideal In a lattice, a set that is closed under the formation of finite least upper bounds and contains all elements of the lattice that are less than elements in the ideal.
Lattice [distributive] Partially ordered set for which the least upper bound $x + y$ and the greatest lower bound xy always exist [a lattice in which the identity $x(y + z) = xy + xz$ holds].
Least upper bound In a partially ordered set, the smallest of all of the elements that are greater than or equal to all of the elements of a given set.
Partially ordered set Set with a relation "$\leq$" that satisfies certain conditions.

A BOOLEAN ALGEBRA is an algebraic system consisting of a set of elements and rules by which the elements of this set are related. Systematic study in this area was initiated by G. Boole in the mid-1800s as a method for describing "the laws of thought" or, in present-day terminology, mathematical logic. The subject's applications are much wider, however, and today Boolean algebras not only are used in mathematical logic, but since they form the basis for the logic circuits of computers, are of fundamental importance in computer science.

I. BASIC DEFINITIONS AND PROPERTIES

A. Definition of a Boolean Algebra

Boolean algebras can be considered from two seemingly unrelated points of view. We shall first give a definition in terms of partially ordered sets. In Section I.C, we shall give an algebraic definition and show that the two definitions are equivalent.

Definition. A partially ordered set (briefly, a poset) is a nonempty set P together with a relation $\leq$ that satisfies

1. $x \leq x$ for all x.
2. If $x \leq y$ and $y \leq z$, then $x \leq z$.
3. If $x \leq y$ and $y \leq x$, then $x = y$.

For example, the set of integers with the usual $\leq$ relation is a poset. The set of subsets of any set together with the inclusion relation $\subseteq$ is a poset. The positive integers with the | relation (recall that $x \mid y$ means that y is divisible by x) are a poset. A chain C is a subset of a poset P if $x \leq y$ or $y \leq x$ for any $x, y \in C$. The integers themselves form a chain under $\leq$ but not under | since $3 \leq 5$ by neither 3 nor 5 is divisible by the other.

In any poset, we write $x < y$ when $x \leq y$ and $x \neq y$. We also use $y \geq x$ synonymously with $x \leq y$.

A subset S of a poset P is said to have an upper bound if there exists an element $p \in S$ such that $s \leq p$ for all $s \in S$. An upper bound p for S is called a least upper bound (lub) provided that if q is any other upper bound for S then $p \leq q$. Similarly l is a greatest lower bound for S if $l \leq s$ for all $s \in S$, and if $m \leq s$ for all $s \in S$ then S then $m \leq l$.

Consider the poset $\mathcal{P}(X)$ of all subsets of a set X under inclusion $\subseteq$. For $S, T \in \mathcal{P}(X)$, the set $S \cup T$ is an upper bound for S and T since $S \subseteq S \cup T$ and $T \subseteq S \cup T$; clearly, any other set that contains both S and T must also contain $S \cup T$, so $S \cup T$ is the least upper bound for S and T.

Least upper bounds (when they exist) are unique. Indeed, if z and z' are both least upper bounds for x and y, then since z is an upper bound and z' is least, we have $z' \leq z$. Reversing the roles of z and z', we have $z \leq z'$, so $z = z'$.

Denote the (unique) least upper bound, if it exists, by $x + y$. Thus, $x \leq x + y$, $y \leq x + y$, and if $x \leq z$, $y \leq z$ then $x + y \leq z$. Similarly $x \cdot y$ (or simply xy) denotes the greatest lower bound of x and y if it exists.

A nonempty poset P in which $x + y$ and xy exist for every pair of elements $x, y \in P$, is called a lattice (the symbols $\vee$ and $\wedge$ are often used as notation instead of $+$ and $\cdot$). A lattice is called distributive if $x(y + z) = xy + xz$ holds for all x, y, z. A poset P has a least element (denoted by 0) if $0 \leq x$ for all $x \in P$ and a greatest element (denoted by 1) if $x \leq 1$ for all $x \in P$. It is evident that, when they exist, 0 and 1 are unique. A lattice L with 0 and 1 is complemented if for each $x \in L$ there exists an element $y \in L$ such that $x + y = 1$ and $xy = 0$. The elements x and y are called complements of one another.

Definition. A Boolean algebra is a poset B that is a complemented distributive lattice. That is, B is a poset that satisfies

1. For each $x, y \in B$, $x + y$ and xy both exist.
2. 0 and 1 exist.
3. $x(y + z) = xy + xz$ is an identity in B.
4. For each $x \in B$ there exists $y \in B$ such that $x + y = 1$ and $xy = 0$.

We shall soon see that, in a Boolean algebra, complements are unique. Thus, for each $x \in B$, $\bar{x}$ will denote the complement of x.

B. Examples

Example. The two-element poset **2**, which consists of {0, 1} together with the relation $0 < 1$, is a Boolean algebra.

Example. Let X be a nonempty set and $\mathcal{P}(X)$ the set of all subsets of X. Then $\mathcal{P}(X)$, with $\subseteq$ as the relation, is a Boolean algebra in which $S + T = S \cup T$, $ST = S \cap T$, $0 = \emptyset$, $1 = X$, and $\bar{S} = X - S$, where $X - S = \{x \in X \mid x \in S\}$. Note that if X has only one member then $\mathcal{P}(X)$ has two elements, $\emptyset$, X, and is essentially the same as the first example.

Diagrams can sometimes be drawn to show the ordering of the elements in a Boolean algebra. Each node represents an element of the Boolean algebra. A node that is connected to one higher in the diagram is "less than" the higher one (Fig. 1).

Example. Let X be a set that is possibly infinite. A subset S of X is cofinite if its complement $X - S$ is finite. The set of all subsets of X that are either finite or cofinite form a Boolean algebra under inclusion.

The preceding example is a special case of the following.

Example. A field of subsets is a nonempty collection $\mathcal{S}$ of subsets of a set $X \neq \emptyset$ that satisfies

1. If $S, T \in \mathcal{S}$, then $S \cap T$ and $S \cup T$ are also in $\mathcal{S}$.
2. If $S \in \mathcal{S}$, then so is $X - S$.

A field of subsets is a Boolean algebra under the inclusion relation, and it is easy to see that

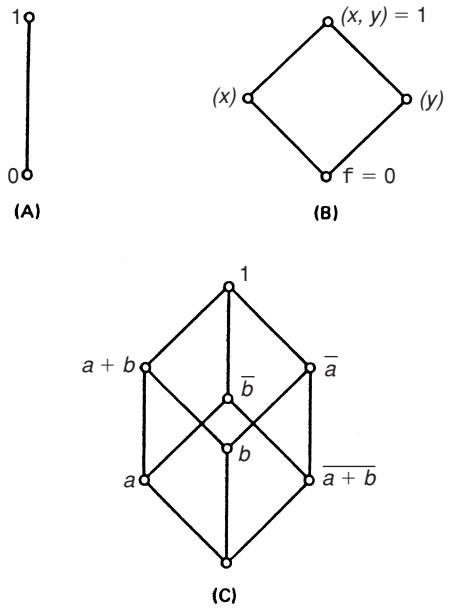

FIGURE 1 Ordering of elements in a Boolean algebra. (A), **2**; (B), $\mathcal{P}(\{x, y, \})$; (C), $\mathcal{P}(\{x, y, z\})$, $a = \{x\}$, $b = \{y\}$.

$$S + T = S \cup T$$
$$ST = S \cap T$$
$$0 = \emptyset$$
$$1 = X$$
$$\bar{S} = X - S$$

Note that $\emptyset$ and X are in $\mathcal{S}$ because $\mathcal{S} \neq 0$, so there exists $S_0 \in \mathcal{S}$. Hence, $\bar{S}_0 \in \mathcal{S}$ and so $\emptyset = S_0 \cap S_0 \in \mathcal{S}$. Also $X = X - \emptyset \in \mathcal{S}$.

This is an important example because the elements of the Boolean algebra are themselves sets rather than abstract symbols.

Example. Let $X \neq \emptyset$ be a topological space. A set S is regular open if $S = \text{INT}(\text{CL}(S))$. The set $\mathcal{S}$ of all regular open subsets of X forms a Boolean algebra under inclusion and

$$S + T = \text{INT}(\text{CL}(S \cup T))$$
$$ST = S \cap T$$
$$S = X - \text{CL(S)}$$
$$0 = \emptyset$$
$$1 = X$$

Note that $\mathcal{S}$ is *not* a field of sets since $S \cup T$ may not be a regular open set.

C. Elementary Properties

The following theorem contains several elementary but useful formulas.

Theorem. In a Boolean algebra B,

1. The following are equivalent:
   (i) $x \leq y$; (ii) $x + y = y$; (iii) $xy = x$.
2. $(x + y) + z = x + (y + z)$; $(xy)z = x(yz)$.
3. $x + y = y + x$; $yx = xy$.
4. $x + x = x$; $xx = x$.
5. $x + xy = x$; $x(x + y) = x$.
6. If $x \leq y$, then $x + z \leq y + z$ and $xz \leq yz$.
7. $xy \leq u + v$ if and only if $x\bar{u} \leq \bar{y} + v$; in particular, $xy = 0$ if and only if $x \leq \bar{y}$, and $x \leq y$ if and only if $\bar{y} \leq \bar{x}$.
8. $\overline{x + y} = \bar{x}\bar{y}$; $\overline{xy} = \bar{x} + \bar{y}$ (de Morgan's laws).
9. $x + yz = (x + y)(x + z)$.
10. Complements are unique.
11. $\bar{\bar{x}} = x$.

Proof. We select some of these properties to prove. First, in 1, we prove that (i) implies (ii). Given $x \leq y$, we want to show that y is the least upper bound of x and y. But this is immediate from the definition of least upper bound. Indeed, $x \leq y$ and $y \leq y$ show that y is an upper bound for x, y. Also if $x \leq z$ and $y \leq z$ for some z, then $y \leq z$, so y is the *least* upper bound.

For the first part of 6, simply note that $y + z$ is an upper bound for x and z (since $x \leq y$) so the *least* upper bound $x + z$ of x and z must satisfy $x + z \leq y + z$.

For 7, first observe from the definition of the greatest lower bound and the least upper bound that $x + 1 = 1$ and $x1 = x$ for all x. Now if $xy \leq u + v$, then

$$\begin{aligned} x\bar{u} &= (x\bar{u})1 = (x\bar{u})(y + \bar{y}) \\ &= (x\bar{u})y + (x\bar{u})\bar{y} \leq x(\bar{u}y) + \bar{y} = x(y\bar{u}) + \bar{y} \\ &= (xy)\bar{u} + \bar{y} \leq (u + v)\bar{u} + \bar{y} \\ &= (u\bar{u} + v\bar{u}) + \bar{y} \leq (0 + v) + \bar{y} = v + \bar{y} \end{aligned}$$

To prove the first part of 8, we show that $\overline{x + y}$ is the greatest lower bound for $\bar{x}$ and $\bar{y}$. Now since $x, y \leq x + y$, we have $\overline{x + y} \leq \bar{x}$ and $\overline{x + y} \leq \bar{y}$, by 7, so $\overline{x + y}$ is a lower bound for $\bar{x}$ and $\bar{y}$. But if $z \leq \bar{x}$ and $z \leq \bar{y}$, then $x \leq \bar{z}$ and $y \leq \bar{z}$, so $x + y \leq \bar{z}$ and thus $z \leq \overline{x + y}$.

Formula 9 is just the "distributive law" with the $+\cdot$ interchanged, and it indeed holds since $(x + y)(x + z) = (x + y)x + (x + y)z = xx + yx + xz + yz = x + xy + xz + yz = x + yz$.

Finally, statement 10, that complements are unique, means that if there exist z_1 and z_2 satisfying $x + z_1 = 1$,

$xz_1 = 0$ and $x + z_2 = 1$, $xz_2 = 0$, then $z_1 = z_2$. Now to prove this, $z_1 = z_1 1 = z_1(x + z_2) = z_1 x + z_1 z_2 = 0 + z_1 z_2 \leq z_2$. Similarly, $z_2 \leq z_1$ so $z_1 = z_2$.

In a Boolean algebra B, any finite set $S = \{x_1, \ldots, x_n\}$ has a least upper bound $(\ldots((x_1 + x_2) + x_3) + \cdots) + x_n$. This can be proved by mathematical induction, and in fact the order and parentheses do not matter. That is, $x_1 + (x_2 + x_3)$, $(x_2 + x_1) + x_3$, etc., all represent the same element, namely, the least member of B that is greater than or equal to x_1, x_2, and x_3. Thus, we use the notation $x_1 + \cdots + x_n$ or $\sum S$ or

$$\sum_{i \in (1,\ldots,n)} x_i$$

for the least upper bound of a nonempty set $S = \{x_1, \ldots, x_n\}$. Similarly, $x_1 \ldots x_n$, ΠS, and

$$\prod_{i \in (1,\ldots,n)} x_i$$

represent the greatest lower bound of S. All of the properties listed above generalize in the obvious way. For example,

1. $\Pi S \leq s \leq \sum S$ for all $s \in S$.
2. $x + \Pi S = \Pi\{x + s \mid s \in S\}$.
3. $\overline{\sum S} = \Pi\{\bar{s} \mid s \in S\}$, $\overline{\Pi S} = \sum\{\bar{s} \mid s \in S\}$.

Note that, if $S = \emptyset$, then 0 satisfies the criteria for being a least upper bound for the set S. So we extend the difinitions of $\sum$ and Π to $\sum \emptyset = 0$, $\Pi\emptyset = 1$.

As mentioned above, Boolean algebras can be defined as algebraic systems

Definition. A Boolean algebra is a set B with two binary operations $+$, $\cdot$, a unary operation $-$, and two distinguished, but not necessarily distinct elements 0, 1 that satisfies the following identities:

1. $(x + y) + z = x + (y + z)$; $(xy)z = x(yz)$.
2. $x + y = y + x$; $xy = yx$.
3. $x + x = x$; $xx = x$.
4. $x + xy = x$; $x(x + y) = x$.
5. $x(y + z) = xy + xz$; $x + yz = (x + y)(x + z)$.
6. $0 + x = x$; $1x = x$.
7. $x + x = 1$; $xx = 0$.

A more concise definition of a Boolean algebra is as an idempotent ring $(R, +, \cdot, 0)$—in the classical algebraic sense—with unity. In this case, the least upper bound is $x + y + xy$; the greatest lower bound is xy; 0 and 1 play their usual role; and $\bar{x} = 1 - x$.

Now that we have two definitions of a Boolean algebra, we must show that they are equivalent. Let us start with the poset definition of B. From the theorem in the last section, it is easy to see that by considering the $+$ and $\cdot$ as operations, rather than as least upper and greatest lower bounds, all of the above identities are true. On the other hand, suppose we start with a Boolean algebra B defined algebraically. We can then define a relation $\leq$ on B by $x \leq y$ if and only if $xy = x$. This relation is in fact a partial order on B since (1) $xx = x$ implies $x \leq x$; (2) if $x \leq y$ and $y \leq z$, then $xy = x$, $yz = y$, so $xz = (xy)z = x(yz) = xy = x$, so $x \leq z$; and (3) if $x \leq y$ and $y \leq x$, then $xy = x$, $yx = y$, so $x = xy = yx = y$. If we continue in this way, $x + y$ turns out to be the least upper bound of x and y under the $\leq$ that we have defined, xy is the greatest lower bound, 0 is the least element, 1 is the greatest, and $\bar{x}$ is the complement of x. Thus B, under $\leq$, is a Boolean algebra.

Since both of these points of view have advantages, we shall use whichever is most appropriate. As we shall see, no confusion will arise on this account.

From the algebraic points of view, the definition of **2** and $\mathcal{P}(\{x, y\})$, shown in Fig. 1, could be given by Table I.

D. Subalgebras

A (Boolean) subalgebra is a subset of a Boolean algebra that is itself a Boolean algebra under the original operations.

A subset B_0 of a Boolean algebra that satisfies the conditions 1–3 below also satisfies the four definitions of a Boolean algebra. This justifies the following:

Definition. A subalgebra B_0 of a Boolean algebra B is a subset of B that satisfies

1. If $x, y \in B_0$, then $x + y$ and $xy \in B_0$.
2. If $x \in B_0$, then $\bar{x} \in B_0$.
3. $0, 1 \in B$.

Every subalgebra of a Boolean algebra contains 0 and 1; $\{0, 1\}$ is itself a subalgebra. The collection of finite and cofinite subsets of a set X forms a subalgebra of $\mathcal{P}(X)$.

TABLE I Operator Tables for 2 and $\mathcal{P}(\{x, y\})$

Boolean Algebra **2**

$+$	0	1
0	0	1
1	1	1

$\cdot$	0	1
0	0	0
1	0	1

$-$	0	1

$-$	0	a	b	1
	1	b	a	0

Now suppose that S is a subset of a Boolean algebra B. Let $S^- = \{\bar{s} \mid s \in S\}$. Then the set of all elements of the form $x = \sum_{i=1}^{n} \prod S_i$, where the S_i are finite nonempty subsets of $S \cup S^-$, form a subalgebra of B. In fact, this set is the smallest subalgebra of B that contains S. It is denoted by $[S]$ and is called the subalgebra of B generated by S. For $x \in B$, $[\{x\}] = \{0, x, \bar{x}, 1\}$; $[\{0, 1\}] = \{0, 1\}$ and $[B] = B$.

E. Ideals and Congruence Relations

Definition. Let B be a Boolean algebra. An ideal I is a nonempty subset of B such that

1. If $x \leq y$, $y \in I$, then $x \in I$.
2. If $x, y \in I$, then $x + y \in I$.

If $I \neq B$, then I is called a proper ideal.

Example. The set I of finite subsets of $\mathcal{P}(X)$ forms an ideal.

Example. $\{0\}$ and B are both ideals in any Boolean algebra B.

Let B be a Boolean algebra. For $b \in B$, the set $\{x \in B \mid x \leq b\}$ is called a principal ideal and is denoted by (b). Now let S be any subset of B. The set $\{x \in B \mid x \leq s_1 + \cdots + s_n, s_i \in S\}$ [denoted by (S)] is the smallest ideal in B that contains S. It is called the ideal generated by S. Of course, if $S = \{b\}$, then $(b) = (\{b\})$.

Ideals are closely related to the standard algebaric notion of a congruence relation. A congruence relation on a Boolean algebra B is a relation Θ that satisfies

1. $(x, x) \in \Theta$ for all $x \in B$.
2. $(x, y) \in \Theta$ implies $(y, x) \in \Theta$.
3. $(x, y)\,(y, z) \in \Theta$ implies$(x, z) \in \Theta$.
4. $(x, y), (x_1, y_1) \in \Theta$ implies $(x + x_1, y + y_1)$, $(xx_1, yy_1) \in \Theta$.
5. $(x, y) \in \Theta$implies $(\bar{x}, \bar{y}) \in \Theta$.

A congruence ralation Θ on B determines a Boolean algebra $B/\Theta = \{[x]_\Theta \mid x \in B\}$, where $[x]_\Theta$ is the congruence class determined by Θ. There is a one-to-one correspondence between the set of all congruences on B and set of all ideals in B. The correspondence is given by $\Theta \to I$, where $x \in I$ if $(x, 0) \in \Theta$. The inverse function $I \to \Theta$ is defined by $(x, y) \in \Theta$ if $x \oplus y \in I$, where $x \oplus y = x\bar{y} + \bar{x}y$ Thus, B/Θ is sometimes written as B/I, where I is the ideal corresponding to Θ. In this notation, B/I is a Boolean algebra in which

$$x/I + y/I = (x + y)/I$$
$$x/I \cdot y/I = (xy)/I$$
$$(\overline{x/I}) = \bar{x}/I$$

and

$$x/I = y/I$$

if there exists $i_0 \in I$ such that

$$x + i_0 = y + i_0$$

F. Homomorphisms

Definition. Let B and B_1 be Boolean algebras. A (Boolean) homomorphism is a function $f : B \to B_1$ that preserves the operations; that is,

1. $f(x + y) = f(x) + f(y)$.
2. $f(xy) = f(x)f(y)$.
3. $f(\bar{x}) = \overline{f(x)}$.
4. $f(0) = 0$, $f(1) = 1$.

Homomorphisms preserve order; that is, if $x \leq y$, then $f(x) \leq f(y)$. But a function that preserves order need not be a homomorphism. Condition 3 is actually a consequence of 1, 2, and 4 since $f(\bar{x})$ is the complement of $f(x)$ and complements are unique.

Example. Let $\mathcal{F}$ be a field of subsets of a set X (see Section I.B) and select an element $p \in X$. Define a function $f : \mathcal{F} \to 2$ by

$$f(S) = \begin{cases} 0 & \text{if} \quad p \notin S \\ 1 & \text{if} \quad p \in S \end{cases}$$

To see that f is a homomorphism, we first show that f preserves order. If $S_1 \subseteq S_2$ and $f(S_2) = 1$, then $f(S_1) \leq 1 = f(S_2)$. But if $f(S_2) = 0$, then $p \in S_2$, so $p \in S_1$, since $S_1 \subseteq S_2$. Therefore, $f(S_1) = 0 = f(S_2)$. Since f preserves order, we have $f(S_1) \leq f(S_1 \cup S_2)$ and $f(S_2) \leq f(S_1 \cup S_2)$, so $f(S_1) + f(S_2) \leq f(S_1 \cup S_2)$. To prove $f(S_1 \cup S_2) \leq f(S_1) + f(S_2)$, suppose that $f(S_1) + f(S_2) = 0$. Then since $\underline{2}$ consists only of 0 and 1, we have $f(S_1) = f(S_2) = 0$, so $p \notin S_1$ and $p \notin S_2$. Hence, $p \notin S_1 \cup S_2$, so $f(S_1 \cup S_2) = 0$. Next, we show $f(S_1)f(S_2) \leq f(S_1 \cap S_2)$; the reserve inclusion follows since f preserves order. If $f(S_1 \cap S_2) = 0$, then $p \notin S_1 \cap S_2$, so either $p \notin S_1$ or $P \notin S_2$. Hence, $f(S_1) = 0$ or $f(S_2) = 0$. In any case, $f(S_1)f(S_2) = 0$. Since 3 is a consequence of 1, 2, and 4 we turn to 4. Now $p \notin \emptyset$ and $p \in X$, so $f(\emptyset) = 0$ and $f(X) = 1$.

Example. Let B be a Boolean algebra and $a \in B$, $a \neq 0$. The ideal (a) is a Boolean algebra (not a subalgebra!) in which, if we denote the least upper bound by $*$, the greatest lower bound by $\times$, and the complement by $^{-a}$, we have for $x, y \in (a]$,

$$x * y = x + y$$
$$x \times y = xy$$
$$\bar{x}^a = a\bar{x}$$

Also, 0 is the least element of $(a]$ and a the greatest element.

The function $f : B \to (a)]$, $f(x) = ax$ is a homomorphism.

Example. Let I be an ideal in a Boolean algebra B. Then $v : B \to B/I$, $v(x) = x/I$ is a homomorphism.

Definition. A homomorphism that is one to one and onto is called an isomorphism.

If there exists an isomorphism f from B to B^1, then it is easy to see that f^{-1} is also an isomorphism. In this case, B and B^1 are said to be isomorphic. This is an important concept because isomorphic Boolean algebras are identical from the point of view of Boolean algebras. That is, there is a one-to-one correspondence between their elements and any property that can be expressed in terms of $\leq, +, \cdot, 0, 1, -$ that is true about one is also true about the other. For example, the Boolean algebra **2** (see Table I) and the field of all subsets of the set $\{p\}$ are isomorphic under the correspondence $0 \leftrightarrow \emptyset$, $1 \leftrightarrow \{p\}$. In fact, we will see later that, for any positive integer n, there is only one (up to isomorphism) Boolean algebra with 2^n elements. Put another way, every Boolean algebra with n elements is isomorphic with the set of all subsets of $\{1, \ldots, n\}$.

The well-known "homomorphism theorem" of classical ring theory applies to Boolean algebras and can be formulated as follows. If $f : B \to B_1$ is an onto homomorphism, then B_1 is isomorphic with B/K, where K is the ideal $K = \{x \in B \mid f(x) = 0\}$. Also let L_1 be a subalgebra of L and I an ideal in L. Then $L_1^1 = \{a \oplus x \mid a \in L_1, x \in I\}$ is a subalgebra of L, and $L_1/(L_1 \cap I)$ is isomorphic with L_1^1/I. (Here, $a \oplus x = \bar{a}x + a\bar{y}$.)

G. Duality

Let P be a mathematical statement concerning Boolean algebras. The dual of P is the statement obtained from P by interchanging the $+$ and $\cdot$ operations and also interchanging the 0's and 1's, where they occur. There are two duality principles that play a role in the study of Boolean algebras. The first—weak duality—is a consequence of the fact that, in the algebraic definition of a Boolean algebra (Section I.C), all of the identities appear along with their dual statements. This implies that, if P is a statement that is true in all Boolean algebras, the dual of P is also true in all Boolean algebras. For example, the statement "If $x + y = \bar{z}$, then $xz = 0$" is always true in any Boolean algebra. Hence, its dual "$xy = \bar{z}$ implies $x + x = 1$" is also true in all Boolean algebras.

The strong-duality principle is that, if a statement is true in a particular Boolean algebra B, its dual is also true in B. The reason for this is that B is "anti-isomorphic" with itself; that is, $x \leq y$ if and only if $\bar{y} \leq \bar{x}$. For example, if there exists an element $b \neq 0$ in a Boolean algebra B such that $0 \leq x < b$ implies $x = 0$, then by strong duality there must also exist an element $c \neq 1$ in B such that $c < x \leq 1$ implies $x = 1$.

II. REPRESENTATION THEORY

A. The Finite Case

In this section we classify all of the finite Boolean algebras. A useful concept for this purpose is that of an atom.

Definition. Let B be a Boolean algebra. An element $a \in B$ is called an atom if $a \neq 0$ and if $x \leq a$, then $x = 0$ or $x = a$.

Theorem. In a Boolean algebra B, the following are equivalent for an element $a \neq 0$.

1. a is an atom.
2. If $a = x + y$, then $a = x$ or $a = y$.
3. If $a \leq x + y$, then $a \leq x$ or $a \leq y$.

Proof. Suppose first that a is an atom and $a = x + y$. Then since $x \leq a$ and $y \leq a$, we have $\{x, y\} \subseteq \{0, a\}$. But x and y cannot both be 0 since $a \neq 0$, so $x = a$ or $y = a$. Next suppose that 2 holds and $a \leq x + y$. Then $a = a(x + y) = ax + ay$, so $a = ax$ or $a = ay$. Hence, $a \leq x$ or $a \leq y$. Finally, if 3 holds and $x \leq a$, then $a = a(x + \bar{x}) = ax + a\bar{x}$; thus, $a = ax$ or $a = a\bar{x}$. So $a \leq x$ or $a \leq \bar{x}$. But $x \leq a$, so if $a \leq x$ then $x = a$, and if $a \leq \bar{x}$ then $x = xa = 0$.

Theorem. Let B be a finite Boolean algebra. Then B is isomorphic with $\mathcal{P}(A)$, where A is the set of atoms of B.

Proof. For each $b \in B$, let $\varphi(b) = \{a \in A \mid a \leq b\}$. Now $b \to \varphi(b)$ preserves order for if $b_1 \leq b_2$ and $a \in \varphi(b_1)$, then $a \leq b_1 \leq b_2$ so $a \in \varphi(b_2)$. Thus, $\varphi(b_1 \cup \varphi(b_2) \subseteq \varphi(b_1 + b_2)$. For the reverse inclusion, let $a \in \varphi(b_1 + b_2)$. Then $a \leq b_1 + b_2$, but by the previous theorem, $a \leq b_1$ or $a \leq b_2$, so $a \in \varphi(b_1)$ or $a \in \varphi(b_2)$. Hence, $a \in \varphi(b_1) \cup \varphi(b_2)$. It is also easily seen that $\varphi(b_1) \cap \varphi(b_2) = \varphi(b_1 b_2)$, $\varphi(0) = \emptyset$, $\varphi(1) = A$, and $\overline{\varphi(b)} = \varphi(\bar{b})$. So φ is a homomorphism. Now for each b, let len(b) be the number of elements in the longest chain in B that has b as its largest element. This definition is possible since B is finite. We shall

prove, by induction, on the length of b that $b = \sum \varphi(b)$ for all $b \in B$. If $\text{len}(b) = 1$, then $b = 0$ so $\varphi(0) = \emptyset$. Hence $0 = \sum\{0\} = \sum \varphi(0)$. Suppose that $\sum \varphi(x) = x$ for all x such that $\text{len}(x) < n$. Now suppose $\text{len}(b) = n$. If b is an atom, then $b \in \varphi(b)$, so $b = \sum\{a \in A \mid a \leq b\} = \varphi(b)$, so we can assume that b is not an atom. Then there exists $c \neq b$ and $d \neq b$ such that $b = c + d$. But since $c < b$ and $d < b$, we can conclude that $\text{len}(c) < n$ and $\text{len}(d) < n$. Thus, $c = \sum \varphi(c)$ and $d = \sum \varphi(d)$. It follows that

$$b = c + d = \sum \varphi(c) + \sum \varphi(d)$$
$$= \sum[\varphi(c) + \varphi(d)] = \sum \varphi(c + d) = \sum \varphi(b)$$

To complete the proof first note that, by distributivity, if $S \subseteq A$, $a \in A$, and $a \leq \sum S$, then $a = a \sum S = \sum\{as \mid s \in S\}$ and each as is either 0 or an atom. Now let $S \in \mathcal{P}(A)$. Then $\sum S \in B$ and $\varphi(\sum S) = \{a \in A \mid a \leq \sum S\} = S$, so φ is onto. Finally, to show that φ is one to one, let $\varphi(b_1) = \varphi(b_2)$; then $b_1 = \sum \varphi(b_1) = \sum \varphi(b_2) = b_2$.

B. General Representation Theory

The representation of finite Boolean algebras as fields of sets can be generalized to arbitrary Boolean algebras. In this section we show how this is done and go farther by showing that, as a category, Boolean algebras and homomorphisms are equivalent to a certain category of topological spaces and continuous functions.

Definition. An ideal I in a Boolean algebra B is maximal provided that

1. $I \neq B$.
2. If J is an ideal and $I \subseteq J \subseteq B$, then $J = I$ or $J = B$.

It is easy to see that a principal ideal $(b]$ is maximal if and only if $\bar{b}$ is an atom. A more general theorem is the following:

Theorem. An ideal I is maximal if and only if $I \neq B$ and $xy \in I$ implies $x \in I$ or $y \in I$.

Proof. First suppose that I is maximal, $xy \in I$, but $x \notin I$ and $y \notin I$. Then the ideal generated by $I \cup \{x\}$ properly contains I and, by hypothesis, must be B. So $1 \in B = (I \cup \{x\}]$ and $1 = i + x$ for some $i \in I$. Thus, $\bar{x} \leq i$ so $\bar{x} \in I$. Similarly, $\bar{y} \in I$ and hence $\overline{xy} = \bar{x} + \bar{y} \in I$. But then $1 = (xy) + (\overline{xy}) \in I$, which implies that $I = B$, a contradiction. So $x \in I$ or $y \in I$.

Now assume the hypothesis of the converse and that there is an ideal J such that $I \subset J \subseteq B$. Let $x \in J - I$. To prove $\bar{B} = J$, let $z \in B$. Then $x(\bar{x}z) = 0 \in I$ and $x \notin I$ so $\bar{x}z \in I$. Hence, $\bar{x}z \in J$. So $x + z = x + \bar{x}z \in J$ and therefore $z \in J$. Thus, $B = J$.

It can also be shown that an ideal I is maximal if and only if B/I is isomorphic with **2** and that the set of homomorphisms of B onto **2** are in one-to-one correspondence with the set of maximal ideals. However, the crucial result about maximal ideals concerns their existence.

Theorem. In a Boolean algebra B every element $b \neq 1$ is contained in a maximal ideal.

Proof. (Note: This proof requires a knowledge of Zorn's lemma.) Let $\mathcal{P}$ be the poset of proper ideals that contain b; $(b]$ is one such ideal. Now if $\mathcal{S}$ is a chain in $\mathcal{P}$, then $\cup \mathcal{S}$ is an upper bound for $\mathcal{S}$ since it is an ideal and, being a union of ideals that do not contain 1, cannot itself contain 1. So by Zorn's lemma, $\mathcal{P}$ has a maximal element, say I. Clearly, I is an ideal that contains b. Now if J is an ideal that contains I, then $b \in J$, so $J \in \mathcal{P}$. But I is a maximal element of $\mathcal{P}$, so $J = I$; hence, I is a maximal ideal.

Let B be a Boolean algebra and $\mathcal{I}$ the set of maximal ideals in B. For each $b \in B$, let $\hat{b} = \{I \in \mathcal{J} \mid b \notin I\}$. It is easy to verify that $\hat{B} = \{\hat{b} \mid b \in B\}$ is a field of sets. Specifically,

$$\hat{b}_1 \cup \hat{b}_2 = b_1 + b_2$$
$$\hat{b}_1 \cap \hat{b}_2 = b_1 b_2$$
$$\hat{0} = \emptyset$$
$$\hat{1} = \mathcal{J}$$
$$\hat{\bar{b}} = \mathcal{J} - \hat{b}$$

Moreover, the assignment $\varphi : b \to \hat{b}$ is an isomorphism. To see that φ is one to one, suppose $b_1 \neq b_2$ and without loss of generality say $b_1 \not\leq b_2$. Then $b_1 + b_2 \neq 1$. So there is a maximal ideal I containing $b_1 + b_2$; thus, $b_2 \in I$ and $b_1 \in I$, so $b_1 \in I$. Thus, $I \in \hat{b}_1$, but $I \notin \hat{b}_2$. Hence, $\hat{b}_1 \neq \hat{b}_2$.

For the topological representation theory, we start with a Boolean algebra B and form a topological space $\mathcal{S}(B)$ as follows. The points of $\mathcal{S}(B)$ are the maximal ideals $\mathcal{J}$ of B, and $\{\hat{x} \mid x \in B\}$ is taken as a basis for the topology. This space is a compact Hausdorff space in which the sets that are both open and closed (these turn out to be exactly $\{\hat{x} \mid x \in B\}$ form a basis. Such a space X is called a Boolean (also Stone) space. Let $\mathcal{B}(X)$ denote the field of open–closed sets of a Boolean space.

Theorem. For a Boolean algebra B, $\mathcal{B}(\mathcal{S}(B))$ is isomorphic with B and for each Boolean space X, $\mathcal{S}(\mathcal{B}(X))$ is homeomorphic with X.

This identification can be extended to a coequivalence $\mathcal{C}$ (in the sense of category theory) that assigns to each Boolean algebra B its corresponding Boolean space $\mathcal{S}(B)$ and for each homomorphism $f : B \to B_1$ the continuous function $f : \mathcal{S}(B_1) \to \mathcal{S}(B)$ defined by $\hat{f}(I) = f^{-1}(I)$,

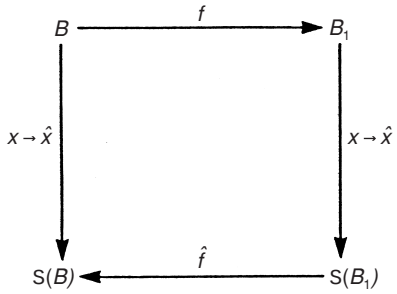

FIGURE 2 Coequivalence between homomorphisms and continuous functions.

$I \in \mathcal{S}(B_1)$. Furthermore, $\hat{f}^{-1}[\hat{x}] = f(x)$ for each $x \in B$ (Fig. 2).

This coequivalence can be very useful since problems in Boolean algebra can be transformed into questions or problems about Boolean spaces that may be more amenable to solution.

III. FREE BOOLEAN ALGEBRAS AND RELATED PROPERTIES

The basic fact about extending functions to homomorphisms is given by the following:

Theorem. Let B, B_1 be Boolean algebras, $\emptyset \neq S \subseteq B$, and $f : S \to B_1$ a function; f can be extended to a homomorphism $g : [S] \to B_1$ if and only if: (l) If $\Pi T_1 \leq \sum T_2$ then $\Pi f[T_1] \leq \sum f[T_2]$, where $T_1 \cup T_2$ is any finite nonempty subset of S. (Note that this includes the cases $\Pi T = 0 \Rightarrow \Pi f[T] = 0$ and $\sum T = 1 \Rightarrow \sum f[T] = 1$, where T is a finite nonempty set).

Sketch of Proof. To define $g : [S] \to B$, we set $g(\sum_{i=1}^{n} \Pi T_i = \sum \Pi f[T_i]$. The condition (1) is sufficient to prove that g is a well-defined homomorphism. Clearly, $g \mid S = f$.

A free Boolean algebra with free generators $\{x_i\}_{i \in I}$ is a Boolean algebra generated by $\{x_i\}_{i \in I}$ and such that any function $f : \{x_i \mid i \in I\} \to B_1$ can be extended to homomorphism. Free Boolean algebras with free generating sets of the same cardinality are isomorphic. For the existence of a free Boolean algebra with a free generating set of cardinality α, we start with a set X of cardinality α. For each $x \in X$, let $S_x = \{S \subseteq X \mid x \in S\}$. Now $\{S_x \mid x \in X\}$ freely generates a subalgebra C of the power set of X. The set $\{S_x \mid x \in X\}$ is said to be independent because if satisfies $\bigcap_{x \in A} S_x \subseteq \bigcup_{y \epsilon B} S_y$ and implies $A \cap B \neq \phi$ for any finite nonempty subset $A \cup B$ of X. But this condition clearly implies that (1) holds, so C is free.

Free Boolean algebras have many interesting properties:

1. Every chain in a free Boolean algebra is finite or countably infinite.
2. Every free Boolean algebra has the property that, if S is a set in which $xy = 0$ for all $x \neq y$ in S, then S is finite or countably infinite. (This is called the countable chain condition).
3. Countable atomless Boolean algebras are free.
4. The finite free Boolean algebras are all of the form $\mathcal{P}(\mathcal{P}(S))$ for finite S.

The Boolean space corresponding to the free Boolean algebra on countably many free generators is the Cantor discontinuum. So for example, the topological version of "Every countable Boolean algebra is projective" is "Every closed subset of the Cantor discontinuum is a retract of itself."

IV. COMPLETENESS AND HIGHER DISTRIBUTIVITY

The canonical work on this topic is "Boolean algebras" by R. Sikorski, and there are many more recent results as well. We present here only a brief introduction.

Definition. A Boolean algebra is complete if $\sum S$ and ΠS exist for all $S \subseteq B$.

For example, $\mathcal{P}(S)$ is complete, as is the Boolean algebra of regular open sets of a topological space. Here one must be careful, for if S is a family of regular open sets, $\cap S$ may not be regular open. It can be shown that $\Pi S = \mathrm{INT}(\cap S)$ and $\sum S = \mathrm{INT}(CL(\cup S))$.

There are many useful ways to generalize the distributive law $x(y + z) = xy = xz$; we will restrict our attention to the following:

Definition. A Boolean algebra is completely distributive provided that, if $\{a_{ij}\}_{i \in I, j \in J}$ is a set of elements such that $\sum_{j \in J} a_{ij}$ exists for each $i \in I$, $\Pi_{i \in I} \sum_{j \in J} a_{ij}$ exists, and $\Pi_{i \in I} a_{i\varphi(i)}$ exists for each $\varphi \in J^I$, then $\sum_{\varphi \in J^I} \Pi_{i \in I} a_{i_\varphi}(i)$ exists and

$$\prod_{i \in I} \sum_{J \in J} a_{ij} = \sum_{\varphi \in J^I} \prod_{i \in I} a_{i\varphi(i)}.$$

A typical result involving these notions is the following:

Theorem. Let B be a Boolean algebra. Then the following are equivalent:

1. B is complete and completely distributive.
2. B is complete and every element is a sum of atoms.
3. B is isomorphic with the field of all subsets of some set.

A striking theorem of Sikorski, from which it follows that the injectives in the category of Boolean algebras are those that are complete, can be formulated as follows:

Theorem. If B_1 is a subalgebra of a Boolean algebra B, A is a complete Boolean algebra, and $f : B_1 \to A$ is a homomorphism, then there exists a homomorphism $g : B \to A$ such that $g \mid B_1 = f$.

Proof. By Zorn's lemma, there exists a homomorphism $f_1 : B_0 \to A$ that is maximal with respect to being an extension of f. We will, of course, be done if $B_0 = B$, so suppose $B_0 \subset B$. Select $a \in B - B_0$ and set

$$b = \sum f_1[\{x \in B_1 \mid x \leq a\} \cap B_0].$$

Now, it can be shown that $a \leq x, x \in B_0 \Rightarrow b \leq f_1(x)$, and $x \leq a, x \in B_0 \Rightarrow f_1(x) \leq b$, so by our theorem on extending functions to homomorphism, f_1 can be extended to $[\{a\} \cup B_0]$, contradicting the maximality of f_1.

Another interesting series of results concerns the embedding of Boolean algebras into ones that are complete. Specifically, a regular embedding $f : B \to B_1$ is a one-to-one homomorphism with the property that, if $\sum S$ exists in B, then $\sum f[S]$ exists in B_1 and is equal to $f(\sum B)$ and similarly for products.

To outline one of the basis results, we shall call an ideal closed if it is an intersection of principal ideals. The set $\bar{B}$ of all closed ideals forms a complete Boolean algebra under inclusion, and the map $v : B \to \bar{B}, v(x) = (x]$ is a regular embedding. The pair (B, v) is called the MacNeille completion of B. B is isomorphic with the Boolean algebra of regular open subsets of the Boolean space of B.

V. APPLICATIONS

A. Logic

One of the most importance areas of application for Boolean algebras is logic. Indeed, many problems in logic can be reformulated in terms of Boolean algebras where a solution can be more easily obtained. For example, the fundamental compactness theorem for the (classical) propositional calculus is equivalent to the theorem that every element $a \neq 1$ in a Boolean algebra is contained in a maximal ideal.

Thus, Boolean algebras can be used as models for logical systems. A striking example of this is the simplification of the independence proofs of P. J. Cohen by means of Boolean models. For example, by studying the appropriate Boolean algebra, we can prove that the axiom of choice is not a consequence of set theory—even with the continuum hypothesis.

To illustrate, we start with the set S of formulas $\alpha, \beta, \gamma, \ldots$ of the classical propositional calculus. An equivalence relation $\equiv$ is defined by identifying α and β, provided the $\alpha \to \beta$ and $\beta \to \alpha$ are both derivable. A Boolean algebra is defined on the classes $[\alpha], [\beta], [\gamma], \ldots$ by the partial ordering $[\alpha] \leq [\beta]$ if and only if $\alpha \to \beta$ is derivable.

The resulting Boolean algebra is called the Lindenbaum–Tarski algebra and is in fact the free Boolean algebras with free generators $[\alpha], [\beta], [\gamma], \ldots$, where α, β, γ are the propositional variables. The construction of the Lindenbaum–Tarski algebra for the restricted prelicate calculus is similar, and it is in this context that the independence proofs can be given.

B. Switching Functions and Electronics

Switching functions are mathematical formulas that enable us to describe and design certain parts of electronic circuits. They are widely used in both communications and computer applications.

First, we shall define some notation. We use 2^n to represent the set of all n-tuples of elements in $\mathbf{2}$. That is, $\mathbf{2}^2 = \{(0, 0), (0, 1), (1, 0), (1, 1)\}$, and so on. For $\sigma \in \mathbf{2}^n$, we sometimes write $\sigma = (\sigma(1), \ldots, \sigma(n))$, so for $\sigma = (0, 1) \in \mathbf{2}^2$, we have $\sigma(1) = 0$ and $\sigma(2) = 1$.

A switching function is any function $f : \mathbf{2}^n \to \mathbf{2}$. For example, if $n = 2$, there are 16 switching functions, the values of which are given in Table II.

Explicity, f_7 is defined by $f_7(0, 0) = 0$; $f_7(0, 1) = 1$; $f_7(1, 0) = 1$; $f_7(1, 1) = 0$.

For $x \in \mathbf{2}$ (that is, $x = 0$ or $x = 1$), we write $x^0 = \bar{x}$ and $x^1 = x$. Now for a fixed value of n, a switching function is called a complete product if it has the form $f(x_1, \ldots, x_n) = x_1^{\sigma(1)} \ldots x_n^{\sigma(n)}$, where $\sigma \in 2^n$. For example, if $n = 3$, then $f(x_1, x_2, x_3) = x_1 \bar{x}_2 x_3$ is a complete product, but $f(x_1 x_2 x_3) = \bar{x}_2 x_3$ is not.

(0, 1)	1	$\bar{x}_1x_2$	$1\cdot\bar{x}_1x_2$
(1, 0)	0	$x_1\bar{x}_2$	$0\cdot x_1\bar{x}_2$
(1, 1)	1	x_1x_2	$1\cdot x_1x_2$

It turns out that every switching function can be written as a sum of complete products. Indeed, if $f:\mathbf{2}^n\to\mathbf{2}$ is any switching function, it can be written in the form.

$$f(x_1,\ldots,x_n)=\sum_{\sigma\in 2^n} f(\sigma)x_1^{\sigma(1)}\ldots x_n^{\sigma(n)}.$$

To illustrate how to do this, suppose $f(0,0)=1$, $f(0,1)=1$, $f(1,0)=0$, and $f(1,1)=1$. Now, form the table represented by Table III. The products in the third column are formed by putting the bar over the ith factor when the ith component of σ is 0.

Next add the terms $f(\sigma)x^{\sigma(1)}x^{\sigma(2)}$ to obtain $f(x_1,x_2)=1\bar{x}_1\bar{x}_2+1\bar{x}_1x_2+0x_1\bar{x}_2+1x_1x_2=\bar{x}_1\bar{x}_2+\bar{x}_1x_2+x_1x_2$. This last form is called the disjunctive normal form, but f can be simplified further since $\bar{x}_1\bar{x}_2+\bar{x}_1x_2+x_1x_2=\bar{x}_1(x_2+x_2)+x_1x_2=\bar{x}_1+x_1x_2=(\bar{x}_1+x_1)(\bar{x}_1+x_2)=\bar{x}_1+x_2$. That is, $f(x_1x_2)=\bar{x}_1+x_2$.

Thus, starting with the values of f, we have shown how to represent f as a switching function in disjunctive normal form. On the other hand, starting with an f defined as a function of $x_1,\ldots,x_n$, it is easy to represent it in disjunctive normal form. Simply multiply each term by $x_i+\bar{x}_i$ for each missing variable x_i. An example will clarify the procedure. To put $x_1\bar{x}_2+x_3$ in disjunctive normal form, write

$$\begin{aligned}x_1\bar{x}_2+x_3 &= x_1\bar{x}_2(x_3+\bar{x}_3)+x_3(x_1+\bar{x}_1)(x_2+\bar{x}_2)\\ &= x_1\bar{x}_2x_3+x_1\bar{x}_2\bar{x}_3+x_1x_2x_3+\bar{x}_1\bar{x}_2x_3\\ &\quad+\bar{x}_1x_2x_3+\bar{x}_1\bar{x}_2x_3\\ &= x_1\bar{x}_2x_3+x_1\bar{x}_2\bar{x}_3+x_1x_2x_3\\ &\quad+\bar{x}_1x_2x_3+\bar{x}_1\bar{x}_2x_3\end{aligned}$$

For a given n, each disjunctive normal form is a distinct function. So there are $2^{(2^n)}$ distinct switching functions of n variables, all of which are uniquely given in disjunctive normal form as described above.

The application of switching functions to circuit design can be described as follows. Suppose that an electric current is flowing from A to B and x_1, x_2 represent on–off switches (Fig. 3A). If x_1 and x_2 are both off, no current will be detected at B, whereas if *either* x_1 of x_2 is on, current will be detected at B. The circuit is therefore represented by x_1+x_2. Figure 3B represents x_1x_2. In Fig. 3C,

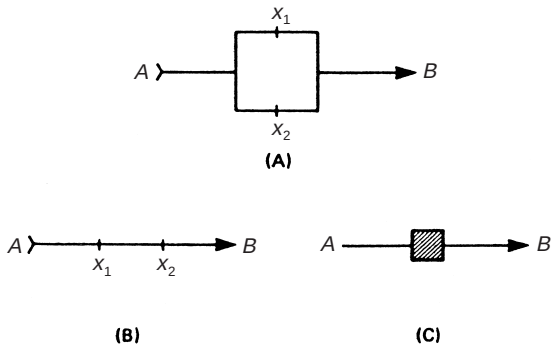

FIGURE 3 Application of switching functions to circuit design. (A) x_1+x_2; (B) x_1x_2; (C)$\bar{x}_1$.

the "black box" inverts the current. That is, if current is flowing at A, no current reaches B, but if current is not flowing from A, current will be detected at B.

To see how switching circuits are used in this context we consider a "half-adder." This is an electronic circuit that performs the following binary arithmetic:

$$\begin{array}{r} 0\\ +0\\ \hline 0\ \text{carry}=0\end{array}\qquad\begin{array}{r} 0\\ +1\\ \hline 1\ \text{carry}=0\end{array}$$

$$\begin{array}{r} 1\\ +0\\ \hline 1\ \text{carry}=0\end{array}\qquad\begin{array}{r} 1\\ +1\\ \hline 0\ \text{carry}=1\end{array}$$

It is called a half-adder because it does not take into account any carries from previous additions.

Now, if the addends are named A and B, the sum S, and the carry C, Table IV describes the arithmetic. From our previous discussion we can write $S=A\bar{B}+\bar{A}B$ and $C=AB$. The design of the half-adder is shown in Fig. 4.

The expression $A\bar{B}+\bar{A}B$ is quite simple, but in designing more complicated circuits, economies can be made by algebraically simplifying the switching functions. There are several such methods. The Veitch–Karnaugh and Quine methods are examples.

C. Other Applications

Boolean algebras, especially with additional operations, have applications to nonclassical logic, measure theory,

TABLE IV Half-Adder Table

A	*B*	Sum	Carry
0	0	0	0
0	1	1	0
1	0	1	0
1	1	0	1

functional analysis, and probability. A detailed summary of these can be found in R. Sikorski's "Boolean Algebras." A concise exposition of nonstandard analysis—via Boolean algebra—can be found in A. Abian's "Boolean Rings."

GLOSSARY

Antiderivative A function F is called the antiderivative of the function f if $F'(x) = f(x)$.

Chain rule Provides a rule for finding the derivative of $f(x)$ if the value of f at x is found by first finding $u = g(x)$, then $h(u)$; that is, $f(x) = h(g(x))$. In this case, if g and h are differentiable, then $f'(x) = h'(g(x))g'(x)$.

Derivative The derivative of a function f is the function f' defined at x by

$$f'(x) = \lim_{h \to 0} \frac{f(x+h) - f(x)}{h}$$

whenever this limits exists.

Differential When the function f has a derivative $f'(x_0)$ at x_0, the differential is the quantity $f'(x_0)h$ where h is a small number; if $y = f(x)$, it is common to represent h by dx and to define the differential to be $dy = f'(x_0)\,dx$.

Exponential function While $f(x) = b^x$ is, for any positive number b, an exponential function, the term is commonly applied to the situation in which $b = e$ where e is the number 2.718 (rounded to three decimals).

Function Rule that assigns to one real number x a unique real number y; one commonly lets a letter f (or g, h, etc.) represent the rule and writes $y = f(x)$. The concept of function is used in more general settings, but always with the idea of assigning to members of one set (the domain of the function) a unique member of another set (the range of the function).

Fundamental theorem Speaking loosely, the two principal ideas of calculus both relate to a graph of a function $y = f(x)$. One is concerned with how to find the slope $f'(x)$ of a line tangent to the graph at any point x; the other asks how to find the area under the graph between $x = a$ and $x = b$. The fundamental theorem relates these seemingly unrelated ideas. A more technical statement of the theorem is to be found below.

Graph If a function f is defined for each real number x in a set, then we may set $y = f(x)$ and plot the points (x, y) in the xy plane to obtain a "picture" corresponding to the function. More formally, the graph of f is the set $G = \{(x, f(x))\colon x \text{ is in the set on which } f \text{ is defined}\}$.

Indefinite integral Another term for the antiderivative.

Infinite series A sequence $\{S_n\}$ in which each term is obtained from the preceding one by adding one term; thus $S_n = S_{n-1} + a_n$. Such a series is commonly represented by $a_1 + a_2 + \cdots$. Terms may be functions $a_n(x)$, so a series may represent a function as well as a constant.

Inflection point If a function f is continuous at x_0, then x_0 is called an inflection point for f if the graph changes from a curve that holds water (convex) to one that sheds water (concave) or conversely at x_0.

Integral Also called the definite integral of f between $x = a$ and $x = b$. It may be described informally as the area under the graph of $y = f(x)$, but such a definition is subject to logical problems. A formal definition of the Riemann integral is given below.

Limit When two variables are related to each other by a clear rule; that is, when $y = f(x)$, we may ask how y is affected by taking values of x closer and closer to some fixed value x_0, or by taking values of x that get larger and larger without bound. If y also gets closer to some fixed y_0, then we say in the two cases described,

$$y_0 = \lim_{x \to x_0} f(x) \qquad \text{or} \qquad y_0 = \lim_{x \to \infty} f(x).$$

Natural logarithm The logarithm of a positive number N to a base $b > 0$ is the exponent r such that $b^r = N$. When the base b is chosen to be the number $e \approx 2.7$, then the logarithm is said to be the natural logarithm of N.

Tangent While there is an intuitive idea of what is meant by a tangent to the graph of $y = f(x)$ at $(x_0, f(x_0))$ (it is the line that just touches the curve at the point), the logically satisfactory way to define it is to say that it is the line through the specified point that has a slope equal to $f'(x_0)$.

CALCULUS is the branch of mathematics that provides computational (or calculating) rules for dealing with problems involving infinite processes. Approximating the circumference of a circle by finding, for larger and larger values of n, the perimeter of a regular inscribed n-sided polygon illustrates an infinite process. Since we cannot hope to complete an infinite process, our only hope is to establish that the longer a certain process is continued, the closer it comes to some limiting position. Thus, calculus is sometimes described as the study of limits, or defined as the discipline that provides algorithms and standard procedures for calculating limits.

I. TWO BASIC PROBLEMS IN CALCULUS

Problem 1. If to each real number x we assign a second number $y = x^2$, the resulting pairs (x, y) may be used as coordinates to locate points relative to a set of perpendicular axes (Fig. 1). The resulting curve is a parabola, a curve studied by the Greeks and frequently encountered in applications of mathematics.

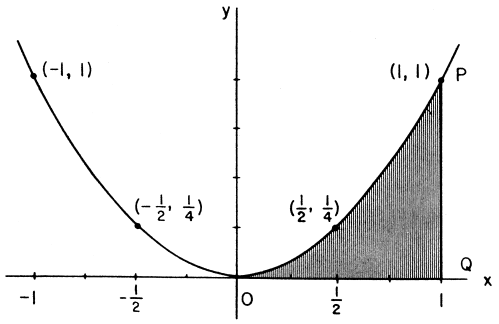

FIGURE 1 The curve is $y = x^2$.

The problem we wish to consider is that of finding the shaded area OPQ under the parabola, above the x axis from 0–1. Archimedes (287–212 B.C.) could have solved this problem using what he called the method of exhaustion. The line of attack we shall use is suggested by Fig. 2, from which we see that the desired area is

(a) less than the area of rectangle A_1 given by

$$R_1 = 1(1)^2 = 1$$

(b) less than the sum of the areas of rectangles B_1 and B_2 given by

$$R_2 = \tfrac{1}{2}\left(\tfrac{1}{2}\right)^2 + \tfrac{1}{2}\left(\tfrac{2}{2}\right)^2$$

(c) less than the sum of the areas of rectangles C_1, C_2, and C_3 given by

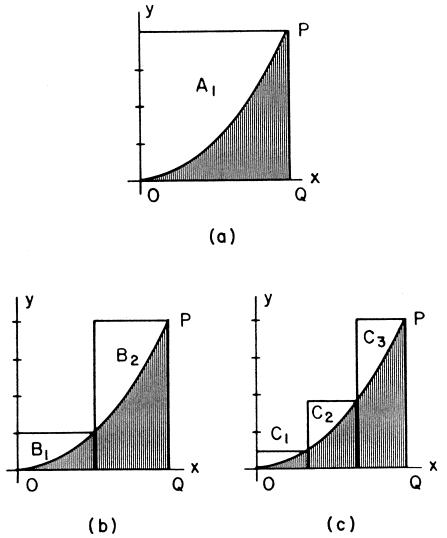

FIGURE 2 The curve is $y = x^2$.

$$R_3 = \tfrac{1}{3}\left(\tfrac{1}{3}\right)^2 + \tfrac{1}{3}\left(\tfrac{2}{3}\right)^2 + \tfrac{1}{3}\left(\tfrac{3}{3}\right)^2$$

Proceeding in this way, we see that after n steps, the desired area will be less than

$$R_n = \frac{1}{n}\left(\frac{1}{n}\right)^2 + \frac{1}{n}\left(\frac{2}{n}\right)^2 + \cdots + \frac{1}{n}\left(\frac{n}{n}\right)^2 \qquad (1)$$

but intuitively, at least, this process should bring us closer and closer to the desired answer.

This is not exactly Archimedes' method of exhaustion, but it is clearly an exhausting process to carry out as n increases. It is, in fact, an infinite process.

Problem 2. Our second problem again makes reference to the graph of $y = x^2$. This time we seek the slope of the line tangent to the graph at $P(1, 1)$. That is, with reference to Fig. 3, we wish to know the ratio of the "rise" BT to the "run" PB (or, stated another way, we wish to know the tangent of the angle that PT makes with the positive x axis). Our method, certainly known to Fermat (1601–1665), is again suggested by a sequence of pictures.

From the graphs in Fig. 4, we see in turn

$$\text{(a)}\quad \text{slope PS}_1 = \frac{\text{B}_1\text{S}_1}{\text{PB}_1} = \frac{(1+1)^2 - 1^2}{1} = 3$$

$$\text{(b)}\quad \text{slope PS}_2 = \frac{\text{B}_2\text{S}_2}{\text{PB}_2} = \frac{(1+1/2)^2 - 1^2}{1/2} = \frac{5}{2}$$

$$\text{(c)}\quad \text{slope PS}_3 = \frac{\text{B}_3\text{S}_3}{\text{PB}_3} = \frac{(1+1/3)^2 - 1^2}{1/3} = \frac{7}{3}$$

And again there is a pattern that enables us to see where we will be after n steps:

$$\text{slope PS}_n = \frac{\text{B}_n\text{S}_n}{\text{PB}_n} = \frac{(1+1/n)^2 - 1^2}{1/n} \qquad (2)$$

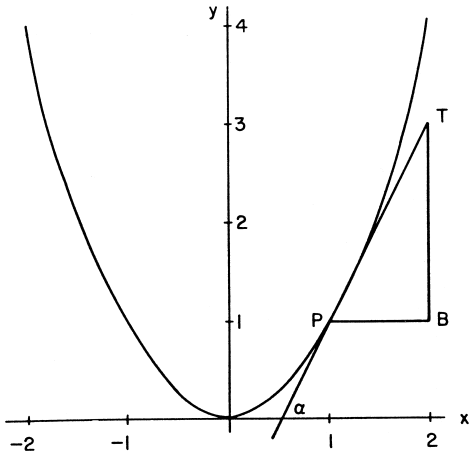

FIGURE 3 The curve is $y = x^2$.

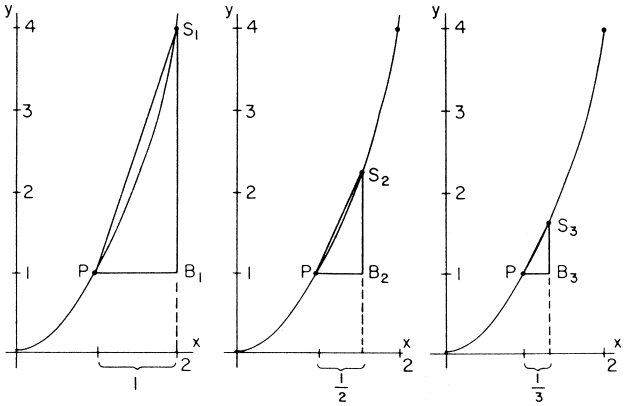

FIGURE 4 The curve is $y = x^2$.

The slope of the desired line is evidently the limiting value of this infinite process.

Our interest in both Eqs. (1) and (2) focuses on what happens as n increases idenfinitely. Using the symbol $\to\infty$ to represent the idea of getting large without bound, mathematicians summarize their interest in Eq. (1) by asking for

$$\lim_{n\to\infty} R_n = \lim_{n\to\infty}\left[\frac{1}{n}\left(\frac{1}{n}\right)^2 + \frac{1}{n}\left(\frac{2}{n}\right)^2 + \cdots + \frac{1}{n}\left(\frac{n}{n}\right)^2\right]$$

and in Eq. (2) by asking for

$$\lim_{n\to\infty} \frac{\text{B}_n\text{S}_n}{\text{PB}_n} = \lim_{n\to\infty} \frac{(1+1/n)^2 - 1^2}{1/n}$$

II. LIMITS

Calculus is sometimes said to be the study of limits. That is because the nature of an infinite process is that we cannot carry it to completion. We must instead make a careful analysis to see if there is some limiting position toward which things are moving.

A. Algebraic Expressions

Limits of certain algebraic expressions can be found by the use of simplifying formulas. Archimedes was greatly aided in his study of the area under a parabola because he had discovered

$$1^2 + 2^2 + \cdots + n^2 = \tfrac{1}{6}n(n+1)(2n+1) \qquad (3)$$

Sometimes the limit of a process is evident from a very minor change of form. The limit of the sum (2) above is easily seen if we write it in the form

$$\lim_{n\to\infty}\frac{B_nS_n}{PB_n}=\lim_{n\to\infty}\frac{(1+1/n)^2-1^2}{1/n}$$
$$=\lim_{n\to\infty}\frac{1+2/n+1/n^2-1}{1/n}$$
$$=\lim_{n\to\infty}(2+1/n)=2 \qquad (4)$$

Not every question about limits is concerned with the consequence of a variable growing large without bound. The student of calculus will very soon encounter problems in which a variable approaches zero. A typical question asks what happens to the quotient

$$\frac{\sqrt{x+h}-\sqrt{x}}{h}$$

as h gets closer and closer to zero. Since both the numerator and the denominator approach zero, the effect on the quotient is not obvious. In this case, a little algebraic trickery helps. One notes that

$$\left(\frac{\sqrt{x+h}-\sqrt{x}}{h}\right)\frac{\sqrt{x+h}+\sqrt{x}}{\sqrt{x+h}+\sqrt{x}}=\frac{(x+h)-x}{h(\sqrt{x+h}+\sqrt{x})}$$
$$=\frac{1}{\sqrt{x+h}+\sqrt{x}}$$

In this form, it is clear that as h gets very small, the quotient approaches $1/(2\sqrt{x})$; we write

$$\lim_{h\to 0}\frac{\sqrt{x+h}-\sqrt{x}}{h}=\frac{1}{2\sqrt{x}} \qquad (5)$$

B. The Natural Base

An investment yielding 8% per year will, for an investment of A dollars, return $A+0.08A=A(1+0.08)$. If the investment is one that adds interest semiannually, then the investment will be worth $A+\frac{1}{2}(0.08)A=A(1+0.08/2)=S$ after 6 months, and by the end of the year it will have grown to $S+\frac{1}{2}(0.08)S=S(1+0.08/2)=A(1+0.08/2)^2=A(1.0816)$.

If interest is added every month (taken for convenience to be $\frac{1}{12}$ of a year), the investment at the end of a year will have grown to

$$A\left(1+\frac{0.08}{12}\right)^{12}=A(1.0830)$$

There is a definite advantage to the investor in having the interest added as frequently as possible.

Jakob Bernoulli (1654–1705) once posed the following problem. An investment of A dollars at i% that adds interest at the end of each of n periods will yield

$$A(1+i/n)^n$$

Will this sum grow infinitely large if the number n of periods is increased to the point where interest is apparently being added instantaneously?

This apparently frivolous problem is one that involves an infinite process. It is also a problem that, as we shall see below, has profound implications. In order to free ourselves from considerations of a particular choice of i and to focus on the principal question of what happens as n increases, let us agree to set $n=mi$:

$$A(1+i/n)^n=A[(1+1/m)^m]^i$$

Now study what happens as m increases to the expression

$$e_m=\left(1+\frac{1}{m}\right)^m \qquad (6)$$

Beginners will be excused if they make the common guess that as m gets increasingly large, e_m gets increasingly close to 1. Even in the face of early evidence provided by the computations

$$e_1=(1+1)=2.00$$
$$e_2=\left(1+\tfrac{1}{2}\right)^2=\tfrac{9}{4}=2.25$$
$$e_3=\left(1=\tfrac{1}{3}\right)^3=\tfrac{64}{27}=2.37$$

beginners find it hard to believe that as m gets larger and larger, e_m will eventually get larger than 2.71, but that it will never get as large as 2.72. They are more incredulous when told that the number that e_m approaches rivals π as one of the most important constants in mathematics, that it has been given the name e as its very own, and that accurate to 10 decimal places, $e=2.7182818285$.

If in Eqs. (6) we replace $1/m$ by h, we get an expression often taken as the definition of e:

$$\lim_{h\to 0}(1+h)^{1/h}=e$$

From here it is a short step to a second limit to which we will refer below:

$$\lim_{h\to 0}\frac{e^h-1}{h}=1 \qquad (7)$$

C. Trigonometric Expressions

A final tricky but important limit must be mentioned. Students in elementary school learn to measure angles in degrees. When the angle x is so measured, then one finds that

$$\frac{\sin 5^\circ}{5}=0.017431 \qquad \frac{\sin 3^\circ}{3}=0.017445$$
$$\frac{\sin 1^\circ}{1}=0.017452$$

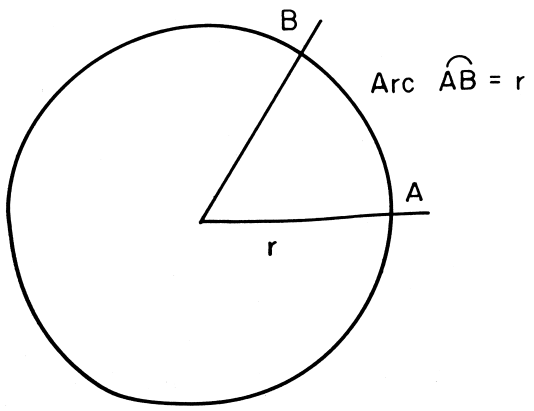

FIGURE 5 Radius of the circle is arbitrary. The angle is 1 radian ≈57°.

and that in general

$$\lim_{x\to 0}\frac{\sin x}{x}=\frac{\pi}{180}=0.017453$$

This awkward number would permeate computations made in calculus, were it not for a uniformly adopted convention. Radians, rather than degrees, are used to measure angles. The central angle of a circle that intercepts an arc of length equal to the radius (Fig. 5) is said to have a measure of one radian. The familiar formula for the circumference of a circle tells us that there will be 2π radians in a full circle of 360°, hence that π radians $=180°$. Using radians to measure the angle x, it turns out that

$$\lim_{x\to 0}\frac{\sin x}{x}=1 \tag{8}$$

For this reason, radians are always used to measure angles in calculus and in engineering applications that depend on calculus.

III. FUNCTIONS AND THEIR GRAPHS

When the value of one variable y is known to depend on a second variable x, it is common in ordinary discourse as well as in mathematics to say that y is a function of x. An important difference must be noted, however. General usage is commonly imprecise about the exact nature of the relationship (corporate income is a function of interest rates), but mathematicians use the term to imply a precise relationship. For a given value of x, a unique value of y is determined. Mathematicians abbreviate this relationship by writing $y=f(x)$.

Just as a corporation may draw a graph showing how its income has varied with changing interest rates, so a mathematician may draw a graph showing how y varies with changes in x. There are short cuts to drawing such graphs, many of them learned in the study of analytic geometry, which is taught prior to or along with calculus. But even without shortcuts, the method of calculating a table of values and then plotting points can be used to sketch a useful graph. This latter process is illustrated in Table I and Fig. 6 for the function $y=f(x)=2\sqrt{x}-x^2$.

TABLE I Table of Values

x	$y=2\sqrt{x}-x^2$
0	0
$\frac{1}{4}$	$2\left(\frac{1}{2}\right)-\frac{1}{16}=\frac{15}{16}$
$\frac{1}{2}$	$2\frac{1}{\sqrt{2}}-\frac{1}{4}\approx 1.2$
1	$2\sqrt{1}-1=1$

IV. DIFFERENTIATION

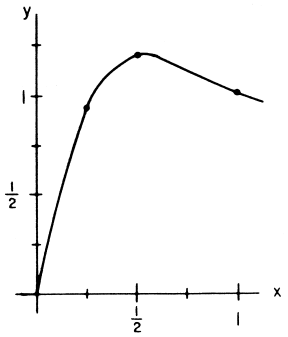
A. The Derivative Defined

Suppose that the distance y that an automobile has travelled in x hours is given by $y=f(x)$. We pose the following question. What does the speedometer read when $x=2$?

As a first step, we might find the average speed during the third hour by computing

$$\frac{(\text{distance at } x=3)-(\text{distance at } x=2)}{\text{time elapsed}}=\frac{f(3)-f(2)}{3-2}$$

It is clear, of course, that the average speed over the third hour hardly tells us the speedometer reading at $x=2$. To get even a reasonable approximation to the speedometer reading at $x=2$, we would want an average over a much smaller time interval near $x=2$. Let h represent some fraction of an hour after $x=2$. The average speed over this time interval would be



x	y
0	0
$\frac{1}{4}$	$\frac{15}{16}$
$\frac{1}{2}$	1.2 (approx.)
1	1

FIGURE 6 This is the graph of $y=2\sqrt{x}-x^2$, drawn by plotting from the table at the right.

$$\frac{(\text{distance at } x = 2 + h) - (\text{distance at } x = 2)}{(2 + h) - 2}$$
$$= \frac{f(2 + h) - f(2)}{h}$$

No information would be gained by setting $h = 0$, but the smaller the positive number h is taken, the better will be our estimate of the speed at $x = 2$. And more generally, the speedometer reading at time x will be approximated by

$$\text{speed at time } x = \lim_{h \to 0} \frac{f(x + h) - f(x)}{h} \tag{9}$$

Consider now a situation in which water runs at 8 in.^{3}/sec into a cone-shaped container that is 12 in. across at the top and 12 in. deep (Fig. 7). The height y of the water rises quickly at first, less quickly as the level rises. In fact, using the formula for the volume of a cone, we can actually determine that the height y at time x will be $y = 2\sqrt[3]{12x/\pi}$, but for our purposes here it suffices to notice that

$$y = f(x)$$

We now ask how fast, in inches per second, y is increasing when $x = 2$. One way to get started is to find the average rate at which y increased during the third minute.

$$\frac{(\text{height at } x = 3) - (\text{height at } x = 2)}{\text{elapsed time}} = \frac{f(3) - f(2)}{3 - 2}$$

Since the rate is slowing down as time passes, however, it is clear that we would get a better approximation to the rate at $x = 2$ if we used a smaller time interval near $x = 2$. Again we let h represent some short interval of time after $x = 2$. Again we see that the desired rate at $x = 2$ will be given by the limit of

$$\frac{(\text{height at } x = 2 + h) - (\text{height at } x = 2)}{h}$$
$$= \frac{f(2 + h) - f(2)}{h}$$

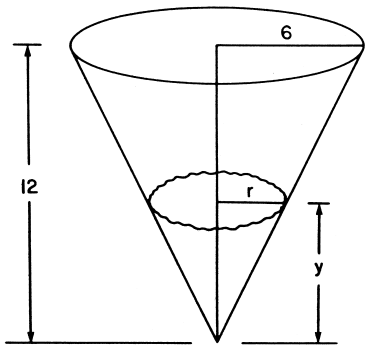


FIGURE 7 Water at height y in cone.

TABLE II Meaning of the Derivative

Given meaning of $f(x)$	Interpretation of $f'(x)$
Distance: $f(x)$ is the distance a moving object travels from some fixed starting point in time x.	Velocity: $f'(x)$ gives the velocity at time x.
Amount: $f(x)$ gives the measure of some changeable quantity (volume of a melting ice cube, length of a shadow) at time x.	Rate of change: $f'(x)$ gives the measure in (units)/(time interval) of the rate at which the quantity is changing.
Graph: The coordinates (x,y) of points on a graph in the plane are related by $y = f(x)$.	Slope of a tangent line: the line tangent to the graph at (x, y) has slope $f'(x)$.

And again for an arbitrary time x, we see that the rate at which height increases is

$$\lim_{h \to 0} \frac{f(x + h) - f(x)}{h} \tag{10}$$

Finally, look again at our introductory Problem 2. Using the notation $f(x) = x^2$ now available to us, we see that Eq. (2) may be written in the form

$$\text{slope PS}_n = \frac{f(1 + 1/n) - f(1)}{1/n}$$

We find the slope of the line tangent to the graph at $x = 1$ by taking the limit of this expression as $n \to 1$. Similar reasoning at an arbitrary point x, making the substitution $h = 1/n$, would lead us to the conclusion that the slope of a line tangent to the graph at x is given by

$$\text{slope} = \lim_{h \to 0} \frac{f(x + h) - f(x)}{h} \tag{11}$$

whenever this limit exists.

The expression that we have encountered in Eqs. (9), (10), and (11) turns up time and again in the applications of mathematics. For a given function f, the derived function or derivative f' is the function defined at x by

$$f'(x) = \lim_{h \to 0} \frac{f(x + h) - f(x)}{h}$$

It is important to recognize that the meaning of the derivative is not restricted to just one interpretation. The three important ones that we have discussed are summarized in Table II. Thus, the computational techniques developed by Fermat and other mathematical pioneers have turned out to be of central importance in modern mathematical analysis.

B. Some Derivatives Calculated

We begin with a calculation that can be checked against the answer of 2 obtained in Eq. (4) as the slope of

the line tangent to the graph of $y=x^2$ at $x=1$. For $f(x)=x^2$, $f(x+h)=(x+h)^2=x^2+2xh+h^2$, so

$$\frac{f(x+h)-f(x)}{h}=\frac{x^2+2xh+h^2-x^2}{h}=\frac{h(2x+h)}{h}$$

$$f'(x)=\lim_{h\to 0}\frac{f(x+h)-f(x)}{h} \tag{12}$$

$$=\lim_{h\to 0}(2x+h)=2x$$

The value of $f'(1)=2$, as predicted.

For the function $f(x)=x^3$, we need to use the fact that $f(x+h)=(x+h)^3=x^3+3x^2h+3xh^2+h^3$. Then

$$f'(x)=\lim_{h\to 0}\frac{f(x+h)-f(x)}{h}$$

$$=\lim_{h\to 0}(3x^2+3xh+h^2)=3x^2 \tag{13}$$

For the function $f(x)=\sqrt{x}$, we make use of the previously noted limit in Eq. (5) to write

$$f'(x)=\lim_{h\to 0}\frac{f(x+h)-f(x)}{h}$$

$$=\lim_{h\to 0}\frac{\sqrt{x+h}-\sqrt{x}}{h}=\frac{1}{2\sqrt{x}} \tag{14}$$

Equations (12), (13), and (14) illustrate a general result that Newton discovered by using the binomial theorem (which he also discovered):

If $f(x)=x^r$ where r is any real number,

then $f'(x)=rx^{r-1}$. (15)

Two special cases, both easy to prove directly, should be noted here because we need them later. When $r=1$, the formula tells us that the derivative of $f(x)=x$ is $f'(x)=1$; and any constant function $f(x)=c$ may be thought of as $f(x)=cx^\circ$, so that the formula gives the correct result, $f'(x)=0$.

The exponential function $E(x)=e^x$ is important in mathematics and important to an application we shall mention below. Let us use the property of exponents that says $e^{x+h}=e^xe^h$ and Eq. (7) to find

$$E'(x)=\lim_{h\to 0}\frac{e^{x+h}-e^x}{h}$$

$$=\lim_{h\to 0}e^x\frac{e^h-1}{h}=e^x \tag{16}$$

Functions of the form $f(x)=ke^x$ are the only functions that satisfy $f'(x)=f(x)$, and this fact accounts for the great importance of the exponential function in mathematical applications.

Finally, we note that differentiation is a linear operation. This means that if f and g are differentiable functions and r and s are real numbers, then the function h defined by $h(x)=rf(x)+sg(x)$ is differentiable, and $h'(x)=rf'(x)+sg'(x)$.

C. The Derivative and Graphing

The rule just stated, together with our ability to differentiate both $\sqrt{x}$ and x^2, enables us to find the derivative of $f(x)=2\sqrt{x}-x^2$, which is graphed in Fig. 6:

$$f'(x)=2/2\sqrt{x}-2x$$

This means that the tangent line to the graph at $x=\frac{1}{4}$ is $f'(\frac{1}{4})=2-\frac{1}{2}=\frac{3}{2}$; at $x=1$, it is $f'(1)=1-2=-1$. Of more interest is the fact that the continuous function $f'(x)$, in passing from $\frac{3}{2}$ at $x=\frac{1}{4}$ to -1 at $x=1$, must be 0 somewhere between $x=\frac{1}{4}$ and $x=\frac{3}{2}$. Where would $f'(x)=0$? Evidently this occurs at the high point of the graph, and herein lies another great source of applications. The maximum or minimum of a function can often be found by finding the value of x for which $f'(x)=0$. For the example at hand, setting

$$1/\sqrt{x}-2x=0$$

gives

$$1/\sqrt{x}=2x$$

Squaring both sides and multiplying through by x gives $1=4x^3$, or $x=\sqrt[3]{\frac{1}{4}}\approx 0.63$. That is not a value that would be easily guessed by plotting points. The information now in hand enables us to draw a much better graph of $y=2\sqrt{x}-x^2$ (see Fig. 8).

The connection between the values of $f'(x)$ and the slope of lines tangent to the graph of $y=f(x)$ enables us to prove the so-called mean value theorem. This theorem says that if two points on the graph of $y=f(x)$, say $(a, f(a))$ and $(b, f(b))$ are connected by a line segment, then at some point c located between $x=a$ and $x=b$, there will be a tangent to the graph that is parallel to the line (Fig. 9). The formal statement of this theorem is as follows.

Mean value theorem. Let f be differentiable on an interval that includes a and b in its interior. Then there is a point c between a and b such that

$$\frac{f(b)-f(a)}{b-a}=f'(c)$$

Suppose f' is positive on a certain interval. Then if $x_1<x_2$, the mean value theorem tells us that

$$f(x_2)-f(x_1)=f'(c)(x_2-x_1)>0$$

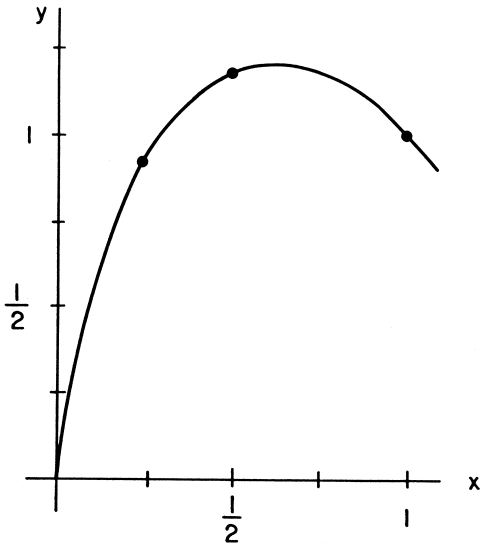

FIGURE 8 The maximum occurs at (0.63, 1.19). This is an improvement on Fig. 6 illustrating that calculus provides information enabling us to improve our graph.

We conclude (Fig. 10) that f must be increasing on the interval. Similar reasoning leads to the conclusion that if $f'(x) < 0$ on an interval, f is decreasing on the interval.

If f is differentiable at a point $x = a$ where its graph achieves a relative high point, then since f swithces from an increasing to a decreasing function at that point, $f'(x)$ switches from positive to negative at $x = a$. We conclude that $f'(a) = 0$ (Fig. 10). It can similarly be shown that a differentiable function will have a derivative of 0 at a relative low point.

An analysis of the graph of $y = S(x) = \sin x$ can help us anticipate what $S'(x)$ might be. In Fig. 11, note the tangent segments sketched at the high point H, low point

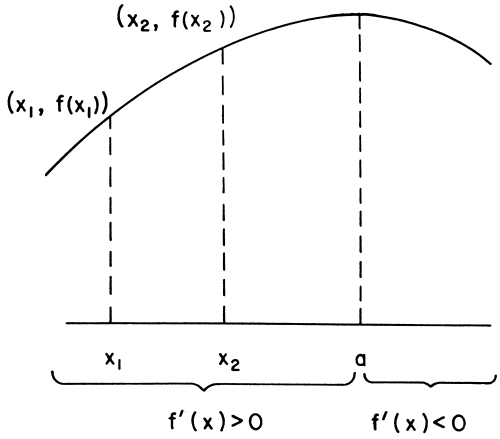

FIGURE 10 The function increases when $f'(x) > 0$, decreases when $f'(x) < 0$.

L, and the points P, Q, and R where the graph of $y = \sin x$ crosses the x axis. The slopes at H and L are clearly 0, meaning that $S'(\pi/2) = S'(3\pi/2) = 0$. We have plotted these points on the second set of axes in anticipation of graphing $y = S'(x)$.

We also note from the symmetry of the graph of $y = \sin x$ that if the slope at P is k, then the slope at Q will be $-k$ and the slope at R will be k again. The appropriate points are again plotted on the second set of axes.

A person familiar with trigonometric functions who thinks about passing a curve through the plotted points might well guess the $S'(x) = \cos x$. Verification of this result depends on use of the addition formulas for the sine function and, as has been mentioned previously, on the use of radian measure, which allows the use of Eq. (8).

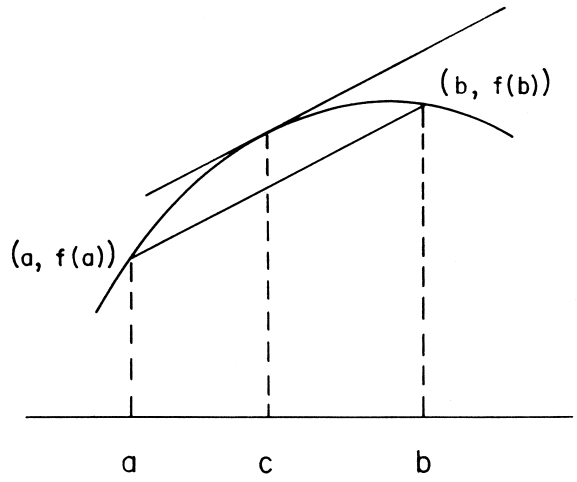

FIGURE 9 The tangent line is parallel to the secant line.

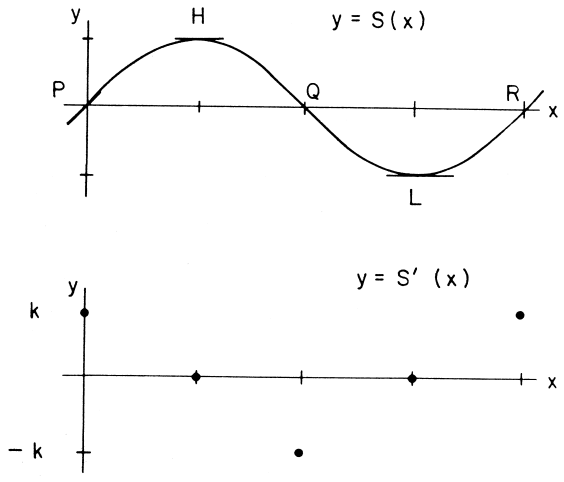

FIGURE 11 The top curve is a sine wave.

D. Four Important Applications

1. Falling Bodies

We have seen that if $y = f(x)$ describes the distance y that a body moves in time x, then $f'(x)$ gives the velocity at time x. Let us take this another step. Suppose the velocity is changing with time. That rate of change, according to the second principle in Table II, will be described by the derivative of $f'(x)$, designated by $f''(x)$. The change of velocity with respect to time is called acceleration; acceleration at time x is $f''(x)$.

When an object is dropped, it picks up speed as it falls. This is called the acceleration due to gravity. There is speculation as to how Galileo (1564–1642), with the measuring instruments available to him, came to believe that the acceleration due to gravity is constant. But he was right; the acceleration is designated by g and is equal to 32.2 ft/sec^2.

Now put the two ideas together. The acceleration is $f''(x)$; the acceleration is constant; $f''(x) = -g$. We use $-g$ because the direction is down. What function, if differentiated, gives the constant $-g$? We conclude that $f'(x) = -gx + c$. The c is included because the derivative of a constant is 0, so we can only be sure of $f'(x)$ up to a constant. Since $f'(x)$ is the velocity at time x, and since $f'(0) = c$, the constant c is usually designated by v_0, which stands for the initial velocity—allowing the possibility that the object was thrown instead of dropped.

The function $f'(x) = -gx + v_0$ is called the antiderivative of $f''(x) = -g$. Now to find the distance y that the object has fallen, we seek the antiderivative of $f'(x)$; what function was differentiated to give $f'(x) = -gx + v_0$? Contemplation of the derivatives computed above leads to the conclusion that

$$y = f(x) = -\tfrac{1}{2}gx^2 + v_0x + y_0$$

this time the constant y_0 represents the initial height from which the object was dropped or thrown.

2. Growth and Decay

Imagine an island nation in which the population p is unaffected by immigration into or out of the country. Let the size of the population at time x be $p = f(x)$. Then according to the second principle of Table II, $f'(x)$ is the rate of growth of the population.

Let us make the reasonable assumption that the rate at which the population grows at time x is proportional to the size of the population at that time. Translated into the language of calculus, this says

$$f'(x) = kf(x) \tag{17}$$

This is a differential equation. We are asked to find a function, the derivative of which is a constant multiple of the function with which we started. If we recall from Eq. (16) that $E'(x) = E(x)$ for $E(x) = e^x$, we can quite easily convince ourselves that a solution to (17) is

$$p = f(x) = e^{kx} \tag{18}$$

This explains why it is said that population grows exponentially.

We need not be talking about people on an island. We might be talking about bacteria growing in a culture, or ice melting in a lake. Anytime the general principle is that growth (or decay) is proportional to the amount present, Eq. (17), perhaps with negative k, describes the action and Eq. (18) provides a solution.

3. Maxima and Minima

The usefulness in practical engineering and scientific problems of our ability to find a high or low point on a graph can be hinted at with the following simple problem. Suppose that a box is to be made from a 3-ft-square piece of sheet metal by cutting squares from each corner, then folding the edges up (see Fig. 12) and welding the seams along the corners. If the edges of the removed squares are x in length, the volume of the box is given by the function

$$y = f(x) = x(3 - 2x)^2 = 4x^3 - 12x^2 + 9x$$

which is graphed in Fig. 13. The derivative is

$$f'(x) = 12x^2 - 24x + 9 = 3(2x - 1)(2x - 3)$$

from which we see that with x restricted by the nature of the problem to be between 0 and $\frac{3}{2}$, the maximum volume is obtained by choosing $x = \frac{1}{2}$.

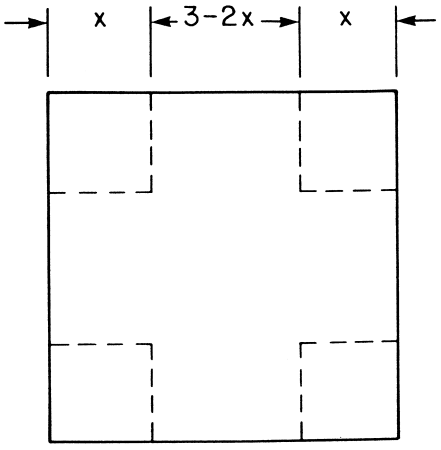

FIGURE 12 Construction of a box.

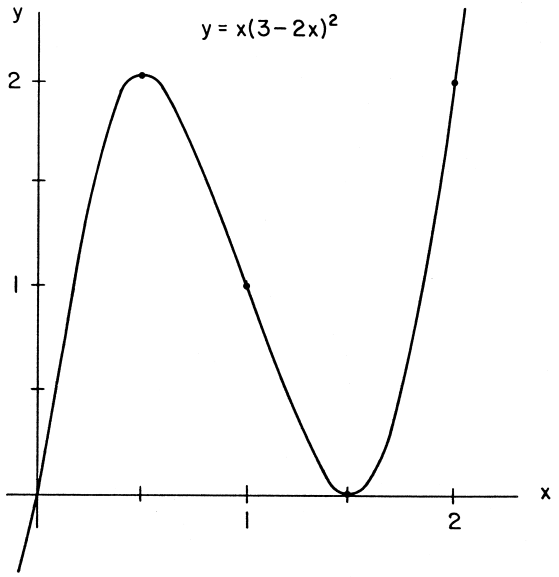

FIGURE 13 Maximum occurs at $(\frac{1}{2}, 2)$.

4. Approximation

Suppose we seek a quick estimate for $\sqrt{9.54}$. We might proceed as follows. The function $f(x)=\sqrt{x}$ has, according to Eq. (14), a derivative of $f'(x)=1/2\sqrt{x}$. The line tangent to the graph of $y=\sqrt{x}$ at $x=9$ has a slope of $f'(9)=\frac{1}{6}$ (Fig. 14). The equation of this line is $y-3=\frac{1}{6}(x-9)$.

When x is a little larger than 9, it is clear that the corresponding value of y on the tangent line is going to be larger than the value of y given by $y=\sqrt{x}$. But if x is not too much larger than 9, the two values will be approximately equal. In fact, when $x = 9.54$, the two values are

$$y = 3 + \tfrac{1}{6}(9.54 - 9) = 3.09$$

$$y = \sqrt{9.54} \approx 3.08869$$

This gives us a method of approximating $f(x)$ near a value x_0 where $f(x_0)$ is easily calculated.

We use

$$y = f(x) \approx f(x_0) + f'(x_0)(x - x_0)$$

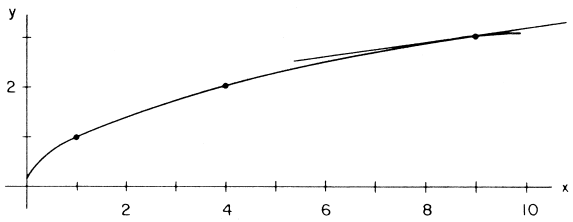

FIGURE 14 The curve is $y=\sqrt{x}$. The line is tangent at (9, 3). Its slope is $\frac{1}{6}$.

There is a school of thought that says that the derivative is best understood as a tool that enables us to approximate $f(x)$ in a neighborhood of x_0 with a linear function.

V. INTEGRATION

A. The Integral Defined

We introduced our discussion of differentiation with a problem about an automobile. We shall do the same in introducing integration.

The acceleration of an automobile is often judged by how fast it can go from a standing position to a speed of 60 mph (88 ft/sec). Consider a car that can do this in 10 sec. Its velocity v is a function of x, the number of seconds since it started: $v=g(x)$, where $g(0)=0$ and $g(10)=88$. The question we pose is this. How far will this car have travelled in the 10-sec test?

Distance equals rate times time, but our problem is that the rate keeps changing. We must therefore approximate our answer. One way to approach the problem is to subdivide the time span into n intervals, to pick a time t_i between each x_{i-1} and x_i, and use $g(t_i)$ as the approximate speed during that interval. Then the approximate distance travelled during the time from x_{i-1} to x_i would be $g(t_i)(x_i - x_{i-1})$, and the total distance traveled would be approximated by

$$\text{distance} = g(t_1)(x_1 - x_0) + g(t_2)(x_2 - x_1) + \cdots + g(t_n)(x_n - x_{n-1}) \tag{19}$$

Intuition tells us that smaller subintervals will result in better approximations to the total distance traveled.

We turn our attention now to the subject of work. Physicists define work done in moving an object to be the product of the force exerted in the direction of motion and the distance moved. If a constant force of 15 lb is exerted in pushing an object 20 ft, then it is said that $20 \times 15 = 300$ ft · lb of work has been done.

Anyone who has pushed an object along a floor knows, however, that it takes more force to get the object moving than to keep it moving. In this and other realistic situations (stretching a spring), the force is likely to change as the distance from the starting point changes. We say that the force F is a function of the distance x: $F = f(x)$.

How, when $f = f(x)$, shall we find the work done in moving from $x=a$ to $x=b$? A sensible approximation might be found in this way: Subdivide the segment from a to b into n subintervals. In each subinterval x_{i-1} to x_i, choose a point t_i and use $f(t_i)$ as an approximation of the force exerted over the subinterval (Fig. 15).

The total work done would then be approximated by the sum

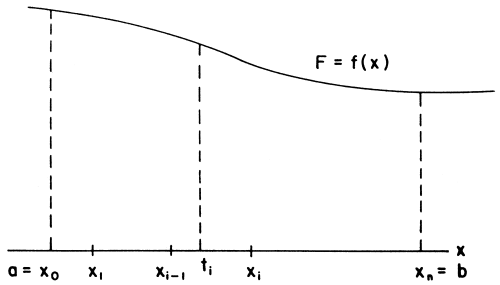

FIGURE 15 Total work done approximation.

$$f(t_1)(x_1 - x_0) + f(t_2)(x_2 - x_1) + \cdots + f(t_n)(x_n - x_{n-1}) \tag{20}$$

Intuition suggests that better approximations can be obtained by taking more intervals of shorter length.

As a final motivating example, we direct attension again to problem 1, the problem of finding the area under the parabolic graph of $y = x^2$ from $x = 0$ to $x = 1$. If we set $f(x) = x^2$, then, corresponding to a partition of the interval into n segments, the area can be approximated (Fig. 16) by the sum

$$f(t_1)(x_1 - x_0) + f(t_2)(x_2 - x_1) + \cdots + f(t_n)(x_n - x_{n-1}) \tag{21}$$

where t_i is chosen to satisfy $x_{i-1} \le t_i < x_i$. Figure 2 shows the areas obtained if we choose $n = 1, 2$, and 3, respectively, if we choose intervals of equal length and if in every case we choose $t_i = x_i$, the right-hand endpoint. If we choose n intervals of equal length so that $x_i - x_{i-1} = 1/n$ for every i, and if we choose $t_i = x_i = i/n$, then Eq. (21) becomes the sum R_n given in Eq. (1).

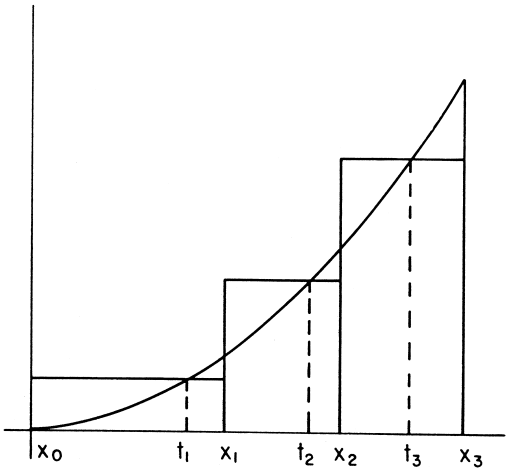

FIGURE 16 The curve is $y = x^2$. The intervals may be unequal, the t_i located differently (not a center, or always the same proportion of the way between x_{i-1} and x_i) within the intervals.

When we write Eq. (1) in the more general form of Eq. (21) and then compare Eq. (21) with Eqs. (19) and (20), we see that the problem Archimedes considered of finding the area under a parabola leads to a computation that comes up in other problems as well. There are, in fact, problems in virtually every area of engineering and science that lead to sums like Eq. (21) above. They are called Riemann sums.

Let us state things formally. A partition of the interval from a to b into n segments is a set P of points:

$$P = \{a = x_0 < x_1 < x_2 < \cdots < x_{n-1} < x_n = b\}$$

In each subinterval we select a tag t_i: $x_{i-1} \le t_i \le x_i$. Nothing in the theory says that the intervals must be of equal length, or that the t_i must all be chosen in a certain way—a fact we emphasized in Fig. 16. The longest of the subintervals is called the gauge of P, and this number is designated by $|P|$. It is to be noted that when we require $|P|$ to be less than some certain g, then every subinterval of P has length less than g. If g is defined for all x between a and b, then corresponding to a choice of a partition P and a selection of tags $\{t_i\}$, we can form the Riemann sum

$$R(f, P, \{t_i\}) = f(t_1)(x_1 - x_0) + f(t_2)(x_2 - x_1) + \cdots + f(t_n)(x_n - x_{n-1})$$

For a large class of functions, it happens that by specifying a small enough number g, we can guarantee that if $|P| < g$, then the sum $R(f, P, \{t_i\})$ will be very close to some fixed number—and this will be true no matter how the tags $\{t_i\}$ are chosen in the subintervals. Such a function f is said to be Riemann integrable on the interval from a to b. The value around which the sums congregate is designated by an elongated S, stretched between an a and ab, and set before the functional symbol f:

$$\int_a^b f$$

This number is called the integral of f.

Which functions are integrable? Numerous answers can be given. Monotone increasing functions, continuous functions, and bounded functions continuous at all but a finite number of points are all integrable. Suffice to say that most functions that turn up in applied mathematics are integrable. This is also a good place to say that following the work of Lebesque (1875–1941), the integral we have defined has been generalized in numerous ways so as to enlarge the class of integrable functions.

B. Evaluation of Integrals

No matter what the source (distance traveled, work done, etc.) of a Riemann sum, the corresponding integral may be interpreted as an area. Thus, for $f(x) = x$, we easily see (Fig. 17) that

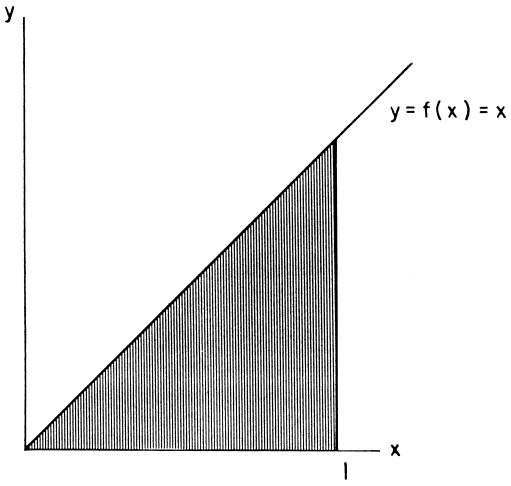

FIGURE 17 Interpreting an integral as an area.

$$\int_0^1 f = \int_0^1 x = \frac{1}{2}$$

When a function is known to be Riemann integrable, then the fact that *all* Riemann sums get close to the correct value for partitions with sufficiently small gauge means that we may use *any* convenient sum. We have seen that for $f(x) = x^2$, one such sum was given by R_n as expressed in Eq. (1):

$$R_n = \frac{1}{n}\left(\frac{1}{n}\right)^2 + \frac{1}{n}\left(\frac{2}{n}\right)^2 + \cdots + \frac{1}{n}\left(\frac{n}{n}\right)^2$$

$$= \frac{1}{n^3}(1^2 + 2^2 + \cdots + n^2)$$

We have already said that Archimedes was helped in his work because he knew Eq. (3), enabling him to write

$$R_n = \frac{1}{n_3}\left[\frac{1}{6}n(n+1)(2n+1)\right]$$

$$= \frac{1}{6}\left(\frac{n}{n}\right)\left(\frac{n+1}{n}\right)\left(\frac{2n+1}{n}\right)$$

$$R_n = \frac{1}{6}\left(1 + \frac{1}{n}\right)\left(2 + \frac{1}{n}\right)$$

Since the partition used here had n equal intervals, the requirement that the gauge get smaller is equivalent to requiring that n get larger. Thus,

$$\int_0^1 x^2 = \lim_{n\to\infty} R_n = \frac{1}{6}(1)(2) = \frac{1}{3}$$

With almost no extra effort, the length of the interval can be extended to an arbitrary b, and it can be determined that

$$\int_0^b x^2 = \frac{b^3}{3}$$

Proceeding in just this way, the mathematician Cavalieri (1598–1647) was able to find formulas similar to Eq. (3) for sums of the form $1^k + 2^k + \cdots + n^k$ for $k = 1, 2, \ldots, 9$. He was thus able to prove that

$$\int_0^b x^k = \frac{b^{k+1}}{k+1} \tag{22}$$

for all positive integers up to 9, and he certainly correctly anticipated that Eq. (22) holds for all positive integers. But each value of k presented a new problem, and as we said, Cavalieri himself stalled on $k = 10$. Reasonable people will be discouraged by the prospect of finding $\int_a^b f$ for more complicated functions. Indeed, the difficulty of such calculations made most such problems intractable until the time of Newton (1642–1727) and Leibniz (1647–1716), when discovery of the fundamental theorem of calculus, discussed below, brought such problems into the realm of feasibility.

The computer age has changed all that. For a given function, it is now possible to evaluate Riemann sums very rapidly. Along with this possibility have come increased emphases on variations of Riemann sums that approximate $\int_a^b f$. These are properly studied in courses on numerical analysis.

Before leaving the topic of evaluation, we note that, like differentiation, integration is a linear operator. For two integrable functions f and g and two real numbers r and s,

$$\int_a^b (rf + sg) = r\int_a^b f + s\int_a^b g$$

Thus, using what we know from our calculations above,

$$\int_0^1 (4x - 2x^2) = 4\int_0^1 x - 2\int_0^1 x^2 = 4\left(\frac{1}{2}\right)$$

$$-2\left(\frac{1}{3}\right) = \frac{4}{3}$$

C. Applications

It seems more difficult to group the diverse applications of integration into major classifications than is the case for differentiation. We shall indicate the breadth of possibilities with several examples typically studied in calculus.

1. Volumes

Suppose the graph of $y = x^2$ is rotated about the x axis to form a so-called solid of revolution that is cut off by the

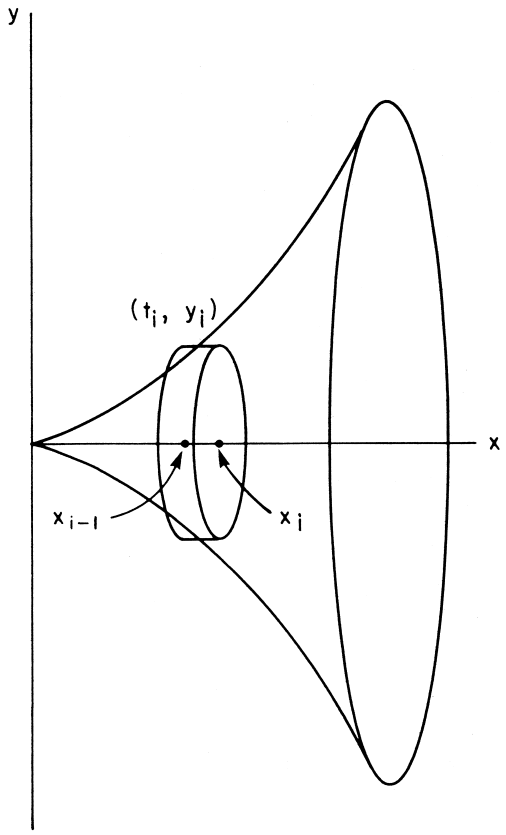

FIGURE 18 The curve $y = x^2$ has been rotated about the x axis to generate a solid figure.

plane $x = 1$ (Fig. 18). A partition of the x axis from 0 to 1 now determines a series of planes that cut off disks, each disk having a volume approximated by $\pi y_i^2(x_i - x_{i-1})$ where $y_i = t_i^2$ for some t_i between x_{i-1} and x_i. Summing these volumes gives

$$\pi t_1^4(x_1 - x_0) + \pi t_2^4(x_2 - x_1) + \cdots + \pi t_n^4(x_n - x_{n-1})$$

which has the form of a Riemann sum for a function $f(x) = \pi x^4$. It converges to an integral that we can evaluate with the help of Eq. (22).

$$\text{Volume} = \int_0^1 \pi x^4 = \pi \int_0^1 x^4 = \pi\left(\frac{1}{5}\right)$$

2. Length of Arc

Suppose the points A and B are connected by a curve that is the graph of $y = g(x)$ for x between a and b (Fig. 19). The length of this curve is clearly approximated by the sum of the lengths of line segments joining points that have as their first coordinates the points of a partition of the x axis from a to b. A typical segment has length

$$l = \sqrt{(x_i - x_{i-1})^2 + (y_i - y_{i-1})^2}$$
$$= \sqrt{(x_i - x_{i-1})^2 + [g(x_i) - g(x_{i-1})]^2}$$

If the function g is differentiable, then from the Mean Value Theorem, we see that

$$g(x_i) - g(x_{i-1}) = g'(t_i)(x_i - x_{i-1})$$

where t_i is between x_{i-1} and x_i. Thus

$$l = \sqrt{1 + [g'(t_i)]^2}\,(x_i - x_{i-1})$$

and the sum of these lengths is

$$\sqrt{1 + [g'(t_1)]^2}\,(x_1 - x_0) + \cdots$$
$$+ \sqrt{1 + [g'(t_n)]^2}\,(x_n - x_{n-1})$$

This has the form of a Riemann sum for the function $f(x) = \sqrt{1 + [g'(x)]^2}$. It converges to an integral we take to be the desired

$$\text{Length} = \int_a^b \sqrt{1 + [g'(x)]^2}$$

3. Normal Distribution

If in a certain town we measure the heights of all the women, or the IQ scores of all the third graders, or the gallons of water consumed in each single family dwelling, we will find that the readings cluster around a number called the mean, $\bar{x}$. A common display of the readings uses a bar graph, a graph in which the percentage of the readings that fall between x_{i-1} and x_i is indicated by the height of a bar drawn over the appropriate interval (Fig. 20a). The sum of all the heights (all the percentages) should, of course, be 1.

As the size of the intervals is decreased and the number of data points is increased, it happens in a remarkable number of cases that the bars arrange themselves under the so-called normal distribution curve (Fig. 20b) that has an equation of the form

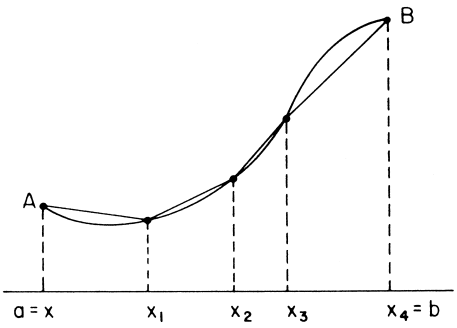

FIGURE 19 An arbitrarily drawn curve, together with a sequence of secant lines being used to (roughly) approximate the length of the curve.

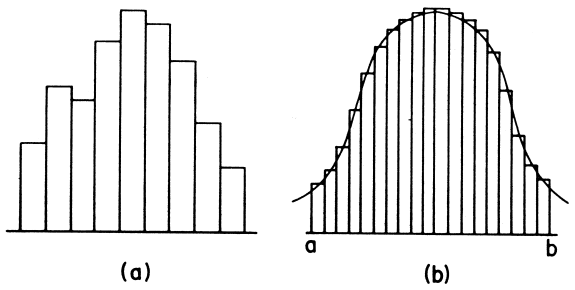

FIGURE 20 A pair of histograms, the second one indicating how an increasing number of columns leads to the concept of a distribution curve.

$$y = de^{-m(x-\bar{x})^2}$$

The constants are related to the relative spread of the bell-shaped curve, and they are chosen so that the area under the curve is 1. The percentage of readings that fall between a and b is then given by

$$\int_a^b de^{-m(x-\bar{x})^2}$$

VI. FUNDAMENTAL THEOREM OF CALCULUS

Up to this point, calculus seems to be neatly separated into two main topics, differential calculus and integral calculus. Historically, the two topics did develop separately, and considerable progress had been made in both areas. The genius of Newton and Leibniz was to see and exploit the connection between the integral and the derivative.

A. Integration by Antidifferentiation

Let $y = f(x)$ be the distance that a moving object has traveled from some fixed starting point in time x. We have seen (Table II) that the velocity of the object at time x is then given by $v = f'(x)$. Since the value of $f'(x)$ is also the slope of the line tangent at (x, y) to the graph of $y = f(x)$, a general sketch of $v = f'(x)$ may be drawn by looking at the graph of $y = f(x)$; see Fig. 21.

From the graph of $y = f(x)$, we see that from time $x = a$ to time $x = b$,

$$\text{Distance traveled} = f(b) - f(a) \qquad (23)$$

At the same time, we argued in setting up Eq. (19) that if the velocity v of a moving object is given by $v = g(t)$, then the distance traveled would be approximated by what we came later to see was a Riemann sum that converged to

$$\int_a^b g$$

Thus, in the present situation with $g = f'$ as the velocity function, we see that from the time $x = a$ to $x = b$,

$$\text{Distance traveled} = \int_a^b f' \qquad (24)$$

Comparison of Eqs. (23) and (24) suggests that

$$\int_a^b f' = f(b) - f(a)$$

The function being integrated is f', the derivative of the function f on the right side of the equal sign. The function f is in turn called the antiderivative of f'. The relationship lies at the heart of the calculus.

Fundamental theorem of calculus. Let F be any antiderivative of f; that is, let F be a function such that $F'(x) = f(x)$. Then

$$\int_a^b f = F(b) - F(a)$$

B. Some Consequences

In Eq. (15), we saw that if $f(x) = x^r$, then $f'(x) = rx^{r-1}$. It follows that the antiderivative of $f(x) = x^r$ would, for $r \neq -1$, be

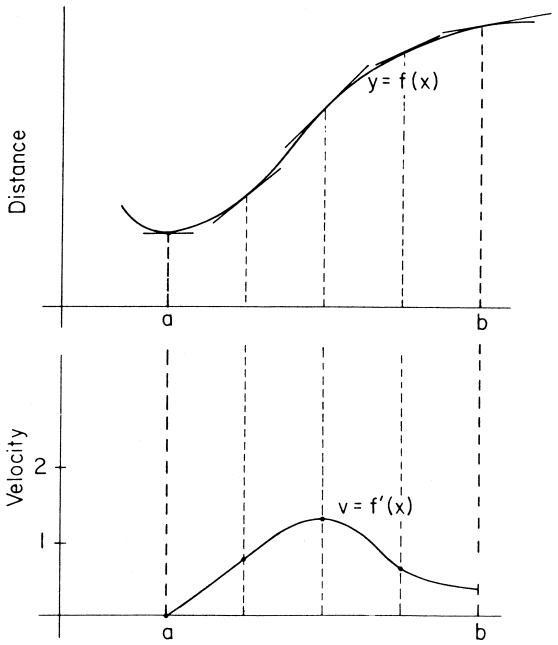

FIGURE 21 A graph of $y = f(x)$ on the top axes with two tangent segments having a slope of 1, an intermediate segment with slope >1, and a low point with slope 0. The lower curve, obtained by plotting the slopes of representative tangent lines, is the graph of $y = f'(x)$.

$$F(x) = \frac{1}{r+1}x^{r+1}$$

Consequently, for any $r \neq -1$ the fundamental theorem gives us

$$\int_a^b x^r = F(b) - F(a) = \frac{1}{r+1}b^{r+1} - \frac{1}{r+1}a^{r+1}$$

For $a = 0$ and r chosen to be a positive integer, we have Cavalieri's result [Eq. (22)].

The case $r = -1$ is of special interest. Since $f(x) = 1/x$ is continuous for $x > 0$,

$$\int_1^b \frac{1}{x}$$

exists for any $b > 0$. Yet the function $f(x) = 1/x$ has no simple antiderivative. Suppose we set

$$L(t) = \int_1^t \frac{1}{x}$$

This function turns out to have the following interesting properties:

$$L'(t) = \frac{1}{t} \qquad L(e^x) = x$$

The second property means that L is the inverse of the exponential function; it exhibits all the properties associated with a logarithm function. Since $L(e) = 1$, we say L is the logarithmic function having e as its base; it is called the natural logarithm.

VII. INFINITE SERIES

In discussing Approximation above, we noted that the value of

$$y = f(x) = \sqrt{x}$$

could be approximated for values of x near 9 by using

$$y = T_1(x) = f(9) + f'(9)(x - 9),$$

the function having as its graph the line tangent at $x = 9$ to the graph of $y = \sqrt{x}$. We might explain the usefulness of T_1 as a way to approximate f near $x = 9$ by observing that T_1 and its first derivative both agree with f at $x = 9$, That is,

$$T_1(9) = f(9) \quad \text{and} \quad T_1'(9) = f'(9)$$

This viewpoint has a wonderfully useful generalization. Consider the function

$$T_2(x) = f(9) + f'(9)(x - 9) + \frac{f''(9)}{2}(x - 9)^2$$

Its first and second derivatives are

$$T_2'(x) = f'(9) + f''(9)(x - 9)$$
$$T_2''(x) = f''(9)$$

This function and its first *two* derivatives agree with f at $x = 9$; that is, we see by substituting in the expressions just given that

$$T_2(9) = f(9), \qquad T_2'(9) = f'(9), \qquad T_2''(9) = f''(9),$$

It seems reasonable, therefore, to guess that T_2 (9.54) will give us a better approximation to $\sqrt{9.54}$ than we got with T_1 (9.54) = 3.09. Indeed, since

$$f''(x) = \left(\frac{1}{2}\right)\left(-\frac{1}{2}\right)x^{-\frac{3}{2}},$$
$$f''(9) = \left(\frac{1}{2}\right)\left(-\frac{1}{2}\right)\frac{1}{3^3} = -\frac{1}{108}$$

and

$$T_2(9.54) = 3 + \frac{1}{6}(0.54) + \frac{1}{2}\left(\frac{-1}{108}\right)(0.54)^2 = 3.08865$$

The actual value correct to five places to the right of the decimal is 3.08869, so we have improved our estimate.

The full generalization is this. Suppose a function and its derivatives at a point x_0 are known or easily calculated. Then the nth degree *Taylor polynomial* is defined to be

$$T_n(x) = f(x_0) + f'(x_0)(x - x_0) + \frac{f''(x_0)}{2}(x - x_0)^2 + \cdots + \frac{f^n(x_0)}{n!}(x - x_0)^n$$

This polynomial can be used to estimate f for values of x near x_0, and the larger n is taken, the better the estimate will be. Taylor polynomials of degree $n = 6$ for some well known functions are seen in Table III.

We are now in a position to get some idea of how calculators determine the values of familiar functions. The following table gives the actual values for the sine and cosine of angles near $x_0 = 0$, and, for comparison, the values of the polynomials $S(x)$ and $C(x)$ defined above. To get the results listed, one must remember that in calculus, angles must be measured in radians.

TABLE III

Function	Taylor polynomial of degree 6
$\sin x$	$S(x) = x - \frac{x^3}{3!} + \frac{x^5}{5!}$
$\cos x$	$C(x) = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!}$
e^x	$E(x) = 1 + x + \frac{x^2}{2!} + \cdots + \frac{x^6}{6!}$
$Arc \tan x$	$A(x) = x - \frac{x^3}{3!} + \frac{x^5}{5!}$

TABLE IV

X (degrees)	x(radians)	Sin x	$S(x)$	Cos x	$C(x)$
1	0.0174533	0.0174524	0.0174524	0.9998477	0.9998477
2	0.0349066	0.0348995	0.0348995	0.9993908	0.9993908
3	0.0523599	0.0523360	0.0523360	0.9986295	0.9986295
4	0.0698132	0.0697565	0.0697565	0.9975641	0.9975641
5	0.0872664	0.0871557	0.0871558	0.9961947	0.9961947
10	0.1745329	0.1736482	0.1736483	0.9848078	0.9848077
15	0.2617994	0.2588192	0.2588192	0.9659258	0.9659258
20	0.3490659	0.3420201	0.3420204	0.9396926	0.9396926
25	0.4363323	0.4226183	0.4226190	0.9063078	0.9063077
30	0.5235987	0.5000000	0.5000023	0.8660254	0.8660252
35	0.6108652	0.5735764	0.5735829	0.8191520	0.8191514

In a table of values accurate to seven places to the right of the decimal, one must get to 5 degrees before any difference shows up between $\sin x$ and its polynomial approximation $S(x)$; and the polynomial approximations $S(x)$ and $C(x)$ give six place accuracy for $\sin x$ and $\cos x$ for values of x all the way through 20 degrees.

Though manufacturers of calculators use variations, the idea illustrated in the Table IV gives correct insight into how calculators find values of trigonometric functions; they make use of polynomial approximations. Greater accuracy can be obtained by using Taylor polynomials of higher degree. It is sufficient, of course, to obtain accuracy up to the number of digits to the right of the decimal that are displayed by the calculator.

The last function listed in Table III, $Arc\tan x$, is the inverse tangent function. If $y = Arc\tan x$, then $x = \tan y$. It is included so we can address another question about which people sometimes wonder. Since $\tan 30^\circ = \frac{1}{\sqrt{3}}$ and $30^\circ = \frac{\pi}{6}$ radians, substitution of $x = \frac{1}{\sqrt{3}}$ into the polynomial approximation for $Arc\tan x$ gives

$$\frac{\pi}{6} \approx \frac{1}{\sqrt{3}} - \frac{1}{3(\sqrt{3})^3} + \frac{1}{5(\sqrt{3})^5} - \frac{1}{7(\sqrt{3})^7} = 0.5230$$

Multiplication by 6 gives us the approximation of $\pi \approx 3.138$ Rounding to two decimals to the right of the decimal, we get the familiar approximation of 3.14. More accuracy can be obtained by using a Taylor polynomial of higher degree, and there are tricks that yield much better approximations using just the 7th degree polynomial employed here, but again we stop, having illustrated our point. Familiar constants such as π (and e) can be approximated using Taylor polynomials.

While our discussion of infinite series has given some indication of the usefulness of the idea, it is important to indicate that a great deal more could be said. Thus, while Taylor series provide an important way to represent functions, they should be seen as just one such representation. Fourier series provide another useful representation, and there are others.

Also, while we have approached infinite series by way of representing functions, we might well have started with the representation of individual numbers. The familiar use of $0.333\cdots = \frac{1}{3}$ is really a statement saying that the infinite sum

$$\frac{3}{10} + \frac{3}{10^2} + \frac{3}{10^3} + \cdots$$

gets closer and closer to $\frac{1}{3}$; that is, the finite sums

$$S_n = \frac{3}{10} + \frac{3}{10^2} + \cdots \frac{3}{10^n}$$

get closer to $\frac{1}{3}$ as n, the number of terms increases.

The addition of an infinite number of terms is not a trivial subject. The history of mathematics includes learned discussions of what value to assign to

$$1 - 1 + 1 - 1 + 1 - \cdots$$

Some argued that an obvious grouping shows that

$$(1 - 1) + (1 - 1) + (1 - 1) + \cdots = 0$$

Others countered that

$$1 - (1 - 1) - (1 - 1) - \cdots = 1$$

and Leibniz, one of the developers of calculus, suggested that the proper value would therefore be $\frac{1}{2}$. There are other instances in which famous mathematicians have challenged one another to find the value of an infinite series of constants. James Bernoulli (1654–1705) made it clear that he would like to know the sum of

$$1 + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \cdots + \frac{1}{n^2} + \cdots.$$

but it wasn't until 1736 that Euler discovered that this sum got closer and closer to $\frac{\pi^2}{6}$

VIII. SOME HISTORICAL NOTES

Archimedes, with his principle of exhaustion, certainly had in hand the notion of approaching a limiting value with a sequence of steps that could be carried on ad infinitum, but he was limited by, among other things, the lack of a convenient notation. The algebraic notation came much later, and the idea of relating algebra to geometry was later still, often attributed to Descartes (1596–1650), but arguably owing more to Fermat (1601–1665). Fermat, Barrow (1630–1677), Newton's teacher, Huygens (1629–1695), Leibniz's teacher, and others set the stage in the first half of the 17th century, but the actual development of the calculus is attributed to Isaac Newton (1642–1727) and Gottfried Wilhelm Leibniz (1646–1716), two geniuses who worked independently and were ultimately drawn into arguments over who developed the subject first.

Evidence seems to substantiate Newton's claim to primacy, but his towering and deserved reputation as one of the greatest thinkers in the history of mankind is surely owing not so much to what he invented, but what he did with it. In Newton's hands, calculus was a tool for changing the way humans understood the universe. Using calculus to extrapolate from his law of universal gravitation and other laws of motion, Newton was able to analyze not only the motion of free falling bodies on earth, but to explain, even predict the motions of the planets. He was widely regarded as having supernatural insight, a reputation the poet Alexander Pope caught with the lines,

Nature and Nature's laws lay hid in night:
God said, "Let Newton be!" and all was light.

Leibniz, on the other hand, developed the notation that made the calculus comprehensible to others, and he gathered around himself the disciples that took the lead away from Newton's followers in England, and made the continent the center of mathematical life for the next century. James (1654–1705) and John (1667–1748) Bernoulli, Leonhard Euler (1707–1783), and others applied calculus to a host of problems and puzzles as well applied problems.

The first real textbook on calculus was *Analyse des Infiniments Petits Pour L'intelligence des Lignes Courbes*, written by the Marquis de l'Hospital in 1696. It wasn't until 1816, however, that a text by Lacroix, *Traité du Calcul Différentiél et du Calcul Intégral*, having been well received in France for many years, was translated into English and so brought the methods used on the continent to the English speaking world. Through all of these books there ran an undercurrent of confusion about the nature of the infinitesimal, and it was not until the work of Cauchy (1789–1857) and Weierstrass (1815–1897) that logical gaps were closed and calculus took the form that we recognize today.

The most recent changes in the teaching of calculus grew out of an effort during the decade from 1985–1995 to reform the way calculus was to be taught in the United States. A summary of that effort is presented in *Calculus, The Dynamics of Change*.

GLOSSARY

Analytic function A complex function with a power series expansion. An analytic function is holomorphic and conversely.

Argument In the polar form $z = re^{i\theta}$ of a complex number, the argument is the angle θ, which is determined up to an integer multiple of 2π.

Cauchy integral formula A basic formula expressing the value of an analytic function at a point as a line integral along a closed curve going around that point.

Cauchy–Riemann equations The system of first-order partial differential equations $u_x = v_y,\ u_y = -v_x$, which is equivalent to the complex function $f(z) = u(x, y) + iv(x, y)$ being holomorphic (under the assumption that all four first-order partial derivatives are continuous).

Conformal maps A map that preserves angles infinitesimally.

Disk A set of the form $\{z : |z - a| < r\}$ is an open disk.

Domain A nonempty connected open set in the complex plane.

Half-plane The upper half-plane is the set of complex numbers with positive imaginary part.

Harmonic function A real function $u(x, y)$ of two real variables satisfying Laplace's equation $u_{xx} + u_{yy} = 0$.

Holomorphic functions A differentiable complex function. See also Analytic functions.

Laurent series An expansion of a complex function as a doubly infinite sum: $f(z) = \sum_{m=-\infty}^{\infty} a_n(z - c)^m$.

Meromorphic function A complex function that is differentiable (or holomorphic) except at a discrete set of points, where it may have poles.

Neighborhood of a point An open set containing that point.

Pole A point a is a pole of a function $f(z)$ if $f(z)$ is analytic on a neighborhood of a but not at a, $\lim_{z\to a} f(z) = \infty$, and $\lim_{z\to a}(z - a)^k f(z)$ is finite for some positive integer k.

Power series or Taylor series An expansion of a complex function as an infinite sum: $f(z) = \sum_{m=0}^{\infty} a_n(z - c)^m$.

Region A nonempty open set in the complex plane.

Riemann surface A surface (in two real dimensions) obtained by cutting and gluing together a finite or infinite number of complex planes.

TO OVERSIMPLIFY, COMPLEX ANALYSIS is calculus using complex numbers rather than real numbers. Because a complex number $a+ib$ is essentially a pair of real numbers, there is more "freedom of movement" over the complex numbers and many conditions become stronger. As a result, complex analysis has many features that distingush it from real analysis. The most remarkable feature, perhaps, is that a differentiable complex function always has a power series expansion. This fact follows from the Cauchy integral formula, which expresses the value of a function in terms of values of the function on a closed curve going around that point.

Many powerful mathematical techniques can be found in complex analysis. Many of these techniques were developed in the 19th century in conjunction with solving practical problems in astronomy, engineering, and physics. Complex analysis is now recognized as an indispensable component of any applied mathematician's toolkit. Complex analysis is also extensively used in number theory, particularly in the study of the distribution of prime numbers.

In addition, complex analysis was the source of many new subjects of mathematics. An example of this is Riemann's attempt to make multivalued complex functions such as the square-root function single-valued by enlarging the range. This led him to the idea of a Riemann surface. This, in turn, led him to the theory of differentiable manifolds, a mathematical subject that is the foundation of the theory of general relativity.

I. THE COMPLEX PLANE

A. Complex Numbers

A complex number is a number of the form $a+ib$, where a and b are real numbers and i is a square root of -1, that is, i satisfies the quadratic equation $i^2+1=0$. Historically, complex numbers arose out of attempts to solve polynomial equations. In particular, in the 16th century, Cardano, Tartaglia, and others were forced to use complex numbers in the process of solving cubic equations, even when all three solutions are real. Because of this, complex numbers acquired a mystical aura that was not dispelled until the early 19th century, when Gauss and Argand proposed a geometric representation for them as pairs of real numbers.

Gauss thought of a complex number $z=a+ib$ geometrically as a point (a, b) in the real two-dimensional space. This represents the set $\mathbf{C}$ of complex numbers as a real two-dimensional plane, called the *complex plane.* The x-axis is called the *real axis* and the real number a is called the *real part* of z. The y-axis is called the *imaginary axis* and the real number b is called the *imaginary part* of z.

The *complex conjugate* $\bar{z}$ of the complex number $z=a+ib$ is the complex number $a-ib$. The *absolute value* $|z|$ is the real number $\sqrt{a^2+b^2}$. The (*multiplicative*) *inverse* or *reciprocal* of z is given by the formula

$$\frac{1}{z}=\frac{\bar{z}}{|z|}=\frac{a-ib}{\sqrt{a^2+b^2}}.$$

The complex number $z=a+ib$ can also be written in the *polar form*

$$z=re^{i\theta}=r(\cos\theta+i\sin\theta),$$

where

$$r=\sqrt{a^2+b^2}, \qquad \tan\theta=y/x.$$

The angle θ is called the *argument* of z. The argument is determined up to an integer multiple of 2π. Usually, one takes the value θ so that $-\pi<\theta\leq\pi$; this is called the *principal value* of the argument.

B. Topology of the Complex plane

The absolute value defines a *metric* or distance function d on the complex plane $\mathbf{C}$ by

$$d(z_1, z_2)=|z_1-z_2|.$$

This metric satisfies the triangle inequality

$$d(z_1, z_2)+d(z_2, z_3)\geq d(z_1, z_3)$$

and determines a topology on the complex plane $\mathbf{C}$. We shall need the notions of open sets, closed sets, closure, compactness, continuity, and homeomorphism from topology.

C. Curves

A *curve* γ is a continuous map from a real interval $[a, b]$ to $\mathbf{C}$. The curve γ is said to be *closed* if $\gamma(a)=\gamma(b)$; it is said to be *open* otherwise. A *simple closed curve* is a closed curve with $\gamma(t_1)=\gamma(t_2)$ if and only if $t_1=a$ and $t_2=b$.

An intuitively obvious theorem about curves that turned out to be very difficult to prove is the Jordan curve theorem. This theorem is usually not necessary in complex analysis, but is useful as background.

The Jordan Curve Theorem. The image of a simple closed curve (not assumed to be differentiable) separates the extended complex plane into two regions. One region is bounded (and "inside" the curve) and the other is unbounded.

D. The Stereographic Projection

It is often useful to extend the complex plane by adding a point ∞ at infinity. The extended plane is called the *extended complex plane* and is denoted $\bar{\mathbf{C}}$. Using a *stereographic projection*, we can represent the extended plane $\bar{\mathbf{C}}$ using a sphere.

Let $\mathcal{S}$ denote the sphere with radius 1 in real three-dimensional space defined by the equation

$$x_1^2 + x_2^2 + x_3^2 = 1$$

Let the x_1-axis coincide with the real axis of $\mathbf{C}$ and let the x_2-axis coincide with imaginary axes of $\mathbf{C}$. The point $(0, 0, 1)$ on $\mathcal{S}$ is called the *north pole.* Let (x_1, x_2, x_3) be any point on $\mathcal{S}$ not equal to the north pole. The point $z = x + iy$ of intersection of the straight line segment emanating from the north pole N going through the point (x_1, x_2, x_3) with the complex plane $\mathbf{C}$ is the *stereographical projection* of (x_1, x_2, x_3). Going backwards, the point (x_1, x_2, x_3) is the *spherical image* of z. The north pole is the spherical image of the point ∞ at infinity. The stereographic projection is a one-to-one mapping of the extended plane $\bar{\mathbf{C}}$ onto the sphere $\mathcal{S}$. The sphere $\mathcal{S}$ is called the *Riemann sphere*. The stereographical projection has the property that the angles between two (differentiable) curves in $\mathbf{C}$ and the angle between their images on $\mathcal{S}$ are equal.

The mathematical formulas relating points and their spherical images are as follows:

$$x_1 = \frac{z + \bar{z}}{1 + |z|^2}, \quad x_2 = \frac{z - \bar{z}}{i(1 + |z|^2)}, \quad x_3 = \frac{|z|^2 - 1}{1 + |z|^2}$$

and

$$z = \frac{x_1 + ix_2}{1 - x_3}$$

Let z_1 and z_2 be two points in the plane $\mathbf{C}$. The *spherical* or *chordal distance* $\sigma(z_1, z_2)$ between their spherical images on $\mathcal{S}$ is

$$\sigma(z_1, z_2) = \frac{2|z_1 - z_2|}{\sqrt{1 + |z_1|^2}\sqrt{1 + |z_2|^2}}.$$

Let $d\sigma$ and ds be the length of the infinitesimal arc on $\mathcal{S}$ and $\mathbf{C}$, respectively. Then

$$d\sigma = 2(1 + |z|^2)^{-1}\, ds.$$

E. Connectivity

We need two notions of connectedness of sets in the complex plane. Roughly speaking, a set is *connected* if it consists of a single piece. Formally, a set S is connected if S is not the union $A \cup B$ of two disjoint nonempty open (and hence, closed) subsets A and B. A set is *simply connected* if every closed curve in it can be contracted to a point, with the contraction occurring in the set. It can be proved that a set is simply connected in $\mathbf{C}$ if its complement in the extended complex plane is connected. If A is not simply connected, then the connected components (that is, open and closed subsets) of its complement $\bar{\mathbf{C}}$ not containing the point ∞ are the "holes" of A.

A *region* is a nonempty open set of $\mathbf{C}$. A *domain* is a non-empty connected open set of $\mathbf{C}$. When $r > 0$, the set $\{z : |z - c| < r\}$ of all complex numbers at distance strictly less than r from the *center* c is called the *open disk with center c and radius r*. Its closure is the *closed disk* $\{z : |z - c| \le r\}$. Open disks are the most commonly used domains in complex analysis.

II. ANALYTIC AND HOLOMORPHIC FUNCTIONS

A. Holomorphic Functions

Let $f(z)$ denote a complex function defined on a set Ω in the complex plane $\mathbf{C}$. The function $f(z)$ is said to be *differentiable* at the point a in Ω if the limit

$$\lim_{h \to 0} \frac{f(a + h) - f(a)}{h}$$

is a finite complex number. This limit is the *derivative* $f'(a)$ of $f(z)$ at a. Note that the limit is taken over all complex numbers h such that the absolute value $|h|$ goes to zero, so that h ranges over a set that has two real dimensions. Thus, differentiability of complex functions is a much stronger condition than differentiability of real functions. For example, the length of every (infinitesimally) small line segment starting from a is changed under the function $f(z)$ by the same real scaling factor $|f'(a)|$, independently of the angle. The formal rules of differentiation in calculus hold also for complex differentiation.

It is possible to construct complex functions that are differentiable at only one point. To exclude these degenerate cases, we only consider complex functions that are differentiable at every point in a region Ω. Such functions are said to be *holomorphic* on Ω.

B. The Cauchy–Riemann Equations and Harmonic Functions

A complex function $f(z)$ can be expressed in the following way:

$$f(z) = f(x + iy) = u(x, y) + iv(x, y)$$

where $u(x, y)$ is the real part of $f(z)$ and $v(x, y)$ is the imaginary part of $f(z)$. The functions $u(x, y)$ and $v(x, y)$ are real functions of two real variables.

Differentiability of the complex function $f(z)$ can be rewritten as a condition on the real functions $u(x, y)$ and $v(x, y)$. Let $f(z) = u(x, y) + iv(x, y)$ be a complex function such that all four first-order partial derivatives of u and v are continuous in the open set Ω. Then a necessary and sufficient condition for $f(z)$ to be holomorphic on Ω is

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \qquad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}$$

These equations are the *Cauchy–Riemann equations.* In polar coordinates $z = re^{i\theta}$, the Cauchy–Riemann equations are

$$r\frac{\partial u}{\partial r} = \frac{\partial v}{\partial \theta}, \qquad \frac{\partial u}{\partial \theta} = -r\frac{\partial v}{\partial r}$$

The square of the absolute value of the derivative is the Jacobian of $u(x, y)$ and $v(x, y)$, that is

$$|f'(z)|^2 = \frac{\partial u}{\partial x}\frac{\partial v}{\partial y} - \frac{\partial u}{\partial y}\frac{\partial v}{\partial x}$$

A *harmonic or potential function* $h(x, y)$ is a real function having continuous second-order partial derivatives in a nonempty open set Ω in $\boldsymbol{R}^2$ satisfying the two-dimensional *Laplace equation*

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} = 0$$

for all $z = x + iy$ in Ω. We shall see that $f(z)$ being holomorphic in Ω implies that every derivative $f^{(n)}(z)$ is holomorphic on Ω, and, in particular, the real functions $u(x, y)$ and $v(x, y)$ have partial derivatives of any order. Hence, by the Cauchy–Riemann equations, $u(x, y)$ and $v(x, y)$ satisfy the Laplace equation and are harmonic functions. The harmonic functions $u(x, y)$ and $v(x, y)$ are called the *conjugate pair* of the holomorphic function $f(z)$.

The two-dimensional Laplace equation governs (incompressible and irrotational) fluid flow and electrostatics in the plane. These give intuitive physical models for holomorphic functions.

C. Power Series and Analytic Functions

Just as in calculus, we can define complex functions using power series. A *power series* is an infinite sum of the form

$$\sum_{m=0}^{\infty} a_m (z - c)^m$$

where the *coefficients* a_m and the *center* c are complex numbers. This series determines a complex number (depending on z) whenever the the series converges. Complex power series work in the same way as power series over the reals.

In particular, a power series has a *radius of convergence,* that is, an extended real number ρ, $0 \le \rho \le \infty$, such that the series converges absolutely whenever $|z - c| < \rho$. The radius of convergence is given explicitly by *Hadamard's formula:*

$$\rho = \frac{1}{\limsup_{n\to\infty} \sqrt[n]{|a_n|}}$$

A function $f(z)$ is *analytic* in the region Ω if for every point c in Ω, there exists an open disk $\{z : |z - c| < r\}$ contained in Ω such that $f(z)$ has a (convergent) power series or *Taylor expansion*

$$f(z) = \sum_{m=0}^{\infty} a_m (z - c)^m$$

When this holds, $f^{(n)}(c)/m! = a_m$.

Polynomials are analytic functions on the complex plane. Other examples of analytic functions on the complex plane are the *exponential function,*

$$e^z = \sum_{m=0}^{\infty} z^n / n!$$

and the two *trigenometric functions,*

$$\cos z = \frac{e^{iz} + e^{-iz}}{2}, \qquad \sin z = \frac{e^{iz} - e^{-iz}}{2i}$$

The inverse under functional composition of e^z is the (*natural*) *logarithm* $\log z$. The easiest way to define it is to put z into polar form. Then

$$\log z = \log re^{i\theta} = \log r + i\theta$$

Since θ is determined up to an integer multiple of 2π, the logarithmic function is multivalued and one needs to extend the range to a Riemann surface (see Section V.D) to make it a function. For most purposes, one takes the value of θ so that $-\pi < \theta \le \pi$. This yields the *principal value* of the logarithm.

III. CAUCHY INTEGRAL FORMULA

A. Line Integrals and Winding Numbers

Line integrals are integrals taken over a curve rather than an interval on a real line. Let $\gamma : [a, b] \to C$ be a piecewise continuously differentiable curve and let $f(z)$ be a continuous complex function defined on the image of γ. Then the *line integral* of $f(z)$ along the path γ is the Riemann integral

$$\int_a^b f(\gamma(t))\gamma'(t)\,dt$$

This integral is denoted by

$$\int_\gamma f(z)\,dz$$

Line integrals are also called *path integrals* or *contour integrals*. Line integrals behave in similar ways to integrals over the real line, except that instead of moving along the real line, we move on a curve.

The *winding number* or *index* $n(\gamma, a)$ of a curve γ *relative to a point* a is the number of time the curve winds or goes around the point a. Formally, we define $n(\gamma; z)$ using a line integral:

$$n(\gamma, a) = \frac{1}{2\pi i}\int_\gamma \frac{d\zeta}{\zeta - a}$$

This definition is consistent with the intuitive definition. One can show, for example, that (a) $n(\gamma, a)$ is always an integer, (b) the winding number of a circle around its center is 1 if the circle goes around in a counterclockwise direction, and -1 if the circle goes around in a clockwise direction, (c) the winding number of a circle relative to a point in its exterior is 0, and (d) if a is a point in the interior of two curves and those two curves can be continuously deformed into one another without going through a, then they have the same winding number relative to a.

B. Cauchy's Integral Formula

In general, line integrals depend on the curve. But if the integrand $f(z)$ is holomorphic, Cauchy's integral theorem implies that the line integral on a simply connected region only depends on the endpoints.

Cauchy's integral theorem. Let $f(z)$ be holomorphic on a simply connected region Ω in $\mathbf{C}$. Then for any closed piecewise continuously differential curve γ in Ω,

$$\int_\gamma f(z)\,dz = 0$$

One way to prove Cauchy's theorem (due to Goursat) is to observe that if the curve is "very small," then the line integral should also be "very small" because holomorphic functions cannot change drastically in a small neighborhood. Hence, we can prove the theorem by carefully decomposing the curve into a union of smaller curves. Another way to think of Cauchy's theorem is that a line integral over a curve γ of a holomorphic function on a region Ω is zero whenever γ can be continuously shrunk to a point in Ω.

Cauchy's integral formula. Let $f(z)$ be holomorphic on a simply connected region Ω in $\mathbf{C}$ and let γ be a simple piecewise continuously differentiable closed path going counterclockwise in Ω. Then for every point z in Ω inside γ,

$$f^{(m)}(z) = \frac{m!}{2\pi i}\int_\gamma \frac{f(\zeta)\,d\zeta}{(\zeta - z)^{m+1}}$$

In particular,

$$f(z) = \frac{1}{2\pi i}\int_\gamma \frac{f(\zeta)\,d\zeta}{\zeta - z}$$

Cauchy's formula for $f(z)$ follows from Cauchy's theorem applied to the function $(f(\zeta) - f(z))/(\zeta - z)$, and the general case follows similarly.

A somewhat more general formulation of Cauchy's formula is in terms of the winding number. If $f(z)$ is analytic on a simply connected nonempty open set Ω and γ is a closed piecewise continuously differentiable curve, then, for every point z in Ω,

$$f^{(m)}(z) = n(\gamma, z)\frac{m!}{2\pi i}\int_\gamma \frac{f(\zeta)\,d\zeta}{(\zeta - z)^{m+1}}$$

Cauchy's integral formula expresses the function value $f(z)$ in terms of the function values around z. Take the curve γ to be a circle $|z - a| = r$ of radius r with center a, where r is sufficiently small so that the circle is in Ω. Using the geometric series expansion

$$\frac{1}{\zeta - z} = \frac{1}{\zeta - a}\sum_{m=0}^{\infty}\left(\frac{z - a}{\zeta - a}\right)^m$$

and interchanging summation and integration (which is valid as all the series converge uniformly), we obtain

$$f(z) = \sum_{m=0}^{\infty}\frac{(z - a)^{m+1}}{2\pi i}\int_{|z-a|=r}\frac{f(\zeta)\,d\zeta}{(\zeta - a)^{m+1}}$$

This gives an explicit formula for the power series expansion of $f(z)$ and shows that a holomorphic function is analytic. Since an analytic function is clearly differentiable, being analytic and being holomorphic are the same property.

C. Geometric Properties of Analytic Functions

Analytic functions satisfy many nice geometric and topological properties. A basic property is the following.

The open mapping theorem. The image of an open set under a non-constant analytic function is open.

Analytic functions also have the nice geometric property that they preserve angles. Let γ_1 and γ_2 be two differentiable curves intersecting at a point z in Ω. The *angle* from γ_1 to γ_2 is the signed angle of their tangent lines at z. A function $f(z)$ is said to be *conformal* at the point z if it preserves the angles of pairs of curves intersecting at z. An analytic function $f(z)$ preserves angles at points z where the derivative $f'(z) \neq 0$. If an analytic function $f(z)$ is conformal at every point in Ω (equivalently, if $f'(z) \neq 0$

for every point z in Ω), then it is said to be a *conformal mapping on* Ω.

Examples of conformal mappings (on suitable regions) are Möbius transformations. Let a, b, c, and d be complex numbers such that $ad - bc \neq 0$. Then the bilinear transformation

$$T(z) = \frac{az + b}{cz + d}$$

is a *Möbius transformation.* Any Möbius transformation can be decomposed into a product of four elementary conformal mappings: translations, rotations, homotheties or dilations, and inversions. In addition to preserving angles, Möbius transformations map circles into circles, provided that a straight line is viewed as a "circle" passing through the point ∞ at infinity.

D. Some Theorems about Analytic Functions

If $f(z)$ is a function on the disk with center 0 and radius ρ and $r < \rho$, let $M_f(r)$ be the maximum value of $|f(z)|$ on the circle $\{z : |z| = r\}$.

Cauchy's inequality. Let $f(z)$ be analytic in the disk with center 0 and radius ρ and let $f(z) = \sum_{m=0}^{\infty} a_n z^n$. If $r < \rho$, then

$$|a_n| r^n \leq M_f(r)$$

A function is *entire* if it is analytic on the entire complex plane. The following are two theorems about entire function. The first follows easily from the case $n = 1$ of Cauchy's inequality.

Liouville's theorem. If $f(z)$ is an entire function and $f(z)$ is bounded on $\mathbf{C}$, then f must be a constant function.

The second is much harder. It implies the fact that if two or more complex numbers are absent from the image of an entire function, then that entire function must be a constant.

Picard's little theorem. An entire function that is not a polynomial takes every value, with one possible exception, infinitely many times.

Applying Liouville's theorem to the reciprocal of a nonconstant polynomial $p(z)$ and using the fact that $p(z) \to \infty$ as $z \to \infty$, one obtains the following important theorem.

The fundamental theorem of algebra. Every polynomial with complex coefficients of degree at least one has a root in $\mathbf{C}$.

It follows that a polynomial of degree n must have n roots in $\mathbf{C}$, counting multiplicities.

The next theorem is a fundamental property of analytic functions.

Maximum principle. Let Ω be a bounded domain in $\mathbf{C}$. Suppose that $f(z)$ is analytic in Ω and continuous in the closure of Ω. Then, $|f(z)|$ attains its maximum value $|f(a)|$ at a boundary point a of Ω. If $f(z)$ is not constant, then

$$|f(z)| < |f(a)|$$

for every point z in the interior of Ω.

Using the maximum principle, one obtains Schwarz's lemma.

Schwarz's lemma. Let $f(z)$ be analytic on the disk $D = \{z : |z| < 1\}$ with center 0 and radius 1. Suppose that $f(0) = 0$ and $|f(z)| \leq 1$ for all points z in D. Then,

$$|f'(0)| \leq 1$$

and for all points z in D,

$$|f(z)| \leq |z|$$

If $|f'(0)| = 1$ or $|f(a)| = |a|$ for some nonzero point a, then $f(z) = \alpha z$ for some complex number α with $|\alpha| = 1$.

Another theorem, which has inspired many generalizations in the theory of partial differential equations, is the following.

Hadamard's three-circles theorem. Let $f(z)$ be an analytic function on the annulus $\{z : \rho_1 \leq |z| \leq \rho_3\}$ and let $\rho_1 < r_1 \leq r_2 \leq r_3 < \rho_3$. Then

$$\log M_f(r_2) \leq \frac{\log r_3 - \log r_2}{\log r_3 - \log r_1} \log M_f(r_1) + \frac{\log r_2 - \log r_1}{\log r_3 - \log r_1} \log M_f(r_3)$$

It follows from the three-circles theorem that $\log M_f(r)$ is a convex function of $\log r$.

Cauchy's integral theorem has the following converse.

Morera's theorem. Let $f(z)$ be a continuous function on a simply connected region Ω in $\mathbf{C}$. Suppose that the line integral

$$\int_{\partial \triangle} g(z)\, dz$$

over the boundary $\partial\triangle$ of every triangle in Ω is zero. Then $f(z)$ is analytic in Ω.

E. Analytic Continuation

An analytic function $f(z)$ is usually defined initially with a certain formula in some region D_1 of the complex plane. Sometimes, one can extend the function $f(z)$ to a function $\hat{f}(z)$ that is analytic on a bigger region D_2 containing D_1 such that $\hat{f}(z) = f(z)$ for all points z on D_1. Such an extension is called *analytic continuation.* Expanding the function as a Taylor (or Laurent series) is one possible

way to extend a function locally from a neighborhood of a point. Contour integration is another way.

Analytic continuation results in a unique extended function when it is possible. It also preserves identities between functions.

The uniqueness theorem for analytic continuation. Let $f(z)$ and $g(z)$ be analytic in a region Ω. If the set of points z in Ω where $f(z) = g(z)$ has a limit point in Ω, then $f(z) = g(z)$ for all z in Ω. In particular, if the set of zeros of $f(z)$ in Ω has a limit point in Ω, then $f(z)$ is identically zero in Ω.

Permanence of functional relationships. If a finite number of analytic functions in a region Ω satisfy a certain functional equation in a part of Ω that has a limit point, then that functional equation holds everywhere in Ω.

For example, the Pythagorean identity

$$\sin^2 x + \cos^2 x = 1$$

holds for all real numbers x. Thus, it holds for all complex numbers.

Deriving a functional equation is often the key step in analytic continuation. A famous example is the Riemann functional equation relating the gamma function and the Riemann zeta function.

A quick and direct way (when it works) is the following method.

Schwarz's reflection principle. Let Ω be a domain in the upper half-plane that contains a line segment L on the real axis. Let $f(z)$ be a function analytic on Ω and continuous on L. Then the function extended by defining $f(z) = \overline{f(\bar{z})}$ for z in the "reflection" $\tilde{\Omega} = \{z | \bar{z} \in \Omega\}$ is an analytic continuation of $f(z)$ from Ω to to the bigger domain $\Omega \cup \tilde{\Omega}$.

We note that not all analytic functions have proper analytic continuations. For example, when $0 < |a| < 1$, the *Fredholm series*

$$\sum_{m=1}^{\infty} a^n z^{n^2}$$

converges absolutely on the closed unit disk $\{z : |z| \le 1\}$ and defines an analytic function $f(z)$ on the open disk $\{z : |z| < 1\}$. However, it can be shown that $f(z)$ has no analytic continuation outside the unit disk. Roughly speaking, the Fredholm functions are not extendable because of "gaps" in the powers of z. The sharpest "gap" theorem is the following.

The Fabry gap theorem. Let

$$f(z) = \sum_{m=0}^{\infty} a_m z^{b_m}$$

where b_m is a sequence of increasing nonnegative integers such that

$$\lim_{m \to \infty} b_m / m = \infty$$

Suppose that the power series has radius of convergence ρ. Then $f(z)$ has no analytic continuation outside the disk $\{z : |z| < \rho\}$.

IV. MEROMORPHIC FUNCTIONS

A. Poles and Meromorphic Functions

A point a is an *isolated singularity* of the analytic function $f(z)$ if $f(z)$ is analytic in a neighborhood of a, except possibly at the point itself. For example, the function $f(z) = 1/z$ is analytic on the entire complex plane, except at the isolated singularity $z = 0$. If the limit $\lim_{z \to a} f(z)$ is a finite complex number c, then we can simply define $f(a) = c$ and $f(z)$ will be analytic on the entire neighborhood. Such an isolated singularity is said to be *removable.*

If the limit $\lim_{z \to a} f(z)$ is infinite, but for some positive real number α, $\lim_{z \to a} |z - a|^{\alpha} |f(z)|$ is finite, then a is a *pole* of $f(z)$. It can be proved that if the last condition holds, then the smallest such real number α must be a positive integer k. In this case, the pole a is said to have order k. Equivalently, k is the smallest positive integer such that $(z - a)^k f(z)$ is analytic on an entire neighborhood of a (including a itself).

If an isolated singularity is neither removable nor a pole, it is said to be *essential.* Weierstrass and Casorati proved that an analytic function comes arbitrarily close to every complex number in every neighborhood of an isolated essential singularity. A refinement of this is a deep theorem of Picard.

Picard's great theorem. An analytic function takes on every complex value with one possible exception in every neighborhood of an essential singularity.

These results say that near an isolated singularity, an analytic function behaves very wildly. Thus, the study of isolated singularities has concentrated on analytic functions with poles. A complex function $f(z)$ is *meromorphic* in a region Ω if it is analytic except at a discrete set of points, where it may have poles.

The *residue* $\mathrm{Res}(f, a)$ of a meromorphic function $f(z)$ at the isolated singularity a is defined by

$$\mathrm{Res}(f, a) = \frac{1}{2\pi i} \int_{\gamma} f(\zeta)\, d\zeta$$

If one allows negative powers, then analytic functions can be expanded as power series at isolated singularities. The idea is to write a meromorphic function $f(z)$ in a neighborhood of a pole a as a sum of an analytic part and a singular part. Suppose the function $f(z)$ is analytic in a region containing the annulus $\{z : \rho_1 < |z - a| < \rho_2\}$.

Then we can define two functions $f_1(z)$ and $f_2(z)$ by:

$$f_1(z) = \frac{1}{2\pi i}\int_{\{\zeta:|\zeta-a|=r\}} \frac{f(\zeta)\,d\zeta}{\zeta - z}$$

where r satisfies $|z-a| < r < \rho_2$, and

$$f_2(z) = -\frac{1}{2\pi i}\int_{\{\zeta:|\zeta-a|=r\}} \frac{f(\zeta)\,d\zeta}{\zeta - z}$$

where r satisfies $\rho_1 < r < |z-a|$. The function $f_1(z)$ is analytic in the disk $\{z : |z-a| < \rho_2\}$ and the function $f_2(z)$ is analytic in the complement $\{z : |z-a| > \rho_1\}$. By the Cauchy integral formula, $f(z) = f_1(z) + f_2(z)$ and this representation is valid in the annulus $\{z : \rho_1 < |z-a| < \rho_2\}$.

The functions $f_1(z)$ and $f_2(z)$ can each be expanded as Taylor series. Using the transformation $z - a \mapsto 1/z$ and some simple calculation, we obtain the *Laurent series* expansion

$$f(z) = \sum_{m=-\infty}^{\infty} a_m (z-a)^m$$

where

$$a_m = \frac{1}{2\pi i}\int_{\{\zeta:|\zeta-a|=r\}} \frac{f(\zeta)\,d\zeta}{(\zeta - z)^{m+1}}$$

valid in the annulus $\{z : \rho_1 < |z-a| < \rho_2\}$. Note that

$$\mathrm{Res}(f, a) = a_{-1},$$

and the point a is a pole of order k if and only if $a_{-k} \neq 0$ and every coefficient a_{-m} with $m > k$ is zero. The polynomial

$$\sum_{m=1}^{k} \frac{a_m}{(z-a)^m}$$

in the variable $1/(z-a)$ is called the *singular* or *principal part* of $f(z)$ at the pole a.

B. Elliptic Functions

Important examples of meromorphic functions are elliptic functions. Elliptic functions arose from attempts to evaluate certain integrals. For example, to evaluate the integral

$$\int_0^1 \sqrt{1-x^2}\,dx$$

which gives the area $\pi/2$ of a semicircle with radius 1, one can use the substitution $x = \sin\theta$. However, to evaluate integrals of the form

$$\int_0^1 \sqrt{(1-x^2)(1-k^2x^2)}\,dx$$

we need elliptic functions. Elliptic functions are doubly periodic generalizations of trigonometric functions.

Let ω_1 and ω_2 be two complex numbers whose ratio ω_1/ω_2 is not real and and let L be the 'integer lattice' $\{c\omega_1 + d\omega_2\}$, where c and d range over all integers. An *elliptic function* is a meromorphic function on the complex plane with two (independent) periods, ω_1 and ω_2, that is, $f(z+\omega_1) = f(z)$, $f(z+\omega_2) = f(z)$, and every complex number ω such that $f(z+\omega) = f(z)$ for all points z in the complex plane is a number in the lattice L.

A specific example of an elliptic function is the *Weierstrass $\wp$-function* defined by the formula

$$\wp(z) = \frac{1}{z^2} + \sum_{\omega\in L\setminus\{0\}} \left(\frac{1}{(z-\omega)^2} - \frac{1}{\omega^2}\right)$$

This defines a meromorphic function on the complex plane that is doubly periodic with periods ω_1 and ω_2. The $\wp$-function has poles exactly at points in L. Weierstrass proved that every elliptic function with periods ω_1 and ω_2 can be written as a rational function of $\wp$ and its derivative $\wp'$.

C. The Cauchy Residue Theorem

A simple but useful generalization of Cauchy's integral formula is the Cauchy residue theorem.

The Cauchy residue theorem. Let Ω be a simply connected region in the complex plane, let $f(z)$ be a function analytic on Ω except at the isolated singularities a_m, and let let γ be a closed piecewise continuously differentiable curve in Ω that does not pass through any of the points a_m. Then

$$\frac{1}{2\pi i}\int_\gamma f(z)dz = \sum n(\gamma, a_m)\mathrm{Res}(f, a_m)$$

where the sum ranges over all the isolated singularities inside the curve γ.

Cauchy's residue theorem has the following useful corollary.

The argument principle. Let $f(z)$ be a meromorphic function in a simply connected region Ω, let $a_1, a_2, \ldots,$ be the zeros of $f(z)$ in Ω, and let $b_1, b_2, \ldots,$ be the poles of $f(z)$ in Ω. Suppose the zero a_m has multiplicity s_m and the pole b_n has order t_n. Let γ be a closed piecewise continuously differentiable curve in Ω that does not pass through any poles or zeros of $f(z)$. Then

$$\frac{1}{2\pi i}\int_\gamma \frac{f'(\zeta)\,d\zeta}{f(\zeta)} = \sum s_m n(\gamma, a_m) - \sum t_j n(\gamma, b_j)$$

where the sum ranges over all the zeros and poles of $f(z)$ contained in the curve γ.

The name "argument principle" came from the following special case. When γ is a circle, the argument principle says that the change in the argument of $f(z)$ as z traces the circle in a counterclockwise direction, equals

$$Z(f) - P(f)$$

the difference between the number $Z(f)$ of zeros and the number $P(f)$ of poles of $f(z)$ inside γ, counting multiplicities and orders.

D. Evaluation of Real Integrals

Cauchy's residue theorem can be used to evaluate real definite integrals that are otherwise difficult to evaluate.

For example, to evaluate an integral of the form

$$\int_0^{2\pi} R(\cos\theta, \sin\theta)\, d\theta$$

where R is a rational function of $\cos\theta$ and $\sin\theta$, let $z = e^{i\theta}$. If we make the substitutions

$$\cos\theta = \frac{z + z^{-1}}{2}, \qquad \sin\theta = \frac{z - z^{-1}}{2i}$$

the integral becomes a line integral over the unit circle of the form

$$\int_{|z|=1} S(z)\, dz$$

where $S(z)$ is a rational function of z. By Cauchy's residue theorem, this integral equals $2\pi i$ times the sum of the residues of the poles of $S(z)$ inside the unit circle. Using this method, one can prove, for example, that if $a > b > 0$,

$$\int_0^{2\pi} \frac{d\theta}{(a + b\cos^2\theta)^2} = \frac{\pi(2a + b)}{a^{3/2}(a + b)^{3/2}}$$

One can also evaluate improper integrals, obtaining formulas such as the following formula due to Euler: For $-1 < p < 1$ and $-\pi < \alpha < \pi$,

$$\int_0^{\infty} \frac{x^{-p}\, dx}{1 + 2x\cos\alpha + x^2} = \frac{\pi \sin p\alpha}{\sin p\pi \sin\alpha}$$

E. Location of Zeros

It is often useful to locate zeros of polynomials in the complex plane. An elegant theorem, which can be proved by elementary arguments, is the following result.

Lucas' theorem. Let $p(z)$ be a polynomial of degree at least 1. All the zeros of the derivative $p'(z)$ lie in the convex closure of the set of zeros of $p(z)$.

Deeper results usually involve using some form of Rouché's theorem, which is proved using the argument principle.

Rouché's theorem. Let Ω be a region bounded by a simple closed piecewise continuously differentiable curve. Let $f(z)$ and $g(z)$ be two functions meromorphic in an open set containing the closure of Ω. If $f(z)$ and $g(z)$ satisfy

$$|f(z) - g(z)| < |f(z)| + |g(z)|$$

for every point z on the curve bounding Ω, then

$$Z(f) - P(f) = Z(g) - P(g)$$

Hurwitz's theorem. Let $(f_n(z) : n = 1, 2, \ldots)$ be a sequence of functions analytic in a region Ω bounded by a simple closed piecewise continuously differentiable curve such that $f_n(z)$ converges uniformly to a nonzero (analytic) function $f(z)$ on every closed subset of Ω. Let a be an interior point of Ω. If a is a limit point of the set of zeros of the functions $f_n(z)$, then a is a zero of $f(z)$. If a is a zero of $f(z)$ with multiplicity m, then every sufficiently small neighborhood K of a contains exactly m zeros of the functions $f_n(z)$, for all n greater than a number N depending on K.

F. Infinite Products, Partial Fractions, and Approximations

A natural way to write a meromorphic function is in terms of its zeros and poles. For example, because $\sin\pi z$ has zeros at the integers, we expect to be able to "factor" it into product. Indeed, Euler wrote down the following product expansion:

$$\sin\pi z = \pi z \prod_{j=1}^{\infty} \left(1 - \frac{z}{n}\right)\left(1 + \frac{z}{n}\right)$$

With complex analysis, one can justify such expansions rigorously.

The question of convergence of an infinite product is easily resolved. By taking logarithms, one can reduce it to a question of convergence of a sum. For example, the product

$$\prod_{m=1}^{\infty}(1 + a_m)$$

converges absolutely if and only if the sum $\sum_{m=1}^{\infty} |\log(1 + a_m)|$ converges absolutely. Since $|\log(1 + a_m)|$ is approximately $|a_m|$, the product converges absolutely if and only if the series $\sum_{m=1}^{\infty} |a_m|$ converges absolutely.

The following theorem allows us to construct an entire function with a prescribed set of zeros.

The Weierstrass product theorem. Let $(a_j : j = 1, 2, \ldots)$ be a sequence of nonzero complex numbers in which no complex number occurs infinitely many times. Suppose that the set $\{a_j\}$ has no (finite) limit point in the complex plane. Then there exists an entire function $f(z)$ with a zero of multiplicity m at 0, zeros in the set $\{a_j\}$ with the correct multiplicity, and no other zeros. This function can be written in the form

$$f(z) = z^m e^{g(z)} \prod_{j=1}^{\infty} \left(1 - \frac{z}{a_j}\right) \times e^{a_j/z + (1/2)(a_j/z)^2 + \cdots + (1/m_j)(a_j/z)^{m_j}}$$

where m_j are positive integers depending on the set $\{a_j\}$, and $g(z)$ is an entire function.

From this theorem, we can derive the following representation of a meromorphic function.

Theorem. A meromorphic function on the complex plane is the quotient of two entire functions. The two entire functions can be chosen so that they have no common zeros.

In particular, one can think of meromorphic functions as generalizations of rational functions.

The *gamma function* $\Gamma(z)$ is a useful function which can be defined by a product formula. Indeed,

$$\Gamma(z) = \frac{e^{-\gamma z}}{z} \prod_{m=1}^{\infty} \left(1 + \frac{z}{m}\right)^{-1} e^{z/m}$$

where γ is the *Euler–Mascheroni constant* defined by

$$\gamma = \lim_{n\to\infty} \left[\left(\sum_{m=1}^{n} \frac{1}{m} \right) - \log n \right]$$

It equals $0.57722\ldots$. The gamma function interpolates the integer factorials. Specifically, $\Gamma(n) = (n-1)!$ for a positive integer n and $\Gamma(z)$ satisfies the functional equation

$$\Gamma(z+1) = z\Gamma(z).$$

Another useful functional equation is the *Legendre formula*

$$\sqrt{\pi}\Gamma(2z) = 2^{2z-1}\Gamma(z)\Gamma(z+1/2)$$

This gives the following useful value: $\Gamma(1/2) = \sqrt{\pi}$.

Rational functions can be represented as partial fractions; so can meromorphic functions.

Mittag-Leffler's theorem. Let $\{b_j : j = 1, 2, \ldots\}$ be a set of complex numbers with no finite limit point in the complex plane, and let $p_j(z)$ be given polynomials with zero constant terms, one for each point b_j. Then there exist meromorphic functions in the complex plane with poles at b_m with singular parts $p_j(1/z - b_j)$. These functions have the form

$$g(z) + \sum_{j=1}^{\infty} \left(p_j\left(\frac{1}{z-b_j}\right) - q_j(z) \right)$$

where $q_j(z)$ are suitably chosen polynomials depending on $p_j(z)$, and $g(z)$ is an entire function.

Taking logarithmic derivatives and integrating, one can derive Weierstrass's product theorem from Mittag-Leffler's theorem.

Two examples of partial fraction exapnsions of meromorphic functions are

$$\frac{\pi^2}{\sin^2 \pi z} = \sum_{m=-\infty}^{\infty} \frac{1}{(z-n)^2}$$

and

$$\pi \cot \pi z = \frac{1}{z} + \sum_{m=1}^{\infty} \frac{2z}{z^2 - n^2}$$

Runge's approximation theorem says that a function analytic on a bounded region Ω with holes can be uniformly approximated by a rational function all of whose poles lie in the holes. Runge's theorem can be proved using a Cauchy's integral formula for compact sets.

Runge's approximation theorem. Let $f(z)$ be an analytic function on a region Ω in the complex plane; let K be a compact subset of Ω. Let $\epsilon > 0$ be a given (small) positive real number. Then there exists a rational function $r(z)$ with all its poles outside K such that

$$|f(z) - r(z)| < \epsilon$$

for all z in K.

V. SOME ADVANCED TOPICS

A. Riemann Mapping Theorem

On the complex plane, most simply connected regions can be mapped conformally in a one-to-one way onto the open unit disk. This is a useful result because it reduces many problems to problems about the unit disk.

Riemann mapping theorem. Let Ω be a simply connected region that is not the entire complex plane, and let a be a point in Ω. Then there exists a unique analytic function $f(z)$ on Ω such that $f(a) = 0$, $f'(a) > 0$, and $f(z)$ is a one-to-one mapping of Ω onto the open disk $\{z : |z| < 1\}$ with radius 1.

For example, the upper half-plane $\{\zeta : \mathrm{Im}(\zeta) > 0\}$ and the unit disk $\{z : |z| < 1\}$ are mapped conformally onto each other by the Möbius transformations

$$\zeta = \frac{i(1+z)}{1-z}, \qquad z = \frac{\zeta - i}{\zeta + i}$$

The Schwarz–Christoffel formula gives an explicit formula for one-to-one onto conformal maps from the open unit disk or the upper half-plane to polygonal domains, which are sets in the complex plane bounded by a a closed simple curve made up of a finite number of straight line segments. It is rather complicated to state, and we refer the reader to the books by Ahlfors and Nehari in the bibliography. As an example, one can map the upper-half complex plane into a triangle with interior angles $\alpha_1\pi$, $\alpha_2\pi$, and $\alpha_3\pi$ (where $\alpha_1 + \alpha_2 + \alpha_3 = 1$) by the inverse of the function

$$F(z) = \int_0^z t^{\alpha_1 - 1}(t-1)^{\alpha_2 - 1}\, dt$$

The function $F(z)$ is called the *triangle function of Schwarz.*

B. Univalent Functions and Bieberbach's Conjecture

Univalent or *Schlicht* functions are one-to-one analytic functions. They have been extensively studied in complex analysis. A famous result in this area was the Bieberbach conjecture, which was proved by de Branges in 1984.

Theorem. Let $f(z)$ be a univalent analytic function on the unit disk $\{z : |z| < 1\}$ with power series expansion

$$f(z) = z + a_2 z^2 + a_3 z^3 + \cdots$$

(that is, $f(0) = 0$ and $f'(0) = 1$). Then

$$|a_n| \le n.$$

When equality holds, $f(z) = e^{-i\theta} K(e^{i\theta} z)$, where

$$K(z) = \frac{z}{(1-z)^2} = z + 2z^2 + 3z^3 + 4z^4 + \cdots$$

The function $K(z)$ is called *Koebe's function.*

Another famous result in this area is due to Koebe.

Koebe's 1/4-theorem. Let $f(z)$ be a univalent function. Then the image of the unit disk $\{z : |z| < 1\}$ contains the disk $\{z : |z| < 1/4\}$ with radius $1/4$.

The upper bound $1/4$ (the "Koebe constant") is the best possible.

C. Harmonic Functions

Harmonic functions, defined in Section II, are real functions $u(x, y)$ satisfying Laplace's equation. We shall use the notation: $u(x, y) = u(x + iy) = u(z)$. Harmonic functions have several important properties.

The mean-value property. Let $u(z)$ be a harmonic function on a region Ω. Then for any disk D with center a and radius r whose closure is contained in Ω,

$$u(a) = \frac{1}{2\pi} \int_0^{2\pi} u(a + re^{i\theta})\, d\theta$$

The maximum principle for harmonic functions. Let $u(z)$ be a harmonic function on the domain Ω. If there is a point a in Ω such that $u(a)$ equals the maximum $\max\{u(z) : z \in \Omega\}$, then $u(z)$ is a constant function.

An important problem in the theory of harmonic function is *Dirichlet's problem.* Given a simply connected domain Ω and a piecewise continuous function $g(z)$ on the boundary $\partial\Omega$, find a function $u(z)$ in the closure $\bar{\Omega}$ such that $u(z)$ is harmonic in Ω, and the restriction of $u(z)$ to the boundary $\bar{\Omega} \backslash \Omega$ equals $g(z)$. (The *boundary* $\partial\Omega$ is the set $\bar{\Omega} \backslash \Omega$.)

For general simply connected domains, Dirichlet's problem is difficult. It is equivalent to finding a Green's function. For a disk, the following formula is known.

The Poisson formula. Let $g(z) = g(e^{i\phi})$, $-\pi < \phi \le \pi$, be a piecewise continuous function on the boundary $\{z : |z| = 1\}$ of the unit disk. Then the function

$$u(z) = u(re^{i\theta}) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \left(\frac{1 - r^2}{1 + r^2 - 2r\cos(\phi - \theta)} \right) g(e^{i\phi})\, d\phi$$

is a solution to Dirichlet's problem for the unit disk.

D. Riemann Surfaces

A *Riemann surface* $\mathcal{S}$ is a one-dimensional complex connected paracompact Hausdorff space equipped with a *conformal atlas*, that is, a set of maps or *charts* $\{h : D \to N\}$, where D is the open disk $\{z : |z| < 1\}$ and N is an open set of $\mathcal{S}$, such that

1. The union of all the open sets N is $\mathcal{S}$.
2. The chart $h : D \to N$ is a homeomorphism of the disk D to N.
3. Let N_1 and N_2 be neighborhoods with charts h_1 and h_2. If the intersection $N_1 \cap N_2$ is nonempty and connected, then the composite mapping $h_2^{-1} \circ h_1$, defined on the inverse image $h_1^{-1}(N_1 \cap N_2)$, is conformal.

Riemann surfaces originated in an attempt to make a "multivalued" analytic function single-valued by making its range a Riemann surface. Examples of multivalued functions are *algebraic functions.* These are functions $f(z)$ satisfying a polynomial equation $P(f(z)) = 0$. A specific example of this is the square-root function $f(z) = \sqrt{z}$, which takes on two values $\pm\sqrt{z}$ except when $z = 0$. This can be made into a single-valued function using the Riemann surface obtained by gluing together two sheets or copies of the complex plane cut from 0 to ∞ along the positive real axis. Another example is the logarithmic function $\log z$, which requires a Riemann surface made from countably infinitely many sheets.

Intuitively, the *genus* of a Riemann surface $\mathcal{S}$ is the number of "holes" it has. The genus can be defined as the maximum number of disjoint simple closed curves that do not disconnect $\mathcal{S}$. For example, the extended complex plane has genus 0 and an annulus has genus 1. There are many results about Riemann surfaces. The following are two results that can be simply stated.

Picard's theorem. Let $P(u, v)$ be an irreducible polynomial with complex coefficients in two variables u and v. If there exist nonconstant entire functions $f(z)$ and $g(z)$ satisfying $P(f(z), g(z)) = 0$ for all complex numbers z,

then the Riemann surface associated with the algebraic equation $P(u, v) = 0$ has genus 0.

Koebe's uniformization theorem. If $\mathcal{S}$ is a simply connected Riemann surface, then $\mathcal{S}$ is conformally equivalent to

1. (Elliptic type) The Riemann sphere. In this case, $\mathcal{S}$ is the sphere.
2. (Parabolic type) The complex plane $\mathbf{C}$. In this case, $\mathcal{S}$ is biholomorphic to $\mathbf{C}$, $\mathbf{C}\backslash\{0\}$, or a torus.
3. (Hyperbolic type) The unit disk $\{z : |z| < 1\}$.

Complex manifolds are higher-dimensional generalizations of Riemann surfaces. They have been extensively studied.

E. Other Topics

Complex analysis is a vast and ever-expanding area. "Nine lifetimes" do not suffice to cover every topic. Some interesting areas that we have not covered are complex differential equations, complex dynamics, Montel's theorem and normal families, value distribution theory, and the theory of complex functions in several variables. Several books on these topics are listed in the Bibliography.

GLOSSARY

Axiom A statement accepted as true without proof.
Backtrack search A method of organizing a search for solutions by a systematic extension of partial solutions.
Computer-based proof A proof with a heavy computer component; one which is impossible to do by hand.
Computer programming A process of creating a sequence of instructions to be used by a computer.
Enumerative proof A proof method by exhibiting and analyzing all possible cases.
Monte Carlo method A method of estimation by performing random choices.
Optimizing a computer program A process of fine-tuning a computer program so that it runs faster.
Predicate A statement whose truth value depends of the values of its arguments.
Proof A demonstration of the truth of a statement.
Proposition A statement which is either true or false, but not both.
Search tree A pictorial representation of the partial solutions encountered in a backtrack search.

EVER SINCE the arrival of computers, mathematicians have used them as a computational aid. Initially, they were used to perform tedious and repetitious calculations. The tremendous speed and accuracy of computers enable mathematicians to perform lengthy calculations without fear of making careless mistakes. Their main application, however, has been to obtain insight into various mathematical problems, which then led to conventional proofs independent of the computer. Recently, there was a departure from this traditional approach. By exploiting the speed of a computer, several famous and long-standing problems were settled by lengthy enumerative proofs, a technique

only suitable for computers. Two notable examples are the four-color theorem and the nonexistence of a finite projective plane of order 10. Both proofs required thousands of hours of computing and gave birth to the term "a computer-based proof." The organization of such a proof requires careful estimation of the necessary computing time, meticulous optimization of the computer program, and prudent control of all possible computer errors. In spite of the difficulty in checking these proofs, mathematicians are starting to accept their validity. As computers are getting faster, many other famous open problems will be solved by this new approach.

I. MATHEMATICAL THEORIES

What is mathematics? It is not possible to answer this question precisely in this short article, but a generally acceptable definition is that *mathematics is a study of quantities and relations using symbols and numbers*. The starting point is often a few undefined objects, such as a *set* and its *elements*. A mathematical theory is then built by assuming some axioms which are statements accepted as true. From these basic components, further properties can then be derived.

For example, the study of geometry can start from the undefined objects called *points*. A *line* is then defined as a set of points. An axiom may state: "Two distinct lines contain at most one common point." This is one of the axioms in Euclidean geometry, where it is possible to have parallel lines. The complete set of axioms of Euclidean geometry was classified by the great German mathematician David Hilbert in 1902. Using these axioms, further results can be derived. Here is an example:

Two triangles are congruent if the three sides of one are equal to the three sides of the other.

To show that these derived results follow logically from the axioms, a system of well-defined principles of mathematical reasoning is used.

A. Mathematical Statements

The ability to demonstrate the truth of a statement is central to any mathematical theory. This technique of reasoning is formalized in the study of *propositional calculus*.

A *proposition* is a statement which is either true or false, but not both. For example, the following are propositions:

- $1 + 1 = 2$.
- 4 is a prime number.

The first proposition is true, and the second one is false.

The statement "$x = 3$" is not a proposition because its truth value depends on the value of x. It is a *predicate*, and its truth value depends of the value of the *variable* or *argument* x. The expression $P(x)$ is often used to denote a predicate P with an argument x. A predicate may have more than one argument, for example, $x + y = 1$ has two arguments. To convert a predicate to a proposition, values have to be assigned to all the arguments. The process of associating a value to a variable is called a *binding*.

Another method of converting a predicate to a proposition is by the quantification of the variables. There are two common quantifiers: *universal* and *existential*. For example, the statement

$$\text{For all } x,\ x < x + 1$$

uses the universal quantifier "for all" to provide bindings for the variable x in the predicate $x < x + 1$. If the predicate is true for every possible value of x, then the proposition is true. The symbol $\forall$ is used to denote the phrase "for all." Thus, the above proposition can also be written as

$$\forall x,\ x < x + 1.$$

The set of possible values for x has to come from a certain *universal* set. The universal set in the above example may be the set of all integers, or it may be the set of all reals. Sometimes, the actual universal set can be deduced from context and, consequently, not stated explicitly in the proposition. A careful mathematician may include all the details, such as

$$\forall \text{ real } x > 1,\ x > \sqrt{x}.$$

The choice is often not a matter of sloppiness, but a conscious decision depending on whether all the exact details will obscure the main thrust of the result.

An existential quantifier asserts that a predicate $P(x)$ is true for one or more x in the universal set. It is written as

$$\text{For some } x,\ P(x),$$

or, using the symbol $\exists$, as

$$\exists x,\ P(x).$$

This assertion is false only if for all x, $P(x)$ is false. In other words,

$$\neg[\exists x,\ P(x)] \equiv [\forall x,\ \neg P(x)].$$

B. Enumerative Proof

A proof of a mathematical result is a demonstration of its truth. To qualify as a proof, the demonstration must be absolutely correct and there can be no uncertainty nor ambiguity in the proof.

Many interesting mathematical results involve quantifiers such as $\exists$ or $\forall$. There are many techniques to prove quantified statements, one of which is the enumerative proof. In this method, the validity of $\forall x, P(x)$ is established by investigating $P(x)$ for every value of x one after another. The proposition $\forall x, P(x)$ is only true if $P(x)$ has been verified to be true for all x. However, if $P(x)$ is false for one of the values, then it is not necessary to consider the remaining values of x, because $\forall x, P(x)$ is already false. Similarly, the validity of $\exists x, P(x)$ can be found by evaluating $P(x)$ for every value of x. The process of evaluation can stop once a value of x is found for which $P(x)$ is true, because $\exists x, P(x)$ is true irrespective of the remaining values of x. However, to establish that $\exists x, P(x)$ is false, it has to be shown that $P(x)$ is false for all values of x.

To ensure a proof that is finite in length, enumerative proofs are used where only a finite number of values of x have to be considered. It may be a case where x can take on only a finite number of values, or a situation where an infinite number of values can be handled by another proof technique, leaving only a finite number of values for which $P(x)$ are unknown.

An enumerative proof is a seldom-used method because it tends to be too long and tedious for a human being. A proof involving a hundred different cases is probably the limit of the capacity of the human mind. Yet, it is precisely in this area that a computer can help, where it can evaluate millions or even billions of cases with ease. Its use can open up new frontiers in mathematics.

C. Kinds of Mathematical Results

Mathematicians love to call their results *theorems*. Along the way, they also prove lemmas, deduce corollaries, and propose conjectures. What are these different classifications? The following paragraphs will give a brief answer to this question.

Mathematical results are classified as lemmas, theorems, and corollaries, dependent on their importance. The most important results are called theorems. A *lemma* is an auxiliary result which is useful in proving a theorem. A *corollary* is a subsidiary result that can be derived from a theorem. These classifications are quite loose, and the actual choice of terminology is based on the subjective evaluation of the discoverer of the results. There are cases where a lemma or a corollary have, over a period of time, attained an importance surpassing the main theorem.

A *conjecture*, on the other hand, is merely an educated guess. It is a statement which may or may not be true. Usually, the proposer of the conjecture suspects that it is highly probable to be true but cannot prove it. Many famous mathematical problems are stated as conjectures. If a proof is later found, then it becomes a theorem.

D. What Makes an Interesting Theorem

Of course, a theorem must be interesting to be worth proving. However, whether something is interesting is a subjective judgement. The following list contains some of the properties of an interesting result:

- Useful
- Important
- Elegant
- Provides insight

While the usefulness of some theorems is immediately obvious, the appreciation of others may come only years later. The importance of a theorem is often measured by the number of mathematicians who know about it or who have tried proving it. An interesting theorem should also give insights about a problem and point to new research directions. A theorem is often appreciated as if it is a piece of art. Descriptions such as "It is a beautiful theorem" or "It is an elegant proof" are often used to characterize an interesting mathematical result.

II. COMPUTER PROGRAMMING

Figure 1 shows a highly simplified view of a computer. There are two major components: the central processing unit (CPU) and memory. Data are stored in the memory. The CPU can perform operations which changes the data. A program is a sequence of instructions which tell the CPU what operations to perform and it is also stored in the computer memory.

Computer programming is the process of creating the sequence of instructions to be used by the computer. Most programming today is done in high-level languages such as Fortran, Pascal, or C. Such languages are designed for the ease of creating and understanding a complex program by human beings. A program written in one of these languages has to be translated by a compiler before it can be used by the computer.

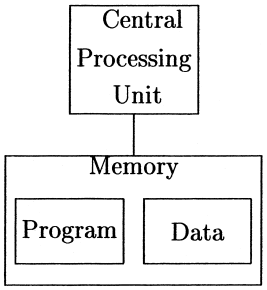

FIGURE 1 A simplified view of a computer.

Due to the speed with which a computer can perform operations it is programmed to do and its capacity in dealing with huge amounts of information, it is well suited to do lengthy or repetitive tasks that human beings are not good at doing.

III. COMPUTER AS AN AID TO MATHEMATICAL RESEARCH

Ever since the arrival of computers, mathematicians have used them as a computational aid. Initially, computers were used to perform tedious and repetitious calculations. The tremendous speed and accuracy of computers enable mathematicians to perform lengthy calculations without fear of making careless mistakes. For example, π can be computed to several billion digits of accuracy, and prime numbers of ever-increasing size are being found continually by computers.

Computer can also help mathematicians manipulate complicated formulae and equations. MACSYMA is the first such symbol manipulation program developed for mathematicians. A typical symbol manipulation program can perform integration and differentiation, manipulate matrices, factorize polynomials, and solve systems of algebraic equations. Many programs have additional features such as two- and three-dimensional plotting or even the generation of high-level language output.

Even though these programs have been used to prove a number of results directly, their main application has been to obtain insight into the behavior of various mathematical objects, which then has led to conventional proofs. Mathematicians still prefer computer-free proofs, if possible. A proof that involves using the computer is difficult to check and so its correctness cannot be determined absolutely. The term "a computer-based proof" is used to refer to a proof where part of it involves extensive computation, for which an equivalent human argument may take millions of years to make.

IV. EXAMPLES OF COMPUTER-BASED PROOFS

In the last 20 years, two of the best known mathematical problems were solved by lengthy calculations: the four-color conjecture and the existence question of a finite projective plane of order 10.

A. Four-Color Conjecture

The *four-color conjecture* says that four colors are sufficient to color any map drawn in the plane or on a sphere so that no two regions with a common boundary line are colored with the same color.

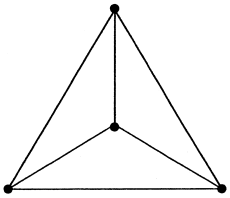

FIGURE 2 The complete graph K_4.

Francis Guthrie was given credit as the originator of this problem while coloring a map of England. His brother communicated the conjecture to DeMorgan in October 1852. Attempts to prove the four-color conjecture led to the development of a major branch of mathematics: graph theory.

A graph $G(V, E)$ is a structure which consists of a set of vertices $V = \{v_1, v_2, \ldots\}$ and a set of edges $E = \{e_1, e_2, \ldots\}$; each edge e is incident on two distinct vertices u and v. For example, Fig. 2 is a graph with four vertices and six edges. The technical name for this graph is the *complete graph* K_4. It is *complete* because there is an edge incident on every possible pair of vertices. Figure 3 is another graph with six vertices and nine edges. It is the *complete bipartite* graph $K_{3,3}$. In a *bipartite* graph, the set of vertices is divided into two classes, and the only edges are those that connect a vertex from one class to one of the other class. The graph $K_{3,3}$ is complete because it contains all the possible nine edges of the bipartite graph. A graph is said to be *planar* if it can be drawn on a plane in such a way that no edges cross one another, except, of course, at common vertices. The graph K_4 in Fig. 2 is drawn with no crossing edges and it is obviously planar. The graph $K_{3,3}$ can be shown to be not planar, no matter how one tries to draw it.

One can imagine that a planar graph is an abstract representation of a map. The vertices represent the capitals of the countries in the map. Two vertices are joined by an edge if the two countries have a common boundary. Instead of coloring regions of a map, colors can be assigned to the vertices of a graph representing the map. A graph is *k-colorable* if there is a way to assign colors to the graph such that no edge is incident on two vertices with the same

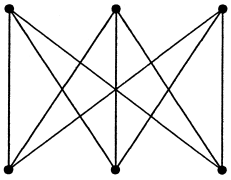

FIGURE 3 The complete bipartite graph $K_{3,3}$.

color. So, the four-color conjecture can also be stated as every planar graph is 4-colorable.

The graph K_4 is not 3-colorable. This can be proved by contradiction. Suppose it is 3-colorable. Since there are four vertices, two of the vertices must have the same color. Since the graph is complete, there is an edge connecting these two vertices of the same color, which is a contradiction.

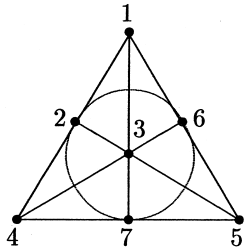
Kempe in 1879 published an incorrect proof of the four-color conjecture. Heawood in 1890 pointed out Kempe's error, but demonstrated that Kempe's method did prove that every planar graph is 5-colorable. Since then, many famous mathematicians have worked on this problem, leading to many significant theoretical advances. In particular, it was shown that the validity of the four-color conjecture depended only on a finite number of graphs. These results laid the foundation for a computer-based proof by Appel and Haken in 1976. Their proof depended on a computer analysis of 1936 graphs which took 1200 h of computer time and involved about 10^{10} separate operations. Finally, the four-color conjecture became the four-color theorem.

B. Projective Plane of Order 10

The question of the possible existence of a projective plane of order 10 was also settled recently by using a computer. A *finite projective plane of order n*, with $n > 0$, is a collection of $n^2 + n + 1$ lines and $n^2 + n + 1$ points such that

1. Every line contains $n + 1$ points.
2. Every point is on $n + 1$ lines.
3. Any two distinct lines intersect at exactly one point.
4. Any two distinct points lie on exactly one line.

The smallest example of a finite projective plane is one of order 1, which is a triangle. The smallest nontrivial example is one of order 2, as shown in Fig. 4. There are seven points labeled from 1 to 7. There are also seven lines labeled $L1$ to $L7$. Six of them are straight lines, but $L6$ is represented by the circle through points 2, 6, and 7.



$$L1 = \{1, 2, 4\}$$
$$L2 = \{2, 3, 5\}$$
$$L3 = \{3, 4, 6\}$$
$$L4 = \{4, 5, 7\}$$
$$L5 = \{5, 6, 1\}$$
$$L6 = \{6, 7, 2\}$$
$$L7 = \{7, 1, 3\}$$

FIGURE 4 The finite projective plane of order 2.

L6	0	1	0	0	0	1	1
L7	1	0	1	0	0	0	1

FIGURE 5 An incidence matrix for the plane of order 2.

The earliest reference to a finite projective plane was in an 1856 book by von Staudt. In 1904, Veblen used the projective plane of order 2 as an exotic example of a finite object satisfying all the Hilbert's axioms for geometry. He also proved that this plane of order 2 cannot be drawn using only straight lines. In a series of papers from 1904 to 1907, Veblen, Bussey, and Wedderburn established the existence of most of the planes of small orders. Two of the smallest orders missing are 6 and 10. In 1949, the celebrated Bruck-Ryser theorem gave an ingenious theoretical proof of the nonexistence of the plane of order 6. The nonexistence of the plane of order 10 was established in 1988 by a computer-based proof.

In the computer, lines and points are represented by their incidence relationship. The *incidence matrix* $A = [a_{ij}]$ of a projective plane of order n is an $n^2 + n + 1$ by $n^2 + n + 1$ matrix where the columns represent the points and the rows represent the lines. The entry a_{ij} is 1 if point j is on line i; otherwise, it is 0. For example, Fig. 5 gives the incidence matrix for the projective plane of order 2. In terms of an incidence matrix, the properties of being a projective plane are translated into

1. A has constant row sum $n + 1$.
2. A has constant column sum $n + 1$.
3. The inner product of any two distinct rows of A is 1.
4. The inner product of any two distinct columns of A is 1.

These conditions can be encapsuled in the following matrix equation:

$$AA^T = nI + J,$$

where A^T denotes the transpose of the matrix A, I denotes the identity matrix, and J denotes the matrix of all 1's.

As a result of intensive investigation by a number of mathematicians, it was shown that the existence question of the projective plane of order 10 can be broken into four starting cases. Each case gives rise to a number of geometric configurations, each corresponding to a partially completed incidence matrix. Starting from these partial matrices, a computer program tried to complete them to a full

plane. After about 2000 computing hours on a CRAY-1A supercomputer in addition to several years of computing on a number of VAX-11 and micro-VAX computers, it was shown that none of the matrices could be completed, which implied the nonexistence of the projective plane of order 10. About 1012 different subcases were investigated.

V. PROOF BY EXHAUSTIVE COMPUTER ENUMERATION

The proofs of both the four-color theorem and the nonexistence of a projective plane order 10 share one common feature: they are both enumerative proofs. This approach to a proof is often avoided by humans, because it is tedious and error prone. Yet, it is tailor-made for a computer.

A. Methodology

Exhaustive computer enumeration is often done by a programming technique called *backtrack search*. A version of the search problem can be defined as follows:

Search problem:

Given a collection of sets of candidates $C_1, C_2, C_3, \ldots, C_m$ and a boolean *compatibility* predicate $P(x, y)$ defined for all $x \in C_i$ and $y \in C_j$, find an *m-tuple* $(x_1, \ldots, x_m)$ with $x_i \in C_i$ such that $P(x_i, x_j)$ is true for all $i \neq j$.

A m-tuple satisfying the above condition is called a *solution*.

For example, if we take $m = n^2 + n + 1$ and let C_i be the set of all candidates for row i of the incidence matrix of a projective plane, then $P(x, y)$ can be defined as

$$P(x, y) = \begin{cases} \text{true} & \text{if } \langle x, y \rangle = 1 \\ \text{false} & \text{otherwise,} \end{cases}$$

where $\langle x, y \rangle$ denotes the inner product of rows x and y. A solution is then a complete incidence matrix.

In a backtrack approach, we generate *k-tuples* with $k \leq m$. A k-tuples $(x_1, \ldots, x_k)$ is a *partial solution* at level k if $P(x_i, x_j)$ is true for all $i \neq j \leq k$. The basic idea of the backtrack approach is to *extend* a partial solution at level k to one at level $k + 1$, and if this extension is impossible, then to go back to the partial solution at level $k - 1$ and attempt to generate a different partial solution at level k.

For example, consider the search for a projective plane of order 1. In terms of the incidence matrix, the problem is to find a 3×3 (0,1)-matrix A satisfying the matrix equation

$$AA^T = I + J.$$

Suppose the matrix A is generated row by row. Since each row of A must have two l's, the candidate sets C_i are all equal to {[110], [101], [011]}. A partial solution at level 1 can be formed by choosing any of these three rows as x_1. If x_1 is chosen to be [110], then there are only two choices for x_2 which would satisfy the predicate $P(x_1, x_2)$, namely, [101] and [011]. Each of these choices for x_2 has a unique extension to a solution.

A nice way to organize the information inherent in the partial solutions is the backtrack *search tree*. Here, the empty partial solution ( ) is taken as the root, and the partial solution $(x_1, \ldots, x_k)$ is represented as the child of the partial solution $(x_1, \ldots, x_{k-1})$. Following the computer science terminology, we call a partial solution a *node*. It is also customary to label a node $(x_1, \ldots, x_k)$ by only x_k because this is the choice made at this level. The full partial solution can be read off the tree by following the branch from the root to the node in question. Figure 6 shows the search tree for the projective plane of order 1. The possible candidates are labeled as r_1, r_2, and r_3. The right-most branch, for example, represents choosing r_3 or [011] as the first row, r_2 as the second row, and r_1 as the third row.

It is often true that the computing cost of processing a node is independent of its level k. Under this assumption, the total computing cost of a search is equal to the number of nodes in the search tree times the cost of processing a node. Hence, the number of nodes in the search tree is an important parameter in a search. This number can be obtained by counting the nodes in every level, with α_i defined as the node count at level i of the tree. For example, in the search tree for the projective plane of order 1 shown in Fig. 6, $\alpha_1 = 3$, $\alpha_2 = 6$, and $\alpha_3 = 6$.

B. Estimation

It is very difficult to predict *a priori* the running time of a backtrack program. Sometimes, one program runs to completion in less than 1 sec, while other programs seem to take forever. A minor change in the strategy used in the

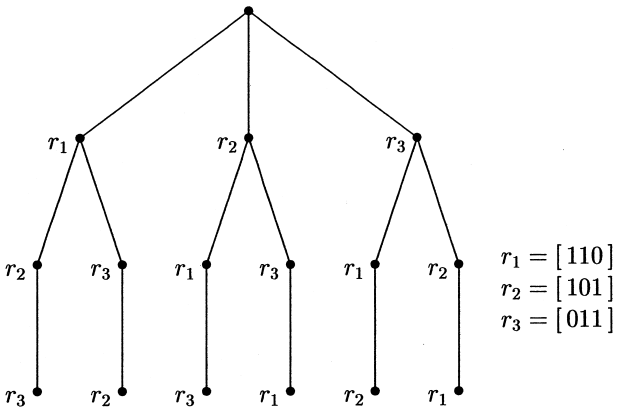

FIGURE 6 Search tree for the projective plane of order 1.

backtrack routine may change the total running time by several orders of magnitude. Some "minor improvements" may speed up the program by a factor of 100, while some other "major improvements" actually slow down the program. It is useful to have a simple and reliable method to estimate the running time of such a program. It can be used to

1. Decide whether the problem can be solved with the available resources.
2. Compare the various methods of "improvement."
3. Design an optimized program to reduce the running time.

A good approximation to the running time of a backtrack program is to multiply the number of nodes in the search tree by a constant representing the time required to process each node. Hence, a good estimate of the running time can be obtained by finding a good estimate to the number of nodes in the search tree. The size of the tree can be approximated by summing up the estimated α_i's, the node counts at each level.

An interesting solution to the estimation problem is a *Monte Carlo* approach developed by Knuth. The idea is to run a number of experiments, with each experiment consisting of performing the backtrack search with a randomly chosen candidate at each level of the search. Suppose we have a partial solution $(x_1, \ldots, x_k)$ for $0 \leq k < n$, where n is the depth of the search tree. We let

$$C'_{k+1} = \{x_{k+1} \in C_{k+1} | P(x_1, \ldots, x_{k+1}) \text{ is true}\}$$

be the set of acceptable candidates which extend $(x_1, \ldots, x_k)$. We choose x_{k+1} at random from C'_{k+1} such that each of the $|C'_{k+1}|$ possibilities are equally likely to be chosen. We let $d_k = |C'_k|$ be the number of elements in C'_k for $k = 1, \ldots, n$. Then the node count at level i, α_i, can be estimated by

$$\alpha_i \approx d_1 \ldots d_i.$$

Now, the total estimated size of the search tree is

$$\sum_{k=1}^{n} d_1 \ldots d_k.$$

The cost of processing a node can be estimated by running a few test cases, counting the nodes, and dividing the running time by the number of nodes.

These estimated values of the node counts can best be presented by plotting the logarithm of α_i, or equivalently the number of digits in α_i, as a function of i. A typical profile is shown in Fig. 7. The value of i for which $\log \alpha_i$ is maximum is called the *bulge* of the search tree. A backtrack search spends most of its time processing nodes near the bulge.

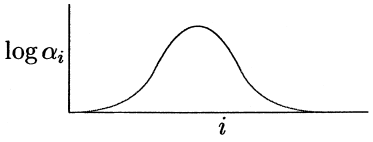

FIGURE 7 Typical shape of a search tree.

C. Optimization

A computer-based proof using backtracking may take a large amount of computing time. Optimization is a process of fine-tuning the computer program so that it runs faster. The optimization methods are divided into two broad classes:

1. Those whose aim is to reduce the size of the search tree
2. Those whose aim is to reduce the cost of the search tree by processing its nodes more efficiently

As a general rule, methods that reduce the size of the search tree, a process also called *pruning* the search tree, can potentially reduce the search by many orders of magnitude, whereas improvements obtained by trying to process nodes more efficiently are often limited to 1 or 2 orders of magnitude. Thus, given a choice, one should first try to reduce the size of the search tree.

There are many methods to prune the search tree. One possibility is to use a more effective compatibility predicate, while preserving the set of solutions. In a search tree, there are many branches which do not contain any solution. If these branches can be identified early, then they can be eliminated, hence reducing the size of the tree.

Another method to prune the search tree is by *symmetry pruning*. Technically, a symmetry is a property preserving operation. For example, two columns of a matrix A can be interchanged without affecting the product AA^T. Consider again the search tree for a projective plane of order 1. The interchange of columns 1 and 2 will induce a relabeling of r_2 as r_3 and vice versa. Thus, after considering the partial solution $x_1 = [101]$, there is no need to consider the remaining partial solution $x_1 = [011]$, because its behavior will be a duplicate of the earlier case. In combinatorial problems, the size of symmetries tends to be large and symmetry pruning can be very effective.

Methods to reduce the cost of processing a node of the search tree are often adaptions of well-known methods in computer programming. For example, one can use a better algorithm such as replacing a linear search by a binary search. We can also replace the innermost loop by an assembly language subroutine, or a faster computer can be used.

One common optimization technique is to move invariant operations from the inside of a loop to the outside. This idea can be applied to a backtrack search in the following manner. We try to do as little as possible for nodes near the bulge, at the expense of more processing away from the bulge. For example, suppose we have a tree of depth 3 and that $\alpha_1 = 1$, $\alpha_2 = 1000$, and $\alpha_3 = 1$. If the time required to process each node is 1 sec, then the processing time for the search tree is 1002 sec. Suppose we can reduce the cost of processing the nodes at level 2 by a factor of 10 at the expense of increasing the processing cost of nodes at levels 1 an 3 by a factor of 100. Then, the total time is reduced to 300 sec.

D. Practical Aspects

There are many considerations that go into developing a computer program which runs for months and years. Interruptions, ranging from power failures to hardware maintenance, are to be expected. A program should not have to restart from the very beginning for every interruption; otherwise, it may never finish. Fortunately, an enumerative computer proof can easily be divided into independent runs. If there is an interruption, just look up the last completed run and restart from that point. Thus, the disruptive effect of an untimely interrupt is now limited to the time wasted in the incomplete run. Typically, the problem is divided into hundreds or even millions of independent runs in order to minimize the time wasted by interruptions.

Another advantage of dividing a problem into many independent runs is that several computers can be used to run the program simultaneously. If a problem takes 100 years to run on one computer, then by running on 100 computers simultaneously the problem can be finished in 1 year.

E. Correctness Considerations

An often-asked question is, "How can one check a computer-based proof?" After all, a proof has to be absolutely correct. The computer program itself is part of the proof, and checking a computer program is no different from checking a traditional mathematical proof. Computer programs tend to be complicated, especially the ones that are highly optimized, but their complexity is comparable to some of the more difficult traditional proofs.

The actual execution of the program is also part of the proof, and the checking of this part is difficult or impossible. Even if the computer program is correct, there is still a very small chance that a computer makes an error in executing the program. In the search for a projective plane of order 10, this error probability is estimated to be 1 in 100,000.

So, it is impossible to have an absolute error-free, computer-based proof! In this sense, a computer-based proof is an experimental result. As scientists in other disciplines have long discovered, the remedy is an independent verification. In a sense, the verification completes the proof.

VI. RECENT DEVELOPMENT: RSA FACTORING CHALLENGE

Recently, there has been a lot of interest in factorizing big numbers. It all started in 1977 when Rivest, Shamir, and Adleman proposed a public-key cryptosystem based on the difficulty of factorizing large numbers. Their method is now known as the RSA scheme. In order to encourage research and to gauge the strength of the RSA scheme, RSA Data Security, Inc. in 1991 started the RSA Factoring Challenge. It consists of a list of large composite numbers. A cash prize is given to the first person to factorize a number in the list. These challenge numbers are identified by the number of decimal digits contained in the numbers. In February 1999, the 140-digit RSA-140 was factorized. In August 1999, RSA-155 was factorized. The best known factorization method divides the task into two parts: a sieving part to discover relations and a matrix reduction part to discover dependencies. The sieving part has many similarities with an enumerative proof. One has to try many possibilities, and the trials can be divided into many independent runs. In fact, for the factorization of RSA-155, the sieving part took about 8000 MIPS years and was accomplished by using 292 individual computers located at 11 different sites in 3 continents. The resulting matrix had 6,699,191 rows and 6,711,336 columns. It took 224 CPU hours and 3.2 Gbytes of central memory on a Cray C916 to solve. Fortunately, there is never any question about the correctness of the final answer, because one can easily verify the result by multiplying the factors together.

VII. FUTURE DIRECTIONS

When the four-color conjecture was first settled by a computer, there was some hesitation in mathematics circles to accept it as a proof. There is first the question of how to check the result. There is also the aesthetic aspect: "Is a computer-based proof elegant?" The result itself is definitely interesting. The computer-based proof of the nonexistence of a projective plane of order 10 again demonstrated the importance of this approach. A lengthy enumerative proof is a remarkable departure

from traditional thinking in terms of simple and elegant proofs. As computers are getting faster, many other famous open problems may be solved by this approach. Mathematicians are slowly coming to accept a computer-based proof as another proof technique. Before long, it will be treated as just another tool in a mathematician's tool box.

GLOSSARY

Algorithm A recipe or set of instructions that, when followed precisely, will produce a desired result.

Binomial coefficient The binomial coefficient $\binom{n}{k}$ is the coefficient of x^k in the expansion of $(1+x)^n$. It counts the number of ways of choosing k objects from a set of n objects.

Computer algebra system A computer package that enables the computer to do symbolic computations such as algebraic simplification, formal differentiation, and indefinite integration.

Diophantine equation An equation in several variables for which only integer solutions are accepted.

Hypergeometric series A finite or infinite summation, $1+a_1+\cdots+a_k+\cdots$, in which the first term is 1 and the ratio of successive summands, a_{k+1}/a_k, is a quotient of polynomials in k.

Hypergeometric term A function of, say, k, that is the kth summand in a hypergeometric series.

Proof certificate A piece of information about a mathematical statement that makes it possible to prove the statement easily and quickly.

Proper hypergeometric term A function of two variables such as n and k that is of the following form: a polynomial in n and k times $x^k y^n$ for some fixed x times a product of quotients of factorials of the form $(an+bk+c)!$ where a, b, and c are fixed integers.

Rising factorial A finite product of numbers in an arithmetic sequence with difference 1. It is written as $(a)_n = a(a+1)(a+2)\cdots(a+n-1)$.

IN A COMPUTER-BASED PROOF, the computer is used as a tool to help guess what is happening, to check cases, to do the laborious computations that arise. The person who is creating the proof is still doing most of the work. In contrast, a computer-generated proof is totally automated. A person enters a carefully worded mathematical statement for which the truth is in doubt, hits the RETURN key, and within a reasonable amount of time the computer responds either that the statement is true or that it is false. A step beyond this is to have the computer do its own searching for reasonable statements that it can test.

Such fully automated algorithms for determining the truth or falsehood of a mathematical statement do exist.

With Doron Zeilberger's program EKHAD, one can enter the statement believed or suspected to be correct. If it is true, the computer will not only tell you so, it is capable of writing the paper ready for submission to a research journal. Even the search for likely theorems has been automated. A good deal of human input is needed to set parameters within which one is likely to find interesting results, but computer searches for mathematical theorems are now a reality.

The possible theorems to which this algorithm can be applied are strictly circumscribed, so narrowly defined that there is still a legitimate question about whether this constitutes true computer-generated proof or is merely a powerful mathematical tool. What is not in question is that such algorithms are changing the kinds of problems that mathematicians need to think about.

I. THE IDEAL VERSUS REALITY

A. What Cannot Be Done

Mathematics is frequently viewed as a formal language with clearly established underlying assumptions or axioms and unambiguous rules for determining the truth of every statement couched in this language. In the early decades of the twentieth century, works such as Russell and Whitehead's *Principia Mathematica* attempted to describe all mathematics in terms of the formal language of logic. Part of the reason for this undertaking was the hope that it would lead to an algorithmic procedure for determining the truth of each mathematical statement. As the twentieth century progressed, this hope receded and finally vanished. In 1931, Kurt Gödel proved that no axiomatic system comparable to that of Russell and Whitehead could be used to determine the truth or falsehood of every mathematical statement. Every consistent system of axioms is necessarily incomplete.

One broad class of theorems deals with the existence of solutions of a particular form. Given the mathematical problem, the theorem either exhibits a solution of the desired type or states that no such solution exists. In 1900, as the tenth of his set of twenty-three problems, David Hilbert challenged the mathematical community: "Given a Diophantine equation with any number of unknown quantities and with rational integral numerical coefficients: To devise a process according to which it can be determined by a finite number of operations whether the equation is solvable in rational integers." A well-known example of such a Diophantine equation is the Pythagorean equation, $x^2 + y^2 = z^2$, with the restriction that we only accept integer solutions such as $x = 3$, $y = 4$, and $z = 5$. Another problem of this type is Fermat's Last Theorem. This theorem asserts that no such positive integer solutions exist for the equation $x^n + y^n = z^n$ when n is an integer greater than or equal to 3. We know that the last assertion is correct, thanks to Andrew Wiles.

For a Diophantine equation, if a solution exists then it can be found in finite (though potentially very long) time just by trying all possible combinations of integers, but if no solution exists then we cannot discover this fact just by trying possibilities. A proof that there is no solution is usually very hard. In 1970, Yuri Matijasevič proved that Hilbert's algorithm could not exist. It is impossible to construct an algorithm that, for every Diophantine equation, is able to determine whether it does or does not have a solution.

There have been other negative results. Let E be an expression that involves the rational numbers, π, $\ln 2$, the variable x, the functions sine, exponential, and absolute value, and the operations of addition, multiplication, and composition. Does there exist a value of x where this expression is zero? As an example, is there a real x for which

$$e^x - \sin(\pi \ln 2) = 0?$$

For this particular expression the answer is "yes" because $\sin(\pi \ln 2) > 0$, but in 1968, Daniel Richardson proved that it is impossible to construct an algorithm that would determine in finite time whether or not, for every such E, there exists a solution to the equality $E = 0$.

B. What Can Be Done

In general, the problem of determining whether or not a solution of a particular form exists is extremely difficult and cannot be automated. However, there are cases where it can be done. There is a simple algorithm that can be applied to each quadratic equation to determine whether or not it has real solutions, and if it does, to find them.

That $x^2 - 4312x + 315 = 0$ has real solutions may not have been explicitly observed before now, but it hardly qualifies as a theorem. The theorem is the statement of the quadratic formula that sits behind our algorithm. The conclusion for this particular equation is simply an application of that theorem, a calculation whose relevance is based on the theory.

But as the theory advances and the algorithms become more complex, the line between a calculation and a theorem becomes less clear. The Risch algorithm is used by computer algebra systems to find indefinite integrals in Liouvillian extensions of difference fields. It can answer whether or not an indefinite integral can be written in a suitably defined closed form. If such a closed form exists, the algorithm will find it. Most people would still classify a specific application of this algorithm as a calculation, but it is no longer always so clear-cut. Even definite integral evaluations can be worthy of being called theorems.

Freeman Dyson conjectured the following integral evaluation for positive integer z in 1962:

$$(2\pi)^{-n}\int_0^{2\pi}\cdots\int_0^{2\pi}\prod_{1\le j<k\le n}\left|e^{i\theta_j}-e^{i\theta_k}\right|^{2z}d\theta_1\cdots d\theta_n = \frac{(nz)!}{(z!)^n}.$$

Four proofs have since been published. Dyson's conjecture cannot be proven by the Risch or any other general integral evaluation algorithm because the dimension of the space over which the integral is taken is a variable, but its proof is now close to the boundary of what can be totally automated.

Most of this article will focus on the WZ method developed by Wilf and Zeilberger in the early 1990s. Given a suitable hypergeometric series, the WZ method will determine whether or not it has a closed form. If it does, the algorithm will find it. It can even be used to find new hypergeometric series that can be expressed in closed form. Again, the important mathematics is the theory that is used to create and justify the algorithm, but specific applications now look very much like theorems. One example of a result that can be proved by the WZ method is the following identity, discovered and proved by J. C. Adams in the nineteenth century. Let $P_n(x)$ be the Legendre polynomial defined by

$$P_n(x) := \frac{1}{2^n}\sum_{k=0}^{n}\binom{n}{k}^2(x-1)^k(x+1)^{n-k},$$

and let $A_k = \binom{2k}{k}$, then

$$\int_{-1}^{1}P_m(x)P_n(x)P_{m+n-2k}(x)\,dx = \frac{1}{(m+n+1/2-k)}\cdot\frac{A_kA_{m-k}A_{n-k}}{A_{m+n-k}}. \qquad (1)$$

Note that the term-by-term integration is not difficult for a computer algebra system. What distinguishes this particular identity is that the number of terms in each summation is left as a variable.

Given a hypergeometric series, the WZ method can be used to find the closed expression that it equals, provided such an expression exists. We take as an example

$$f(n) = \sum_{0\le k\le n/3}2^k\frac{n}{n-k}\binom{n-k}{2k}.$$

The algorithm produces a recursion satisfied by $f(n)$:

$$f(n+3)-2f(n+2)+f(n+1)-2f(n)=0.$$

This is a particularly nice example because the coefficients are constants and standard techniques can be applied to discover that

$$\sum_{0\le k\le n/3}2^k\frac{n}{n-k}\binom{n-k}{2k} = 2^{n-1}+\frac{1}{2}(i^n+(-i)^n), \qquad n\ge 2.$$

In general, the coefficients in the recursion will be polynomials in n. In 1991 Marko Petkovšek created an algorithm that will find a closed form solution for such a recursion, or prove that no such formula exists. The combination of the WZ method with Petkovšek's algorithm gives an automated proof that a particular type of solution cannot exist, or else it finds such a solution. As an example, there is a computer-generated proof of the fact that

$$\sum_{k=0}^{n}\binom{n}{k}^2\binom{n+k}{k}^2$$

cannot be written as a linear combination of hypergeometric terms in n.

The WZ method combined with Petkovšek's algorithm is producing fully automated proofs of results that, until recently, have required considerable human ingenuity. Significantly, it replies not just with a statement that a particular identity is true, but also with a proof certificate, a critical insight that enables anyone with pencil and paper and a little time to verify that this identity is correct. At the very least, these algorithms have moved the line of demarcation between what constitutes a proof and what is only a computation.

II. HYPERGEOMETRIC SERIES IDENTITIES

A. What Is a Hypergeometric Series?

A series, $1+a_1+a_2+a_3+\cdots$, is called hypergeometric if the ratio of consecutive terms, a_{n+1}/a_n, is a rational function of n, say $a_{n+1}/a_n = P(n)/Q(n)$, where P and Q are polynomials. Most of the commonly encountered power series are hypergeometric or can be expressed in terms of hypergeometric series (see Fig. 1). A hypergeometric term is a function of n that is a summand of a hypergeometric series indexed by n. In particular, a hypergeometric term is of the form

$$a_k = \prod_{n=0}^{k-1}\frac{a_{n+1}}{a_n} = \prod_{n=0}^{k-1}\frac{P(n)}{Q(n)},$$

for some pair of polynomials P and Q.

If we factor P and Q,

$$P(n) = c_1(n+\alpha_1)(n+\alpha_2)\cdots(n+\alpha_m),$$

$$Q(n) = c_2(n+\beta_1)(n+\beta_2)\cdots(n+\beta_{n+1}),$$

Exponential function:

$$e^x = 1 + \sum_{n=1}^{\infty} \frac{x^n}{n!}, \quad \frac{a_{n+1}}{a_n} = \frac{x}{n+1},$$

Sine function:

$$\sin x = x\left(1 + \sum_{n=1}^{\infty} \frac{(-1)^n x^{2n}}{(2n+1)!}\right), \quad \frac{a_{n+1}}{a_n} = \frac{-x^2}{4(n+1)(n+3/2)},$$

Bessel function of the first kind:

$$J_k(x) = \frac{x^k}{\Gamma(k+1)}\left(1 + \sum_{n=1}^{\infty} \frac{(-1)^n x^{2n}}{4^n\, n!\, (k+1)_n}\right), \quad \frac{a_{n+1}}{a_n} = \frac{-x^2}{4(n+1)(n+k+1)},$$

Error function:

$$\operatorname{erf}(x) = \frac{2x}{\sqrt{\pi}}\left(1 + \sum_{n=1}^{\infty} \frac{(-1)^n x^{2n}}{(2n+1)\, n!}\right), \quad \frac{a_{n+1}}{a_n} = -x^2\, \frac{(2n+1)\, n}{(2n+3)(n+1)}.$$

FIGURE 1 Examples of common functions expressed in terms of hypergeometric series.

then the hypergeometric term can be written as

$$a_k = c\, \frac{(\alpha_1)_k (\alpha_2)_k \cdots (\alpha_m)_k}{(\beta_1)_k (\beta_2)_k \cdots (\beta_{n+1})_k},$$

where $c = c_1/c_2$ and $(\alpha)_k$ is the rising factorial:

$$(\alpha)_k = \alpha(\alpha+1)(\alpha+2)\cdots(\alpha+k-1).$$

B. The Chu–Vandermonde Identity

A large part of the impetus behind the development of the WZ method and the reason why it has become such an influential tool is that there is a rich and ever-expanding store of useful identities for hypergeometric series. These recur throughout mathematics, playing important roles in the solutions of both theoretical and applied problems.

The binomial theorem was the first and is the most fundamental of these identities. It is the foundation upon which all others are proved. Mathematicians have been building upon the binomial theorem for many years. In 1303, Chu Shih-Chieh wrote *Precious Mirror of the Four Elements* (*Ssu Yü Chien*), in which he may have been the first person to state the fundamental result:

$$\sum_{i=0}^{\infty} \binom{a}{i}\binom{b}{k-i} = \binom{a+b}{k}. \tag{2}$$

In Chu's identity, a, b, and k are positive integers. Note that all summands will be zero once i is greater than a or k. Equation (2) is easily derived from the binomial theorem by comparing the coefficients of x^k in

$$(1+x)^a (1+x)^b = \sum_{i=0}^{a} \binom{a}{i} x^i \sum_{j=0}^{b} \binom{b}{j} x^j,$$

and

$$(1+x)^{a+b} = \sum_{k=0}^{a+b} \binom{a+b}{k} x^k.$$

Equation (2) was rediscovered by Alexandre Vandermonde in 1772 and is today known as the *Chu–Vandermonde Identity*.

The ratio of successive terms in the summation is

$$\binom{a}{n+1}\binom{b}{k-n-1} \Big/ \binom{a}{n}\binom{b}{k-n} = \frac{(n-a)(n-k)}{(n+1)(n+b-k+1)}.$$

If we divide both sides of Eq. (2) by the first summand, $\binom{b}{k}$, it can be rewritten in terms of rising factorials as

$$1 + \sum_{n=1}^{\infty} \frac{(-a)_n (-k)_n}{n!(b-k+1)_n} = \frac{(a+b)!\,(b-k)!}{(a+b-k)!\,b!}. \tag{3}$$

In 1797, Johann Friedrich Pfaff showed that, subject only to convergence conditions, Eq. (3) holds for complex values, in which case it can be expressed as

$$1 + \sum_{n=1}^{\infty} \frac{(\alpha)_n (\beta)_n}{n!(\gamma)_n} = \frac{\Gamma(\gamma-\alpha-\beta)\Gamma(\gamma)}{\Gamma(\gamma-\alpha)\Gamma(\gamma-\beta)}. \tag{4}$$

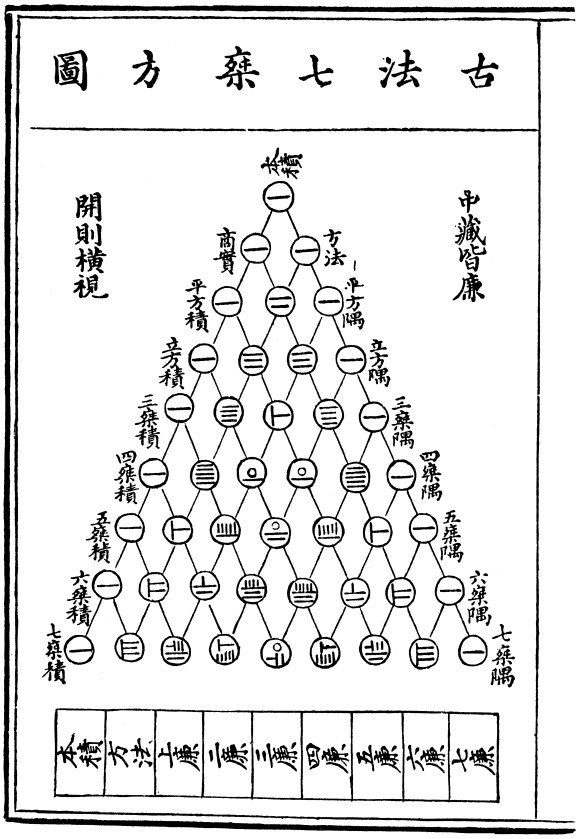

FIGURE 2 The representation of "Pascal's" triangle in Chu's *Precious Mirror of the Four Elements* of 1303. (Reprinted with the permission of Cambridge University Press.)

Pfaff's student, Carl Friedrich Gauss, used hypergeometric series in his astronomical work and advanced their study. Among his contributions, he found sharp criteria for whether or not a hypergeometric series converges. Throughout the nineteenth and twentieth century, a great number of identities for hypergeometric series were discovered, many of which were collected in the Bateman Manuscript Project published as *Higher Transcendental Functions* in 1953–1955.

C. Standardized Notation

Most hypergeometric series can be written as sums of rational products of binomial coefficients, but this representation is problematic because it is not unique. As an example,

$$\sum_{n=0}^{m} 2^{m-k-2n}\binom{m}{n}\binom{m-n}{n+k} = \binom{2m}{m+k}$$

appears to be different from the Chu-Vandermonde identity [Eq. (2)]. But if we look at the ratio of consecutive summands, it is

$$\frac{1}{4}\frac{(m-2n-k-1)(m-2n-k)}{(n+1)(n+k+1)}$$

$$= \frac{(n+(k+1-m)/2)(n+(k-m)/2)}{(n+1)(n+k+1)}.$$

This is simply the Chu-Vandermonde identity with $\alpha = (k+1-m)/2$, $\beta = (k-m)/2$, and $\gamma = k+1$.

There is clearly an advantage to using the rising factorial notation, in which case we write

$${}_mF_n\left(\begin{matrix}\alpha_1,\ldots,\alpha_m\\ \beta_1,\ldots,\beta_n\end{matrix};\, x\right) := 1+\sum_{k=1}^{\infty}\frac{(\alpha_1)_k\cdots(\alpha_m)_k}{k!(\beta_1)_k\cdots(\beta_n)_k}\,x^k.$$

Even with this standardized notation, there are equivalent identities that look different because there are nontrivial transformation formulas for hypergeometric series. As an example, provided the series in question converge, we have that

$${}_2F_1\left(\begin{matrix}a,\ b\\ 2a\end{matrix};\, x\right) = \left(1-\frac{x}{2}\right)^{-b}$$

$$\times\,{}_2F_1\left(\begin{matrix}b/2,\ (b+1)/2\\ a+1/2\end{matrix};\, \left(\frac{x}{2-x}\right)^2\right).$$

This is why, even if all identities for hypergeometric series were already known, it would not be enough to have a list of them against which one could compare the candidate in question. Just establishing the equivalence of two identities can be a very difficult task. This makes the WZ method all the more remarkable because it is independent of the form in which the identity is given and can even be used to verify (or disprove) a conjectured transformation formula.

III. THE WZ METHOD

A. Sister Celine's Technique

The WZ method for finding and proving identities for hypergeometric series builds on a succession of developments that began with the Ph.D. thesis of Sister Mary Celine Fasenmyer at the University of Michigan in 1945. We consider a sum of the form

$$f(n) = \sum_k F(n,k),$$

where $F(n,k)$ is a proper hypergeometric term. This means that it is a polynomial in n and k times $x^k y^n$, for fixed x and y, times a product of quotients of factorials of the form $(an+bk+c)!$, where a and b, and c are fixed integers. As an example,

$$\sum_{0\le k\le n/3} 2^k \frac{n}{n-k}\binom{n-k}{2k} = \sum_{0\le k\le n/3} n\cdot 2^k \cdot \frac{(n-k-1)!}{(2k)!\,(n-3k)!}.$$

is such a series.

Every such sum of proper hypergeometric terms will satisfy a finite recursion of the form

$$\sum_{j=0}^{J} a_j(n)\, f(n+j) = 0.$$

Sister Celine showed how to reduce the problem of finding these coefficients to one of solving a system of linear equations. It was Doron Zeilberger who realized that this gives us an algorithm for proving hypergeometric series identities because we need only verify that each side satisfies the same recursion and the same initial conditions. The problem with using Sister Celine's approach is that her particular algorithm for finding the coefficients is slow. Later developments would speed it up considerably, though in the process would lose the easy generalization of Sister Celine's technique to summations over several indices.

B. Gosper's algorithm

In 1977 and 1979, R. W. Gosper, Jr., took a different approach and became one of the first people to use computers to discover and check identities for hypergeometric series. Given a proper hypergeometric term $F(n,k)$, Gosper showed how to automate a search for a proper hypergeometric term $G(n,k)$ with the property that

$$G(n,k+1) - G(n,k) = F(n,k).$$

If such a G could be found, then

$$\begin{aligned} f(n) &= \sum_{k=0}^{n} (G(n,k+1) - G(n,k)) \\ &= G(n,n+1) - G(n,0). \end{aligned}$$

An example of the application of this algorithm is the computer-generated proof of an identity discovered and first proved by J. S. Lomont and John Brillhart: Let $1\le m\le n$, where $n\ge 2$ and $1\le s\le \min(m, n-1)$, then

$$\sum_{j=0}^{s}\left[(-1)^j(m+n-2j)\binom{m}{j}\binom{m-j}{m-s}\binom{n}{j}\binom{n-j}{n-s}\right.$$
$$\left.\times\binom{m+n}{j}\binom{m+n-s-j-1}{s-j}\Big/\binom{s}{j}^2\right] = 0.$$

Given this conjecture, the program EKHAD replies with the proof certificate:

$$-s,\ j*(m+n-s-j)/(m+n-2*j).$$

This means that if $F(n,j)$ is the summand in the conjectured identity, then

$$-sF(n,j) = G(n,j+1) - G(n,j),$$

where $G(n,j) = j(m+n-s-j)F(n,j)/(m+n-2j)$. The sum over j of $G(n,j+1)-G(n,j)$ telescopes, and therefore the original summation equals $[G(n,s+1) - G(n,0)]/(-s) = 0$.

Gosper's algorithm is a fertile approach that is often applicable, but it is limited by the fact that such a G does not always exist.

C. Wilf and Zeilberger

Major progress was made by Doron Zeilberger who, starting in 1982, began to combine the ideas of Sister Celine and William Gosper. In the early 1990s, Herbert Wilf joined Zeilberger in extending and refining these methods into a fully automated proof machine that is now known as the WZ method. If $F(n,k)$ is a proper hypergeometric term, then there always is a proper hypergeometric term $G(n,k)$ such that $G(n,k+1)-G(n,k)$ is equal to a linear combination of $\{F(n+j,k)\mid 0\le j\le J\}$ for some explicitly computable J,

$$\sum_{j=0}^{J} a_j(n)F(n+j,k) = G(n,k+1) - G(n,k), \qquad (5)$$

where the $a_j(n)$ are polynomials in n. If $f(n) = \sum_{k=0}^{K} F(n,k)$, then we can sum both sides of Eq. (5) over $0\le k\le K$. The right side telescopes, and we are left with the recursive formula

$$\sum_{j=0}^{J} a_j(n)\, f(n+j) = G(n,K+1) - G(n,0).$$

Gosper's technique—which is very fast—can be used to find the function G. The coefficients $a_j(n)$ are then found by solving a system of linear equations.

Gosper's algorithm is the special case of the WZ method in which $J=0$. The other case of particular interest is when $J=1$ and $a_1 = -a_0 = 1$. Consider the conjectured identity:

$$\sum_k \binom{n}{2k}\binom{2k+1}{k}\frac{n+2}{2k+1}\,2^{n-2k-1} = \binom{2n+1}{n}. \qquad (6)$$

If we divide each side by $\binom{2n+1}{n}$, this can be rewritten as

$$f(n) = \sum_k \binom{n}{2k}\binom{2k+1}{k}\frac{n+2}{2j+1}\,2^{n-2k-1}\Big/$$
$$\binom{2n+1}{n} = 1.$$

If this is true, then $f(n)$ satisfies the recursion $f(n+1)-f(n)=0$. Let $F(n,k)$ be the summand,

$$F(n,k)=\binom{n}{2k}\binom{2k+1}{k}\frac{n+2}{2j+1}2^{n-2k-1}\Big/\binom{2n+1}{n}.$$

If we could find a proper hypergeometric term $G(n,k)$ for which

$$F(n+1,k)-F(n,k)=G(n,k+1)-G(n,k), \quad (7)$$

then it would follow that $f(n+1)-f(n)=0$, and so $f(n)$ would be constant. It would be enough to check that $f(0)=1$.

In fact, such a G does exist. The WZ method finds it. The proof certificate is the rational function,

$$\frac{G(n,k)}{F(n,k)}=\frac{4k(k+1)}{(2n+3)(2k-n-1)}.$$

To check Eq. (6), we only need to verify that F and G, which we now know, do indeed satisfy Eq. (7).

In general, the WZ method returns either the ratio $G(n,k)/F(n,k)$ [if the recursion is of the form given in Eq. (7)], or it returns the actual recursive formula satisfied by $f(n)$. The only drawback to the WZ method is that the number of terms in the recursive formula may be too large for practical use.

D. Petkovšek and Others

In his Ph.D. thesis of 1991, Marko Petkovšek showed how to find a closed form solution—or to show that such a solution does not exist—for any recursive formula of the form

$$\sum_{j=0}^{J}a_j(n)f(n+j)=g(n),$$

in which $g(n)$ and the $a_j(n)$ are polynomials in n. By closed form, we mean a linear combination of a fixed number of hypergeometric terms.

Combined with the WZ method, Petkovšek's algorithm implies that in theory if not in practice, given any summation of proper hypergeometric terms, there is a completely automated computer procedure that will either find a closed form for the summation or prove that no such closed from exists. A full account of the WZ method and Petkovšek's algorithm is given in the book $A=B$ by Petkovšek, Wilf, and Zeilberger.

Others have worked on implementing and extending the ideas of the WZ method. One of the centers for this work has been a group headed by Peter Paule at the University of Linz in Austria. Ira Gessel has been at the forefront of those who have used this algorithm to implement computer searches that both discovered and proved a large number of new identities for hypergeometric series.

IV. EXTENSIONS, FUTURE WORK, AND CONCLUSIONS

A. Extensions and Future Work

All of the techniques described in this article have been extended to q-hypergeometric series such as

$$1+\sum_{k=0}^{n}q^{k^2}\frac{(1-q^n)(1-q^{n-1})\cdots(1-q^{n-k+1})}{(1-q)(1-q^2)\cdots(1-q^k)},$$

in which the ratio of consecutive summands is a rational function of q^k.

Many general determinant evaluations can be reduced to problems that can be solved using the WZ method. Work is progressing on fully automating proofs of such results.

There are other theorems that appear to be amenable to an automated computer attack. These include results on real closed fields using techniques of George Collins and geometrical theorems proved using algebraic techniques such as Gröbner bases.

B. Conclusions

The net effect of the algorithms that prove identities for hypergeometric series is that a piece of mathematics that once could only be done by those with cleverness and insight has been turned into a purely mechanical calculation. Rather than limiting the scope of mathematics, the WZ method has widened it. Problems that had once been intractable are now within reach. The situation is different in degree but not in kind from the invention of calculus. This was the discovery of mechanical procedures that enabled scientists to shift their attention away from laborious and ingenious techniques for finding areas and tangent lines and to begin addressing the really interesting questions.

Perhaps this will always be the fate of computer-generated proofs. That one class of problems has been moved into the category of those that can be solved by computers means that we are freed to direct our attention to those questions that are most important.

Convex Sets

A. C. Thompson
Dalhousie University

GLOSSARY

Affine map The composition of a linear map and a translation; i.e., if T is linear, then $A(x) := T(x + x_0) = T(x) + T(x_0)$ is an affine map.

Compact set A closed and bounded set in $\mathbb{R}^n$; in a metric space, a set C such that if (x_k) is a sequence of elements of C there is a subsequence that converges to a point of C.

Dual space The collection of all linear functions from a vector space to the set of real numbers. These functions can be added and multiplied by real numbers in a point-by-point fashion which makes this collection into another vector space.

Hyperplane A *level set* of a function in the dual space; i.e., if f is a linear function from a vector space X to $\mathbb{R}$ and if α is a number, then $H_f^\alpha := \{x \in X : f(x) = \alpha\}$ is a typical hyperplane.

Line segment The set of points (vectors) $\{x : x = a + \lambda(b - a),\ \ 0 \le \lambda \le 1\} = \{x : x = (1 - \lambda)a + \lambda b,\ \ 0 \le \lambda \le 1\}$ is called the *line segment* joining a and b and is denoted by $[a, b]$.

Linear map (transformation) A function T between vector spaces that respects the vector operations of addition and multiplication by numbers; i.e., $T(\alpha x + \beta y) = \alpha T(x) + \beta T(y)$.

$\mathbb{R}^n$ The most usual vector spaces consisting of n-tuples of real numbers that are added and multiplied by numbers in a coordinate-by-coordinate fashion.

Vector space A collection of things called *vectors* or *points* that can be added (via a parallelogram law) and multiplied by numbers (also called *scalars*). Here the numbers will be real but in other contexts complex or other number systems are possible.

I. INTRODUCTION

Relatively few shapes in the natural world are convex. When they do occur— for example, soap bubbles, drops of dew, smoothly worn stones on the beach, single crystals of amethyst and salt— we find them to be esthetically pleasing. Among manufactured objects, rectangles, circles, hexagons, cubes, cylinders, and cones are quite ubiquitous. We first encounter them as children and enjoy the shapes of wooden building blocks and colored tiles.

Convexity is the study of these shapes. Two-dimensional convex shapes (circles, ellipses, triangles, polygons) and the regular Platonic solids have been objects of mathematical study for a very long time. The study of convexity as a specific mathematical topic dates back only to the end of the 19th century. The primary influence was the pioneering work of Minkowski for which one should consult his collected works.[3] For a good historical summary, see the article by Peter Gruber in the *Handbook of Convex Geometry*.[2] This chapter covers only some of the topics that fall under the heading of convexity. Other aspects can be found in articles in Reference 2. There is not space to mention the many interactions of convexity with other branches of mathematics. The book by Roger Webster[5] is a readable, elementary introduction to the subject and has some interesting applications.

To define convex sets precisely we need an ambient space in which they may exist. This space requires one type of mathematical structure and usually comes equipped with another.

The structure that is required is that of a *vector* or *linear space*; the most familiar vector spaces are those that we denote by $\mathbb{R}^2$, $\mathbb{R}^3$, and, in general, $\mathbb{R}^n$. This space consists of n-tuples of numbers $(\xi_1, \xi_2, \ldots, \xi_n)$ whose entries are called the *coordinates* of the vector. It is customary to write single vectors as *rows*, but matrices (and other functions that operate on vectors) are usually written to the left of the vector. This means that the vectors should 'really' be viewed as *columns*.

If a vector y is expressed in the form:

$$y = \alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_k x_k$$

then it is said to be a *linear combination* of the vectors $\{x_i : i = 1 \ldots, k\}$. The usual basis for $\mathbb{R}^n$ consists of the vectors:

$$e_1 = (1, 0, 0, \ldots, 0), \quad e_2 = (0, 1, 0, \ldots, 0), \quad \ldots,$$

$$e_n = (0, 0, 0, \ldots, 1)$$

where the ith vector has a 1 as the ith coordinate and a 0 elsewhere. Any vector $x = (\xi_1, \xi_2, \ldots, \xi_n)$ can be expressed uniquely as:

$$x = \xi_1 e_1 + \xi_2 e_2 + \cdots + \xi_n e_n.$$

A set of vectors $\mathcal{B}$ with the property that every vector has a unique representation as a finite linear combination of the vectors in $\mathcal{B}$ is called a *basis* for X. Each vector space has a basis, and all bases for the same space have the same number of elements. That number is called the *dimension* of the space. The dimension of $\mathbb{R}^n$ is n. The space is said to be *finite dimensional* if it has a basis with a finite number of elements and is *infinite dimensional* otherwise. We shall be concerned almost entirely with finite dimensional spaces.

A linear map is called an *isomorphism* if it is one to one and onto. If X is finite dimensional, then, corresponding to a basis $(x_1, x_2, \ldots, x_n)$, there is an isomorphism, T, of X onto $\mathbb{R}^n$ defined as follows: each $x \in X$ has a unique representation as $x = \sum \alpha_i x_i$; set $T(x) := (\alpha_1, \alpha_2, \ldots, \alpha_n)$. In this sense, there is no real loss of generality if, when dealing with finite dimensional spaces, we restrict attention to $\mathbb{R}^n$.

The linear mappings from X to $\mathbb{R}$ are given the special name of *linear functionals*. The set of all of them is called the *dual space* of X and denoted by X^*. If X is finite dimensional and if it is given a basis, then the linear functionals can be represented by $1 \times n$ matrices (i.e., row vectors of the same size as the column vectors from X). Thus, in the finite dimensional case, the dimension of X^* is the same as that of X.

In $\mathbb{R}^n$, the length of a vector $x = (\xi_1, \xi_2, \ldots, \xi_n)$ is denoted by $\|x\|$ and is defined to be the number:

$$\|x\| := \left(\sum_{i=1}^{n} |\xi_i|^2 \right)^{1/2}.$$

The structure that is usually present in discussions of convex sets in addition to the vector space structure just outlined is that of a *topological space*. Most frequently the topology derives from a metric or distance. This is the case in $\mathbb{R}^n$ where the distance between two vectors x and y, $d(x, y)$, is defined to be the length of $x - y$:

$$d(x, y) := \|x - y\|.$$

The topological structure allows one to talk about convergence, continuity, and such concepts as open sets, closed sets, connected sets, and compact sets. The Heine-Borel Theorem asserts that C is a compact subset of $\mathbb{R}^n$ if and only if it is both closed and bounded. This is no longer true in infinite dimensional spaces.

II. DEFINITIONS

Definition. A set K in a vector space X is said to be *convex* if whenever $x, y \in K$ then the line segment $[x, y]$ is contained in K. Thus, in Fig. 1, the set (a) is convex while (b) is not.

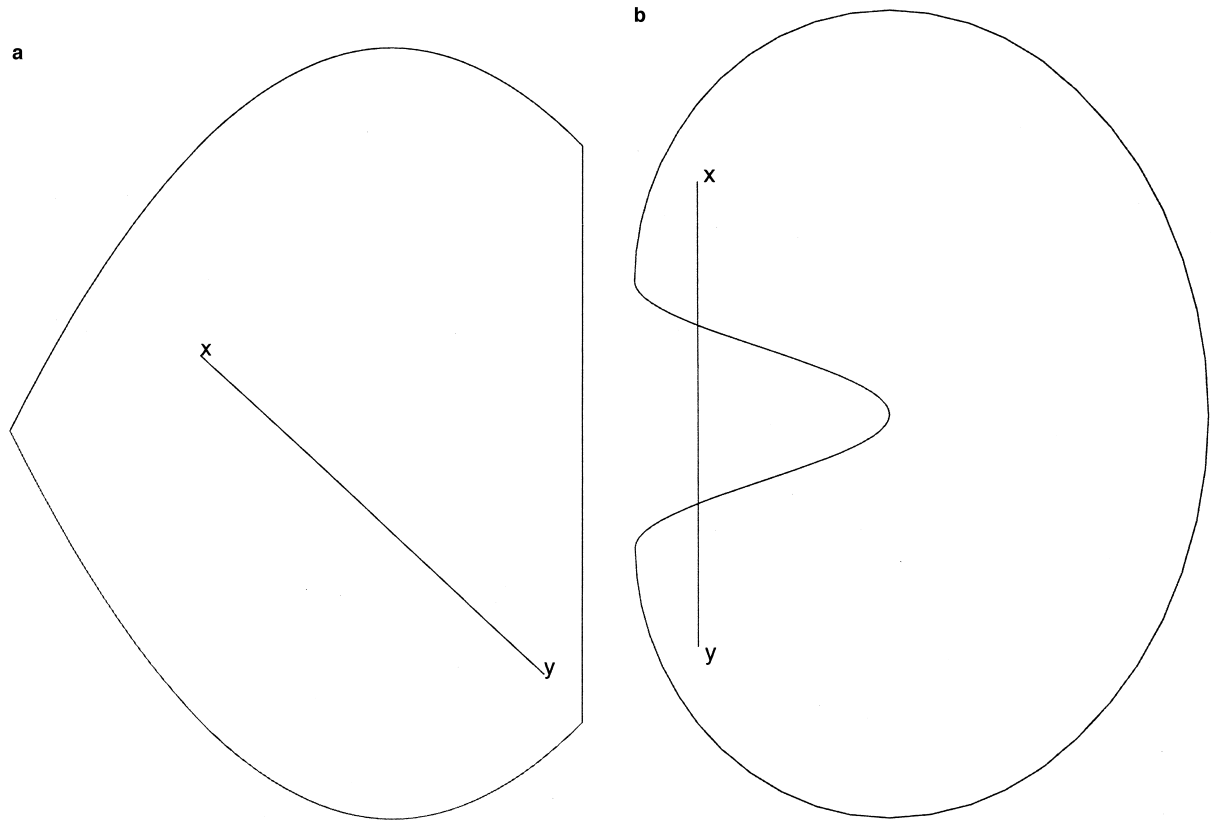

FIGURE 1

A point of the line segment $[a, b]$— a point of the form:

$$a + \lambda(b - a) = (1 - \lambda)a + \lambda b,\ 0 \le \lambda \le 1,$$

is said to be a convex combination of a and b.

A related notion is that of being *star shaped*. A set S is star shaped about a point x_0 if for all x in S the line segment $[x, x_0]$ is contained in S. In Fig. 2, the set (a) is star shaped about x but not about y, and (b) is not star shaped about any point. A set is convex if and only if it is star shaped about every point. Each convex set (and each star-shaped set) is connected.

In the one-dimensional space $\mathbb{R}$ the collections of convex sets, star-shaped sets, and connected sets coincide. Each of these is the class of intervals (closed, open, half-open, bounded, and unbounded). Therefore, in order to have an interesting theory of convexity, the dimension of the underlying space should be at least 2.

There is also a definition of convexity as an adjective that applies to functions rather than sets:

Definition. A real valued function f defined on a convex set K is said to be *convex* if, for all x and y in K,

$$f(\lambda x + (1 - \lambda)y) \le \lambda f(x) + (1 - \lambda) f(y).$$

Note that the convexity of K is needed to ensure that $\lambda x + (1 - \lambda)y$ is in the domain of f when x and y are.

The relation between the definitions of convexity for a function and for a set is twofold. The *graph* of f is a subset of $K \times \mathbb{R}$ and is defined as:

$$\text{graph}(f) := \{(x, \eta) :\ f(x) = \eta\}.$$

Extending this idea, the *epigraph* of f is the set that lies above the graph of f:

$$\text{epigraph}(f) := \{(x, \eta) :\ f(x) \le \eta\}.$$

Then, f is convex (as a function) if and only if epigraph(f) is convex as a set. Secondly, if f is convex then, for each (extended) real number α, the sets $\{x :\ f(x) \le \alpha\}$ and $\{x :\ f(x) < \alpha\}$ are convex. This illustrates the connection between convexity and certain types of inequality.

A function is sublinear if it is both subadditive— $f(x + y) \le f(x) + f(y)$—and *non-negatively homogeneous*— $f(\alpha x) = \alpha f(x)$ for all $\alpha \ge 0$. From now on, "homogeneity" will mean "non-negative homogeneity." All linear functionals are sublinear and all sublinear functions are convex. Hence, if f is sublinear then sets of the form $\{x :\ f(x) \le \alpha\}$ are convex.

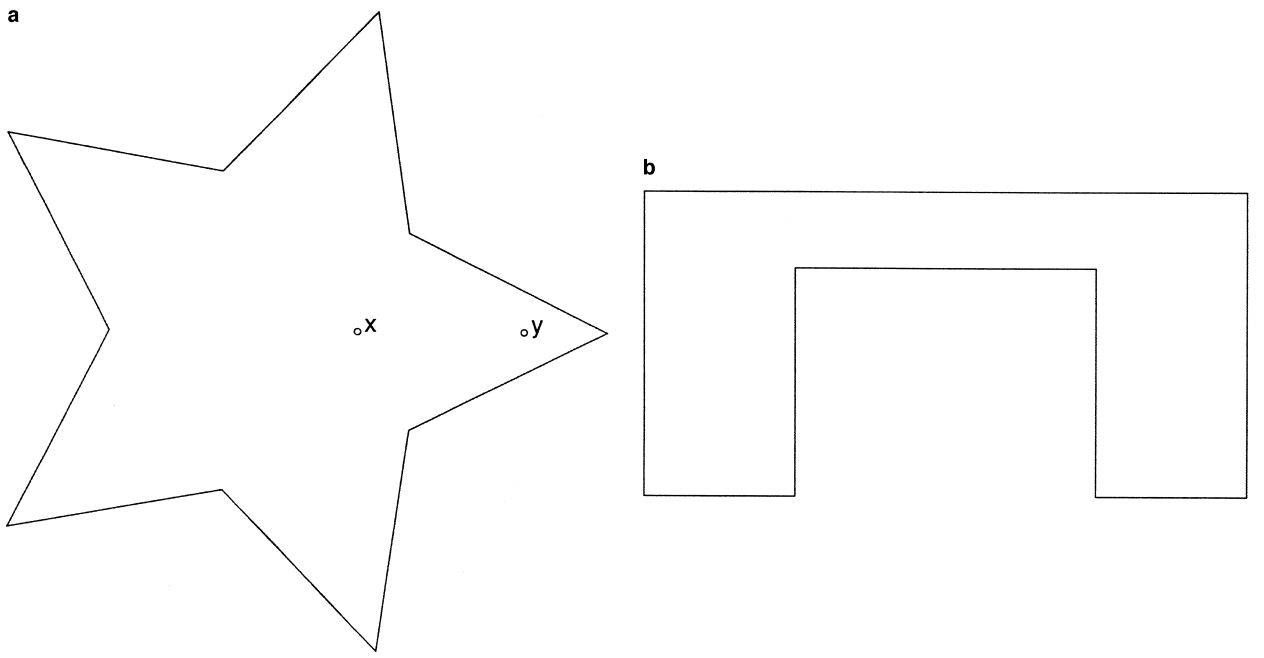

FIGURE 2

III. EXAMPLES

If K is a convex set and if A is an affine mapping, then $A(K) := \{Ax : x \in K\}$ is also convex. Affine mappings include translations, rotations, dilations, and reflections. Therefore, it is often convenient to think of examples as being located at some particular point in space (centered at the origin, for example) or with some particular orientation or with some particular scaling. These are not relevant to the property of being convex and may not be very relevant to other properties of the convex sets.

1. A single point is a convex set.

2. Lines, line segments (with or without the end points), and rays (sets of the form $\{x : x = a + \lambda b$, with $\lambda \geq 0\}$) are convex sets. As indicated in Section II, in $\mathbb{R}$ the only convex sets are intervals.

3. The ball of radius 1 centered at the origin (briefly, the unit ball),

$$B := B[0, 1] := \{x : \|x\| \leq 1\}$$

is convex. While this is geometrically clear in two and three dimensions, the proof (the same in all dimensions) is not so immediate. We need to show that the norm is a sublinear functional. That it is homogeneous is easy; the fact that it is subadditive,

$$\|x + y\| \leq \|x\| + \|y\|,$$

is usually referred to as the *triangle inequality* and is a consequence of the Cauchy-Schwarz inequality.

Any closed ball $B[x_0, r] := \{x : \|x - x_0\| \leq r\}$ of center x_0 and radius r is convex. An open ball, $B(x_0, r) := \{x : \|x - x_0\| < r\}$ is also convex (in general, the interior of a convex set is also convex). Note that we may consider, for example, a two-dimensional ball (a disc) as a subset of $\mathbb{R}^3$ or a higher dimensional space. It is still convex, but whereas as a subset of $\mathbb{R}^2$ it has interior points, in $\mathbb{R}^3$ it does not. We shall say more about the idea of relative interior in Section IV. Closed and bounded convex sets are called *convex bodies*. Some authors use this term to also imply that the set has a non-empty interior.

4. The image of the unit ball under any invertible affine map is convex. This gives the important class of convex bodies known as *ellipsoids*.

5. The *unit cube* is defined to be the set $\{x = (\xi_1, \xi_2, \ldots, \xi_n) : 0 \leq \xi_i \leq 1\}$. If a cube centered at the origin is required, we often consider one that is dilated by a factor of 2 and call it the *standard cube*, C_n:

$$C_n := \{x = (\xi_1, \xi_2, \ldots, \xi_n) : -1 \leq \xi_i \leq 1\}.$$

This set is a convex body in $\mathbb{R}^n$. The image of a standard cube under an invertible affine map is called a *parallelotope*.

6. The *standard simplex*, S_n, is defined by the following equation:

$$S_n := \left\{x = (\xi_1, \xi_2, \ldots, \xi_n) : \xi_i \geq 0 \text{ and } \sum \xi_i \leq 1\right\}.$$

A general n-simplex is the image of S_n under an invertible affine map.

7. The *standard cross-polytope* in $\mathbb{R}^n$, $\mathcal{O}_n$, is defined by:

$$\mathcal{O}_n := \left\{x = (\xi_1, \xi_2, \ldots, \xi_n) : \sum |\xi_i| \leq 1\right\}.$$

The letter $\mathcal{O}$ is used because in $\mathbb{R}^3$ this set is a regular octahedron. Note that $\mathcal{O}_2$ and C_2 are both squares but they are oriented differently.

8. A *hyperplane* $H_f^\alpha := \{x : f(x) = \alpha\}$ (where f is a linear functional) is convex. A (closed) *half-space* is a set of the form $H_f^{\alpha-} := \{x : f(x) \leq \alpha\}$ and is described as one side of the hyperplane H_f^α. This set is convex as is its interior (the open half-space for whose definition $\leq$ is replaced by $<$). One also has the half-space $H_f^{\alpha+} := \{x : f(x) \geq \alpha\} = H_{-f}^{-\alpha-}$.

9. In addition to the standard Euclidean ball B in $\mathbb{R}^n$ we may consider the ℓ_p ball $B(p)$ which is defined by:

$$B(p) := \left\{x : \sum |\xi_i|^p \leq 1\right\}.$$

If $1 \leq p$, then this set is convex.

There will be more examples of convex sets in Sections IV and V, where we discuss general methods of constructing them and of getting new sets from old ones.

IV. DESCRIPTIONS OF CONVEX SETS

How should a convex set be specified? How does one decide whether a given point is inside a particular convex set or not? There are more sophisticated computational versions of these questions: What are the most efficient algorithms for describing a convex set or for deciding whether a point is inside or not? These are difficult questions which will not be tackled here. Instead, we give a variety of answers to the more general questions, any one of which may be the best for a particular situation.

The intersection of an arbitrary collection of convex sets is convex. Since any set is contained in at least one convex set (the whole vector space in which it sits), it follows that any set, A, is contained in a smallest convex set, namely the intersection of *all* the convex sets that contain A. It is called the *convex hull* of A and is written co$A$. Thus,

$$\text{co}A := \bigcap K$$

where the intersection is taken over all convex sets K with $A \subseteq K$. One visualizes the convex hull as the set obtained by stretching a rubber sheet around the set A or, in two dimensions, an elastic band (see Fig. 3).

Therefore, one may describe a convex set either as the intersection of certain simpler convex sets or as the convex hull of some simpler set.

The convex hull of a finite set is called a *convex polytope*. Sometimes more general types of polytopes may be considered but here the word will always denote a closed, convex set and extra adjectives will be dropped.

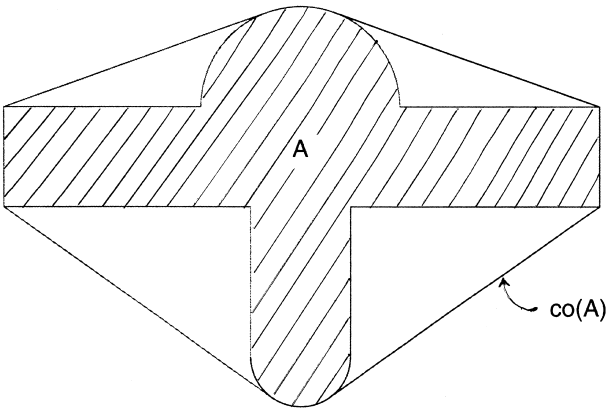

FIGURE 3

Alternatively, a polytope may be described as the intersection of finitely many closed half-spaces. There is a difference between the two notions. The convex hull of finitely many points is always bounded; the intersection of half-spaces may not be. A bounded polytope that has an interior may be described either by the points of which it is the convex hull or by the bounding hyperplanes. This is the first example of the duality relationship discussed in Section V.

Examples. The standard simplex is the convex hull of the finite set $\{0, e_1, e_2, \ldots, e_n\}$. The standard octahedron is the convex hull of the finite set $\{\pm e_1, \pm e_2, \ldots, \pm e_n\}$. The standard cube is the intersection of the following half-spaces: $\{x : f_i(x) \leq 1\}$ and $\{x : -f_i(x) \leq 1\}$, where $f_i(x) = \xi_i$ and $i = 1, 2, \ldots, n$.

Here we digress to discuss the dimension of a convex set. An affine combination of vectors $\{x_1, x_2, \ldots, x_k\}$ is a linear combination $\alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_k x_k$ in which $\sum \alpha_i = 1$. If K is a convex set, then the set of all affine linear combinations of elements of K is called the *affine hull* of K. If $0 \in K$, then the affine hull of K is the same as the set of all linear combinations (because one can add a suitable multiple of 0 to make the coefficients sum to 1). Hence, in this case, the affine hull of K is a subspace (containing K). In the general case, the affine hull of K is a flat (the older term is *affine variety*)—i.e., the translate of a subspace. Subspaces and hence flats have a well-defined dimension. The dimension of a convex set is the dimension of its affine hull.

Related to this notion are the following concepts. First, a finite set of points with n elements is said to be in general position if its affine hull (or, equivalently, its convex hull) has dimension $(n-1)$ which is the maximum possible. Two distinct points are always in general position, three points if they are not collinear, four points if they are not

coplanar, and so on. The convex hull of $(n+1)$ points in general position (necessarily in $\mathbb{R}^m$ with $m \geq n$) is an n-simplex. To see that there is an affine map of this set onto S_n observe that there is a translation that takes one point to 0 and then a linear map that takes the remaining n to the usual basis vectors. Second, the relative interior of K is the interior when K is regarded as a subset of its affine hull. The relative interior of a non-empty convex set is always non-empty.

Definition. A *face* F of a convex set K is a convex subset of K with the property that if y is in F and if y can be represented in the form $y = \alpha x_1 + (1-\alpha)x_2$ with x_1 and x_2 in K, then, in fact, x_1 and x_2 are in F. A more geometrical description is that if an open line segment in K contains points of F then the whole line segment lies in F. If P is an n-dimensional polytope in $\mathbb{R}^n$, then its 0-dimensional faces are called *vertices*, its one-dimensional faces are called *edges*, and the $(n-1)$ dimensional faces will be called *facets* (this latter term is not universally used).

Examples. The faces of the standard cube C_3 in $\mathbb{R}^3$ are the cube itself, the six facets of the cube (the sets where one fixed coordinate has a prescribed value from $\{-1, 1\}$), the 12 edges of the cube (the sets where two fixed coordinates have prescribed values from $\{-1, 1\}$), and the eight vertices (the sets where all three coordinates have prescribed values from $\{-1, 1\}$).

The faces of the standard simplex S_3 in $\mathbb{R}^3$ are S_3; the four facets of the simplex (the intersections of S_3 with the planes $\{x : \xi_i = 0\}$ and $\{x : \sum \xi_i = 1\}$); the six edges (the line segments $[0, e_i]$, $[e_1, e_2]$, $[e_2, e_3]$, $[e_3, e_1]$); and the four vertices $\{0\}$, $\{e_i\}$.

Faces of a convex set K that are single points $\{z\}$ are called *extreme points* of K.

Theorem (Minkowski). A convex body in $\mathbb{R}^n$ is the convex hull of its extreme points.

There is an infinite dimensional extension of this theorem due to Krein and Milman which states that each compact convex set in a normed linear space is the closed convex hull of its extreme points.

A face of a convex set that is a ray is called an *extreme ray*. Another generalization of Minkowski's theorem is that any closed convex set that contains no lines is the convex hull of its extreme points and extreme rays.

The set of extreme points of a compact set need not be closed. This is shown by the following example.

Example. In $\mathbb{R}^3$ let K be the convex hull of the circle $\{x : \xi_1^2 + \xi_2^2 = 1\}$ and the points $(1, 0, 1)$ and $(1, 0, -1)$. K looks like a double slanted cone. The extreme points are $(1, 0, 1)$, $(1, 0, -1)$, and all the points of the circle except $(1, 0, 0)$.

The next way to describe a convex set is to first suppose that the origin is an interior point of the set. This effectively means that the set has interior points because one can always either translate the set or choose the origin appropriately. Then one describes the set by saying how far in any direction the boundary is from the origin.

Definition. If K is a convex set with 0 as an interior point, then the *radial function* of K, $r_K(x)$, is defined by:

$$r_K(x) := \sup\{\lambda : \lambda x \in K\}.$$

A slight variant of this is to say how much K has to be dilated to contain a given vector.

Definition. If K is a convex set with 0 as an interior point, then the *gauge function* (or Minkowski functional) of K, $g_K(x)$, is defined by:

$$g_K(x) := \inf\{\lambda \geq 0 : x \in \lambda K\}.$$

It is evident that $1/r_K(x) = g_K(x)$ (with $1/\infty = 0$ if K is unbounded). The function g_K has the advantage of being both homogeneous and subadditive (i.e., sublinear). If K is bounded, then the radial function is finite for all $x \neq 0$ and the gauge function is non-zero for $x \neq 0$. If, in addition, K is symmetric about the origin so that $g_K(-x) = g_K(x)$, then the gauge function has the properties of a norm. This leads to the use of convexity in the study of normed spaces.

If K is closed, it is described as $K = \{x : g_K(x) \leq 1\}$. The boundary of K (denoted by ∂K) is the set of points for which $g_K(x) = r_K(x) = 1$.

Instead of thinking of the boundary of K as a set of points, we may also regard it as an envelope of half-spaces (in the same way that a polytope was described as a finite intersection of half-spaces).

Definition. A hyperplane H_f^α is said to be a *support hyperplane* for a convex body K if (1) $K \cap H_f^\alpha \neq \emptyset$, and (2) K is contained in one of the half-spaces $H_f^{\alpha+}$, $H_f^{\alpha-}$.

If K is a convex body, if f is a linear functional, and if $\alpha := \max\{f(x) : x \in K\}$, then H_f^α is a support hyperplane of K. This leads to the idea of the support function of K.

Definition. If K is a closed convex set then the *support function* of K, $h_K(f)$, is defined by:

$$h_K(f) := \sup\{f(x) : x \in K\}.$$

The support function is a sublinear function. If K is bounded, then h_K is finite for all x and we may replace sup by max. If $0 \in K$, then h_K is non-negative, and if 0 is an interior point, then h_K is strictly positive. If K is symmetric, then h_K is a norm on the dual space. There are generalizations of this idea to infinite dimensional spaces, but there

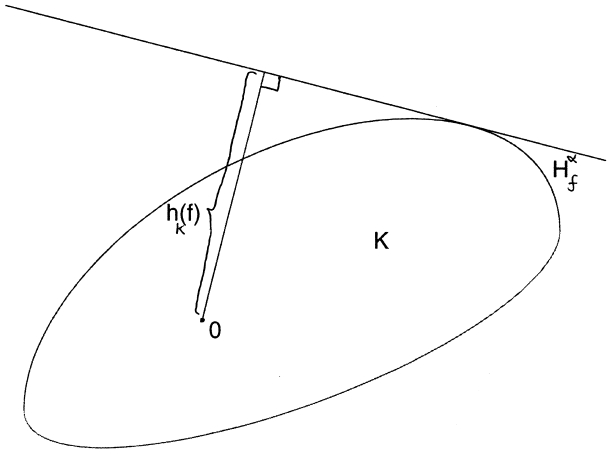

FIGURE 4

the dual space has a slightly different connotation—one must restrict attention to continuous linear functionals.

Most books on convexity that restrict attention to finite dimensional spaces identify the dual space $(\mathbb{R}^n)^*$ with $\mathbb{R}^n$ by means of the inner product. By that we mean that for each linear functional f there is a vector y_f such that $f(x) = \langle y_f, x\rangle$ where the symbol $\langle\,.\,,\,.\,\rangle$ denotes the inner product. In this case, the definition of support function is given in terms of the inner product.

To interpret the support function geometrically, we restrict our attention to linear functionals f with length 1. In this special case, the α that appears in the equation of the hyperplane:

$$f(x) = \alpha$$

represents the perpendicular distance from the origin to the hyperplane. Therefore, the support function (restricted to linear functions of length 1) represents the perpendicular distance from the origin to the supporting hyperplane of K that is in the direction f (see Fig. 4).

The following theorems are important.

Theorem. If f is a sublinear functional on $\mathbb{R}^n$, then there is a convex body K such that $f = h_K$.

Theorem. If K is a non-empty convex body, then $K = \{x : f(x) \le h_K(f)$ for all linear functionals $f\}$.

The proof of the second theorem requires the separation theorem from Section VII. There are a variety of proofs of the first theorem (see Schneider[4]).

V. NEW CONVEX SETS FROM OLD

A. The Convex Hull

We begin this section with a second look at the operation of the convex hull, the intersection of all convex sets containing A. Rather than cut down to the convex hull from outside the set, we may also build up the convex hull from inside.

If $x_1, x_2, \ldots, x_k$ is a finite set of vectors, then y is said to be a *convex combination* of these vectors if:

$$y = \lambda_1 x_1 + \lambda_2 x_2 + \cdots + \lambda_k x_k \text{ with } \lambda_i \ge 1 \text{ and } \sum \lambda_i = 1.$$

The definition of convexity uses only two points but, by induction, one shows that if K is convex then every convex combination of points in K is also in K. If A is not convex, every convex combination of points from A is in co$A$. Finally, one shows that the set of all convex combinations of points from A is a convex set. Therefore, co$A$ is precisely the set of all convex combinations of points from A.

Note that k, the length of the convex combination, is arbitrary but Carathéodory's Theorem in Section VII shows that in finite dimensional spaces this is really not so.

Theorem. The convex hull of a compact set is compact and of an open set is open.

Theorem. If A is a non-empty bounded set in $\mathbb{R}^n$, then the diameter of co$A$ is the same as the diameter of A. (Here, "diameter" means the supremum of the distances between points of A.)

A nice application of the ideas here is the Gauss-Lucas Theorem. A short and elegant proof can be found in Webster.[5]

Theorem. If $p(z)$ is a non-constant polynomial, then the roots of $p'(z)$ (the derivative of p) are contained in the convex hull of the roots of $p(z)$.

B. The Polar of a Convex Set

By definition, the convex hull operator assigns to each set a convex set. The next very important operation does the same thing.

Definition. If A is a non-empty subset of X, then the *polar* of A, denoted by A° (or A^*), is defined by:

$$A^\circ := \{f \in X^* : f(x) \le 1 \text{ for all } x \in A\}.$$

If $A \subseteq X$, then $A^\circ \subseteq X^*$. Often, the distinction between X and X^* is obscured and the inner product is used in the definition of A°. Similarly, for a non-empty set B in X^* we have:

$$B^\circ := \{x \in X : f(x) \le 1 \text{ for all } f \in B\}.$$

Repeated applications of this operation are indicated without parentheses, thus $A^{\circ\circ}$, $B^{\circ\circ}$, and so on. For all sets A (in either X or X^*) we have $A \subseteq A^{\circ\circ}$. The operation

reverses inclusions: If $A_1 \subseteq A_2$, then $A_2^\circ \subseteq A_1^\circ$. It follows that $A^\circ = A^{\circ\circ\circ}$ always.

The definition of B° reveals it to be an intersection of closed half-spaces so it is always a closed, convex set in X that contains 0. The same holds for A° in X^*. If $A = \{0\}$, then $A^\circ = X^*$ and $X^\circ = \{0\}$. If A is a single point other than 0, then A° is a half-space. Thus, the duality between points and half-spaces (encountered in Section IV) is implemented by this operation. However, if A is a half-space, then A° is not a singleton but a line segment joining the expected point to 0. Because A° is always a closed, convex set containing the origin, in order to get an exact duality we must restrict attention to this class of sets.

Theorem. If K is a closed, convex set with $0 \in K$, then $K = K^{\circ\circ}$.

This is a most important theorem whose proof relies on the separation theorem in Section VII. For an arbitrary set A, $A^{\circ\circ}$ is the closed convex hull of A and 0.

On the collection of closed convex sets that contain 0, the polar mapping is one to one and maps this collection onto the corresponding collection in X^*. If 0 is an interior point of K, then K° is compact. If K is compact, then K° has 0 as an interior point. Thus, the polar operation also maps the class of compact convex sets with 0 as an interior point onto the same class in X^*. If K is also symmetric about 0, then so is K°. In this last case, K plays the role of the unit ball in a normed space and K° is the dual ball in the dual space X^*.

Examples. If B is the unit ball in X, then B° is the unit ball in X^*.

If C_n is the standard cube in $\mathbb{R}^n$, then C_n° is the standard cross-polytope and conversely.

If S_n is the standard simplex, then S_n° is the following unbounded set. If $f = (\phi_1, \phi_2, \ldots, \phi_n)$, then $f \in S_n^\circ$ if and only if $\phi_i \leq 1$ for all i.

Finally, this duality also connects the gauge (and radial function) of K with the support function of K°.

Theorem. If K is a convex body with 0 as an interior point, then the gauge function of K° is the support function of K, and the gauge function of K is the support function of K°.

Since the radial function is the reciprocal of the gauge function, this is readily rewritten using the radial functions.

C. The Collection of Convex Sets as a Lattice

The intersection of two convex sets is again a (possibly empty) convex set. It is the largest convex set contained in both of them. The union of two convex sets need not be convex, but the convex hull of the union is the smallest convex set that contains both of them. Therefore, we define the following binary operations:

$$K_1 \wedge K_2 := K_1 \cap K_2$$

$$K_1 \vee K_2 := \mathrm{co}(K_1 \cup K_2).$$

With these operations, the collection of convex sets is a *lattice*. The underlying order relation is that of inclusion.

There are two important sublattices: the collection of closed convex sets that contain 0 and the collection of compact convex sets with 0 as an interior point. On each of these sublattices, the polar map is a bijection that reverses inclusion and hence reverses the lattice operations:

$$(K_1 \wedge K_2)^\circ = (K_1 \cap K_2)^\circ = K_1^\circ \vee K_2^\circ = \mathrm{co}\left(K_1^\circ \cup K_2^\circ\right)$$

$$(K_1 \vee K_2)^\circ = (\mathrm{co}(K_1 \cup K_2))^\circ = K_1^\circ \wedge K_2^\circ = K_1^\circ \cap K_2^\circ.$$

D. Algebraic Operations on Convex Sets

In addition to the operations just discussed, vector operations can be performed on the collection of convex sets. These are done "elementwise."

Definition. If K_1 and K_2 are convex sets in a vector space X and λ is a non-negative scalar, then:

$$K_1 + K_2 := \{x : x = x_1 + x_2 \text{ with } x_i \in K_i\}$$

and

$$\lambda K_1 := \{\lambda x : x \in K_1\}.$$

The reason for the restriction to $\lambda \geq 0$ is twofold. First, although we may define $(-1)K$, it may be (if K is symmetric) that $(-1)K = K$. Furthermore, the distributive law:

$$(\lambda + \mu)K = \lambda K + \mu K$$

only holds generally if $\lambda, \mu \geq 0$. Hence, there is no such thing as $K + (-1)K = \{0\}$. With the restriction to non-negative scalars, all the usual algebraic identities are valid. Despite this, we shall occasionally have need to talk about $-K := (-1)K$ below. Any non-negative linear combination of convex sets is again convex. This is the basis of what is called the *Brunn-Minkowski Theory* of convex sets (see Schneider[4]).

Examples. The sum of a convex set K with a single point $\{x_0\}$ is the same as the translation of K by x_0. In general, $K + L$ is the union of translates of K by points in L (or vice versa). Hence, one way to think of this operation is to visualize one of the convex sets K with its boundary ∂K and the other one L with the origin as a reference point somewhere in L. First translate L so that the reference point lies on ∂K and then slide L round K (just

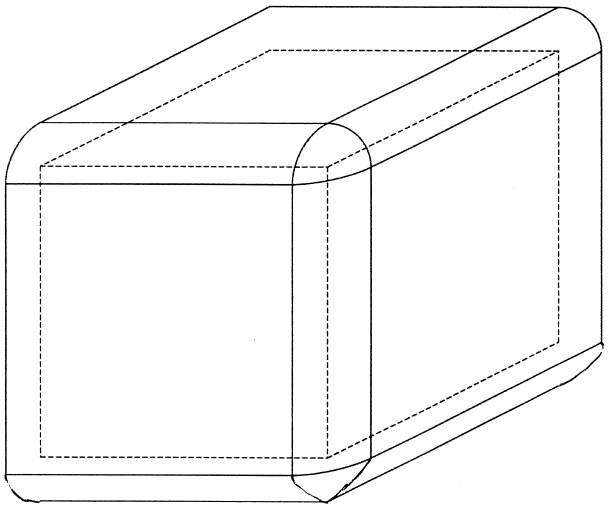

FIGURE 5

by translation) so that the reference point stays on ∂K and eventually has traversed all of it. The convex body swept out in this process is $K + L$.

In $\mathbb{R}^2$, the sum of the line segments $[-e_1, e_1]$ and $[-e_2, e_2]$ is the square C_2. If, in $\mathbb{R}^3$, we now add the line segment $[-e_3, e_3]$, we get the standard cube in $\mathbb{R}^3$. In general, the cube C_n is the sum of the line segments $[-e_i, e_i]$ for $i = 1, 2, \ldots, n$.

In $\mathbb{R}^2$, if we add the line segment $[(-1, -1),\ (1, 1)]$ to the square C_2 we get a hexagon with vertices at $(2, 0),\ (2, 2),\ (0, 2)$ and their negatives.

The sum of a finite number of line segments is a special type of polytope called a *zonotope*. These have a number of significant properties (see Section X). The sum of the cube C_3 and a multiple λB of the unit ball is shown in Fig. 5.

One of the reasons that the support function is so important is that it behaves well for these operations:

$$h_{K_1+K_2} = h_{K_1} + h_{K_2} \text{ and } h_{\lambda K} = \lambda h_K.$$

For the gauge and radial functions, we have:

$$g_{\lambda K} = \lambda^{-1} g_K \text{ and } r_{\lambda K} = \lambda r_K.$$

For the polar operation, likewise:

$$(\lambda K)^\circ = \lambda^{-1}(K^\circ).$$

Finally, these operations can be defined for arbitrary sets, and then the convex hull operation is also well behaved:

$$\text{co}(A + B) = \text{co}(A) + \text{co}(B) \text{ and } \text{co}\lambda A = \lambda \text{co}(A).$$

E. Operations that Increase Dimension

So far we have been concerned with operations that take place within one fixed vector space X or from that space to its dual X^*. We now consider two vector spaces X and Y and their Cartesian product $X \times Y$, which has dimension equal to the sum of the dimensions of X and Y (assuming all are finite dimensional). There is a natural embedding of X into $X \times Y$ that sends a vector x to $(x, 0)$ and similarly for Y. Then $X \times Y$ is the direct sum of these embedded spaces.

If K is a convex set in X and L is one in Y, then $K \times L$ (the Cartesian product) is a convex set in $X \times Y$. However, if we apply the embedding maps to K and L so that both can be thought of as lying in $X \times Y$, then $K \times L = K + L$.

In this sense, the cube C_n can be thought of either as a sum of line segments (as above) or as the Cartesian product of the interval $[-1, 1]$ with itself n times.

Examples. The product of the unit ball in $\mathbb{R}^2$ and the interval $[-1, 1]$ in $\mathbb{R}$ is the standard circular cylinder in $\mathbb{R}^3$. Likewise, the product of any convex set K with a line segment is a cylinder. In the case when K is a polytope, the word "prism" is often used instead of cylinder.

Another operation that can be performed on K and L as above is the suspension operation. As just indicated, we may think of both K and L as embedded in $X \times Y$ and then $K * L$, the suspension of K and L, is defined to be $\text{co}(K \cup L) = K \vee L$.

Example. The standard cross-polytope is built up from the interval $[-1, 1]$ by repeated suspension operations.

If we are careful to interpret the polar operations in the appropriate spaces, we then get:

$$(K + L)^\circ = K^\circ * L^\circ \text{ and } (K * L)^\circ = K^\circ + L^\circ.$$

F. Symmetrizing Operations

The question of symmetry is an important one. A convex set is said to be *symmetric* about the origin if $K = -K$. It is often useful to operate on a convex set in such a way as to make it more symmetrical. For example, to prove certain inequalities where some quantity is maximized by a ball, one may be able to show that the quantity increases under a symmetrizing operation.

The first of these is quite simple. We define the *difference set* of K to be the convex set $D(K) := K - K := K + (-1)K$. The set $D(K)$ is always symmetric about 0. One readily checks that the support function of $-K$ is given by $h_{-K}(f) = h_K(-f)$, hence $h_{D(K)}(f) = h_K(f) + h_K(-f)$. For linear functionals f of norm 1, this last quantity is defined to be the *width* of K in the direction f and is denoted by $w_K(f)$. It represents the distance between parallel supporting hyperplanes with normal direction f (see Fig. 6).

A set is said to be of constant width if $w_K(f)$ is constant for all f with $\|f\| = 1$; that is, if $h_{D(K)}$ (restricted to those f with $\|f\| = 1$) is constant, which is so if and only if $D(K) = B$. We shall say more about these sets in Section X. For now, note that the only convex set of constant width that is symmetric about 0 is the ball.

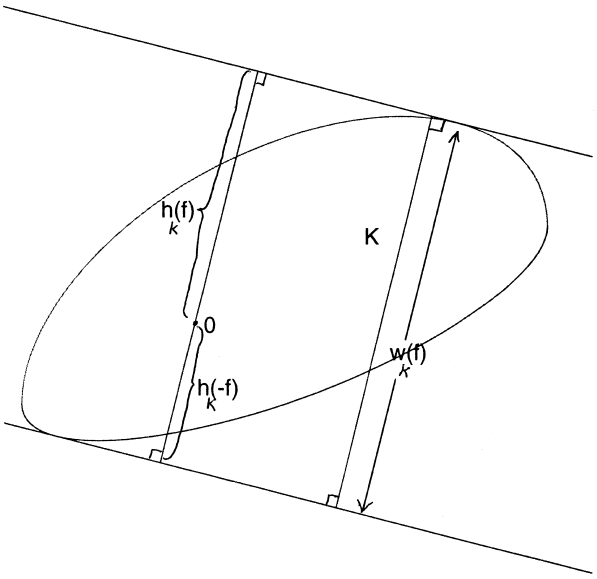

FIGURE 6

Examples. From some points of view, the most asymmetric convex set is the standard simplex. The difference body is rather regular. The difference body of the standard two-simplex S_2 is an affine regular hexagon and that of S_3 is an affine regular cuboctahedron (see Fig. 7).

The most well-known and simplest example of a non-symmetric set of constant width is the Reuleaux triangle (see Section X for a definition of this set; see Fig. 8 for a representation of it.)

The second symmetrizing operation is more complicated and requires an inner product and hence a notion of orthogonality. It is due to Jakob Steiner, is called *Steiner symmetrization*, and deals with symmetry with respect to a hyperplane.

Let K be a compact convex set in X. We wish to symmetrize K with respect to a hyperplane H in X. For each point $x \in H$ let $\ell(x)$ denote the line through x orthogonal to H. The intersection $\ell(x) \cap K$ is a line segment, a point, or is empty. If it is a line segment, let $S(x)$ be the translation of $\ell(x) \cap K$ whose midpoint is at x; if the intersection is a point, then $S(x) = x$, otherwise, $S(x)$ is empty. The Steiner symmetral of K with respect to H, $S_H(K)$, is defined by the equation $S_H(K) := \cup S(x)$.

It turns out that $S_H(K)$ is convex. If K has interior, then so does $S_H(K)$. If K and L are compact convex sets, then $S_H(K) + S_H(L) \subseteq S_H(K + L)$. The most important property of this symmetrization is that, given any convex body K, one may, by symmetrizing successively with a suitable sequence of hyperplanes, obtain a convex body that approximates a ball to within any degree of accuracy. Although we have not defined these measures, we also point out here that Steiner symmetrization leaves volume unchanged and does not increase either the surface area or the diameter of the set.

The third such operation is similar but reverses the roles of line and hyperplane. If ℓ is a line, for each point $x \in \ell$ let $H(x)$ be the hyperplane through x orthogonal to ℓ. If $H(x) \cap K \neq \emptyset$, let $B(x)$ be the $(n-1)$-dimensional ball centered at x and lying in $H(x)$ whose $(n-1)$-dimensional volume (see Section VIII) is the same as that of $H(x) \cap K$. Let $S_\ell(K) := \cup B(x)$. This object is also convex. It is called the *Schwarz symmetral* of K.

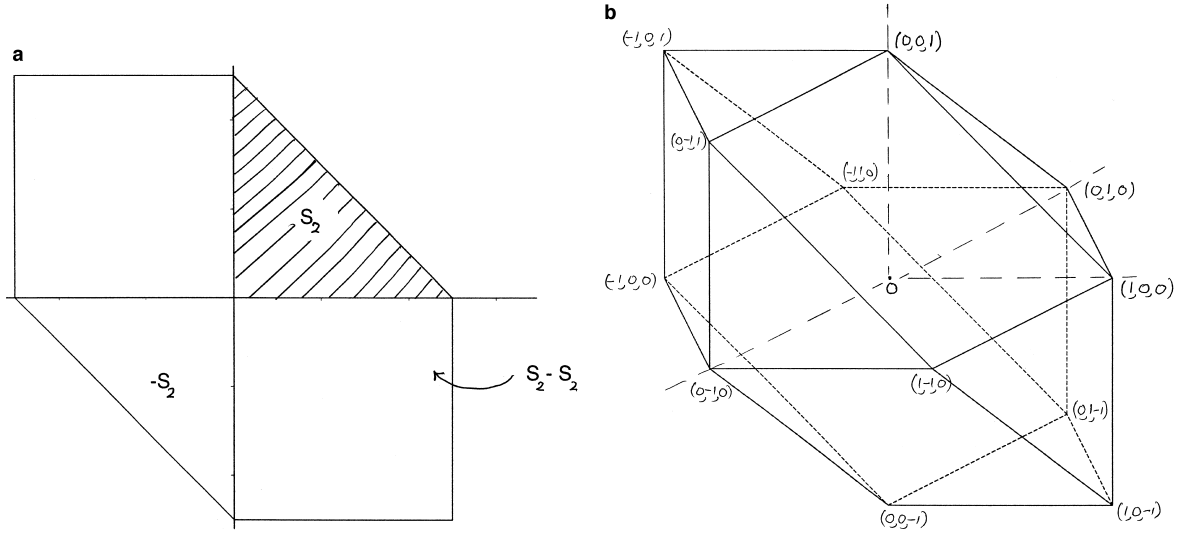

FIGURE 7

G. Other Operations

Two more ways to get new convex sets from old ones ought to be mentioned. The first is the projection body operator Π. There are several ways to define this operation; the simplest way is to use orthogonal projections. If K is a convex body in X, for each unit vector u in X consider the projection of K onto the hyperplane H_u orthogonal to u. This projection is the set $p_u(K)$ consisting of those points $x \in H_u$ such that the line $x + \lambda u$ has a non-empty intersection with K. Now let $h(u)$ be the $(n-1)$-dimensional volume (see Section VIII) of $p_u(K)$. It turns out that this function is subadditive. If it is extended to all of X by (positive) homogeneity, then it is sublinear and hence is the support function of a convex body in X^* called the *projection body* of K, $\Pi(K)$.

This is a most interesting object. It is always symmetric with respect to the origin. If K is a polytope, then $\Pi(K)$ is not just a polytope but is a zonotope (a sum of line segments) which has all of its faces centrally symmetric.

Examples. The construction (explained in Section X) of projection bodies of polytopes is relatively easy. The projection body of C_3 is (up to a scaling) C_3 itself. The projection body of $\mathcal{O}_3$ is a rhombic dodecahedron. This object has eight vertices that coincide with those of C_3 and six that are at $\pm 2e_1, \pm 2e_2, \pm 2e_3$. It has 12 facets that are all alike and are rhombi, hence the name.

The second operation is (in some not entirely clear way) a dual construction to Π. We begin with a convex body K such that $0 \in K$. Let f be a norm 1 linear functional in X^*. Let H_f be the hyperplane that is the kernel of f. Let $i_f(K) := K \cap H_f$ and let $r(f)$ be the $(n-1)$-dimensional volume (see Section VIII) of $i_f(K)$. Now let $I(K)$ be the set in X^* consisting of all the line segments $[0, r(f)f]$. In other words, by again extending r, we make it the radial function of $I(K)$. It is an important theorem (whose proof is difficult) of Busemann that if K is symmetric about 0 then $I(K)$ is convex. It is called the *intersection body* of K. For more general convex sets, $I(K)$ is star shaped. Lutwak has shown that the "proper" setting for this operation is the class of star-shaped sets.

VI. SPACES OF CONVEX SETS

In the last section, various operations on the collection of all convex sets were considered. With the algebraic operations of addition and multiplication by (non-negative) scalars, the collection of convex sets has many of the attributes of a vector space. In this section, we show that the collection of compact convex sets is also a metric space. In fact, there are two metrics that can be considered. One is defined on all compact convex sets in a given vector space regardless of their dimension. The second distinguishes between points, line-segments, two-dimensional convex sets, and so on.

A. The Hausdorff Metric

If K and L are two compact convex sets, then they are bounded. Hence, there exist non-negative scalars λ, μ such that:

$$K \subseteq L + \lambda B \text{ and } L \subseteq K + \mu B.$$

Now let λ_0 be the infimum (in fact, the minimum) of all such λ's and similarly for μ_0. The numbers λ_0 and μ_0 may also be defined directly in terms of the norm (or distance) on X by:

$$\lambda_0 = \min_{x \in L} \max_{y \in K} \|x - y\|$$

and similarly for μ_0.

Definition. The *Hausdorff metric* δ on the set of compact convex sets is defined by the equation:

$$\delta(K, L) := \max\{\lambda_0, \mu_0\}.$$

Theorem. The function δ is a metric on the set of all compact convex sets in X.

If the support functions of convex sets are restricted to the unit ball in X^*, then the support function of a multiple λB of the unit ball is just the constant λ; hence, $K \subseteq (L + \lambda B)$ if and only if $h_K \leq h_L + \lambda$, which implies that the Hausdorff metric between the sets is the same as the uniform metric between the support functions. All the operations discussed in the previous section are continuous with respect to this metric as are several important functions that are defined in later sections.

The most important fact about this metric is a compactness result, known as the *Blaschke selection theorem* (the name refers to the selection of a convergent subsequence from a given bounded sequence).

Theorem (Blaschke). The set of compact convex sets contained in some ball $B[x, r]$ and equipped with the Hausdorff metric is compact.

Various collections of convex sets, for example the collection of all ellipsoids, form closed subsets in this metric. Therefore, a bounded sequence of ellipsoids has a subsequence that converges to another ellipsoid (provided we allow degenerate cases such as points and line segments).

Other important classes are dense in this metric. For example, the collection of all polytopes is dense. Therefore, any convex body can be approximated as closely as we please (with respect to the Hausdorff metric) by a polytope. This, together with the continuity of various functions, means that the proof of a theorem can often be

accomplished by first proving the result for polytopes and then extending it to all convex bodies "by continuity."

A convex set is said to be strictly convex if its boundary does not contain any line segment (of positive length). A convex set is said to be smooth if there is a unique supporting hyperplane at each point of its boundary. The sets of smooth, of strictly convex, and of both smooth and strictly convex bodies are all dense in the set of all convex bodies.

B. The Banach-Mazur Metric

It is sometimes appropriate to consider that convex sets of different dimension are infinitely far apart. This section is concerned with metrics of this sort. We limit our attention to convex bodies with 0 as an interior point.

If K and L are two convex bodies with 0 in their interiors, then there are scalars λ and μ such that:

$$K \subseteq \lambda L \text{ and } L \subseteq \mu K.$$

As before, we can now take λ_0 and μ_0 to be the minimal such λ and μ. Then set $\Phi(K, L) := \lambda_0\mu_0$. The fundamental result is now John's Theorem.

Theorem (John). If K is a centrally symmetric convex body in an n-dimensional space X and if 0 is an interior point of K, then there is an ellipsoid E such that:

$$E \subseteq K \subseteq \sqrt{n}E$$

The standard cube C_n and cross polytope $\mathcal{O}_n$ show that $\sqrt{n}$ cannot be improved. If we remove the condition that K be centrally symmetric, then we must replace $\sqrt{n}$ by n. This bound is attained by the simplex S_n.

The ellipsoid E that appears in this result is of considerable interest. It is the ellipsoid of maximal volume contained in K and is called the *Löwner-John ellipsoid*. It occurs in linear and nonlinear programming in Khachiyan's polynomial time algorithm and in Schor's algorithm.

The functional Φ is not a metric for two reasons. First, the construction is multiplicative rather than additive; e.g., $\Phi(K, K) = 1$ rather than 0. If we want a genuine metric we must take the logarithm of Φ. Since not all authors do so, one should be careful when reading the literature to see the precise definition.

Second, $\log(\Phi(K, \alpha K)) = 0$; Therefore, one should consider equivalence classes of multiples of K. However, it is more appropriate to enlarge the equivalence classes and say that the sets K_1 and K_2 are equivalent if there is an invertible linear map T such that $T(K_1) = K_2$. Finally, the definition of the Banach-Mazur metric is $\Delta(K, L) := \inf\{\log[\Phi(K, T(L))] : T \text{ is an invertible linear map}\}$.

An infimum is used here because it is also a useful definition in the case of infinite dimensional spaces. Restricted to the finite dimensional case, the infimum is attained. The functional Δ is a metric on the equivalence classes of convex sets under the above equivalence relation. If we consider the norms generated by K and L, then the equivalence relation is one of isometry between normed spaces and Δ measures the distance between equivalence classes of normed spaces.

John's Theorem now says that the distance between the equivalence class containing K and the set of ellipsoids (which is the equivalence class containing B) is no more than $(\log n)/2$. Hence, the distance between any two equivalence classes is no more than $\log n$. If we allow non-symmetric sets, then these numbers are doubled. It is surprising that the exact diameter of these metric spaces is only known in the case of two dimensions.

VII. BASIC THEOREMS

A. Separation and Support Theorems

The notion of separation involves placing a hyperplane between two convex sets. There are varying degrees of separation that can be considered.

Definition. A hyperplane $H = H_f^\alpha$ is said to *separate* the convex sets K and L if K lies in one of the closed half-spaces determined by H, and L lies in the other. The separation is *proper* if it is not the case that both sets lie in H. The separation is *strict* if one can replace "closed" by "open" in the first sentence. Finally, the separation is *strong* if there exist α and β with $\alpha < \beta$ and $K \subseteq H_f^{\alpha-}$ and $L \subseteq H_f^{\beta+}$ (or vice versa).

Separation Theorem. Let K be a convex set in $\mathbb{R}^n$ and suppose x is not in K, then K and x can be separated. If K is closed, then K and x can be strongly separated.

It follows from the second statement that every closed convex set can be represented as an intersection of closed half-spaces. It follows from the first statement that if K has a non-empty interior then at each point x of the boundary of K there is a supporting hyperplane obtained by separating x from the interior of K.

There is a converse to this theorem. If A is a closed set with a non-empty interior and if, at each boundary point, there is a supporting hyperplane, then A is convex.

The separation theorem can be generalized to the following: If K and L are two convex sets whose relative interiors are disjoint, then K and L can be separated. If one set is closed and the other is compact, then the separation is strong.

The proof of the seemingly more general statement follows from the earlier one because K and L can be (strongly) separated if and only if $K - L$ and $\{0\}$ can be (strongly) separated. Also, if one set is compact and the other closed, then $K - L$ is closed. This is *not* true in general for two closed sets.

Example. In $\mathbb{R}^2$ the sets $K := \{(x, y) : y = 0\}$ and $L := \{(x, y) : x \geq 0 \text{ and } y \geq 1/x\}$ are both closed and convex. They cannot be strongly (or even strictly) separated, and the set $K - L$ is open.

These theorems have very important analogs in infinite dimensional spaces. In that setting, they are all consequences of the Hahn-Banach Theorem, which is one of the most important theorems of functional analysis.

B. Carathéodory's Theorem and Its Relatives

The following theorems are all closely related, but the Carathéodory result appears the most fundamental.

Theorem (Carathéodory). If A is a subset of an n-dimensional space and if $x \in \text{co}A$, then x can be expressed as a convex combination of $(n + 1)$ or fewer points.

Other ways of phrasing the conclusion is to say that x is a convex combination of a set of points in general position. Another is to say that x lies in a simplex whose vertices are in A. Thus, when constructing the convex hull, the length of the convex combinations needed is bounded (in finite dimensional spaces).

Theorem (Radon). If a finite set F of points in an n-dimensional space is *not* in general position, then it may be decomposed into two disjoint subsets F_1 and F_2 such that $\text{co}(F) \cap \text{co}(G) \neq \emptyset$.

In particular, this is true of any set of at least $(n + 2)$ points.

Theorem (Helly). Let $K_1, K_2, \ldots, K_m$ be a finite family of convex sets in an n-dimensional space ($m \geq n + 1$). If every subfamily with exactly $(n + 1)$ members has a non-empty intersection, then the whole family has a non-empty intersection.

Eggleston[1] shows how Helly's Theorem can be derived from Carathéodory's and conversely.

Since any family of compact sets has a non-empty intersection if every finite subfamily does, there is an easy extension to infinite families of compact convex sets. If an arbitrary family of compact convex sets in an n-dimensional space is such that every subfamily with $(n + 1)$ members has a non-empty intersection, then so does the whole family. A transversal for a family of sets is a line that meets every member of the family.

Corollary. If $\mathcal{F}$ is a finite family of parallel line segments in $\mathbb{R}^2$ such that every three of them has a transversal, then the whole family has a transversal.

Corollary. Let $\mathcal{F}$ be a finite family of convex sets in $\mathbb{R}^n$ and let K be a convex set. If for every finite subfamily with $(n + 1)$ elements there is a translate of K that intersects each member of the subfamily, then there is a single translate of K which intersects every member of the whole family.

Theorem (Kirchberger). Let F_1 and F_2 be finite sets in an n-dimensional space such that $F_1 \cup F_2$ has at least $(n + 2)$ elements. Suppose that for every subset F of $F_1 \cup F_2$ with exactly $(n + 2)$ points the sets $F \cap F_1$ and $F \cap F_2$ can be strictly separated, then F_1 and F_2 can be strictly separated.

Webster[5] gives an elegant proof of Jung's theorem also based on Helly's theorem.

Theorem (Jung). Every set A in $\mathbb{R}^n$ with diameter 1 is contained in a closed ball of radius no more than $\sqrt{n/(2n + 2)}$.

Finally, we give Krasnosel'skiĭ's Theorem (sometimes called the "Art Gallery" Theorem).

Theorem (Krasnosel'skiĭ). Let A be a compact subset of $\mathbb{R}^n$. If, for every $(n + 1)$ points, $a_1, a_2, \ldots, a_{n+1}$ of A there is a point x of A such that the line segments $[x, a_i]$ all lie in A, then A is star shaped.

In other words, in an art gallery, if for every finite set of $(n + 1)$ pictures there is a point in the gallery from which one can see all $(n + 1)$, then there is a point from which one can see the whole art gallery.

All of these theorems have been much generalized. For one collection of such results, see the article by J. Eckhoff in the *Handbook of Convex Geometry*.[2]

VIII. VOLUMES AND MIXED VOLUMES

For many of the more interesting properties of convex sets it is necessary to measure them in some way. Such measurement requires more advanced ideas than were presented in Section I. The basic concept is that of volume in an n-dimensional space. There are several approaches which coincide for compact convex sets but may not for more general types of sets.

The most straightforward approach is Eggleston's,[1] which says that the volume of a convex set in $\mathbb{R}^n$ is its n-dimensional Lebesgue measure. The volume of a set in $\mathbb{R}^n$ will be denoted by $V_n(K)$. One-dimensional volume is usually called *length*, and V_2 is usually called *area*. In

n-dimensional space, V_{n-1} is also frequently referred to as area. No confusion should arise.

The volume functional takes values in the extended real numbers and has a number of very important properties:

1. It is non-negative—$V_n(K) \geq 0$ for all convex sets K in $\mathbb{R}^n$—and is strictly positive if K has a non-empty interior (has dimension n).
2. It is countably additive, in the sense that, if $\{K_m: m = 1, 2, \ldots, \}$ is a sequence of disjoint convex sets, then $V_n(\cup_m K_m) = \sum_m V_n(K_m)$.
3. It is finite for compact sets; $V_n(K) < \infty$ if $K \subseteq \mathbb{R}^n$ is compact.
4. It is continuous with respect to the Hausdorff metric.
5. It is monotonic; if $K \subseteq L$, then $V_n(K) \leq V_n(L)$ (this follows from (property 2)).
6. It is translation invariant; $V_n(K + x) = V_n(K)$.
7. For linear transformations T, it has the property that $V_n(T(K)) = \det T\ V_n(K)$.
   In particular:
8. $V_n(\lambda K) = \lambda^n V_n(K)$ and also V_n is invariant under rigid motions.

The important fact from the theory of Haar measure is that, up to a scalar factor, there is only one functional that has properties 1, 2, 3, and 6.

However, if we relax property 2 a little, then a number of important functions are relevant to the theory of convex sets.

A real-valued function v defined on a collection of sets $\mathcal{S}$ is said to be a valuation if:

$$v(K \cup L) + v(K \cap L) = v(K) + v(L)$$

whenever $K,\ L,\ K \cup L$, and $K \cap L$ are all in $\mathcal{S}$.

It follows that for finitely many disjoint sets, a valuation is additive, hence, if its values are non-negative, it is monotonic. Volume is a valuation.

The n-dimensional volume of a convex set may be calculated by integrating the $(n-1)$-dimensional volumes of its cross sections in some particular direction. Thus, if f is a linear functional and if K is a convex set and if we let $K_\alpha := K \cap H_f^\alpha$, then:

$$V_n(K) = \int_{-\infty}^{\infty} V_{n-1}(K_\alpha) d\alpha.$$

Examples. The above formula can be used inductively to prove that:

$$V_n(B) = \frac{\pi^{n/2}}{\Gamma(1 + n/2)}.$$

This number is abbreviated ϵ_n (many authors use κ_n).

There is a more general formula for the n-dimensional p-ball $B(p)$:

$$V_n(B(p)) = \frac{2^n \Gamma(1 + 1/p)^n}{\Gamma(1 + n/p)}.$$

The volume of the standard cube C_n is $V_n(C_n) = 2^n$.

The volume of the standard simplex S_n is $V_n(S_n) = 1/n!$.

The volume of the standard cross-polytope $\mathcal{O}_n$ is $V_n(\mathcal{O}_n) = 2^n/n!$.

If K is a convex set such that $K \subseteq H_f^\alpha$ with $\alpha \neq 0$ and $\| f \| = 1$, then the pyramid with vertex at 0 and base K is the convex hull of K and 0. The volume of this pyramid is $\alpha V_{n-1}(K)/n$.

The previous formula can be generalized. If P is a polytope with 0 as an interior point and if $F_i,\ i = 1, 2, \ldots, m$, denote the facets of P and if α_i is the perpendicular distance from 0 to the hyperplane containing F_i, then $V_n(P) = (1/n) \sum_1^m \alpha_i V_{n-1}(F_i)$.

With a notion of surface area, this can be further generalized to arbitrary convex sets:

$$V_n(K) = \frac{1}{n} \int_{S^{n-1}} h_K(f) d\sigma_K(f)$$

where σ_K is the "surface area measure" induced on the surface of the dual unit ball S^{n-1} by K (see Schneider[4] for details).

Properties (7) and (8) show how V_n behaves for scalar multiples and under linear maps. The basic question, first considered by Brunn and Minkowski toward the end of the 19th century, is how does V_n behave with respect to the addition of sets; i.e., how is property 6 extended from singletons to general convex sets?

To see how this might work, consider the special case of $K + \lambda K$; then:

$$V_n(K + \lambda K) = V_n((1 + \lambda)K) = (1 + \lambda)^n V_n(K)$$
$$= \sum \binom{n}{i} \lambda^i V_n(K);$$

that is, we get a polynomial in λ whose coefficients are multiples of $V_n(K)$. In fact, we always get a polynomial.

Theorem. If K and L are convex bodies, then $V_n(K + \lambda L)$ is a polynomial in λ of degree n whose coefficients are written in the following way:

$$V_n(K + \lambda L) = \sum_0^n \binom{n}{i} V(K, n - i; L, i) \lambda^i.$$

The numbers $V(K, n - i; L, i)$ are called the *mixed volumes* of K and L. The numbers $n - i$ and i are inserted in this notation because the mixed volumes are functions of n variables and here K and L occur $n - i$ times and i times, respectively. Since this is true for a summand with two terms, it can be extended inductively to sums with an arbitrary number of terms. The essential feature

is that the volume of a linear combination $(\sum \lambda_i K_i)$ is a homogeneous polynomial in the λ_i's of degree n whose coefficients are functions of precisely n of the K_i's.

Example. Referring again to Figure 5, one sees that

$$V_3(C_3+\lambda B) = V_3(C_3) + A(C_3)\lambda + (3\pi)L(C_3)\lambda^2 + V_3(B)\lambda^3$$

where $A(C_3)$ is the sum of the areas of the facets of the cube and $L(C_3)$ is the length of an edge of the cube and measures the width of the cube. Thus, in this instance, we have $V(C_3, C_3, C_3) = V_3(C_3)$, $V(C_3, C_3, B) = A(C_3)/3$, $V(C_3, B, B) = \pi L(C_3)$, and $V(B, B, B) = V_3(B)$.

Mixed volumes have the following properties:

1. They are non-negative.
2. They are monotonic in each variable.
3. They are homogeneous (for non-negative scalars) in each variable. Recall that with the notation $V(K, n-i; L, i)$ the variable K occurs $n-i$ times.
4. They are additive in each variable.
5. They are translation invariant (in each variable).
6. They are continuous with respect to the Hausdorff metric.
7. $V(K, K, \ldots, K) = V_n(K)$.

The example shows that mixed volumes of the form $V(K, n-i; B, i)$ are closely related to the geometry of K. For this, the notation is modified.

Definition. The *quermassintegrals* or *cross-sectional measures* or *Minkowski functionals* of K are written $W_i(K)$ and are defined by $W_i(K) := V(K, i; B, n-i)$ (note the change of place of i).

Then, $W_0(K) = V_n(K)$, $W_1(K) = A(K)/n$, and $W_{n-1}(K) = \epsilon_n b(K)/2$, where $A(K)$ is the surface area of K and $b(K)$ is the mean width of K. These last two equations may either be taken as the definition of these quantities or, if they are defined in other ways, then as theorems. Perhaps surprisingly, even $W_n(K)$ has relevance to the set K: $W_n(K) = \epsilon_n \chi(K)$, where $\chi(K)$ is the Euler characteristic of K which (for convex sets) is always 1.

Since W_1 is the coefficient of λ in a certain polynomial, it (and hence $A(K)$) can be obtained via differentiation in the usual way.

Theorem. The surface area $A(K)$ of K is obtained by the formula:

$$A(K) = \lim_{\lambda \to 0} \frac{V_n(K+\lambda B) - V_n(K)}{\lambda}.$$

There are also integral formulas for both $A(K)$ and $b(K)$:

Theorem (Cauchy). If K is a convex body in $\mathbb{R}^n$, then:

$$A(K) = \frac{1}{n\epsilon_n} \int_{S^{n-1}} V_{n-1}(p_u(K)) d\omega(u)$$

where S^{n-1} is the surface of the unit ball, $d\omega$ is surface area measure (Lebesgue measure) on S^{n-1}, u is a unit vector, and $p_u(K)$ is the projection of K onto the subspace orthogonal to u.

Theorem. If K is a convex body in $\mathbb{R}^n$, then:

$$b(K) = \frac{2}{n\epsilon_n} \int_{S^{n-1}} h_K(u) d\omega(u).$$

(This is often taken as the definition of $b(K)$).

There are various relationships between the functionals W_i expressed as integral formulas.

All the functionals W_i are valuations and, in a certain precise sense, these are *all* the valuations.

Theorem (Hadwiger). If v is a valuation on the collection of convex bodies that is invariant under rigid motions and is either continuous or monotonic, then:

$$v(K) = \sum_0^n \alpha_i W_i(K)$$

where the coefficients α_i are real if v is continuous and non-negative if v is monotonic. The first straightforward proof of this theorem was given in 1995 by Dan Klain.

IX. INEQUALITIES

There is a huge variety of inequalities that relate to convex sets in one way or another. We present a brief sample. The reader is referred to the work of Erwin Lutwak and, in particular, his article in the *Handbook of Convex Geometry*.[2] We do not always give the most general result (which may need more notation or definitions); many extensions can be found in Schneider.[4] The word "homothetic" often occurs in the conditions for equality. The sets A and B are homothetic if $A = \lambda B + a$ $(\lambda > 0)$; i.e., A is the image of B under a translation and a (positive) dilation.

We begin with the fact that the nth root of the volume is a concave function.

Theorem (Brunn-Minkowski). If K and L are convex bodies with interior in $\mathbb{R}^n$ and if $0 \le \alpha \le 1$, then:

$$V_n^{1/n}(\alpha K + (1-\alpha)L) \ge \alpha V_n^{1/n}(K) + (1-\alpha)V_n^{1/n}(L)$$

with equality if and only if K and L are homothetic.

Theorem (Minkowski inequality for mixed volumes). If K and L are convex bodies in $\mathbb{R}^n$, then:

$$V(K, n-1; L, 1)^n \geq V_n(K)^{n-1} V_n(L)$$

with equality if and only if K and L are homothetic.

The power of this inequality is shown by the fact that, substituting the unit ball for L, one immediately gets the isoperimetric theorem for convex sets.

Theorem (Isoperimetric). If K is a convex body in $\mathbb{R}^n$ with prescribed volume v, then $A(K) \geq A(B_v)$, where B_v is the dilation of B with volume v. Moreover, equality holds if and only if K is a translate of B_v.

Corollary (Isoperimetric inequality). If K is a convex body in $\mathbb{R}^n$, then:

$$\frac{A(K)^n}{V_n(K)^{n-1}} \geq \frac{A(B)^n}{V_n(B)^{n-1}} = n^n \epsilon_n.$$

Theorem (Urysohn). If K is a convex body in $\mathbb{R}^n$, then:

$$\frac{b(K)^n}{V_n(K)} \geq \frac{b(B)^n}{V_n(B)} = 2^n/\epsilon_n.$$

Since $b(K) \leq D(K)$ (the diameter of K), we get the following corollary.

Corollary (Isodiametric inequality). If K is a convex body in $\mathbb{R}^n$, then:

$$\frac{D(K)^n}{V_n(K)} \geq \frac{D(B)^n}{V_n(B)} = 2^n/\epsilon_n.$$

In the last three inequalities, equality holds if and only if K is a ball.

The next set of inequalities relate the volume functional to the operations given in Section V. However, they are also affine inequalities because the quantities involved are unchanged by affine transformations.

Theorem (Blaschke-Santaló). If K is a convex body in $\mathbb{R}^n$, then:

$$V_n(K) V_n(K^\circ) \leq V_n(B) V_n(B^\circ) = \epsilon_n^2$$

with equality if and only if K is an ellipsoid.

The quantity $V_n(K)V_n(K^\circ)$ is called the *volume product* of K and is an affine invariant. There is a conjecture of Mahler on the lower bound for the volume product. It has been proved for zonoids (the closure, in the Hausdorff metric, of the set of zonotopes).

Theorem (Reisner). If K is a zonoid in $\mathbb{R}^n$, then:

$$V_n(K)V_n(K^\circ) \geq V_n(C_n)V_n(C_n^\circ) = V_n(\mathcal{O}_n)V_n(\mathcal{O}_n^\circ) = 4^n/n!$$

with equality if and only if $K = C_n$ ($\mathcal{O}_n$ is not a zonoid).

Theorem (Rogers-Shephard). If K is a convex body in $\mathbb{R}^n$ then

$$2^n V_n(K) \leq V_n(D(K)) \leq \binom{2n}{n} V_n(K)$$

with equality on the left if and only if K is symmetric and on the right if and only if K is a simplex. (The left-hand inequality is trivial; it is the other one that is due to Rogers and Shephard.)

Theorem (Busemann intersection inequality). If K is a convex body in $\mathbb{R}^n$ with 0 as an interior point, then:

$$\frac{V_n(I(K))}{V_n(K)^{n-1}} \leq \frac{V_n(I(B))}{V_n(B)^{n-1}} = \frac{\epsilon_{n-1}^n}{\epsilon_n^{n-2}}$$

with equality if and only if K is an ellipsoid.

Theorem (Petty projection inequality). If K is a convex body in $\mathbb{R}^n$, then:

$$V_n(K)^{n-1} V_n([\Pi(K)^\circ]) \leq V_n(B)^{n-1} V_n([\Pi(B)^\circ]) = (\epsilon_n/\epsilon_{n-1})^n$$

with equality if and only if K is an ellipsoid.

Here, we insert results dealing with two problems that generated a great deal of research in the latter part of the 20th century: the Busemann-Petty problem and its "dual," the Shephard problem. Both deal with convex bodies symmetric about 0 because otherwise it is easy to give a negative answer to both questions.

Question (Busemann-Petty). If K and L are two centrally symmetric convex bodies in $\mathbb{R}^n$ and if, for every linear functional f, we have:

$$V_{n-1}\big(K \cap H_f^0\big) \leq V_{n-1}\big(L \cap H_f^0\big)$$

does it follow that $V_n(K) \leq V_n(L)$?

The breakthrough on this problem came when Lutwak showed that the answer is "yes" if the body K is an intersection body (in a broader sense than our definition), otherwise, there will be a convex body L yielding a counter example. The work of many authors and finally of Zhang, Gardner, and Koldobsky showed that the answer to the problem is "no" in all dimensions ≥ 5 but that for $n = 2, 3, 4$ the answer is "yes."

Question (Shephard). If K and L are two centrally symmetric convex bodies in $\mathbb{R}^n$ and if, for every direction u, we have:

$$V_{n-1}(p_u(K)) \leq V_{n-1}(p_u(L))$$

does it follow that $V_n(K) \leq V_n(L)$?

Petty and Schneider showed that the answer is "no" in general but "yes" if the body L is a projection body. Since all symmetric convex bodies in $\mathbb{R}^2$ are projection bodies, the answer is "yes" in $\mathbb{R}^2$ but "no" in all higher dimensions.

Finally we mention two well-known inequalities that relate to the finite (and infinite) dimensional ℓ_p-spaces.

Theorem (Hölder's inequality). If the numbers $p \geq 1$ and q are related by the equation $p^{-1} + q^{-1} = 1$ and if $x = (\xi_i)$ and $y = (\eta_i)$ are two vectors in $\mathbb{R}^n$, then:

$$\left| \sum \xi_i \eta_i \right| \leq \left(\sum |\xi_i|^p \right)^{1/p} \left(\sum |\eta_i|^q \right)^{1/q}.$$

A consequence of this inequality is that of Minkowski.

Theorem (Minkowski's inequality). If x and y are vectors in $\mathbb{R}^n$ and if $\|x\|_p := (\sum |\xi_i|^p)^{1/p}$, then

$$\|x + y\|_p \leq \|x\|_p + \|y\|_p.$$

Therefore, the functional $\|x\|_p$ is a norm and the set $B(p)$ defined in Example 9 in Section III is convex.

X. SPECIAL CLASSES OF CONVEX SETS

A. Polytopes

In this section we deal with bounded polytopes. Recall that such a polytope is a convex body that may be regarded either as the convex hull of finitely many points or, dually, as the intersection of finitely many half-spaces. Polygons and polyhedra have been studied since the beginnings of mathematics. The existence theorem of Minkowski is very important.

Theorem (Minkowski). If $\{u_1, u_2, \ldots u_k\}$ is a set of dual unit vectors which do not all lie in a hyperplane and if $\{\alpha_1, \alpha_2, \ldots, \alpha_k\}$ are positive real numbers such that:

$$\sum_i^k \alpha_i u_i = 0$$

then there is a polytope (unique up to translation) that has k facets whose areas are given by the α_i's and whose "normals" are given by the u_i's.

There is a generalization of this theorem to general convex bodies determined by general "surface area measures" (see Schneider[4]).

By the facial structure of a polytope, we mean the collection of all of its faces classified by their dimension. If P is an n-dimensional polytope, then there is precisely one n-dimensional face, P itself. The empty set is usually included as the unique face of dimension -1. The 0-dimensional faces are the vertices, the one-dimensional faces are the edges, and the $(n-1)$-dimensional faces are the facets. The f-vector of P is the vector $(f_0, f_1, f_2, \ldots, f_{n-1})$ where f_i is the number of faces of dimension i. The faces of P form a lattice under the inclusion relation (this is why P and $\emptyset$ are included as faces). The lattice of faces of P° forms the dual lattice.

A key combinatorial problem is to characterize those vectors that are f-vectors of some polytope. Only in three dimensions has this problem been solved. The primary necessary condition for a vector to be an f-vector is that it satisfies the so-called Euler relation.

Theorem. If f_i denotes the number of faces of a polytope of dimension i, then

$$\sum_0^n (-1)^i f_i = 1.$$

The number 1 is the Euler characteristic of P.

Corollary. In three-dimensional space, the number of vertices f_0 of edges f_1 and of facets f_2 satisfy the equation $f_2 - f_1 + f_0 = 2$.

Theorem (Steinitz). In three-dimensional space, (f_0, f_1, f_2) is the f-vector of a polyhedron if and only if it satisfies, in addition to the Euler relation, the following inequalities:

1. $4 \leq f_0 \leq 2f_2 - 4$
2. $4 \leq f_2 \leq 2f_0 - 4$

Such conditions are not completely known in higher dimensions but there are many partial results, especially for $n = 4$ (see the survey article by Bayer and Lee[2]). However, it is known that the Euler relation is the only affine relation satisfied by all f vectors.

Of particular appeal are the regular figures. If $n = 2$, then there is an infinite family of regular polygons. Up to rigid motions and dilations, there is precisely one for each number k of vertices (edges). If $n = 3$, then there are precisely five regular polyhedra (the Platonic solids). There are many proofs that there can be no more. We outline one. Suppose that the facets are p-gons and that q meet at each vertex. Then the Euler relation implies that $p^{-1} + q^{-1} > 1/2$. Since $p, q \geq 3$, only the values $(p, q) = (3, 3)$, $(3, 4)$, $(4, 3)$, $(3, 5)$ and $(5, 3)$ are possible.

In all dimensions it is possible to construct a regular cube C_n, a regular cross-polytope $\mathcal{O}_n$, and a regular simplex (a linear image of S_n). For $n \geq 5$, these are the only regular polytopes. When $n = 4$, there are three more with, respectively, 24 octahedral facets, 120 dodecahedral facets, and 600 tetrahedral facets.

A great variety of polytopes have some degree of regularity; for example, the cuboctahedron has six square facets and eight that are equilateral triangles and whose vertices are all alike. Its dual is the rhombic dodecahedron, which has all its facets alike (they are all rhombi).

B. Zonotopes

This special class of polytopes was first brought to attention by Federov in connection with crystallography. They are centrally symmetric but, more than that, they are characterized by having all their two-dimensional faces centrally symmetric. A theorem of Alexandrov implies that *all* of the faces are centrally symmetric. Thus, when $n = 3$, the zonohedra are those polyhedra with centrally symmetric facets. For $n > 3$, there are polytopes whose facets are centrally symmetric but are not zonotopes.

From the point of view of the Brunn-Minkowski theory based on sums and scalar multiples of convex sets, zonotopes are the simplest objects because they are the ones that can be expressed as sums of line segments. To simplify matters, the line segments can be centered at 0 so that the zonotope is also symmetric about 0. The support function of a line segment $[-x, x]$ is $h_{[-x,x]}(f) = |f(x)|$ and, since support functions respect addition, if $Z := \sum_i [-x_i, x_i]$, then $h_Z(f) = \sum_i |f(x_i)|$.

In addition to crystallography, these objects are important in several areas of mathematics. First, if we restrict the domain of the projection body operator Π to the polytopes, its range is the set of zonotopes. Moreover, if the domain is restricted to the centrally symmetric polytopes, then Π is one–one.

If P is a polytope, then the action of Π on P is described in the following way. Let the facets of P be denoted by $F_1, F_2, \ldots, F_m$. Each F_i is contained in a hyperplane $H_{f_i}^{\alpha_i}$ with $\|f_i\| = 1$. The functional f_i is called the unit *normal* to the facet F_i; the sign is usually chosen so that it is directed outwards but that is immaterial here. The f_i's are in the directions of the vertices of P°. If μ_i denotes the area of the facet F_i, then:

$$\Pi(P) = 1/2 \sum_i^m \mu_i / 2[-f_i,\ f_i].$$

One factor of $1/2$ is to make the line segments be of length μ_i, the other is because the projection of P in some direction is covered twice by the projections of the facets; if P is symmetric, the sum can be taken over half the facets, one from each pair. This construction reveals that Π maps objects in X to objects in the dual space X^*.

Examples. For the standard cube C_3, the normals are the usual basis vectors (and their negatives). The areas are all 4, hence, $\Pi(C_3) = \sum 2[-e_i, e_i] = 2C_3$.

For the standard octahedron $\mathcal{O}_3$, the normals are

$$3^{-1/2}(1, 1, 1),\ 3^{-1/2}(1, -1, 1)\ 3^{-1/2}(-1, -1, 1)$$
$$3^{-1/2}(-1, 1, 1)$$

and the areas are all $\sqrt{3}/2$. Another way to find the sum of the corresponding line segments is as the convex hull of the vectors:

$$1/4(\pm(1, 1, 1) \pm (1, -1, 1) \pm (-1, -1, 1) \pm (-1, 1, 1))$$

where all (16) possible choices of signs are taken. Of these, 14 are vertices and the other two are interior points (they are 0). These vertices are those of the rhombic dodecahedron, as stated in Section V (with an extra factor of $1/2$).

For the standard simplex, $\Pi(S_3)$ is also a sum of four line segments and is combinatorially the same as $\Pi(\mathcal{O}_3)$ but it has different proportions. However, the two are affinely equivalent showing that Π is not one to one on the set of all polytopes.

There are two other useful characterizations of zonotopes. If P is a centrally symmetric polytope with k pairs of opposite vertices, then P is a projection of $\mathcal{O}_k$. Similarly, if a zonotope is a sum of k line segments, then it is a projection of C_k. The dual characterization is that the dual of a zonotope is a central cross section of $\mathcal{O}_k$ for some suitable k.

A problem of great antiquity is that of characterizing and classifying the tilings of space. A more tractable problem is to ask what objects can be used as a single tile that will tile space by translation. In $\mathbb{R}^3$ these are known. There are five such objects and all are zonohedra. In higher dimensions, it is known (Venkov) that such objects are centrally symmetric polytopes with centrally symmetric facets. However, for $n > 3$ it was noted above that these need not be zonotopes. For results on tilings, see the article of that title by Schulte.[2]

C. Zonoids

Whereas the polytopes form a dense set among the convex bodies in $\mathbb{R}^n$, this is far from true of the zonotopes. The class of zonoids is defined as the closure of the set of zonotopes in the Hausdorff metric (in some fixed vector space). Thus, every zonoid is the limit of a sequence of zonotopes. Since the map from convex body to support function is continuous, it follows that the support function of a zonoid is the limit of a sequence of functions of the form $\sum_i |f(x_i)|$. Such limits can be written as an integral. Thus, a convex body Z is a zonoid if and only if its support function has the form:

$$h_Z(f) = \int |f(x)| d\rho(x)$$

where the integral is over the surface of the unit ball and ρ is an even measure on that surface.

The set of zonoids is also the range of the projection body operator Π when its domain is the set of all convex

bodies. This operator is one to one on the set of centrally symmetric bodies. An important context in which zonoids arise is that of vector measures. The range of any non-atomic vector measure is a zonoid.

In finite-dimensional normed spaces, there are several ways in which area can be defined. For that due to Holmes and Thompson the solution to the isoperimetric problem is always a zonoid. This fact makes that definition especially suitable for integral geometry. An interesting open question is whether there are non-Euclidean normed spaces for which the solution to the isoperimetric problem is the unit ball. For further results about zonoids, consult the article by Goodey and Weil.[2]

D. Ellipsoids

An ellipsoid in $\mathbb{R}^n$ was defined in Section III to be an affine image of the unit ball. Here, we restrict attention to ellipsoids with the origin as center and as an interior point; that is, the image of the unit ball under an invertible linear map T. Alternatively, if S is a positive definite symmetric matrix, the ellipsoid E_S is defined (using the inner product) by:

$$E_S := \{x : \langle Sx, x\rangle \leq 1\}.$$

Thus, the unit ball B is E_I where I is the identity matrix. The two approaches are connected by the fact that if T is an invertible matrix then $S := T^{-1*}T^{-1}$ is positive definite symmetric and $T(B) = T(E_I) = E_S$. Conversely, a positive definite matrix S has a positive definite square root $S^{1/2}$ and

$$E_S = S^{-1/2}(E_I) = S^{-1/2}(B).$$

Many properties of ellipsoids may be regarded as facts about positive definite symmetric matrices and conversely. If an ellipsoid E is given in the form $E = T(B)$, then $V_n(E) = \det T\, \epsilon_n$. Similarly, $V_n(E_S) = \epsilon_n/\sqrt{\det S}$. Useful here is the fact that the determinant of a matrix is the product of its eigenvalues.

The gauge function of a centrally symmetric convex body with 0 as an interior point is a norm. Ellipsoids are precisely those bodies whose corresponding norms come from an inner product—a Euclidean norm and (in infinite dimensions) a Hilbert space norm. Therefore, theorems that characterize ellipsoids among convex bodies also characterize inner product spaces among normed spaces (and conversely). Theorems of this type are extremely numerous in the literature. Here we give a small sample.

The most well-known characterization of inner product spaces is via the parallelogram law and is due to Jordan and von Neumann: a norm $\|\,.\,\|$ comes from an inner product if and only if:

$$\|x + y\|^2 + \|x - y\|^2 = \|x\|^2 + \|y\|^2$$

for all vectors x and y. Thus, a convex body is an ellipsoid if and only if its gauge function satisfies the above equation. Another characterization of inner product spaces is that of Kakutani and is closely related to the Blaschke result below.

Theorem (Kakutani). If $(X, \|\,.\,\|)$ is a normed space of dimension $n \geq 3$ and if for every two-dimensional subspace H of X there is a projection of X onto H which does not increase the norm of any vector, then the norm comes from an inner product.

Ellipsoids are characterized by the equality case in a number of the inequalities in Section IX. A few more geometric results are the following.

Theorem (Bertrand, Brunn). Let K be a convex body. For every vector x, consider the chords of K that are parallel to x. The midpoints of these chords all lie on a hyperplane if and only if K is an ellipsoid with center on that hyperplane.

Definition. If K is a convex body, if $x \neq 0$ is a vector, and if L_x is the line spanned by x, then the shadow boundary of K in the direction x is the set $\mathcal{S}_x := \partial(K + L_x) \cap \partial K$.

The image here is of a beam of light shining on K in the direction x. Part of the body is illuminated and part is in shadow. The set $\mathcal{S}_x$ is the "edge" of the shadow. If K has some flat parts to its boundary, the edge may be broad.

Theorem (Blaschke). If $n \geq 3$ and if K is a convex body, then the shadow boundary $\mathcal{S}_x$ lies in a hyperplane for all x if and only if K is an ellipsoid.

Theorem (Shaĭdenko, Goodey). If $\lambda \geq 3$ and if K and L are two convex bodies such that for all translates $L + x$ of L (except if $L + x = K$) the set $\partial K \cap \partial(L + x)$ is contained in a hyperplane, then K and L are homothetic ellipsoids.

Lastly, we recall the Löwner-John ellipsoids (see Section VI). For every convex body K, there is a *unique* ellipsoid of maximal volume inscribed to K and a *unique* ellipsoid of minimal volume circumscribed to K.

E. Simplices

In many respects, among convex bodies simplices stand at the opposite extreme from ellipsoids. Whereas ellipsoids

are among the most symmetric of bodies, simplices are among the most asymmetric. In some of the inequalities in Section IX, ellipsoids are precisely at one extreme and simplices at the other.

The place where many students and users of mathematics meet the word "simplex" is in the terms *simplex method* or *simplex algorithm*; see Webster.[5]

Choquet observed that if K is a convex body such that its intersection with any homothetic image is again a homothetic image then K is a simplex. He used this idea to define a simplex in infinite-dimensional spaces. Moreover, if K is of dimension $(n-1)$ and is contained in a hyperplane H_f^1 in $\mathbb{R}^n$ (*not* a hyperplane through 0), then one can construct a cone $C_K := \{\lambda x : x \in K,\ \lambda \geq 0\}$ which induces an order relation on $\mathbb{R}^n$ by:

$$x \leq y \text{ if and only if } y - x \in C_K.$$

This order relation makes $\mathbb{R}^n$ into a lattice if and only if K is a simplex. This is the starting point of a far-reaching theory of infinite-dimensional spaces initiated by Choquet.

Finally, we give a characterization due to Martini that nicely connects three of the operations of Section V.

Theorem (Martini). A polytope is a simplex if and only if $D(K) = \lambda \Pi(K)^\circ$ for some $\lambda > 0$.

Other characterizations of (and information about) simplices can be found in the article by Heil and Martini in the *Handbook of Convex Geometry*.[2]

F. Sets of Constant Width

The width of a convex set in a direction f, $w_K(f)$, was defined in Section V and sets of constant width were also introduced there. In Section V, it was shown that K is of constant width if and only if $D(K)$ is a ball. If K_1 and K_2 are each of constant width, then so is $K_1 + K_2$.

For each point x in ∂K, if we define the diameter of K at x to be $d_K(x) := \sup\{\|x - y\| : y \in K\}$, then K is of constant width if and only if $d_K(x)$ is constant.

If the convex body K has diameter d, we may define the spherical hull of K, $\mathrm{sh}(K)$, to be the intersection of all balls of radius d with center in K:

$$\mathrm{sh}(K) := \bigcap \{B[x, d] : x \in K\}.$$

Then $K \subseteq \mathrm{sh}(K)$ and equality occurs if and only if K is of constant width. Sets of constant width are precisely those sets of diameter d such that if $y \notin K$ then $\mathrm{diam}(K \cup \{y\}) > d$. Moreover, every set K of diameter d is contained in a set of constant width d.

The inradius of a convex body K is the maximal radius of a ball contained in K, and the circumradius is the minimal radius of a ball that contains K. If K has inradius r and circumradius R and is of constant width w, then there is a unique inscribed ball of radius r and a unique circumscribed ball of radius R, these balls are concentric, and $r + R = w$.

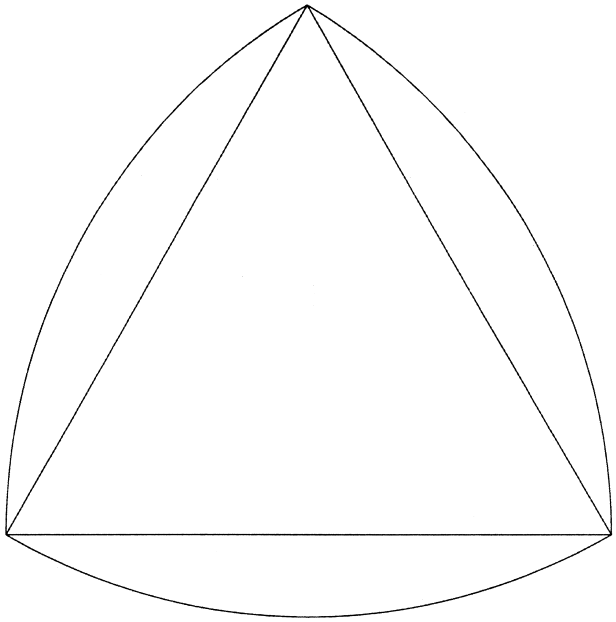

FIGURE 8

There is an inequality relating the volume and surface area of bodies of constant width w in R^n:

$$V_n(K)/V_{n-1}(\partial K) \leq w/2n.$$

Two-dimensional sets of constant width have been much studied. A Reuleaux triangle of width w is the intersection of three discs of radius w centered at the vertices of an equilateral triangle (see Fig. 8). Reuleaux polygons with any odd number of sides may be constructed similarly. Discs $B[x, w/2]$ are the sets of constant width w whose area is maximal.

Theorem (Blaschke, Lebesgue). If K is a two-dimensional set of constant width w, then:

$$V_2(K) \geq \left(\pi - \sqrt{3}\right) w^2/2$$

with equality if and only if K is a Reuleaux triangle.

The corresponding problem in higher dimensions is unsolved. Constructions analogous to the Reuleaux polygons can be made in higher dimensions but not so easily.

Cauchy's formula for surface area (Section IX) yields an elegant result for bodies of constant width in $\mathbb{R}^2$. The length of the perimeter of such a body is πw where w is the width.

GLOSSARY

Bagging A method that averages predictions from several models to achieve better predictive accuracy.
Boosting A method that uses outcome-based weighting to achieve improved predictive accuracy in a classification rule.
Classification The statistical problem of assigning new cases into categories based on observed values of explanatory variables, using previous information on a sample of cases for which the categories are known.
Clustering The operation of finding groups within multivariate data. One wants the cases within a group to be similar and cases in different groups to be clearly distinct.
Curse of dimensionality The unfortunate fact that statistical inference becomes increasingly difficult as the number of explanatory variables becomes large.
Nonparametric regression Methods that attempt to find a functional relationship between a response variable and one or more explanatory variables without making strong assumptions (such as linearity) about the form of the relationship.
Principle of parsimony This asserts that a simpler model usually has better predictive accuracy than a complex model, even if the complex model fits the original sample of data somewhat better.
Projection pursuit An exploratory technique in which one looks for low-dimensional projections of high-dimensional data that reveal interesting structure or define useful new explanatory variables.
Recursive partitioning An approach to regression or classification in which one fits different models in different regions of the space of explanatory variables and the data are used to identify the regions that require distinct models.
Smoothing Any operation that does local averaging or local fitting of the response values in order to estimate a functional relationship.

DATA MINING is an emerging analytical area of research activity that stands at the intellectual intersection of

statistics, computer science, and database management. It deals with very large datasets, tries to make fewer theoretical assumptions than has traditionally been done in statistics, and typically focuses on problems of classification, clustering, and regression. In such domains, data mining often uses decision trees or neural networks as models and frequently fits them using some combination of techniques such as bagging, boosting/arcing, and racing. These domains and techniques are the primary focus of the present article. Other activities in data mining focus on issues such as causation in large-scale systems (e.g., Spirtes *et al.* 2001; Pearl, 2000), and this effort often involves elaborate statistical models and, quite frequently, Bayesian methodology and related computational techniques (e.g., Cowell *et al.*, 1999, Jordan, 1998). For an introductory discussion of this dimension of data mining see Glymour *et al.* (1997).

The subject area of data mining began to coalesce in 1990, as researchers from the three parent fields discovered common problems and complementary strengths. The first KDD workshop (on Knowledge Discovery and Data Mining) was held in 1989. Subsequent workshops were held in 1991, 1993, and 1994, and these were then reorganized as an annual international conference in 1995. In 1997 the *Journal of Data Mining and Knowledge Discovery* was established under the editorship of Usama Fayyad. It has published special issues on electronic commerce, scalable and parallel computing, inductive logic programming, and applications to atmospheric sciences. Interest in data mining continues to grow, especially among businesses and federal statistical agencies; both of these communities gather large amounts of complex data and want to learn as much from their collections as is possible.

The needs of the business and federal communities have helped to direct the growth of data mining research. For example, typical applications in data mining include the following:

- Use of historical financial records on bank customers to predict good and bad credit risks.
- Use of sales records and customer demographics to perform market segmentation.
- Use of previous income tax returns and current returns to predict the amount of tax a person owes.

These three examples imply large datasets without explicit model structure, and the analyses are driven more by management needs than by scientific theory. The first example is a classification problem, the second requires clustering, and the third would employ a kind of regression analysis.

In these examples the raw data are numerical or categorical values, but sometimes data mining treats more exotic situations. For example, the data might be satellite photographs, and the investigator would use data mining techniques to study climate change over time. Or they can be other forms of images such as those arising from functional magnetic resonance imaging in medicine, or robot sensors. Or the data might be continuous functions, such as spectra from astronomical studies of stars. This review focuses upon the most typical applications, but the reader can obtain a fuller sense of the scope by examining the repository of benchmark data maintained at the University of California at Irvine (Bay, 1999). This archive is resource for the entire machine learning community, who use it to test and tune new algorithms. It contains, among other datasets, all those used in the annual KDD Cup contest, a competitive comparison of data mining algorithms run by the organizers of the KDD conference.

It is unclear whether data mining will continue to gain intellectual credibility among academic researchers as a separate discipline or whether it will be subsumed as a branch of statistics or computer science. Its commercial success has created a certain sense of distance from traditional research universities, in part because so much of the work is being done under corporate auspices. But there is broad agreement that the content of the field has true scientific importance, and it seems certain that under one label or another, the body of theory and heuristics that constitutes the core of data mining will persist and grow.

The remainder of this article describes the two practical problems whose tension defines the ambit of data mining, then reviews the three basic kinds of data mining applications: classification, clustering, and regression. In parallel, we describe three relatively recent ideas that are characteristic of the intellectual cross-fertilization that occurs in data mining, although they represent just a small part of the work going on in this domain. Boosting is discussed in the context of classification, racing is discussed in the context of clustering, and bagging is discussed in the context of regression. Racing and bagging have broad applicability, but boosting is (so far) limited in application to classification problems. Other techniques for these problems of widespread interest not discussed here include support vector machines and kernel smoothing methods (e.g., Vapnik, 2000).

I. TWO PROBLEMS

Data mining exists because modern methods of data collection and database management have created sample sizes large enough to overcome (or partially overcome) the limitations imposed by the curse of dimensionality. However, this freedom comes at a price—the size of the datasets severely restricts the complexity of the calculations that can be made. These two issues are described in the following subsections.

A. The Curse of Dimensionality

The curse of dimensionality (COD) was first described by Richard Bellman, a mathematician, in the context of approximation theory. In data analysis, the term refers to the difficulty of finding hidden structure when the number of variables is large.

For all problems in data mining, one can show that as the number of explanatory variables increases, the problem of structure discovery becomes harder. This is closely related to the problem of variable selection in model fitting. Classical statistical methods, such as discriminant analysis and multiple linear regression, avoided this problem by making the strong model assumption that the mathematical relationship between the response and explanatory variables was linear. But data miners prefer alternative analytic approaches, since the linearity assumption is usually wrong for the kinds of applications they encounter.

For specificity, consider the case of regression analysis; here one looks for structure that predicts the value of the response variable Y from explanatory variables $\boldsymbol{X} \in \mathbb{R}^p$. Thus one might want to predict the true amount of tax that an individual owes from information reported in the previous year, information declared on the current form, and ancillary demographic or official information. The COD arises when p is large.

There are three essentially equivalent descriptions of the COD, but each gives a usefully different perspective on the problem:

1. For large p nearly all datasets are too sparse.
2. The number of regression functions to consider grows quickly (faster than exponentially) with p, the dimension of the space of explanatory variables.
3. For large p, nearly all datasets are multicollinear (or concurve, the nonparametric generalization of multicollinearity).

These problems are minimized if data can be collected using an appropriate statistical design, such as Latin hypercube sampling (Stein, 1987). However, aside from simulation experiments, this is difficult to achieve.

The first version of the curse of dimensionality is most easily understood. If one has five points at random in the unit interval, they tend to be close together, but five random points in the unit square and the unit cube tend to be increasingly dispersed. As the dimension increases, a sample of fixed size provides less information on local structure in the data.

To quantify this heuristic about increasing data sparsity, one can calculate the side length of a p-dimensional subcube that is expected to contain half of the (uniformly random) data in the p-dimensional unit cube. This side-length is $(0.5)^{1/p}$, which increases to 1 as p gets large. Therefore the expected number of observations in a fixed volume in $\mathbb{R}^p$ goes to zero, which implies that the data can provide little information on the local relationship between $\boldsymbol{X}$ and Y. Thus it requires very large sample sizes to find local structure in high dimensions.

The second version of the COD is related to complexity theory. When p is large there are many possible models that one might fit, making it difficult for a finite sample properly to choose among the alternative models. For example, in predicting the amount of tax owed, competing models would include a simple one based just on the previous year's payment, a more complicated model that modified the previous year's payment for wage inflation, and a truly complex model that took additional account of profession, location, age, and so forth.

To illustrate the explosion in the number of possible models, suppose one decides to use only a polynomial model of degree 2 or less. When $p = 1$ (i.e., a single explanatory variable), there are seven possible regression models:

$$
\begin{aligned}
Y &= \beta_0 + \epsilon, \\
Y &= \beta_0 + \beta_1 X_1 + \epsilon, \\
Y &= \beta_0 + \beta_1 X_1 + \beta_2 X_1^2 + \epsilon, \\
Y &= \beta_1 X_1 + \epsilon, \\
Y &= \beta_0 + \beta_2 X_1^2 + \epsilon, \\
Y &= \beta_1 X_1 + \beta_2 X_1^2 + \epsilon, \\
Y &= \beta_0 + \beta_2 X_1^2 + \epsilon,
\end{aligned}
$$

where ϵ denotes noise in the observation of Y. For $p = 2$ there are 63 models to consider (including interaction terms of the form $X_1 X_2$), and simple combinatorics shows that, for general p, there are $2^{1+p+p(p+1)/2} - 1$ models of degree 2 or less. Since real-world applications usually explore much more complicated functional relationships than low-degree polynomials, data miners need vast quantities of data to discriminate among the many possibilities.

Of course, it is tempting to say that one should include all the explanatory variables, and in the early days of data mining many naive computer scientists did so. But statisticians knew that this violated the principle of parsimony and led to inaccurate prediction. If one does not severely limit the number of variables (and the number of transformations of the variables, and the number of interaction terms between variables) in the final model, then one ends up *overfitting* the data. Overfit happens when the chosen model describes the accidental noise as well as the true signal. For example, in the income tax problem it

might by chance happen that people whose social security numbers end in 2338 tend to have higher incomes. If the model fitting process allowed such frivolous terms, then this chance relationship would be used in predicting tax obligation, and such predictions would be less accurate than those obtained from a more parsimonious model that excluded misinformation. It does no good to hope that one's dataset lacks spurious structure; when p is large, it becomes mathematically certain that chance patterns exist.

The third formulation of the COD is more subtle. In standard multiple regression, multicollinearity arises when two or more of the explanatory variables are highly correlated, so that the the data lie mostly inside an affine subspace of $\mathbb{R}^p$ (e.g., close to a line or a plane within the p-dimensional volume). If this happens, there are an uncountable number of models that fit the data about equally well, but these models are dramatically different with respect to predictions for future responses whose explanatory values lie outside the subspace. As p gets large, the number of possible subspaces increases rapidly, and just by chance a finite dataset will tend to concentrate in one of them.

The problem of multicollinearity is aggravated in nonparametric regression, which allows nonlinear relationships in the model. This is the kind of regression most frequently used in data mining. Here the analogue of multicollinearity arises when predictors concentrate on a smooth manifold within $\mathbb{R}^p$, such as a curved line or sheet inside the p-volume. Since there are many more manifolds than affine subspaces, the problem of concurvity in nonparametric regression distorts prediction even more than does multicollinearity in linear regression.

When one is interested only in prediction, the COD is less of a problem for future data whose explanatory variables have values close to those observed in the past. But an unobvious consequence of large p is that nearly all new observation vectors tend to be far from those previously seen. Furthermore, if one needs to go beyond simple prediction and develop interpretable models, then the COD can be an insurmountable obstacle. Usually the most one can achieve is local interpretability, and that happens only where data are locally dense. For more detailed discussions of the COD, the reader should consult Hastie and Tibshirani (1990) and Scott and Wand (1991).

The classical statistical or psychometrical approach to dimensionality reduction typically involves some form of principal component analysis or multidimensional scaling. Roweis and Saul (2000) and Tenenbaum *et al.* (2000) suggest some novel ways to approach the problem of nonlinear dimensionality reduction in very high dimensional problems such as those involving images.

B. Massive Datasets

Massive datasets pose special problems in analysis. To provide some benchmarks of difficulty, consider the following taxonomy by dataset size proposed by Huber (1995):

Type	Size (bytes)
Tiny	10^2
Small	10^4
Medium	10^6
Large	10^8
Huge	10^{10}
Monster	10^{12}

Huber argues that the category steps, which are factors of 100, correspond to reasonable divisions at which the quantitative increase in sample size compels a qualitative change in the kind of analysis.

For tiny datasets, one can view all the data on a single page. Computational time and storage are not an issue. This is the realm in which classical statistics began, and most problems could be resolved by intelligent inspection of the data tables.

Small datasets could well defeat tabular examination by humans, but they invite graphical techniques. Scatterplots, histograms, and other visualization techniques are quite capable of structure discovery in this realm, and modern computers permit almost any level of analytic complexity that is wanted. It is usually possible for the analyst to proceed adaptively, looking at output from one trial in order to plan the next modeling effort.

Medium datasets begin to require serious thought. They will contain many outliers, and the analyst must develop automatic rules for detecting and handling them. Visualization is still a viable way to do structure discovery, but when the data are multivariate there will typically be more scatterplots and histograms than one has time to examine individually. In some sense, this is the first level at which the entire analytical strategy must be automated, which limits the flexibility of the study. This is the lowest order in the taxonomy in which data mining applications are common.

Large datasets are difficult to visualize; for example, it is possible that the point density is so great that a scatterplot is completely black. Many common statistical procedures, such as cluster analysis or regression and classification based on smoothing, become resource-intensive or impossible.

Huge and monster datasets put data processing issues at the fore, and analytical methods become secondary. Simple operations such as averaging require only that data be read once, and these are feasible at even the largest

size, but analyses that require more than $\mathcal{O}(n)$ or perhaps $\mathcal{O}(n \log(n))$ operations, for n the sample size, are impossible.

The last three taxa are a mixed blessing for data mining. The good news is that the large sample sizes mitigate the curse of dimensionality, and thus it is possible, in principle, to discover complex and interesting structure. The bad news is that many of the methods and much of the theory developed during a century of explosive growth in statistical research are impractical, given current data processing limitations.

From a computational standpoint, the three major issues in data mining are processor speed, memory size, and algorithmic complexity. Speed is proportional to the number of floating point operations (flops) that must be performed. Using PCs available in 2000, one can undertake analyses requiring about about 10^{13} flops, and perhaps up to 10^{16} flops on a supercomputer. Regarding memory, a single-processor machine needs sufficient memory for about four copies of the largest array required in the analysis, and the backup storage (disk) should be able to hold an amount equal to about 10 copies of the raw data (otherwise one has trouble storing derived calculations and exploring alternative analyses). The algorithmic complexity of the analysis is harder to quantify; at a high level it depends on the number of logical branches that the analyst wants to explore when planning the study, and at a lower level it depends on the specific numerical calculations employed by particular model fitting procedures.

Datasets based on extracting information from the World Wide Web or involving all transactions from banks or grocery stores, or collections of fMRI images can rapidly fill up terabytes of disk storage, and all of these issues become relevant. The last issue, regarding algorithmic complexity, is especially important added on top of the sheer size of some datasets. It implies that one cannot search too widely in the space of possible models, and that one cannot redirect the analysis in midstream to respond to an insight found at an intermediate step.

For more information on the issues involved in preparing superlarge datasets for analysis, see Banks and Parmigiani (1992). For additional discussion of the special problems proposed in the analysis of superlarge datasets, see the workshop proceedings on massive datasets produced by the National Research Council (1997).

II. CLASSIFICATION

Classification problems arise when one has a training sample of cases in known categories and their corresponding explanatory variables. One wants to build a decision rule that uses the explanatory variables to predict category membership for future observations. For example, a common data mining application is to use the historical records on loan applicants to classify new applicants as good or bad credit risks.

A. Methods

Classical classification began in 1935, when Sir Ronald Fisher set his children to gather iris specimens. These specimens were then classified into three species by a botanist, and numerical measurements were made on each flower. Fisher (1936) then derived mathematical formulas which used the numerical measurements to find hyperplanes that best separated the three different species.

In modern classification, the basic problem is the same as Fisher faced. One has a training sample, in which the correct classification is known (or assumed to be accurate with high probability). For each case in the training sample, one has additional information, either numerical or categorical, that may be used to predict the unknown classifications of future cases. The goal is use the information in the learning sample to build a decision function that can reliably classify future cases.

Most applications in data mining use either logistic regression, neural nets, or recursive partitioning to build the decision functions. The next three subsections describe these approaches. For information on the more traditional discriminant analysis techniques, see Press (1982).

1. Logistic Regression

Logistic regression is useful when the response variable is binary but the explanatory variables are continuous. This would be the case if one were predicting whether or not an customer is a good credit risk, using information on their income, years of employment, age, education, and other continuous variables.

In such applications one uses the model

$$P[Y = 1] = \frac{\exp(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{\theta})}{1 + \exp(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{\theta})}, \tag{1}$$

where $Y = 1$ if the customer is a good risk, $\boldsymbol{X}$ is the vector of explanatory variables for that customer, and $\boldsymbol{\theta}$ are the unknown parameters to be estimated from the data. This model is advantageous because, under the transformation

$$p = \ln \frac{P[Y = 1]}{1 - P[Y = 1]}$$

one obtains the linear model $p = \boldsymbol{X}^{\mathrm{T}}\boldsymbol{\theta}$. Thus all the usual machinery of multiple linear regression will apply.

Logistic regression can be modified to handle categorical explanatory variables through definition of dummy

variables, but this becomes impractical if there are many categories. Similarly, one can extend the approach to cases in which the response variable is polytomous (i.e., takes more than two categorical values). Also, logistic regression can incorporate product interactions by defining new explanatory variables from the original set, but this, too, becomes impractical if there are many potential interactions. Logistic regression is relatively fast to implement, which is attractive in data mining applications that have large datasets. Perhaps the chief value of logistic regression is that it provides an important theoretical window on the behavior of more complex classification methodologies (Friedman *et al.*, 2000).

2. Neural Nets

Neural nets are a classification strategy that employs an algorithm whose architecture is intended to mimic that of a brain, a strategy that was casually proposed by von Neumann. Usually, the calculations are distributed across multiple nodes whose behavior is analogous to neurons, their outputs are fed forward to other nodes, and these results are eventually accumulated into a final prediction of category membership.

To make this concrete, consider a simple perceptron model in which one is attempting to use a training set of historical data to teach the network to identify customers who are poor credit risks. Figure 1 shows a hypothetical situation; the inputs are the values of the explanatory variables and the output is a prediction of either 1 (for a good risk) or −1 (for a bad risk). The weights in the nodes are developed as the net is trained on the historical sample,

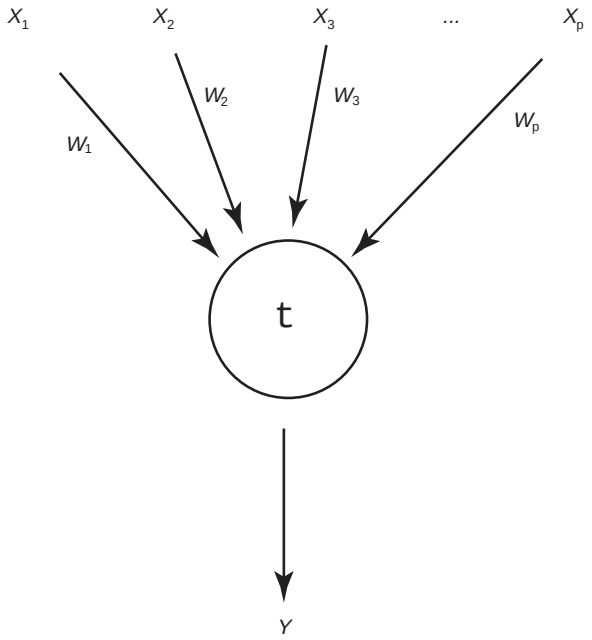

FIGURE 1 Simple perceptron.

and may be thought of as estimated values of model parameters. As diagrammed in Fig. 1, the simple perceptron fits the model

$$y = \text{signum}\left\{\sum_{i=1}^{p} w_i x_i + \tau\right\},$$

where the weights w_i and the threshhold parameter τ are estimated from the training sample.

Unlike logistic regression, it is easy for the simple perceptron to include categorical explanatory variables such as profession or whether the applicant has previously declared bankruptcy, and there is much less technical difficulty in extending the perceptron to the prediction of polytomous outcomes. There is no natural way, however, to include product interaction terms automatically; these still require hand-tuning.

The simple perceptron has serious flaws, and these have been addressed in a number of ways. The result is that the field of neural networks has become complex and diverse. The method shown in Fig. 1 is too primitive to be commonly used in modern data mining, but it serves to illustrate the basic ideas.

As a strategy, neural networks go back to the pioneering work of McCulloch and Pitts (1943). The computational obstacles in training a net went beyond the technology then available. There was a resurgence of attention when Rosenblatt (1958) introduced the perceptron, an early neural net whose properties were widely studied in the 1960s; fundamental flaws with the perceptron design were pointed out by Minsky and Papert (1969). The area languished until the early 1980s, when the Hopfield net (Hopfield, 1982) and the discovery of the backpropagation algorithm [Rumelhart *et al.* (1985) were among several independent inventors] led to networks that could be used in practical applications. Additional information on the history and development of these ideas can be found in Ripley (1996).

The three major drawbacks in using neural nets for data mining are as follows:

1. Neural nets require such computer-intensive that fitting even Huber's large datasets can be infeasible. In practice, analysts who are intent on applying neural nets to their problems typically train the net on only a small fraction of the learning sample and then use the remainder to estimate the accuracy of their classifications.
2. They are difficult to interpret. It is hard to examine a trained network and discover which variables are most influential and what are the functional relationships between the variables. This impedes the kind of scientific insight that is especially important to data miners.

3. Neural nets do not automatically provide statements of uncertainty. At the price of greatly increased computation one can use statistical techniques such as cross-validation, bootstrapping, or jackknifing to get approximate misclassification rates or standard errors or confidence intervals.

Nonetheless, neural nets are one of the most popular tools in the data mining community, in part because of their deep roots in computer science.

Subsection IV.A.4 revisits neural nets in the context of regression rather than classification. Instead of describing the neural net methodology in terms of the nodes and connections which mimic the brain, it develops an equivalent but alternative representation of neural nets as a procedure for fitting a mathematical model of a particular form. This latter perspective is the viewpoint embraced by most current researchers in the field.

3. Recursive Partitioning

Data miners use recursive partitioning to produce decision trees. This is one of the most popular and versatile of the modern classification methodologies. In such applications, the method employs the training sample to recursively partition the set of possible explanatory measurements. The resulting classification rule can displayed as a decision tree, and this is generally viewed as an attractive and interpretable rule for inference.

Formally, recursive partitioning splits the training sample into increasingly homogeneous groups, thus inducing a partition on the space of explanatory variables. At each step, the algorithm considers three possible kinds of splits using the vector of explanatory values $\boldsymbol{X}$:

1. Is $X_i \leq t$ (univariate split)?
2. Is $\sum_{i=1}^{p} w_i x_i \leq t$ (linear combination split)?
3. Does $x_i \in S$ (categorical split, used if x_i is a categorical variable)?

The algorithm searches over all possible values of t, all coefficients $\{w_i\}$, and all possible subsets S of the category values to find the split that best separates the cases in the training sample into two groups with maximum increase in overall homogeneity.

Different partitioning algorithms use different methods for assessing improvement in homogeneity. Some seek to minimize Gini's index of diversity, others use a "twoing rule," and hybrid methods can switch criteria as they move down the decision tree. Similarly, some methods seek to find the greatest improvement on both sides of the split, whereas other methods choose the split that achieves maximum homogeneity on one side or the other. Some methods grow elaborate trees and then prune back to improve predictive accuracy outside the training sample (this is a partial response to the kinds of overfit concerns that arise from the curse of dimensionality).

However it is done, the result is a decision tree. Figure 2 shows a hypothetical decision tree that might be built from credit applicant data. The first split is on income, a continuous variable. To the left-hand side, corresponding to applicants with incomes less than $25,000, the next split is categorical, and divides according to whether the applicant has previously declared bankruptcy. Going back the the top of the tree, the right-hand side splits on a linear combination; the applicant is considered a good risk if a linear combination of their age and income exceeds a threshold. This is a simplistic example, but it illustrates the interpretability of such trees, the fact that the same variable may be used more than once, and the different kinds of splits that can be made.

Recursive partitioning methods were first proposed by Morgan and Sonquist (1963). The method became widely popular with the advent of CART, a statistically sophisticated implementation and theoretical evaluation developed by Breiman *et al.* (1984). Computer scientists have also contributed to this area; prominent implementations of decision trees include ID3 and C4.5 (Quinlan, 1992). A treatment of the topic from a statistical perspective is given by Zhang and Singer (1999). The methodology extends to regression problems, and this is described in Section IV.A.5 from a model-fitting perspective.

B. Boosting

Boosting is a method invented by computer scientists to improve weak classification rules. The idea is that if one has a classification procedure that does slightly better than chance at predicting the true categories, then one can apply this procedure to the portions of the training sample that are misclassified to produce new rules and then weight all the rules together to achieve better predictive accuracy. Essentially, each rule has a weighted vote on the final classification of a case.

The procedure was proposed by Schapire (1990) and improved by Freund and Schapire (1996) under the name AdaBoost. There have been many refinements since, but the core algorithm for binary classification assumes one has a weak rule $g_1(\mathbf{X})$ that takes values in the set $\{1, -1\}$ according to the category. Then AdaBoost starts by putting equal weight $w_i = n^{-1}$ on each of the n cases in the training sample. Next, the algorithm repeats the following steps K times:

1. Apply the procedure g_k to the training sample with weights $w_1, \ldots, w_n$.

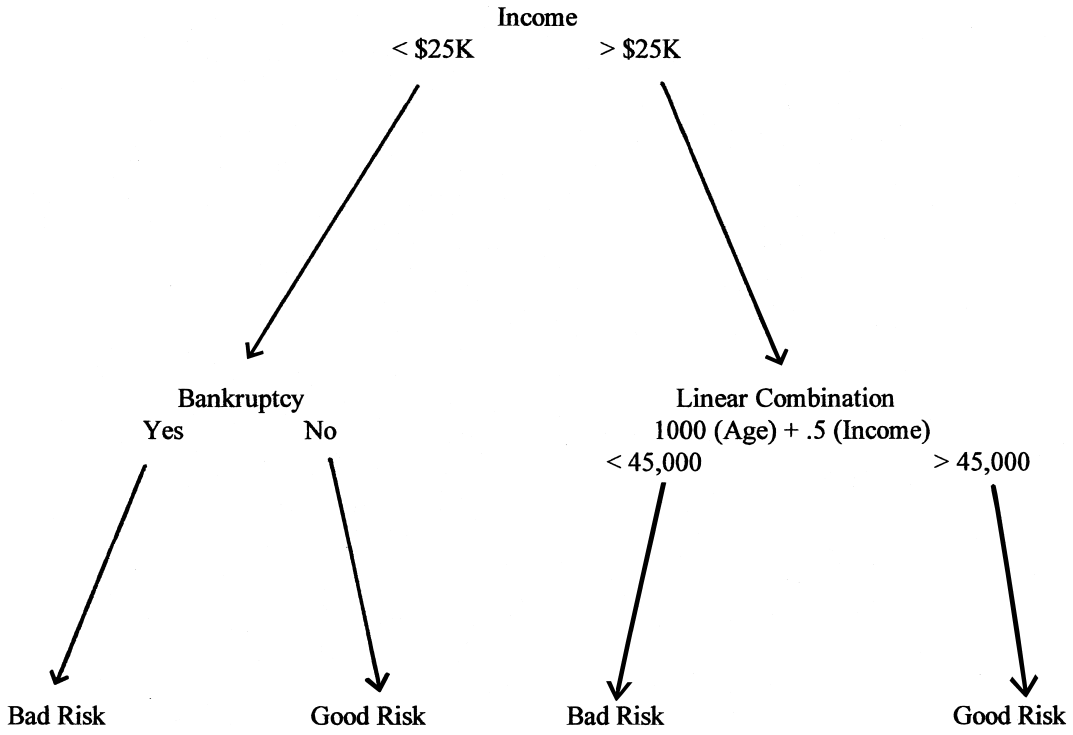

FIGURE 2 Decision tree.

2. Find the empirical probability p_w of misclassification under these weightings.
3. Calculate $c_k = \ln[(1 - p_w)/p_w]$.
4. If case i is misclassified, replace w_i by $w_i \exp c_k$. Then renormalize so that $\sum_i w_i = 1$ and go to step 1.

The final inference is the sign of $\sum_{k=1}^{K} c_k g_k(\boldsymbol{X})$, which is a weighted sum of the determinations made by each of the K rules formed from the original rule g_1.

This rule has several remarkable properties. Besides provably improving classification, it is also resistant to overfit, which arises when K is large. The procedure allows quick computation, and thus can be made practical even for huge datasets, and it can be generalized to handle more than two categories. Boosting therefore provides an automatic and effective way to increase the capability of almost any classification technique. As a new method, it is the object of active research; Friedman *et al.* (2000) describe the current thinking in this area, linking it to the formal role of statistical models such as logistic regression and generalized additive models.

III. CLUSTER ANALYSIS

Cluster analysis is the term that describes a collection of data mining methods which take observations and form groups that are usefully similar. One common application is in market segmentation, where a merchant has data on the purchases made by a large number of customers, together with demographic information on the customers. The merchant would like to identify clusters of customers who make similar purchases, so as to better target advertising or forecast the effect of changes in product lines.

A. Clustering Strategies

The classical method for grouping observations is hierarchical agglomerative clustering. This produces a cluster tree; the top is a list of all the observations, and these are then joined to form subclusters as one moves down the tree until all cases are merged in a single large cluster. For most applications a single large cluster is not informative, however, and so data miners require a rule to stop the agglomeration algorithm before complete merging occurs. The algorithm also requires a rule to identify which subcluster should be merged next for each stage of the tree-building process.

Statisticians have not found a universally reliable rule to determine when to stop a clustering algorithm, but many have been suggested. Milligan and Cooper (1985) described a large simulation study that included a range of realistic situations. They found that no rule dominated all the others, but that the cubic clustering criterion was rarely

bad and often quite good. However, in practice, most analysts create the entire tree and then inspect it to find a point at which further linkages do not seem to further their purpose. For the market segmentation example, a merchant might be pleased to find clusters that can be interpreted as families with children, senior citizens, yuppies, and so forth, and would want to stop the clustering algorithm when further linkage would conflate these descriptive categories.

Similar diversity exists when choosing a subcluster merging rule. For example, if the point clouds associated with the final interpretable clusters appear ellipsoidal with similar shape and orientation, then one should probably have used a joining rule that connects the two subclusters whose centers have minimum Mahalanobis (1936) distance. Alternatively, if the final interpretable clusters are nonconvex point clouds, then one will have had to discover those by using some kind of nearest neighbor joining rule. Statisticians have devised many such rules and can show that no single approach can solve all clustering problems (Van Ness, 1999).

In data mining applications, most of the joining rules developed by statisticians require infeasible amounts of computation and make unreasonable assumptions about homogeneous patterns in the data. Specifically, large, complex data sets do not generally have cluster structure that is well described by sets of similar ellipsoids. Instead, data miners expect to find structures that look like sheets, ellipsoids, strings, and so forth (rather as astronomers see when looking at the large-scale structure of the universe).

Therefore, among agglomerative clustering schemes, data miners almost always use nearest neighbor clustering. This is one of the fastest clustering algorithms available, and is basically equivalent to finding a minimum spanning tree on the data. Using the Prim (1957) algorithm for spanning trees, the computation takes $\mathcal{O}(n^2)$ comparisons (where n is the number of observations). This is feasible for medium datasets in Huber's taxonomy. Furthermore, nearest neighbor methods are fairly robust at finding the diverse kinds of structure that one anticipates.

As an alternative to hierarchical agglomerative clustering, some data miners use k-means cluster analysis, which depends upon a strategy pioneered by MacQueen (1967). Starting with the assumption that the data contain a prespecified number k of clusters, this method iteratively finds k cluster centers that maximize between-cluster distances and minimize within-cluster distances, where the distance metric is chosen by the user (e.g., Euclidean, Mahalanobis, sup norm, etc.). The method is useful when one has prior beliefs about the likely number of clusters in the data. It also can be a useful exploratory tool. In the computer science community, k-means clustering is known as the quantization problem and is closely related to Voronoi tesselation.

The primary drawback to using k-means clustering in data mining applications is that exact solution requires extensive computation. Approximate solutions can be obtained much more rapidly, and this is the direction in which many researchers have gone. However, the quality of the approximation can be problematic.

Both k-means and agglomerative cluster analysis are strongly susceptible to the curse of dimensionality. For the market segmentation example, it is easy to see that customers could form tight clusters based upon their first names, or where they went to elementary school, or other misleading features that would not provide commercial insight. Therefore it is useful to do variable selection, so that clustering is done only upon features that lead to useful divisions. However, this requires input from the user on which clusters are interpretable and which are not, and encoding such information is usually impractical. An alternative is to use robust clustering methods that attempt to find a small number of variables which produce well-separated clusters. Kaufman and Rousseeuw (1990) review many ideas in this area and pay useful attention to computational issues.

For medium datasets in Huber's taxonomy, it is possible to use visualization to obtain insight into the kinds of cluster structure that may exist. This can provide guidance on the clustering algorithms one should employ. Swayne *et al.* (1997) describe software that enables data miners to see and navigate across three-dimensional projections of high-dimensional datasets. Often one can see groups of points or outliers that are important in the application.

B. Racing

One of the advances that came from the data mining synergy between statisticians and computer scientists is a technique called 'racing' (Maron and Moore, 1993). This enables analysts to do much larger searches of the space of models than was previously possible.

In the context of cluster analysis, suppose one wanted to do variable selection to discover which set of demographic features led to, say, 10 consumer clusters that had small intracluster variation and large intercluster variation. One approach would be to consider each possible subset of the demographic features, run the clustering algorithm, and then decide which set of results had the best cluster separation. Obviously, this would entail much computation.

An alternative approach is to consider many feature subsets simultaneously and run the clustering algorithm for perhaps 1% of the data on each subset. Then one compares the results to see if some subsets lead to less well-defined clusters than others. If so, those subsets are eliminated and the remaining subsets are then tested against each other on a larger fraction of the data. In this way one can weed out poor feature subset choices with minimal computation

and reserve resources for the evaluation of the very best candidates.

Racing can be done with respect to a fixed fraction of the data or a fixed amount of runtime. Obviously, this admits the possibility of errors. By chance a good method might appear poor when tested with only a fraction of the data or for only a fixed amount of computer time, but the probability of such errors can be controlled statistically, and the benefit far outweighs the risk. If one is using racing on data fractions, the problem of chance error makes it important that the data be presented to the algorithm in random order, otherwise the outcome of the race might depend upon subsamples that are not representative of the entire dataset.

Racing has much broader application than cluster analysis. For classification problems, competing classifiers can be tested against each other, and those with high misclassification rates are quickly eliminated. Similarly, for regression problems, competing regression models are raced to quickly eliminate those that show poor fit. In both applications one can easily obtain a 100-fold increase in the size of the model space that is searched, and this leads to the discovery of better classifiers and better regression functions.

IV. NONPARAMETRIC REGRESSION

Regression is a key problem area in data mining and has attracted a substantial amount of research attention. Among dozens of new techniques for nonparametric regression that have been invented over the last 15 years, we detail seven that are widely used. Section IV.A describes the additive model (AM), alternating conditional expectation (ACE), projection pursuit regression (PPR), neural nets (NN), recursive partitioning regression (RPR), multivariate adaptive regression splines (MARS), and locally weighted regression (LOESS). Section IV.B compares these techniques in terms of performance and computation, and Section IV.C describes how bagging can be used to improve predictive accuracy.

A. Seven Methods

The following seven methods may seem very different, but they employ at most two distinct strategies for addressing the curse of dimensionality. One strategy fits purely local models; this is done by RPR and LOESS. The other strategy uses low-dimensional smoothing to achieve flexibility in fitting specific model forms; this is done by AM, ACE, NN, and PPR. MARS combines both strategies.

1. The Additive Model (AM)

Many researchers have developed the AM; Buja *et al.* (1989) describe the early development in this area. The simplest AM says that the expected value of an observation Y_i can be written

$$\mathrm{E}[Y_i] = \theta_0 + \sum_{j=1}^{p} f_j(X_{ij}), \tag{2}$$

where the functions f_j are unspecified but have mean zero.

Since the functions f_j are estimated from the data, the AM avoids the conventional statistical assumption of linearity in the explanatory variables; however, the effects of the explanatory variables are still additive. Thus response is modeled as a sum of arbitrary smooth univariate functions of explanatory variables. One needs about 100 data points to estimate each f_j, but under the model given in (1), the requirement for data grows only linearly in p.

The backfitting algorithm is the essential tool used in estimating an additive model. This algorithm requires some smoothing operation (e.g., kernel smoothing or nearest neighbor averages; Hastie and Tibshirani, 1990) which we denote by $Sm(\cdot|\cdot)$. For a large classes of smoothing operations, the backfitting algorithm converges uniquely.

The backfitting algorithm works as follows:

1. At initialization, define functions $f_j^{(0)} \equiv 0$ and set $\theta_0 = \bar{Y}$.
2. At the ith iteration, estimate $f_j^{(i+1)}$ by
$$f_j^{(i+1)} = Sm\left(\boldsymbol{Y} - \theta_0 - \sum_{k \neq j} f_k^i \middle| X_{1j}, \ldots, X_{nj}\right)$$
for $j = 1, \ldots, p$.
3. Check whether $|f_j^{(i+1)} - f_j^{(i)}| < \delta$ for all $j = 1, \ldots, p$, for δ the prespecified convergence tolerance. If not, go back to step 2; otherwise, take the current $f_j^{(i)}$ as the additive function estimate of f_j in the model.

This algorithm is easy to code. Its speed is chiefly determined by the complexity of the smoothing function.

One can generalize the AM by permitting it to add a few multivariate functions that depend on prespecified explanatory variables. Fitting these would require bivariate smoothing operations. For example, if one felt that prediction of tax owed in the AM would improved by including a function that depended upon both a person's previous year's declaration and their current marital status, then this bivariate smoother could be used in the second step of the backfitting algorithm.

2. Alternating Conditional Expectations (ACE)

A generalization of the AM allows a smoothing transformation of the response variable as well the smoothing of the p explanatory variables. This uses the ACE algorithm, as developed by Breiman and Friedman (1985), and it fits the model

$$\mathrm{E}[g(Y_i)] = \theta_0 + \sum_{j=1}^{p} f_j(X_{ij}). \tag{3}$$

Here all conditions are as stated before for (1), except that g is an arbitrary smooth function scaled to ensure the technically necessary requirement that $\mathrm{var}[g(Y)] = 1$ (if not for this constraint, one could get a perfect fit by setting all functions to be identically zero).

Given data Y_i and $\boldsymbol{X}_i$, one wants to find g, θ_0, and $f_1, \ldots, f_p$ such that $\mathrm{E}[g(Y_i) \mid \boldsymbol{X}_i] - \theta_0 - \sum_{j=1}^{p} f_j(X_{ij})$ is well described as independent error. Thus one solves

$$(\hat{g}, \hat{f}_1, \ldots, \hat{f}_p) = \underset{(g, f_1, \ldots, f_p)}{\operatorname{argmin}} \times \left\{ \sum_{i=1}^{n} \left[g(Y_i) - \sum_{j=1}^{p} f_j(X_{ij}) \right]^2 \right\},$$

where $\hat{g}$ is constrained to satisfy the unit-variance requirement. The algorithm for achieving this is described by Breiman and Friedman (1985); they modify the backfitting algorithm to provide a step that smoothes the left-hand side while maintaining the variance constraint.

ACE analysis returns sets of functions that maximize the linear correlation between the sum of the smoothed explanatory variables and the smoothed response variable. Therefore ACE is more similar in spirit to the multiple correlation coefficient than to multiple regression. Because ACE does not directly attempt a regression analysis, it has certain undesirable features; for example, small changes in the data can lead to very different solutions (Buja and Kass, 1985), it need not reproduce model transformations, and, unlike regression, it treats the explanatory and response variables symmetrically.

To redress some of the drawbacks in ACE, Tibshirani (1988) devised a modification called AVAS, which uses a variance-stabilizing transformation in the backfitting loop when fitting the explanatory variables. This modification is somewhat technical, but in theory it leads to improved properties when treating regression applications.

3. Projection Pursuit Regression (PPR)

The AM uses sums of functions whose arguments are the natural coordinates for the space $\mathbb{R}^p$ of explanatory variables. But when the true regression function is additive with respect to pseudovariables that are linear combinations of the explanatory variables, then the AM is inappropriate. PPR was developed by Friedman and Stuetzle (1981) to address such situations.

Heuristically, imagine there are two explanatory variables and suppose the regression surface is shaped like a sheet of corrugated aluminum. If that sheet is oriented to make the corrugations parallel to the axis of the first explanatory variable (and thus perpendicular to the second), then AM works well. When the aluminum sheet is rotated slightly so that the corrugations do not parallel a natural axis, however, AM fails because the true function is a nonadditive function of the explanatory variables. PPR would succeed, however, because the true function can be written as an additive model whose functions have arguments that are linear combinations of the explanatory variables.

PPR combines the backfitting algorithm with a numerical search routine, such as Gauss–Newton, to fit models of the form

$$\mathrm{E}[Y_i] = \sum_{k=1}^{r} f_k(\boldsymbol{\alpha}_k' \boldsymbol{X}_i). \tag{4}$$

Here the $\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_r$ are unit vectors that define a set of r linear combinations of explanatory variables. The linear combinations are similar to those used for principal components analysis (Flury, 1988). These vectors need not be orthogonal, and are chosen to maximize predictive accuracy in the model as estimated by cross-validation.

Operationally, PPR alternates calls to two routines. The first routine conditions on a set of pseudovariables given by linear combinations of original variables; these are fed into the backfitting algorithm to obtain an AM in the pseudovariables. The other routine conditions on the estimated AM functions from the previous step and then searches to find linear combinations of the original variables which maximize the fit of those functions. By alternating iterations of these routines, the result converges to a unique solution.

PPR is often hard to interpret for $r > 1$ in (3). When r is allowed to increase without bound, PPR is consistent, meaning that as the sample size grows, the estimated regression function converges to the true function.

Another improvement that PPR offers over AM is this it is invariant to affine transformations of the data; this is often desirable when the explanatory variables are measured in the same units and have similar scientific justifications. For example, PPR might be sensibly used to predict tax that is owed when the explanatory variables are shares of stock owned in various companies. Here it makes sense that linear combinations of shares across commercial sectors would provide better prediction of portfolio appreciation than could be easily obtained from the raw explanatory variables.

4. Neural Nets (NN)

Many neural net techniques exist, but from a statistical regression standpoint (Barron and Barron, 1988), nearly all variants fit models that are weighted sums of sigmoidal

functions whose arguments involve linear combinations of the data. A typical feedforward network uses a model of the form

$$\mathrm{E}[Y] = \beta_0 + \sum_{i=1}^{m} \beta_i f\left(\boldsymbol{\alpha}_i^{\mathrm{T}} \boldsymbol{x} + \gamma_{i0}\right),$$

where $f(\cdot)$ is a logistic function and the β_0, γ_{i0}, and $\boldsymbol{\alpha}_i$ are estimated from the data. Formally, this approach is similar to that in PPR. The choice of m determines the number of hidden nodes in the network and affects the smoothness of the fit; in most cases the user determines this parameter, but it is also possible to use statistical techniques, such as cross-validation to assess model fit, that allow m to be estimated from the data.

Neural nets are widely used, although their performance properties, compared to alternative regression methods, have not been thoroughly studied. Ripley (1996) describes one assessment which finds that neural net methods are not generally competitive. Schwarzer *et al.* (1986) review the use of neural nets for prognostic and diagnostic classification in clinical medicine and reach similar conclusions. Another difficulty with neural nets is that the resulting model is hard to interpret. The Bayesian formulation of neural net methods by Neal (1996) provides a some remedy for this difficulty.

PPR is very similar to neural net methods. The primary difference is that neural net techniques usually assume that the functions f_k are sigmoidal, whereas PPR allows more flexibility. Zhao and Atkeson (1992) show that PPR has similar asymptotic properties to standard neural net techniques.

5. Recursive Partitioning Regression (RPR)

RPR has become popular since the release of CART (Classification and Regression Tree) software developed by Breiman *et al.* (1984). This technique has already been described in the context of classification, so this subsection focuses upon its application to regression. The RPR algorithm fits the model

$$\mathrm{E}[Y_i] = \sum_{j=1}^{M} \theta_j I_{R_j}(\boldsymbol{X}_i),$$

where the $R_1, \ldots, R_M$ are rectangular regions which partition $\mathbb{R}^p$, and $I_{R_j}(\boldsymbol{X}_i)$ denotes an indicator function that takes the value 1 if and only if $\boldsymbol{X}_i \in R_j$ and is otherwise zero. Here θ_j is the estimated numerical value of all responses with explanatory variables in R_j.

RPR was intended to be good at discovering local low-dimensional structure in functions with high-dimensional global dependence. RPR is consistent; also, it has an attractive graphic representation as a decision tree, as illustrated for classification in Fig. 2. Many common functions are difficult for RPR, however; for example, it approximates a straight line by a stairstep function. In high dimensions it can be difficult to discover when the RPR piecewise constant model closely approximates a simple smooth function.

To be concrete, suppose one used RPR to predict tax obligation. The algorithm would first search all possible splits in the training sample observations and perhaps divide on whether or not the declared income is greater than $25,000. For people with lower incomes, the next search might split the data on marital status. For those with higher incomes, subsequent split might depend on whether the declared income exceeds $75,000. Further splits might depend on the number of children, the age and profession of the declarer, and so forth. The search process repeats in every subset of the training data defined by previous divisions, and eventually there is no potential split that sufficiently reduces variability to justify further partitions. At this point RPR fits the averages of all the training cases within the most refined subsets as the estimates θ_j and shows the sequence of chosen divisions in a decision tree. (Note: RPR algorithms can be more complex; e.g., CART "prunes back" the final tree by removing splits to achieve better balance of observed fit in the training sample with future predictive error.)

6. Multivariate Adaptive Regression Splines (MARS)

Friedman (1991) proposed a data mining method that combines PPR with RPR through use of multivariate adaptive regression splines. It fits a model formed as a weighted sum of multivariate spline basis functions (tensor-spline basis functions) and can be written as

$$\mathrm{E}[Y_i] = \sum_{k=0}^{q} a_k B_k(\boldsymbol{X}_i),$$

where the coefficients a_k are estimated by (generalized) cross-validation fitting. The constant term is obtained by setting $B_0(X_1, \ldots, X_n) \equiv 1$, and the multivariate spline terms are products of univariate spline basis functions:

$$B_k(x_1, \ldots, x_n) = \prod_{s=1}^{r_k} b\left(x_{i(s,k)} \mid t_{s,k}\right), \qquad 1 \le k \le r.$$

The subscript $i(s,k)$ identifies a particular explanatory variable, and the basis spline for that variable puts a knot at $t_{s,k}$. The values of q, the $r_1, \ldots, r_q$, the knot locations, and the explanatory variables selected for inclusion are determined from the data adaptively.

MARS output can be represented and interpreted in a decomposition similar to that given by analysis of vari-

ance. It is constructed to work well if the true function has local dependence on only a few variables. MARS can automatically accommodate interactions between variables, and it handles variable selection in a natural way.

7. Locally Weighted Regression (LOESS)

Cleveland (1979) developed a technique based on locally weighted regression. Instead of simply taking a local average, LOESS fits the model $\mathrm{E}[Y] = \boldsymbol{\theta}(\boldsymbol{x})'\boldsymbol{x}$, where

$$\hat{\boldsymbol{\theta}}(\boldsymbol{x}) = \underset{\boldsymbol{\theta}\in\mathbb{R}^p}{\operatorname{argmin}} \sum_{i=1}^{n} w_i(\boldsymbol{x})(Y_i - \boldsymbol{\theta}'\boldsymbol{X}_i)^2 \qquad (5)$$

and w_i is a weight function that governs the influence of the ith datum according to the direction and distance of $\boldsymbol{X}_i$ from $\boldsymbol{x}$.

LOESS is a consistent estimator but may be inefficient at finding relatively simple structures in the data. Although not originally intended for high-dimensional regression, LOESS uses local information with advantageous flexibility. Cleveland and Devlin (1988) generalized LOESS to perform polynomial regression rather than the linear regression $\boldsymbol{\theta}'\boldsymbol{X}_i$ in (4), but from a data mining perspective, this increases the cost of computation with little improvement in overall predictive accuracy.

B. Comparisons

Nonparametric regression is an important area for testing the performance of data mining methods because statisticians have developed a rich theoretical understanding of the issues and obstacles. Some key sources of comparative information are as follows:

- Donoho and Johnstone (1989) make asymptotic comparisons among the more mathematically tractable techniques. They indicate that projection-based methods (PPR, MARS) perform better for radial functions but kernel-based methods (LOESS) are superior for harmonic functions. (Radial functions are constant on hyperspheres centered at $\mathbf{0}$, while harmonic functions vary sinusoidally on such hyperspheres.)
- Friedman (1991) describes simulation studies of MARS, and related work is cited by his discussants. Friedman focuses on several criteria; these include scaled versions of mean integrated squared error (MISE) and predictive-squared error (PSE). From the standpoint of data mining practice, the most useful conclusions are (1) for data that are pure noise in 5 and 10 dimensions, and sample sizes of 50, 100, and 200, AM and MARS are comparable and both are unlikely to find false structure, and (2) if test data are generated from the following additive function of five variables

$$Y = 0.1\exp(4X_1) + \frac{4}{1+\exp(-20X_2+10)} + 3X_3 + 2X_4 + X_5,$$

with five additional noise variables and sample sizes of 50, 100, and 200, MARS had a slight tendency to overfit, particularly for the smallest sample sizes.

All of these simulations, except for the pure noise condition, have large signal-to-noise ratios.

- Barron (1991, 1993) proved that in a narrow sense, the MISE for neural net estimates in a certain class of functions has order $\mathcal{O}(1/m) + \mathcal{O}(mp/n)\ln n$, where m is the number of nodes, p is the dimension, and n is the sample size. Since this is linear in dimension, it evades the COD; similar results have been obtained by Zhao and Atkeson (1992) for PPR, and it is probable that a similar result holds for MARS. These findings have limited practical value; Barron's class of functions consists of those whose Fourier transform $\tilde{g}$ satisfies $\int |\omega||\tilde{g}(\omega)|\,d\omega < c$ for some fixed c. This excludes such simple cases as hyperflats, and the class becomes smoother as dimension increases.
- De Veaux *et al.* (1993) tested MARS and a neural net on two functions; they found that MARS was faster and had better MISE.
- Zhang and Singer (1999) applied CART, MARS, multiple logistic regression, and other methods in several case studies and found that no method dominates the others. CART was often most interpretable, but logistic regression led more directly to estimation of uncertainty.

The general conclusions are (1) parsimonious modeling is increasingly important in high dimensions, (2) hierarchical models using sums of piecewise-linear functions are relatively good, and (3) for any method, there are datasets on which it succeeds and datasets on which it fails.

In practice, since it is hard to know what methods works best in a given situation, data miners usually hold out a part of the data, apply various regression techniques to the remaining data, and then use the models that are built to estimate the hold-out sample. The method that achieves minimum prediction error is likely to be the best for that application.

Most of the software detailed in this section is available from the StatLib archive at `http://lib.stat.cmu.edu`; this includes AM, ACE, LOESS, and PPR. Both MARS and CART are commercially available from Salford Systems, Inc., at `http://www.salford-systems.com`. Splus includes versions of RPR, the (generalized) AM, ACE, PPR, and LOESS; this

is commercially available from Mathsoft, Inc., at http://www.splus.mathsoft.com.

C. Bagging

Bagging is a strategy for improving predictive accuracy by model averaging. It was proposed by Breiman (1996), but has a natural pedigree in Bayesian work on variable selection, in which one often puts weights on different possible models and then lets the data update those weights.

Concretely, suppose one has a training sample and a nonparametric regression technique that takes the explanatory variables and produces an estimated response value. Then the simplest form of bagging proceeds by drawing K random samples (with replacement) from the training sample and applying the regression technique to each random sample to produce regression rules $T_1(\boldsymbol{X}), \ldots, T_K(\boldsymbol{X})$. For a new observation, say $\boldsymbol{X}^*$, the bagging predictor of the response Y^* is $K^{-1}\sum_{k=1}^{K} T_k(\boldsymbol{X}^*)$.

The idea behind bagging is that model fitting strategies usually have high variance but low bias. This means that small changes in the data can produce very different models but that there is no systematic tendency to produce models which err in particular directions. Under these circumstances, averaging the results of many models can reduce the error in the prediction that is associated with model instability while preserving low bias.

Model averaging strategies are moving beyond simple bagging. Some employ many different kinds of regression techniques rather than just a single method. Others modify the bagging algorithm in fairly complex ways, such as arcing (Brieman, 1998). A nice comparison of some of the recent ideas in this area is given by Dietterich (1998), and Hoeting *et al.* (1999) give an excellent tutorial on more systematic Bayesian methods for model averaging. Model averaging removes the analyst's ability to interpret parameters in the models used and can only be justified in terms of predictive properties.

Designs and Error-Correcting Codes

K. T. Phelps
C. A. Rodger
Auburn University

GLOSSARY

Binary sum, $u+v$ Componentwise addition of u and v with $1+1=0$ (exclusive or).
Binary word A string (or vector or sequence) of 0's and 1's
Code A set of (usually binary) words, often all of the same length.
Combinatorial design A collection of subsets of a set satisfying additional regularity properties.
Decoding Finding the most likely codeword (or message) transmitted.
Distance, $d(u, v)$ The number of coordinates in which u and v differ.
Encoding The assignment of codewords to messages.
Information rate The fraction of information per transmitted bit.
Weight, $wt(u)$ The number of nonzero bits in the word u.

I. INTRODUCTION

Both error-correcting codes and combinatorial designs are areas of discrete (not continuous) mathematics that began in response to applied problems, the first in making the electronic transmission of information reliable and the second in the design of experiments with results being statistically analyzed. It turns out that there is substantial overlap between these two areas, mainly because both are looking for uniformly distributed subsets within certain finite sets. In this article we provide a brief introduction to both areas and give some indication of their interaction.

A. Error-Correcting Codes

Error-correcting codes is a branch of discrete mathematics, electrical engineering, and computer science that has developed over the past 50 years, largely in response to

the dramatic growth of electronic transfer and storage of information. Coding Theory began in the late 1940s and early 1950s with the seminal work of Shannon (1948), Hamming (1950), and Golay (1949). Error-correcting codes' first significant application was in NASA's deep space satellite communications. Other important applications since then have been in storage devices (e.g., compact discs), wireless telephone channels, and geopositioning systems. They are now routinely used in all satellite communications and mobile wireless communications systems.

Since no communication system is ideal, information can be altered, corrupted, or even destroyed by *noise*. Any communication system needs to be able to recognize or *detect* such errors and have some scheme for recovering the information or *correcting* the error. In order to protect against the more likely errors and thus improve the reliability, redundancy must be incorporated into the message. As a crude example, one could simply transmit the message several times in the expectation that the majority will appear correctly at their destination, but this would greatly increase the cost in terms of time or the rate of transmission (or space in storage devices).

The most basic error control scheme involves simply detecting errors and requesting retransmission. For many communications systems, requests for retransmission are impractical or impose unacceptable costs on the communication system's performance. In deep space communications, a request for retransmission would take too long. In speech communications, noticeable delays are unacceptable. In broadcast systems, it is impractical given the multitude of receivers. The problem of correcting errors and recovering information becomes of paramount importance in such constrained situations.

Messages can be thought of as words over some alphabet, but for all practical purposes, all messages are simply strings of 0's and 1's, or *binary words*. Information can be partitioned or blocked up into a sequence of binary words or messages of fixed length k. A (*block*) *code*, C, is a set of binary words of fixed length n, each element of which is called a *codeword*. Mathematically, codewords can be considered to be vectors of length n with elements being chosen from a finite field, normally of order 2, but in some cases from the field $GF(2^r)$. [So, for example, the binary codeword 01101 could also be represented as the vector (0, 1, 1, 0, 1).] There are also convolutional codes where the codewords do not have fixed length (or have infinite length), but these will be discussed later. *Encoding* refers to the method of assigning messages to codewords which are then transmitted. Clearly, the number of codewords has to be at least as large as the number of k-bit messages. The *rate* of the code is k/n, since k bits of information result in n bits being transmitted.

The key to being able to detect or correct errors that occur during transmission is to have a code, C, such that no two codewords are close. The *distance* between any two words u and v, denoted by $d(u, v)$, is simply the number of coordinates in which the two words differ. The *weight* of u, $wt(u)$, is just the number of nonzero coordinates in u. Using the binary sum (so $1+1=0$), we have $d(u, v) = wt(u+v)$.

Under the assumptions that bits are more likely to be transmitted correctly than incorrectly (a natural assumption) and that messages are equally likely to be transmitted (this condition can be substantially relaxed), it is easy to show that for any received word w, the most likely codeword originally transmitted is the codeword $c \in C$ for which $d(c, w)$ is least; that is, the most likely codeword sent is the one closest to the received word. This leads to the definition of the *minimum distance* $d(C) = \min_{c_1, c_2 \in C}\{d(c_1, c_2)\}$ of a code C, the distance between the two closest codewords in C. Clearly, if a word w is received such that $d(c, w) \le t = \lfloor (d(C)-1)/2 \rfloor$ for some $c \in C$, then the unique closest codeword to w is c; therefore, c is the most likely codeword sent and we *decode* w to c. (Notice that if c was the codeword that was originally transmitted, then at most t bits were altered in c during transmission to result in w being received.) So decoding each received word to the closest codeword (known as *maximum likelihood decoding*, or MLD) will always result in correct decoding provided at most t errors occur during transmission. Furthermore, if c_1 and c_2 are the two closest codewords [so $d(c_1, c_2) = d(C)$], then it is clearly possible to change $t+1$ bits in c_1 so that the resulting word w satisfies $d(c_1, w) > d(c_2, w)$. Therefore, if these $t+1$ bits are altered during the transmission of c_1, then, using MLD, we would incorrectly decode the received word w to c_2. Since MLD results in correct decoding for C no matter which codeword is transmitted and no matter which set of up to t bits are altered during transmission, and since this is not true if we replace t with $t+1$, C is known as a *t-error-correcting code*, or as an $(n, |C|, d)$ code where $d = d(C) \ge 2t+1$.

The *construction problem* is to find an $(n, |C|, d)$ code, C, such that the minimum distance d (and thus t) is large—this improves the error-correction ability and thus the reliability of transmission; and where $|C|$ is large, so the rate of transmission ($\log_2 |C|/n = k/n$) is closer to 1. Since messages are usually blocked up into k-bit words, one usually has $\log_2 |C| = k$. Clearly, these aims compete against each other. The more codewords one packs together in C, the harder it is to keep them far apart. In practice one needs to make decisions about the reliability of the channel and the need to get the message transmitted correctly and then weigh that against the cost of decreasing the rate of transmission (or increasing the amount of data to be stored). It

is possible to obtain bounds on one of the three parameters n, d, and $|C|$ in terms of the other two, and in some cases families of codes have been constructed which meet these bounds. Two of these families are discussed in this article: the *perfect codes* are codes that meet the Hamming Bound and are described in Section II; the *maximum distance separable* (or MDS) codes are codes that meet the Singleton Bound and are described in Section IV.

The second problem associated with error-correcting codes is the *encoding problem*. Each message m is to be assigned a unique codeword c, but this must be done efficiently. One class of codes that have an efficient encoding algorithm are *linear* codes; that is, the *binary sum* of any pair of codewords in the code C is also a codeword in C (here, *binary sum* means componentwise binary addition of the binary digits or the *exclusive or* of the two codewords). This means that C is a vector space and thus has a basis which we can use to form the rows of a *generating* matrix G. Then each message m is encoded to the codeword $c = mG$. One might also require that C have the additional property of being *cyclic*; that is, the cyclic shift $c' = x_n x_1 x_2 \ldots x_{n-1}$ of any codeword $c = x_1 x_2 \ldots x_n$ (where $x_i \in \{0, 1\}$) is also a codeword for every codeword c in C. If C is cyclic and linear, then encoding can easily be completed using a shift register design. The representation of a code is critical in decoding. For example, Hamming codes (see Section II) possess a cyclic representation but also have equivalent representations that are not cyclic.

The final main problem associated with error-correcting codes is the *decoding problem*. It is all well and good to know from the design of the code that all sets of up to t errors occurring during transmission result in a received word, w, that is closer to the codeword c that was sent than it is to any other codeword; but given w, how do you efficiently find c and recover m? Obviously, one could test w against each possible codeword and perhaps eventually decode which is closest, but some codes are very big. Not only that, but it can also be imperative that decoding be done extremely quickly, as the following example demonstrates.

The introduction of the compact disc (CD) by Phillips in 1979 revolutionized the recording industry. This may not have been possible without the heavy use of error-correcting codes in each CD. (Errors can occur, for example, from incorrect cutting of the CD.) Each codeword on each CD represents less than 0.0001 sec of music, is represented by a binary word of length 588 bits, and is initially selected from a Reed-Solomon code (see Section III) that contains 2^{192} codewords. Clearly, this is an application where all decoding must take place with no delay, as nobody will buy a CD that stops the music while the closest codeword is being found! It turns out that not only are the Reed-Solomon codes excellent in that they meet the Singleton Bound (see Section III), but they also have an extremely efficient decoding algorithm which finds the closest codeword without having to compare the received word to all 2^{192} codewords.

Again, the class of linear codes also has a relatively efficient decoding algorithm. Associated with each linear code C is the dual code $C^{\perp}$ consisting of all vectors (codewords) such that the dot product with any codeword in C is 0 (again using *xor* or *binary* arithmetic). This is useful because of the fact that if H is a generating matrix for $C^{\perp}$, then $Hw^T = 0$ if and only if w is a codeword. H is also known as the *parity check* matrix for C. The word $s = Hw^T$ is known as the *syndrome* of w. Syndromes are even more useful because it turns out that for each possible syndrome s, there exists a word e_s with the property that a closest codeword to *any* received word w with syndrome s is $w + e_s$. This observation is taken even further to obtain a very efficient decoding algorithm for the Reed-Solomon codes that can deal with the 2^{196} codewords in real time; it incorporates the fact that these codes are not only linear but also cyclic.

Another family of codes that NASA uses is the *convolutional codes*. Theoretically, these codes are infinite in length, so a completely different decoding algorithm is required in this case (see Section V).

In the following sections, we focus primarily on the construction of some of the best codes, putting aside discussion of the more technical problem of describing decoding algorithms for all except the convolutional codes in Section V. This allows the interaction between codes and designs to be highlighted.

B. Combinatorial Designs

Although (combinatorial) designs were studied earlier by such people as Euler, Steiner, Kirkman, it was Yates (1936) who gave the subject a shot in the arm in 1935 by pointing out their use in statistics in the design of experiments. In particular, he defined what has become known as an (n, k, λ) *balanced incomplete block design* (BIBD) to be a set V of n elements and a set B of subsets (called *blocks*) of V such that

1. Each block has size $k < n$.
2. Each pair of elements in V occur as a subset of exactly λ blocks in B.

Fisher and Yates (1938) went on to find a table of small designs, and Bose (1939) soon after began a systematic study of the existence of such designs. Bose made use of finite geometries and finite fields in many of his constructions.

A natural generalization of BIBD is to replace (2) with

2′. Each $(t+1)$-element subset of V occurs as a subset of exactly λ blocks of B.

Such designs are known as $(t+1)$ *designs*, which can be briefly denoted by $S_\lambda(t+1, k, n)$; in the particular case when $\lambda = 1$, they are known as *Steiner* $(t+1)$ *designs* which are denoted by $S(t+1, k, n)$. By elementary counting techniques, one can show that if $s < t$, then an $S_\lambda(t+1, k, n)$ design is also an $S_\mu(s, k, u)$ design where $\mu = \lambda\binom{n-s}{t+1-s}/\binom{k-s}{t+1-s}$. Since μ must be an integer, this provides several necessary conditions for the existence of a $(t+1)$ design.

For many values of n, k, and t, an $S(t+1, k, n)$ design cannot exist. A *partial* $S(t+1, k, n)$ design then is a set of k subsets of an n set where any $(t+1)$ subset is contained in at most one block. This is equivalent to saying that any two k subsets intersect in at most t elements. Partial designs are also referred to as *packings*, and much research has focused on finding maximum packings for various parameters.

There are very few results proving the existence of s designs once $s \geq 3$. Hanani found exactly when there exists an $S_\lambda(3, 4, v)$ [also called Steiner Quadruple Systems; see Lindner and Rodger (1975) for a simple proof and Hartman and Phelps (1992) for a survey], and Teirlinck (1980) proved that there exists an $S_\lambda(s, s+1, v)$ whenever $\lambda = ((s+1)!)^{2s+1}$, $v \geq s+1$, and $v \equiv s$ (modulo $((s+1)!)^{2s+1}$. Otherwise, just a few s designs are known [see Colbourn and Dinitz (1996)]. Much is known about their existence when $s = 2$. In particular, over 1000 papers have been written [see Colbourn and Rosa (1999)] about $S_\lambda(2, 3, v)$ designs (known as *triple systems*, and as *Steiner triple systems* if $\lambda = 1$). We only need to consider designs with $\lambda = 1$ in this article.

Certainly, $(t+1)$ designs and maximum packings are of interest in their own right, but they also play a role in the construction of good codes. To see how, suppose we have a $(t+1)$ design (or packing) (V, B). For each block b in B, we form its *characteristic vector* c_b of length n, indexed by the elements in V, by placing a 1 in position i if $i \in B$ and placing a 0 in position i if $i \notin B$. Let C be the code $\{c_b \mid b \in B\}$. Then C is a code of length n in which all codewords have exactly k 1's (we say each codeword has *weight* k). The fact that (V, B) is a $t+1$ design (or packing) also says something about the minimum distance of C: since each pair of blocks intersect in at most t elements, each pair of codewords have at most t positions where both are 1, so each pair of codewords disagree in at least $2k - 2t$ positions, so $d(C) \geq 2k - 2t$. This connection is considered in some detail in Section III. We also show in Section II that the codewords of weight d in perfect codes together form the characteristic vectors of a $(t+1)$ design.

There is much literature on the topic of combinatorial designs [see Colbourn and Dinitz (1996) for an encyclopedia of designs and Lindner and Rodger (1997) for an introductory text], and this topic is also considered elsewhere in this encyclopedia, so here we restrict our attention to designs that arise in connection with codes.

II. PERFECT CODES

Let C be a code of length n with minimum distance d. Let $t = \lfloor (d-1)/2 \rfloor$. Then, as described in Section I, for each codeword c in C, and for each binary word w of length n with $d(w, c) \leq t$, the *unique* closest codeword to w is c. Since we can choose any i of the n positions to change in c in order to form a word of length n distance exactly i from c, the number of words distance i from c is $\binom{n}{i} = n!/(n-i)!i!$. So the total number of words of length n that are distance at most t from c is $\binom{n}{0} + \binom{n}{1} + \cdots + \binom{n}{t}$, one of which is c, thus the number of words of length n distance at most t from some codeword in C is $|C| \sum_{i=0}^{t} \binom{n}{i}$ (by the definition of t, no codeword is within distance t of two codewords). Of course, the total number of binary words of length n is 2^n. Therefore, it must be the case that

$$|C| \leq 2^n \Big/ \sum_{i=0}^{t} \binom{n}{i}.$$

This bound is known as the *Hamming Bound* or the *sphere packing bound*. Any code that satisfies equality in the Hamming Bound is known as a *perfect code*, in which case $d = 2t + 1$.

From the argument above, it is clear that for any perfect code, each word of length n must be within distance t of a unique codeword (if a code is not perfect, then there exist words for which the distance to any closest codeword is more than t). In particular, if C is a perfect code with $d = 2t + 1$, then the codewords of minimum weight d in C are the characteristic vectors of the blocks of an $S(t+1, 2t+1, n)$ design. To see this, note that each word w of weight $t+1$ is within distance t of a unique codeword c, where clearly c must have weight $d = 2t + 1$. Equivalently, each $(t+1)$ subset is contained in a unique d subset, the characteristic vector of which is a codeword. In fact, for any codeword $c \in C$, one can define the neighborhood packing,

$$NS(c) = \{x + c \mid x \in C \text{ and } d(x, c) = d\}.$$

Then, the code C will be perfect *if and only if* every neighborhood packing is, in fact, the characteristic vectors of an $S(t+1, 2t+1, n)$ design. To see the converse, suppose C is a code with every $NS(c)$ an $S(t+1, 2t+1, n)$ design. If w is any word, let $c \in C$ be the closest codeword and assume $d(c, w) \geq t+1$. Choose any $t+1$ coordinates where c and w disagree. Since $NS(c)$ is an $S(t+1, 2t+1, n)$ design, these coordinates uniquely determine a block of size

$2t+1$ in the design and, hence, a codeword c' such that $d(c,c')=2t+1$. So c' disagrees with c in the same $t+1$ coordinates as does w, and thus, c' agrees with w in these $t+1$ coordinates. Thus,

$$\begin{aligned} d(c',w) &\le d(c,c') - (t+1) + d(c,w) - (t+1) \\ &\le d(c,w) - 1, \end{aligned}$$

which contradicts the assumption that c was the closest codeword and thus $d(c,w) \le t$.

It turns out that perfect binary codes are quite rare. The Hamming codes are an infinite family of perfect codes of length 2^r-1, for any $r \ge 2$, in which the distance is 3 and the number of codewords is 2^{2^r-1-r}. A linear Hamming code can always be formed by defining its parity check matrix, H, to be the $r \times n$ matrix in which the columns form all nonzero binary words of length r. Notice also that, in view of the comments earlier in this section, the codewords of weight 3 in any Hamming code form a Steiner triple system, $S(2,3,n)$.

The other perfect binary code is the Golay code, which has length 23, distance 7, and 2^{12} codewords.

Tietäväinen (1973), based on work by van Lint, showed that these are the only perfect binary codes and, in fact, generalized this result to codes over finite fields [see also Zinov'ev and Leont'ev (1973)]. For a survey of results on perfect codes, see van Lint (1975).

III. CONSTANT WEIGHT CODES

A *constant weight code* (CW) with parameters n, d, w is a set C of binary words of length n all having weight w such that the distance between any two codewords is at least d. All nontrivial (n,d,w) CW codes have $d \le 2w$. Let $A(n,d,w)$ be the largest number of codewords in any CW code with these parameters. The classic problem then is to detemine this number or find the best upper and lower bounds on $A(n,d,w)$.

Binary CW codes have found application in synchronization problems, in areas such as optical codedivision multiple-acces (CDMA) communications systems, frequency-hopping spread-spectrum communications, modile radio, radar and sonar signal design, and the construction of protocol sequences for multiuser collision channel without feedback. Constant weight codes over other alphabets have received some attention, but so far there have been few applications. We will only discuss the binary CW codes.

Constant weight codes have been extensively studied, and a good reference is MacWilliams and Sloane (1977). Eric Raines and Neil Sloane maintain a table of the best known lower bounds on $A(n,d,w)$ on the web site: http://www.research.att.com/njas/codes/Andw/. We will present an overview of this topic with an emphasis on the connections with designs.

Since the sum of any two binary words of the same weight always has even weight, we have $A(n,2\delta-1,w) = A(n,2\delta,w)$. We will assume from now on that the distance d is even. We also have $A(n,d,w) = A(n,d,n-w)$, since whenever two words are distance d apart, so are their complements. This means one only needs to consider the case $w \le n/2$.

The connection between CW codes and designs is immediate. In terms of sets, a CW code is just a collection of w subsets of an n set where the intersection of any two w subsets contains at most $t = w - \frac{d}{2}$ elements. Equivalently, a CW code is a partial $S(w-\frac{d}{2}+1, w, n)$ Steiner system. We then have

$$A(n,d,w) \le \frac{n(n-1)\cdots(n-w+d/2)}{w(w-1)\cdots(d/2)}$$

with equality if and only if a Steiner system $S(w-\frac{d}{2}+1, w, n)$ exists.

The interest in CW codes also comes from the problem of finding linear (or nonlinear) codes (n, M, d) of maximum size M. Obviously, $A(n,d,w)$ is an upper bound on the number of words of a given weight in such a maximum code. Conversely, such codes (or their cosets) can give lower bounds for $A(n,d,w)$. In particular, the stronger version of the Hamming Bound (given in the section on perfect codes) was originally proved using $A(n, 2t+2, 2t+1)$.

$A(n,2t+2,2t+1)$ is just the number of blocks in a maximum partial $S(t+1, 2t+1, n)$ design or packing. If C is a t-error-correcting code, then for any $c \in C$, the number of blocks in a neighborhood packing $|NS(c)| \le A(n,2t+2,2t+1)$. The number of words that are distance $t+1$ from c but not distance t from any other codeword is

$$\begin{aligned} \binom{n}{t+1} - \binom{2t+1}{t+1}|NS(c)| &\ge \binom{n}{t+1} \\ &- \binom{2t+1}{t+1} A(n,2t+2,2t+1). \end{aligned}$$

Each such word is distance $t+1$ from at most $\lfloor n/t+1 \rfloor$ other codewords. Thus, summing over all $c \in C$, each such word is counted at most this many times. This gives a stronger version of the Hamming bound:

$$|C|\left(\left(\sum_{i=0}^{t}\binom{n}{i}\right) + \frac{\binom{n}{t+1} - \binom{2t+1}{t+1}A(n,2t+2,2t+1)}{\lfloor n/(t+1) \rfloor}\right) \le 2^n.$$

Constant weight codes cannot be linear, since this would mean the zero vector was in the code, but one can have

a code with all nonzero words having the same weight. These codes are sometime referred to as linear *equidistant codes*. The dual of the Hamming code (also called the *simplex code*) is an example of such a code. In fact, it has been proved that the only such codes are formed by taking several copies of a simplex code. The proofs that all such codes are generalized simplex codes come explicitly from coding theory (Bonisoli, 1983) and also implicitly from results on designs and set systems (Teirlinck, 1980). There is a close connection between linear equidistant codes and finite geometries. The words of a simplex code correspond to the hyperplanes of projective space [over $GF(2)$] just as the words of weight 3 in the Hamming code correspond to lines in this projective space. [For connections between codes and finite geometries, see Black and Mullin (1976).]

Another variation on CW codes are optical orthogonal codes (OOC) which were motivated by an application to optical CDMA communication systems. Briefly, an (n, w, t_a, t_b) OOC is a CW code, C, of length n and weight w such that for any $c = (c_0, c_1, \ldots, c_{n-1}) \in C$, and each $y \in C$, $c \neq y$ and each $i \not\equiv 0 \pmod n$,

$$\sum_{j=0}^{n-1} c_j c_{j+i} \leq t_a, \tag{1}$$

and

$$\sum_{j=0}^{n-1} c_j y_{j+i} \leq t_c. \tag{2}$$

Equation (1) is the autocorrelation property, and Eq. (2) is the cross-correlation property. Most research has focused on the case where $t_a = t_c = t$, in which case we refer to an (n, w, t) OOC. Again, one can refomulate these properties in terms of (partial) designs or packings. In this case, an OOC is a collection of w subsets of the integers $(\bmod n)$, such that for subsets $c, b \in C$,

$$|(c + i) \cap (c + j)| \leq t_a \ (i \neq j), \tag{3}$$

and

$$|(c + i) \cap (b + j)| \leq t_c. \tag{4}$$

Here, $c + i = \{x + i (\bmod n) \mid x \in c\}$.

An OOC code is equivalent to a cyclic design or packing. A code or packing is said to be cyclic if every cyclic shift of a codeword (or block) is another codeword. The set of all cyclic shifts of a codeword is said to be an *orbit*. A representative from that orbit is often called a base block. An (n, w, t) OOC is a set of base blocks for a cyclic (partial) $S(t + 1, w, n)$ design or packing (assuming $t < w$). Conversely, given such a cyclic partial $S(t + 1, w, n)$ design or packing, one can form an (n, w, t) OOC by taking one representative block or codeword from each orbit.

IV. MAXIMUM DISTANCE SEPARABLE CODES

For any linear code C, recall that the minimum distance equals the minimum weight of any nonzero codeword. Also, if C has dimension k, then $C^\perp$ has dimension $n - k$ and any parity check matrix H of C has rank $n - k$. If $c \in C$ is a codeword of minimum weight, $wt(c) = d$, then $Hc^\top = 0$ implies that d columns of H are dependent, but no $d - 1$ columns are dependent. Since H has rank $n - k$, every $n - k + 1$ columns of H are dependent. Thus,

$$d \leq n - k + 1.$$

This is known as the *Singleton Bound*, and any code meeting equality in this bound is known as a *maximum distance separable* code (or MDS code).

There are no interesting binary MDS codes, but there are such codes over other alphabets, for example, the Reed-Solomon codes used in CD encoding of order 256 (Reed-Solomon codes are described below). Even though such codes are treated mathematically as codes with 256 different "digits," each still has an implementation as a binary code, since each of the digits in the finite field $GF(2^8)$ can be represented by a binary word of length 8; that is, by one byte. So the first step in encoding the binary string representing all the music onto a CD is to divide it into bytes and to regard each such byte, as a field element in $GF(2^8)$.

We now consider a code $C \subseteq F^n$ as a set of codewords over the alphabet F, where F is typically the elements of a finite field. The are several equivalent definitions for a linear code C of length n and dimension k to be an MDS code:

1. C has minimum distance $d = n - k + 1$,
2. Every k column of G, the generating matrix for C, is linearly independent.
3. Every $n - k$ column of H, the parity check matrix for C, is linearly independent.

Note, that from item (3) above C is MDS if and only if $C^\perp$ is MDS.

If one arranges the codewords of C in an $|C| \times n$ array, then from item (2) this array will have the property that for any choice of k columns (or coordinates) and any word of length k, $w \in F^k$, there will be exactly one row of this array that has w in these coordinates. An *orthogonal array* is defined to be a $q^k \times n$ array with entries from a set F, $|F| = q$, with precisely this property: restricting the array to any k columns, every word $w \in F^k$ occurs exactly once in this $q^k \times k$ subarray. Two rows of an orthogonal array can agree in at most $k - 1$ coordinates, which means that they must disagree in at least $n - (k - 1)$ coordinates. Thus, the distance between any two rows of an orthogonal

array is $d = n - k + 1$. Obviously, the row vectors of an orthogonal array are also codewords of an MDS code, except that orthogonal arrays (and MDS codes) do not need to be linear and exist over arbitrary alphabets.

Orthogonal arrays were also introduced in the design of experiments in statistical studies and are closely related to designs and finite geometries. In fact, the construction for Reed-Solomon codes was first published by Bush as a construction of orthogonal arrays (see Bush, 1952; Colbourn and Dinitz, 1996).

There are various representations of the Reed-Solomon codes. We present the most perspicuous one. Again, let F denote a finite field and let $F_k[x]$ denote the space of all polynomials of degree less than k with coefficients from F. Choose $n > k$ different (nonzero) field elements $\alpha_1, \alpha_2, \ldots, \alpha_n \in F$. For each polynomial $f(x) \in F_k[x]$, form the *valuation vector* $c_f = (f(\alpha_1), f(\alpha_2), \ldots, f(\alpha_n))$. Define

$$C = \{c_f \mid f(x) \in F_k[x]\}.$$

First, we note that C is a linear code, since $c_f + c_g = c_{f+g}$. Second, for any two different polynomials $f(x), g(x) \in F_k[x]$, we have $c_f \neq c_g$; if c_f and c_g were equal, then the polynomial $f(x) - g(x)$ would have n roots but degree $< k (< n)$. This means that $|F_k[x]| = |F^k| = q^k = |C|$, and thus, C has dimension k and length n. Finally, since $f(\alpha_i) = 0$ if and only if α_i is a root of $f(x)$, and moreover any polynomial of degree $\leq k-1$ has at most $k-1$ roots, then c_f has at most $k-1$ zeros and at least $n-k+1$ nonzero entries. Therefore, the minimum distance for C is $n-k+1$ and C is an MDS code.

Reed-Solomon codes also have a representation as a cyclic code and a relatively efficient decoding algorithm (see Hoffman *et al.*, 1991, for example).

V. CONVOLUTIONAL CODES

Convolutional codes are practical codes, having been adopted for use by both NASA and the European Space Agency. In fact, they encode messages twice: first using a Reed-Solomon code, then the resulting codeword is encoded using a convolutional code.

Convolutional codes are infinite length codes that are both linear and cyclic. The messages to be considered are strung together into a stream of bits which form a single message m that is encoded by feeding m into a shift register (see Fig. 1). Initially, μ codewords are formed: for $1 \leq i \leq \mu$, and for each *tick* $t \geq 0$, the contents of certain registers are added together to form the t^{th} bit in the output of the codeword $c_i = c_{i,0}, c_{i,1}, c_{i,2}, \ldots$. The single codeword c to which m is encoded is then formed by $c = c_{1,0}c_{2,0}, \ldots, c_{\mu,0}c_{1,1}c_{2,1}, \ldots, c_{\mu,1}, \ldots$.

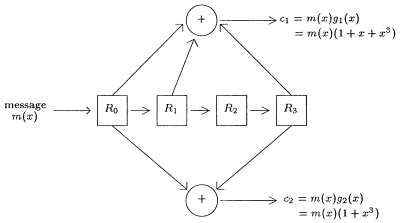

FIGURE 1 Convolutional code encoding.

Algebraically, one can represent the registers whose contents are added to form c_i by the polynomial $g_i = g_{i,0}x^0 + g_{i,1}x + \ldots g_{i,\ell}x^\ell$, where $g_{i,j} = 1$ if the contents in register R_j are used when forming c_i, and is 0 otherwise. Then by writing the message $m = m_0 m_1 m_2, \ldots$ in polynomial form $m(x) = m_0 + m_1 x + m_2 x^2 + \cdots$, it turns out that $c_i(x) = m(x)g_i(x)$. This representation of convolutional code encoding makes it clear why the code is cyclic and linear.

Convolutional codes can also be represented graphically. Assuming one message bit is moved into the shift register at each tick, the vertices of the directed graph are the 2^ℓ binary words $(r_0, r_1, \ldots, r_{\ell-1})$ that can make up the contents of the first ℓ registers $R_0, R_1, \ldots, R_{\ell-1}$, and there is a directed edge from $r = (r_0, r_1, \ldots, r_{\ell-1})$ to $s = (s_0, s_1, \ldots, s_{\ell-1})$ if and only if $s_i = r_{i-1}$ for $1 \leq i \leq \ell - 1$. So there is a directed edge from r to s if in one tick the contents of the first ℓ registers can change from r into s. Furthermore, the directed edge from $(m_{t+\ell}, m_{t+\ell-1}, \ldots, m_t)$ to $(m_{t+\ell+1}, m_{t+\ell}, \ldots, m_{t+1})$ is labeled with the t^{th} bits of $c_1, c_2, \ldots, c_\mu$; so this label is the contribution to c made at the t^{th} tick. This directed graph is essentially the transition diagram of the finite state machine formed by the shift register.

Representing a convolutional code with this directed graph D is helpful in understanding both encoding and decoding. Codewords simply correspond to walks in D with the codeword being the concatenation of the labels on the edges in the walk. If message bits are moved into the shift register one at a time, then there are exactly two arcs directed out of each vertex (corresponding to a message bit of a 0 or a 1 being moved into R_0), so the walk can head off in one of two possible directions. It is this observation that makes it clear what is involved in decoding. At each tick, decoding one message bit requires deciding which of the two directions to take from the current vertex (state). This decision cannot be based on knowing the entire received word, since it has arbitrarily long length. Instead, one gathers the next τ ticks worth of the received word, which together form, say, w', then finds which walk W emanating from the current state most closely matches w', then finally makes a decoding decision to take one step along W. This process can

be efficiently implemented by using the Viterbi Decoder. Deciding on how large to make τ can affect the codeword to which w is decoded (see Hoffman *et al*., 1991, for example).

In deciding which convolutional code to use, choices have to made about $g_1(x), \ldots, g_\mu(x)$ and the number k of message symbols to move into the shift register at each tick, usually chosen to be 1. The rate of the code is then k/μ.

Differential Equations, Ordinary

Anthony N. Michel
University of Notre Dame

GLOSSARY

Equilibrium or rest position For the system of equations $x' = f(t, x)$, any point x_e such that $f(t, x_e) = 0$ for all t is an equilibrium point or a rest position.

Fundamental matrix If $\{\phi_1, \ldots, \phi_n\}$ denotes a set of linearly independent solutions for the equation $x' = A(t)x$, then the matrix $\Phi = [\phi_1, \ldots, \phi_n]$ is a fundamental matrix of $x' = A(t)x$.

Initial-value problem The system of ordinary differential equations $x' = f(t, x)$ along with the initial data $x(\tau) = \xi$ is an initial value problem, where τ denotes initial time and ξ denotes the initial condition or the initial state.

***n*th-Order ordinary differential equations** Equation of the form $y^{(n)} = h(t, y^{(1)}, \ldots, y^{(n-1)})$ is an nth-order ordinary differential equation, where $y^{(i)}$ denotes the ith derivative of y with respect to t.

Qualitative theory of ordinary differential equations Study of families of solutions of ordinary differential equations, such as, for example, the (stability) properties of solutions near an equilibrium point.

Solution of an initial-value problem n-Vector-valued function ϕ is a solution of an initial-value problem if ϕ satisfies the equation $x' = f(t, x)$ andif $\phi(\tau) = \xi$.

State transition matrix For the initial value problem $x' = A(t)x$, $x(\tau) = \xi$, the matrix given by $\Phi(t, \tau) \triangleq \Phi(t)\Phi^{-1}(\tau)$ is the state transition matrix, where Φ denotes a fundamental matrix for $x' = A(t)x$ and Φ^{-1} denotes the inverse of Φ; the unique solution of the initial value problem is then $\phi(t, \tau, \xi) = \Phi(t, \tau)\xi$.

System of linear homogeneous differential equations System of equations given by $x' = A(t)x$ where x is an n vector and $A(t)$ denotes an $n \times n$ (time-varying) matrix is a linear homogeneous system of ordinary differential equations.

System of ordinary differential equations The system of equations given by $x' = f(t, x)$ where x is an n vector, t is real (time), f is a function, and x' denotes differentiation of x with respect to t is a system of n ordinary differential equations of the first order.

EQUATIONS containing the derivatives or differentials of one or more dependent variables, with respect to one or more independent variables, are called *differential equations*. If such equations contain only ordinary derivatives of one or more dependent variables, with respect to a single independent variable, then one speaks of *ordinary differential equations*. Equations involving the partial

derivatives of one or more dependent variables of two or more independent variables are called *partial differential equations*.

I. INTRODUCTION

In what follows, we will concern ourselves only with ordinary differential equations. The study of such equations may be divided into qualitative theory and quantitative theory (e.g., the numerical solution of differential equations). We will concern ourselves almost exclusively only with a qualitative theory for such equations.

Ordinary differential equations, which were first considdered in the seventeenth century by Leibnitz and Newton, arise in nearly all disciplines of science (physics, chemistry, biology, and the like) and engineering (aerospace, chemical, civil, electrical, mechanical, nuclear, and so forth) as well as in economics and societal systems. It is not an overstatement to say that a very great deal of applied mathematics involves in some way the study of differential equations.

The study of ordinary differential equations can be from fairly elementary and down-to-earth to rather advanced and abstract levels. In the current treatment we will follow a path between these two extremes. The study of ordinary differential equations at a very basic level requires as a prerequisite some knowledge of elementary calculus. At an intermediate level, the study of such equations demands some background in real variables and linear algebra, while at the advanced level, the study of differential equations may involve facts from measure and integration theory as well as functional analysis.

II. INITIAL-VALUE PROBLEMS

A. First-Order Ordinary Differential Equations

We let D denote a domain (i.e., an open, non-empty, and connected set) in the R^{n+1} space. We call R^{n+1} the (t, x) space, and we denote elements of R^{n+1} by $(t, x_1, \ldots, x_n) = (t, x)$ and elements of R^n by $(x_1, \ldots, x_n) = x$. Next we consider n functions $f_i, i = 1, \ldots, n$, which map D into the real numbers R. To express this, we write $f_i : D \to R$. We assume that each f_i is continuous at all points in D and we express this by writing $f_i \in C(D)$. Finally, we let $x_i^{(n)}$ denote the nth derivative of x_i with respect to t (provided that it exists) (i.e., $d^n x_i/dt^n = x_i^{(n)}$). In particular, when $n = 1$, we frequently write

$$x_i^{(1)} \triangleq x_i' = dx_i/dt$$

We call the system of equations given by:

$$x_i' = f_i(t, x_1, \ldots, x_n), \qquad i = 1, \ldots, n \qquad (\mathrm{E}_i)$$

a **system of n ordinary differential equations of the first order.** By a **solution** of the system of ordinary differential equations (E_i) we shall mean n continuously differentiable functions $\phi_1, \ldots, \phi_n$ defined on an interval $J = (a, b)$ (recall that (a, b) is the set of all t in R with the property $a < t < b$) such that $(t, \phi_1(t), \ldots, \phi_n(t)) \in D$ for all $t \in J$ and such that

$$\phi_i'(t) = f_i(t, \phi_1(t), \ldots, \phi_n(t))$$
$$i = 1, \ldots, n$$

for all $t \in J$.

Next, we let $(\tau, \xi_1, \ldots, \xi_n) \in D$. Then the **initial-value problem** associated with (E_i) is given by:

$$\begin{aligned} x_i' &= f_i(t, x_1, \ldots, x_n), && i = 1, \ldots, n \\ x_i(\tau) &= \xi_i, && i = 1, \ldots, n \end{aligned} \qquad (\mathrm{I}_i)$$

A set of functions $(\phi_1, \ldots, \phi_n)$ is a **solution** of (I_i) if $(\phi_1, \ldots, \phi_n)$ is a solution of (E_i) on some interval J containing τ and if $(\phi_1(\tau), \ldots, \phi_n(\tau)) = (\xi_1 \ldots, \xi_n)$.

In Fig. 1, the solution of a hypothetical initial-value problem is given when $n = 1$. Note that at (τ, ξ), $\phi'(\tau) = f(\tau, \phi(\tau)) = m$ is the slope of line L in the figure.

In dealing with systems of equations, we find it convenient to use vector notation, such as:

$$x = \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix}, \qquad \xi = \begin{bmatrix} \xi_1 \\ \vdots \\ \xi_n \end{bmatrix}, \qquad \phi = \begin{bmatrix} \phi_1 \\ \vdots \\ \phi_n \end{bmatrix}$$

$$f(t, x) = \begin{bmatrix} f_1(t, x_1, \ldots, x_n) \\ \vdots \\ f_n(t, x_1, \ldots, x_n) \end{bmatrix}$$

$$= \begin{bmatrix} f_1(t, x) \\ \vdots \\ f_n(t, x) \end{bmatrix}$$

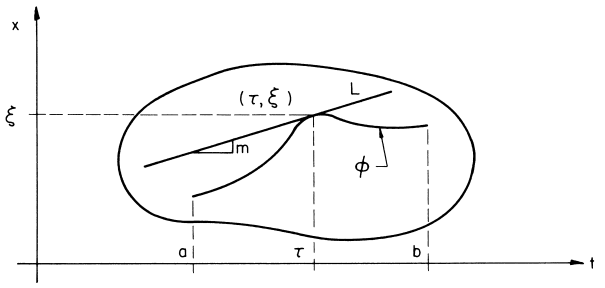

FIGURE 1 Solution of an initial-value problem; t interval $J = (a, b)$, m (slope of line L) $= f(\tau, \phi(\tau))$.

$$x' = \begin{bmatrix} x_1' \\ \vdots \\ x_n' \end{bmatrix}, \qquad \begin{bmatrix} \int_\tau^t f_1(s, \phi(s))\, ds \\ \vdots \\ \int_\tau^t f_n(s, \phi(s))\, ds \end{bmatrix}$$

$$= \int_\tau^t f(s, \phi(s))\, ds$$

With this notation we can express the initial-value problem (I_i) by:

$$x' = f(t, x), \qquad x(\tau) = \xi \tag{I}$$

It is an easy matter to verify that the initial-value problem (I) can equivalently be expressed by an integral equation of the form:

$$\phi(t) = \xi + \int_\tau^t f(s, \phi(s))\, ds \tag{V}$$

where ϕ denotes the solution of (I).

B. Classification of Systems of First-Order Differential Equations

We are now ready to classify systems of first-order differential equations in a variety of ways:

1. If in (I), $f(t, x) \equiv f(x)$ for all (t, x) in D, then

$$x' = f(x) \tag{A}$$

and we call (A) an **autonomous system** of first-order ordinary differential equations.

2. If $(t + T, x) \in D$ when $(t, x) \in D$ and if $f(t, x) = f(t + T, x)$ for all $(t, x) \in D$ then (I) assumes the form

$$x' = f(t, x) = f(t + T, x) \tag{P}$$

Such a system is called a **periodic system** of first-order differential equations of period T. The smallest $T > 0$ for which (P) is true is the **least period** of this system of equations.

3. When in (I), $f(t, x) = A(t)x$, where $A(t) = [a_{ij}(t)]$ is a real $n \times n$ matrix with elements $a_{ij}(t)$ which are defined and at least piecewise continuous on a t interval J, then we have

$$x' = A(t)x \tag{LH}$$

and we speak of a **linear homogeneous system** of ordinary differential equations.

4. If for (LH) $A(t)$ is defined for all real t and if there is a $T > 0$ such that $A(t) = A(t + T)$ for all t, then we have

$$x' = A(t)x = A(t + T)x \tag{LP}$$

This system is called a **linear periodic system** of ordinary differential equations.

5. If in (I), $f(t, x) = A(t)x + g(t)$, where $g(t)^{\mathrm{T}} = [g_1(t), \ldots, g_n(t)]$ and where $g_i: J \to R$, then we have

$$x' = A(t)x + g(t) \tag{LN}$$

In this case we speak of a **linear nonhomogeneous system of ordinary differential equations.**

6. If in (I), $f(t, x) = Ax$, where $A = [a_{ij}]$ is a real $n \times n$ matrix with constant coefficients, then we have

$$x' = Ax \tag{L}$$

This type of system is called a **linear, autonomous, homogeneous** system of ordinary differential equations.

C. *n* th-Order Ordinary Differential Equations

Thus far we have concerned ourselves with systems of first-order ordinary differential equations. It is also possible to characterize initial value problems by means of nth-order ordinary differential equations. To this end, we let h be a real function which is defined and continuous on a domain D of the real $(t, y_1, \ldots, y_n)$ space. Then

$$y^{(n)} = h\big(t, y^{(1)}, \ldots, y^{(n-1)}\big) \tag{E_n}$$

is an nth-**order ordinary differential equation.** A **solution** of (E_n) is a real function ϕ which is defined on a t interval $J = (a, b)$ which has n continuous derivatives on J and satisfies $(t, \phi(t), \ldots, \phi^{(n-1)}(t)) \in D$ for all $t \in J$ and

$$\phi^{(n)}(t) = h\big(t, \phi(t), \ldots, \phi^{(n-1)}(t)\big)$$

for all $t \in J$.

Now for a given $(\tau, \xi_1, \ldots, \xi_n) \in D$, the initial value problem for (E_n) *is*

$$\begin{aligned} y^{(n)} &= h\big(t, y, y^{(1)}, \ldots, y^{(n-1)}\big) \\ y^{(\tau)} &= \xi_1, \ldots, y^{(n-1)}(\tau) = \xi_n \end{aligned} \tag{I_n}$$

A function ϕ is a solution of (I_n) if ϕ is a solution of Eq. (E_n) on some interval containing τ and if $\phi(\tau) = \xi_1, \ldots, \phi^{(n-1)}(\tau) = \xi_n$.

As in the case of systems of first-order equations, we single out several special cases.

1. Consider equations of the form

$$y^{(n)} + a_{n-1}(t)y^{(n-1)} + \cdots + a_1(t)y^{(1)} + a_0(t)y = g(t) \tag{1}$$

where $a_{n-1}(t), \ldots, a_0(t)$ are real continuous functions defined on the interval J. We refer to Eq. (1) as a **linear homogeneous ordinary differential equation of order** n.

2. If in (1) we let $g(t) \equiv 0$, then

$$y^{(n)} + a_{n-1}(t)y^{(n-1)} + \cdots + a_1(t)y^{(1)} + a_0(t)y = 0 \tag{2}$$

We call Eq. (2) a **linear homogeneous ordinary differential equation of order** n.

3. If in (2) we have $a_i(t) \equiv a_i$, $i = 0, 1, \ldots, n-1$, then

$$y^{(n)} + a_{n-1}y^{(n-1)} + \cdots + a_1 y^{(1)} + a_0 y = 0 \qquad (3)$$

and we call Eq. (3) a **linear, autonomous, homogeneous ordinary differential equation of order** n.

We can, of course, also define **periodic** and **linear periodic ordinary differential equations of order** n in the obvious way.

It turns out that the theory of nth-order ordinary differential equations reduces to the theory of a system of n first-order ordinary differential equations. To this end, we let $y = x_1$, $y^{(1)} = x_2, \ldots, y^{(n-1)} = x_n$ in Eq. (I_n). Then we have the system of first-order ordinary differential equations:

$$\begin{aligned} x_1' &= x_2 \\ x_2' &= x_3 \\ &\vdots \\ x_n' &= h(t, x_1, \ldots, x_n) \end{aligned} \qquad (4)$$

which is defined for all $(t, x_1, \ldots, x_n) \in D$. Assume that the vector $\phi = (\phi_1, \ldots, \phi_n)^{\mathrm{T}}$ is a solution of (4) on an interval J. Since $\phi_2 = \phi_1', \phi_3 = \phi_2', \ldots, \phi_n = \phi_1^{(n-1)}$, and since

$$\begin{aligned} &h(t, \phi_1(t), \ldots, \phi_n(t)) \\ &\quad = h\big(t, \phi_1(t), \ldots, \phi_1^{(n-1)}(t)\big) = \phi_1^{(n)}(t) \end{aligned}$$

it follows that the first component ϕ_1 of the vector ϕ is a solution of Eq. (E_n) on the interval J. Conversely, if ϕ_1 is a solution of (E_n) on J, then the vector $(\phi, \phi^{(1)}, \ldots, \phi^{(n-1)})^{\mathrm{T}}$ is clearly a solution of Eq. (4). Moreover, if $\phi_1(\tau) = \xi_1, \ldots, \phi_1^{(n-1)}(\tau) = \xi_n$, then the vector ϕ satisfies $\phi(\tau) = \xi = (\xi_1, \ldots, \xi_n)^{\mathrm{T}}$. The converse is also true.

D. Examples of Initial-Value Problems

We conclude the present section with several representative examples.

1. Consider the second-order ordinary differential equation given by:

$$m\, d^2x/dt^2 + g(x) = 0 \qquad (5)$$

where $m > 0$ is a constant and $g: R \to R$ is continuous. This equation, along with $x(0) = \xi_1$ and $x'(0) = \xi_2$ specified, constitutes an initial-value problem. If we let $x_1 = x$ and $x_2 = x'$, then Eq. (5) can equivalently be represented by a system of two first-order ordinary differential equations given by:

$$x_1' = x_2, \qquad x_2' = -(1/m)g(x_1) \qquad (6)$$

with $x_1(0) = \xi_1$ and $x_2(0) = \xi_2$.

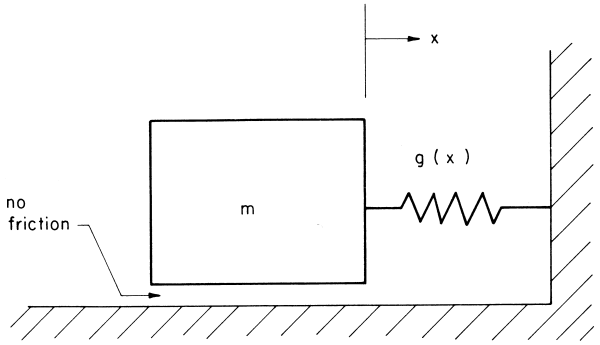

FIGURE 2 Mass–spring system.

Equation (5) can be used to describe a variety of physical phenomena. Consider, for example, the mass–spring system depicted in Fig. 2. When the system is in the rest position, then $x = 0$; otherwise, x is positive in the direction of the arrow or negative otherwise. The function $g(x)$ denotes the restoring force of the spring while the mass is expressed by m (in a consistent set of units).

There are several well-known special cases for Eq. (5):

(a) If $g(x) = kx$, where $k > 0$ is known as Hooke's constant, then Eq. (5) is a linear ordinary differential equation called the *harmonic oscillator*.

(b) If $g(x) = k(1 + a^2x^2)x$, where $k > 0$ and $a^2 > 0$ are parameters, then Eq. (5) is a nonlinear ordinary differential equation and one refers to the resulting system as a "mass and a hard spring."

(c) If $g(x) = k(1 - a^2x^2)x$, where $k > 0$ and $a^2 > 0$ are parameters, then Eq. (5) is a nonlinear ordinary differential equation and one refers to the resulting system as a "mass and a soft spring."

Alternatively, Eq. (5) can be used to describe the behavior of the pendulum shown in Fig. 3 with $\theta = x$. In this case, the restoring force $g(x)$ is specified by:

$$g(x) = m(g/l)\sin x$$

2. Using Kirchhoff's voltage and current laws, the circuit of Fig. 4 can be modeled by the linear system of equations:

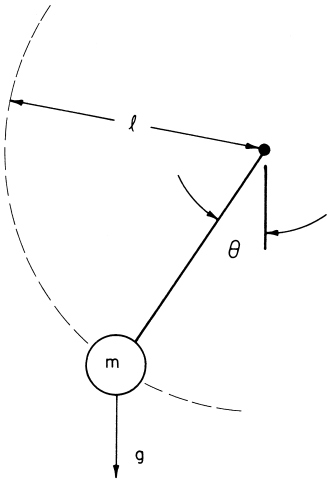

FIGURE 3 Simple pendulum.

$$
\begin{aligned}
v_1' &= -\frac{1}{C_1}\left(\frac{1}{R_1}+\frac{1}{R_2}\right)v_1 + \frac{1}{R_2C_2}v_2 + \frac{v}{R_1C_1} \\
v_2' &= -\frac{1}{C_1}\left(\frac{1}{R_1}+\frac{1}{R_2}\right)v_1 - \left(\frac{R_2}{L}-\frac{1}{R_2C_1}\right)v_2 \\
&\quad + \frac{R_2}{L}v_3 + \frac{v}{R_1C_1} \\
v_3' &= \frac{1}{R_2C_2}v_1 - \frac{1}{R_2C_2}v_2
\end{aligned}
\tag{7}
$$

In order to complete the description of this circuit, we need to specify the initial conditions $v_1(0)$, $v_2(0)$, and $v_3(0)$.

III. FUNDAMENTAL THEORY

In this section, we address the following questions:

1. Under what conditions has the initial-value problem (I) *at least one solution* for a given set of initial data (τ, ξ)?
2. Under what conditions has (I) *exactly one solution* for given (τ, ξ)?

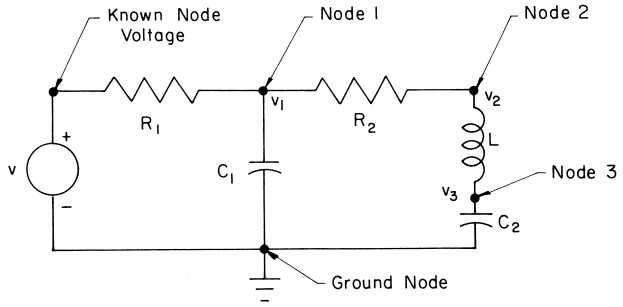

FIGURE 4 An example of an electric circuit.

3. What is the extent of the time interval over which one or more solutions exist for (I)?
4. How do solutions for (I) behave when the initial data (τ, ξ) (or some other parameters for the differential equation) are varied?

The significance of the preceding questions is brought further to light when the following examples are considered.

1. For the initial-value problem,

$$x' = -\operatorname{sgn} x, \qquad x(0) = 0, \quad t \geq 0 \tag{8}$$

where

$$\operatorname{sgn} x = \begin{cases} 1, & x > 0 \\ 0, & x = 0 \\ -1, & x < 0 \end{cases}$$

no continuously differentiable function ϕ exists which satisfies Eq. (8). Hence, *no solution* (as defined in Section II) exists for the present initial-value problem.

2. The initial-value problem,

$$x' = 1/(2x), \qquad x(0) = 0, \quad t \geq 0 \tag{9}$$

has *two solutions* given by $\phi(t) = \pm t^{1/2}$ which exist for all $t \geq 0$.

3. The initial-value problem,

$$x' = 1 + x^2, \qquad x(0) = 0, \quad t \geq 0 \tag{10}$$

has the *unique solution* given by $\phi(t) = \tan t$. This solution exists only when $0 \leq t < \pi/2$, since ϕ is not continuously differentiable at $t = \pi/2$. In this case, we say that this solution has *finite escape time*.

4. The initial-value problem given by:

$$x' = ax, \qquad x(\tau) = \xi \tag{11}$$

where a is a fixed parameter, has a unique solution given by $\phi(t) = \phi(t, \tau, \xi) = \xi e^{a(t-\tau)}$ which exists for all real t. Note that the solution ϕ is continuous with respect to the parameters, a, τ, and ξ.

A. Existence of Solutions

In order to simplify our presentation, we will consider in the next few results one-dimensional initial value problems (i.e., we will assume that for (I), $n = 1$). Later in this section we will show how these results are modified for higher dimensional systems. Thus, we have a domain $D \in R^2$, we are given $(\tau, \xi) \in D$ and $f \in C(D)$, and *we seek a solution for the initial-value problem*,

$$x' = f(t, k), \qquad x(\tau) = \xi \tag{I'}$$

In doing so, it suffices to find a solution of the integral equation:

$$\phi(t) = \xi + \int_{\tau}^{t} f(s, \phi(s))\, ds \qquad (V')$$

One way of solving the above problem is by considering approximations to a solution first; an ε-**approximate solution** for (I′) on an interval J containing τ is a real-valued function ϕ which is piecewise continuously differentiable on J and satisfies $\phi(\tau) = \xi$, $(t, \phi(t)) \in D$ for all $t \in J$, and which satisfies:

$$|\phi'(t) - f(t, \phi(t))| < \varepsilon$$

at all points t of J where $\phi'(t)$ exists.

Let us now consider a subset S of D defined by:

$$S = \{(t, x) \in D: |t - \tau| \le a, |x - \xi| \le b\} \subset D$$

Since $f \in C(D)$, there is an $M \ge 0$ such that $|f(t, x)| \le M$ for all $(t, x) \in S$. Now define $c \triangleq \min\{a, b/M\}$ and, depending on the size of M relative to a, define one of the triangular regions shown either in Fig. 5a or 5b.

It is now not too difficult to prove the following results:

If $f \in C(D)$ and if c is as defined above, then for any $\varepsilon > 0$ there is an ε-approximate solution of (I′) *on the interval $|t - \tau| \le c$.*

Indeed, for a given $\varepsilon > 0$, such a solution will be of the form:

$$\begin{aligned} \phi(t) &= \phi(t_j) + f(t_j, \phi(t_j))(t - t_j) \\ t_j &\le t \le t_{j+1}, \qquad j = 0, 1, 2, \ldots, m-1 \end{aligned} \qquad (12)$$

when $t \ge \tau = t_0$ (the case in which $t \le \tau$ is modified in the obvious way). In Eq. (12), the choice of m and of $\max|t_{j+1} - t_j|$ will depend on ε but not on t, but in any

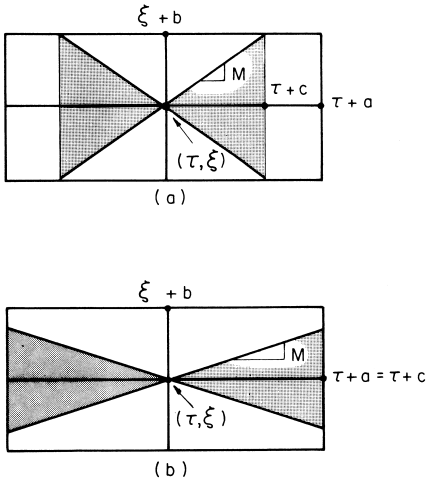

FIGURE 5 (a) Case $c = b/M$. (b) Case $c = a$.

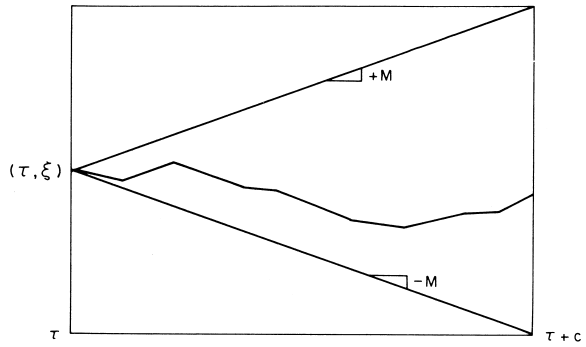

FIGURE 6 Typical ε-approximation solution.

case, we have $\sum_{j=0}^{m-1} |t_{j+1} - t_j| = c$. In Fig. 6, a typical ε-approximate solution is shown.

Next, let us consider a monotone decreasing sequence of real numbers with limit zero, and let us denote this sequence by $\{\varepsilon_m\}$. An example of such a sequence would be the case when $\varepsilon_m = 1/m$, where m denotes all positive integers greater or equal to one. Corresponding to each ε_m, let us consider now an ε_m-approximate solution which we denote by ϕ_m. Next, let us consider the family of ε_m-approximate solutions $\{\phi_m\}$, $m = 1, 2, \ldots$. This family $\{\phi_m\}$ is an example of an *equicontinuous* family of functions. Now, according to *Ascoli's lemma*, an equicontinuous family $\{\phi_m\}$, as constructed above, will contain a subsequence of functions, which we denote by $\{\phi_{m_k}\}$, which converges uniformly on the interval $[\tau - c, \tau + c]$ to a continuous function ϕ; that is,

$$\lim_{k \to \infty} \phi_{m_k}(t) = \phi(t), \qquad \text{uniformly in } t \qquad (13)$$

Now it turns out that ϕ is continuously differentiable on the interval $(\tau - c, \tau + c)$ and that it satisfies the integral equation (V′) and, hence, the initial-value problem (I′). In other words, ϕ is a solution of (I′).

The preceding discussion gives rise to the **Cauchy–Peano existence theorem:**

If $f \in C(D)$ and $(\tau, \xi) \in D$, then the initial-value problem (I′) *has a solution defined on $|t - \tau| \le c$ where c is as defined in Fig. 5.*

We mention in passing that a special case of Eq. (12),

$$\phi(t_{j+1}) = \phi(t_j) + f(t_j, \phi(t_j))(t_{j+1} - t_j) \qquad (14)$$

is known as **Euler's method** of solving ordinary differential equations.

It should be noted that the above result yields only a *sufficient condition.* In other words, when f is not continuous on the domain D, then the initial-value problem (I′) may or may not possess a solution in the sense defined in Section II.

The above result asserts the existence of a solution (I′) "locally," that is, only on a sufficiently short time interval (determined by $|t-\tau| \le c$). In general, this assertion cannot be changed to existence of a solution for all $t \ge \tau$ (or for all $t \le \tau$) as the following example shows:

The initial-value problem,

$$x' = x^2, \qquad x(\tau) = \xi$$

has a solution $\phi(t) = \xi[1 - \xi(t-\tau)]^{-1}$ which exists forward in time for $\xi > 0$ only until $t = \tau + \xi^{-1}$.

B. Continuation of Solutions

Our next task is to determine if it is possible to extend a solution ϕ to a larger interval than was indicated above ($|t-\tau| \le c$). The answer to this is affirmative. To see this, suppose that $f \in C(D)$ and suppose also that f is bounded on D. Suppose also that by some procedure, as above, it was possible to show that ϕ is a solution of the scalar differential equation,

$$x' = f(t, x) \qquad (\mathrm{E}')$$

on an interval $J = (a, b)$. Using expression (V′) for ϕ it is an easy matter to show that the limit of $\phi(t)$ as t approaches a from the right exists and that the limit of $\phi(t)$ as t approaches b from the left exists; that is,

$$\lim_{t \to a^+} \phi(t) = \phi(a^+)$$

and

$$\lim_{t \to b^-} \phi(t) = \phi(b^-)$$

Now clearly, if the point $(a, \phi(a^+)) \in D$ (resp., if $(b, \phi(b^-)) \in D$), then by repeating the procedure given in the above results (ε-approximate solution result and Peano–Cauchy theorem), the solution ϕ can be continued to the left past the point $t = a$ (resp., to the right past the point $t = b$). Indeed, it should be clear that repeated applications of these procedures will make it possible to continue the solution ϕ to the boundary of D. This is depicted in Fig. 7. It is worthwhile to note that the solution ϕ in this figure exists over the interval J' and not over the interval $\tilde{J}$.

We summarize the preceding discussion in the following **continuation result**:

If $f \in C(D)$ and if f is bounded on D, then all solutions of (E′) *can be extended to the boundary of D. These solutions are then* **noncontinuable**.

C. Uniqueness of Solutions

Next, we address the question of uniqueness of solutions. To accomplish this, we require the following concept:

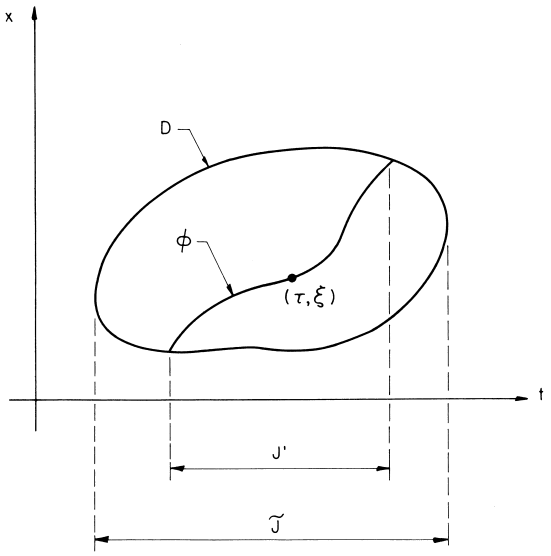

FIGURE 7 Continuation of a solution ϕ to ∂D.

$f \in C(D)$ is said to satisfy a **Lipschitz condition** on D (with respect to x) with **Lipschitz constant** L if

$$|f(t, \bar{\bar{x}}) - f(t, \bar{x})| \le L|\bar{\bar{x}} - \bar{x}| \qquad (15)$$

for all $(t, \bar{x})(t, \bar{\bar{x}})$ in D. The function f is said to be **Lipschitz continuous** in x on D in this case.

For example, it can be shown that if $\partial f(t, x)/\partial x$ exists and is continuous on D, then f will be Lipschitz continuous on any compact and convex subsect D_0 of D.

In order to establish a uniqueness result for solutions of the initial value problem (I′), we will also require a result known as the **Gronwall inequality**: Let r and k be continuous nonnegative real functions defined on an interval $[a, b]$ and let $\delta \ge 0$ be a constant. If

$$r(t) \le \delta + \int_a^t k(s) r(s)\, ds \qquad (16)$$

then

$$r(t) \le \delta \exp\left(\int_a^t k(s)\, ds \right) \qquad (17)$$

Now suppose that for (I′) the Cauchy–Peano theorem holds and suppose that for *one* given $(\tau, \xi) \in D$, *two* solutions ϕ_1 and ϕ_2 exist over some interval $|t-\tau| \le d$, $d > 0$. On the interval $\tau \le t \le \tau + d$ we now have, using (V′) to express ϕ_1 and ϕ_2,

$$\phi_1(t) - \phi_2(t) = \int_\tau^t [f(s, \phi_1(s)) - f(s, \phi_2(s))]\, ds \qquad (18)$$

Now if, in addition, f is Lipschitz continuous in x, then Eq. (18) yields:

$$|\phi_1(t) - \phi_2(t)| \le \int_\tau^t L|\phi_1(s) - \phi_2(s)|\, ds$$

Letting $r(t) = |\phi_1(t) - \phi_2(t)|$, $\delta = 0$, and $k(t) \equiv L$, and applying the Gronwall inequality, we now obtain:

$$|\phi_1(t) - \phi_2(t)| \le 0 \quad \text{for all} \quad \tau \le t \le \tau + d$$

Hence, it must be true that $\phi_1(t) = \phi_2(t)$ on $\tau \le t \le \tau + d$. A similar argument will also work for the interval $\tau - d \le t \le \tau$.

Summarizing, we have the following **uniqueness result**:

If $f \in C(D)$ and if f satisfies a Lipschitz condition on D with Lipschitz constant L, then the initial-value problem (I′) *has at most one solution on any interval $|t - \tau| \le d$, $d > 0$.*

If the solution ϕ of (I′) is unique, then the ε-approximate solutions constructed before will tend to ϕ as $\varepsilon \to 0^+$ and this is the basis for justifying Euler's method—a numerical method of constructing approximations to ϕ. Now, if we assume that f satisfies a Lipschitz condition, an alternative classical method of approximation is the **method of successive approximations**. Specifically, let $f \in C(D)$ and let S be the rectangle in D centered at (τ, ξ) shown in Fig. 5 and let c be defined as in Fig. 5. Successive approximations for (I′), or equivalently for (V′), are defined as:

$$\phi_0(t) = \xi$$

$$\phi_{m+1}(t) = \xi + \int_\tau^t f(s, \phi_m(s))\, ds, \qquad (19)$$

$$m = 0, 1, 2, \ldots$$

for $|t - \tau| \le c$.

The following result is the basis for justifying the method of successive approximations:

If $f \in C(D)$ and if f is Lipschitz continuous on S with constant L, then the successive approximations ϕ_m, $m = 0, 1, 2, \ldots$, given in Eq. (19) *exist on $|t - \tau| \le c$, are continuous there, and converge uniformly, as $m \to \infty$, to the unique solution of* (I′).

D. Continuity of Solutions with Respect to Parameters

Our next objective is to study the dependence of solutions ϕ of (I′) on initial data (τ, ξ). In this connection, we find it advantageous to highlight this dependence by writing $\phi(t) = \phi(t, \tau, \xi)$.

Now suppose that $f \in C(D)$ and suppose that f satisfies a Lipschitz condition on D with Lipschitz constant L. Furthermore, suppose that ϕ and ψ solve:

$$x' = f(t, x) \qquad (\mathrm{E}')$$

on an interval $|t - \tau| \le d$ with $\psi(\tau) = \xi_0$ and $\phi(\tau) = \xi$. Then, by using (V′), we obtain:

$$|\phi(t, \tau, \xi) - \psi(t, \tau, \xi_0)| \le |\xi - \xi_0| + \int_\tau^t L\,|\phi(s, \tau, \xi) - \psi(s, \tau, \xi_0)|\, ds$$

and by using the Gronwall inequality with $\delta = |\xi - \xi_0|$, $L \equiv k(s)$, and $r(t) = |\phi(t) - \psi(t)|$, we obtain the estimate:

$$|\phi(t, \tau, \xi) - \psi(t, \tau, \xi_0)| \le |\xi - \xi_0| \exp(L\,|t - \tau|)$$

$$t \in |t - \tau| \le d \qquad (20)$$

If, in particular, we consider a sequence of initial conditions $\{\xi_m\}$ having the property that $\xi_m \to \xi_0$ as $m \to \infty$, then it follows from Eq. (20) that $\phi(t, \tau, \xi_m) \to \phi(t, \tau, \xi_0)$, uniformly in t on $|t - \tau| \le d$.

Summarizing, we have the following **continuous dependence result**:

Let $f \in C(D)$ and assume that f satisfies a Lipschitz condition on D. Then, the unique solution $\phi(t, \tau, \xi)$ of (I′)*, existing on some bounded interval containing τ, depends continuously on ξ, uniformly in t.*

This means that if $\xi_m \to \xi_0$ then $\phi(t, \tau, \xi_m) \to \phi(t, \tau, \xi_0)$, uniformly in t on $|t - \tau| \le d$ for some $d > 0$.

In a similar manner we can show that $\phi(t, \tau, \xi)$ will depend continuously on the initial time τ. Furthermore, if the differential equation (E′) depends on a parameter, say μ, then the solutions of the corresponding initial value problem may also depend in a continuous manner on μ, provided that certain safeguards are present. We consider a specific case in the following.

Consider the initial-value problem,

$$x' = f(t, x, \mu), \qquad x(\tau) = \xi_\mu = \mu + 1 \qquad (\mathrm{I}'_\mu)$$

where μ is a scalar parameter. Let f satisfy Lipschitz conditions with respect to x and μ for $(t, x) \in D$ and for $|\mu - \mu_0| < c$. Using an argument similar to the one employed in connection with Eq. (20), we can show that the solution $\phi(t, \tau, \xi_\mu, \mu)$ of (I'_μ), where ξ_μ depends continuously on μ, is a continuous function of μ (i.e., as $\mu \to \mu_0$, $\xi_\mu \to \xi_{\mu 0}$, and $\phi(t, \tau, \xi_\mu, \mu) \to \phi(t, \tau, \xi_{\mu 0}, \mu_0)$).

As an example, consider the initial-value problem

$$x' = x + \mu t, \qquad x(\tau) = \xi_\mu = \mu + 1 \qquad (21)$$

The right-hand side of Eq. (21) has a Lipschitz constant with respect to x equal to one and with respect to μ equal to $|a - b|$, where $J = (a, b)$ is assumed to be a bounded t-interval. The solution of (I'_μ) is

$$\phi(t, \tau, \xi_\mu, \mu) = [\mu(\tau + 2) + 1]e^{(t-\tau)} - \mu(t + 1) \qquad (22)$$

At $t = \tau$, we have $\phi(\tau, \tau, \xi_\mu, \mu) = \mu + 1 = x(\tau)$. Now what happens when $\mu \to 0$? In this case, Eq. (21) becomes:

$$x' = x, \qquad x(\tau) = 1 \qquad (23)$$

while the solution of Eq. (23) is

$$\phi(t) = e^{t-\tau} \tag{24}$$

If we let $\mu \to 0$ in Eq. (22), then we also obtain:

$$\phi(t, \tau, \xi_0, 0) = e^{t-\tau} \tag{25}$$

as expected.

E. Systems of Equations

In the interests of simplicity, we have considered thus far in this section the one-dimensional initial-value problem (I′). It turns out that the preceding results can be restated and proved for initial-value problems (I) involving systems of equations (E). In doing so, one must replace absolute values of scalars by norms of vectors or matrices, convergence of scalars by convergence of vectors and matrices, and so forth.

Rather than go through the task of restating the preceding results for systems of equations, we present as an illustration an additional result. Specifically, consider the linear system of equations

$$x' = A(t)x + g(t) = f(t, x) \tag{LN}$$

where $A(t) = [a_{ij}(t)]$ is an $n \times n$ matrix and $g(t)$ is an n-vector. We assume that $a_{ij}(t)$, $i, j = 1, \ldots, n$, and $g_i(t)$, $i = 1, \ldots, n$, are real and continuous functions defined on an interval J.

By making use of the taxicab norm given by

$$|x| = \sum_{i=1}^{n} |x_i|$$

it is an easy matter to show that for t on any compact subinterval J_0 of J there exists $L_0 \geq 0$ such that

$$|f(t, \bar{x}) - f(t, \bar{\bar{x}})| \leq \left(\sum_{i=1}^{n} \max_{1 \leq j \leq n} |a_{ij}(t)| \right) |\bar{x} - \bar{\bar{x}}|$$
$$\leq L_0 |\bar{x} - \bar{\bar{x}}| \tag{26}$$

If we now invoke the results of the present section (rephrased for systems of equations), we obtain the following:

Suppose that $A(t)$ and $g(t)$ in (LN) *are defined and continuous on an interval J. Then for any τ in J and any ξ in R^n, Eq.* (LN) *has a unique solution satisfying $x(\tau) = \xi$. This solution exists on the entire interval J and is continuous in (t, τ, ξ). If A and g depend continuously on parameters $\lambda \in R^l$, then the solution will also vary continuously with λ.*

It is emphasized that the above result is a *global* result, since the solution ϕ exists over the *entire* interval J. On the other hand, as noted before, our earlier results in this section will in general be of a *local* nature.

F. Differentiability of Solutions with Respect to Parameters

In some of the preceding results we investigated the continuity of solutions with respect to parameters. Next, we address the question of differentiability of solutions with respect to parameters for the initial-value problem,

$$x' = f(t, x), \qquad x(\tau) = \xi \tag{I}$$

Again we assume that $f \in C(D)$, $(\tau, \xi) \in D \subset R^{n+1}$, where D is a domain. In addition, we assume that $f(t, x)$ is differentiable with respect to $x_1, \ldots, x_n$ and we form the Jacobian matrix $f_x(t, x)$ given by:

$$f_x(t, x) = \frac{\partial f}{\partial x}(t, x)$$
$$= \begin{bmatrix} \frac{\partial f_1}{\partial x_1}(t, x) & \frac{\partial f_1}{\partial x_2}(t, x) & \cdots & \frac{\partial f_1}{\partial x_n}(t, x) \\ \vdots & \vdots & & \vdots \\ \frac{\partial f_n}{\partial x_1}(t, x) & \frac{\partial f_n}{\partial x_2}(t, x) & \cdots & \frac{\partial f_n}{\partial x_n}(t, x) \end{bmatrix} \tag{27}$$

Under the above conditions, it can be shown that when f_x exists and is continuous, then the solution ϕ of (I) depends smoothly on the parameters of the problem. More specifically,

Let $f \in C(D)$, let f_x exist, and let $f_x \in C(D)$. If $\phi(t, \tau, \xi)$ is the solution of (E) *such that $\phi(\tau, \tau, \xi) = \xi$, then ϕ is continuously differentiable in (t, τ, ξ). Each vector-valued function $\partial\phi/\partial\xi_i$ or $\partial\phi/\partial\tau$ will solve*:

$$y' = f_x(t, \phi(t, \tau, \xi))y$$

as a function of t while

$$\frac{\partial \phi}{\partial \tau}(\tau, \tau, \xi) = -f(\tau, \xi)$$

and

$$\frac{\partial \phi}{\partial \xi}(\tau, \tau, \xi) = E_n$$

where E_n denotes the $n \times n$ identity matrix.

G. Comparison Theory

We conclude this section by touching on the **comparison theory** for differential equations. This theory is useful in continuation of solutions, in establishing estimates on bounds of solutions, and, as we will see later, in stability theory. Before we can present some of the main results of this theory we need to introduce a few concepts.

Once again we consider the scalar initial-value problem,

$$x' = f(t, x), \qquad x(\tau) = \xi \tag{I'}$$

where $f \in C(D)$ and $(\tau, \xi) \in D$. For (I′) we define the **maximal solution** ϕ_M as that noncontinuable solution of (I′) having the property that if ϕ is any other solution of (I′), then $\phi_M(t) \geq \phi(t)$ as long as both solutions are defined. The **minimal solution** ϕ_m of (I′) is defined in a similar manner. It is not too difficult to prove that ϕ_M and ϕ_m actually exist.

In what follows, we also need the concept of **upper right Dini derivative** D^+x. Given $x: (\alpha, \beta) \to R$ and $x \in C(\alpha, \beta)$ (i.e., x is a continuous real-valued function defined on the interval (α, β)), we define:

$$D^+x(t) = \lim_{h \to 0^+} \sup[x(t+h) - x(t)]/h$$

$$\triangleq \overline{\lim}[x(t+h) - x(t)]/h$$

where lim sup denotes the limit supremum. The **lower right Dini derivative** D^-x is defined similarly, replacing the lim sup by the lim inf.

We will also require the concept of differential inequalities, such as, for example, the inequality,

$$D^+x(t) \leq f(t, x(t)) \qquad \text{on} \quad D \tag{28}$$

Any function ϕ satisfying Eq. (28) is called a *solution* for (28). Differential inequalities involving D^-x are defined similarly.

Our first comparison result is now as follows:

Suppose that the maximal solution ϕ_M of (I′) stays in D for all $t \in [\tau, T]$. If a continuous function $\psi(t)$ with $\psi(\tau) = \xi$ satisfies

$$\psi'(t) \triangleq D^+\psi(t) \leq f(t, \psi(t)) \qquad \text{on} \quad D$$

then it is true that

$$\psi(t) \leq \phi_M(t) \qquad \text{for all} \quad t \in [\tau, T]$$

A similar result involving minimal solutions can also be established.

The above result can now be applied to systems of equations to obtain estimates for the norms of solutions. We have the following:

Let $f \in C(D)$, $D \subset R^{n+1}$, and let ϕ be a solution of

$$x' = f(t, x), \qquad x(\tau) = \xi \tag{I}$$

Let $F(t, v)$ be a scalar-valued continuous function such that

$$|f(t, x)| \leq F(t, |x|) \qquad \text{for all} \quad (t, x) \in D$$

where $|f(t, x)|$ denotes any one of the equivalent norms of $f(t, x)$ on R^n. If $\eta \leq |\phi(\tau)|$ and if v_M denotes the maximal solution of the scalar comparison equation given by:

$$v' = F(t, v), \qquad u(\tau) = \eta \tag{29}$$

then

$$|\phi(t)| \leq v_M(t)$$

for as long as both functions exist. (Here, $|\phi(t)|$ denotes the norm of $\phi(t)$.)

As an application of this result, suppose that $f(t, x)$ in (E) is such that

$$|f(t, x)| \leq A|x| + B$$

for all $t \in J$ and for all $x \in R^n$, where $J = [t_0, T]$, and where $A > 0$, $B > 0$ are parameters. Then Eq. (29) assumes the form:

$$v' = Au + B, \qquad v(\tau) = \eta$$

According to the above result, we now have

$$v_M(t) = e^{A(t-\tau)}(\eta - B/A) + B/A$$

Since $v_M(t)$ exists for all $t \in J$, then so do the solutions of (E). Also, if ϕ is any solution of (E) with $|\phi(\tau)| \leq \eta$, then the estimate,

$$|\phi(t)| \leq e^{A(t-\tau)}(\eta - (\beta/A)) + (\beta/A)$$

is true.

IV. LINEAR SYSTEMS

Both in the theory of differential equations and in their applications, linear systems of ordinary differential equations are extremely important. In this section we first present the general properties of linear systems. We then turn our attention to the special cases of linear systems of ordinary differential equations with constant coefficients and linear systems of ordinary differential equations with periodic coefficients. We also address some of the properties of nth-order linear ordinary differential equations.

A. Linear Homogeneous and Nonhomogeneous Systems

We first consider linear homogeneous systems,

$$x' = A(t)x \tag{LH}$$

As noted in Section III, this system possesses unique solutions for every $(\tau, \xi) \in D$ where $x(\tau) = \xi$,

$$D = \{(t, x): t \in J = (a, b),\ x \in R^n (\text{or } x \in C^n)\}$$

when each element $a_{ij}(t)$ of matrix $A(t)$ is continuous over J. These solutions exist over the entire interval $J = (a, b)$

and they depend continuously on the initial conditions. In applications it is typical that $j = (-\infty, \infty)$. We note that $\phi(t) \equiv 0$, for all $t \in J$, is a solution of (LH), with $\phi(\tau) = 0$. This is called the **trivial solution** of (LH).

In this section we consider matrices and vectors which will be either real or complex valued. In the former case, the field of scalars for the x space is the field of real numbers ($F = R$) and in the latter case, the field for the x space is the field of complex numbers ($F = C$).

Now let V denote the set of all solutions of (LH) on J; let α_1, α_2 be scalars (i.e., $\alpha_1, \alpha_2 \in F$); and let ϕ_1, ϕ_2 be solutions of (LH) (i.e., $\phi_1, \phi_2 \in V$). Then it is easily verified that $\alpha_1\phi_1 + \alpha_2\phi_2$ will also be a solution of (LH) (i.e., $\alpha_1\phi_1 + \alpha_2\phi_2 \in V$). We have thus shown that V is a vector space. Now if we choose n linearly independent vectors $\xi_1, \ldots, \xi_n$ in the n-dimensional x-space, then there exist n solutions $\phi_1, \ldots, \phi_n$ of (LH) such that $\phi_1(\tau) = \xi_1, \ldots, \phi_n(\tau) = \xi_n$. It is an easy matter to verify that this set of solutions $\{\phi_1, \ldots, \phi_n\}$ is linearly independent and that it spans V. Thus, $\{\phi_1, \ldots, \phi_n\}$ is a basis of V and any solution ϕ can be expressed as a linear combination of the vectors $\phi_1, \ldots, \phi_n$.

Summarizing, we have

The set of solutions of (LH) *on the interval J forms an n-dimensional vector space.*

In view of the above result it now makes sense to define a **fundamental set of solutions** for (LH) as a set of n linearly independent solutions of (LH) on J. If $\{\phi_1, \ldots, \phi_n\}$ is such a set, then we can form the matrix:

$$\Phi = [\phi_1, \ldots, \phi_n] \tag{30}$$

which is called a **fundamental matrix** of (LH).

In the following, we enumerate some of the important properties of fundamental matrices. All of these properties are direct consequences of definition (30) and of the properties of solutions of (LH). We have

1. *A fundamental matrix Φ of* (LH) *satisfies the matrix equation*:

$$X' = A(t)X \tag{31}$$

where $X = [x_{ij}]$ denotes an $n \times n$ matrix. (*Observe that Eq.* (31) *consists of a system of n^2 first-order ordinary differential equations.*)

2. *If Φ is a solution of the matrix equation* (31) *on an interval J and if τ is any point of J, then*

$$\det \Phi(t) = \det \Phi(\tau) \exp\left(\int_\tau^t \operatorname{tr} A(s)\, ds \right) \quad \text{for every } t \in J$$

(*Here,* det Φ *denotes the determinant of* Φ *and* tr A *denotes the trace of the matrix A.*) *This result is known as* **Abel's formula**.

3. *A solution Φ of matrix equation* (31) *is a fundamental matrix of* (LH) *if and only if its determinant is nonzero for all $t \in J$.* (*This result is a direct consequence of Abel's formula*.)

4. *If Φ is a fundamental matrix of* (LH) *and if C is any nonsingular constant $n \times n$ matrix, then ΦC is also a fundamental matrix of* (LH). *Moreover, if Ψ is any other fundamental matrix of* (LH), *then there exists a constant $n \times n$ nonsingular matrix P such that $\Psi = \Phi P$.*

In the following, we let $\{e_1, e_2, \ldots, e_n\}$ denote the set of vectors $e_1^{\mathrm{T}} = (1, 0, \ldots, 0)$, $e_2^{\mathrm{T}} = (0, 1, 0, \ldots, 0)$, $\ldots$, $e_n^{\mathrm{T}} = (0, \ldots, 0, 1)$. We call a fundamental matrix Φ of (LH) whose columns are determined by the linearly independent solutions $\phi_1, \ldots, \phi_n$ with

$$\phi_1(\tau) = e_1, \ldots, \phi_n(\tau) e_n, \qquad \tau \in J$$

the **state transition matrix** Φ for (LH). Equivalently, if Ψ is *any* fundamental matrix of (LH), then the matrix Φ determined by:

$$\Phi(t, \tau) \triangleq \Psi(t)\Psi^{-1}(\tau) \qquad \text{for all} \quad t, \tau \in J$$

is said to be the **state transition matrix** of (LH).

We now enumerate several properties of state transition matrices. All of these are direct consequences of the definition of state transition matrix and of the properties of fundamental matrices. In the following we let $\tau \in J$, we let $\phi(\tau) = \xi$, and we let $\Phi(t, \tau)$ denote the state transition matrix for (LH) for all $t \in J$. Then,

1. $\Phi(t, \tau)$ *is the unique solution of the matrix equation*:

$$\frac{\partial}{\partial t}\Phi(t, \tau) \triangleq \Phi'(t, \tau) = A(t)\Phi(t, \tau)$$

with $\Phi(\tau, \tau) = E$, the $n \times n$ identity matrix.

2. $\phi(t, \tau)$ *is nonsingular for all $t \in J$.*

3. *For any $t, \sigma, \tau \in J$, we have*

$$\Phi(t, \tau) = \Phi(t, \sigma)\Phi(\sigma, \tau)$$

4. $[\Phi(t, \tau)]^{-1} \triangleq \Phi^{-1}(t, \tau) = \Phi(\tau, t)$ *for all* $t, \tau \in J$.

5. *The unique solution $\phi(t, \tau, \xi)$ of* (LH) *with $\phi(\tau, \tau, \xi) = \xi$ specified, is given by*:

$$\phi(t, \tau, \xi) = \Phi(t, \tau)\xi \qquad \text{for all} \quad t \in J \tag{32}$$

In engineering and physics applications, $\phi(t)$ is interpreted as representing the "state" of a (dynamical) system represented by (LH) at time t and $\phi(\tau) = \xi$ is interpreted as representing the "state" at time τ. In Eq. (32), $\Phi(t, \tau)$

relates the "states" of (LH) at t and τ. This motivated the name "state transition matrix."

Let us now consider a couple of specific examples.

1. For the system of equations

$$\begin{aligned} x_1' &= 5x_1 - 2x_2 \\ x_2' &= 4x_1 - x_2 \end{aligned} \tag{33}$$

we have

$$A(t) \equiv A = \begin{bmatrix} 5 & -2 \\ 4 & -1 \end{bmatrix} \qquad \text{for all} \quad t \in (-\infty, \infty)$$

Two linearly independent solutions for Eq. (33) are

$$\phi_1(t) = \begin{bmatrix} e^{3t} \\ e^{3t} \end{bmatrix}, \qquad \phi_2(t) = \begin{bmatrix} e^{t} \\ 2e^{t} \end{bmatrix}$$

The matrix

$$\Phi(t) = \begin{bmatrix} e^{3t} & e^{t} \\ e^{3t} & 2e^{t} \end{bmatrix}$$

satisfies the equation $\Phi' = A\Phi$ and

$$\det \Phi(t) = e^{4t} \neq 0 \qquad \text{for all} \quad t \in (-\infty, \infty)$$

Thus, Φ is a fundamental matrix for Eq. (33). Also, in view of Abel's formula, we obtain:

$$\begin{aligned} \det \Phi(t) &= \det \Phi(\tau) \exp\left[\int_\tau^t \operatorname{tr} A(s)\, ds \right] \\ &= e^{4\tau} \exp\left[\int_\tau^t 4\, ds \right] = e^{4t} \end{aligned}$$

for all $t \in (-\infty, \infty)$

as expected. Finally, since

$$\Phi^{-1}(t) = \begin{bmatrix} 2e^{-3t} & -e^{-3t} \\ -e^{-t} & -e^{-t} \end{bmatrix}$$

we obtain for the transition matrix of Eq. (33),

$$\Psi(t)\Psi^{-1}(\tau) = \begin{bmatrix} 2e^{3(t-\tau)} - e^{t-\tau} & -e^{3(t-\tau)} + e^{t-\tau} \\ 2e^{3(t-\tau)} - 2e^{t-\tau} & -e^{3(t-\tau)} + 2e^{t-\tau} \end{bmatrix}$$

2. For the system,

$$x_1' = x_2, \qquad x_2' = tx_2 \tag{34}$$

we have

$$A(t) \begin{bmatrix} 0 & 1 \\ 0 & t \end{bmatrix} \qquad \text{for all} \quad t \in (-\infty, \infty)$$

Two linearly independent solutions of Eq. (34) are

$$\phi_1(t) = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \qquad \phi_2(t) = \begin{bmatrix} \displaystyle\int_\tau^t e^{\eta^2/2}\, d\eta \\ e^{t^2/2} \end{bmatrix}$$

The matrix

$$\Phi(t) = \begin{bmatrix} 1 & \displaystyle\int_\tau^t e^{\eta^2/2} \\ 0 & e^{t^2/2} \end{bmatrix}$$

satisfies the matrix equation $\Phi' = A(t)\Phi$ and

$$\det \Phi(t) = e^{t^2/2} \qquad \text{for all} \quad t \in (-\infty, \infty)$$

Therefore, Φ is a fundamental matrix for Eq. (34). Also, in view of Abel's formula, we have

$$\begin{aligned} \det \Phi(t) &= \det \Phi(\tau) \exp\left[\int_\tau^t \operatorname{tr} A(s)\, ds \right] \\ &= e^{\tau^2/2} \exp\left[\int_\tau^t \eta\, d\eta \right] = e^{-t^2/2} \end{aligned}$$

for all $t \in (-\infty, \infty)$

as expected. Also, since

$$\Phi^{-1}(t) = \begin{bmatrix} 1 & -e^{-t^2/2} \displaystyle\int_\tau^t e^{\eta^2/2}\, d\eta \\ 0 & -e^{-t^2/2} \end{bmatrix}$$

we obtain for the state transition of Eq. (34),

$$\Phi(t)\Phi^{-1}(\tau) = \begin{bmatrix} 1 & e^{-\tau^2/2} \displaystyle\int_\tau^t e^{\eta^2/2}\, d\eta \\ 0 & e^{(t^2-\tau^2)/2} \end{bmatrix}$$

Finally, suppose that $\phi(\tau) = \xi = [1, 1]^{\mathrm{T}}$. Then

$$\phi(t, \tau, \xi) = \Phi(t, \tau)\xi = \begin{bmatrix} 1 + e^{-\tau^2/2} \displaystyle\int_\tau^t e^{\eta^2/2}\, d\eta \\ e^{(t^2-\tau^2)/2} \end{bmatrix}$$

Next, we consider linear nonhomogeneous systems,

$$x' = A(t)x + g(t) \tag{LN}$$

We assume that $A(t)$ and $g(t)$ are defined and continuous over $R = (-\infty, \infty)$ (i.e., each component $a_{ij}(t)$ of $A(t)$ and each component $g_k(t)$ of $g(t)$ is defined and continuous on R). As noted in Section III, system (LN) has for any $\tau \in R$ and any $\xi \in R^n$ a unique solution satisfying $x(\tau) = \xi$. This solution exists on the *entire* real line R and is continuous in (t, τ, ξ). Furthermore, if A and g depend continuously on parameters $\lambda \in R^l$, then the solution will also vary continuously with λ. Indeed, if we differentiate the function

$$\phi(t, \tau, \xi) = \Phi(t, \tau)\xi + \int_\tau^t \Phi(t, \eta) g(\eta)\, d\eta \tag{35}$$

with respect to t to obtain $\phi'(t, \tau, \xi)$, and if we substitute ϕ and ϕ' into (LN) (for x), then it is an easy matter to

verify that Eq. (35) is in fact the unique solution of (LN) with $\phi(t, \tau, \xi) = \xi$.

We note that when $\xi = 0$, then Eq. (35) reduces to

$$\phi_p(t) = \int_\tau^t \Phi(t, \eta) g(\eta)\, d\eta \tag{36}$$

and when $\xi \neq 0$ but $g(t) \equiv 0$, then Eq. (35) reduces to

$$\phi_h(t) = \Phi(t, \tau)\xi \tag{37}$$

Thus, the solution of (LN) may be viewed as consisting of a component due to the "forcing term" $g(t)$ and another component due to the initial data ξ. This type of separation is in general possible only in linear systems of differential equations. We call ϕ_p the **particular solution** and ϕ_h the **homogeneous solution** of (LN).

Before proceeding to linear systems with constant coefficients, we introduce adjoint equations. Let Φ be a fundamental matrix for the linear homogeneous system (LH). Then,

$$(\Phi^{-1})' = -\Phi^{-1}\Phi'\Phi^{-1} = -\Phi^{-1}A(t)$$

Taking the conjugate transpose of both sides, we obtain:

$$(\Phi^{*-1})' = -A^*(t)\Phi^{*-1}$$

This implies that Φ^{*-1} is a fundamental matrix for the system:

$$y' = -A^*(t)y, \qquad t \in J \tag{38}$$

We call Eq. (38) the **adjoint** to (LH), and we call the matrix equation,

$$Y' = -A^*(t)Y, \qquad t \in J$$

the **adjoint** to matrix equation (31).

One of the principal properties of adjoint systems is summarized in the following result:

If Φ is a fundamental matrix for (LH)*, then Ψ is a fundamental matrix for its adjoint* (38) *if and only if*

$$\Psi^*\Phi = C$$

where C is some constant nonsingular matrix.

B. Linear Systems with Constant Coefficients

We now turn our attention to linear systems with constant coefficients. For purposes of motivation, we first consider the scalar initial-value problem:

$$x' = ax, \qquad x(\tau) = \xi \tag{39}$$

It is easily verified that Eq. (39) has the solution:

$$\phi(t) = e^{a(t-\tau)}\xi \tag{40}$$

It turns out that a similar result holds for the system of linear equations with constant coefficients,

$$x' = Ax \tag{L}$$

By making use of the Weierstrass M test, it is not difficult to verify the following result:

Let A be a constant $n \times n$ matrix which may be real or complex and let $S_N(t)$ denote the partial sum of matrices defined by the formula,

$$S_N(t) = E + \sum_{k=1}^{N} \frac{t^k}{k!}A^k \tag{41}$$

where E denotes the $n \times n$ identity matrix and $k!$ stands for k factorial. Then each element of the matrix $S_N(t)$ converges absolutely and uniformly on any finite t interval $(-a, a)$, $a > 0$, as $N \to \infty$.

This result enables us to define the matrix,

$$e^{At} = E + \sum_{k=1}^{\infty} \frac{t^k}{k!}A^k \tag{42}$$

for any $-\infty < t < \infty$.

It should be clear that when $A(t) \equiv A$, system (LH) reduces to system (L). Consequently, the results we established above for (LH) are also applicable to (L). Now by making use of these results, the definition of e^{At} in Eq. (42), and the convergence properties of $S_N(t)$ in Eq. (42), it is not difficult to establish several important properties of e^{At} and of (L). To this end we let $J = (-\infty, \infty)$ and $\tau \in j$, and we let A be a given constant $n \times n$ matrix for (L). Then the following is true:

1. $\Phi(t) \triangleq e^{At}$ *is a fundamental matrix for* (L) *for* $t \in J$.
2. *The state transition matrix for* (L) *is given by* $\Phi(t, \tau) = e^{A(t-\tau)} \triangleq \Phi(t - \tau)$, $t \in J$.
3. $e^{At_1}e^{At_2} = e^{A(t_1+t_2)}$ *for all* $t_1, t_2 \in J$.
4. $Ae^{At} = e^{At}A$ *for all* $t \in J$.
5. $(e^{At})^{-1} = e^{-At}$ *for all* $t \in J$.
6. *The unique solution ϕ of* (L) *with* $\phi(\tau) = \xi$ *is given by*:

$$\phi(t, \tau, \xi) = e^{A(t-\tau)}\xi \tag{43}$$

Notice that solution (43) of (L) such that $\phi(\tau) = \xi$ depends on t and τ only via the difference $t - \tau$. This is the typical situation for *general autonomous* systems that satisfy uniqueness conditions. Indeed, if $\phi(t)$ is a solution of

$$x' = F(x), \qquad x(0) = \xi$$

then clearly $\phi(t - \tau)$ will be a solution of

$$x' = F(x), \qquad x(\tau) = \xi$$

Next, we consider the "forced" system of equations,

$$x' = Ax + g(t) \tag{44}$$

where $g\colon J \to R^n$ is continuous. Clearly, Eq. (44) is a special case of (LN). In view of Eq. (35) we thus have

$$\phi(t) = e^{A(t-\tau)}\xi + e^{At}\int_\tau^t e^{-A\eta}g(\eta)\,d\eta \tag{45}$$

for the solution of Eq. (44).

Next, we address the problem of evaluating the state transition matrix. While there is no general procedure for evaluating such a matrix for a time-varying matrix $A(t)$, there are several such procedures for determining e^{At} when $A(t) \equiv A$. In the following, we consider two such methods.

We begin by recalling the Laplace transform. To this end, we consider a vector $f(t) = [\,f_1(t), \ldots, f_n(t)]^{\mathrm{T}}$, where $f_i\colon [0, \infty) \to R$, $i = 1, \ldots, n$. Letting s denote a complex variable, we define the *Laplace transform* of f_i as:

$$\hat{f}_i(s) = \mathscr{L}[\,f_i(t)] \triangleq \int_0^\infty f_i(t)e^{-st}\,dt \tag{46}$$

provided, of course, that the integral in Eq. (46) exists. (In this case f_i is said to be Laplace transformable.) Also, we define the Laplace transform of the vector $f(t)$ by:

$$\hat{f}(s) = [\,\hat{f}_1(s), \ldots, \hat{f}_n(s)]^{\mathrm{T}},$$

and we define the Laplace transform of a matrix $C(t) = [c_{ij}(t)]$ similarly. Thus, if $c_{ij}\colon [0, \infty) \to R$ and if each c_{ij} is Laplace transformable, then the Laplace transform of $C(t)$ is defined by:

$$\hat{C}(s) = \mathscr{L}[c_{ij}(t)] = [\mathscr{L}c_{ij}(t)] = [\hat{c}_{ij}(s)]$$

Now consider the initial value problem,

$$x' = Ax, \qquad x(0) = \xi \tag{47}$$

Taking the Laplace transform of both sides of Eq. (47), we obtain:

$$sx(s) - \xi = Ax(s)$$

or

$$(sE - A)x(s) = \xi$$

or

$$x(s) = (sE - A)^{-1}\xi \tag{48}$$

where E denotes the $n \times n$ identity matrix. It can be shown by analytic continuation that $(sE - A)^{-1}$ exists for all s, except at the eigenvalues of A (i.e., except at those values of s where the equation $\det(sE - A) = 0$ is satisfied). Taking the inverse Laplace transform of Eq. (48) (i.e., by reversing the procedure and obtaining, for example, in Eq. (46) $f_i(t)$ from $f_i(s)$ we obtain for the solution of Eq. (47),

$$\phi(t) = \mathscr{L}^{-1}[(sE - A)^{-1}]\xi = \Phi(t, 0)\xi = e^{At}\xi \tag{49}$$

where $\mathscr{L}^{-1}[\,\hat{f}(s)] = f(t)$ denotes the inverse Laplace transform of $\hat{f}(s)$. It follows from Eqs. (49) and (48) that

$$\hat{\Phi}(s) = (sE - A)^{-1}$$

and

$$\Phi(t, 0) \triangleq \Phi(t) = \mathscr{L}^{-1}[(sE - A)^{-1}] = e^{At} \tag{50}$$

Finally, note that when the initial time $\tau \neq 0$, we can immediately compute $\Phi(t, \tau) = \Phi(t - \tau) = e^{A(t-\tau)}$.

Next, let us consider a "forced" system of the form:

$$x' = Ax + g(t), \qquad x(0) = \xi \tag{51}$$

and let us assume that the Laplace transform of g exists. Taking the Laplace transform of both sides of Eq. (51) yields:

$$s\hat{x}(s) - \xi = A\hat{x}(s) + \hat{g}(s)$$

or

$$(sE - A)\hat{x}(s) = \xi + \hat{g}(s)$$

or

$$\begin{aligned}\hat{x}(s) &= (sE - A)^{-1}\xi + (sE - A)^{-1}\hat{g}(s)\\ &= \hat{\Phi}(s)\xi + \hat{\Phi}(s)\hat{g}(s) \triangleq \hat{\phi}_{\mathrm{h}}(s) + \hat{\phi}_{\mathrm{p}}(s)\end{aligned} \tag{52}$$

Taking the inverse Laplace transform of both sides of Eq. (52) and using Eq. (45), we obtain:

$$\begin{aligned}\phi(t) &= \phi_{\mathrm{h}}(t) + \phi_{\mathrm{p}}(t)\\ &= \mathscr{L}^{-1}[(sE - A)^{-1}]\xi + \mathscr{L}^{-1}[(sE - A)^{-1}\hat{g}(s)]\\ &= \Phi(t, 0)\xi + \int_0^t \Phi(t - \eta)g(\eta)\,d\eta\end{aligned} \tag{53}$$

Therefore,

$$\phi_{\mathrm{p}}(t) = \int_0^t \Phi(t - \eta)g(\eta)\,d\eta \tag{54}$$

as expected. We call the expression in Eq. (54) the **convolution** of Φ and g. Clearly, convolution of Φ and g in the time domain corresponds to multiplication of Φ and g in the s domain.

Let us now consider the specific initial-value problem,

$$\begin{aligned}x_1' &= -x_1 + x_2, &\qquad x_1(0) &= -1\\ x_2' &= -2x_2 + u(t), &\qquad x_2(0) &= 0\end{aligned} \tag{55}$$

where

$$u(t) = \begin{cases}1 & \text{for} \quad t > 0\\ 0 & \text{elsewhere}\end{cases}$$

We have, in this case,

$$(sE - A) = \begin{bmatrix} s+1 & -1 \\ 0 & s+2 \end{bmatrix}$$

$$\hat{\Phi}(s) = (sE - A)^{-1} = \begin{bmatrix} \frac{1}{s+1} & \left(\frac{1}{s+1} - \frac{1}{s+2}\right) \\ 0 & \frac{1}{s+2} \end{bmatrix}$$

and

$$\Phi(t) = e^{At} = \mathscr{L}^{-1}[\hat{\Phi}(s)] = \begin{bmatrix} e^{-t} & (e^{-t} - e^{-2t}) \\ 0 & e^{-2t} \end{bmatrix}$$

It now follows that

$$\phi_{\mathrm{h}}(t) = \begin{bmatrix} e^{-t} & (e^{-t} - e^{-2t}) \\ 0 & e^{-2t} \end{bmatrix} \begin{bmatrix} -1 \\ 0 \end{bmatrix} = \begin{bmatrix} -e^{-t} \\ 0 \end{bmatrix}$$

Also, since $\hat{u}(s) = 1/s$, we have

$$\hat{\phi}_{\mathrm{p}}(s) = \begin{bmatrix} \frac{1}{s+1} & \left(\frac{1}{s+1} - \frac{1}{s+2}\right) \\ 0 & \frac{1}{s+2} \end{bmatrix} \begin{bmatrix} 0 \\ \frac{1}{s} \end{bmatrix}$$

$$= \begin{bmatrix} \frac{1}{2} & \left(\frac{1}{s}\right) + \frac{1}{2} & \left(\frac{1}{s+2}\right) - \frac{1}{s+1} \\ \frac{1}{2} & \left(\frac{1}{s}\right) - \frac{1}{2} & \left(\frac{1}{s+2}\right) \end{bmatrix}$$

and

$$\phi_{\mathrm{p}}(t) = \begin{bmatrix} \frac{1}{2} + \frac{1}{2}e^{-2t} - e^{-t} \\ \frac{1}{2} - \frac{1}{2}e^{-2t} \end{bmatrix}$$

Therefore, the solution of the initial value problem (55) is

$$\phi(t) = \phi_{\mathrm{p}}(t) + \phi_{\mathrm{h}}(t) = \begin{bmatrix} \frac{1}{2} - 2e^{-t} + \frac{1}{2}e^{-2t} \\ \frac{1}{2} - \frac{1}{2}e^{-2t} \end{bmatrix}$$

A second method of evaluating e^{At} and of solving initial value problems for (L) and Eq. (44) involves the transformation of A into a Jordan canonical form. Specifically, it is shown in linear algebra that for every complex $n \times n$ matrix A there exists a nonsingular $n \times n$ matrix P (i.e., $\det P \neq 0$) such that the matrix,

$$J = P^{-1}AP \tag{56}$$

is in the canonical form,

$$J = \begin{bmatrix} J_0 & & \\ & J_1 & 0 \\ & 0 & \ddots \\ & & & J_s \end{bmatrix} \tag{57}$$

where J_0 is a diagonal matrix with diagonal elements $\lambda_1, \ldots, \lambda_k$ (not necessarily distinct); that is,

$$J_0 = \begin{bmatrix} \lambda_1 & & & \\ & & 0 & \\ & \ddots & & \\ & 0 & & \\ & & & \lambda_k \end{bmatrix} \tag{58}$$

and each J_p is an $n_p \times n_p$ matrix of the form ($p = 1, \ldots, s$):

$$J_q = \begin{bmatrix} \lambda_{k+p} & 1 & 0 & \cdots & 0 \\ 0 & \lambda_{k+p} & 1 & & \\ \vdots & \vdots & \vdots & & \vdots \\ & & & \cdots & 1 \\ 0 & 0 & 0 & \cdots & \lambda_{k+p} \end{bmatrix} \tag{59}$$

where λ_{k+p} need not be different from λ_{k+q} if $p \neq q$ and $k + n_1 + \cdots + n_s = n$. The numbers λ_i, $i = 1, \ldots, k+s$, are the eigenvalues of A (i.e., the roots of the equation $\det(\lambda E - A) = 0$). If λ_i is a simple eigenvalue of A (i.e., it is not a repeated root of $\det(\lambda E - A) = 0$), then it appears in the block J_0. The blocks $J_0, J_1, \ldots, J_s$ are called **Jordan blocks** and J is called the **Jordan canonical form** of A.

Returning to the subject at hand, we consider once more the initial value problem (47) and let P be a real $n \times n$ nonsingular matrix which transforms A into a Jordan canonical form J. Consider the transformation $x = Py$ or, equivalently, $y = P^{-1}x$. Differentiating both sides with respect to t, we obtain:

$$\begin{aligned} y' &= P^{-1}x' = P^{-1}APy = Jy \\ y(\tau) &= P^{-1}\xi \end{aligned} \tag{60}$$

The solution of Eq. (60) is given as

$$\psi(t) = e^{J(t-\tau)}P^{-1}\xi \tag{61}$$

Using Eq. (61) and $x = Py$, we obtain for the solution of Eq. (47),

$$\phi(t) = Pe^{J(t-\tau)}P^{-1}\xi \tag{62}$$

In the case in which A has n *distinct* eigenvalues $\lambda_1, \ldots, \lambda_n$, we can choose $P = [p_1, p_2, \ldots, p_n]$ in such a way that p_i is an eigenvector corresponding to the eigenvalue λ_i, $i = 1, \ldots, n$ (i.e., $p_i \neq 0$ satisfies the equation

$\lambda_i p_i = Ap_i$). Then the Jordan matrix $J = P^{-1}AP$ assumes the form:

$$J = \begin{bmatrix} \lambda_1 & & 0 \\ & \ddots & \\ 0 & & \lambda_n \end{bmatrix}$$

Using the power series representation, Eq. (42), we immediately obtain the expression:

$$e^{Jt} = \begin{bmatrix} e^{\lambda_1 t} & & 0 \\ & \ddots & \\ 0 & & e^{\lambda_n t} \end{bmatrix}$$

In this case, we have the expression for the solution of Eq. (47):

$$\phi(t) = P \begin{bmatrix} e^{\lambda_1(t-\tau)} & & 0 \\ & \ddots & \\ 0 & & e^{\lambda_n(t-\tau)} \end{bmatrix} P^{-1}\xi$$

In the general case when A has repeated eigenvalues, we can no longer diagonalize A and we have to be content with the Jordan form given by Eq. (57). In this case, $P = [v_1, \ldots, v_n]$, where the v_i denote generalized eigenvectors. Using the power series representation, Eq. (42) and the very special nature of the Jordan blocks (58) and (59), it is not difficult to show that in the case of repeated eigenvalues we have

$$e^{Jt} = \begin{bmatrix} e^{J_0 t} & & & 0 \\ & e^{J_1 t} & & \\ & & \ddots & \\ 0 & & & e^{J_s t} \end{bmatrix} \quad -\infty < t < \infty$$

where

$$e^{J_0 t} = \begin{bmatrix} e^{\lambda_1 t} & & 0 \\ & \ddots & \\ 0 & & e^{\lambda_k t} \end{bmatrix}$$

and

$$e^{tJ_i} = e^{\lambda_{k+i} t} \begin{bmatrix} 1 & t & \cdots & t^{n_i-1}/(n_i-1)! \\ 0 & 1 & \cdots & t^{n_i-2}/(n_i-2)! \\ \vdots & \vdots & & \vdots \\ 0 & 0 & & 1 \end{bmatrix} \quad i = 1, \ldots, s$$

From Eq. (62), it now follows that the solution of Eq. (47) is given by:

$$\phi(t) = P \begin{bmatrix} e^{J_0(t-\tau)} & & & 0 \\ & e^{J_1(t-\tau)} & & \\ & & \ddots & \\ 0 & & & e^{J_s(t-\tau)} \end{bmatrix} P^{-1}\xi$$

As a specific example of the above procedure of determining the state transition matrix, consider the initial-value problem:

$$x_1' = -x_1 + x_2, \qquad x_1(0) = 1$$
$$x_2' = -2x_2, \qquad x_2(0) = 2$$

In this case, we have

$$A = \begin{bmatrix} -1 & 1 \\ 0 & -2 \end{bmatrix}$$

with eigenvalues $\lambda_1 = -1$ and $\lambda_2 = -2$ and with corresponding eigenvectors,

$$P_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \qquad P_2 = \begin{bmatrix} -1 \\ 1 \end{bmatrix}$$

We thus have

$$P = [p_1, p_2] = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix}, \qquad P^{-1} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$$

and

$$J = \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix}$$

Furthermore,we obtain:

$$\begin{bmatrix} \phi_1(t) \\ \phi_2(t) \end{bmatrix} = Pe^{Jt}P^{-1}\xi$$
$$= \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} e^{-t} & 0 \\ 0 & e^{-2t} \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 \\ 2 \end{bmatrix}$$
$$= \begin{bmatrix} 3e^{-t} - 2e^{-2t} \\ 2e^{-2t} \end{bmatrix}$$

C. Linear Systems With Periodic Coefficients

Next, we consider linear homogeneous periodic systems of the form:

$$x' = A(t)x, \qquad -\infty < t < \infty \qquad \text{(P)}$$

where the elements of A are continuous functions on R and where

$$A(t) = A(t+T) \qquad (63)$$

for some $T > 0$ which is a period of A.

The principal result for (P) which we shall present here (called **Floquet theory**) involves the logarithm of a matrix, the existence of which is not too difficult to establish. We have the following:

Let B be a nonsingular $n \times n$ matrix. Then there exists an $n \times n$ matrix F, called the logarithm of B, such that

$$e^F = B$$

Using properties of the fundamental matrix as well as the concept of the logarithm of a matrix, we are in a position to prove the following fundamental result for (P):

Let Eq. (63) *be true and let $A(t)$ be continuous on $(-\infty, \infty)$. If $\Phi(t)$ is a fundamental matrix for* (P)*, then so is $\Phi(t+T)$, $-\infty < t < \infty$. Moreover, corresponding to every Φ, there exists a nonsingular matrix P which is also periodic with period T and a constant matrix R, such that*

$$\Phi(t) = P(t)e^{tR} \tag{64}$$

It is not difficult to show, using Eq. (64), that if the fundamental matrix Φ for (P) is known over *any* interval of length T, then it is automatically known for all $-\infty < t < \infty$. For example, if $\Phi(t)$ is known for all t over the interval $[t_0, t_0 + T]$, then we can show that

$$\Phi(t) = P(t)e^{tT^{-1}\log C} \tag{65}$$

where $C = \Phi(t_0)^{-1}\Phi(t_0 + T)$. Thus, since $P(t)$ is periodic, $\Phi(t)$ as given in Eq. (65) will be known for all t over $(-\infty, \infty)$.

It can also be shown that even though the fundamental matrix Φ does not determine R uniquely in Eq. (64), the set of all fundamental matrices of (P), and hence of $A(t)$, determines uniquely all quantities associated with e^{TR} which are invariant under a similarity transformation. Specifically, the set of all fundamental matrices of $A(t)$ determine a unique set of eigenvalues of the matrix e^{TR}, $\lambda_1, \ldots, \lambda_n$, which are called the **Floquet multipliers** associated with $A(t)$. None of these vanishes since $\Pi\ \lambda_i = \det e^{TR} \neq 0$. Also, the eigenvalues of R, $\rho_1, \ldots, \rho_n$, are called the **characteristic exponents** of $A(t)$.

Now let us suppose that all ρ_i are such that $\text{Re}\ \rho_i < 0$ (i.e., the real part of each ρ_i is negative) and let $\alpha = \min_i |\text{Re}\ \rho_i|$. Now, if we arrange things so that R in Eq. (64) is in Jordan canonical form, then it is a simple matter to show that there exists a $k > 0$ such that for each component $\phi_i(t)$ of the solution $\phi(t)$,

$$|\phi_i(t)| \leq ke^{\alpha t} \qquad \text{for all} \quad t \geq 0 \tag{66}$$

and $|\phi_i(t)| \to 0$ as $t \to \infty$. In other words, if the eigenvalues ρ_i, $i = 1, \ldots, n$, of R have negative real parts, then the norm of any solution of (P) tends to zero as $t \to \infty$ at an exponential rate.

Finally, by using Eq. (64) we can write:

$$P(t) = \Phi(t)e^{-tR} \tag{67}$$

which in turn can be used to see that $AP - P' = PR$. Thus, for the transformation,

$$x = P(t)y \tag{68}$$

we compute

$$\begin{aligned} x' &= A(t)x = A(t)P(t)y \\ &= P'(t)y + P(t)y' = (P(t)y)' \end{aligned}$$

or

$$\begin{aligned} y' &= P^{-1}(t)[A(t)P(t) - P'(t)]y \\ &= P^{-1}(t)(P(t)R)y = Ry \end{aligned}$$

This shows that *transformation* (68) *reduces the linear, homogeneous, periodic system* (P) to

$$y' = Ry \tag{69}$$

a linear homogeneous system with constant coefficients. Since $P(t)$ is nonsingular, we are thus able to deduce the properties of the solutions of (P) from those of Eq. (69), provided of course that we can determine the matrix $P(t)$.

D. Linear *n* th-Order Ordinary Differential Equations

We conclude this section by considering some of the more important aspects of linear nth-order ordinary differential equations. We shall consider equations of the form,

$$y^{(n)} + a_{n-1}(t)y^{(n-1)} + \cdots + a_1(t)y^{(1)} + a_0(t)y = b(t) \tag{70}$$

$$y^{(n)} + a_{n-1}(t)y^{(n-1)} + \cdots + a_1(t)y^{(1)} + a_0(t)y = 0 \tag{71}$$

and

$$y^{(n)} + a_{n-1}y^{(n-1)} + \cdots + a_1y^{(1)} + a_0y = 0 \tag{72}$$

In Eqs. (70) and (71) the functions $a_k(t)$ and $b(t)$, $k = 1, \ldots, n-1$, are continuous on some appropriate time interval J. If we define the differential operator L_n by:

$$L_n = \frac{d^n}{dt^n} + a_{n-1}(t)\frac{d^{n-1}}{dt^{n-1}} + \cdots + a_1(t)\frac{d}{dt} + a_0(t) \tag{73}$$

then we can rewrite Eqs. (70) and (71) more compactly as

$$L_n y = b(t) \tag{74}$$

and

$$L_n y = 0 \tag{75}$$

respectively. We can rewrite Eq. (72) similarly by defining a differential operator L in the obvious way.

Following the procedure in Section II, we can reduce the study of Eq. (71) to the study of the system of n first-order ordinary differential equations,

$$x' = A(t)x \tag{LH}$$

where $A(t)$ is the **companion matrix** given by:

$$A(t) = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \\ 0 & 0 & 0 & \cdots & 1 \\ -a_0(t) & -a_1(t) & -a_2(t) & \cdots & -a_{n-1}(t) \end{bmatrix} \tag{76}$$

Since $A(t)$ is continuous on J, we know from Section III that there exists a unique solution $\phi(t)$, for all $t \in J$, to the initial-value problem,

$$x' = A(t)x, \qquad x(\tau) = \xi, \qquad \tau \in J$$

where $\xi = (\xi_1, \ldots, \xi_n)^{\mathrm{T}} \in R^n$. The first component of this solution is a solution of $L_n y = 0$ satisfying $y(\tau) = \xi_1, y'(\tau) = \xi_2, \ldots, y^{(n-1)}(\tau) = \xi_n$.

Now let $\phi_1, \ldots, \phi_n$ be n solutions of Eq. (75). Then we can easily show that the matrix,

$$\Phi(t) = \begin{bmatrix} \phi_1 & \phi_2 & \cdots & \phi_n \\ \phi_1' & \phi_2' & \cdots & \phi_n' \\ \vdots & \vdots & & \vdots \\ \phi_1^{(n-1)} & \phi_2^{(n-1)} & \cdots & \phi_n^{(n-1)} \end{bmatrix}$$

is a solution of the matrix equation,

$$X' = A(t)X \tag{77}$$

where $A(t)$ is defined by Eq. (76). We call the determinant of Φ the **Wronskian** for Eq. (75) with respect to the solutions $\phi_1, \ldots, \phi_n$ and we denote it by:

$$W(\phi_1, \ldots, \phi_n) = \det \Phi(t)$$

Note that $W(\phi_1, \ldots, \phi_n)(t)$ depends on $t \in J$. Since Φ is a solution of matrix equation (77), then by Abel's formula it follows that for any $\tau \in J$ and for any $t \in J$,

$$\begin{aligned} W(\phi_1, \ldots, \phi_n)(t) &= \det \Phi(\tau) \exp\left[\int_\tau^t \operatorname{tr} A(s)\, ds \right] \\ &= W(\phi_1, \ldots, \phi_n)(\tau) \\ &\quad \times \exp\left\{ \int_\tau^t -a_{n-1}(s)\, ds \right\} \end{aligned} \tag{78}$$

As an example, consider the second-order differential equation

$$t^2 y'' + t y' - y = 0, \qquad 0 < t < \infty$$

which can be written equivalently as:

$$y'' + (1/t)y' - (1/t^2)y = 0, \qquad 0 < t < \infty \tag{79}$$

The functions $\phi_1(t = t$ and $\phi_2(t) = 1/t$ are clearly solutions of Eq. (79). We now form the matrix,

$$\Phi(t) = \begin{bmatrix} \phi_1 & \phi_2 \\ \phi_1' & \phi_2' \end{bmatrix} = \begin{bmatrix} t & 1/t \\ 1 & 1/t^2 \end{bmatrix}$$

which yields the Wronskian

$$W(\phi_1, \phi_2)(t) = \det \Phi(t) = -2/t, \qquad t > 0$$

In the notation of Eq. (76) we have $a_1(t) = 1/t$, $a_0(t) = -1/t^2$, and thus $a_1(s) = 1/s$. In view of Eq. (78), we have for any $\tau > 0$,

$$\begin{aligned} W(\phi_1, \phi_2)(t) &= \det \Phi(t) \\ &= W(\phi_1, \phi_2)(\tau) \exp\left\{ \int_\tau^t -a_1(s)\, ds \right\} \\ &= -(2/\tau) e^{\ln(\tau/t)} = -2/t, \qquad t > 0 \end{aligned}$$

as expected.

Similarly as in the case of systems of equations, we can prove the following result for nth-order differential equations:

A set of n solutions of Eq. (75), $\phi_1, \ldots, \phi_n$, *is linearly independent on J if and only if* $W(\phi_1, \ldots, \phi_n)(t) \neq 0$ *for all* $t \in J$. *Moreover, every solution of Eq.* (75) *is a linear combination of any set of n linearly independent solutions.*

The above result enables us to make the following definition:

A set of n linearly independent solutions of Eq. (75) *on* j, $\phi_1, \ldots, \phi_n$, *is called a* ***fundamental set*** *of solutions for Eq.* (75).

Next, we turn our attention to nonhomogeneous linear nth-order ordinary differential equations of the form (70). As shown in Section II, the study of Eq. (70) reduces to the study of the system of n first-order ordinary differential equations,

$$x' = A(t)x + g(t) \tag{80}$$

where $A(t)$ is given by Eq. (76) and $g(t) = [0, \ldots, 0, b(t)]^{\mathrm{T}}$. Recall that for given $\tau \in J$ and given $x(\tau) = \xi \in R^n$, Eq. (80) has a unique solution given by $\phi = \phi_{\mathrm{h}} + \phi_{\mathrm{p}}$, where $\phi_h(t) = \Phi(t, \tau)\xi$ is a solution of (LH),

$\phi(t,\tau)$ denotes the state transition matrix of $A(t)$, and ϕ_p is a particular solution of Eq. (80), given by:

$$\phi_p(t) = \int_\tau^t \Phi(t,s)g(s)\,ds = \Phi(t)\int_\tau^t \Phi^{-1}(s)g(s)\,ds$$

We now specialize this result from the n-dimensional system (80) to the corresponding nth-order equation (70) to obtain the following result:

If $\{\phi_1,\ldots,\phi_n\}$ is a fundamental set for the equation $L_n y = 0$, then the unique solution ψ of the equation $L_n y = b(t)$ satisfying $\psi(\tau)=\xi_1,\ldots,\psi^{(n-1)}(\tau)=\xi_n$ is given by:

$$\psi(t) = \psi_h(t) + \psi_P(t) = \psi_h(t) + \sum_{k=1}^{n}\phi_k(t) \times \int_\tau^t \frac{W_k(\phi_1,\ldots,\phi_n)(s)}{W(\phi_1,\ldots,\phi_n)(s)} b(s)\,ds \tag{81}$$

Here, ψ_h is the solution of $L_n y = 0$ such that $\psi(\tau)=\xi_1$, $\psi'(\tau)=\xi_2,\ldots,\psi^{(n-1)}(\tau)=\xi_n$, and $W_k(\phi_1,\ldots,\phi_n)(t)$ is obtained from $W(\phi_1,\ldots,\phi_n)(t)$ by replacing the kth column in $W(\phi_1,\ldots,\phi_n)(t)$ by $(0,\ldots,0,1)^T$.

We apply the above example to the second-order differential equation,

$$y'' + (1/t)y' - (y/t^2) = b(t), \qquad 0 < t < \infty$$

where $b(t)$ is a real continuous function for all $t>0$. From the example involving Eq. (79) we have $\phi_1(t)=t$, $\phi_2(t)=1/t$, and $W(\phi_1,\phi_2)(t)=-2/t$, $t>0$. Also,

$$W_1(\phi_1,\phi_2)(t) = \begin{vmatrix} 0 & 1/t \\ 1 & -1/t^2 \end{vmatrix} = -\frac{1}{t},$$

$$W_1(\phi_1,\phi_2)(t) = \begin{vmatrix} t & 0 \\ 1 & 1 \end{vmatrix} = t$$

From Eq. (81) we now have

$$\psi(t) = \psi_h(t) + \psi_p(t) = \psi_h(t) + \frac{t}{2}\int_\tau^t b(s)\,ds - \frac{1}{2t}\int_\tau^t s^2 b(s)\,ds$$

Next, we consider nth-order ordinary differential equations with constant coefficients given by Eq. (72) which can equivalently be written as $L_n y = 0$, where

$$L_n = \frac{d^n}{dt^n} + a_{n-1}\frac{d^{n-1}}{dt^{n-1}} + \cdots + a_1\frac{d}{dt} + a_0$$

We assume that $J=(-\infty,\infty)$, we call

$$p(\lambda) = \lambda^n + a_{n-1}\lambda^{n-1} + \cdots + a_1\lambda + a_0 \tag{82}$$

the **characteristic polynomial** of the differential equation (72), and we call

$$p(\lambda) = 0 \tag{83}$$

the **characteristic equation** of Eq. (72). The roots of $p(\lambda)$ are called the **characteristic roots** of Eq. (72).

We see that the study of Eq. (72) reduces to the study of the system of first-order ordinary differential equations with constant coefficients given by $x' = Ax$, where

$$A = \begin{bmatrix} 0 & 1 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & 0 & \cdots & 1 \\ -a_0 & -a_1 & -a_2 & -a_3 & \cdots & -a_{n-1} \end{bmatrix} \tag{84}$$

The following result, which is proved in a straightforward manner, connects Eq. (72) and $x' = Ax$ with A given by Eq. (84):

The characteristic polynomial of A in Eq. (83) *is precisely the characteristic polynomial $p(\lambda)$ given by Eq.* (82), *that is,*

$$p(\lambda) = \det(\lambda E_n - A)$$

The next result enumerates a fundamental set for Eq. (72):

Let $\lambda_1,\ldots,\lambda_s$ be the distinct roots of the characteristic equation (83) *and suppose that λ_i has multiplicity m_i, $i=1,\ldots,s$, with $\sum_{i=1}^s m_i = n$. Then the following set of functions is a fundamental set for Eq.* (72):

$$t^k e^{\lambda_i t}, \qquad k = 0,1,\ldots,m_i-1, \quad i = 1,\ldots,s \tag{85}$$

As a specific example, consider:

$$p(\lambda) = (\lambda-2)(\lambda+3)^2(\lambda+i)(\lambda-i)(\lambda-4)^4 \tag{86}$$

Then, $n=9$, and $\{e^{2t}, e^{-3t}, te^{-3t}, e^{-it}, e^{+it}, e^{4t}, te^{4t}, t^2e^{4t}, t^3e^{4t}\}$ is a fundamental set for the differential equation corresponding to the characteristic equation (86).

We conclude this section by considering adjoint equations. Corresponding to the operator L_n given in Eq. (73), we define a second linear operator L_n^+ of order n, which we call the **adjoint** of L_n, as follows. The domain of L_n^+ is the set of all continuous functions defined on J such that $[\bar{a}_j(t)y(t)]$ has j continuous derivatives on J. (Here, $\bar{a}_j(t)$ denotes the complex conjugate of $a_j(t)$.) For each function y, define:

$$L_n^+ y = (-1)^n y^{(n)} + (-1)^{n-1}(\bar{a}_{n-1}y)^{n-1} + \cdots + (-1)(\bar{a}_1 y)' + \bar{a}_0 y$$

The equation,

$$L_n^+ y = 0, \qquad t \in J$$

is called the **adjoint equation** to $L_n y = 0$.

When Eq. (75) is written in companion form (LH) with $A(t)$ given by Eq. (76), then the adjoint system is $z' = -A^*(t)z$, where

$$A^*(t) = \begin{bmatrix} 0 & 0 & \cdots & 0 & -\bar{a}_0(t) \\ 1 & 0 & \cdots & 0 & -\bar{a}_1(t) \\ 0 & 1 & \cdots & 0 & -\bar{a}_2(t) \\ \vdots & \vdots & & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & -\bar{a}_{n-1}(t) \end{bmatrix}$$

This adjoint system can be written in component form as:

$$\begin{aligned} z_1' &= \bar{a}_0(t) z_n \\ z_j' &= -z_{j-1} + \bar{a}_{j-1}(t) z_n, \qquad 2 \le j \le n \end{aligned} \tag{87}$$

If $\psi = [\psi_1, \psi_2, \ldots, \psi_n]^{\mathrm{T}}$ is a solution of Eq. (87) and if $a_j \psi_n$ has j derivatives, then

$$\psi_n' - (\bar{a}_{n-1}\psi_n) = -\psi_{n-1}$$

and

$$\psi_n'' - (\bar{a}_{n-1}\psi_n)' = -\psi_{n-1}' = \psi_{n-1} - (\bar{a}_{n-2}\psi_n)$$

or

$$\psi_n'' - (\bar{a}_{n-1}\psi_n)' + (\bar{a}_{n-2}\psi_n) = \psi_{n-2}$$

Continuing in this manner, we see that ψ_n solves $L_n^+ \psi = 0$.

V. STABILITY

Since there are no general rules for determining explicit formulas for the solutions of systems ofordinary differential equations (E), the analysis of initial-value problems (I) is accomplished along two lines: (1) a quantitative approach is used which usually involves the numerical solution of such problems by means of simulations on a digital computer, and (2) a qualitative approach is used which is usually concerned with the behavior of families of solutions of a given differential equation and which usually does not seek specific explicit solutions. As mentioned in Section I, we will concern ourselves primarily with qualitative aspects of ordinary differential equations.

The principal results of the qualitative approach include stability properties of an equilibrium point (rest position) and the boundedness of solutions of ordinary differential equations. We shall consider these topics in the present section.

A. The Concept of an Equilibrium Point

We shall concern ourselves with systems of equations,

$$x' = f(t, x) \tag{E}$$

where $x \in R^n$. When discussing *global results*, such as global asymptotic stability, we shall always assume that $f: R^+ \times R^n \to R^n$. On the other hand, when considering *local results*, we shall usually assume that $f: R^+ \times B(h) \to R^n$ for some $h > 0$, where $R^+ = [0, \infty)$, $B(h) = \{x \in R^n : |x| < h\}$ and $|\cdot|$ is any one of the equivalent norms on R^n. On some occasions we assume that $t \in R = (-\infty, \infty)$ rather than $t \in R^+$. Unless otherwise stated, we assume that for every (t_0, ξ), $t_0 \in R^+$, the initial-value problem,

$$x' = f(t, x), \qquad x(t_0) = \xi \tag{I}$$

possesses a unique solution $\phi(t, t_0, \xi)$ which is defined for all $t \ge t_0$ and which depends continuously on the initial data (t_0, ξ). Since it is natural in this section to think of t as representing time, we shall use the symbol t_0 in (I) to represent the initial time (rather than τ as was done earlier). Furthermore, we shall frequently use the symbol x_0 in place of ξ to represent the initial state.

A point $x_e \in R^n$ is called an **equilibrium point** of (E) (at time $t^* \in R^+$) if $f(t, x_e) = 0$ for all $t \ge t^*$. Other terms for equilibrium point include **stationary point, singular point, critical point**, and **rest position**.

We note that if x_e is an equilibrium point of (E) at t^*, then it is an equilibrium point at all $\tau \ge t^*$. Note also that in the case of autonomous systems,

$$x' = f(x) \tag{A}$$

and in case of T-periodic systems,

$$x' = f(t, x), \qquad f(t, x) = f(t + T, x) \tag{P}$$

a point $x_e \in R^n$ is an equilibrium at some t^* if and only if it is an equilibrium point at all times. Also note that if x_e is an equilibrium (at t^*) of (E), then the transformation $s = t - t^*$ reduces (E) to $dx/ds = f(s + t^*, x)$ and x_e is an equilibrium (at $s = 0$) of this system. For this reason, we shall henceforth assume that $t^* = 0$ in the above definition and we shall not mention t^* further. Note also that if x_e is an equilibrium point of (E), then for any $t_0 \ge 0$, $\phi(t, t_0, x_e) = x_e$ for all $t \ge t_0$ (i.e., x_e is a unique solution of (E) with initial data given by $\phi(t_0, t_0, x_e) = x_e$).

As a specific example, consider the simple pendulum introduced in Section II, which is described by equations of the form,

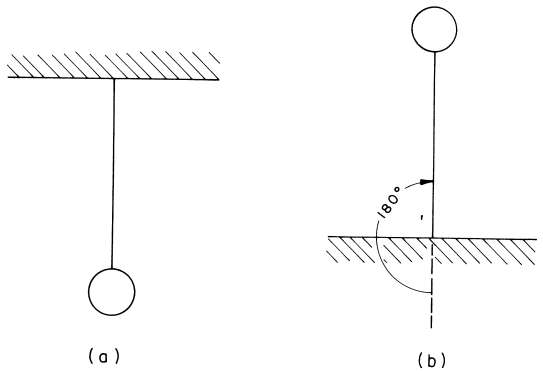

FIGURE 8 (a) Stable and (b) unstable equilibria of the simple pendulum.

$$\begin{aligned} x_1' &= x_2 \\ x_2' &= k \sin x_1, \qquad k > 0 \end{aligned} \tag{88}$$

Physically, the pendulum has two equilibrium points. One of these is located as shown in Fig. 8a and the second point is located as shown in Fig. 8b. However, the *model* of this pendulum, described by Eq. (88), has countably infinitely many equilibrium points located in R^2 at the points $(\pi n, 0)$, $n = 0, \pm 1, \pm 2, \ldots$.

An equilibrium point x_e of (E) is called an **isolated equilibrium point** if there is an $r > 0$ such that $B(x_e, r) \subset R^n$ contains no equilibrium points of (E) other than x_e itself. (Here, $B(x_e, r) = \{x \in R^n : |x - x_e| < r\}$.)

All equilibrium points of Eq. (88) are isolated equilibria in R^2. On the other hand, for the system,

$$\begin{aligned} x_1' &= -ax_1 + bx_1x_2 \\ x_2' &= -bx_1x_2 \end{aligned} \tag{89}$$

where $a > 0$, $b > 0$ are constants, every point on the positive x_2 axis is an equilibrium point for Eq. (89).

It should be noted that there are systems with *no equilibrium points* at all, as is the case, for example, in the system,

$$\begin{aligned} x_1' &= 2 + \sin(x_1 + x_2) + x_1 \\ x_2' &= 2 + \sin(x_1 + x_2) - x_1 \end{aligned} \tag{90}$$

Many important classes of systems possess only *one equilibrium point*. For example, the linear homogeneous system,

$$x' = A(t)x \tag{LH}$$

has a unique equilibrium at the origin if $A(t_0)$ is nonsingular for all $t_0 \geq 0$. Also, the system,

$$x' = f(x) \tag{A}$$

where f is assumed to be continuously differentiable with respect to all of its arguments and where

$$J(x_e) = \frac{\partial f}{\partial x}(x)\bigg|_{x=x_e}$$

denotes the $n \times n$ Jacobian matrix defined by $\partial f/\partial x = [\partial f_i/\partial x_j]$ has an isolated equilibrium at x_e if $f(x_e) = 0$ and $J(x_e)$ is nonsingular.

Unless otherwise stated, we shall assume throughout this section that a given equilibrium point is an isolated equilibrium. Also, we shall assume, unless otherwise stated, that in a given discussion, the equilibrium of interest is located at the origin of R^n. This assumption can be made without any loss of generality. To see this, assume that $x_e \neq 0$ is an equilibrium point of (E) (i.e., $f(t, x_e) = 0$ for all $t \geq 0$). Let $w = x - x_e$. Then $w = 0$ is an equilibrium of the transformed system,

$$w' = F(t, w) \tag{91}$$

where

$$F(t, w) = f(t, w + x_e) \tag{92}$$

Since Eq. (92) establishes a one-to-one correspondence between the solutions of (E) and Eq. (91), we may assume henceforth that (E) possesses the equilibrium of interest located at the origin. The equilibrium $x = 0$ will sometimes be referred to as the **trivial solution** of (E).

B. Definitions of Stability and Boundedness

We now state several definitions of stability of an equilibrium point, in the sense of Lyapunov.

The equilibrium $x = 0$ of (E) is **stable** if for every $\varepsilon > 0$ and any $t_0 \in R^+$ there exists a $\delta(\varepsilon, t_0) > 0$ such that:

$$|\phi(t, t_0, \xi)| < \varepsilon \qquad \text{for all} \quad t \geq t_0 \tag{93}$$

whenever

$$|\xi| < \delta(\varepsilon, t_0) \tag{94}$$

It is an easy matter to show that if the equilibrium $x = 0$ satisfies Eq. (93) for a single t_0 when Eq. (94) is true, then it also satisfies this condition at every initial time $t_0' > t_0$. Hence, in the preceding definition it suffices to take the single value $t = t_0$ in Eqs. (93) and (94).

Suppose that the initial-value problem (I) has a unique solution ϕ defined for t on an interval J containing t_0. By the **motion** through $(t_0, \xi = x(t_0))$ we mean the set $\{t, \phi(t) : t \in J\}$. This is, of course, the graph of the function ϕ. By the **trajectory** or **orbit** through $(t_0, \xi = x(t_0))$ we mean the set $C(x(t_0)) = \{\phi(t) : t \in J\}$. The **positive semitrajectory** (or **positive semiorbit**) is defined as $C^+(x(t_0)) = \{\phi(t) : t \in J \text{ and } t \geq t_0\}$. Also, the **negative trajectory** (or **negative semiorbit**) is defined as $C^-(x(t_0)) = \{\phi(t) : t \in J \text{ and } t \leq \tau\}$.

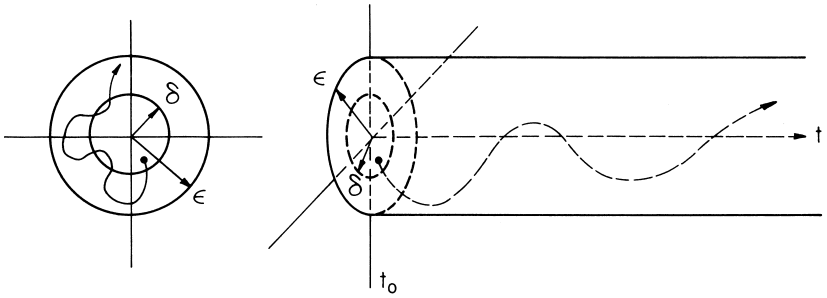

FIGURE 9 Stability of an equilibrium point.

Now, in Fig. 9 we depict the behavior of the trajectories in the vicinity of a stable equilibrium for the case $x \in R^2$.

When $x_e = 0$ is stable, by choosing the initial points in a sufficiently small spherical neighborhood, we can force the graph of the solution for $t \geq t_0$ to lie entirely inside a given cylinder.

In the above definition of stability, δ depends on ε and t_0 (i.e., $\delta = \delta(\varepsilon, t_0)$). If δ is independent of t_0 (i.e., $\delta = \delta(\varepsilon)$). then the equilibrium $x = 0$ of (E) is said to be **uniformly stable**.

The equilibrium $x = 0$ of (E) is said to be **asymptotically stable** if (1) it is stable, and (2) for every $t_0 \geq 0$ there exists an $\eta(t_0) > 0$ such that $\lim_{t \to \infty} \phi(t, t_0, \xi) = 0$ whenever $|\xi| < \eta$. Furthermore, the set of all $\xi \in R^n$ such that $\phi(t, t_0, \xi) \to 0$ as $t \to \infty$ for some $t_0 \geq 0$ is called the **domain of attraction** of the equilibrium $x = 0$ of (E). Also, if for (E) condition (2) is true, then the equilibrium $x = 0$ is said to be **attractive**.

The equilibrium $x = 0$ of (E) is said to be **uniformly asymptotically stable** if (1) it is uniformly stable, and (2) there is a $\delta_0 > 0$ such that for every $\varepsilon > 0$ and for any $t_0 \in R^+$ there exists a $T(\varepsilon) > 0$, independent of t_0, such that $|\phi(t, t_0, \xi)| < \varepsilon$ for all $t \geq t_0 + T(\varepsilon)$ whenever $|\xi| < \delta_0$.

In Fig. 10 we depict property (2), for uniform asymptotic stability, pictorially. *By choosing the initial points in a sufficiently small spherical neighborhood at $t = t_0$, we can force the graph of the solution to lie inside a given cylinder for all $t > t_0 + T(\varepsilon)$.* Condition (2) can be rephrased by saying that there exists a $\delta_0 > 0$ such that $\lim_{t \to \infty} \phi(t + t_0, t_0, \xi) = 0$ uniformly in (t_0, ξ) for $t_0 \geq 0$ and for $|\xi| \leq \delta_0$.

In applications, we are frequently interested in the following special case of uniform asymptotic stability: the equilibrium $x = 0$ of (E) is **exponentially stable** if there exists an $\alpha > 0$, and for every $\varepsilon > 0$ there exists a $\delta(\varepsilon) > 0$, such that $|\phi(t, t_0, \xi)| \leq \varepsilon e^{\alpha(t - t_0)}$ for all $t \geq t_0$ whenever $|\xi| < \delta(\varepsilon)$ and $t \geq 0$.

In Fig. 11, the behavior of a solution in the vicinity of an exponentially stable equilibrium $x = 0$ is shown.

The equilibrium $x = 0$ of (E) is said to be **unstable** if it is not stable. In this case, there exists a $t_0 \geq 0$, $\varepsilon > 0$, a sequence $\xi_m \to 0$ of initial points, and a sequence $\{t_m\}$ such that $|\phi(t_0 + t_m, t_0, \xi_m)| \geq \varepsilon$ for all m, $t_m \geq 0$.

If $x = 0$ is an unstable equilibrium of (E), it still can happen that all the solutions tend to zero with increasing t. Thus, instability and attractivity are compatible concepts. Note that the equilibrium $x = 0$ is necessarily unstable if every neighborhood of the origin contains initial points corresponding to unbounded solutions (i.e., solutions whose norm $|\phi(t, t_0, \xi)|$ grows to infinity on a sequence $t_m \to \infty$). However, it can happen that a system (E) with unstable equilibrium $x = 0$ may have only bounded solutions.

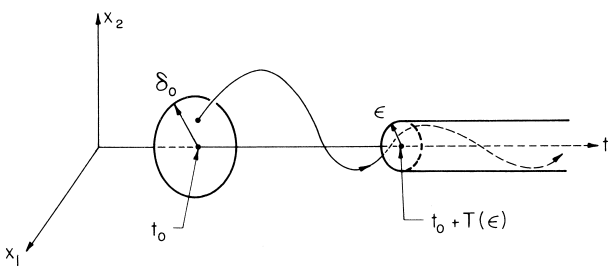

FIGURE 10 Attractivity of an equilibrium point.

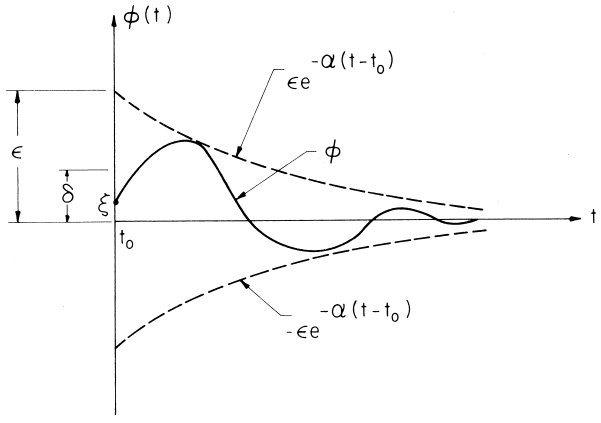

FIGURE 11 Exponential stability of an equilibrium point.

The above concepts pertain to *local properties of an equilibrium.* In the following definitions, we consider some *global characterizations of an equilibrium.*

A solution $\phi(t, t_0, \xi)$ of (E) is **bounded** if there exists a $\beta > 0$ such that $|\phi(t, t_0, \xi)| < \beta$ for all $t \geq t_0$, where β may depend on each solution. System (E) is said to possess **Lagrange stability** if for each $t_0 \geq 0$ and ξ the solution $\phi(t, t_0, \xi)$ is bounded.

The solutions of (E) are **uniformly bounded** if for any $\alpha > 0$ and $t_0 \in R^+$ there exists a $\beta = \beta(\alpha) > 0$ (independent of t_0) such that if $|\xi| < \alpha$, then $|\phi(t, t_0, \xi)| < \beta$ for all $t \geq t_0$.

The solutions of (E) are **uniformly ultimately bounded** (with bound B) if there exists a $B > 0$ and if corresponding to any $\alpha > 0$ and $t_0 \in R^+$ there exists a $T = T(\alpha)$ (independent of t_0) such that $|\xi| < \alpha$ implies that $|\phi(t, t_0, \xi)| < \beta$ for all $t \geq t_0 + T$.

In contrast to the boundedness properties given in the preceding three paragraphs, the concepts introduced earlier as well as those stated in the following are usually referred to as stability (respectively, instability) **in the sense of Lyapunov**.

The equilibrium $x = 0$ of (E) is **asymptotically stable in the large** if it is stable and if every solution of (E) tends to zero as $t \to \infty$. In this case, the domain of attraction of the equilibrium $x = 0$ of (E) is all of R^n. Note that in this case, $x = 0$ is the *only* equilibrium of (E).

The equilibrium $x = 0$ of (E) is **uniformly asymptotically stable in the large** if (1) it is uniformly stable, and (2) for any $\alpha > 0$ and any $\varepsilon > 0$, and $t_0 \in R^+$, there exists $T(\varepsilon, \alpha) > 0$, independent of t_0 such that if $|\xi| < \alpha$, then $|\phi(t, t_0, \xi)| < \varepsilon$ for all $t \geq t_0 + T(\varepsilon, \alpha)$.

Finally, the equilibrium $x = 0$ of (E) is **exponentially stable in the large** if there exists $\alpha > 0$ and for any $\beta > 0$, there exists $k(\beta) > 0$ such that $|\phi(t, t_0, \xi)| \leq k(\beta)|\xi|e^{-\alpha(t-t_0)}$ for all $t \geq t_0$ whenever $|\xi| < \beta$.

At this point it may be worthwhile to consider some specific examples:

1. The scalar equation,

$$x' = 0 \tag{95}$$

has for any initial condition $x(0) = c$ the solution $\phi(t, 0, c) = c$. All solutions are equilibria of Eq. (95). The trivial solution is *stable*; in fact, it is *uniformly stable*. However, it is not asymptotically stable.

2. The scalar equation,

$$x' = ax, \qquad a > 0 \tag{96}$$

has for every $x(0) = c$ the solution $\phi(t, 0, c) = ce^{at}$ and $x = 0$ is the only equilibrium of Eq. (96). This equilibrium is *unstable*.

3. The scalar equation,

$$x' = -ax, \qquad a > 0 \tag{97}$$

has for every $x(0) = c$ the solution $\phi(t, 0, c) = ce^{-at}$ and $x = 0$ is the only equilibrium of Eq. (97). This equilibrium is *exponentially stable in the large*.

4. The scalar equation,

$$x' = [-1/(t + 1)]x \tag{98}$$

has for every $x(t_0) = c$, $t_0 \geq 0$, a unique solution of the form $\phi(t, t_0, c) = (1 + t_0)c/(t + 1)$ and $x = 0$ is the only equilibrium of Eq. (98). This equilibrium is *uniformly stable* and *asymptotically stable in the large*, but it is not uniformly asymptotically stable.

C. Some Basic Properties of Autonomous and Periodic Systems

Making use of the properties of solutions and using the definitions of stability in the sense of Lyapunov it is not difficult to establish the following general stability results for systems described by:

$$x' = f(x) \tag{A}$$

and

$$x' = f(t, x), \qquad f(t, x) = f(t + T, x) \tag{P}$$

1. *If the equilibrium $x = 0$ of* (P) *(or of* (A)*) is stable, then it is in fact uniformly stable.*

2. *If the equilibrium $x = 0$ of* (P) *(or of* (A)*) is asymptotically stable, then it is uniformly asymptotically stable.*

D. Linear Systems

Next, by making use of the general properties of the solutions of linear autonomous homogeneous systems,

$$x' = Ax, \qquad t \geq 0 \tag{L}$$

and of linear homogeneous systems (with $A(t)$ continuous),

$$x' = A(t)x, \qquad t \geq t_0, \quad t_0 \geq 0 \tag{LH}$$

the following results are easily verified:

1. *The equilibrium $x = 0$ of* (LH) *is stable if and only if the solutions of* (LH) *are bounded. Equivalently, the equilibrium $x = 0$ of* (LH) *is stable if and only if*:

$$\sup_{t \geq t_0} |\Phi(t, t_0)| \stackrel{\Delta}{=} c(t_0) < \infty$$

where $|\Phi(t, t_0)|$ denotes the matrix norm induced by the vector norm used on R^n and sup denotes supremum.

2. *The equilibrium* $x = 0$ *of* (LH) *is uniformly stable if and only if*:

$$\sup_{t_0 \geq 0} c(t_0) \triangleq \sup_{t_0 \geq 0} \left(\sup_{t \geq t_0} |\Phi(t, t_0)| \right) \triangleq c_0 < \infty$$

3. *The following statements are equivalent*: (a) *The equilibrium* $x = 0$ *of* (LH) *is asymptotically stable.* (b) *The equilibrium* $x = 0$ *of* (LH) *is asymptotically stable in the large.* (c) $\lim_{t \to \infty} = 0$.

4. *The equilibrium* $x = 0$ *of* (LH) *is uniformly asymptotically stable if and only if it is exponentially stable*.

5. (a) *The equilibrium* $x = 0$ *of* (L) *is stable if all eigenvalues of* A *have nonpositive real parts and every eigenvalue of* A *that has a zero real part is a simple zero of the characteristic polynomial of* A. (b) *The equilibrium* $x = 0$ *of* (L) *is asymptotically stable if and only if all eigenvalues of* A *have negative real parts. In this case, there exist constants* $k > 0, \sigma > 0$ *such that* $|\Phi(t, t_0)| \leq k \exp[-\sigma(t - t_0)]$, $t_0 \leq t \leq \infty$, *where* $\Phi(t, t_0)$ *denotes the state transition matrix of* (L).

We shall find it convenient to use the following convention, which has become standard in the literature: A real $n \times n$ matrix A is called **stable** or a **Hurwitz matrix** if all of its eigenvalues have negative real parts. If at least one of the eigenvalues has a positive real part, then A is called **unstable**. A matrix A which is neither stable nor unstable is called **critical** and the eigenvalues of A with zero real parts are called **critical eigenvalues**.

Thus, the equilibrium $x = 0$ of (L) is asymptotically stable if and only if A is stable. If A is unstable, then $x = 0$ is unstable. If A is critical, then the equilibrium is stable if the eigenvalues with zero real parts correspond to a simple zero of the characteristic polynomial of A; otherwise, the equilibrium may be unstable.

Next, we consider the stability properties of linear periodic systems,

$$x' = A(t)x, \qquad A(t) = A(t + T) \qquad \text{(PL)}$$

where $A(t)$ is a continuous matrix for all $t \in R$. For such systems, the following results follow directly from Floquet theory:

1. *The equilibrium* $x = 0$ *of* (PL) *is uniformly stable if all eigenvalues of* R *in Eq.* (64) *have nonpositive real parts and any eigenvalue of* R *having zero real part is a simple zero of the characteristic polynomial of* R.

2. *The equilibrium* $x = 0$ *of* (PL) *is uniformly asymptotically stable if and only if all eigenvalues of* R *have negative real parts*.

E. Two-Dimensional Linear Systems

Before we present the principal results of the Lyapunov theory for general systems (E), we consider in detail the behavior of trajectories near an equilibrium point $x = 0$ of two-dimensional linear systems of the form

$$\begin{aligned} x_1' &= a_{11}x_1 + a_{12}x_2 \\ x_2' &= a_{21}x_1 + a_{22}x_2 \end{aligned} \qquad (99)$$

We can rewrite Eq. (99) equivalently as

$$x' = Ax \qquad (100)$$

where

$$A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \qquad (101)$$

When $\det A \neq 0$ system (99) will have one and only one equilibrium point, namely $x = 0$. We shall classify this equilibrium point (and, hence, system (99)) according to the following cases which the eigenvalues λ_1, λ_2 of A can assume:

1. λ_1, λ_2 are real and $\lambda_1 < 0, \lambda_2 < 0$: $x = 0$ is an asymptotically stable equilibrium point called a **stable node**.
2. λ_1, λ_2 are real and $\lambda > 0, \lambda_2 > 0$: $x = 0$ is an unstable equilibrium point called an **unstable node**.
3. λ_1, λ_2 are real and $\lambda_1 \lambda_2 < 0$: $x = 0$ is an unstable equilibrium point called a **saddle**.
4. λ_1, λ_2 are complex conjugates and $\text{Re } \lambda_1 = \text{Re } \lambda_2 < 0$: $x = 0$ is an asymptotically stable equilibrium point called a **stable focus**.
5. λ_1, λ_2 are complex conjugates and $\text{Re } \lambda_1 = \text{Re } \lambda_2 > 0$: $x = 0$ is an unstable equilibrium point called an **unstable focus**.
6. λ_1, λ_2 are complex conjugates and $\text{Re } \lambda_1 = \text{Re } \lambda_2 = 0$: $x = 0$ is a stable equilibrium called a **center**.

Using the results of Section IV, it is possible to solve Eq. (99) explicitly and verify that the qualitative behavior of the trajectories near the equilibrium $x = 0$ is as shown in Figs. 12–14 for the cases of a stable node, unstable node,

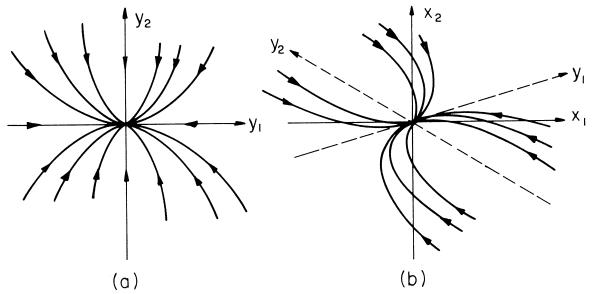

FIGURE 12 Trajectories near a stable node.

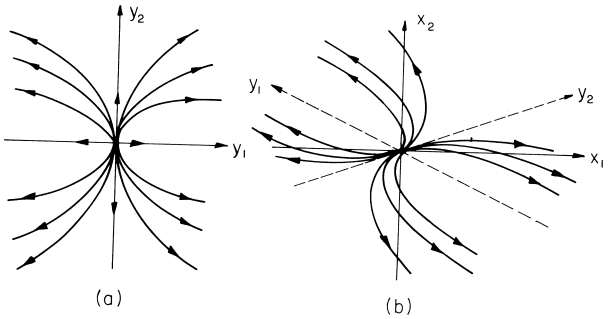

FIGURE 13 Trajectories near an unstable node.

and saddle, respectively. (The arrows on the trajectories point into the direction of increasing time.) In these cases, the figures labeled (a) correspond to systems in which A is in Jordan canonical form while the figures labeled (b) correspond to systems in which A is in some arbitrary form. In a similar manner, it is possible to verify that the qualitative behavior of the trajectories near the equilibrium $x = 0$ is as shown in Figs. 15–18 for the cases of a stable node (repeated eigenvalue case), an unstable focus, a stable focus, and a center, respectively. (For purposes of convention, we assumed in these figures that when λ_1, λ_2 are real and not equal, then $\lambda_1 > \lambda_2$.)

F. Lyapunov Functions

Next, we present general stability results for the equilibrium $x = 0$ of a system described by (E). Such results involve the existence of realvalued functions $v: D \to R$. In the case of local results (e.g., stability, instability, asymptotic stability, and exponential stability results), we shall usually only require that $D = B(h) \subset R^n$ for some $H > 0$, or $D = R^+ \times B(h)$. (Recall that $R^+ = (0, \infty)$ and $B(h) = \{x \in R^n : |x| < h\}$ where $|x|$ denotes any one of the equivalent norms of x on R^n.) On the other hand, in the case of global results (e.g., asymptotic stability in the large, exponential stability in the large, and uniform boundedness of solutions), we have to assume that $D = R^n$ or

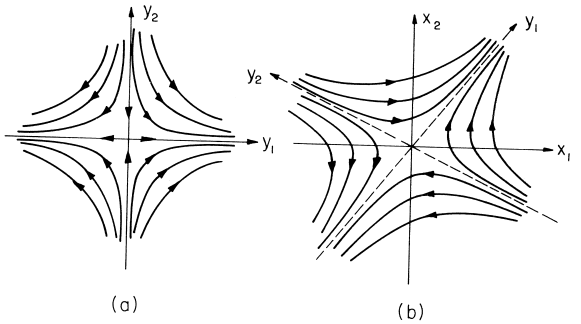

FIGURE 14 Trajectories near a saddle.

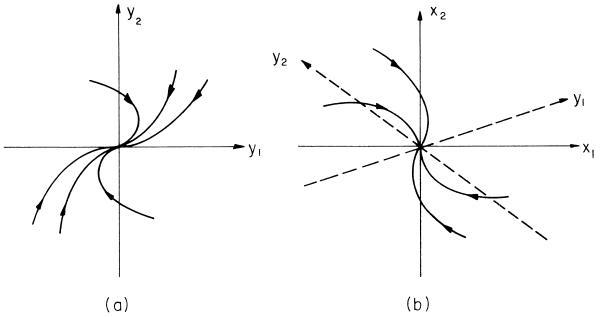

FIGURE 15 Trajectories near a stable node (repeated eigenvalue case).

$D = R^+ \times R^n$. Unless stated otherwise, we shall always assume that $v(t, 0) = 0$ for all $t \in R^+$ (resp., $v(0) = 0$).

Now let ϕ be an arbitrary solution of (E) and consider the function $t \mapsto v(t, \phi(t))$. If v is continuously differentiable with respect to all of its arguments, then we obtain (by the chain rule) the derivative of v with respect to t along the solutions of (E), $v'_{(E)}$, as:

$$v'_{(E)}(t, \phi(t)) = \frac{\partial v}{\partial t}(t, \phi(t)) + \nabla v(t, \phi(t))^T f(t, \phi(t))$$

Here, ∇v denotes the gradient vector of v with respect to x. For a solution $\phi(t, t_0, \xi)$ of (E), we have

$$v(t, \phi(t)) = v(t_0, \xi) + \int_{t_0}^{t} v'_{(E)}(\tau, \phi(\tau, t_0, \xi))\, d\tau$$

The above observations motivate the following: let v: $R^+ \times R^n \to R$ (resp., $v: R^+ \times B(h) \to R$) be continuously differentiable with respect to all of its arguments and let ∇v denote the gradient of v with respect to x. Then $v'_{(E)}: R^+ \times R^n \to R$ (resp., $v'_{(E)}: R^+ \times B(h) \to R$) is defined by:

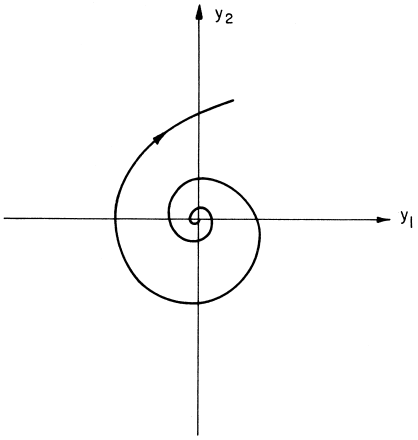

FIGURE 16 Trajectory near an unstable focus.

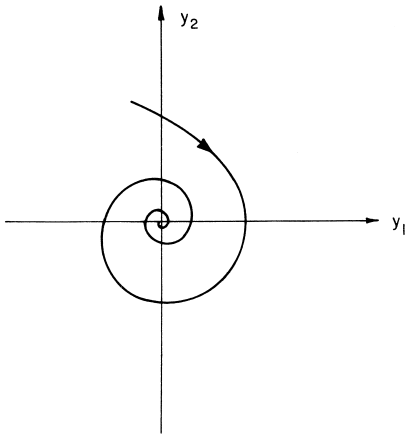

FIGURE 17 Trajectory near a stable focus.

$$v'_{(\mathrm{E})}(t,x) = \frac{\partial v}{\partial t}(t,x) + \sum_{i=1}^{n} \frac{\partial v}{\partial x_i}(t,x)\, f_i(t,x)$$

$$= \frac{\partial v}{\partial t}(t,x) + \nabla v(t,x)^{\mathrm{T}} f(t,x) \qquad (102)$$

We call $v'_{(\mathrm{E})}$ the **derivative of** v (**with respect to** t) **along the solutions of** (E).

It is important to note that in Eq. (102) the derivative of v with respect to t, along the solutions of (E), is evaluated *without having to solve* (E). The significance of this will become clear later. We also note that when $v\colon R^n \to R$ (resp., $v\colon B(h) \to R$), then Eq. (102) reduces to $v'_{(\mathrm{E})}(t,x) = \nabla v(x)^{\mathrm{T}} f(t,x)$. Also, in the case of autonomous systems (A), if $v\colon R^n \to R$ (resp., $v\colon B(h) \to R$), we have

$$v'_{(\mathrm{A})}(x) = \nabla v(x)^{\mathrm{T}} f(x) \qquad (103)$$

Occasionally, we shall require only that v be continuous on its domain of definition and that it satisfy locally a Lipschitz condition with respect to x. In such cases we define the **upper right-hand derivative of** v **with respect to** t **along the solutions of** (E) by:

$$v'_{(\mathrm{E})}(t,x) = \lim_{\theta \to 0^+} \sup(1/\theta)\{v(t+\theta, \phi(t+\theta,t,x)) - v(t,x)\}$$

$$= \lim_{\theta \to 0^+} \sup(1/\theta)\{v(t+\theta, x+\theta \cdot f(t,x)) - v(t,x)\} \qquad (104)$$

When v is continuously differentiable, then Eq. (104) reduces to Eq. (102).

We now give several important properties that v functions may possess. In doing so, we employ **Kamke comparison functions** defined as follows: a continuous function $\psi\colon [0, r_1] \to R^+$ (resp., $\psi\colon (0,\infty) \to R^+$) is said to belong to the **class** K (i.e., $\psi \in K$), if $\psi(0) = 0$ and if ψ is strictly increasing on $[0, r_1]$ (resp., on $[0,\infty)$). If $\psi\colon R^+ \to R^+$, if $\psi \in K$ and if $\lim_{r\to\infty} \psi(r) = \infty$, then ψ is said to belong to **class** KR.

We are now in a position to characterize v-functions in several ways. In the following, we assume that $v\colon R^+ \times R^n \to R$ (resp., $v\colon R^+ \times B(h) \to R$), that $v(0,t) = 0$ for all $t \in R^+$, and that v is continuous.

1. v is **positive definite** if, for some $r > 0$, there exists a $\psi \in K$ such that $v(t,x) \geq \psi(|x|)$ for all $t \geq 0$ and for all $x \in B(r)$.
2. v is **decrescent** if there exists a $\psi \in K$ such that $|v(t,x)| \leq \psi(|x|)$ for all $t \geq 0$ and for all $x \in B(r)$ for some $r > 0$.
3. $v\colon R^+ \times R^n \to R$ is **radially unbounded** if there exists a $\psi \in KR$ such that $v(t,x) \geq \psi(|x|)$ for all $t \geq 0$ and for all $x \in R^n$.
4. v is **negative definite** if $-v$ is positive definite.
5. v is **positive semidefinite** if $v(t,x) \geq 0$ for all $x \in B(r)$ for some $r > 0$ and for all $t \geq 0$.
6. v is **negative semidefinite** if $-v$ is positive semidefinite.

The definitions involving the above concepts, when $v\colon R^n \to R$ or $v\colon B(h) \to R$ (where $B(h) \subset R^n$ for some $h > 0$) involve obvious modifications. We now consider several specific cases:

1. The function $v\colon R^3 \to R$ given by $v(x) = x^{\mathrm{T}}x = x_1^2 + x_2^2 + x_3^2$ is positive definite and radially unbounded. (Here, x^{T} denotes the transpose of x.)
2. The function $v\colon R^3 \to R$ given by $v(x) = x_1^2 + (x_2 + x_3)^2$ is positive semidefinite (but not positive definite).
3. The function $v\colon R^2 \to R$ given by $v(x) = x_1^2 + x_2^2 - (x_1^2 + x_2^2)^3$ is positive definite but not radially unbounded.
4. The function $v\colon R^3 \to R$ given by $v(x) = x_1^2 + x_2^2$ is positive semidefinite (but not positive definite).

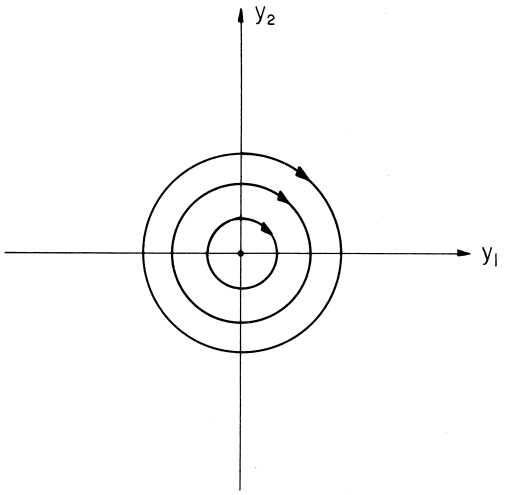

FIGURE 18 Trajectories near a center.

5. The function $v: R^2 \to R$ given by $v(x) = x_1^4/(1 + x_1^4) + x_2^4$ is positive definite but not radially unbounded.
6. The function $v: R^+ \times R^2 \to R$ given by $v(t, x) = (1 + \cos^2 t)x_1^2 + 2x_2^2$ is positive definite, decrescent, and radially unbounded.
7. The function $v: R^+ \times R^2 \to R$ given by $v(t, x) = (x_1^2 + x_2^2)\cos^2 t$ is positive semidefinite and decrescent.
8. The function $v: R^+ \times R^2 \to R$ given by $v(t, x) = (1 + t)(x_1^2 + x_2^2)$ is positive definite and radially unbounded but not decrescent.
9. The function $v: R^+ \times R^2 \to R$ given by $v(t, x) = x_1^2/(1 + t) + x_2^2$ is decrescent and positive semidefinite but not positive definite.
10. The function $v: R^+ \times R^2 \to R$ given by $v(t, x) = (x_2 - x_1)^2(1 + t)$ is positive semidefinite but not positive definite or decrescent.

Of special interest are functions $v: R^n \to R$ that are **quadratic forms** given by:

$$v(x) = x^{\mathrm{T}} B x = \sum_{i,k=1}^{n} b_{ik} x_i x_k \tag{105}$$

where $B = [b_{ij}]$ is a real symmetric $n \times n$ matrix (i.e., $B^T = B$). Since B is symmetric, it is diagonizable and all of its eigenvalues are real. For Eq. (105) one can prove the following:

1. *v is positive definite (and radially unbounded) if and only if all principal minors of B are positive; that is, if and only if*

$$\det \begin{bmatrix} b_{11} & \cdots & b_{1k} \\ \vdots & & \vdots \\ b_{k1} & \cdots & b_{kk} \end{bmatrix} > 0, \qquad k = 1, \ldots, n$$

2. *v is negative definite if and only if*

$$(-1)^k \det \begin{bmatrix} b_{11} & \cdots & b_{1k} \\ \vdots & & \vdots \\ b_{k1} & \cdots & b_{kk} \end{bmatrix} > 0, \qquad k = 1, \ldots, n$$

3. *v is* **definite** *(i.e., either positive definite or negative definite) if and only if all eigenvalues are nonzero and have the same sign.*
4. *v is* **semidefinite** *(i.e., either positive semidefinite or negative semidefinite) if and only if the nonzero eigenvalues of B have the same sign.*
5. *If λ_m and λ_M denote the smallest and largest eigenvalues of B and if $|x|$ denotes the Euclidean norm of x, then $\lambda_m |x|^2 \leqslant v(x) \leqslant \lambda_M |x|^2$ for all $x \in R^n$.* (The Euclidean norm of x is defined as $(x^{\mathrm{T}}x)^{1/2} = (\sum_{i=1}^n x_i^2)^{1/2}$.)
6. *v is* **indefinite** *(i.e., in every neighborhood of the origin $x = 0$, v assumes positive and negative values) if and only if B possesses both positive and negative eigenvalues.*

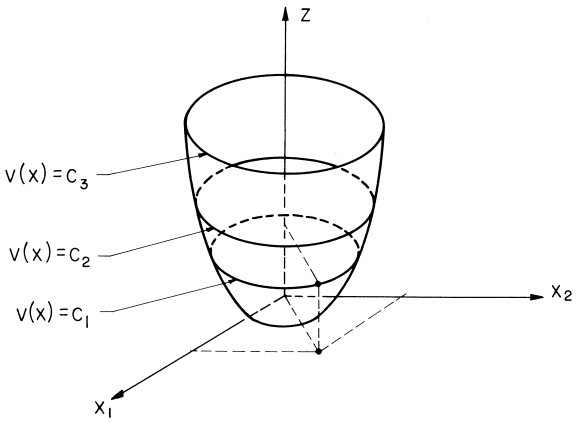

FIGURE 19 Surface described by a quadratic form.

Quadratic forms (105) have some interesting geometric properties. To see this, let $n = 2$, and assume that both eigenvalues of B are positive so that v is positive definite and radially unbounded. In R^3, let us now consider the surface determined by:

$$z = v(x) = x^{\mathrm{T}} B x \tag{106}$$

This equation describes a cup-shaped surface as depicted in Fig. 19. Note that corresponding to every point on this cup-shaped surface there exists one and only one point in the x_1x_2 plane. Note also that the loci defined by $C_i = \{x \in R^2: v(x) = c_i \geqslant 0\}$, $c_i =$ const, determine closed curves in the x_1x_2 plane as shown in Fig. 20. We call these curves **level curves**. Note that $C_0 = \{0\}$ corresponds to the case in which $z = c_0 = 0$. Note also that this function v can be used to *cover the entire* R^2 plane with closed curves by selecting for z all values in R^+.

In the case when $v = x^{\mathrm{T}} B x$ is a positive definite quadratic form with $x \in R^n$, the preceding comments are still true; however, in this case, the closed curves C_i must be replaced by closed hypersurfaces in R^n and a simple geometric visualization as in Figs. 19 and 20 is no longer possible.

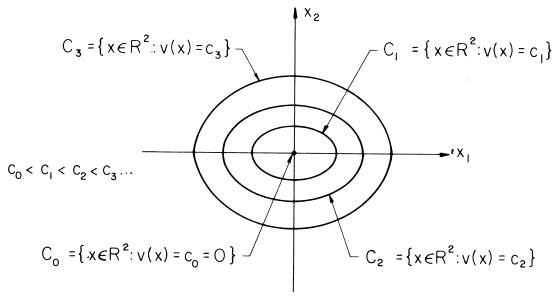

FIGURE 20 Level curves determined by a quadratic form.

G. Lyapunov Stability and Instability Results: Motivation

Before we summarize the principal Lyapunov-type of stability and instability results, we give a geometric interpretation of some of these results in R^2. To this end, we consider the system of equations,

$$x_1' = f_1(x_1, x_2), \qquad x_2' = f_2(x_1, x_2) \tag{107}$$

and we assume that f_1 and f_2 are such that for every (t_0, x_0), $t_0 \geqslant 0$, Eq. (107) has a unique solution $\phi(t, t_0, x_0)$ with $\phi(t_0, t_0, x_0) = x_0$. We also assume that $(x_1, x_2)^{\mathrm{T}} = (0, 0)^{\mathrm{T}}$ is the only equilibrium in $B(h)$ for some $h > 0$.

Next, let v be a positive definite, continuously differentiable function with nonvanishing gradient ∇v on $0 < |x| \leqslant h$. Then, $v(x) = c$, $c \geqslant 0$, defines for sufficiently small constants $c > 0$ a family of closed curves C_i which cover the neighborhood $B(h)$ as shown in Fig. 21. Note that the origin $x = 0$ is located in the interior of each such curve and in fact, $C_0 = \{0\}$.

Now suppose that all trajectories of Eq. (107) originating from points on the circular disk $|x| \leq r_1 < h$ cross the curves $v(x) = c$ from the exterior toward the interior when we proceed along these trajectories in the direction of increasing values of t. Then, we can conclude that these trajectories approach the origin as t increases (i.e., the equilibrium $x = 0$ is in this case asymptotically stable).

In terms of the given v function, we have the following interpretation. For a given solution $\phi(t, t_0, x_0)$ to cross the curve $v(x) = r$, $r = v(x_0)$, the angle between the outward normal vector $\nabla v(x_0)$ and the derivative of $\phi(t, t_0, x_0)$ at $t = t_0$ must be greater than $\pi/2$; that is,

$$v_{(107)}'(x_0) = \nabla v(x_0)\, f(x_0) < 0$$

For this to happen at all points, we must have $v_{(107)}'(x) < 0$ for $0 < |x| \leq r_1$. The same results can be arrived at from an analytic point of view. The function $V(t) = v(\phi(t, t_0, x_0))$ decreases monotonically as t increases. This implies that the derivative $v'(\phi(t, t_0, x_0))$ along the solution $(\phi(t, t_0, x_0))$ must be negative definite in $B(r)$ for $r > 0$ sufficiently small.

Next, let us assume that, Eq. (107) has only one equilibrium (at $x = 0$) and that v is positive definite and radially unbounded. It turns out that in this case, the relation $v(x) = c$, $c \in R^+$, can be used to cover *all* of R^2 by closed curves of the type shown in Fig. 21. If for arbitrary (t_0, x_0), the corresponding solution of Eq. (107), $\phi(t, t_0, x_0)$, behaves as already discussed, then it follows that the derivative of v along this solution, $v'(\phi(t, t_0, x_0))$, will be negative definite in R^2.

Since the foregoing discussion was given in terms of an arbitrary solution of Eq. (107), we may suspect that the following results are true:

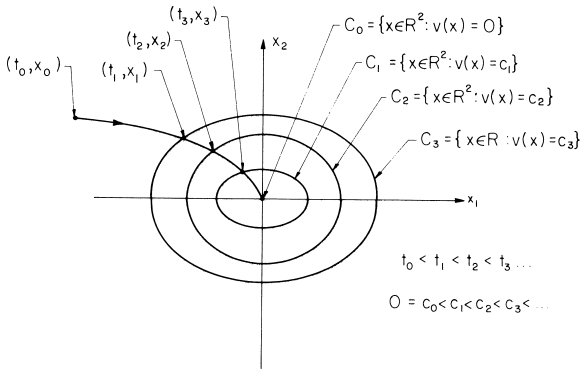

FIGURE 21 Trajectory near an asymptotically stable equilibrium point.

1. *If there exists a positive definite function v such that $v_{(107)}'$ is negative definite, then the equilibrium $x = 0$ of Eq.* (107) *is asymptotically stable.*

2. *If there exists a positive definite and radially unbounded function v such that $v_{(107)}'$ is negative definite for all $x \in R^2$, then the equilibrium $x = 0$ of Eq.* (107) *is asymptotically stable in the large.*

Continuing our discussion by making reference to Fig. 22, let us assume that we can find for Eq. (107) a continuously differentiable function $v: R^2 \to R$ which is indefinite and has the properties discussed below. Since v is indefinite, there exist in each neighborhood of the origin points for which $v > 0$, $v < 0$, and $v(0) = 0$. Confining our attention to $B(k)$, where $k > 0$ is sufficiently small, we let $D = \{x \in B(k): v(x) < 0\}$. ($D$ may consist of several subdomains.) The boundary of D, ∂D, as shown in Fig. 22, consists of points in $\partial B(k)$ and of points determined by $v(x) = 0$. Assume that in the interior of D, v is bounded. Suppose $v_{(107)}'(x)$ is negative definite in D

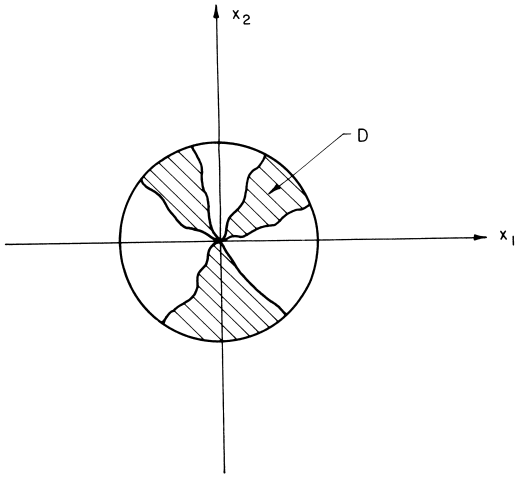

FIGURE 22 Instability of an equilibrium point.

and that $x(t)$ is a trajectory of Eq. (107) which originates somewhere on the boundary of D ($x(t_0) \in \partial D$) with $v(x(t_0)) = 0$. Then, this trajectory will penetrate the boundary of D at points where $v = 0$ as t increases and it can never again reach a point where $v = 0$. In fact, as t increases, this trajectory will penetrate the set of points determined by $|x| = k$ (since; by assumption, $v'_{(107)} < 0$ along this trajectory and $v < 0$ in D). But, this indicates that the equilibrium $x = 0$ of Eq. (107) is unstable.

We are once more led to a conjecture:

3. *Let a function* v: $R^2 \to R$ *be given which is continuously differentiable and which has the following properties*: (a) *There exist points x arbitrarily close to the origin such that* $v(x) < 0$; *they form the domain D bounded by the set of points determined by* $v = 0$ *and the disk* $|x| = k$. (b) *In the interior of D,* v *is bounded.* (c) *In the interior of D,* $v'_{(107)}$ *is negative. Then, the equilibrium* $x = 0$ *of Eq.* (107) *is unstable*.

H. Principal Lyapunov Stability and Instability Theorems

It turns out that results of the type given above for Eq. (107) are true for general systems (E). These results, which are proved by standard δ–ε arguments, comprise the **direct method of Lyapunov**, which is also sometimes called the **second method of Lyapunov**. The reason for this nomenclature is clear: Results of the kind presented here allow us to make qualitative statements about whole families of solutions of (E), without actually solving this equation.

In the following, we enumerate some of the more important results of the direct method. We shall assume that v: $R^+ \times B(h) \to R$ (resp., v: $R^+ \times R^n \to R$).

1. *If there exists a continuously differentiable positive definite function* v *with a negative semidefinite (or identically zero) derivative* $v'_{(E)}$, *then the equilibrium* $x = 0$ *of* (E) *is stable*.

As an example, consider the system given by:

$$x'_1 = x_2, \qquad x'_2 = -x_2 - e^{-t}x_1 \tag{108}$$

which has an equilibrium at $(x_1, x_2)^T = (0, 0)^T$. For Eq. (108), choose the positive definite function $v(t, x_1, x_2) = x_1^2 + e^t x_2^2$. We obtain $v'_{(108)}(t, x_1, x_2) = -e^t x_2^2$ which is negative semidefinite. We conclude that the equilibrium $x = 0$ of Eq. (108) is *stable*.

2. *If there exists a continuously differentiable, positive definite, decrescent function* v *with negative semidefinite derivative* $v'_{(E)}$, *then the equilibrium* $x = 0$ *of* (E) *is uniformly stable*.

As an example, consider the simple pendulum,

$$x'_1 = x_2, \qquad x'_2 = -k \sin x_1 \tag{109}$$

where $k > 0$ is a constant. As noted earlier, Eq. (109) has an isolated equilibrium at $x = 0$. Choose $v(x_1, x_2) = \frac{1}{2}x_2^2 + k\int_0^{x_1} \sin\eta \, d\eta$, which is continuously differentiable and positive definite. Also, since v does not depend on t, it will automatically be decrescent. Furthermore, $v'_{(109)}(x_1, x_2) = (k \sin x_1)x'_1 + x_2 x'_2 = (k \sin x_1)x_2 + x_2(-k \sin x_1) = 0$. Therefore, the equilibrium $x = 0$ of Eq. (109) is *uniformly stable*.

3. *If there exists a continuously differentiable, positive definite, decrescent function* v *with a negative definite derivative* $v'_{(E)}$, *then the equilibrium* $x = 0$ *of* (E) *is uniformly asymptotically stable*.

For an example, the system,

$$\begin{aligned} x'_1 &= (x_1 - c_2 x_2)\big(x_1^2 + x_2^2 - 1\big) \\ x'_2 &= (c_1 x_1 + x_2)\big(x_1^2 + x_2^2 - 1\big) \end{aligned} \tag{110}$$

has an isolated equilibrium at the origin $x = 0$. Choosing $v(x) = c_1 x_1^2 + c_2 x_2^2$, we obtain $v'_{(110)}(x) = 2(c_1 x_1^2 + c_2 x_2^2)(x_1^2 + x_2^2 - 1)$. If $c_1 > 0, c_2 > 0$, then v is positive definite (and decrescent) and $v'_{(110)}$ is negative definite in the domain $x_1^2 + x_2^2 < 1$. Therefore, the equilibrium $x = 0$ *of* Eq. (110) *is uniformly asymptotically stable*.

4. *If there exists a continuously differentiable, positive definite, decrescent, and radially unbounded function* v *such that* $v'_{(E)}$ *is negative definite for all* $(t, x) \in R^+ \times R^n$, *then the equilibrium* $x = 0$ *of* (E) *is uniformly asymptotically stable in the large*.

As an example, consider the system,

$$\begin{aligned} x'_1 &= x_2 + c x_1\big(x_1^2 + x_2^2\big) \\ x'_2 &= -x_1 + c x_2\big(x_1^2 + x_2^2\big) \end{aligned} \tag{111}$$

where c is a real constant. Note that $x = 0$ is the only equilibrium. Choosing the positive definite, decrescent, and radially unbounded function $v(x) = x_1^2 + x_2^2$, we obtain $v'_{(111)}(x) = 2c(x_1^2 + x_2^2)^2$. We conclude that if $c = 0$, then $x = 0$ of Eq. (111) is *uniformly stable* and if $c < 0$, then $x = 0$ of Eq. (111) is *uniformly asymptotically stable in the large*.

5. *If there exists a continuously differentiable function* v *and three positive constants* c_1, c_2, *and* c_3 *such that*

$$c_1|x|^2 \le v(t, x) \le c_2|x|^2$$
$$v'_{(E)}(t, x) \le -c_3|x|^2$$

for all $t \in R^+$ *and for all* $x \in B(r)$ *for some* $r > 0$, *then the equilibrium* $x = 0$ *of* (E) *is exponentially stable*.

6. *If there exist a continuously differentiable function* v *and three positive constants* c_1, c_2, *and* c_3 *such that*

$$c_1|x|^2 \le v(t,x) \le c_2|x|^2$$
$$v'_{(E)}(t,x) \le -c_3|x|^2$$

for all $t \in R^+$ *and for all* $x \in R^n$, *then the equilibrium* $x=0$ *of* (E) *is exponentially stable in the large*.

As an example, consider the system,

$$\begin{aligned} x_1' &= -a(t)x_1 - bx_2 \\ x_2' &= bx_1 - c(t)x_2 \end{aligned} \tag{112}$$

where b is a real constant and where a and c are real and continuous functions defined for $t \ge 0$ satisfying $a(t) \ge \delta > 0$ and $c(t) \ge \delta > 0$ for all $t \ge 0$. We assume that $x=0$ is the only equilibrium for Eq. (112). If we choose $v(x) = \frac{1}{2}(x_1^2 + x_2^2)$, then $v'_{(112)}(t,x) = -a(t)x_1^2 - c(t)x_2^2 \le -\delta(x_1^2 + x_2^2)$. Hence, the equilibrium $x=0$ of Eq. (112) is *exponentially stable in the large.*

7. *If there exists a continuously differentiable function* v *defined on* $|x| \ge R$ (*where* R *may be large*) *and* $0 \le t \le \infty$, *and if there exist* $\psi_1, \psi_2 \in KR$ *such that* $\psi_1(|x|) \le v(t,x) \le \psi_2(|x|)$, $v'_{(E)}(t,x) \le 0$ *for all* $|x| \ge R$ *and for all* $0 \le t < \infty$, *then the solutions of* (E) *are uniformly bounded.*

8. *If there exists a continuously differentiable function* v *defined on* $|x| \ge R$ (*where* R *may be large*) *and* $0 \le t < \infty$, *and if there exist* $\psi_1, \psi_2 \in KR$ *and* $\psi_3 \in K$ *such that* $\psi_1(|x|) \le v(t,x) \le \psi_2(|x|)$, $v'_{(E)}(t,x) \le -\psi_3(|x|)$ *for all* $|x| \ge R$ *and* $0 \le t < \infty$, *then the solutions of* (E) *are uniformly ultimately bounded.*

As an example, consider the system,

$$x' = -x - \sigma, \qquad \sigma' = -\sigma - f(\sigma) + x \tag{113}$$

where $f(\sigma) = \sigma(\sigma^2 - 6)$. There are isolated equilibrium points at $x = \sigma = 0$, $x = -\sigma = 2$, and $x = -\sigma = -2$. Choosing the radially unbounded and decrescent function $v(x,\sigma) = \frac{1}{2}(x^2 + \sigma^2)$, we obtain $v'_{(113)} = (x,\sigma) = -x^2 - \sigma^2(\sigma^2 - 5) \le -x^2 - (\sigma^2 - \frac{5}{2})^2 + \frac{25}{4}$. Also $v'_{(113)}$ is negative for all (x,σ) such that $x^2 + \sigma^2 > R^2$, where, for example, $R = 10$ will do. Therefore, all solutions of Eq. (113) are *uniformly bounded* and, in fact, *uniformly ultimately bounded.*

9. *The equilibrium* $x=0$ *of* (E) *is unstable* (*at* $t = t_0 \ge 0$) *if there exists a continuously differentiable, decrescent function* v *such that* $v'_{(E)}$ *is positive definite (negative definite) and if in every neighborhood of the origin there are points* x *such that* $v(t_0,x) > 0 (v(t_0,x) < 0)$.

Reconsider system (111), this time assuming that $c > 0$. If we choose $v(x) = x_1^2 + x_2^2$, then $v'_{(111)}(x) = 2c(x_1^2 + x_2^2)^2$ and we can conclude from the above result that the equilibrium $x=0$ of (E) is *unstable.*

10. *Let there exist a bounded and continuously differentiable function* $v: D \to R$, $D = \{(t,x) \ge t_0, x \in B(h)\}$, *with the following properties*: (a) $v'_{(E)}(t,x) = \lambda v(t,x) + w(t,x)$, *where* $\lambda > 0$ *is a constant and* $w(t,x)$ *is either identically zero or positive semidefinite*; (b) *in the set* $D_1 = \{(t,x): t = t_1, x \in B(h_1)\}$ *for fixed* $t_1 \ge t_0$ *and with arbitrarily small* h_1, *there exist values* x *such that* $v(t_1,x) > 0$. *Then the equilibrium* $x=0$ *of* (E) is *unstable*.

As a specific example, consider:

$$\begin{aligned} x_1' &= x_1 + x_2 + x_1x_2^4 \\ x_2' &= x_1 + x_2 - x_1^2x_2 \end{aligned} \tag{114}$$

which has an isolated equilibrium $x=0$. Choosing $v(x) = (x_1^2 - x_2^2)/2$, we obtain $v'_{(114)}(x) = \lambda v(x) + w(x)$, where $w(x) = x_1^2x_2^4 + x_1^2x_2^2$ and $\lambda = 2$. It follows from the above result that the equilibrium $x=0$ of Eq. (114) is *unstable*.

11. *Let there exist a continuously differentiable function* v *having the following properties*: (a) *For every* $\varepsilon > 0$ *and for every* $t \ge 0$, there exist points $\bar{x} \in B(\varepsilon)$ *such that* $v(t,\bar{x}) < 0$. *We call the set of all points* (t,x) *such that* $x \in B(h)$ *and such that* $v(t,x) < 0$ *the "domain* $v < 0$." *It is bounded by the hypersurfaces which are determined by* $|x| = h$ *and* $v(t,x) = 0$ *and it may consist of several component domains.* (b) *In at least one of the component domains* D *of the domain* $v < 0$, v *is bounded from below and* $0 \in \partial D$ *for all* $t \ge 0$. (c) *In the domain* D, $v'_{(E)} \le -\Psi(|v|)$, *where* $\psi \in K$. *Then, the equilibrium* $x=0$ *of* (E) *is unstable*.

As an example, consider the system,

$$\begin{aligned} x_1' &= x_1 + x_2 \\ x_2' &= x_1 - x_2 + x_1x_2 \end{aligned} \tag{115}$$

which has an isolated equilibrium at the origin $x=0$. Choosing $v(x) = -x_1x_2$, we obtain $v'_{(115)}(x) = -x_1^2 - x_2^2 - x_1^2x_2$. Let $D = \{x \in R^2: x_1 > 0, x_2 > 0,$ and $x_1^2 + x_2^2 < 1\}$. Then, for all $x \in D$, $v < 0$ and $c'_{(115)} < 2v$. We see that the above result is applicable and conclude that the equilibrium $x=0$ of Eq. (115) is *unstable*.

The results given in items 1–11 are also true when v is continuous (rather than continuously differentiable). In this case, $v'_{(E)}$ must be interpreted in the sense of Eq. (104).

For the case of systems (A),

$$x' = f(x) \tag{A}$$

it is sometimes possible to relax the conditions on $v'_{(A)}$ when investigating the asymptotic stability of the equilibrium $x=0$, by insisting that $v'_{(A)}$ be only negative semidefinite. In doing so, we require the following concept: A set Γ of points in R^n is **invariant (with respect to** (A)) if

every solution of (A) starting in Γ remains in Γ for all time.

We are now in a position to state our next result which is part of **invariance theory** for ordinary differential equations.

12. *Assume that there exists a continuously differentiable, positive definite, and radially unbounded function* $v: R^n \to R$ *such that* (a) $v'_{(A)}(x) \le 0$ *for all* $x \in R^n$, *and* (b) *the origin* $x = 0$ *is the only invariant subset of the set* $E = \{x \in R^n: v'_{(A)}(x) = 0\}$. *Then, the equilibrium* $x = 0$ *of* (A) *is asymptotically stable in the large*.

As a specific example, consider the *Liénard equation* given by:

$$x'_1 = x_2, \qquad x'_2 = -f(x_1)x_2 - g(x_1) \tag{116}$$

where it is assumed that f and g are continuously differentiable for all $x_1 \in R$, $g(x_1) = 0$ if and only if $x_1 = 0$, $x_1 g(x_1) > 0$ for all $x_1 \neq 0$ and $x_1 \in R$,

$$\lim_{|x_1| \to \infty} \int_0^{x_1} g(\eta)\, d\eta = \infty$$

and $f(x_1) > 0$ for all $x_1 \in R$. Then $(x_1, x_2) = (0, 0)$ is the only equilibrium of Eq. (116). Let us choose the v function,

$$v(x_1, x_2) = \frac{1}{2}x_2^2 + \int_0^{x_1} g(\eta)\, d\eta$$

(for Eq. (116)) which is positive definite and radially unbounded. Along the solutions of Eq. (116) we have $v'_{(116)}(x_1, x_2) = -x_2^2 f(x_1) \le 0$ for all $(x_1, x_2) \in R^2$. It is easily verified that the set E in the above theorem is in our case the x_1 axis. Furthermore, a moment's reflection shows that the largest invariant subset (with respect to Eq. (116)) of the x_1 axis is the set $\{(0, 0)^T\}$. Thus, by the above result, the origin $x = 0$ of Eq. (116) is *asymptotically stable in the large*.

I. Linear Systems Revisited

One of the great drawbacks of the Lyapunov theory, as developed above, is that there exist no general rules of choosing v functions, which are called **Lyapunov functions**. However, for the case of linear systems,

$$x' = Ax \tag{L}$$

it is possible to construct Lyapunov functions, as shown by the following result:

Assume that the matrix A has no eigenvalues on the imaginary axis. Then, there exists a Lyapunov function v *of the form*:

$$v(x) = x^T B x, \qquad B = B^T \tag{117}$$

whose derivative $v'_{(L)}$, *given by*:

$$v'_{(L)}(x) = -x^T C x$$

where

$$-C = A^T B + BA, \qquad C = C^T \tag{118}$$

is definite (*i.e., negative definite or positive definite*).

The above result shows that if A is a stable matrix, then for (L), our earlier Lyapunov result for asymptotic stability in the large constitutes also necessary conditions for asymptotic stability. Also, if A is an unstable matrix with no eigenvalues on the imaginary axis, then according to the above result, our earlier instability result given in item 9 above yields also necessary conditions for instability.

In view of the above result, the v function in Eq. (117) is easily constructed by assuming a definite matrix C (either positive definite or negative definite) and by solving the **Lyapunov matrix equation** (118) for the $n(n+1)/2$ unknown elements of the symmetric matrix B.

J. Domain of Attraction

Next, we should address briefly the problem of estimating the domain of attraction of an equilibrium $x = 0$. Such questions are important when $x = 0$ is not the only equilibrium of a system or when $x = 0$ is not asymptotically stable in the large.

For purposes of discussion, we consider a system,

$$x' = f(x) \tag{A}$$

and we assume that for (A) there exists a Lyapunov function v which is *positive definite* and *radially unbounded*. Also, we assume that over some domain $D \subset R^n$ containing the origin, $v'_{(A)}(x)$ is *negative*, except at the origin, where $v'_{(A)} = 0$. Now let C_i denote $C_i = \{x \in R^n: v(x) \le c_i\}$, $c_i > 0$. Using similar reasoning as was done in connection with Eq. (107), we can show that as long as $C_i \subset D$, C_i will be a subset of the domain of attraction of $x = 0$. Thus, if $c_i > 0$ is the largest number for which this is true, then it follows that C_i will be contained in the domain of attraction of $x = 0$. The set C_i will be the best estimate that we can obtain for our particular choice of v function.

K. Converse Theorems

Above we showed that for system (L) there exist actually converse Lyapunov (stability and instability) theorems. It turns out that for virtually every result which we gave above (in items 1–11) there exists a converse. Unfortunately, these **Lyapunov converse theorems** are not much help in constructing v functions in specific cases. For purposes of illustration, we cite here an example of such a converse theorem:

If f and $f_x = \partial f/\partial x$ are continuous on the set $(R^+ \times B(r))$ for some $r > 0$, and if the equilibrium $x = 0$ of (E) *is uniformly asymptotically stable, then there exists a Lyapunov function v which is continuously differentiable on $(R^+ \times B(r_1))$ for some $r_1 > 0$ such that v is positive definite and decrescent and such that $v'_{(E)}$ is negative definite.*

L. Comparison Theorems

Next, we consider once more some comparison results for (E), as was done in Section III. We shall assume that $f: R^+ \times B(r) \to R^n$ for some $r_1 > 0$ and that f is continuous there. We begin by considering a scalar ordinary differential equation of the form,

$$y' = G(t, y) \tag{$\tilde{C}$}$$

where $y \in R, t \in R^+$, and $F: R^+ \times [0, r) \to R$ for some $r > 0$. Assume that G is continuous on $R^+ \times [0, r)$ and that $G(t, 0) = 0$ for all t. Also, assume that $y = 0$ is an isolated equilibrium for ($\tilde{C}$).

The following results are the basis of the **comparison principle** in the stability analysis of the isolated equilibrium $x = 0$ of (E):

Let f and G be continuous on their respective domains of definition. Let $v: R^+ \times B(r) \to R$ be a continuously differentiable, positive-definite function such that

$$v'_{(E)}(t, x) \leq G(t, v(t, x)) \tag{119}$$

Then, the following statements are true: (1) *If the trivial solution of* ($\tilde{C}$) *is stable, then the trivial solution of system* (E) *is stable.* (2) *If v is decrescent and if the trivial solution of* ($\tilde{C}$) *is uniformly stable, then the trivial solution of* (E) *is uniformly stable.* (3) *If v is decrescent and if the trivial solution of* ($\tilde{C}$) *is uniformly asymptotically stable, then the trivial solution of* (E) *is uniformly asymptotically stable.* (4) *If there are constants $a > 0$ and $b > 0$ such that $a|x|^b \leq v(t, x)$, if v is decrescent, and if the trivial solution of* ($\tilde{C}$) *is exponentially stable, then the trivial solution of* (E) *is exponentially stable.* (5) *If $f: R^+ \times R^n \to R^n$, $G: R^+ \times R \to R$, $v: R^+ \times R^n \to R$ is decrescent and radially unbounded, if Eq.* (119) *holds for all $t \in R^+$, $x \in R^n$, and if the solutions of* ($\tilde{C}$) *are uniformly bounded* (*uniformly ultimately bounded*), *then the solutions of* (E) *are also uniformly bounded* (*uniformly ultimately bounded*).

The above results enable us to analyze the stability and boundedness properties of an n-dimensional system (E), which may be complex, in terms of the corresponding properties of a one-dimensional comparison system ($\tilde{C}$), which may be quite a bit simpler. The generality and effectiveness of the above results can be improved and extended by considering *vector-valued comparison equations and vector Lyapunov functions*.

M. Lyapunov's First Method

We close this section by answering the following question: Under what conditions does it make sense to linearize a nonlinear system about an equilibrium $x = 0$ and then deduce the properties of $x = 0$ from the corresponding linear system? This is known as **Lyapunov's first method** or **Lyapunov's indirect method.**

We consider systems of n real nonlinear first-order ordinary differential equations of the form:

$$x' = Ax + F(t, x) \tag{PE}$$

where $F: R^+ \times B(h) \to R^n$ for some $h > 0$ and A is a real $n \times n$ matrix. Here, we assume that Ax constitutes the **linear part** of the right-hand side of (PE) and $F(t, x)$ represents the remaining terms which are of order higher than one in the various components of x. Such systems may arise in the process of linearizing nonlinear equations of the form:

$$x' = g(t, x) \tag{G}$$

or they may arise in some other fashion during the modeling process of a physical system.

To be more specific, let $g: R \times D \to R^n$ where D is some domain in R^n. If g is continuously differentiable on $R \times D$ and if ϕ is a given solution of (E) defined for all $t \geq t_0 \geq 0$, then we can **linearize** (G) **about** ϕ in the following manner. Define $y = x - \phi(t)$ so that

$$\begin{aligned} y' &= g(t, x) - g(t, \phi(t)) \\ &= g(t, y + \phi(t)) - g(t, \phi(t)) \\ &= (\partial g/\partial t)(t, \phi(t))y + G(t, y) \end{aligned}$$

Here,

$$G(t, y) = [g(t, y+\phi(t)) - g(t, \phi(t))] - (\partial g/\partial x)(t, \phi(t))y$$

is $o(|y|)$ as $|y| \to 0$ uniformly in t on compact subsets of $[t_0, \infty)$.

Of special interest is the case when g is independent of t (i.e., when $g(t, x) \equiv g(x)$) and $\phi(t) = \xi_0$ is a constant (equilibrium point). Under these conditions we have

$$y' = Ay + G(y)$$

where $A = (\partial g/\partial x)(x)|_{x=\xi_0}$, where $(\partial g/\partial x)(x)$ denotes the Jacobian of $g(x)$.

By making use of the result for the Lyapunov function (117), we can readily prove the following results:

1. *Let A be a real, constant, and stable $n \times n$ matrix and let $F: R^+ \times B(h) \to R^n$ be continuous in (t, x) and satisfy $F(t, x) = o(|x|)$ as $|x| \to 0$, uniformly in $t \in R^+$.*

Then, the trivial solution of (PE) *is uniformly asymptotically stable.*

As a specific example, consider the *Liénard equation* given by:

$$x'' + f(x)x' + x = 0 \qquad (120)$$

where $f: R \to R$ is a continuous function with $f(0) > 0$. We can rewrite Eq. (120) as:

$$x_1' = x_2, \qquad x_2' = -x_1 - f(0)x_2 + [f(0) - f(x_1)]x_2$$

and we can apply the above result with $x = (x_1, x_2)^{\mathrm{T}}$,

$$A = \begin{bmatrix} 0 & 1 \\ -1 & -f(0) \end{bmatrix}$$

$$F(t, x) = \begin{bmatrix} 0 \\ [f(0) - f(x_1)]x_2 \end{bmatrix}$$

Noting that A is a stable matrix and that $F(t, x) = o(|x|)$ as $|x| \to 0$, uniformly in $t \in R^+$, we conclude that the trivial solution $(x, x') = (0, 0)$ of Eq. (120) is uniformly asymptotically stable.

2. *Assume that A is a real $n \times n$ matrix with no eigenvalues on the imaginary axis and that at least one eigenvalue of A has positive real part. If $F: R^+ \times B(h) \to R^n$ is continuous and satisfies $F(t, x) = o(|x|)$ as $|x| \to 0$, uniformly in $t \in R^+$, then the trivial solution of* (PE) *is unstable.*

As a specific example, consider the simple pendulum,

$$x'' + k \sin x = 0, \qquad k > 0 \qquad (121)$$

Note that $x_e = \pi, x_e' = 0$ is an equilibrium of Eq. (121). Let $y = x - x_e$ so that

$$y'' + a \sin(y + \pi) = y'' - ay + a(\sin(y + \pi) + y) = 0$$

This equation can be put into the form (PE) with

$$A = \begin{bmatrix} 0 & 1 \\ a & 0 \end{bmatrix}$$

$$F(t, x) = \begin{bmatrix} 0 \\ a(\sin(y + \pi) + y) \end{bmatrix}$$

Applying the above result we conclude that the equilibrium point $(\pi, 0)$ is *unstable.*

Differential Equations, Partial

Martin Schechter
University of California, Irvine

GLOSSARY

Boundary Set of points in the closure of a region not contained in its interiors.
Bounded region Region that is contained in a sphere of finite radius.
Eigenvalue Scalar λ for which the equation $Au = \lambda u$ has a nonzero solution u.
Euclidean *n* dimensional space $\mathbb{R}^n$ Set of vectors $x = (x_1, \ldots, x_n)$ where each component x_j is a real number.
Partial derivative Derivative of a function of more than one variable with respect to one of the variables keeping the other variables fixed.

A PARTIAL DIFFERENTIAL EQUATION is an equation in which a partial derivative of an unknown function appears. The order of the equation is the highest order of the partial derivatives (of an unknown function) appearing in the equation. If there is only one unknown function $u(x_1, \ldots, x_n)$, then a partial differential equation for u is of the form:

$$F\left(x_1, \ldots, x_n, u, \frac{\partial u}{\partial x_1}, \ldots, \frac{\partial u}{\partial x_n}, \frac{\partial^2 u}{\partial x_1^2}, \ldots, \frac{\partial^k u}{\partial x_1^k}, \ldots\right) = 0$$

One can have more than one unknown function and more than one equation involving some or all of the unknown functions. One then has a system of j partial differential equations in k unknown functions. The number of equations may be more or less than the number of unknown functions. Usually it is the same.

I. IMPORTANCE

One finds partial differential equations in practically every branch of physics, chemistry, and engineering. They are also found in other branches of the physical sciences and in the social sciences, economics, business, etc. Many parts of theoretical physics are formulated in terms of partial differential equations. In some cases, the axioms require that the states of physical systems be given by solutions of partial differential equations. In other cases, partial differential equations arise when one applies the axioms to specific situations.

II. HOW THEY ARISE

Partial differential equations arise in several branches of mathematics. For instance, the Cauchy–Riemann equations,

$$\frac{\partial u(x, y)}{\partial x} = \frac{\partial v(x, y)}{\partial y}, \qquad \frac{\partial u(x, y)}{\partial y} = -\frac{\partial v(x, y)}{\partial x}$$

must be satisfied if

$$f(z) = u(x, y) + iv(x, y)$$

is to be an analytic function of the complex variable $z = x + iy$. Thus, the rich and beautiful branch of mathematics known as analytic function theory is merely the study of solutions of a particular system of partial differential equations.

As a simple example of a partial differential equation arising in the physical sciences, we consider the case of a vibrating string. We assume that the string is a long, very slender body of elastic material that is flexible because of its extreme thinness and is tightly stretched between the points $x = 0$ and $x = L$ on the x axis of the x,y plane. Let x be any point on the string, and let $y(x, t)$ be the displacement of that point from the x axis at time t. We assume that the displacements of the string occur in the x,y plane. Consider the part of the string between two close points x_1 and x_2. The tension T in the string acts in the direction of the tangent to the curve formed by the string. The net force on the segment $[x_1, x_2]$ in the y direction is

$$T \sin\varphi_2 - T \sin\varphi_1$$

where φ_i is the angle between the tangent to the curve and the x axis at x_i. According to Newton's second law, this force must equal mass times acceleration. This is

$$\int_{x_1}^{x_2} \rho\, \partial^2 y/\partial t^2\, dx$$

where ρ is the density (mass per unit length) of the string. Thus, in the limit

$$T \frac{\partial}{\partial x} \sin\varphi = \rho \frac{\partial^2 y}{\partial t^2}$$

We note that $\tan\varphi = \partial y/\partial x$. If we make the simplifying assumption (justified or otherwise) that

$$\cos\varphi \approx 1, \qquad \frac{\partial}{\partial x} \cos\varphi \approx 0$$

we finally obtain:

$$T\partial^2 y/\partial x^2 = \rho\, \partial^2 y/\partial t^2$$

which is the well-known equation of the vibrating string.

The derivation of partial differential equations from physical laws usually brings about simplifying assumptions that are difficult to justify completely. Most of the time they are merely plausibility arguments. For this reason, some branches of science have accepted partial differential equations as axioms. The success of these axioms is judged by how well their conclusions describe past observations and predict new ones.

III. SOME WELL-KNOWN EQUATIONS

Now we list several equations that arise in various branches of science. Interestingly, the same equation can arise in diverse and unrelated areas.

A. Laplace's Equation

In n dimensions this equation is given by:

$$\Delta u = 0$$

where

$$\Delta = \frac{\partial^2}{\partial x_1^2} + \cdots + \frac{\partial^2}{\partial x_n^2}$$

It arises in the study of electromagnetic phenomena (e.g., electrostatics, dielectrics, steady currents, magnetostatics), hydrodynamics (e.g., irrotational flow of a perfect fluid, surface waves), heat flow, gravitation, and many other branches of science. Solutions of Laplace's equation are called *harmonic functions.*

B. Poisson's Equation

$$\Delta u \equiv f(x), \qquad x = (x_1, \ldots, x_n)$$

Here, the function $f(x)$ is given. This equation is found in many of the situations in which Laplace's equation appears, since the latter is a special case.

C. Helmholtz's Equation

$$\Delta u \pm \alpha^2 u = 0$$

This equation appears in the study of elastic waves, vibrating strings, bars and membranes, sound and acoustics, electromagnetic waves, and the operation of nuclear reactors.

D. The Heat (Diffusion) Equation

This equation is of the form:

$$u_t = a^2 \Delta u$$

where $u(x_1, \ldots, x_n, t)$ depends on the variable t(time) as well. It describes heat conduction or diffusion processes.

E. The Wave Equation

$$\Box u \equiv (1/c^2) - \Delta u = 0$$

This describes the propagation of a wave with velocity c. This equation governs most cases of wave propagation.

F. The Telegraph Equation

$$\Box u + \sigma u_t = 0$$

This applies to some types of wave propagation.

G. The Scalar Potential Equation

$$\Box u = f(x, t)$$

H. The Klein–Gordon Equation

$$\Box u + \mu^2 u = 0$$

I. Maxwell's Equations

$$\nabla \times \mathbf{H} = \sigma \mathbf{E} + \varepsilon\, \partial \mathbf{E}/\partial t$$
$$\nabla \times \mathbf{E} = -\mu\, \partial \mathbf{H}/\partial t$$

Here $\mathbf{E}$ and $\mathbf{H}$ are three-dimensional vector functions of position and time representing the electric and magnetic fields, respectively. This system of equations is used in electrodynamics.

J. The Cauchy–Riemann Equations

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \qquad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}$$

These equations describe the real and imaginary parts of an analytic function of a complex variable.

K. The Schrödinger Equation

$$-\frac{\hbar^2}{2m}\Delta\psi + V(x)\psi = i\hbar\frac{\partial \psi}{\partial t}$$

This equation describes the motion of a quantum mechanical particle as it moves through a potential field. The function $V(x)$ represents the potential energy, while the unknown function $\psi(x)$ is allowed to have complex values.

L. Minimal Surfaces

In three dimensions a surface $z = u(x, y)$ having the least area for a given contour satisfies the equation:

$$\left(1 + u_y^2\right)u_{xx} - 2u_x u_y u_{xy} + \left(1 + u_x^2\right)u_{yy} = 0$$

where $u_x = \partial u/\partial x$, etc.

M. The Navier–Stokes Equations

$$\frac{\partial u_j}{\partial t} + \sum_k \frac{\partial u_j}{\partial x_k}u_k + \frac{1}{\rho}\frac{\partial p}{\partial x_j} = \gamma\, \Delta u_j$$
$$\sum_k \frac{\partial u_k}{\partial x_k} = 0$$

This system describes viscous flow of an incompressible liquid with velocity components u_k and pressure p.

N. The Korteweg–Devries Equation

$$u_t + cuu_x + u_{xxx} = 0$$

This equation is used in the study of water waves.

IV. TYPES OF EQUATIONS

In describing partial differential equations, the following notations are helpful. Let $\mathbb{R}^n$ denote Euclidean n dimensional space, and let $\mathbf{x} = (x_1, \ldots, x_n)$ denote a point in $\mathbb{R}^n$. One can consider partial differential equations on various types of manifolds, but we shall restrict ourselves to $\mathbb{R}^n$. For a real- or complex-valued function $u(x)$ we shall use the following notation:

$$D_k u = \partial u / i\partial x_k, \qquad 1 \leqq k \leqq n$$

If $\mu = (\mu_1, \ldots, \mu_n)$ is a multi-index of nonnegative integers, we write:

$$x^\mu = x_1^{\mu_1} \ldots x_n^{\mu_n}, \qquad |\mu| = \mu_1 + \cdots + \mu_n$$
$$D^\mu = D_1^{\mu_1} \cdots D_n^{\mu_n}$$

Thus, D^μ is a partial derivative of order $|\mu|$.

A. Linear Equations

The most general linear partial differential equation of order m is

$$Au \equiv \sum_{|\mu| \leqq m} a_\mu(x) D^\mu u = f(x) \tag{1}$$

It is called linear because the operator A is linear, that is, satisfies:

$$A(\alpha u + \beta v) = \alpha Au + \beta Av$$

for all function u, v and all constant scalars α, β. If the equation cannot be put in this form, it is nonlinear. In Section III, the examples in Sections A–K are linear.

B. Nonlinear Equations

In general, nonlinear partial differential equations are more difficult to solve than linear equations. There may be no solutions possible, as is the case for the equation:

$$|\partial u/\partial x| + 1 = 0$$

There is no general method of attack, and only special types of equations have been solved.

1. Quasilinear Equation

A partial differential equation is called *quasilinear* if it is linear with respect to its derivatives of highest order. This means that if one replaces the unknown function $u(x)$ and all its derivatives of order lower than the highest by known functions, the equation becomes linear. Thus, a quasilinear equation of order m is of the form:

$$\sum_{|\mu|=m} a_\mu(x, u, Du, \ldots, D^{m-1}u)D^\mu u = f(x, u, Du, \ldots, D^{m-1}u) \quad (2)$$

where the coefficients a_μ depend only on x, u, and derivatives of u up to order $m-1$. Quasilinear equations are important in applications. In Section III, the examples in Sections L–N are quasilinear.

2. Semilinear Equation

A quasilinear equation is called *semilinear* if the coefficients of the highest-order derivatives depend only on x. Thus, a semilinear equation of order m is of the form:

$$Au \equiv \sum_{|\mu|=m} a_\mu(x)D^\mu u = f(x, u, Du, \ldots, D^{m-1}u) \quad (3)$$

where A is linear. Semilinear equations arise frequently in practice.

C. Elliptic Equations

The quasilinear equation (2) is called *elliptic* in a region $\Omega \subset \mathbb{R}^n$ if for every function $v(x)$ the only real vector $\xi = (\xi_1, \ldots, \xi_n) \varepsilon \mathbb{R}^n$ that satisfies:

$$\sum_{|\mu|=m} a_\mu(x, v, Dv, \ldots, D^{m-1}v)\xi^\mu = 0$$

is $\xi = 0$. It is called *uniformly elliptic* in Ω if there is a constant $c_0 > 0$ independent of x and v such that:

$$c_0|\xi|^m \leqq \left| \sum_{|\mu|=m} a_\mu(x, v, Dv, \ldots, D^{m-1}v)\xi^\mu \right|$$

where $|\xi|^2 = \xi_1^2 + \cdots \xi_n^2$. The equations in Sections A–C and J–L are elliptic equations or systems.

D. Parabolic Equations

When $m = 2$, the quasilinear equation (2) becomes:

$$\sum_{j,k} a_{jk}(x, u, Du)\frac{\partial^2 u}{\partial x_j \partial x_k} = f(x, u, Du) \quad (4)$$

We shall say that Eq. (4) is *parabolic* in a region $\Omega \subset \mathbb{R}^n$ if for every choice of the function $v(x)$, the matrix $\Lambda = (a_{jk}(x, v, Dv))$ has a vanishing determinant for each $x \in \Omega$. The equation in Section III.D is a parabolic equation.

E. HYPERBOLIC EQUATIONS

Equation (4) will be called *ultrahyperbolic* in Ω if for each $v(x)$ the matrix $\Lambda = (a_{jk}(x, v, Dv))$ has some positive, some negative, and no vanishing eigenvalues for each $x \in \Omega$. It will be called *hyperbolic* if all but one of the eigenvalues of Λ have the same sign and none of them vanish in Ω. The equations in Sections III.E–H are hyperbolic equations.

The only time Eq. (4) is neither parabolic nor ultrahyperbolic is when all the eigenvalues of Λ have the same sign with none vanishing. In this case, Eq. (4) is elliptic as described earlier.

F. Equations of Mixed Type

If the coefficients of Eq. (1) are variable, it is possible that the equation will be of one type in one region and of another type in a different region. A simple example is

$$\partial^2 u/\partial x^2 - x\partial^2 u/\partial y^2 = 0$$

in two dimensions. In the region $x > 0$ it is hyperbolic, while in the region $x < 0$ it is elliptic. (It becomes parabolic on the line $x = 0$.)

G. Other Types

The type of an equation is very important in determining what problems can be solved for it and what kind of solutions it will have. As we saw, some equations can be of different types in different regions. One can define all three types for higher order equations, but most higher order equations will not fall into any of the three categories.

V. PROBLEMS ASSOCIATED WITH PARTIAL DIFFERENTIAL EQUATIONS

In practice one is rarely able to determine the most general solution of a partial differential equation. Usually one looks for a solution satisfying additional conditions. One may wish to prescribe the unknown function and/or some of its derivatives on part or all of the boundary of the region

in question. We call this a *boundary-value problem.* If the equation involves the variable t (time) and the additional conditions are prescribed at some time $t = t_0$, we usually refer to it as an *initial-value problem.*

A problem associated with a partial differential equation is called *well posed* if:

1. A solution exists for all possible values of the given data.
2. The solution is unique.
3. The solution depends in a continuous way on the given data.

The reason for the last requirement is that in most cases the given data come from various measurements. It is important that a small error in measurement of the given data should not produce a large error in the solution. The method of measuring the size of an error in the given data and in the solution is a basic question for each problem. There is no standard method; it varies from problem to problem.

The kinds of problems that are well posed for an equation depend on the type of the equation. Problems that are suitable for elliptic equations are not suitable for hyperbolic or parabolic equations. The same holds true for each of the types. We illustrate this with several examples.

A. Dirichlet's Problem

For a region $\Omega \subset \mathbb{R}^n$, Dirichlet's problem for Eq. (2) is to prescribe u and all its derivatives up to order $\frac{1}{2}m - 1$ on the boundary $\partial\Omega$ of Ω. This problem is well posed only for elliptic equations. If $m = 2$, only the function u is prescribed on the boundary. If Ω is unbounded, one may have to add a condition at infinity.

It is possible that the Dirichlet problem is not well posed for a linear elliptic equation of the form (1) because 0 is an eigenvalue of the operator A. This means that there is a function $w(x) \not\equiv 0$ that vanishes together with all derivatives up to order $\frac{1}{2}m - 1$ on $\partial\Omega$ and satisfies $Aw = 0$ in Ω. Thus, any solution of the Dirichlet problem for Eq. (1) is not unique, for we can always add a multiple of w to it to obtain another solution. Moreover, it is easily checked that one can solve the Dirichlet problem for Eq. (1) only if:

$$\int_\Omega f(x)w(x)\,dx$$

is a constant depending on w and the given data. Thus, we cannot solve the Dirichlet problem for all values of the given data. When Ω is bounded, one can usually remedy the situation by considering the equation,

$$Au + \varepsilon u = f \tag{5}$$

in place of Eq. (1) for ε sufficiently small.

B. The Neumann Problem

As in the case of the Dirichlet problem, the Neumann problem is well posed only for elliptic operators. The Neumann problem for Eq. (2) in a region Ω is to prescribe on $\partial\Omega$ the normal derivatives of u from order $\frac{1}{2}m$ to $m - 1$. (In both the Dirichlet and Neumann problems, exactly $\frac{1}{2}m$ normal derivatives are prescribed on $\partial\Omega$. In the Dirichlet problem, the first $\frac{1}{2}m$ are prescribed [starting from the zeroth-order derivative—u itself]. In the Neumann problem the next $\frac{1}{2}m$ normal derivatives are prescribed.)

As in the case of the Dirichlet problem, the Neumann problem for a linear equation of the form (1) can fail to be well posed because 0 is an eigenvalue of A. Again, this can usually be corrected by considering Eq. (5) in place of Eq. (1) for ε sufficiently small.

When $m = 2$, the Neumann problem consists of prescribing the normal derivative $\partial u/\partial n$ of u on $\partial\Omega$. In the case of Laplace's or Poisson's equation, it is easily seen that 0 is indeed an eigenvalue if Ω is bounded, for then any constant function is a solution of:

$$\Delta w = 0 \quad \text{in} \quad \Omega, \qquad \partial w/\partial n = 0 \quad \text{on} \quad \partial\Omega \tag{6}$$

Thus, adding any constant to a solution gives another solution. Moreover, we can solve the Neumann problem:

$$\Delta u = f \quad \text{in} \quad \Omega, \qquad \frac{\partial u}{\partial n} = g \quad \text{on} \quad \partial\Omega \tag{7}$$

only if

$$\int_\Omega f(x)\,dx = \int_{\partial\Omega} g\,ds$$

Thus, we cannot solve Eq. (7) for all f and g. If Ω is unbounded, one usually requires that the solution of the Neumann problem vanish at infinity. This removes 0 as an eigenvalue, and the problem is well posed.

C. The Robin Problem

When $m = 2$, the Robin problem for Eq. (2) consists of prescribing:

$$Bu = \alpha\,\partial u/\partial n + \beta u \tag{8}$$

on $\partial\Omega$, where $\alpha(x)$, $\beta(x)$ are functions and $\alpha(x) \neq 0$ on $\partial\Omega$. If $\beta(x) \equiv 0$, this reduces to the Neumann problem. Again this problem is well posed only for elliptic equations.

D. Mixed Problems

Let B be defined by Eq. (8), and assume that $\alpha(x)^2 + \beta(x)^2 \neq 0$ on $\partial\Omega$. Consider the boundary value problem consisting of finding a solution of Eq. (4) in Ω and prescribing Bu on $\partial\Omega$. On those parts of $\partial\Omega$ where $\alpha(x) = 0$,

we are prescribing Dirichlet data. On those parts of $\partial\Omega$ where $\beta(x) = 0$, we are prescribing Neumann data. On the remaining sections of $\partial\Omega$ we are prescribing Robin data. This is an example of a mixed boundary-value problem in which one prescribes different types of data on different parts of the boundary. Other examples are provided by parabolic and hyperbolic equations, to be discussed later.

E. General Boundary-Value Problems

For an elliptic equation of the form (2) one can consider general boundary conditions of the form:

$$B_j u \equiv \sum_{|\mu| \leqq m_j} b_{j\mu} D^\mu u = g_j \quad \text{on} \quad \partial\Omega, \qquad 1 \leqq j \leqq m/2 \tag{9}$$

Such boundary-value problems can be well posed provided the operators B_j are independent in a suitable sense and do not "contradict" each other or Eq. (2).

F. The Cauchy Problem

For Eq. (2), the Cauchy problem consists of prescribing all derivatives of u up to order $m-1$ on a smooth surface S and solving Eq. (2) for u in a neighborhood of S. An important requirement for the Cauchy problem to have a solution is that the boundary conditions not "contradict" the equation on S. This means that the coefficient of $\partial^m u/\partial n^m$ in Eq. (2) should not vanish on S. Otherwise, Eq. (2) and the Cauchy boundary conditions,

$$\partial^k u/\partial n^k = g_k \quad \text{on} \quad S, k = 0, \ldots, n-1 \tag{10}$$

involve only the function g_k on S. This is sure to cause a contradiction unless f is severely restricted. When this happens we say that the surface S is *characteristic* for Eq. (2). Thus, for the Cauchy problem to have a solution without restricting f, it is necessary that the surface S be noncharacteristic. In the quasilinear case, the coefficient of $\partial^m u/\partial n^m$ in Eq. (2) depends on the g_k. Thus, the Cauchy data (10) will play a role in determining whether or not the surface S is characteristic for Eq. (2). The Cauchy–Kowalewski theorem states that for a noncharacteristic analytic surface S, real analytic Cauchy data g_k, and real analytic coefficients a_μ, f in Eq. (2), the Cauchy problem (2) and (10) has a unique real analytic solution in the neighborhood of S. This is true irrespective of the type of the equation. However, this does not mean that the Cauchy problem is well posed for all types of equations. In fact, the hypotheses of the Cauchy–Kowalewski theorem are satisfied for the Cauchy problem,

$$u_{xx} + u_{yy} = 0, \qquad y > 0$$
$$u(x, 0) = 0, \qquad u_y(x, 0) = n^{-1} \sin nx$$

and, indeed, it has a unique analytic solution:

$$u(x, y) = n^{-2} \sinh ny \sin nx$$

The function $n^{-1} \sin nx$ tends uniformly to 0 as $n \to \infty$, but the solution does not become small as $n \to \infty$ for $y \neq 0$. It can be shown that the Cauchy problem is well posed only for hyperbolic equations.

VI. METHODS OF SOLUTION

There is no general approach for finding solutions of partial differential equations. Indeed, there exist linear partial differential equations with smooth coefficients having no solutions in the neighborhood of a point. For instance, the equation:

$$\frac{\partial u}{\partial x_1} + i\frac{\partial u}{\partial x_2} + 2i(x_1 + ix_2)\frac{\partial u}{\partial x_3} = f(x_3) \tag{11}$$

has no solution in the neighborhood of the origin unless $f(x_3)$ is a real analytic function of x_3. Thus, if f is infinitely differentiable but not analytic, Eq. (11) has no solution in the neighborhood of the origin. Even when partial differential equations have solutions, we cannot find the "general" solution. We must content ourselves with solving a particular problem for the equation in question. Even then we are rarely able to write down the solution in closed form. We are lucky if we can derive a formula that will enable us to calculate the solution in some way, such as a convergent series or iteration scheme. In many cases, even this is unattainable. Then, one must be satisfied with an abstract theorem stating that the problem is well posed. Sometimes the existence theorem does provide a method of calculating the solution; more often it does not.

Now we describe some of the methods that can be used to obtain solutions in specific situations.

A. Separation of Variables

Consider a vibrating string stretched along the x axis from $x = 0$ and $x = \pi$ and fixed at its end points. We can assign the initial displacement and velocity. Thus, we are interested in solving the mixed initial and boundary value problem for the displacement $u(x, t)$:

$$\Box u = 0, \qquad 0 < x < \pi, \quad t > 0 \tag{12}$$
$$u(x, 0) = f(x),$$
$$u_t(x, 0) = g(x), \qquad 0 \leqq x \leqq \pi \tag{13}$$
$$u(0, t) = u(\pi, t) = 0, \qquad t \geqq 0 \tag{14}$$

We begin by looking for a solution of Eq. (12) of the form:

$$u(x, t) = X(x)T(t)$$

Such a function will be a solution of Eq. (12) only if:

$$\frac{T''}{T} = c^2 \frac{X''}{X} \tag{15}$$

Since the left-hand side of Eq. (15′) is a function of t only and the right-hand side is a function of x only, both sides are constant. Thus, there is a constant K such that $X''(x) = KX(x)$. If $K = \lambda^2 > 0$, X must be of the form:

$$X = Ae^{-\lambda x} + Be^{\lambda x}$$

For Eq. (14) to be satisfied, we must have

$$X(0) = X(\pi) = 0 \tag{15′}$$

This can happen only if $A = B = 0$. If $K = 0$, then X must be of the form:

$$x = A + Bx$$

Again, this can happen only if $A = B = 0$. If $K = -\lambda^2 < 0$, then X is of the form:

$$X = A\cos\lambda x + B\sin\lambda x$$

This can satisfy Eq. (15) only if $A = 0$ and $B\sin\lambda\pi = 0$. Thus, the only way that X should not vanish identically is if λ is an integer n. Moreover, T satisfies:

$$T'' + n^2c^2T = 0$$

The general solution for this is

$$T = A\cos nct + B\sin nct$$

Thus,

$$u(x,t) = \sin nx(A_n\cos nct + B_n\sin nct)$$

is a solution of Eqs. (12) and (14) for each integer n. However, it will not satisfy Eq. (13) unless $f(x)$, $g(x)$ are of a special form. The linearity of the operator $\Box$ allows one to add solutions of Eqs. (12) and (14). Thus,

$$u(x,t) = \sum_{n=1}^{\infty} \sin nx(A_n\cos nct + B_n\sin nct) \tag{16}$$

will be a solution provided the series converges. Moreover, it will satisfy Eq. (13) if:

$$f(x) = \sum_{n=1}^{\infty} A_n \sin nx,$$

$$g(x) = \sum_{n=1}^{\infty} ncB_n \sin nx$$

This will be true if $f(x)$, $g(x)$ are expandable in a Fourier sine series. If they are, then the coefficients A_n, B_n are given by:

$$A_n = \frac{2}{\pi}\int_0^{\pi} f(x)\sin nx\,dx,$$

$$B_n = \frac{2}{nc\pi}\int_0^{\pi} g(x)\sin nx\,dx$$

With these values, the series (16) converges and gives a solution of Eqs. (12)–(14).

B. Fourier Transforms

If we desire to determine the temperature $u(x,t)$ of a system in $\mathbb{R}^n$ with no heat added or removed and initial temperature given, we must solve:

$$u_t = a^2\Delta u, \qquad x\,\varepsilon\,\mathbb{R}^n, \quad t > 0 \tag{17}$$

$$u(x,0) = \varphi(x), \qquad x\,\varepsilon\,\mathbb{R}^n \tag{18}$$

If we apply the Fourier transform,

$$\hat{f}(\xi) = (2\pi)^{-n/2}\int e^{-i\xi x} f(x)\,dx \tag{19}$$

where $\xi x = \xi_1x_1 + \cdots + \xi_nx_n$, we obtain:

$$\hat{u}_t(\xi,t) + a^2|\xi|^2\hat{u}(\xi,t) = 0$$

The solution satisfying Eq. (18) is

$$\hat{u}(\xi,t) = e^{-a^2|\xi|^2t}\hat{\varphi}(\xi)$$

If we now make use of the inverse Fourier transform,

$$f(x) = (2\pi)^{-n/2}\int e^{i\xi x}\hat{f}(\xi)\,d\xi$$

we have

$$u(x,t) = \int K(x-y,t)\varphi(y)\,dy$$

where

$$K(x,t) = (2\pi)^{-n}\int e^{ix\xi - a^2|\xi|^2t}\,d\xi$$

If we introduce the new variable,

$$\eta = at^{1/2}\xi - \tfrac{1}{2}ia^{-1}t^{-1/2}x$$

this becomes

$$(2\pi)^{-n}a^{-n}t^{-n/2}e^{-|x|^2/4a^2t}\int e^{-|\eta|^2}\,d\eta$$

$$= (4\pi a^2t)^{-n/2}e^{-|x|^2/4a^2t}$$

This suggests that a solution of Eqs. (17) and (18) is given by:

$$u(x,t) = (4\pi a^2t)^{-n/2}\int e^{-|x-y|^2/4a^2t}\varphi(y)\,dy \tag{20}$$

It is easily checked that this is indeed the case if φ is continuous and bounded. However, the solution is not unique unless one places more restriction on the solution.

C. Fundamental Solutions, Green's Function

Let

$$K(x, y) = \frac{|x - y|^{2-n}}{(2-n)\omega_n} + h(x), \qquad n > 2,$$

$$K(x, y) = \frac{\log 4}{2\pi} + h(x), \qquad n = 2$$

where $\omega_n = 2\pi^{n/2}/\Gamma(\frac{1}{2}n)$ is the surface area of the unit sphere in $\mathbb{R}^n$ and $h(x)$ is a harmonic function in a bounded domain $\Omega \subset \mathbb{R}^n$ (i.e., $h(x)$ is a solution of $\Delta h = 0$ in Ω). If the boundary $\partial\Omega$ of Ω is sufficiently regular and $h \in C^2(\bar{\Omega})$, then Green's theorem implies for $y \in \Omega$:

$$u(y) = \int_\Omega K(x, y)\Delta u(x)\, dx + \int_{\partial\Omega} \left(u(x)\frac{\partial K(x, y)}{\partial n} - K(x, y)\frac{\partial u}{\partial n} \right) dS_x \quad (21)$$

for all $u \in C^2(\bar{\Omega})$. The function $K(x, y)$ is called a *fundamental solution* of the operator Δ. If, in addition, $K(x, y)$ vanishes for $x \in \partial\Omega$, it is called a *Green's function*, and we denote it by $G(x, y)$. In this case,

$$u(y) = \int_{\partial\Omega} u(x)\frac{\partial G(x, y)}{\partial n}\, dS_x, \qquad y \in \Omega \quad (22)$$

for all $u \in C^2(\bar{\Omega})$ that are harmonic in Ω. Conversely, this formula can be used to solve the Dirichlet problem for Laplace's equation if we know the Green's function for Ω, since the righthand side of Eq. (22) is harmonic in Ω and involves only the values of $u(x)$ on $\partial\Omega$. It can be shown that if the prescribed boundary values are continuous, then indeed Eq. (22) does give a solution to the Dirichlet problem for Laplace's equation.

It is usually very difficult to find the Green's function for an arbitrary domain. It can be computed for geometrically symmetric regions. In the case of a ball of radius R and center 0, it is given by:

$$G(x, y) = K(x, y) - (|y|/R)^{2-n} K(x, R^2|y|^{-2}y)$$

D. Hilbert Space Methods

Let

$$P(D) = \sum_{|\mu|=m} a_\mu D^\mu$$

be a positive, real, constant coefficient, homogeneous, elliptic partial differential operator of order $m = 2r$. This means that $P(D)$ has only terms of order m, and

$$c_0|\xi|^m \leqq P(\xi) \leqq C_0|\xi|^m, \qquad \xi \in \mathbb{R}^n \quad (23)$$

holds for positive constants c_0, C_0. We introduce the norm,

$$|v|_r = \left(\int |\xi|^m |\hat{v}(\xi)|^2\, d\xi \right)^{1/2}$$

for function v in $C_0^\infty(\Omega)$, the set of infinitely differentiable functions that vanish outside Ω. Here, Ω is a bounded domain in $\mathbb{R}^n$ with smooth boundary, and $\hat{v}(\xi)$ denotes the Fourier transform given by Eq. (19). By Eq. (23) we see that $(P(D)v, v)$ is equivalent to $|v|_r^2$ on $C_0^\infty(\Omega)$, where

$$(u, v) = \int_\Omega u(x)\overline{v(x)}\, dx$$

Let

$$a(u, v) = (u, P(D)v), \quad u, v \in C_0^\infty(\Omega) \quad (24)$$

If $u \in C^m(\bar{\Omega})$ is a solution of the Dirichlet problem,

$$P(D)u = f \quad \text{in} \quad \Omega \quad (25)$$

$$D^\mu u = 0 \quad \text{on} \quad \partial\Omega, \qquad |\mu| < r \quad (26)$$

then it satisfies

$$a(u, v) = (f, v), \qquad v \in C_0^\infty(\Omega) \quad (27)$$

Conversely, if $\partial\Omega$ is sufficiently smooth and $u \in C^m(\bar{\Omega})$ satisfies Eq. (27), then it is a solution of the Dirichlet problem, Eqs. (25) and (26). This is readily shown by integration by parts. Thus, one can solve Eqs. (25) and (26) by finding a function $u \in C^m(\bar{\Omega})$ satisfying Eq. (27). Since $a(u, v)$ is a scalar product, it would be helpful if we had a theorem stating that the expression (f, v) can be represented by the expression $a(u, v)$ for some u. Such a theorem exists (the Riesz representation theorem), provided $a(u, v)$ is the scalar product of a Hilbert space and

$$|(f, v)| \leqq Ca(v, v)^{1/2} \quad (28)$$

We can fit our situation to the theorem by completing $C_0^\infty(\Omega)$ with respect to the $|v|_r$ norm and making use of the fact that $a(v, v)^{1/2}$ and $|v|_r$ are equivalent on $C_0^\infty(\Omega)$ and consequently on the completion $H_0^r(\Omega)$. Moreover, inequality (28) follows from the Poincare inequality,

$$\|v\| \leqq M^r|v|_r, \qquad v \in C_0^\infty(\Omega) \quad (29)$$

which holds if Ω is contained in a cube of side length M. Thus, by Schwarz's inequality,

$$|(f, v)| \leqq \|f\|\,\|v\| \leqq \|f\|M^r|v|_r \leqq ca(v, v)^{1/2}$$

The Riesz representation theorem now tells us that there is a $u \in H_0^r(\Omega)$ such that Eq. (27) holds. If we can show that u is in $C^m(\bar{\Omega})$, it will follow that u is indeed a solution of the Dirichlet problem, Eqs. (25) and (26). As it stands now, u is only a *weak solution* of Eqs. (25) and (26). However,

it can be shown that if $\partial\Omega$ and f are sufficiently smooth, then u will be in $C^m(\bar{\Omega})$ and will be a solution of Eqs. (25) and (26).

The proof of the Poincare inequality (29) can be given as follows. It sufficies to prove it for $r = 1$ and Ω contained in the slab $0 < x_1 < M$. Since $v \in C_0^\infty(\Omega)$,

$$\begin{aligned} v(x_1, \ldots, x_n)^2 &= \left(\int_0^{x_1} v_{x1}(t, x_2, \ldots, x_n)\, dt \right)^2 \\ &\leqq x_1 \int_0^{x_1} v_{x1}(t, x_2, \ldots, x_n)^2\, dt \\ &\leqq M \int_0^{M} v_{x1}(t, x_2, \ldots, x_n)^2\, dt \end{aligned}$$

Thus,

$$\int_0^M v(x_1, \ldots, x_n)^2\, dx_1 \leqq M^2 \int_0^M v_{x1}(t, x_2, \ldots, x_n)^2\, dt$$

If we now integrate over $x_2, \ldots, x_n$, we obtain:

$$\|v\| \leqq M \|v_{x1}\|$$

But, by Parseval's identity,

$$\begin{aligned} \int |v_{x1}|^2\, dx &= \int |\hat{v}_{x1}|^2\, d\xi \\ &= \int \xi_1^2 |\hat{v}|^2\, d\xi \leqq \int |\xi|^2 |\hat{v}|^2\, d\xi = |v|_1^2 \end{aligned}$$

E. Iterations

An important method of solving both linear and nonlinear problems is that of *successive approximations*. We illustrate this method for the following Dirichlet problem:

$$\Delta u = f(x, u), x \in \Omega \tag{30}$$

$$u = 0 \quad \text{on} \quad \partial\Omega \tag{31}$$

We assume that the boundary of Ω is smooth and that $f(x, t) = f(x_1 \ldots, x_n, t)$ is differentiable with respect to all arguments. Also we assume that:

$$|f(x, t)| \leqq N, \qquad x \in \Omega, \quad -\infty < t < \infty \tag{32}$$

$$|\partial f(x, t)/\partial t| \leqq \psi(t), \quad x \in \Omega \tag{33}$$

where $\psi(t)$ is a continuous function.

First, we note that for every compact subset G of Ω there is a constant C such that:

$$\max_G |\nabla v| \leqq C(\sup_\Omega |\Delta v| + \sup_\Omega |v|) \tag{34}$$

for all $v \in C^2(\Omega)$. Assume this for the moment, and let $w(x)$ be the solution of the Dirichlet problem,

$$\Delta w = -N \quad \text{in} \quad \Omega, \qquad w = 0 \quad \text{on} \quad \partial\Omega \tag{35}$$

It is clear that $w(x) \geqq 0$ in Ω. For otherwise it would have a negative interior mininum in Ω. At such a point, one has $\partial^2 w/\partial x_k^2 \geqq = 0$ for each k, and consequently. $\Delta w \geqq 0$ contradicting Eq. (35). Since $w \in C(\bar{\Omega})$, there is a constant C_t such that:

$$0 \leqq w(x) \leqq C_1, \qquad x \in \Omega$$

Let

$$K = \max_{|t| \leqq C_1} \psi(t)$$

Then, by Eq. (33):

$$|\partial f(x, t)/\partial t| \leqq K, \qquad |t| \leqq C_1 \tag{36}$$

Consequently,

$$f(x, t) - f(x, s) \leqq K(t - s) \tag{37}$$

when $-C_1 \leqq s \leqq t \leqq C_1$. We define a sequence $\{u_k\}$ of functions as follows. We take $u_0 = w$ and once u_{k-1} has been defined, we let u_k be the solution of the Dirichlet problem:

$$Lu_k \equiv \Delta u_k - K u_k = f(x, u_{k-1}) - K u_{k-1} \tag{38}$$

in Ω with $u_k = 0$ on $\partial\Omega$. The solution exists by the theory of linear elliptic equations. We show by induction that:

$$-w \leqq u_k \leqq u_{k-1} \leqq w \tag{39}$$

To see this for $k = 1$, note that:

$$L(u_1 - w) = f(x, w) - K w - \Delta w + K w \geqq 0$$

From this we see that $u_1 \leqq w$ in Ω. If $u_1 - w$ had an interior positive maximum in Ω, we would have

$$L(u_1 - w) = \Delta(u_1 - w) - K(u_1 - w) < 0$$

at such a point. Thus, $u_1 \leqq w$ in Ω. Also we note:

$$\Delta(u_1 + w) = f(x, w) + K(u_1 - w) + \Delta w \leqq K(u_1 - w)$$

This shows that $u_1 + w$ cannot have a negative minimum inside Ω. Hence, $u_1 + w \geqq 0$ in Ω, and Eq. (39) is verified for $k = 1$. Once we know it is verified for k, we note that:

$$\begin{aligned} L[u_{k+1} - u_k] = {} & f(x, u_k) - f(x, u_{k-1}) \\ & - K(u_k - u_{k-1}) \geqq 0 \end{aligned}$$

by Eq. (37). Thus, $u_{k-1} \leqq u_k$ in Ω. Hence,

$$\begin{aligned} \Delta(u_{k+1} + w) = {} & f(x, u_k) - K u_k + K u_{k+1} \\ & + \Delta w \leqq K(u_{k+1} - u_k) \end{aligned}$$

Again, we deduce from this that $u_{k+1} + w \geqq 0$ in Ω. Hence, Eq. (39) holds for $k + 1$ and consequently for all k. In particular, we see that the u_k are uniformly bounded in Ω, and by Eq. (38) the same is true of the functions Δu_k.

Hence, by Eq. (34), the first derivatives of the u_k are uniformly bounded on compact subsets of Ω. If we differentiate Eq. (38), we see that the sequence $\Delta(\partial u_k/\partial x_j)$ is uniformly bounded on compact subsets of Ω (here we make use of the continuous differentiability of f). If we now make use of Eq. (34) again, we see that the second derivatives of the u_k are uniformly bounded on compact subsets of Ω. Hence, by the Ascoli–Arzela theorem, there is a subsequence that converges together with its first derivatives uniformly on compact subsets of Ω. Since the sequence u_k is monotone, the whole sequence must converge to a continuous function u that satisfies $|u(x)| \leqq w(x)$. Hence, u vanishes on $\partial\Omega$. By Eq. (38), the functions Δu_k must converge uniformly on compact subsets, and by Eq. (34), the same must be true of the first derivatives of the u_k. From the differentiated Eq. (38) we see that the $\Delta(\partial u_k/\partial x_j)$ converge uniformly on bounded subsets and consequently the same is true of the second derivatives of the u_k by Eq. (34). Since the u_k converge uniformly to u in Ω and their second derivatives converge uniformly on bounded subsets, we see that $u \in C^2(\Omega)$ and $\Delta u_k \to \Delta u$. Hence,

$$\begin{aligned}\Delta u &= \lim \Delta u_k \\ &= \lim[\, f(x, u_{k-1}) + K(u_k - u_{k-1})] = f(x, u)\end{aligned}$$

and u is the desired solution.

It remains to prove Eq. (34). For this purpose we let $\varphi(x)$ be a function in $C_0^\infty(\Omega)$ which equals one on G. Then we have, by Eq. (21),

$$\varphi(y)v(y) = \int_\Omega K(x, y)\Delta(\varphi(x)v(x))\, dx$$

(the boundary integrals vanish because φ is 0 near $\partial\Omega$). Thus, if $y \in G$,

$$\begin{aligned}v(y) &= \int_\Omega K\{\varphi\Delta v + 2\nabla\varphi \cdot \nabla v + v\Delta\varphi\}\, dx \\ &= \int_\Omega \{\varphi K\Delta v - 2v\nabla K \cdot \nabla\varphi - vK\Delta\varphi\}\, dx\end{aligned}$$

by integration by parts. We note that $\nabla\varphi$ vanishes near the singularity of K. Thus, we may differentiate under integral sign to obtain:

$$\frac{\partial v(y)}{\partial y_j} = \int_\Omega \left\{\varphi\frac{\partial K}{\partial y_j}\Delta v - 2v\frac{\partial \nabla k}{\partial y_j}\cdot\nabla\varphi - v\frac{\partial k}{\partial y_j}\Delta\varphi\right\} dx$$

Consequently,

$$\begin{aligned}\left|\frac{\partial v}{\partial y_j}\right| &\leqq \sup_\Omega |\Delta v| \int_\Omega \left|\frac{\partial K}{\partial y_j}\right| dx \\ &\quad + \sup_\Omega |v| \int_\Omega \left\{|\nabla\varphi|\left|\frac{\partial K}{\partial y_j}\right| + |\Delta\varphi|\left|\frac{\partial K}{\partial y_j}\right| K\right\} dx\end{aligned}$$

and all of the integrals are finite. This gives Eq. (34), and the proof is complete.

F. Variational Methods

In many situations, methods of the calculus of variations are useful in solving problems for partial differential equations, both linear and nonlinear. We illustrate this with a simple example. Suppose we wish to solve the problem,

$$-\sum \frac{\partial}{\partial x_k}\left[p_k(x)\frac{\partial u(x)}{\partial x_k}\right] + q(x)u(x) = 0 \quad \text{in} \quad \Omega \tag{40}$$

$$u(x) = g(x) \quad \text{on} \quad \partial\Omega \tag{41}$$

Assume that $p_k(x) \geqq c_0$, $q(x) \geqq c_0$, $c_0 > 0$ for $x \in \Omega$, Ω bounded, $\partial\Omega$ smooth, and that g is in $C^1(\partial\Omega)$. We consider the expression,

$$\begin{aligned}a(u, v) = \int_\Omega \Bigg\{&\frac{1}{2}\sum p_k(x)\frac{\partial u(x)}{\partial x_k}\frac{\partial v(x)}{\partial x_k} \\ &+ q(x)u(x)v(x)\Bigg\} dx\end{aligned}$$

and put $a(u) = a(u, u)$. If $u \in C^2(\Omega) \cap C^0(\bar{\Omega})$, satisfies, Eq. (41), and

$$a(u) \leqq a(w) \tag{42}$$

for all w satisfying Eq. (41), then it is readily seen that u is a solution of Eq. (40). Let v be a smooth function which vanishes on $\partial\Omega$. Then, for any scalar β,

$$a(u) \leqq a(u + \beta v) = a(u) + 2\beta a(u, v) + \beta^2 a(v)$$

and, consequently,

$$2\beta a(u, v) + \beta^2 a(v)^2 \geqq 0$$

for all β. This implies $a(u, v) = 0$. Integration by parts now yields Eq. (40). The problem now is to find a u satisfying Eq. (42). We do this as follows. Let H denote the Hilbert space obtained by completing $C^2(\bar{\Omega})$ with respect to the norm $a(w)$, and let H_0 be the subspace of those functions in H that vanish on $\partial\Omega$. Under the hypotheses given it can be shown that H_0 is a closed subspace of H. Let w be an element of H satisfying Eq. (41), and take a sequence $\{v_k\}$ of functions in H_0 such that:

$$a(w - v_k) \to d = \inf_{v \in H_0} a(w - v)$$

The parallelogram law for Hilbert space tells us that:

$$\begin{aligned}&a(2w - v_j - v_k) + a(v_j - v_k) \\ &\quad = 2a(w - v_j) + 2a(w - v_k)\end{aligned}$$

But,

$$a(2w - v_j - v_k) = 4a\big(w - \tfrac{1}{2}(v_j + u_k)\big) \geqq 4d$$

Hence,

$$4d + a(v_j - v_k) \leqq 2a(w - v_j) + 2a(w - v_k) \to 4d$$

Thus,

$$a(v_j - v_k) \to 0$$

and $\{v_k\}$ is a Cauchy sequence in H_0. Since H_0 is complete, there is a $v \in H_0$ such that $a(v_k - v) \to 0$. Put $u = w - v$. Then clearly u satisfies Eqs. (41) and (42), hence $a(u, v) = 0$ for all $v \in H_0$. If u is in $C^2(\Omega)$, then it will satisfy Eq. (40) as well. The rub is that functions in H need not be in $C^2(\Omega)$. However, the day is saved if the $p_k(x)$ and $q(x)$ are sufficiently smooth. For then one can show that functions $u \in H$ which satisfy $a(u, v) = 0$ for all $v \in H_0$ are indeed in $C^2(\Omega)$.

G. Critical Point Theory

Many partial differential equations and systems are the Euler–Lagrange equations corresponding to a real valued functional G defined on some Hilbert space E. Such a functional usually represents the energy or related quantity of the physical system governed by the equations. In such a case, solutions of the partial differential equations correspond to critical points of the functional. For instance, if the equation to be solved is

$$-\Delta u(x) = f(x, u), x \in \Omega \subset \mathbb{R}^n \tag{43}$$

then solutions of Eq. (43) are the critical points of the functional,

$$G(u) = \|\nabla u\|^2 - 2\int_\Omega F(x, u)\, dx$$

where the norm is that of $L^2(\Omega)$ and

$$F(x, t) = \int_0^t f(x, s)\, ds$$

The history of this approach can be traced back to the calculus of variations in which equations of the form:

$$G'(u) = 0 \tag{44}$$

are the Euler–Lagrange equations of the functional G. The original method was to find maxima or minima of G by solving Eq. (44) and then show that some of the solutions are extrema. This approach worked well for one-dimensional problems. In this case, it is easier to solve Eq. (44) than it is to find a maximum or minimum of G. However, in higher dimensions it was realized quite early that it is easier to find maxima and minima of G than it is to solve Eq. (44). Consequently, the tables were turned, and critical point theory was devoted to finding extrema of G. This approach is called the *direct method* in the calculus of variations. If an extremum point of G can be identified, it will automatically be a solution of Eq. (44).

The simplest extrema to find are global maxima and minima. For such points to exist one needs G to be semi-bounded. However, this in itself does not guarantee that an extremum exists. All that can be derived from the semi-boundedness is the existence of a sequence $\{u_k\} \subset E$ such that:

$$G(u_k) \to c, G'(u_k) \to 0 \tag{45}$$

where c is either the supremum or infimum of G. The existence of such a sequence does not guarantee that an extremum exists. However, it does so if one can show that the sequence has a convergent subsequence. This condition is known as the *Palais–Smale condition*. A sequence satisfying Eq. (45) is called a *Palais–Smale sequence.*

Recently, researchers have discovered several sets of sufficient conditions on G which will guarantee the existence of a Palais–Smale sequence. If, in addition, the Palais–Smale condition holds, then one obtains a critical point. These conditions can apply to functionals which are not semibounded. Points found by this method are known as *mountain pass points* due to the geometrical interpretation that can be given. The situation can be described as follows. Suppose Q is an open set in E and there are two points e_0, e_1 such that $e_0 \in Q$, $e_1 \notin \bar{Q}$, and

$$G(e_0), G(e_1) \le b_0 = \inf_{\partial Q} G \tag{46}$$

Then there exists a Palais–Smale sequence, Eq. (45), with c satisfying:

$$b_0 \le c < \infty \tag{47}$$

When G satisfies Eq. (46) we say that it exhibits mountain pass geometry.

It was then discovered that other geometries (i.e., configurations) produce Palais–Smale sequences, as well. Consider the following situation. Assume that

$$E = M \oplus N$$

is a decomposition of E into the direct sum of closed subspaces with

$$\dim N < \infty$$

Suppose there is an $R > 0$ such that

$$\sup_{N \cap \partial B_R} G \le b_0 = \inf_M G$$

Then, again, there is a sequence satisfying Eqs. (45) and (47). Here, B_R denotes the ball of radius R in E and ∂B_R denotes its boundary.

In applying this method to solve Eq. (43), one discovers that the asymptotic behavior of $f(x, t)$ at ∞ plays an important role. One can consider several possibilities. When

$$\lim_{|t| \to \infty} \sup |f(x, t)/t| = \infty \tag{48}$$

we say that problem (43) is *superlinear*. Otherwise, we call it *sublinear*. If

$$f(x,t)/t \to b_{\pm}(x) \ \ as \ \ t \to \pm\infty \tag{49}$$

and the $b_{\pm}$ are different, we say that it has a nonlinearity at ∞. An interesting special case of Eq. (49) is when the $b_{\pm}(x)$ are constants. If $b_{-}(x) \equiv a$ and $b_{+}(x) \equiv b$, we say that (a, b) is in the Fučík spectrum $\sum$ if:

$$-\Delta u = bu^{+} - au^{-}$$

has a nontrivial solution, where $u^{\pm} = \max\{\pm u, 0\}$. Because of its importance in solving Eq. (43), we describe this spectrum. It has been shown that emanating from each eigenvalue λ_ℓ of $-\Delta$, there are curves $\mu_\ell(a)$, $\nu_{\ell-1}(a)$ (which may coincide) which are strictly decreasing at least in the square $S = [\lambda_{\ell-1}, \lambda_{\ell+1}]^2$ and such that $(a, \mu_\ell(a))$ and $(a, \nu_{\ell-1}(a))$ are in $\sum$ in the square S. Moreover, the regions $b > \mu_\ell(a)$ and $b < \nu_{\ell-1}(a)$ are free of $\sum$ in S. These curves are known exactly only in the one-dimensional case (ordinary differential equations). In higher dimensions it is not known in general how many curves of $\sum$ emanate from each eigenvalue. It is known that there is at least one (when $\mu_\ell(a)$ and $\nu_{\ell-1}(a)$ coincide). If there are two or more curves emanating from an eigenvalue, the status of the region between them is unknown in general. If the eigenvalue is simple, there are at most two curves of $\sum$ emanating from it, and any region between them is not in $\sum$. On the other hand, examples are known in which many curves of $\sum$ emanate from a multiple eigenvalue. In the higher dimensional case, the curves have not been traced asymptotically.

If

$$f(x,t)/t \to \lambda_\ell \ \ as \ \ |t| \to \infty \tag{50}$$

where λ_ℓ is one of the eigenvalues of $-\Delta$, we say that Eq. (43) has asymptotic resonance. One can distinguish several types. One can have the situation:

$$f(x,t) = \lambda_\ell t + p(x,t) \tag{51}$$

where $p(x,t) = o(|t|^{\beta})$ as $|t| \to \infty$ for some $\beta < 1$. Another possibility is when $p(x,t)$ satisfies:

$$|p(x,t)| \le V(x) \in L^2(\Omega) \tag{52}$$

and

$$p(x,t) \to p_{\pm}(x) \ \ a.e. \ \ as \ \ t \to \pm\infty$$

A stronger form occurs when

$$p(x,t) \to 0 \ \ as \ \ |t| \to \infty \tag{53}$$

and

$$|P(x,t)| \le W(x) \in L^1(\Omega) \tag{54}$$

where

$$P(x,t) := \int_0^t p(x,s)\,ds$$

This type of problem is more difficult to solve; it is called *strong resonance.* Possible situations include:

$$P(x,t) \to P_{\pm}(x) \ \ as \ \ t \to \pm\infty \tag{55}$$

and

$$P(x,t) \to P_0(x) \ \ as \ \ |t| \to \infty \tag{56}$$

What is rather surprising is that the stronger the resonance, the more difficult it is to solve Eq. (43). There is an interesting connection between Eq. (43) and nonlinear eigenvalue problems of the form:

$$G'(u) = \beta u \tag{57}$$

for functionals. This translates into the problem

$$-\Delta u = \lambda f(x,u) \tag{58}$$

for partial differential equations. It can be shown that there is an intimate relationship between Eqs. (44) and (57) (other than the fact that the former is a special case of the latter). In fact, the absence of a certain number of solutions of Eq. (44) implies the existence of a rich family of solutions of Eq. (57) on all spheres of sufficiently large radius, and vice versa. The same holds true for Eqs. (43) and (58).

H. Periodic Solutions

Many problems in partial differential equations are more easily understood if one considers periodic functions. Let

$$Q = \left\{x \in \mathbb{R}^n : 0 \le x_j \le 2\pi\right\}$$

be a cube in $\mathbb{R}^n$. By this we mean that Q consists of those points $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$ such that each component x_j satisfies $0 \le x_j \le 2\pi$. Consider n-tuples of integers $\mu = (\mu_1, \ldots, \mu_n) \in \mathbb{Z}^n$, where each $\mu_j \ge 0$, and write $\mu x = \mu_1 x_1 + \cdots + \mu_n x_n$. For $t \in \mathbb{R}$ we let H_t be the set of all series of the form:

$$u = \sum a_\mu e^{i\mu x} \tag{59}$$

where the a_μ are complex numbers satisfying:

$$\alpha_{-\mu} = \bar{\alpha}_\mu$$

(this is done to keep the functions u real valued), and

$$\|u\|_t^2 = (2\pi)^n \sum (1+\mu^2)^t |\alpha_\mu|^2 < \infty \tag{60}$$

where $\mu^2 = \mu_1^2 + \cdots + \mu_n^2$. It is not required that the series (59) converge in anyway, but only that Eq. (60) hold. If

$$u = \sum a_\mu e^{i\mu x}, \qquad v = \sum \beta_\mu e^{i\mu x}$$

are members of H_t, we can introduce the scalar product:

$$(u, v)_t = (2\pi)^n \sum (1+\mu^2)^t \alpha_\mu \beta_{-\mu} \tag{61}$$

With this scalar product, H_t becomes a Hilbert space. If

$$f(x) = \sum \gamma_\mu e^{i\mu x} \tag{62}$$

we wish to solve

$$-\Delta u = f \tag{63}$$

In other words, we wish to solve:

$$\sum \mu^2 \alpha_\mu e^{i\mu x} = \sum \gamma_\mu e^{i\mu x}$$

This requires:

$$\mu^2 \alpha_\mu = \gamma_\mu \quad \forall \mu$$

In order to solve for α_μ, we must have

$$\gamma_0 = 0 \tag{64}$$

Hence, we cannot solve for all f. However, if Eq. (64) holds, we can solve Eq. (63) by taking:

$$\alpha_\mu = \gamma_\mu / \mu^2 \ \ when \ \ \mu \neq 0 \tag{65}$$

On the other hand, we can take α_0 to be any number we like, and u will be a solution of Eq. (63) as long as it satisfies Eq. (65). Thus, we have Theorem 0.1:

Theorem 0.1. *If f, given by Eq. (62), is in H_t and satisfies Eq. (64), then Eq. (63) has a solution $u \in H_{t+2}$. An arbitrary constant can be added to the solution.*

If we wish to solve:

$$-(\Delta + \lambda)u = f \tag{66}$$

where $\lambda \in \mathbb{R}$ is any constant, we want $(\mu^2 - \lambda)\alpha_\mu = \gamma_\mu$, or

$$\alpha_\mu = \gamma_\mu / (\mu^2 - \lambda) \ \ when \ \ \mu^2 \neq \lambda \tag{67}$$

Therefore, we must have

$$\gamma_\mu = 0 \ \ when \ \ \mu^2 = \lambda \tag{68}$$

Not every λ can equal some μ^2. This is certainly true if $\lambda < 0$ or if $\lambda \notin \mathbb{Z}$. But even if λ is a positive integer, there may be no μ such that:

$$\lambda = \mu^2 \tag{69}$$

For instance, if $n = 3$ and $\lambda = 7$ or 15, there is no μ satisfying Eq. (69). Thus, there is a subset:

$$0 = \lambda_0 < \lambda_1 < \cdots < \lambda_k < \cdots$$

of the positive integers for which there are n-tuples μ satisfying Eq. (69). For $\lambda = \lambda_k$, we can solve Eq. (66) only if Eq. (68) holds. In that case, we can solve by taking α_μ to be given by Eq. (67) when Eq. (69) does not hold, and to be given arbitrarily when Eq. (69) does hold. On the other hand, if λ is not equal to any λ_k, then, Eq. (69) never holds, and we can solve Eq. (66) by taking the α_μ to satisfy Eq. (67). Thus, we have Theorem 0.2:

Theorem 0.2. *There is a sequence $\{\lambda_k\}$ of nonnegative integers tending to $+\infty$ with the following properties. If $f \in H_t$ and $\lambda \neq \lambda_k$ for every k, then there is a unique solution $u \in H_{t+2}$ of Eq. (66). If $\lambda = \lambda_k$ for some k, then one can solve Eq. (66) only if f satisfies Eq. (68). The solution is not unique; there is a finite number of linearly independent periodic solutions of:*

$$(\Delta + \lambda_k)u = 0 \tag{70}$$

which can be added to the solution.

The values λ_k for which Eq. (70) has a nontrivial solution (i.e., a solution which is not $\equiv 0$) are called *eigenvalues*, and the corresponding nontrivial solutions are called *eigen functions.*

To analyze the situation a bit further, suppose $\lambda = \lambda_k$ for some k, and $f \in H_t$ is given by Eq. (62) and satisfies Eq. (68). If $v \in H_t$ is given by:

$$v = \sum \beta_\mu e^{i\mu x} \tag{71}$$

then

$$(f, v)_t = (2\pi)^n \sum (1+\mu^2)^t \gamma_\mu \beta_{-\mu}$$

by Eq. (61). Hence, we have

$$(f, v)_t = 0$$

for all $v \in H_t$ satisfying Eq. (71) and

$$\beta_\mu = 0 \ \ when \ \ \mu^2 \neq \lambda_k \tag{72}$$

On the other hand,

$$(\Delta + \lambda_k)v = \sum (\lambda_k - \mu^2)\beta_\mu e^{i\mu x} \tag{73}$$

Thus, v is a solution of Eq. (70) if and only if it satisfies Eq. (72). Conversely, if $(f, v)_t = 0$ for all v satisfying Eqs. (71) and (72), then f satisfies Eq. (68). Combining these, we have Theorem 0.3:

Theorem 0.3. If $\lambda = \lambda_k$ for some k, *then there is a solution $u \in H_{t+2}$ of Eq. (66) if and only if*:

$$(f, v)_t = 0 \tag{74}$$

for all $v \in H_t$ satisfying:

$$(\Delta + \lambda_k)v = 0 \tag{75}$$

Moreover, any solution of Eq. (75) can be added to the solution of Eq. (66).

What are the solutions of Eq. (75)? By Eq. (73), they are of the form:

$$v = \sum_{\mu^2=\lambda_k} \beta_\mu e^{i\mu x} = \sum_{\mu^2=\lambda_k} [a_\mu \cos \mu x + b_\mu \sin \mu x]$$

where we took $\beta_\mu = \alpha_\mu - i b_\mu$.Thus, Eq. (74) becomes:

$$(f, \cos \mu x)_t = 0, (f, \sin \mu x)_t = 0 \ \ when \ \ \mu^2 = \lambda_k$$

The results obtained for periodic solutions are indicative of almost all regular boundary-value problems.

I. Sobolev's Inequalities

Certain inequalities are very useful in solving problems in partial differential equations. The following are known as the Sobolev inequalities.

Theorem 0.4. *For each* $p \geq 1$, $q \geq 1$ *satisfying*:

$$\frac{1}{p} \leq \frac{1}{q} + \frac{1}{n} \tag{76}$$

there is a constant C_{pq} *such that:*

$$|u|_q \leq C_{pq}(|\nabla u|_p + |u|_p), \qquad u \in C^1(Q) \tag{77}$$

where

$$|u|_q = \left(\int_Q |u|^q \, dx \right)^{1/q} \tag{78}$$

and

$$|\nabla u| = \left(\sum_{k=1}^{n} \left| \frac{\partial u}{\partial x_k} \right|^2 \right)^{1/2} \tag{79}$$

As a corollary, we have Corollary 0.1:

Corollary 0.1. $|u|_q \leq C_q ||u||_1$, $u \in H_1$, *where* $1 \leq q \leq 2^* := 2n/(n-2)$.

GLOSSARY

Algorithm Systematic procedure or prescribed series of steps followed in order to solve a problem.
Binary Pertaining to the digits 0 and 1.
Event Set of occurrences defined with respect to some probabilistic process.
Identity Mathematical equation that always holds.
Integers The numbers 0, 1, 2, . . . and their negatives.
List Ordered sequence of elements.
Mutually exclusive Events that cannot occur simultaneously.
Prime Integer greater than 1 that cannot be evenly divided by any integer other than itself and 1.
Set Unordered collection of elements.
String Ordered sequence of letters taken from some alphabet.
Universal set Set that contains all elements relevant to the current discussion.

COMBINATORICS is a branch of discrete mathematics that involves the study of arrangements of various objects. Typically, the focus of combinatorics is on determining whether arrangements can be found that satisfy certain properties or on counting all possible arrangements of such objects. While the roots of combinatorics extend back several thousands of years, its relevance to modern science and engineering is increasingly evident.

I. NATURE OF COMBINATORICS

Combinatorics constitutes a rapidly growing area of contemporary mathematics and is one with an enviable repertoire of applications to areas as diverse as biology, chemistry, physics, engineering, communications, cryptography, and computing. Of particular significance is its symbiotic relationship to the concerns and constructs of computer science. On the one hand, the advent of high-speed computers has facilitated the detailed study of existing combinatorial patterns as well as the discovery of new arrangements. On the other hand, the design and analysis of computer algorithms frequently require the insights and tools of combinatorics. It is not at all surprising, then, that computer science, which is ultimately concerned with

the manipulation of finite sets of symbols (e.g., strings of binary digits), and combinatorial mathematics, which provides tools for analyzing such patterns of symbols, have rapidly achieved prominence together. Moreover, since the symbols themselves can be abstract objects (rather than simply numerical quantities), combinatorics supports the more abstract manipulations of symbolic mathematics and symbolic computer languages.

Combinatorics is at heart a problem-solving discipline that blends mathematical techniques and concepts with a necessary touch of ingenuity. In order to emphasize this dual nature of combinatorics, the sections that follow will first present certain fundamental combinatorial principles and then illustrate their application through a number of diverse examples. Specifically, Sections II–IV provide an introduction to some powerful techniques for counting various combinatorial arrangements, and Section V examines when certain patterns can be guaranteed to exist.

II. BASIC COUNTING TECHNIQUES

A. Fundamental Rules of Sum and Product

Two deceptively simple, but fundamentally important, rules allow the counting of complex patterns by decomposition into simpler patterns. The first such principle states, in essence, that if we slice a pie into two nonoverlapping portions, then indeed the whole (pie) is equal to the sum of its two parts.

Rule of Sum. Suppose that event E can occur in m different ways, that event F can occur in n different ways, and that the two events are mutually exclusive. Then, the compound event where at least one of the two events happens can occur in $m + n$ ways.

The second principle indicates the number of ways that a menu of choices (one item chosen from E, another item chosen from F) can be selected.

Rule of Product. Suppose that event E can occur in m different ways and that subsequently event F can occur in n different ways. Then, a choice from E followed by a choice from F can be made in $m \times n$ ways.

EXAMPLE 1. A certain state anticipates a total of 2,500,000 registered vehicles within the next ten years. Can the current system of license plates (consisting of six digits) accommodate the expected number of vehicles? Should there instead be a change to a proposed new system consisting of two letters followed by four digits?

Solution. To analyze the current situation, there are ten possibilities (0–9) for each of the six digits, so application of the product rule yield $10 \times 10 \times 10 \times 10 \times 10 \times 10 = 1{,}000{,}000$ possibilities, not enough to accommodate the expected number of vehicles. By contrast, the proposed new system allows (again by the product rule) $26 \times 26 \times 10 \times 10 \times 10 \times 10 = 6{,}760{,}000$ possibilities, more than enough to satisfy the anticipated demand.

EXAMPLE 2. DNA (deoxyribonucleic acid) consists of a chain of nucleotide bases (adenine, cytosine, guanine, thymine). How many different three-base sequences are possible?

Solution. For each of the three positions in the sequence, there are four possibilities for the base, so (by the product rule) there are $4 \times 4 \times 4 = 64$ such sequences.

EXAMPLE 3. In a certain computer programming language, each identifier (variable name) consists of either one or two alphanumeric characters (A–Z, 0–9), but the first character must be alphabetic (A–Z). How many different identifier names are possible in this language?

Solution. In this case, analysis of the compound event can be broken into counting the possibilities for event E, a single-character identifier, and for event F, a two-character identifier. The number of possibilities for E is 26, whereas (by the product rule) the number of possibilities for F is $26 \times (26 + 10) = 936$. Since the two events E and F are mutually exclusive, the total number of distinct identifiers is $26 + 936 = 962$.

B. Permutations and Combinations

In the analysis of combinatorial problems, it is essential to recognize when order is important in the arrangement and when it is not. To emphasize this distinction, the set $X = [x_1, x_2, \ldots, x_n]$ consists of n elements x_i, assembled without regard to order, whereas the list $X = [x_1, x_2, \ldots, x_n]$ contains elements arranged in a prescribed order.

In the previous examples, the order of arrangement was clearly important so lists were implicitly being counted. More generally, arrangements of objects into a list are referred to as *permutations*. For example, the objects a, b, c can be arranged into the following permutations: $[a, b, c]$, $[a, c, b]$, $[b, a, c]$, $[b, c, a]$, $[c, a, b]$, $[c, b, a]$. By the product rule, n distinct objects can be arranged into:

$$n! = n \times (n-1) \times (n-2) \times \cdots \times 2 \times 1$$

different permutations. (The symbol $n!$, or n factorial, denotes the product of the first n positive integers.) A permutation of size k is a list with k elements chosen from the n given objects, and there are exactly

$$P(n, k) = n \times (n-1) \times (n-2) \times \cdots \times (n-k+1)$$

such permutations.

EXAMPLE 4. In a manufacturing plant, a particular product is fabricated by processing in turn on four different machines. If any processing sequence using all four machines is permitted, how many different processing orders are possible? How many processing orders are there if only two machines from the four need to be used?

Solution. Each processing order corresponds to a permutation of the four machines, so there are $P(4, 4) = 4! = 24$ different orders. If processing on any two machines is allowable then there are $P(4, 2) = 4 \times 3 = 12$ different orders.

When the order of elements occurring in the arrangement is not pertinent, then a way of arranging k objects, chosen from n distinct objects, is called a *combination* of size k. For example, the objects a, b, c can be arranged into the following combinations, or sets, of size 2: $\{a, b\}, \{a, c\}, \{b, c\}$. The number of combinations of size k from n objects is given by the formula:

$$C(n, k) = P(n, k)/k!$$

EXAMPLE 5. A group of ten different blood samples is to be split into two batches, each consisting of five "pooled" samples. Further chemical analysis will then be performed on the two batches. In how many ways can the samples be split in this fashion?

Solution. Any division of the samples $S_1, S_2, \ldots, S_{10}$ into the two batches can be uniquely identified by those samples belonging to the first batch. For example, $\{S_1, S_2, S_5, S_6, S_8\}$ defines one such division. Since the order of samples within each batch is not important, there are $C(10, 5) = 252$ ways to divide the original samples.

EXAMPLE 6. Suppose that 12 straight lines are drawn on a piece of paper, with no two lines being parallel and no three meeting at a single point. How many different triangles are formed by these lines?

Solution. Any three lines form a triangle since no lines are parallel. As a result, there are as many triangles as choices of three lines selected from the 12, giving $C(12, 3) = 220$ such triangles.

EXAMPLE 7. How many different solutions are there in nonnegative integers x_i to the equation $x_1 + x_2 + x_3 + x_4 = 8$?

Solution. We can view this problem as an equivalent one in which eight balls are placed into four numbered boxes. For example, the solution $x_1 = 2, x_2 = 3, x_3 = 2, x_4 = 1$ corresponds to placing 2, 3, 2, 1 balls into boxes 1, 2, 3, 4. This solution can also be represented by the string * * | * * * | * * | * which shows the number of balls residing in the four boxes. The number of solutions is then the number of ways of constructing a string of 11 symbols (eight stars and three bars); namely, we can select the three bars in $C(11, 3) = 165$ ways.

C. Binomial Coefficients

Ways of arranging objects can also be viewed from an algebraic perspective. To understand this correspondence, consider the product of n identical factors $(1+x)$, namely:

$$(1 + x)^n = (1 + x)(1 + x) \cdots (1 + x)$$

The coefficient of x^k in the expansion of this product is juh the number of ways to select the symbol x from exactly k of the factors. However, the number of ways to select these k factors from the n available is $C(n, k)$, meaning that:

$$(1 + x)^n = C(n, 0) + C(n, 1)x + C(n, 2)x^2 + \cdots + C(n, n)x^n \quad (1)$$

Because the coefficients $C(n, k)$ arise in this way from the expansion of a two-term expression, they are also referred to as *binomial coefficients*. These coefficients can be convenienthvaced in a triangular array, called *Pascal's triangle*, as shown in Fig. 1. Row n of Pascal's triangle contains the values $C(n, 0), C(n, 1), \ldots, C(n, n)$. Several patterns are apparent from this figure. First, the binomial coefficients are symmetrically placed within each row: namely, $C(n, k) = C(n, n - k)$. Second, the coefficient appearing in any row equals the sum of the two coefficients appearing in the previous row just to the left and to the right. For example, in row 5 the third entry, 10, is the sum of the second and third entries, 4 and 6, from the previous row. In general, the binomial coefficients satisfy the identity:

$$C(n, k) = C(n - 1, k - 1) + C(n - 1, k)$$

The binomial coefficients satisfy a number of other interesting and useful identities. To illustrate one way of

n = 1: 1 1

n = 2: 1 2 1

n = 3: 1 3 3 1

n = 4: 1 4 6 4 1

n = 5: 1 5 10 10 5 1

n = 6: 1 6 15 20 15 6 1

FIGURE 1 Arrangement of binomial coefficients $C(n, k)$ in Pascal's triangle.

discovering such identities, formally substitute the value $x = 1$ into both sides of Eq. (1), yielding the identity:

$$2^n = C(n, 0) + C(n, 1) + C(n, 2) + \cdots + C(n, n)$$

In other words, the binomial coefficients for n must sum to the value 2^n. If instead, the value $x = -1$ is formally substituted into Eq. (1), the following identity results:

$$0 = C(n, 0) - C(n, 1) + C(n, 2) - \cdots + (-1)^n C(n, n)$$

This simply states that the alternating sum of the binomial coefficients in any row of Fig. 1 must be zero.

A final identity involving the numbers in Fig. 1 concerns a string of coefficients progressing from the left-hand border along a downward sloping diagonal to any other entry in the figure. Then, the sum of these coefficients will be found as the value just below and to the left of the last such entry. For instance, the sum $C(2, 0) + C(3, 1) + C(4, 2) + C(5, 3) = 1 + 3 + 6 + 10 = 20$ is indeed the same as the binomial coefficient $C(6, 3)$. In general, this observation can be expressed as the identity:

$$C(n + k + 1, k) = C(n, 0) + C(n + 1, 1) + C(n + 2, 2) + \cdots + C(n + k, k)$$

This identity can be given a pleasant combinatorial interpretation, namely, consider selecting k items (without regard for order) from a total of $n + k + 1$ items, which can be done in $C(n + k + 1, k)$ ways. In any such selection, there will be some item number r so that items $1, 2, \ldots, r$ are selected but $r + 1$ is not. This then leaves $k - r$ items to be selected from the remaining $n + k + 1 - (r + 1) = n + k - r$ items, which can be done in $C(n + k - r, k - r)$ ways. Since the cases $r = 0, 1, \ldots, k$ are mutually exclusive, the sum rule shows the total number of selections is also equal to $C(n + k, k) + C(n + k - 1, k - 1) + \cdots + C(n + 1, 1) + C(n, 0)$. Thus, by counting the same group of objects in two different ways, one can verify the above identity. This technique of "double counting" provides a powerful tool applicable to a number of other combinatorial problems.

D. Discrete Probability

Probability theory is an important area of mathematics in which combinatorics plays an essential role. For example, if there are only a finite number of outcomes $S_1, S_2, \ldots, S_m$ to some process, the ability to count the number of occurrences of S_i provides valuable information on the likelihood that outcome S_i will in fact be observed. Indeed, many phenomena in the physical sciences are governed by probabilistic rather than deterministic laws; therefore, one must generally be content with assessing the probability that certain desirable (or undesirable) outcomes will occur.

EXAMPLE 8. What is the probability that a hand of five cards, dealt from a shuffled deck of cards, contains at least three aces?

Solution. The population of 52 cards can be conveniently partitioned into set A of the 4 aces and set N of the 48 non-aces. In order to obtain exactly three aces, the hand must contain three cards from set A and two cards from set N, which can be achieved in $C(4, 3)\,C(48, 2) = 4512$ ways. To obtain exactly 4 aces, the hand must contain four cards from A and one card from N, which can be achieved in $C(4, 4)\,C(48, 1) = 48$ ways. Since the total number of possible hands of five cards chosen from the 52 is $C(52, 5) = 2{,}598{,}960$, the probability of the required hand is $(4512 + 48)/2{,}598{,}960 = 0.00175$, indicating a rate of occurrence of less than twice in a thousand.

EXAMPLE 9. In a certain state lottery, six winning numbers are selected from the numbers $1, 2, \ldots, 40$. What are the odds of matching all six winning numbers? What are the odds of matching exactly five? Exactly four?

Solution. The number of possible choices is the number of ways of selecting six numbers from the 40, or $C(40, 6) = 3{,}838{,}380$. Since only one of these is the winning selection, the odds of matching all six numbers is $1/3{,}838{,}380$. To match exactly five of the winning numbers, there are $C(6, 5) = 6$ ways of selecting the five matching numbers and $C(34, 1) = 34$ ways of selecting a nonmatching number, giving (by the product rule) $6 \times 34 = 204$ ways, so the odds are $204/3{,}838{,}380 = 17/319{,}865$ for matching five numbers. To match exactly four winning numbers, there are $C(6, 4) = 15$ ways of selecting the four matching numbers and $C(34, 2) = 561$ ways of selecting the nonmatching numbers, giving $15 \times 561 = 8415$ ways, so the odds are $8415/3{,}838{,}380 = 561/255{,}892$ (or approximately 0.0022) of matching four numbers.

EXAMPLE 10. An alarm system is constructed from five identical components, each of which can fail (independently of the others) with probability q. The system is designed with a certain amount of redundancy so that it functions whenever at least three of the components are working. How likely is it that the entire system functions?

Solution. There are two states for each individual component, either good or failed. The state of the system can be represented by a binary string $x_1x_2x_3x_4x_5$, where x_i is 1 if component i is good and is 0 if it fails. A functioning state for the system thus corresponds to a binary string having at most two zeros. The number of states with exactly two zeros is $C(5, 2) = 10$, so the probability

of two failed and three good components is $10q^2(1-q)^3$. Similarly, the probability of exactly one failed component is $C(5,1)q^1(1-q)^4 = 5q(1-q)^4$, and the probability of no failed components is $C(5,0)(1-q)^5 = (1-q)^5$. Altogether, the probability that the system functions is given by $10q^2(1-q)^3 + 5q(1-q)^4 + (1-q)^5$. For example, when $q = 0.01$, the system will operate with probability 0.99999015 and thus fail with probability 0.00000985; this shows how adding redundancy to a system composed of unreliable components (1% failure rate) produces a highly reliable system (0.001% failure rate).

III. RECURRENCE RELATIONS AND GENERATING FUNCTIONS

A. Recurrence Relations and Counting Problems

Not all counting problems can be solved as readily and as directly as in Section II. In fact, the best way to solve specific counting problems is often to solve instead a more general, and presumably more difficult, problem. One technique for doing this involves the use of recurrence relations.

Recall that the binomial coefficients satisfy the relation:

$$C(n,k) = C(n-1,k-1) + C(n-1,k)$$

Such an expression shows how the value $C(n,k)$ can be calculated from certain "prior" values $C(n-1,k-1)$ and $C(n-1,k)$. This type of relation is termed a recurrence relation, since it enables any specific value in the sequence to be obtained from certain previously calculated values.

EXAMPLE 11. How many strings of eight binary digits contain no consecutive pair of zeros?

Solution. It is easy to find the number f_1 of such strings of length 1, since the strings "0" and "1" are both acceptable, yielding $f_1 = 2$. Also, the only forbidden string of length 2 is "00" so $f_2 = 3$. There are three forbidden strings of length 3 ("001," "100," and "000"), whereupon $f_3 = 5$. At this point, it becomes tedious to calculate subsequent values directly, but they can be easily found by noticing that a certain recurrence relation governs the sequence f_n. In an acceptable string of length n, either the first digit is a 1 or it is a 0. In the former case, the remaining digits can be any acceptable string of length $n-1$ (and there are f_{n-1} of these). In the latter case, the second digit must be a 1 and then the remaining digits must form an acceptable string of length $n-2$ (there are f_{n-2} of these). These observations provide the recurrence relation:

$$f_n = f_{n-1} + f_{n-2} \qquad (2)$$

Using the initial conditions $f_1 = 2$ and $f_2 = 3$, the values $f_3, f_4, \ldots, f_8$ can be calculated in turn by substitution into Eq. (2):

$$f_3 = 5, \qquad f_4 = 8, \qquad f_5 = 13,$$
$$f_6 = 21, \qquad f_7 = 34, \qquad f_8 = 55$$

Therefore, 55 binary strings of length 8 have the desired property.

In this problem it was clearly expedient to solve the general problem by use of a recurrence relation that stressed the interdependence of solutions to related problems. The particular sequence obtained for this problem, $[1, 2, 3, 5, 8, 13, 21, 34, \ldots]$, with $f_0 = 1$ added for convenience, is called the *Fibonacci sequence*, and it arises in numerous problems of mathematics as well as biology, physics, and computer science.

EXAMPLE 12. Suppose that ten straight lines are drawn in a plane so that no two lines are parallel and no three intersect at a single point. Into how many different regions will the plane be divided by these lines?

Solution. As seen in Fig. 2, the number of regions created by one straight line is $f_1 = 2$, the number created by two lines is $f_2 = 4$, and the number created by three lines is $f_3 = 7$. The picture becomes excessively complicated with more added lines, so it is prudent to seek a general solution for f_n, the number of regions created by n lines in the plane. Suppose that $n-1$ lines have already been drawn and that line n is now added. Because the lines are all mutually nonparallel, line n must intersect each existing line exactly once. These $n-1$ intersection points divide the new line into n segments and each segment serves to subdivide an existing region into two regions. Thus, the n segments increase the number of regions by exactly n, producing the recurrence relation:

$$f_n = f_{n-1} + n$$

Given the initial condition $f_1 = 2$, application of this recurrence relation yields the values $f_2 = f_1 + 2 = 4$ and $f_3 = f_2 + 3 = 7$, as previously verified. In fact, such a recurrence relation can be explicitly solved, giving:

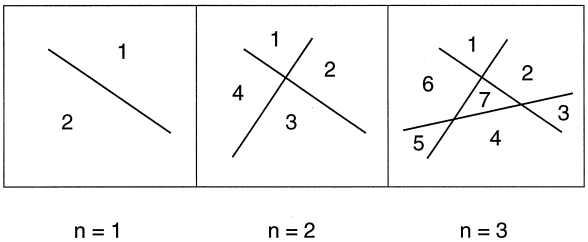

FIGURE 2 Number of regions created by the placement of n lines.

$$f_n = (n^2 + n + 2)/2$$

indicating that there are $f_{10} = 112/2 = 56$ regions bounded by ten lines.

In representing mathematical expressions, the placement of parentheses can be crucial. For example, $((x - y) - z)$ does not in general give the same result as $(x - (y - z))$. Moreover, the placement of parentheses must be syntactically valid as in $((x - y) - z)$ or $(x - (y - z))$, whereas $(x) - y) - (z$ is not syntactically valid.

EXAMPLE 13. How many valid ways are there of parenthesizing an expression involving n variables?

Solution. Notice that there is only one valid form for a single variable x, namely (x), giving $f_1 = 1$; similarly, it can be verified that $f_2 = 1$ and $f_3 = 2$. More generally, suppose that there are n variables. Then any valid form must be expressible as (AB), where A and B are themselves valid forms. Notice that if A contains k variables, then B must contain $n - k$ variables, so in this case the f_k valid forms for A can be combined with the f_{n-k} valid forms for B to yield $f_k f_{n-k}$ valid forms for the whole expression. Since the different possibilities for k ($k = 1, 2, \ldots, n - 1$) are mutually exclusive, we obtain the recurrence relation:

$$f_n = f_1 f_{n-1} + f_2 f_{n-2} + \cdots + f_{n-2} f_2 + f_{n-1} f_1$$

This equation can be explicitly solved for f_n in terms of binomial coefficients:

$$f_n = C(2n - 2, n - 1)/n$$

The numbers in this sequence, $[1, 1, 2, 5, 14, 42, 132, \ldots]$, are called *Catalan numbers* (Eugène Catalan, 1814–1894), and they occur with some regularity as solutions to a variety of combinatorial problems (such as triangulating convex polygons, counting voting sequences, and constructing rooted binary trees).

B. Generating Functions and Counting Problems

The examples in Part A of this section serve to illustrate the theme that solving a specific problem can frequently be aided by relating the given problem to other, often simpler, problems of the same type. For example, a problem of size n might be related to a problem of size $n - 1$ and to another problem of size $n - 3$. Another way of pursuing such interrelationships among problems of different sizes is through use of a generating function. As a matter of fact, this concept has already been previewed in studying the binomial coefficients. Specifically, Eq. (1) shows that $f(x) = (1 + x)^n$ can be viewed as a generating function for the binomial coefficients $C(n, k)$:

$$f(x) = C(n, 0) + C(n, 1)x + C(n, 2)x^2 + \cdots + C(n, n)x^n$$

The variable x simply serves as a formal symbol and its exponents represent placeholders for carrying the coefficient information. More generally, a generating function is a polynomial in the variable x:

$$f(x) = a_0 + a_1 x + a_2 x^2 + \cdots + a_n x^n + \cdots$$

and it serves as a template for studying the sequence of coefficients $[a_0, a_1, a_2, \ldots, a_n, \ldots]$.

Recall that the binomial coefficients $C(n, k)$ count the number of combinations of size k derived from a set $\{1, 2, \ldots, n\}$ of n elements. In this context, the generating function $f(x) = (1 + x)^n$ for the binomial coefficients can be developed by the following reasoning. At each step $k = 1, 2, \ldots, n$ a decision is made as to whether or not to include element k in the current combination. If x^0 is used to express exclusion and x^1 inclusion, then the factor $(x^0 + x^1) = (1 + x)$ at step k compactly encodes these two choices. Since each element k presents the same choices (exclude/include), the product of the n factors $(1 + x)$ produces the desired enumerator $(1 + x)^n$. This reasoning applies more generally to cases where the individual choices at each step are not identical, so the factors need not all be the same (as in the case of the binomial coefficients). The following examples give some idea of the types of problems that can be addressed through the use of generating functions.

EXAMPLE 14. In how many different ways can change for a dollar be given, using only nickels, dimes, and quarters?

Solution. The choices for the number of nickels to use can be represented by the polynomial:

$$(1 + x^5 + x^{10} + \cdots) = (1 - x^5)^{-1}$$

where x^i signifies that exactly i cents worth of nickels are used. Similarly, the choices for dimes are embodied in:

$$(1 + x^{10} + x^{20} + \cdots) = (1 - x^{10})^{-1}$$

and the choices for quarters in:

$$(1 + x^{25} + x^{50} + \cdots) = (1 - x^{25})^{-1}$$

Multiplying together these three polynomials produces the required generating function:

$$f(x) = (1 - x^5)^{-1}(1 - x^{10})^{-1}(1 - x^{25})^{-1}$$

The coefficient of x^n in the expanded form of this generating function indicates the number of ways of making change for n cents. In particular, there are 29 different ways of making change for a dollar ($n = 100$). This can be verified by using a symbolic algebra package such as *Mathematica* or *Maple*.

A *partition* of the positive integer n is a set of positive integers (or "parts") that together sum to n. For example,

the number 4 has the five partitions: {1, 1, 1, 1}, {1, 1, 2}, {1, 3}, {2, 2}, and {4}.

EXAMPLE 15. How many partitions are there for the integer n?

Solution. The choices for the number of ones to include as parts is represented by the polynomial:

$$(1 + x + x^2 + \cdots) = (1 - x)^{-1}$$

where the x^i term means that 1 is to appear i times in the partition. Similarly, the choices for the number of twos to include is given by:

$$(1 + x^2 + x^4 + \cdots) = (1 - x^2)^{-1}$$

the choices for the number of threes is given by:

$$(1 + x^3 + x^6 + \cdots) = (1 - x^3)^{-1}$$

and so forth. Therefore, the number of partitions of n can be found as the coefficient of x^n in the generating function:

$$f(x) = (1 - x)^{-1}(1 - x^2)^{-1}(1 - x^3)^{-1} \cdots$$

EXAMPLE 16. Find the number of partitions of the integer n into *distinct* parts.

Solution. Since the parts must be distinct, the choices for any integer i are whether to include it (x^i) or not (x^0) in the given partition. As a result, the generating function for this problem is

$$f(x) = (1 + x)(1 + x^2)(1 + x^3) \cdots$$

For example, the coefficient of x^8 in the expansion of $f(x)$ is found to be 6, meaning that there are six partitions of 8 into distinct parts: namely, {8}, {1, 7}, {2, 6}, {3, 5}, {1, 2, 5}, {1, 3, 4}.

IV. INCLUSION–EXCLUSION PRINCIPLE

Another important counting technique is based on the idea of successively adjusting an initial count through systematic additions and subtractions that are guaranteed to produce a correct final answer. This technique, called the *inclusion–exclusion principle*, is applicable to many instances where direct counting would be impractical.

As a simple example, suppose we wish to count the number of elements that are *not* in some subset A of a given universal set U. Then, the required number of elements equals the total number of elements in U, denoted by $N = N(U)$, minus the number of elements in A, denoted by $N(A)$. Expressed in this notation,

$$N(A') = N - N(A)$$

where $A' = U - A$ designates the set of elements in U that do not appear in A. Figure 3a depicts this relation using a Venn diagram (John Venn, 1834–1923), in which the enclosing rectangle represents the set U, the inner circle represents A, and the shaded portion represents A'. The quantity $N(A')$ is thus obtained by excluding $N(A)$ elements from N.

EXAMPLE 17. The letters a, b, c, d, e are used to form five-letter words, using each letter exactly once. How many words do *not* contain the sequence *bad*?

Solution. The universe here consists of all words, or permutations, formed from the five letters, so there are $N = 5! = 120$ words in total. Set A consists of all such words containing *bad*. By treating these three letters as a new "megaletter" x, the set A equivalently contains all words formed from x, c, e so $N(A) = 3! = 6$. The number of words not containing *bad* is then $N - N(A) = 120 - 6 = 114$.

Figure 3b shows the situation for two sets, A and B, contained in the universal set U. As this figure suggests,

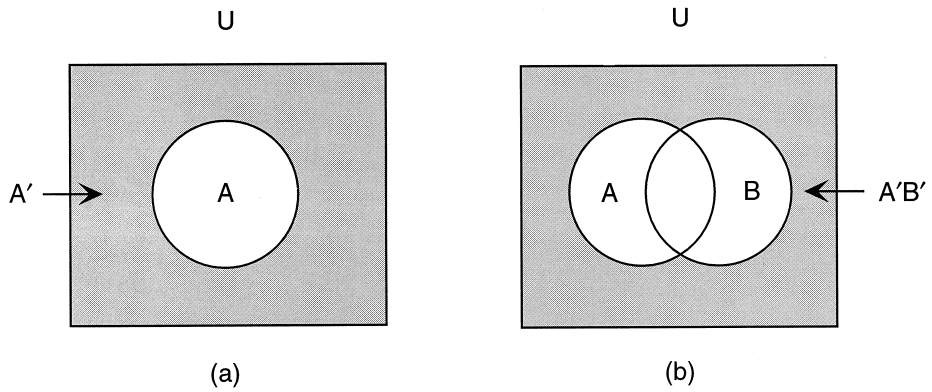

FIGURE 3 Venn diagrams relative to a universal set U. (a) Sets A and A'; (b) Sets A, B, and $A'B'$.

the number of elements in either A or B (or both) is then the number of elements in A plus the number of elements in B, minus the number of elements in both:

$$N(A \cup B) = N(A) + N(B) - N(AB) \qquad (3)$$

Here $A \cup B$ denotes the elements either in A or in B, or in both, whereas AB denotes the elements in both A and B. Since the sum $N(A)+N(B)$ counts the elements of AB twice rather than just once, $N(AB)$ is subtracted to remedy the situation. The number of elements $N(A'B')$ in neither A nor B is $N - N(A \cup B)$, thus an alternative form of Eq. (3) is

$$N(A'B') = N - [N(A) + N(B)] + N(AB) \qquad (4)$$

This form shows how terms are alternately included and excluded to produce the desired result.

EXAMPLE 18. In blood samples obtained from 50 patients, laboratory tests show that 20 patients have antibodies to type A bacteria, 29 patients have antibodies to type B bacteria, and 8 patients have antibodies to both types. How many patients have antibodies to neither of the two types of bacteria?

Solution. The given data state that $N = 50$, $N(A) = 20$, $N(B) = 29$, and $N(AB) = 8$. Therefore, by Eq. (4):

$$N(A'B') = 50 - [20 + 29] + 8 = 9$$

meaning that nine patients are immune to neither type of bacteria.

The foregoing equations generalize in a natural way to three sets A, B, and C:

$$N(A \cup B \cup C) = N(A) + N(B) + N(C) - [N(AB) + N(AC) + N(BC)] + N(ABC) \qquad (5)$$

$$N(A'B'C') = N - [N(A) + N(B) + N(C)] + [N(AB) + N(AC) + N(BC)] - N(ABC) \qquad (6)$$

In each of these forms, the final result is obtained by successive inclusions and exclusions, thus justifying these as manifestations of the inclusion–exclusion principle.

EXAMPLE 19. An electronic assembly is comprised of components 1, 2, and 3 and functions only when at least two components are working. If all components fail independently of one another with probability q, what is the probability that the entire assembly functions?

Solution. Let A denote the event in which components 1 and 2 work, let B denote the event in which components 1 and 3 work, and let C denote the event in which components 2 and 3 work. Of interest is the probability that at least one of the events A, B, or C occurs. The analogous form of Eq. (5) in the probabilistic case is

$$Pr(A \cup B \cup C) = Pr(A) + Pr(B) + Pr(C) - [Pr(AB) + Pr(AC) + Pr(BC)] + Pr(ABC)$$

Here, $Pr(A)$ is the probability of event A occurring, $Pr(AB)$ is the probability of event AB occurring, and so forth. Notice that $Pr(A) = Pr(B) = Pr(C) = (1-q)^2$ and $Pr(AB) = Pr(AC) = Pr(BC) = Pr(ABC) = (1-q)^3$, so the assembly functions with probability:

$$Pr(A \cup B \cup C) = 3(1-q)^2 - 3(1-q)^3 + (1-q)^3 = 3(1-q)^2 - 2(1-q)^3$$

Two positive integers are called *relatively prime* if the only positive integer evenly dividing both is the number 1. For example, 7 and 15 are relatively prime, whereas 6 and 15 are not (they share the common divisor 3).

EXAMPLE 20. How many positive integers not exceeding 60 are relatively prime to 60?

Solution. The appropriate universe here is $U = \{1, 2, \ldots, 60\}$ and the (prime) divisors of $N = 60$ are 2, 3, 5. Relative to U, let A be the set of integers divisible by 2, let B be the set of integers divisible by 3, and let C be the set of integers divisible by 5. The problem here is to calculate $N(A'B'C')$, the number of integers that share no divisors with 60. Because every other integer is divisible by 2, we have $N(A) = 60/2 = 30$. Similarly, $N(B) = 60/3 = 20$ and $N(C) = 60/5 = 12$. Because any integer divisible by both 2 and 3 must also be divisible by 6, we have $N(AB) = 60/6 = 10$. Likewise, $N(AC) = 60/10 = 6$, $N(BC) = 60/15 = 4$, and $N(ABC) = 60/30 = 2$. Substituting these values into Eq. (6) gives:

$$N(A'B'C') = 60 - [30 + 20 + 12] + [10 + 6 + 4] - 2 = 16$$

so there are 16 positive numbers not exceeding 60 that are relatively prime to 60.

EXAMPLE 21. Each package of a certain product contains one of three possible prizes. How likely is it that a purchaser of five packages of the product will get at least one of each prize?

Solution. The number of possible ways in which this event can occur will first be calculated, after which a probabilistic statement can be deduced. Let the prizes be denoted a, b, c, and let the contents of the five packages be represented by a string of five letters (where repetition is allowed). For example, the string *bacca* would represent one possible occurrence. Define A to be the set of all such strings that do not include a. In similar fashion, define B (respectively, C) to be the set of strings that do not include b (respectively, c). It is required then to calculate

$N(A'B'C')$, the number of instances in which a, b, and c all occur. The approach will be to use the inclusion–exclusion relation, Eq. (6), to calculate this quantity. Here, N is the number of strings of five letters over the alphabet $\{a, b, c\}$, so (by the product rule) $N = 3^5 = 243$. Also, $N(A)$ is the number of strings from the alphabet $\{b, c\}$, whereupon $N(A) = 2^5 = 32$. By similar reasoning, $N(B) = N(C) = 32$, $N(AB) = N(AC) = N(BC) = 1^5 = 1$, and $N(ABC) = 0$. As a result,

$$N(A'B'C') = 243 - 3(32) + 3(1) - 0 = 150$$

In summary, the total number of possible strings is 243 and all three prizes are obtained in 150 of these cases. If all strings are equally likely (i.e., any package is just as likely to contain each prize), then the required probability is $150/243 = 0.617$, indicating a better than 60% chance of obtaining three different prizes in just five packages. A similar analysis shows that for six packages, the probability of obtaining all three prizes increases to 0.741; for seven packages, there is a 0.826 probability.

V. EXISTENCE PROBLEMS

A. Pigeonhole Principle

In certain combinatorial problems, it may be exceedingly difficult to count the number of arrangements of a prescribed type. In fact, it might not even be clear that any such arrangement actually exists. What is needed then is some guiding mathematical assurance that configurations of the desired type do indeed exist. One such principle is the so-called *pigeonhole principle*. While its statement is overwhelmingly self-evident, its applications range from the simplest to the most challenging problems in combinatorics.

The pigeonhole principle states that if there are more than k objects (or pigeons) to be placed in k locations (or pigeonholes), then some location must house two (or possibly more) such objects. A simple illustration of this principle assures that at least two residents of a town with 400 inhabitants have the same birthday. Here, the objects are the residents and the locations are the 356 possible birthdays. Since there are more objects than locations, some location must contain at least two objects, meaning that some two residents (or more) must share the same birthday. Notice that this principle only guarantees the *existence* of two such residents; it does not give any information about finding them.

EXAMPLE 22. In any selection of five different elements from $\{1, 2, \ldots, 8\}$, there must be some pair of selected elements that sum to 9.

Solution. Here the objects are the numbers $1, 2, \ldots, 8$ and the locations are the four sets $A_1 = \{1, 8\}$, $A_2 = \{2, 7\}$, $A_3 = \{3, 6\}$, and $A_4 = \{4, 5\}$. Notice that for each of these sets its two elements sum to 9. According to the pigeonhole principle, placing five numbers into these four sets results in some set A_i having both its elements selected, so the sum of these two elements (by the construction of set A_i) must equal 9.

EXAMPLE 23. In a room with $n \geq 2$ persons, there must be two persons having exactly the same number of friends in the room.

Solution. The number of possible friendships for any given person ranges from 0 to $n-1$. However, if $n-1$ occurs then that person is a friend of everyone else, and (assuming that friendship is a mutual relation) no other person can be without friends. Thus, both 0 and $n-1$ cannot simultaneously occur in a group of n persons. If $1, 2, \ldots, n-1$ are the possible numbers of friendships, then using these $n-1$ numbers as locations for the n persons (objects), the pigeonhole principle assures that some number in $\{1, 2, \ldots, n-1\}$ must appear twice. A similar result can be established for the case $\{0, 1, \ldots, n-2\}$, demonstrating there must always be at least two persons having the same number of friends in the room.

Two strings $x = x_1x_2 \cdots x_n$ and $y = y_1y_2 \cdots y_m$ over the alphabet $\{a, b, \ldots, z\}$ are said to be disjoint if they share no common letter and are said to overlap otherwise.

EXAMPLE 24. In any collection of at least six strings, there must either be three strings that are mutually disjoint or three strings that mutually overlap.

Solution. For a given string x, let the $k \geq 5$ other strings in the collection be divided into two groups, D and O; D consists of those strings that are disjoint from x, and O consists of those that overlap with x. By a generalization of the pigeonhole principle, one of these two sets must contain at least three elements. Suppose that it is set D. Then, either D contains three mutually overlapping strings or it contains two disjoint strings y and z. In the first case, these three strings satisfy the stated requirements. In the second case, the elements x, y, z are all mutually disjoint, so again the requirements are met. A similar argument can be made if O is the set containing at least three elements. In any event, there will either be three mutually disjoint strings or three mutually overlapping strings.

This last example is a special case of *Ramsey's theorem* (Frank Ramsey, 1903–1930), which guarantees that if there are enough objects then configurations of certain types will always be guaranteed to exist. Not only does this theorem (which generalizes the pigeonhole principle) produce some very deep combinatorial results, but it has also

been applied to problems arising in geometry, the design of communication networks, and information retrieval.

B. Combinatorial Designs

Combinatorial designs involve ways of arranging objects into various groups in order to meet specified requirements. Such designs find application in the planning of statistical experiments as well as in other areas of mathematics (number theory, coding theory, geometry, and algebra).

As one illustration, suppose that an experiment is to be designed to test the effects of five different drugs using five different subjects. One clear requirement is that each subject should receive all five drugs, since otherwise the results could be biased by variation among the subjects. Each drug is to be administered for one week, so that at the end of five weeks the experiment will be completed. However, the order in which drugs are administered could also have an effect on their observed potency, so it is also desirable for all drugs to be represented on any given week of the experiment. One way of designing such an experiment is depicted in Fig. 4, which shows one source of variation—the subjects ($S_1, S_2, \ldots, S_5$)—appearing along the rows and the other source of variation—the weeks ($W_1, W_2, \ldots, W_5$)—appearing along the columns. The entries within each row show the order in which the drugs ($A, B, \ldots, E$) are administered to each subject on a weekly basis. Such an arrangement is termed a *Latin square*, since the five treatments (drugs) appear exactly once in each row and exactly once in each column.

Figure 4 clearly demonstrates the existence of a 5×5 Latin square; more generally, Latin squares of size $n \times n$ exist for each value of $n \geq 1$. There are also occasions when it is desirable to superimpose certain pairs of $n \times n$ Latin squares. An example of this arises in testing the effects of n types of fertilizer and n types of insecticide on the yield of a particular crop. Suppose that a field on which the crop is grown is divided into an $n \times n$ grid of plots. In order to minimize vertical and horizontal variations in the composition and drainage properties of the soil, each fertilizer should appear on exactly one plot in each "row" and exactly one plot in each "column" of the grid. Likewise, each insecticide should appear once in each row and once in each column of the grid. In other words, a Latin square design should be used for each of the two treatments. Figure 5a shows a Latin square design for four fertilizer types (A, B, C, D), and Fig. 5b shows another Latin square design for four insecticide types (a, b, c, d).

In addition, the fertilizer and insecticide treatments can themselves interact, thus an ideal design would ensure that each of the n^2 possible combinations of the n fertilizers and n insecticides appear together once. Figure 5c shows that the two Latin squares in Figs. 5a and b (when superimposed) have this property; namely, each fertilizer–insecticide pair occurs exactly once on a plot. Such a pair of Latin squares is called *orthogonal*.

A pair of orthogonal $n \times n$ Latin squares need not exist for all values of $n \geq 2$. However, it has been proved that the only exceptions occur when $n = 2$ and $n = 6$. In all other cases, an orthogonal pair can be constructed.

Latin squares are special instances of *complete* designs, since every treatment appears in each row and in each

	W_1	W_2	W_3	W_4	W_5

column. Another useful class of combinatorial designs is one in which not all treatments appear within each test group. Such *incomplete* designs are especially relevant when the number of treatments is large relative to the number of tests that can be performed on an experimental unit.

As an example of an incomplete design, consider an experiment in which subjects are to compare $v = 7$ brands of soft drink ($A, B, \ldots, G$). For practical reasons, every subject is limited to receiving $k = 3$ types of soft drink. Moreover, to ensure fairness in the representation of the various beverages, each soft drink should be tasted by the same number $r = 3$ of subjects, and each pair of soft drinks should appear together the same number $\lambda = 1$ of times. It turns out that such a design can be constructed using $b = 7$ subjects, with the soft drinks compared by each subject i given by the set B_i below:

$$B_1 = \{A, B, D\}; \qquad B_2 = \{A, C, F\};$$
$$B_3 = \{A, E, G\}; \qquad B_4 = \{B, C, G\};$$
$$B_5 = \{B, E, F\}; \qquad B_6 = \{C, D, E\};$$
$$B_7 = \{D, F, G\}$$

The sets B_i are referred to as *blocks*, and such a design is termed a (b, v, r, k, λ) *balanced incomplete block design*. In any such design, the parameters b, v, r, k, λ must satisfy the following conditions:

$$bk = vr, \qquad \lambda(v - 1) = r(k - 1)$$

In the previous example, these relations hold since $7 \times 3 = 7 \times 3$ and $1 \times 6 = 3 \times 2$. While the above conditions must hold for any balanced incomplete block design, there need not exist a design corresponding to every set of parameters satisfying these conditions.

GLOSSARY

Banach space Normed vector space in which every Cauchy sequence has a limit; normed space complete with respect to the norm topology.

Cauchy sequence Sequence $\{x_n\} \in X$ is called a *Cauchy sequence* if $\lim_{n,m\to\infty} \|x_n - x_m\| = 0$; an element $x \in X$ is its limit if $\lim_{n\to\infty} \|x_n - x\| = 0$.

Normed vector space $X \equiv (X, \|\cdot\|)$ Linear vector space X furnished with a measure of distance between its elements $d(x, y) = \|x - y\|$, $\|x\| = d(0, x)$ satisfying: (a) $\|x\| \geq 0$, $\|x\| = 0$ iff $x = 0$, (b) $\|x + y\| \leq \|x\| + \|y\|$, (c) $\|\alpha x\| = |\alpha|\, \|x\|$ for all $x, y \in X$, and α scalar.

Reflexive Banach space Banach space X is reflexive if it is equivalent to (isomorphic to, indistinguishable from) its bidual $(X^*)^* \equiv X^{**}$.

Strictly convex normed space Normed space X is said to be strictly convex if, for every pair $x, y \in X$ with $x \neq y$, $\|\frac{1}{2}(x + y)\| < 1$ whenever $\|x\| \leq 1$, $\|y\| \leq 1$.

Uniformly convex normed space Normed space X is said to be uniformly convex if, for every $\varepsilon > 0$, there exists a $\delta > 0$, such that $\|x - y\| > \varepsilon$ implies that $\|\frac{1}{2}(x + y)\| < 1 - \delta$; for $\|x\| \leq 1$, $\|y\| \leq 1$; a uniformly convex Banach space is reflexive.

Weak convergence and weak topology Sequence $\{x_n\} \in X$ is said to be weakly convergent to x if, for every $x^* \in X^*$, $x^*(x_n) \to x^*(x)$ as $n \to \infty$; the notion of weak convergence induces a topology different from the norm topology and is called the weak topology; the spaces L_p, $1 \leq p < \infty$, are weakly (sequentially) complete.

Weak* convergence and w^*-topology Sequence $\{x_n^*\} \in X^*$ is said to be w^*-convergent to x^* if, for every $x \in X$, $x_n^*(x) \to x^*(x)$ as $n \to \infty$; the corresponding topology is called *w^*-topology*.

Weak and weak* compactness Set K in a Banach space X is said to be weakly (sequentially) compact if every sequence $\{x_n\} \in K$ has a subsequence $\{x_{n_k}\}$ and an $x_0 \in K$ such that, for each $x^* \in X^*$, $x^*(x_{n_k}) \to x^*(x_0)$; weak* compactness is defined similarly by interchanging the rolls of X^* and X.

DISTRIBUTED PARAMETER SYSTEMS are those whose state evolves with time distributed in space. More precisely, they are systems whose temporal evolution of state can be completely described only by elements of ∞-dimensional spaces. Such systems can be described by

partial differential equations, integro-partial differential equations, functional equations, or abstract differential or integro-differential equations on topological spaces.

I. SYSTEM MODELS

Mysteries of the universe have baffled scientists, poets, philosphers, and even the prophets. Scientists have tried to learn the secrets of nature by building and studying mathematical models for various systems. It is a difficult task to give a precise definition of what is meant by a *system*. But, roughly speaking, you may think of any physical or abstract entity that obeys certain systematic laws, deterministic or probabilistic, as being a system.

Systems can be classified into two major categories: (a) lumped parameter systems, and (b) distributed parameter systems. Lumped parameter systems are those whose temporal evolution can be described by a finite number of variables. That is, they are systems having finite degrees of freedom and they are governed by ordinary differential or difference equations in a finite-dimensional space. On the other hand, distributed parameter systems are those whose temporal evolution can be described only by elements of an ∞-dimensional space called the *state space*. These systems are governed by partial differential equations or functional differential equations or a combination of partial and ordinary differential equations.

A. Examples of Physical Systems

In this section we present a few typical examples of distributed parameter systems. The Laplace equation in $\mathbb{R}^n$ is given by:

$$\Delta\phi \equiv \sum_{i=1}^{n} \frac{\partial^2 \phi}{\partial x_i^2} = 0 \tag{1}$$

For $n = 3$, this equation is satisfied by the velocity potential of an irrotational incompressible flow, by the gravitational field outside the attracting masses, by electrostatic and magnetostatic fields, and also by the temperature of a body in thermal equilibrium. In addition to its importance on its own merit, the Laplacian is also used as a basic operator in diffusion and wave propagation problems. For example, the temperature of a body is governed by the so-called heat equation:

$$\frac{\partial T}{\partial t} = k\Delta T + f(t, x), \qquad (t, x) \in I \times \Omega, \qquad \Omega \subset \mathbb{R}^3 \tag{2}$$

where k is the thermal conductivity of the material and f is an internal source of heat. The classical wave equation in R^n is given by:

$$\frac{\partial^2 \psi}{\partial t^2} = c^2 \Delta\psi \tag{3}$$

where c denotes the speed of propagation. It may represent the displacement of a vibrating string, or propagation of acoustic or light waves and surface waves on shallow water.

Maxwell's equation, for a nonconducting medium with permeability μ and permittivity ε describing the temporal evolution of electric and magnetic field vectors H and E, respectively, in $\mathbb{R}_3$, is given by:

$$\begin{aligned} \mu\frac{\partial H}{\partial t} + \nabla \times E &= 0, \\ \varepsilon\frac{\partial E}{\partial t} - \nabla \times H &= 0 \\ \operatorname{div} E \equiv \nabla \cdot E &= 0, \\ \operatorname{div} H \equiv \nabla \cdot H &= 0 \end{aligned} \tag{4}$$

Under the assumptions of small displacement, the classical elastic waves in $\mathbb{R}^3$ are governed by the system of equations,

$$\begin{aligned} \rho\frac{\partial^2 y_i}{\partial t^2} &= \mu\,\Delta y_i + (\lambda + \mu)\frac{\partial}{\partial x_i}(\operatorname{div} y) \\ i &= 1, 2, 3, \\ y &= (y_1, y_2, y_3) \\ y_i &= y_i(t, x_1, x_2, x_3) \end{aligned} \tag{5}$$

where y represents the displacement of the elastic body from its unstrained configuration, ρ is the mass density, and λ, μ, are Lamé constants. In $\mathbb{R}^3$, the state of a single particle of mass m subject to a field of potential $v = v(t, x_1, x_2, x_3)$ is given by the Schrödinger equation:

$$i\hbar\frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2m}\Delta\psi + v\psi \tag{6}$$

where $\hbar = 2\pi h$ is Planck's constant.

In recent years the nonlinear Schrödinger's equation has been used to take into account nonlinear interaction of particles in a beam by replacing $v\psi$ by a suitable nonlinear function $g(t, x, \psi)$.

The equation for an elastic beam allowing moderately large vibration is governed by a nonlinear equation of the form:

$$\begin{aligned} \rho A\frac{\partial^2 y}{\partial t^2} + \beta\frac{\partial y}{\partial t} + \frac{\partial^2}{\partial x^2}\left(EI\frac{\partial^2 y}{\partial x^2}\right) + N\frac{\partial^2 y}{\partial x^2} &= f(t, x) \\ N = \frac{EA}{2l}\int_0^l \left(\frac{\partial y}{\partial x}\right)^2 dx \\ x \in (0, l), \qquad t \geq 0 \end{aligned} \tag{7}$$

where E denotes Young's modulus, I the moment of area of the cross section A of the beam, l the length, ρ the mass density, N the membrane force, and f the applied force. For small displacements, neglecting N and β, one obtains the Euler equation for thin beams. The dynamics of Newtonian fluid are governed by the Navier–Stokes equations:

$$\rho\left(\frac{\partial v}{\partial t} + v \cdot \nabla v\right) - \nu\,\Delta v - (3\lambda + \nu)\,\text{grad div } v + \text{grad } p = f \tag{8}$$

$$\frac{\partial \rho}{\partial t} + \text{div}(\rho v) = 0, \qquad t \geq 0, \qquad x \in \Omega \subset \mathbb{R}^n$$

obtained from momentum and mass conservation laws, where ρ is the mass density, v the velocity vector, p the pressure, f the force density, and ν, λ are constant parameters.

Magnetohydrodynamic equations for a homogeneous adiabatic fluid in $\mathbb{R}^3$ is given by:

$$\begin{aligned} &\frac{\partial v}{\partial t} + v \cdot \nabla v + \rho^{-1}\nabla p + (\mu\rho)^{-1}(B \times \text{ rot } B) = f \\ &\frac{\partial \rho}{\partial t} + \text{ div}(\rho v) = 0, \qquad \frac{\partial s}{\partial t} + v \cdot \nabla s = 0 \\ &\frac{\partial B}{\partial t} - \text{ rot}(v \times B) = 0, \qquad \text{div} B = 0 \\ &p = g(\rho, s), \qquad \text{rot } B \equiv \nabla \times B \end{aligned} \tag{9}$$

where v, ρ, p, and f are as in Eq. (8); s is the entropy; B, the magnetic induction vector; and μ, the permeability.

In recent years semilinear parabolic equations of the form,

$$\frac{\partial \phi}{\partial t} = D\,\Delta\phi + f(t, x; \phi), \qquad t \geq 0, \qquad x \in \Omega \subset \mathbb{R}^n \tag{10}$$

have been extensively used for modeling biological, chemical, and ecological systems, where D represents the migration or diffusion coefficient.

The dynamics of a spacecraft with flexible appendages is governed by a coupled system of ordinary and partial differential equations.

In the following two sections we present abstract models that cover a wide variety of physical systems including those already mentioned.

B. Linear Systems

A general spatial differential operator used to construct system models is given by:

$$A(x, D)\phi \equiv \sum_{|\alpha| \leq 2m} a_\alpha(x)\, D^\alpha \phi$$

$$x \in \Omega \equiv \text{open subset of } \mathbb{R}^n \tag{11}$$

Under suitable smoothness conditions on the coefficient a_α and the boundary $\partial\Omega$ of Ω one can express Eq. (11) in the so-called divergence form:

$$A(x, D)\phi \equiv \sum_{|\alpha|, |\beta| \leq m} (-1)^{|\alpha|} D^\alpha \left(a_{\alpha\beta} D^\beta \phi\right) \tag{12}$$

The operator A is said to be strongly uniformly elliptic on Ω if there exists a $\gamma > 0$ such that

$$(-1)^m \text{ Re}\left\{\sum_{|\alpha|=2m} a_\alpha(x)\xi^\alpha\right\} \geq \gamma\,|\xi|^{2m} \qquad \text{for all} \quad x \in \Omega \tag{13}$$

or

$$\text{Re}\left\{\sum_{|\alpha|=|\beta|=m} a_{\alpha\beta}(x)\xi^\alpha\xi^\beta\right\} \geq \gamma\,|\xi|^{2m} \tag{14}$$

Many physical processes in steady state (for example, thermal equilibrium or elastic equilibrium) can be described by elliptic boundary value problems given by:

$$\begin{aligned} A(x, D)\phi &= f \qquad \text{on} \quad \Omega \\ B(x, D)\phi &= g \qquad \text{on} \quad \partial\Omega \end{aligned} \tag{15}$$

where $B = \{B_j,\ 0 \leq j \leq m-1\}$ is a system of suitable boundary operators. For example, the boundary operator may be given by the Dirichlet operator,

$$B \equiv \left\{\frac{\partial^j}{\partial \nu^j}, 0 \leq j \leq m-1\right\}$$

where $\partial/\partial\nu$ denotes spatial derivatives along the outward normal to the boundary $\partial\Omega$. The boundary operators $\{B_j\}$ cannot be chosen arbitrarily; they must satisfy certain compatibility conditions with respect to the operator A. Only then is the boundary value problem (15) well posed; that is, one can prove the existence of a solution and its continuous dependence on the data f and $g = \{g_j,\ 0 \leq j \leq m-1\}$. The order of each of the operators B_j is denoted by m_j.

Evolution equations of parabolic type arise in the problems of heat transfer, chemical diffusions, and also in the study of Markov processes. The most general model describing such phenomenon is given by:

$$\begin{aligned} &\frac{\partial \phi}{\partial t} + A\phi = f, \qquad t, x \in I \times \Omega = Q \\ &B\phi = g, \qquad t, x \in I \times \partial\Omega \\ &\phi(0) = \phi_0, \qquad x \in \Omega \end{aligned} \tag{16}$$

where f, g, and ϕ_0 are the given data.

Second-order evolution equations of hyperbolic type describing many vibration and wave propagation problems have the general form:

$$\begin{aligned} \frac{\partial^2\phi}{\partial t^2} + A\phi &= f, \qquad t, x \in I \times \Omega \\ B\phi &= g, \qquad t, x \in I \times \Omega \\ \phi(0) &= \phi_0, \qquad x \in \Omega \\ \dot{\phi}(0) &= \phi_1, \end{aligned} \tag{17}$$

Schrödinger-type evolution equations are obtained if A is replaced by iA in Eq. (16).

In the study of existence of solutions of these problems, Garding's inequality is used for *a priori* estimates. If A is strongly uniformly elliptic, the principal coefficients satisfy Hölder conditions on Ω uniformly with respect to $t \in I$, and the other coefficients are bounded measurable, then one can prove the existence of a $\lambda \in \mathbb{R}$ and $\alpha > 0$ such that

$$a(t, \phi, \phi) + \lambda|\phi|_H^2 > \alpha\|\phi\|_V^2, \qquad t \in I \tag{18}$$

where

$$a(t, \phi, \psi) \equiv \sum_{|\alpha|,|\beta|\le m} \langle a_{\alpha,\beta}(t, \cdot) D^\beta\phi, D^\alpha\psi\rangle_\Omega \tag{19}$$

and V is any reflexive Banach space continuously and densely embedded in $H = L_2(\Omega)$ where $L_p(\Omega)$ is the equivalence classes of pth-power Lebesgue integrable functions on $\Omega \subset R^n$, with the norm given by:

$$\|f\|_{L_{p(\Omega)}} \equiv \begin{cases} \left(\int \Omega |f(x)|^p\, dx\right)^{1/p} & \text{for} \quad 1 \le p < \infty \\ \text{ess sup}\{f(x), x \in \Omega\} & \text{for} \quad p = \infty \end{cases}$$

For example, V could be $W_0^{m,p}$, $W^{m,p}$, or $W_0^{m,p} \subset V \subset W^{m,p}$ for $p \ge 2$ where $W_0^{m,p}(\Omega)$ is the closure of C^∞ functions with compact support on Ω in the topology of $W^{m,p}$, and

$$W^{m,p}(\Omega) \equiv \left\{ f \in L_p(\Omega) : D^\alpha f \in L_p(\Omega), \quad |\alpha| \le m \right\}$$

furnished with the norm topology:

$$\|f\|_{W^{m,p}} \equiv \sum_{|\alpha|\le m} \|D^\alpha f\|_{L_p(\Omega)}, \qquad p \ge 1$$

$$D^\alpha \equiv D_1^{\alpha_1} D_1^{\alpha_2} \cdots D_n^{\alpha_n}, \qquad D_i^{\alpha_i} \equiv \frac{\partial^{\alpha_i}}{\partial x_i^{\alpha_i}}$$

$$\|\alpha\| = \sum_{i=1}^n \alpha_i, \qquad \alpha_i \equiv \text{nonnegative integers}$$

C. Nonlinear Evolution Equations and Differential Inclusions

Nonlinear systems are more frequently encountered in practical problems than the linear ones. There is no clear-cut classification for these systems. We present here a few basic structures that seem to cover a broad area in the field.

1. Elliptic Systems

The class of elliptic problems which have received considerable attention in the literature is given by:

$$\begin{aligned} A\psi &= 0 \qquad \text{on} \quad \Omega \\ D^\alpha\psi &= 0 \qquad \text{on} \quad \partial\Omega, \qquad |\alpha| \le m - 1 \end{aligned} \tag{20}$$

where

$$A\psi \equiv \sum_{|\alpha|\le m} (-1)^{|\alpha|} D^\alpha(|D^\alpha\psi|^{p-2} D^\alpha\psi) + \sum_{|\beta|\le m-1} (-1)^{|\beta|} \times D^\beta\left(b_\beta(x, \psi, D^1\psi, \ldots, D^m\psi)\right) \tag{21}$$

2. Semilinear Systems

The class of nonlinear evolution equations that can be described in terms of a linear operator and a nonlinear operator containing lower order derivatives has been classified as semilinear. These systems have the form:

$$\begin{aligned} \frac{d\psi}{dt} + A(t)\psi + f(t, \psi) &= 0 \\ \psi(0) &= \psi_0 \end{aligned} \tag{22}$$

and

$$\begin{aligned} \frac{d^2\psi}{dt^2} + A(t)\psi + f(t, \psi) &= 0 \\ \psi(0) &= \psi_0, \\ \dot{\psi}(0) &= \psi_1 \end{aligned} \tag{23}$$

where $A(t)$ may be a differential operator of the form (11) and the nonlinear operator f may be given by:

$$f(t, \psi) \equiv \sum_{|\alpha|\le 2m-1} (-1)^{|\alpha|} D^\alpha \times \left(b_\alpha(t, \cdot; \psi, D^1\psi, \ldots, D^{2m-1}\psi)\right) \tag{24}$$

For example, a second-order semilinear parabolic equation is given by:

$$\frac{\partial\phi}{\partial t} + \sum_{i,J} a_{ij}(t, x)\phi_{x_i x_j} + a(t, x, \phi, \phi_x) = 0 \tag{25}$$

which certainly covers the ecological model, Eq. (10). In short, Eq. (22) is an abstract model for a wide variety of

nonlinear diffusions. It covers the Navier–Stokes equation (8) and many others including the first-order semilinear hyperbolic system:

$$\frac{\partial y}{\partial t} + \left(\sum_{i=1}^{n} A_i(t,x) \frac{\partial y}{\partial x_i} + B(t,x)y \right) + f(t,x,y) = 0 \tag{26}$$

The second-order abstract semilinear equation (23) covers a wide variety of nonlinear vibration and wave propagation problems.

3. Quasilinear Systems

The most general form of systems governed by quasilinear evolution equations that have been treated in the literature is given by:

$$\frac{d\psi}{dt} + A(t,\psi)\psi + f(t,\psi) = 0 \qquad \psi(0) = \psi_0 \tag{27}$$

It covers the quasilinear second-order parabolic equation or systems of the form:

$$\frac{\partial \psi}{\partial t} + \sum_{i,J}^{n} a_{ij}(t,x;\psi,\psi_x)\psi_{x_i x_j} + a(t,x,\psi,\psi_x) = 0 \tag{28}$$

where, for parabolicity, one requires that

$$a_{ij}(t,x,p,q)\xi_i\xi_j \geq \gamma|\xi|^2$$
$$\gamma > 0, \qquad t,x \in Q, \qquad p \in \mathbb{R}, \qquad q \in \mathbb{R}^n$$

It covers the quasilinear hyperbolic systems of the form:

$$A_0(t,x,y)\frac{\partial y}{\partial t} + \sum_{i}^{n} A_i(t,x,y)\frac{\partial y}{\partial x_i} + B(t,x,y) = 0 \tag{29}$$

including the magnetohydrodynamic equation (9).

4. Differential Inclusions

In recent years abstract differential inclusions have been used as models for controlled systems with discontinuities. For example, consider the abstract semilinear equation (22). In case the operator f, as a function of the state ψ, is discontinuous but otherwise well defined as a set-valued function in a suitable topological space, one may consider Eq. (22) as a differential inclusion:

$$-\dot{\psi}(t) \in A(t)\psi(t) + f(t,\psi(t)) \quad \text{a.e.} \qquad \psi(0) = \psi_0 \tag{30}$$

Such equations also arise from variational inequalities.

D. Stochastic Evolution Equations

In certain situations because of lack of precise knowledge of the system parameters arising from inexact observation or due to gaps in our fundamental understanding of the physical world, one may consider stochastic models to obtain most probable answers to many scientific questions. Such models may be described by stochastic evolution equations of the form:

$$d\psi = (A(t)\psi + f(t,\psi))\,dt + \sigma(t,\psi)\,dW \qquad \psi(0) = \psi_0 \tag{31}$$

where A is a differential operator possibly of the form (11), f is a nonlinear operator of the form (24), and σ is a suitable operator-valued function. The variable $W = \{W(t), t \geq 0\}$ represents a Wiener process with values in a suitable topological space and defined on a probability space. The uncertainty may arise from randomness of ψ_0, the process W, and even from the operators A, f, and σ. This is further discussed in Sections II and III.

II. LINEAR EVOLUTION EQUATIONS

In this section, we present some basic results from control theory for systems governed by linear evolution equations.

A. Existence of Solutions for Linear Evolution Equations and Semigroups

A substantial part of control theory for distributed parameter systems has been developed for first- and second-order evolution equations of parabolic and hyperbolic type of the form:

$$\frac{d\phi}{dt} + A(t)\phi = f, \qquad \phi(0) = \phi_0 \tag{32}$$

$$\frac{d^2\phi}{dt^2} + A(t)\phi = f, \qquad \phi(0) = \phi_0, \quad \dot{\phi}(0) = \phi_1 \tag{33}$$

A fundamental question that must be settled before a control problem can be considered is the question of existence of solutions of such equations.

We present existence theorems for problems (32) and (33) and conclude the section with a general result when the operator A is only a generator of a c_0-semigroup (in case of constant A) or merely the generator of an evolution operator in a Banach space (in case A is variable). The concepts of semigroups and evolution operators are introduced at a convenient place while dealing with the questions of existence.

For simplicity we consider time-invariant systems, although the result given below holds for the general case.

Theorem 1. Consider system (33) with the operator A time invariant and self-adjoint and suppose it satisfies the conditions:

(a1) $|\langle A\phi, \psi\rangle| \le c\|\phi\|_V\|\psi\|_V$

$c \ge 0, \qquad \phi, \psi \in V$

(a2) $\langle A\phi, \phi\rangle + \lambda|\phi|_H^2 \ge \alpha\|\phi\|_V^2$

$\lambda \in R, \qquad \alpha > 0, \qquad \phi \in V$

Then, for every $\phi_0 \in V$, $\phi_1 \in H$, and $f \in L_2(I, H)$, system (33) has a unique solution ϕ satisfying:

(c1) $\phi \in L_\infty(I, V) \cap C(\bar{I}, V)$

(c2) $\dot{\phi} \in L_\infty(I, V) \cap C(\bar{I}, H)$

and

(c3) $(\phi_0, \phi_1, f) \to (\phi, \dot{\phi})$

is a continuous mapping from $V \times H \times L_2(I, H)$ to $C(\bar{I}, V) \times C(\bar{I}, H)$.

Proof (*Outline*). The proof is based on Galerkin's approach which converts the infinite-dimensional system (33) into its finite-dimensional approximation, then by use of *a priori* estimates and compactness arguments one shows that the approximating sequence has a subsequence that converges to the solution of problem (33). □

Note that the second-order evolution equation (33) can be written as a first-order equation $d\psi/dt + \tilde{A}\psi = \tilde{f}$ where

$$\psi = \begin{bmatrix} \phi \\ \dot{\phi} \end{bmatrix}, \qquad \tilde{A} = \begin{bmatrix} 0 & -I \\ A & 0 \end{bmatrix}$$
$$\tilde{f} = \begin{bmatrix} 0 \\ f \end{bmatrix} \tag{34}$$

Defining $X = V \times H$, with the product topology, as the state space, it follows from Theorem 1(c3) that there exists an operator-valued function $S(t)$, $t \ge 0$, with values $S(t) \in \mathcal{L}(X)$ so that

$$\psi(t) = S(t)\psi_0 + \int_0^t S(t-\theta)\tilde{f}(\theta)\, d\theta \tag{35}$$

The family of operators $\{S(t), t \ge 0\}$ forms a c_0-semigroup in X and $\psi \in C(\bar{I}, X)$ where $C(I, X)$ is the space of continuous functions on I with values in the Banach space X with the norm (topology):

$$\|f\| = \sup\{|f(t)|_X, t \in I\}$$

For system (32) one can prove the following result using the same procedure.

Theorem 2. Consider system (32) and suppose that the operator A satisfies assumptions (a1) and (a2) (see Theorem 1). Then, for each $\phi_0 \in H$ and $f \in L_2(I, V^*)$, system (32) has a unique solution:

$$\phi \in L_2(I, V) \cap L_\infty(I, H) \cap C(\bar{I}, H)$$

and further

$$(\phi_0, f) \to \phi$$

is a continuous map from $H \times L_2(I, V^*)$ to $C(\bar{I}, H)$.

As a consequence of this result there exists an evolution operator $U(t, s)$, $0 \le s \le t \le \infty$, with values $U(t, s) \in \mathcal{L}(H)$ such that

$$\phi(t) = U(t, 0)\phi_0 + \int_0^t U(t, \theta) f(\theta)\, d\theta \tag{36}$$

is a (mild) weak solution of problem (32).

We conclude this section with some results on the question of existence of solutions for a class of general time-invariant linear systems on Banach space.

Let X be a Banach space, and $S(t)$, $t \ge 0$, a family of bounded linear operators from X to X satisfying the properties:

(a) $S(0) = I$ (identity operator)

(b) $S(t + \tau) = S(t)S(\tau), \qquad t, \tau \ge 0$ (37)

(c) Strong $\lim_{t \downarrow 0^+} S(t)\xi = \xi \in X$

The operator $S(t)$, $t \ge 0$, satisfying the above properties is called a *strongly continuous semigroup* or, in short, a c_0-semigroup. Let A be a closed, densely defined linear operator with domain $D(A) \subset X$ and range $R(A) \subset X$. Suppose there exist numbers $M > 0$ and $\omega \in R$ such that

$$\|(\lambda I - A)^{-1}\|_X \le M/(\lambda - \omega)$$

for all real $\lambda > \omega$. Then, by a fundamental theorem from the semigroup theory known as the Hille–Yosida theorem, there exists a unique c_0-semigroup $S(t)$, $t \ge 0$, with A as its infinitesimal generator. The semigroup $S(t)$, $t \ge 0$, satisfies the properties:

(a) $\|S(t)\|_{\mathcal{L}(X)} \le Me^{\omega t}, \qquad t \ge 0$

(b) for $\xi \in D(A)$

$S(t)\xi \in D(A)$ for all $t \ge 0$ (38)

(c) for $\xi \in D(A)$

$$\frac{d}{dt}S(t)\xi = AS(t)\xi = S(t)A\xi, \qquad t \ge 0$$

If $\omega = 0$, we have a *bounded semigroup*; for $\omega = 0$ and $M = 1$ we have a *contraction semigroup*, and for $\omega < 0$, we have a *dissipative semigroup*. In general, the abstract Cauchy problem:

$$\frac{dy}{dt} = Ay, \qquad y(0) = \xi \tag{39}$$

has a unique solution $y(t) = S(t)\xi$, $t > 0$, with $y(t) \in D(A)$, provided $\xi \in D(A)$. If $\xi \in D(A)$ and f is any strongly continuously differentiable function with values $f(t) \in X$, then the inhomogeneous problem,

$$\frac{dy}{dt} = Ay + f, \qquad y(0) = \xi \tag{40}$$

has a unique continuously differentiable solution y given by:

$$y(t) = S(t)\xi + \int_0^t S(t-\theta) f(\theta)\, d\theta$$
$$\text{with} \quad y(t) \in D(A) \qquad \text{for all} \quad t \geq 0 \tag{41}$$

A solution satisfying these conditions is called a *classical solution*. For control problems these conditions are rather too strong since, in general, we do not expect the controls, for example $f(t)$, to be even continuous. Thus, there is a need for a broader definition and this is provided by the so-called mild solution.

Any function $y\colon I \to X$ having the integral representation (41) is called a mild solution of problem (40). In this regard we have the following general result.

Theorem 3. Suppose A is the generator of a c_0-semigroup $S(t), t \geq 0$, in X and let $y_0 \in X$ and $f \in L_p(I, X)$, $1 \leq p \leq \infty$, where $L_p(I, X)$ is the space of strongly measurable functions on I taking values in a Banach space X with norm:

$$\| f \|_{L_p(I,X)} = \begin{cases} \left(\int_I | f(t)|_X^p \, dt \right)^{1/p}, & 1 \leq p < \infty \\ \text{ess sup } \{| f(t)|_X, t \in I\}, & p = \infty \end{cases}$$

Then, evolution Eq. (40) has a unique mild solution y given by:

$$y(t) = S(t)y_0 + \int_0^t S(t-\theta) f(\theta)\, d\theta \tag{42}$$

In this case $y(t)$ does not necessarily belong to $D(A)$. Another special but important class of strongly continuous semigroups $S(t)$, $t \geq 0$, that satisfies the property:

$$S(t)X \subset D(A) \qquad \text{for all} \quad t > 0$$

is called the *analytic* (holomorphic, parabolic) *semigroup*. An analytic semigroup has the following properties:

(a) $S(t)X \subset D(A^n)$ for all integers $n \geq 0$ and $t > 0$,

(b) $S(t), d^n S(t)/dt^n = A^n S(t)$ are all bounded operators for $t > 0$.

One reason for calling the analytic semigroups parabolic semigroups is that $S(t)$, $t \geq 0$, turns out to be the fundamental solution of certain parabolic evolution equations. Consider the differential operator,

$$L(x, D) = \sum_{|\alpha| \leq 2m} a_\alpha(x) D^\alpha$$

and suppose it is strongly elliptic of order $2m$ and

$$B_j(x, D) = \sum_{|\alpha| \leq m_j} b_{j,\alpha} D^\alpha, \qquad 0 \leq j \leq m-1$$

is a set of normal boundary operators as defined earlier. Define

$$D(A) = W^{2m,p}(\Omega) \cap W_0^{m,p}(\Omega)$$
$$(A\phi)(x) = -L(x, D)\phi(x), \qquad \phi \in D(A) \tag{43}$$

Then, under certain technical assumptions, A generates an analytic semigroup $S(t)$, $t \geq 0$, in the Banach space $X = L_p(\Omega)$. The initial boundary value problem,

$$\frac{\partial \phi}{\partial t}(t, x) + L(x, D)\phi(t, x) = f(t, x)$$
$$t \in (0, T), \qquad x \in \Omega$$
$$(D^\alpha \phi)(t, x) = 0 \tag{44}$$
$$|\alpha| \leq m-1, \qquad t \in (0, T), \qquad x \in \partial\Omega$$
$$\phi(0, x) = \phi_0(x), \qquad x \in \Omega$$

can be considered to be an abstract evolution equation in $X = L_p(\Omega)$ and be written as:

$$\frac{d\phi}{dt} = A\phi + f$$
$$\phi(0) = \phi_0$$

with mild solution given by:

$$\phi(t) = S(t)\phi_0 + \int_0^t S(t-\theta) f(\theta)\, d\theta \tag{45}$$

where $f \in L_p(I, X)$.

B. Stability

The question of stability is of signnificant interest to system scientists, since every physical system must be stable to function properly.

In this section, we present a Lyapunov-like result for the abstract evolution equation,

$$\frac{dy}{dt} = Ay \tag{46}$$

where A is the generator of a strongly continuous semigroup $S(t)$, $t \geq 0$ on H. Let $\mathscr{L}^+(H)$ denote the class of symmetric, positive, self-adjoint operators in H; that is,

$T \in \mathcal{L}(H)$, $T = T^*$, and $(T\xi, \xi) > 0$ for $\xi\ (\neq 0) \in H$. We can prove the following result.

Theorem 4. A necessary and sufficient condition for the system $dy/dt = Ay$ to be exponentially stable in the Lyapunov sense (i.e., there exist $M \geq 1$, $\beta > 0$ such that $\|y(t)\| \leq Me^{-\beta t}$) is that the operator equation,

$$A^*Y + YA = -\Gamma \tag{47}$$

has a solution $Y \in \mathcal{L}^+(H)$ for each $\Gamma \in \mathcal{L}^+(H)$ with $(\Gamma\xi, \xi) \geq \gamma|\xi|_H^2$ for some $\gamma > 0$.

REMARK. Equation (47) is understood in the sense that the equality,

$$0 = (\Gamma\xi, \eta) + (A\xi, Y\eta) + (Y\xi, A\eta)$$

holds for all $\xi,\ \eta \in D(A)$.

Corollary 5. If the autonomous system (46) is asymptotically stable, then the system,

$$\frac{dy}{dt} = Ay + f, \qquad t \geq 0 \tag{48}$$

is stable in the L_p sense; that is, for every $y_0 \in H$ and input $f \in L_p(0, \infty; H)$, the output $y \in L_p(0, \infty; H)$ for all $1 \leq p \leq \infty$ and in particular, for $1 \leq p < \infty$, $y(t) \to 0$ as $t \to \infty$.

We conclude this section with a remark on the solvability of Eq. (47). Let $\{\lambda_i\}$ be the eigenvalues of the operator A, each repeated as many times as its multiplicity requires, and let $\{\xi_i\}$ denote the corresponding eigenvectors complete in H. Consider Eq. (47) and form

$$\left(A^*Y\xi_i, \xi_j\right) + (YA\xi_i, \xi_j) = -(\Gamma\xi_i, \xi_j) \tag{49}$$

for all integers $i,\ j \geq 1$. Clearly, from this equation, it follows that

$$(Y\xi_i, \xi_j) = -(\Gamma\xi_i, \xi_j)/(\lambda_i + \bar{\lambda}_j) \tag{50}$$

Hence, if $\lambda_i + \bar{\lambda}_j \neq 0$ for all i, j, Γ determines Y uniquely, and if $\lambda_i + \bar{\lambda}_j = \text{Re}\ \lambda_i < 0$ for all i, then $Y \in \mathcal{L}^+(H)$. In other words, if system (46) is asymptotically stable then the operator equation (47) always has a positive solution.

C. System Identification

A system analyst may know the structure of the system—for example, the order of the differential operator and its type (parabolic, hyperbolic, etc.)—but the parameters are not all known. In that case, the analyst must identify the unknown parameters from available information. Consider the natural system to be given by $\dot{y}^* = A(q^*)y^*$. Assume that q^* is unknown to the observer but the observer can observe certain data z^* from a Hilbert space K, the output space, which corresponds to the natural history y^*. The observer chooses a feasible set Q, where q^* may possibly lie, and constructs the model system,

$$\begin{aligned} \dot{y}(q) &= A(q)y(q), \qquad y(q)(0) = y_0 \\ z(q) &= Cy(q) \end{aligned} \tag{51}$$

where C is the observation or output operator, an element of $\mathcal{L}(H, K)$. The analyst may choose to identify the parameter approximately by minimizing the functionl,

$$J(q) = \frac{1}{2}\int_0^T |z(q) - z^*|_K^2\, dt \qquad \text{over } Q \tag{52}$$

Similarly, one may consider identification of an operator appearing in system equations. For example, one may consider the system,

$$\begin{aligned} &\frac{d^2y}{dt^2} + Ay + B^*y = f \\ &y(0) = y_0, \qquad \dot{y}(0) = y_1 \\ &z = Cy \end{aligned} \tag{53}$$

where the operator A is known but the operator B^* is unknown. One seeks an element B from a feasible set $P^0 \subset \mathcal{L}(V, V^*)$ so that

$$J(B) = \int_0^T g(t, y(B), \dot{y}(B))\, dt \tag{54}$$

is minimum, where g is a suitable measure of discrepancy between the model output, $z(B) = Cy(B)$, and the observed data z^* corresponds to the natural history y^*.

In general, one may consider the problem of identification of all the operators A, B including the data y_0, y_1, and f. For simplicity, we shall consider only the first two problems and present a couple sample results. First, consider problem (51) and (52).

Theorem 6. Let the feasible set of parameters Q be a compact subset of a metric space and suppose for each $q \in Q$ that $A(q)$ is the generator of a strongly continuous contraction semigroup in H. Let

$$(\gamma I - A(q_n))^{-1} \to (\gamma I - A(q_0))^{-1} \tag{55}$$

in the strong operator topology for each $\gamma > 0$ whenever $q_n \to q_0$ in Q. Then there exists $q^0 \in Q$ at which $J(q)$ attains its minimum.

Proof. The proof follows from the fact that under assumption (55) the semigroup $S_n(t)$, $t \geq 0$, corresponding to q_n strongly converges on compact intervals to the semigroup $S_0(t)$, $t \geq 0$, corresponding to q_0. Therefore, J is continuous on Q and, Q being compact, it attains its minimum on Q. □

The significance of the above result is that the identification problem is well posed.

For the second-order evolution equation (53) we have the following result.

Theorem 7. Consider system (53). Let P^0 be a compact (in the sense of strong operator topology) subset of the ball,

$$P_b \equiv \left\{B \in \mathcal{L}(V, V^*): \|B\|_{\mathcal{L}(V,V^*)} \leq b\right\}$$

Then, for each g defined on $I \times V \times H$ which is measurable in the first variable and lower semi continuous in the rest, the functional $J(B)$ of Eq. (54) attains its minimum on P^0.

The best operator B^0 minimizing the functional $J(B)$ can be determined by use of the following necessary conditions of optimality.

Theorem 8. Consider system (53) along with the functional,

$$J(B) \equiv \frac{1}{2}\int_0^T |Cy(B) - z^*(t)|_K^2 \, dt$$

with the observed data $z^* \in L_2(I, K)$, the observer $C \in \mathcal{L}(H, K)$, $f \in L_2(I, H)$, $y_0 \in V$, $y_1 \in H$ and P^0 as in Theorem 7. Then, for B^0 to be optimal, it is necessary that there exists a pair $\{y, x\}$ satisfying the equations,

$$\begin{aligned} &\ddot{y} + Ay + B^0 y = f \\ &\ddot{x} + A^*x + (B^0)^*x = C^*\Lambda_K(Cy(B^0) - z^*) \\ &y(0) = y_0, \qquad x(T) = 0 \\ &\dot{y}(0) = y_1, \qquad \dot{x}(T) = 0 \end{aligned} \tag{56}$$

and the inequality

$$\int_0^T \langle B^0 y(B^0), x\rangle_{V^*,V} \, dt \geq \int_0^T \langle By(B^0), x\rangle_{V^*,V} \, dt \tag{57}$$

for all $B \in P^0$, where Λ_K is the canonical isomorphism of K onto K^* such that $\|\Lambda_K e\|_{K^*} = \|e\|_K$.

By solving Eqs. (56) and (57) simultaneously one can determine B^0. In fact, a gradient-type algorithm can be developed on the basis of Eqs. (56) and (57).

D. Controllability

Consider the controlled system,

$$\dot{\phi} = A\phi + Bu, \qquad t \geq 0 \tag{58}$$

with ϕ denoting the state and u the control. The operator A is the generator of a strongly continuous semigroup $S(t)$, $t \geq 0$, in a Banach space X and B is the control operator with values in $\mathcal{L}(E, X)$ where E is another Banach space. Let $\mathcal{U}$ denote the class of admissible controls, possibly a proper subset of $L_p^{\text{loc}}(E) \equiv$ locally pth power summable E-valued functions on $\mathbb{R}_0 = [0, \infty)$. For a given initial state $\phi_0 \in \mathcal{U}$,

$$\phi(t) = S(t)\phi_0 + \int_0^t S(t-\theta)Bu(\theta)\, d\theta, \qquad t \geq 0$$

denotes the mild (weak) solution of problem (58).

Given $\phi_0 \in X$ and a desired target $\phi_1 \in X$, is it possible to find a control from $\mathcal{U}$ that transfers the system from state ϕ_0 to the desired state ϕ_1 in finite time? This is the basic question of controllability. In other words, for a given $\phi_0 \in X$, one defines the attainable set:

$$\mathcal{A}(t) \equiv \left\{x \in X: x = S(t)\phi_0 + \int_0^t S(t-\theta)Bu(\theta)\, d\theta, \; u \in \mathcal{U}\right\}$$

and inquires if there exists a finite time $\tau \geq 0$, such that $\phi_1 \in \mathcal{A}(\tau)$ or equivalently,

$$\phi_1 - S(\tau)\phi_0 \in R(\tau) \equiv \mathcal{A}(\tau) - S(\tau)\phi_0$$

The set $\mathcal{R}(\tau)$, given by:

$$\mathcal{R}(\tau) \equiv \left\{\xi \in X: \xi = L_\tau u \equiv \int_0^\tau S(\tau-\theta)Bu(\theta)\, d\theta, \; u \in \mathcal{U}\right\}$$

is called the *reachable set*. If $S(t)B$ is a compact operator for each $t \geq 0$, then $\mathcal{R}(\tau)$ is compact, hence the given target may not be attainable. A similar situation arises if $BE \subset D(A)$ and $\phi_0 \in D(A)$ and $\phi_1 \notin D(A)$. As a result, an appropriate definition of controllability for ∞-dimensional systems may be formulated as follows.

Definition. System (58) is said to be controllable (exactly controllable) in the time interval $[0, \tau]$ if $R(\tau)$ is dense in $X[\mathcal{R}(\tau) = X]$ and it is said to be controllable (exactly controllable) in finite time if $\cup_{\tau>0} R(\tau)$ is dense in $X[\cup_{\tau>0} R(\tau) = X]$. Note that for finite-dimensional systems, $X = R^n$, $E = R^m$, and controllability and exact controllability are all and the same. It is only for ∞-dimensional systems that these concepts are different.

We present here a classical result assuming that both X and E are self-adjoint Hilbert spaces with $\mathcal{U} = L_2^{\text{loc}}(E)$.

Theorem 9. For system (58) the following statements are equivalent:

(a) System (58) is controllable in time τ

(b) $\left(L_\tau L_\tau^*\right) \in \mathcal{L}^+(X)$

(c) $\text{Ker } L_\tau^* \equiv \left\{\xi \in X: L_\tau^*\xi = 0\right\} = \{0\}$

where L_τ^* is the adjoint of the operator L_τ and $L_\tau u \equiv \int_0^\tau S(\tau-\theta)\,Bu(\theta)\,d\theta$.

Note that by our definition, here controllability means approximate controllability; that is, one can reach an arbitrary neighborhood of the target but never exactly at the target itself. Another interesting difference between finite- and infinite-dimensional systems is that in case $X = R^n$, $E = R^m$, condition (b) implies that $(L_\tau L_\tau^*)^{-1}$ exists and the control achieving the desired transfer from ϕ_0 to ϕ_1 is given by:

$$u = \left(L_\tau L_\tau^*\right)^{-1}(\phi_1 - S(\tau)\phi_0)$$

For ∞-dimensional systems, the operator $(L_\tau L_\tau^*)$ does not in general have a bounded inverse even though the operator is positive.

Another distinguishing feature is that in the finite-dimensional case the system is controllable if and only if the rank condition,

$$\operatorname{rank}(B, AB, \ldots, A^{n-1}B) = n$$

holds. In the ∞-dimensional case there is no such condition; however, if $BE \subset \bigcap_{n=1}^\infty D(A^n)$ then the system is controllable if

$$\text{closure}\left\{\bigcup_{n=0}^{\infty} \text{range}(A^n B)\right\} = X \tag{59}$$

This condition is also necessary and sufficient if $S(t)$, $t \geq 0$, is an analytic semigroup and $BE \subset \bigcup_{t>0} S(t)X$.

In recent years, much more general results that admit very general time-varying operators $\{A(t),\ B(t),\ t \geq 0\}$, including hard constraints on controls, have been proved. We conclude this section with one such result. The system,

$$\begin{aligned} \dot{y} &= A(t)y + B(t)u, \qquad t \geq 0 \\ y(0) &= y_0 \end{aligned} \tag{60}$$

is said to be globally null controllable if it can be steered to the origin from any initial state $y_0 \in X$.

Theorem 10. Let X be a reflexive Banach space and Y a Banach space densely embedded in X with the injection $Y \subset X$ continuous. For each $t \geq 0$, $A(t)$ is the generator of a c_0-semigroup satisfying the stability condition and $A \in L_1^{\text{loc}}(0, \infty; \mathcal{L}(Y, X))$ where $\mathcal{L}(X, Z)$ is the space of bounded linear operators from a Banach space X to a Banach space Z; $\mathcal{L}(X) \equiv \mathcal{L}(X, X)$, $B \in L_q^{\text{loc}}(0, \infty; \mathcal{L}(E, X))$, and $\mathcal{U} = \{u \in L_p^{\text{loc}}(E);\ u(t) \in \Gamma \text{ a.e.}\}$ where Γ is a closed bounded convex subset of E with $o \in \Gamma$ and $p^{-1} + q^{-1} = 1$. Then a necessary and sufficient condition for global null controllability of system (60) is that

$$\int_0^\infty H_\Gamma(B^*(t)\psi(t))\,dt = +\infty \tag{61}$$

for all nontrivial weak solutions of the adjoint system

$$\dot{\psi} + A^*(t)\psi = 0, \qquad t \geq 0$$

where $H_\Gamma(\xi) = \sup\{(\xi, e)_{E^*,E},\ e \in \Gamma\}$.

E. Existence of Optimal Controls

The question of existence of optimal controls is considered to be a fundamental problem in control theory. In this section, we present a simple existence result for the hyperbolic system,

$$\begin{aligned} \ddot{\phi} + A\phi &= f + Bu, \qquad t \in I \equiv (0, T) \\ \phi(0) &= \phi_0, \qquad \dot{\phi}(0) = \phi_1 \end{aligned} \tag{62}$$

Similar results hold for parabolic systems. Suppose the operator A and the data ϕ_0, ϕ_1, f satisfy the assumptions of Theorem 1. Let E be a real Hilbert space and $\mathcal{U}_0 \subset L_2(I, E)$ the class of admissible controls and $B \in \mathcal{L}(E, H)$. Let $S_0 \subset V$ and $S_1 \subset H$ denote the set of admissible initial states. By Theorem 1, for each choice of $\phi_0 \in S_0$, $\phi_1 \in S_1$, and $u \in \mathcal{U}_0$ there corresponds a unique solution ϕ called the *response*. The quality of the response is measured through a functional called the *cost functional* and may be given by an expression of the form,

$$\begin{aligned} J(\phi_0, \phi_1, u) \equiv \alpha \int_0^T g_1(t, \phi(t), \dot{\phi}(t))\,dt \\ + \beta g_2(\phi(T), \dot{\phi}(T)) + \lambda g_3(u) \end{aligned} \tag{63}$$

$\alpha + \beta > 0$; $\alpha, \beta, \gamma \geq 0$, where g_1, g_2, and g_3 are suitable functions to be defined shortly. One may interpret g_1 to be a measure of discrepancy between a desired response and the one arising from the given policy $\{\phi_0, \phi_1, u\}$. The function g_2 is a measure of distance between a desired target and the one actually realized. The function g_3 is a measure of the cost of control applied to system (62). A more concrete expression for J will be given in the following section. Let $P \equiv S_0 \times S_1 \times \mathcal{U}_0$ denote the set of admissible policies or controls. The question is, does there exist a policy $p^0 \in P$ such that $J(p^0) \leq J(p)$ for all $p \in P$? An element $p^0 \in P$ satisfying this property is called an *optimal policy*. A set of sufficient conditions for the existence of an optimal policy is given in the following result.

Theorem 11. Consider system (62) with the cost functional (63) and let S_0, S_1, and $\mathcal{U}_0$ be closed bounded convex subsets of V, H, and $L_2(I, E)$, respectively. Suppose for each $(\xi, \eta) \in V \times H$, $t \to g_1(t, \xi, \eta)$ is measurable on I and, for each $t \in I$, the functions $(\xi, \eta) \to g_1(t, \xi, \eta)$ and $(\xi, \eta) \to g_2(\xi, \eta)$ are weakly lower semicontinuous on $V \times H$ and the function g_3 is weakly lower

semicontinuous on $L_2(I, E)$. Then, there exists an optimal policy,

$$p^0 = \left(\phi_0^0, \phi_1^0, u^0\right) \in P$$

Another problem of considerable interest is the question of existence of time-optimal controls. Consider system (33) in the form (34) with

$$f = Bu, \qquad \tilde{f} = \begin{pmatrix} 0 \\ Bu \end{pmatrix}$$

and solution given by:

$$\psi(t) = S(t)\psi_0 + \int_0^t S(t-\theta)\tilde{f}(\theta)\, d\theta \qquad (35')$$

where $S(t)$, $t \geq 0$, is the c_0-semigroup in $X \equiv V \times H$ with the generator $-\tilde{A}$ as given Eq. (34). Here, one is given the initial and the desired final states ψ_0, $\psi_1 \in X$ and the set of admissible controls $\mathcal{U}_0$. Given that the system is controllable from state ψ_0 to ψ_1 in finite time, the question is, does there exist a control that does the transfer in minimum time? A control satisfying this property is called a *time-optimal control*. We now present a result of this kind.

Theorem 12. If $\mathcal{U}_0$ is a closed bounded convex subset of $L_2(I, E)$ and if systems (34) and (35′) are exactly controllable from the state ψ_0 to $\psi_1 \in X$, then there exists a time-optimal control.

Proof. Let $\psi(u)$ denote the response of the system corresponding to control $u \in \mathcal{U}_0$; that is,

$$\psi(u)(t) = S(t)\psi_0 + \int_0^t S(t-\theta)\begin{pmatrix} 0 \\ Bu(\theta) \end{pmatrix} d\theta$$

Let $\mathcal{U}_{00} \subset \mathcal{U}_0$ denote the set of all controls that transfer the system from state ψ_0 to state ψ_1 in finite time. Define

$$\mathcal{I} = \{t \geq 0 : \psi(u)(0) = \psi_0,\ \psi(u)(t) = \psi_1, u \in \mathcal{U}_{00}\}$$

and $\tau^* = \inf\{t \geq 0 : t \in \mathcal{I}\}$. We show that there exists a control $u^* \in \mathcal{U}_{00}$ having the transition time τ^*. Let $\{\tau_n\} \in \mathcal{I}$ such that τ_n is nonincreasing and $\tau_n \to \tau^*$. Since $\tau_n \in \mathcal{I}$ there exists a sequence $u_n \in \mathcal{U}_{00} \subset \mathcal{U}_0$ such that $\psi(u_n)(0) = \psi_0$ and $\psi(u_n)(\tau_n) = \psi_1$. Denote by f_n the element $\binom{0}{B}u_n$. By virtue of our assumption, $\mathcal{U}_0$ is weakly compact, B is bounded, and there exists a subsequence of the sequence $\{f_n\}$ relabeled as $\{f_n\}$ and

$$f^* = \begin{pmatrix} 0 \\ Bu^* \end{pmatrix} \in L_2(I, X)$$

with $u^* \in \mathcal{U}_0$ such that $f_n \to f^*$ weakly in $L_2(I, X)$. We must show that $u^* \in \mathcal{U}_{00}$. Clearly, by definition of $\{\tau_n\}$ we have

$$\psi_1 = \psi(u_n)(\tau_n) \equiv S(\tau_n)\psi_0 + \int_0^{\tau_n} S(\tau_n - \theta) f_n(\theta)\, d\theta \qquad \text{for all} \quad n$$

Let $x^* \in X^* \equiv V^* \times H$, where X^* is the dual of the Banach space X which is the space of continuous linear functionals on X; for example,

$$X = L_p, \qquad 1 \leq p < \infty$$
$$X^* = L_q \qquad \text{with} \quad p^{-1} + q^{-1} = 1$$

Then,

$$x^*(\psi_1) = x^*(S(\tau_n)\phi_0) + x^*\left(\int_0^{\tau_n} S(\tau_n - \theta) f_n(\theta)\, d\theta\right) \qquad (64)$$

By virtue of the c_0-property of the semigroup $S(t)$, $t \geq 0$,

$$\lim_{n\to\infty} x^*(S(\tau_n)\psi_0) = x^*\left(S(\tau^*)\psi_0\right) \qquad (65)$$

Splitting the integral in Eq. (64) into two parts, we have

$$\begin{aligned} &x^*\left(\int_0^{\tau_n} S(\tau_n - \theta) f_n(\theta)\, d\theta\right) \\ &\quad = x^*\left(\int_0^{\tau^*} S\left(\tau_n - \tau^*\right) S(\tau^* - \theta) f_n(\theta)\, d\theta\right) \\ &\qquad + x^*\left(\int_{\tau^*}^{\tau_n} S(\tau_n - \theta) f_n(\theta)\, d\theta\right) \\ &\quad = \left\langle \int_0^{\tau^*} S(\tau^* - \theta) f_n(\theta)\, d\theta,\ S^*\left(\tau_n - \tau^*\right)x^* \right\rangle_{X, X^*} \\ &\qquad + x^*\left(\int_{\tau^*}^{\tau_n} S(\tau_n - \theta) f_n(\theta)\, d\theta\right) \end{aligned}$$

where S^* is the dual of the operator S. $\mathcal{L}_u(X, Y)$ is the space of unbounded linear operators from X into Y. Let $\{x^*, y^*\} \in X^* \times Y^*$ be the set of all pairs for which

$$\langle y^*, Sx\rangle_{Y^*, Y} = \langle x^*, x\rangle_{X^*, X}$$

for all $x \in D(S) \subset X$ where

$$x^*(x) = \langle x^*, x\rangle_{X^*, X} = \langle x, x^*\rangle_{X, X^*}$$

is the duality pairing between the elements $x \in X$ and $x^* \in X^*$ or the value of x^* at x. If $D(S)$ is dense in X (i.e., closure of $D(S) = X$), then the above relation determines uniquely the dual S^* of S and its domain $D(S^*) \subset Y^*$. If $D(S) = X$, then $S \in \mathcal{L}(X, Y)$ and $S^* \in \mathcal{L}(Y^*, X^*)$. Clearly,

$$\begin{aligned} &\int_0^{\tau^*} S(\tau^* - \theta) f_n(\theta)\, d\theta \\ &\qquad \xrightarrow{w} \int_0^{\tau^*} S(\tau^* - \theta) f^*(\theta)\, d\theta \qquad \text{in } X \end{aligned} \qquad (66)$$

and since V and hence V^* are all reflexive Banach spaces S^* is a c_0-semigroup in X^* and consequently

$$S^*\left(\tau_n - \tau^*\right)x^* \xrightarrow{s} x^* \qquad \text{in } X^* \qquad (67)$$

Further, by the c_0-property of $S(t)$, $t \geq 0$ there exists a finite $M > 0$ such that

$$\left| x^*\left(\int_{\tau^*}^{\tau_n} S(\tau_n - \theta) f_n(\theta)\, d\theta \right) \right|$$

$$\leq M \|x^*\|_{X^*} \left(\int_{\tau^*}^{\tau_n} \| f_n(\theta)\|_X^2\, d\theta \right)^{1/2} \left(\tau_n - r^*\right)^{1/2} \quad (68)$$

Since $\mathcal{U}_0$ is bounded, it follows from this that

$$\lim_{n\to\infty} x^*\left(\int_{\tau^*}^{\tau_n} S(\tau_n - \theta) f_n(\theta)\, d\theta \right) = 0$$

Using Eqs. (65) to (67) in (64) we obtain:

$$x^*(\psi_1) = x^*\big(S(\tau^*)\psi_0\big) + x^*\left(\int_0^{\tau^*} S(\tau^* - \theta) f^*(\theta)\, d\theta \right)$$

for all $x^* \in X^*$. Hence,

$$\psi_1 = S(\tau^*)\psi_0 + \int_0^{\tau *} S(\tau^* - \theta) f^*(\theta)\, d\theta$$

and $u^* \in \mathcal{U}_{00}$. This completes the proof. □

The method of proof of the existence of time-optimal controls presented above applies to much more general systems.

F. Necessary Conditions of Optimality

After the questions of controllability and existence of optimal controls are settled affirmatively, one is faced with the problem of determining the optimal controls. For this purpose, one develops certain necessary conditions of optimality and constructs a suitable algorithm for computing the optimal (extremal) controls. We present here necessary conditions of optimality for system (62) with a quadratic cost functional of the form,

$$\begin{aligned} J(u) \equiv \alpha \int_0^T (C\phi(t) - z_1(t), C\phi(t) - z_1(t))_{H_1}\, dt \\ + \beta \int_0^T (D\dot{\phi}(t) - z_2(t), D\dot{\phi}(t) - z_2(t))_{H_2}\, dt \\ + \gamma \int_0^T (N(t)u, u)_E\, dt \end{aligned} \quad (69)$$

where $\alpha, \beta, \gamma > 0$. The output spaces, where observations are made, are given by two suitable Hilbert spaces H_1 and H_2 with output operators $C \in \mathcal{L}(H, H_1)$ and $D \in \mathcal{L}(H, H_2)$. The desired trajectories are given by $z_1 \in L_2(I, H_1)$ and $z_2 \in L_2(I, H_2)$. The last integral in Eq. (69) gives a measure of the cost of control with $N(t) \geq \delta I$ for all $t \in I$, with $\delta > 0$. We assume that $N(t) = N^*(t)$, $t \geq 0$. Our problem is to find the necessary and sufficient conditions an optimal control must satisfy. By Theorem 11, we know that, for the cost functional (69) subject to the dynamic constraint (62), an optimal control exists. Since in this case J is strictly convex, there is, in fact, a unique optimal control. For characterization of optimal controls, the concept of Gateaux differentials plays a central role. A real-valued functional f defined on a Banach space X is said to be Gateaux differentiable at the point $x \in X$ in the direction $h \in X$ if

$$\lim_{\varepsilon\to 0} \left\{ \frac{f(x + \varepsilon h) - f(x)}{\varepsilon} \right\} = f'(x, h) \quad (70)$$

exists. In general, $h \to f'(x, h)$ is a homogeneous functional, and, in case it is linear in h, we write:

$$f'(x, h) = (f'(x), h)_{X^*, X} \quad (71)$$

with the Gateaux derivative $f'(x) \in X^*$. Since the functional J, defined on the Hilbert space $L_2(I, E)$, is Gateaux differentiable and strictly convex, and the set of admissible controls $\mathcal{U}_0$ is a closed convex subset of $L_2(I, E)$, a control $u^0 \in \mathcal{U}_0$ is optimal if and only if

$$(J'(u^0), u - u^0) \geq 0 \qquad \text{for all} \quad u \in \mathcal{U}_0 \quad (72)$$

Using this inequality, we can develop the necessary conditions of optimality.

Theorem 13. Consider system (62) with the cost functional (69) and $\mathcal{U}_0$, a closed bounded convex subset of $L_2(I, E)$. For $u^0 \in \mathcal{U}_0$ to be optimal, it is necessary that there exists a pair

$$\{\phi^0, \psi^0\} \in C(\bar{I}, V) \times C(\bar{I}, V)$$

with

$$\{\dot{\phi}^0, \dot{\psi}^0\} \in C(\bar{I}, H) \times C(\bar{I}, H)$$

satisfying the equations:

$$\begin{aligned} \ddot{\phi}^0 + A\phi^0 &= f + Bu^0 \\ \phi^0(0) &= \phi_0, \\ \dot{\phi}^0(0) &= \phi_1 \end{aligned} \quad (73a)$$

$$\begin{aligned} &\ddot{\psi}^0 + A^*\psi^0 + \int_t^T g_1\, d\theta + g_2 = 0 \\ &\psi^0(T) = 0, \qquad \dot{\psi}^0(T) = 0 \\ &g_1 = 2\alpha C^* \Lambda_1 \big(C\phi^0 - z_1\big) \\ &g_2 = 2\beta D^* \Lambda_2 \big(D\dot{\phi}^0 - z_2\big) \end{aligned} \quad (73b)$$

and the inequality

$$\int_0^T \left(u - u^0, 2\gamma N u^0 + \Lambda_E^{-1} B^* \dot{\psi}^0\right)_E dt \geq 0 \qquad (74)$$

for all $u \in \mathcal{U}_0$.

Proof. By taking the Gateaux differential of J at u^0 in the direction w we have

$$\begin{aligned}(J'(u^0), w) \equiv \int_0^T dt \{ & 2\alpha \left(C\hat{\phi}(u^0, w), C\phi(u^0) - z_1\right)_{H_1} \\ & + 2\beta \left(D\dot{\hat{\phi}}(u^0, w), D\dot{\phi}(u^0) - z_2\right)_{H_2} \\ & + 2_\gamma (w, N u^0)_E \} \end{aligned} \qquad (75)$$

where $\hat{\phi}(u^0, w)$ denotes the Gateaux differential of ϕ at u^0 in the direction w, which is given by the solution of

$$\begin{aligned} \ddot{\hat{\phi}}(u^0, w) + A\hat{\phi}(u^0, w) &= Bw \\ \hat{\phi}(u^0, w)(0) = 0, \qquad \dot{\hat{\phi}}(u^0, w)(0) &= 0 \end{aligned} \qquad (76)$$

Introducing the duality maps,

$$\Lambda_1 : H_1 \to H_1^*, \qquad \Lambda_2 : H_2 \to H_2^*$$

in expression (75) and defining

$$\begin{aligned} g_1(t, \phi(u^0)) &\equiv 2\alpha C^* \Lambda_1 \left(C\phi(u^0) - z_1(t)\right) \\ g_2(t, \phi(u^0)) &\equiv 2\beta D^* \Lambda_2 \left(D\dot{\phi}(u^0) - z_2(t)\right) \end{aligned}$$

we obtain:

$$\begin{aligned}(J'(u^0), w) = \int_0^T dt \{ & \left(\hat{\phi}(u^0, w), g_1\right)_H + \left(\dot{\hat{\phi}}(u^0, w), g_2\right)_H \\ & + (w, 2\gamma N u^0)_E \} \end{aligned} \qquad (77)$$

for all $w \in \mathcal{U}_0$.

Defining $\hat{\phi}_1 = \hat{\phi}$, $\hat{\phi}_2 = \dot{\hat{\phi}}$ one can rewrite Eq. (76) as a first-order evolution equation:

$$\begin{aligned} \frac{d}{dt}\begin{pmatrix}\hat{\phi}_1 \\ \hat{\phi}_2\end{pmatrix} &= \begin{pmatrix} 0 & I \\ -A & 0 \end{pmatrix}\begin{pmatrix}\hat{\phi}_1 \\ \hat{\phi}_2\end{pmatrix} + \begin{pmatrix} 0 \\ Bw \end{pmatrix} \\ \begin{pmatrix}\hat{\phi}_1(0) \\ \hat{\phi}_2(0)\end{pmatrix} &= \begin{pmatrix} 0 \\ 0 \end{pmatrix} \end{aligned} \qquad (78)$$

Then, by introducing the adjoint evolution equation,

$$\begin{aligned} \frac{d}{dt}\begin{pmatrix}p_1 \\ p_2\end{pmatrix} &= -\begin{pmatrix} 0 & -A^* \\ I & 0 \end{pmatrix}\begin{pmatrix}p_1 \\ p_2\end{pmatrix} + \begin{pmatrix} g_1 \\ g_2 \end{pmatrix} \\ \begin{pmatrix}p_1(T) \\ p_2(T)\end{pmatrix} &= \begin{pmatrix} 0 \\ 0 \end{pmatrix} \end{aligned} \qquad (79)$$

one can easily verify from Egs. (78) and (79) that

$$\int_0^T \{(\hat{\phi}_1, g_1)_H + (\hat{\phi}_2, g_2)_H\}\, dt = -\int_0^T (Bw, p_2)_H\, dt \qquad (80)$$

Using Eq. (80) in Eq. (77) and the duality map Λ_E: $E \to E^*$, we obtain, for $w = u - u^0$,

$$\begin{aligned}(J'(u^0), u - u^0) = \int_0^T \left(2\gamma N u^0 - \Lambda_E^{-1} B^* p_2, u - u^0\right)_E dt \\ u \in \mathcal{U}_0 \end{aligned} \qquad (81)$$

Defining $\psi^0(t) = \int_t^T p_2(\theta)\, d\theta$, one obtains the adjoint equation (73b), and the necessary inequality (74) follows from Eqs. (72) and (81).

REMARK 1. In case $\beta = 0$, the adjoint equation is given by a differential equation rather than the integro-differential equations (73b). That is, p_2 satisfies the equation:

$$\begin{aligned} \ddot{p}_2 + A^* p_2 + g_1 &= 0 \\ p_2(T) = 0, \qquad \dot{p}_2(T) &= 0 \end{aligned}$$

and in Eq. (74) one may replace $\dot{\psi}^0$ by $-p_2$.

REMARK 2. In case of terminal observation, the cost functional (69) may be given by:

$$\begin{aligned} J(u) \equiv \alpha \|C\phi(T) - z_1\|_{H_1}^2 + \beta \|D\dot{\phi}(T) - z_2\|_{H_2}^2 \\ + \gamma \int_0^T (N(t)u, u)_E\, dt \end{aligned} \qquad (82)$$

where $z_1 \in H_1$ and $z_2 \in H_2$.

In this case, the necessary conditions of optimality are given by:

$$\begin{aligned} \int_0^T \left(u - u^0, 2\gamma N u^0 - \Lambda_E^{-1} B^* p_2\right) dt \geq 0 \\ u \in \mathcal{U}_0 \end{aligned} \qquad (83)$$

where p_2 satisfies the differential equation,

$$\begin{aligned} \frac{d^2 p_2}{dt^2} + A^* p_2 &= 0 \\ p_2(T) = g_2 &\equiv 2\beta D^* \Lambda_2 \left(D\dot{\phi}^0(T) - z_2\right) \\ \dot{p}_2(T) = -g_1 &\equiv -2\alpha C^* \Lambda_1 \left(C\phi^0(T) - z_1\right) \end{aligned} \qquad (84)$$

In recent years several interesting necessary conditions of optimality for time- optimal control problems have been reported. We present here one such result. Suppose the system is governed by the evolution equation,

$$\frac{dy}{dt} = Ay + u$$

in a Banach space X, and let

$$\mathcal{U} \equiv \left\{u \in L_p^{\text{loc}}(R_0, X) : u(t) \in B_1\right\}$$

with $p > 1$, $B_1 =$ unit ball in X, denote the class of admissible controls.

Theorem 14 (Maximum Principle.) Suppose A is the generator of a c_0-semigroup $S(t)$, $t \geq 0$, in X and there exists a $t > 0$ such that $S(t)X = X$. Let y_0, $y_1 \in X$, and suppose u^0 is the time-optimal control, with transition time τ, that steers the system from the initial state y_0 to the final state y_1. Then there exists an $x^* \in X^*$ (=dual of X) such that

$$\begin{aligned}\langle S^*(\tau - t)x^*, u^0(t)\rangle_{X^*,X} &= \sup\left\{\langle S^*(\tau - t)x^*, e\rangle, e \in B_1\right\} \\ &= |S^*(\tau - t)x^*|_{X^*} \end{aligned} \tag{85}$$

Suppose X is a reflexive Banach space and there exists a continuous map v: $X^*\backslash\{0\} \to X$ such that, for $\xi^* \in X^*$,

$$|v(\xi^*)|_X = 1$$

and

$$\langle \xi^*, v(\xi^*)\rangle_{X^*,X} = |\xi^*|_{X^*}$$

then the optimal control is bang-bang and is given by $u^0(t) = v(S^*(\tau - t)x^*)$, and it is unique if X is strictly convex.

Maximum principle for more general control problems are also available.

G. Computational Methods

In order to compute the optimal controls one is required to solve simultaneously the state and adjoint equations (73a) and (73b), along with inequality (74). In case the admissible control set $\mathcal{U}_0 \equiv L_2(I, E)$, the optimal control has the form:

$$u^0 = -(1/2\gamma)N^{-1}\Lambda_E^{-1}B^*\psi^0$$

Substituting this expression in Eqs. (73a) and (73b), one obtains a system of coupled evolution equations, one with initial conditions and the other with final conditions specified. This is a two-point boundary-value problem in an ∞-dimensional space, which is a difficult numerical problem. However, in general one can develop a gradient-type algorithm to compute an approximating sequence of controls converging to the optimal. The required gradient is obtained from the necessary condition (74). The solutions for the state and adjoint equations, (73a) and (73b), can be obtained by use of any of the standard techniques for solving partial differential equations, for example, the finite difference, finite element, or Galerkin method.

In order to use the result of Theorem 13 to compute the optimal controls, one chooses an arbitrary control $u^1 \in \mathcal{U}_0$ and solves Eq. (73a) to obtain ϕ^1, which is then used in Eq. (73b) to obtain ψ^1. Then, on the basis of Eq. (74) one takes

$$J'(u^1) = 2\gamma Nu^1 + \Delta_E^{-1}B^*\psi^1$$

as the gradient at u^1 and constructs a new control $u^2 = u^1 - \varepsilon_1 J'(u^1)$, with $\varepsilon_1 > 0$ sufficiently small so that $J(u^2) \leq J(u^1)$. This way one obtains a sequence of approximating controls,

$$u^{n+1} = u^n - \varepsilon_n J'(u^n)$$

with $J(u^{n+1}) \leq J(u^n)$, $n = 1, 2, \ldots$. In practical applications, a finite number of iterations produces a fairly good approximation to the optimal control.

H. Stochastic Evolution Equations

In this section we present a very brief account of stochastic linear systems. Let $(\Sigma, \mathcal{A}, P)$ denote a complete probability space and $\mathcal{F}_t$, $t \geq 0$, a nondecreasing family of right-continuous, completed subsigma algebras of the σ-algebra $\mathcal{A}$; that is, $\mathcal{F}_s \subset \mathcal{F}_t$ for $0 \leq s \leq t$. Let H be a real separable Hilbert space and $\{W(t), t \geq 0\}$ an H-valued Wiener process characterized by the properties:

(a) $P\{W(0) = 0\} = 1$,

(b) $W(t)$, $t \geq 0$, has independent increments over disjoint intervals, and

(c) $E\left\{e^{i(W(t),h)}\right\} = \exp[-t/2(Qh, h)]$,

where $E\{\cdot\} \equiv \int_\Sigma \{\cdot\}\, dP$ and $Q \in \mathcal{L}^+(H)$ is the space of positive self-adjoint bounded operators in H. Symbolically, a stochastic linear differential equation is written in the form

$$dy = Ay\, dt + \sigma(t)\, dW(t), \qquad t \geq 0, \qquad y(0) = y_0$$

where A is the generator of a c_0-semigroup $S(t)$, $t \geq 0$, in H and $\sigma \in \mathcal{L}(H)$ and y_0 is an H-valued random variable independent of the Wiener process. The solution y is given by:

$$y(t) = S(t)y_0 + \int_0^t S(t - \theta)\sigma(\theta)\, dW(\theta), \qquad t \geq \theta$$

Under the given assumptions one can easily show that $E|y(t)|_H^2 < \infty$ for finite t, whenever $E|y_0|_H^2 < \infty$, and further $y \in C(I, H)$ a.s. (a.s. $\equiv$ with probability one). In fact, $\{y(t), t \geq 0\}$ is an $\mathcal{F}_t$–Markov random process and one can easily verify that

$$E\{y(t) \mid \mathcal{F}_\tau\} = S(t - \tau)y(\tau)$$

for $0 \leq \tau \leq t$. The covariance operator $C(t)$, $t \geq 0$, for the process $y(t)$, $t \geq 0$, defined by:

$$(C(t)h, g) = E\{(y(t) - Ey(t), h)(y(t) - Ey(t), g)\}$$

is then given by:

$$(C(t)h, g) = \int_0^t (S(t-\theta)\sigma(\theta)Q\sigma^*(\theta) \times S^*(t-\theta)h, g)\, d\theta + (S(t)C_0S^*(t)h, g)$$

Denoting the positive square root of the operator Q by $\sqrt{Q}$ we have

$$(C(t)h, h) = \int_0^t |\sqrt{Q}\sigma^*(\theta)S^*(t-\theta)h|_H^2\, d\theta + \left(C_0S^*(t)h, S^*(t)h\right)$$

This shows that $C(t) \in \mathcal{L}^+(H)$ if and only if the condition,

$$S^*(t)h = 0, \qquad \text{or}$$
$$\sigma^*(\theta)S^*(t-\theta)h \equiv 0, \qquad 0 \le \theta \le t$$

implies $h = 0$. This is precisely the condition for (approximate) controllability as seen in Theorem 9. Hence, the process $y(t)$, $t \ge 0$, is a nonsingular H-valued Gaussian process if and only if the system is controllable. Similar results hold for more general linear evolution equations on Banach spaces with operators A and σ both time varying.

Linear stochastic evolution equations of the given form arise naturally in the study of nonlinear filtering of ordinary Ito stochastic differential equations in R^n. Such equations are usually written in the weak form,

$$d\pi_t(f) = \pi_t(Af)\, dt + \pi_t(\sigma f)\, dW_t$$
$$t \ge 0, \qquad f \in D(A)$$

where A is a second-order partial differential operator and $\{W(t), t \ge 0\}$ is an $\mathbb{R}^d$-valued Wiener process ($d \le n$). One looks for solutions π_t, $t \ge 0$, that belong to the Banach space of bounded Borel measures satisfying $\pi_t(f) \ge 0$ for $f \ge 0$. Questions of existence of solutions for stochastic systems of the form,

$$dy = (A(t)y + f(t))\, dt + \sigma(t)\, dW$$
$$y(0) = y_0, \qquad t \in (0, T)$$
$$dz = -((A^*(t) - B(t))z + g)\, dt + \sigma(t)\, dW$$
$$z(T) = 0, \qquad t \in (0, T)$$

have been studied in the context of control theory. A fundamental problem arises in the study of the second equation and it has been resolved by an approach similar to the Lax–Milgram theorem in Hilbert space. Questions of existence and stability of solutions of nonhomogeneous boundary value problems of the form,

$$\frac{\partial y}{\partial t} + A(t)y = f(t), \qquad \text{on} \quad I \times \Omega$$
$$By = g(t), \qquad \text{on} \quad I \times \partial\Omega$$
$$u(0) = y_0, \qquad \text{on} \quad \Omega$$

have been studied where f and g have been considered as generalized random processes and y_0 as a generalized random variable. Stability of similar systems with g replaced by a generalized white noise process has been considered recently. Among other things, it has been shown that $y(t)$, $t \ge 0$, is a Feller process on H, a Hilbert space, and there exists a Feller semigroup T_t, $t \ge 0$, on $C_b(H)$, a space of bounded continuous functions on H, whose dual U_t determines the flow $\mu_t = U_t\mu_0$, $t \ge 0$, of the measure induced by $y(t)$ on H. μ_t, $t \ge 0$, satisfies the differential equation:

$$\frac{d}{dt}\mu_t(f) = \mu_t(Gf), \qquad t \ge 0$$

for all $f \in D(G) \subset C_b(H)$ where G is the infinitesimal generator of the semigroup $T_t, t \ge 0$. Optimal control problems for a class of very general linear stochastic systems of the form,

$$dy = (A(t)y + B(t)u)\, dt + \sigma(t)\, dW(t)$$
$$J(u) = E\left\{ \int^T \left[|Cy - z_d|^2 + (Nu, u)\right] dt \right\} \equiv \min$$

have been considered in the literature, giving results on the existence of optimal controls and necessary conditions of optimality, including feedback controls. In this work, A, B, σ, C, and N were considered as operator-valued random processes.

III. NONLINEAR EVOLUTION EQUATIONS AND DIFFERENTIAL INCLUSIONS

The two major classes of nonlinear systems that occupy most of the literature are the semilinear and quasilinear systems. However, control theory for such systems has not been fully developed; in fact, the field is wide open. In this section, we shall sample a few results.

A. Existence of Solutions, Nonlinear Semigroup

We consider the questions of existence of solutions for the two major classes of systems, semilinear and quasilinear. In their abstract form we can write them as

$$\frac{d\phi}{dt} + A(t)\phi = f(t, \phi) \qquad \text{(semilinear)} \quad (86)$$

$$\frac{d\phi}{dt} + A(t, \phi)\phi = f(t, \phi) \qquad \text{(quasilinear)} \quad (87)$$

and consider them as evolution equations on suitable state space which is generally a topological space having the structure of a Banach space, or a suitable manifold therein.

For example, let us consider the semilinear parabolic equation with mixed initial and boundary conditions:

$$\begin{aligned} \frac{\partial \phi}{\partial t} + L\phi &= g(t, x; \phi, D\phi, \ldots, D^{2m-1}\phi) \\ &\qquad (t, x) \in I \times \Omega \equiv Q \\ \phi(0, x) &= \phi_0(x), \qquad x \in \Omega \\ D_\nu^k \phi &= 0, \qquad 0 \le k \le m-1 \\ &\qquad (t, x) \in I \times \partial\Omega \end{aligned} \tag{88}$$

where

$$(L\phi)(t, x) \equiv \sum_{|\alpha| \le 2m} a_\alpha(t, x) D^\alpha \phi \tag{89}$$

and $D_\nu^k \phi = \partial^k \phi / \partial \nu^k$ denotes the kth derivative in the direction of the normal ν to $\partial\Omega$. We assume that L is strongly elliptic with principal coefficients a_α, $|\alpha| = 2m$, in $C(\bar{Q})$ and the lower order coefficients a_α, $|\alpha| \le 2m-1$, $L_\infty(Q)$, and further they are all Hölder continuous in t uniformly on $\bar{\Omega}$. Let $1 < p < \infty$ and define the operator-valued function $A(t)$, $t \in I$, by:

$$\begin{aligned} D(A(t)) \equiv \{\psi \in X = L_p(\Omega) : (L\psi)(t, \cdot) \in X \\ \text{and } D_\nu^k \psi \equiv 0 \text{ on } \partial\Omega, 0 \le k \le m-1\} \end{aligned} \tag{90}$$

The domain of $A(t)$ is constant and is given by:

$$D \equiv W^{2m,p} \cap W_0^{m,p} \tag{91}$$

Then, one can show that for each $t \in I$, $-A(t)$ is the generator of an analytic semigroup and there exists an evolution operator $U(t, \tau) \in \mathcal{L}(X)$, $0 \le \tau \le t \le T$, that solves the abstract Cauchy problem:

$$\begin{aligned} \frac{dy}{dt} + A(t)y &= 0 \\ y(0) &= y_0 \end{aligned} \tag{92}$$

for each $y_0 \in X$; that is, $y(t) = U(t, 0)y_0$, $t \in I$, with $y \in C(\bar{I}, X)$ and $\dot{y} \in C((0, T], X)$. In general, if $f \in L_p(I, X)$, then y, given by:

$$y(t) = U(t, 0)y_0 + \int_0^t U(t, \tau) f(\tau)\, d\tau \tag{93}$$

is a mild solution of the Cauchy problem,

$$\begin{aligned} \frac{dy}{dt} + A(t)y &= f \\ y(0) &= y_0 \end{aligned} \tag{94}$$

This would be the generalized (weak) solution of the parabolic initial boundary value problem (88) if g were replaced by $f \in L_p(I, X)$. In order to solve problem (88), one must introduce an operator f such that

$$f(t, u) \equiv g(t, \cdot; u, D^1 u, \ldots, D^{2m-1} u) \in X \qquad \text{a.e.}$$

for u in a suitable subspace Y with $D(A) \subset Y \subset X$. Problem (88) can then be considered as an abstract Cauchy problem,

$$\begin{aligned} \frac{d\phi}{dt} + A(t)\phi &= f(t, \phi) \\ \phi(0) &= \phi_0 \end{aligned} \tag{95}$$

In view of Eq. (93), a mild solution of Eq. (95) is given by a solution of the integral equation,

$$\phi(t) = U(t, 0)\phi_0 + \int_0^t U(t, \theta) f(\theta, \phi(\theta))\, d\theta \tag{96}$$

if one exists. Defining the operator G by:

$$(G\phi)(t) \equiv U(t, 0)\phi_0 + \int_0^t U(t, \theta) f(\theta, \phi(\theta))\, d\theta$$

one then looks for a fixed point for G, that is, an element ϕ such that $\phi = G\phi$. Using *a priori* estimates, the most difficult part of the program, one can establish the existence of a solution by use of a suitable fixed-point theorem—for example, Banach, Schauder, or Leray–Schauder fixed-point theorems. We state the following result without proof.

Theorem 15. Consider the semilinear parabolic problem (88) in the abstract form (95) and suppose A generates the evolution operator $U(t, \tau)$, $0 \le \tau \le t \le T$, and f satisfies the properties:

$$\begin{aligned} \text{(F1)} \qquad & \|f(t, u)\|_X \le c\{1 + \|A^\beta(t)u\|_X\} \\ & t \in I \\ & \text{for constants} \quad c > 0, \quad 0 \le \beta < 1 \\ & \text{and } u \in D(A^\beta), \end{aligned} \tag{97}$$

$$\begin{aligned} \text{(F2)} \qquad & \|f(t, u) - f(t, w)\|_X \\ & \le C\{\|A^\beta(t)v - A^\beta(t)w\|_X^\rho\} \\ & \quad t \in I \\ & \text{for some} \quad 0 < \rho \le 1, \\ & u, w \in D(A^\beta) \end{aligned} \tag{98}$$

Then, Eq. (95) has a mild solution $\phi \in C(I, X)$, hence the semilinear parabolic equation (88) has a generalized solution. The solution is unique if $\rho = 1$.

REMARK 1. Condition (F1) is satisfied if the function g satisfies the growth condition:

$$|g(t, x, u, Du, \ldots, D^{2m-1}u)| \le k\left\{1 + \sum_{j=0}^{2m-1} |D^j u|_j^r\right\}$$

for $0 \le r_j \le (2m + n/q)/(j + n/q)$, $1 < q < \infty$, and a number β satisfying $(2m-1)/2m < \beta < 1$. In the case

$\rho = 1$, condition (F2) is satisfied if the function g is Lipschitz in the last $2m$ variables uniformly with respect to $(t, x) \in \overline{I \times \Omega}$.

If the coefficients $\{a_\alpha, |\alpha| \le 2m\}$ in Eq. (89) are also dependent on ϕ so that $\{a_\alpha = a_\alpha(t, x; \phi, D^1\phi, \ldots, D^{2m-1}\phi)$ then system (88) becomes a quasilinear system and parabolic if

$$(-1)^m \operatorname{Re}\left\{ \sum_{|\alpha|=2m} a_\alpha(t, x; \eta)\xi^\alpha \right\} \ge c|\xi|^{2m} \qquad c > 0 \quad (99)$$

for $(t, x) \in \bar{Q}$ and $\eta \in R^N$, where $N = \sum_{j=0}^{2m-1} N_j$ with N_j denoting the number of terms representing derivatives of order exactly j appearing in the arguments of $\{a_\alpha\}$. System (88) then takes the form:

$$\frac{d\phi}{dt} + A(t, \phi)\phi = f(t, \phi), \qquad \phi(0) = \phi_0 \quad (100)$$

This problem is again solved by use of *a priori* estimates and a fixed-point theorem under the following assumptions:

(A1) The operator $A_0 = A(0, \phi_0)$ is a closed operator with domain D dense in X and

$$\left\|(\lambda I - A_0)^{-1}\right\| \le k/(1 + |\lambda|) \qquad \text{for all } \lambda, \quad \operatorname{Re}\lambda \le 0.$$

(A2) A_0^{-1} is a completely continuous operator that is; it is continuous in X and maps bounded sets into compact subsets of X.

(A3) There exist numbers ε, ρ satisfying $0 < \varepsilon \le 1$, $0 < \rho \le 1$, such that for all $t, \tau \in I$,

$$\|(A(t, u) - A(\tau, w))A^{-1}(\tau, w)\| \le k_R\left\{|t - \tau|^\varepsilon + \left\|A_0^\beta u - A_0^\beta w\right\|^\rho\right\}$$

for all u, w such that $\|A_0^\beta u\|, \|A_0^\beta w\| < R$ with k_R possibly depending on R.

(F1) For all $t, \tau \in I$,

$$\|f(t, v) - f(t, w)| \le k_R\left\{\left\|A_0^\beta v - A_0^\beta w\right\|^\rho\right\}$$

for all $v, w \in X$ such that $\|A_0^\beta v\|, \|A_0^\beta w\| \le R$.

Theorem 16. Under assumptions (A1) to (A3) and (F1) there exists a $t^* \in (0, T)$ such that Eq. (100) has at least one mild solution $\phi \in C([0, t^*], X)$ for each $\phi_0 \in D(A_0^\beta)$ with $\|A_0^\beta \psi_0\| \le R$. Further, if f also satisfies the Hölder condition in t, the solution is C^1 in $t \in (0, t^*]$. If $\rho = 1$, the solution is unique.

Proof. We discuss the outline of a proof. The differential equation (100) is converted into an integral equation and then one shows that the integral equation has a solution. Let $v \in C([0, t^*], X)$ and define:

$$A^v(t) \equiv A\big(t, A_0^{-\beta} v(t)\big), \qquad f^v(t) \equiv f\big(t, A_0^{-\beta} v(t)\big)$$

and consider the linear system,

$$\frac{dy}{dt} + A^v(t)y = f^v(t), \quad t \in [0, t^*], \qquad y(0) = \phi_0 \quad (101)$$

By virtue of assumptions (A1) to (A3), $-A^v(t)$, $t \in [0, t^*]$, is the generator of an evolution operator $U^v(t, \tau)$, $0 \le t \le t^*$. Hence, the system has a mild solution given by:

$$y^v(t) = U^v(t, 0)\phi_0 + \int_0^t U^v(t, \theta) f^v(\theta)\, d\theta \qquad 0 \le t \le t^* \quad (102)$$

Defining an operator G by setting

$$(Gv)(t) \equiv A_0^\beta U^v(t, 0)\phi_0 + \int_0^t A_0^\beta U^v(t, \theta) f^v(\theta)\, d\theta \quad (103)$$

one then looks for a fixed point of the operator G, that is, an element $v^* \in C([0, t^*], X)$ such that $v^* = Gv^*$. In fact, one shows, under the given assumptions, that for sufficiently small $t^* \in I$, there exists a closed convex set $K \subset C([0, t^*], X)$ such that $GK \subset K$ and GK is relatively compact in $C([0, t^*], X)$ and hence, by the Schauder fixed-point theorem (which is precisely as stated) has a solution $v^* \in K$. The solution (mild) of the original problem (100) is then given by $\phi^* = A_0^{-\beta} v^*$. This is a genuine (strong) solution if f is also Holder continuous in t. If $\rho = 1$, G has the contraction property and the solution is unique. □

According to our assumptions, for each $t \in [0, t^*]$ and $y \in D(A_0^\beta)$, the operator $A(t, y)$ is the generator of an analytic semigroup. This means that Theorem 16 can handle only parabolic problems and excludes many physical problems arising from hydrodynamics and wave propagation phenomenon including the semilinear and quasilinear symmetric hyperbolic systems discussed in Section I. This limitation is overcome by allowing $A(t, y)$, for each t, y in a suitable domain, to be the generator of a c_0-semigroup rather than an analytic semigroup. The fundamental assumptions required are:

(H1) X is a reflexive Banach space with Y being another Banach space which is continuously and densely

embedded in X and there is an isometric isomorphism S of Y onto X.

(H2) For $t \in [0, T]$, $y \in W \equiv$ an open ball in Y, $A(t, y)$ is the generator of a c_0-semigroup in X.

(H3) For $t, y \in [0, T] \times W$,

$$(SA(t, y) - A(t, y)S)S^{-1} = B(t, y) \in \mathcal{L}(Y, X)$$

and $\|B(t, y)\|_{\mathcal{L}(Y,X)}$ is uniformly bounded on $I \times Y$.

Theorem 17. Under assumptions (H1) to (H3) and certain Lipschitz and boundedness conditions for A and f on $[0, T] \times W$, the quasilinear system (100) has, for each $\phi_0 \in W$, a unique solution,

$$\phi \in C([0, t^*), W) \cap C^1([0, t^*), X) \quad \text{for some} \quad 0 < t^* \leq T$$

The proof of this result is also given by use of a fixed-point theorem but without invoking the operator A_0. Here, for any $v \in C([0, t^*), W)$, one defines $A^v(t) = A(t, v(t))$, $f^v(t) = f(t, v(t))$ and $U^v(t, \tau)$, $0 \leq \tau \leq t \leq T$, the evolution operator corresponding to $-A^v$ and constructs the operator G by setting

$$(Gv)(t) = U^v(t, 0)\phi_0 + \int_0^t U^v(t, \tau) f^v(\tau)\, d\tau$$

where the expression on the right-hand side is the mild solution of the linear equation (101). Any v^* satisfying $v^* = Gv^*$ is a mild solution of the original problem (100).

From the preceding results it is clear that the solutions are defined only over a subinterval $(0, t^*) \subset (0, T)$ and it may actually blow up at time t^*. Mathematically this is explained through the existence of singularities, which physically correspond to the occurrence of, for example, turbulence or shocks in hydrodynamic problems. However, global solutions are defined for systems governed by differential equations with monotone operators. We present a few general results of this nature.

Let X be a Banach space with dual X^* and suppose A is an operator from $D(A) \subset X$ to X^*. The operator A is said to be monotone if

$$(Ax - Ay, x - y)_{X^*,X} \geq 0 \quad \text{for all} \quad x, y \in D(A) \tag{104}$$

It is said to be demicontinuous on X if

$$Ax_n \overset{w}{\to} Ax_0 \quad \text{in } X^* \quad \text{whenever} \quad x_n \overset{s}{\to} x_0 \quad \text{in } X \tag{105}$$

And, it is said to be hemicontinuous on X if

$$A(x + \theta y) \overset{w}{\to} Ax \quad \text{in } X^* \quad \text{whenever} \quad \theta \to 0 \tag{106}$$

Let H be a real Hilbert space and V a subset of H having the structure of a reflexive Banach space with V dense in H. Let V^* denote the (topological) dual of V and suppose H is identified with its dual H^*. Then we have $V \subset H \subset V^*$. Using the theory of monotone operators we can prove the existence of solutions for nonlinear evolution equations of the form,

$$\frac{d\phi}{dt} + B(t)\phi = f, \qquad t \in I = (0, T)$$
$$\phi(0) = \phi_0 \tag{107}$$

where $B(t)$, $t \in I$, is a family of nonlinear monotone operators from V to V^*.

Theorem 18. Consider system (107) and suppose the operator B satisfy the conditions:

(B1) B: $L_p(I, V) \to L_q(I, V^*)$ is hemicontinuous:

$$\|B\phi\|_{L_q(I,V^*)} \leq K_1\big(1 + \|\phi\|^{p-1}_{L_p(I,V)}\big) \tag{108}$$

where $K_1 > 0$, and $1 < p, q < \infty$, $1/p + 1/q = 1$.

(B2) For all $\phi, \psi \in L_p(I, V)$,

$$(B\phi - B\psi, \phi - \psi)_{L_q(I,V^*),L_p(I,V)} \geq 0 \tag{109}$$

That is, B is a monotone operator form $L_p(I, V)$ to $L_q(I, V^*)$.

(B3) There exists a nonnegative function C: $\mathbb{R} \to \bar{R}$ with $C(\xi) \to +\infty$ as $\xi \to \infty$ such that for $\psi \in L_p(I, V)$,

$$(B\psi, \psi)_{L_q(I,V^*),L_p(I,V)} \geq C(\|\psi\|)\|\psi\| \tag{110}$$

Then for each $\phi_0 \in H$ and $f \in L_q(I, V^*)$ system (107) has a unique solution $\phi \in L_p(I, V) \cap C(\bar{I}, H)$ and $\dot{\phi} \in L_q(I, V^*)$. Further, ϕ is an absolutely continuous V^*-valued function on $\bar{I}$.

It follows from the above result that, for $\phi_0 \in H$, $\phi \in C(\bar{I}, H)$ and hence $\phi(t) \in H$ for $t \geq 0$. For $f \equiv 0$, the mapping $\phi_0 \to \phi(t)$ defines a nonlinear evolution operator $U(t, \tau)$, $0 \leq \tau \leq t \leq T$, in H. In case B is time invariant, we have a nonlinear semigroup $S(t)$, $t \geq 0$, satisfying the properties:

(a) $S(0) = I$ and, as $t \to 0$,

(b) $S(t)\xi \to {}^s\xi$ in H and, due to uniqueness,

(c) $S(t + \tau)\xi = S(t)S(\tau)\xi, \xi \in H$.

Further, it follows from the equation $\dot{\phi} + B\phi = 0$ that $(\dot{\phi}(t), \phi(t)) + (B\phi(t), \phi(t)) = 0$; hence,

$$|\phi(t)|^2_H = |\phi_0|^2_H - 2\int_0^t (B\phi(\theta), \phi(\theta)\, d\theta, \qquad t \geq 0$$

Thus, by virtue of (B3), $|\phi(t)|_H \leq |\phi_0|_H$; that is, $|S(t)\phi_0|_H \leq |\phi_0|_H$. Hence the semigroup $\{S(t), t \geq 0\}$ is

a family of nonlinear contractions in H, and its generator is $-B$.

A classical example is given by the nonlinear initial boundary-value problem,

$$\begin{aligned} \frac{\partial \phi}{\partial t} - \sum_i \frac{\partial}{\partial x_i}\left(\left|\frac{\partial \phi}{\partial x_i}\right|^{p-2}\frac{\partial \phi}{\partial x_i}\right) &= f \qquad \text{in} \quad I \times \Omega = Q \\ \phi(0, x) &= \phi_0(x) \\ \phi(t, x) &= 0 \qquad \text{on} \quad I \times \partial\Omega \end{aligned} \tag{111}$$

For this example, $V = W_0^{1,p}(\Omega)$ with $V^* = W^{-1,q}$ and $H = L_2(\Omega)$ and

$$Bu = -\sum \frac{\partial}{\partial x_i}\left(\left|\frac{\partial v}{\partial x_i}\right|^{p-2}\frac{\partial v}{\partial x_i}\right), \qquad p \geq 2$$

$$f \in L_q(I, W^{-1,q}), \qquad \phi_0 \in L_2(\Omega)$$

We can rewrite problem (111) in its abstract form,

$$\begin{aligned} \frac{d\phi}{dt} + B\phi &= f, \qquad t \in I \\ \phi(0) &= \phi_0 \end{aligned}$$

noting that V absorbs the boundary condition.

We conclude this section with one of the most general results involving monotone operators. Basically we include a linear term in model (107) which is more singular than the operator B. For convenience of presentation in the sequel we shall write this model as:

$$\frac{d\phi}{dt} = A(t)\phi + f(t, \phi), \qquad \phi(0) = \phi_0 \tag{112}$$

where f represents $-B + f$ of the previous model (107) and $A(t)$, $t \in I$, is a family of linear operators more singular than f in the sense that it may contain partial differentials of higher order than that in f and hence may be an unbounded operator.

For existence of solutions we use the following assumptions for A and f:

(A1) $\{A(t),\ t \in I\}$ is a family of densely defined linear operators in H with domains $D(A(t)) \subset V$ and range $R(A(t)) \subset V^*$ for $t \in I$.

(A2) $\langle A(t)e, e\rangle_{V^*,V} \leq 0$ for all $e \in D(A(t))$.

(F1) The function $t \to \langle f(t, e), g\rangle$ is measurable on I for $e, g \in V$, and $f: I \times V \to V^*$ is demicontinuous in the sense that for each $e \in V$

$$\langle f(t_n, \xi_n), e\rangle_{V^*,V} \to \langle f(t, \xi), e\rangle$$

whenever $t_n \to t$ and $\xi_n \to \xi$ in V.

(F2) $\langle f(t, \xi) - f(t, \eta), \xi - \eta\rangle_{V^*,V} \leq 0$ for all $\xi, \eta \in V$.

(F3) There exists an $h \in L_q(I, R_+)$, $R_+ = [0, \infty)$, and $\alpha \geq 0$ such that

$$|f(t, \xi)|_{V^*} \leq h(t) + \alpha(\|\xi\|_V)^{p/q} \qquad \text{a.e.}$$

for each $\xi \in V$.

(F4) There exists an $h_1 \in L_1(I, R)$ and $\beta > 0$ such that

$$\langle f(t, \xi), \xi\rangle_{V^*,V} \leq h_1(t) - \beta(\|\xi\|_V)^p \qquad \text{a.e.}$$

for each $\xi \in V$.

Theorem 19. Consider system (112) and suppose assumptions (A1) to (A2) and (F1) to (F4) hold. Then, for each $\phi_0 \in H$, Eq. (112) has a unique (weak) solution $\phi \in L_p(I, V) \cap C(\bar{I}, H)$ and further the solution ϕ is an absolutely continuous V^*-valued function.

The general result given above also applies to partial differential equations of the form:

$$\begin{aligned} &\frac{\partial \phi}{\partial t} + \sum_{|\alpha| \leq m+1} (-1)^{|\alpha|} D^\alpha \left(a_{\alpha\beta}(t, x) D^\beta \phi\right) \\ &\quad + \sum_{|\alpha| \leq m} (-1)^{|\alpha|} D^\alpha F_\alpha(t, x; \phi, D^1\phi, \ldots, D^m\phi) \\ &\qquad = 0 \qquad \text{on} \quad I \times \Omega \\ &\qquad \phi(0, x) = \phi_0(x) \qquad \text{on} \quad \Omega \\ &\qquad (D^\alpha \phi)(t, x) = 0, \qquad 0 \leq |\alpha| \leq m \\ &\qquad\qquad \text{on} \quad I \times \partial\Omega \end{aligned} \tag{113}$$

where the operator $A(t)$ in Eq. (112) comes from the linear part and the boundary conditions, and the nonlinear operator f comes from the nonlinear part in Eq. (113). The space V can be chosen as $W_0^{m,p}$, $p \geq 2$, with $V^* \equiv W^{-m,q}$ where $1/p + 1/q = 1$.

REMARK 2. Again, if both A and f are time invariant, it follows from Theorem 19 that there exists a nonlinear semigroup $S(t)$, $t \geq 0$, such that $\phi(t) = S(t)\phi_0$, $\phi_0 \in H$.

In certain situations the function $\{F_\alpha, |\alpha| \leq m\}$ may be discontinuous in the variables $\{\phi, D^1\phi, \ldots, D^m\phi\}$ and as a result the operator f, arising from the corresponding Dirichlet form, may be considered to be a multivalued function. In other words $f(t, \xi)$, for $t, \xi \in I \times V$, is a nonempty subset of V^*. In that case, the differential equation becomes a differential inclusion $\dot{\phi} \in A(t)\phi + f(t, \phi)$. Differential inclusions may also arise from variational evolution inequalities. Define the operator S by:

$$S_t g = U(t, 0)\phi_0 + \int_0^t U(t, \theta) g(\theta)\, d\theta$$

$$t \in I, \qquad g \in L_1(I, V^*) \tag{114}$$

where U is the transition operator corresponding to the generator A and ϕ_0 is the initial state. Then, one questions the existence of a $g \in L_1(I, V^*)$ such that $g(t) \in f(t, S_t g)$ a.e. If such a g exists, then one has proved the existence of a solution of the initial value problem:

$$\begin{aligned} \dot{\phi}(t) &\in A(t)\phi(t) + f(t, \phi(t)) \\ \phi(0) &= \phi_0 \end{aligned} \tag{115}$$

These questions have been considered in control problems.

B. Stability, Identification, and Controllability

We present here some simple results on stability and some comments on the remaining topics.

We consider the semilinear system,

$$\frac{d\phi}{dt} = A\phi + f(\phi) \tag{116}$$

in a Hilbert space $(H, \|\cdot\|)$ and assume that f is weakly nonlinear in the sense that (a) $f(0) = 0$, and (b) $\|f(\xi)\| = o(\|\xi\|)$, where

$$\lim_{\|\xi\| \to 0} \left\{ \frac{o(\|\xi\|)}{\|\xi\|} \right\} = 0 \tag{117}$$

Theorem 20. If the linear system $\dot{\phi} = A\phi$ is asymptotically stable in the Lyapunov sense and f is a weakly nonlinear continuous map from H to H, then the nonlinear system (116) is locally asymptotically stable near the zero state.

The proof is based on Theorem 4.

For finite-dimensional systems, Lyapunov stability theory is most popular in that stability or instability of a system is characterized by a scalar-valued function known as the Lyapunov function. For ∞-dimensional systems a straight forward extension is possible only if strong solutions exist.

Consider the evolution equation (116) in a Hilbert space H, and suppose that A is the generator of a strongly continuous semigroup in H and f is a continuous map in H bounded on bounded sets. We assume that Eq. (116) has strong solutions in the sense that $\dot{\phi}(t) = A\phi(t) + f(\phi(t))$ holds a.e., and $\phi(t) \in D(A)$ whenever $\phi_0 \in D(A)$. Let T_t, $t \geq 0$, denote the corresponding nonlinear semigroup in H so that $\phi(t) = T_t(\phi_0)$, $t \geq 0$. Without loss of generality we may consider $f(0) = 0$ (if necessary after proper translation in H) and study the question of stability of the zero state. Let Ω be a nonempty open connected set in H containing the origin and define $\Omega_D \equiv \Omega \cap D(A)$, and $B_a(D) \equiv \{\xi \in H : |\xi|_H < a\} \cap D(A)$ for each $a > 0$. The system is said to be stable in the region Ω_D if, for each ball $B_R(D) \subset \Omega_D$, there exists a ball $B_r(D) \subset B_R(D)$ such that $T_t(\phi_0) \in B_R(D)$ for all $t \geq 0$ whenever $\phi_0 \in B_r(D)$. The zero state is said to be asymptotically stable if $\lim_{t \to \infty} T_t(\phi_0) = 0$ whenever $\phi_0 \in \Omega_D$.

A function $V : \Omega_D \to [0, \infty]$ is said to be positive definite if it satisfies the properties:

(a) $V(x) > 0$ for $x \in \Omega_D \backslash \{0\}$, $V(0) = 0$.
(b) V is continuous on Ω_D and bounded on bounded sets.
(c) V is Gateaux differentiable on Ω_D in the direction of H, in the sense that, for each $x \in \Omega_D$ and $h \in H$,

$$\lim_{\varepsilon \to 0} \left\{ \frac{V(x + \varepsilon h) - V(x)}{\varepsilon} \right\} \equiv V'(x, h)$$

exists, and for each $h \in H$, $x \to V'(x, h)$ is continuous.

The following result is the ∞-dimensional analog of the classical Lyapunov stability theory.

Theorem 21. Suppose the system $\dot{\phi} = A\phi + f(\phi)$ has strong solutions for each $\phi_0 \in D(A)$ and there exists a positive definite function V on Ω_D such that along any trajectory $\phi(t)$, $t \geq 0$, starting from $\phi_0 \in \Omega_D$,

$$V'(\phi(t), A\phi(t) + f(\phi(t))) \leq 0 \qquad (<0) \tag{118}$$

for all $t \geq 0$. Then the system is stable (asymptotically stable) in the region Ω_D.

If the system admits only mild solutions, Theorem 21 must be modified by using positive definite functions which have Gateaux derivatives in the directions $\{h\}$ in spaces larger than H.

We conclude this section with a result for systems governed by monotone nonlinear operators as in Eqs. (107) and (112).

Theorem 22. Consider system (112) with the operators A and f satisfying the assumptions of Theorem 19 for all $t \geq 0$, and suppose $h_1 \in L_1(0, \infty; R)$ and the injection $V \subset H$ is continuous. Then, the system is globally asymptotically stable with respect to the origin in H.

The questions of identification of parameters appearing in any of the system equations treated above can be dealt with in a similar way as in the linear case. In fact, an identification problem may be considered as a special case of a control problem with controls appearing in the system coefficients. Such classes of problems have been covered well in the literature. However, controllability questions for the general systems are more difficult and almost nothing is known.

C. Existence of Optimal Controls

Existence of optimal controls for strongly nonlinear parabolic systems and more general nonlinear evolution

equations of the form (86) have been treated in the literature. The technical details are rather involved and long. We shall limit ourselves to a brief summary of some results.

Consider system (107) with controls denoted by u:

$$\frac{d\phi}{dt} + B(t)\phi = f(t, u) \tag{119}$$

where the operator B is nonlinear and may be given by the expression:

$$B(t)\phi = \sum_{|\alpha|\le m} (-1)^{|\alpha|} D^{\alpha} F_{\alpha}(t, x; \phi, D^1\phi, \ldots, D^m\phi), \quad t, x \in I \times \Omega \tag{120}$$

Under quite general assumptions on the function F_α, the operator B has properties (B1) to (B3) of Theorem 18. For the space V one may choose $W_0^{m,p}$, $p \ge 2$, or any closed subspace of $W^{m,p}$ so that $W_0^{m,p} \subset V \subset W^{m,p}$. Here V is a reflexive Banach space. For admissible controls we choose any reflexive Banach space E of functions defined on Ω and Γ, a closed bounded convex subset of E, and consider $\mathcal{U}$ to be the class of admissible controls which are strongly measurable functions defined on $I = (0, T)$, with values in Γ. Let $f\colon I \times \Gamma \to V^*$, so that for each t, $f(t, \cdot)$ is weakly continuous (or more generally demicontinuous) on Γ; for each $v \in \Gamma$, $f(\cdot, v)$ is measurable on I (or continuous), and for each $u \in \mathcal{U}$, $f(u) \in L_q(I, V^*)$ where $f(u)(t) \equiv f(t, u(t))$.

The system,

$$\begin{aligned} \frac{d\phi}{dt} + B(t)\phi &= f(t, u(t)), \qquad t \in I \\ \phi(0) &= \phi_0, \qquad\quad u \in \mathcal{U} \end{aligned} \tag{121}$$

is written in its weak form:

$$\begin{aligned} &(L\phi, \psi) + b(\phi, \psi) = (f(u), \psi) \\ &\quad \text{for all} \quad \psi \in L_p(I, V) \cap C(\bar{I}, H) \\ &\qquad \phi(0) = \phi_0, \qquad u \in \mathcal{U} \end{aligned} \tag{122}$$

where L denotes the extension of d/dt as an operator from the space $L_p(I, V)$ to the space $L_q(I, V^*)$ and b is the Dirichlet form given by:

$$b(\phi, \psi) \equiv \int_I \sum_{|\alpha|\le m} \int_\Omega F_\alpha(t, x, \phi, D^1\phi, \ldots, D^m\phi) \cdot D^\alpha \psi \, dx \, dt \tag{123}$$

We consider the following control problems:

(P1) *Terminal control.* Let $J(u) = Z(\phi(T))$, where Z is a real-valued function on H and the pair $\{u, \phi\}$ is subject to the dynamic constraint (122). The problem is to find a control $u \in \mathcal{U}$ that minimizes the functional J.

(P2) *Time-optimal control.* Let M, a subset of H, be the target set. The requirement is to find a control $u \in \mathcal{U}$ that transfers the system from the state $\phi_0 \in H$ to the target set M in minimum time.

The existence of optimal controls depends on the properties of admissible trajectories, attainable sets, and the cost functionals. Let $\mathcal{X}$ denote the set of admissible trajectories, that is, the set of all $\{\phi\} \in L_p(I, V) \cap C(\bar{I}, H)$ such that ϕ is a solution of Eq. (122) corresponding to some control $u \in \mathcal{U}$. Similarly, the attainable set may be defined as:

$$\mathcal{A}(t) \equiv \{\xi \in H : \xi = \phi(t) \quad \text{for some} \quad \phi \in \mathcal{X}\}$$

Under a number of technical assumptions on the operators B and f and the control set Γ one can prove the following result.

Theorem 23. (a) The set of admissible trajectories $\mathcal{X}$ is a weakly closed and weakly sequentially compact subset of $L_p(I, V)$. (b) For each $t \in [0, T]$, the attainable set $\mathcal{A}(t)$, is a weakly compact subset of H.

Using the preceding result, one can prove the existence of optimal controls for problems (P1) and (P2).

Theorem 24. Let Z be a weakly lower semicontinuous functional defined on H and bounded from below. Then there exists an optimal control solving problem (P1).

Theorem 25 (P2)**.** Suppose the given target set M is a weakly closed subset of H and the system is controllable in the sense that there exists an admissible u, and $\tau \in \bar{I}$, such that $\phi(u)(\tau) \in M$. Then there exists an optimal control that steers the systems from state ϕ_0 to the target set M in minimum time.

Optimal control problems for the more general system (112) recently have been studied in several papers giving existence results for measurable controls and measure-valued controls. Systems governed by differential inclusions of the form (115) and their associated control problems also have been studied recently. The technical details are too long for presentation here. Interested readers may consult the Bibliography.

D. Necessary Conditions of Optimality

For completeness we shall present a result on the necessary conditions of optimality. Consider system (122) along with the cost functional given by:

$$J(u) = Z(\phi(T) + \int_0^T f^0(t, \phi(t), u(t)\, dt \tag{124}$$

The problem is to find a control $u^0 \in \mathcal{U}$ that minimizes the functional J subject to constraint (122). Let $\{F_\alpha(t, x, \xi)\}$,

$t,\ x \in I \times \Omega, \xi = \{\xi_\alpha, |\alpha| \le m\} \in R^N$, denote the functions defining the operator B (see Eqs. (119) and (120)) and $\{F_\alpha^\beta, |\beta| \le m\}$ their directional derivatives with respect to $\xi \in R^N$. We assume that for fixed $t,\ x \in I \times \Omega$, the functions $\xi \to F_\alpha^\beta(t, x, \xi)$ are continuous on R^N for all α, β satisfying $|\alpha|, |\beta| \le m$, and, for fixed $\xi \in R^N$, $(t, x) \to F_\alpha^\beta(t, x, \xi)$ are measurable on $I \times \Omega$. For any fixed $\phi \in L_p(I, V)$, the bilinear form,

$$b_\phi(\psi, \nu) \equiv \sum_{|\alpha|,|\beta| \le m} \int_I \langle D^\alpha \psi, F_\beta^\alpha(t, x; \phi, D^1\phi, \ldots, D^m\phi) D^\beta \nu \rangle_\Omega \, dt \tag{125}$$

is well defined on $L_p(I,\ V) \times L_p(I,\ V)$. Let

$$\begin{aligned} f_1^0 &: I \times V \times E \to V^* \\ f_2^0 &: I \times V \times E \to E^* \end{aligned} \tag{126}$$

denote the linear Gateaux differentials of f^0 with respect to the state and control variables, respectively, and let

$$F: I \times E \to \mathcal{L}(E, V^*) \tag{127}$$

denote the linear Gateaux differential of f with respect to the control variable.

Under a number of technical assumptions on the functions $\{F_\alpha, |\alpha| \le m\}$, f, f^0, and Z and the control constraint set $\Gamma \subset E$, one can prove the folowing necessary conditions of optimality.

Theorem 26. Consider system (122) with the cost functional (124). For the pair $\{u^0, \phi^0\} \in \mathcal{U} \times \mathcal{X}$ to be optimal it is necessary that there exists a $\psi^0 \in L_p(I, V) \cap C(\bar{I}, H)$ so that the triple $\{u^0, \psi^0, \phi^0\}$ satisfy the conditions:

(a) $(L\phi^0, \nu) + b(\phi^0, \nu) = (f(u^0), \nu), \qquad \phi^0(0) = \phi_0$

for all

$$\nu \in \mathcal{F}_1 \equiv \{\nu \in L_p(I, V) \cap C(\bar{I}, H): \nu(T) = 0\}$$

(b) $-(L\psi^0, \nu) + b_{\phi^0}(\psi^0, \nu) + (f_1^0, \nu) = 0,$

$$\psi^0(T) = -Z'(\phi^0(T))$$

for all

$$\nu \in \mathcal{F}_0 \equiv \{\nu \in L_p(I, V) \cap C(\bar{I}, H): \nu(0) = 0\}$$

(c) $$\int_I \langle f_2^0(t, \phi^0(t), u^0(t)) - F^*(t, u^0(t))\psi^0(t),\ w(t) - u^0(t) \rangle_{E^*,E} \, dt \ge 0 \tag{128}$$

for all $w \in \mathcal{U}$, where F^* denotes the dual of the operator $F(t,\ u^0(t)) \in \mathcal{L}(E,\ V^*)$ and Z' the Gateaux derivative of Z on H.

For time-optimal controls, similar necessary conditions exist. In this case, the optimal control is also characterized by inequality (c), with the exceptions that $f_2^0 \equiv 0$ and the upper limit of the integral is the optimal time t^0 instead of T.

A number of interesting observations can be made from the above result. For example, if $f(t,\ u) = T(t)u$ and $f^0(t, \phi,\ u) = \tilde{f}^0(t,\ \phi) + \langle Nu, u \rangle_{E^*,E}$ and the control set $\Gamma = E$, then it follows from inequality (c) that

$$(N + N^*)u^0(t) = T^*(t)\psi^0(t) \tag{129}$$

Hence, if E is reflexive and $N = N^*$ and N is invertible, then $u^0(t) = \frac{1}{2}N^{-1}T^*(t)\psi^0(t)$. This is precisely the form of optimal controls for linear systems with quadratic cost functionals.

E. Nonlinear Stochastic Evolution Equations

We present here a brief account of nonlinear stochastic systems. The simplest nonlinear stochastic evolution equation may be given by:

$$dy = Ay\,dt + f(y)\,dW(t), \qquad t \ge 0, \qquad y(0) = y_0 \tag{130}$$

where W is the Wiener process with covariance operator $Q \in \mathcal{L}^+(H)$ as in the linear case. A is the generator of a c_0-semigroup $S(t)$, $t \ge 0$, on H, and $f: H \to \mathcal{L}(H)$ satisfying:

$$\begin{aligned} &\text{(a)} \quad \|f(x)\|_{\mathcal{L}(H)}^2 \le K^2(1 + |x|_H^2) \\ &\text{(b)} \quad \|f(x) - f(y)\|_{\mathcal{L}(H)}^2 \le K^2|x - y|_H^2 \end{aligned} \tag{131}$$

Define the nonlinear operator G by:

$$(Gx)(t) \equiv S(t)y_0 + \int_0^t S(t - \theta) f(x(\theta))\, dW(\theta) \tag{132}$$

for $x \in X \equiv C(I, L_2(\Omega, H))$, where X is a Banach space with respect to the topology given by:

$$\|x\|_X \equiv \sqrt{\sup\{E|x(t)|_H^2, t \in I\}}$$

Under the above assumptions one can prove the existence of an integer n, such that the nth iteration of G, denoted by G^n, is a contraction in X. Hence, by the Banach fixed-point theorem, there exists $y \in X$ such that $y = Gy$. In other words, the integral equation in X,

$$y(t) = S(t)y_0 + \int_0^t S(t - \theta) f(y(\theta))\, dW(\theta) \qquad t \in [0, T]$$

has a unique solution $y \in X$ whenever $y_0 \in L_2(\Sigma,\ H)$, hence y is a mild solution of system (130).

Existence theory for semilinear stochastic evolution equations of the form,

$$dy = (A(t)y + f(t, y))\,dt + \sigma(t)\,dW \qquad (133)$$

has been developed under much weaker hypotheses on the operators A and f using the Leray–Schauder degree theory. There are also results in which A has been considered to be a strongly measurable function from $(\Sigma, \mathcal{A}, P)$ to $\mathcal{L}_c(H)$, the space of closed densely defined linear (not necessarily bounded) operators in H. In this case, A is assumed to generate a strongly measurable (random) c_0-semigroup in H. Existence theory for nonlinear stochastic boundary value problems of the form,

$$\begin{aligned} \frac{\partial \phi}{\partial t} + A(t)\phi &= f + F(\phi) \qquad \text{on} \quad I \times \Omega \\ B\phi &= g + G(\phi) \qquad \text{on} \quad I \times \partial\Omega \\ \phi(0) &= \phi_0 \qquad \text{on} \quad \Omega \end{aligned} \qquad (134)$$

has been considered with f, g being generalized random processes, ϕ_0 a generalized random variable, and F, G nonlinear accretive operators. Stability problems for systems of the form (134) with $f = 0$; $g = N$, a generalized white noise; $G = 0$; and F being a monotone operator have been studied. It has been shown that the system is asymptotically stable with respect to a ball around the origin with radius determined by the trace of the covariance operator of the associated Wiener process.

It appears from the literature that for nonlinear systems the theory of optimal control, filtering, identification, and controllability is far from satisfactory. This is a difficult but fascinating field and certainly a challenging subject of the future.

IV. RECENT ADVANCES IN INFINITE-DIMENSIONAL SYSTEMS AND CONTROL

In this section we discuss some recent advances in the theory and applications of distributed parameter systems since the time of first publication of this encyclopedia. Details of these new developments can be found in the references. There has been substantial theoretical development of distributed parameter systems, as indicated in References 11 to 36. These include general boundary control problems, control of deterministic and stochastic evolution inequalities and differential inclusions, uncertain systems, and the so-called B-evolutions. Due to space limitations, we cannot include the details. Here we shall give only a brief outline of the major new concepts introduced in recent years. On the theoretical front, there are three new major developments:

1. The first one is in the area of control theory for systems governed by m-times integrated semigroups or distribution semi groups.
2. The second one is in the area of fundamental concepts, in particular, the notion of solution, a new notion of solutions, called *measure solutions*, has been introduced very recently and has been used in the theory of control of distributed parameter systems.
3. The third front extends the concept of impulsive systems to infinite dimensional Banach spaces; we shall discuss briefly these new developments and their implication in mathematical sciences.
4. The fourth front represents recent applications of the theory of distributed parameter systems to the physical sciences.

A. *m*-Times Integrated Semigroups

The classical semigroup theory, as seen in Section II, is based on the assumptions that A is closed and $D(A)$ is dense in X and that the Hille–Yosida inequality,

$$\|R(\lambda, A)\| \equiv \|(\lambda I - A)^{-1}\| \le M/(\lambda - \omega), \qquad \lambda \in \rho(A) \supset (\omega, \infty) \qquad (135)$$

holds for some $M \ge 0$ and $\omega \in R$. These are the necessary and sufficient conditions for the existence of a C_0-semigroup $S(t)$, $t \ge 0$, and hence the existence of a solution of the Cauchy problem,

$$\dot{x} = Ax, \qquad x(0) = \xi \qquad (136)$$

in X. The solution is given by $x(t) = S(t)\xi$, $t \ge 0$. No doubt this covers a very large class of partial differential operators with given boundary conditions and hence a large class of distributed parameter systems. However, there are classes of operators A which do not satisfy the Hille–Yosida theorem, yet such systems have solutions in some generalized sense. According to the Hille–Yosida theorem, $R(\lambda, A)$ is the Laplace transform of some operator-valued function $S(t)$, $t \ge 0$. It is now known that the Cauchy problem stated above has a solution in some generalized sense even if only $R_m(\lambda, A) \equiv R(\lambda, A)/\lambda^m$, $\lambda \in \rho(A)$, is the Laplace transform of an operator-valued function $T(t)$, $t \ge 0$. In this case, $T(t)$, $t \ge 0$, is said to be the m-times integrated semigroup and A is said to be its infinitesimal generator. The classical solution for the Cauchy problem as stated above is now given by:

$$x(t) = (d^m/dt^m)T(t)\xi, t \ge 0, \qquad \text{for} \quad \xi \in D(A^{m+1})$$

In general, if $\xi \in X$ there is no classical solution but we may admit generalized derivatives and hence generalized solutions. For example, if $D(A^{m+1})$ is dense in X, one can choose a sequence $\{\xi_k\}$ converging strongly to ξ and

consider the entity x as the generalized solution if it satisfies the identity:

$$\int_0^\tau \langle x(t), \phi(t)\rangle_{X,X^*}\, dt = (-1)^m \lim_{k\to\infty} \int_0^\tau \left\langle T(t)\xi_k, D^m\phi(t)\right\rangle_{X,X^*} dt \quad (137)$$

for all ϕ in a class of test functions. A suitable class of test functions for this problem is the Sobolev class $W_0^{m,1}(I, X^*)$ which consists of X^*-valued functions whose derivatives up to order $m-1$ vanish on the boundary of the set $I \equiv (0, \tau)$ and belong to $L_1(I, X^*)$. By duality, the solution $x \in W^{-m,\infty}(I, X)$. For further details on m-times integrated semigroups, generalized solutions, stochastic systems, and optimal controls of systems involving operators that generate such semigroups, the reader may consult References 13, 21, and 24.

B. Measure Solution

Consider the system,

$$\dot{x} = f(x), \qquad x(0) = \xi \in E \quad (138)$$

It is well known that if $E = R^n$ is a finite-dimensional space and f is merely continuous, the system has at least one local solution in the sense that there exists a maximal interval of time $(0, \tau_m)$ and an absolutely continuous function $x^*(t)$, $t \in (0, \tau_m)$, that satisfies the differential equation along with the initial condition $x^*(0) = \xi$, with the possibility of blow-up at time τ_m. That is,

$$\lim_{t\to\tau_m} \|x^*(t)\| = \infty \quad (139)$$

An elementary example is $\dot{y} = y^2$, $y(0) = \gamma$. If $\gamma > 0$, the blow-up time is $\tau_m = (1/\gamma)$.

In contrast, if E is an infinite-dimensional Banach space, mere continuity of $f : E \to E$ is no more sufficient to guarantee even a local solution. Even continuity and boundedness of this map do not guarantee existence. Compactness is necessary. However, under mere continuity and local boundedness assmptions, one can prove the existence of generalized (to be defined shortly) solutions. This is what prompted the concept and development of measure-valued solutions. Consider the semilinear system,

$$\dot{x} = Ax + f(x), t \geq 0, \qquad x(0) = x_0 \quad (140)$$

and suppose A is the infinitesimal generator of a C_0-semigroup in E. Let $BC(E)$ denote the Banach space of bounded continuous functions on E with the standard topology induced by the sup norm $\|\phi\| \equiv \sup\{|\phi\ (\xi)|, \xi \in E\}$. The dual of this space is the space of regular, bounded, finitely additive measures denoted by $\sum_{rba}(E)$ and defined on the algebra of sets generated by closed subsets of E. This is a Banach space with respect to the topology induced by the total variation norm. Let $\Pi_{rba}(E) \subset \sum_{rba}(E)$ denote the space of regular, finitely additive probability measures. For a $\nu \in \sum_{rba}(E)$ and $\phi \in BC(E)$, the pairing

$$(\nu, \phi) \equiv \nu(\phi) \equiv \int_E \phi(\xi)\nu(d\xi)$$

is well defined. Letting $D\phi$ denote the Frechet derivative of $\phi \in BC(E)$, we introduce the class,

$$\mathcal{F} \equiv \{\phi \in BC(E) : D\phi \text{ continuous with } \phi,\ D\phi \text{ having bounded supports}\}$$

for test functions. Define the operator $\mathcal{A}$ with domain:

$$D(\mathcal{A}) \equiv \{\phi \in F : \mathcal{A}\phi \in BC(E^+)\}$$

where for $\phi \in D(\mathcal{A})$,

$$\mathcal{A}\phi \equiv \langle A^* D\phi(\xi), \xi\rangle_{E^*,E} + \langle D\phi(\xi),\ f(\xi)\rangle_{E^*,E} \quad (141)$$

and E^+ is a suitable compactification of E that makes E^+ a compact Hausdorff space containing E as a dense subspace. The new notion of a solution for the Cauchy problem (140) can be stated as follows.

Definition: A measure function μ_t, $t \geq 0$, with values in $\Pi_{rba}(E)$, is said to be a generalized solution of the semilinear evolution equation if, for each $\phi \in D(\mathcal{A})$, the following identity holds:

$$\mu_t(\phi) = \phi(x_0) + \int_0^t \mu_s(\mathcal{A}\phi)\, ds, \qquad t \geq 0 \quad (142)$$

The concepts of measure solutions and stochastic evolution equations have been extended. For example, consider the infinite-dimensional stochastic systems on a Hilbert space H, governed by Eq. (130) or, more generally, the equation:

$$dx = Ax\, dt + f(x)\, dt + \sigma(x)\, dW, \qquad x(0) = x_0 \quad (143)$$

Again, if f and ω are merely continuous and bounded on bounded sets, all familiar notions of solutions (strong, mild, weak, martingale) fail. However, measure solutions are well defined. In this case, expression (142) must be modified as follows:

$$\mu_t(\phi) = \phi(x_0) + \int_0^t \mu_s(\mathcal{A}\phi)\, ds + \int_0^t \langle \mu_s(\mathcal{B}\phi), dW(s)\rangle, \qquad t \geq 0 \quad (144)$$

where now the operator $\mathcal{A}$ is given by the second-order partial differential operator,

$$\mathcal{A}\phi \equiv (1/2)Tr(D^2\phi\sigma\sigma^*) + \langle A^*D\phi(\xi), \xi\rangle_H + \langle D\phi(\xi),\ f(\xi)\rangle_H \tag{145}$$

and the operator $\mathcal{B}$ is given by:

$$\mathcal{B}\phi \equiv \sigma^* D\phi$$

The last term is a stochastic integral with respect to a cylindrical Brownian motion (for details, see Reference 31). The operators $\mathcal{A}$ and $\mathcal{B}$ are well defined on a class of test functions given by:

$$\mathcal{F} \equiv \{\phi \in BC(E) : \phi,\ D\phi,\ D^2\phi \text{ continuous having bounded supports and } Tr(D^2\phi\sigma\sigma^*(\xi)) < \infty, \xi \in H\} \tag{146}$$

A detailed account of measure solutions and their optimal control for semilinear and quasilinear evolution equations can be found in References 20, 22, 28, and 30–32.

C. Impulsive Systems

In many physical problems, a system may be subjected to a combination of continuous as well as impulsive forces at discrete points of time. For example, in building construction, piling is done by dropping massive weights on the top of vertically placed steel bars. This is an impulsive input. In the management of stores, inventory is controlled by an agreement from the supplier to supply depleted goods. An example from physics is a system of particles in motion which experience collisions from time to time, thereby causing instantaneous changes in directions of motion. In the treatment of patients, medications are administered at discrete points of time, which could be considered as impulsive inputs to a distributed physiological system.

The theory of finite dimensional impulsive systems is well known.[12] Only in recent years has the study of infinite dimensional impulsive systems been initiated.[27,33–36] Here, we present a brief outline of these recent advances. Let $I \equiv [0, T]$ be a closed bounded interval of the real line and define the set $D \equiv \{t_1, t_2, \cdot, \cdot, t_n\} \in (0, T)$. A semilinear impulsive system can be described by the following system of equations:

$$\begin{aligned} \dot{x}(t) &= Ax(t) + f(x(t)), \\ t &\in I\backslash D, \qquad x(0) = x_0, \\ \Delta x(t_i) &= F_i(x(t_i)), \\ 0 = t_0 < t_1 < t_2, \cdots < t_n < t_{n+1} &= T \end{aligned} \tag{147}$$

where, generally, A is the infinitesimal generator of a C_0-semigroup in a Banach space E, the function f is a continuous nonlinear map from E to E, and $F_i : E \to E$, $i = 1, 2, \cdot, \cdot, n$, are continuous maps. The difference operator $\Delta_x(t_i) \equiv x(t_i + 0) - x(t_i - 0) \equiv x(t_i + 0) - x(t_i)$ denotes the jump operator. This represents the jump in the state x at time t_i with F_i determining the jump size at time t_i. Similarly, a controlled impulsive system is governed by the following system of equation:

$$\begin{aligned} dx(t) &= [Ax(t) + f(x(t))]\,dt + g(x(t))\,dv(t), \\ t &\in I\backslash D, x(0) = x_0, \\ \Delta x(t_i) &= F_i(x(t_i)), \\ 0 = t_0 < t_1 < t_2, \cdots < t_n < t_{n+1} &= T \end{aligned} \tag{148}$$

where $g : E \to \mathcal{L}(F, E)$ and the control $v \in BV(I, F)$. For maximum generality, one can choose the Banach space $BV(I, F)$ of functions of bounded variation on I with values in another Banach space F as the space of admissible controls. This class allows continuous as well as jump controls. For each $r > 0$, let $B_r \equiv \{\xi \in E : \|\xi\| \le r\}$ denote the ball of radius r around the origin. Let $PWC_\ell(I, E)$ denote the Banach space of piecewise continuous functions on I taking values from E, with each member being left continuous, having right-hand limits. For solutions and their regularity properties we have the following.

Theorem 27. Suppose the following assumptions hold:

(A1) A is the infinitesimal generator of a C_0-semigroup in E.

(A2) The maps $g, F_i, i = 1, 2, \cdot, \cdot, n$ are continuous and bounded on bounded subsets of E with values in $\mathcal{L}(F, E)$ and E, respectively,

(A3) The map f is locally Lipschitz having at most linear growth; that is, there exist constants $K > 0, K_r > 0$, such that:

$$\|f(x) - f(y)\|_E \le K_r\|x - y\|_E, \qquad x, y \in B_r$$
$$\text{and} \quad \|f(x)\| \le K(1 + \|x\|)$$

Then, for every $x_0 \in E$ and $v \in BV(I, F)$, system (148) has a unique mild solution, $x \in PWC_l(I, E)$.

Using this result one can construct necessary conditions of optimality. We present here one such result of the author.[35] Consider $\mathcal{U} \in BV(I, F)$ to be the class of controls comprised of pure jumps at a set of arbitrary but prespecified points of time $J \equiv \{0 = t_0 = s_0 < s_1 < s_2, \cdot, \cdot, < s_{m-1} < s_m, m \ge n\} \subset [0, T)$. Clearly $\mathcal{U}$ is isometrically isomorphic to the product space $\mathcal{F} \equiv \prod_{k=1}^{m+1} F$, furnished with the product topology. We choose a closed convex subset $\mathcal{U}_{ad} \subset \mathcal{U}$ to be the class of admissible controls. The

basic control problem is to find a control policy that imparts a minimum to the following cost functional,

$$J(v) = J(q) \equiv \int_0^T \ell(x(t), v(t))\, dt + \varphi(v) + \Phi(x(T))$$
$$\equiv \int_0^T \ell(x(t), q)\, dt + \varphi(q) + \Phi(x(T))$$

Theorem 28. Suppose assumptions (A1) to (A3) hold, with $\{f, F_i, g\}$ all having Frechet derivatives continuous and bounded on bounded sets, and the functions ℓ, φ, Φ are once continuously Gateaux differentiable on $E \times F, \mathcal{F}, E$, respectively. Then, if the pair $\{v^o (or q^o), x^o\}$ is optimal, there exists a $\psi \in PWC_r(I, E^*)$ so that the triple $\{v^0, x^0, \psi\}$ satisfies the following inequality and evolution equation:

$$\text{(a)} \quad \sum_{i=0}^{m} \left\langle \left\{ g^*\big(x^o(s_i)\big)\psi(s_i) + \varphi_{q_i}(q^o) + \int_{s_i}^{T} \ell_u(x^o(t), v^o(t))\, dt \right\}, q_i - q_i^o \right\rangle_{F^*,F} \geq 0$$

for all $q = \{q_0, q_1, \cdot, \cdot, q_m\} \in \mathcal{U}_{ad}$.

$$\text{(b)} \quad d\psi = -\big(A^*\psi + f_x^*(x^o(t))\psi - \ell_x(x^o(t), v^o(t))\, dt - g_x^*(x^o(t), \psi(t))\, dv^o, \qquad t \in I \backslash D$$
$$\psi(T) = \Phi_x(x^o(T))$$
$$\Delta_r \psi(t_i) = -F_{i,x}^*\big(x^o(t_i)\big)\psi(t_i), \qquad i = 1, 2, \cdot, \cdot, n$$

where the operator Δ_r is defined by $\Delta_r f(t_i) \equiv f(t_i - 0) - f(t_i)$.

(c) The process x^o satisfies the system equation (148) (in the mild sense) corresponding to the control v^o.

In case a hard constraint is imposed on the final state requiring $x^o(T) \in \mathcal{K}$ where $\mathcal{K}$ is a closed convex subset of E with nonempty interior, the adjoint equation given by (b) requires modification. The terminal equality condition is replaced by the inclusion $\psi(T) \in \partial I_{\mathcal{K}}(x^o(T))$, where $I_{\mathcal{K}}$ is the indicator function of the set $\mathcal{K}$.

Recently a very general model for evolution inclusions has been introduced:[36]

$$\begin{aligned} \dot{x}(t) &\in Ax(t) + F(x(t)), \\ &\qquad t \in I \backslash D, \qquad x(0) = x_0, \\ \Delta x(t_i) &\in G_i(x(t_i)), \\ 0 = t_0 < t_1 < t_2, \cdots < t_n < t_{n+1} &\equiv T \end{aligned} \tag{2.3}$$

Here, both F and $\{G_i,\ i = 1, 2, \cdot, \cdot, n\}$ are multivalued maps. This model may arise under many different situations. For example, in case of a control problem where one wishes to control the jump sizes in order to achieve certain objectives, one has the model,

$$\begin{aligned} \dot{x}(t) &\in Ax(t) + F(x(t)), \\ &\qquad t \in I \backslash D, \qquad x(0) = x_0, \\ \Delta x(t_i) &= g_i(x(t_i), u_i)), \\ 0 = t_0 < t_1 < t_2, \cdots < t_n < t_{n+1} &\equiv T \end{aligned}$$

where the controls u_i may take values from a compact metric space U. In this case, the multis are given by $G_i(\zeta) = g_i(\zeta, U)$. For more details on impulsive evolution equations and, in general, inclusions, the reader may consult References 35 and 36.

D. Applications

The slow growth of application of distributed systems theory is partly due to its mathematical and computational complexities. In spite of this, in recent years there have been substantial applications of distributed control theory in aerospace engineering, including vibration suppression of aircraft wings, space shuttle orbiters, space stations, flexible artificial satellites, and suspension bridges. Several papers on control of fluid dynamical systems governed by Navier–Stokes equations have appeared over the past decade with particular reference to artificial heart design. During the same period, several papers on the control of quantum mechanical and molecular systems have appeared. Distributed systems theory has also found applications in stochastic control and filtering. With the advancement of computing power, we expect far more applications in the very near future.

Dynamic Programming

Martin L. Puterman
The University of British Columbia

GLOSSARY

Action One of several alternatives available to the decision maker when the system is observed in a particular state.
Decision rule Function that determines for the decision maker which action to select in each possible state of the system.
Discount factor Present value of a unit of currency received one period in the future.
Functional equation Basic entity in the dynamic programming approach to solving sequential decision problems. It relates the optimal value for a $(t+1)$-stage decision problem to the optimal value for a t-stage problem. Its solution determines an optimal decision rule at a particular stage.
Horizon Number of stages.
Markov chain Sequence of random variables in which the conditional probability of the future is independent of the past when the present state is known.
Markov decision problem Stochastic sequential decision problem in which the set of actions, the rewards, and the transition probabilities depend only on the current state of the system and the current action selected; the history of the problem has no effect on current decisions.
Myopic policy Policy in which each decision rule ignores the future consequence of the decision and uses the action at each stage that maximizes the immediate reward.
Policy Sequence of decision rules.
Stage Point in time at which a decision is made.
State Description of the system that provides the decision maker with all the information necessary to make future decisions.
Stationary Referring to a problem in which the set of actions, the set of states, the reward function, and the transition function are the same at each decision point or to a policy in which the same decision rule is used at every decision point.

IN ALL AREAS of endeavor, decisions are made either explicitly or implicitly. Rarely are decisions made in isolation. Today's decision has consequences for the future because it could affect the availability of resources or limit the options for subsequent decisions. A sequential decision problem is a mathematical model for the problem faced by a decision maker who is confronted with a sequence of interrelated decisions and wishes to make them in an optimal fashion. Dynamic programming is a collection of mathematical and computational tools for analyzing sequential decision problems. Its main areas of

application are operations research, engineering, statistics, and resource management. Improved computing capabilities will lead to the wide application of this technique in the future.

I. SEQUENTIAL DECISION PROBLEMS

A. Introduction

A system under the control of a decision maker is evolving through time. At each point of time at which a decision can be made, the decision maker, who will be referred to as "he" with no sexist connotations intended, observes the state of the system. On the basis of this information, he chooses an action from a set of alternatives. The consequences of this action are two-fold; the decision maker receives an immediate reward or incurs an immediate cost, and the state that the system will occupy at subsequent decision epochs is influenced either deterministically or probabilistically. The problem faced by the decision maker is to choose a sequence of actions that will optimize the performance of the system over the decision-making horizon. Since the action selected at present affects the future evolution of the system, the decision maker cannot choose his action without taking into account future consequences.

Dynamic programming is a procedure for finding optimal policies for sequential decision problems. It differs from linear, nonlinear, and integer programming in that there is no standard dynamic programming problem formulation. Instead, it is a collection of techniques based on developing mathematical recursions to decompose a multistage problem into a series of single-stage problems that are analytically or computationally more tractable. Its implementation often requires ingenuity on the part of the analyst, and the formulation of dynamic programming problems is considered by some practitioners to be an art. This subject is best understood through examples. This section proceeds with a formal introduction of the basic sequential decision problem and follows with several examples. The reader is encouraged to skip back and forth between these sections to understand the basic ingredients of such a problem. Dynamic programming methodology is discussed in Sections II and III.

B. Problem Formulation

Some formal notation follows. Let T denote the set of time points at which decisions can be made. The set T can be classified in two ways; it is either finite or infinite and either a discrete set or a continuum. The primary focus of this article is when T is discrete. Discrete-time problems are classified as either finite horizon or infinite horizon according to whether the set T is finite or infinite. The problem formulation in these two cases is almost identical; however, the dynamic programming methods of solution differ considerably. For discrete-time problems, T is the set $\{1, 2, \ldots, N\}$ in the finite case and $\{1, 2, \ldots\}$ in the infinite case. The present decision point is denoted by t and the subsequent point by $t+1$. The points of time at which decisions can be made are often called stages. Almost all the results in this article concern discrete-time models; the continuous-time model is briefly mentioned in Section IV.

The set of possible states of the system at time t is denoted by S_t. In finite-horizon problems, this is defined for $t = 1, 2, \ldots, N+1$, although decisions are made only at times $t = 1, 2, \ldots, N$. This is because the decision at time N often has future conseqences that can be summarized by evaluating the state of the system at time $N+1$. This is analagous to providing boundary values for differential equations. If at time t the decision maker observes the system in state $s \in S_t$, he chooses an action a from the set of allowable actions at time t, $A_{s,t}$. As above, S_t and $A_{s,t}$ can be either finite or infinite and discrete or continuous. This distinction has little consequence for the problem formulation.

As a result of choosing action a when the system is in state s at time t, the decision maker receives an immediate reward $r_t(s, a)$. This reward can be positive or negative. In the latter case it can be thought of as a cost. Furthermore, the choice of action affects the system evolution either deterministically or probabilistically. In the deterministic case, the choice of action determines the state of the system at time $t+1$ with certainty. Denote by $w_t(s, a) \in S_{t+1}$ the state the system will occupy if action a is chosen in state s at time t; $w_t(s, a)$ is called the transfer function. When the system evolves probabilistically, the subsequent state is random and choice of action specifies its probability distribution. Let $p_t(j|s, a)$ denote the probability that the system is in state $j \in S_{t+1}$ if action a is chosen in state s at time t; $p_t(j|s, a)$ is called the transition probability function. When S_t is a continuum, $p_t(j|s, a)$ is a probability density. Such models are discussed briefly in Section IV. A sequential decision problem in which the transitions from state to state are governed by a transition probability function and the set of actions and rewards depends only on the current state and stage is called a Markov decision problem.

The deterministic model is a special case of the probabilistic model obtained by choosing $p_t(j|s, a) = 1$ if $j = w_t(s, a)$ and $p_t(j|s, a) = 0$ if $j \neq w_t(s, a)$. Even though there is this equivalence, the transfer function representation is more convenient for deterministic problems.

A decision rule is a function $d_t : S_t \to A_{s,t}$ that specifies the action the decision maker chooses when the system is

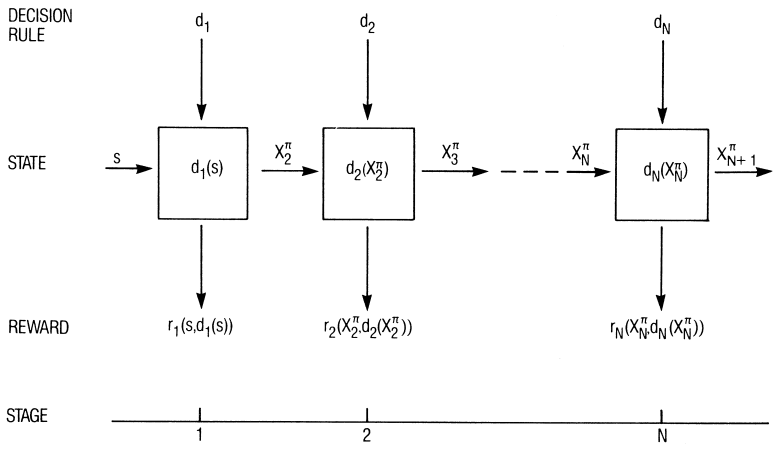

FIGURE 1 Evolution of the sequential decision model under the policy $\pi = (d_1, d_2, \ldots, d_N)$. The state at stage 1 is s.

in state s at time t; that is, $d_t(s)$ specifies an action in $A_{s,t}$ for each s in S_t. A decision rule of this type is called Markovian because it depends only on the current state of the system. The set of allowable decision rules at time t is denoted by D_t and is called the decision set. Usually it is the set of all functions mapping S_t to $A_{s,t}$, but in some applications, it might be a proper subset.

Many generalizations of deterministic Markovian decision rules are possible. Decision rules can depend on the entire history of the system, which is summarized in the sequence of observed states and actions observed up to the present, or they can depend only on the initial and current state of the system. Furthermore, the decision rule might be randomized; that is, in each state it specifies a probability distribution on the set of allowable actions so that by using such a rule the decision maker chooses his action at each decision epoch by a probabilistic mechanism. For the problems considered in this article, using deterministic Markovian decision rules at each stage is optimal so that the generalizations referred to above will not be discussed further.

A policy specifies the sequence of decision rules to be used by the decision maker over the course of the planning horizon. A policy π is a finite or an infinite sequence of decision rules; that is, $\pi = \{d_1, d_2, \ldots, d_N\}$, where $d_t \in D_t$ for $t = 1, 2, \ldots, N$ if the horizon is finite, or $\pi = \{d_1, d_2, \ldots\}$, where $d_t \in D_t$ for $t = 1, 2, \ldots$ if the horizon is infinite. Let Π denote the set of all possible policies; $\Pi = D_1 \times D_2 \times \cdots \times D_N$ in the finite case and $\Pi = D_1 \times D_2 \times \cdots$ in the infinite case.

In deterministic problems, by specifying a policy at the start of the problem, the decision maker completely determines the future evolution of the system. For each policy the sequence of states the system will occupy is known with certainty, and hence the sequence of rewards the decision maker will receive over the planning horizon is known. Let X_t^π denote the state the system occupies at time t if the decision maker uses policy π over the planning horizon. In the first period the decision maker receives a reward of $r_1(s, d_1(s))$, in the second period a reward of $r_2(X_2^\pi, d_2(X_2^\pi))$, and in the tth period $r_t(X_t^\pi, d_t(X_t^\pi))$. Figure 1 depicts the evolution of the process under a policy $\pi = \{d_1, d_2, \ldots, d_N\}$ in both the deterministic and stochastic cases. The quantity in each box indicates the interaction of the incoming state with the prespecified decision rule to produce the indicated action $d_t(X_t^\pi)$. The arrow to the right of a box indicates the resulting state, and the arrow downward the resulting reward to the decision maker. The system is assumed to be in state s before the first decision.

The decision maker evaluates policies by comparing the value of a function of the policy's income stream. Many such evaluation functions are available, but it is most convenient to assume a linear, additive, and risk-neutral utility function over time, which leads to using the total reward over the planning horizon for evaluation. Let $v_N^\pi(s)$ be the total reward over the planning horizon. It is given by the expression

$$v_N^\pi(s) = \sum_{t=1}^{N+1} r_t\left(X_t^\pi, d_t\left(X_t^\pi\right)\right), \tag{1}$$

in which it is implicit that $X_1^\pi = s$. For deterministic problems, evaluation formulas such as Eq. (1) always depend on the initial state of the process, although this is not explicitly stated below.

In probabilistic problems, by specifying a policy at the start of the problem, the decision maker determines the transition probability functions of a nonstationary Markov chain. The sequence of states the system will occupy is not known with certainty, and consequently the sequence of rewards the decision maker will receive over the planning

horizon is not known. Instead, what is known is the joint probability distribution of system states and rewards. In this case, expectations with respect to the joint probability distributions of the Markov chain conditional on the state at the first decision epoch are often used to evaluate policy performance. As in the deterministic case, let X_t^π denote the state the system occupies at time t if the decision maker uses policy π over the planning horizon. For finite-horizon problems, let $v_N^\pi(s)$ equal the total expected reward over the planning horizon. It is given by the expression

$$v_N^\pi(s) = E_{\pi,s}\left\{\sum_{t=1}^{N+1} r_t\left(X_t^\pi, d_t\left(X_t^\pi\right)\right)\right\}, \qquad (2)$$

where $E_{\pi,s}$ denotes the expectation with respect to probability distribution determined by π conditional on the initial state being s.

In both the deterministic and stochastic problems the decision maker's problem is to choose at time 1 a policy π in Π to make $v_N^\pi(s)$ as large as possible and to find the maximal reward,

$$v_N^*(s) = \sup_{\pi\in\Pi} v_N^\pi(s) \qquad \text{for all} \quad s \in S_1. \qquad (3)$$

Frequently the problem is such that the supremum in Eq. (3) is attained—for example, when both $A_{s,t}$ and S_t are finite for all $t \in T$. In such cases the decision maker's objective is to maximize $v_N^\pi(s)$ and find its maximal value.

For infinite-horizon problems, the total reward or the expected total reward the decision maker receives will not necessarily be finite; that is, the summations in Eqs. (1) and (2) usually will not converge. To evaluate policies in infinite-horizon problems, decision makers often use discounting or averaging. Let λ represent the discount factor, usually $0 \le \lambda < 1$. It measures the value at present of one unit of currency received one period from now. Let $v_\lambda^\pi(s)$ equal the total discounted reward in deterministic problems or the expected total discounted reward for probabilistic problems if the system is in state s, before choosing the first action. For deterministic problems it is given by

$$v_\lambda^\pi(s) = \sum_{t=1}^{\infty} \lambda^{t-1} r_t\left(X_t^\pi, d_t\left(X_t^\pi\right)\right), \qquad (4)$$

and for stochastic problems it is given by

$$v_\lambda^\pi(s) = E_{\pi,s}\left\{\sum_{t=1}^{\infty} \lambda^{t-1} r_t\left(X_t^\pi, d_t\left(X_t^\pi\right)\right)\right\}. \qquad (5)$$

In this setting the decision maker's problem is to choose at time 1 a policy π in Π to make $v_\pi^\lambda(s)$ as large as possible and to find the supremal reward,

$$v_\lambda^*(s) = \sup_{\pi\in\Pi} v_\lambda^\pi(s) \qquad \text{for all} \quad s \in S_1. \qquad (6)$$

Alternatively in the infinite-horizon setting, the decision maker might not be willing to assume that a reward received in the future is any less valuable than a reward received at present. For example, if decision epochs are very close together in real time, then all rewards the decision maker receives would have equal value. In this case the decision maker's objective might be to choose a policy that maximizes the average or expected average reward per period. This quantity is frequently called the gain of a policy. For a specified policy it is denoted by $g^\pi(s)$ and in both problems is given by

$$g^\pi = \lim_{N\to\infty} \frac{1}{N} v_N^\pi(s), \qquad (7)$$

where $v_N^\pi(s)$ is defined in Eqs. (1) and (2).

In this setting the decision maker's problem is to choose at time 1 a policy π in Π to make $g^\pi(s)$ as large as possible and to find the supremal average reward,

$$g^*(s) = \sup_{\pi\in\Pi} g^\pi(s) \qquad \text{for all} \quad s \in S_1. \qquad (8)$$

Dynamic programming methods with the average reward criteria are quite complex and are discussed only briefly in Section III. The reader is referred to the works cited in the Bibliography for more details.

Frequently in infinite-horizon problems, the data are stationary. This means that the set of states, the set of allowable actions in each state, the one-period rewards, the transition or transfer functions, and the decision sets are the same at every stage. When this is the case, the time subscript t is deleted and the notation S, A_s, $r(s,a)$, $p(j|s,a)$ or $w(s,a)$, and D is used. Often stationary policies are optimal in this setting. By a stationary policy is meant a policy that uses the identical decision rule in each period; that is, $\pi = (d, d, \ldots)$. Often it is denoted by d when there is no possible source of confusion.

C. Examples

The following examples clarify the notation and formulation described in the preceding sections. The first example illustrates a deterministic, finite-state, finite-action, finite-horizon problem; the second a deterministic, infinite-state, infinite-action, finite-horizon problem; and the third a stochastic, finite-state, finite-action problem with both finite- and infinite-horizon versions. In Sections II and III, these examples will be solved by using dynamic programming methodology.

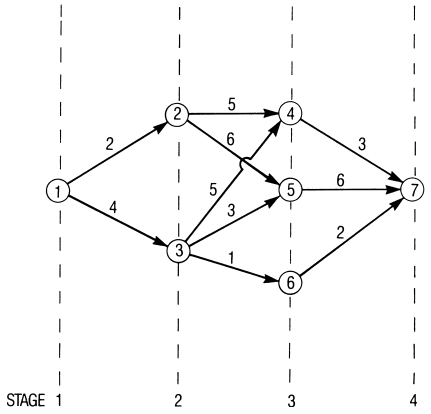

FIGURE 2 Network for the longest-route problem.

1. A Longest-Route Problem

A finite directed graph is depicted in Fig. 2. The circles are called nodes, and the lines connecting them are called arcs. On each arc, an arrow indicates the direction in which movement is possible. The numerical value on the arc is the reward the decision maker receives if he chooses to traverse that arc on his journey from node 1 to node 7. His objective is to find the path from node 1 to node 7 that maximizes the total reward he receives on his journey. Such a problem is called a longest-route problem. A practical application is determining the length of time needed to complete a project. In such problems, the arc length represents the time to complete a task. The entire project is not finished until all tasks are performed. Finding the longest path through the network gives the minimum amount of time for the entire project to be completed since it corresponds to that sequence of tasks that requires the most time. The longest path is called a critical path because, if any task in this sequence is delayed, the entire project will be delayed.

In other applications the values on the arcs represent lengths of road segments, and the decision maker's objective is to find the shortest route from the first node to the terminal node. Such a problem is called a shortest-route problem. All deterministic, finite-state, finite-action, finite-horizon dynamic programming problems are equivalent to shortest- or longest-route problems. Another example of this will appear in Section II.

An important assumption is that the network contains no directed cycle; that is, there is no route starting at a node that returns to that node. If this were the case, the longest route would be infinite and the problem would not be of interest.

The longest-route problem is now formulated as a sequential decision problem. This requires defining the set of states, actions, decision sets, transfer functions, and rewards. They are as follows:

Decision points:

$$T = \{1, 2, 3\}$$

States (numbers correspond to nodes):

$$S_1 = \{1\}; \qquad S_2 = \{2, 3\}; \qquad S_3 = \{4, 5, 6\};$$
$$S_4 = \{7\}$$

Actions (action j selected in node i corresponds to choosing to traverse the arc between nodes i and j; the first subscript on A is the state and the second the stage):

$$A_{1,1} = \{2, 3\}$$
$$A_{2,2} = \{4, 5\}; \qquad A_{3,2} = \{4, 5, 6\}$$
$$A_{4,3} = \{7\}; \qquad A_{5,3} = \{7\}; \qquad A_{6,3} = \{7\}$$

Rewards:

$$r_1(1, 2) = 2; \qquad r_1(1, 3) = 4$$
$$r_2(2, 4) = 5; \qquad r_2(2, 5) = 6;$$
$$r_2(3, 4) = 5, \qquad r_2(3, 5) = 3; \qquad r_2(3, 6) = 1$$
$$r_3(4, 7) = 3; \qquad r_3(5, 7) = 6; \qquad r_3(6, 7) = 2$$

Transfer function:

$$w_t(s, a) = a$$

The remaining ingredients in the sequential decision problem formulation are the decision set, the set of policies, and an evaluation formula. The decision set at stage t is the set of all arcs emanating from nodes at stage t. A policy is a list of arcs in which there is one arc starting at each node (except 7) in the network. The policy set contains all such lists. Each policy contains a route from node 1 to node 7 and some superfluous action selections. The value of the policy is the total of the rewards along this route, and the decision maker's problem is to choose a policy that maximizes this total reward.

The structure of a policy is described in more detail through an example. Consider the policy $\pi = \{(1, 2), (2, 4), (3, 4), (4, 7), (5, 7), (6, 7)\}$. Implicit in this definition is a sequence of decision rules $d_t(s)$ for each state and stage. They are $d_1(1) = 2$, $d_2(2) = 4$, $d_2(3) = 4$, $d_3(4) = 7$, $d_3(5) = 7$, and $d_3(6) = 7$. This policy can be formally denoted by $\pi = \{d_1, d_2, d_3\}$. The policy contains one unique routing through the graph, namely, $1 \to 2 \to 4 \to 7$ and several unnecessary decisions. We use the formal notation $X_1^\pi = 1$, $X_2^\pi = 2$, $X_3^\pi = 4$, and $X_4^\pi = 7$ so that

$$\begin{aligned} v_3^\pi(1) &= r_1(1, d_1(1)) + r_2(2, d_2(2)) + r_3(4, d_3(4)) \\ &= r_1(1, 2) + r_2(2, 4) + r_3(4, 7) \\ &= 2 + 5 + 3 = 10. \end{aligned}$$

In such a small problem, one can easily evaluate all policies by enumeration and determine that the longest route through the network is $1 \to 2 \to 5 \to 7$ with a return of 14. For larger problems this is not efficient; dynamic programming methods will be seen to offer an efficient means of determining the longest route.

The reader might note that the formal sequential decision process notation is quite redundant here. The subscript for stage does not convey any useful information and the specification of a policy requires making decisions in nodes that will never be reached. Solution by dynamic programming methods will require this superfluous information. In other settings this information will be useful.

2. A Resource Allocation Problem

A decision maker has a finite amount K of a resource to allocate between N possible activities. Using activity i at level x_i consumes $c_i(x_i)$ units of the resource and yields a reward or utility of $f_i(x_i)$ to the decision maker. The maximum level of intensity for activity i is M_i. His objective is to determine the intensity for each of the activities that maximizes his total reward. When any level of the activity is possible, this is a nonlinear programming problem. When the activity can operate only at a finite set of levels, this is an integer programming problem. In the special case that the activity can be either utilized or not ($M_i = 1$ and x_i is an integer) this is often called a knapsack problem. This is because it can be used to model the problem of a camper who has to decide which of N potential items to carry in his knapsack. The value of item i is $f_i(1)$ and it weighs $c_i(1)$. The camper wishes to select the most valuable set of items that do not weigh more than the capacity of the knapsack.

The mathematical formulation of the resource allocation problem is as follows:

Maximize $f_1(x_1) + f_2(x_2) + \cdots + f_N(x_N)$
subject to

$$c_1(x_1) + c_2(x_2) + \cdots + c_N(x_N) \le K \tag{9}$$

and

$$0 \le x_t \le M_t, \qquad t = 1, 2, \ldots, N. \tag{10}$$

The following change of variables facilitates the sequential decision problem formulation. Define the new variable $s_i = c_i(x_i)$ and assume that c_i is a monotone increasing function on $[0, M_i]$. this assumption says that the more intense the activity level, the more resource utilized. Define $g_i(s_i) = f_i(c_i^{-1}(s_i))$ and $m_i = c_i^{-1}(M_i)$. This change of variables corresponds to formulating the problem in terms of the quantity of resource being used. In this notation the formulation above becomes

Maximize $g_1(s_1) + g_2(s_2) + \cdots + g_N(s_N)$
subject to

$$s_1 + s_2 + \cdots + s_N \le K \tag{11}$$

and

$$0 \le s_t \le m_t, \qquad t = 1, 2, \ldots, N. \tag{12}$$

It is not immediately obvious that this problem is a sequential decision problem. The formulation is based on treating the problem as if the decision to allocate resources to the activities were done sequentially through time with allocation to activity 1 first and activity N last. Decisions are coupled, since successive allocations must take the quantity of the resource allocated previously into account. That is, if $K - s$ units of resource have been allocated to the first t activities, then s units are available for activities $t+1, t+2, \ldots, N$.

The following sequential decision problem formulation is based on the second formulation above:

Decision points (correspond to activity number):

$$T = \{1, 2, \ldots, N\}$$

States (amount of resource available for allocation in remaining stages): For $0 \le t \le N$,

$$S_t = \begin{cases} \{s : 0 \le s \le m_t\} \\ \qquad \text{if resource levels are continuous} \\ \{0, 1, 2, \ldots, m_t\} \\ \qquad \text{if resource levels are discrete} \end{cases}$$

For $t = N + 1$,

$$S_t = \begin{cases} \{s : 0 \le s \le K\} \\ \qquad \text{if resource levels are continuous} \\ \{0, 1, 2, \ldots, K\} \\ \qquad \text{if resource levels are discrete} \end{cases}$$

Actions (s is amount of resource available for stages t, $t+1, \ldots, N$):

$$A_{s,t} = \begin{cases} \{u : 0 \le u \le \min(s, m_t)\} \\ \qquad \text{if resource levels are continuous} \\ \{0, 1, 2, \ldots, \min(s, m_t)\} \\ \qquad \text{if resource levels are discrete} \end{cases}$$

Rewards:

$$r_t(s, a) = g_t(a)$$

Transfer function:

$$w_t(s, a) = s - a$$

The decision set at stage t is the set of all functions from S_t to $A_{s,t}$, and a policy is a sequence of such functions, one for each $t \in T$. A decision rule specifies the amount of resource to allocate to activity t if s units are available for allocation to activities $t, t+1, \ldots, N$, and a policy

specifies which decision rule to use at each stage of the sequential allocation. As in the longest-route problem, a policy specifies decisions in many eventualities that will not occur using that policy. This may seem wasteful at first but is fundamental to the dynamic programming methodology. The quantity X_t^π is the amount of remaining resource available for allocation to activities $t, t+1, \ldots, N$ using policy π. Clearly, $X_1^\pi = K$, $X_2^\pi = K - d_1(K)$, and so forth. The decision maker compares policies through the quantity $v_N^\pi(K)$, which is given by

$$v_N^\pi(K) = g_1(d_1(K)) + g_2\big(d_2\big(X_2^\pi\big)\big) + \cdots + g_N\big(d_N\big(X_N^\pi\big)\big).$$

When the set of activities is discrete, the resource allocation problem can be formulated as a longest-route problem, as can any discrete state and action sequential decision problem. This is depicted in Fig. 3 for the following specific example:

$$\begin{aligned} &\text{Maximize} && 3s_1^2 + s_2^3 + 4s_3 \\ &\text{subject to} \\ & && s_1 + s_2 + s_3 \le 4, \end{aligned}$$

s_1, s_2, and s_3 are integers, and

$$0 \le s_1 \le 2; \qquad 0 \le s_2 \le 2; \qquad 0 \le s_3 \le 2.$$

In the longest-route formulation, the node labels are the amount of resource available for allocation at subsequent stages. A fifth stage is added so that there is a unique destination and all decisions at stage 4 correspond to moving from a node at stage 4 to node 0 with no reward. This is because an unallocated resource has no value to the decision maker in this formulation. The number on each arc is the reward, and the amount of resource allocated is the difference between the node label at stage t and that at stage $t+1$. For instance, if at stage 2, there are 3 units of resource available for allocation over successive stages and the decision maker decides to allocate 2 units, he will receive a reward of $2^3 = 8$ units and move to node 1.

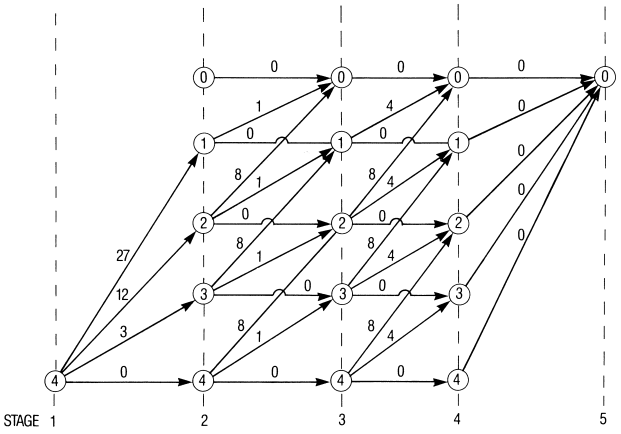

FIGURE 3 Network for the resource allocation problem.

When the resource levels form a continuum, the network representation is no longer valid. The problem is reduced to a sequence of constrained one-dimensional nonlinear optimization problems through dynamic programming. Such an example will be solved in Section II by using dynamic programming methods.

3. A Stochastic Inventory Control Problem

Each month, the manager of a warehouse must determine how much of a product to keep in stock to satisfy customer demand for the product. The objective is to maximize expected total profit (sales revenue less inventory holding and ordering costs), which may or may not be discounted. The demand throughout the month is random, with a known probability distribution. Several simplifying assumptions make a concise formulation possible:

a. The decision to order additional stock is made at the beginning of each month and delivery occurs instantaneously.

b. Demand for the product arrives throughout the month but is filled on the last day of the month.

c. If demand exceeds the stock on hand, the customer goes elsewhere to purchase the product.

d. The revenues and costs and the demand distribution are identical each month.

e. The product can be sold only in whole units.

f. The warehouse capacity is M units.

Let s_t denote the inventory on hand at the beginning of month t, a_t the additional product ordered in month t, and D_t the random demand in month t. The demand has a known probability distribution given by $p_d = P\{D_t = d\}$, $d = 0, 1, 2, \ldots$. The cost of ordering u units in any month is $O(u)$ and the cost of storing u units for 1 month is $h(u)$. The ordering cost is given by

$$O(u) = \begin{cases} K + c(u), & \text{if} \quad u > 0 \\ 0, & \text{if} \quad u = 0, \end{cases} \tag{13}$$

where $c(u)$ and $h(u)$ are increasing functions of u. For finite-horizon problems, if u units of inventory are on hand at the end of the planning horizon, its value is $g(u)$. Finally, if u units of product are demanded in a month and the inventory is sufficient to satisfy demand, the manager receives $f(u)$. Define $F(u)$ to be the expected revenue in a month if the inventory before receipt of customer orders is u units. It is given in period t by

$$F(u) = \sum_{j=0}^{u-1} f(j)p_j + f(u)P\{D_t \ge u\}. \tag{14}$$

Equation (14) can be interpreted as follows. If the inventory on hand exceeds the quantity demanded, j, the revenue is $f(j)$; p_j is the probability that the demand in a period is j units. If the inventory on hand is u units and the quantity demanded is at least u units, then the revenue is $f(u)$ and $P\{D_t \geq u\}$ is the probability of such a demand. The combined quantity is the probability-weighted, or expected, revenue.

This is a stochastic sequential decision problem (Markov decision problem), and its formulation will include a transition probability function instead of a transfer function. The formulation follows:

Decision points:

$$T = \{1, 2, \ldots, N\};$$
N may be finite or infinite

States (units of inventory on hand at the start of a month):

$$S_t = \{0, 1, 2, \ldots M\}, \qquad t = 1, 2, \ldots, N+1$$

Actions (the amount of additional stock to order in month t):

$$A_{s,t} = \{0, 1, 2, \ldots, M - s\}$$

Expected rewards (expected revenue less ordering and holding costs):

$$r_t(s, a) = F(s + a) - O(a) - h(s + a), \quad t = 1, 2, \ldots, N$$

Value of terminal inventory (no actions are possible):

$$r_{N+1}(s, a) = g(s)$$

Transition probabilities (see explanation below):

$$p_t(j|s, a) = \begin{cases} 0, & \text{if} \quad j > s + a \\ p_j, & \text{if} \quad j = s + a - D_t, \\ & \quad s + a \leq M, \quad \text{and} \\ & \quad s + a > D_t \\ q_{s+a}, & \text{if} \quad j = 0, \quad s + a \leq M, \\ & \quad \text{and} \quad s + a \leq D_t \end{cases}$$

where

$$q_{s+a} = P\{D_t \geq s + a\} = \sum_{d=s+a}^{\infty} p_d.$$

A brief explanation of the transition probabilities might be helpful. If the inventory on hand at the beginning of period t is s units and an order is placed for a units, the inventory before external demand is $s + a$ units. If the demand of j units is less than $s + a$ units, then the inventory at the beginning of period $t + 1$ is $s + a - j$ units. This occurs with probability p_j. If the demand exceeds $s + a$ units, then the inventory at the start of period $t + 1$ is 0 units. This occurs with probability q_{s+a}. Finally, the probability that the inventory level ever exceeds $s + a$ units is zero, since this demand is nonnegative.

The decision sets consist of all rules that assign the quantity of inventory to be ordered each month to each possible starting inventory position in a month. A policy is a sequence of such ordering rules. Unlike deterministic problems, in which a decision rule is specified for many states that will never be reached, in stochastic problems such as this, it is necessary for the decision maker to determine the decision rule for *all* states. This is because the evolution of the inventory level over time is random, which makes any inventory level possible at any decision point. Consequently the decision maker must plan for each of these eventualities.

An example of a decision rule is as follows: Order only if the inventory level is below 3 units at the start of the month and order the quantity that raises the stock level to 10 units on receipt of the order. In month t this is given by

$$d_t(s) = \begin{cases} 10 - s, & s < 3 \\ 0, & s \geq 3. \end{cases}$$

The evaluation method for a policy depends on the time horizon under consideration. For finite-horizon problems, the total expected cost conditional on the initial stock level is a convenient summary. Assuming the stock level at time 1 is s, the expected total reward for policy π is

$$v_N^{\pi}(s) = E_{\pi,s}\left\{\left[\sum_{t=1}^{N} F\left(X_t^{\pi} + d_t^{\pi}\left(X_t^{\pi}\right)\right) - O\left(d_t^{\pi}\left(X_t\right)\right) - h\left(X_t^{\pi} + d_t\left(X_t^{\pi}\right)\right)\right] - g\left(X_{N+1}^{\pi}\right)\right\}.$$

If, instead, the decision maker wishes to discount future profit at a monthly discount rate of λ, $0 \leq \lambda < 1$, the term λ^{t-1} is inserted before each term in the above summation and λ^N before the terminal reward g. For an infinite-horizon problem, the expected total discounted profit is given by

$$v_{\lambda}^{\pi} = E_{\pi,s}\left\{\sum_{t=1}^{\infty} \lambda^{t-1}\left[F\left(X_t^{\pi} + d_t\left(X_t^{\pi}\right)\right) - O\left(d_t^{\pi}\left(X_t^{\pi}\right)\right) + h\left(X_t^{\pi} + d_t(X^{\pi})\right)\right]\right\}.$$

The decision maker's problem is to choose a sequence of decision rules to maximize expected total or total discounted profits.

Many modifications of this inventory problem are possible; for example, excess demand in any period could be backlogged and a penalty for carrying unsatisfied demand could be charged, or there could be a time lag between placing the order and its receipt. The formulation herein

can easily be modified to include such changes; the interested reader is encouraged to consult the Bibliography for more details.

A numerical example is now provided in complete detail. It will be solved in subsequent sections by using dynamic programming methods. The data for the problem are as follows: $K = 4$, $c(u) = 2u$, $g(u) = 0$, $h(u) = u$, $M = 3$, $N = 3$, $f(u) = 8(u)$, and

$$p_d = \begin{cases} \frac{1}{4}, & \text{if} \quad d = 0 \\ \frac{1}{2}, & \text{if} \quad d = 1 \\ \frac{1}{4}, & \text{if} \quad d = 2. \end{cases}$$

The inventory is constrained to be 3 or fewer units, and the decision maker wishes to consider the effects over three periods. All the costs and revenues are linear. This means that for each unit ordered the per unit cost is 2, for each unit held in inventory for 1 month the per unit cost is 1, and for each unit sold the per unit revenue is 8. The expected revenue when u units of stock are on hand before receipt of an order is given by

u	$F(u)$
0	0
1	$0 \times \frac{1}{4} + 8 \times \frac{3}{4} = 6$
2	$0 \times \frac{1}{4} + 8 \times \frac{1}{2} + 16 \times \frac{1}{4} = 8$
3	$0 \times \frac{1}{4} + 8 \times \frac{1}{2} + 16 \times \frac{1}{4} = 8$

Combining the expected revenue with the expected shortage and holding costs gives the expected profit in period t if the inventory level is s at the start of the period and an order for a units is placed. If $a = 0$, the ordering and holding cost equals s, and if a is positive, it equals $4 + s + 3a$. It is summarized in the tabulations below, where an X corresponds to an action that is infeasible. Transition probabilities depend only on the total inventory on hand before the receipt of orders. They are the same for any s and a that have the same total $s + a$. So that redundant information is reduced, transition probabilities are presented as functions of $s + a$ only. The information in the following tabulations defines this problem completely:

	$r_t(s, a)$			
s	$a = 0$	$a = 1$	$a = 2$	$a = 3$
0	0	−1	−2	−5

II. FINITE-HORIZON DYNAMIC PROGRAMMING

A. Introduction

Dynamic programming is a collection of methods for solving sequential decision problems. The methods are based on decomposing a multistage problem into a sequence of interrelated one-stage problems. Fundamental to this decomposition is the *principle of optimality*, which was developed by Richard Bellman in the 1950s. Its importance is that an optimal solution for a multistage problem can be found by solving a functional equation relating the optimal value for a $(t + 1)$-stage problem to the optimal value for a t-stage problem.

Solution methods for problems depend on the time horizon and whether the problem is deterministic or stochastic. Deterministic finite-horizon problems are usually solved by backward induction, although several other methods, including forward induction and reaching, are available. For finite-horizon stochastic problems, backward induction is the only method of solution. In the infinite-horizon case, different approaches are used. These will be discussed in Section III. The backward induction procedure is described in the next two sections. This material might seem difficult at first; the reader is encouraged to refer to the examples at the end of this section for clarification.

B. Functional Equation of Dynamic Programming

Let $v^t(s)$ be the maximal total reward received by the decision maker during stages $t, t + 1, \ldots, N + 1$, if the system is in state s immediately before the decision at stage t. When system transitions are stochastic, $v^t(s)$ is the maximal expected return. Recall that decisions are made at stages $1, 2, \ldots, N$ and not at time $N + 1$; however, a reward might be received at stage $N + 1$ as a consequence of the decision in stage N. In most deterministic problems, S_1 consists of one element, whereas in stochastic problems, solutions are usually required for all possible initial states.

The basic entity of dynamic programming is the functional equation, or Bellman equation, which relates $v^t(s)$ to $v^{t+1}(s)$. For deterministic problems it is given by

$$v^t(s) = \max_{a \in A_{s,t}} \{ r_t(s, a) + v^{t+1}(w_t(s, a)) \}, \qquad t = 1, \ldots, N \tag{15}$$

and

$$v^{N+1}(s) = 0, \tag{16}$$

where Eq. (15) is valid for all $s \in S_t$ and Eq. (16) is valid for all $s \in S_{N+1}$. Equation (15) is the basis for the backward

induction algorithm for solving sequential decision problems. This equation corresponds to a one-stage problem in which the decision maker observes the system in state s and must select an action from the set $A_{s,t}$. The consequence of this action is that the decision maker receives an immediate reward of $r_t(s, a)$ and the system moves to state $w_t(s, a)$, at which he receives a reward of $v^{t+1}(w_t(s, a))$. Equation (15) says that he chooses the action that maximizes the total of these two rewards. This is exactly the problem faced by the decision maker in a one-stage sequential decision problem when the terminal reward function is v^{t+1}. Equation (16) provides a boundary condition. When the application dictates, this value 0 can be replaced by an arbitrary function that assigns a value to the terminal state of the system. Such might be the case in the inventory control example.

Equation (15) emphasizes the dynamic aspects of the sequential decision problem. The decision maker chooses that action which maximizes his immediate reward *plus* his reward over the remaining decision epochs. This is in contrast to the situation in which the decision maker behaves myopically and chooses the decision rule that maximizes the reward only in the current period and ignores future consequences. Some researchers have given conditions in which such a myopic policy is optimal; however, in almost all problems dynamic aspects must be taken into account.

The expression "max" requires explanation because it is fundamental to the dynamic programming methodology. If $f(x, y)$ is any function of two variables with $x \in X$ and $y \in Y$, then

$$g(x) = \max_{y \in Y}\{f(x, y)\}$$

if for each $x \in X$, $g(x) \geq f(x, y)$ for all $y \in Y$ and there exists a $y^* \in Y$ with the properties that $f(x, y^*) \geq f(x, y)$ for all $y \in Y$ and $g(x) = f(x, y^*)$. Thus, Eq. (15) states that the decision maker chooses $a \in A_{s,t}$ to make the expression in braces as large as possible. The quantity $v^t(s)$ is set equal to this maximal value.

In stochastic problems, the functional equation (15) is modified to account for the probabilistic transition structure. It is given by

$$v^t(s) = \max_{a \in A_{s,t}}\left\{r_t(s, a) + \sum_{j \in S_{t+1}} p_t(j|s, a)v^{t+1}(j)\right\}, \quad t = 1, \ldots, N. \tag{17}$$

The stochastic nature of the problem is accounted for in Eq. (17) by replacing the fixed transition function $w_t(s, a)$ by the random state j, which is determined by the probability transition function corresponding to selecting action a. The second expression in this equation equals the expected reward received over the remaining periods as a consequence of choosing action a in period t.

C. Backward Induction and the Principle of Optimality

Backward induction is a procedure that uses the functional equation in an iterative fashion to find the optimal total value function and an optimal policy for a finite-horizon sequential decision problem. That this method achieves these objectives is demonstrated by the principle of optimality. The principle of optimality is not a universal truth that applies to all sequential decision problems but a mathematical result that requires formal proof in each application. For problems in which the (expected) total reward criterion is used, as considered in this article, it is valid. A brief argument of why it holds in such problems is given below.

To motivate backward induction, the following iterative procedure for finding the total reward of some specified policy $\pi = (d_1, d_2, \ldots, d_N)$ is given. It is called the policy evaluation algorithm. To simplify notation, assume that $p_t(j|s, a) = p(j|s, a)$ and $r_t(s, a) = r(s, a)$ for all s, a, and j.

a. Set $t = N + 1$ and $v^{N+1}(s) = 0$ for all $s \in S_{N+1}$.

b. Substitute $t - 1$ for $t(t - 1 \to t)$ and compute $v^t(s)$ for each $s \in S_t$ in the deterministic case by

$$v^t(s) = r(s, d_t(s)) + v^{t+1}(w_t(s, d_t(s))), \tag{18}$$

or in the stochastic case by

$$v^t(s) = r(s, d_t(s)) + \sum_{j \in S_{t+1}} p(j|s, d_t(s))v^{t+1}(j). \tag{19}$$

c. If $t = 1$, stop; otherwise, return to step b.

This procedure inductively evaluates the policy by first fixing its value at the last stage and then computing its value at the previous stage by adding its immediate reward to the previously computed total value. This process is repeated until the first stage is reached. This computation process yields the quantities $v^1(s)$, $v^2(s), \ldots, v^{N+1}(s)$. The quantity $v^1(s)$ equals the expected total value of policy π, which in earlier notation is given by $v_\pi^N(s)$. The quantities $v^1(s)$ correspond to the value of this policy from stage t onward. This procedure is extended to optimization by iteratively choosing and evaluating a policy consisting of the actions that give the maximal return from each stage to the end of the planning horizon instead of just evaluating a fixed prespecified policy.

The backward induction algorithm proceeds as follows:

a. Set $t = N + 1$ and $v^{N+1}(s) = 0$ for all $s \in S_{N+1}$.
b. Substitute $t - 1$ for $t(t - 1 \to t)$ and compute $v^t(s)$ for each $s \in S_t$ using Eq. (15) or (17) depending on which is appropriate. Denote by $A^*_{s,t}$ the set of actions a^* for which in the deterministic case,

$$v^t(s) = r(s, a^*) + v^{t+1}\big(w_t(s, a^*)\big), \tag{20}$$

or in the stochastic case,

$$v^t(s) = r(s, a^*) + \sum_{j \in S_{t+1}} p(j|s, a^*) v^{t+1}(j). \tag{21}$$

c. If $t = 1$, stop; otherwise, return to step b.

By comparing this procedure with the policy evaluation procedure above, we can easily see that the backward induction algorithm accomplishes three objectives:

a. It finds sets of actions $A^*_{s,t}$ that contain all actions in $A_{s,t}$ that obtain the maximum in Eq. (15) or (17).
b. It evaluates any policy made up of actions selected from the sets $A^*_{s,t}$.
c. It gives the total return or expected total return $v_t(s)$ that would be obtained if a policy corresponding to selecting actions in $A^*_{s,t}$ were used from stage t onward.

Thus, if the decision maker had specified a policy that selected actions in the sets $A^*_{s,t}$ before applying the policy evaluation algorithm, these two procedures would be identical. It will be argued below that any policy obtained by selecting an action from $A^*_{s,t}$ in each state at every stage is optimal and consequently $v^1(s)$ is the optimal value function for the problem; that is, $v^1(s) = v^*_N(s)$.

In deterministic problems, specifying a policy often provides much superfluous information, since if the state of the system is known before the first decision, a policy determines the system evolution with certainty and only one state is reached at each stage. Since all deterministic problems are equivalent to longest-route problems, the objective in such problems is *only* to find a longest route. The following route selection algorithm does this. The system state is known before decision 1, so S_1 contains a single state.

a. Set $t = 1$ and for $s \in S_t$ define $d_t(s) = a^*$ for some $a^* \in A^*_{s,t}$. Set $u = w_t(s, a^*)$.
b. For $u \in S_{t+1}$, define $d_{t+1}(u) = a^*$ for some $a^* \in A^*_{u,t+1}$. Replace u by $u = w_{t+1}(u, a^*)$.
c. If $t + 1 = N$, stop; otherwise, $t + 1 \to t$ and return to step b.

In this algorithm, the choice of an action at each node determines which arc will be traversed, and decisions are necessary only at nodes that can be reached from the initial state. the algorithm traces forward through the network along the path determined by decisions that obtain the maximum in Eq. (15). It produces *one* route through the network with longest length. If at any stage the set $A^*_{s,t}$ contains more than one action, then several optimal routings exist, and if all are desired, the procedure must be carried out to trace each path.

A problem closely related to the longest-route problem is that of finding the longest route from *each* node to the final node. When there is only one action in $A^*_{s,t}$ for each s and t, then specifying the decision rule that in each state is equal to the unique maximizing action produces these routings. This is closer in spirit to the concept of a policy than a longest route.

That the above procedure results in an optimal policy and optimal value function is due to the additivity of rewards in successive periods. A formal proof of these results is based on induction, but the following argument gives the main idea. The backward induction algorithm chooses maximizing actions in reverse order. It does not matter what happened before the current stage. The only important information for future decisions is the current state of the system. First, for stage N the best action in each state is selected. Clearly, $v^N(s)$ is the optimal value function for a one-stage problem beginning in stage s at stage N. Next, in each state at stage $N - 1$, an action is found to maximize the immediate reward plus the reward that will be obtained if, after reaching a state at stage N, the decision maker chooses the optimal action at that stage. Clearly, $v^{N-1}(s)$ is the optimal value for a one-stage problem with terminal reward $v^N(s)$. Since $v^N(s)$ is the optimal value for the one-stage problem starting at stage N, no greater total reward can be obtained over these two stages. Hence, $v^{N-1}(s)$ is the optimal reward from stage $N - 1$ onward starting in state s. Now, since the sets $A^*_{s,N}$ and $A^*_{s,N-1}$ have been determined by the backward induction algorithm, choosing any policy that selects actions from these sets at each stage and evaluating it with the policy evaluation algorithm above will also yield $v^{N-1}(s)$. Thus, this policy is optimal over these two stages since its value equals the optimal value. This argument is repeated at stages $N - 2, N - 3, \ldots, 1$ to conclude that a policy that selects an action from $A^*_{s,t}$ at each stage is optimal.

The above argument contains the essence of the principle of optimality, which appeared in its original form on p. 83 of Bellman's classic book, "Dynamic Programming," as follows:

> An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.

The functional equations (15) and (17) are mathematical statements of this principle.

It might not be obvious to the reader why the backward induction algorithm is more attractive than an enumeration procedure for solving sequential decision problems. To see this, suppose that there are N stages, M states at each stage, and K actions that can be chosen in each state. Then there are $(K^M)^N$ policies. Solving a deterministic problem by enumeration would require $N(K^M)^N$ additions and $(K^M)^N$ comparisons. By backward induction, solution would require NMK additions and NK comparisons, a potentially astronomical savings in work. Solving stochastic problems requires additional M multiplications at each state at each stage to evaluate expectations. Enumeration requires $MN(K^M)^N$ multiplications, whereas backward induction would require NKM multiplications. Clearly, backward induction is a superior method for solving any problem of practical significance.

D. Examples

In this section, the use of the backward induction algorithm is illustrated in terms of the examples that were presented in Section I. First, the longest-route problem in Fig. 2 is considered.

1. A Longest-Route Problem

Note that $N = 3$ in this example.

a. Set $t = 4$ and $v^4(7) = 0$.
b. Since $t \neq 1$, continue. Set $t = 3$ and

$$\begin{aligned} v^3(4) &= r_3(4, 7) + v^4(7) \\ &= 3 + 0 = 3, \\ A^*_{6,3} &= \{7\}, \\ v^3(5) &= r_3(5, 7) + v^4(7) \\ &= 6 + 0 = 6, \\ A^*_{5,3} &= \{7\}, \\ v^3(6) &= r_3(6, 7) + v^4(7) \\ &= 2 + 0 = 2, \\ A^*_{4,3} &= \{7\}. \end{aligned}$$

c. Since $t \neq 1$, continue. Set $t = 2$ and

$$\begin{aligned} v^2(2) &= \max\{r_2(2, 4) + v^3(4), r_2(2, 5) + v^3(5)\} \\ &= \max\{5 + 3, 6 + 6\} = 12, \\ v^2(3) &= \max\{r_2(3, 4) + v^3(4), r_2(3, 5) + v^3(5), \\ &\quad r_2(3, 6) + v^3(6)\} \\ &= \max\{5 + 3, 3 + 6, 1 + 2\} = 9, \\ A^*_{2,2} &= \{5\}; \qquad A^*_{3,2} = 5. \end{aligned}$$

d. Since $t \neq 1$, continue. Set $t = 1$ and

$$\begin{aligned} v^1(1) &= \max\{r_1(1, 2) + v^2(2), r_1(1, 3) + v^2(3)\} \\ &= \max\{2 + 12, 4 + 9\} = 14, \\ A^*_{1,1} &= \{2\}. \end{aligned}$$

e. Since $t = 1$, stop.

This algorithm yields the information that the longest route from node 1 to node 7 has length 14, the longest route from node 2 to node 7 has length 12, and so on. To find the choice of arcs that corresponds to the longest route, we must apply the route selection algorithm:

a. Set $t = 1$, $d_1(1) = 2$, and $u = 2$.
b. Set $d_2(2) = 5$ and $u = 5$.
c. Since $t + 1 \neq 3$, continue. Set $t = 2$, $d_3(5) = 7$, and $u = 7$.
d. Since $t + 1 = 3$, stop.

This procedure gives the longest path through the network, namely, $1 \to 2 \to 5 \to 7$, which can easily be seen to have length 14. Note that choosing the myopic policy at each node would not have been optimal. At node 1, the myopic policy would have selected action 3; at node 3, action 4; and at node 4, action 7. The path $1 \to 3 \to 4 \to 7$ has length 12. By not taking future consequences into account at the first stage, the decision maker would have found himself in a poor position for subsequent decisions.

The backward induction algorithm has also obtained an optimal policy. It is given by

$$\pi^* = (d_1^*, d_2^*, d_3^*),$$

where

$$\begin{aligned} &d_1^*(1) = 2, \qquad d_2^*(2) = 5, \qquad d_2^*(3) = 5, \\ &d_3^*(4) = 7, \qquad d_3^*(5) = 7, \qquad \text{and} \qquad d_3^*(6) = 7. \end{aligned}$$

This policy provides the longest route from each node to node 7, as promised by the principle of optimality. In the language of graph theory, this corresponds to a maximal spanning tree. The longest route from each node to node 7 is depicted in Fig. 4.

2. A Resource Allocation Problem

The backward induction algorithm is now applied to the continuous version of the resource allocation problem of Section 1. Computation in the discrete problem is almost identical to that in the longest-route problem and will be left to the reader.

The bounds on the s_i's are changed to simplify exposition. The problem that will be solved is given by

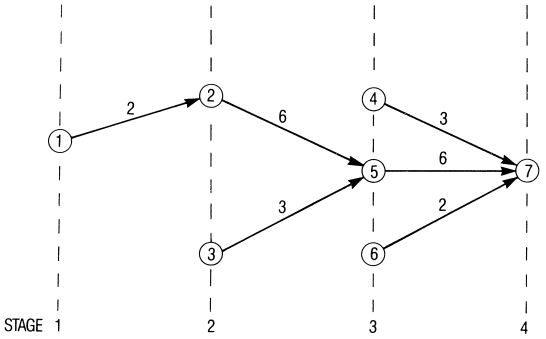

FIGURE 4 Solution to the longest-route problem.

Maximize $3s_1^2 + s_2^3 + 4s_3$

subject to

$$s_1 + s_2 + s_3 \le 4$$

and

$$0 \le s_1 \le 3; \qquad 0 \le s_2; \qquad 0 \le s_3.$$

The backward induction is applied as follows:

a. Set $t = 4$ and $v^4(s) = 0$, $0 \le s \le 4$.
b. Since $t \ne 1$, continue. Set $t = 3$ and

$$v^3(s) = \max_{0 \le a \le s} \{r_3(s, a) + v^4(s - a)\}$$

$$= \max_{0 \le a \le s} \{4a\} = 4s$$

and $A^*_{s,3} = \{s\}$.
c. Since $t \ne 1$, continue. Set $t = 2$ and

$$v^2(s) = \max_{0 \le a \le s} \{r_2(s, a) + v^3(s - a)\}$$

$$= \max_{0 \le a \le s} \{a^3 + 4(s - a)\},$$

$$v^2(s) = \begin{cases} 4s, & 0 \le s \le 2 \\ s^3, & 2 \le s \le 4, \end{cases}$$

and

$$A^*_{s,2} = \begin{cases} \{0\}, & 0 \le s \le 2 \\ \{s\}, & 2 \le s \le 4. \end{cases}$$

d. Since $t \ne 1$, continue. Set $t = 1$. A solution is obtained for $v^1(4)$ only. Obviously it is optimal to allocate all resources in this problem. In most problems one would obtain a $v^1(s)$ for all s. That is quite tedious in this example and unnecessary for solution of the original problem.

$$v^1(4) = \max_{0 \le a \le 3} \{r_1(s, a) + v^2(4 - a)\}$$

$$= \max \left\{ \max_{\substack{0 \le a \le 3 \\ 0 \le 4 - a \le 2}} \{3a^2 + 4(4 - a)\}, \right.$$

$$\left. \max_{\substack{0 \le a \le 3 \\ 2 \le 4 - a}} \{3a^2 + 4(4 - a)^3\} \right\}$$

$$= \max \left\{ \max_{2 \le a \le 3} \{3a^2 + 4(4 - a)\}, \right.$$

$$\left. \max_{0 \le a \le 2} \{3a^2 + (4 - a)^3\} \right\}$$

$$= \max\{31, 30\} = 31$$

and $A^*_{4,1} = \{3\}$.
e. Since $t = 1$, stop.

The objective function value for this constrained resource allocation problem is 31. To find the optimal resource allocation, we must use the second algorithm above:

a. Set $t = 1$, $d_1(4) = 3$, and $u = 1$.
b. Set $d_2(1) = 0$ and $u = 1$.
c. Since $t + 1 \ne 3$, continue. Set $t = 2$, $d_3(1) = 1$, and $u = 0$.
d. Since $t + 1 = 3$, stop.

This procedure gives the optimal allocation, namely, $s_1 = 3$, $s_2 = 0$, and $s_3 = 1$, which corresponds to the optimal value of 31.

3. The Inventory Example

The backward induction algorithm is now applied to the numerical stochastic inventory example of Section I. Since the data are stationary, the time index will be deleted. Also, the following additional notation will be useful. Define $v^t(s, a)$ by

$$v^t(s, a) = r(s, a) + \sum_{j \in S} p(j|s, a) v^{t+1}(j). \tag{22}$$

a. Set $t = 4$ and $v^4(s) = 0$, $s = 0, 1, 2, 3$.
b. Since $t \ne 1$, continue. Set $t = 3$, and for $s = 0, 1, 2, 3$,

$$v^3(s) = \max_{a \in A_s} \left\{ r(s, a) + \sum_{j \in S} p(j|s, a) v^4(j) \right\}$$

$$= \max_{a \in A_s} \{r(s, a)\}. \tag{23}$$

It is obvious from inspecting the values of $r(s, a)$ that in each state the maximizing action is 0; that is, do not order. Thus,

s	$v^3(s)$	$A^*_{s,3}$
0	0	0
1	5	0
2	6	0
3	5	0

c. Since $t \neq 1$, continue. Set $t = 2$ and

$$v^2(s) = \max_{a \in A_s}\{v^2(s, a)\},$$

where, for instance,

$$\begin{aligned} v^2(0, 2) &= r(0, 2) + p(0|0, 2)v^3(0) + p(1|0, 2)v^3(1) \\ &\quad + p(2|0, 2)v^3(2) + p(3|0, 2)v^3(3) \\ &= -2 + \left(\tfrac{1}{4}\right) \times 0 + \left(\tfrac{1}{2}\right) \times 5 + \left(\tfrac{1}{4}\right) \times 6 + \\ &\quad 0 \times 5 = 2. \end{aligned}$$

The quantities $v^2(s, a)$, $v^2(s)$, and $A^*_{s,2}$ are summarized in the following tabulation, where Xs denote infeasible actions:

	$v^2(s, a)$					
s	$a = 0$	$a = 1$	$a = 2$	$a = 3$	$v^2(s)$	$A^*_{s,2}$
0	0	$\frac{1}{4}$	2	$\frac{1}{2}$	2	2
1	$6\frac{1}{4}$	4	$2\frac{1}{2}$	X	$6\frac{1}{4}$	0
2	10	$4\frac{1}{2}$	X	X	10	0
3	$10\frac{1}{2}$	X	X	X	$10\frac{1}{2}$	0

d. Since $t \neq 1$, continue. Set $t = 1$ and

$$v^1(s) = \max_{a \in A_s}\{v^1(s, a)\}.$$

The quantities $v^1(s, a)$, $v^1(s)$, and $A^*_{s,1}$ are summarized in the following tabulation, where Xs denote infeasible actions:

	$v^1(s, a)$					
s	$a = 0$	$a = 1$	$a = 2$	$a = 3$	$v^1(s)$	$A^*_{s,1}$
0	2	$\frac{33}{16}$	$\frac{66}{16}$	$\frac{67}{16}$	$\frac{67}{16}$	3
1	$\frac{129}{16}$	$\frac{98}{16}$	$\frac{99}{16}$	X	$\frac{129}{16}$	0
2	$\frac{194}{16}$	$\frac{131}{16}$	X	X	$\frac{194}{16}$	0
3	$\frac{227}{16}$	X	X	X	$\frac{227}{16}$	0

e. Since $t = 1$, stop.

This procedure has produced the optimal reward function $v^*_3(s)$ and optimal policy $\pi^* = (d^*_1(s), d^*_2(s), d^*_3(s))$, which are as follows:

s	$d^*_1(s)$	$d^*_2(s)$	$d^*_3(s)$	$v^*_3(s)$
0	3	2	0	$\frac{67}{16}$
1	0	0	0	$\frac{129}{16}$
2	0	0	0	$\frac{194}{16}$
3	0	0	0	$\frac{227}{16}$

This policy has a particularly simple form: If at decision point 1 the inventory in stock is 0 units, order 3 units; otherwise, do not order. If at decision point 2 the inventory in stock is 0 units, order 2 units; otherwise, do not order. And at decision point 3 do not order. The quantity $v^*_3(s)$ gives the expected total reward obtained by using this policy when the inventory before the first decision epoch is s units.

A policy of this type is called an (s, S) policy. An (s, S) policy is implemented as follows. If in period t the inventory level is s^t units or below, order the number of units required to bring the inventory level up to S^t units. Under certain convexity and linearity assumptions on the cost functions, Scarf showed in an elegant and important 1960 paper that (s, S) policies are optimal for the stochastic inventory problem. His proof of this result is based on using backward induction to show analytically that, for each t, $v^t(s)$ is K-convex, which ensures that there exists a maximizing policy of (s, S) type. This important result plays a fundamental role in stochastic operations research and has been extended in several ways.

III. INFINITE-HORIZON DYNAMIC PROGRAMMING

A. Introduction

Solution methods for infinite-horizon sequential decision problems are based on solving a stationary version of the functional equation. In this section, the state and action sets, the rewards, and the transition probabilities are assumed to be stationary and only the stochastic version of the problem is considered. Reward streams are summarized using the expected total discounted reward criterion, and the objective is to find a policy with maximal expected total discounted reward as well as this value. The two main solution techniques are value iteration and policy iteration. The former is the extension of backward induction to infinite-horizon problems and is best analyzed from the perspective of obtaining a fixed point for the Bellman equation. Policy iteration corresponds to using a generalization of Newton's method for finding a zero of the functional equation. It is not appropriate for finite-horizon problems. Other solution methods include modified policy iteration, linear programming, Gauss-Seidel

iteration, successive overrelaxation, and extrapolation. Of these, only modified policy iteration and linear programming will be discussed.

B. Basic Results

The basic data of the stationary, infinite-horizon, stochastic sequential decision model are the state space S; the set of allowable actions in state s, A_s; the one-period expected reward if action a is selected in state s, $r(s, a)$; the probability the system is in state j at the next stage if it is in state s and action a is selected, $p(j|s, a)$; and the discount factor λ, $0 \leq \lambda < 1$. Both S and A_s are assumed to be finite. Let M denote the number of elements in S.

For a policy $\pi = (d_1, d_2, \ldots)$, the infinite-horizon expected total discounted reward is denoted by $v_\lambda^\pi(s)$. Let $p_\pi^m(j|s) = P\{X_{m+1}^\pi = j | X_1^\pi = s\}$. For $m = 2$ it can be computed by

$$p_\pi^2(j|s) = \sum_{k \in S} p(j|k, d_2(k)) p(k|s, d_1(s)).$$

This is the matrix product of the transition probability matrices corresponding to the decision rules $d_1(s)$ and $d_2(s)$. In general $p_\pi^m(j|s)$ is given by the matrix product of the matrices corresponding to $d_1, d_2, \ldots, d_m$. Using this notation, we can compute $v_\lambda^\pi(s)$ by

$$\begin{aligned} v_\lambda^\pi(s) &= r(s, d_1(s)) + \sum_{j \in S} \lambda p(j|s, d_1(s)) r(j, d_2(j)) \\ &\quad + \sum_{j \in S} \lambda^2 p_\pi^2(j|s) r(j, d_3(j)) + \cdots. \end{aligned} \tag{24}$$

Equation (24) cannot be implemented since an arbitrary nonstationary infinite-horizon policy cannot be completely specified. However, if the rewards are bounded, the above infinite series is convergent, because $\lambda < 1$. When the policy is stationary, Eq. (24) simplifies so that a policy can be evaluated either inductively or by solution of a system of linear equations. Let d denote the stationary policy that uses decision rule $d(s)$ at each stage and $p_d^m(j|s)$ its corresponding m-step transition probabilities. Then,

$$\begin{aligned} v_\lambda^d(s) &= r(s, d(s)) + \sum_{j \in S} \lambda p(j|s, d(s)) r(j, d(j)) \\ &\quad + \sum \lambda^2 p_d^2(j|s) r(j, d(j)) \\ &\quad + \sum_{j \in S} \lambda^3 p_d^3(j|s) r(j, d(j)) + \cdots \end{aligned} \tag{25}$$

$$= r(s, d(s)) + \sum_{j \in S} \lambda p(j|s, d(s)) v_\lambda^d(j). \tag{26}$$

Equation (26) is derived from Eq. (25) by explicitly writing out the matrix powers, factoring out the term $p(j|s, d(s))$ from all summations, and recognizing that the remaining terms are exactly $v_\lambda^d(s)$ Equation (26) can be rewritten as

$$\sum_{j \in S} [\delta(j, s) - \lambda p(j|s, d(s)] v_\lambda^d(j) = r(s, d(s)),$$

where $\delta(j, s) = 1$ if $j = s$ and 0 if $j \neq s$. This equation can be re-expressed in matrix terms as

$$(I - \lambda P_d) \mathbf{v}_\lambda^\mathbf{d} = \mathbf{r}_\mathbf{d}, \tag{27}$$

where P_d is the matrix with entries $p(j|s, d(s))$, I is the identity matrix, and $\mathbf{r}_\mathbf{d}$ is the vector with elements $r(s, d(s))$. Equation (27) has a unique solution, which can be obtained by Gaussian elimination, successive approximations, or any other numerical method. A consequence of this equation is the following convenient representation for $v_\lambda^d(s)$:

$$\mathbf{v}_\lambda^\mathbf{d} = (I - \lambda P_d)^{-1} \mathbf{r}_\mathbf{d}. \tag{28}$$

The inverse in Eq. (28) exists because P_d is a probability matrix, so that its spectral radius is less than or equal to 1 and $0 \leq \lambda < 1$.

The functional equation of infinite-horizon discounted dynamic programming is the stationary equivalent of Eq. (17). It is given by

$$\begin{aligned} v(s) &= \max_{a \in A_s} \left\{ r(s, a) + \sum_{j \in S} \lambda p(j|s, a) v(j) \right\} \\ &\doteq T v(s). \end{aligned} \tag{29}$$

Equation (29) defines the nonlinear operator T on the space of bounded M vectors or real-valued functions on S. Since T is a contraction mapping (see Section III.C.1), this equation has a unique solution. This solution is the expected discounted reward of an optimal policy. To see this, let $v^*(s)$ denote the solution of this equation. Then for any decision rule $d_t(s)$,

$$v^*(s) \geq r(s, d_t(s)) + \sum_{j \in S} \lambda p(j|s, d_t(s)) v^*(j). \tag{30}$$

By repeatedly substituting the above inequality into the right-hand side of Eq. (30) and noting that $\lambda^n \to 0$ as $n \to \infty$, we can see that what follows from Eq. (24) is that $v^*(s) \geq v_\lambda^\pi(s)$ for any policy π. Also, if $d^*(s)$ is the decision rule that satisfies

$$\begin{aligned} &r(s, d^*(s)) + \sum_{j \in S} \lambda p(j|s, d^*(s)) v^*(j) \\ &\quad = \max \left\{ r(s, a) + \sum_{j \in S} \lambda p(j|s, a) v^*(j) \right\}, \end{aligned} \tag{31}$$

then the stationary policy that uses $d^*(s)$ each period is optimal. This follows because if d^* satisfies Eq. (31), then

$$v^*(s) = r(s, d^*(s)) + \sum_{j \in S} \lambda p(j|s, d^*(s)) v^*(j),$$

but since this equation has a unique solution,

$$v^*(s) = v_\lambda^{d^*}(s) = v_\lambda^*(s).$$

These results are summarized as follows. There exists an optimal policy to the infinite-horizon discounted stochastic sequential decision problem that is stationary and can be found by using Eq. (31). Its value function is the unique solution of the functional equation of discounted dynamic programming.

This result plays the same role as the principle of optimality in finite-horizon dynamic programming. It says that for us to solve the infinite-horizon dynamic programming problem, it is sufficient to obtain a solution to the functional equation. In the next section, methods for solving the functional equation will be demonstrated.

C. Computational Methods

The four methods to be discussed here are value iteration, policy iteration, modified policy iteration, and linear programming. Only the first three are applied to the example in Section III.D. Value iteration and modified policy iteration are iterative approximation methods for solving the dynamic programming functional equation, whereas policy iteration is exact. To study the convergence of an approximation method, we must have a notion of distance. If $\mathbf{v}$ is a real-valued function on S (an M vector), the norm of $\mathbf{v}$, denoted by $\|\mathbf{v}\|$ is defined as

$$\|\mathbf{v}\| = \max_{s \in S} |v(s)|.$$

The distance between two vectors $\mathbf{v}$ and $\mathbf{u}$ is given by $\|\mathbf{v} - \mathbf{u}\|$. This means that two vectors are ε units apart if the maximum difference between any two components is ε units. This is often called the L^∞ norm.

A policy π is said to be ε-optimal if $\|\mathbf{v}_\lambda^\pi - \mathbf{v}_\lambda^*\| < \varepsilon$. If ε is specified sufficiently small, the two iterative algorithms can be used to find policies whose expected total discounted reward is arbitrarily close to optimum. Of course, the more accurate the approximation, the more iterations of the algorithm that are required.

1. Value Iteration

Value iteration, or successive approximation, is the direct extension of backward induction to infinite-horizon problems. It obtains an ε-optimal policy d^ε as follows:

a. Select $\mathbf{v}^0$, specify $\varepsilon > 0$, and set $n = 0$.
b. Compute $\mathbf{v^{n+1}}$ by

$$v^{n+1}(s) = \max_{a \in A_s} \left\{ r(s,a) + \sum_{j \in S} \lambda p(j|s,a) v^n(j) \right\}. \quad (32)$$

c. If $\|\mathbf{v^{n+1}} - \mathbf{v^n}\| < \varepsilon(1-\lambda)/2\lambda$, go to step d. Otherwise, increment n by 1 and return to step b.
d. For each $s \in S$, set $d^\varepsilon(s)$ equal to an $a \in A_s$ that obtains the maximum on the right-hand side of Eq. (32) at the last iteration and stop.

This algorithm can best be understood in vector space notation. In Eq. (29), the operator T is defined on the set of bounded real-valued M vectors. Solving the functional equation corresponds to finding a fixed point of T, that is, a $\mathbf{v}$ such that $\mathbf{Tv} = \mathbf{v}$. The value iteration algorithm starts with an arbitrary $\mathbf{v^0}$ (0 is usually a good choice) and iterates according to $\mathbf{v^{n+1}} = T\mathbf{v^n}$. Since T is a contraction mapping, that is,

$$\|T\mathbf{v} - T\mathbf{u}\| \leq \boldsymbol{\lambda}\|\mathbf{v} - \mathbf{u}\|$$

for any $\mathbf{v}$ and $\mathbf{u}$, the iterative method is convergent for any v^0. This is because

$$\|\mathbf{v^{n+1}} - \mathbf{v^n}\| \leq \boldsymbol{\lambda}^n \|\mathbf{v^1} - \mathbf{v^0}\|,$$

and the space of bounded real-valued M vectors is a Banach space (a complete normed linear space) with respect to the norm used here. Since a contraction mapping has a unique fixed point, $\mathbf{v}_\lambda^*$, $\mathbf{v_n}$ converges to it. The rate of convergence is geometric with parameter λ, that is,

$$\|\mathbf{v^n} - \mathbf{v}^*\| \leq \boldsymbol{\lambda}^n \|\mathbf{v^0} - \mathbf{v}^*\|.$$

The algorithm terminates with a value function $\mathbf{v_{n+1}}$ and a decision rule $\mathbf{d}^\varepsilon$ with the following property:

$$v^{n+1}(s) = r(s, d^\varepsilon(s)) + \sum_{j \in S} \lambda p(j|s, d^\varepsilon(s)) v^n(j). \quad (33)$$

The stopping rule in step c ensures that the stationary policy that uses $\mathbf{d}^\varepsilon$ every period is ε-optimal.

The sequence of iterates $\mathbf{v^n}$ have interesting interpretations. Each iterate corresponds to the optimal expected total discounted return in an n-period problem in which the terminal reward equals $\mathbf{v^0}$. Alternatively, they correspond to the expected total discounted returns for the policy in an n-period problem that is obtained by choosing a maximizing action in each state at each iteration.

2. Policy Iteration

Policy iteration, or approximation in the policy space, is an algorithm that uses the special structure of infinite-horizon stationary dynamic programming problems to find all optimal policies. The algorithm is as follows:

a. Select a decision rule $d^0(s)$ for all $s \in S$ and set $n = 0$.

b. Solve the system of equations

$$\sum_{j\in S}[\delta(j,s)-\lambda p(j|s,d^n(s))]v^n(j)=r(s,d^n(s)) \quad (34)$$

for $v^n(s)$.

c. For each s, and each $a\in A_s$, compute

$$r(s,a)+\sum_{j\in S}\lambda p(j|s,a)v^n(j). \quad (35)$$

For each s, put a in $A^*_{n,s}$ if a obtains the maximum value in Eq. (35).

d. If, for all s, $d^n(s)$ is contained in $A^*_{n,s}$, stop. Otherwise, proceed.

e. Set $d^{n+1}(s)$ equal to any a in $A^*_{n,s}$ for each s in S, increment n by 1, and return to step b.

The algorithm consists of two main parts: step b, which is called policy evaluation, and step c, which is called policy improvement. The algorithm terminates when the set of maximizing actions found in the improvement stage repeats, that is, if the same decision obtains the maximum in step b on two successive passes through the iteration loop.

This algorithm terminates in a *finite* number of iterations with an optimal stationary policy and its expected total discounted reward. This is because the improvement procedure guarantees that $v^{n+1}(s)$ is strictly greater than $v^n(s)$, for some $s\in S$, until the termination criterion is satisfied, at which point $v^n(s)$ is the solution of the dynamic programming functional equation. Since each $\mathbf{v^n}$ is the expected total discounted reward of the stationary policy $\mathbf{d^n}$, and there are only finitely many stationary policies, the procedure must terminate in a finite number of iterations.

If only an ε-optimal policy is desired, a stopping rule similar to that in step c of the value iteration procedure can be used.

3. Modified Policy Iteration

The evaluation step of the policy iteration algorithm is usually implemented by solving the linear system

$$(I-\lambda P_{d^n})\mathbf{v^{d^n}}=\mathbf{r_{d^n}} \quad (36)$$

by using Gaussian elimination, which requires $\frac{1}{3}M^3$ multiplications and divisions. When the number of states is large, exact solution of Eq. (34) can be computationally prohibitive. An alternative is to use successive approximations to obtain an approximate solution. This is the basis of the modified policy iteration, or value-oriented successive approximation, method. The modified policy iteration algorithm of order m is as follows:

a. Select $\mathbf{v^0}$, specify $\varepsilon>0$, and set $n=0$.

b. For each s and each $a\in A_s$, compute

$$r(s,a)+\sum_{j\in S}\lambda p(j|s,a)v^n(j). \quad (37)$$

For each s, put a in $A^*_{n,s}$ if a obtains the maximum value in Eq. (37).

c. For each s in S, set $d^n(s)$ equal to any a in $A^*_{n,s}$.

(i) Set $k=0$ and define $u^0(s)$ by

$$u^0(s)=\max_{a\in A_s}\left\{r(s,a)+\sum_{j\in S}\lambda p(j|s,a)v^n(j)\right\}. \quad (38)$$

(ii) If $\|\mathbf{u^0}-\mathbf{v^n}\|<\varepsilon(1-\lambda)/2\lambda$, go to step d. Otherwise, go to step (iii).

(iii) Compute u^{k+1} by

$$u^{k+1}(s)=r(s,d^n(s))+\sum_{j\in S}\lambda p(j|s,d^n(s))u^k(j). \quad (39)$$

(iv) If $k=m$, go to step (v). Otherwise, increment k by 1 and return to step (i).

(v) Set $\mathbf{v^{n+1}}=\mathbf{u^{m+1}}$, increment k by 1, and go to step b.

d. For each $s\in S$, set $d^\varepsilon(s)=d^n(s)$ and stop.

This algorithm combines features of both policy iteration and value iteration. Like value iteration, it is an iterative algorithm that terminates with an ε-optimal policy; however, value iteration avoids step c above. The stopping criterion used in step (ii) is identical to that of value iteration, and the computation of $\mathbf{u^0}$ in step (i) requires no extra work because it has already been determined in step b. Like policy iteration, the algorithm contains an improvement step, step b, and an evaluation step, step c. However, the evaluation is not done exactly. Instead, it is carried out iteratively in step c, which is repeated m times. Note that m can be selected in advance or adaptively during the algorithm. For instance, m can be chosen so that $\|\mathbf{u^{m+1}}-\mathbf{u^m}\|$ is less than some prespecified tolerance that can vary with n. Recent studies have shown that low orders of m work well, while adaptive choice is better.

The modified policy iteration algorithm serves as a bridge between value iteration and policy iteration. When $m=0$, it is equivalent to value iteration, and when m is infinite, it is equivalent to policy iteration. It will converge in fewer iterations than value iteration and more iterations than policy iteration; however, the computational effort per iteration exceeds that for value iteration and is less than that for policy iteration. When the number of states, M, is large, it has been shown to be the most computationally efficient method for solving Markov decision problems.

4. Linear Programming

The stationary infinite-horizon discounted stochastic sequential decision problem can be formulated and solved by linear programming. The primal problem is given by

Minimize

$$\sum_{j\in S} \alpha_j v(j)$$

subject to, for $a \in A_s$ and $s \in S$,

$$v(s) \geq r(s,a) + \sum_{j\in S} \lambda p(j|s,a) v(j),$$

and $v(s)$ is unconstrained.

The constants α_j are positive and arbitrary. The dual problem is given by

Maximize

$$\sum_{s\in S} \sum_{a\in A_s} x(s,a) r(s,a)$$

subject to, for $J \in S$,

$$\sum_{a\in A_s} x(j,a) - \sum_{s\in S} \sum_{a\in A_s} \lambda p(j|s,a) x(s,a) = \alpha_j,$$

and $x(j,a) \geq 0$ for $a \in A_j$ and $j \in S$.

Using a general-purpose linear programming code for solving dynamic programming problems is not computationally attractive. The dynamic programming methods are more efficient. The interest in the linear programming formulation is primarily theoretical but allows inclusion of side constraints. Some interesting observations are as follows:

a. The dual problem is always feasible and bounded. Any optimal basis has the property that for each $s \in S$, $x(s,a) > 0$ for only one $a \in A_s$. An optimal stationary policy is given by $d^*(s) = a$ if $x(s,a) > 0$.

b. The same basis is optimal for all α_j's.

c. When the dual problem is solved by the simplex algorithm with block pivoting, it is equivalent to policy iteration.

d. When policy iteration is implemented by only changing the action that gives the maximum improvement over all states, it is equivalent to solving the dual problem by the simplex method.

D. Numerical Examples

In this section, an infinite-horizon version of the stochastic inventory example presented earlier is solved by using value iteration, policy iteration, and modified policy iteration. The data are as analyzed in the finite-horizon case; however, the discount rate λ is chosen to be .9. The objective is to determine the stationary policy that maximizes the expected total infinite-horizon discounted reward.

1. Value Iteration

To initiate the algorithm, we will take $\mathbf{v^0}$ to be the zero vector; ε is chosen to be .1. The algorithm will terminate with a stationary policy that is guaranteed to have an expected total discounted reward within .1 of optimal. Calculations proceed as in the finite-horizon backward induction algorithm until the stopping criterion of

$$\|\mathbf{v^{n+1}} - \mathbf{v^n}\| \leq \frac{\varepsilon(1-\lambda)}{2\lambda} = \frac{.1 \times .1}{2 \times .9} = .0056$$

is satisfied. The value functions $\mathbf{v^n}$ and the maximizing actions obtained in step b at each iteration are provided in the tabulation on the following page. The above algorithm terminates after 58 iterations, at which point $\|\mathbf{v^{58}} - \mathbf{v^{57}}\| = .0054$. The .1-optimal stationary policy is $\mathbf{d}^\varepsilon = (3, 0, 0, 0)$, which means that if the stock level is 0, order 3 units; otherwise, do not order. Observe that the optimal policy was first identified at iteration 3, but the algorithm did not terminate until iteration 58. In larger problems such additional computational effort is extremely wasteful. Improved stopping rules and more efficient algorithms are described in Section III.E.

2. Policy Iteration

To initiate policy iteration, choose the myopic policy, namely, that which maximizes the immediate one-period reward $r(s,a)$. The algorithm proceeds as follows:

a. Set $d^0 = (0, 0, 0, 0)$ and $n = 0$.

b. Solve the evaluation equations:

$$\begin{aligned}
(1 - .9 \times 1)v^0(0) &= 0,\\
(-.9 \times .75)v^0(0) + (1 - .9 \times 25)v^0(1) &= 5,\\
(-.9 \times .25)v^0(0) + (-.9 \times .5)v^0(1) &\\
+ (1 - .9 \times 25)v^0(2) &= 6,
\end{aligned}$$

and

$$\begin{aligned}
(-.9 \times .25)v^0(1) + (-.9 \times .50)v^0(2) &\\
+ (1 - .9 \times .25)v^0(3) &= 5.
\end{aligned}$$

These equations are obtained by substituting the transition probabilities and rewards corresponding to policy $\mathbf{d^0}$ into Eq. (34). The solution of these equations is $\mathbf{v^0} = (0, 6.4516, 11.4880, 14.9951)$.

c. For each s, the quantities

$$r(s,a) + \sum_{j=0}^{3} \lambda p(j|s,a) v^0(j)$$

are computed for $a = 0, \ldots, 3 - s$, and the actions that achieve the maximum are placed into $A^*_{0,s}$. In this example

	$v^n(s)$				$d^n(s)$			
n	$s=0$	$s=1$	$s=2$	$s=3$	$s=0$	$s=1$	$s=2$	$s=3$
0	0	0	0	0	0	0	0	0
1	0	5.0	6.0	5.0	2	0	0	0
2	1.6	6.125	9.6	9.95	2	0	0	0
3	3.2762	7.4581	11.2762	12.9368	3	0	0	0
4	4.6632	8.8895	12.6305	14.6632	3	0	0	0
5	5.9831	10.1478	13.8914	15.9831	3	0	0	0
10	10.7071	14.8966	18.6194	20.7071	3	0	0	0
15	13.5019	17.6913	21.4142	23.0542	3	0	0	0
30	16.6099	20.7994	24.5222	26.6099	3	0	0	0
50	17.4197	21.6092	25.3321	27.4197	3	0	0	0
56	17.4722	21.6617	25.3845	27.4722	3	0	0	0
57	17.4782	21.6676	25.3905	27.4782	3	0	0	0
58	17.4736	21.6730	25.3959	27.4836	3	0	0	0

there is a unique maximizing action in each state, and it is given by

$$A^*_{0,0} = \{3\}; \qquad A^*_{0,1} = \{2\};$$
$$A^*_{0,2} = \{0\}; \qquad A^*_{0,3} = \{0\}.$$

d. Since $d^0(0) = 0$, it is not contained in $A^*_{0,0}$, so continue.

e. Set $\mathbf{d^1} = (3, 2, 0, 0)$ and $n = 1$, and return to the evaluation step.

The detailed step-by-step calculations for the remainder of the algorithm are omitted. The value functions and corresponding maximizing actions are presented below. Since there is a unique maximizing action in the improvement step at each iteration, $A^*_{n,s}$ is equivalent to $d^n(s)$ and only the latter is displayed.

The algorithm terminates in three iterations with the optimal policy $\mathbf{d}^* = (3, 0, 0, 0)$. Observe that an evaluation was unnecessary at iteration 3 since $\mathbf{d^2} = \mathbf{d^3}$ terminated the algorithm before the evaluation step. Unlike value iteration, the algorithm has produced an optimal policy as well as its expected total discounted reward $\mathbf{v^3}$, which is the optimal expected total discounted reward. This computation shows that the .1-optimal policy found by using value iteration is in fact optimal. This information could not be obtained by using value iteration unless the action elimination method described in Section III.E were used.

3. Modified Policy Iteration

The following illustrates the application of modified policy iteration of order 5. The first pass through the algorithm is described in detail; calculations for the remainder are presented in tabular form below.

a. Set $\mathbf{v^0} = (0, 0, 0, 0)$, $n = 0$, and $\varepsilon = .1$.

b. Observe that

$$r(s, a) + \sum_{j=0}^{3} \lambda p(j|s, a) v^0(j) = r(s, a),$$

so that for each s the maximum value occurs for $a = 0$. Thus, $A^*_{n,s} = \{0\}$ for $s = 0, 1, 2, 3$ and $\mathbf{d^n} = (0, 0, 0, 0)$.

(i) Set $k = 0$ and $\mathbf{u^0} = (0, 5, 6, 5)$.

(ii) Since $\|\mathbf{u^0} = \mathbf{v^0}\| = 6 > .0056$, continue.

(iii) Compute $\mathbf{u^1}$ by

$$u^1(s) = r(s, d^0(s)) + \sum_{j=0}^{3} \lambda p(j|s, d^0(s)) u^0(j)$$
$$= r(s, 0) + \sum_{j=0}^{3} \lambda p(j|s, 0) u^0(j) \qquad (40)$$
$$= 0 + .9 \times 1 \times 0 = 0, \qquad \text{for} \quad s = 0,$$
$$= 5 + .9 \times \tfrac{3}{4} \times 0 + .9 \times \tfrac{1}{4} \times 5 = 6.125, \quad \text{for} \quad s = 1,$$
$$= 6 + .9 \times \tfrac{1}{4} \times 0 + .9 \times \tfrac{1}{2} \times 5 + .9 \times \tfrac{1}{4} \times 6 = 9.60, \quad \text{for} \quad s = 2,$$
$$= 6 + 9 \times \tfrac{1}{4} \times 5 + .9 \times \tfrac{1}{2} \times 6 + .9 \times \tfrac{1}{4} \times 5 = 10.95, \quad \text{for} \quad s = 3,$$

so that $\mathbf{u^1} = (0, 6.125, 9.60, 10.95)$.

(iv) Since $k = 1 < 5$, continue.

	$v^n(s)$				$d^n(s)$			
n	$s=0$	$s=1$	$s=2$	$s=3$	$s=0$	$s=1$	$s=2$	$s=3$
0	0	6.4516	11.4880	14.9951	0	0	0	0
1	10.7955	12.7955	18.3056	20.7955	3	2	0	0
2	17.5312	21.7215	25.4442	27.5318	3	0	0	0
3	X	X	X	X	3	0	0	0

	$v^n(s)$				$d^n(s)$			
n	$s=0$	$s=1$	$s=2$	$s=3$	$s=0$	$s=1$	$s=2$	$s=3$
0	0	0	0	0	0	0	0	0
1	0	6.4507	11.4765	14.9200	3	2	0	0
2	7.1215	9.1215	14.6323	17.1215	3	0	0	0
3	11.5709	15.7593	19.4844	21.5709	3	0	0	0
4	14.3639	18.5534	22.2763	24.3639	3	0	0	0
5	15.8483	20.0377	23.7606	25.8483	3	0	0	0
10	17.4604	21.6499	25.3727	27.4604	3	0	0	0
11	17.4938	21.6833	25.4062	27.4938	3	0	0	0

The loop is repeated four more times to evaluate $\mathbf{u^2}$, $\mathbf{u^3}$, $\mathbf{u^4}$, and $\mathbf{u^5}$. Then $\mathbf{v^1}$ is set equal to $\mathbf{u^5}$ and the maximization in step b is carried out. The resulting iterates are shown at the bottom of the page. In step (ii), following iteration 11, the computed value of $\mathbf{u^0}$ is (17.4976, 21.6871, 25.4100, 27.4976), so that $\|\mathbf{u^0} - \mathbf{v^{11}}\| = .0038$, which guarantees that the policy (3, 0, 0, 0) is ε-optimal with $\varepsilon = .1$.

4. Comparison of the Algorithms

Value iteration required 58 iterations to obtain a .1-optimal solution. At each iteration a maximization was required so that each action had to be evaluated to determine Eq. (32) at each iteration. Modified policy iteration of order 5 required 11 iterations to determine a .1-optimal policy so that the maximization step was carried out only 11 times. However, at each iteration the inner loop of the algorithm in step c was invoked five times. Thus, modified policy iteration required far fewer maximizations than did value iteration. This would lead to considerable computational savings when the action sets or the problem had many states.

Policy iteration found an optimal policy in three iterations; however, each iteration required both the evaluation of all actions in each state and the solution of a linear system of equations. In this small example, it is not time consuming to solve the linear system by using Gaussian elimination, but when the number of states is large, this can be prohibitive. In such cases, modified iteration is preferred over both policy iteration and value iteration; however, which order is the best to use is an open question.

E. Bounds on the Optimal Total Expected Discounted Reward

At each stage of the value iteration, policy iteration, and modified policy iteration, the computed value of $\mathbf{v^n}$ can be used to obtain upper and lower bounds on the optimal expected discounted reward. These bounds can be used to terminate any of the iterative algorithms, eliminate suboptimal actions at each iteration of an algorithm, and develop improved algorithms.

Bounds are given for value iteration; however, they have also been obtained for policy iteration and modified policy iteration. First, define the following two quantities:

$$L^n = \min_{s\in S}\{v^{n+1}(s) - v^n(s)\}$$

and

$$U^n = \max_{s\in S}\{v^{n+1}(s) - v^n(s)\}.$$

Then, for each n and $s \in S$,

$$v^n(s) + \frac{1}{1-\lambda}L^n \le v^{d^n}(s) \le v^*(s) \le v_\lambda^n(s) + \frac{1}{1-\lambda}U^n. \tag{41}$$

We can easily see, using the two extreme bounds, that if $U^n - L^n < \varepsilon(1-\lambda)$, then

$$0 \le v_\lambda^*(s) - \left(v^n(s) + \frac{1}{1-\lambda}L^n\right) \le \varepsilon. \tag{42}$$

This provides an alternative stopping criterion for value iteration and can be modified for any of the above algorithms. In particular in value iteration, if the algorithm is terminated when $U^n - L^n < \varepsilon(1-\lambda)$, then the quantity $v_n(s) + (1-\lambda)^{-1}L^n$ is within ε of the optimal value function. If this had been implemented in the value iteration algorithm, in Section III.C., it would have terminated after 9, as opposed to 58, iterations, when $\varepsilon(1-\lambda) = .1 \times (1 - .9) = .01$.

These bounds can be used at each iteration to eliminate actions that cannot be part of an optimal policy. This is important computationally because the maximization in the improvement step can be made more efficient if all of A_s need not be evaluated at each iteration. Elimination is based on the result that action a is suboptimal in state s, if

$$r(s,a) + \sum_{j\in S}\lambda p(j|s,a)v_\lambda^*(j) < v_\lambda^*(s). \tag{43}$$

Of course, $v_\lambda^*(s)$ is not known in Eq. (43), but by substituting an upper bound for it on the left-hand side and a lower bound on the right-hand side, one can use the result to eliminate suboptimal actions in state s. The bounds in Eq. (41) can be used.

Action elimination procedures are especially important in approximation algorithms such as value iteration and modified policy iteration that produce only ε-optimal policies. If a unique optimal policy exists, by eliminating suboptimal actions at each iteration, one obtains an optimal policy when only one action remains in each state. This will occur in finitely many iterations.

F. Turnpike and Planning-Horizon Results

Infinite-horizon sequential decision models are usually approximations to long finite-horizon problems with many decision points. A question of practical concern is, *When is the optimal policy for the infinite-horizon model optimal for the finite-horizon problem?* An answer to this question is provided through planning-horizon, or turnpike, theory. The basic result is the following. There exists an N^*, called the planning horizon, such that, for all $n \geq N^*$, the optimal decision when there are n periods remaining is one of the decisions that is optimal when the horizon is infinite. This result means that if there is a unique optimal stationary policy d^* for the infinite-horizon problem, then in an n-period problem with $n \geq N^*$, it is optimal to use the stationary strategy for the initial $n - N^*$ decisions and to find the optimal policy for the remaining N^* periods by using the backward induction methods of Section II. The optimal infinite-horizon strategy is called the turnpike, and it is reached after traveling N^* periods on the nonstationary "side roads." The term *turnpike* originates in mathematical economics, where it refers to the policy path that produces optimal economic growth.

Another interpretation of the above result is that it is optimal to use d^* for the first decision in any finite-horizon problem in which it is known that the horizon exceeds N^*. Thus, it is not necessary to specify the horizon, only to know that there are at least N^* decisions to be made. Bounds on N^* are available, and this concept has been extended to nonstationary infinite-horizon problems and the expected average reward criteria. This is referred to as a rolling horizon approach.

The computational results for the value iteration algorithm in Section III.D give further insight into the planning-horizon result. There, $N^* = 3$, so that in any problem with horizon greater than 3, it is optimal to use the decision rule (3, 0, 0, 0) until there are three decisions left to be made, at which point it is optimal to use the decision rule (2, 0, 0, 0) for two periods and (0, 0, 0, 0) in the last period.

G. The Average Expected Reward Criteria

In many applications in which infinite-horizon formulations are natural, the total discounted reward criterion is not relevant. For instance, in a large telecommunications network, millions of packet and call routing decisions are made every second, so that discounting the consequences of latter decisions makes little sense. An alternative is the expected average reward criterion defined in Eq. (7). Using this criterion means that rewards received at each time period receive equal weight.

Computational methods for the average reward criterion are more complex than those for the discounted reward problem. This is because the form of the average reward function, $g^\pi(s)$, depends on the structure of the Markov chain corresponding to the stationary policy π. If the policy is unichain, that is, the Markov chain induced by the policy has exactly one recurrent class and possibly several transient classes, then $\mathbf{g}^\pi$ is a constant vector. In this case, the functional equation is

$$v(s) = \max_{a \in A_s} \left\{ r(s,a) - g + \sum_{s \in S} p(j|s,a) v(j) \right\}. \quad (44)$$

Solving this equation uniquely determines g and determines $v(s)$ up to an additive constant. The quantity g is the optimal expected average reward. For us to specify $\mathbf{v}$ uniquely, it is sufficient to set $v(s_0) = 0$ for some s_0 in the recurrent class of a policy corresponding to choosing a maximizing action in each state. If this is done, $v(s)$ is called a relative value function and $v(j) - v(k)$ is the difference in expected total reward obtained by using an optimal policy and starting the system in state j as opposed to state k.

As in the discounted case, an optimal policy is found by solving the functional equation. This is best done by policy iteration. The theory of value iteration is quite complex in this setting and is not discussed here. The policy iteration algorithm is given below. It is assumed that all policies are unichain.

a. Select a decision rule $\mathbf{d^0}$ and set $n = 0$.

b. Solve the system of equations

$$\sum_{j \in S} [\delta(j,s) - p(j|s, d^n(s))] v^n(j) - g^n = r(s, d^n(s)), \quad (45)$$

where $v^n(s_0) = 0$ for some s_0 in the recurrent class of d^n.

c. For each s, and each $a \in A_s$, compute

$$r(s,a) + \sum_{j \in S} p(j|s,a) v^n(j). \quad (46)$$

For each s, put a in $A^*_{n,s}$ if a obtains the maximum value in Eq. (46).

d. If for each s, $d^n(s)$ is contained in $A^*_{n,s}$, stop. Otherwise, proceed.

e. Set $d^{n+1}(s)$ equal to any a in $A^*_{n,s}$ for each s in S, increment n by 1, and return to step b.

Note that this algorithm is almost identical to that for the discounted case. The only difference is the linear system of equations solved in step b. If the assumption that all policies are unichain is dropped, solution of the functional equation [Eq. (44)] is no longer sufficient to determine an optimal policy. Instead, a nested pair of optimality equations is required.

IV. FURTHER TOPICS

A. Historical Perspective

The development of dynamic programming is usually credited to Richard Bellman. His numerous papers in the 1950s presented a formal development of this subject and numerous interesting examples. Most of this pioneering work is summarized in his book, "Dynamic Programming." However, many of the themes of dynamic programming and sequential decision processes are scattered throughout earlier works. These include studies that appeared between 1946 and 1953 on water resource management by Masse; sequential analysis in statistics by Wald; games of pursuit by Wald; inventory theory by Arrow, Blackwell, and Girshick; Arrow, Harris, and Marshak; and Dvoretsky, Kiefer, and Wolfowitz; and stochastic games by Shapley.

Although Bellman coined the phrase "Markov decision processes," this aspect of dynamic programming got off the ground with Howard's monograph, "Dynamic Programming and Markov Processes" in 1960. The first formal theoretical treatment of this subject was by Blackwell in 1962. In 1960, deGhellinck demonstrated the equivalence between Markov decision processes and linear programming. Other major contributions are those of Denardo in 1968, in which he showed that value iteration can be analyzed by the theory of contraction mappings; Veinott in 1969, in which he introduced a new family of optimality criteria for dynamic programming problems; and Federgruen and Schweitzer between 1978 and 1980, in which they investigated the properties of the sequences of policies obtained from the value iteration algorithm. Modified policy iteration is usually attributed to Puterman and Shin in 1978; however, similar ideas appeared earlier in works of Kushner and Kleinman and of van Nunen. In 1978, Puterman and Brumelle demonstrated the equivalence of policy iteration to Newton's method. Puterman's book "Markov Decision Processes" provides a comprehensive overview of theory, application, and calculations.

B. Applications

Dynamic programming methods have been applied in many areas. These methods have been used numerically to compute optimal policies, as well as analytically to determine the form of an optimal policy under various assumptions on the rewards and transition probabilities. A brief and by no means complete summary of applications appears in Table I. Only stochastic dynamic programming is considered; however, in many cases, the problems have also been analyzed in the deterministic setting. In these applications, probability distributions of the random quantities are assumed to be known before solution of the problem; adaptive estimation of parameters is not necessary.

A major limitation in the practical application of dynamic programming has been computational. When the set of states at each stage is large—for example, if the state description is vector-valued—then solving a sequential decision problem by dynamic programming requires considerable storage as well as computationl time. Bellman recognized the difficulty early on and referred to it as the "curse of dimensionality." Research in the 1990s addressed this issue by developing approximation methods for large-scale applications. These methods combined concepts from stochastic approximation, simulation, and artificial intelligence and are sometimes referred to as reinforcement learning. A comprehensive treatment of this line of research appears in "Neuro-Dynamic Programming" by Bertsekas and Tsitsiklis.

C. Extensions

In the models considered in this article, it has been assumed that the decision maker knows the state of the system before making a decision, that decisions are made at discrete time points, that the set of states is finite and discrete (with the exception of the example in Section II.D.2), and the model rewards and transition probabilities are known. These models can be modified in several ways: the state of the system may be only partially observed by the decision maker, the sets of decision points and states may be continuous, or the transition probabilities or rewards may not be known. These modifications are discussed briefly below.

1. Partially Observable Models

This model differs from the fully observable model in that the state of the system is not known to the decision maker at the time of decision. Instead, the decision maker receives a signal from the system and on the basis of this signal updates his estimate of the probability distribution of the system state. Updating is done using Bayes' theorem. Decisions are based on this probability distribution, which is a sufficient statistic for the history of the process.

When the set of states is discrete, these models are referred to as partially observable Markov decision processes. Computational methods in this case are quite

TABLE I Stochastic Dynamic Programming Applications

Area	States	Actions	Reward	Stochastic aspect
Capacity expansion	Size of plant	Maintain or add capacity	Costs of expansion and production at current capacity	Demand for product
Cash management	Cash available	Borrow or invest	Transaction costs less interest	External demand for cash
Catalog mailing	Customer purchase record	Type of catalog to send to customer, if any	Purchases in current period less mailing costs	Customer purchase amount
Clinical trials	Number of successes with each treatment	Stop or continue the trial, and if stopped, choose best treatment if any	Costs of treatment and incorrect decisions	Response of a subject to a treatment
Economic growth	State of the economy	Investment or consumption	Utility of consumption	Effect of investment
Fisheries management	Fish stock in each age class	Number of fish to harvest	Value of the catch	Population size
Football	Position of ball	Play to choose	Expected points scored	Outcome of play
Forest management	Size and condition of stand	Harvesting and reforestation activities	Revenues less harvesting costs	Stand growth and price fluctuations
Gambling	Current wealth	Stop or continue playing the game	Cost of playing	Outcome of the game
Hotel and airline reservations	Number of confirmed reservations	Accept, wait-list, or reject new reservations	Profit from satifisfied reservations less overbooking penalties	Demand for reservations and number of arrivals
Inventory control	Stock on hand	Order additional stock	Revenue per item sold less ordering, holding, and penalty costs	Demand for items
Project selection	Status of each project	Project to invest in at present	Return from investing in project	Change of project status
Queuing control	Number in the queue	Accept or reject arriving customers or control service rate	Revenue from serving customer less delay costs	Interarrival times and service times
Reliability	Age or status of equipment	Inspect and repair or replace if necessary	Inspection and repair costs plus failure cost	Failure and deterioration
Scheduling	Activites completed	Next activity to schedule	Cost of activity	Length of time to complete activity
Selling an asset	Current offer	Accept or reject the offer	The offer less the cost of holding the asset for one period	Size of the offer
Water resource management	Level of water in each reservoir in river system	Quantity of water to release	Value of power generated	Rainfall and runoff

complex, and only very small problems have been solved numerically. When the states form a continuum, this problem falls into the venue of control theory. An extremely important result in this area is the Kalman filter, which provides an updating formula for the expected value and covariance matrix of the system state. Another important result is the separation theorem, which gives conditions that allow decomposition of this problem into separate problems of estimation and control.

2. Continuous-State, Discrete-Time Models

The resource allocation problem in Section I is an example of a continuous-state, discrete-time, deterministic model. Its solution using dynamic programming methodology is given in Section II. When transitions are stochastic, only minor modifications to the general sequential decision problem are necessary. Instead of a transition probability function, a transition probability density is used, and summations are replaced by integrations throughout. This modification causes considerable theoretical complexity; the main issues concern measurability and integrability of value functions.

Problems of this type fall into the realm of stochastic control theory. Although dynamic programming is used to solve such problems, the formulation is quite different. Instead of explicitly giving a transition probability function for the state, the theory requires use of a dynamic equation

to relate the state at time $t+1$ to the state at time t. A major result in this area is that when the state dynamics are linear in the state, action, and random component and the cost is quadratic in the state and the action, then a closed-form solution is available for the optimal decision rule and it is linear in the system state. These problems have been studied extensively in the engineering literature.

3. Continous-Time Models

Stochastic continuous-time models are categorized according to whether the state space is continuous or discrete. The discrete-time model has been widely studied in the operations research literature. The stochastic nature of the problem is modeled as either a Markov process, a semi-Markov process, or a general jump process. The decision maker can control the transition rates, transition probabilities, or both. The infinite-horizon versions of the Markov and semi-Markov decision models are analyzed in a similar fashion to the discrete-time Markov decision process; however, general jump processes are considerably more complex. These models have been widely applied to problems in queuing and inventory control.

When the state space is continuous and Markovian assumptions are made, diffusion processes are used to model the transitions. The decision maker can control the drift of the system or can cause instantaneous state transitions or jumps. The discrete-time optimality equation is replaced by a nonlinear second-order partial differential equation and is usually solved numerically. These models are studied in the stochastic control theory literature and have been applied to inventory control, finance, and statistical modeling.

4. Adaptive Control

When transition probabilities and/or rewards are unknown, the decision maker must adaptively estimate them to control the system optimally. The usual approach to analysis of such systems is to assume that the rewards and transition probabilities depend on an unknown parameter, such as the arrival rate to a queuing system, and then use the observed sequence of system states to adaptively estimate this parameter. In a Bayesian analysis of such models, uncertainty about the parameter value is described through a probability distribution which is periodically updated as information becomes available. The classical approach to such models uses maximum likelihood theory to estimate the parameter and derive its statistical properties.

Fourier Series

James S. Walker
University of Wisconsin–Eau Claire

GLOSSARY

Bounded variation A function f has *bounded variation* on a closed interval $[a, b]$ if there exists a positive constant B such that, for all finite sets of points $a = x_0 < x_1 < \cdots < x_N = b$, the inequality $\sum_{i=1}^{N} |\mathrm{f}(x_i) - \mathrm{f}(x_{i-1})| \leq B$ is satisfied. Jordan proved that a function has bounded variation if and only if it can be expressed as the difference of two nondecreasing functions.

Countably infinite set A set is *countably infinite* if it can be put into one-to-one correspondence with the set of natural numbers $(1, 2, \ldots, n, \ldots)$. Examples: The integers and the rational numbers are countably infinite sets.

Continuous function If $\lim_{x \to c} \mathrm{f}(x) = \mathrm{f}(c)$, then the function f is *continuous* at the point c. Such a point is called a *continuity point* for f. A function which is continuous at all points is simply referred to as continuous.

Lebesgue measure zero A set S of real numbers is said to have *Lebesgue measure zero* if, for each $\epsilon > 0$, there exists a collection $\{(a_i, b_i)\}_{i=1}^{\infty}$ of open intervals such that $S \subset \cup_{i=1}^{\infty}(a_i, b_i)$ and $\sum_{i=1}^{\infty}(b_i - a_i) \leq \epsilon$. Examples: All finite sets, and all countably infinite sets, have Lebesgue measure zero.

Odd and even functions A function f is *odd* if $\mathrm{f}(-x) = -\mathrm{f}(x)$ for all x in its domain. A function f is *even* if $\mathrm{f}(-x) = \mathrm{f}(x)$ for all x in its domain.

One-sided limits $\mathrm{f}(x-)$ and $\mathrm{f}(x+)$ denote limits of $\mathrm{f}(t)$ as t tends to x from the left and right, respectively.

Periodic function A function f is *periodic,* with *period* $P > 0$, if the identity $\mathrm{f}(x + P) = \mathrm{f}(x)$ holds for all x. Example: $\mathrm{f}(x) = |\sin x|$ is periodic with period π.

FOURIER SERIES has long provided one of the principal methods of analysis for mathematical physics, engineering, and signal processing. It has spurred generalizations and applications that continue to develop right up to the present. While the original theory of Fourier series applies to periodic functions occurring in wave motion, such as with light and sound, its generalizations often

relate to wider settings, such as the time-frequency analysis underlying the recent theories of wavelet analysis and local trigonometric analysis.

I. HISTORICAL BACKGROUND

There are antecedents to the notion of Fourier series in the work of Euler and D. Bernoulli on vibrating strings, but the theory of Fourier series truly began with the profound work of Fourier on heat conduction at the beginning of the 19th century. Fourier deals with the problem of describing the evolution of the temperature $T(x, t)$ of a thin wire of length π, stretched between $x = 0$ and $x = \pi$, with a constant zero temperature at the ends: $T(0, t) = 0$ and $T(\pi, t) = 0$. He proposed that the initial temperature $T(x, 0) = \mathrm{f}(x)$ could be expanded in a series of sine functions:

$$\mathrm{f}(x) = \sum_{n=1}^{\infty} b_n \sin nx \tag{1}$$

with

$$b_n = \frac{2}{\pi} \int_0^{\pi} \mathrm{f}(x) \sin nx \, dx. \tag{2}$$

A. Fourier Series

Although Fourier did not give a convincing proof of convergence of the infinite series in Eq. (1), he did offer the conjecture that convergence holds for an "arbitrary" function f. Subsequent work by Dirichlet, Riemann, Lebesgue, and others, throughout the next two hundred years, was needed to delineate precisely which functions were expandable in such trigonometric series. Part of this work entailed giving a precise definition of function (Dirichlet), and showing that the integrals in Eq. (2) are properly defined (Riemann and Lebesgue). Throughout this article we shall state results that are always true when Riemann integrals are used (except for Section IV where we need to use results from the theory of Lebesgue integrals).

In addition to positing Eqs. (1) and (2), Fourier argued that the temperature $T(x, t)$ is a solution to the following *heat equation with boundary conditions:*

$$\begin{aligned} \frac{\partial T}{\partial t} &= \frac{\partial^2 T}{\partial x^2}, && 0 < x < \pi, \ t > 0 \\ T(0, t) &= T(\pi, t) = 0, && t \geq 0 \\ T(x, 0) &= f(x), && 0 \leq x \leq \pi. \end{aligned}$$

Making use of Eq. (1), Fourier showed that the solution $T(x, t)$ satisfies

$$T(x, t) = \sum_{n=1}^{\infty} b_n e^{-n^2 t} \sin nx. \tag{3}$$

This was the first example of the use of Fourier series to solve *boundary value problems* in partial differential equations. To obtain Eq. (3), Fourier made use of D. Bernoulli's method of *separation of variables,* which is now a standard technique for solving boundary value problems.

A good, short introduction to the history of Fourier series can be found in *The Mathematical Experience*. Besides his many mathematical contributions, Fourier has left us with one of the truly great philosophical principles: "The deep study of nature is the most fruitful source of knowledge."

II. DEFINITION OF FOURIER SERIES

The Fourier sine series, defined in Eqs. (1) and (2), is a special case of a more general concept: the Fourier series for a *periodic function.* Periodic functions arise in the study of wave motion, when a basic waveform repeats itself periodically. Such periodic waveforms occur in musical tones, in the plane waves of electromagnetic vibrations, and in the vibration of strings. These are just a few examples. Periodic effects also arise in the motion of the planets, in AC electricity, and (to a degree) in animal heartbeats.

A function f is said to have period P if $\mathrm{f}(x + P) = \mathrm{f}(x)$ for all x. For notational simplicity, we shall restrict our discussion to functions of period 2π. There is no loss of generality in doing so, since we can always use a simple change of scale $x = (P/2\pi)t$ to convert a function of period P into one of period 2π.

If the function f has period 2π, then its *Fourier series* is

$$c_0 + \sum_{n=1}^{\infty} \{a_n \cos nx + b_n \sin nx\} \tag{4}$$

with *Fourier coefficients* c_0, a_n, and b_n defined by the integrals

$$c_0 = \frac{1}{2\pi} \int_{-\pi}^{\pi} \mathrm{f}(x) \, dx \tag{5}$$

$$a_n = \frac{1}{\pi} \int_{-\pi}^{\pi} \mathrm{f}(x) \cos nx \, dx, \tag{6}$$

$$b_n = \frac{1}{\pi} \int_{-\pi}^{\pi} \mathrm{f}(x) \sin nx \, dx. \tag{7}$$

[*Note:* The sine series defined by Eqs. (1) and (2) is a special instance of Fourier series. If f is initially defined over the interval $[0, \pi]$, then it can be extended to $[-\pi, \pi]$ (as an odd function) by letting $\mathrm{f}(-x) = -\mathrm{f}(x)$, and then extended periodically with period $P = 2\pi$. The Fourier series for this odd, periodic function reduces to the sine series in Eqs. (1) and (2), because $c_0 = 0$, each $a_n = 0$, and each b_n in Eq. (7) is equal to the b_n in Eq. (2).]

It is more common nowadays to express Fourier series in an algebraically simpler form involving complex exponentials. Following Euler, we use the fact that the complex exponential $e^{i\theta}$ satisfies $e^{i\theta} = \cos\theta + i\sin\theta$. Hence

$$\cos\theta = \frac{1}{2}(e^{i\theta} + e^{i\theta}),$$
$$\sin\theta = \frac{1}{2i}(e^{i\theta} - e^{-i\theta}).$$

From these equations, it follows by elementary algebra that Formulas (5)–(7) can be rewritten (by rewriting each term separately) as

$$c_0 + \sum_{n=1}^{\infty} \{c_n e^{inx} + c_{-n} e^{-inx}\} \tag{8}$$

with c_n defined for all integers n by

$$c_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} \mathrm{f}(x) e^{-inx}\, dx. \tag{9}$$

The series in Eq. (8) is usually written in the form

$$\sum_{n=-\infty}^{\infty} c_n e^{inx}. \tag{10}$$

We now consider a couple of examples. First, let f_1 be defined over $[-\pi, \pi]$ by

$$\mathrm{f}_1(x) = \begin{cases} 1 & \text{if } |x| < \pi/2 \\ 0 & \text{if } \pi/2 \le |x| \le \pi \end{cases}$$

and have period 2π. The graph of f_1 is shown in Fig. 1; it is called a *square wave* in electric circuit theory. The constant c_0 is

$$c_0 = \frac{1}{2\pi} \int_{-\pi}^{\pi} \mathrm{f}_1(x)\, dx$$
$$= \frac{1}{2\pi} \int_{-\pi/2}^{\pi/2} 1\, dx = \frac{1}{2}.$$

While, for $n \neq 0$,

$$c_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} \mathrm{f}_1(x) e^{-inx}\, dx$$
$$= \frac{1}{2\pi} \int_{-\pi/2}^{\pi/2} e^{-inx}\, dx$$
$$= \frac{1}{2\pi} \frac{e^{-in\pi/2} - e^{in\pi/2}}{-in}$$
$$= \frac{\sin(n\pi/2)}{n\pi}.$$

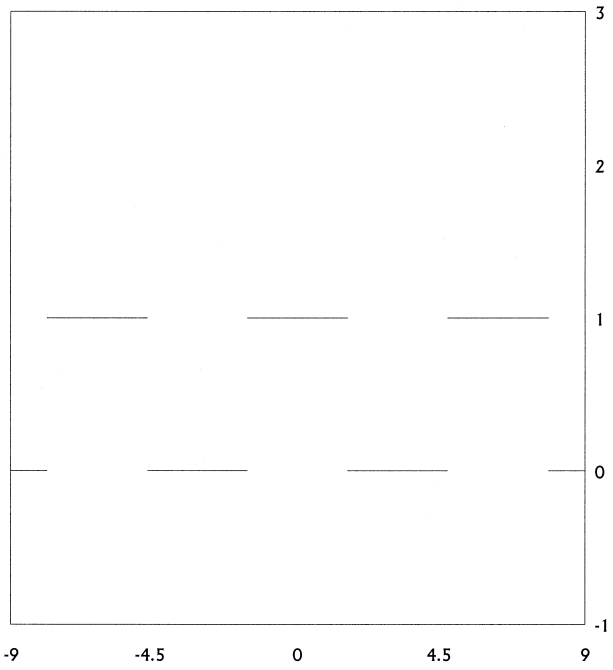

FIGURE 1 Square wave.

Thus, the Fourier series for this square wave is

$$\frac{1}{2} + \sum_{n=1}^{\infty} \frac{\sin(n\pi/2)}{n\pi}(e^{inx} + e^{-inx})$$
$$= \frac{1}{2} + \sum_{n=1}^{\infty} \frac{2\sin(n\pi/2)}{n\pi} \cos nx. \tag{11}$$

Second, let $\mathrm{f}_2(x) = x^2$ over $[-\pi, \pi]$ and have period 2π, see Fig. 2. We shall refer to this wave as a *parabolic wave.* This parabolic wave has $c_0 = \pi^2/3$ and c_n, for $n \neq 0$, is

$$c_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} x^2 e^{-inx}\, dx$$
$$= \frac{1}{2\pi} \int_{-\pi}^{\pi} x^2 \cos nx\, dx - \frac{i}{2\pi} \int_{-\pi}^{\pi} x^2 \sin nx\, dx$$
$$= \frac{2(-1)^n}{n^2}$$

after an integration by parts. The Fourier series for this function is then

$$\frac{\pi^2}{3} + \sum_{n=1}^{\infty} \frac{2(-1)^n}{n^2}(e^{inx} + e^{-inx})$$
$$= \frac{\pi^2}{3} + \sum_{n=1}^{\infty} \frac{4(-1)^n}{n^2} \cos nx. \tag{12}$$

We will discuss the convergence of these Fourier series, to f_1 and f_2, respectively, in Section III.

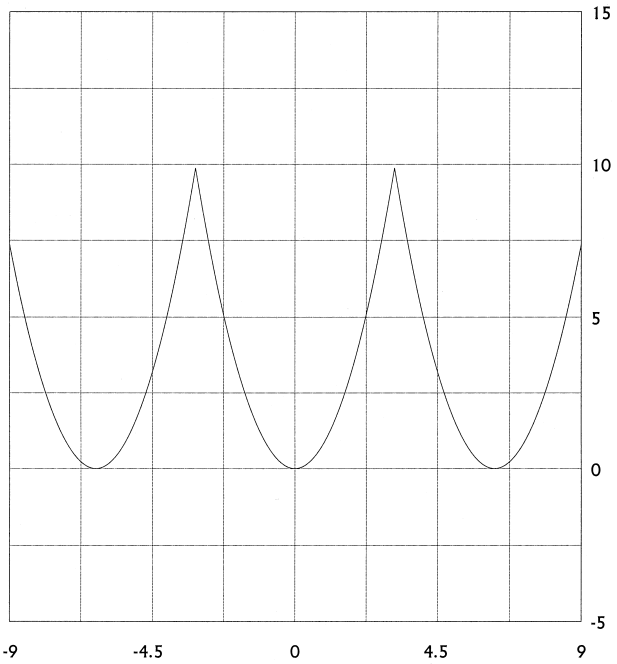

FIGURE 2 Parabolic wave.

Returning to the general Fourier series in Eq. (10), we shall now discuss some ways of interpreting this series. A complex exponential $e^{inx} = \cos nx + i \sin nx$ has a smallest period of $2\pi/n$. Consequently it is said to have a *frequency* of $n/2\pi$, because the form of its graph over the interval $[0, 2\pi/n]$ is repeated $n/2\pi$ times within each unit-length. Therefore, the integral in Eq. (9) that defines the Fourier coefficient c_n can be interpreted as a *correlation* between f and a complex exponential with a precisely located frequency of $n/2\pi$. Thus the whole collection of these integrals, for all integers n, specifies the *frequency content* of f over the set of frequencies $\{n/2\pi\}_{n=-\infty}^{\infty}$. If the series in Eq. (10) converges to f, i.e., if we can write

$$\mathrm{f}(x) = \sum_{n=-\infty}^{\infty} c_n e^{inx}, \tag{13}$$

then f is being expressed as a superposition of elementary functions $c_n e^{inx}$ having frequency $n/2\pi$ and amplitude c_n. (The validity of Eq. (13) will be discussed in the next section.) Furthermore, the correlations in Eq. (9) are *independent* of each other in the sense that correlations between distinct exponentials are zero:

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} e^{inx} e^{-imx}\, dx = \begin{cases} 0 & \text{if } m \neq n \\ 1 & \text{if } m = n. \end{cases} \tag{14}$$

This equation is called the *orthogonality property* of complex exponentials.

The orthogonality property of complex exponentials can be used to give a derivation of Eq. (9). Multiplying Eq. (13) by e^{-imx} and integrating term-by-term from $-\pi$ to π, we obtain

$$\int_{-\pi}^{\pi} \mathrm{f}(x) e^{-imx}\, dx = \sum_{n=-\infty}^{\infty} c_n \int_{-\pi}^{\pi} e^{inx} e^{-imx}\, dx.$$

By the orthogonality property, this leads to

$$\int_{-\pi}^{\pi} \mathrm{f}(x) e^{-imx}\, dx = 2\pi c_m,$$

which justifies (in a formal, nonrigorous way) the definition of c_n in Eq. (9).

We close this section by discussing two important properties of Fourier coefficients, *Bessel's inequality* and the *Riemann-Lebesgue lemma.*

Theorem 1 (Bessel's Inequality): If $\int_{-\pi}^{\pi} |\mathrm{f}(x)|^2\, dx$ is finite, then

$$\sum_{n=-\infty}^{\infty} |c_n|^2 \leq \frac{1}{2\pi}\int_{-\pi}^{\pi} |\mathrm{f}(x)|^2\, dx. \tag{15}$$

Bessel's inequality can be proved easily. In fact, we have

$$0 \leq \frac{1}{2\pi}\int_{-\pi}^{\pi} \left| \mathrm{f}(x) - \sum_{n=-N}^{N} c_n e^{inx} \right|^2 dx$$

$$= \frac{1}{2\pi}\int_{-\pi}^{\pi} \left(\mathrm{f}(x) - \sum_{m=-N}^{N} c_m e^{imx} \right) \left(\overline{\mathrm{f}(x)} - \sum_{n=-N}^{N} \overline{c_n} e^{-inx} \right) dx.$$

Multiplying out the last integrand above, and making use of Eqs. (9) and (14), we obtain

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \left| \mathrm{f}(x) - \sum_{n=-N}^{N} c_n e^{inx} \right|^2 dx$$

$$= \frac{1}{2\pi}\int_{-\pi}^{\pi} |\mathrm{f}(x)|^2\, dx - \sum_{n=-N}^{N} |c_n|^2. \tag{16}$$

Thus, for all N,

$$\sum_{n=-N}^{N} |c_n|^2 \leq \frac{1}{2\pi}\int_{-\pi}^{\pi} |\mathrm{f}(x)|^2\, dx \tag{17}$$

and Bessel's inequality (15) follows by letting $N \to \infty$.

Bessel's inequality has a physical interpretation. If f has *finite energy,* in the sense that the right side of Eq. (15) is finite, then the sum of the moduli-squared of the Fourier coefficients is also finite. In Section IV, we shall see that the inequality in Eq. (15) is actually an equality, which says that the sum of the moduli-squared of the Fourier coefficients is precisely the same as the energy of f.

Because of Bessel's inequality, it follows that

$$\lim_{|n|\to\infty} c_n = 0 \tag{18}$$

holds whenever $\int_{-\pi}^{\pi} |f(x)|^2\,dx$ is finite. The Riemann-Lebesgue lemma says that Eq. (18) holds in the following more general case:

Theorem 2 (Riemann-Lebesgue Lemma): If $\int_{-\pi}^{\pi} |f(x)|\,dx$ is finite, then Eq. (18) holds.

One of the most important uses of the Riemann-Lebesgue lemma is in proofs of some basic pointwise convergence theorems, such as the ones described in the next section.

See Krantz and Walker (1998) for further discussions of the definition of Fourier series, Bessel's inequality, and the Riemann-Lebesgue lemma.

III. CONVERGENCE OF FOURIER SERIES

There are many ways to interpret the meaning of Eq. (13). Investigations into the types of functions allowed on the left side of Eq. (13), and the kinds of convergence considered for its right side, have fueled mathematical investigations by such luminaries as Dirichlet, Riemann, Weierstrass, Lipschitz, Lebesgue, Fejér, Gelfand, and Schwartz. In short, convergence questions for Fourier series have helped lay the foundations and much of the superstructure of mathematical analysis.

The three types of convergence that we shall describe here are *pointwise*, *uniform*, and *norm* convergence. We shall discuss the first two types in this section and take up the third type in the next section.

All convergence theorems are concerned with how the *partial sums*

$$S_N(x) := \sum_{n=-N}^{N} c_n\, e^{inx}$$

converge to $f(x)$. That is, *does* $\lim_{N\to\infty} S_N = f$ *hold in some sense*?

The question of pointwise convergence, for example, concerns whether $\lim_{N\to\infty} S_N(x_0) = f(x_0)$ for each fixed x-value x_0. If $\lim_{N\to\infty} S_N(x_0)$ does equal $f(x_0)$, then we say that the *Fourier series for* f *converges to* $f(x_0)$ *at* x_0.

We shall now state the simplest pointwise convergence theorem for which an elementary proof can be given. This theorem assumes that a function is Lipschitz at each point where convergence occurs. A function is said to be *Lipschitz at a point* x_0 if, for some positive constant A,

$$|f(x) - f(x_0)| \le A\,|x - x_0| \tag{19}$$

holds for all x near x_0 (i.e., $|x - x_0| < \delta$ for some $\delta > 0$). It is easy to see, for instance, that the square wave function f_1 is Lipschitz at all of its continuity points.

The inequality in Eq. (19) has a simple geometric interpretation. Since both sides are 0 when $x = x_0$, this inequality is equivalent to

$$\left|\frac{f(x) - f(x_0)}{x - x_0}\right| \le A \tag{20}$$

for all x near x_0 (and $x \ne x_0$). Inequality (20) simply says that the difference quotients of f (i.e., the slopes of its secants) near x_0 are bounded. With this interpretation, it is easy to see that the parabolic wave f_2 is Lipschitz at all points. More generally, if f has a derivative at x_0 (or even just left- and right-hand derivatives), then f is Lipschitz at x_0.

We can now state and prove a simple convergence theorem.

Theorem 3: Suppose f has period 2π, that $\int_{-\pi}^{\pi} |f(x)|\,dx$ is finite, and that f is Lipschitz at x_0. Then the Fourier series for f converges to $f(x_0)$ at x_0.

To prove this theorem, we assume that $f(x_0) = 0$. There is no loss of generality in doing so, since we can always subtract the constant $f(x_0)$ from $f(x)$. Define the function g by $g(x) = f(x)/(e^{ix} - e^{ix_0})$. This function g has period 2π. Furthermore, $\int_{-\pi}^{\pi} |g(x)|\,dx$ is finite, because the quotient $f(x)/(e^{ix} - e^{ix_0})$ is bounded in magnitude for x near x_0. In fact, for such x,

$$\left|\frac{f(x)}{e^{ix} - e^{x_0}}\right| = \left|\frac{f(x) - f(x_0)}{e^{ix} - e^{x_0}}\right| \le A\left|\frac{x - x_0}{e^{ix} - e^{x_0}}\right|$$

and $(x - x_0)/(e^{ix} - e^{x_0})$ is bounded in magnitude, because it tends to the reciprocal of the derivative of e^{ix} at x_0.

If we let d_n denote the nth Fourier coefficient for $g(x)$, then we have $c_n = d_{n-1} - d_n e^{ix_0}$ because $f(x) = g(x)(e^{ix} - e^{ix_0})$. The partial sum $S_N(x_0)$ then telescopes:

$$\begin{aligned} S_N(x_0) &= \sum_{n=-N}^{N} c_n e^{inx_0} \\ &= d_{-N-1} e^{-iNx_0} - d_N\, e^{i(N+1)x_0}. \end{aligned}$$

Since $d_n \to 0$ as $|n| \to \infty$, by the Riemann-Lebesgue lemma, we conclude that $S_N(x_0) \to 0$. This completes the proof.

It should be noted that for the square wave f_1 and the parabolic wave f_2, it is not necessary to use the general Riemann-Lebesgue lemma stated above. That is because for those functions it is easy to see that $\int_{-\pi}^{\pi} |g(x)|^2\,dx$ is

finite for the function g defined in the proof of Theorem 3. Consequently, $d_n \to 0$ as $|n| \to \infty$ follows from Bessel's inequality for g.

In any case, Theorem 3 implies that the Fourier series for the square wave f_1 converges to f_1 at all of its points of continuity. It also implies that the Fourier series for the parabolic wave f_2 converges to f_2 at all points. While this may settle matters (more or less) in a pure mathematical sense for these two waves, it is still important to examine specific partial sums in order to learn more about the nature of their convergence to these waves.

For example, in Fig. 3 we show a graph of the partial sum S_{100} superimposed on the square wave. Although Theorem 3 guarantees that $S_N \to f_1$ as $N \to \infty$ at each continuity point, Fig. 3 indicates that this convergence is at a rather slow rate. The partial sum S_{100} differs significantly from f_1. Near the square wave's jump discontinuities, for example, there is a severe spiking behavior called *Gibbs' phenomenon* (see Fig. 4). This spiking behavior does *not* go away as $N \to \infty$, although the width of the spike does tend to zero. In fact, the peaks of the spikes overshoot the square wave's value of 1, tending to a limit of about 1.09. The partial sum also oscillates quite noticeably about the constant value of the square wave at points away from the discontinuities. This is known as *ringing.*

These defects do have practical implications. For instance, oscilloscopes—which generate wave forms as combinations of sinusoidal waves over a limited range of frequencies—cannot use S_{100}, or any partial sum S_N, to produce a square wave. We shall see, however, in Section V that a clever modification of a partial sum does produce an acceptable version of a square wave.

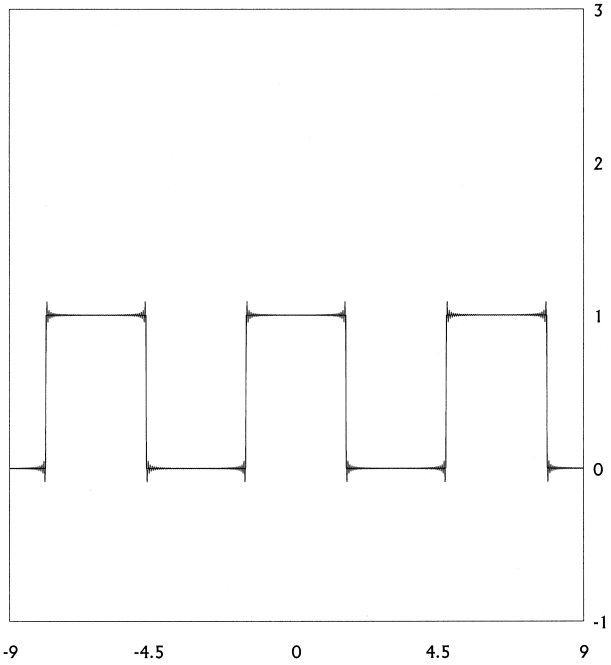

FIGURE 3 Fourier series partial sum S_{100} superimposed on square wave.

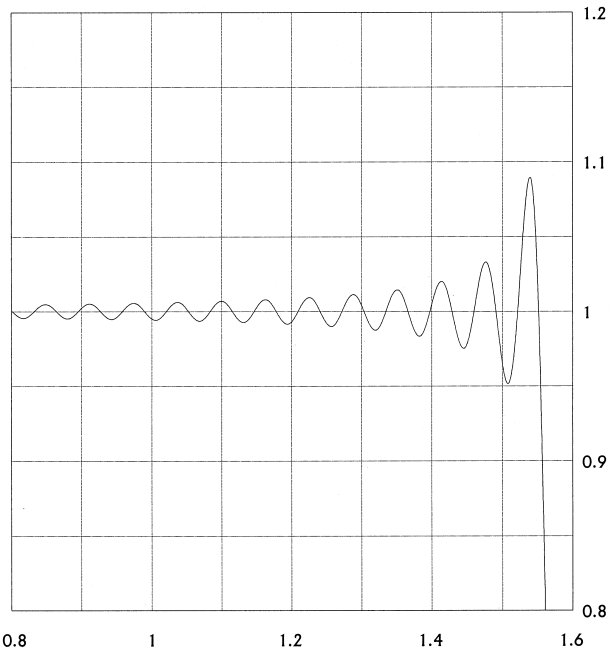

FIGURE 4 Gibbs' phenomenon and ringing for square wave.

The cause of ringing and Gibbs' phenomenon for the square wave is a rather slow convergence to zero of its Fourier coefficients (at a rate comparable to $|n|^{-1}$). In the next section, we shall interpret this in terms of energy and show that a partial sum like S_{100} does not capture a high enough percentage of the energy of the square wave f_1.

In contrast, the Fourier coefficients of the parabolic wave f_2 tend to zero more rapidly (at a rate comparable to n^{-2}). Because of this, the partial sum S_{100} for f_2 is a much better approximation to the parabolic wave (see Fig. 5). In fact, its partial sums S_N exhibit the phenomenon of *uniform convergence.*

We say that the Fourier series for a function f *converges uniformly* to f if

$$\lim_{N\to\infty} \left\{ \max_{x\in[-\pi,\pi]} |f(x) - S_N(x)| \right\} = 0. \qquad (21)$$

This equation says that, for large enough N, we can have the maximum distance between the graphs of f and S_N as small as we wish. Figure 5 is a good illustration of this for the parabolic wave.

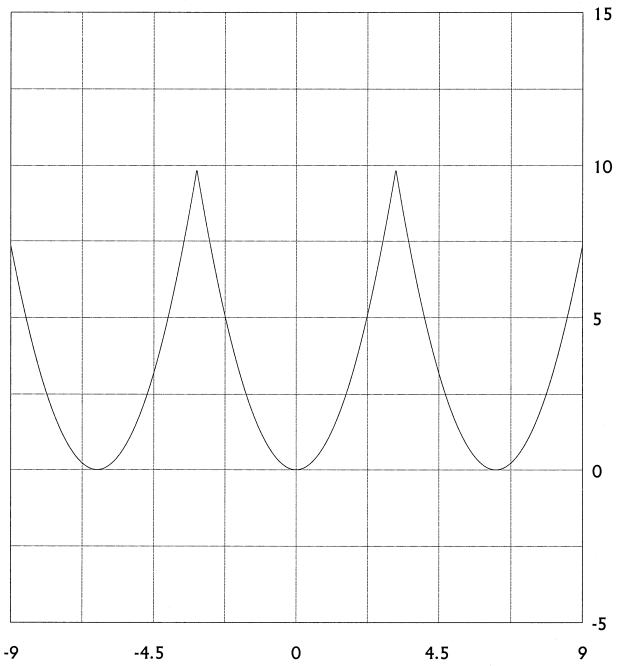

FIGURE 5 Fourier series partial sum S_{100} for parabolic wave.

We can verify Eq. (21) for the parabolic wave as follows. By Eq. (21) we have

$$\begin{aligned} |f_2(x) - S_N(x)| &= \left| \sum_{n=N+1}^{\infty} \frac{4(-1)^n}{n^2} \cos nx \right| \\ &\le \sum_{n=N+1}^{\infty} \left| \frac{4(-1)^n}{n^2} \cos nx \right| \\ &\le \sum_{n=N+1}^{\infty} \frac{4}{n^2}. \end{aligned}$$

Consequently

$$\begin{aligned} \max_{x\in[-\pi,\pi]} |f_2(x) - S_N(x)| &\le \sum_{n=N+1}^{\infty} \frac{4}{n^2} \\ &\to 0 \quad \text{as } N \to \infty \end{aligned}$$

and thus Eq. (21) holds for the parabolic wave f_2.

Uniform convergence for the parabolic wave is a special case of a more general theorem. We shall say that f is *uniformly Lipschitz* if Eq. (19) holds for all points using the same constant A. For instance, it is not hard to show that a continuously differentiable, periodic function is uniformly Lipschitz.

Theorem 4: Suppose that f has period 2π and is uniformly Lipschitz at all points, then the Fourier series for f converges uniformly to f.

A remarkably simple proof of this theorem is described in Jackson (1941). More general uniform convergence theorems are discussed in Walter (1994).

Theorem 4 applies to the parabolic wave f_2, but it does not apply to the square wave f_1. In fact, the Fourier series for f_1 cannot converge uniformly to f_1. That is because a famous theorem of Weierstrass says that a uniform limit of continuous functions (like the partial sums S_N) must be a continuous function (which f_1 is certainly not). The Gibbs' phenomenon for the square wave is a conspicuous failure of uniform convergence for its Fourier series.

Gibbs' phenomenon and ringing, as well as many other aspects of Fourier series, can be understood via an integral form for partial sums discovered by Dirichlet. This integral form is

$$S_N(x) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(x-t) D_N(t)\, dt \tag{22}$$

with *kernel* D_N defined by

$$D_N(t) = \frac{\sin(N + 1/2)t}{\sin(t/2)}. \tag{23}$$

This formula is proved in almost all books on Fourier series (see, for instance, Krantz (1999), Walker (1988), or Zygmund (1968)). The kernel D_N is called *Dirichlet's kernel*. In Fig. 6 we have graphed D_{20}.

The most important property of Dirichlet's kernel is that, for all N,

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} D_N(t)\, dt = 1.$$

From Eq. (23) we can see that the value of 1 follows from cancellation of signed areas, and also that the contribution

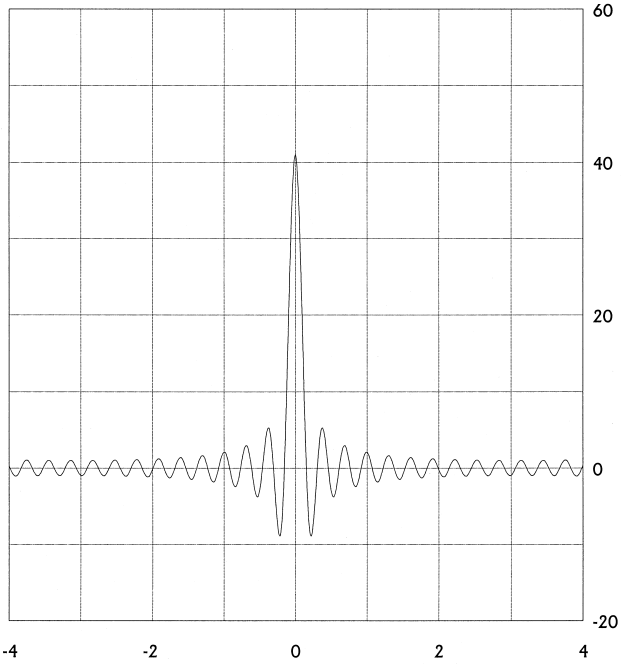

FIGURE 6 Dirichlet's kernel D_{20}.

of the main lobe centered at 0 (see Fig. 6) is significantly greater than 1 (about 1.09 in value).

From the facts just cited, we can explain the origin of ringing and Gibbs' phenomenon for the square wave. For the square wave function f_1, Eq. (22) becomes

$$S_N(x) = \frac{1}{2\pi}\int_{x-\pi/2}^{x+\pi/2} D_N(t)\,dt. \tag{24}$$

As x ranges from $-\pi$ to π, this formula shows that $S_N(x)$ is proportional to the signed area of D_N over an interval of length π centered at x. By examining Fig. 6, which is a typical graph for D_N, it is then easy to see why there is ringing in the partial sums S_N for the square wave. Gibbs' phenomenon is a bit more subtle, but also results from Eq. (24). When x nears a jump discontinuity, the central lobe of D_N is the dominant contributor to the integral in Eq. (24), resulting in a spike which overshoots the value of 1 for f_1 by about 9%.

Our final pointwise convergence theorem was, in essence, the first to be proved. It was established by Dirichlet using the integral form for partial sums in Eq. (22). We shall state this theorem in a stronger form first proved by Jordan.

Theorem 5: If f has period 2π and has bounded variation on $[0, 2\pi]$, then the Fourier series for f converges at all points. In fact, for all x-values,

$$\lim_{N\to\infty} S_N(x) = \tfrac{1}{2}[f(x+) + f(x-)].$$

This theorem is too difficult to prove in the limited space we have here (see Zygmund, 1968). A simple consequence of Theorem 5 is that the Fourier series for the square wave f_1 converges at its discontinuity points to $1/2$ (although this can also be shown directly by substitution of $x = \pm\pi/2$ into the series in (Eq. (11)).

We close by mentioning that the conditions for convergence, such as Lipschitz or bounded variation, cited in the theorems above cannot be dispensed with entirely. For instance, Kolmogorov gave an example of a period 2π function (for which $\int_{-\pi}^{\pi} |f(x)|\,dx$ is finite) that has a Fourier series which fails to converge at *every* point.

More discussion of pointwise convergence can be found in Walker (1998), Walter (1994), or Zygmund (1968).

IV. CONVERGENCE IN NORM

Perhaps the most satisfactory notion of convergence for Fourier series is convergence in L^2-norm (also called L^2-convergence), which we shall define in this section. One of the great triumphs of the Lebesgue theory of integration is that it yields necessary and sufficient conditions for L^2-convergence. There is also an interpretation of L^2-norm in terms of a generalized Euclidean distance and this gives a satisfying geometric flavor to L^2-convergence of Fourier series. By interpreting the square of L^2-norm as a type of energy, there is an equally satisfying physical interpretation of L^2-convergence. The theory of L^2-convergence has led to fruitful generalizations such as Hilbert space theory and norm convergence in a wide variety of function spaces.

To introduce the idea of L^2-convergence, we first examine a special case. By Theorem 4, the partial sums of a uniformly Lipschitz function f converge uniformly to f. Since that means that the maximum distance between the graphs of S_N and f tends to 0 as $N \to \infty$, it follows that

$$\lim_{N\to\infty} \frac{1}{2\pi}\int_{-\pi}^{\pi} |f(x) - S_N(x)|^2\,dx = 0. \tag{25}$$

This result motivates the definition of L^2-convergence.

If g is a function for which $|g|^2$ has a finite Lebesgue integral over $[-\pi, \pi]$, then we say that g is an L^2-function, and we define its L^2-norm $\|g\|_2$ by

$$\|g\|_2 = \sqrt{\frac{1}{2\pi}\int_{-\pi}^{\pi} |g(x)|^2\,dx}\,.$$

We can then rephrase Eq. (25) as saying that $\|f - S_N\|_2 \to 0$ as $N \to \infty$. In other words, *the Fourier series for* f *converges to* f *in* L^2*-norm.* The following theorem generalizes this result to all L^2-functions (see Rudin (1986) for a proof).

Theorem 6: If f is an L^2-function, then its Fourier series converges to f in L^2-norm.

Theorem 6 says that Eq. (25) holds for every L^2-function f. Combining this with Eq. (16), we obtain *Parseval's equality:*

$$\sum_{n=-\infty}^{\infty} |c_n|^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi} |f(x)|^2\,dx. \tag{26}$$

Parseval's equation has a useful interpretation in terms of energy. It says that the energy of the set of Fourier coefficients, defined to be equal to the left side of Eq. (26), is equal to the energy of the function f, defined by the right side of Eq. (26).

The L^2-norm can be interpreted as a generalized Euclidean distance. To see this take square roots of both sides of Eq. (26): $\sqrt{\sum |c_n|^2} = \|f\|_2$. The left side of this equation is interpreted as a Euclidean distance in an (infinite-dimensional) coordinate space, hence the L^2-norm $\|f\|_2$ is equivalent to such a distance.

As examples of these ideas, let's return to the square wave and parabolic wave. For the square wave f_1, we find that

$$\|f_1 - S_{100}\|_2^2 = \sum_{|n|>100} \frac{\sin^2(n\pi/2)}{(n\pi)^2}$$
$$= 1.0 \times 10^{-3}.$$

Likewise, for the parabolic wave f_2, we have $\|f_2 - S_{100}\|_2^2 = 2.6 \times 10^{-6}$. These facts show that the energy of the parabolic wave is almost entirely contained in the partial sum S_{100}; their energy difference is almost three orders of magnitude smaller than in the square wave case. In terms of generalized Euclidean distance, we have $\|f_2 - S_{100}\|_2 = 1.6 \times 10^{-3}$ and $\|f_1 - S_{100}\|_2 = 3.2 \times 10^{-2}$, showing that the partial sum is an order of magnitude closer for the parabolic wave.

Theorem 6 has a converse, known as the *Riesz-Fischer theorem.*

Theorem 7 (Riesz-Fischer): If $\sum |c_n|^2$ converges, then there exists an L^2-function f having $\{c_n\}$ as its Fourier coefficients.

This theorem is proved in Rudin (1986). Theorem and the Riesz-Fischer theorem combine to give necessary and sufficient conditions for L^2-convergence of Fourier series, conditions which are remarkably easy to apply. This has made L^2-convergence into the most commonly used notion of convergence for Fourier series.

These ideas for L^2-norms partially generalize to the case of L^p-norms. Let p be real number satisfying $p \geq 1$. If g is a function for which $|g|^p$ has a finite Lebesgue integral over $[-\pi, \pi]$, then we say that g is an L^p-function, and we define its L^p-norm $\|g\|_p$ by

$$\|g\|_p = \left[\frac{1}{2\pi}\int_{-\pi}^{\pi} |g(x)|^p \, dx\right]^{1/p}.$$

If $\|f - S_N\|_p \to 0$, then we say that the Fourier series for f converges to f in L^p-norm. The following theorem generalizes Theorem 6 (see Krantz (1999) for a proof).

Theorem 8: If f is an L^p-function for $p > 1$, then its Fourier series converges to f in L^p-norm.

Notice that the case of $p = 1$ is not included in Theorem 8. The example of Kolmogorov cited at the end of Section III shows that there exist L^1-functions whose Fourier series do not converge in L^1-norm. For $p \neq 2$, there are no simple analogs of either Parseval's equality or the Riesz-Fischer theorem (which say that we can characterize L^2-functions by the magnitude of their Fourier coefficients). Some partial analogs of these latter results for L^p-functions, when $p \neq 2$, are discussed in Zygmund (1968) (in the context of *Littlewood-Paley* theory).

We close this section by returning full circle to the notion of pointwise convergence. The following theorem was proved by Carleson for L^2-functions and by Hunt for L^p-functions ($p \neq 2$).

Theorem 9: If f is an L^p-function for $p > 1$, then its Fourier series converges to it at almost all points.

By *almost all points*, we mean that the set of points where divergence occurs has Lebesgue measure zero. References for the proof of Theorem 9 can be found in Krantz (1999) and Zygmund (1968). Its proof is undoubtedly the most difficult one in the theory of Fourier series.

V. SUMMABILITY OF FOURIER SERIES

In the previous sections, we noted some problems with convergence of Fourier series partial sums. Some of these problems include Kolmogorov's example of a Fourier series for an L^1-function that diverges everywhere, and Gibbs' phenomenon and ringing in the Fourier series partial sums for discontinuous functions. Another problem is Du Bois Reymond's example of a continuous function whose Fourier series diverges on a countably infinite set of points, see Walker (1968). It turns out that all of these difficulties simply disappear when new summation methods, based on appropriate modifications of the partial sums, are used.

The simplest modification of partial sums, and one of the first historically to be used, is to take *arithmetic means.* Define the Nth arithmetic mean σ_N by $\sigma_N = (S_0 + S_1 + \cdots + S_{N-1})/N$. From which it follows that

$$\sigma_N(x) = \sum_{n=-N}^{N} \left(1 - \frac{|n|}{N}\right) c_n \, e^{inx}. \tag{27}$$

The factors $(1 - |n|/N)$ are called *convergence factors.* They modify the Fourier coefficients c_n so that the amplitude of the higher frequency terms (for $|n|$ near N) are damped down toward zero. This produces a great improvement in convergence properties as shown by the following theorem.

Theorem 10: Let f be a periodic function. If f is an L^p-function for $p \geq 1$, then $\sigma_N \to f$ in L^p-norm as $N \to \infty$. If f is a continuous function, then $\sigma_N \to f$ uniformly as $N \to \infty$.

Notice that L^1-convergence is included in Theorem 10. Even for Kolmogorov's function, it is the case that $\|f - \sigma_N\|_1 \to 0$ as $N \to \infty$. It also should be noted that no assumption, other than continuity of the periodic function, is needed in order to ensure uniform convergence of its arithmetic means.

For a proof of Theorem 10, see Krantz (1999). The key to the proof is Fejér's integral form for σ_N:

$$\sigma_N(x) = \frac{1}{2\pi}\int_{-\pi}^{\pi} \mathrm{f}(x-t)F_N(t)\,dt \tag{28}$$

where *Fejér's kernel* F_N is defined by

$$F_N(t) = \frac{1}{N}\left(\frac{\sin Nt/2}{\sin t/2}\right)^2. \tag{29}$$

In Fig. 7 we show the graph of F_{20}. Compare this graph with the one of Dirichlet's kernel D_{20} in Fig. 6. Unlike Dirichlet's kernel, Fejér's kernel is positive $[F_N(t) \geq 0]$, and is close to 0 away from the origin. These two facts are the main reasons that Theorem 10 holds. The fact that Fejér's kernel satisfies

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} F_N(t)\,dt = 1$$

is also used in the proof.

An attractive feature of arithmetic means is that Gibbs' phenomenon and ringing do not occur. For example, in Fig. 8 we show σ_{100} for the square wave and it is plain that these two defects are absent. For the square wave function f_1, Eq. (28) reduces to

$$\sigma_N(x) = \frac{1}{2\pi}\int_{x-\pi/2}^{x+\pi/2} F_N(t)\,dt.$$

As x ranges from $-\pi$ to π, this formula shows that $\sigma_N(x)$ is proportional to the area of the positive function F_N over

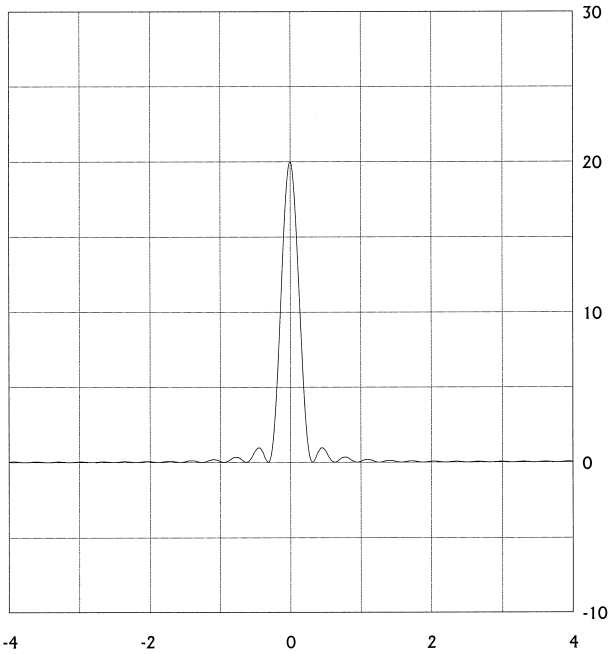

FIGURE 7 Fejér's kernel F_{20}.

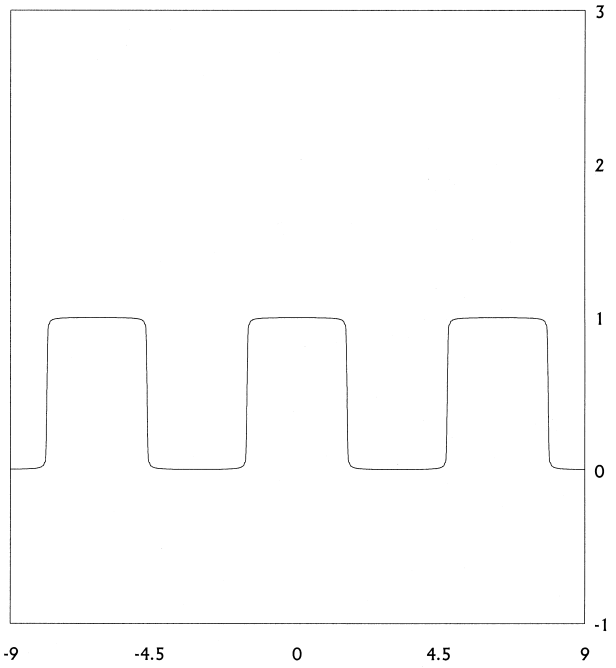

FIGURE 8 Arithmetic mean σ_{100} for square wave.

an interval of length π centered at x. By examining Fig. 7, which is a typical graph for F_N, it is easy to see why ringing and Gibbs' phenomenon do not occur for the arithmetic means of the square wave.

The method of arithmetic means is just one example from a wide range of summation methods for Fourier series. These summation methods are one of the major elements in the area of *finite impulse response filtering* in the fields of electrical engineering and signal processing.

A *summation kernel* K_N is defined by

$$K_N(x) = \sum_{n=-N}^{N} m_n\, e^{inx}. \tag{30}$$

The real numbers $\{m_n\}$ are the *convergence factors* for the kernel. We have already seen two examples: Dirichlet's kernel (where $m_n = 1$) and Fejér's kernel (where $m_n = 1 - |n|/N$).

When K_N is a summation kernel, then we define the modified partial sum of f to be $\sum_{n=-N}^{N} m_n\, c_n\, e^{inx}$. It then follows from Eqs. (14) and (30) that

$$\sum_{n=-N}^{N} m_n\, c_n\, e^{inx} = \frac{1}{2\pi}\int_{-\pi}^{\pi} \mathrm{f}(x-t)K_N(t)\,dt. \tag{31}$$

The function defined by both sides of Eq. (31) is denoted by $K_N * \mathrm{f}$. It is usually more convenient to use the left side of Eq. (31) to compute $K_N * \mathrm{f}$, while for theoretical purposes (such as proving Theorem 11 below), it is more convenient to use the right side of Eq. (31).

We say that a summation kernel K_N is *regular* if it satisfies the following three conditions.

1. For each N,
$$\frac{1}{2\pi}\int_{-\pi}^{\pi} K_N(x)\,dx = 1.$$
2. There is a positive constant C such that
$$\frac{1}{2\pi}\int_{-\pi}^{\pi} |K_N(x)|\,dx \le C.$$
3. For each $0 < \delta < \pi$,
$$\lim_{N\to\infty}\left\{\max_{\delta\le|x|\le\pi} |K_N(x)|\right\} = 0.$$

There are many examples of regular summation kernels. Fejér's kernel, which has $m_n = 1 - |n|/N$, is regular. Another regular summation kernel is Hann's kernel, which has $m_n = 0.5 + 0.5\cos(n\pi/N)$. A third regular summation kernel is de le Vallée Poussin's kernel, for which $m_n = 1$ when $|n| \le N/2$, and $m_n = 2(1 - |m/N|)$ when $N/2 < |m| \le N$. The proofs that these summation kernels are regular are given in Walker (1996). It should be noted that Dirichlet's kernel is *not* regular, because properties 2 and 3 do not hold.

As with Fejér's kernel, all regular summation kernels significantly improve the convergence of Fourier series. In fact, the following theorem generalizes Theorem 10.

Theorem 11: Let f be a periodic function, and let K_N be a regular summation kernel. If f is an L^p-function for $p \ge 1$, then $K_N * \mathrm{f} \to \mathrm{f}$ in L^p-norm as $N \to \infty$. If f is a continuous function, then $K_N * \mathrm{f} \to \mathrm{f}$ uniformly as $N \to \infty$.

For an elegant proof of this theorem, see Krantz (1999).

From Theorem 11 we might be tempted to conclude that the convergence properties of regular summation kernels are all the same. They do differ, however, in the *rates* at which they converge. For example, in Fig. 9 we show $K_{100} * \mathrm{f}_1$ where the kernel is Hann's kernel and f_1 is the square wave. Notice that this graph is a much better approximation of a square wave than the arithmetic mean graph in Fig. 8. An oscilloscope, for example, can easily generate the graph in Fig. 9, thereby producing an acceptable version of a square wave.

Summation of Fourier series is discussed further in Krantz (1999), Walker (1996), Walter (1994), and Zygmund (1968).

VI. GENERALIZED FOURIER SERIES

The classical theory of Fourier series has undergone extensive generalizations during the last two hundred years.

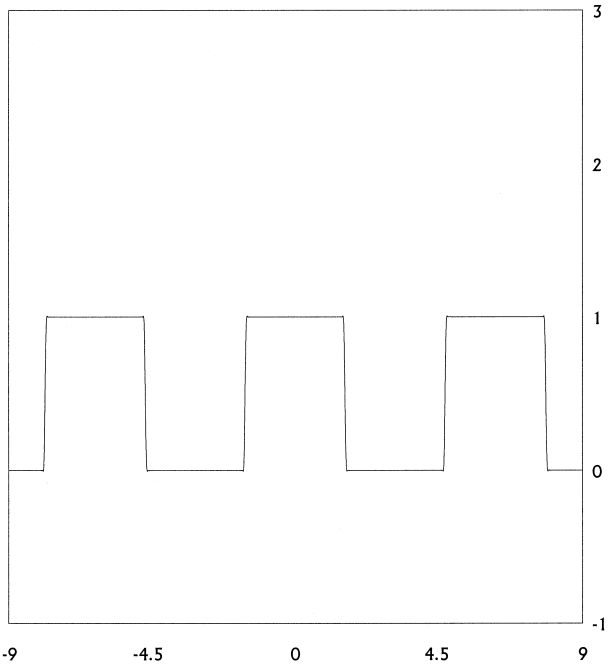

FIGURE 9 Approximate square wave using Hann's kernel.

For example, Fourier series can be viewed as one aspect of a general theory of *orthogonal series expansions.* In this section, we shall discuss a few of the more celebrated orthogonal series, such as Legendre series, Haar series, and wavelet series.

We begin with Legendre series. The first two *Legendre polynomials* are $P_0(x) = 1$, and $P_1(x) = x$. For $n = 2, 3, 4, \ldots$, the nth Legendre polynomial P_n is defined by the recursion relation

$$nP_n(x) = (2n-1)xP_{n-1}(x) + (n-1)P_{n-2}(x).$$

These polynomials satisfy the following *orthogonality relation*

$$\int_{-1}^{1} P_n(x)\,P_m(x)\,dx = \begin{cases} 0 & \text{if } m \ne n \\ (2n+1)/2 & \text{if } m = n. \end{cases} \tag{32}$$

This equation is quite similar to Eq. (14). Because of Eq. (32)—recall how we used Eq. (14) to derive Eq. (9)—the *Legendre series* for a function f over the interval $[-1, 1]$ is defined to be

$$\sum_{n=0}^{\infty} c_n P_n(x) \tag{33}$$

with

$$c_n = \frac{2}{2n+1}\int_{-1}^{1} \mathrm{f}(x)\,P_n(x)\,dx. \tag{34}$$

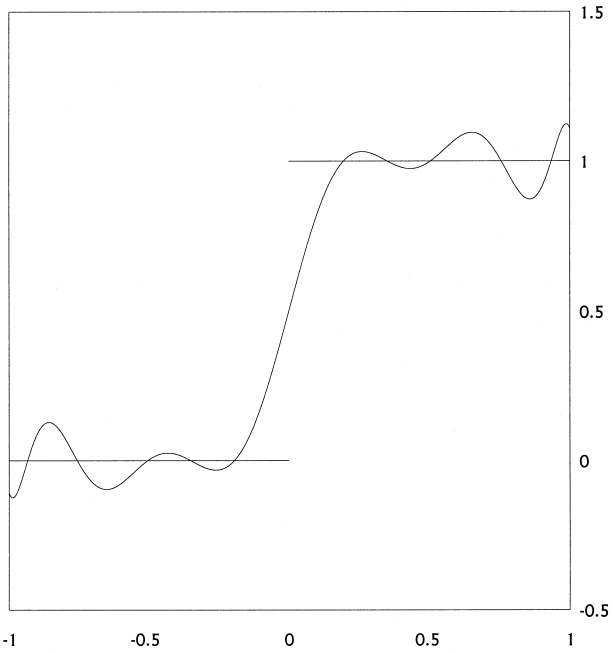

FIGURE 10 Step function and its Legendre series partial sum S_{11}.

The partial sum S_N of the series in Eq. (33) is defined to be

$$S_N(x) = \sum_{n=0}^{N} c_n P_n(x).$$

As an example, let $f(x) = 1$ for $0 \le x \le 1$ and $f(x) = 0$ for $-1 \le x < 0$. The Legendre series for this step function is [see Walker (1988)]:

$$\frac{1}{2} + \sum_{k=0}^{\infty} \frac{(-1)^k (4k+3)(2k)!}{4^{k+1}(k+1)!k!} P_{2k+1}(x).$$

In Fig. 10 we show the partial sum S_{11} for this series. The graph of S_{11} is reminiscent of a Fourier series partial sum for a step function. In fact, the following theorem is true.

Theorem 12: If $\int_{-1}^{1} |f(x)|^2 \, dx$ is finite, then the partial sums S_N for the Legendre series for f satisfy

$$\lim_{N \to \infty} \int_{-1}^{1} |f(x) - S_N(x)|^2 \, dx = 0.$$

Moreover, if f is Lipschitz at a point x_0, then $S_N(x_0) \to f(x_0)$ as $N \to \infty$.

This theorem is proved in Walter (1994) and Jackson (1941). Further details and other examples of *orthogonal polynomial series* can be found in either Davis (1975), Jackson (1941), or Walter (1994). There are many important orthogonal series—such as Hermite, Laguerre, and Tchebysheff—which we cannot examine here because of space limitations.

We now turn to another type of orthogonal series, the Haar series. The defects, such as Gibbs' phenomenon and ringing, that occur with Fourier series expansions can be traced to the unlocalized nature of the functions used for expansions. The complex exponentials used in classical Fourier series, and the polynomials used in Legendre series, are all non-zero (except possibly for a finite number of points) over their domains. In contrast, Haar series make use of localized functions, which are non-zero only over tiny regions within their domains.

In order to define Haar series, we first define the *fundamental Haar wavelet* $H(x)$ by

$$H(x) = \begin{cases} 1 & \text{if } 0 \le x < 1/2 \\ -1 & \text{if } 1/2 \le x \le 1. \end{cases}$$

The *Haar wavelets* $\{H_{j,k}(x)\}$ are then defined by

$$H_{j,k}(x) = 2^{j/2} H(2^j x - k)$$

for $j = 0, 1, 2, \ldots$; $k = 0, 1, \ldots, 2^j - 1$. Notice that $H_{j,k}(x)$ is non-zero only on the interval $[k2^{-j}, (k+1)2^{-j}]$, which for large j is a tiny subinterval of $[0, 1]$. As k ranges between 0 and $2^j - 1$, these subintervals partition the interval $[0, 1]$, and the partition becomes finer (shorter subintervals) with increasing j.

The *Haar series* for a function f is defined by

$$b + \sum_{j=0}^{\infty} \sum_{k=0}^{2^j - 1} c_{j,k} H_{j,k}(x) \tag{35}$$

with $b = \int_0^1 f(x) \, dx$ and

$$c_{j,k} = \int_0^1 f(x) H_{j,k}(x) \, dx.$$

The definitions of b and $c_{j,k}$ are justified by orthogonality relations between the Haar functions (similar to the orthogonality relations that we used above to justify Fourier series and Legendre series).

A partial sum S_N for the Haar series in Eq. () is defined by

$$S_N(x) = b + \sum_{\{j,k \mid 2^j + k \le N\}} c_{j,k} H_{j,k}(x).$$

For example, let f be the function on $[0, 1]$ defined as follows

$$f(x) = \begin{cases} x - 1/2 & \text{if } 1/4 < x < 3/4 \\ 0 & \text{if } x \le 1/4 \text{ or } 3/4 \le x. \end{cases}$$

In Fig. 11 we show the Haar series partial sum S_{256} for this function. Notice that there is no Gibbs' phenomenon with this partial sum. This contrasts sharply with the Fourier

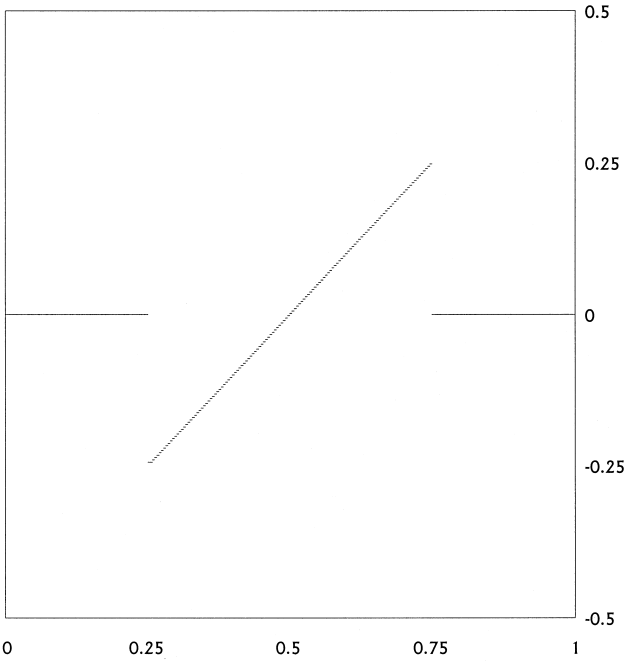

FIGURE 11 Haar series partial sum S_{256}, which has 257 terms.

series partial sum, also using 257 terms, which we show in Fig. 12.

The Haar series partial sums satisfy the following theorem [proved in Daubechies (1992) and in Meyer (1992)].

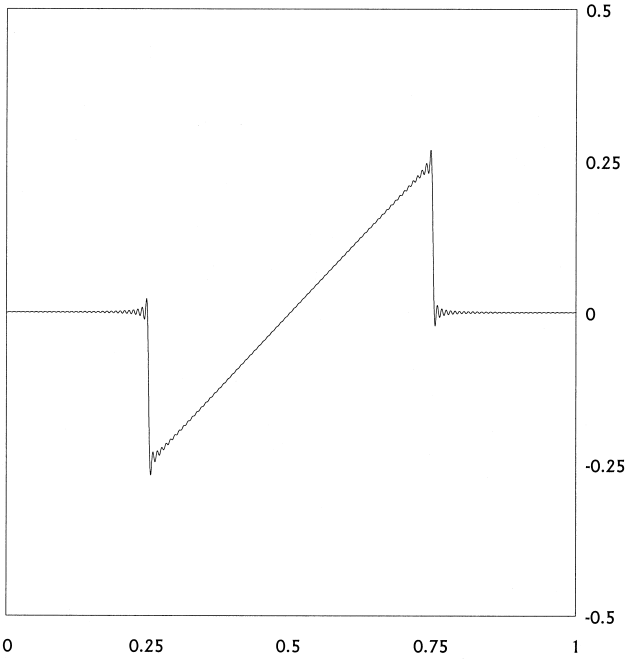

FIGURE 12 Fourier series partial sum S_{128}, which has 257 terms.

Theorem 13: Suppose that $\int_0^1 |f(x)|^p\,dx$ is finite, for $p \geq 1$. Then the Haar series partial sums for f satisfy

$$\lim_{N\to\infty}\left[\int_0^1 |f(x) - S_N(x)|^p\,dx\right]^{1/p} = 0.$$

If f is continuous on [0, 1], then S_N converges uniformly to f on [0, 1].

This theorem is reminiscent of Theorems 10 and 11 for the modified Fourier series partial sums obtained by arithmetic means or by a regular summation kernel. The difference here, however, is that for the Haar series no modifications of the partial sums are needed.

One glaring defect of Haar series is that the partial sums are discontinuous functions. This defect is remedied by the wavelet series discovered by Meyer, Daubechies, and others. The fundamental Haar wavelet is replaced by some new fundamental wavelet Ψ and the set of wavelets $\{\Psi_{j,k}\}$ is then defined by $\Psi_{j,k}(x) = 2^{-j/2}\Psi[2^j x - k]$. (The bracket symbolism $\Psi[2^j x - k]$ means that the value, $2^j x - k \bmod 1$, is evaluated by Ψ. This technicality is needed in order to ensure periodicity of $\Psi_{j,k}$.) For example, in Fig. 13, we show graphs of $\Psi_{4,1}$ and $\Psi_{6,46}$ for one of the Daubechies wavelets (a Coif18 wavelet), which is *continuously differentiable.* For a complete discussion of the definition of these wavelet functions, see Daubechies (1992) or Mallat (1998).

The *wavelet series,* generated by the fundamental wavelet Ψ, is defined by

$$b + \sum_{j=0}^{\infty}\sum_{k=0}^{2^j-1} c_{j,k}\Psi_{j,k}(x) \tag{36}$$

with $b = \int_0^1 f(x)\,dx$ and

$$c_{j,k} = \int_0^1 f(x)\Psi_{j,k}(x)\,dx. \tag{37}$$

This wavelet series has partial sums S_N defined by

$$S_N(x) = b + \sum_{\{j,k\,|\,2^j+k\leq N\}} c_{j,k}\Psi_{j,k}(x).$$

Notice that when Ψ is continuously differentiable, then so is each partial sum S_N. These wavelet series partial sums satisfy the following theorem, which generalizes Theorem 13 for Haar series, for a proof, see Daubechies (1992) or Meyer (1992).

Theorem 14: Suppose that $\int_0^1 |f(x)|^p\,dx$ is finite, for $p \geq 1$. Then the Daubechies wavelet series partial sums for f satisfy

$$\lim_{N\to\infty}\left[\int_0^1 |f(x) - S_N(x)|^p\,dx\right]^{1/p} = 0.$$

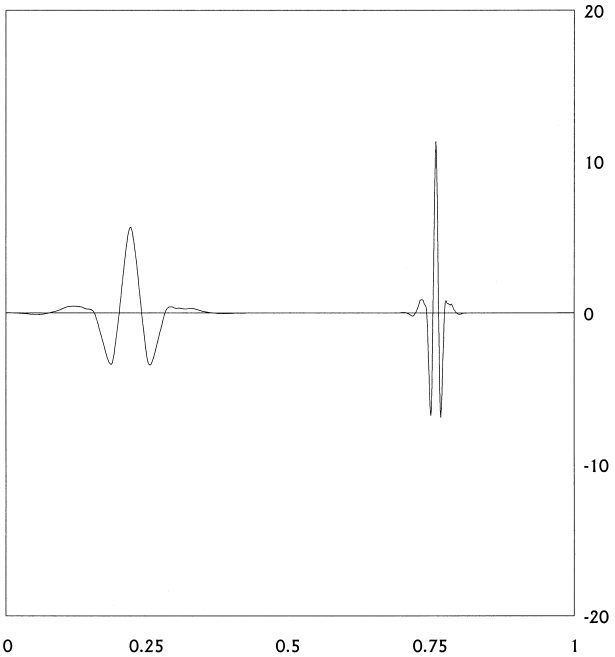

FIGURE 13 Two Daubechies wavelets.

If f is continuous on [0, 1], then S_N converges uniformly to f on [0, 1].

Theorem 14 does not reveal the full power of wavelet series. In almost all cases, it is possible to rearrange the terms in the wavelet series *in any manner whatsoever* and convergence will still hold. One reason for doing a rearrangement is in order to add the terms in the series with coefficients of largest magnitude (thus largest energy) *first* so as to speed up convergence to the function. Here is a convergence theorem for such permuted series.

Theorem 15: Suppose that $\int_0^1 |\mathrm{f}(x)|^p\,dx$ is finite, for $p > 1$. If the terms of a Daubechies wavelet series are permuted (in any manner whatsoever), then the partial sums S_N of the permuted series satisfy

$$\lim_{N\to\infty}\left[\int_0^1 |\mathrm{f}(x) - S_N(x)|^p\,dx\right]^{1/p} = 0.$$

If f is uniformly Lipschitz, then the partial sums S_N of the permuted series converge uniformly to f.

This theorem is proved in Daubechies (1992) and Meyer (1992). This type of convergence of wavelet series is called *unconditional convergence*. It is known [see Mallat (1998)] that unconditional convergence of wavelet series ensures an optimality of compression of signals. For details about compression of signals and other applications of wavelet series, see Walker (1999) for a simple introduction and Mallat (1998) for a thorough treatment.

VII. DISCRETE FOURIER SERIES

The digital computer has revolutionized the practice of science in the latter half of the twentieth century. The methods of computerized Fourier series, based upon the *fast Fourier transform* algorithms for digital approximation of Fourier series, have completely transformed the application of Fourier series to scientific problems. In this section, we shall briefly outline the main facts in the theory of discrete Fourier series.

The Fourier series coefficients $\{c_n\}$ can be discretely approximated via Riemann sums for the integrals in Eq. (9). For a (large) positive integer M, let $x_k = -\pi + 2\pi k/M$ for $k = 0, 1, 2, \ldots, M-1$ and let $\Delta x = 2\pi/M$. Then the nth Fourier coefficient c_n for a function f is approximated as follows:

$$c_n \approx \frac{1}{2\pi}\sum_{k=0}^{M-1} \mathrm{f}(x_k)\,e^{-i2\pi n x_k}\Delta x$$

$$= \frac{e^{-in\pi}}{M}\sum_{k=0}^{M-1} \mathrm{f}(x_k)e^{-i2\pi kn/M}.$$

The last sum above is called the *Discrete Fourier Transform* (DFT) of the finite sequence of numbers $\{\mathrm{f}(x_k)\}$. That is, we define the DFT of a sequence $\{g_k\}_{k=0}^{M-1}$ of numbers by

$$G_n = \sum_{k=0}^{M-1} g_k\,e^{-i2\pi kn/M}. \tag{38}$$

The DFT is the set of numbers $\{G_n\}$, and we see from the discussion above that the Fourier coefficients of a function f can be approximated by a DFT (multiplied by the factors $e^{-in\pi}/M$). For example, in Fig. 14 we show a graph of approximations of the Fourier coefficients $\{c_n\}_{n=-50}^{50}$ of the square wave f_1 obtained via a DFT (using $M = 1024$). For all values, these approximate Fourier coefficients differ from the exact coefficients by no more than 10^{-3}. By taking M even larger, the error can be reduced still further.

The two principal properties of DFTs are that they can be inverted and they preserve energy (up to a scale factor). The inversion formula for the DFT is

$$g_k = \sum_{n=0}^{M-1} G_n\,e^{i2\pi kn/M}. \tag{39}$$

And the conservation of energy property is

$$\sum_{k=0}^{M-1} |g_k|^2 = \frac{1}{N}\sum_{n=0}^{M-1} |G_n|^2. \tag{40}$$

Interpreting a sum of squares as energy, Eq. (40) says that, up to multiplication by the factor $1/N$, the energy of the discrete signal $\{g_k\}$ and its DFT $\{G_n\}$ are the same. These

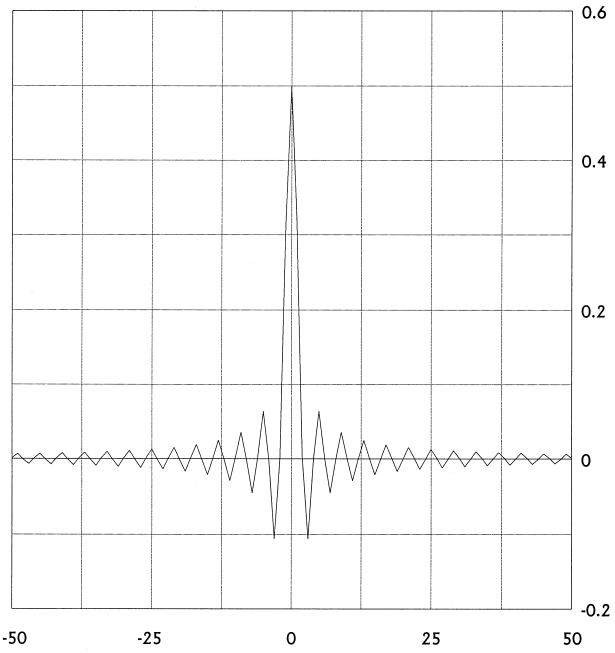

FIGURE 14 Fourier coefficients for square wave, $n = -50$ to 50. Successive values are connected with line segments.

facts are proved in Briggs and Henson (1995) and Walker (1996).

An application of inversion of DFTs is to the calculation of Fourier series partial sums. If we substitute $x_k = -\pi + 2\pi k/M$ into the Fourier series partial sum $S_N(x)$ we obtain (assuming that $N < M/2$ and after making a change of indices $m = n + N$):

$$\begin{aligned} S_N(x_k) &= \sum_{n=-N}^{N} c_n\, e^{in(-\pi+2\pi k/M)} \\ &= \sum_{n=-N}^{N} c_n\,(-1)^n\, e^{i2\pi nk/M} \\ &= \sum_{m=0}^{2N} c_{m-N}\,(-1)^{m-N}\, e^{-i2\pi kN/M}\, e^{i2\pi km/M}. \end{aligned}$$

Thus, if we let $g_m = c_{m-N}$ for $m = 0, 1, \ldots, 2N$ and $g_m = 0$ for $m = 2N+1, \ldots, M-1$, we have

$$S_M(x_k) = e^{-i2\pi kN/M} \sum_{m=0}^{M-1} g_m\,(-1)^{m-N}\, e^{i2\pi km/M}.$$

This equation shows that $S_M(x_k)$ can be computed using a DFT inversion (along with multiplications by exponential factors). By combining DFT approximations of Fourier coefficients with this last equation, it is also possible to approximate Fourier series partial sums, or arithmetic means, or other modified partial sums. See Briggs and Henson (1995) or Walker (1996) for further details.

These calculations with DFTs are facilitated on a computer using various algorithms which are all referred to as *fast Fourier transforms* (FFTs). Using FFTs, the process of computing DFTs, and hence Fourier coefficients and Fourier series, is now practically instantaneous. This allows for rapid, so-called *real-time*, calculation of the frequency content of signals. One of the most widely used applications is in calculating *spectrograms*. A spectrogram is calculated by dividing a signal (typically a recorded, digitally sampled, audio signal) into a successive series of short duration subsignals, and performing an FFT on each subsignal. This gives a portrait of the main frequencies present in the signal as time proceeds. For example, in Fig. 15a we analyze discrete samples of the function

$$\begin{aligned} &\sin(2\nu_1\pi x)e^{-100\pi(x-0.2)^2} + [\sin(2\nu_1\pi x) + \cos(2\nu_2\pi x)] \\ &\quad \times e^{-50\pi(x-0.5)^2} + \sin(2\nu_2\pi x)e^{-100\pi(x-0.8)^2} \end{aligned} \tag{41}$$

where the frequencies ν_1 and ν_2 of the sinusoidal factors are 128 and 256, respectively. The signal is graphed at the bottom of Fig. 15a and the magnitudes of the values of its spectrogram are graphed at the top. The more intense spectrogram magnitudes are shaded more darkly, while white regions indicate magnitudes that are essentially zero. The dark blobs in the graph of the spectrogram magnitudes clearly correspond to the regions of highest energy in the signal and are centered on the frequencies 128 and 256, the two frequencies used in Eq. (41).

As a second example, we show in Fig. 15b the spectrogram magnitudes for the signal

$$e^{-5\pi[(x-0.5)/0.4]^{10}}[\sin(400\pi x^2) + \sin(200\pi x^2)\,]. \tag{42}$$

This signal is a combination of two tones with sharply increasing frequency of oscillations. When run through a sound generator, it produces a sharply rising pitch. Signals like this bear some similarity to certain bird calls, and are also used in radar. The spectrogram magnitudes for this signal are shown in Fig. 15b. We can see two, somewhat blurred, line segments corresponding to the factors $400\pi x$ and $200\pi x$ multiplying x in the two sine factors in Eq. (42).

One important area of application of spectrograms is in *speech coding*. As an example, in Fig. 16 we show spectrogram magnitudes for two audio recordings. The spectrogram magnitudes in Fig. 16a come from a recording of a four-year-old girl singing the phrase "twinkle, twinkle, little star," and the spectrogram magnitudes in Fig. 16b come from a recording of the author of this article singing the same phrase. The main frequencies are seen to be in harmonic progression (integer multiples of a lowest, fundamental frequency) in both cases, but the young girl's main frequencies are higher (higher in pitch) than the adult male's. The slightly curved ribbons of frequency content are known as *formants* in linguistics. For more

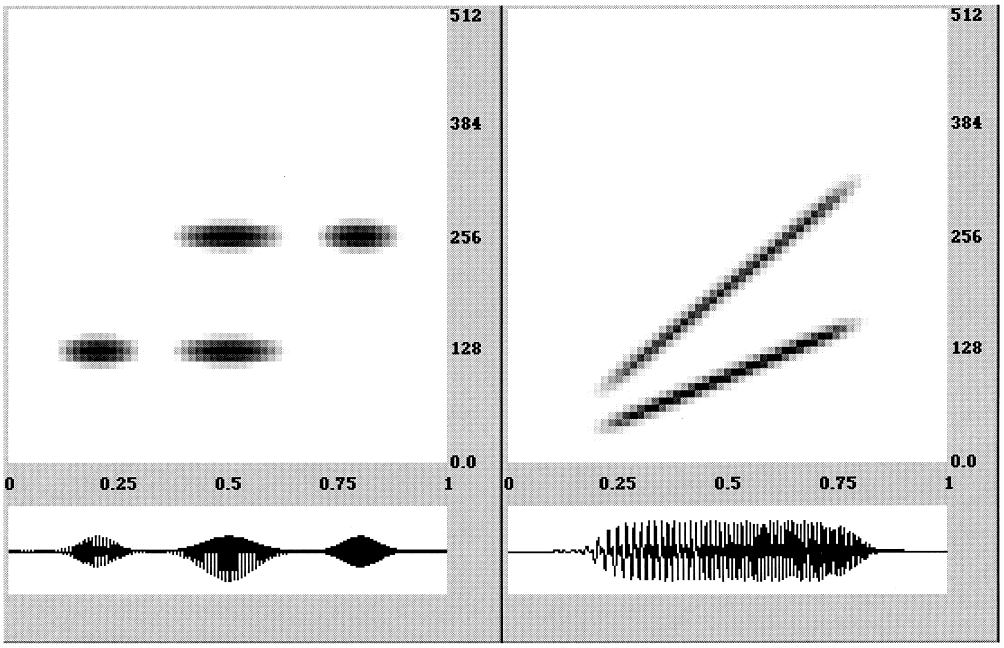

FIGURE 15 Spectrograms of test signals. (a) Bottom graph is the signal in Eq. (41). Top graph is the spectrogram magnitudes for this signal. (b) Signal and spectrogram magnitudes for the signal in (42). Horizontal axes are time values (in sec); vertical axes are frequency values (in Hz). Darker pixels denote larger magnitudes, white pixels are near zero in magnitude.

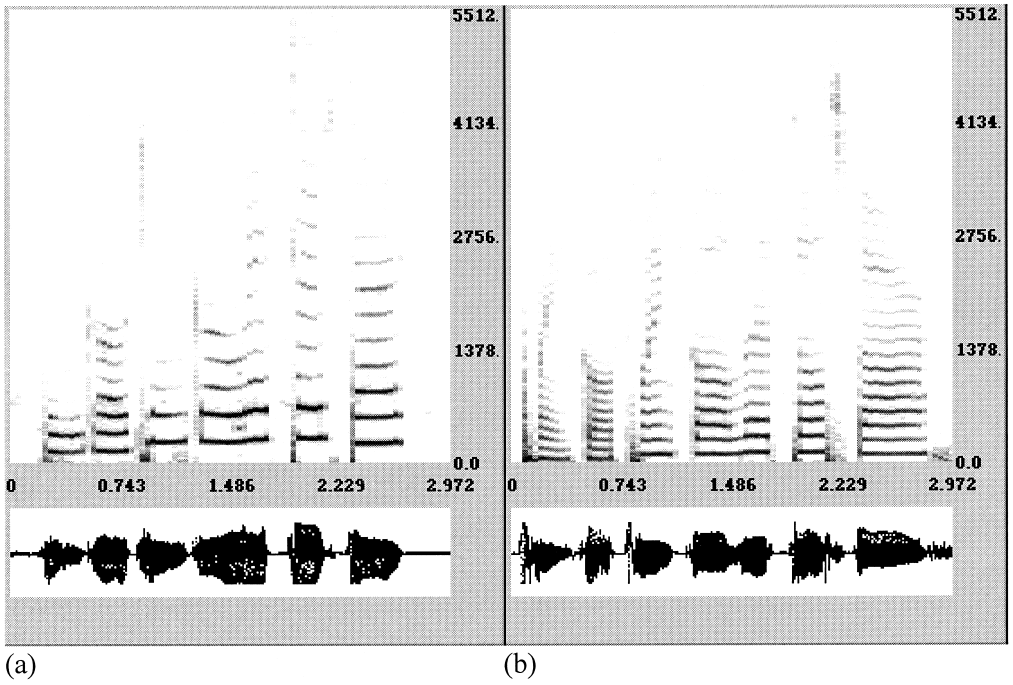

FIGURE 16 Spectrograms of audio signals. (a) Bottom graph displays data from a recording of a young girl singing "twinkle, twinkle, little star." Top graph displays the spectrogram magnitudes for this recording. (b) Similar graphs for the author's rendition of "twinkle, twinkle, little star."

details on the use of spectrograms in signal analysis, see Mallat (1998).

It is possible to invert spectrograms. In other words, we can recover the original signal by inverting the succession of DFTs that make up its spectrogram. One application of this inverse procedure is to the *compression of audio signals.* After discarding (setting to zero) all the values in the spectrogram with magnitudes below a threshold value, the inverse procedure creates an approximation to the signal which uses significantly less data than the original signal. For example, by discarding all of the spectrogram values having magnitudes less than $1/320$ times the largest magnitude spectrogram value, the young girl's version of "twinkle, twinkle, little star" can be approximated, *without noticeable degradation of quality,* using about one-eighth the amount of data as the original recording. Some of the best results in audio compression are based on sophisticated generalizations of this spectrogram technique—referred to either as *lapped transforms or as local cosine expansions*, see Malvar (1992) and Mallat (1998).

VIII. CONCLUSION

In this article, we have outlined the main features of the theory and application of one-variable Fourier series. Much additional information, however, can be found in the references. In particular, we did not have sufficient space to discuss the intricacies of multivariable Fourier series which, for example, have important applications in crystallography and molecular structure determination. For a mathematical introduction to multivariable Fourier series, see Krantz (1999), and for an introduction to their applications, see Walker (1988).

Fractals

Benoit B. Mandelbrot
Michael Frame
Yale University

GLOSSARY

Dimension An exponent characterizing how some aspect—mass, number of boxes in a covering, etc.—of an object scales with the size of the object.
Lacunarity A measure of the distribution of hole sizes of a fractal. The prefactor in the mass–radius scaling is one such measure.
Self-affine fractal A shape consisting of smaller copies of itself, all scaled by affinities, linear transformations with different contraction ratios in different directions.
Self-similar fractal A shape consisting of smaller copies of itself, all scaled by similitudes, linear transformations with the same contraction ratios in every direction.

FRACTALS have a long history: after they became the object of intensive study in 1975, it became clear that they had been used worldwide for millenia as decorative patterns. About a century ago, their appearance in pure mathematics had two effects. It led to the development of tools like fractal dimensions, but marked a turn toward abstraction that contributed to a deep and long divide between mathematics and physics. Quite independently from fundamental mathematical physics as presently defined, fractal geometry arose in equal parts from an awareness of past mathematics and a concern for practical, mundane questions long left aside for lack of proper tools.

The mathematical input ran along the lines described by John von Neumann: "A large part of mathematics which became useful developed with absolutely no desire to be useful . . . This is true for all science. Successes were largely due to . . . relying on . . . intellectual elegance. It was by following this rule that one actually got ahead in the long run, much better than any strictly utilitarian course would have permitted . . . The principle of laissez-faire has led to strange and wonderful results."

The influence of mundane questions grew to take on far more importance than was originally expected, and recently revealed itself as illustrating a theme that is common

in science. Every science started as a way to organize a large collection of messages our brain receives from our senses. The difficulty is that most of these messages are very complex, and a science can take off only after it succeeds in identifying special cases that allow a workable first step. For example, acoustics did not take its first step with chirps or drums but with idealized vibrating strings. These led to sinusoids and constants or other functions invariant under translation in time. For the notion of roughness, no proper measure was available only 20 years ago. The claim put forward forcibly in Mandelbrot (1982) is that a workable entry is provided by rough shapes that are dilation invariant. These are fractals.

Fractal roughness proves to be ubiquitous in the works of nature and man. Those works of man range from mathematics and the arts to the Internet and the financial markets. Those works of nature range from the cosmos to carbon deposits in diesel engines. A sketchy list would be useless and a complete list, overwhelming. The reader is referred to Frame and Mandelbrot (2001) and to a Panorama mentioned therein, available on the web. This essay is organized around the mathematics of fractals, and concrete examples as illustrations of it.

To avoid the need to discuss the same topic twice, mathematical complexity is allowed to fluctuate up and down. The reader who encounters paragraphs of oppressive difficulty is urged to skip ahead until the difficulty becomes manageable.

I. SCALE INVARIANCE

A. On Choosing a "Symmetry" Appropriate to the Study of Roughness

The organization of experimental data into simple theoretical models is one of the central works of every science; invariances and the associated symmetries are powerful tools for uncovering these models. The most common invariances are those under Euclidean motions: translations, rotations, reflections. The corresponding ideal physics is that of uniform or uniformly accelerated motion, uniform or smoothly varying pressure and density, smooth submanifolds of Euclidean physical or phase space. The geometric alphabet is Euclidean, the analytical tool is calculus, the statistics is stationary and Gaussian.

Few aspects of nature or man match these idealizations: turbulent flows are grossly nonuniform; solid rocks are conspicuously cracked and porous; in nature and the stock market, curves are nowhere smooth. One approach to this discrepancy, successful for many problems, is to treat observed objects and processes as "roughened" versions of an underlying smooth ideal. The underlying geometry is Euclidean or locally Euclidean, and observed nature is written in the language of noisy Euclidean geometry.

Fractal geometry was invented to approach roughness in a very different way. Under magnification, smooth shapes are more and more closely approximated by their tangent spaces. The more they are magnified, the simpler ("better") they look. Over some range of magnifications, looking more closely at a rock or a coastline does not reveal a simpler picture, but rather more of the same kind of detail. Fractal geometry is based on this ubiquitous *scale invariance*. "A fractal is an object that doesn't look any better when you blow it up." Scale invariance is also called "symmetry under magnification."

A manifestation is that fractals are sets (or measures) that can be broken up into pieces, each of which closely resembles the whole, except it is smaller. If the pieces scale isotropically, the shape is called *self-similar*; if different scalings are used in different directions, the shape is called *self-affine*.

There are deep relations between the geometry of fractal sets and the renormalization approach to critical phenomena in statistical physics.

B. Examples of Self-Similar Fractals

1. Exact Linear Self-Similarity

A shape S is called *exactly (linearly) self-similar* if the whole S splits into the union of parts S_i: $S = S_1 \cup S_2 \cup \ldots \cup S_n$. The parts satisfy two restrictions: (a) each part S_i is a copy of the whole S scaled by a linear contraction factor r_i, and (b) the intersections between parts are empty or "small" in the sense of dimension. Anticipating Section II, if $i \neq j$, the fractal dimension of the intersection $S_i \cap S_j$ must be lower than that of S. The roughness of these sets is characterized by the *similarity dimension* d. In the special equiscaling case $r_1 = \cdots = r_n = r$, $d = \log(n)/\log(1/r)$. In general, d is the solution of the *Moran equation*

$$\sum_{i=1}^{n} r_i^d = 1.$$

More details are given in Section II.

Exactly self-similar fractals can be constructed by several elegant mathematical approaches.

a. Initiator and generator. An *initiator* is a starting shape; a *generator* is a juxtaposition of scaled copies of the initiator. Replacing the smaller copies of the initiator in the generator with scaled copies of the generator sets in motion a process whose limit is an exactly self-similar fractal. Stages before reaching the limit are called *protofractals*. Each copy is anchored by a fixed point, and one may have to specify the orientation of each replacement. The

FIGURE 1 Construction of the Sierpinksi gasket. The initiator is a filled-in equilateral triangle, and the generator (on the left) is made of $N=3$ triangles, each obtained from the initiator by a contraction map T_i of reduction ratio $r=1/2$. The contractions' fixed points are the vertices of the initiator. The middle shows the second stage, replacing each copy of the initiator with a scaled copy of the generator. On the right is the seventh stage of the construction.

Sierpinski gasket (Fig. 1) is an example. The eye spontaneously splits the whole S into parts. The simplest split yields $N=3$ parts S_i, each a copy of the whole reduced by a similitude of ratio $1/2$ and with fixed point at a vertex of the initiator. In finer subdivisions, $S_i \cap S_j$ is either empty or a single point, for which $d=0$. In this example, but not always, it can be made empty by simply erasing the topmost point of every triangle in the construction.

Some of the most familiar fractals were orignally constructed to provide instances of curves that exemplify properties deemed counterintuitive: classical curves may have one multiple point (like Fig. 8) or a few. To the contrary, the Sierpinski gasket (Fig. 2, far left) is a curve with dense multiple points. The Sierpinski carpet (Fig. 2, mid left) is a universal curve in the sense that one can embed in the carpet every plane curve, irrespective of the collection of its multiple points. The Peano curve [initiator the diagonal segment from (0, 0) to (1, 1), generator in Fig. 2 mid right] is actually not a curve but a motion. It is plane-filling: a continuous onto map $[0,1] \to [0,1] \times [0,1]$.

b. Iterated function systems. Iterated function systems (IFS) are a formalism for generating exactly self-similar fractals based on work of Hutchinson (1981) and Mandelbrot (1982), and popularized by Barnsley (1988). IFS are the foundation of a substantial industry of image compression. The basis is a (usually) finite collection $\{T_1, \ldots, T_n\}$ of contraction maps $T_i: \mathbf{R}^n \to \mathbf{R}^n$ with contraction ratios $r_i < 1$. Each T_i is assigned a probability p_i that serves, at each (discrete) instant of time, to select the next map to be used. An IFS attractor also can be viewed as the limit set of the orbit $\mathcal{O}^+(x_0)$ of any point x_0 under the action of the semigroup generated by $\{T_1, \ldots, T_n\}$.

The formal definition of IFS, which is delicate and technical, proceeds as follows. Denoting by $\mathcal{K}$ the set of nonempty compact subsets of $\mathbf{R}^n$ and by h the Hausdorff metric on $\mathcal{K}$ [$h(A, B) = \inf\{\delta: A \subset B_\delta \text{ and } B \subset A_\delta\}$, where $A_\delta = \{x \in \mathbf{R}^n: d(x, y) \le \delta \text{ for some } y \in A\}$ is the δ-*thickening* of A, and d is the Euclidean metric], the T_i together define a transformation $\mathcal{T}: \mathcal{K} \to \mathcal{K}$ by $\mathcal{T}(A) = \bigcup_{i=1}^n \{T_i(x): x \in A\}$, a contraction in the Hausdorff metric with contraction ratio $r = \max\{r_1, \ldots, r_n\}$. Because $(\mathcal{K}, h)$ is complete, the contraction mapping principle guarantees there is a unique fixed point C of $\mathcal{T}$. This fixed point is the *attractor* of the IFS $\{T_1, \ldots, T_n\}$. Moreover, for any $K \in \mathcal{K}$, the sequence $K, \mathcal{T}(K), \mathcal{T}^2(K), \ldots$ converges to C in the sense that $\lim_{n\to\infty} h(\mathcal{T}^n(K), C) = 0$.

The IFS *inverse problem* is, for a given compact set A and given tolerance $\delta > 0$, to find a set of transformations $\{T_1, \ldots, T_n\}$ with attractor C satisfying $h(A, C) < \delta$. The search for efficient algorithms to solve the inverse problem is the heart of *fractal image compression*. Detailed discussions can be found in Barnsley and Hurd (1993) and Fischer (1995).

2. Exact Nonlinear Self-Similarity

A broader class of fractals is produced if the decomposition of S into the union $S = S_1 \cup S_2 \cup \ldots \cup S_n$ allows the S_i to be the images of S under nonlinear transformations.

a. Quadratic Julia sets. For fixed complex number c, the "quadratic orbit" of the starting complex number z is a sequence of numbers that begins with $f_c(z) = z^2 + c$, then $f_c^2(z) = (f_c(z))^2 + c$ and continues by following the rule $f_c^n(z) = f_c(f_c^{n-1}(z))$. The *filled-in (quadratic) Julia set* consists of the starting points that do not iterate to infinity, formally, the points $\{z: f_c^n(z)$ remains bounded as $n \to \infty\}$. The *(quadratic) Julia set* J_c is the boundary of the filled-in Julia set. Figure 3 shows the Julia set J_c for $c = 0.4 + 0 \cdot i$ and the filled-in Julia set for $c = -0.544 + 0.576 \cdot i$. The latter has an attracting 5-cycle, the black region is the basin of attraction of the

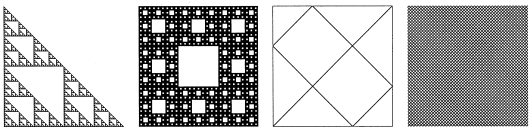

FIGURE 2 The Sierpinski gasket, Sierpinski carpet, the Peano curve generator, and the fourth stage of the Peano curve.

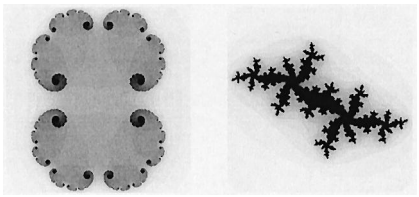

FIGURE 3 The Julia set of $z^2 + 0.4$ (left) and the filled-in Julia set for $z^2 - 0.544 + 0.576 \cdot i$ (right).

5-cycle, and the Julia set is the boundary of the black region. Certainly, J_c is invariant under f_c and under the inverses of f_c, $f_{c+}^{-1}(z) = \sqrt{z-c}$ and $f_{c-}^{-1}(z) = -\sqrt{z-c}$. Polynomial functions allow several equivalent characterizations: J_c is the closure of the set of repelling periodic points of $f_c(z)$ and J_c is the attractor of the nonlinear IFS $\{f_{c+}^{-1}, f_{c-}^{-1}\}$.

Much is known about Julia sets of quadratic functions. For example, McMullen proved that at a point whose rotation number has periodic continued-fraction expansion, the J set is asymptotically self-similar about the critical point.

The J sets are defined for functions more general than polynomials. Visually striking and technically interesting examples correspond to the Newton function $N_f(z) = z - f(z)/f'(z)$ for polynomial families $f(z)$, or entire functions like $\lambda \sin z$, $\lambda \cos z$, or $\lambda \exp z$ (see Section VIII.B). Discussions can be found in Blanchard (1994), Curry *et al*. (1983), Devaney (1994), Keen (1994), and Peitgen (1989).

b. The Mandelbrot set. The quadratic orbit $f_c^n(z)$ always converges to infinity for large enough values of z. Mandelbrot attempted a computer study of the set M^0 of those values of c for which the orbit does *not* converge to infinity, but to a stable cycle. This approach having proved unrewarding, he moved on to a set that promised an easier calculation and proved spectacular. Julia and Fatou, building on fundamental work of Montel, had shown that the Julia set J_c of $f_c(z) = z^2 + c$ must be either connected or totally disconnected. Moreover, J_c is connected if, and only if, the orbit $\mathcal{O}^+(0)$ of the critical point $z = 0$ remains bounded. The set M defined by $\{c\colon f_c^n(0)$ remains bounded$\}$ is now called the *Mandelbrot set* (see the left side of Fig. 4). Mandelbrot (1980) performed a computer investigation of its structure and reported several observations. As is now well known, small copies of the M set are infinitely numerous and dense in its boundary. The right side of Fig. 4 shows one such small copy, a nonlinearly distorted copy of the whole set. Although the small copy on the right side of Fig. 4 appears to be an isolated "island," Mandelbrot conjectured and Douady and Hubbard (1984) proved that the M set is connected. Sharpening an observation by Mandelbrot, Tan Lei (1984) proved the convergence of appropriate magnifications of Julia sets and the M set at certain points named after Misiurewicz. Shishikura (1994) proved Mandelbrot's (1985) and Milnor's (1989) conjecture that the boundary of the M set has Hausdorff dimension 2. Lyubich proved that the boundary of the M set is asymptotically self-similar about the Feigenbaum point.

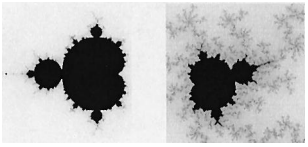

FIGURE 4 Left: The Mandelbrot set. Right: A detail of the Mandelbrot set showing a small copy of the whole. Note the nonlinear relation between the whole and the copy.

Mandelbrot's first conjecture, that the interior of the M set consists entirely of components (called *hyperbolic*) for which there is a stable cycle, remains unproved in general, though McMullen (1994) proved it for all such components that intersect the real axis. Mandelbrot's notion that M may be the closure of M^0 is equivalent to the assertion that the M set is locally connected. Despite intense efforts, that assertion remains a conjecture, though Yoccoz and others have made progress.

Other developments include the theory of quadratic-like maps (Douady and Hubbard, 1985), implying the universality and ubiquity of the M set. This result was presaged by the discovery (Curry *et al*., 1983) of a Mandelbrot set in the parameter space of Newton's method for a family of cubic polynomials.

The recent book by Tan Lei (2000) surveys current results and attests to the vitality of this field.

c. Circle inversion limit sets. Inversion I_C in a circle C with center O and radius r transforms a point P into the point P' lying on the ray OP and with $d(O, P) \cdot d(O, P') = r^2$. This is the orientation-reversing involution defined on $\mathbf{R}^2 \cup \{\infty\}$ by $P \to I_C(P) = P'$. Inversion in C leaves C fixed, and interchanges the interior and exterior of C. It contracts the "outer" component not containing O, but the contraction ratio is not bounded by any $r < 1$.

Poincaré generalized from inversion in one circle to a collection of more than one inversion. As an example, consider a collection of circles $C_1, \ldots, C_N$ each of which is external to all the others. That is, for all $j \neq i$, the disks bounded by C_i and C_j have disjoint interiors. The *limit set* $\Lambda(C_1, \ldots, C_N)$ of inversion in these circles is the set of limit points of the orbit $\mathcal{O}^+(P)$ of any point P, external to $C_1, \ldots, C_N$, under the group generated by $I_{C_1}, \ldots, I_{C_N}$. Equivalently, it is the set left invariant by every one of the inversions $I_{C_1}, \ldots, I_{C_N}$.

The limit set Λ is nearly always fractal but the nonlinearity of inversion guarantees that Λ is nonlinearly self-similar. An example is shown in Fig. 5: the part of the limit set inside C_1 is easily seen to be the transform by I_1 of the part of the limit set inside C_2, C_3, C_4, and C_5.

How can one draw the limit set Λ when the arrangement of the circles $C_1, \ldots, C_N$ is more involved? Poincaré's original algorithm converges extraordinarily slowly. The first alternative algorithm was advanced in Mandelbrot

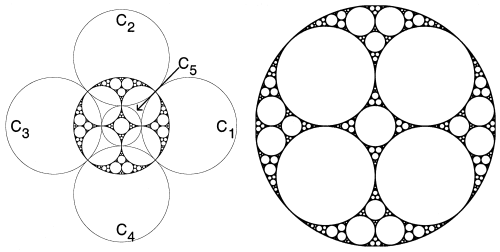

FIGURE 5 Left: The limit set generated by inversion in the five circles $C_1, \ldots, C_5$. Right: A magnification of the limit set.

(1982, Chapter 18); it is intuitive and the large-scale features of Λ appear very rapidly, followed by increasingly fine features down to any level a computer's memory can support.

d. Kleinian group limit sets. A Kleinian group (Beardon, 1983; Maskit, 1988) is a discrete group of Möbius transformations

$$z \to \frac{az+b}{cz+d}$$

acting on the Riemann sphere $\hat{\mathbf{C}}$, the sphere at infinity of hyperbolic 3-space $\mathbf{H}^3$. The isometries of $\mathbf{H}^3$ can be represented by complex matrices

$$\begin{bmatrix} a & b \\ c & d \end{bmatrix}.$$

[More precisely, by their equivalence classes in $PSL_2(\mathbf{C})$.] Sullivan's side-by-side dictionary (Sullivan, 1985) between Kleinian groups and iterates of rational maps is another deep mathematical realm informed, at least in part, by fractal geometry. Thurston's "geometrization program" for 3-manifolds (Thurston, 1997) involves giving many 3-manifolds hyperbolic structures by viewing them as quotients of $\mathbf{H}^3$ by the action of a Kleinian group G (Epstein, 1986). The corresponding action of G on $\hat{\mathbf{C}}$ determines the limit set $\Lambda(G)$, defined as the intersection of all nonempty G-invariant subsets of $\hat{\mathbf{C}}$. For many G, the limit set is a fractal. An example gives the flavor of typical results: the limit set of a finitely generated Kleinian group is either totally disconnected, a circle, or has Hausdorff dimension greater than 1 (Bishop and Jones, 1997). The Hausdorff dimension of the limit set has been studied by Beardon, Bishop, Bowen, Canary, Jones, Keen, Mantica, Maskit, McMullen, Mumford, Parker, Patterson, Sullivan, Tricot, Tukia, and many others. Poincaré exponents, eigenvalues of the Laplacian, and entropy of geodesic flows are among the tools used.

Figure 5 brings forth a relation between some limit sets of inversions or Kleinian groups and Apollonian packings (Keen *et al.*, 1993). In fact, the limit set of the Kleinian groups that are in the Maskit embedding (Keen and Series, 1993) of the Teichmüller space of any finite-type Riemann surface are Apollonian packings. These correspond to hyperbolic 3-manifolds having totally geodesic boundaries. McShane *et al.* (1994) used automatic group theory to produce efficient pictures of these limit sets, and Parker (1995) showed that in many cases the Hausdorff dimension of the limit set equals the circle packing exponent, easily estimated as the slope of the log–log plot of the number of circles of radius $\geq r$ (y axis) versus r (x axis).

Limit sets of Kleinian group actions are an excellent example of a deep, subtle, and very active area of pure mathematics in which fractals play a central role.

3. Statistical Self-Similarity

A tree's branches are not exact shrunken copies of that tree, inlets in a bay are not exact shrunken copies of that bay, nor is each cloud made up of exact smaller copies of that cloud. To justify the role of fractal geometry as a geometry of nature, one must take a step beyond exact self-similarity (linear or otherwise). Some element of randomness appears to be present in many natural objects and processes. To accommodate this, the notions of self-similarity and self-affinity are made statistical.

a. Wiener brownian motion: its graphs and trails. The first example is classical. It is one-dimensional Brownian motion, the random process $X(t)$ defined by these properties: (1) with probability 1, $X(0) = 0$ and $X(t)$ is continuous, and (2) the increments $X(t+\Delta t) - X(t)$ of $X(t)$ are Gaussian with mean 0 and variance Δt. That is,

$$Pr\{X(t+\Delta t) - X(t) \leq x\} = \frac{1}{\sqrt{2\pi\,\Delta t}} \times \int_{-\infty}^{x} \exp\left(\frac{-u^2}{2\Delta t}\right) du.$$

An immediate consequence is independence of increments over disjoint intervals. A fundamental property of Brownian motion is statistical self-affinity: for all $s > 0$,

$$Pr\{X(s(t+\Delta t)) - X(st) \leq \sqrt{s}x\} = Pr\{X(t+\Delta t) - X(t) \leq x\}.$$

That is, rescaling t by a factor of s, and of x by a factor of $\sqrt{s}$, leaves the distribution unchanged. This correct rescaling is shown on the left panel of Fig. 6: t (on the horizontal axis) is scaled by 4, x (on the vertical axis) is scaled by $2 = 4^{1/2}$. Note that this magnification has about the same degree of roughness as the full picture. In the center panel, t is scaled by 4, x by 4/3; the magnification is flatter than the original. In the right panel, both t and

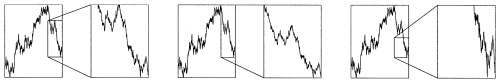

FIGURE 6 Left panel: Correct rescaling illustrating the self-affinity of Brownian motion. Center and right panels: Two incorrect rescalings.

x are scaled by 4; the magnification is steeper than the original.

A sequence of increments of Brownian motion is called Gaussian white noise. Even casual inspection of the graph reveals some fundamental features. The width of an old pen-plotter line being equal to the spacing between successive difference values, the bulk of the difference plot merges into a "band" with the following properties (see Fig. 7):

- The band's width is approximately constant.
- The values beyond that band stay close to it (this is due to the fact that the Gaussian has "short tails").
- The values beyond that band do not cluster.

Positioning E independent one-dimensional Brownian motions along E coordinate axes gives a higher dimensional Brownian motion: $B(t) = \{X_1(t), \ldots, X_E(t)\}$. Plotted as a curve in E-dimensional space, the collection of points that $B(t)$ visits between $t = 0$ and $t = 1$ defines a *Brownian trail*.

When $E > 2$, this is an example of a statistically self-similar fractal. To split the Brownian trail into N reduced-scale parts, pick $N - 1$ arbitrary instants t_n with $0 = t_0 < t_1 < \cdots < t_{N-1} < t_N = 1$. The Brownian trail for $0 \le t \le 1$ splits into N subtrails B_n for the interval $t_{n-1} < t < t_n$. The parts B_n follow the same statistical distribution as the whole, after the size is expanded by $(t_n - t_{n-1})^{-1/2}$ in every direction.

Due to the definition of self-similarity, this example reveals a pesky complication: for $i \neq j$, $B_i \cap B_j$ must be of dimension less than B. This is indeed the case if $E > 2$, but not in the plane $E = 2$. However, the overall idea can be illustrated for $E = 2$. The right side of Fig. 8 shows $B_1(t)$ for $0 \le t \le 1/4$, expanded by a factor of $2 = (1/4 - 0)^{-1/2}$ and with additional points interpolated so the part and the whole exhibit about the same number of turns. The details for $E = 2$ are unexpectedly complex, as shown in Mandelbrot (2001b, Chapter 3).

The dimensions (see Sections II.B and II.E) of some Brownian constructions are well-known, at least in most cases. For example, with probability 1:

FIGURE 7 Plot of 4000 successive Brownian increments.

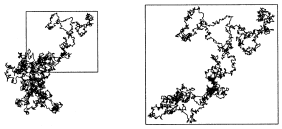

FIGURE 8 A Brownian trail. Right: The first quarter of the left trail, magnified and with additional turns interpolated so the left and right pictures have about the same number of turns.

- For $E \ge 2$ a Brownian trail $B: [0, 1] \to \mathbf{R}^E$ has Hausdorff and box dimensions $d_{\mathrm{H}} = d_{\mathrm{box}} = 2$, respectively.
- The graph of one-dimensional Brownian motion $B: [0, 1] \to \mathbf{R}$ has $d_{\mathrm{H}} = d_{\mathrm{box}} = 3/2$.

Some related constructions have been more resistant to theoretical analysis. Mandelbrot's *planar Brownian cluster* is the graph of the complex $B(t)$ constrained to satisfy $B(0) = B(1)$. It can be constructed by linearly detrending the x- and y-coordinate functions: $(X(t) - tX(1), Y(t) - tY(1))$. See Fig. 9. The cluster is known to have dimension 2. Visual inspection supported by computer experiments led to the $4/3$ *conjecture*, which asserts that the boundary of the cluster has dimension $4/3$ (Mandelbrot, 1982, p. 243). This has been proved by Lawler *et al*. (2000).

Brownian motion is the unique stationary random process with increments independent over disjoint intervals and with finite variance. For many applications, these conditions are too restrictive, drawing attention to other random processes that retain scaling but abandon either independent increments or finite variance.

b. Fractional Brownian motion. For fixed $0 < H < 1$, *fractional Brownian motion* (FBM) of exponent H is a random process $X(t)$ with increments $X(t + \Delta t) - X(t)$ following the Gaussian distribution with mean 0 and standard deviation $(\Delta t)^H$. Statistical self-affinity is straightforward: for all $s > 0$

$$Pr\{X(s(t + \Delta t)) - X(st) \le s^H x\}$$
$$= Pr\{X(t + \Delta t) - X(t) \le x\}.$$

The correlation is the expected value of the product of successive increments. It equals

FIGURE 9 A Brownian cluster.

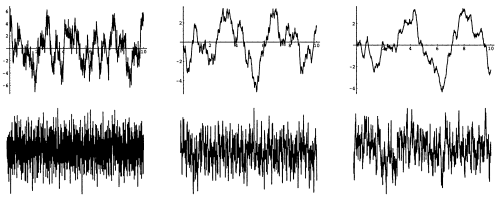

FIGURE 10 Top: Fractional Brownian motion simulations with $H = 0.25$, $H = 0.5$, and $H = 0.75$. Bottom: Difference plots $X(t+1) - X(t)$ of the graphs above.

$$E((X(t) - X(0)) \cdot (X(t+h) - X(t))) = \tfrac{1}{2}((t+h)^{2H} - t^{2H} - h^{2H}).$$

If $H = 1/2$, this correlation vanishes and the increments are independent. In fact, FBM reduces to Brownian motion. If $H > 1/2$, the correlation is positive, so the increments tend to have the same sign. This is *persistent FBM*. If $H < 1/2$, the correlation is negative, so the increments tend to have opposite signs. This is *antipersistent FBM*. See Fig. 10. The exponent determines the dimension of the graph of FBM: with probability 1, $d_{\mathrm{H}} = d_{\mathrm{box}} = 2 - H$. Notice that for $H > 1/2$, the central band of the difference plot moves up and down, a sign of long-range correlation, but the outliers still are small. Figure 11 shows the trails of these three flavors of FBM. FBM is the main topic of Mandelbrot (2001c).

c. Lévy stable processes. While FBM introduces correlations, its increments remain Gaussian and so have small outliers. The Gaussian distribution is characterized by its first two moments (mean and variance), but some natural phenomena appear to have distributions for which these are not useful indicators. For example, at the critical point of percolation there are clusters of all sizes and the expected cluster size diverges.

Paul Lévy studied random walks for which the jump distributions follow the power law $Pr\{X > x\} \approx x^{-\alpha}$. There is a geometrical approach for generating examples of Lévy processes.

The *unit step function* $\xi(t)$ is defined by

$$\xi(t) = \begin{cases} 0 & \text{for } x < 0 \\ 1 & \text{for } x \geq 0 \end{cases}$$

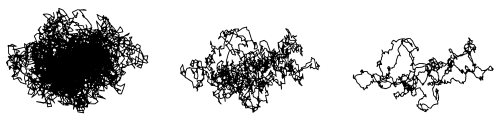

FIGURE 11 Top: Fractional Brownian motion simulations with $H = 0.25$, $H = 0.5$, and $H = 0.75$. Bottom: Difference plots $X(t+1) - X(t)$ of the graphs above.

FIGURE 12 Lévy flight on the line. Left: the graph as a function of time. Right, the increments.

and a (one-dimensional) Lévy stable process is defined as a sum

$$f(t) = \sum_{k=1}^{\infty} \lambda_k \xi(t - t_k),$$

where the pulse times t_n and amplitudes λ_n are chosen according to the following Lévy measure: given t and λ, the probability of choosing (t_i, λ_i) in the rectangle $t < t_i < t + dt$, $\lambda < \lambda_i < \lambda + d\lambda$ is $C\lambda^{-\alpha-1}\, d\lambda\, dt$. Figure 12 shows the graph of a Lévy process or flight, and a graph of its increments.

Comparing Figs. 7, 10, and 12 illustrates the power of the increment plot for revealing both global correlations (FBM) and long tails (Lévy processes).

The effect of large excursions in Lévy processess is more visible in the plane. See Fig. 13. These Lévy flights were used in Mandelbrot (1982, Chapter 32) to mimic the statistical properties of galaxy distributions.

Using fractional Brownian motion and Lévy processes, Mandelbrot (in 1965 and 1963) improved upon Bachelier's Brownian model of the stock market. The former corrects the independence of Brownian motion, the latter corrects its short tails. The original and corrected processes in the preceding sentence are statistically self-affine random fractal processes. This demonstrates the power of invariances in financial modeling; see Mandelbrot (1997a,b).

d. Self-affine cartoons with mild to wild randomness. Many natural processes exhibit long tails or global dependence or both, so it was a pleasant surprise that both can be incorporated in an elegant family of simple cartoons. (Mandelbrot, 1997a, Chapter 6; 1999, Chapter N1; 2001a). Like for self-similar curves (Section I.B.1.a), the basic construction of the cartoon involves an initiator and a

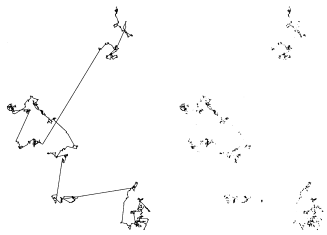

FIGURE 13 Left: Trail of the Lévy flight in the plane. Right: The Lévy dust formed by the turning points.

FIGURE 14 The initiator (left), generator (middle), and first generation (right) of the Brownian cartoon.

generator. The process used to generate the graph consists in replacing each copy of the initiator with an appropriately rescaled copy of the generator. For a Brownian cartoon, the initiator can be the diagonal of the unit square, and the generator, the broken line with vertices (0, 0), (4/9, 2/3), (5/9, 1/3), and (1, 1). Pictured in Fig. 14 are the initiator (left), generator (middle), and first iteration of the process (right).

To get an appreciation for how quickly the local roughness of these pictures increases, the left side of Fig. 15 shows the sixth iterate of the process.

Self-affinity is built in because each piece is an appropriately scaled version of the whole. In Fig. 14, the scaling ratios have been selected to match the "square root" property of Brownian motion: for each segment of the generator we have $|\Delta x_i| = (\Delta t_i)^{1/2}$.

More generally, a cartoon is called *unifractal* if there is a constant H with $|\Delta x_i| = (\Delta t_i)^H$ for each generator segment, where $0 < H < 1$. If different H are needed for different segments, the cartoon is *multifractal*.

The left side of Figure 15 is too symmetric to mimic any real data, but this problem is palliated by shuffling the order in which the three pieces of the generator are put into each scaled copy. The right side of Fig. 15 shows a Brownian cartoon randomized in this way.

Figure 16 illustrates how the statistical properties of the increments can be modified by adjusting the generator in a symmetrical fashion. Keeping fixed the endpoints (0, 0) and (1, 1), the middle turning points are changed into $(a, 2/3)$ and $(1-a, 1/3)$ for $0 < a \le 1/2$.

e. Percolation clusters (Stauffer and Aharony, 1992). Given a square lattice of side length L and a number $p \in [0, 1]$, assign a random number $x \in [0, 1]$ to each lattice cell and fill the cell if $x \le p$. A *cluster* is a maximal collection of filled cells, connected by sharing common edges. Three examples are shown in Fig. 17. A

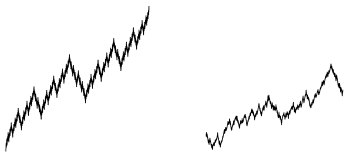

FIGURE 15 Left: The sixth iterate of the process of Fig. 14. Right: A sixth iterate of a randomized Brownian cartoon.

spanning cluster connects opposite sides of the lattice. For large L there is a *critical probability* or *percolation threshold* p_c; spanning clusters do not arise for $p < p_c$. Numerical experiments suggest $p_c \approx 0.59275$. In Fig. 17, $p = 0.4$, 0.6, and 0.8. Every lattice has its own p_c.

At $p = p_c$ the masses of the spanning clusters scale with the lattice size L as L^d, independently of the lattices. Experiment yields $d = 1.89 \pm 0.03$, and theory yields $d = 91/49$. This d is the mass dimension of Section II.C. In addition, spanning clusters have holes of all sizes; they are statistically self-similar fractals.

Many fractals are defined as part of a percolation cluster. The *backbone* is the subset of the spanning cluster that remains after removing all parts that can be separated from both spanned sides by removing a single filled cell from the spanning cluster. Numerical estimates suggest the backbone has dimension 1.61. The backbone is the path followed by a fluid diffusing through the lattice.

The *hull* of a spanning cluster is its boundary. It was observed by R. F. Voss in 1984 and proven by B. Duplantier that the hull's dimension is 7/4.

A more demanding definition of the boundary yields the *perimeter*. It was observed by T. Grossman and proven by B. Duplantier that the perimeter's dimension is 4/3.

Sapoval *et al.* (1985) examined discrete diffusion and showed that it involves a fractal diffusion front that can be modeled by the hull and the perimeter of a percolation cluster.

f. Diffusion-limited aggregation (DLA; Vicsek, 1992). DLA was proposed by Witten and Sander (1981, 1983) to simulate the aggregates that carbon particles form in a diesel engine. On a grid of square cells, a cartoon of DLA begins by occupying the center of the grid with a "seed particle." Next, place a particle in a square selected at random on the edge of a large circle centered on the seed square and let it perform a simple random walk. With each tick of the clock, with equal probabilities it will move to an adjacent square, left, right, above, or below. If the moving particle wanders too far from the seed, it falls off the edge of the grid and another wandering particle is started at a randomly chosen edge point. When a wandering particle reaches one of the four squares adjacent to the seed, it sticks to form a cluster of two particles, and another moving particle is released. When a moving particle reaches a square adjacent to the cluster, it sticks there. Continuing in this way builds an arbitrarily large object called a diffusion-limited aggregate (DLA) because the growth of the cluster is governed by the particles' diffusing across the grid. Figure 18 shows a moderate-size DLA cluster.

Early computer experiments on clusters of up to the 10^4 particles showed the mass $M(r)$ of the part of the cluster a distance r from the seed point scales as $M(r) \approx k \cdot r^d$,

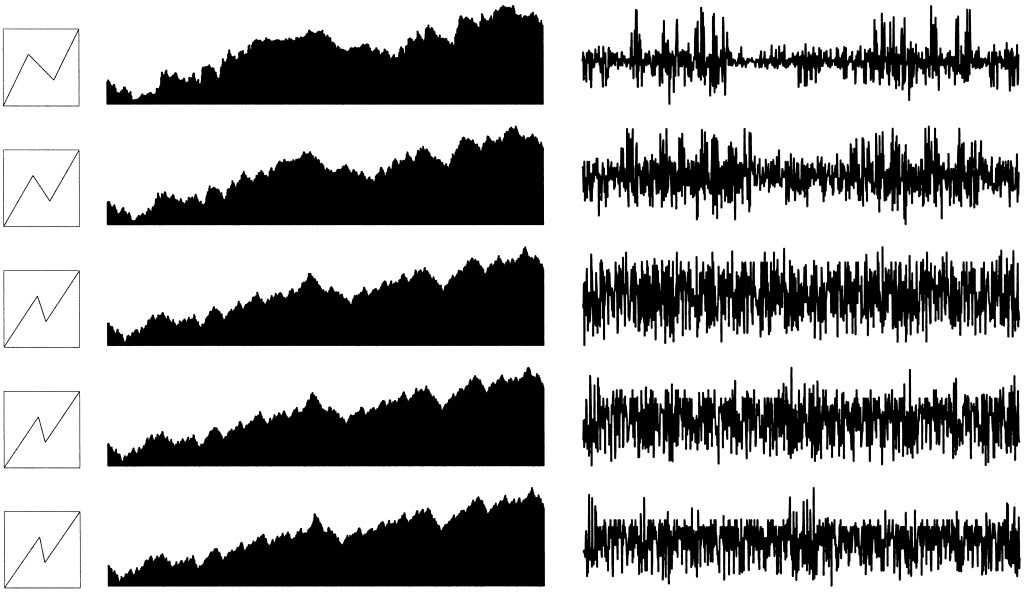

FIGURE 16 Generators, cartoons and difference graphs for symmetric cartoons with turning points $(a, 2/3)$ and $(1-a, 1/3)$, for $a = 0.333, 0.389, 0.444, 0.456,$ and 0.467. The same random number seed is used in all graphs.

with $d \approx 1.71$ for clusters in the plane and $d \approx 2.5$ for clusters in space. This exponent d is the mass dimension of the cluster. (See Sections II.C and V.) These values match measured scalings of physical objects moderately, but not terribly well. A careful examination of much larger clusters revealed discrepancies that added in due time to a very complex picture of DLA. Mandelbrot *et al.* (1995) investigated clusters in the 10^7 range; careful measurement reveals an additional dimension of 1.65 ± 0.01. This suggests the clusters become more compact as they grow. Also, as the cluster grows, more arms develop and the largest gaps decrease in size; i.e., the lacunarity decreases. (See Section VI.)

II. THE GENERIC NOTION OF FRACTAL DIMENSION AND A FEW SPECIFIC IMPLEMENTATIONS

The first, but certainly not the last, step in quantifying fractals is the computation of a dimension. The notion of Euclidean dimension has many aspects and therefore extends in several fashions. The extensions are distinct in the most general cases but coincide for exactly self-similar fractals. Many other dimensions cannot be mentioned here.

A more general approach to quantifying degrees of roughness is found in the article on *Multifractals*.

FIGURE 17 Percolation lattices well below, near, and well above the percolation threshold.

A. Similarity Dimension

The definition of similarity dimension is rooted in the fact that the unit cube in D-dimensional Euclidean space is self-similar: for any positive integer b the cube can be decomposed into $N = b^D$ cubes, each scaled by the similarity ratio $r = 1/b$, and overlapping at most along $(D-1)$-dimensional cubes.

The equiscaling or isoscaling case. Provided the pieces do not overlap significantly, the power-law relation $N = (1/r)^D$ between the number N and scaling factor r of the pieces generalizes to all exactly self-similar sets with all pieces scaled by the factor r. The *similarity dimension* d_{sim} is

$$d_{\text{sim}} = \frac{\log(N)}{\log(1/r)}.$$

FIGURE 18 A moderate-size DLA cluster.

The pluriscaling case. More generally, for self-similar sets where each piece is scaled by a possibly different factor r_i, the similarity dimension is the unique positive root d of the *Moran equation*

$$\sum_{i=1}^{N} r_i^d = 1.$$

The relation $0 \le d_{\text{sim}} \le E$. If the fractal is a subset of E-dimensional Euclidean space, E is called the *embedding dimension*.

So long as the overlap of the parts is not too great (technically, under the *open set condition*), we have $d_{\text{sim}} \le E$. If at least two of the r_i are positive, we have $d_{\text{sim}} > 0$. However, Section III.F shows that some circumstances introduce a latent dimension d, related indirectly to the similarity dimension, and that can satisfy $d < 0$ or $d > E$.

B. Box Dimension

The similarity dimension is meaningful only for exactly self-similar sets. For more general sets, including experimental data, it is often replaced by the box dimension. For any bounded (nonempty) set A in E-dimensional Euclidean space, and for any $\delta > 0$, a *δ-cover* of A is a collection of sets of diameter δ whose union contains A. Denote by $N_\delta(A)$ the smallest number of sets in a δ-cover of A. Then the *box dimension* d_{box} of A is

$$d_{\text{box}} = \lim_{\delta \to 0} \frac{\log(N_\delta(A))}{\log(1/\delta)}$$

when the limit exists. When the limit does not exist, the replacement of lim with lim sup and lim inf defines the *upper* and *lower box dimensions*:

$$\overline{d_{\text{box}}} = \limsup_{\delta \to 0} \frac{\log(N_\delta(A))}{\log(1/\delta)},$$

$$\underline{d_{\text{box}}} = \liminf_{\delta \to 0} \frac{\log(N_\delta(A))}{\log(1/\delta)}.$$

The box dimension can be thought of as measuring how well a set can be covered with small boxes of equal size, because the limit (or lim sup and lim inf) remain unchanged if $N_\delta(A)$ is replaced by the smallest number of E-dimensional cubes of side δ needed to cover A, or even the number of cubes of a δ lattice that intersect A.

Section V describes methods of measuring the box dimension for physical datasets.

C. Mass Dimension

The mass $M(r)$ of a d-dimensional Euclidean ball of constant density ρ and radius r is given by

$$M(r) = \rho \cdot V(d) \cdot r^d$$

$$\text{with} \quad V(d) = \left(\Gamma\left(\tfrac{1}{2}\right)^d\right) \Big/ \Gamma\left(d + \tfrac{1}{2}\right),$$

where $V(d)$ is the volume of the d-dimensional unit sphere. That is, for constant-density Euclidean objects, the ordinary dimension—among many other roles—is the exponent relating mass to size. This role motivated the definition of mass dimension for a fractal. The definition of mass is delicate. For example, the mass of a Sierpinski gasket cannot be defined by starting with a triangle of uniform density and removing middle triangles; this process would converge to a mass reduced to 0. One must, instead, proceed as on the left side of Fig. 1: take as initiator a triangle of mass 1, and as generator three triangles each scaled by $1/2$ and of mass $1/3$. Moreover, two very new facts come up.

Firstly, the $=$ sign in the formula for $M(r)$ must be replaced by $\approx$. That is, $M(r)$ fluctuates around a multiple of r^d. For example, as mentioned in Sections I.B.3.e and I.B.3.f, the masses of spanning percolation clusters and diffusion-limited aggregates scale as a power-law function of size. Consequently, the exponent in the relation $M(r) \approx k \cdot r^{d_{\text{mass}}}$ is called the *mass dimension*.

Second, in the Euclidean case the center is arbitrary but in the fractal case it must belong to the set under consideration. As an example, Fig. 19 illustrates attempts to measure the mass dimension of the Sierpinski gasket. Suppose we take circles centered at the lower left vertex of the initiator, and having radii $1/2$, $1/4, 1/8, \ldots$. We obtain $M(1/2^i) = 1/3^i = (1/2^i)^d$, where $d_{\text{mass}} = \log 3 / \log 2$. See the left side of Fig. 19. That is, the mass dimension agrees with the similarity dimension.

On the other hand, if the circle's center is randomly selected in the interior of the initiator, the passage to the limit $r \to 0$ almost surely eventually stops with circles bounding no part of the gasket. See the middle of Fig. 19.

Taking a family of circles with center c a point of the gasket, the mass–radius relation becomes $M(r) = k(r, c) \cdot r^d$, where the prefactor $k(r, c)$ fluctuates and depends on both r and c. See the right side of Fig. 19. Even in this case, the exponent is the mass dimension. The prefactor is no longer a constant density, but a random variable, depending on the choice of the origin.

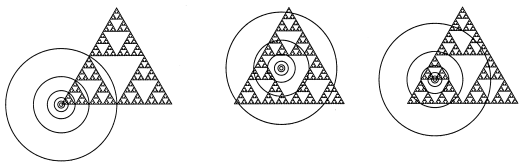

FIGURE 19 Attempts at measuring the mass dimension of a Sierpinski gasket using three families of circles.

Section V describes methods of measuring the mass dimension for physical datasets.

D. Minkowski–Bouligand Dimension

Given a set $A \subset \mathbf{R}^E$ and $\delta > 0$, the *Minkowski sausage* of A, also called the *δ-thickening* or *δ-neighborhood* of A, is defined as $A_\delta = \{x \in \mathbf{R}^E : d(x, y) \le \delta \text{ for some } y \in A\}$. (See Section I.B.b.) In the Euclidean case when A is a smooth m-dimensional manifold imbedded in $\mathbf{R}^E$, one has $vol(A_\delta) \sim \Lambda \cdot \delta^{E-m}$. That is, the E-dimensional volume of A_δ scales as δ to the codimension of A. This concept extends to fractal sets A: if the limit exists,

$$E - \lim_{\delta \to 0} \frac{\log(vol(A_\delta))}{\log(\delta)}$$

defines the *Minkowski–Bouligand dimension*, $d_{\mathrm{MB}}(A)$ (see Mandelbrot, 1982, p. 358). In fact, it is not difficult to see that $d_{\mathrm{MB}}(A) = d_{\mathrm{box}}(A)$. If the limit does not exist, lim sup gives $\underline{d}_{\mathrm{box}}(A)$ and lim inf gives $\overline{d}_{\mathrm{box}}(A)$.

In the privileged case when the limit

$$\lim_{\delta \to 0} \frac{vol(A_\delta)}{\delta^{E-m}}$$

exists, it generalizes the notion of Minkowski content for smooth manifolds A. Section VI will use this prefactor to measure lacunarity.

E. Hausdorff–Besicovitch Dimension

For a set A in Euclidean space, given $s \ge 0$ and $\delta > 0$, consider the quantity

$$\mathcal{H}^s_\delta(A) = \inf\left\{ \sum_i |U_i|^s : \{U_i\} \text{ is a } \delta\text{-cover of } A \right\}.$$

A decrease of δ reduces the collection of δ-covers of A, therefore $\mathcal{H}^s_\delta(A)$ increases as $\delta \to 0$ and $\mathcal{H}^s(A) = \lim_{\delta \to 0} \mathcal{H}^s_\delta(A)$ exists. This limit defines the *s-dimensional Hausdorff measure* of A. For $t > s$, $\mathcal{H}^t_\delta(A) \le \delta^{t-s} \mathcal{H}^s_\delta(A)$. It follows that a unique number d_{H} has the property that

$$s < d_{\mathrm{H}} \quad \text{implies} \quad \mathcal{H}^s(A) = \infty$$

and

$$s > d_{\mathrm{H}} \quad \text{implies} \quad \mathcal{H}^s(A) = 0.$$

That is,

$$d_{\mathrm{H}}(A) = \inf\{s : \mathcal{H}^s(A) = 0\} = \sup\{s : \mathcal{H}^s(A) = \infty\}.$$

This quantity d_{H} is the *Hausdorff–Besicovitch dimension* of A. It is of substantial theoretical significance, but in most cases is quite challenging to compute, even though it suffices to use coverings by disks. An upper bound often is relatively easy to obtain, but the lower bound can be much more difficult because the inf is taken over the collection of all δ-covers. Because of the inf that enters in its definition, the Hausdorff–Besicovitch dimension cannot be measured for any physical object.

Note: If A can be covered by $N_\delta(A)$ sets of diameter at most δ, then $\mathcal{H}^s_\delta(A) \le N_\delta(A) \cdot \delta^s$. From this it follows $d_{\mathrm{H}}(A) \le \underline{d}_{\mathrm{box}}(A)$, so $d_{\mathrm{H}}(A) \le d_{\mathrm{box}}(A)$ if $d_{\mathrm{box}}(A)$ exists. This inequality can be strict. For example, if A is any countable set, $d_{\mathrm{H}}(A) = 0$ and yet $d_{\mathrm{box}}(\text{rationals in } [0, 1]) = 1$.

F. Packing Dimension

Hausdorff dimension measures the efficiency of covering a set by disks of varying radius. Tricot (1982) introduced packing dimension to measure the efficiency of packing a set with disjoint disks of varying radius. Specifically, for $\delta > 0$ a *δ-packing* of A is a countable collection of disjoint disks $\{B_i\}$ with radii $r_i < \delta$ and with centers in A. In analogy with Hausdorff measure, define

$$\mathcal{P}^s_\delta(A) = \sup\left\{ \sum_i |B_i|^s : \{B_i\} \text{ is a } \delta\text{-packing of } A \right\}.$$

As δ decreases, so does the collection of δ-packings of A. Thus $\mathcal{P}^s_\delta(A)$ decreases as δ decreases and the limit

$$\mathcal{P}^s_0(A) = \lim_{\delta \to 0} \mathcal{P}^s_\delta(A)$$

exists. A technical complication requires an additional step. The *s-dimensional packing measure* of A is defined as

$$\mathcal{P}^s(A) = \inf\left\{ \sum_i \mathcal{P}^s_0(A_i) : A \subset \bigcup_{i=1}^{\infty} A_i \right\}.$$

Then the *packing dimension* $d_{\mathrm{pack}}(A)$ is

$$d_{\mathrm{pack}}(A) = \inf\{s : \mathcal{P}^s(A) = 0\} = \sup\{s : \mathcal{P}^s(A) = \infty\}.$$

Packing, Hausdorff, and box dimensions are related:

$$d_{\mathrm{H}}(A) \le d_{\mathrm{pack}}(A) \le \overline{d}_{\mathrm{box}}(A).$$

For appropriate A, each inequality is strict.

III. ALGEBRA OF DIMENSIONS AND LATENT DIMENSIONS

The dimensions of ordinary Euclidean sets obey several rules of thumb that are widely used, though rarely stated explicitly. For example, the union of two sets of dimension d and d' usually has dimension $\max\{d, d'\}$. The projection of a set of dimension d to a set of dimension d' usually gives a set of dimension $\min\{d, d'\}$. Also, for Cartesian products, the dimensions usually add:

$\dim(A \times B) = \dim(A) + \dim(B)$. For the intersection of subsets A and B of $\mathbf{R}^E$, it is the codimensions that usually add: $E - \dim(A \cap B) = (E - \dim(A)) + (E - \dim(B))$, but only so long as the sum of the codimensions is nonnegative. If this sum is negative, the intersection is empty. Mandelbrot (1984, Part II) generalized those rules to fractals and (see Section III.G) interpreted negative dimensions as measures of "degree of emptiness."

For simplicity, we restrict our attention to generaling these properties to the Hausdorff and box dimensions of fractals.

A. Dimension of Unions and Subsets

Simple applications of the definition of Hausdorff dimension give

$$A \subseteq B \quad \text{implies} \quad d_H(A) \leq d_H(B)$$

and

$$d_H(A \cup B) = \max\{d_H(A), d_H(B)\}.$$

Replacing max with sup, this property holds for countable collections of sets. The subset and finite union properties hold for box dimension, but the countable union property fails.

B. Product and Sums of Dimensions

For all subsets A and B of Euclidean space, $d_H(A \times B) \geq d_H(A) + d_H(B)$. Equality holds if one of the sets is sufficiently regular. For example, if $d_H(A) = \overline{d_H}(A)$, then $d_H(A \times B) = d_H(A) + d_H(B)$. Equality does not always hold: Besicovitch and Moran (1945) give an example of subsets A and B of $\mathbf{R}$ with $d_H(A) = d_H(B) = 0$, yet $d_H(A \times B) = 1$.

For upper box dimensions, the inequality is reversed: $\overline{d_{box}}(A \times B) \leq \overline{d_{box}}(A) + \overline{d_{box}}(B)$.

C. Projection

Denote by $\text{proj}_P(A)$ the projection of a set $A \subset \mathbf{R}^3$ to a plane $P \subset \mathbf{R}^3$ through the origin. If A is a one-dimensional Euclidean object, then for almost all choices of the plane P, $\text{proj}_P(A)$ is one-dimensional. If A is a two- or three-dimensional Euclidean object, then for almost all choices of the plane P, $\text{proj}_P(A)$ is two-dimensional of positive area. That is, $\dim(\text{proj}_P(A)) = \min\{\dim(A), \dim(P)\}$.

The analogous properties hold for fractal sets A. If $d_H(A) < 2$, then for almost all choices of the plane P, $d_H(\text{proj}_P(A)) = d_H(A)$. If $d_H(A) \geq 2$, then for almost all choices of the plane P, $d_H(\text{proj}_P(A)) = 2$ and $\text{proj}_P(A)$ has positive area. So again, $d_H(\text{proj}_P(A)) = \min\{d_H(A), d_H(P)\}$.

The obvious generalization holds for fractals $A \subset \mathbf{R}^E$ and projections to k-dimensional hyperplanes through the origin.

Projections of fractals can be very complicated. There are fractal sets $A \subset \mathbf{R}^3$ with the surprising property that for almost every plane P through the origin, the projection $\text{proj}_P(A)$ is any prescribed shape, to within a set of area 0. Consequently, as Falconer (1987) points out, in principle we could build a fractal digital sundial.

D. Subordination and Products of Dimension

We have already seen operations realizing the sum, max, and min of dimensions, and in the next subsection we shall examine the sum of codimensions. For certain types of fractals, multiplication of dimensions is achieved through "subordination," a process introduced in Bochner (1955) and elaborated in Mandelbrot (1982). Examples are constructed easily from the Koch curve generator (Fig. 20a). The initiator (the unit interval) is unchanged, but the new generator is a subset of the original generator. Figure 20 shows three examples.

In Fig. 20, generator (b) gives a fractal dust (B) of dimension $\log 3/\log 3 = 1$. Generator (c) gives the standard Cantor dust (C) of dimension $\log 2/\log 3$. Generator (d) gives a fractal dust (D) also of dimension $\log 2/\log 3$. Thinking of the Koch curve K as the graph of a function $f\colon [0, 1] \to K \subset \mathbf{R}^2$, the fractal (B) can be obtained by restricting f to the Cantor set with initiator [0, 1] and generator the intervals [0, 1/4], [1/4, 1/2], and [1/2, 3/4]. In this case, the *subordinand* is a Koch curve, the *subordinator* is a Cantor set, and the *subordinate* is the fractal (B). The identity

$$\frac{\log 3}{\log 3} = \frac{\log 4}{\log 3} \cdot \frac{\log 3}{\log 4}$$

expresses that the dimensions multiply,

$$\dim(\text{subordinate}) = \dim(\text{subordinand}) \cdot \dim(\text{subordinator}).$$

Figure 20, (C) and (D) give other illustrations of this multiplicative relation. The *seeded universe* model of the distribution of galaxies (Section IX.D.1) uses subordination to obtain fractal dusts; see Mandelbrot (1982, plate 298).

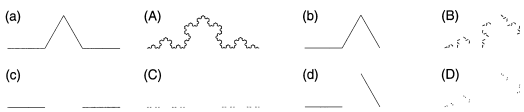

FIGURE 20 The Koch curve (A) and its generator (a); (b), (c), and (d) are subordinators, and the corresponding subordinates of the subordinand (A) are (B), (C), and (D).

E. Intersection and Sums of Codimension

The dimension of the intersection of two sets obviously depends on their relative placement. When $A \cap B = \emptyset$, the dimension vanishes. The following is a typical result. For Borel subsets A and B of $\mathbf{R}^E$, and for almost all $x \in \mathbf{R}^E$,

$$d_{\mathrm{H}}(A \cap (B + x)) \leq \max\{0, d_{\mathrm{H}}(A \times B) - E\}.$$

If $d_{\mathrm{H}}(A \times B) = d_{\mathrm{H}}(A) + d_{\mathrm{H}}(B)$, this reduces to

$$d_{\mathrm{H}}(A \cap (B + x)) \leq \max\{0, d_{\mathrm{H}}(A) + d_{\mathrm{H}}(B) - E\}.$$

This is reminiscent of the transversality relation for intersections of smooth manifolds.

Corresponding lower bounds are known in more restricted circumstances. For example, there is a positive measure set M of similarity transformations of $\mathbf{R}^E$ with

$$d_{\mathrm{H}}(A \cap T(B)) \geq d_{\mathrm{H}}(A) + d_H(B) - E$$

for all $T \in M$. Note $d_{\mathrm{H}}(A \cap T(B)) = d_{\mathrm{H}}(A) + d_{\mathrm{H}}(B) - E$ is equivalent to the addition of codimensions: $E - d_{\mathrm{H}}(A \cap T(B)) = (E - d_{\mathrm{H}}(A)) + (E - d_{\mathrm{H}}(B))$.

F. Latent Dimensions below 0 or above E

A blind application of the rule that codimensions are additive easily yields results that seem nonsensical, yet become useful if they are properly interpreted and the Hausdorff dimension is replaced by a suitable new alternative.

1. Negative Latent Dimensions as Measures of the "Degree of Emptiness"

Section E noted that if the codimension addition rule gives a negative dimension, the actual dimension is 0. This exception is an irritating complication and hides a feature worth underlining.

As background relative to the plane, consider the following intersections of two Euclidean objects: two points, a point and a line, and two lines. Naive intuition tells us that the intersection of two points is emptier than the intersection of a point and a line, and that the latter in turn is emptier than the intersection of two lines (which is almost surely a point). This informal intuition fails to be expressed by either a Euclidean or a Hausdorff dimension. On the other hand, the formal addition of codimensions suggests that the three intersections in question have the respective dimensions -2, -1, and 0. The inequalities between those values conform with the above-mentioned naive intuition. Therefore, they ushered in the search for a new mathematical definition of dimension that can be measured and for which negative values are legitimate and intuitive. This search produced several publications leading to Mandelbrot (1995). Two notions should be mentioned.

Embedding. A problem that concerns $\mathbf{R}^2$ can often be reinterpreted as a problem that really concerns $\mathbf{R}^E$, with $E > 2$, but must be approached within planar intuitions by $\mathbf{R}^2$. Conversely, if a given problem can be embedded into a problem concerning $\mathbf{R}^E$, the question arises, "which is the 'critical' value of $E - 2$, defined as the smallest value for which the intersection ceases to be empty, and precisely reduces to a point?" In the example of a line and a point, the critical $E - 2$ is precisely 1: once embedded in $\mathbf{R}^3$, the problem transforms into the intersection of a plane and a line, which is a point.

Approximation and pre-asymptotics in mathematics and the sciences. Consider a set defined as the limit of a sequence of decreasing approximations. When the limit is not empty, all the usual dimensions are defined as being properties of the limit, but when the limit is empty and all the dimensions vanish, it is possible to consider instead the limits of the properties of the approximations. The Minkowski–Bouligand formal definition of dimension generalizes to fit the naive intuitive values that may be either positive or negative.

2. Latent Dimensions That Exceed That of the Embedding Space

For a strictly self-similar set in $\mathbf{R}^E$, the Moran equation defines a similarity dimension that obeys $d_{\mathrm{sim}} \leq E$. On the other hand, a generator that is a self-avoiding broken line can easily yield $\log(N)/\log(1/r) = d_{\mathrm{sim}} > E$. Recursive application of this generator defines a parametrized motion, but the union of the positions of the motion is neither a self-similar curve nor any other self-similar set. It is, instead, a set whose points are covered infinitely often. Its box dimension is $\leq E$, which *a fortiori* is $< d_{\mathrm{sim}}$. However, one can load a mass on this set by following the route that applies in the absence of multiple points. Mass is distributed on the generator's intervals in proportion to the values of $r_i^{d_{\mathrm{sim}}}$. By infinite recursion, the difference between the times t' and t'' when points P' and P'' are visited is defined as the mass supported by the portion of the curve that links these points.

If so and $d_{\mathrm{sim}} > E$, the similarity dimension acquires a useful role as a latent dimension. For example, consider the multiplication of dimensions in Section III.D. Suppose that our recursively constructed set is not lighted for all instants of time, but only intermittently when time falls within a fractal dust of dimension d''. Then, the rule of thumb is that the latent dimension of the lighted points is $d_{\mathrm{sim}}d''$. When $d_{\mathrm{sim}}d'' < E$, the rule of thumb is that the true dimension is also $d_{\mathrm{sim}}d''$.

Figure 21 shows an example. The generator has $N = 6$ segments, each with scaling ratio $r = 1/2$, hence latent dimension $d_{\mathrm{sim}} = \log 6/\log 2 > 2$. Taking as subordinator

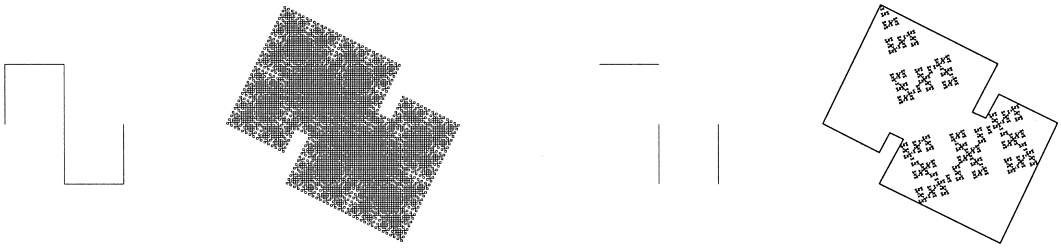

FIGURE 21 Left: Generator and limiting shape with latent dimension exceeding 2. Right: generator and limiting shape of a subordinate with dimension <2. For comparison, this limiting shape is enclosed in the outline of the left limiting shape.

a Cantor set with generator having $N = 3$ segments, each with scaling ratio $r = 1/2$, yields a self-similar fractal with dimension $\log 3/\log 2$.

G. Mapping

Recall f satisfies the Hölder condition with exponent H if there is a positive constant c for which $|f(x) - f(y)| \le c|x - y|^H$. For such functions, $d_H(f(A)) \le (1/H)d_H(A)$. If $H = 1$, f is called a Lipschitz function; f is bi-Lipschitz if there are constants c_1 and c_2 with $c_1|x - y| \le |f(x) - f(y)| \le c_2|x - y|$. Hausdorff dimension is invariant under bi-Lipschitz maps. The analogous properties hold for box-counting dimension.

IV. METHODS OF COMPUTING DIMENSION IN MATHEMATICAL FRACTALS

Upper bounds for the Hausdorff dimension can be relatively straightforward: it suffices to consider a specific family of coverings of the set. Lower bounds are more delicate. We list and describe briefly some methods for computing dimension.

A. Mass Distribution Methods

A *mass distribution* on a set A is a measure μ with $\text{supp}(\mu) \subset A$ and $0 < \mu(A) < \infty$. The *mass distribution principle* (Falconer, 1990, p. 55) establishes a lower bound for the Hausdorff dimension: Let μ be a mass distribution on A and suppose for some s there are constants $c > 0$ and $\delta > 0$ with $\mu(U) \le c \cdot |U|^s$ for all sets U with $|U| \le \delta$. Then $\delta \le d_H(A)$.

Suitable choice of mass distribution can show that no individual set of a cover can cover too much of A. This can eliminate the problems caused by covers by sets of a wide range of diameters.

B. Potential Theory Methods

Given a mass distribution μ, the *s-potential* is defined by Frostman (1935) as

$$\phi_s(x) = \int \frac{d\mu(x)}{|x - y|^s}.$$

If there is a mass distribution μ on a set A with $\int \phi_s(x)\, d\mu(x) < \infty$, then $d_H(A) \ge s$. Potential theory has been useful for computing dimension of many sets, for example, Brownian paths.

C. Implicit Methods

McLaughlin (1987) introduced a geometrical method, based on local approximate self-similarities, which succeeds in proving that $d_H(A) = \overline{d_{box}}(A)$, without first determining $d_H(A)$. If small parts of A can be mapped to large parts of A without too much distortion, or if A can be mapped to small parts of A without too much distortion, then $d_H(A) = \overline{d_{box}}(A) = s$ and $\mathcal{H}^s(A) > 0$ (in the former case) or $\mathcal{H}^s(A) < \infty$ (in the latter case). Details and examples can be found in Falconer (1997, Section 3.1).

D. Thermodynamic Formalism

Sinai (1972), Bowen (1975), and Ruelle (1978) adapted methods of statistical mechanics to determine the dimensions of fractals arising from some nonlinear processes. Roughly, for a fractal defined as the attractor A of a family of nonlinear contractions F_i with an inverse function f defined on A, the *topological pressure* $P(\phi)$ of a Lipschitz function ϕ: $A \to \mathbf{R}$ is

$$P(\phi) = \lim_{k\to\infty} \frac{1}{k} \log \left\{ \sum_{x \in \text{Fix}(f^k)} \exp[\phi(x) + \phi(f(x)) + \cdots \phi(f^{k-1}(x))] \right\},$$

where $\text{Fix}(f^k)$ denotes the set of fixed points of f^k. The sum plays the role of the partition function in statistical mechanics, part of the motivation for the name "thermodynamic formalism." There is a unique s for which

$P(-s\log|f'|)=0$, and $s=d_{\mathrm{H}}(A)$. Under these conditions, $0<\mathcal{H}^s(A)<\infty$, $\mathcal{H}^s(A)$ is a Gibbs measure on A, and many other results can be deduced. Among other places, this method has been applied effectively to the study of Julia sets.

V. METHODS OF MEASURING DIMENSION IN PHYSICAL SYSTEMS

For shapes represented in the plane—for example, coastlines, rivers, mountain profiles, earthquake faultlines, fracture and cracking patterns, viscous fingering, dielectric breakdown, growth of bacteria in stressed environments—box dimension is often relatively easy to compute. Select a sequence $\epsilon_1>\epsilon_2>\cdots>\epsilon_n$ of sizes of boxes to be used to cover the shape, and denote by $N(\epsilon_i)$ the number of boxes of size ϵ_i needed to cover the shape. A plot of $\log(N(\epsilon_i))$ against $\log(1/\epsilon_i)$ often reveals a scaling range over which the points fall close to a straight line. In the presence of other evidence (hierarchical visual complexity, for example), this indicates a fractal structure with box dimension given by the slope of the line. Interpreting the box dimension in terms of underlying physical, chemical, and biological processes has yielded productive insights.

For physical objects in three-dimensional space—for example, aggregates, dustballs, physiological branchings (respiratory, circulatory, and neural), soot particles, protein clusters, terrain maps—it is often easier to compute mass dimension. Select a sequence of radii $r_1>r_2>\cdots>r_n$ and cover the object with concentric spheres of those radii. Denoting by $M(r_i)$ the mass of the part of the object contained inside the sphere of radius r_i, a plot of $\log(M(r_i))$ against $\log(r_i)$ often reveals a scaling range over which the points fall close to a straight line. In the presence of other evidence (hierarchical arrangements of hole sizes, for example), this indicates a fractal structure with mass dimension given by the slope of the line. Mass dimension is relevant for calculating how density scales with size, and this in turn has implications for how the object is coupled to its environment.

VI. LACUNARITY

Examples abound of fractals sharing the same dimension but looking quite different. For instance, both Sierpinski carpets in Fig. 22 have dimension $\log 40/\log 7$. The holes' distribution is more uniform on the left than on the right. The quantification of this difference was undertaken in Mandelbrot (1982, Chapter 34). It introduced *lacunarity* as one expression of this difference, and took another step in characterizing fractals through associated numbers. How can the distribution of a fractal's holes or gaps ("lacunae") be quantified?

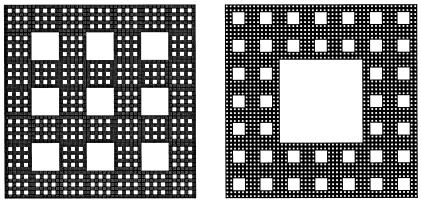

FIGURE 22 Two Sierpinski carpet fractals with the same dimension.

A. The Prefactor

Suppose A is either carpet in Fig. 22, and let A_δ denote the δ-thickening of A. As mentioned in Section II.D, $\mathrm{area}(A_\delta)\sim\Lambda\cdot\delta^{2-\log 40/\log 7}$. One measure of lacunarity is $1/\Lambda$, if the appropriate limit exists.

It is well known that for the box dimension, the limit as $\epsilon\to 0$ can be replaced by the sequential limit $\epsilon_n\to 0$, for ϵ_n satisfying mild conditions. For these carpets, natural choices are those ϵ_n just filling successive generations of holes. Applied to Fig. 22, these ϵ_n give $1/\Lambda\approx 0.707589$ and 0.793487, agreeing with the notion that higher lacunarity corresponds to a more uneven distribution of holes.

Unfortunately, the prefactor is much more sensitive than the exponent: different sequences of ϵ_n give different limits. Logarithmic averages can be used, but this is work in progress.

B. The Crosscuts Structure

An object is often best studied through its *crosscuts* by straight lines, concentric circles, or spheres. For a fractal of dimension d in the plane, the rule of thumb is that the crosscuts are Cantor-like objects of dimension $d-1$. The case when the gaps between points in the crosscut are statistically independent was singled out by Mandelbrot as defining "neutral lacunarity." If the crosscut is also self-similar, it is a Lévy dust.

Hovi *et al.* (1996) studied the intersection of lines (linear crosscuts) with two- and three-dimensional critical percolation clusters, and found the gaps are close to being statistically independent, thus a Lévy dust.

In studying very large DLA clusters, Mandelbrot *et al.* (1995) obtained a crosscut dimension of $d_c=0.65\pm 0.01$, different from the value 0.71 anticipated if DLA clusters were statistically self-similar objects with mass dimension $d_{\mathrm{mass}}=1.71$. The difference can be explained by asserting the number of particles $N_c(r/l)$ on a crosscut

of radius r scales as $N_c(r/l) = \Lambda(r)(r/l)^{d_c}$. Here l is the scaling length, and the lacunarity prefactor varies with r. Assuming slow variation of $\Lambda(r)$ with r, the observed linear log–log fit requires $\Lambda(r) \sim r^{\delta d}$, where $\delta d = d_{\text{mass}} - 1 - d_c = 0.06 \pm 0.01$. Transverse crosscut analysis reveals lacunarity decreases with r for large DLA clusters.

C. Antipodal Correlations

Select an occupied point p well inside a random fractal cluster, so that the $R \times R$ square centered at p lies within the cluster. Now select two vectors V and W based at p and separated by the angle θ. Finally, denote by x and y the number of occupied sites within the wedges with apexes at p, apex angles ϕ much less than θ, and centered about the vectors V and W. The *angular correlation function* is

$$C(\theta) = \frac{\langle xy \rangle - \langle x \rangle \langle y \rangle}{\langle x^2 \rangle - \langle x \rangle \langle x \rangle},$$

where $\langle \cdots \rangle$ denotes an average over many realizations of the random fractal. *Antipodal correlations* concern $\theta = \pi$. Negative and positive antipodal correlations are interpreted as indicating high and low lacunarity; vanishing correlation is a weakened form of neutral lacunarity.

Mandelbrot and Stauffer (1994) used antipodal correlations to study the lacunarity of critical percolation clusters. On smaller central subclusters, they found the antipodes are uncorrelated.

Trema random fractals. These are formed by removing randomly centered discs, tremas, with radii obeying a power-law scaling. For them, $C(\pi) \to 0$ with ϕ because a circular hole that overlaps a sector cannot overlap the opposite sector. But nonconvex tremas introduce positive antipodal correlations. For θ close to π, needle-shaped tremas, though still convex, yield $C(\theta)$ much higher than for circular trema sets. From this more refined viewpoint, needle tremas' lacunarity is much lower.

VII. FRACTAL GRAPHS AND SELF-AFFINITY

A. Weierstrass Functions

Smooth functions' graphs, as seen under sufficient magnification, are approximated by their tangents. Unless the function itself is linear, the existence of a tangent contradicts the scale invariance that characterizes fractals. The early example of a continuous, nowhere-differentiable function devised in 1834 by Bolzano remained unpublished until the 1920s. The first example to become widely known was constructed by Weierstrass in 1872. The *Weierstrass sine function* is

$$W(t) = \sum_{n=0}^{\infty} b^{-Hn} \sin(2\pi b^n t),$$

and the complex *Weierstrass function* is

$$W_0(t) = \sum_{n=0}^{\infty} b^{-Hn} \exp(2\pi i b^n t).$$

Hardy (1916) showed $W(t)$ is continuous and nowhere-differentiable if and only if $b > 1$ and $0 < H < 1$.

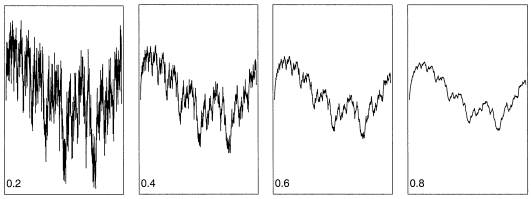

FIGURE 23 The effect of H on Weierstrass graph roughness. In all pictures, $b = 1.5$ and H has the indicated value.

As shown in Fig. 23, the parameter H determines the roughness of the graph. In this case, H is not a perspicuous "roughness exponent." Indeed, as b increases, the amplitudes of the higher frequency terms decrease and the graph is more clearly dominated by the lowest frequency terms. This effect of b is a little-explored aspect of lacunarity.

B. Weierstrass–Mandelbrot Functions

The Weierstrass function revolutionized mathematics but did not enter physics until it was modified in a series of steps described in Mandelbrot (1982, pp. 388–390; (2001d, Chapter H4). The step from $W_0(t)$ to $W_1(t)$ added low frequencies in order to insure self-affinity. The step from $W_1(t)$ to $W_2(t)$ added to each addend a random phase φ_n uniformly distributed on [0, 1]. The step from $W_1(t)$ to $W_3(t)$ added a random amplitude $A_n = \sqrt{-2 \log V}$, where V is uniform on [0, 1]. A function $W_4(t)$ that need not be written down combines a phase and an amplitude. The latest step leads to another function that need not be written down: it is $W_5(t) = W_4(t) + W_4(-t)$, where the two addends are statistically independent. Contrary to all earlier extensions, $W_5(t)$ is not chiral. We have

$$W_1(t) = \sum_{n=-\infty}^{\infty} b^{-Hn}(\exp(2\pi i b^n t) - 1),$$

$$W_2(t) = \sum_{n=-\infty}^{\infty} b^{-Hn}(\exp(2\pi i b^n t) - 1)\exp(i\varphi_n),$$

$$W_3(t) = \sum_{n=-\infty}^{\infty} A_n b^{-Hn}(\exp(2\pi i b^n t) - 1).$$

C. The Hölder Exponent

A function $f:[a,b]\to\mathbf{R}$ has *Hölder exponent* H if there is a constant $c>0$ for which

$$|f(x)-f(y)|\le c\cdot|x-y|^H$$

for all x and y in $[a,b]$ (recall Section III.G). If f is continuous and has Hölder exponent H satisfying $0<H\le 1$, then the graph of f has box dimension $d_{\text{box}}\le 2-H$.

The Weierstrass function $W(t)$ has Hölder exponent H, hence its graph has $d_{\text{box}}\le 2-H$. For large enough b, $d_{\text{box}}=2-H$, so one can think of the Hölder exponent as a measure of roughness of the graph.

VIII. FRACTAL ATTRACTORS AND REPELLERS OF DYNAMICAL SYSTEMS

The modern renaissance in dynamical systems is associated most often with chaos theory. Consequently, the relations between fractal geometry and chaotic dynamics, mediated by symbolic dynamics, are relevant to our discussion. In addition, we consider fractal basin boundaries, which generalize Julia sets to much wider contexts including mechanical systems.

A. The Smale Horseshoe

If they exist, intersections of the stable and unstable manifolds of a fixed point are called *homoclinic points*. Poincaré (1890) recognized that homoclinic points cause great complications in dynamics. Yet much can be understood by labeling an appropriate coarse-graining of a neighborhood of a homoclinic point and translating the corresponding dynamics into a string of symbols (the coarse-grain bin labels). The notion of symbolic dynamics first appears in Hadamard (1898), and Birkhoff (1927) proved every neighborhood of a homoclinic point contains infinitely many periodic points.

Motivated by work of Cartwright and Littlewood (1945) and Levinson (1949) on the forced van der Pol oscillator, Smale (1963) constructed the *horseshoe map*. This is a map from the unit square into the plane with completely invariant set a Cantor set Λ, roughly the Cartesian product of two Cantor middle-thirds sets. Restricted to Λ, with the obvious symbolic dynamics encoding, the horseshoe map is conjugate to the shift map on two symbols, the archetype of a chaotic map.

This construction is universal in the sense that it occurs in every transverse homoclinic point to a hyperbolic saddle point. The Conley–Moser theorem (see Wiggins, 1990) establishes the existence of chaos by conjugating the dynamics to a shift map on a Cantor set under general conditions. In this sense, chaos often equivalent to simple dynamics on an underlying fractal.

B. Fractal Basin Boundaries

For any point c belonging to a hyperbolic component of the Mandelbrot set, the Julia set is the boundary of the basins of attraction of the attracting cycle and the attracting fixed point at infinity. See the right side of Fig. 3.

Another example favored by Julia is found in Newton's method for finding the roots of a polynomial $f(z)$ of degree at least 3. It leads to the dynamical system $z_{n+1}=N_f(z_n)=z_n-f(z_n)/f'(z_n)$. The roots of $f(z)$ are attracting fixed points of $N_f(z)$, and the boundary of the basins of attraction of these fixed points is a fractal; an example is shown on the left side of Fig. 24. If contaminated by even small uncertainties, the fate of initial points near the basin boundary cannot be predicted. Sensitive dependence on initial conditions is a signature of chaos, but here we deal with something different. The eventual behavior is completely predictable, except for initial points taken exactly on the basin boundary, usually of two-dimensional Lebesgue measure 0.

The same complication enters mechanical engineering problems for systems with multiple attractors. Moon (1984) exhibited an early example. Extensive theoretical and computer studies by Yorke and coworkers are described in Alligood and Yorke (1992). The driven harmonic oscillator with two-well potential

$$\frac{d^2x}{dt^2}+f\frac{dx}{dt}-\frac{1}{2}x(1-x^2)=A\cos(\omega t)$$

is a simple example. The undriven system has two equilibria, $x=-1$ and $x=+1$. Initial values (x,x') are painted white if the trajectory from that point eventually stays in the left basin, black if it eventually stays in the right basin. The right side of Fig. 24 shows the initial condition portrait for the system with $f=0.15$, $\omega=0.8$, and $A=0.094$.

IX. FRACTALS AND DIFFERENTIAL OR PARTIAL DIFFERENTIAL EQUATIONS

The daunting task to which a large portion of Mandelbrot (1982) is devoted was to establish that many works of nature and man [as shown in Mandelbrot (1997), the latter includes the stock market!] are fractal. New and often important examples keep being discovered, but the hardest present challenge is to discover the *causes* of fractality. Some cases remain obscure, but others are reasonably clear.

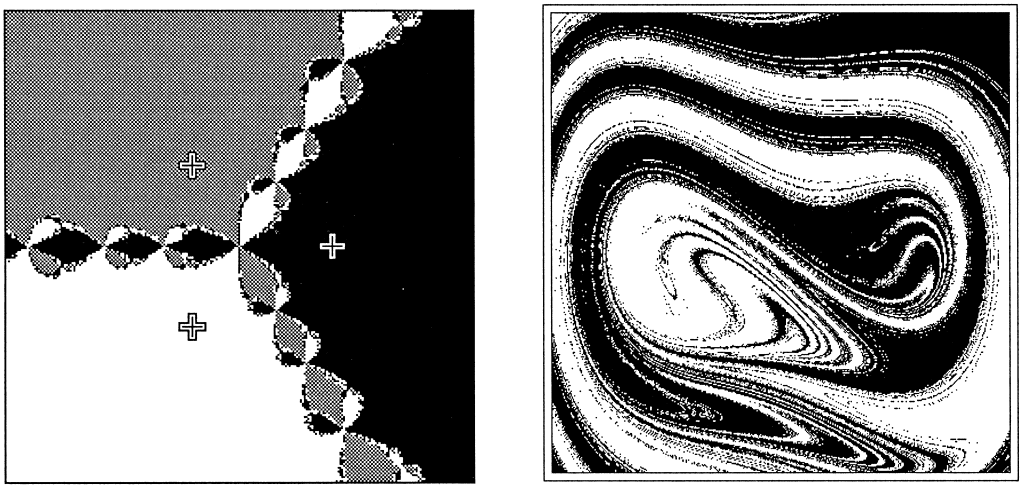

FIGURE 24 Left: The basins of attraction of Newton's method for finding the roots of $z^3 - 1$. Right: The basins of attraction for a damped, driven two-well harmonic oscillator.

Thus, the fractality of the physical percolation clusters (Section I.B.3.e) is the geometric counterpart of scaling and renormalization: the analytic properties of those objects follow a wealth of power-law relations. Many mathematical issues, some of them already mentioned, remain open, but the overall renormalization framework is firmly rooted. Renormalization and the resulting fractality also occur in the structure of attractors and repellers of dynamical systems. Best understood is renormalization for quadratic maps. Feigenbaum and others considered the real case. For the complex case, renormalization establishes that the Mandelbrot set contains infinitely many small copies of itself.

Unfortunately, additional examples of fractality proved to be beyond the scope of the usual renormalization. A notorious case concerns DLA (Section I.B.3.f).

A. Fractal Attractors of Ordinary Differential Equations

The Lorenz equations for fluid convection in a two-dimensional layer heated from below are

$$\frac{dx}{dt} = \sigma(y-x), \quad \frac{dy}{dt} = -xz+rx-y, \quad \frac{dz}{dt} = xy-bz.$$

Here x denotes the rate of convective overturning, y the horizontal temperature difference, and z the departure from a linear vertical temperature gradient. For the parameters $\sigma = 10$, $b = 8/3$, and $r = 28$, Lorenz (1963) suggested that trajectories in a bounded region converge to an attractor that is a fractal, with dimension about 2.06, as estimated by Liapunov exponents. The Lorenz equations are very suggestive but do not represent weather systems very well. However, Haken established a connection with lasers. The sensitivity to initial conditions common to chaotic dynamics is mediated by the intricate fractal interleaving of the multiple layers of the attractor. In addition, Birman and Williams (1983) showed an abundance of knotted periodic orbits embedded in the Lorenz attractor, though Williams (1983) showed all such knots are prime. Grist (1997) constructed a *universal template*, a branched 2-manifold in which all knots are embedded. Note the interesting parallel with the universal aspects of the Sierpinski carpet (Section I.B.1.a). It is not yet known if the attractor of any differential equation contains a universal template. The Poincaré–Bendixson theorem prohibits fractal attractors for differential equations in the plane, but many other classical ordinary differential equations in at least three dimensions exhibit similar fractal attractors in certain parameter ranges.

B. Partial Differential Equations on Domains with Fractal Boundaries ("Can One Hear the Shape of a Fractal Drum?")

Suppose $D \subset \mathbf{R}^n$ is an open region with boundary ∂D. Further, suppose the eigenvalue problem $\nabla^2 u = -\lambda u$ with boundary conditions $u(x) = 0$ for all $x \in \partial D$ has real eigenvalues $0 < \lambda_1 < \lambda_2 < \cdots$. For D with sufficiently smooth boundary, a theorem of Weyl (1912) shows $N(\lambda) \sim \lambda^{n/2}$, where the *eigenvalue counting function* $N(\lambda) = \{\text{the number of } \lambda_i \text{ for which } \lambda_i \leq \lambda\}$. If the boundary ∂D is a fractal, Berry (1979, pp. 51–53) postulated that some form of the dimension of ∂D appears in the second term in the expansion of $N(\lambda)$, therefore can be recovered from the eigenvalues. This *could not* be the Hausdorff dimension, but Lapidus (1995) showed that it

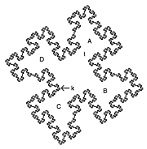

FIGURE 25 Perimeter of an extensively studied fractal drum.

is the Minkowski–Bouligard dimension. The analysis is subtle, involving some deep number theory.

For regions with fractal boundaries, the heat equation $\nabla^2 u = (\partial/\partial t)u$ shows heat flow across a fractal boundary is related to the dimension of the boundary. Sapoval (1989) and Sapoval *et al*. (1991) conducted elegant experimenths to study the modes of fractal drums. The perimeter of Fig. 25 has dimension $\log 8/\log 4 = 3/2$. A membrane stretched across this fractal curve was excited acoustically and the resulting modes observed by sprinkling powder on the membrane and shining laser light transverse to the surface. Sapoval observed modes localized to bounded regions A, B, C, and D shown in Fig. 25. By carefully displacing the acoustic source, he was able to excite each separately.

Theoretical and computer-graphic analyses of the wave equation on domains with fractal boundaries have been carried out by Lapidus *et al*. (1996), among others.

C. Partial Differential Equations on Fractals

The problem is complicated by the fact that a fractal is not a smooth manifold. How is the Laplacian to be defined on such a space? One promising approach was put forward by physicists in the 1980s and made rigorous in Kigami (1989): approximate the fractal domain by a sequence of graphs representing successive protofractals, and define the fractal Laplacian as the limit of a suitably renormalized sequence of Laplacians on the graphs. Figure 26 shows the first four graphs for the equilateral Sierpinski gasket. The values at the boundary vertices are specified by the boundary conditions at any nonboundary vertex x_0. The mth approximate Laplacian of a function $f(x)$ is the product of a renormalization factor by $\sum(f(y) - f(x_0))$, where the sum is taken over all vertices y in the mth protofractal graph corresponding to the mth-stage reduction of the whole graph.

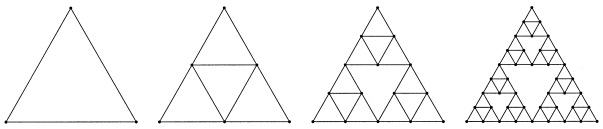

FIGURE 26 Graphs corresponding to protofractal approximations of the equilateral Sierpinski gasket.

With this Laplacian, the heat and wave equations can be defined on fractals. Among other things, the wave equation on domains with fractal boundaries admits localized solutions, as we saw for the wave equation on fractal drums. A major challenge is to extend these ideas to fractals more complicated than the Sierpinski gasket and its relatvives.

D. How Partial Differential Equations Generate Fractals

A quandary: It is universally granted that physics is ruled by diverse partial differential equations, such as those of Laplace, Poisson, and Navier–Stokes. A differential equation necessarily implies a great degree of local smoothness, even though close examination shows isolated singularities or "catastrophes." To the contrary, fractality implies everywhere-dense roughness or fragmentation. This is one of the several reasons that fractal models in diverse fields were initially perceived as being "anomalies" contradicting one of the firmest foundations of science.

A conjecture–challenge responding to the preceding quandry. There is no contradiction at all: fractals arise unavoidably in the long-time behavior of the solution of very familiar and innocuous-looking equations. In particular, many concrete situations where fractals are observed involve equations that allow free and moving boundaries, interfaces, or singularities. As a suggestive "principle," Mandelbrot (1982, Chapter 11) described the following possibility: under broad conditions that largely remain to be specified, these free boundaries, interfaces, and singularities converge to suitable fractals. Many equations have been examined from this viewpoint, but we limit ourselves to two examples of central importance.

1. The Large-Scale Distribution of Galaxies

Chapters 9 and 33–35 of Mandelbrot (1982) conjecture that the distribution of galaxies is fractal. This conjecture results from a search for invariants that was central to every aspect of the construction of fractal geometry. Granted that the distribution of galaxies certainly deviates from homogeneity, one broad approach consists in correcting for local inhomogeneity by using local "patches." The next simplest global assumption is that the distribution is nonhomogeneous but scale invariant, therefore fractal.

Excluding the strict hierarchies, two concrete constructions of random fractal sets were subjected to detailed mathematical and visual investigation. These constructions being random, self-similarity can only be statistical. But a strong counteracting asset is that the self-similarity ratio can be chosen freely, is not restricted to powers of a prescribed r_0. A surprising and noteworthy finding came forth. These constructions exhibited a strong hierarchical

structure that is not a deliberate and largely arbitrary input. Details are given in Mandelbrot (1982).

The first construction is the *seeded universe* based on a Lévy flight. Its Hausdorff-dimensional properties were well known. Its correlation properties (Mandelbrot 1975) proved to be nearly identical to those of actual galaxy maps. The second construction is the *parted universe* obtained by subtracting from space a random collection of overlapping tremas. Either construction yields sets that are highly irregular and involve no special center, yet, with no deliberate design, exhibit a clear-cut clustering, "filaments" and "walls." These structures were little known when these constructions were designed.

Conjecture: Could it be that the observed "clusters," "filaments," and "walls" need not be explained separately? They may not result from unidentified features of specific models, but represent unavoidable consequences of a variety of unconstrained forms of random fractality, as interpreted by a human brain.

A problem arose when careful examination of the simulations revealed a clearly incorrect prediction. The simulations in the *seeded universe* proved to be visually far more "lacunar" than the real world. That is, the simulations' holes are larger than in reality. The *parted universe* model fared better, since its lacunarity can be adjusted at will and fit to the actual distribution. A lowered lacunarity is expressed by a positive correlation between masses in antipodal directions. Testing this specific conjecture is a challenge for those who analyze the data.

Does dynamics make us expect the distribution of galaxies to be fractal? Position a large array of point masses in a cubic box in which opposite sides are identified to form a three-dimensional torus. The evolution of this array obeys the Laplace equation, with the novelty that the singularities of the solution are the positions of the points, therefore movable. All simulations we know (starting with those performed at IBM around 1960) suggest that, even when the pattern of the singularities begins by being uniform or Poisson, it gradually creates clusters and a semblance of hierarchy, and appears to tend toward fractality. It is against the preceding background that the limit distribution of galaxies is conjectured to be fractal, and fractality is viewed as compatible with Newton's equations.

2. The Navier–Stokes Equation

The first concrete use of a Cantor dust in real spaces is found in Berger and Mandelbrot (1963), a paper on noise records. This was nearly simultaneous with Kolmogorov's work on the intermittence of turbulence. After numerous experimental tests designed to create an intuitive feeling for this phenomenon (e.g., listening to turbulent velocity records that were made audible), the fractal viewpoint was extended to turbulence, and circa 1964 led to the following conjecture.

Conjecture. The property of being "turbulently dissipative" should not be viewed as attached to domains in a fluid with significant interior points, but as attached to fractal sets. In a first approximation, those sets' intersection with a straight line is a Cantor-like fractal dust having a dimension in the range from 0.5 to 0.6. The corresponding full sets in space should therefore be expected to be fractals with Hausdorff dimension in the range from 2.5 to 2.6.

Actually, Cantor dust and Hausdorff dimension are not the proper notions in the context of viscous fluids because viscosity necessarily erases the fine detail essential to fractals. Hence the following conjecture (Mandelbrot, 1982, Chapter 11; 1976). The dissipation in a viscous fluid occurs in the neighborhood of a singularity of a nonviscous approximation following Euler's equations, and the motion of a nonviscous fluid acquires singularities that are sets of dimension about 2.5–2.6. Several numerical tests agree with this conjecture (e.g., Chorin, 1981).

A related conjecture, that the Navier–Stokes equations have fractal singularities of much smaller dimension, has led to extensive work by V. Scheffer, R. Teman, and C. Foias, and many others. But this topic is not exhausted.

Finally, we mention that fractals in phase space entered the transition from laminar to turbulent flow through the work of Ruelle and Takens (1971) and their followers. The task of unifying the real- and phase-space roles of fractals is challenging and far from being completed.

X. FRACTALS IN THE ARTS AND IN TEACHING

The Greeks asserted art reflects nature, so it is little surprise that the many fractal aspects of nature should find their way into the arts—beyond the fact that a representational painting of a tree exhibits the same fractal branching as a physical tree. Voss and Clarke (1975) found fractal power-law scaling in music, and self-similarity is designed in the music of the composers György Ligeti and Charles Wuorinen. Pollard-Gott (1986) established the presence of fractal repetition patterns in the poetry of Wallace Stevens. Computer artists use fractals to create both abstract aesthetic images and realistic landscapes. Larry Poons' paintings since the 1980s have had rich fractal textures. The "decalcomania" of the 1830s and the 1930s and 1940s used viscous fingering to provide a level of visual complexity. Before that, Giacometti's Alpine wildflower paintings are unquestionably fractal. Earlier still, relatives of the Sierpinski gasket occur as decorative motifs in Islamic and Renaissance art. Fractals abound in architecture, for example, in the cascades of spires in Indian temples, Bramante's

plan for St. Peter's, Malevich's Architektonics, and some of Frank Lloyd Wright's designs. Fractals occur in the writing of Clarke, Crichton, Hoag, Powers, Updike, and Wilhelm, among others, and in at least one play, Stoppard's *Arcadia*. Postmodern literary theory has used some concepts informed by fractal geometry, though this application has been criticized for its overly free interpretations of precise scientific language. Some have seen evidence of power-law scaling in historical records, the distribution of the magnitudes of wars and of natural disasters, for example. In popular culture, fractals have appeared on t-shirts, totebags, book covers, MTV logos, been mentioned on public radio's *A Prairie Home Companion*, and been seen on television programs from *Nova* and *Murphy Brown*, through several incarnations of *Star Trek*, to *The X-Files* and *The Simpsons*. While Barnsley's (1988) slogan, "fractals everywhere," is too strong, the degree to which fractals surround us outside of science and engineering is striking.

A corollary of this last point is a good conclusion to this high-speed survey. In our increasingly technological world, science education is very important. Yet all too often humanities students are presented with limited choices: the first course in a standard introductory sequence, or a survey course diluted to the level of journalism. The former builds toward major points not revealed until later courses, the latter discusses results from science without showing how science is done. In addition, many efforts to incorporate computer-aided instruction attempt to replace parts of standard lectures rather than engage students in exploration and discovery.

Basic fractal geometry courses for non-science students provide a radical departure from this mode. The subject of fractal geometry operates at human scale. Though new to most, the notion of self-similarity is easy to grasp, and (once understood) handles familiar objects from a genuinely novel perspective. Students can explore fractals with the aid of readily available software. These instances of computer-aided instruction are perfectly natural because computers are so central to the entire field of fractal geometry. The contemporary nature of the field is revealed by a supply of mathematical problems that are simple to state but remain unsolved. Altogether, many fields of interest to non-science students have surprising examples of fractal structures. Fractal geometry is a powerful tool for imparting to non-science students some of the excitement for science often invisible to them. Several views of this are presented in Frame and Mandelbrot (2001).

The importance of fractals in the practice of science and engineering is undeniable. But fractals are also a proven force in science education. Certainly, the boundaries of fractal geometry have not yet been reached.

Functional Analysis

C. W. Groetsch
University of Cincinnati

GLOSSARY

Banach space A complete normed linear space.
Bounded linear operator A continuous linear operator acting between normed linear spaces.
Compact linear operator A linear operator that maps weakly convergent sequences into convergent sequences.
Decomposition theorem A Hilbert space is the sum of any closed subspace and its orthogonal complement.
Fredholm alternative A theorem that characterizes the solvability of a compact linear operator equation of the second kind.
Hilbert space A complete inner product space.
Inner product A positive definite (conjugate) symmetric bilinear form defined on a linear space.
Linear operator A mapping acting between linear spaces that preserves linear combinations.
Linear functional A linear operator whose range is the field of scalars.
Norm A real-valued function on a linear space having the properties of length.
Orthogonal complement All vectors which are orthogonal to a given set.
Orthogonal vectors Vectors whose inner product is zero; a generalization of perpendicularity.
Riesz representation theorem A theorem that identifies bounded linear functionals on a Hilbert space with vectors in the space.
Spectral theorem Characterizes the range of a compact self-adjoint linear operator as the orthogonal sum of eigenspaces.

FUNCTIONAL ANALYSIS strives to bring the techniques and insights of geometry to bear on the study of functions by treating classes of functions as "spaces." The interplay between such spaces and transformations between them is the central theme of this *geometrization* of mathematical analysis. The spaces in question are *linear* spaces, that is, collections of functions (or more general "vectors") endowed with operations of addition and scalar multiplication that satisfy the well-known axioms of a vector space. The subject is rooted in the vector analysis of J. Willard Gibbs and the investigations of Vito Volterra and David Hilbert in the theory linear integral equations; it enjoyed youthful vigor, spurred by applications in potential theory and quantum mechanics, in

the works of Stefan Banach, John von Neumann, and Marshal Stone on the theory of linear operators, and settled into a dignified maturity with the contributions of M. A. Naimark, S. L. Sobolev, and L. V. Kantorovich to normed rings, partial differential equations, and numerical analysis, respectively. Functional analysis provides a general context, that is rich in geometric and algebraic nuances, for organizing and illuminating the structure of many areas of mathematical analysis and mathematical physics. Further, the subject enables rigorous justification of mathematical principles by use of general techniques of great power and wide applicability. In recent decades functional analysis has become the lingua franca of applied mathematics, mathematical physics and the computational sciences, and it has made inroads into statistics and the engineering sciences. In this survey we will concentrate on functional analysis in normed linear spaces, with special emphasis on Hilbert space.

I. LINEAR SPACES

Functional analysis is a geometrization of analysis accomplished via the notion of a linear space. Linear spaces provide a natural algebraic and geometric framework for the description and study of many problems in analysis.

Definition. A *linear space* (vector space) is a collection $\mathcal{V}$ of elements, called *vectors*, along with an associated field of *scalars*, F, and two operations, vector addition (denoted "+") and multiplication of a vector by a scalar (the scalar product of $\alpha \in F$ with $x \in \mathcal{V}$ is denoted αx). The set $\mathcal{V}$ is assumed to form a commutative group under vector addition (the additive identity is called the *zero vector*, denoted θ, and the additive inverse of a vector x is denoted as $-x$). In addition, the scalar product respects the usual algebraic customs, namely:

$$\begin{aligned} 1x &= x, \\ \alpha(\beta x) &= (\alpha\beta)x, \\ (\alpha+\beta)x &= \alpha x + \beta x, \\ \alpha(x+y) &= \alpha x + \alpha y, \end{aligned}$$

for any $\alpha, \beta \in F$ and any $x, y \in \mathcal{V}$, where 1 denotes the multiplicative identity in F.

The vector $x + (-y)$ is normally written $x - y$. We always take the field F to be the field of real numbers, $\mathbf{R}$, or (less frequently) the field of complex numbers, $\mathbf{C}$. The prototype of all linear spaces is Euclidean n-space, that is, the vector space $\mathbf{R}^n$ consisting of all ordered n-tuples of real numbers with addition and scalar multiplication defined componentwise. That is, for

$$\begin{aligned} x &= [x_1, x_2, \ldots, x_n] \\ y &= [y_1, y_2, \ldots, y_n] \end{aligned}$$

in $\mathbf{R}^n$, and $\alpha \in \mathbf{R}$, the vector operations are defined by

$$\begin{aligned} x + y &= [x_1 + y_1, x_2 + y_2, \ldots, x_n + y_n] \\ \alpha x &= [\alpha x_1, \alpha x_2, \ldots, \alpha x_n] \end{aligned}$$

The most useful linear spaces are *function spaces*. For example, the space, $\mathcal{F}(\Omega)$, of all real-valued functions defined on a set Ω is a linear space when fitted out with the operations

$$\begin{aligned} (f+g)(s) &= f(s) + g(s) \\ (\alpha f)(s) &= \alpha f(s). \end{aligned}$$

Taking $\Omega = \{1, 2, \ldots, n\}$ we see that, with obvious notational conventions, Euclidean n-space is a special case of the function space $\mathcal{F}(\Omega)$. A more useful space is the space $C[a, b]$ consisting of all real-valued functions defined on the interval $[a, b]$ that are continuous at each point of $[a, b]$.

Definition. A subset $\mathcal{S}$ of a linear space $\mathcal{V}$ is called a *subspace* of $\mathcal{V}$ if $\alpha x + \beta y \in \mathcal{S}$ for all $x, y \in \mathcal{S}$ and all $\alpha, \beta \in F$.

A subspace is therefore a subset of a linear space which is a linear space in its own right. Applying the definition iteratively, one sees that a subspace $\mathcal{S}$ contains all *linear combinations* of the form

$$\alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_n x_n$$

where n is a positive integer, $\alpha_1, \alpha_2, \ldots, \alpha_n$ are arbitrary scalars and $x_1, x_2, \ldots, x_n$ are arbitrary vectors in S. A set of vectors $\mathcal{W}$ is called *linearly independent* if no vector in $\mathcal{W}$ can be written as a linear combination of other vectors in the set $\mathcal{W}$. One might then say that a linearly independent set contains no "linear redundancies." A *basis* for a subspace $\mathcal{S}$ is a set of linearly independent vectors $\mathcal{B} \subset \mathcal{S}$ with the property that every vector in $\mathcal{S}$ can be written as a linear combination of vectors in $\mathcal{B}$. If a subspace has a basis consisting of finitely many vectors, then the subspace is called *finite-dimensional*. For example, the set of all real polynomials of degree not more than 7 is an eight-dimensional subspace of $C[a, b]$; the set of polynomials $\{1, t, t^2, \ldots, t^7\}$ is a basis for this subspace. On the other hand, the set of all real polynomials is an infinite dimensional subspace of $C[a, b]$.

Subspaces allow a layering of sets of increasingly regular vectors while preserving the linear structure of the space. For example, the set $C^1[a, b]$ of all real-valued functions on $[a, b]$ which also have a continuous derivative is a subspace of $C[a, b]$, while $C_0^2[a, b]$, the space of all twice continuously differentiable real-valued functions

on $[a, b]$ that vanish at the endpoints of the interval, is a subspace of $C^1[a, b]$.

The space $AC[a, b]$ of *absolutely continuous* functions is another important subspace of $C[a, b]$. A function f is called absolutely continuous if the sum $\sum |f(b_i) - f(a_i)|$ can be made arbitrarily small for all finite collections of subintervals $\{[a_i, b_i]\}$ whose total length $\sum(b_i - a_i)$ is sufficiently small. The importance of absolutely continuous functions resides in the fact that they are precisely those functions which have integrable (but not necessarily continuous) derivatives on $[a, b]$. Functions in $C^1[a, b]$ are absolutely continuous because such functions have uniformly bounded derivatives. We therefore have the following relationships for these subspaces of $C[a, b]$:

$$C^1[a, b] \subset AC[a, b] \subset C[a, b].$$

A somewhat less specialized notion than a subspace, that of a convex set, is crucial in various applications of functional analysis.

Definition. A subset K of a linear space is called *convex* if $(1 - t)x + ty \in K$ for all $x, y \in K$ and all real numbers t with $0 \le t \le 1$.

Convex sets have a natural geometric interpretation. Given two vectors x and y, the set of vectors of the form $\{(1 - t)x + ty : t \in [0, 1]\}$ is called, in analogy with the corresponding situation in Euclidean space, the *segment* between x and y. A convex set is then a subset of a linear space which contains the segment between any two of its vectors. Of course, every subspace is a convex set.

A. Normed Linear Spaces

Vector spaces become more serviceable when a metric fabric is stretched over the linear framework. Such a metric structure is provided by a function defined on the space which generalizes the concept of length in Euclidean spaces.

Definition. A nonnegative real-valued function $\|\cdot\|$ defined on a linear space $\mathcal{V}$ is called a *norm* if:

(i) $\|x\| = 0$ if and only if $x = \theta$ (the zero vector in $\mathcal{V}$),

(ii) $\|x + y\| \le \|x\| + \|y\|$, for all $x, y \in \mathcal{V}$,

(iii) $\|tx\| = |t|\|x\|$, for all scalars t and all $x \in \mathcal{V}$.

A linear space that comes bundled with a norm is called a *normed linear space*. For specificity, we will sometimes indicate a linear space $\mathcal{V}$ equipped with a norm $\|\cdot\|$ by the pair $(\mathcal{V}, \|\cdot\|)$. For example, $(C[a, b], \|\cdot\|_\infty)$ is a normed linear space under the so-called *uniform norm*

$$\|f\|_\infty = \max\{|f(t)| : t \in [a, b]\}.$$

The space $C[a, b]$ is also a normed linear space when endowed with the norm

$$\|f\|_1 = \int_a^b |f(t)|\, dt$$

and hence $(C[a, b], \|\cdot\|_1)$ is another distinct normed space consisting of the same set of vectors as the normed linear space $(C[a, b], \|\cdot\|_\infty)$. As another example, $C_0^1[a, b]$ is a normed linear space when equipped with the norm $\|f\| = \|f'\|_\infty$, where f' is the derivative of f.

A norm allows the possibility of measuring the distance between two vectors and it also gives meaning to "equality in the limit," that is, to *convergence*.

Definition. A sequence $\{x_n\}$ of vectors is said to *converge* to a vector x, with respect to the norm $\|\cdot\|$, if $\|x_n - x\| \to 0$ as $n \to \infty$.

The notion of convergence is norm-dependent. For example, let l_n denote the "spike" function in $C[0, 1]$ whose graph is obtained by connecting the points $(0, 0), (\frac{1}{2n}, 1), (\frac{1}{n}, 0), (1, 0)$ with straight line segments. The sequence $\{l_n\}$ converges with respect to the $\|\cdot\|_1$ norm to the zero function since $\|l_n\|_1 = \frac{1}{2n}$. However, this sequence does not converge to the zero function in the uniform norm since $\|l_n\|_\infty = 1$. But note that every sequence that converges with respect to the uniform norm also converges with respect to the norm $\|\cdot\|_1$ since $\|f\|_1 \le \|f\|_\infty$ for all $f \in C[0, 1]$. As another example, consider the space $C_0^1[a, b]$ with the norm $\|f\| = \|f'\|_2$. Wirtinger's inequality asserts that if $f \in C_0^1[a, b]$, then

$$\pi^2 \int_a^b |f(t)|^2\, dt \le (b - a)^2 \int_a^b |f'(t)|^2\, dt$$

Hence, if $\|\cdot\|_2$ is the norm on $C_0^1[a, b]$ defined by

$$\|f\|_2 = \sqrt{\int_a^b |f(t)|^2\, dt}$$

then $m\|f\|_2 \le \|f\|$, where $m = \pi/(b - a)$. Therefore, convergence in the norm $\|\cdot\|$ implies convergence in the norm $\|\cdot\|_2$. Wirtinger's inequality can be generalized to functions defined on domains in $\mathbf{R}^n$; the resulting inequality is known as *Poincaré's inequality*.

Two norms $\|\cdot\|_a$ and $\|\cdot\|_b$ on a linear space $\mathcal{V}$ are called *equivalent* if there are positive constants c_1 and c_2 such that

$$c_1\|x\|_a \le \|x\|_b \le c_2\|x\|_a$$

for all $x \in \mathcal{V}$. Equivalence therefore means equivalent in the sense of convergence: a sequence converges with respect to the norm $\|\cdot\|_a$ if and only if it converges with respect to the norm $\|\cdot\|_b$. It can be shown that any two norms on a finite-dimensional linear space are equivalent and hence when speaking of convergence in a finite-dimensional space one can dispense with mentioning the norm. However, as we have seen above, convergence is norm-dependent in infinite dimensional spaces.

Definition. The *closure*, $\overline{W}$, of a subset W of a normed linear space $(\mathcal{V}, \|\cdot\|)$ is the set consisting of elements of W along with all limits of convergent sequences in W. A set which is its own closure is called *closed*.

For example, the closure of the set of all polynomials in the space $(C[a, b], \|\cdot\|_\infty)$ is, by virtue of the *Weierstrass approximation theorem*, the space $C[a, b]$ itself. Also, for example, the set of nonnegative functions in $C[a, b]$ is a closed subset of $C[a, b]$.

B. Banach Spaces

Certain sequences of vectors in a normed linear space tend to "bunch up" in a way that imitates convergent sequences. Such sequences are named after the nineteenth century mathematician Augustin Cauchy.

Definition. A sequence of vectors $\{x_n\}$ in a normed linear space $(\mathcal{V}, \|\cdot\|)$ is called a *Cauchy* sequence if $\lim_{n,m\to\infty} \|x_n - x_m\| = 0$.

It is easy to see that every convergent sequence is Cauchy, however, it is not necessarily the case that a Cauchy sequence is convergent. Consider, for example, the "ramp" function h_n in $C[-1, 1]$ whose graph consists of the straight line segments connecting the points $(-1, 0), (-\frac{1}{n}, 0), (0, 1), (1, 1)$. The sequence of ramp functions is Cauchy with respect to the norm $\|\cdot\|_1$ since

$$\|h_n - h_m\|_1 = \frac{1}{2}\left|\frac{1}{n} - \frac{1}{m}\right| \to 0, \quad \text{as} \quad n, m \to \infty.$$

However, $\{h_n\}$ does not converge, with respect to the norm $\|\cdot\|_1$, to a function in $C[-1, 1]$ (the $\|\cdot\|_1$ limit of this sequence of ramp functions is the discontinuous Heaviside function). Spaces, such as $(C[-1, 1], \|\cdot\|_1)$, which do not accommodate limits of Cauchy sequences are in some sense "incomplete." A normed linear space is called *complete* if every Cauchy sequence in the space converges to some vector in the space.

Definition. A *Banach space* is a complete normed linear space.

We have just seen that $C[a, b]$ with the norm $\|\cdot\|_1$ is not a Banach space. However, $C[a, b]$ with the uniform norm is a Banach space. The Lebesgue spaces are particularly important Banach spaces. For $1 \le p < \infty$ the space $L^p[a, b]$ consists of measurable real-valued functions f defined on $[a, b]$ such that $|f|^p$ has a finite Lebesgue integral. The norm $\|\cdot\|_p$ on $L^p[a, b]$ is defined by

$$\|f\|_p = \left\{\int_a^b |f(t)|^p \, dt\right\}^{\frac{1}{p}}.$$

Every normed linear space can be imbedded as a dense subspace of a Banach space by an abstract process of "completion." Essentially, the completion process involves adjoining to the original space, for each Cauchy sequence in the original space, a vector in an extended space (the *completion*) which is the limit in the extended space of the Cauchy sequence. For example, it can be shown that the completion of the space $(C[a, b], \|\cdot\|_1)$ is the space $(L^1[a, b], \|\cdot\|_1)$.

C. Hilbert Spaces

Perpendicularity, the key ingredient in the Pythagorean theorem, is one of the fundamental concepts in geometry. A successful geometrization of analysis requires the incorporation of this concept. The essential aspects of perpendicularity are captured in special normed linear spaces called inner product spaces.

Definition. An *inner product* on a real linear space $\mathcal{V}$ is a function $\langle\cdot, \cdot\rangle : \mathcal{V} \times \mathcal{V} \to \mathbf{R}$ which satisfies:

(i) $\langle x, x\rangle \ge 0$ for all $x \in \mathcal{V}$,

(ii) $\langle x, x\rangle = 0$ if and only if $x = \theta$ (the zero vector),

(iii) $\langle x, y\rangle = \langle y, x\rangle$ for all $x, y \in \mathcal{V}$,

(iv) $\langle tx, y\rangle = t\langle x, y\rangle$ for all $x, y \in \mathcal{V}$ and all $t \in \mathbf{R}$,

(v) $\langle x + y, z\rangle = \langle x, z\rangle + \langle y, z\rangle$, for all $x, y, z \in \mathcal{V}$.

Properties (iii)–(v) are summarized by saying that $\langle\cdot, \cdot\rangle$ is a symmetric bilinear form; properties (i) and (ii) say that $\langle\cdot, \cdot\rangle$ is nonnegative and definite. A linear space endowed with an inner product is called an *inner product space*.

The most familiar inner product space is the Euclidean space $\mathbf{R}^n$ with the inner product

$$\langle x, y\rangle = x_1y_1 + x_2y_2 + \cdots + x_ny_n.$$

Of course other inner products may be used on the same underlying linear space. For example, in statistics, the Euclidean space is often used with a *weighted* inner product

$$\langle x, y\rangle = w_1x_1y_1 + w_2x_2y_2 + \cdots + w_nx_ny_n$$

where $w_1, w_2, \ldots, w_n$ are fixed positive weights.

Function spaces serve up a particularly rich stew of inner product spaces. For example, the theory of Fourier series can be developed in the Lebesgue space $L^2[a, b]$ with the inner product

$$\langle f, g\rangle = \int_a^b f(t)g(t)\, dt$$

and many variations are possible. For instance, the space $C^1[0, 1]$ with

$$\langle f, g\rangle = \int_0^1 f'(t)g'(t)\,dt + f(0)g(0)$$

is an inner product space.

In the case of a linear space over the field $\mathbf{C}$ of complex scalars the definition of an inner product requires some modification. Here the inner product is a complex valued function that satisfies the properties above, save that (iii) is replaced by

$$\langle x, y\rangle = \overline{\langle y, x\rangle},$$

where the bar indicates complex conjugation, and (iv) is required to hold for all $t \in \mathbf{C}$. Note that this implies that $\langle x, ty\rangle = \bar{t}\langle x, y\rangle$.

Every inner product on a linear space generates a corresponding norm by way of the definition $\|x\| = \sqrt{\langle x, x\rangle}$. The proof that this defines a norm relies on the *Cauchy-Schwarz inequality*:

$$|\langle x, y\rangle|^2 \le \langle x, x\rangle\langle y, y\rangle.$$

Any norm induced by an inner product must satisfy, by virtue of the bilinearity of the inner product, the *Parallelogram Law*:

$$\|x + y\|^2 + \|x - y\|^2 = 2\|x\|^2 + 2\|y\|^2.$$

Therefore, any norm which does not satisfy the parallelogram law is not induced by an inner product. For example, the space $(C[-1, 1], \|\cdot\|_\infty)$ is not an inner product space since the parallelogram law for $\|\cdot\|_\infty$ fails for the continuous ramp functions h_1 and h_2 introduced above.

Definition. Two vectors x and y in an inner product space are called *orthogonal*, denoted $x \perp y$, if $\langle x, y\rangle = 0$. A subset S of an inner product space is called an orthogonal set if $x \perp y$ for each distinct pair of vectors $x, y \in S$.

From the properties of the inner product it follows immediately that

$$x \perp y \quad \text{if and only if} \quad \|x + y\|^2 = \|x\|^2 + \|y\|^2.$$

This extension of the classical Pythagorean theorem to inner product spaces is what justifies our association of orthogonality, a purely *algebraic* concept, with the geometrical notion of perpendicularity.

Given a subset S of an inner product space $\mathcal{V}$, the *orthogonal complement* of S is the closed subspace

$$S^\perp = \{y \in \mathcal{V} : \langle x, y\rangle = 0 \quad \text{for all} \quad x \in S\}.$$

For example, consider the space $C^1[0, 1]$ of continuously differentiable real functions on $[0, 1]$ equipped with the inner product

$$\langle f, g\rangle = \int_0^1 f'(t)g'(t)\,dt + f(0)g(0).$$

Let S be the set of linear functions. Then $g \in S^\perp$ if and only if

$$0 = \langle 1, g\rangle = g(0) \quad \text{and} \quad 0 = \langle t, g\rangle = \int_0^1 g'(t)\,dt = g(1) - g(0).$$

Therefore, $S^\perp = C_0^1[0, 1]$, the space of continuously differentiable functions which vanish at the end points of $[0, 1]$. If $\mathcal{W}$ is a subspace, then its second orthogonal complement is its closure: $\mathcal{W}^{\perp\perp} = \overline{W}$.

Definition. A *Hilbert space* is a complete inner product space.

The best known Hilbert space is the space $L^2[a, b]$. The fact that this space is complete is known as the *Riesz-Fischer Theorem*. The *Sobolev spaces* are important Hilbert spaces used in the theory of differential equations. Let Ω be a bounded domain in $\mathbf{R}^n$. $C^m(\Omega)$ denotes the space of all continuous real-valued functions on $\overline{\Omega}$ having bounded continuous partial derivatives through order m. An inner product $\langle\cdot, \cdot\rangle_m$ is defined on $C^m(\Omega)$ by

$$\langle f, g\rangle_m = \sum_{|\alpha| \le m} \langle D^\alpha f, D^\alpha g\rangle$$

where $\langle\cdot, \cdot\rangle$ denotes the usual L^2 inner product, $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_n)$ is a multi-index of nonnegative integers, $|\alpha| = \alpha_1 + \cdots + \alpha_n$, and D^α is the differential operator

$$D^\alpha f = \frac{\partial^{|\alpha|}}{\partial x_n^{\alpha_n} \cdots \partial x_1^{\alpha_1}} f.$$

The Sobolev space $H^m(\Omega)$ is the completion of $C^m(\Omega)$ with respect to the norm $\|\cdot\|_m$ generated by the inner product $\langle\cdot, \cdot\rangle_m$. A closely associated Sobolev space is the space $H_0^m(\Omega)$ which is formed in the same way, but using as base space the space $C_0^m(\Omega)$ of all functions in $C^m(\Omega)$ which vanish off of some closed bounded subset of Ω (that is, the space of all *compactly supported* functions in $C^m(\Omega)$). The advantage of using such spaces in the study of differential equations lies in the fact that in these spaces ordinary functions are very smooth, convergence is very strict (convergence in $H^m(\Omega)$ implies uniform convergence on compact subsets of all derivatives through order $m - 1$), and Sobolev spaces are *complete*, allowing the deployment of all the weapons of Hilbert space theory. In particular, Hilbert space theory can be used to develop a rich theory of *weak solutions* of partial differential equations and a corresponding theory of finite element approximations to weak solutions.

An orthogonal set of unit vectors (i.e., vectors of norm one) is called an *orthonormal set*. If S is an orthonormal set in a Hilbert space H, then for any $y \in H$ at most countably many of the numbers $\langle y, x\rangle$, where $x \in S$, are nonzero and

$$\sum_{x\in S} |\langle y, x\rangle|^2 \le \|y\|^2$$

(this is called *Bessel's inequality*). The numbers $\{\langle y, x\rangle: x \in S\}$ are called the *Fourier coefficients* of y with respect to the orthonormal set S. If the orthonormal set S has the property that the Fourier coefficients of a vector completely determine the vector in the sense that if, for any vector $y \in H$

$$\langle y, x\rangle = 0 \quad \text{for all } x \in S \quad \text{implies} \quad y = \theta$$

then S is called a *complete orthonormal set*.

Definition. A Hilbert space is called *separable* if it contains a sequence which is a complete orthonormal set. Any such complete orthonormal sequence is called a *basis* for the Hilbert space.

It is not hard to see that an orthonormal sequence $\{\phi_n\}$ in a Hilbert space H is complete if and only if

$$\sum_n |\langle y, \phi_n\rangle|^2 = \|y\|^2$$

for each $y \in H$ (*Parseval's identity*). This is equivalent to the assertion

$$\sum_n \langle y, \phi_n\rangle \phi_n = y$$

where the convergence of the series is understood in the sense of the norm generated by the inner product $\langle \cdot, \cdot \rangle$.

For example, the complex space $L^2[-\pi, \pi]$ with inner product

$$\langle f, g\rangle = \int_{-\pi}^{\pi} f(t)\overline{g(t)}\, dt$$

is a separable Hilbert space with complete orthonormal sequence

$$\phi_n(t) = \frac{1}{\sqrt{2\pi}} e^{int}, \qquad , n = 0, \pm 1, \pm 2, \ldots.$$

Note that these orthonormal vectors are integer dilates of a single complex wave, that is,

$$\phi_n(t) = \phi(nt),$$

where

$$\phi(t) = \frac{1}{\sqrt{2\pi}} e^{it} = \frac{1}{\sqrt{2\pi}} (\cos t + i \sin t).$$

None of the functions ϕ_n just defined lies in the space $L^2(-\infty, \infty)$ because the waves do not "die out" as $|t| \to \infty$. Special bases for $L^2(-\infty, \infty)$ that have particularly attractive decay properties, called *wavelet* bases, have been studied and applied extensively in recent years. We now show how to construct the simplest wavelet basis, the *Haar basis*. As in the previous example, we seek a single function to generate all the basis vectors, but instead of a wave, we choose a function that decays quickly, in fact a function that vanishes off an interval. Our choice is the Haar "wavelet"

$$\psi(t) = \begin{cases} 1 & \text{for} \quad 0 \le t < \frac{1}{2} \\ -1 & \text{for} \quad \frac{1}{2} \le t < 1 \\ 0 & \text{otherwise} \end{cases}$$

Taking dilates of this wavelet will serve the same purpose as the higher frequency waves in the previous example, that is, the dilates of the fundamental wave ϕ. However, this by itself will not serve to represent functions defined over the entire line. To do that we must also shift the dilates about. If this is done properly, then all the needed time and frequency attributes are captured and the resulting wavelets are orthonormal. Specifically, it can be shown that the functions $\{\psi_{j,k}: j, k = 0, \pm 1, \pm 2, \ldots\}$ defined by

$$\psi_{j,k}(t) = 2^{\frac{j}{2}} \psi(2^j t - k)$$

form an orthonormal basis for $L^2(-\infty, \infty)$ called the *Haar basis*.

II. LINEAR OPERATORS

Mappings between linear spaces that preserve the linear structure are called linear operators.

Definition. A mapping T defined on a linear space $\mathcal{V}$ and taking values in a linear space $\mathcal{W}$ is called *linear* if

$$T(x + y) = Tx + Ty, \quad \text{for all} \quad x, y \in \mathcal{V}$$

and

$$T(tx) = tTx, \quad \text{for all} \quad x \in \mathcal{V} \quad \text{and all scalars} \quad t.$$

The space $\mathcal{V}$ on which a linear operator T is defined is called the *domain* of T and denoted $\mathcal{D}(T)$. In finite-dimensional spaces linear operators have matrix representations relative to specific ordered bases. For example, the differentiation operator acting on the space of polynomials of degree not greater that n has, relative to the basis $\{1, t, \ldots, t^n\}$, the $(n+1) \times (n+1)$ matrix representation

$$\begin{bmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 2 & \ldots & 0 \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ 0 & 0 & 0 & \ldots & n \\ 0 & 0 & 0 & \ldots & 0 \end{bmatrix}.$$

In functional analysis the primary interest is the study of linear operators on infinite dimensional function spaces that are defined intrinsically, that is, without regard to a specific basis. For example, given a real-valued function $k(\cdot, \cdot)$ which is continuous on the square $[0, 1] \times [0, 1]$ one can define the linear integral operator T on $C[0, 1]$, taking values in $C[0, 1]$, by $Tf = g$ where

$$g(s) = \int_0^1 k(s, t) f(t)\, dt.$$

Such integral operators may be viewed as natural generalizations of matrices to the case of continuous, rather than discrete, variables.

Two important subspaces, the *nullspace* and *range*, are associated with each linear operator. The nullspace, $N(T)$, of a linear operator T consists of all vectors that T maps to the zero vector: $N(T) = \{x \in \mathcal{D}(T)\colon Tx = \theta\}$. For example, the differentiation operator acting on the space $C^1[a, b]$ has nullspace consisting of all constant functions. The range, $R(T)$, of a linear operator T is the set of all images of vectors under T, that is, $R(T) = \{Tx\colon x \in \mathcal{D}(T)\}$. For example, the range of the integral operator on $C[0, 1]$ generated by the kernel $k(s, t) = \exp(s + t)$ consists of all scalar multiples of the exponential function $f(s) = \exp(s)$.

A. Bounded Operators

Linear operators acting between normed linear spaces that are continuous with respect to the norms are called bounded.

Definition. A linear operator T defined on a normed linear space $(\mathcal{V}, \|\cdot\|_v)$ and taking values in a normed linear space $(\mathcal{W}, \|\cdot\|_w)$ is called *bounded* if there is a constant L such that $\|Tx\|_w \le L\|x\|_v$ for all $x \in \mathcal{V}$.

The notational specification of norms on various linear spaces is tiresome and annoying; we will therefore often dispense with it and rely on the reader to understand appropriate norms from the context. Hence we will say that a linear operator T is bounded if $\|Tx\| \le L\|x\|$ for all $x \in \mathcal{D}(T)$ and some constant L. The smallest constant L for which this inequality holds is called the *norm* of the operator T and is denoted $\|T\|$. Equivalently,

$$\|T\| = \sup_{x \ne \theta} \frac{\|Tx\|}{\|x\|}$$

where "sup" stands for supremum, or least upper bound. Using linearity of T one sees that

$$\|Tx - Ty\| \le \|T\|\|x - y\|$$

and hence $\|T\|$ gives the smallest universal bound for the relative "spread" that a bounded linear operator T can accomplish. From this it also follows that every bounded linear operator is continuous (relative to the norms in question) and, in fact, every continuous linear operator is bounded. Indeed, if T is linear and continuous, then there is a $\delta > 0$ such that $\|z\| \le \delta$ implies $\|Tz\| \le 1$. For any $x \ne \theta$ one then has $\|T(\delta x/\|x\|)\| \le 1$, that is, $\|Tx\| \le \frac{1}{\delta}\|x\|$ for all x. Therefore, T is bounded and $\|T\| \le 1/\delta$.

The set $L(\mathcal{V}, \mathcal{W})$ of all bounded linear operators from a normed linear space $\mathcal{V}$ to a normed linear space $\mathcal{W}$ is itself a normed linear space under the natural notions of operator sum and scalar multiplication:

$$(T + S)(x) = Tx + Sx$$
$$(tT)(x) = t(Tx)$$

and with the norm on bounded linear operators as defined above. Further, if $\mathcal{W}$ is a Banach space, then so is $L(\mathcal{V}, \mathcal{W})$. If the image space $\mathcal{W}$ is the scalar field (**R**, or **C**), then $L(\mathcal{V}, \mathcal{W})$ is called the *dual space*, $\mathcal{V}^*$, of $\mathcal{V}$. An operator in $\mathcal{V}^*$ is called a *bounded linear functional* on $\mathcal{V}$. For example, given a fixed $t_0 \in [a, b]$, the point evaluation operator E_{t_0}, defined by

$$E_{t_0}(f) = f(t_0)$$

is a bounded linear functional on the space $(C[a, b], \|\cdot\|_\infty)$. The dual space of $C[a, b]$ may be identified with the space of all functions of bounded variation on $[a, b]$ in the sense that any bounded linear functional ℓ on $C[a, b]$ has a unique representation of the form

$$\ell(f) = \int_a^b f(t)\, dg(t)$$

for some function g of bounded variation (the integral is a Riemann-Stieljes integral). In the case of point evaluation the representative function g is the Heaviside function at t_0:

$$g(t) = \begin{cases} 0 & , \quad t < t_0 \\ 1 & , \quad t_0 \le t. \end{cases}$$

It can be shown that for $1 < p < \infty$,

$$(L^p[a, b])^* = L^q[a, b]$$

where $\frac{1}{p} + \frac{1}{q} = 1$, in the sense that every bounded linear functional ℓ on $L^p[a, b]$ has the form

$$\ell(f) = \int_a^b f(t)g(t)\, dt$$

for some $g \in L^q[a, b]$ that is uniquely determined by ℓ. With this understanding the space $L^2[a, b]$ is self-dual.

In fact, by the *Riesz Representation Theorem*, all Hilbert spaces are self-dual for the following reason: a bounded linear functional ℓ on a Hilbert space H has the form $\ell(x) = \langle x, z\rangle$, for some vector $z \in H$ which is uniquely

determined by ℓ. Further, $\|\ell\| = \|z\|$, where the first norm is an operator norm and the other is the underlying Hilbert space norm. The association of the bounded linear functional ℓ with its Riesz representor z provides the identification of H^* with H.

Bounded linear functionals may be thought of as linear measurements on a Hilbert space in that a bounded linear functional gives a numerical measure on vectors in the space which is continuous with respect to the norm. Such measures distinguish vectors in the space because $x \neq y$ if and only if there is a vector z with $\langle x, z\rangle \neq \langle y, z\rangle$. However, it may happen that no such linear measure can ultimately distinguish the vectors in a sequence from a certain fixed vector. This gives rise to the notion of weak convergence.

Definition. A sequence $\{x_n\}$ in a Hilbert space H is said to converge *weakly* to a vector x, denoted $x_n \rightharpoonup x$, if $\langle x_n, z\rangle \to \langle x, z\rangle$ for all $z \in H$.

It is a consequence of the Cauchy-Schwarz inequality that every convergent sequence is weakly convergent to the same limit. Also, Bessel's inequality shows that every orthonormal sequence of vectors converges weakly to the zero vector.

B. Adjoint Operators

Adjoint operators mimic the behavior of the transpose matrix on real Euclidean space. Recall that the transpose A^T of a real $m \times n$ matrix A satisfies

$$\langle Ax, y\rangle = \langle x, A^T y\rangle$$

for all $x \in \mathbf{R}^n$ and $y \in \mathbf{R}^m$, where $\langle \cdot, \cdot\rangle$ is the Euclidean inner product. If T is a bounded linear operator from a Hilbert space H_1 into a Hilbert space H_2, i.e., $T : H_1 \to H_2$, then for fixed $y \in H_2$ the linear functional ℓ defined on H_1 by

$$\ell(x) = \langle Tx, y\rangle$$

is bounded and hence by the Riesz Representation Theorem

$$\langle Tx, y\rangle = \langle x, z\rangle$$

for some $z \in H_1$. This z is uniquely determined by y, via T, and we denote it by T^*y, that is,

$$\langle Tx, y\rangle = \langle x, T^*y\rangle.$$

The operator $T^* : H_2 \to H_1$ is a bounded linear operator called the *adjoint* of T. If T is a bounded linear operator, then $\|T\| = \|T^*\|$ and $T^{**} = T$.

Suppose, for example, the linear operator $T : L^2[a, b] \to L^2[c, d]$ is generated by the kernel $k(\cdot, \cdot) \in C([c, d] \times [a, b])$, that is,

$$(Tf)(s) = \int_a^b k(s, t) f(t)\, dt, \qquad s \in [c, d],$$

then

$$\begin{aligned}\langle Tf, g\rangle &= \int_c^d \int_a^b k(s, t) f(t)\, dt\, g(s)\, ds \\ &= \int_a^b \int_c^d k(s, t) g(s)\, ds\ f(t)\, dt = \langle f, T^* g\rangle\end{aligned}$$

and hence T^* is the integral operator generated by the kernel $k^*(\cdot, \cdot)$ defined by $k^*(t, s) = k(s, t)$. In particular, if the kernel k is symmetric and $[a, b] = [c, d]$, then the operator T is self-adjoint.

C. Compact Operators

A linear operator $T : H_1 \to H_2$ is called an operator of *finite rank* if its range is spanned by finitely many vectors in H_2. In other words, T has finite rank if there are linearly independent vectors $\{v_1, \ldots, v_m\}$ in H_2 such that

$$Tx = \sum_{k=1}^{m} a_k(x) v_k$$

where the coefficients a_k are bounded linear functionals on H_1. Therefore, by the Riesz Representation Theorem,

$$Tx = \sum_{k=1}^{m} \langle x, u_k\rangle v_k$$

for certain vectors $\{u_1, \ldots, u_m\} \subset H_1$. Note that every finite rank operator is continuous, but more is true. If $\{x_n\}$ is a weakly convergent sequence in H_1, say $x_n \rightharpoonup w$, then

$$Tx_n = \sum_{k=1}^{m} \langle x_n, u_k\rangle v_k \to \sum_{k=1}^{m} \langle w, u_k\rangle v_k = Tw,$$

and hence a finite rank operator T maps weakly convergent sequences into strongly convergent sequences. Finite rank operators are a special case of an important class of linear operators that enjoy this weak-to-strong continuity property.

Definition. A linear operator $T : H_1 \to H_2$ is called *compact* (also called *completely continuous*) if $x_n \rightharpoonup w$ implies $Tx_n \to Tw$.

Note that every finite rank operator is completely continuous and every completely continuous operator is *a fortiori* continuous. Also, limits of finite rank operators are compact. More precisely, if $\{T_n\}$ is a sequence of finite rank operators converging in operator norm to an operator T, then T is compact.

Completely continuous operators acting on a Hilbert space have a particularly simple structure expressed in terms of certain characteristic subpaces known as

eigenspaces. The *eigenspace* of a linear operator $T: H \to H$ associated with a scalar λ is the subspace

$$N(T - \lambda I) = \{x \in H : Tx = \lambda x\}.$$

In general, an eigenspace may be trivial, that is, it may consist only of the zero vector. If $N(T - \lambda I) \neq \{\theta\}$, we say that λ is an *eigenvalue* of T. If T is self-adjoint, then the eigenvalues of T are real numbers and vectors in distinct eigenspaces are orthogonal to each other. If T is self-adjoint, compact, and of infinite rank, then the eigenvalues of T form a sequence of real numbers $\{\lambda_n\}$. This sequence converges to zero, for taking an orthonormal sequence $\{x_n\}$ with $x_n \in N(T - \lambda_n I)$ we have $\lambda_n x_n = Tx_n \to \theta$ since $x_n \rightharpoonup \theta$ (a consequence of Bessel's inequality). Since $\|x_n\| = 1$, it follows that $\lambda_n \to 0$. The fact that $Tx_n \to 0$ for a sequence of unit vectors $\{x_n\}$ is an abstract version of the *Riemann-Lebesgue Theorem*.

The prime exemplar of a compact self-adjoint operator is the integral operator on the real space $L^2[a, b]$ generated by a symmetric kernel $k(\cdot, \cdot) \in L^2([a, b] \times [a, b])$:

$$(Tf)(s) = \int_a^b k(s, t) f(t)\, dt.$$

This operator is compact because it is the limit in operator norm of the finite rank operators

$$T_N f = \sum_{n,m \leq N} c_{n,m} \int_a^b f(t)\phi_m(t)\, dt \phi_n$$

where $\{\phi_n\}_1^\infty$ is a complete orthonormal sequence in $L^2[a, b]$ and

$$k(s, t) = \sum_{n,m=1}^{\infty} c_{n,m}\phi_n(s)\phi_m(t)$$

is the Fourier expansion of $k(\cdot, \cdot)$ relative to the orthonormal basis $\{\phi_n(s)\phi_m(t)\}$ for $L^2([a, b] \times [a, b])$.

D. Unbounded Operators

It is not the case that every interesting linear operator is bounded. For example, the differentiation operator acting on the space $C^1[0, \pi]$ and taking values in the space $C[0, \pi]$, both with the uniform norm, is unbounded. Indeed, for the functions $\phi_n(t) = \sin(nt)$ we find that the quotient

$$\frac{\|\phi_n'\|_\infty}{\|\phi_n\|_\infty} = n$$

is unbounded.

Multiplication by the variable in the space $L^2(-\infty, \infty)$ is another famous example of an unbounded operator. Let

$$\mathcal{D}(M) = \left\{ f \in L^2(-\infty, \infty) : \int_{-\infty}^{\infty} t^2 |f(t)|^2\, dt < \infty \right\}.$$

Then $\mathcal{D}(M)$ is a dense subspace of $L^2(-\infty, \infty)$ and one can define the linear operator $M: \mathcal{D}(M) \to L^2(-\infty, \infty)$ by

$$Mf = g \quad \text{where} \quad g(t) = tf(t).$$

Let $\phi_n(t) = 1$ for $t \in [n, n + 1]$ and $\phi_n(t) = 0$ otherwise. Then $\|\phi_n\|_2 = 1$ and $\|M\phi_n\|_2 > n$, and hence M is unbounded. The multiplication operator has an important interpretation in quantum mechanics.

The adjoint operator may also be defined for unbounded linear operators with dense domains. Given a linear operator $T: \mathcal{D}(T) \subset H_1 \to H_2$ with dense domain $\mathcal{D}(T)$, let $\mathcal{D}(T^*)$ be the subspace of all vectors $y \in H_2$ satisfying

$$\langle Tx, y\rangle = \langle x, y^*\rangle$$

for some vector $y^* \in H_1$ and all $x \in \mathcal{D}(T)$. The vector y^* is then uniquely defined and we set $T^* y = y^*$. Then the operator $T^*: \mathcal{D}(T^*) \subset H_2 \to H_1$ is densely defined and linear.

As an example, let $\mathcal{D}(T)$ be the space of absolutely continuous complex-valued functions f defined on $[0, 1]$ with $f' \in L^2[0, 1]$ satisfying the periodic boundary condition $f(0) = f(1)$. Then $\mathcal{D}(T)$ is dense in $L^2[0, 1]$. Define $T: \mathcal{D}(T) \to L^2[0, 1]$ by $Tf = if'$. For $g \in \mathcal{D}(T)$ we have

$$\begin{aligned}\langle Tf, g\rangle &= \int_0^1 if'(t)\overline{g(t)}\, dt \\ &= i\overline{g(t)} f(t)\,\big|_0^1 - i\int_0^1 f(t)\overline{g'(t)}\, dt \\ &= \int_0^1 f(t)\overline{ig'(t)}\, dt = \langle f, ig'\rangle\end{aligned}$$

for all $f \in \mathcal{D}(T)$. Therefore, $\mathcal{D}(T) \subset \mathcal{D}(T^*)$ and, in fact, it can be shown that $\mathcal{D}(T^*) = \mathcal{D}(T)$. This calculation shows that $T^* g = Tg$, that is, T is self-adjoint.

A linear operator $T: \mathcal{D}(T) \subseteq H_1 \to H_2$ is called *closed* if its graph $\mathcal{G}(T) = \{(x, Tx) : x \in \mathcal{D}(T)\}$ is a closed subspace of the product Hilbert space $H_1 \times H_2$. This means that if $\{x_n\} \subset \mathcal{D}(T)$, $x_n \to x \in H_1$, and $Tx_n \to y \in H_2$, then $(x, y) \in \mathcal{G}(T)$, that is, $x \in \mathcal{D}(T)$ and $Tx = y$. For example, the differentiation operator defined in the previous paragraph is closed. In fact, the adjoint of any densely defined linear operator is closed.

A densely defined linear operator $T: \mathcal{D}(T) \subseteq H \to H$ is called *symmetric* if

$$\langle Tx, y\rangle = \langle x, Ty\rangle \quad \text{for all} \quad x, y \in \mathcal{D}(T).$$

Every self-adjoint transformation is, of course, symmetric; however, a symmetric transformation is not necessarily self-adjoint. Consider, for instance, a slight modification of the previous example. Let $\mathcal{D}(T)$ be the space of absolutely continuous complex-valued functions on $[0, 1]$ which vanish at the end points, and let $Tf = if'$. For

$f, g \in \mathcal{D}(T)$, integration by parts gives $\langle Tf, g\rangle = \langle f, Tg\rangle$, and hence T is symmetric, and the adjoint of T satisfies $T^*g = if'$. However, $\mathcal{D}(T^*)$ is a proper extension of $\mathcal{D}(T)$, in that no boundary conditions are imposed on functions in $\mathcal{D}(T^*)$, and hence T is not self-adjoint. The examples just given show that a symmetric linear operator is not necessarily bounded. The *Hellinger-Toeplitz* Theorem gives sufficient conditions for a symmetric operator to be bounded: a symmetric linear operator whose domain is the entire space is bounded.

If a linear operator $T : \mathcal{D}(T) \subseteq H_1 \to H_2$ is closed, then $\mathcal{D}(T)$ is a Hilbert space when endowed with the *graph inner product*:

$$\langle (x, Tx), (y, Ty)\rangle = \langle x, y\rangle + \langle Tx, Ty\rangle.$$

If T is closed and everywhere defined, i.e., $\mathcal{D}(T) = H_1$, then since the graph norm dominates the norm on H_1, we find, by the corollary to Banach's theorem (see the *inversion* section), that the norm in H_1 is equivalent to the graph norm. In particular, the operator T is then bounded. This is the *closed graph theorem*: a closed everywhere defined linear operator is bounded.

III. CONTRACTIONS

Suppose X is a Banach space and $D \subseteq X$. A vector $x \in D$ is called a *fixed point* of the mapping $T : D \to X$ if $Tx = x$. Every linear operator has a fixed point, namely the zero vector. But a nonlinear mapping may be free of fixed points. However, a mapping that draws points together in a uniform relative sense (a condition called contractivity) is guaranteed to have a fixed point.

Definition. A mapping $T : D \subseteq X \to X$ is called a *contraction* (relative to the norm $\|\cdot\|$ on X) if, $\|Tx - Ty\| \le \alpha\|x - y\|$, for all $x, y \in D$ and some positive constant $\alpha < 1$.

For example, if $L : X \to X$ is a bounded linear operator with $\|L\| < 1$, and $g \in X$, then the (*affine*) mapping $T : X \to X$ defined by $Tx = Lx + g$ is a contraction with contraction constant $\alpha = \|L\|$. As another example, consider the nonlinear integral operator $T : C[0, 1] \to C[0, 1]$ defined by

$$(Tu)(s) = \int_0^1 k(s, u(t))\, dt$$

where $k(\cdot, \cdot) \in C^1([0, 1] \times \mathbf{R})$ is a given kernel. If the kernel satisfies

$$\left|\frac{\partial}{\partial t}k(s, t)\right| \le \alpha, \quad \text{for all} \quad s, t$$

then

$$|(Tw)(s) - (Tu)(s)| = \left|\int_0^1 k(s, w(t)) - k(s, u(t))\, dt\right|$$
$$\le \alpha \int_0^1 |w(t) - u(t)|\, dt \le \alpha\|w - u\|.$$

Therefore, $\|Tw - Tu\| \le \alpha\|w - u\|$ and hence T is a contraction for the uniform norm if $\alpha < 1$.

The *Contraction Mapping Theorem* (elucidated by Banach in 1922) is a constructive existence and uniqueness theorem for fixed points. If D is a closed subset of a Banach space and $T : D \to D$ is a contraction, then the theorem guarantees the existence of a unique fixed point $x \in D$. This fixed point is the limit of any sequence constructed iteratively by $x_{n+1} = Tx_n$, where x_0 is an arbitrary vector in D. If α is a contraction constant for T, then there is an a priori error bound

$$\|x_n - x\| \le \frac{\alpha^n}{1 - \alpha}\|x_1 - x_0\|$$

and an *a posteriori* error bound

$$\|x_n - x\| \le \frac{1}{1 - \alpha}\|x_{n+1} - x_n\|$$

for x_n as an approximation to the unique fixed point x.

The contraction mapping theorem is often used to establish the existence and uniqueness of solutions of problems in function spaces. One such application is a simple *implicit function theorem*. Suppose $f \in C([a, b] \times \mathbf{R})$ satisfies

$$0 < m \le \left|\frac{\partial f}{\partial s}(t, s)\right| \le M$$

for some constants m and M. Then one can show that the equation $f(t, x) = 0$ implicitly defines a continuous function x on $[a, b]$. Indeed, the nonlinear operator $T : C[a, b] \to C[a, b]$ defined by

$$(Tx)(t) = x(t) - \frac{2}{m + M} f(t, x(t))$$

is, under the stated conditions, a contraction mapping on $C[a, b]$ with contraction constant $\alpha = (M - m)/(M + m)$. Therefore, T has a unique fixed point $x \in C[a, b]$. That is, there is a unique function $x \in C[a, b]$ satisfying

$$x(t) = x(t) - \frac{2}{m + M} f(t, x(t))$$

or, equivalently $f(t, x(t)) = 0$.

IV. SOME PRINCIPLES AND TECHNIQUES

A. Projection and Decomposition

The *projection property* is a key feature of the geometry of Hilbert space: a closed convex subset of a Hilbert space

contains a unique vector of smallest norm. By shifting the origin to a vector x, one sees that this is equivalent to saying that given a closed convex subset S of a Hilbert space H and a vector $x \in H$, there is a unique vector $Px \in S$ satisfying

$$\|x - Px\| = \min_{y \in S} \|x - y\|.$$

This purely geometric projection property has important applications in optimization theory. For example, consider the following simple example of optimal control of a one-dimensional dynamical system. Suppose a unit point mass is steered from the origin with initial velocity 1 by a control (external force) u. We are interested in a control that will return the particle to a "soft landing" at the origin in unit time while expending minimal effort, where the measure of effort is

$$\int_0^1 |u(t)|^2 \, dt.$$

We may formulate this problem in the Hilbert space $L^2[0, 1]$. The dynamics of the system are governed by the equations

$$\ddot{x} = u, \quad x(0) = 0, \quad \dot{x}(0) = 1, \quad x(1) = 0, \quad \dot{x}(1) = 0.$$

Suppose C is the set of all vectors u in $L^2[0, 1]$ for which the equations above are satisfied for some vector $x \in H^2[0, 1]$. It may be routinely verified that C is a closed convex subset of $L^2[0, 1]$ and hence C contains a unique vector of smallest L^2-norm, i.e., there is a unique minimal effort control that steers the system in the specified manner.

The (generally nonlinear) operator P defined above is called the (metric) *projection* of H onto S. If S is a closed subspace of H, then P is a bounded self-adjoint linear operator and $I - P$, where I is the identity operator, is the projection of H onto $S^\perp$. Since $x = Px + (I - P)x$, this provides a Cartesian decomposition of H, written $H = S \oplus S^\perp$, meaning that each vector in H can be written uniquely as a sum of a vector in S and a vector in $S^\perp$.

For example, suppose H is the completion of the space $C^1[0, 1]$ with respect to the inner product

$$\langle f, g \rangle = \int_0^1 f'(t)g'(t) \, dt + f(0)g(0),$$

and let S be the subspace of linear functions. Then $H = S \oplus S^\perp$ and we have seen that $S^\perp$ consists of those functions in H which vanish at 0 and 1. So in this instance the decomposition theorem expresses the fact that each function in H can be uniquely decomposed into the sum of a linear function and a function in H that vanishes at both end points of $[0, 1]$.

If S is a separable closed subspace of a Hilbert space H, then a representation of the projection operator P of H onto the subspace S can be given in terms of a complete orthonormal sequence $\{\phi_n\}$ for S. Indeed, if $x \in H$, then

$$\sum_n \langle x, \phi_n \rangle \phi_n - x \in S^\perp$$

since this vector is orthogonal to each member of the basis $\{\phi_n\}$ for S. Therefore,

$$Px = Px + P\left(\sum_n \langle x, \phi_n \rangle \phi_n - x \right) = \sum_n \langle x, \phi_n \rangle \phi_n.$$

There is an important relationship involving the nullspace, range, and adjoint of a bounded linear operator acting between Hilbert spaces. If $T : H_1 \to H_2$ is a bounded linear operator, then $N(T^*) = R(T)^\perp$. To see this, note that $w \in R(T)^\perp$ if and only if

$$0 = \langle Tx, w \rangle = \langle x, T^* w \rangle$$

for all $x \in H_1$, that is, if and only if $w \in N(T^*)$. By a previously discussed result on the second orthogonal complement we get the related result that $\overline{R(T)} = N(T^*)^\perp$. In particular, if T is a bounded linear operator with closed range, then the equation $Tf = g$ has a solution if and only if g is orthogonal to all solutions x of the homogeneous adjoint equation $T^* x = \theta$.

Replacing T with T^* and noting that $T^{**} = T$, we obtain two additional relationships between the nullspace, range, and adjoint. Taken together these relationships, namely

$$N(T^*) = R(T)^\perp, \qquad N(T^*)^\perp = \overline{R(T)},$$
$$N(T) = R(T^*)^\perp, \qquad N(T)^\perp = \overline{R(T^*)}$$

are sometimes collectively called the theorem on the *four fundamental subspaces*.

The Riesz Representation Theorem is a simple consequence of the decomposition theorem. If ℓ is a nonzero bounded linear functional on a Hilbert space H, then $N(\ell)^\perp = R(\ell^*)$ is one-dimensional and $H = N(\ell) \oplus N(\ell)^\perp$. Let $y \in N(\ell)^\perp$ be a unit vector. Then $x = Px + \langle x, y \rangle y$, where P is the projection operator of H onto $N(\ell)$. Therefore,

$$\ell(x) = \ell(\langle x, y \rangle y) = \langle x, y \rangle \ell(y) = \langle x, z \rangle$$

where $z = \overline{\ell(y)} y$.

B. The Spectral Theorem

We limit our discussion of the spectral theorem to the case of a compact self-adjoint operator. The spectral theorem gives a particularly simple characterization of the range

of such an operator. We have seen that the nonzero eigenvalues of a compact self-adjoint operator T of infinite rank form a sequence of real numbers $\{\lambda_n\}$ with $\lambda_n \to 0$ as $n \to \infty$. The corresponding eigenspaces $N(T - \lambda_n I)$ are all finite-dimensional and there is a sequence $\{v_n\}$ of orthonormal eigenvectors, that is, vectors satisfying

$$\|v_j\| = 1, \quad \langle v_i, v_j \rangle = 0, \quad \text{for} \quad i \neq j,$$
$$\text{and,} \quad Tv_j = \lambda_j v_j.$$

The closure of the range of T is the closure of the span of this sequence of eigenvectors. Since T is self-adjoint, $N(T)^\perp = \overline{R(T)}$; the decomposition theorem then gives the representation

$$w = Pw + \sum_{j=1}^{\infty} \langle w, v_j \rangle v_j$$

for all $w \in H$, where P is the projection operator from H onto $N(T)$. The range of T then has the form

$$Tw = \sum_{j=1}^{\infty} \lambda_j \langle w, v_j \rangle v_j.$$

This result is known as the spectral theorem. It can be extended (in terms of a Stieljes integral with respect to a projection valued measure on the real line) to bounded self-adjoint operators (and beyond).

C. The Singular Value Decomposition

The decomposition of a Hilbert space into the nullspace and eigenspaces of a compact self-adjoint operator can be simply extended to obtain a similar decomposition, called the *singular value decomposition* (SVD), for compact operators which are not necessarily self-adjoint. If $T : H_1 \to H_2$ is a compact linear operator from a Hilbert space H_1 into a Hilbert space H_2, then the operators T^*T and TT^* are both self-adjoint compact linear operators with nonnegative eigenvalues. By the spectral theorem, T^*T has an orthonormal sequence of eigenvectors, $\{u_j\}$, associated with its positive eigenvalues $\{\lambda_j\}$, that is complete in the subspace

$$\overline{R(T^*T)} = N(T^*T)^\perp = N(T)^\perp.$$

The numbers $\mu_j = \sqrt{\lambda_j}$ are called the *singular values* of T. If the vectors $\{v_j\}$ are defined by $v_j = \mu_j^{-1} T u_j$, then $\{v_j\}$ is a complete orthonormal set for $N(T^*)^\perp$ and the following relations hold:

$$Tu_j = \mu_j v_j \qquad \text{and} \qquad T^* v_j = \mu_j u_j.$$

The system $\{u_j, v_j; \mu_j\}$ is called a *singular system* for the operator T, and any $f \in H_1$ has, by the decomposition theorem, a representation in the form

$$f = Pf + \sum_{j=1}^{\infty} \langle f, u_j \rangle u_j$$

where P is the projection of H_1 onto $N(T)$ (the sum is finite if T has finite rank). It then follows that

$$Tf = \sum_{j=1}^{\infty} \mu_j \langle f, u_j \rangle v_j.$$

This is called the SVD of the compact linear operator T. The SVD may be viewed as a nonsymmetric spectral representation.

D. Operator Equations

Suppose $T : H_1 \to H_2$ is a compact linear operator and $\lambda \in \mathbf{C}$. If $\lambda \neq 0$, then it can be shown that $R(T - \lambda I)$ is closed. The *Fredholm Alternative* Theorem completely characterizes the solubility of equations of the type

$$Tf - \lambda f = g$$

where $\lambda \neq 0$ and $g \in H_2$. Such equations are called linear operator equations of the *second kind*. The "alternative" is this: either the operator $(T - \lambda I)$ has a bounded inverse, or λ is an eigenvalue of T. If the first alternative holds, then the equation has the unique solution $f = (T - \lambda I)^{-1} g$, and this solution depends continuously on g. In this case we say that the equation of the second kind is *well-posed*. On the other hand, if λ is an eigenvalue of T, then $\bar{\lambda}$ is an eigenvalue of T^* and the equation has a solution only if

$$g \in R(T - \lambda I) = N(T^* - \lambda I)^\perp.$$

That is, the equation has a solution only if g is orthogonal to the finite-dimensional eigenspace $N(T^* - \bar{\lambda} I)$.

The Fredholm Alternative is particularly simple if $T : H \to H$ is self-adjoint. In this case the eigenvalues are real and $N(T^* - \bar{\lambda} I) = N(T - \lambda I)$. Therefore, if λ is not an eigenvalue of T, that is, if the equation $Tf - \lambda f = g$ has no more than one solution, then

$$H = \{\theta\}^\perp = N(T - \lambda I)^\perp = R(T - \lambda I)$$

and hence the equation has a solution for any $g \in H$. Simply put, the Fredholm Alternative for a self-adjoint compact operator says that uniqueness of solutions $(N(T - \lambda I) = \{\theta\})$ implies existence of solutions for any right hand side $(R(T - \lambda I) = H)$.

The contraction mapping theorem can be applied to establish the existence and uniqueness of the solutions of certain *nonlinear* operator equations of the second kind, that is, equations of the form $Tf - \lambda f = g$. For example,

suppose $T: X \to Y$ is a mapping from a Banach space X to a Banach space Y, satisfying $\|Tu - Tv\| \le \mu\|u - v\|$. For nonzero $\lambda \in \mathbf{C}$ the equation $Tf - \lambda f = g$ then has a unique solution $f \in X$ for each $g \in Y$, if $\mu < |\lambda|$. Indeed, a solution of this equation is the unique fixed point of the contractive mapping $Af = \frac{1}{\lambda}(Tf - g)$. Further, the inverse mapping $g \mapsto f$ is continuous, that is, the original nonlinear equation of the second kind is well-posed.

Monotone operators form another general class of nonlinear operators for which unique solutions of certain operator equations of the second kind can be assured. Suppose H is a real Hilbert space. An operator $T: H \to H$ is called monotone if $\langle Tx - Ty, x - y\rangle \ge 0$ for all $x, y \in H$. If T is a continuous monotone operator and $\lambda < 0$, then a theorem of Minty insures the existence of a unique solution f of the operator equation of the second kind $Tf - \lambda f = g$, for each $g \in H$. Further, the inverse operator $J = (T - \lambda I)^{-1}$ is not just continuous, but *nonexpansive*, i.e., $\|Jh - Jg\| \le \|h - g\|$.

When $\lambda = 0$, the linear operator equation equation treated above becomes an operator equation of the *first kind*:

$$Tf = g.$$

In this case, the role of the Fredholm Alternative Theorem is to some extent played by *Picard's Theorem*. Let $\{u_j, v_j; \mu_j\}$ be a singular system for the compact linear operator T. Then $\{v_j\}$ is a complete orthonormal system for $\overline{R(T)}$. Picard's Theorem gives a necessary and sufficient condition for a vector $g \in \overline{R(T)} = N(T^*)^\perp$ to lie in $R(T)$, that is, for the equation of the first kind to have a solution. The condition, *Picard's criterion*, is that the singular coefficients of g decay sufficiently quickly, specifically, that

$$\sum_{j=1}^{\infty} \mu_j^{-2} |\langle g, v_j\rangle|^2 < \infty.$$

If Picard's criterion is satisfied, then the series

$$\sum_{j=1}^{\infty} \frac{\langle g, v_j\rangle}{\mu_j} u_j$$

converges to some vector $f \in H_1$ and

$$Tf = \sum_{j=1}^{\infty} \langle g, v_j\rangle v_j = g,$$

and hence the equation has a solution, namely f. The solution is unique only if $N(T) = \{\theta\}$.

E. Inversion

An invertible bounded linear operator need not have a bounded inverse. For example, the operator $T: L^2[0,1] \to C[0,1]$ defined by $(Tf)(s) = \int_0^s f(t)\,dt$ has an inverse defined on the subspace of absolutely continuous functions which vanish at 0. But the inverse operator $T^{-1}g = g'$ is an unbounded operator.

If $T \in L(X, Y)$, where X and Y are Banach spaces, then the existence of a bounded inverse for T is equivalent to the condition $\|Tx\| \ge m\|x\|$ for some $m > 0$. Indeed, if this condition is satisfied, then $N(T) = \{\theta\}$, $R(T)$ is closed in Y, and $T^{-1}: R(T) \to X$ satisfies $\|T^{-1}\| \le m^{-1}$. On the other hand, if T^{-1} is bounded, then the condition holds with $m = \|T^{-1}\|^{-1}$. If T is bijective, i.e., if $N(T) = \{\theta\}$ and $R(T) = Y$, then *Banach's Theorem* insures that the inverse of T is also bounded, i.e., $T^{-1} \in L(Y, X)$. One consequence of this fact is that if a normed linear space X is a Banach space under two norms $\|\cdot\|_1$ and $\|\cdot\|_2$, and if these norms satisfy $\|x\|_2 \le M\|x\|_1$ for some $M > 0$, then the norms are equivalent (apply Banach's Theorem to the identity operator $I: (X, \|\cdot\|_1) \to (X, \|\cdot\|_2)$).

The familiar geometric series has an operator analog. If X is a Banach space and $T: X \to X$ is a bounded linear operator with $\|T\| < 1$, then $(I - T)^{-1} \in L(X, X)$ and, in fact,

$$(I - T)^{-1} = I + T + T^2 + \cdots$$

where the series, called the *Neumann series*, converges in the operator norm. This result can be used immediately to guarantee the existence of a unique solution of the linear operator equation of the second kind $Tf - \lambda f = g$, if $|\lambda|$ is sufficiently large ($|\lambda| > \|T\|$ does the trick).

The existence of an inverse of $T \in L(X, Y)$ is equivalent to the unique solvability of the equation $Tf = g$ for each $g \in Y$. This, in turn, is equivalent to $R(T) = Y$ and $N(T) = \{\theta\}$. If either of these conditions is violated, then there is no inverse, but all is not lost. In certain circumstances a *generalized inverse* can be defined; we limit our discussion of the generalized inverse to the Hilbert space context. Suppose $T: H_1 \to H_2$ is a bounded linear operator from a Hilbert space H_1 to a Hilbert space H_2. Suppose we wish to solve the equation $Tf = g$. If $g \notin R(T)$, then the equation has no solution and we might settle for finding an $f \in H_1$ whose image under T is a close to g as possible, that is, we seek $f \in H_1$ satisfying

$$\|Tf - g\| = \inf\{\|Tx - g\| : x \in H_1\}.$$

Such an f is called a *least-squares solution* of $Tf = g$. A least-squares solution exists if and only if the projection of g onto $\overline{R(T)}$ actually lies in $R(T)$. This is equivalent to requiring g to lie in the dense subspace $R(T) + R(T)^\perp$ of H_2. The condition for a least-squares solution may also be phrased as requiring that $Tf - g \in R(T)^\perp = N(T^*)$ (see the theorem on the four fundamental subspaces). This gives another characterization of least-squares solutions: u is a least-squares solution of $Tf = g$ if and only if u

satisfies the *normal equation* $T^*Tu = T^*g$. Since T is bounded, the set of solutions of the normal equation is closed and convex, and hence, by the projection theorem, if there is a least-squares solution, then there is a least-squares solution of smallest norm. These ideas enable us to define a generalized inverse (the *Moore-Penrose generalized inverse*) for T. Let $\mathcal{D}(T^\dagger) = R(T) + R(T)^\perp$ and for $g \in \mathcal{D}(T^\dagger)$, define $T^\dagger g$ to be the least-squares solution having smallest norm. The Moore-Penrose generalized inverse, $T^\dagger : \mathcal{D}(T^\dagger) \subseteq H_2 \to H_1$, is a closed densely defined linear operator. However, $T^\dagger$ is bounded if and only if $R(T)$ is closed. If T is compact, then $R(T)$ is closed if and only if T has finite rank. In particular, a linear integral operator generated by a square integrable kernel has a bounded Moore-Penrose generalized inverse if and only if the kernel is degenerate. If T is compact with singular system $\{u_j, v_j; \mu_j\}$, the the Moore-Penrose generalized inverse has the explicit representation

$$T^\dagger g = \sum_j \frac{\langle g, v_j \rangle}{\mu_j} u_j.$$

F. Variational Inequalities

Suppose H is a real Hilbert space with inner product $\langle \cdot, \cdot \rangle$ and corresponding norm $\|\cdot\|$. A bilinear form $a(\cdot, \cdot): H \times H \to \mathbf{R}$ is called *bounded* if there is a constant C such that

$$|a(u, v)| \le C\|u\|\|v\| \quad \text{for all} \quad u, v \in H$$

and *coercive* if there is a constant $m > 0$ such that

$$m\|u\|^2 \le a(u, u)$$

for all $u \in H$. A fundamental result of Stampacchia asserts that if $a(\cdot, \cdot)$ is a bounded, coercive bilinear form (which *need not be symmetric*), and if $f \in H$ and K is a closed convex subset of H, then there is a unique $u \in K$ satisfying

$$a(u, v - u) \ge \langle f, v - u \rangle \quad \text{for all} \quad v \in K.$$

This is called a *variational inequality* for the form $a(\cdot, \cdot)$, the closed convex set K, and the vector $f \in H$.

The fundamental nature of this result becomes apparent when one notices that the projection property for Hilbert space is a special case of this result on variational inequalities. Indeed, if $a(x, y) = \langle x, y \rangle$, then the theorem insures the existence of a unique $u \in K$ satisfying

$$\langle u, v - u \rangle \ge \langle f, v - u \rangle$$

or, equivalently

$$\langle f - u, v - u \rangle \le 0 \quad \text{for all} \quad v \in K.$$

Geometrically, this says that the angle between the vectors $f - u$ and $v - u$ is obtuse for all vectors $v \in K$. From this it follows that $u \in K$ is the vector in K that is nearest to f, that is, $u = Pf$, the metric projection of f onto K.

A nonsymmetric version of the Riesz Representation Theorem also follows from the theorem on variational inequalities. Suppose ℓ is a bounded linear functional on H. Then, by the Riesz Representation Theorem, there is a $f \in H$ such that $\ell(w) = \langle f, w \rangle$ for all $w \in H$. Let the closed convex set K be the entire Hilbert space H, then there is a unique $u \in H$ satisfying

$$a(u, v - u) \ge \langle f, v - u \rangle \quad \text{for all} \quad v \in H$$

and hence $a(u, w) \ge \langle f, w \rangle$ for all $w \in H$. Replacing w by $-w$, we also get $a(u, -w) \ge \langle f, -w \rangle$ for all $w \in H$. Therefore, $a(u, w) = \langle f, w \rangle$ for all $w \in H$. That is, the functional ℓ has the representation $\ell(w) = a(u, w)$ for a unique $u \in H$. This representation of bounded linear functional in terms of a possibly nonsymmetric bilinear form is known as the *Lax-Milgram lemma*. The Lax-Milgram lemma can be used to establish the existence of a unique weak solution for certain nonsymmetric elliptic boundary value problems in the same way that the Riesz Representation Theorem is used to prove the existence of a unique weak solution of the Poisson problem.

As a simple application of the Lax-Milgram lemma, consider the two-point boundary value problem

$$-u'' + u' + u = f, \qquad u'(0) = u'(1) = 0.$$

Integration by parts yields $a(u, v) = \langle f, v \rangle$, where $\langle \cdot, \cdot \rangle$ is the $L^2[0, 1]$ inner product and $a(u, v)$ is the nonsymmetric, bounded, coercive, bilinear form defined on $H^1[0, 1]$ by

$$a(u, v) = \int_0^1 (u'v' + u'v + uv)(s)\, ds.$$

The Lax-Milgram lemma then ensures the existence of a unique weak solution $u \in H^1[0, 1]$ of the boundary value problem, that is, a unique vector $u \in H^1[0, 1]$ satisfying

$$a(u, v) = \langle f, v \rangle \quad \text{for all} \quad v \in H^1[0, 1].$$

V. A FEW APPLICATIONS

A. Weak Solutions of Poisson's Equation

Suppose Ω is a bounded domain in $\mathbf{R}^2$ with smooth boundary $\partial\Omega$. Given $f \in C(\Omega)$ a classical solution of Poisson's equation is a function $u \in C^2(\Omega)$ satisfying

$$\begin{aligned} -\Delta u &= f \quad \text{in} \quad \Omega \\ u &= 0 \quad \text{on} \quad \partial\Omega \end{aligned}$$

where Δ is the Laplacian operator. If the Poisson equation is multiplied by $v \in C_0^2(\Omega)$ and integrated over Ω, then Green's identity gives

$$\langle \nabla u, \nabla v \rangle = \langle f, v \rangle$$

where ∇ is the gradient operator and $\langle \cdot, \cdot \rangle$ is the $L^2(\Omega)$ inner product. There are two things to notice about this equation: $\langle f, v \rangle$ is defined for $f \in L^2(\Omega)$, allowing consideration of "rougher" data f, and on the left-hand side only first derivatives are required rather than second derivatives, allowing less smooth "solutions" u. These observations permit us to propose a *weaker* formulation of the Poisson problem.

The bilinear form $a(\cdot, \cdot)$ defined by $a(u, v) = \langle \nabla u, \nabla v \rangle$ is an inner product (sometimes called the *energy* inner product) on the space $C_0^1(\Omega)$ (this is a consequence of Poincaré's inequality: $a(u, u) \geq C\|u\|_2^2$, where $\|\cdot\|_2$ is the L^2 norm). The norm generated by this inner product is equivalent to the Sobolev $H_0^1(\Omega)$ norm. Therefore, the completion of $C_0^1(\Omega)$ relative to this inner product is the Sobolev space $H_0^1(\Omega)$, and we define a *weak solution* of the Poisson problem to be a vector $u \in H_0^1(\Omega)$ satisfying

$$a(u, v) = \langle f, v \rangle$$

for all $v \in H_0^1(\Omega)$. The linear functional $\ell : H_0^1(\Omega) \to \mathbf{R}$ defined by $\ell(v) = \langle f, v \rangle$ is (again, as a consequence of Poincaré's inequality) a bounded linear functional on $H_0^1(\Omega)$, and hence, by the Riesz Representation Theorem, there is a unique $u \in H_0^1(\Omega)$ satisfying

$$a(u, v) = \langle f, v \rangle \quad \text{for all} \quad v \in H_0^1(\Omega).$$

In other words, Poisson's problem has a unique weak solution for each $f \in L^2(\Omega)$.

B. A Finite Element Method

A finite element method is a constructive precedure for approximating a weak solution by a linear combination of "basis" functions. As a simple illustration we treat a piecewise linear finite element method for the Poisson problem in the plane. A finite dimensional subspace U_N of $H_0^1(\Omega)$ chosen and a basis (whose members are called *finite elements*) is selected for U_N. The finite element approximation to the weak solution will be a certain linear combination of these basis functions, i.e., a member of U_N. First the region Ω is triangulated; the vertices of the resulting triangles are called *nodes* of the triangulation. The functions in U_N will be continuous on Ω, linear on each triangle, and zero on the boundary of Ω. With each interior node of the triangulation we associate a basis function which is 1 at the node and zero at all other nodes of the triangulation (these basis functions are called the linear *Lagrange* elements).The dimension of the finite element subspace is therefore equal to the number of interior nodes in the triangulation and each basis function has a pyramidal shape with a peak at the associated nodal point of the triangulation.

A finite element solution of the Poisson problem is defined by restricting the conditions for a weak solution to the subspace of finite elements, that is, $u_N \in U_N$ is a finite element solution of the Poisson problem if

$$a(u_N, v) = \langle f, v \rangle \quad \text{for all} \quad v \in U_N.$$

When this condition is expressed in terms of the finite element basis, the resulting coefficient matrix is positive definite and hence there is a unique finite element solution.

If u is the weak solution of the Poisson problem, then

$$a(u - u_N, v) = \langle f, v \rangle - \langle f, v \rangle = 0$$

for all $v \in U_N$. Geometrically, this says that the finite element solution is the projection (relative to the energy inner product) of the weak solution onto the finite element subspace and hence,

$$\|u - u_N\| \leq \|u - v\|$$

for all $v \in U_N$, where $\|\cdot\|$ is the energy norm. That is, the finite element solution is the best approximation to the weak solution, with respect to the energy norm, in the finite element subspace.

C. Two-Point Boundary Value Problems

We briefly treat a simple class of Sturm-Liouville problems. The goal is to find $x \in C^2[a, b]$ satisfying the differential equation

$$\frac{d}{ds}\left[p(s)\frac{dx}{ds}\right] - [\mu + q(s)]\,x(s) = f(s)$$

where $q,\ f \in C[a, b]$ and $p \in C^1[a, b]$ are given functions and $\mu \neq 0$ is a given scalar. Define $T : C_0^2[a, b] \to C[a, b]$ by

$$Tx = [px']' - qx.$$

We suppose the this differential operator is *nonsingular*, that is, $N(T) = \{\theta\}$ (such is the case, for example, if $p(s) < 0$ and $q(s) \leq 0$). Then there is a symmetric *Green's function* $k(\cdot, \cdot) \in C[a, b] \times C[a, b]$ for T. That is, T^{-1} is the integral operator generated by the kernel $k(\cdot, \cdot)$. In other words, $Tx = h$ if and only if

$$x(s) = \int_a^b k(s, t)h(t)\,dt.$$

The original problem may then be expressed as

$$Tx = \mu x + f$$

or, in terms of the Green's function $k(\cdot, \cdot)$:

$$x(s) = \int_a^b k(s, t)[\mu x(t) + f(t)]\,dt.$$

Equivalently,

$$Kx - \lambda x = g$$

where $\lambda = 1/\mu$ and $g = -\lambda K f$, where K is the compact self-adjoint operator on $L^2[a, b]$ generated by the kernel $k(\cdot, \cdot)$. If λ is not an eigenvalue of K, then this integral equation of the second kind has, by Fredholm's Alternative, a solution which is expressable, via the spectral theorem, as a series of eigenfunctions of K. Specifically, $\overline{R(K)}$ has an orthonormal basis of eigenfunctions $\{v_j\}$ of K and therefore,

$$x = (K - \lambda I)^{-1} g = -\lambda (K - \lambda I)^{-1} K f = \sum_j \frac{\lambda \lambda_j}{\lambda - \lambda_j} \langle f, v_j \rangle v_j .$$

D. Inverse Problems

Many inverse problems in mathematical physics can be modeled as operator equations of the first kind, $Kx = y$, where K is a compact linear operator acting between Hilbert spaces. Consider, for example, the simple model problem in gravimetry in which the vertical component of gravity, $y(s)$, along a horizontal segment $0 \le s \le 1$ is engendered by a mass distribution $x(p)$, $0 \le p \le 1$ on a parallel segment one unit distant from the first. The relationship between y and x is given by

$$y(s) = \gamma \int_0^1 ((s - p)^2 + 1)^{-\frac{3}{2}} x(p)\, dp$$

where γ is a constant. The inverse problem consists of determining the mass distribution from observations of the vertical force y. The model may be phrased abstractly as $y = Kx$, where $K : H \to H$ is a compact linear operator acting on the Hilbert space $H = L^2[0, 1]$.

Formally, the inverse problem may be solved by using the Moore-Penrose generalized inverse: $x = K^\dagger y$. However, the representation of $K^\dagger$ in terms of the SVD of K

$$x = K^\dagger y = \sum_{j=1}^{\infty} \frac{\langle y, v_j \rangle}{\mu_j} u_j$$

points to a serious problem. The singular values $\{\mu_j\}$ converge to zero leading to instability in the solution process. The vector y is a measured entity and hence is subject to error. Suppose, for example, the measured data consists of a vector $y^\delta \in H$ satisfying $\|y - y^\delta\| \le \delta$, where δ is a known bound for the measurement error. While $y^\delta \to y$ as $\delta \to 0$, generally $\|K^\dagger y - K^\dagger y^\delta\| \to \infty$ as $\delta \to 0$. For example, if $\delta = \sqrt{\mu_n}$, where $n = 1, 2, \ldots$, and $y^\delta = y + \sqrt{\mu_n} v_n$, then $\|y - y^\delta\| = \sqrt{\mu_n} \to 0$, while $\|K^\dagger y - K^\dagger y^\delta\| = 1/\sqrt{\mu_n} \to \infty$ as $n \to \infty$. The lesson is that even very accurate measurements can lead to wildly unstable computations.

Stability can be restored (at the expense of accuracy) by the method of *regularization*. In its simplest form this method replaces the normal equation with an augmented (or *regularized*) normal equation

$$K^* K x_\alpha + \alpha x_\alpha = K * y,$$

where $\alpha > 0$ is a *regularization parameter*. That is, an ill-posed equation of the first kind is replaced by an approximating well-posed equation of the second kind. The solution x_α of the regularized equation is stable with respect to perturbations in the data y since $-\alpha < 0$ is not an eigenvalue of $K^* K$ and hence, by the Fredholm Alternative, $(K^* K + \alpha I)^{-1}$ is bounded.

The regularized normal equation must be solved using the available data y^δ and hence the choice of the regularization parameter, in terms of the available data, is a matter of considerable importance. One general method for choosing the regularization parameter is known as Morozov's discrepancy principle. According to this principle, if the signal-to-noise ratio is greater than one, i.e., $\|y^\delta\| > \delta \ge \|y - y^\delta\|$ and $x_\alpha^\delta = (K^* K + \alpha I)^{-1} K^* y^\delta$, then the equation

$$\left\| K x_\alpha^\delta - y^\delta \right\| = \delta$$

has a unique positive solution $\alpha = \alpha(\delta)$ and $x_{\alpha(\delta)}^\delta \to K^\dagger y$ as $\delta \to 0$.

E. Heisenberg's Principle

Heisenberg's uncertainty principle in quantum mechanics is a consequence of an inequality involving unbounded self-adjoint operators. We will consider only a very simple case. Suppose a particle moves in one dimension, its position at a given time t denoted by $x \in (-\infty, \infty)$. In the quantum mechanical formalism the position of the particle is understood to be a random variable and it is the *state*, rather than the position, that is at issue. The state is a function ψ which is a unit vector in the complex Hilbert space $H = L^2(-\infty, \infty)$; the interpretation being that

$$\int_a^b \psi(s) \overline{\psi(s)}\, ds$$

represents the probability that at the time in question the particle is positioned between a and b. In other words, the integrable real-valued function $\psi \bar{\psi}$ is a probability density for the position. In general, a unit vector in H is called a *state*. A self-adjoint linear operator $T : \mathcal{D}(T) \subseteq H \to H$ is called an *observable*. The *expected value* of an observable T when the system is in state ψ is

$$E(T) = \langle T\psi, \psi \rangle = \int_{-\infty}^{\infty} T\psi(s) \overline{\psi(s)}\, ds$$

For example, the expected value of the multiplication by the independent variable operator, $(M\psi)(x) = x\psi(x)$,

$$E(M) = \int_{-\infty}^{\infty} x\psi(x)\overline{\psi(x)}\, dx$$

is the mean position of the particle (slight modifications of the arguments given in the section on unbounded operators show that M is unbounded and self-adjoint). For this reason the observable M is called the *position* operator. The *variance* of an observable T when the system is in state ψ is defined by

$$Var(T) = \|(T - E(T)I)\psi\|^2.$$

That is, the variance gives a measure of the dispersion of an observable from its expected value.

Definition. The *commutator* of two observables S and T is the observable $[S, T] : \mathcal{D}(ST) \cap \mathcal{D}(TS) \to H$ defined by $[S, T] = ST - TS$.

S and T are said to *commute* if $ST = TS$, i.e., $\mathcal{D}(ST) = \mathcal{D}(TS)$ and $[S, T] = 0$. In abstract form the Heisenberg principle says that for any state $\psi \in \mathcal{D}([S, T])$

$$\frac{1}{4}|E([S, T])|^2 \leq Var(S) \times Var(T).$$

Suppose $\mathcal{D}(\mathcal{P})$ is the subspace of all absolutely continuous functions in H whose first derivative is also in H. Define the operator $\mathcal{P} : \mathcal{D}(\mathcal{P}) \to H$ by

$$\mathcal{P}\psi(x) = \frac{h}{2\pi i}\psi'(x)$$

where h is *Planck's constant*. Then $\mathcal{P}$ is self-adjoint, that is, an observable. A physical argument shows that $E(\mathcal{P})$ is the expected value of the momentum of the system and hence $\mathcal{P}$ is called the *momentum operator*. The commutator of the momentum and position operators can be found from the relation

$$(\mathcal{P}M\psi)(x) = \frac{h}{2\pi i}\frac{d}{dx}[x\psi(x)] = \frac{h}{2\pi i}[\psi(x) + x\psi'(x)]$$
$$= \frac{h}{2\pi i}\psi(x) + (M\mathcal{P}\psi)(x)$$

i.e., for all $\psi \in \mathcal{D}([\mathcal{P}, M])$:

$$[\mathcal{P}, M]\psi = \frac{h}{2\pi i}\psi.$$

The general Heisenberg principle then gives

$$Var(\mathcal{P}) \times Var(M) \geq \left(\frac{h}{4\pi}\right)^2.$$

This is an expression of the physical uncertainty principle: no matter the state ψ, the position and momentum can not both be determined with arbitrary certainty.

Generalized Functions

Ram P. Kanwal
Pennsylvania State University

GLOSSARY

Convolution The convolution $f * g$ of two functions $f(x)$ and $g(x)$ is defined as $\int_{-\infty}^{\infty} f(y)\, g(x-y)\, dy$. This concept carries over to the generalized functions also.

Dirac delta function $\delta(x)$ This function is intuitively defined to be zero when $x \neq 0$ and infinite at $x = 0$, in such a way that the area under it is unity.

Distribution A linear continuous functional.

Distributional (generalized) derivatives Nonclassical derivatives of the generalized functions which do not have classical derivatives at their singularities.

Functional A rule which assigns a number $\langle t, \phi \rangle$ to a test function $\phi(x)$ through a generalized function $t(x)$.

Hadamard finite part Finite difference of two infinite terms for defining divergent integrals.

Impulse response The particular solution of a differential equation with $\delta(x)$ (impulse) as its forcing term.

Pseudo-function Singular functions such as $1/x^k$ which are regularized at their singularity with the help of concepts such as the Hadamard finite part.

Regular distributions Distributions based on locally integrable functions.

Singular distributions (generalized functions) Distributions which are not regular.

Test function space A space of suitable smooth functions $\phi(x)$ which is instrumental in defining a generalized function such as $\delta(x)$ as a distribution.

GENERALIZED FUNCTIONS are objects, such as the Dirac delta function, with such inherent singularities that they cannot be integrated or differentiated in the classical sense. By defining them as functionals (distributions) which carry smooth functions to numbers, we can overcome the difficulty. Then they possess remarkable properties that extend the capabilities of the classical mathematics. Indeed, the techniques based on the generalized functions not only solve the classical problems in a simple fashion but also produce many new concepts. Accordingly, they have influenced many topics in mathematical and physical sciences.

I. INTRODUCTION

Functions such as Dirac's delta function and Heaviside function have been used by scientists even though the former is not a function and the latter is not a differentiable function in the classical sense. The theory of distributions has provided us not only with mathematical foundations for these functions but also for various other nonclassical functions. The rudiments of the theory of distributions can be found in the concepts of the Hadamard finite part of the divergent integrals and sequences which in the limit behave like delta function. However, it was Sobolev and Schwartz who established the modern theory of distributions.

The Dirac delta function $\delta(x-\xi)$, also called the impulse function, is usually defined as a function which is zero everywhere except at $x=\xi$, where it has a spike such that $\int_{-\infty}^{\infty}\delta(x-\xi)\,dx=1$. More generally, it is defined by its sifting property,

$$\int_{-\infty}^{\infty} f(x)\delta(x-\xi)\,dx = f(\xi), \tag{1}$$

for all continuous functions $f(x)$. However, for any acceptable definition of integration there can be no such function. This difficulty was subsequently overcome by two approaches. The first is to define the delta function as the limit of delta sequences, while the second is to define it as a distribution. The reasoning behind a delta sequence is that although the delta function cannot be justified mathematically, there are sequences $\{s_m(x)\}$ which in the limit $m\to\infty$ satisfy the relation (1). An interesting sequence is

$$s_m(x) = \frac{1}{\pi}\frac{m}{1+m^2x^2}. \tag{2}$$

It is instructive to imagine (2) as a continuous charge distribution on a line, so that the total charge $s_m(x)$ to the left of x is $r_m(x)=\int_{-\infty}^{x}s_m(u)\,du=\frac{1}{2}+(1/\pi)\tan^{-1}mx$. Because $\int_{-\infty}^{\infty}s_m(x)\,dx=1$, the total charge on the line is equal to unity. Furthermore, it can be readily proved that

$$\lim_{m\to\infty}\int_{-\infty}^{\infty} f(x)s_m(x)\,dx = f(0).$$

Accordingly, it satisfies the sifting property (1).

Defining $\delta(x)$ as a distribution is much more convenient and useful. Moreover, the theory of distributions helps us define many more functions which are singular in nature.

II. DISTRIBUTIONS

To make $\delta(x)$ meaningful, we appeal to various spaces of smooth functions. We start with the real-valued functions $\phi(\boldsymbol{x})$, where $\boldsymbol{x}=(x_1,\ldots,x_n)\in\mathbb{R}^n$, the n-dimensional Euclidean space. To describe various properties of these functions we introduce the multi-index notation. Let $\boldsymbol{k}$ be an n-tuple of non-negative integers: $\boldsymbol{k}=(k_1\ldots,k_n)$. Then we define

$$\begin{aligned}
&|\boldsymbol{k}| = k_1+\cdots+k_n; \qquad \boldsymbol{x}^{\boldsymbol{k}} = x_1^{k_1}\cdots x_n^{k_n};\\
&\boldsymbol{k}! = k_1!\cdots k_n!;\\
&\binom{\boldsymbol{k}}{\boldsymbol{m}} = \frac{\boldsymbol{k}!}{m!(\boldsymbol{k}-\boldsymbol{m})!}; \qquad D_j = \frac{\partial}{\partial x_j};\\
&\boldsymbol{D}^{\boldsymbol{k}} = \frac{\partial^{|\boldsymbol{k}|}}{\partial x_1^{k_1}\cdots\partial x_n^{k_n}} = \frac{\partial^{k_1+\cdots+k_n}}{\partial x_1^{k_1}\cdots\partial x_n^{k_n}} = D_1^{k_1}\ldots D_n^{k_n}.
\end{aligned} \tag{3}$$

We are now ready to state the properties of the functions $\phi(\boldsymbol{x})$. They are (1) $D^{\boldsymbol{k}}\phi(\boldsymbol{x})$ exists for all multi-indices $\boldsymbol{k}$. (2) There exists a number A such that $\phi(\boldsymbol{x})$ vanishes for $r>A$, where r is the radial distance $r=(x_1^2+\cdots+x_n^2)^{1/2}$. This means that $\phi(\boldsymbol{x})$ has a compact support. These two properties are written symbolically as $\phi(\boldsymbol{x})\in C_0^\infty$, where the superscript stands for infinite differentiability, the subscript for the compact support. This space of functions is denoted by $\mathcal{D}$, and $\phi(\boldsymbol{x})$ are called the test functions. The prototype example in $\mathbb{R}$ is

$$\phi(x) = \begin{cases} \exp\left(-\dfrac{a^2}{a^2-x^2}\right), & |x|<a,\\ 0, & |x|>a. \end{cases} \tag{4}$$

Note that the definition of $\mathcal{D}$ does not demand that all $\phi(\boldsymbol{x})$ have the same support. Furthermore, we observe that (a) $\mathcal{D}$ is a linear (vector) space, because if ϕ_1 and ϕ_2 are in $\mathcal{D}$, then so is $c_1\phi_1+c_2\phi_2$ for arbitrary real numbers. (b) If $\phi\in\mathcal{D}$, then so is $D^{\boldsymbol{k}}\phi$. (c) For a C^∞ function of $f(\boldsymbol{x})$ and a $\phi(\boldsymbol{x})\in\mathcal{D}$, $f\phi\in\mathcal{D}$. (d) If $\phi(x_1,\ldots,x_m)$ is an m-dimensional test function and $\psi(x_{m+1,\ldots,x_n})$ is an $(n-m)$-dimensional test function, then $\phi\psi$ is an n-dimensional test function in the variables $x_1,\ldots,x_n$.

With the following four definitions we are able to grasp the concept of distributions:

1. A sequence $\{\phi_m(\boldsymbol{x})\}$, $m = 1, 2, \ldots$, for all $\phi_m \in \mathcal{D}$, converges to ϕ_0 if the following two conditions are satisfied. (a) All ϕ_m as well as ϕ_0 vanish outside a common region. (b) $D^{\boldsymbol{k}}\phi_m \to \mathcal{D}^{\boldsymbol{k}}\phi_0$ uniformly over $\mathbb{R}^n$ as $m \to \infty$, for all multi-indices $\boldsymbol{k}$. For the special case $\phi_0 = 0$, the sequence $\{\phi_m\}$ is called a null sequence.
2. A linear functional $t(\boldsymbol{x})$ on the space $\mathcal{D}$ is an operation by which we assign to every test function $\phi(\boldsymbol{x})$ a real number $\langle t(\boldsymbol{x}), \phi(\boldsymbol{x})\rangle$ such that $\langle t, c_1\phi_1 + c_2\phi_2\rangle = c_1\langle t, \phi_1\rangle + c_2\langle t, \phi_2\rangle$ for arbitrary test functions $\phi_1(\boldsymbol{x})$ and $\phi_2(\boldsymbol{x})$ and real numbers c_1 and c_2. Then it follows that $\langle t, \sum_{j=1}^{m} c_j\langle\phi_j\rangle = \sum_{j=1}^{m} c_j\langle t, \phi_j\rangle$, where c_j are arbitrary real numbers.
3. A linear functional $t(\boldsymbol{x})$ on $\mathcal{D}$ is called *continuous* if and only if the sequence of numbers $\langle t, \phi_m\rangle \to \langle t, \phi\rangle$, as $m\to\infty$, when the sequence $\{\phi_m\}$ of test functions converges to $\phi \in \mathcal{D}$, that is,
$$\lim_{m\to\infty}\langle t, \phi_m\rangle = \langle t, \lim_{m\to\infty}\phi_m\rangle.$$
4. A continuous linear functional on the space $\mathcal{D}$ is called a distribution.

The set of distributions that is most useful is the ones generated by locally integrable functions $f(x)$ (that is, $\int_\Omega[f(\boldsymbol{x})]\,d\boldsymbol{x}$ exists for every bounded region Ω of $\mathbb{R}^n$). Indeed, every locally integrable function $f(\boldsymbol{x})$ generates a distribution through the relation $\langle f, \phi\rangle = \int_\Omega f(\boldsymbol{x})\phi(\boldsymbol{x})\,d\boldsymbol{x}$. The linearity and continuity of this functional can be readily proved. The distributions produced by locally integrable functions are called *regular distributions* or distributions of order zero. All the other ones are called *singular distributions*. We present two examples in the one-dimensional space $\mathbb{R}$.

1. Heaviside distribution:
$$H(x) = \begin{cases} 0, & x < 0, \\ 1, & x > 0. \end{cases}$$
The Heaviside distribution defines the regular distribution $\langle H, \phi\rangle = \int_0^\infty \phi(x)\,dx$. It is clearly a linear functional. It is also continuous because $\lim_{m\to\infty}\langle H(x), \phi_m(x)\rangle = \lim_{m\to\infty}\int_0^\infty \phi_m(x) = \int_0^\infty \phi(x)\,dx$, where $\phi(x)$ is the limit of the sequence $\{\phi_m(x)\}$ as $m \to \infty$. Thus,
$$\lim_{m\to\infty}\langle H(x), \phi_m(x)\rangle = \langle H(x), \lim_{m\to\infty}\phi_m(x)\rangle.$$

2. The Dirac delta function $\delta(x-\xi)$. By the sifting property (1) we have $\langle\delta(x-\xi), \phi(x)\rangle = \int_{-\infty}^{\infty}\delta(x-\xi)\times\phi(x)\,dx = \phi(\xi)$, a number. The linearity also follows from the sifting property. This functional is continuous because $\lim_{m\to\infty}\langle\delta(x-\xi), \phi_m(x)\rangle = \lim_{m\to\infty}\phi_m(\xi) = \langle\delta(x-\xi), \lim_{m\to\infty}\phi_m(x)\rangle$. Since $\delta(x-\xi)$ is not a locally integrable function, it produces a singular distribution. These results hold in $\mathbb{R}^n$ as well. The functions which generate singular distributions are called generalized functions. We shall use these words interchangeably. The definition of a distribution can be extended to include complex-valued functions.

The dual space $\mathcal{D}'$. The space of all distributions on $\mathcal{D}$ is called the *dual space* of $\mathcal{D}$ and is denoted as $\mathcal{D}'$. It is also a linear space.

There are many other interesting spaces. For example, the test function space $\mathcal{E}$ consists of all the functions $\phi(\boldsymbol{x})$, so there is no limit on their growth at infinity. Accordingly, $\mathcal{E} \supset \mathcal{D}$. The corresponding space $\mathcal{E}'$ consists of the distributions which have compact support, so that $\mathcal{E}' \supset \mathcal{D}'$. The distributions of slow growth are defined in Sect. IX.

III. ALGEBRAIC OPERATIONS ON DISTRIBUTIONS

Let $\langle t(x), \phi(x)\rangle$ be a regular distribution generated by a locally integrable function $t(x) \times \in \mathbb{R}$. Let $x = ay - b$, where a and b are constants. Then we have
$$\begin{aligned}\langle t(ay-b), \phi(y)\rangle &= \int_{-\infty}^{\infty} t(ay-b)\phi(y)\,dy \\ &= \frac{1}{|a|}\int_{-\infty}^{\infty} t(x)\phi\left(\frac{x+b}{a}\right)dx \\ &= \frac{1}{|a|}\left\langle t(x), \phi\left(\frac{x+b}{a}\right)\right\rangle. \qquad (5)\end{aligned}$$
For the special case $a = 1$, relation (5) becomes $\langle t(y-b), \phi(y)\rangle = \langle t(x), \phi(x+b)\rangle$. As another special case, (5) yields $\langle\delta(-y), \phi(y)\rangle\langle\delta(x), \phi(-x)\rangle = \phi(0)$. Thus $\delta(x)$ is an even function.

A distribution is called homogeneous of degree λ if $t(ax) = a^\lambda t(x)$, $a > 0$. In view of relation (5) with $b = 0$, we find that for a homogeneous distribution we have $\langle t(ay), \phi(y)\rangle = (1/a)\langle t(x), \phi(x/a)\rangle = a^\lambda\langle t(x), \phi(y)\rangle$, so that $\langle t(x), \phi(x/a)\rangle = a^{\lambda+1}\langle t(x), \phi(x)\rangle$.

All these relations hold also for distributions $t(\boldsymbol{x})$, $\boldsymbol{x} \in \mathbb{R}^n$. In that case we set $\boldsymbol{x} = \boldsymbol{A}y - \boldsymbol{B}$, where $\boldsymbol{A}$ is a nonsingular $n \times n$ matrix and $\boldsymbol{B}$ is a constant vector. Then we have $\langle t(\boldsymbol{A}y - \boldsymbol{B}), \phi(y)\rangle = (1/\det\boldsymbol{A})\langle t(\boldsymbol{x}), \phi[\boldsymbol{A}^{-1}(\boldsymbol{x} + \boldsymbol{B})]\rangle$, where $\boldsymbol{A}^{-1}$ is the inverse of the matrix $\boldsymbol{A}$.

Product of a distribution and a fucntion: In general it is difficult to define the product of two distributions,

even for two regular distributions. Indeed, if we take $f(x)=g(x)=1/\sqrt{x}$, which is a regular distribution, then their product $1/x$ is not a locally integrable function in the neighborhood of $x=0$ and as such does not define a regular distribution (we shall discuss the function $1/x$ in Sect. V). However, we can multiply a distribution $t(\boldsymbol{x})$ with a C^∞ function $\psi(x)$ so that we have $\langle \psi t, \phi\rangle = \langle t, \psi\phi\rangle$. Because $\psi\phi \in \mathcal{D}$, it follows that ψt is a distribution.

IV. ANALYTIC OPERATIONS ON DISTRIBUTIONS

Let us start with a regular distribution generated by C^1 function $t(x)$, $x\in\mathbb{R}$, so that $\langle t(x), \phi(x)\rangle = \int_{-\infty}^{\infty} t(x)\phi(x)\,dx$. When we integrate the quantity $\int_{-\infty}^{\infty} t'(x),\ \phi(x)\,dx$ by parts, we get $\int_{-\infty}^{\infty} t'(x)\times \phi(x)\,dx = -\int_{-\infty}^{\infty} t(x)\phi'(x)\,dx$, where we have used the fact that $\phi(x)$ has a compact support. Thus, $\langle t'(x), \phi(x)\rangle = -\langle t(x),\ \phi'(x)\rangle$. Because $\phi'(x)$ is also in $\mathcal{D}$, this relation helps us in defining the distributional derivative $t'(x)$ of a distribution $t(x)$ (regular or singular) as above. Continuing this process, we have $\langle t^{(n)}(x), \phi(x)\rangle = (-1)^n\langle t(x), \phi^{(n)}(x)\rangle$, where the superscript (n) stands for nth-order differentiation. The corresponding formula in $\mathbb{R}^n$ is

$$\langle D^{\boldsymbol{k}} t(\boldsymbol{x}), \phi(\boldsymbol{x})\rangle = (-1)^{\boldsymbol{k}}\langle t(\boldsymbol{x}), \boldsymbol{D}^{\boldsymbol{k}}\phi(\boldsymbol{x})\rangle. \tag{6}$$

Thus a generalized function is infinitely differentiable. This result has tremendous ramifications, as we shall soon discover.

The primitive of a distribution $t(x)$ is a solution of $ds(x)/dx = t(x)$. This means that we seek $s(x)\in\mathcal{D}'$ such that $\langle s, \phi'\rangle = -\langle t, \phi\rangle$, $\phi\in\mathcal{D}$.

Let us illustrate the concept of distributional differentiation with the help of a few applications.

1. Recall that the Heaviside function is defined as a distribution by the relation (6) $\langle H(x), \phi(x)\rangle = \int_0^\infty \phi(x)\,dx$. According to definition (6), we have $\langle H'(x), \phi(x)\rangle = -\langle H(x), \phi'(x)\rangle = -\int_0^\infty \phi'(x) = \phi(0) = \langle \delta(x), \phi(x)\rangle$, where we have use the fact that $\phi(x)$ vanishes at ∞. Thus,

$$\frac{dH}{dx} = \delta(x). \tag{7}$$

Because $H(x)$ is a distribution of order zero, $\delta(x)$ is a distribution of order 1. We can continue this process and find that $\langle \delta^{(n)}(x), \phi(x)\rangle = (-1)^n\langle \delta(x), \phi^{(n)}(x)\rangle$. Just as $\delta(x)$ stands for an impulse or a pole at $x=0$, $\delta'(x)$ stands for a dipole and $\delta^{(n)}(x)$ is a multiple of order $(n+1)$ as well as a distribution of order $(n+1)$.

2. *Impulse response*. With the help of the formula (7) we can find the derivative of the signum function sgn x, which is 1 for $x>0$ and -1 for $x<0$. Thus, sgn $x = 2H(x)-1$. Then it follows from (7) that $(\text{sgn } x)' = 2\delta(x)$. This result, in turn, helps us in finding the derivative of the function $|x|$. Indeed, $\langle |x|, \phi(x)\rangle = \int_{-\infty}^{\infty} |x|\phi(x)\,dx = \int_0^\infty x\phi(x)\,dx - \int_{-\infty}^0 x\phi(x)\,dx$. Thus, $\langle |x|', \phi(x)\rangle = -\langle |x|, \phi'(x)\rangle = -\int_0^\infty x\phi'(x)\,dx + \int_\infty^0 x\phi'\times(x)\,dx$, which, when integrated by parts, yields the formula $\langle |x|', \phi(x)\rangle = \langle \text{sgn } x, \phi(x)\rangle$. Thus, $|x|' = \text{sgn } x$. The second differentiation yields $(d^2/dx^2)(|x|) = 2\delta(x)$.

3. A distribution $E(\boldsymbol{x})$ is said to be a fundamental solution or a free-space Green's function or an impulse response if it satisfies the relation $L\,E(\boldsymbol{x}) = \delta(\boldsymbol{x})$, where L is a differential operator. Then from the previous paragraph we find that $\frac{1}{2}|x|$ is the impulse response for the differential operator $L = (d^2/dx^2)$.

Relation (6) for differentiation helps us in deriving many interesting formulas such as

$$\begin{aligned} t(x)\delta^{(n)}(x) = {} & (-1)^n t^{(n)}(0)\delta(x) \\ & + (-1)^{(n-1)} t^{(n-1)}(0)\delta'(x) \\ & + (-1)^{n-2}\frac{n(n-1)}{2!} t^{(n-2)}(0)\delta''(x) + \cdots \\ & + f(0)\delta^{(n)}(x) \end{aligned} \tag{8}$$

for a distribution $t(x)$. The proof follows by evaluating the quantity $\langle t(x)\delta^{(n)}(x), \phi(x)\rangle = \langle \delta^{(n)}(x), t(x)\phi(x)\rangle = (-1)^n\,\langle\, \delta(x), (t(x)\phi(x))^{(n)}\rangle$. For $n=0$ and 1, formula (8) becomes

$$\begin{aligned} t(x)\delta(x) &= t(0)\delta(x); \\ t(x)\delta'(x) &= -t'(0)\delta(x) + t(0)\delta'(x). \end{aligned} \tag{9}$$

One of the most important consequences of (8) is

$$x^m\delta^{(n)}(x) = \begin{cases} (-1)^m\dfrac{n!}{(n-m)!}\delta^{(n-m)}(x), & n\geq m, \\ 0, & n<m. \end{cases} \tag{10}$$

4. Next, we attempt to evaluate $\delta[f(x)]$. Let us first assume that $f(x)$ has a simple zero at x_1 such that $f(x_1)=0$ but $f'(x_1)>0$ [the case $f'(x)_1<0$ follows in a similar fashion]. Thus $f(x)$ increases monotonically in the neighborhood of x_1 so that $H[f(x)] = H(x-x_1)$, where $H(x)$ is the Heaviside function. Then we use (7) and find that $(d/dx)H[f(x)] = \delta(x-x_1)$ or $\delta[f(x)] = |(f'(x_1))|^{-1}\delta(x-x_1)$. If there are n zeros of $f(x)$, then the above result yields

$$\delta[f(x)] = \sum_{m=1}^{n}\frac{\delta(x-x_m)}{f'(x_m)}. \tag{11}$$

This result has many applications.

5. The formula $(\operatorname{sgn} x)' = 2\delta(x)$, derived in Example 2, is also instrumental in deriving an integral representation for the delta function. Indeed, if we appeal to the relations

$$\int_{-\infty}^{\infty} \frac{\sin tx}{x}\,dx = \begin{cases} \pi, & t > 0 \\ -\pi, & t < 0; \end{cases} \qquad \int_{-\infty}^{\infty} \frac{\cos tx}{x} = 0,$$

from calculus, we find that $(1/2\pi)\int_{-\infty}^{\infty}(e^{itx}/ix)\,dx = \frac{1}{2}\operatorname{sgn} t$. When we differentiate this relation with respect to t we get the important formula

$$\delta(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{itx}\,dx = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-itx}\,dx, \qquad (12)$$

where we have used the fact that $\delta(t)$ is an even function. This formula can be generalized to n dimensions if we observe that $\delta(x_1, \ldots, x_n) = \delta(x_1)\cdots\delta(x_n)$. Accordingly, in the four-dimensional space (x_1, x_2, x_3, t), relation (12) yields the planewave expansion of the delta function,

$$\delta(\boldsymbol{x}, t) = \frac{1}{(2\pi)^4}\int_{-\infty}^{\infty} e^{-i(\boldsymbol{k}\cdot\boldsymbol{x} - \omega t)} d^3\boldsymbol{k}\,d\omega, \qquad (13)$$

where $\boldsymbol{k} = (k_1, k_2, k_3)$ and we have a fourfold integral.

V. PSEUDO-FUNCTION, HADAMARD FINITE PART AND REGULARIZATION

The functions $1/x^m$ and $H(x)/x^m$, where m is an integer, are not locally integrable at $x = 0$ and, as such, do not define distributions. However, we can appeal to the concepts of Cauchy principal value and the Hadamard finite part and define these functions as distributions. The simplest example is the function $1/x$. For a test function $\phi(x)$ the integral $\int[\phi(x)/x]\,dx$ is not absolutely convergent unless $\phi(0) = 0$. However, it has an interpretation as a principal value integral, namely,

$$\left\langle Pv\left(\frac{1}{x}\right), \phi(x)\right\rangle = \lim_{\epsilon\to 0}\int_{|x|>\epsilon} \frac{\phi(x)}{x}\,dx. \qquad (14)$$

Writing $\phi(x) = \phi(0) + [\phi(x) - \phi(0)]$, relation (14) takes the form

$$\left\langle Pv\left(\frac{1}{x}\right), \phi(x)\right\rangle = \lim_{\epsilon\to 0}\int_{|x|>\epsilon} \frac{\phi(0)}{x}\,dx + \int_{|x|>\epsilon} \frac{[\phi(x) - \phi(0)]}{x}\,dx. \qquad (15)$$

Since the function $1/x$ is odd, the first term on the right side of (15) vanishes. The integrand in the second integral on the right side of (15) approaches $\phi'(0)$ as $x \to 0$. Accordingly, we have

$$\left\langle Pv\left(\frac{1}{x}\right), \phi(x)\right\rangle = \lim_{\epsilon\to 0}\int_{|x|>\epsilon} \frac{\phi(x) - \phi(0)}{x}\,dx.$$

Because $\epsilon > 0$ is arbitrary, the previous relation is also written as

$$\left\langle Pv\left(\frac{1}{x}\right), \phi(x)\right\rangle = \lim_{\epsilon\to 0}\int_{|x|>1} \frac{\phi(x) - \phi(0)}{x}\,dx. \qquad (16)$$

In this form the function $Pv(1/x)$ is easily proved to be a linear continuous function. As such, it is a distribution and is written as $Pf(1/x)$, where Pf stands for pseudo-function.

We come across many divergent integrals whose principal values do not exist. Consider, for instance, the integral $\int_a^b dx/x^2$, $a < 0 < b$. Because

$$\int_{[a,b]/[-\epsilon,\epsilon]} \frac{dx}{x^2} = \lim_{\epsilon\to 0}\left(-\frac{1}{b} + \frac{1}{a} + \frac{2}{\epsilon}\right), \qquad (17)$$

we cannot get the principal value. In these situations the concept of the Hadamard finite part becomes helpful. Indeed, in relation (17), the value $(-1/b + 1/a)$ is the finite part and $(2/\epsilon)$ is the infinite part. Thus, we write

$$Fp\int_a^b \frac{dx}{x^2} = -\frac{1}{b} + \frac{1}{a}. \qquad (18)$$

As another example, we consider the integral $\int_0^1 dx/x^\alpha$. It is divergent if $\alpha \geq 1$. Indeed, for $\alpha > 1$, we obtain

$$\int_\epsilon^1 \frac{dx}{x^\alpha} = \frac{1}{1-\alpha} - \frac{\epsilon^{1-\alpha}}{1-\alpha} \qquad (19)$$

so that we have

$$Fp\int_0^1 \frac{dx}{x^\alpha} = \frac{1}{1-\alpha}, \qquad \alpha > 1. \qquad (20)$$

When $\alpha = 1$, $\int_\epsilon^1 dx/x = -\ln\epsilon$, which is infinite, so that

$$Fp\int_0^1 \frac{dx}{x} = 0. \qquad (21)$$

The process of finding the principal value and the finite part of divergent integrals is called the regularization of these integrals. When both of them exist, they are equal.

Let us use the definition of the Hadamard finite part to regularize the function $H(x)/x$. The action of $H(x)/x$ on a test function $\phi(x)$ is $\int_0^\infty(\phi(x)/x)\,dx$. Thus, we consider

$$\int_\epsilon^\infty \frac{\phi(x)}{x}\,dx = \int_\epsilon^1 \frac{\phi(x)}{x}\,dx + \int_1^\infty \phi(x)\,dx. \qquad (22)$$

In the numerator of the first term on the right side of this equation we add and subtract $\phi(0)$ to get

$$\int_\epsilon^\infty \frac{\phi(x)}{x}\,dx = \int_\epsilon^1 \frac{\phi(0)}{x}\,dx + \int_\epsilon^1 \frac{\phi(x)-\phi(x)}{x} + \int_1^\infty \phi(x)\,dx$$

$$= -\phi(0)\ln\epsilon + \int_\epsilon^1 \frac{\phi(x)-\phi(0)}{x}\,dx + \int_1^\infty \frac{\phi(x)}{x}\,dx.$$

The first term on the right side of this equation is infinite as $\epsilon \to 0$, while the other two terms are finite. Accordingly, we define

$$\int \frac{H(x)\phi(x)}{x}\,dx = \int_\epsilon^1 \frac{\phi(x)-\phi(0)}{x}\,dx + \int_1^\infty \frac{\phi(x)}{x}\,dx. \tag{23}$$

The function $Pf(1/|x|)$ can be regularized in the same way. Indeed,

$$\left\langle Pf\left(\frac{1}{|x|}\right), \phi(x)\right\rangle = \int_{|x|\le 1} \frac{\phi(x)-\phi(0)}{|x|}\,dx + \int_{|x|>1} \frac{\phi(x)}{|x|}\,dx. \tag{24}$$

These concepts can be used to regularize the functions $1/x^m$ and $H(x)/x^m$ to yield the generalized functions $Pf(1/x^m)$ and $Pf(H(x)/x^m)$. The combination of $Pf(1/x^m)$ and $\delta^{(m)}(x)$ yield the Heisenberg distributions

$$\delta^{\pm(m)}(x) = \frac{1}{2}\delta^{(m)}(x) \mp \frac{1}{2\pi i}\,Pf\left(\frac{1}{x^m}\right).$$

They arise in quantum mechanics.

Let us end this section by solving the equation $xt(x) = g(x)$. The homogeneous part $xt(x) = 0$ has the solution $t(x) = \delta(x)$ because $x\delta(x) = 0$. Thus, the complete solution is

$$t(x) = \delta(x) + g(x)Pf\left(\frac{1}{x}\right). \tag{25}$$

VI. DISTRIBUTIONAL DERIVATIVES OF DISCONTINUOUSFUNCTIONS

Let us start with $x \in \mathbb{R}$ and consider a function $F(x)$ that has a jump discontinuity at $x = \xi$ of magnitude a but that has the drivative $F'(x)$ in the intervals $x < \xi$ and $x > \xi$. The derivative is undefined at $x = \xi$. To find the distributional derivative of $F(x)$ in the entire interval we define the function $f(x) = F(x) - aH(x-\xi)$, where H is the Heaviside function. This function is continuous at $x = \xi$ and has a derivative which coincides with $F'(x)$ on both sides of ξ. Accordingly, we differentiate both sides of this equation and get $F'(x) = \bar{F}'(x) - a\delta(x-\xi)$, where the bar over F stands for the generalized (distributional) derivative of F. Thus,

$$\bar{F}'(x) = F'(x) + [F]\delta(x-\xi), \tag{26}$$

where $[F] = a$ is the value of the jump of F at $x = \xi$. Before we present the corresponding n-dimensional theory, we give an interesting application of (26) to the Sturm-Liouville differential equation,

$$\frac{d}{dx}\left[p(x)\frac{dE(x;\xi)}{dx}\right] = q(x)E(x,\xi) - \delta(x-\xi), \tag{27}$$

where $E(x,\xi)$ stands for the impulse response and $p(x)$ and $q(x)$ are continuous at $x = \xi$. When we compare (22) and (23) and use the continuity of $p(x)$ at $x=\xi$, we find that the jump of $[dE/dx]_{x=\xi}$ is

$$[dE/dx]_{x=\xi} = -1/p(\xi).$$

These concepts easily generalize to higher-order derivatives and to the surfaces of discontinuity and, therefore, have applications in the theory of wave fronts. Accordingly, we include time t in our discussion and consider a function $F(\boldsymbol{x}, t)$, $\boldsymbol{x} \in \mathbb{R}^n$, which has a jump discontinuity across a moving surface $\Sigma(\boldsymbol{x}, t)$. Such a surface can be represented locally either as an implicit equation of the form $u(x_1, \ldots, x_n, t) = 0$, or in terms of the curvilinear Gaussian coordinates $v_1, \ldots, v_{n-1}$ on the surface: $x_i = x_i(v_1, \ldots, v_{n-1}, t)$. The surface Σ is regular, so the above-mentioned functions have derivatives of all orders with respect to each of their arguments, and for all values of t, the corresponding Jacobian matrices of transformation have appropriate ranks, that is, grad $u \neq 0$, and the rank of the matrix $(\partial x_i/\partial v_j) = n-1$. Furthermore, Σ divides the space into two parts, which we shall call positive and negative.

The basic distribution concentrated on a moving and a deforming surface $\Sigma(\boldsymbol{x}, t)$ is the delta function $\delta[\Sigma(\boldsymbol{x}, t)]$ whose action on a test function $\phi(\boldsymbol{x}, t) \in \mathcal{D}$ is

$$\langle \delta(\Sigma), \phi\rangle = \int_{-\infty}^{\infty}\int_\Sigma \phi(\boldsymbol{x}, t)\,dS(\boldsymbol{x})\,dt, \tag{28}$$

where dS is the surface element on Σ. This is a simple layer. The second surface distribution is the normal derivative operator, given as

$$\langle d_n\delta(\Sigma),\phi\rangle = -\int_{-\infty}^{\infty}\int_{\Sigma}\frac{d\phi}{dn}\,dS(\boldsymbol{x})\,dt, \tag{29}$$

where $d\phi/dn$ stands for the differentiation along the normal to the surface. This is a dipole layer. Another surface distribution that we need in our discussion is $\delta'(\Sigma)$, defined as

$$\delta'(\Sigma) = n_i\frac{\bar\partial}{\partial x_i}[\delta(\Sigma)], \tag{30}$$

where n_i are the components of the unit normal vector $\boldsymbol{n}$ to the surface. These three distributions are connected by the relation

$$d_n\delta(\Sigma) = \delta'(\Sigma) - 2\Omega\delta(\Sigma), \tag{31}$$

where Ω is the mean curvature of Σ.

Let a function $F(\boldsymbol{x},t)$ have a jump discontinuity across $\Sigma(\boldsymbol{x},t)$. Then the formulas for the time derivative, gradient, and curl of a discontinuous function $F(\boldsymbol{x},t)$ can be derived in a manner similar to (26). Indeed,

$$\frac{\bar\partial \boldsymbol{F}}{\partial t} = \frac{\partial \boldsymbol{F}}{\partial t} - G[\boldsymbol{F}]\delta(\Sigma), \tag{32}$$

$$\overline{\text{grad}}\,\boldsymbol{F} = \text{grad}\,\boldsymbol{F} + \boldsymbol{n}[\boldsymbol{F}]\delta(\Sigma), \tag{33}$$

$$\overline{\text{div}}\,\boldsymbol{F} = \text{div}\,\boldsymbol{F} + \boldsymbol{n}[\boldsymbol{F}]\delta(\Sigma), \tag{34}$$

$$\overline{\text{curl}}\,\boldsymbol{F} = \text{curl}\,\boldsymbol{F} + \boldsymbol{n}\times[\boldsymbol{F}]\delta(\Sigma), \tag{35}$$

where G is the normal speed of the front Σ and $[\boldsymbol{F}] = \boldsymbol{F}_+ - \boldsymbol{F}_-$ is the jump of $\boldsymbol{F}$ across Σ.

Before we extend these concepts, we apply relation (33) to a scalar function F and derive the distributional derivative of $1/r$, where r is the radial distance. In mathematical physics the function $1/r$ is important because it describes the gravitational and the Coulomb potentials. In the modern theories of small particles the singularity of $1/r$ at $r=0$ makes a significant contribution. Accordingly, its distributional derivatives are needed to get the complete picture of the singularity at $r=0$ and we present it as follows. For the sake of computational simplicity, we restrict ourselves to $\mathbb{R}^3$, so that $r=(x_1^2+x_2^2+x_3^3)^{1/2}$. The function $1/r$ corresponds to the $Pf[H(x)/x]$ that we considered in the previous section. Accordingly, we introduce the function $F(\boldsymbol{x}) = H(r-\epsilon)/r$, where $H(r-\epsilon)$ is the Heaviside function, which is unity for $r>\epsilon$ and is zero for $r<\epsilon$. This, in turn, helps us in defining the distribution $1/r$ as

$$\left\langle\frac{1}{r},\phi(\boldsymbol{x})\right\rangle = \lim_{\epsilon\to 0}\int_{-\infty}^{\infty}\frac{1}{r}H(r-\epsilon)\phi(\boldsymbol{x})\,dx. \tag{36}$$

Our aim is to differentiate $1/r$ by taking into account the singularity at $r=0$. For this we appeal to formula (33) and observe that $F(\boldsymbol{x}) = H(r-\epsilon)/r$ so that the jump of this function at the spherical surface of discontinuity $\Sigma: r=\epsilon$, is $1/\epsilon$. Thus, formula (33) becomes

$$\frac{\bar\partial}{\partial x_j}\left(\frac{H(r-\epsilon)}{r}\right) = -\frac{x_j}{r^3}H(r-\epsilon) + \hat r_j\frac{1}{\epsilon}\delta(\Sigma), \tag{37}$$

where $n_j = \hat r_j - x_j/r$. To evaluate the limit of the second term on the right side of (37) we evaluate $\lim_{\epsilon\to 0}\int_\Sigma \phi(\boldsymbol{x})(1/\epsilon)\hat r\,dS = \lim_{\epsilon\to 0}(1/\epsilon)\int_{\Sigma(1)}\phi(\boldsymbol{x})\hat r\,\epsilon^2\,d\omega = 0$, where $\Sigma(1)$ is the unit sphere and ω is the solid angle. Thus $\bar\partial/\partial x_j(1/r) = -x_j/r^3$, which is the same as the classical derivative. In order to compute the second-order distributional derivatives we apply formula (33) to the function $(\partial/\partial x_j)[H(r-\epsilon)/r]$ and get

$$\begin{aligned}\frac{\bar\partial^2}{\partial x_i\,\partial x_j}\left[\frac{H(r-\epsilon)}{r}\right] &= \left[\frac{\partial^2}{\partial x_i\,\partial x_j}\left(\frac{1}{r}\right)\right]H(r-\epsilon)\\ &\quad+\left(\frac{x_i}{r}\right)\left(\frac{-x_j}{r^3}\right)\delta(\Sigma)\\ &= \left(\frac{3x_ix_j - r^2\delta_{ij}}{r^5}\right)H(r-\epsilon)\\ &\quad-\frac{x_ix_j}{r^4}\delta(\Sigma),\end{aligned} \tag{38}$$

where δ_{ij} is the Kronecker delta, which is 1 when $i=j$ and 0 when $i\neq j$. Because $\lim_{\epsilon\to 0}\int_\Sigma(x_ix_j/r^4)\phi(\boldsymbol{x})\,dS = (4\pi/3)\delta_{ij}\phi(\boldsymbol{0})$, relation (38) becomes

$$\frac{\bar\partial^2}{\partial x_i\partial x_j}\left(\frac{1}{r}\right) = \frac{3x_ix_j - r^2\delta_{ij}}{r^5} - \frac{4\pi}{3}\delta_{ij}\delta(\boldsymbol{x}). \tag{39}$$

From this formula we can derive the impulse response for the Laplace operator. Indeed, if we set $i=j$ and sum on j, we get $\nabla^2(1/r) = -4\pi\delta(\boldsymbol{x})$. Thus, the impulse response of $-\nabla^2$ is $1/4\pi r$. We can continue this process and drive the nth-order distributional derivative of the function $1/r^k$.

With the help of the foregoing analysis we can obtain the results that correspond to (32)–(35) for singular surfaces which carry infinite singularities, such as charge sheets and vortex sheets. Suppose that the surface of discontinuity $\Sigma(\boldsymbol{x},t)$ carries a single layer of strength $f(\boldsymbol{x},t)\delta(\Sigma)$. Then

$$\frac{\bar\partial}{\partial t}[f\delta(\Sigma)] = \frac{\bar\delta f}{\delta t}\delta(\Sigma) - Gf\delta'(\Sigma), \tag{40}$$

where $\bar\delta/\delta t = \bar\partial f/\partial t + G\,df/dn$ is the distributional time derivative as apparent to an observer moving with the front Σ. Similarly, $\bar\delta f/\delta x_i = \bar\partial f/\partial x_i - n_i\,df/dn$ is the distributional surface derivative with respect to the Cartesian coordinates of the surrounding space. Thereby,

$$\frac{\bar\partial}{\partial x_i}[f\delta(\Sigma)] = \frac{\bar\delta f}{\delta x_i}\delta(\Sigma) + n_i f\delta'(\Sigma). \tag{41}$$

If we use relation (31) between $d_n\delta(\Sigma)$ and $\delta'(\Sigma)$, we can rewrite formulas (40) and (41) which contain the mean curvature Ω.

VII. CONVERGENCE OF DISTRIBUTIONS AND FOURIER SERIES

A sequence $\{t_m(\boldsymbol{x})\}$ of distributions with $t_m(\boldsymbol{x}) \in \mathcal{D}'$, $m = 1, 2, \ldots$, is said to converge to a distribution $t(\boldsymbol{x}) \in \mathcal{D}'$ if $\lim_{m\to\infty}\langle t_m, \phi\rangle = \langle t, \phi\rangle$ for all $\phi \in \mathcal{D}$. This is called distributional (or weak) convergence. An important consequence is that if the sequence $\{t_m(\boldsymbol{x})\}$ converges to $t(\boldsymbol{x})$, then the sequence $\{D^{\boldsymbol{k}}t_m\}$ converges to $\{D^{\boldsymbol{k}}t\}$ because $\lim_{m\to\infty}\langle D^{\boldsymbol{k}}t_m, \phi\rangle = \lim_{m\to\infty}(-1)^{|\boldsymbol{k}|}\langle t_m, D^{\boldsymbol{k}}\phi\rangle = (-1)^{|\boldsymbol{k}|}\langle t, D^{\boldsymbol{k}}\phi\rangle = \langle D^{\boldsymbol{k}}t, \phi\rangle$. As an example, consider the sequence $\{\cos mx/m\}$, $x \in \mathbb{R}$, which is a sequence of regular distributions and converges to zero pointwise. Then the sequence $\{-\sin mx\}$ which arises by differentiating $\{\cos mx/m\}$, also converges to zero. It is remarkable because the sequence $\{\sin mx\}$ does not have a pointwise limit, as $m \to \infty$, in the classical sense.

A series of distributions $\sum_{p=1}^{\infty} s_p(x)$ converges distributionally to $t(x)$ if the sequence of the partial sums $\{t_m(x)\} = \{\sum_{p=1}^{m} s_p(x)\}$ converges to t distributionally. Thus, we observe from the above analysis that term-by-term differentiation of a convergent series is always possible, provided the resultant series is interpreted in the sense of distributions.

It is known that the Fourier series $\sum_{m=-\infty}^{\infty} c_m e^{imx}$ converges uniformly if for a large m, $|c_m| \le M/m^k$ where m is a constant and k is an integer greater than 2. The series may diverge for other values of k. However, the above analysis assures us that the series converges distributionally for any integer because it can be obtained from the uniformly convergent series $\sum_{m=-\infty}^{\infty}(im)^{k-2}c_m e^{imx}$ by $(k+2)$ successive differentiations. For example, the series $\sum_{m=-\infty}^{\infty} e^{imx}$ has no meaning in the classical sense, but it can be written as $1 + (d^2/dx^2)\{\sum_{m=-\infty}^{\infty}(1/m^2)e^{imx}\}$. Accordingly, the series $\sum_{m=-\infty}^{\infty} e^{imx}$ is distributionally convergent.

VIII. DIRECT PRODUCT AND CONVOLUTION OF DISTRIBUTIONS

The direct product of distributions is defined by using the space of test functions in two variables x and y. Let us denote the direct product of the distributions $s(x) \in \mathcal{D}'(x)$ and $t(y) \in \mathcal{D}'(y)$ as $s(x) \otimes t(y)$. Then

$$\langle s(x) \otimes t(y), \phi(x, y)\rangle = \langle s(x), \langle (t(y), \phi(x, y)\rangle\rangle \quad (42)$$

where $\phi(x, y)$ is a test function in $\mathcal{D}(x, y)$. This makes sense because the function $\psi(x) = \langle t(y), \phi(x, y)\rangle$ is a test function in $\mathcal{D}(x)$ and $D^k\psi(x) = \langle t(y), D_x^k\phi(x, y)\rangle$, where D_x^k implies kth-order derivative with respect to x. Thus, $s(x) \otimes t(y)$ is a functional in $\mathcal{D}'(x, y)$. Indeed, it is a linear and continuous functional. Let us mention some of the properties of the direct product:

1. Linearity: $s \otimes (\alpha t + \beta u) = \alpha s \otimes t + \beta s \otimes u$.
2. Commutativity: $s \otimes t = t \otimes s$.
3. Continuity: if $s_m(x) \to s(x)$, in $\mathcal{D}'(x)$ as $m \to \infty$, then $s_m(x) \otimes t(y) \to s(x) \otimes t(y)$ in $\mathcal{D}'(x, y)$ as $m \to \infty$.
4. Associativity: when $s(x) \in \mathcal{D}'(x)$, $t(y) \in \mathcal{D}'(y)$ and $u(z) \in \mathcal{D}'(z)$, then $s(x) \otimes [t(y) \otimes u(z) = s(x) \otimes t(y)] \otimes u(z)$.
5. Support: $\text{supp}\,(s \times t) = \text{supp}\, s \times \text{supp}\, t$, where $\times$ stands for the Cartesian product.
6. Differentiation: $D_x^k[s(x) \otimes t(y)] = D^k[s(x)] \otimes t(y)$.
7. Translation: $(s \otimes t)(x + h, y) = s(x + h) \otimes t(y)$.

An interesting example of the direct product is $\delta(x) \otimes \delta(y) = \delta(x, y)$, where $\delta(x, y)$ is the two-dimensional delta function. This follows by observing that $\langle \delta(x) \otimes \delta(y), \phi(x, y)\rangle = \langle \delta(x), \langle \delta(y), \phi(x, y)\rangle\rangle = \langle \delta(y), \phi(0, y)\rangle = \phi(0, 0) = \langle \delta(x, y), \phi(x, y)\rangle$.

The *convolution* $s * t$ of two functions $s(x)$ and $t(x)$ is $(s * t)(x) = \int_{-\infty}^{\infty} s(y)t(x - y)\,dy = \int_{-\infty}^{\infty} t(y)s(x - y)\,dy = t * s(x)$. When the functions $s(x)$ and $t(x)$ are locally integrable, then $s(x) * t(x)$ is also locally integrable, and as such, defines a regular distribution.

Next, let us examine $\langle s * t, \phi\rangle$:

$$\begin{aligned}
\langle s * t, \phi\rangle &= \int_{-\infty}^{\infty} (s * t)\phi(z)\,dz \\
&= \int_{-\infty}^{\infty} \left[\int_{-\infty}^{\infty} s(z - y)t(y)\,dy\right] \phi(z)\,dz \\
&= \int_{-\infty}^{\infty} t(y) \left[\int_{-\infty}^{\infty} s(z - y)\phi(z)\right] dy \\
&= \int_{-\infty}^{\infty} t(y) \int_{-\infty}^{\infty} [s(x)\phi(x + y)\,dx]\,dy \\
&= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} s(x)t(y)\phi(x + y)\,dx\,dy.
\end{aligned}$$

Thus,

$$\langle s(x) * t(y), \phi(x, y)\rangle = \langle s(x) \otimes t(y), \phi(x + y)\rangle. \quad (43)$$

There is, however, one difficulty with this definition. Even though the function $\phi(x + y)$ is infinitely differentiable, its support is not bounded in the (x, y) plane because x and y may be unboundly large while $x + y$ remains finite. This is remedied by ensuring that the intersection of the supports of $s(x) \otimes t(y)$ and $\phi(x + y)$ is a bounded set. This happens if (1) either s or t has a bounded support or (2) both s and t have support bounded on the same side.

As an example, we find that $(\delta * t)(x) = \int \delta(y)\, t(x-y)\, dx = t(x)$, that is, $\delta(x)$ is the unit element in the convolution algebra. The operation of the convolution has the following properties:

1. Linearity: $s * (\alpha t + \beta u) = \alpha s * t + \beta s * u$.
2. Commutivity: $s * t = t * s$.
3. Associativity: $(s * t) * u = s * (t * u)$.
4. Differentiation: $(D^k s) * t = D^k(s * t) = s * D^k t$.
5. For instance, $[H(x) * t(x)]' = \delta(x) * t(x) = H(x) * t'(x)$.

IX. FOURIER TRANSFORM

Let us write formula (12) as

$$\frac{1}{2\pi} \int_{-\infty}^{\infty} e^{iu(x-\xi)}\, du = \delta(x-\xi),$$

and multiply both sides of this formula by $f(x)$, integrate with respect to x from $-\infty$ to ∞, use the sifting property, and interchange the order of integration. The result is the celebrated Fourier integral theorem,

$$f(\xi) = \frac{1}{2\pi} \int_{-\infty}^{\infty} du \int_{-\infty}^{\infty} f(x) e^{iu(x-\xi)}\, dx, \qquad (44)$$

which splits into the pair

$$\hat{f}(u) = \int_{-\infty}^{\infty} f(x) e^{iux}\, dx, \qquad (45)$$

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{f}(u) e^{-iux}\, du, \qquad (46)$$

where we have relabeled ξ with x in (46). The quantity $\hat{f}(u)$ is the Fourier transform of $f(x)$, while formula (46) gives the inverse Fourier transform $F^{-1}[f(u)]$. We shall now examine formula (45) in the context of test functions and distributions. If we attempt to define the Fourier transform of a distribution $t(x)$ as in (45), then we get $\hat{t}(u) = \langle t(x),\ e^{iux} \rangle$, but we are in trouble because e^{iux} is not in $\mathcal{D}$. We could try Parseval's theorem, $\int_{-\infty}^{\infty} \hat{f}(x) g(x)\, dx = \int_{-\infty}^{\infty} f(x) \hat{g}(x)\, dx$, which follows from (45) and (46) and connects the Fourier transforms of two functions. Then we have $\langle \hat{t}, \phi \rangle = \langle t, \hat{\phi} \rangle$, $\phi \in \mathcal{D}$. We again run into trouble because $\hat{\phi}$ may not be in $\mathcal{D}$ even if ϕ is in it. These difficulties are overcome by enlarging the class of test functions.

Test functions of rapid decay. The space $\mathcal{S}$ of test functions of rapid decay contains the complex-valued functions $\phi(\boldsymbol{x})$ with the properties: (1) $\phi(\boldsymbol{x}) \in C^\infty$, (2) $\phi(\boldsymbol{x})$ and its derivatives of all orders vanish at infinity faster than the reciprocal of any polynomial, i.e., $|\boldsymbol{x}^{\boldsymbol{p}} D^{\boldsymbol{k}} \phi(\boldsymbol{x})| < C_{pq}$, where $\boldsymbol{p} = (p_1, \ldots, p_n)$, $\boldsymbol{k} = (k_1, \ldots, k_n)$ are n-tuples and C_{pq} is a constant depending on $\boldsymbol{p}, \boldsymbol{k}$ and $\phi(\boldsymbol{x})$. Another way of saying this is that after multiplication by any polynomial $P(\boldsymbol{x})$, the function $P(\boldsymbol{x})\phi(\boldsymbol{x})$ still tends to zero as $\boldsymbol{x} \to \infty$. Clearly, $S \supset \mathcal{D}$. Convergence in this space is defined as follows. The sequence of functions $\{\phi_m(\boldsymbol{x})\} \to \phi(\boldsymbol{x})$ if and only if $|\boldsymbol{x}^k (D^{\boldsymbol{k}} \phi_m - D^{\boldsymbol{k}} \phi)| < C_{pq}$ for all multi-indices $\boldsymbol{p}$ and $\boldsymbol{k}$ and all m.

Functions of slow growth. A function $f(\boldsymbol{x})$ in $\mathbb{R}^n$ is of slow growth if $f(\boldsymbol{x})$, together with all its derivatives, grows at infinity more slowly than some polynomial, i.e., there exist constants C, m, and A such that $|D^{\boldsymbol{k}} f(\boldsymbol{x})| \langle C|\boldsymbol{x}|^m,\ |\boldsymbol{x}| \rangle A$.

Tempered distributions. A linear continuous functional $t(\boldsymbol{x})$ over the space S of test functions is called a *distribution of slow growth* or *tempered distribution*. According to each $\phi \in S$, there is assigned a complex number $\langle t, \phi \rangle$ with the properties: (1) $\langle t, c_1\phi_1 + c_2\phi_2 \rangle = c_1\langle t, \phi_1 \rangle + c_2 \langle t, \phi_2 \rangle$; (2) $\lim_{m \to 0} \langle t, \phi_m \rangle = 0$, for every null sequence $\{\phi_m(\boldsymbol{x})\} \in S$. This yields us the dual space S'. If follows from the definitions of convergence in $\mathcal{D}$ and S that a sequence $\{\phi_m(\xi)\}$ that converges in the sense of $\mathcal{D}$ also converges in the sense of S, so that $S' \subset \mathcal{D}'$. Fortunately, most of the distributions in $\mathcal{D}'$ encountered previously are also in S'. However, some locally integrable functions in D' are not in S'. The regular distributions in S' are those generated by functions $f(x)$ of slow growth through the formula $\langle f, \phi \rangle = \int_{\infty}^{\infty} f(x)\phi(x)\, dx$, $\phi \in S$. It is a linear continuous functional.

Fourier transform of the test functions. We shall first give the analysis in $\mathbb{R}$ and then state the corresponding results in $\mathbb{R}^n$. For $\phi(x) \in S$, we can use the definition (45) so that $\hat{\phi}(u) = \int_{\infty}^{\infty} \phi(x) e^{iux}\, dx$. The inverse follows from (46). Since $\hat{\phi}(u)$ is also in S, as can be easily proved, the difficulty encountered earlier has disappeared. Moreover, it follows by the inversion formula (46) that

$$[\hat{\phi}]\hat{}(x) = 2\pi\phi(-x), \qquad (47)$$

which shows that every function $\phi(x) \in S$ is a Fourier transform of some function in S. Indeed, the Fourier transform and its inverse are linear, continuous, and one-to-one mapping of S on to itself.

In order to obtain the transform of tempered distributions, we need some specific formulas of the transform of the test functions $\phi(x)$. Let us list them and prove some of them. The transform of $d^k\phi/dx^k$ is equal to $\int_{-\infty}^{\infty} (d^k\phi/dx^k) e^{iux}\, dx = (-iu)^k \int_{-\infty}^{\infty} \phi(x) e^{iux}\, dx$ so that $[d^k\phi/dx^k]\hat{}(u) = (-iu)^k \hat{\phi}(u)$. Thus, if $P(\lambda)$ is an arbitrary polynomial with constant coefficients, we find that

$[P(d/dx)\phi]\hat{} = P(-iu)\hat{\phi}(u)$. Similarly, from the relation $\int_{-\infty}^{\infty}(ix)^k\phi(x)e^{iux}\,dx = (d^k/du^k)\int_{-\infty}^{\infty}\phi(x)e^{iux}\,dx$, we derive the relation $[x^k\phi]\hat{}(u) = P(-d/du)\hat{\phi}(u)$. Because $\int_{-\infty}^{\infty}\phi(x-a)e^{iux}\,dx = e^{iua}\int_{-\infty}^{\infty}\phi(y)e^{iuy}\,dy$, we have $[\phi(x-a)]\hat{}(u) = e^{iau}\hat{\phi}(u)$. Similarly, $[\phi(x)]\hat{}(u+a) = [e^{ax}(x)]\hat{}(u)$ and $[\phi(ax]\hat{}(u) = (1/|a|\hat{\phi}(u/a))$. The corresponding n-dimensional formulas are listed below.

$$\hat{\phi}(\boldsymbol{u}) = \int_{-\infty}^{\infty} e^{i\boldsymbol{u}\cdot\boldsymbol{x}}\phi(\boldsymbol{x})\,d\boldsymbol{x}, \tag{48}$$

$$\phi(x) = \frac{1}{(2\pi)^n}\int_{-\infty}^{\infty} e^{i\boldsymbol{u}\cdot\boldsymbol{x}}\hat{\phi}(\boldsymbol{u})\,d\boldsymbol{u}, \tag{49}$$

$$[\hat{\phi}]\hat{}(\boldsymbol{u}) = (2\pi)^n\phi(-\boldsymbol{u}), \tag{50}$$

$$[\boldsymbol{D}^{\boldsymbol{k}}\phi]\hat{}(\boldsymbol{u}) = (-i\boldsymbol{u})^{\boldsymbol{k}}\hat{\phi}(\boldsymbol{u}), \tag{51}$$

$$\left[P\left(\frac{\partial}{\partial x_1},\ldots,\frac{\partial}{\partial x_n}\right)\phi(\boldsymbol{x})\right]\hat{}(\boldsymbol{u}) = P(-iu_1,.,-u_n)\hat{\phi}(\boldsymbol{x}), \tag{52}$$

$$[\boldsymbol{x}^k\phi]\hat{}(\boldsymbol{x}) = (-i\boldsymbol{D})^k x\hat{\phi}(u), \tag{53}$$

$$[P(x_1,\ldots,x_n)\phi]\hat{}(\boldsymbol{u}) = P\left(-i\frac{\partial}{\partial u_1},\ldots,-i\frac{\partial}{\partial u_n}\right)\hat{\phi}(\boldsymbol{u}), \tag{54}$$

$$[\phi(\boldsymbol{x}-a)]\hat{}(\boldsymbol{u}) = e^{i\boldsymbol{a}\cdot\boldsymbol{u}}\hat{\phi}(\boldsymbol{u}), \tag{55}$$

$$[\hat{\phi}(\boldsymbol{x})](\boldsymbol{u}+\boldsymbol{a}) = [e^{i\boldsymbol{a}\cdot\boldsymbol{x}}]\hat{}\phi(\boldsymbol{u}), \tag{56}$$

$$[\phi(\boldsymbol{A}\boldsymbol{x})]\hat{}(u) = |\det\boldsymbol{A}|^{-1}\hat{\phi}(\boldsymbol{A}^T)\boldsymbol{u}), \tag{57}$$

where $\boldsymbol{u}\cdot\boldsymbol{x} = u_1x_1+\cdots+u_nx_n$, $\boldsymbol{A}$ is a nonsingular matrix, and $\boldsymbol{A}^T$ is its transpose. We shall refer to the numbered formulas above for $n=1$ also.

As a simple example we consider the function $\exp(-x^2/2)$, which is clearly a member of S. To find its transform we first observe that it satisfies the equation $\phi'(x)+x\phi(x)=0$. Taking Fourier transforms of both sides of this equation and using (52) and (53), we find that $(d/du)[\hat{\phi}(u)e^{u^2/2}]=0$. Thus, $\hat{\phi}(u) = Ce^{-u^2/2}$, where C is a constant. To evaluate C, we observe that $\hat{\phi}(u) = \int_{-\infty}^{\infty}\exp(-x^2/2)\,dx = \sqrt{2\pi}$, so that $C=\sqrt{2\pi}$ and we have $\hat{\phi}(u) = \sqrt{2\pi}\phi(u)$. Thus we have found a function which is its own inverse. [The multiplicative $\sqrt{2\pi}$ disappear if we use the factors $1/\sqrt{2\pi}$ in the definition of the transform pairs (48) and (49)].

Fourier transform of tempered distributions. Having discovered that $\hat{\phi}\in S$ when ϕ is, we can apply the relation $\langle\hat{t},\phi\rangle = \langle t,\hat{\phi}\rangle$ to define the Fourier transform of the tempered distributions $t(x)$. Then all the formulas given above for $\hat{\phi}$ carry over for $\hat{t}$. For instance, $\langle|(d^k/dx^k)t(x)]\hat{}u, \phi(u)]\rangle = \langle d^kt/dx^k,\ \hat{\phi}(x)\rangle = (-1)^k\langle t(x), [(d^k/dx^k)\phi(x)]\hat{}\rangle = \langle t(x), (-iu)^k\phi(u)]\hat{}(x)\rangle = \langle\hat{t}(u), (-iu)^k\phi(u)\rangle = \langle(-iu)^k\hat{t}(u), \phi(u)\rangle$, which shows that $[d^kt/dx^k]\hat{}(u) = (-iu)^k\hat{t}(u)$, which agrees with (51). Instead of writing the formulas (50)–(57) all over again for a distribution $t(x)$, we shall merely refer to them with ϕ replaced by t. Let us now give some important applications of these formulas.

1. *Delta function.* $\langle[\delta(x)]\hat{}, \phi(u)\rangle = \langle\delta(x), \int_{-\infty}^{\infty}\phi(u)e^{iux}\,du\rangle = \int_{-\infty}^{\infty}\phi(u)du = \langle 1, \phi(u)\rangle$. Thus $\hat{\delta}(x)=1$ so that $\hat{1} = 2\pi\delta(x)$. In the n-dimensional case, the corresponding formulas are $\hat{\delta}(x)=1$ and $\hat{1} = (2\pi)^n\delta(\boldsymbol{x})$. Incidentally, we recover formula (12) from this relation.

2. *Heaviside function.* We use formula (51), so that $[t'(x)]\hat{}(u) = -iu\hat{t}(u)$. Because $t(x)=H(x)$, we have $[\delta(x)]\hat{}(u) = -iu[H(x)]\hat{}(u)$ or $u(H)(x)]\hat{}(u) = i$, whose solution follows from (25) as $[H(x)]\hat{}(u) = c\delta(u) + iPf(1/u)$. Similarly, from (57) and the above result we have $[H(-x)]\hat{}(u) = c\delta(u) - iPf(1/u)$. To find the constant c we observe that $H(x)+H(-x)=1$, whose Fourier transform is $2c\delta(u) = 2\pi\delta(u)$, so that $c=1$. Thus $[H(\pm x)]\hat{}(u) = \pi\delta(u) \pm iPf(1/u)$.

3. *Signum function.* Because $\operatorname{sgn}x = H(x)-H(-x)$, we take Fourier transforms of both sides and use Example 2 above to get $[\operatorname{sgn}x]\hat{}(u) = 2iPf(1/u)$.

4. $Pf(1/x)$. We use formulas (47) for $t(x)$ and the example above. The result is $[(\operatorname{sgn}x)\hat{}(u)](x) = [2iPf(-1/u)]\hat{}(x)$, so that

$$\left[Pf\left(\frac{1}{x}\right)\right]\hat{}(u) = i\pi\operatorname{sgn}u. \tag{58}$$

5. *The function* $|x|$. We write it as $|x| = xH(x) - xH(-x)$. Taking the Fourier transforms of both sides of this equation, we get

$$\begin{aligned}[|x|]\hat{}(u) &= [xH(x)]\hat{}(u) - [xH(-x)]\hat{}(u)\\ &= -i\frac{d}{du}[H(x)]\hat{}(u) + i\frac{d}{du}[H(-x)]\hat{}(u)\\ &= -i\frac{d}{du}\left[\pi\delta(u) + iPf\left(\frac{1}{u}\right)\right]\\ &\quad \pm i\frac{d}{du}\left[\pi\delta(u) - iPf\left(\frac{1}{u}\right)\right]\\ &= \frac{2}{u^2}.\end{aligned}$$

Thus $[|x|]\hat{}(u) = 2/u^2$.

6. *The function* $1/x^2$. To find its transform we appeal to the previous example and relation (47) so that $[(|x|)\hat{}(u)]\hat{}(x) = (2/u^2)\hat{}(x)$ and we get $(1/x^2)\hat{}(u) = \frac{1}{2}|x|$.

7. *Polynomial* $P(x) = a_0 + a_1 + \cdots + a_nx^n$. Formula (54) gives $[P(x)t(x)]\hat{}(u) = P[-i(d/du)\hat{t}(u)]$. When we

substitute $t(x)=1$ in this formula and use Example 1, we get $[P(x)]\hat{}(u)=2\pi P(-i\,d/du)\delta(u)$. Thus,

$$\left[a_0+a_1+\cdots+a_nx^n\right]\hat{}(u)=2\pi\,(a_0\delta-ia_1\delta'+\cdots+(-i)^na_n\delta^{(n)}(u)\Big]. \quad (59)$$

In particular, $\hat{x}(u)=-2\pi i\delta'(u)$, $[x^2]\hat{}(u)=-2\pi\delta''(u)$, $\ldots$, $[x^n]\hat{}(u)=(-i)^n2\pi\delta^{(n)}(u)$.

8. $Pf(1/|x|)$. With the help of the definition (24) of this function we have

$$\left\langle Pf\left(\frac{1}{|x|}\right)\right]\hat{}(u),\phi(u)\Big\rangle=\left\langle Pf\left(\frac{1}{|x|}\right),\hat{\phi}(x)\right\rangle$$

$$=\int_{-1}^{1}\frac{\hat{\phi}(x)-\hat{\phi}(0)}{|x|}\,dx+\int_{|x|>1}\frac{\hat{\phi}(x)}{|x|}\,dx,$$

which, after some algebraic manipulation, yields

$$\left[Pf\left(\frac{1}{|x|}\right)\right]\hat{}(u)=-2(\gamma+\ln|u|), \quad (60)$$

where γ is Euler's constant.

9. $\ln|x|$. For evaluation of the Fourier transform of this important function, we take the Fourier transform of both sides of (60), use formula (47), and obtain

$$Pf\left(\frac{1}{|x|}\right)=2[2\pi\gamma\delta(x)+[\ln(u)]\hat{}(x)]$$

and relabel. The result is

$$[\ln|x|]\hat{}(u)=-\left[\pi\,Pf\frac{1}{2|u|}+2\pi\gamma\delta(u)\right]. \quad (61)$$

In the theories of wavelets, sampling, and interpolation, we need the Fourier transforms of the square and triangular functions. We derive them in the next two examples.

10. *The square function.* It is defined as $f(x)=H(x+\frac{1}{2})-H(x-\frac{1}{2})$. Thus

$$\hat{f}(u)=\int_{-1/2}^{1/2}e^{iux}\,dx=\left[\frac{1}{iu}e^{iux}\right]_{-1/2}^{1/2}$$

$$=\frac{2}{u}\sin\left(\frac{u}{2}\right)=\operatorname{sinc}\left(\frac{u}{2}\right), \quad (62)$$

where $\operatorname{sinc}t=\sin t/t$.

11. *The triangular function.* It is defined as

$$f(x)=\begin{cases}1-|x|, & |x|<1,\\ 0, & |x|>1,\end{cases}$$

so that

$$\hat{f}(u)=\int_{-1}^{0}(1+x)\,e^{iux}dx+\int_{0}^{1}(1-x)e^{iux}\,dx.$$

By a routine computation it yields

$$\hat{f}(u)=\left[\frac{\sin(u/2)}{(u/2)}\right]^2=\left[\operatorname{sinc}\left(\frac{u}{2}\right)\right]^2. \quad (63)$$

12. *Fourier transform of an integral.* We have found previously that taking the Fourier transform of the diferential of a distribution $t(x)$ has the effect of multiplying $\hat{t}(u)$ by $(-iu)$. In the case of taking the Fourier transform of the integral of $t(x)$, it amounts to dividing $\hat{t}(u)$ by $(-iu)$ so that

$$\left\{\int_a^x[t(s)\,ds]\right\}\hat{}\,(u)=\frac{i\hat{t}(u)}{u}. \quad (64)$$

Similarly,

$$\left\{\int_{-\infty}^x[t(s)\,ds]\right\}\hat{}\,(u)=\frac{i\hat{t}(u)}{u}+\frac{1}{2}\hat{t}(0)\delta(u). \quad (65)$$

13. *Fourier transform of the convolution.* The Fourier transform of the convolution $f*g$ of two locally integrable functions f and g is $[f*g]\hat{}(u)=\int_{-\infty}^{\infty}f*ge^{iux}=\int_{-\infty}^{\infty}e^{iux}\int_{-\infty}^{\infty}f(x-y)g(y)\,dy=\int_{-\infty}^{\infty}g(y)e^{iuy}\,dy\times\int_{-\infty}^{\infty}f(x-y)\,e^{iu(x-y)}\,d(x-y)=\hat{g}(u)\,\hat{f}(u)=\hat{f}(u)\hat{g}(u)$. Thus, the Fourier transform of the convolution of two regular distributions is the product of their transforms. This relation also holds for singular distributions with slight restrictions. For instance, if at least one of these distributions has compact support, then the relation holds.

X. POISSON SUMMATION FORMULA

To derive the Poisson summation formula we first find the Fourier series of the delta function in the period $[0,2\pi]$: $\delta(x)=\sum_{m=0}^{\infty}(a_m\cos mx+b_m\sin mx)$, where the coefficients a_m, b_m are given by $a_0=(1/2\pi)\int_0^{2\pi}\delta(x)\,dx=(1/2\pi)$, $a_m=(1\pi)\int_0^{2\pi}\delta(x)\cos mx\times dx=(1/\pi)$, and $b_m=(1/\pi)\int_0^{\pi}\delta(x)\sin mx\,dx=0$. Thus, we have

$$\delta(x)=\frac{1}{2\pi}\left(1+2\sum_{m=1}^{\infty}\cos mx\right)=\frac{1}{2\pi}\sum_{m=-\infty}^{\infty}e^{imx}. \quad (66)$$

Now we periodize $\delta(x)$ by putting the row of deltas at the points $2\pi m$ so that relation (66) can be written as

$$\sum_{m=-\infty}^{\infty}\delta(x-2\pi m)=\frac{1}{2\pi}\left(1+2\sum_{m=1}^{\infty}\cos mx\right)$$

$$=\frac{1}{2\pi}\sum_{m=-\infty}^{\infty}e^{imx}.$$

When we set $x = 2\pi y$ in this relation and use the formula $\delta[2\pi(y-m)] = (1/2\pi)\delta(y-m)$ and relabel, we obtain

$$\sum_{m=-\infty}^{\infty} \delta(x-m) = 1 + 2\sum_{m=1}^{\infty} \cos 2\pi mx = \sum_{m=-\infty}^{\infty} e^{i2\pi mx}. \tag{67}$$

The action of this formula on a function $\phi(x) \in \mathcal{S}$ yields

$$\sum_{m=-\infty}^{\infty} \phi(m) = \hat{\phi}(2\pi m), \tag{68}$$

which relates the sum of functions ϕ and their Fourier transforms $\hat{\phi}$ and is a very useful formula.

In the classical theory, it is necessary that both sides of relation (68) converge. Moreover, they must converge in the same interval. With the help of the theory of distributions we can obtain many variants of relation (68) which are applicable even when one or both of the series (68) are divergent. As an example, we set $x = x/\lambda$, where λ is a real number, and use the relation $\delta[(x/\lambda) - m] = |\lambda|\delta(x - m\lambda)$. Then relation (67) becomes

$$(\lambda) \sum_{m=-\infty}^{\infty} \delta(x - m\lambda) = \sum_{m=-\infty}^{\infty} e^{2i\pi xm/\lambda}. \tag{69}$$

When we multiply both sides of this relation by a test function $\phi(x)$ and integrate with respect to x, we obtain a variant of (68) as

$$\sum_{m=-\infty}^{\infty} \phi(m\lambda) = \frac{1}{|\lambda|} \sum_{m=-\infty}^{\infty} \hat{\phi}\left(\frac{2\pi m}{\lambda}\right). \tag{70}$$

This is called the distributional Poisson summation formula. Among other things, the Poisson summation formula (70) transforms a slowly converging series to a rapidly converging series. For instance, if we take $\phi(x) = e^{-x^2}$, then $\hat{\phi}(u) = \sqrt{\pi}e^{-u^2/2}$, so that (70) becomes

$$\sum_{m=-\infty}^{\infty} e^{-m^2\lambda^2} = (\pi/\lambda)^{1/2} \sum_{m=-\infty}^{\infty} e^{-m^2\pi^2/\lambda^2}. \tag{71}$$

The series on the left side of (71) converges rapidly for large λ, that on the right side for small λ.

XI. ASYMPTOTIC EVALUATION OF INTEGRALS: A DISTRIBUTIONAL APPROACH

Let $g(x)$ and $h(x)$ be sufficiently smooth functions on the interval $[a, b]$, then the main contribution to the Laplace integral,

$$I(\lambda) = \int_a^b e^{-\lambda h(x)} g(x)\, dx, \qquad \lambda \to \infty \tag{72}$$

arises from the points where the function $h(x)$ has a minimum. If x_0 is the only global minumum of $h(x)$, then we have the Laplace formula

$$I(\lambda) \sim \left[\frac{2\pi}{\lambda h''(x_0)}\right]^{1/2} g(x_0) e^{-\lambda h(x_0)}. \tag{73}$$

If we could somehow prove that $e^{-\lambda h(x)}$ has an asymptotic series of delta functions such that

$$e^{-\lambda h(x)} \sim \left[\frac{2\pi}{\lambda h'(x_0)}\right]^{1/2} e^{-\lambda h(x_0)} \delta(x - x_0), \tag{74}$$

then all that we have to do is to substitute (74) in (72) and use the sifting property of the delta function and formula (73) follows immediately. To achieve the expansion (74) we first define the moments of a function $f(x)$. They are

$$\mu_n = \langle f(x), x^n \rangle = \int_{-\infty}^{\infty} f(x) x^n\, dx. \tag{75}$$

The Taylor expansion of a test function $\phi(x)$ at $x = 0$ is

$$\phi(x) = \sum_{n=0}^{\infty} \phi^{(n)}(0) \frac{x^n}{n!}. \tag{76}$$

Then it follows from (75) that

$$\begin{aligned} \langle f(x), \phi(x) \rangle &= \left\langle f(x), \sum_{n=0}^{\infty} \phi^{(n)}(0) \frac{x^n}{n!} \right\rangle \\ &= \sum_{n=0}^{\infty} \phi^n(0) \frac{\mu_n}{n!}. \end{aligned} \tag{77}$$

But $\phi^n(0) = (-1)^n \langle \delta^{(n)}(x), \phi(x) \rangle$, so that (77) becomes

$$\langle f(x), \phi(x) \rangle = \left\langle \sum_{n=0}^{\infty} \frac{(-1)^n \mu_n \delta^{(n)}(x)}{n!}, \phi(x) \right\rangle. \tag{78}$$

Thus

$$f(x) = \sum_{n=0}^{\infty} \frac{(-1)^n \mu_n \delta^{(n)}(x)}{n!}. \tag{79}$$

Finally, we use the formula $\delta^{(n)}(\lambda x) = (1/\lambda^{n+1})\delta^n(x)$ in (79) and obtain the complete asymptotic expansion

$$f(\lambda x) = \sum_{n=-\infty}^{\infty} \frac{(-1)^n \mu_n \delta^{(n)}(x)}{n!\, \lambda^{n+1}}, \qquad \lambda \to \infty. \tag{80}$$

In the case of the Laplace integral (72) we have $f(x) = e^{-\lambda h(x)}$. At the minimum point x_0, $h(x) \sim h(x_0) + [h''(x_0)(x - x_0)^2]/2$. Accordingly, we can find an increasing smooth function $\psi(x)$ with $\psi(x_0) = 0$, $\psi'(x_0) > 0$, so that $h(x) = h(x_0) + [\psi(x)]^2$ in the support of $h(x)$. Then $h'(x_0) = 2\psi(x_0)\psi'(x_0) = 0$, which yields $h'(x_0) = 0$ as required for $h(x)$ to have minimum at x_0. Also,

$h''(x) = 2[\psi'(x)]^2 + 2\psi(x)\psi''(x)$, which, for $x = x_0$, becomes $h''(x_0) = 2[\psi'(x_0)]^2$ or

$$\psi'(x_0) = \frac{1}{2}[h''(x_0)]^{1/2}. \tag{81}$$

Substituting this information about $h(x)$ in the Laplace integral (72), we obtain

$$I(\lambda) = e^{-\lambda h(x_0)} \int_{-\infty}^{\infty} e^{-\lambda[\psi(x)]^2} g(x)\, dx. \tag{82}$$

The next step is to set $u = \psi(x)$, which gives $dx = du/\psi'(x)$ so that (82) becomes

$$I(\lambda) = e^{-\lambda h(x_0)} \int_{-\infty}^{\infty} e^{-\lambda u^2} \frac{g(u)}{\psi'(x_0)}\, du, \tag{83}$$

so we need the asymptotic expansion of $e^{-\lambda u^2}$ from formula (80). This is obtained by finding the moments of e^{-u^2}, and they are

$$\mu_n = \int_{-\infty}^{\infty} e^{-u^2} u^n\, du = \begin{cases} \Gamma\left(\dfrac{n+1}{2}\right), & n \text{ even}, \\ 0, & n \text{ odd}. \end{cases} \tag{84}$$

Then formula (80) yields

$$e^{-\lambda u^2} = \sum_{n=0}^{\infty} \frac{\Gamma[(2n+1)/2]\delta^{(2n)}(u)}{(2n)!\lambda[(2n+1)/2]} \tag{85}$$

so that formula (83) becomes

$$I(\lambda) = e^{-\lambda h(x_0)} \int_{-\infty}^{\infty} \sum_{n=0}^{\infty} \frac{\Gamma[(2n+1)/2]}{2n!} \frac{\delta^{(2n)}(u)}{\lambda^{(2n+1/2)}} \times \frac{g(u)}{\psi'(x_0)}\, du. \tag{86}$$

The interesting feature of the distributional approach is that we have obtained the complete asymptotic expansion. Thereafter, we evaluate as many terms as are needed to get the best approximation.

The first term of formula (86) is

$$I(\lambda) = e^{-\lambda h(\alpha_0)} \int_{-\infty}^{\infty} \Gamma\left(\frac{1}{2}\right) \frac{\delta(u)}{\sqrt{\lambda}} \frac{g(u)}{\psi'(x_0)}\, du.$$

When we substitute the value of $\psi'(x_0)$ from relation (81) in the above relation and use the sifting property of $\delta(u)$, we obtain

$$I(\lambda) \sim \left[\frac{2\pi}{\lambda h''(x_0)}\right]^{1/2} g(x_0) e^{-\lambda h(x_0)},$$

which agrees with (73).

The *oscillatory integral*

$$I(\lambda) = \int_{-\infty}^{\infty} e^{i\lambda h(x)} g(x)\, dx, \qquad \lambda \to \infty \tag{87}$$

can also be processed in the same manner as the Laplace integral. Indeed, the steps leading (87) to relation

$$I(\lambda) = e^{-i\lambda h(x_0)} \int_{-\infty}^{\infty} e^{i\lambda u^2} \frac{g(u)}{\psi'(x_0)}\, du \tag{88}$$

are almost the same as these from (72) to (83). The difference arises in the value of the moments μ_n which now are

$$\mu_n = \int_{-\infty}^{\infty} e^{i\lambda u^2} u^n\, du = \begin{cases} \Gamma\left(\dfrac{n\pi}{2}\right) e^{\pi i[(2n+1)/4]}, & n \text{ even}, \\ 0, & n \text{ odd}. \end{cases} \tag{89}$$

This yields the moment expansion for $e^{i\lambda u^2}$ as

$$e^{i\lambda u^2} = \sum_{n=0}^{\infty} \frac{\Gamma[(2n+1)/2]\, e^{-\pi i[(2n+1)/4]}\delta^{(2n)}(u)}{(2n)!\lambda^{(2n+1)/2}}\, du. \tag{90}$$

When we substitute this value for $e^{i\lambda u^2}$ in integral (88) we obtain

$$I(\lambda) \sim e^{-ih(x_0)} \int_{-\infty}^{\infty} \sum_{n=0}^{\infty} \frac{\Gamma[(2n+1)/2]\, e^{-\pi i[(2n+1)/4]}}{(2n)!} \times \frac{\delta^{(2n)}(n)}{\lambda^{(2n+1/2)}} \frac{g(u)}{\psi'(x_0)}\, du. \tag{91}$$

The first term of this formula yields

$$I(\lambda) \sim e^{i(\lambda h(x_0) + \pi/4)} \left[\frac{2\pi}{h''(x_0)}\right]^{1/2} \frac{\phi(x_0)}{\sqrt{\lambda}}, \tag{92}$$

where we have used relation (81).

Let us observe an essential difference between the Laplace integral and the oscillatory integral. In the case of the Laplace integral we collect the contributions only from the points where $h(x)$ has the minimum such that $h'(x) = 0$ and $h''(x) > 0$. For the oscillatory integral we collect the contributions from all the points where $h(x)$ is stationary such that $h'(x) = 0, h''(x) \neq 0$. For this reason the classical method for the oscillatory integral is called the method of stationary phase.

GLOSSARY

Bipartite graph A graph whose vertices can be partitioned into two sets of independent vertices.
Connectivity (edge) The minimum number of vertices (edges) which when deleted leaves a disconnected graph.
Coloring (edge) An assignment of colors to the vertices (edges) of a graph so that adjacent vertices (edges) have different colors.
Component A maximal connected subgraph of a graph.
Digraph A pair consisting of a finite nonempty set called the vertex set and a collection of ordered pairs of the vertices called the arc set.
Factorization A collection of subgraphs of a graph which partition the edges of the graph.
Good algorithm An algorithm with a polynomial upper bound on the time required to terminate in the worst case.
Graph A pair consisting of a finite nonempty set called the vertex set and a collection of unordered pairs of the vertices called the edge set.
Independent set A set of vertices (edges) such that no pair is adjacent.
Isomorphism A one-to-one map from the vertices of one graph onto the vertices of another graph which preserves edges.
Matching A collection of independent edges in a graph.

Network A directed graph in which each arc is given a label.

Planar graph A graph which can be embedded in the plane or on a sphere.

Reconstructible graph (edge) A graph which is determined by its subgraphs obtained by deleting a single vertex (edge) of the graph.

Tournament A directed graph obtained by orienting the edges of a complete graph.

Tree A connected graph which has no cycles.

A GRAPH is a finite collection of elements, which are called vertices, and a finite collection of lines or curves, which are called edges, that join certain pairs of these vertices. This is an abstract mathematical structure which is of interest on its own, but it is also of interest as a structure which can be used to model a wide variety of real-life situations and problems. Street maps, communications systems, electrical networks, organizational structures, and chemical molecules all can be viewed as graphs. Some historical roots of the subject, important results about the structure and theory of graphs, outstanding open problems in graph theory, and graphs as mathematical models will be presented in this article. Procedures (called algorithms) for solving graphical problems will be described, and the application of the structure of graphs and graphical algorithms to problems modeled by graphs will also be discussed.

I. INTRODUCTION

A *graph* G is generally thought of as a collection of points together with curves or lines which join certain pairs of these points. Thus, this simple structure is a natural model for many real-life situations. For example, a road map uses a graph as a model. The cities are represented by points and the roads between cities are represented by curves or lines. Organizational charts can be considered as graphs, with the points representing the individuals in the organization and lines indicating that one person is an immediate supervisor of another. In this case it may be more appropriate to think of the lines as being directed from the supervisor to the person being supervised. Communication systems, electrical networks, family trees, and molecules in chemistry can all be represented as graphs. Our initial objectives will be to formalize this idea of graph, introduce some standard notation and terminology, develop the basic concepts, and illustrate these with examples.

A *graph* G is a nonempty finite set $V(G)$ together with a finite set $E(G)$ of distinct unordered pairs of elements of $V(G)$. Each element in $V(G)$ is called a vertex and each element in $E(G)$ is called an edge. When it is clear just what graph is being considered, the vertex set $V(G)$ and the edge set $E(G)$ will be written as just V and E, respectively. The *order* of G, usually denoted by $|V|$, is the number of elements in V, while the *size* of G is the number of elements in E, and is denoted by $|E|$.

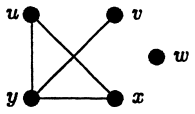

FIGURE 1 Graph G.

For vertices u and v of V the edge $e = \{u, v\}$ will be expressed more compactly as just uv. We say that u is adjacent to v and e is incident to u and v. The edge e is said to join the vertices u and v. Also, two edges incident to a common vertex are said to be adjacent to each other. The neighborhood $N_G(v)$ [or just $N(v)$] of a vertex v is the set of vertices of G which are adjacent to v, and the number of elements in $N(v)$ is called the *degree* of v and is denoted by $d_G(v)$ [or just $d(v)$]. Of course, the degree $d_G(v)$ is also the number of edges of G incident to v.

A graph has a useful geometric representation in the plane, with points representing vertices and curves or lines representing edges. The graph G pictured in Fig. 1 can be used to illustrate the notation that has been presented. The graph G has order 5 and size 4 with $V = \{u, v, w, x, y\}$ and $E = \{ux, uy, vy, xy\}$. The degrees of the vertices are $d(u) = d(x) = 2, d(v) = 1, d(y) = 3$, and $d(w) = 0$. We say that w is an *isolated* vertex.

With this minimal background we can now make an elementary but useful observation. If we sum the degrees of vertices of a graph, then each edge of the graph will be counted exactly twice, once at each end. This gives the following result.

Theorem 1.1: *If G is a graph of order p and size q with $V = \{v_1, v_2, \ldots, v_p\}$, then $\sum_{i=1}^{p} d(v_i) = 2q$.*

The concept of substructure is of basic importance in graph theory. A graph H is a *subgraph* of a graph G if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. Also, the graph G is said to be a *supergraph* of H. If the edges of H are precisely the edges of G which join pairs of vertices of H, then H is an *induced* subgraph of G. If H is a subgraph with $V(H) = V(G)$, then H is called a *spanning subgraph* of G. There are some special subgraphs and supergraphs of a graph G that occur so frequently that special notation is given to them. If $e \in E$, then $G - e$ is the subgraph of G with the same vertices and edges as G except the edge e is deleted. Similarly, if $v \in V$, then $G - v$ is the subgraph of G with the vertex v deleted from the vertex set and all the edges incident to v deleted from the edge set. There are

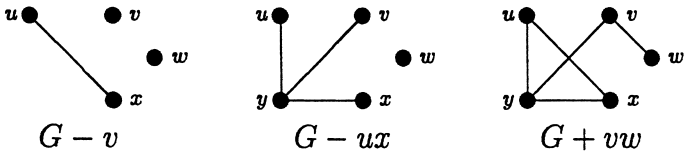

FIGURE 2

obvious generalizations to sets of vertices or edges. Also, if e is an edge not in E, then $G+e$ is the supergraph of G with the same vertex set as G but with e added to the edge set. The concepts of subgraph and supergraph are illustrated in Fig. 2, with G being the graph pictured in Fig. 1.

Two graphs G and H are identical (written as $G=H$) if $V(G)=V(H)$ and $E(G)=E(H)$. However, it is possible for graphs to have the same appearance if they are appropriately labeled but yet not be identical. Two graphs G and H are said to be *isomorphic* (written as $G\cong H$) if there is a one-to-one mapping (called an isomorphism) θ of $V(G)$ onto $V(H)$ such that edge uv is in $E(G)$ if and only if the edge $\theta(u)\theta(v)$ is in $E(H)$. The graph G pictured in Fig. 3 is isomorphic to the graph H of Fig. 3; in fact, the map θ defined by $\theta(u)=a, \theta(v)=d, \theta(w)=f, \theta(x)=b$ and $\theta(y)=c$ is an isomorphism from G onto H.

Some classes of graphs occur so frequently that special names are given to them. A graph of order n in which every pair of its vertices are adjacent is called a *complete graph* and is denoted by K_n. Each vertex in K_n has degree $n-1$ and the size of the graph is $\binom{n}{2}=n(n-1)/2$. The *complement* $\bar{G}$ of a graph G is the graph with vertex set $V(G)$ such that two vertices are adjacent in $\bar{G}$ if and only if they are not adjacent in G. Thus $\bar{K}_n$ is a graph with no edges. A *bipartite* graph is one in which the vertices can be partitioned into two sets, say A and B, such that every edge of the graph joins a vertex in A and a vertex in B. The sets A and B are called the parts of the bipartite graph. If every vertex in A is joined to every vertex in B, then the bipartite graph is called a *complete bipartite graph*, and is denoted by $K_{m,n}$ if $|A|=m$ and $|B|=n$. Thus, $K_{m,n}$ has order $m+n$ and size mn. The special complete bipartite graph $K_{1,n}$ is called a *star* of size n (and order $n+1$). A collection of vertices of a graph are said to be *independent* if there are no edges joining them. Thus, the vertices of the complement of a complete graph and the vertices in the parts of a bipartite graph are independent.

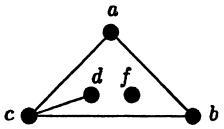

FIGURE 3 Isomorphic graph H.

If all of the vertices of a graph have the same degree r, then the grahph is said to be *r-regular* or just *regular*. The complete graph K_{r+1} and the complete bipartite graph $K_{r,r}$ are examples of r-regular graphs. There are many other special graphs, but we conclude with the graph C_n, a *cycle* of length n. This is a connected graph of order n which is 2-regular. The graph C_5 is pictured in Fig. 4 along with other examples of complete graphs, bipartite graphs, and their complements.

Up to this point only one form of a "graph" has been discussed, and that is what is sometimes called a simple graph. No edges of the form vv, which are called *loops*, were allowed. Also, any pair of vertices in a graph were joined by at most one edge, not *multiple edges*. If loops and multiple edges are allowed, the structure is called a *multigraph*. This definition of a multigraph is not completely standard because loops are sometimes not allowed. Figure 5a shows an example of a multigraph which has multiple edges joining vertices u and x and loops at the vertex v. All edges have to this point been assumed to have no direction, so that the edge uv is the same as the edge vu. Sometimes it is appropriate for each edge to have a direction, and such directed edges will be called *arcs*. Therefore each arc is an ordered pair of distinct vertices, and the arc uv is not the same as the arc vu. Such structures are called *directed graphs* or *digraphs*. An example of a digraph is given in Fig. 5b. All of these structures and some additional variations will be considered later.

There are many ways to describe or determine a particular graph. So far, we have generally described graphs by using the definition and listing the vertices and edges of the graph. In a few cases, a picture or drawing of the

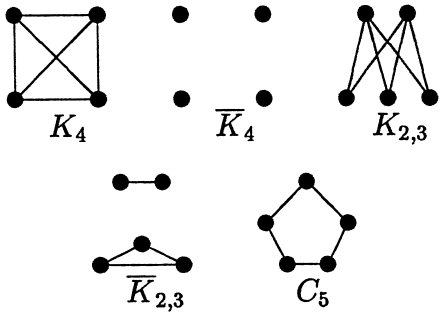

FIGURE 4 Special graphs and complements.

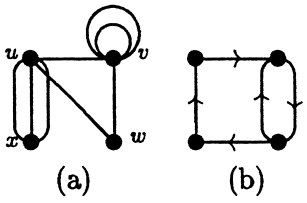

FIGURE 5 (a) Multigraph. (b) Digraph.

graph was used to determine the graph. The *adjacency matrix* $A(G)$ of a graph G is a common and useful structure to describe a graph. If G has order n, then $A(G)$ is an n by n matrix with n rows and columns and 0 or 1 entries in which the ith vertex corresponds to the ith row and column. The (i, j) entry is 1 if and only if the ith vertex is adjacent to the jth vertex. The matrix $A(G)$ depends on an ordering of the vertices, and a different ordering of the vertices will cause a permutation of the rows and columns of the adjacency matrix. Also, $A(G)$ is a symmetric matrix with only 0's on the diagonal, and the number of 1's in the ith row (column) is the degree of ith vertex. Similar adjacency matrices can be defined for digraphs and multigraphs.

The study of procedures or *algorithms* for solving graphical problems is central in the theory of graphs. After the existence of an algorithm has been verified, the question of efficiency must be answered. An algorithm is said to be *good* if it is a polynomial-time algorithm. This means that if n is some parameter which describes the magnitude of the graph (such as order or size), then there exists positive constants c and k such that in the worst case the time (the number of operations such as additions or comparisons) required for the algorithm to terminate is bounded above by cn^k. An n^k algorithm is one in which the time required is at most cn^k for some positive constant c. If $k = 1$, then the algorithm is said to be linear.

The reason for searching for good algorithms as opposed to those with no polynomial upper bound is that those with exponential growth can be extremely inefficient. The following is a dramatic example of this. If $n = 20$, which is a relatively small number, then $n^3 = 8000$. On the other hand $n!$ is a number with 19 digits. If a computer could do 1,000,000,000 calculations a second, it would take less than 1/(100,000)th of a second to do n^3 calculations, but it would take over 75 years to do $n!$ calculations. However, some care must be taken in interpreting the relative efficiencies of algorithms for small values of n. Although an n^3 algorithm will be quicker than an n^5 or an $n!$ algorithm for large values of n, for small values of n the constant associated with each of the algorithms may be the dominant factor. Either an n^5 or $n!$ algorithm could be faster than an n^3 algorithm for small values of n.

Consider two graphs G and H of the same order (say, n) and size, which are each described by a vertex and edge set. There is a good algorithm to determine if the graphs are identical. First determine if $V(G) = V(H)$. If this is true, order the vertex sets in the same way and form the adjacency matrices $A(G)$ and $A(H)$. If $A(G) = A(H)$, then G and H are identical. Each of these steps takes at most n^2 comparisons, so we have a good algorithm; in fact, this is an n^2 algorithm for determining if two graphs are identical. Next consider the problem of determining if G and H are isomorphic. A reasonable approach would be to order the sets $V(G)$ and $V(H)$ (they need not be identical) and construct the adjacency matrices $A(G)$ and $A(H)$. However, $G \cong H$ if and only if there is some ordering of the sets $V(G)$ and $V(H)$ such that $A(G) = A(H)$. Unfortunately, there are $n!$ possible permutations of an ordered set with n elements. Since $n!$ is not polynomial in n, this approach will not give a good algorithm. It is not known if a good algorithm for isomorphism exists. In fact, this problem, the *isomorphism problem*, is one of the outstanding problems in graph theory.

In the remaining sections, selected but representative topics from the theory of graphs will be discussed. The topics are by no means exhaustive; for example, graphical enumeration, algebraic graph theory, and matroids are not discussed, and all are important and interesting topics.

II. CONNECTEDNESS

Connectedness is a fundamental concept in graph theory, and most readers will have an intuitive feel for it. However, we first need to introduce some elementary related ideas to present the concept carefully. In a graph G, a *walk* from a vertex u to a distinct vertex v is a finite sequence of alternating vertices and edges $W = v_0 e_1 v_1 \cdots v_{k-1} e_k v_k$ with $v_0 = u$, $v_k = v$ and with each edge of the sequence incident in G to each of the vertices on either side of it in the sequence. The length of the walk W is k, the number of edges in W. If all of the edges of the sequence are distinct, then W is called a *trail*. If, in addition, all of the vertices of W are distinct, it is called a *path*. If the initial vertex and the final vertex are allowed to be the same ($u = v$), the walk, trail or path is called *closed*. A closed path of length at least three determines a graph which is called a *cycle*. A path (or cycle) with n vertices is usually denoted by P_n (or C_n).

Two vertices u and v in a graph G are connected if there is a path from u to v. A graph G is *connected* if each pair of its vertices are connected. Even when G is not connected, all of the vertices of G connected to a fixed vertex form a connected subgraph of G. Thus, a disconnected graph G can be partitioned into connected subgraphs, which are

called the *components* of G. The components are the maximal connected subgraphs of a graph. For example, the graph G of Fig. 1 has two components, one with the four vertices $\{u, v, x, y\}$ and the other with the single vertex w.

Associated with any pair of vertices u and v of a graph G is the distance $d_G(u, v)$ [or just $d(u, v)$ when the graph G is obvious], which is the length of a shortest path from u to v. A natural and interesting problem is the determination of a good procedure or algorithm for finding $d(u, v)$. A brute-force approach of checking all possible paths from u to v would not be very satisfactory, since the number of such paths could be quite large—in fact, of order of magnitude $(n-2)!$ for a graph G of order n.

A good "shortest-path algorithm" was discovered by Dijkstra and determines the distance from a fixed vertex of a graph G of order n to each of the remaining vertices, and it works in order of magnitude n^2. Also, this algorithm will handle the more general structure of a weighted graph G in which each edge e of G is assigned a real number $w(e)$, called its weight. For a weighted graph, the length of a path is the sum of the weights of the edges of the path. It should be noted that any graph G can be considered as a *weighted graph* by assigning weight 1 to each edge of G. The algorithm of Dijkstra is of greedy design and uses a breadth-first search of the graph. It starts by finding the vertex in G which is "closest" to a fixed vertex v. At each step the "next closest" vertex is found using the information about the distance from v to vertices whose distances from v have already been determined. Each of the n steps involves at most n comparisons and n additions of real numbers, and thus n^2 is an upper bound on the order of magnitude of the algorithm.

The "shortest-path algorithm" can be used to determine the components of a graph. All vertices in the same component of a fixed vertex v of a graph would have finite distance from v, while the remaining vertices would have infinite distance. Although there are more efficient methods for finding the components of a graph, the shortest path algorithm is a good one for this purpose.

Connectedness in a graph which is being used as a model for a transportation or communication system is clearly desirable. However, connectedness alone might not be sufficient. If the connected graph G which represented a communication network had a vertex v such that $G-v$ was disconnected (v is called a *cut-vertex* of G), then it would be critical that no failure occur at v, for this could result in a failure of the entire system. Thus, we need some measure of the extent of the connectedness of a graph. With that objective in mind we introduce some additional concepts.

If S is a collection of vertices of a graph G, then $G-S$ is the graph obtained from G by deleting the vertices of S. If G is connected but $G-S$ is disconnected, then S is called a *cut-set*, and the set S is said to separate vertices x and y if they are in different components of $G-S$. The connectivity (sometimes called *vertex connectivity*) $\kappa(G)$ of a graph G is the minimum number of vertices in a cut-set of G. The only graphs without cut-sets are complete graphs, and there the connectivity is one less than the order of the complete graph. A graph G is k-connected if $\kappa(G) \geq k$. Thus, for example, a graph of order at least 3 and with no cut-vertices is 2-connected. It is easily checked that $\kappa(P_n) = 1, \kappa(C_n) = 2, \kappa(K_n) = n-1$, and $\kappa(K_{m,n}) = n$ when $m \geq n$. One would expect that as the connectivity of a graph becomes larger, there would be an increase in the number of "alternative" paths between pairs of vertices. The following results verify this expectation.

Theorem 2.1 (Menger): *For distinct nonadjacent vertices u and v of a graph, the maximum number of internally disjoint (vertex disjoint except for u and v) paths between u and v is equal to the minimum number of vertices that separate u and v.*

Theorem 2.2 (Menger-Whitney): *A graph is k-connected if and only if for each pair of distinct vertices of the graph there are at least k internally vertex disjoint paths between them.*

Vertex connectivity has an analog, *edge connectivity*, denoted by $\kappa_1(G)$. Each of the previous definitions and results concerning vertices has a natural edge analog. For example, if e is an edge of a connected graph G and the graph $G-e$ (the graph obtained from G by deleting the edge e) is disconnected, then e is called a cut-edge. An edge-cut-set is a collection of edges which, when deleted, disconnect the graph, and the edge connectivity is the minimum number of edges in an edge-cut-set. There are results analogous to those of Menger and Whitney which also say that high edge connectivity is equivalent to the existence of many edge disjoint paths between any pair of vertices.

III. TREES

A tree is usually defined as a connected graph which contains no cycles. However, this very useful class of graphs has many other characterizations. The following theorem gives five equivalent statements, each of which could be used as a definition of a tree.

Theorem: 3.1 *The following statements are equivalent for a graph of order n:*

(i) G is connected and has no cycles.
(ii) G is connected and has size $n-1$.
(iii) G has no cycles and has size $n-1$.
(iv) G is a graph in which every edge is a cut-edge.

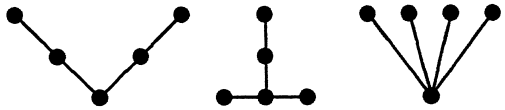

FIGURE 6 Trees of order 5.

(v) G is a graph with a unique path between each pair of distinct vertices.

All nonisomorphic trees of order 5 are pictured in Fig. 6.

Any connected graph G has a *spanning tree*. This is easy to observe. If an edge e is on a cycle of a connected graph, then its deletion will not disconnect the graph. Thus, by successive deletion of edges on cycles of appropriate connected subgraphs of G, one eventually obtains a connected subgraph of G which has no cycles. This graph is a spanning tree T of G. This tree is not in general unique (unless G is itself a tree), but it will have size $n-1$ if G has order n, and there will be no smaller size connected spanning subgraph of G. The number of spanning trees in a graph can be quite large, as the following result of Cayley indicates.

Theorem 3.2 (Cayley): *For $n \geq 2$, the graph K_n has n^{n-2} nonidentical spanning trees.*

There is a more general result on the number of spanning trees of a graph, and this result can be used to prove the theorem of Cayley. Let G be a graph and let $A(G)$ be the adjacency matrix of G. The matrix $D(G)$, called the *degree matrix*, is the diagonal matrix with the degrees of the vertices on the diagonal. Thus, the sum of the entries of each row (column) of the matrix $D(G)-A(G)$ is 0. This implies that all of the cofactors of this matrix $D(G)-A(G)$ are the same. This is the setting for the following result.

Theorem 3.3 (Kirchhoff, matrix tree): *The number of nonidentical spanning trees in any graph G is the value of any cofactor of the matrix $D(G)-A(G)$.*

Consider the problem of building a transportation system that connects (but not necessarily each pair directly) a collection of cities. The cost of constructing the link between each pair of cities is known, and we want to minimize the total cost of the system by selecting the appropriate links. This translates directly into finding a minimal cost spanning tree of a weighted graph. The result of Cayley indicates that the brute-force method of considering all possible spanning trees is not very efficient. An intuitive and good algorithm [of order $n^2/ln(n)$] for finding such a minimal spanning tree was developed by Kruskal. First, the edges of the graph are sorted in increasing order by weight. A subgraph is built by successively adding edges from this sorted list (starting with those of smallest weight), subject only to the condition that an edge is never added if it creates a cycle. This will generate a minimal cost spanning tree.

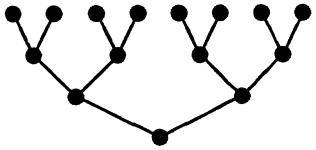

FIGURE 7 Complete binary tree.

Trees are also useful as information structures. One example of this is a binary tree used as a search tree. The *complete binary tree* T of depth k can be defined inductively as a tree with a root vertex v which is adjacent to two vertices v_L and v_R, called the left and right children of v, such that v_L and v_R are roots of disjoint complete binary trees of depth $k-1$ in $T-v$. Figure 7 shows a complete binary tree of depth 3. The tree T has $2^{k+1}-1$ vertices, and the paths from the root to other vertices of the tree have length at most k. Elements from an ordered set with $n=2^{k+1}-1$ elements can be stored at the vertices of the tree in such a way that for any complete binary subtree the elements in any "left tree" are less than the root and elements in the "right tree" are greater than the root. Thus, with the binary search tree the number of comparisons needed to search for an element from this ordered set with n elements has an upper bound of $\log_2(n+1)$, which is considerably less than a naive straightforward approach would require.

IV. EULERIAN AND HAMILTONIAN GRAPHS

In the first paper on graph theory, Euler (1736) considered the problem of traversing the seven bridges of Königsberg (see Fig. 8a) without crossing any bridge twice. He showed that it was not possible. This is equivalent to showing that the multigraph G of Fig. 8b does not contain a trail which uses all of the edges of G.

An *(closed) eulerian trail* of a graph G is a (closed) trail which uses all of the edges of the graph. A graph which contains a closed eulerian trail is called *eulerian*.

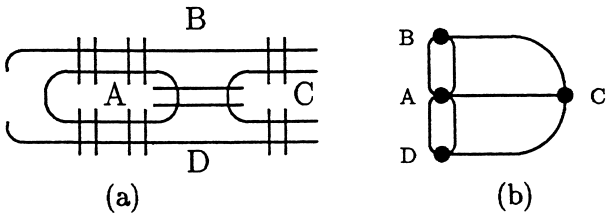

FIGURE 8 Königsberg bridges and multigraph.

Euler showed that the graph G of Fig. 8b has no eulerian trail. For a graph to have such a trail, it is clear that the graph must be connected and that each vertex, except for possibly the first and last vertex of the trail, must have even degree. These conditions are also sufficient, as the following result states.

Theorem 4.1 (Euler): *Let G be a connected graph (multigraph). Then, G has a closed eulerian trail if and only if each vertex has even degree, and G has an "open" eulerian trail if and only if there are precisely two vertices of odd degree.*

A consequence of Theorem 1.1 is that a graph has an even number of vertices of odd degree. There is a useful immediate corollary of Theorem 4.1. If a connected graph G has $2k$ vertices of odd degree, then the edges of G can be "covered" with k trails, and this is the minimum number of trails which will suffice. This observation is the basis of many puzzles and games.

Also, related to eulerian graphs is the *Chinese postman problem*, which is to determine the shortest closed walk that contains all of the edges in a connected graph G. Such a walk is called for obvious reasons a postman's walk. If G has size m, then the postman's walk will have length m if and only if G is eulerian. At the other extreme, this shortest walk will have length $2m$ if and only if G is a tree. There is the obvious extension of the Chinese postman problem to weighted graphs and minimizing the sum of the weights along the postman's walk. There are several good algorithms for solving this problem.

A graph G is *hamiltonian* if it contains a spanning cycle, and the spanning cycle is called a hamiltonian cycle. The name is derived from the mathematician Sir William Rowan Hamilton, who in 1857 introduced a game, whose object was to form such a cycle. In Euler's problem the object was to visit each of the edges exactly once. In the hamiltonian case the object is to visit each of the vertices exactly once, so the problems seem closely related. However, in sharp contrast to the eulerian case, there are no known necessary and sufficient conditions for a graph to be hamiltonian, and the problem of finding such conditions is considered to be very difficult. There are numerous sufficient conditions for the existence of a hamiltonian cycle and a few necessary conditions. The following is an example of one of the better-known sufficient conditions.

Theorem 4.2 (Ore): *If for each pair of nonadjacent vertices u and v of a graph G of order $n \geq 3$, $d(u) + d(v) \geq n$, then G is hamiltonian.*

A traveling salesman wishes to visit all of the cities on his route precisely one time and return to his home city in the smallest possible time. The *traveling salesman problem* is to determine the route which will minimize the time (distance) of the trip. Another version of the same problem is presented by a robot that is tightening screws on a piece of equipment on an assembly line. An order for tightening the screws should be determined so that the distance traveled by the arm of the robot is minimized. The corresponding graph problem in both cases is to determine a minimum-weight hamiltonian cycle in a complete graph, with weights assigned to each edge. The weight assigned to an edge would represent the time or cost of that edge. A brute-force approach of examining all possible hamiltonian cycles could be quite expensive, since there are $(n-2)!$ possibilities in a complete graph of order n. Although there are good solutions for special classes of graphs, no good algorithm is known for determining such a hamiltonian cycle in the general case; in fact, the traveling salesman problem is known to be *NP-complete*. This means that it is not known if a good algorithm exists, but the existence of a good algorithm to solve this problem would imply the existence of good algorithms to solve many other outstanding problems, such as the graph isomorphism problem. Some of these problems will be mentioned in later sections. Although there is no known good algorithm which always gives a minimum solution, there are procedures which give reasonable solutions most of the time.

V. COLORINGS OF GRAPHS

A coloring (sometimes called a vertex coloring) of the vertices of a graph is an assignment of one color to each vertex. If k colors are used, it is called a k-coloring, and if adjacent vertices are given different colors, it is a proper coloring. The minimum number of colors in a proper coloring of a graph G is called the (vertex) *chromatic number* of G and is denoted by $\chi(G)$. The chromatic number of many special graphs is easy to determine. For example, $\chi(K_n) = n$, $\chi(C_n) = 3$ if n is odd, and $\chi(B) = 2$ for any bipartite graph B with at least one edge. Therefore, all paths, all cycles of even length, and all trees have chromatic number 2, since they are bipartite. In general, the chromatic number of a graph is difficult to determine; in fact, from an algorithm point of view it is an NP-complete problem just like the traveling salesman problem.

In a proper coloring of a graph the set of all vertices assigned the same color must be independent. A proper k-coloring is thus a way of partitioning the vertices V of a graph G into k independent sets, and thus, the chromatic number is the minimum number of independent sets in such a partition.

Consider the problem of storing n chemicals (or other objects) when certain pairs of these chemicals cannot be

stored in the same building. There is a natural model associated with this problem, which is a graph G of order n. The vertices are the chemicals, and the edges are pairs of objects that cannot be stored together. The chromatic number $\chi(G)$ is the minimum number of buildings needed to safely store the objects, since the buildings partition the objects into sets corresponding to independent sets of vertices.

The chromatic number $\chi(G)$ is related to other graphical parameters which are easy to determine, such as $\Delta(G)$, the maximum degree of a vertex of G. The maximum degree gives an upper bound on the chromatic number.

Theorem 5.1 (Brooks): *For any graph G, $\chi(G) \leq \Delta(G)+1$, and if G is a connected graph which is not an odd cycle or a complete graph, then $\chi(G) \leq \Delta(G)$.*

A maximal complete subgraph of a graph is called a *clique*. If a graph G contains a clique of order m, then clearly $\chi(G) \geq m$. However, the determination of the order of the largest clique in a graph is also an NP-complete problem. In addition, the chromatic number of a graph can be very large without the graph even containing a complete graph with three vertices or any small cycle. There is no relation between $\chi(G)$ and the largest clique of a graph G that would simplify the problem of determining $\chi(G)$. The *girth* of a graph G is the length of a shortest cycle in the graph. The following result indicates that a graph can be very sparse and still have a large chromatic number.

Theorem 5.2 (Erdős, Lovász): *For any pair of positive integers k and m, there is a graph with chromatic number at least k and girth at least m.*

This result is interesting, but the proof technique that was used may be of even more interest. The probabilistic method, which was introduced by Paul Erdős, is the basis for the proof. It its simplest form, this powerful technique merely counts the number of graphs which do not satisfy a certain property and verifies that this number is less than the total number of graphs. Therefore, there must be at least one graph with the desired property. This results in a proof of the existence of a graph, but it does not necessarily exhibit such a graph.

There is an edge analog to the vertex coloring of a graph. An assignment of a color to each edge of a graph is called an edge coloring, and it is called a k-edge coloring if at most k colors are used. A proper edge coloring is one in which adjacent edges are assigned different colors. The *edge chromatic number* $\chi_1(G)$ of a graph G is the minimum k for which there is a proper k-edge coloring of G. It should be noted that this concept applies to any multigraph without loops. A lower bound for $\chi_1(G)$ is $\Delta(G)$, since each of the edges incident to a fixed vertex must have different colors. An upper bound is given by the following result.

Theorem 5.3 (Vizing): *For any graph G, $\chi_1(G) = \Delta(G)$ or $\Delta(G)+1$.*

The theorem of Vizing implies that a graph G falls into one of two categories, depending on whether $\chi_1(G) = \Delta(G)$ or not. "Most" graphs are in the first category ($\chi_1 = \Delta$). In particular, all bipartite graphs are in this category. If n is odd, then the cycle has C_n edge chromatic number 3, but maximum degree 2, so there are graphs in the second category. No characterization for graphs in either of these two categories is known.

There are two scheduling problems that can be considered as graph coloring problems. We briefly describe each of the problems along with a solution. The first problem involves a vertex coloring and the second problem involves an edge coloring.

A schedule of classes is to determined that will accommodate the requests of a group of students. If each class is offered at a different time, then each student will be able to take the classes he or she wanted. This could result in a large number of class periods, with some being at very undesirable times. The problem is to determine the minimum number of time periods in which the classes can be scheduled so that each student will get the schedule he or she requested. Consider a graph G with the vertices being the classes to be scheduled. Two classes are joined by an edge if some student would like to take both classes. If two classes are scheduled at the same time, then no student requested to take both of these classes, so such classes must be independent in the graph G. This suggests that the chromatic number $\chi(G)$ is the minimum number of time periods needed for the scheduling. This fact is not difficult to verify.

A similar scheduling problem deals with the scheduling of teachers for classes. A collection of teachers T are to be scheduled to teach a set of classes C. The number of sections of each class for which each teacher is responsible is known. The problem is to determine a schedule which uses a minimum number of time periods. The assumption is made that, in any period, a teacher can teach only one class and each class is taught by only one teacher. Consider the bipartite graph B (actually it is a bipartite multigraph without loops) with T as the vertices in one part and C as the vertices in the other part. If a teacher t in T is scheduled to teach m sections of a class c in C, then place m edges between the vertex t and the vertex c. The construction of a schedule is really a proper edge coloring of the bipartite graph B using the time periods as colors. This observation can be used to verify that the minimum number of periods that must be used in the scheduling is the edge chromatic number $\chi_1(B)$, and this is the maximum degree $\Delta(B)$.

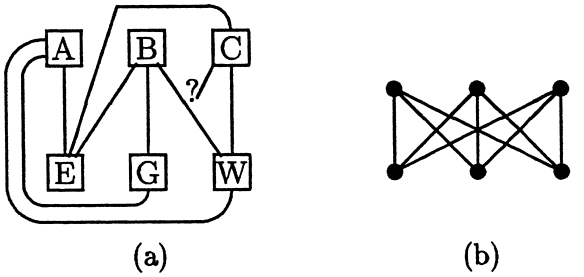

FIGURE 9 Houses-and-utilities problem.

VI. PLANAR GRAPHS

The houses-and-utilities problem is a classical puzzle whose solution can be described using graph theory. Suppose there are three houses (A, B, and C), and three utilities (E, G, and W for electricity, gas, and water) as pictured in Fig. 9a. The problem is to connect each of the utilities to each of the houses without any of the utility lines crossing. Pictured in Fig. 9a is an attempt to do this that failed. The graph theoretical form of this problem is to determine if the complete bipartite graph $K_{3,3}$ (Fig. 9b) can be drawn or pictured in the plane in such a way that the lines which represent the edges do not intersect except at the vertices of the graph. This leads to the concepts of plane and planar graphs.

A *planar graph* is one that can be drawn in the plane with points representing the vertices, and "nice smooth curves or lines" that do not intersect representing the edges. Once such a graph is drawn or embedded in the plane, it is called a *plane graph*. Thus, the three-utilities problem is equivalent to determining if $K_{3,3}$ is a planar graph. It is also a question that has a surprisingly uncomplicated answer, not only for the special graph $K_{3,3}$, but for any graph.

Figure 10 is a diagram of a plane graph G. Associated with this diagram are points (vertices of G), curves (edges of G), and regions (faces of G). The regions are the connected portions of the plane that remain after the points and curves of the diagram are deleted. Also note that one of these regions, namely R_4, is unbounded. If p, q, and r are the number of vertices, edges, and faces of a plane graph G, respectively, then $p = 6$, $q = 8$, and $r = 4$ for the graph in Fig. 10. An induction proof can be employed to verify that the following linear equality is always satisfied by these parameters.

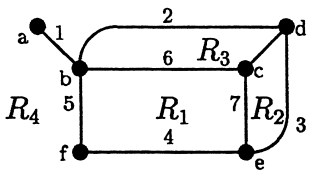

FIGURE 10 Plane graph.

Theorem 6.1 (Euler formula): *If G is a plane graph with p vertices, q edges, and r faces, then $p - q + r = 2$.*

The above result is a useful and powerful tool in proving that certain graphs are not planar. The boundary of each region of a plane graph has at least three edges, and of course each edge can be on the boundary of at most two regions. Thus, the number of edges and regions in a plane graph satisfies the inequality $r \leq 2q/3$. This inequality and Theorem 6.1 imply the relationship $q \leq 3p - 6$ between the number of vertices and edges in a planar graph. This type of reasoning and the observation that in a bipartite plane graph each region will have at least four edges on its boundary give the following result.

Theorem 6.2: *If G is a connected planar graph with p (≥ 3) vertices and q edges, then $q \leq 3p - 6$. If, in addition, G is a bipartite graph, then $q \leq 2p - 4$.*

The second inequality of Theorem 6.2 implies that the bipartite graph $K_{3,3}$ is not planar, since $9 > 2(6) - 4$. The first inequality of Theorem 6.2 implies that the complete graph K_5 is also not planar, since $p = 5$ and $q = 10$ for K_5. In some sense any graph that is not planar must contain either K_5 or $K_{3,3}$. We now describe what we mean by "in some sense." To *subdivide* an edge uv of a graph is to replace an edge with a vertex w and two edges uw and wv. This is like placing a vertex in the middle of an edge. A *subdivision* of a graph is obtained by successively subdividing the edges of a graph. Clearly, a subdivision of a graph is planar if and only if the graph is planar. We can now give a characterization of planar graphs.

Theorem 6.3 (Kuratowski): *A graph is planar if and only if it contains no subdivision of K_5 or $K_{3,3}$.*

One of the most famous problems in mathematics is the four-color problem, which was first proposed in 1852. Consider a map, such as the map of Europe. We would like to color the countries (which we will assume to be connected) so that two countries that have a common boundary (not just a point) will have different colors. Is it possible to color any such map with at most four colors? It is easy to show that six colors will suffice, since any planar graph must have a vertex of degree at most 5. Also, there is a clever but elementary proof which shows that five colors is sufficient. However, the question of whether four colors are enough remained an open question for many years. Many mathematicians (both professional and amateur) worked on this problem, and many incorrect proofs were generated.

A map M with five countries is pictured in Fig. 11a. Associated with this map is a planar graph G, whose

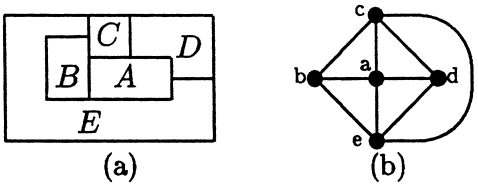

FIGURE 11 Map and plane graph.

vertices are the countries and whose edges join countries with a common boundary. An embedding of G is given in Fig. 11b. It is important to note that the graph G is planar. Coloring the map M so that adjacent countries have different colors is the same as giving a proper vertex coloring of the planar graph G of Fig. 11b. Associated with any map is a planar graph, and conversely, associated with a plane graph is a map. Thus, solving the four-color problem is equivalent to showing that no planar graph has chromatic number greater than four. In 1976 a positive solution to this problem was obtained by Appel and Haken by reducing the problem to a finite number of classes of planar graphs, and then by analyzing these cases with the aid of a computer. Since that time, the number of cases left to computer verification has been decreased, and also independent computer programs have been created to verify the remaining cases. However, all present proofs are still dependent on computer verification of a large number of cases.

Theorem 6.4 (Appel-Haken): *For any planar graph* G, $\chi(G) \leq 4$.

For many applications, planarity is a very desirable property to have. If the graph that represents an electrical circuit is planar, then the circuit can be printed on a board. Also, there are good algorithms (in fact, linear in the number of edges of the graph) for testing graphs for planarity and for embedding planar graphs in the plane.

For graphs which are not planar, there are several measures of how "nonplanar" they are. We mention three of the most common measures. One of these is the genus of a graph. The surface obtained from a sphere by adding m handles (like a handle on a coffee cup) is a *surface of genus* m. Embeddings for these surfaces is defined in the same way as it is for the plane: curves which represent edges must not intersect except at points which represent vertices. A graph G has *genus* m if it can be embedded in a surface of genus m but not in a surface of genus $m-1$. Any finite graph can be embedded in a surface of sufficiently large genus, so every graph has finite genus. Embedding a graph in the plane is equivalent to embedding the graph on a sphere. Since a sphere is a surface of genus 0, the planar graphs are precisely the graphs of genus 0.

If a graph G is not planar, then it can be "broken" into subgraphs which are planar. The minimum number of planar subgraphs of G, whose union of edges is all of the edges of G, is called the *thickness* of G. Therefore, a planar graph has thickness 1.

If a graph G is not planar, then any drawing of it in the plane would require that at least two of the edges "cross" at some point other than at a vertex. The minimum number of such crossings possible for some representation in the plane is called the *crossing number* of G. Clearly, planar graphs have crossing number 0.

In general, the determination of the genus, thickness or crossing number of a graph is an extremely difficult problem, even for special classes of graphs. For example, both the genus and thickness of all complete graphs are known, but the proofs are not easy. Also, the crossing number is not known for complete graphs with more than 10 vertices.

VII. FACTORIZATION THEORY

A spanning subgraph of a graph G is called a *factor* of G. If $E(G)$ is the edge disjoint union of the edges of factors of G, then these factors form a *factorization* of G. Thus a factorization is a partitioning of the edges of the graph. A factor of a graph which is r-regular is called an *r-factor*, and any factorization of a graph with r-factors is called an *r-factorization*. A hamiltonian cycle in a graph is an example of a 2-factor. Of particular interest are 1-factors of graphs, also called *perfect matchings*. A perfect matching of a graph of order n (clearly n must be even) thus consists of $n/2$ independent edges (edges which are not adjacent). A collection of independent edges, which may not necessarily span the graph, is called a *matching*. A matching with the most edges is called a maximum matching. In a cycle C_{2k} of even length the alternate edges in the cycle form a perfect matching in the cycle. There are thus two such perfect matchings, and they form a 1-factorization of the cycle.

Factorizations of complete graphs have been studied extensively. For example, K_{2n} has a 1-factorization. Thus K_{2n} will have an r-factorization if and only if $2n$ is a multiple of r. Of course K_{2n+1} cannot have a 1-factor because of its order, but it does have a 2-factorization. In fact, it has a factorization consisting of hamiltonian cycles. In Fig. 12a, a 1-factorization of K_4 is displayed, and a 2-factorization of K_5 is given in Fig. 12b. There are many other kinds of interesting factors and factorizations of complete graphs, such as factoring with paths or trees.

One of the earliest general results in this area involves a characterization of graphs which have 2-factorizations. Clearly, a graph G cannot have an r-factorization unless it is m-regular for some multiple m of r. In the case when $r = 2$, this condition is also sufficient.

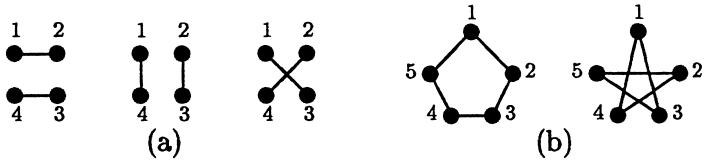

FIGURE 12 (a) 1-Factorization of K_4. (b) 2-Factorization of K_5.

Theorem 7.1 (Petersen): *A graph has a* 2*-factorization if and only if it is* m*-regular with* m *even.*

A similar characterization for 1-factorizations in bipartite graphs exists.

Theorem 7.2 (Kőnig): *A bipartite graph has a* 1*-factorization if and only if it is regular.*

Perfect matchings of graphs have been investigated more extensively than any other factors. Fortunately, there is a very useful characterization of bipartite graphs which have perfect matchings. If G is a bipartite graph with parts A and B, then a matching M is said to *saturate* A if each vertex in A is incident to an edge of M. Thus, if $|A| = |B|$, any matching which saturates A is a perfect matching. Also, if M is a matching which saturates A, then for any subset S of A, the neighborhood $N(S)$ of S (vertices not in S which are adjacent to some vertex of S) must have as many vertices as S, because just the matching M implies this. This condition is also sufficient to imply the existence of a perfect matching.

Theorem 7.3 (Philip Hall): *If* G *is a bipartite graph with parts* A *and* B*, then there is a matching which saturates* A *if and only if* $|N(S)| \geq |S|$ *for all* $S \subseteq A$.

A characterization of all graphs which have perfect matchings also exists, but it is more complicated. If S is a separating set for a graph G, then $G - S$ may have several components. Any component C with an odd number of vertices (called an odd component) cannot within itself have a perfect matching. So, any perfect matching of G would have at least one edge joining a vertex of C with a vertex of S. Thus, if G has a perfect matching, the number of odd components cannot exceed the number of vertices in S. This condition on the number of odd components is also sufficient for the existence of a perfect matching.

Theorem 7.4 (Tutte): *A graph* G *has a perfect matching if and only if for each* $S \subseteq V(G)$ *the number of odd components in* $G - S$ *does not exceed* $|S|$.

Although both Theorem 7.3 and Theorem 7.4 are useful results, they cannot be applied directly to obtain good algorithms for finding perfect matchings (or maximum matchings) in graphs. This is true because there are 2^n different subsets in a set with n elements. However, good algorithms do exist for finding maximum matchings in graphs. One such algorithm for bipartite graphs uses the idea of an alternating path. If M is a matching of a graph G, then an M-alternating path is a path whose edges alternate between edges in M and edges not in M. If the first and last vertices of the path are not in M, then the path is an M-augmenting path. If P is an M-augmenting path, then replacing the edges of P which are in M with the edges of P not in M will give a larger matching in G. Thus a maximum matching M never has an M-augmenting path. Berge showed that this was a necessary and sufficient condition for a matching to be maximum.

The algorithm based on this result searches for augmenting paths by constructing a tree rooted at a vertex which is not saturated by the the matching. Also, all of the paths in this tree are alternating. Either this tree will give an augmenting path, which will give a larger matching, or the matching will be a maximum matching. The condition of Hall can be shown to be violated if the maximum matching is not a perfect matching.

There are many applications of matchings in graphs. An obvious one is the *assignment problem*. Assume there are n workers and n jobs, and each worker can perform certain of the jobs. The assignment problem is to determine if it is possible to assign each person a job (two workers can not be assigned the same job), and if so, make the assignment. The graph model is a bipartite graph with the workers in one part and the jobs in the other part. An edge is placed between a worker and any job he can perform. The assignment problem reduces to finding a maximal matching in this bipartite graph. If this matching is a perfect matching, then an assignment can be made. Otherwise, it is not possible. Since there is a good algorithm for finding maximal matchings in bipartite graphs, there is a good algorithm for solving the assignment problem.

The assignment problem can also be considered when the number of jobs and the number of workers are not the same. However, for example, in this case when the number of workers exceeds the number of jobs, the objective is to assign all of the jobs. This will unfortunately leave some of the workers unemployed. The graph model is still the same bipartite graph, and the objective is to find a matching which saturates the vertices associated with the jobs. The same algorithm used when the number of jobs is the same as the number of workers applies in this case.

A generalization of the assignment problem is the *optimal assignment problem*. Here there are also n workers and

n jobs. However, in this case, the ith worker can perform the jth job with some efficiency c_{ij}. The problem is to assign each worker a job such that the sum of the efficiencies is a maximum. Again, a brute-force approach of examining all possible assignments is not efficient, since there are $n!$ such possibilities. However, there is a good algorithm for solving the optimal assignment problem which utilizes finding maximum matchings in a series of appropriately defined bipartite graphs. Associated with a given assignment of jobs there is a bipartite graph. A maximum matching is determined in this bipartite graph. If the maximum matching is not a perfect matching, then it can be used to obtain a better assignment which determines a new bipartite graph. If the matching is perfect, then the assignment is optimal and the algorithm terminates.

VIII. GRAPH RECONSTRUCTION

A famous unsolved problem in graph theory is the Kelly-Ulam conjecture. A graph G of order n is *reconstructible* if it is uniquely determined by its n subgraphs $G - v$ for $v \in V(G)$. In Fig. 13 there is an example of the four graphs obtained from single vertex deletions of a graph of order 4, and the graph they uniquely determine.

Reconstruction Conjecture (Kelly-Ulam): *Any graph of order at least* 3 *is reconstructible.*

The initial but equivalent formulation of the conjecture involved two graphs. If G and H are graphs with $V(G) = \{u_1, u_2, \ldots, u_n\}$ and $V(H) = \{v_1, v_2, \ldots, v_n\}$, and if $G - u_i \cong H - v_i$ for $1 \le i \le n$, then $G \cong H$. Note that to say that a graph G is reconstructible does not mean that there is a good algorithm which will construct the graph G from the graphs $G - v$ for $v \in V$. A positive solution to the conjecture might still leave open the question of the complexity of algorithms that would generate a solution to the problem.

Although it is not known in general if a graph is reconstructible, certain properties and parameters of the graph are reconstructible. It is straightforward to reconstruct from the vertex-deleted subgraphs both the size of a graph and the degree of each vertex. Let G be a graph of size q with vertices $\{v_1, v_2, \ldots, v_p\}$, and for each i let q_i be the size of the graph $G - v_i$. Each edge in G would appear in precisely $p - 2$ of the vertex deleted subgraphs, hence

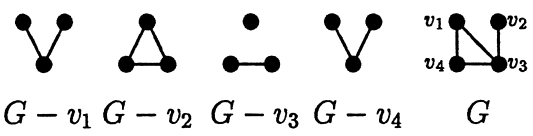

FIGURE 13 Graph reconstruction.

$$q = \left(\sum_{i=1}^{p} q_i \right) \Big/ (p - 2).$$

Also, clearly the vertex v_i has degree $q - q_i$. An immediate consequence of these facts is that any regular graph is reconstructible.

Several properties dealing with the connectedness of a graph are reconstructible, including the number of components of the graph. A subgraph of a graph is a *block* if it is a maximal 2-connected subgraph. The blocks of a graph partition the edges of a graph, and the only vertices that are in more than one block are the cut-vertices. If a graph has at least two blocks, then the blocks of the graph can also be determined. However, this does not mean the graph can be reconstructed from the blocks.

There are many special classes of graphs which are reconstructible, but we list only three well-known classes.

Theorem 8.1: *The following classes of graphs are reconstructible:*

(i) Disconnected graphs
(ii) Trees
(iii) Regular graphs

Corresponding to the "vertex" reconstruction conjecture is an *edge reconstruction conjecture*, which states that a graph G of size $m \ge 4$ is uniquely determined by the m subgraphs $G - e$ for $e \in E(G)$. Such a graph is said to be *edge-reconstructible*. Just as in the vertex case, the edge conjecture is open. The two conjectures are related, as the following result indicates.

Theorem 8.2 (Greenwell): *If a graph with at least four edges and no isolated vertices is reconstructible, then is is edge-reconstructible.*

Theorem 8.2 implies that trees, regular graphs, and disconnected graphs with two nontrivial components are edge reconstructible. There are also results which show that graphs with "many" edges are edge-reconstructible. For example, Lovász has shown that if a graph G has order n and size m with $m \ge n(n-1)/4$, then G is edge-reconstructible.

Intuitively, the edge-reconstruction conjecture is weaker than the reconstruction conjecture. This is confirmed by Theorem 8.2. However, there is another way of relating the two conjectures. Associated with each graph G is the line graph $L(G)$ of G. The vertices of $L(G)$ are the edges of G and two vertices of $L(G)$ (which are edges of G) are adjacent in $L(G)$ if and only if they were adjacent edges in G. The following result relates reconstruction and edge reconstruction.

Theorem 8.3 (Harary, Hemminger, Palmer): *A graph with size at least four is edge-reconstructible if and only if its line-graph is reconstructible.*

The line graphs of some special classes of graphs are easy to determine. For example, the line graph of a star $K_{1,n}$ is K_n, a complete graph, and the line graph of a cycle C_n is the cycle C_n of the same length. Therefore, the graphs K_3 and $K_{1,3}$ have isomorphic line graphs, namely, K_3. With this one exception, the line graphs of nonisomorphic connected graphs are also nonisomorphic. However, this does not imply that every graph is the line graph of some graph. In fact, there are numerous characterizations of line graphs. In particular, no graph which has an induced subgraph isomorphic to $K_{1,3}$ can be the line graph of a graph.

Since not every graph is the line graph of some graph, Theorem 8.3 does not imply that the edge reconstruction conjecture and the vertex reconstruction conjecture are equivalent.

IX. EXTREMAL THEORY

There are a large number of optimization problems and results in graph theory which could be considered in a discussion of extremal graph theory. However, we will restrict our consideration to the Turán-type extremal problem of determining the maximum number of edges a graph can have without containing a certain subgraph. For example, consider the problem of determining how many edges there can be in a graph of order n which does not contain a K_3 (triangle). For n even, the complete bipartite graph $K_{n/2,n/2}$ has $n^2/4$ edges and no triangle, and, in fact, no odd cycle of any length. Also, any graph with n vertices and $(n^2/4)+1$ edges (for n even) can be shown to contain a triangle. Thus, when n is even, the maximum number of edges in a triangle-free graph of order n is $n^2/4$.

The original problem of Turán, who initiated this kind of investigation, was to determine the maximum number of edges a graph of order n can have without containing a complete graph K_p. The case $p=3$ was just considered. The general case, while more complicated, is entirely parallel.

Multipartite graphs are a class of graphs which occur in this type of study. A graph G is called a *k-partite graph* if the vertices V can be partitioned into k parts such that the only edges in G join vertices in different parts. Thus, bipartite graphs are simply 2-partite graphs. If all edges between each pair of k parts are in the graph, the graph is called a *complete k-partite graph*. In any k-partite graph the vertices in each part are independent, and if the graph is a complete k-partite graph then the chromatic number of the graph is clearly k. Let $T(n, k)$ denote the complete k-partite graph of order n in which the difference in the number of vertices in any pair of parts is at most 1. That is, if $n = km + r$ with $0 \le r < m$, there will be r parts with $m+1$ vertices and the remaining $k-r$ parts will have m vertices. Let $t(n, k)$ denote the size of the graph $T(n, k)$. Turán proved the following result.

Theorem 9.1 (Turán): *The maximum number of edges in a graph of order n which does not contain a K_p is $t(n, p-1)$, and the graph $T(n, p-1)$ is the only graph of that order and size with no K_p.*

For a fixed graph F, which we will call the forbidden graph, the extremal number $\mathrm{ex}(n, F)$ is the maximum size of a graph of order n which does not contain an F as subgraph. The collection of graphs of order n and size $\mathrm{ex}(n, F)$ are called the extremal graphs for F and is denoted by $\mathrm{Ex}(n, F)$. The extremal problem consists of finding $\mathrm{ex}(n, F)$ and also $\mathrm{Ex}(n, F)$, if possible. In the case when the forbidden graph is K_p, the result of Turán states that $\mathrm{ex}(n, K_p) = t(n, p-1)$ and $\mathrm{Ex}(n, Kp) = \{T(n, p-1)\}$. Note that

$$t(n, p-1) = \left(\frac{p-2}{p-1}\right)\binom{n}{2}$$

when n is a multiple of $p-1$ and is close to that for all other values of n. If p is thought of as the chromatic number of the complete graph K_p, then the extremal result for an arbitrary graph F is closely related to the result for the complete graph. In fact, the chromatic number $\chi(F)$ determines the order of magnitude of the extremal number if the graph is not bipartite. In the following result, an "error function" is needed. Denote by $o(n^2)$ a function of n with the property that $\lim_{n\to\infty} o(n^2)/n^2 = 0$.

Theorem 9.2 (Erdős-Simonovits): *For any nontrivial graph F with chromatic number $k \ge 3$,*

$$\mathrm{ex}(n, F) = \left(\frac{k-2}{k-1}\right)(n^2) + o(n^2).$$

Also, any graph in $\mathrm{Ex}(n, F)$ *can be obtained from $T(n, k-1)$ by deleting or adding at most $o(n^2)$ edges.*

If F is not a bipartite graph, then the first term in the expression for $\mathrm{ex}(n, F)$ in Theorem 9.2 is of order n^2, so the error function $o(n^2)$ becomes insignificant for sufficiently large values of n. However, when F is a bipartite graph, this first term is 0, and thus Theorem 9.2 gives little information. The extremal problem for a bipartite graph is called the *degenerate extremal problem*. In this case, there are many interesting open questions, and no general asymptotic result like Theorem 9.2 is known in the degenerate case. Examples which give lower bounds for the number $\mathrm{ex}(n, F)$ are difficult to find when F is a bipartite graph, and in many cases involve designs. We mention two results which give upper bounds. Sharp lower bounds are not known for either of the classes of graphs considered

below, except for a few small-order cases such as C_4, C_6, C_{10}, and $K_{3,3}$.

Theorem 9.3 (Kővári-Sós-Turán): *If $r \le s$, then there exists a constant c_{rs} (depending only on r and s) such that*

$$\mathrm{ex}(n, K_{r,s}) \le c_{rs} n^{[2-(1/r)]}.$$

Theorem 9.4 (Erdős): *There is a constant c_k such that* $\mathrm{ex}(n, C_{2k}) \le c_k n^{[1+(1/k)]}$.

In the special case when the forbidden bipartite graph F is a tree, more is known about $\mathrm{ex}(n, F)$. When $p-1$ divides n, a disjoint union of complete graphs K_{p-1} implies that $\mathrm{ex}(n, Tp) \ge (p-2)n/2$ for any tree with p vertices. Erdős and Sós conjectured that $(p-2)n/2$ is an upper bound as well for all values of n. This is known to be true for stars and paths.

The extremal problem can be generalized to consider a family of forbidden graphs, not just one graph. However, the extremal results for a family of forbidden graphs is essentially the same as for one forbidden graph. The important parameter in the case of a family of graphs is the smallest chromatic number of a graph which is in the family. Therefore, if there is at least one subgraph in the family which is bipartite, then the extremal number will be $o(n^2)$. Also, if a graph G of order n has more than $\mathrm{ex}(n, F)$ edges, then it has at least one copy of F. An interesting problem is to determine the number of copies of F that G must have as a function of the number of edges k in G.

An area of extremal theory which predates theory related to the Turán type of theory is *Ramsey theory*. In Ramsey theory, pairs of "forbidden" graphs are considered, say, F_1 and F_2, and one is interested in determining whether for each graph G of order n, F_1 is a subgraph of G, or F_2 is a subgraph of the complement $\bar{G}$ of G. A consequence of a result of Frank Ramsey proved in 1930 is that this is always true if n is sufficiently large. The smallest n for which it is true is called the Ramsey number of the pair (F_1, F_2) and is denoted by $r(F_1, F_2)$. In general, these numbers are difficult to determine. In the classical case when F_1 and F_2 are complete graphs, only a few of the Ramsey numbers are known; in fact, Table I gives all of the known Ramsey numbers $r(K_m, K_n)$ for $3 \le m \le n$.

TABLE I Ramsey Numbers $r(K_m, K_n)$

$m\backslash n$	3	4	5	6	7	8	9
3	6	9	14	18	23	29	36

X. DIRECTED GRAPHS

A *directed graph* or *digraph* D is a finite collection of elements, which are called vertices, and a collection of ordered pairs of this vertices, which are called arcs. Thus, a digraph is similar to a graph except that each arc in a digraph has a direction, while an edge in a graph does not. Just as in the case for graphs, the vertices and arcs of D will be denoted by V and E, respectively. However, in this case the arc $e = uv$ does not join vertices u and v, but it joins u to v. Thus, $uv \ne vu$. The terms adjacent with and incident with will be replaced by the terms adjacent to, adjacent from, incident to, and incident from. The order and size of a digraph is the same as for a graph.

Most of the concepts for graphs have obvious analogs for digraphs, for example, *subdigraph* and directed walks of various types. However, the degree of a vertex v is split into two parts: $d^+(v)$ is the number of arcs incident from v and is called the *outdegree*, and $d^-(v)$ is the number of arcs incident to v and is called the *indegree*. The degree $d(v) = d^+(v) + d^-(v)$. Associated with each digraph D is an underlying graph G obtained from D by removing the directions from the edges of D and then removing any one of any pair of multiple edges that are produced from removing the directions.

The concept of connectivity is more complicated for directed graphs, and several types of connectivity arise. We will mention two that are most commonly used. A digraph D is connected if the underlying graph is connected. A vertex v is *reachable* from a vertex u if there is a directed path from u to v. The digraph is *strongly connected* or *diconnected* if each pair of distinct vertices is reachable from each other. Clearly, diconnectedness implies connectedness, but the digraph in Fig. 14a shows that the two concepts are not the same. Just as connectivity can be used to partition the vertices of a graph into components, diconnectedness can be used to partition the vertices

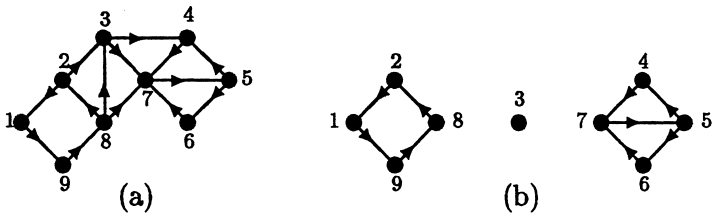

FIGURE 14 (a) Digraph. (b) Components.

of a digraph into dicomponents. Any pair of vertices in the same dicomponent are mutually reachable. The dicomponents of the digraph D in Fig. 14a are shown in Fig. 14b. Thus, the digraph in Fig. 14a is an example of a graph which is connected, but yet it has three diconnected components.

The lengths of paths or cycles in the underlying graph of a digraph give no information about the length of directed paths or cycles. However, it is surprising that the chromatic number of a digraph (which is the same as the chromatic number of the underlying graph) does provide some information, as the following two results indicate. The first of these results can be obtained as a corollary of the second.

Theorem 10.1 (Gallai-Roy): *Every digraph D contains a directed path of length at least $\chi(D)$.*

Theorem 10.2 (Bondy): *Every diconnected digraph D contains a cycle of length at least $\chi(D)$.*

Just as in the case for graphs, there are natural questions concerning the existence of special subdigraphs in digraphs. Conditions which imply the existence of eulerian directed trails, cycles, or other subdigraphs in digraphs are many times analogs of conditions in graphs. The following are just two such examples from among many.

Theorem 10.3 *A digraph D has a closed eulerian directed trail if and only if $d^+(v) = d^-(v)$ for all $v \in V$.*

Theorem 10.4 (Woodall): *If D is a digraph of order n such that $uv \notin E(D)$ implies that $d^+(u) + d^-(v) \geq n$, then D has a directed hamiltonian cycle.*

Consider a city which has had both one-way and two-way streets, but because of the additional traffic flow must make each street one-way. Is it possible that the direction of the streets can be chosen so that a motorist can get from any one point in the city to any other point in the city? Given a graph G, an *orientation* of the graph is an assignment of a direction to each of the edges of the graph. Thus, the oriented graph obtained in this way is a digraph. The graph theory form of the initial problem is to determine for which graphs there is an orientation which makes the resulting digraph diconnected. If the graph contains a *bridge* (an edge which disconnects the graph), then clearly no such orientation exists. The lack of such a bridge, which means that at least two edges must be deleted to disconnect the graph and so the graph is 2-edge-connected, is also a sufficient condition.

Theorem 10.5 (Robbins): *Every 2-edge-connected graph has an orientation which gives a diconnected digraph.*

A digraph obtained from orientating a complete graph is called a tournament. See Fig. 15 for an example of a

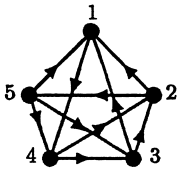

FIGURE 15 Diconnected tournament.

tournament which is diconnected and in fact has a directed hamiltonian cycle. The use of the term "tournament" is a natural one. If a "tennis tournament" were played with each pair of participants playing each other (round robin tournament), then the results of the tournament could be modeled by this type of directed graph. A directed edge from u to v indicates that u defeated v. Tournaments are a class of digraphs that has been studied extensively. If T is a tournament of order n, then the chromatic number $\chi(T)$ is n. Therefore Theorem 10.1 and Theorem 10.2 have the following immediate consequences.

Theorem 10.6 (Re'dei): *Every tournament has a directed hamiltonian path.*

Theorem 10.7 (Camion): *Every tournament of order at least 3 has a directed hamiltonian cycle if and only if it is diconnected.*

Theorem 10.6 implies that in any round-robin tournament the players can always be ordered such that the ith player defeated the $(i+1)$th player. In this case the first player could be considered the "best" player. However, the hamiltonian path is not necessarily unique, so there could be another ordering which would give a different first person who could also claim to be the "best." Theorem 10.7 implies that the players can be cyclically ordered such that the ith player defeated the $(i+1)$th if and only if for each pair of players A and B there is a sequence from A to B such that each player defeated the next player in the sequence. In this case any person could make an argument for being the "best" player in the tournament.

Most of the algorithms dealing with graphs have digraph analogs. Also, in general, the complexity of the corresponding algorithms are approximately the same. If there is a good algorithm in the graph case, then the corresponding digraph algorithm will usually be good, and if the graph algorithm is NP-complete, then the corresponding digraph algorithm will be NP-complete. For example, there is a good algorithm to find the dicomponents of a digraph just as there is a good algorithm to find the components of a graph. The existence of hamiltonian cycles is NP-complete in both the directed and undirected case.

XI. NETWORKS

The term "network" is used in several different contexts and has many meanings. For example, there are communication networks and there are electrical networks. We will generally restrict our consideration to one kind of network, which we now define. The purpose is to build a model for determining how to maximize the flow of goods from one point to another in some transportation system. A *network* is a digraph D with two specified vertices s (which is called the *source*) and t (which is called the *sink*), and a function c (called the capacity) which assigns to each arc of the network a non-negative integer. A *flow* on D is a function f from $E(D)$ into the non-negative integers such that the following two conditions are satisfied:

$$f(e) \le c(e) \qquad \text{for all} \quad e \in E, \quad \text{and}$$

$$\sum_{uv \in E} f(uv) = \sum_{vw \in E} f(vw) \qquad \text{for all} \quad v \in D - s, t.$$

The first condition merely states that the flow cannot exceed the capacity of the arc, and the second condition requires that the flow into an intermediate vertex is the same as the flow out of the vertex. The object is to find a maximum flow from the source s to the sink t. The value to be maximized is the net flow out of s, which is $\sum_{sv \in E} f(sv) - \sum_{vs \in E} f(vs)$. An example of a network with a flow is given in Fig. 16. The first number of the pair by each arc is the flow and the second number is the capacity. The net flow in this example is 4.

A *cut* in a network D is a partition of the vertices V into two subsets S and $\bar{S}$ with $s \in S$ and $t \in \bar{S}$. The capacity of the cut is the sum of the capacities of the edges from S to $\bar{S}$. The following is called the max-flow min-cut theorem.

Theorem 11.1 (Ford-Fulkerson): *In a network the value of a maximum flow is equal to the capacity of a minimum cut.*

There is a good algorithm for finding a maximum flow in a network. It is based on starting with any flow—say, the 0 flow—and successively increasing this flow by finding a path (with possibly some arcs reversed) from source to the sink on which the flow can be increased. If at any step this cannot be done, the algorithm generates a cut whose capacity is equal to the flow. This, of course, implies that the flow is maximum.

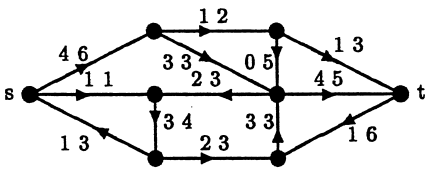

FIGURE 16 Network.

The networks considered here were single-source and single-sink networks. This is not a restriction, since it is simple to go from a multiple-source and multiple-sink network to a network with a single source and a single sink. A new network can be constructed by adding a "super source" which is adjacent to all of the sources and a "super sink" which is adjacent from all of the sinks. A solution to the maximum flow problem for this single-source and single-sink network will give a solution to the maximum flow problem for the multiple-source and multiple-sink network.

There are many applications and consequences to the max-flow min-cut theorem. The matching result of Hall and the various forms of Menger's theorems for both graphs and digraphs can be proved using this result.

Digraphs with labels on the directed edges, such as the network just described, can be used as models for many situations. In operations research, activity networks are useful as models for the planning of activities of large projects. A digraph with a single source and sink (representing the beginning and end of the project) will have directed edges which represent the activities of the project. The directed edges also indicate which activities must be completed before others can be started. The label on each edge will represent the time required to complete that activity. Algorithms which calculate path lengths can be used to determine optimal schedules for such projects and to determine which activities are critical in keeping such a schedule.

XII. RANDOM GRAPHS

Paul Erdős first introduced probabilistic methods to graph theory in the 1940s, and this powerful technique of studying "random graphs" has had an extraordinary impact on the development of graph theory. There are several models for studying random graphs, but we will just discuss one. Consider the collection of all labeled graphs (the vertices are distinguishable) of order n on the vertices $\{1, 2, \ldots, n\}$. The complete graph on the set of vertices has $N = \binom{n}{2}$ edges, and the number of different labeled graphs is 2^N, since there is the choice of either choosing or rejecting each of the N edges. Given a positive number p with $(0 \le p \le 1)$, this collection of graphs becomes a probability space, which we will denote by $\mathcal{G}(n, p)$, by choosing each edge with independent probability p. Therefore the probability that a *random graph* in $\mathcal{G}(n, p)$ is a fixed graph G that has m edges is $p^m(1-p)^{N-m}$.

Using the probability space $\mathcal{G}(n, p)$, it is possible to prove the existence of a graph with certain properties without actually exhibiting the graph. This is done by counting the number of graphs that do not satisfy a

specified property and showing that this number is smaller than the total number of graphs. An example of this type of result is the following result of Erdős concerning an exponential lower bound for Ramsey number $r(K_s, K_s)$.

Theorem 12.1 (Erdős): *There is a positive constant c such that $r(K_n, K_n) > cs^{s/2}$.*

The lower bound of the previous theorem has been improved using random graphs (probabilistic techniques), but at this point no graphs have actually been described that satisfy the bound. It was mentioned earlier that given positive integers k and m there is a graph G with the chromatic number $\chi(G) \geq k$ and girth $g(G) \geq m$. Again, the major tool used in this proof is the probabilistic method.

If R is a graphical property, then the probability that a graph G in $\mathcal{G}(n, p)$ has property R will be denoted by $P[R \cap \mathcal{G}(n, p)]$. We say that *almost all graphs* have property R if $\lim_{n\to\infty} P[R \cap \mathcal{G}(n, p)] = 1$. There is the corresponding definition for *almost no graphs*. As the value of p increases, the expected number of edges of a random graph G in $\mathcal{G}(n, p)$ will also increase. Thus, if p is a fixed positive real number, then the expected number in edges in a random graph G in $\mathcal{G}(n, p)$ is $p\binom{n}{2}$, which is substantial. Therefore, these graphs are dense, so it is not surprising that the following is true.

Theorem 12.2: *If p is a fixed positive number $(0 < p < 1)$, then for any fixed positive integer k, almost all graphs [in the probability model $\mathcal{G}(n, p)$] have the following properties (among others):*

(i) Diameter 2
(ii) Contain any finite subgraph H as an induced subgraph
(iii) k-Connected
(iv) Hamiltonian
(v) Genus exceeding k
(vi) Chromatic number exceeding k

It is obvious that a p increases, the number of edges of graphs in a random graph in $\mathcal{G}(n, p)$ increases, but it is not obvious that random graphs undergo significant structural changes as the number of edges increases. This behavior can be described in terms of *threshold functions* for a graphical property in the probability space $\mathcal{G}(n, p)$ for the probability $p = p(n)$. If R is a graphical property then $t(n)$ is a threshold function for property R when $\lim_{n\to\infty} p(n)/t(n) = \infty$, then almost all graphs have property R and when $\lim_{n\to\infty} p(n)/t(n) = 0$, then almost no graphs have property R. The following two results are examples of threshold functions for the property of being "connected" and the property of being "hamiltonian."

Theorem 12.3: *Assume that $\lim_{n\to\infty} g(n) = \infty$, and let $p_1(n) = [\ln n - g(n)]/n$ and $p_2(n) = [\ln n + g(n)]/n$. Then, almost no graphs in $\mathcal{G}[n, p_1(n)]$ are connected, and almost all graphs in $\mathcal{G}[n, p_2(n)]$ are connected.*

The previous theorem implies that $t(n) = (\ln n)/n$ is the threshold function for connectivity, and the next result implies that $t(n) = [(\ln n)/n + \ln\ln n]/n$ is the threshold function for hamiltonicity.

Theorem: 12.4: *Assume that $\lim_{n\to\infty} g(n) = \infty$, and let $p_1(n) = [\ln n + \ln\ln n - g(n)]/n$ and $p_2(n) = [\ln n + \ln\ln n + g(n)]/n$. Then, almost no graphs in $\mathcal{G}[n, p_1(n)]$ are hamiltonian, and almost all graphs in $\mathcal{G}[n, p_2(n)]$ are hamiltonian.*

There are corresponding threshold functions results for a wide range of graphical properties.

GLOSSARY

Box plot Graph displaying the outliers, adjacent values, quartiles, and median. The distribution caricature is especially useful as a terse summary and for comparing the distributions of different groups.

Conditioned plots Multiple juxtaposed panels where only the cases that satisfy constraints associated with a panel appear in or define the contents of the panel. Controls for the variation in related variables. Useful for reducing three-, four-, and five-dimensional relationships to a sequence of planar views.

Conditioned maps Multiple panels of juxtaposed maps where only the regions with variables that satisfy constraints associated with a panel appear highlighted in panel. Useful or controlling the variation of a variable display on a map due to one or more independent variables.

Glyph plots Graphs that encode variables as something other than position along an axis. Sometimes useful for showing several variables.

Linked plots A set of panels representing different variables of the same cases. The representation of the variables of the same case are connected by lines, color, point position, or other features that allow matching. Useful for assessing higher-dimensional relationships using mode dimensional views.

Mean difference plot A scatterplot that plots the difference of paired values on the y-axis and the mean of pair values on the x-axis.

Multidimensional scaling An algorithmic method that represents points in a lower-dimensional space while attempting to preserve the distances between all point pairs. An infrequently used method for embedding data in lower dimensions.

Paired comparison plot A scatterplot of values that have been paired because they are measurements on the same entity or process in two different circumstances.

Parallel coordinate plots Graph with parallel axes for each of the variables. Lines connect the coordinates of the same case between adjacent axes. Is especially useful in showing many variables, and graphically highlighting subsets of data.

Principal components A method of constructing linear combinations of the data to produce new orthogonal variables. The first new variable has the largest variance. The second new variable has the second largest variance and so on. Commonly used for approximating the data in a lower-dimensional space by dropping the last of the new variables.

Quantile plot Graph that relates the ordered observations in a batch of data to cumulative probabilities.

Quantile–quantile plot Graph for comparing two distributions. Good for several tasks like judging relative tail thickness, ratios of standard deviations, and changes in mean.

Scatterplot matrix Graph displaying scatterplots of all pairs of variables, arranged in square array with individual variables corresponding to rows and columns. Especially useful in the early stages of studying joint relationships across several variables.

Three-dimensional scatterplot Graph with points plotted against three orthogonal axes. Perceived via a stereo pair view or via motion parallax. Especially useful in seeing three-dimensional structure. Useful as a framework for showing additional coordinates using glyphs.

THE PURPOSE of graphics in the physical sciences is to help scientific and public understanding of the phenomena being studied. The graphics and design issues for the respective audiences differ. This article emphasizes graphics for scientists who are often interested in the discovery and analysis of data.

Scientists involved in discovery can face many challenges. These may include

- The complexity of the phenomena being studied,
- The difficulty of parsimoniously conceptualizing this complexity,
- The logistic and political impediments to collecting adequate, representative data,
- The limits of computational resources,
- The limits of human perception and cognition for understanding multivariate summaries.

Graphics can help in conceptualizing and characterizing the phenomena being student. The Crick and Watson discovery of the DNA's double-helix structure was a major step forward. Now the exponentially expanding studies of genes can boggle the mind. Graphical bookkeeping (for example, see biochemical pathways at http://www.expasy.ch/cgi-bin/show thumbnails.pl.) helps scientists cope with the ever-increasing details. The possibilities of combinatorial chemistry and genetics are hard to imagine. The physical scientists monitoring the earth also face huge datasets. Consider one multispectral dataset with 30-m resolution over the 8 million km^2 of the continental United States. A quick calculation indicates that it takes over 7000 screen images to examine this data on a 1024×1280 monitor. That encodes all of the multispectral information for a 30-m region into the color of a pixel. To appreciate the multispectral resolution requires many times more images. The human visual system may be able to handle on the order of 10 ~7 bits per second of visual input, so flashing through the images may not take all that long. However, encoding the information in a way that helps scientists is a real challenge. Norretranders estimates that consciousness is limited to about 16 bits a second. If care is not taken none of what is seen will get into those precious 16 bits or whatever gets in might be distorted.

The brief monochrome article cannot do justice to methods available for quantitative visualization in the physical sciences. One book of over 400 pages catalogues monochrome chart types. The possibilities grow combinatorially from this when considering the addition of color, texture, interactivity, and further composition of forms.

This article presents some of the basic methods associated with the field of statistical graphics, along with a discussion of related cognitive and perceptual principles that help to provide guidance when moving beyond the basic forms. The principles are, of course, not correct in every detail, but provide a reasonable basis for selecting among the options. Before proceeding, a few comments on data and estimates are appropriate.

The varied sources of physical science data include laboratory studies, field samples, and electronically collected data such as satellite imagery and computer simulation. Most data need to be transformed into estimates that are suitable for scientific analysis. Each type of data and collection circumstances poses it own issues in addressing the processes of producing estimates that are worthy of evaluation. Recurrent types of issues include calibration of instruments, scaling of variables, adequacy of variables as surrogates for the desired variables of interest, adjustments for covariates, representative coverage of the population or phenomena of interest, and validation of simulated or indirect estimates.

Graphics can be no better than the estimates presented (unless they are being used to show how bad the estimates are). Readers should look for indications of estimate quality either in the accompanying text or in the graphics. The display of confidence bounds for estimates provides a good indication. The lack of confidence bounds is sometimes a warning that estimates have not been assessed with respect to accuracy (bias) and precision (variability).

The heart of graphics is visual comparison. One common task is to assess estimated density patterns. This involves comparing local densities from different parts of a plot. Another task compares data to a conjectured functional relationship. Other common tasks include comparing estimates against reference values and comparing two or more sets of estimates against each other. Much of graphics design concerns facilitating accurate comparisons.

I. UNIVARIATE GUIDELINES

Assuming accurate comparison is important, it is advantageous to encode estimates so that humans can decode them accurately. Cleveland and McGill (1984) discuss perceptual accuracy of extraction and indicate preferred methods for univariate encoding. In this research subjects judged relative magnitudes of graphically encoded variables. As presented here the results put the graphical encoding methods into three classes, labeled best, good, and poor.

The two best encoding methods represent variables using position along a common scale as shown in Fig. 1 and position along identical nonaligned scales. Humans do well in judging the position of a point relative to scale. Locating the position of objects is a fundamental visual task. Mapmakers have long used position along a scale as the fundamental encoding for spatial coordinates. Length, angle, and orientation are good encodings. Figure 2 shows that transforming line segments into a standard position converts the task of judging length into a task of judging the position of one endpoint against a scale. While this is not necessarily what people do, the example suggests that judging line length is more complicated than judging position.

Figure 3 shows angle encoding. Rotation of the angles puts them in position for comparison against equivalent angular scales shown in gray. The transformation suggests that while angle comparisons work pretty well, they are more complicated than direct comparison against angle scales. Area, volume, point density, and color saturation are poor encodings. Those familiar with experimental results involving Steven's Law will not be surprised about poor results for the area and volume encodings. Steven's Law states that the perceived magnitude of a stimulus follows a power law.

$$p(x) = a\,x^b$$

where x is the magnitude of the true stimulus (for example, length, area, or volume), and where the constants a and b depend on the type of stimulus. The range of characteristic exponents b for length is [.9 , 1.1], area s

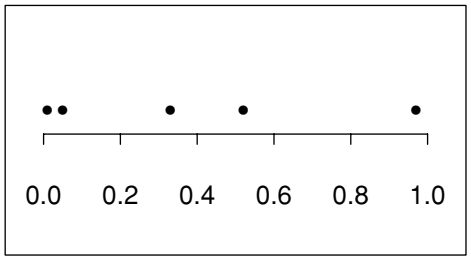

FIGURE 1 Position along a scale. This is the preferred encoding for a continuous variable.

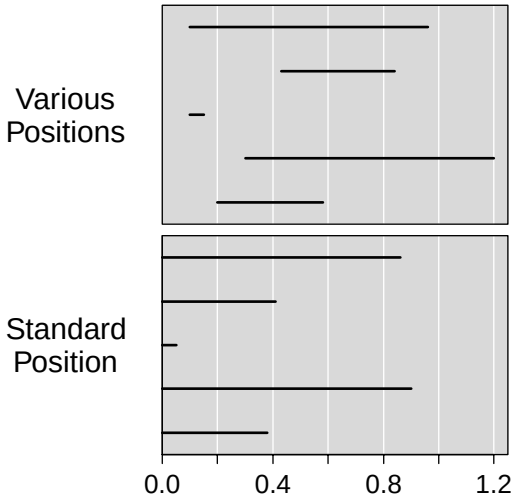

FIGURE 2 Transforming lengths. This changes the decoding task from taking differences to judging position along a scale.

[.6, .9] and volume [.5, .8]. With an exponent of about 1, people's perception of length tends to be direction proportional to object length. However, we tend judge area and volume nonlinearly. Consider comparing areas, one of 4 square units and the other of 1 square unit. With an exponent of .75, the ratio of perceived magnitudes is 2.8 to 1, rather than convert 4 to 1. We underjudge the large areas relative to small areas. If everyone had the same exponent, graphical encoding could adjust for systematic human bias. However, the range of values for the exponent "b" vary substantially from person to person. Providing a

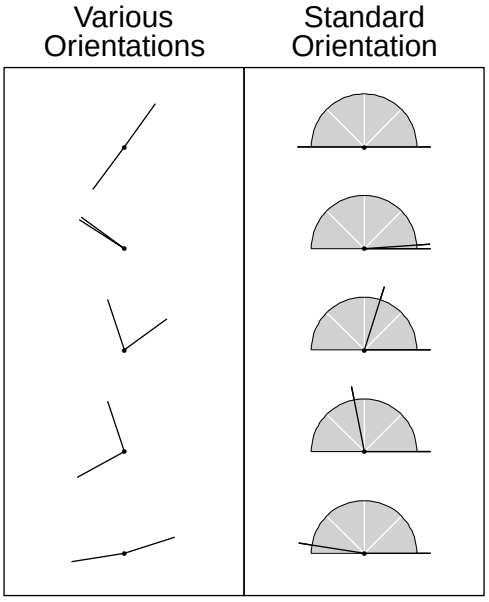

FIGURE 3 Transforming angles. This reduces the decoding task from taking differences to judging position along an angular scale.

set of reference symbols in a legend helps people calibrate to the intended interpretation, but the preferred strategy is to use better encodings whenever possible.

Weber's law, a fundamental law in human perception, also has significant ramifications in terms of accurate human decoding. A simple example gives the basic notion of the law. The probability of detecting that a 1.01-in. line is longer than a 1-in. line is nearly the same as the probability of detecting that a 1.01-ft line is longer than a 1-ft line. In absolute terms .01 in. is much smaller than .01 ft. Using a finer resolution scale allows more accurate judgments on an absolute scale. For example the tic marks on a ruler help us make more accurate assessments. The graphical equivalent uses grid lines to provide a finer resolution scale for more precise comparisons. In interactive graphics, zooming in effectively provides a finer scale. Computer human interface implementations often provide sliders that allow the reader to change the reference scale and make accurate judgments.

We render most graphics on a plane. We could show values of a continuous variable as points on a line. However, we do not usually do so. We may see gap between points quite well, but we do not judge point density very well. Consequently the standard approach for this simple case is to estimate the density and show it using a bivariate plot.

II. BIVARIATE GUIDELINES

Edward Tufte notes that it took over 5000 years to mankind to generalize from early clay tablets maps to representing general variables using a scatterplot. A scatterplot is an excellent representation since the two orthogonal axes allow two coordinates to be independently encoded as position along a common scale. The popular press in the United States still considers the scatterplot too complicated for the general public, but in the sciences the scatterplot is the standard for representing continuous bivariate data. Common bivariate activities include assessing univariate distributions, comparing univariate distributions, and looking for functional relationships.

A. Univariate Density Estimates

When we are interested in data density it is advantageous to compute and show the density as accurately as possible. Figure 4 illustrates the construction of a kernel density estimate based on a sample of five univariate values. The locations of the white triangles relative to the x-axis indicate the magnitudes of observed values. The basic idea is that each observed value is a surrogate for values in a neighborhood. We then construct a relative likelihood for a neighborhood about the value. Figure 4 shows the five

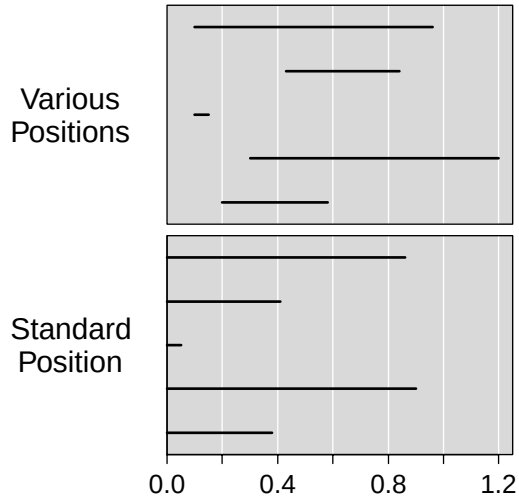

FIGURE 4 Density estimate. This shows construction of a kernel density estimate from five points by averaging bumps.

likelihoods (or kernels) as bell-shaped curves, one in each of the top panels. For each location where we want to estimate the data density (the x locations of white lines in Fig. 4) we simply average values from the five constructed likelihoods. The white lines indicate the locations of the density estimates. In the bottom panel each white line is the average height of all the white lines directly above it. (When panels have no white lines directly above, they contribute zero to the average.) The construction is straightforward.

Scott (1992) provides the theory behind density estimation. For a valid density estimate, the kernel needs to integrate to 1. The hard part is in deciding how wide to make the kernel. Scott describes methods for making this decision.

B. Quantile Plots

The integral of the estimated density up to a value approximates that the cumulative probability of observations begin less than or equal to that value. A cumulative distribution plot plots the sorted values on the x-axis and cumulative probabilities on the y-axis. A quantile plot is essentially the same plot transposed. For quantile plots the x-axis shows cumulative probabilities and the y-axis shows the sorted data values. Figure 5, a quantile plot, shows the pairs (p_i, q_i) where p_i is the cumulative probability and q_i represents the ith largest observation. Cleveland's convention connects the point pairs as shown.

There are different methods for approximating cumulative probabilities. The order statistics approach here follows Cleveland (1993) and uses the expression $(i - .5)/n$ for $i = 1, \ldots, n$ to calculate the cumulative probabilities, where n is the sample size. The probability corresponding

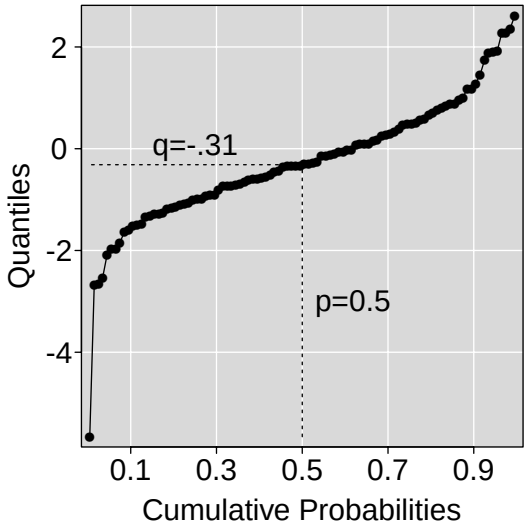

FIGURE 5

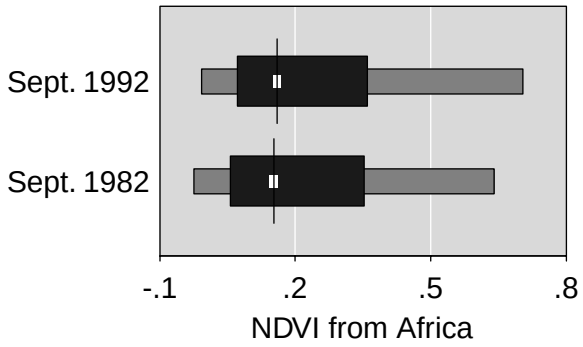

FIGURE 6 Box plots. This compare two distributions of values taken from Fig. 8. Vertical lines show the medians. First and third quartiles bind the thicker gray rectangles. Adjacent values bind the thinner gray rectangles. No outlines appear in the example. When interior white rectangles do not overlap, medians are not significantly different.

to the smallest observation in a sample of size 10 would be $(1 - .5)/10 = .05$. An interpretation is that if the observations were from a random sample of size 10, the probability of a future observation being smaller than the currently observed smallest observation is .05.

Another common textbook approach for calculating cumulative probabilities is the empirical method. For this method the cumulative probability for a value is the fraction of observations less than or equal to the value. This approach treats the curve as a step function jumping at each observation. The step function jumps from 0 to $1/10$ at the smallest observation in a sample of size 10. This suggests that the probability of a future observation being smaller than the smallest one already observed is 0. The sample does not allow determination of the true probability. The probability .05 seems reasonable. As the sample gets larger the discrepancy between the two calculation approaches get smaller.

Interpretation is straightforward. For any probability covered on the x-axis it is possible to determine a quantile. To obtain the .5 quantile (or estimated median) go straight up from .5 on the x-axis to the curve and then straight across to the y-axis to obtain x units. Starting with .25 and .75 yields corresponding quantiles are also known as the 1st and 3rd quartiles, or 25th and 75th percentiles, respectively. Similarly one can go from quantiles to cumulative probabilities. Since scientists use such plots to describe convenience collections from a population as well as random samples from a population, the trickiest interpretation task is often to decide if the probabilities really extend to a larger population.

Quantile plots are helpful on maps and provide a frame of reference for observing change over time. For example, one can tell if the 50th percentile (the median) has changed. For maps it is possible to save space by representing selected cumulative probability and quantile pairs using a parallel coordinate approach.

C. Box Plots

The box plot is a distribution caricature that has achieved wide acceptance. While used to represent individual distributions, the common use is to compare distributions. Figure 6 shows two boxplots. The features shown include the median, quartiles, and adjacent values. The notion of adjacent values sets a bound on what will be called outliers and warrant a note on how it is calculated. The upper adjacent value is the largest observation less than the 3rd quartile $+1.5$ times the interquartile range (the 3rd quartile $-$1st quartile). The lower adjacent value is determined correspondingly. Outliers, if any, are more extreme than the adjacent values. Not all box plot variations are the same. Some just show the maximum and minimum values rather than adjacent values and outliers. The design variation in Fig. 6 has an additional feature. It uses a white line to provide comparison intervals for the medians. If two comparison intervals do not overlap the medians are significantly different.

D. Quantile–Quantile Plots

Some authors consider the quantile–quantile (QQ) plots as the preferred graphic to make detailed continuous distribution comparisons. For theoretical distributions, the cumulative distribution function, $F()$, provides the correspondence between the probability and quantile pairs via $p = F(q)$. When $F()$ is a strictly increasing function the quantile function, $Q()$, is the inverse of $F()$ and $Q(p) = q$. Familiar pq pairs from the standard normal distribution

are (.5, 0) and (.025, −1.96). Comparison of two distributions, denoted 1 and 2, proceeds by plotting quantile pairs ($Q_1(p)$, $Q_2(p)$) over a range of probabilities, such as from .01 to .99 in steps of .01. For two distributions of observed data, the calculations described for the quantile plots (previously described) are appropriate. Figure 6 shows a QQplot for two sets of data. The x-axis shows quantiles from Set 1 and the y-axis shows quantiles from Set 2. Sometimes statistician chose $Q_1(p)$ to be from a theoretical family of distributions, such as the normal family, to see if parametric modeling is reasonable using the normal (Gaussian) family of distributions.

A merit of QQplots is that in simple cases they have a nice interpretation. If points fall on a straight line then the distributions have the similar shape differing only in the first 2 moments. This is the case in Fig. 7 since the robust fit (thin) line matches the quantiles quite well.

The slope and intercept of the approximating straight line tell about the discrepancies in the second moment (standard deviation) and first moment (mean). The slope of the thin line tells about the ratio of standard deviations. The thick line in the figure is the reference line for identical distributions. The lines are not quite parallel in Fig. 7 so the standard deviations are not quite the same. Multiplying Set 2 quantiles by a factor and then adding a constant changes the slope and intercept of the robust fit line. Graphical input and visual assessment provides a quick way to find the two numbers that make the lines

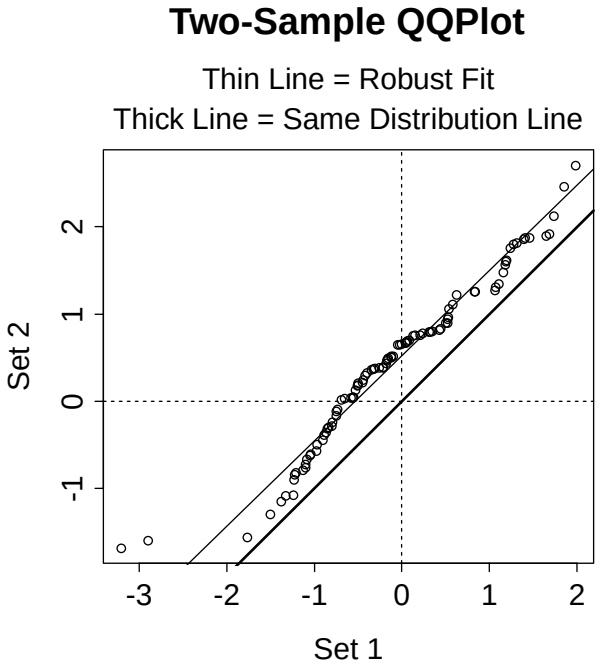

FIGURE 7 Quantile–Quantile (QQ) Plot. This compares distributions. When the points fall near a straight line, they have the same shape and differ only in the standard deviation and mean.

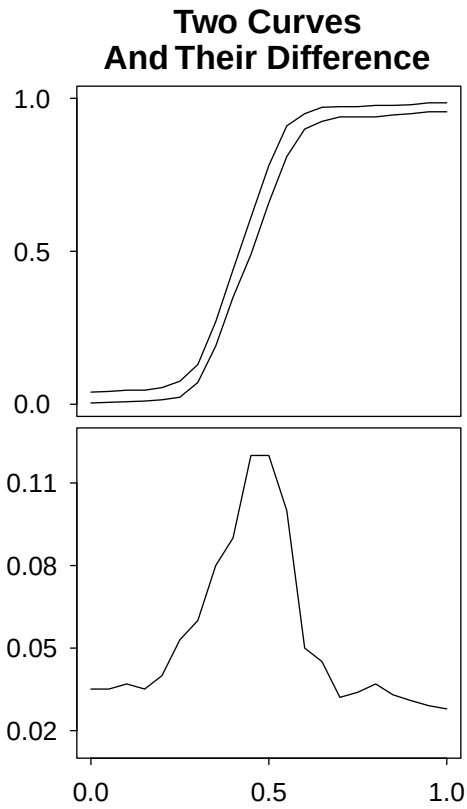

FIGURE 8 Explicit difference of two curves. Humans tend to see closest differences between curves, not differences parallel to the y-axis.

match. These two numbers then indicate the ratio of the standard deviations and the defference in the means after the Set 2 scale adjustment. In Fig. 7 the lines are nearly parallel so a reasonable guess is that the distribution differ in mean by about .5.

QQplots avoid the visually deceptive procedure of superimposing two cumulative distribution functions or two survival curves. As Fig. 8 suggests, we are really poor at judging the distance between curves. Our visual processing assesses the closest differences between curves rather than the correct vertical distances. This deficiency applies to comparing spectra and time series as well. Adding grid lines can help, but it is often better to plot the difference explicitly or make distribution comparisons using QQplots.

E. Direct Comparison of Two Distributions and the Mean Difference Plot

Before and after comparisons are common in science. The basic idea is to control for variation in experimental units by studying the change of experimental unit values. This differs from QQ plots in that the study unit is the basis for pairing values rather than cumulative percentages. Figure 9 shows a paired comparison plot for two

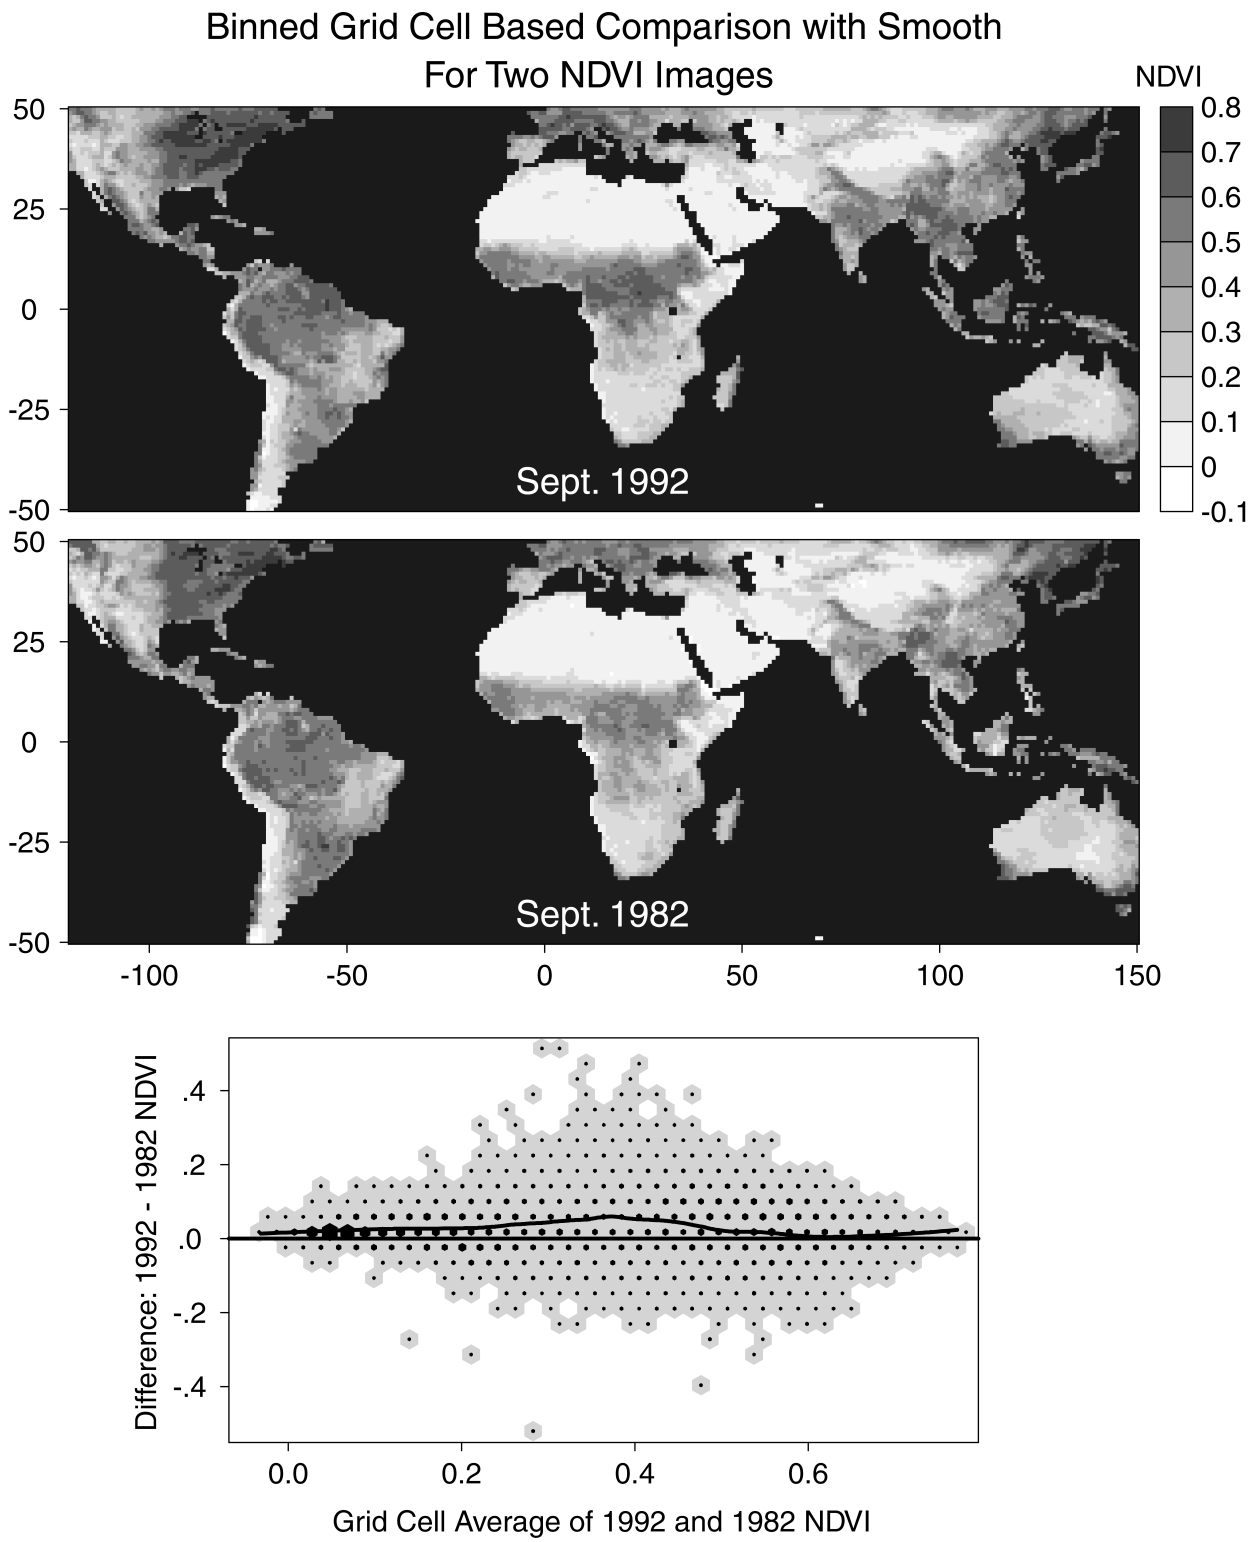

FIGURE 9 Pair Difference Plot (bottom panel). Top panels represent the Device Vegetation Index (NDVI) values on a 1° grid using gray levels. The images were taken about a decade apart. The bottom panel shows the difference of location paired values. The mean and difference plots show the mean on the x-axis and the difference on the y-axis. The reference line is $x = 0$. This plot handles many thousands of points by hexagon binning. Large hexagon symbols show more counts. While there are many exceptions, the smooth line indicates a tendency for 1992 values to be larger.

low-resolution satellite images of the same region. The top two images show NDVI values on a 1° grid. NDVI stands for normalized device vegetation index and provides a measure of greenness. The traditional reference line for equality is a 45° line through origin. John Tukey suggested making the reference line horizontal by plotting differences on the y-axis and mean on the x-axis. The bottom of Figure 9 shows a mean difference plot. Making transformations to simplify the visual reference and reduce the visual calculation burden is an important graphic design principle.

The data for the panels in Fig. 9 consist of over 27,000 point pairs. The overplotting in the bottom panel would cause a problem. Since we do not judge density well the bottom panel bins the data into hexagon bins and represents the count with the size of the hexagon symbol plotted. Such binning is a fast but rudimentary way to obtain a bivariate density estimate. Carr lists the merits of hexagon binning over square binning. An alternative view estimates the density surface on a higher-resolution bivariate grid and displays the surface with perspective views or contours.

The line in the bottom panel of Fig. 9 shows a smooth of the data. The upward shift indicates increased greenness in 1992. Symbols below the zero reference line for no change indicate that the change is a decrease in some locations. The smooth indicates that the increase tends to be highest for intermediate values of NDVI.

F. Functional Relationships and Smoothing

When y is considered a function of x, common practice is to enhance scatterplots of (x, y) pairs by adding a smooth curve. This is done in Fig. 9 to see if the difference is related to the average of the two values. To avoid the considerable human variability in sketching a fit, the standard procedure is to model the data using a procedure that others can replicate. Figure 10 shows a scatterplot with the smooth line generated using loess (see Cleveland *et al.* for more details). Loess fits the data using weighted local regression. That is, the regression uses data local to $x0$ to predict a value at $x0$. Points closest to $x0$ receive the greatest weight. The use of many local regressions produces a set of pairs (x, y) that are connected to produce the smooth. Each local regression in the smooth shown in Fig. 10 used a linear model in x and included the closest 60% of the observations to the prediction point $x0$. Such a smooth is reproduceable. The smooth in Fig. 10 draws further attention to the distinction between ocean and land states and additional modeling is appropriate.

Smoothing is an extremely important visual enhancement technique. It helps us see the structure through the noise. The decomposition of data into smooth and residual parts is fundamental technique in statistical modeling.

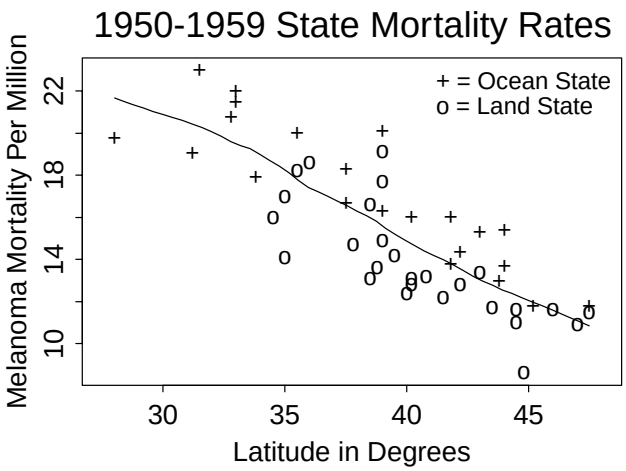

FIGURE 10 A smooth. The smooth curve suggests a functional relationship. The two types of points suggest there are two different functional relationships involved.

Hastie and Tibshirani provide a good introduction to a variety of smoothing methods.

Numerous smoothers are available. Historically, many researchers used cubic spline as smoothers. Cubic splines have a continuous second derivative and that is sufficient to make curves appear smooth to humans. The elegant mathematical formulation behind splines increased their popularity within the statistical community. However, there is no *a priori* best smoother. New methods, such as the wavelet smoothing, keep appearing in statistical software. Recently developed wavelet smoothers are supposed to be better than many smoothers at tracking discontinuities in the functional form. However, the old local median smoothers still do well at handling discontinuities.

Smoothers typically have a smoothing parameter that needs to be estimated or specified by the user. With computational power at hand, cross-validation methods have become increasingly popular as a community standard. This reduces the judgment burdens on the analyst. However, this does not guarantee a match between an empirical curve and a hypothesized true but unknown underlying curve.

III. MULTIVARIATE VISUALIZATION

Visualization in the physical sciences is inherently multivariate. Scientists are interested in the relationships among many attributes and the attributes have space–time coordinates. The purpose of multivariate graphics is to show multivariate patterns and to facilitate comparisons. As in low dimensions, the patterns often concern data distributions or models with at least one dependent variable.

After converting attributes and their space–time coordinates to images for evaluation, human visual comparisons

typically fall into three categories, comparison of external images to each other, comparisons of external images to external visual references, and comparison of external images to the analyst's internal references. Internal references include scientific knowledge, statistical expectations, and process models. The visual investigation process often involves converting internal references into external visual references subject to further manipulation. With external images and references available, the next step often involves graphical transformation to simpler forms in terms of our perceptual–cognitive processing abilities.

Multivariate graphics must deal with the problem of showing higher-dimensional relationships and, as in lower dimensions, often have to deal with the noise that obscures patterns and the overplotting due to many points.

A. Graphical Design Principles and Resources

The description indicates the increased complexity as we move to higher dimensions. At the same time, Kosslyn warns that "The spirit is willing but the mind is weak." We should approach the multivariate challenge prepared to do battle. Our arsenal of tools includes design principles that help us in uncharted territory. Some of our tools include:

- Distributional caricatures such as box plots to help us deal with large data sets
- Map caricatures that let us show small multiples
- Modeling to reduce noise and complexity
- Layering and separating to constrain and guide the information flow
- Partitioning and sorting to simplify appearance and facilitate comparisons
- Linking low-dimensional views to get insight into higher-dimensional relationships.

The basic formats for comparison graphics include juxtaposition, superposition, or the direct display differences. The art of multivariate graphics is to select the methods and enhancements that work best in view of the phenomena's complexity view and in view of human perceptual and cognitive limitations.

This entry suggests just a few representation tools and principles. Good reference include books by Cleveland, Kosslyn, Wilkinson, and Ware. The books by Tufte provide wonderful examples of putting design principles into practice. MacEachren provides a good introduction on mapping and Cleveland and McGill provide an early survey on dynamic multivariate graphics that go beyond the scope of the entry. As more work is done in computing environments, issues of the computer human interface become increasingly important. Card *et al.* edited a book of readings that gathers many important concepts.

The entry only briefly describes color since it is not an option here. However, color provides an important tool. Different hues provide a good way to distinguish categories of a categorical variable. The cartographic guidance limits categories or hues to six or fewer. Humans are very sensitive to a second dimension of color, a dark-to-light scale that is referred to in literature by terms such as value, lightness, or brightness. Gray levels provide ordered scale so it is thinkable to represent a continuous variable using value or gray level. Humans are less sensitive to the dimension of color called saturation. A saturation scale going from an achromatic color such as medium-gray to a vivid red is also an ordered scale. However, humans can make fewer saturation distinctions than lightness distinctions. Generally color is a poor choice for representing a continuous variable. Humans perceive that hue and brightness are integral dimensions so we should not use them to encode two or three variables. Brewer *et al*. discuss additional considerations that apply to the color-vision impaired.

Since most people can work with four chunks of information, this article suggests attempting to fit the guidelines into four broad categories of quantitative design principles:

- Use encodings that have high perceptual accuracy of extraction
- Provide context for appropriate interpretation
- Strive for simple appearance
- Involve the reader

These organizing categories contain some conflicting guidelines. For example, a long list of caveats may provide the context for appropriate interpretation but conflict with simple appearance and reader involvement. Composing graphics that balance among the guidelines remains something of an art form. The communication objectives influence the balance.

B. Communication Objectives

Multivariate graphics can have many different communication objectives. Four common objectives include providing an overview, telling a story, suggesting hypotheses, and criticizing a model. In providing an overview, broad coverage is important. Achieving clarity often involves hiding details and working with caricatures. Similarly, in telling a story the predetermined message must shine through. Scientists often fail to tell simple stories because they are eager to list caveats and a host of details that qualify the basic results. Interactive web graphics can alleviate the archival side of this problem providing ready access to metadata, supplemental documents, and gigabyte databases. However, it still takes careful design to draw readers to the details.

This entry emphasizes graphics of discovery. Discovery objectives include suggesting hypotheses and criticizing models. The graphics in this article can often be used to display residuals from models and to review patterns in the residuals. For discovery, it is often crucial to see through the known and miscellaneous sources of variation. In the context of mortality mapping, John Tukey said, "the unadjusted plot should not be made." Today mortality maps control for known variation by being sex and race specific. The maps control for age by limiting the age range or by showing adjusted statistical rates. In the physical sciences there are often known factors that contribute to variation that warrant making adjustments. Thus the graphics of discovery often show model residuals.

C. Surface Views

In some ways multivariate visualization is similar to lower-dimension visualization. The general tasks are still to show densities and functional relationships. The difference is that more variables including spatial and temporal indices are called into play. The density of bivariate points constitutes a third coordinate. The basic idea in bivariate kernel density estimation is similar to that for univariate estimation: average local likelihoods. The key difference is that local neighborhood is bivariate. The result is surface $z = f(x, y)$. Figure 11 shows the contours of a bivariate density surface. Figure 12 shows a wireframe perspective view.

Estimating functional relationships of the form $z = f(x, y)$ also follows the pattern established with one less variable. In the context of maps some approaches to modeling address the issue of spatial correlation. Common monochrome views again include contour and wireframe plots. Fully rendered color surfaces with highlights provide better a view of the wireframes. Pairing of contour and surface plots can aid understanding. The surface tends to provide a good overall impression (except for what is hidden) while the contours help to locate features, such as local extrema, on the plane. Wireframes and translucent surfaces can be superimposed on maps or contour plots.

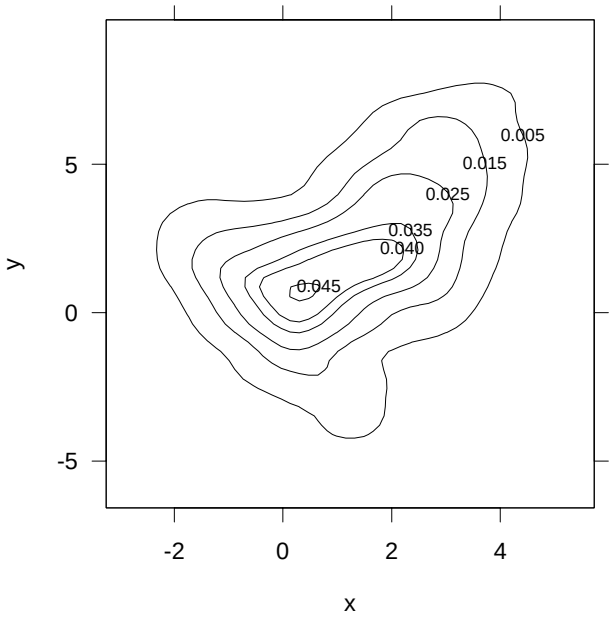

FIGURE 11 A contour plot. This plot represents the computed density of bivariate points.

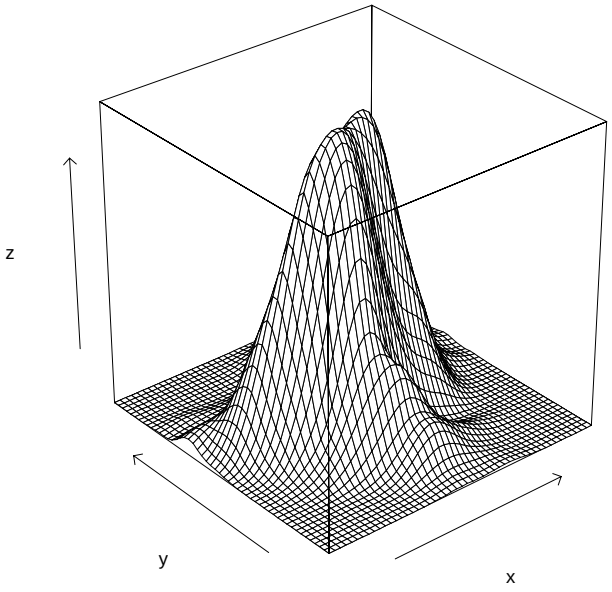

FIGURE 12 A perspective view or wireframe plot. This surface shows the density of bivariate points.

Perspective views appeal to many people and have also been used to show local values as the animated flyovers of three-dimensional bar charts as well as surfaces. How perspective foreshortening complicates accurate decoding of values and comparisons. For a detailed study of surfaces, Cleveland recommends dropping back a dimension. By conditioning on intervals of x or y it is possible to return study strips of the surface using two-dimensional plots.

For comparing surfaces there are three standard approaches. One is to superimpose surfaces, for example, rendering them in translucent color. A second is to juxtapose displays of two surfaces. The third option of calculating and showing the difference of two surfaces is often best.

D. Distance Judgments and 3-D Scatterplots

In the multivariate context, accurate interpoint distance judgments are crucial to geometrically based visual interpretation. For two points in a scatterplot the cognitive task becomes one of judging the length of an implicit line between the two points. As indicated previously, humans

perceive length in a plane with good perceptual accuracy of extraction. For higher-dimensional representations, assessing interpoint distances becomes increasingly difficult. The position here is that our ability to judge distance in three-, four-, and five-dimensional representations provides a strong basis for ranking point encoding methods.

At first thought, a stereo three-dimensional scatterplot might seem ideal for representing continuous three-dimensional data. Judging distance between two points then equates to judging the length of a line segment. On closer inspection, there is substantial change from two-dimensions to three-dimensions. Depth perception for the third coordinate derives from horizontal binocular discrepancies (parallax). The horizontal discrepancies involve only a small fraction of our full horizontal field of view. Horizontal visual acuity within this small interval determines how many distinct depth planes we can resolve. This cannot match the horizontal resolution across the full field of view. Stereo three-dimensional plots are less than ideal since humans do not judge depth as accurately as they judge vertical and horizontal position. While stereo three-dimensional distance judgments are not as accurate as two-dimensional distance judgments, we live in a three-dimensional world and have strong intuitions about three-dimensional relationships. For those with good depth perception the testable conjecture here is that three-dimensional scatterplots allow the most accurate assessment of interpoint distances of the available encoding for three continuous variables.

Historically most analysts created depth views via rotation (motion parallax). This approach is very powerful. The main drawbacks are that moving points are harder to study than stationary points and that interacting with moving data is awkward. Using both stereo and rotation maintains the depth when rotation stops. Overplotting obscures points and some authors suggest we can only see two and one-half dimensions. Mostly one sees the edges of the data cloud. Different viewing angles bring out different edges. Slicing or sectioning helps to reveal the inside of the cloud. In the virtual reality (VR) settings one can fly through data clouds and touch points (or density features) to gain additional detail. Since we do not judge density accurately there is good reason to estimate trivariate densities and study the hypersurfaces $w = f(x, y, z)$. Scott provides instructive graphics that simultaneously show three contours of hypersurfaces.

E. Scatterplot Matrices, Parallel Coordinates, and Stereo Ray Glyphs

If we have points on a surface $w = f(x, y, z)$ there are many different ways to view the points. It is instructive to consider how the different views reveal that the data are from a surface and not points distributed throughout four

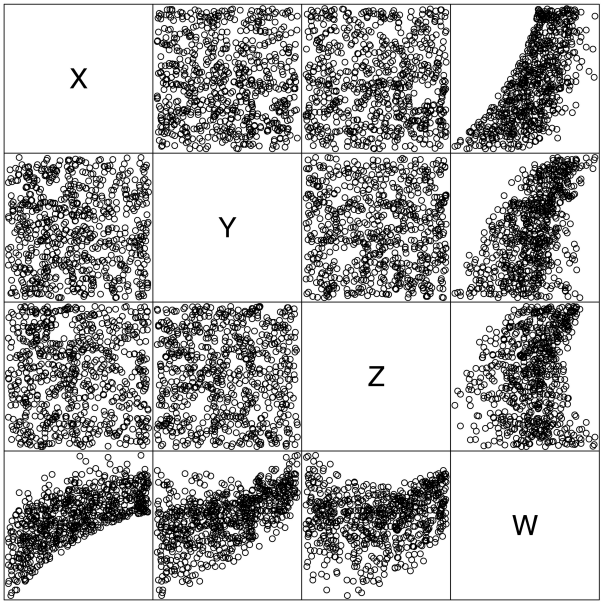

FIGURE 13 A scatterplot matrix. The four-dimensional points fall on a hypersurface defined by $w = f(x, y, z)$. The point cloud edges in last row and column suggest the date are a lower-dimensional object embedded in four dimensions. The cloud interiors do not show much.

dimensions. The three views considered here are scatterplot matrices, parallel coordinates, and stereo ray glyphs.

Figure 13 shows a scatterplot matrix. The panels in the matrix show scatterplots for all pairs of variables. Some variations of the scatterplot matrix show only the upper or lower triangle of panels since otherwise the same point pairs appear (transposed) in a second panel. If fact, thoughtful construction allows two data sets to be juxtaposed using upper and lower triangles. Returning to the task at hand, the edges of the cloud in the panels of the last row and column of the scatterplot matrix suggest there is some kind of relationship $w = f(x, y, z)$.

Figure 14 shows a parallel coordinate plot. This has four parallel axes. The plot scales each variable to the interval [0 1] and equates this to the length of the corresponding axis. Each component of a four-dimensional point is plotted on the respective axis and the components are connected. The clue about the relationships is limited to the line patterns in the last pair of axes.

Figure 15 shows a stereo ray glyph plot in a side-by-side stereo pair view. The three coordinates are represented by the point's three-dimensional location. The angle of the ray represents the fourth coordinate. The small size of a side by side stereo plot complicates views, but the smooth variation of the ray angle locally in three-dimensional space is evident. The locally smooth variation of the ray angle indicates there is a relationship.

As a demonstration of the inferior nature of nonpositional glyphs in low dimensions, one can generate, say

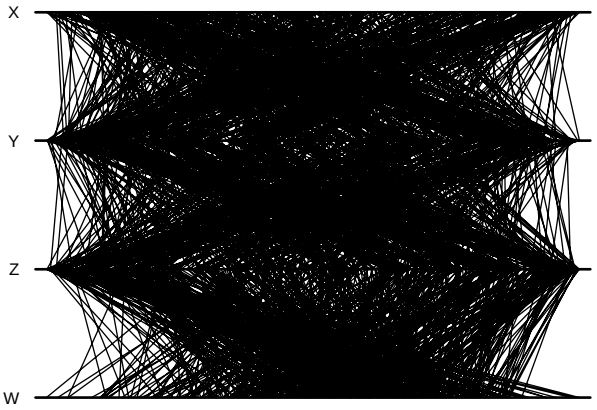

FIGURE 14 A parallel coordinate plot. The same four-dimensional points as in Fig. 13. The weak hints of a dimension reducing constraint appear in only in lines between the the z and w axes. The plot is useful for graphical input and for viewing many coordiates.

a thousand points of three-dimensional data embedded in four dimensions. That is, select the triples (u, v, w) randomly, say from a normal distribution, and then let $x1 = f1(u, v, w)$, $x2 = f2(u, v, x)$, $x3 = f3(u, v, w)$, and $x4 = f4(u, v, w)$ where the four functions are simple distinct polynomials. The structure in the stereo ray glyph plot will immediately suggest the existence of a constraint and the fact the data are not four-dimensional. The ability to observe smooth variation can easily be masked by noise in real data. Still it should be clear that the scatterplot matrix and the parallel coordinate plot do not help us to see in three dimensions as well as three-dimensional scatterplots do. Our brains are not wired for the task of constructing higher-dimensional views from projections in lower dimensions.

Few researchers have seriously tackled the visualization of six-dimensional data. Bayly and co-authors provide a notable exception. They successfully used colored stereo ellipsoids to evaluate problems in improving an electrostatic potential model. Their article includes color side-by-side stereo figures. In a long sequence of efforts they failed to obtain insight using a wide variety of encodings. Their eventual success suggests that using position along a scale to represent three variables has merit.

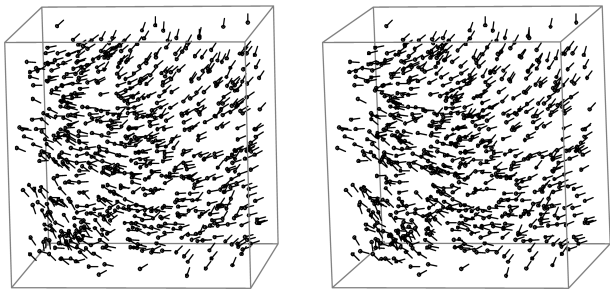

FIGURE 15 A stereo ray glyph plot. The ray pointing down to show small values and up to show large values. Some people can fuse the stereo pair images without a viewer. The smooth local variation of the ray angle strongly suggests that lower dimensional structure is embedded in four dimensions.

As we move beyond four dimensions, our ability to judge interpoint distances deteriorates quickly. We are forced to use clustering algorithms and other computational methods to bring out patterns. Simple graphical methods do not work well except when there is a very simple geometric structure embedded in high-dimensional space. For complex multivariate structure, Furnas and Buja indicate how we can lower the viewing dimensionality by slicing or sectioning (adding linear constraints). We can also condition on categorical variables. This divide-and-conquer approach can reveal a plethora of patterns, but it is only the rare individual that can integrate a catalog of low-dimensional views into a coherent higher-dimensional framework. Few people claim to fully understand the richness of even four-dimensional structures.

F. Glyphs and Layouts

Glyphs provide one way to represent observations with several variables as points. The climate description maps of the U.S. Environmental Data Service have some interesting glyphs. These include a wind rose glyph showing 16 variables representing the percentage of time the wind is blowing in the major compass directions, and bar chart glyphs show 12 variables indexed by month of the year. In both these cases the glyph controlling variables are statistical summaries. It is not a requirement that variables controlling glyph characteristics be direct measures.

Chernoff faces seem to be the glyphs that draw the most attention. Different variables control different facets of caricature faces. Examples appear in Fig. 16. Since a significant portion of our brain is devoted to face recognition, the encoding idea intrigues many people. While humans get a gestalt impression that they can often relate to an emotion, it is difficult to respond to the individual components of the face. Few glyphs see much use. The star glyph, a variant of a parallel coordinate plot for a single case, seems to appear with some frequency.

A simple example plotting a few hundred faces or stars representing points on a hypersurface is instructive. The hypersurface relationship remains obscure. That is discouraging. In contrast to the map glyphs introduced previously, glyphs are often laid out arbitrarily on a regular grid. This wastes using the favored representation, position along a scale, for two coordinates. Position using possibilities that can lead to overplotting include using the first two principal components of multivariate data, and

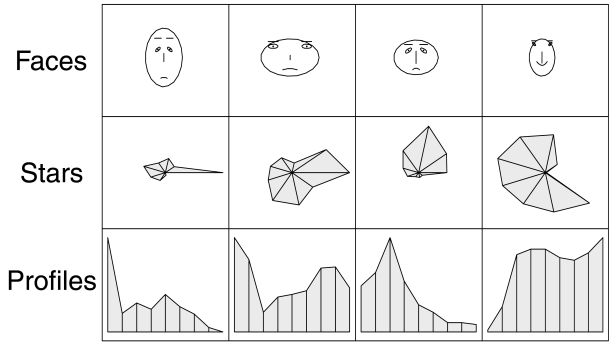

FIGURE 16 Three types of glyphs. Here a face, profile, and star glyph represent nine coordinates. In this case the coordinates represents a gene's mRNA production levels at nine animal ages.

multidimensional scaling provides another option. There are additional options that avoid overplotting.

G. Linked Plots

Linking points across plots provides a way to connect cases whose variables are represented in different plots. Linking provides a weaker binding of the multivariate observations than glyphs. Linking methods include linking by lines, colors, names, pointers, and spatial linking by juxtaposition. The following discussion emphasizes line linking and color linking.

The parallel coordinate plot (see Fig. 14) provides an example of linking with lines. The lines connect components of the same case across the axes showing the different variables. In many applications of line linking the lines overplot and this complicates decoding the plot.

Painting points on a screen provides a common way of linking points using color. A common application involves scatterplot matrices. Painting some points in one panel selects the corresponding cases. The color then highlights views of the selected cases in the other panels. This notion extends to different types of panels. When there are spatial coordinates one of the panels is often a map.

H. Conditioned Plots

Conditioned plots partition the estimates (or data) into sets based on classes defined for conditioning variables. The different plots for the sets then appear as juxtaposed panels. The visualization task is then to study how the distributions or function relationships shown in the panels vary across the conditioned panels. Tukey and Tukey provide an early example called a casement display. Conditioned plots appearing as a one-way or two-way layout are typically two-dimensional plots, but they can be three-dimensional wireframe plots or other higher-dimensional plots. Many people readily understand one- and two-way conditioning and the corresponding layout of panels. For example, defining each of two conditioning variables as low, medium, and high leads to a 3×3 layout of panel showing other variables of interest. Thus conditioned plots are one of the more effective ways to study relationships involving three to five dimensions.

IV. CLOSING REMARKS

This entry provides a description of several templates for low-dimensional graphics. When datasets have higher dimensions there are a variety methods that will reduce the dimensions of many datasets to something that we can view using the templates. The methods include principal components, projection, and sectioning. The methods have some limitations including the sizes of data sets to which they apply.

Increasingly, the size, detail, and complexity of data sets overwhelm our direct visualization capacity. Our dimension reduction and case reduction methods are stretched thin and overwhelmed at times. The number of plausibly important views of data exceeds the time we have to look and study. In thinking about the future, John Tukey coined the term "cognostics" (diagnostics interpreted by a computer rather than by a human). The idea was to compute features of merit and have computers rank plots by their by potential interest to humans. Researchers have developed projection pursuit methods that help us to find interesting views in lower dimensions. There is much more to be done along this line. The work can be frightening because our algorithms can miss details like the hole in the ozone layer. On the other hand we miss a lot because our viewing is not optimized. We also miss a lot because we do not really put computers to work to find the representations that are optimal for our understanding! While our visualization methods fall further behind the increasing amounts of data, it remains the case that we can do much more than we are doing now.

GLOSSARY

Abelian group Group in which the operation is commutative.
Center Subgroup of a given group consisting of all elements which commute with every group element.
Commutator subgroup Subgroup of a given group generated by the subset of all commutators.
Cyclic group Group generated by a single element.
Homomorphism Function mapping a group into a group and preserving the group operation.
Isomorphism One-to-one homomorphism from one group onto another.
Linear representation of a group Homomorphism of a group into the group of all invertible linear operators on a fixed vector space.
Permutation representation of a group Homomorphism of a group into the group of all permutations of a fixed set.
Quotient group of a group *G* Group of all cosets of a fixed normal subgroup of G.
Representation of a group Homomorphism of the group into the full group of all symmetries or automorphisms of some fixed mathematical object.
Simple group Group whose only normal subgroups are the identity subgroup and the group itself.
Solvable group Group which has a normal series of subgroups such that each of the factors (quotient groups) of the series is abelian.
Subgroup Subset of a group which is a group under the same operation.
Sylow *p*-subgroup Subgroup of a group which is maximal with respect to the property that each element has order a power of the prime p.

A GROUP is a nonempty set G of invertible functions mapping a set X to itself such that whenever $f, g \in G$, then also $f^{-1} \circ g \in G$. (There is also a more abstract definition which we shall give in the next section.) Thus, in particular, G is a subset (subgroup) of the group $S(X)$ of all invertible functions whose domain and range is the set X.

Any such function may be thought of as a permutation or symmetry of the set X, and $S(X)$ is generally referred to as the symmetry group of X or as the symmetric group on the set X.

Historically, groups emerged first in the work of Lagrange, Ruffini, and Cauchy around 1800 as sets of permutations of a *finite* set X. In this context the definition may be simplified. A nonempty set G of permutations of a finite set X is a group if and only if G is closed under composition of permutations. Closure under functional inversion follows automatically. The condition of closure under composition puts severe restrictions on the group G, e.g., the remarkable fact discovered by Lagrange that if $|X| = n$ [and so $|S(X)| = n!$] and G is any subgroup of $S(X)$, then $|G|$ is a divisor of $n!$

The subject was greatly enriched by Evariste Galois, who demonstrated around 1830 how to associate to each polynomial equation a finite group (called its Galois group) whose structure encodes considerable information concerning the algebraic relationships among the roots of the equation. An analogous theory for differential equations was developed later in the century by Lie, Picard, and Vessiot. The relevant groups in this setting were no longer finite groups but rather continuous groups (more commonly known as Lie groups).

Starting around 1850, Cayley championed the idea of studying groups abstractly rather than via some specific representation. This notion simplifies numerous arguments and constructions, notably the construction of quotient groups. The first modern definition of a group was given by Dyck in 1882, who also pioneered the study of infinite groups.

I. FUNDAMENTAL CONCEPTS

We shall freely use the standard notation of naive set theory with regard to sets, subsets, elements, relations, functions, etc. By a binary operation $\circ$ on a set S, we shall mean a function $\circ : S \times S \to S$. It is customary to say that S is closed under the binary operation $\circ$ in this situation, and it is customary to write $x \circ y$ for the value of $\circ$ at the ordered pair $(x, y) \in S \times S$. The symbols $\mathbf{Z}$, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{C}$ will denote the sets of integers, rational numbers, real numbers, and complex numbers, respectively.

We now give the promised abstract definition of a group.

Definition: *A group is an ordered pair* $(G, \circ)$ *such that* G *is a set closed under the binary operation* $\circ$ *satisfying*:

(1) $(x \circ y) \circ z = x \circ (y \circ z)$ *for all* $x, y, z \in G$.
(2) *There is an element* $e \in G$ *with* $e \circ x = x = x \circ e$ *for all* $x \in G$.
(3) *For any* $x \in G$, *there is an element* $x^{-1} \in G$ *such that* $x^{-1} \circ x = e = x \circ x^{-1}$.

This definition makes the group operation the prominent feature and is indifferent to the kind of mathematical objects which the elements of G might be.

The element e is unique and is called the identity element of G, and the element x^{-1} is uniquely determined by x and is called the inverse of the element x. Henceforth in this article we shall in general write xy for $x \circ y$. Also, we shall typically speak of a group G, with the operation $\circ$ being tacitly understood. It is important to note that in general $xy \neq yx$. A group in which the commutative law

$$xy = yx \qquad \text{for all } x, y \in G$$

holds is called an abelian group in honor of Nils Abel, who first recognized that a polynomial equation whose Galois group is abelian is solvable by radicals. Other groups are called nonabelian groups.

Sometimes when G is an abelian group, the operation is denoted by $+$ and the identity element by 0. Many important sets of numbers form abelian groups under $+$, for example, $(\boldsymbol{C}, +)$ and such subsets as $(\mathbf{Z}, +)$, $(\mathbf{Q}, +)$, and $(\mathbf{R}, +)$.

Groups of numbers like $(\mathbf{R}, +)$ seem quite different from groups of functions. However, we may identify $(\mathbf{R}, +)$ with the group $(\mathbf{T}, \circ)$ of all translation functions $T_a : \mathbf{R}^1 \to \mathbf{R}^1$ defined by

$$T_a(x) = a + x \qquad \text{for all } x \in \mathbf{R}^1.$$

More generally, as observed by Cayley and Jordan, if $(G, \cdot)$ is any abstract group, then G may be regarded as a group of invertible functions on the set G by regarding the element $g \in G$ as the function $\lambda_g : G \to G$ defined by

$$\lambda_g(x) = gx \qquad \text{for all } x \in G.$$

It is for this reason that our two definitions of group are essentially the same. The mapping $G \to S(G)$ taking g to λ_g is called the (left) regular representation of G.

Groups like $(\mathbf{Z}, +)$, $(\mathbf{Q}, +)$, and $(\mathbf{R}, +)$ are instances of subgroups of $(\mathbf{C}, +)$ in the following sense.

Definition: *Let* $(G, \circ)$ *be a group. A nonempty subset* H *of* G *is a subgroup of* G *if* $(H, \circ_H)$ *is itself a group, where* $\circ_H$ *is the restriction of the function* $\circ$ *to* $H \times H$.

It follows readily that the identity in H is the identity in G and that inverses of elements in H are the same as their inverses in G.

Given any subgroup H of a group G, we may define an equivalence relation on the group G by the rule

$$g \equiv_H g_1 \qquad \text{if } g^{-1}g_1 \in H.$$

The equivalence classes determined by this equivalence relation are called the left cosets of H in G. Thus the left coset containing the element g is just

$$gH = \{gh : h \in H\}.$$

The set $G\backslash H$ of all left cosets of H in G forms a space on which G acts by left multiplication, in the sense that to each element $g \in G$ there is naturally associated a function $L_g : G\backslash H \to G\backslash H$ by $L_g(xH) = gxH$ and the functional equation $L_{gg_1} = L_g \circ L_{g_1}$ holds for all $g, g_1 \in G$. The left regular representation of G is the special case where $H = \{e\}$. However, although the map $g \to \lambda_g$ is one-to-one, in general, many elements of G may give rise to the same function on $G\backslash H$.

The fact that all left cosets of H have the same cardinality yields the first important theorem about finite groups.

Lagrange's Theorem: *Let G be a finite group and H a subgroup of G. Then $|H|$ is a divisor of $|G|$.*

In a similar way, it is possible to define the right cosets Hg of a subgroup H. An important class of subgroups, first studied by Galois, is the normal subgroups, which are those for which the right and left cosets coincide.

Definition: *A subgroup N of a group G is a normal subgroup if and only if $gN = Ng$ for all $g \in G$. When N is a normal subgroup of G, we write $N \lhd G$.*

Given a group G and a normal subgroup N, we can construct a new group G/N, called the quotient group of G by N.

Definition: *Let G be a group and N a normal subgroup of G. The set $G\backslash N$ with the operation $(gN)(g'N) = gg'N$ is a group, called the quotient group G/N.* (*Note that it is conventional to replace $\backslash$ by $/$ when the set is regarded as a group.*)

The normality condition is necessary for the multiplication on $G\backslash H$ to be well defined. The identity subgroup {e} and the entire group G are always normal subgroups of every group G. A group G whose only normal subgroups are {e} and G is said to be a simple group. Simple groups play the role in the theory of finite groups that prime numbers play in the theory of numbers, as remarked by Michael Solomon, among others. All finite groups are "composed" from the simple ones.

At the other extreme, every subgroup of an abelian group is normal. If G is any group and $g \in G$, then the subset $\{g^n : n \in \mathbf{Z}\}$ forms a subgroup of G called the cyclic subgroup generated by g and often denoted $\langle g \rangle$. If $G = \langle g \rangle$, then G is called a cyclic group. It follows that an abelian simple group must be cyclic, indeed cyclic of cardinality p for some prime p.

The quotient construction affords important examples of cyclic groups. Namely, for each positive integer n, the subset $n\mathbf{Z}$ of all multiples of n in $\mathbf{Z}$ is a subgroup of the abelian group $\mathbf{Z}$ and hence we have cyclic groups $\mathbf{Z}/n\mathbf{Z}$, generated by the coset $1 + n\mathbf{Z}$. Cyclic groups arise in many natural contexts. For instance, the set $Z(n)$ of all complex nth roots of 1 forms a cyclic group of cardinality n under multiplication. Likewise, the group of all rotational symmetries of a regular n-sided polygon is a cyclic group C_n of cardinality n, under composition of functions. The groups $\mathbf{Z}/n\mathbf{Z}$, $Z(n)$, and C_n have identical properties as abstract groups, although their manifestations in the "real world" are different. Under such circumstances the groups are called isomorphic. The formal definition follows.

Definition: *The function $\Phi : (G, \circ) \to (H, \cdot)$ is an isomorphism* (*of groups*) *if $\Phi : G \to H$ is a bijective function satisfying*:

$$\Phi(g \circ g') = \Phi(g) \cdot \Phi(g') \qquad \text{for all } g, g' \in G.$$

Two groups which are isomorphic are indistinguishable as abstract groups, and the isomorphism may be regarded as a dictionary for translating from one group to the other. Much of the power of abstract group theory derives from the fact that a given theorem about abstract groups may have numerous important instantiations via different realizations of the abstract groups. For later reference, we note that an isomorphism $\Phi : G \to G$ between a group and itself is called an automorphism of G. The set of all automorphisms of G itself forms a group, Aut(G), under composition of functions. (We shall refer later to an automorphism of a field, which has a similar meaning.)

Returning to cyclic and abelian groups, we observe that we now know, up to isomorphism, every cyclic group and every abelian simple group.

Theorem:

(1) *Every cyclic group is isomorphic either to $\mathbf{Z}$ or to $\mathbf{Z}/n\mathbf{Z}$ for some positive integer n; and*
(2) *Every abelian simple group is isomorphic to $\mathbf{Z}/p\mathbf{Z}$ for some prime p.*

In contrast to this elementary result, the classification of the finite nonabelian simple groups was a very challenging and complex undertaking, and the classification of infinite simple groups is surely impossible. In any case, a strategy for the analysis of a general (finite) group is to "decompose" it into simple factors via an iterated quotient group construction. This is meaningful for finite groups thanks to the following theorem.

Jordan–Hölder Theorem: *Let G be a finite group. Then there is an integer $n \geq 0$ and a chain of subgroups*

$$G = G_0 \geq G_1 \geq \cdots \geq G_{n-1} \geq G_n = \{e\}$$

such that $G_{i+1} \triangleleft G_i$ for all $i < n$ and G_i/G_{i+1} is a nonidentity simple group for all i. The chain is not necessarily unique, but the list $G_0/G_1, G_1/G_2, \ldots, G_{n-1}/G_n$ is uniquely determined by the group G, up to changing the order of the groups in the list and replacing groups by isomorphic copies.

The chain of subgroups is called a composition series for G, and the set of quotient groups is called the set of composition factors of G. Continuing the analogy with numbers, the Jordan–Hölder theorem plays the role of the fundamental theorem of arithmetic. In contrast to a number, however, a group G is hardly ever determined up to isomorphism by its set of composition factors. Indeed, already in the elementary case, where the set of composition factors is $\{\mathbf{Z}/p\mathbf{Z}, \mathbf{Z}/p\mathbf{Z}\}$, there are two nonisomorphic possibilities for the group G, one cyclic and the other not.

II. IMPORTANT EXAMPLES

We begin with some important examples of abelian groups. We have already mentioned the abelian group $(\mathbf{C}, +)$ and some of its subgroups. Sometimes the operation in an abelian group is naturally thought of as multiplication. Indeed, the algebraic object called a field may be defined as a set F closed under two binary operations $+$ and $\cdot$ such that $(F, +)$ is an abelian group with identity element 0, $(F - \{0\}, \cdot)$ is also an abelian group (with identity element 1), and the two operations are intertwined by the distributive law:

$$x(y + z) = xy + xz \qquad \text{for all } x, y, z \in F.$$

Thus, for example, $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{C}$ are fields, and so in particular $(\mathbf{Q} - \{0\}, \cdot)$, $(\mathbf{R} - \{0\}, \cdot)$, and $(\mathbf{C} - \{0\}, \cdot)$ are abelian groups with identity element 1. An important example of a subgroup of $\mathbf{C} - \{0\}$ is the circle group S^1:

$$S^1 = \{a + bi \in \mathbf{C} : a^2 + b^2 = 1\}.$$

Further examples of abelian groups are afforded by any vector space V with the operation of vector addition.

There are two particularly important sets of examples of nonabelian groups. The first are the symmetric groups $S(X)$, where X is any set and $S(X)$ is the group of all bijective functions $f : X \to X$, with the operation being composition of functions. If $\Phi : X \to Y$ is a bijection of sets, then there is an induced bijection $\tilde{\Phi} : S(X) \to S(Y)$ by

$$\tilde{\Phi}(f) = \Phi \circ f \circ \Phi^{-1},$$

which is in fact an isomorphism of groups. $S(X)$ is a nonabelian group whenever $|X| \geq 3$.

If X is any set with $|X| = n$, then we often denote by S_n the symmetric group $S(X)$. Since the isomorphism type of $S(X)$ is completely determined by the cardinality of X, this notation is justified. It is clear that every permutation σ of a finite set X can be written as a product of transpositions (permutations which interchange two points and fix the rest). We call σ an even (odd) permutation if the product involves an even (odd) number of transpositions. (Although the product is not unique, the parity turns out to depend only on σ.) The set of all even permutations is a subgroup of $S(X)$ called the alternating group $\mathrm{Alt}(X)$ (or A_n) of cardinality $n!/2$.

The second important class of groups is the family of general linear groups $\mathrm{GL}(V)$, where V is a vector space over a field F and $\mathrm{GL}(V)$ is the group of all invertible linear operators on V, i.e., invertible linear transformations $T : V \to V$. Again the operation is composition of functions, and indeed $\mathrm{GL}(V)$ is clearly a subgroup of the symmetric group $S(V)$. $\mathrm{GL}(V)$ is nonabelian whenever $\dim(V) > 1$. As above, if $\Phi : V \to W$ is an isomorphism between the F-vector spaces V and W, i.e., an invertible linear transformation mapping V onto W, then, exactly as before, Φ induces an isomorphism of groups between the groups $\mathrm{GL}(V)$ and $\mathrm{GL}(W)$. Thus the isomorphism type of $\mathrm{GL}(V)$ is completely determined by the field F and the dimension of V as an F-vector space. Indeed, if $\dim(V) = n$ is finite, then any choice of basis for V determines a (noncanonical) isomorphism of groups between the group $\mathrm{GL}(V)$ and the multiplicative group $\mathrm{GL}(n, F)$ of all $n \times n$ invertible matrices with entries taken from the field F. (This is simply an extension of the standard identification of a linear operator $T : V \to V$ with an $n \times n$ matrix A, the identification depending on a choice of basis for V.) If $|F|$ is finite, then it may be shown that (up to isomorphism of fields) there is only one field of cardinality $|F|$ and thus the notation $\mathrm{GL}(n, q)$, where $q = |F|$, is common and unambiguous. This is no longer the case when $|F|$ is infinite.

Certain subgroups of $\mathrm{GL}(V)$ are of particular importance and were first studied in depth by C. Jordan and L. E. Dickson. They are often referred to as the classical linear groups or classical matrix groups. First is $\mathrm{SL}(V)$, the subgroup of all elements of $\mathrm{GL}(V)$ of determinant 1. The others are subgroups which preserve a geometric structure on the space V.

Definition. *A bilinear form on an F-vector space V is a function $b : V \times V \to F$ which is linear in both positions, i.e.,*

$$b(cu + dv, w) = cb(u, w) + db(v, w)$$

and

$$b(u, cv + dw) = cb(u, v) + db(u, w)$$

for all $u, v, w \in V$ and all $c, d \in F$. We say that the form is symmetric if $b(u, v) = b(v, u)$ for all $u, v \in V$. We say that the form is alternating if $b(v, v) = 0$ for all $v \in V$.

Definition: *A quadratic form on an F-vector space V is a function $Q : V \to F$ such that*

(1) $Q(av) = a^2 Q(v)$ *for all* $a \in F$, $v \in V$; *and*
(2) $b(u, v) = Q(u + v) - Q(u) - Q(v)$ *defines a bilinear form* (*necessarily symmetric*) *on* V.

If (V, b) is a space with a symmetric bilinear form and if u and v are vectors in V of length 1, i.e., $b(u, u) = 1 = b(v, v)$, then $b(u, v)$ may be thought of as the cosine of the angle between the vectors u and v. In all cases, if $b(u, v) = 0$ we say that u and v are orthogonal vectors. Note that if $b(v, v) = 0$ for all $v \in V$, then $b(u, v) = -b(v, u)$ for all $u, v \in V$, and so in both the alternating and symmetric cases, orthogonality is a symmertic relation on V.

Definition: *If (V, b) is a space with an alternating or symmetric form b, we let*

$$V^{\perp} = \{v \in V : b(u, v) = 0 \text{ for all } u \in V\}.$$

If (V, Q) is a space with a quadratic form Q and associated symmetric bilinear form b, then we let

$$\mathrm{Rad}(V) = \{v \in V^{\perp} : Q(v) = 0\}.$$

We say that a space (V, b) with an alternating form b is a symplectic space if $V^{\perp} = \{0\}$. It may be shown that a finite-dimensional symplectic space V must have even dimension and for every even positive integer $2n$ and field F, there is (up to isometry) exactly one symplectic F-space of dimension $2n$. We say that a space (V, Q) with a quadratic form Q is an orthogonal space if $\mathrm{Rad}(V) = \{0\}$. There may be many orthogonal spaces of a given dimension over a given field; the number depends on both the field and the dimension. The classical law of inertia of Sylvester asserts in particular that there are exactly $n + 1$ nonisometric orthogonal structures on a real vector space of dimension n. An orthogonal space (V, Q) is completely determined by its associated bilinear structure (V, b) when the field F has characteristic different from 2 (e.g., when F is a subfield of $\mathbf{C}$).

The symplectic and orthogonal groups are the isometry groups of symplectic and orthogonal spaces, respectively, in the following sense.

Definition: *If (V, b) is a symplectic space and $T : V \to V$ is a linear operator, then T is an isometry of (V, b) if*

$$b(u, v) = b(T(u), T(v)) \qquad \text{for all } u, v \in V.$$

The symplectic group $Sp(V)$ is the group of all isometries of the symplectic space (V, b). [*As (V, b) is unique up to isometry, it is unambiguous* (*up to isomorphism*) *to write* Sp (V).] *If (V, Q) is an orthogonal space and $T : V \to V$ is a linear operator, then T is an isometry of (V, Q) if*

$$Q(v) = Q(T(v)) \qquad \text{for all } v \in V.$$

The orthogonal group $O(V, Q)$ is the group of all isometries of the orthogonal space (V, Q).

An isometry is necessarily a bijection, whence $\mathrm{Sp}(V)$ and $O(V, Q)$ are subgroups of $\mathrm{GL}(V)$. Classical mechanics focusses on the case where $F = \mathbf{R}$ and Q is positive definite, i.e.,

$$Q(x_1, x_2, \ldots, x_n) = x_1^2 + x_2^2 + \cdots + x_n^2,$$

and so often in the physics literature the group $O(\mathbf{R}^n, Q)$ for this choice of Q is denoted simply $O(n)$. The Lorentz group, however, which arises in relativity theory, is an orthogonal group defined with respect to a four-dimensional indefinite quadratic form.

Symplectic isometries always have determinant 1. There is a somewhat larger group $\mathrm{CSp}(V)$ of symplectic similarities, i.e., linear operators $T : (V, b) \to (V, b)$ such that for all $v, w \in V$,

$$b(T(v), T(w)) = \lambda_T b(v, w),$$

for some nonzero scalar $\lambda_T \in F$. This group will reappear toward the end of Section V.

Orthogonal isometries have determinant ± 1. The subgroup of $O(V, Q)$ consisting of isometries of determinant 1 is called the special orthogonal group, $\mathrm{SO}(V, Q)$. In the case of $O(n)$, it is denoted $\mathrm{SO}(n)$ and interpreted as the group of all orientation-prserving isometries of $\mathbf{R}^n$ fixing the origin. For $n = 3$, SO(3) is the group of all rotations of $\mathbf{R}^3$ about an axis through (0, 0, 0). The earliest classification theorem for a class of nonabelian groups was the classification of finite subgroups of SO(3), achieved in the mid-nineteenth century.

Theorem: *A finite subgroup of* SO(3) *is a subgroup of the full group of symmetries of one of the following objects centered at* (0, 0, 0): *a regular polygon lying in a plane through* (0, 0, 0) *or one of the five regular polyhedra* (*Platonic solids*): *the tetrahedron*, *the cube*, *the octahedron*, *the dodecahedron*, *or the icosahedron.*

It follows that a finite subgroup G of SO(3) is either a cyclic group or is the dihedral group D_n of all symmetries of a regular n-gon or is the tetrahedral, octahedral, or icosahedral group (the group of rotational symmetries of the tetrahedron, octahedron, or icosahedron, respectively).

Finally, when the field F admits an involutory automorphism σ (i.e., $\sigma^2 = I \neq \sigma$), there is a further important

family of classical linear groups, namely, the unitary groups.

Definition: *Let F be a field and let σ be an involutory automorphism of F. A (σ-)hermitian form on an F-vector space V is a function $h: V \times V \to F$ which is linear in the first position and which satisfies*

$$h(v, w) = h(w, v)^{\sigma} \qquad \text{for all } v, w \in V.$$

A pair (V, h) with V an F-vector space and h a σ-Hermitian form on V is said to be a unitary space if $V^{\perp} = \{0\}$. We denote by $U(V, h)$ the group of all isometries of the unitary space (V, h) and call it the unitary group of (V, h). The subgroup of unitary isometries of determinant 1 is the special unitary group, $\mathrm{SU}(V, h)$.

Of course the most important of all involutory automorphisms is the complex conjugation map on $\mathbf{C}$. When h is the standard positive definite inner product on $\mathbf{C}^n$, the unitary group $U(\mathbf{C}^n, h)$ is often denoted simply $U(n)$. There are, however, other inequivalent hermitian forms on $\mathbf{C}^n$. There is a famous twofold covering map from SU(2) onto SO(3) called the spin covering because of its connection with the concept of spin in quantum mechanics.

If F is a finite field with $|F| = q^2$ for some prime power q, then F admits an involutory automorphism and it is possible to define unitary groups of isometries of finite-dimensional F-vector spaces. Up to isomorphism, in the finite field case, the unitary group is uniquely determined by the field F and the dimension n of the vector space. Unfortunately, if $|F| = q^2$, some group theorists denote this group $U_n(q^2)$, while others write $U_n(q)$. This is only one instance of the notational inconsistencies which litter the terrain of classical linear groups. The original notations of Jordan and Dickson have been largely abandoned or modified in favor of a "classical" notation dating from the time of Weyl. However, when Cartan (for the field $\mathbf{R}$) and later Chevalley and Steinberg (for arbitrary fields) constructed these groups from a Lie-theoretic standpoint, they adopted the notation of Killing, which is completely different from Weyl's notation. Moreover, even within the Weyl framework, there are treacherous inconsistencies. For instance, some write $\mathrm{Sp}_n(F)$ and others $\mathrm{Sp}_{2n}(F)$, both meaning the group of symplectic isometries of a $2n$-dimensional F-vector space. Let the reader beware.

III. BASIC CONSTRUCTIONS

In Section I we addressed the problem of decomposing a group into its constituent simple composition factors (when possible). Now we consider the opposite problem of "composing" two or more groups to create a new and larger group. One fundamental construction is the direct product construction.

Definition: *Let G and H be groups. The Cartesian product set $G \times H$ with the operation*

$$(g, h) \cdot (g', h') = (gg', hh')$$

is a group, called the direct product $G \times H$.

This construction can be iterated to define direct products $\prod G_i$ over arbitary index sets I. Another important generalization is the semidirect product. Before defining this, we must generalize the notion of an isomorphism of groups.

Definition: *Let $(G, \circ)$ and $(H, \cdot)$ be groups. A function $f: G \to H$ is a homomorphism of group provided that*

$$f(g \circ g') = f(g) \cdot f(g') \qquad \text{for all } g, g' \in G.$$

Thus an isomorphism of groups is a bijective homomorphism of groups. In general, failure of injectivity for homomorphisms is measured by the following subgroup.

Definition: *Let $f: G \to H$ be a homomorphism of groups. The kernel of f is defined by*

$$\mathrm{Ker}(f) = \{g \in G : f(g) = e_H\},$$

where e_H is the identity element of the group H.

The pre-image $f^{-1}(h)$ of each element in $f(G)$ is both a left and right coset of $\mathrm{Ker}(f) = f^{-1}(e_H)$ and so has the same cardinality as $\mathrm{Ker}(f)$. In particular, f is injective if and only if $\mathrm{Ker}(f) = \{e_G\}$, where e_G is the identity element of G. There is an intimate connection between normal subgroups and homomorphisms.

Theorem: *Let $f: G \to H$ be a homomorphism of groups with kernel K. Then K is a normal subgroup of G and f induces an isomorphism between G/K and $f(G)$. Conversely, if K is any normal subgroup of the group G, then the function $\pi: G \to G/K$ defined by*

$$\pi(g) = gK \qquad \text{for all } g \in G$$

is a homomorphism of groups with kernel K.

Now we can describe the semidirect product construction of groups.

Definition: *Let K and H be groups and let $\phi: H \to \mathrm{Aut}(K)$ be a homomorphism of groups. The semidirect product $K :^{\phi} H$ (or simply $K : H$) is the group whose underlying set is the Cartesian product set $K \times H$ with multiplication defined by*

$$(k, h)(k', h') = (k\phi(h)(k'), hh') \qquad \text{for all } k, k' \in K, h, h' \in H.$$

The direct product $K \times H$ is the special case of the above construction in which ϕ is the homomorphism mapping every element of H to the identity automorphism

of K. In all cases, $\{(k, e_H) : k \in K\}$ is a normal subgroup of $K : H$, which is isomorphic to K. The subset $H_0 = \{(e_K, h) : h \in H\}$ is a subgroup of $K : H$ isomorphic to H, but is not in general a normal subgroup of $K : H$. Indeed, H_0 is also normal if and only if $K : H \cong K \times H$.

If all composite (i.e., not simple) groups could be constructed from proper subgroups by an iterated semidirect product construction, then the classification of all finite groups, or even all groups having a composition series, would at least be thinkable, if not doable. However, not, all composite groups can be so constructed, as is illustrated by the easy example of the cyclic group C_{p^2}. The obstruction to a composite group "splitting" as a semidirect product was first analyzed by Schur. The attempt to parametrize the set of all groups which are an "extension" of a given normal subgroup by a given quotient group was one of the motivating forces for the development of the cohomology theory of groups.

In the context of finitely generated abelian groups, a complete classification is nevertheless possible and essentially goes back to Gauss. (A group G is finitely generated if there is a finite subset S of G such that every element of G is expressible as a finite word in the "alphabet" S. We write $G = \langle S \rangle$ if G is generated by the elements of the subset S. In particular, every finite group G is finitely generated: you may take $S = G$.)

Theorem: *If A is a finitely generated abelian group, then A is a finite direct product of cyclic groups.*

On the other hand, the enumeration of all finite p-groups is an unthinkable problem. For p a prime, we call a group P a p-group if all of the elements of P have order a power of p. By theorems of Lagrange and Cauchy, P is a finite p-group if and only if $|P| = p^n$ for some $n \geq 0$. G. Higman and Sims have established that the number $P(n)$ of p-groups of cardinality p^n is asymptotic to a function of the form $p^{\frac{2}{27}n^3 + o(n^3)}$ as $n \to \infty$.

In a different direction, another important generalization of the direct product is the central product. First we introduce an important normal subgroup of a group G.

Definition. *Let G be a group. The center, $Z(G)$, of G is defined by*

$$Z(G) = \{z \in G : zg = gz \text{ for all } g \in G\}.$$

Definition: *Let H, K, and C be groups and let $\alpha : C \to Z(H)$ and $\beta : C \to Z(K)$ be injective homomorphisms. Let*

$$Z = \{(\alpha(c), \beta(c)) \in H \times K : c \in C\}.$$

Then the central product $H \circ_C K$ is the quotient group $(H \times K)/Z$.

Sometimes the central product is (ambiguously) written $H \circ K$. Often this is done when $Z(H) \cong Z(K)$ and α and β are understood to be isomorphisms. Like the direct product, all of these product constructions can be iterated.

In some ways dual to the center of G is the commutator quotient.

Definition: *Let G be a group. If $x, y \in G$, then the commutator $[x, y] = x^{-1}y^{-1}xy$. The commutator subgroup $[G, G]$ of G is defined by*

$$[G, G] = \langle [x, y] : x, y \in G \rangle,$$

i.e., $[G, G]$ is the subgroup of G generated by all commutators of elements of G. Then $[G, G]$ is a normal subgroup of G and the commutator quotient $G/[G, G]$ is the largest abelian quotient group of G.

Note that G is an abelian group if and only if $Z(G) = G$ if and only if $[G, G] = \{e\}$. Sometimes $G/[G, G]$ is called the abelianization of G.

This leads to the definition of the following important classes of groups.

Definition: *A nonidentity finite group G is quasi-simple if $G = [G, G]$ and $G/Z(G)$ is a (nonabelian) simple group. A finite group G is semisimple if $G = G_1 \circ G_2 \circ \cdots \circ G_r$, where each G_i is a quasisimple group.*

In the contexts of Lie groups and algebraic groups, a group is called simple if every proper closed normal subgroup is finite. Thus the group $SL(n, \mathbf{C})$, whose center is isomorphic to the finite group of complex nth roots of 1, would be called a simple group by a Lie theorist and a quasi-simple (but not simple) group by a finite group theorist. There is a notion of semisimple group in the categories of linear algebraic groups and Lie groups which coincides with the definition above for connected groups.

Some slightly larger classes of groups play an important role in many areas. The following definitions are not standard. The concept of a connected reductive group is fundamental in the theory of algebraic groups, in which context it is defined to be the product of a normal semisimple group and a torus (a group isomorphic to a product of GL_1's). The second definition below approximates this notion in the category of all groups.

Definitions: *A group G is almost simple if G has a normal subgroup E which is quasi-simple and $G/Z(E)$ is isomorphic to a subgroup of* Aut(E). *A group G is almost semisimple if G has a normal subgroup $E = S \circ Z(E)$ with $S = S_1 \circ S_2 \circ \cdots \circ S_r$ semisimple (with each S_i quasi-simple) and $G/Z(E)$ is isomorphic to a subgroup of* Aut(S) *normalizing each S_i.*

Most of the classical groups described above are almost semisimple. Indeed, S is a quasi-simple group in most cases. Also, the Levi complements of parabolic subgroups

(stabilizers of flags of totally singular subspaces) of the classical linear groups are usually almost semisimple, exceptions arising over small fields or because of the peculiar structure of certain four-dimensional orthogonal groups. In a vast number of cases of importance in mathematics and the physical sciences, the symmetry group (or automorphism group) of an interesting structure is either an almost semisimple group or has the form $G = V : H$ as the semidirect product of an abelian group V and an almost semisimple group H. For example, the group of all rigid motions of Euclidean space $\mathbf{R}^n$ has the structure $\mathbf{R}^n : O(n)$. Similarly, if V is an affine space, then the group AGL(V) of all affine transformations of V has the structure $\mathrm{AGL}(V) = V : \mathrm{GL}(V)$.

The proof of the classification of finite simple groups necessitated in fact the classification of all finite almost-simple groups. Thus, as a consequence of the classification (along with the classification of finite abelian groups), there is essentially a complete description of all finite almost-semisimple groups. The analogous result for infinite groups is out of reach, but if one restricts to the categories of algebraic groups or Lie groups, then a description of all connected reductive groups is again a part of the fundamental classification theorems.

IV. PERMUTATION GROUPS AND GEOMETRIC GROUPS

Definition: *A group G is said to have a permutation action* (*or*, *simply*, *to act*) *on a set X if there is a homomorphism $f : G \to S(X)$. If f is injective, then we may identify G with $f(G)$, a subgroup of $S(X)$. In this case we say that G is a permutation group. In any case we may write $g(x)$ for $f(g)(x)$.*

As noted earlier, the action of G on the set G by left multiplication defines an injective homomorphism of G into $S(G)$, called the left regular representation of G. Thus every group is a permutation group.

Definition: *If G acts on the set X and $x \in X$, we say that the G-orbit containing x is the subset*

$$x^G = \{g(x) : g \in G\}.$$

The G-orbits form a partition of the set X. If $X = x^G$, we say that G acts transitively on the set X. We say that the stabilizer in G of the point x is the subgroup

$$G_x = \{g \in G : g(x) = x\}.$$

The following is a version of Lagrange's theorem.

Theorem: *If G is a finite group acting on the set X and if $x \in X$, then*

$$|G| = |G_x|\,|x^G|.$$

If G acts transitively on the set X, then the permutation action of G on X is permutation isomorphic to the action by left multiplication of G on the left coset space $G\backslash G_x$. Conversely, for any subgroup H of a group G, the left multiplication action of G on $G\backslash H$ defines a transitive permutation action of G. Thus the classification of transitive permutation actions of a group G is equivalent to the classification (up to G-conjugacy) of subgroups of G. Here G-conjugacy refers to yet another important class of permutation actions of a group G.

Definition: *Let G be a group and X a subset of G. Let*

$$X^G = \{gXg^{-1} : g \in G\}.$$

The members of X^G are called the G-conjugates of X and X^G is called the G-conjugacy class of X. G acts transitively by conjugation on X^G. The subgroup G_X is denoted $N_G(X)$ and is called the normalizer in G of X.

Thus Lagrange's theorem in this context asserts that $|G| = |N_G(X)||X^G|$. (Another notational caution: For many mathematicians, X^G would be interpreted as the subset of X fixed pointwise by G. This is not the usage in this article.)

Definition: *A transitive permutation action of a group G on a set X is said to be imprimitive if there is a partition $\mathcal{B}$ of X into sets $B_i, i \in I$, with $|I| > 1$ and $|B_i| > 1$, satisfying: for all $i \in I$ and all $g \in G$, there exists $j \in I$ such that $g(B_i) = B_j$. The partition $\mathcal{B}$ is called a system of imprimitivity and the members B_i are called blocks. If there is no such system of imprimitivity for the action of G, the action is called primitive.*

In the theory of permutation groups, primitive permutation actions roughly play the role of simple groups in the abstract theory of groups: all permutation actions may be considered to be built up out of primitive permutation actions. Thus the classification of primitive permutation groups and primitive permutation actions has received considerable attention.

An elementary but basic fact is that if G acts transitively on the set X, then the stabilizer G_x of a point $x \in X$ is a maximal subgroup of G (i.e., there is no subgroup of G properly between G_x and G) if and only if the action of G on X is primitive. Thus the classification of primitive permutation actions is equivalent to the classification (up to G-conjugacy) of the maximal subgroups of the permutation group G.

An important class of examples of primitive permutation groups is the class of affine general linear groups $\mathrm{AGL}(V) = V : \mathrm{GL}(V)$ acting naturally on the affine space V as the group of all affine transformations of V. The

subgroup V of translation maps is a regular normal subgroup, i.e., V transitively permutes the vectors of V via translation and the stabilizer V_u of any vector u is $\{I\}$, the identity function (regarded as translation by $\mathbf{0}$). Thus $\mathrm{AGL}(V)_0 = \mathrm{GL}(V)$.

In the theory of permutation groups an important role is played by the socle of G, which is the product of all minimal normal subgroups of G. There exist rather detailed theorems concerning the structure of primitive permutation groups, in particular describing the structure of the socle and its intersection with the stabilizer of a point.

Theorem (O'Nan-Scott): *Let G be a primitive permutation group on a finite set X with $|X| = n$, and let B be the socle of G. Then one of the following holds*:

1. *X may be regarded as an affine space with $n = p^m$ for some prime p, B is the abelian group of all translations of X and G is a subgroup of the affine group* $\mathrm{AGL}(X)$; *or*
2. *$B = S^k$ is the direct product of $k \geq 1$ isomorphic nonabelian simple groups acting via the product action on the Cartesian product set $X = Y^k$, where S is a primitive simple subgroup of $S(Y)$; or*
3. *$B = S^k$ is the direct product of $k > 1$ nonabelian simple groups acting either via diagonal action with $|X| = |S|^{k-1}$ and with B_x a diagonally embedded copy of S, or via twisted wreath action with $|X| = |S|^k$ and $B_x = 1$.*

The O'Nan-Scott theorem focuses attention on the primitive permutation actions of nonabelian simple groups and indeed, in the wake of the classification of finite simple groups, considerable effort has been invested in the program of determining all maximal subgroups of all finite simple groups and all closed maximal subgroups of all simple algebraic groups. There exist detailed structure theorems for these maximal subgroups, as well as extensive specific information. Besides the case-by-case enumerations of maximal subgroups for the sporadic simple groups, most of this theory has been developed in the context of simple algebraic and Lie groups by Dynkin, Seitz, Liebeck, and others. Lifting theorems, originating with Steinberg, make it possible to a certain extent to transfer maximal subgroup questions concerning finite classical linear and exceptional groups to analogous questions about algebraic groups over the algebraic closure of the finite field.

Since the mid-nineteenth century there has been considerable interest in highly transitive permutation groups.

Definition: *Let G be a permutation group on a set X and let k be a positive integer. We say that G acts k-transitively on X if for any two ordered k-tuples $(x_1, \ldots, x_k)$ and $(y_1, \ldots, y_k)$ with $x_i \neq x_j$ and $y_i \neq y_j$ for $i \neq j$, there exists an element $g \in G$ with $g(x_i) = y_i$ for all i.*

Thus transitive is the same as 1-transitive. In the 1860s, Mathieu discovered two remarkable groups, M_{12} and M_{24}, which act 5-transitively on sets of cardinality 12 and 24, respectively. Despite considerable effort, the only known proof of the following theorem is as a corollary of the classification of finite simple groups.

Theorem: *Let G be a finite k-transitive permutation group on a set X for some $k \geq 4$. Then either $G = S(X)$ with $|X| \geq 4$ or $G = \mathrm{Alt}(X)$ with $|X| \geq 6$ or $G = M_{11}$, M_{12}, M_{23}, or M_{24}.* [*Here M_{11} (resp. M_{23}) is the stabilizer of a point in M_{12} (resp. M_{24}).*]

Highly transitive permutation groups lead to tight combinatorial designs which may often be interpreted as error-correcting codes or dense sphere-packing lattices. Specifically, Witt described designs (or Steiner systems) $S(5, 6, 12)$ and $S(5, 8, 24)$ associated with the Mathieu groups M_{12} and M_{24}, respectively. These yield the ternary and binary Golay codes, respectively.

There is also a complete description of finite k-transitive permutation groups for $k = 2$ and 3. One important class of examples of 2-transitive permutation groups is the class of projective general linear groups $\mathrm{PGL}(V)$. For V any vector space (over a field F) of dimension at least 2, we may form the projective space $P(V)$ whose objects are the k-dimensional subspaces of V, $k \geq 1$, with incidence being given by symmetrized containment of subspaces. Then $\mathrm{GL}(V)$ acts on the points of $P(V)$ and the kernel of the action is $Z(GL(V))$, the group of scalar linear transformations on V. The projective general linear group $\mathrm{PGL}(V) = \mathrm{GL}(V)/Z(\mathrm{GL}(V))$ then acts as a 2-transitive permutation group on the set $P(V)$. The image of $\mathrm{SL}(V)$ in the symmetric group on $P(V)$ is the subgroup of $\mathrm{PGL}(V)$, denoted $\mathrm{PSL}(V)$, and it too acts 2-transitively on $P(V)$.

The lines of projective spaces are coordinatized by the elements of the field F plus one extra "point at infinity." As no element of $\mathrm{PGL}(V)$ can map three collinear points to three noncollinear points, the action of $\mathrm{PGL}(V)$ cannot be 3-transitive unless the geometry contains only one line. This is precisely the case when $\dim(V) = 2$, and indeed in this case the action is 3-transitive. If V is two-dimensional over the finite field F with $|F| = q$, then we write $\mathrm{PGL}(V) = \mathrm{PGL}(2, q)$ and $\mathrm{PSL}(V) = \mathrm{PSL}(2, q)$. If $q = 2^m$, then $\mathrm{PGL}(2, q) = \mathrm{PSL}(2, q)$, while if q is odd, then the $\mathrm{PSL}(2, q)$ is a normal subgroup of $\mathrm{PGL}(2, q)$ of index 2.

Theorem: *Let G be a finite 3-transitive* (*but not 4-transitive*) *permutation group on a set X. Then one of the following holds*:

1. *X may be regarded as an affine space with $|X| = 2^n$ and either $G = \mathrm{AGL}(X)$ or $|X| = 16$ and $G = X : A_7$; or*
2. *The socle of G is $\mathrm{PSL}(2, q)$ and $X = \mathrm{PG}(1, q)$ is the projective line of order q, $q \geq 2$; or*
3. *$G = M_{22}$ (the stabilizer of a point in M_{23}).*

The description of finite 2-transitive (but not 3-transitive) permutation groups G is much more elaborate. Again the examples fall into two major classes. The first are affine groups $G = V : H$, with H acting as a subgroup of $\mathrm{GL}(V)$ transitive on the nonzero vectors of V. These were enumerated by Hering, using the classification theorem for finite simple groups. There are three infinite classes and several additional small examples. In the second class, the socle of G is a nonabelian simple group. These too have been completely enumerated using the classification theorem. The socles of the generic examples are $\mathrm{PSL}(n, q)$ acting on the points of projective space, $\mathrm{Sp}(2n, 2)$ acting on spaces of quadratic forms, and the split BN pairs of rank 1 acting on the coset space $G \backslash B$. There are also several isolated examples.

At one time it was suspected that every nonabelian finite simple group had a 2-transitive permutation action on some set. This is far from the case. However, a vast number of simple groups come close in the sense of being rank k permutation groups for $k \leq 3$, as defined below.

Definition: *A permutation group G acting on a set X is said to have a rank k action on X if G is transitive on X and a point stabilizer G_x has exactly k orbits on X.*

A 2-transitive group G is a rank 2 group in this sense. A considerable number of finite simple groups are rank 3 permutation groups. For example, the classical projective linear groups $\mathrm{PSp}(V)$, $\mathrm{PU}(V, h)$, and $\mathrm{PO}(V, Q)$ are rank 3 in their actions on the singular points of $P(V)$ [i.e., all points in the symplectic case and those points v such that $h(v, v) = 0$, resp. $Q(v) = 0$ in the unitary and orthogonal cases respectively], provided (in the unitary and orthogonal cases) that the geometries contain totally singular planes, i.e., planes on which the form is identically 0. There are tight combinatorial conditions on rank 3 permutation actions, developed by D. G. Higman and others. The study of rank 3 permutation groups led to the discovery of several of the so-called sporadic simple groups, as discussed in Section VI.

The action of a group G on the coset space $G \backslash H$ for a single subgroup H leads to a transitive permutation action. When a family $\{G_i\}_{i \in I}$ of subgroups and coset spaces $G \backslash G_i$ are considered simultaneously, this may be regarded as a geometry with objects of type i, $i \in I$, transitively permuted by G, and with incidence defined by

$$xG_i \text{ is incident with } yG_j \text{ for } i \neq j \text{ if } xG_i \cap yG_j \neq \emptyset.$$

Thus, if $G = \mathrm{GL}(V)$ and G_i is taken to be the full stabilizer of a fixed i-dimensional subspace V_i, $0 < i < \dim(V)$, then we recover the projective geometry $\mathrm{PG}(V)$. Analogous constructions using stabilizers of totally singular subspaces yield the classical polar geometries for $\mathrm{PSp}(V)$, $\mathrm{PO}(V, Q)$, and $\mathrm{PU}(V, h)$. This type of construction was generalized by Tits to yield the theory of buildings and BN pairs. Tits gave an elegant axiomatic treatment for a large class of geometries, which he dubbed "buildings." Most of these geometries have large (flag-transitive) automorphism groups, and the corresponding axiomatization of these groups underlies the theory of BN pairs or Tits systems.

V. GROUP REPRESENTATIONS AND LINEAR GROUPS

A linear representation of a group G is a homomorphism $\rho : G \to \mathrm{GL}(V)$ for some vector space V. Throughout this section all vector spaces will be assumed to be over a given field F. The systematic study of finite-dimensional group representations began in the 1890s, notably in the work of Frobenius. Many of the basic ideas are analogous to those in the theory of permutation representations. Thus the decomposition of a set into G-orbits has its correspondent in the decomposition of the finite-dimensional vector space V into G-invariant subspaces V_i:

$$V = V_1 \oplus \cdots \oplus V_n,$$

where each V_i is indecomposable in the sense that it cannot be written as the direct sum of two proper G-invariant subspaces. The Krull-Schmidt theorem asserts in this context the uniqueness of the isomorphism classes of G-invariant spaces in the unordered list $V_1, \ldots, V_n$. (In the case of infinite-dimensional representations of a Lie group G, this direct sum decomposition must often be replaced by a direct integral of G-invariant subspaces of a Hilbert space. We see this already in the classical Fourier integral which arises in the representation theory of the real line $\mathbf{R}^1$.)

Immediately at this stage the representation theory of finite groups bifurcates into two cases: ordinary representation theory, where the field F has characteristic 0, and modular representation theory, where the field F has characteristic p and p divides $|G|$. (When F has characteristic p and p does not divide $|G|$, the theory is essentially the same as the characteristic 0 theory.)

Maschke's theorem: *If G is a finite group and F is a field of characteristic* 0 (*e.g., a subfield of* **C**), *then every finite-dimensional G-space V is completely reducible*

in the sense that each indecomposable summand V_i is irreducible, i.e., V_i has no proper G-invariant subspaces.

On the other hand, every finite group of order divisible by a prime p has a p-modular representation space V which is indecomposable but not irreducible. The p-modular representation theory for cyclic p-groups is precisely the theory of unipotent Jordan canonical matrices. A unipotent Jordan block represents an indecomposable module and is irreducible only if it is a 1×1 block. Similar considerations play a significant role in the representation theory of Lie groups and algebraic groups. Thus a fundamental result in Lie theory asserts the complete reducibility of finite-dimensional complex representations of complex semisimple Lie groups. By contrast, nilpotent Lie groups typically have indecomposable finite-dimensional complex representations which are not irreducible.

For the remainder of this section we shall assume that V is finite-dimensional, although many of the concepts such as characters and induced representations have wider applicability.

In characteristic 0, a G-representation ρ is completely determined by its trace function or character χ_ρ, defined by

$$\chi_\rho(g) = \mathrm{Tr}(\rho(g)) \qquad \text{for all } g \in G,$$

where Tr is the trace of the matrix $\rho(g)$. As similar matrices have the same trace, χ_ρ is a class function, i.e., it is constant on G-conjugacy classes. The (ordinary) character theory of finite groups was developed by Frobenius, Burnside, and Schur around 1900. For abelian groups, complex characters are simply homomorphisms into $\boldsymbol{C}^\times$, and they arose in the number-theoretic investigations of Legendre, Gauss, and Dirichlet. It was Dedekind whose letter to Frobenius stimulated the extension of this theory to nonabelian groups.

The following concept goes back to Galois.

Definition: *A group G is solvable if and only if there is a series*

$$G = G_0 > G_1 > \cdots > G_{n-1} > G_n = \{e\},$$

with $G_{i+1} \triangleleft G_i$ for all $i < n$ and with G_i/G_{i+1} an abelian group.

For finite groups this is equivalent to the assertion that the composition factors of G are all cyclic of prime order. Galois established that a polynomial equation is "solvable by radicals" if and only if its Galois group is a finite solvable group, extending the result of Abel mentioned in Section I. Sylow proved that a finite group of prime-power cardinality is necessarily a solvable group. One of the great early achievements of character theory was the proof of the following result.

Burnside's p^aq^b Theorem: *If G is a finite group with $|G| = p^aq^b$, with p and q primes, then G is a solvable group.*

There is also a theory of Brauer characters in the context of modular representation theory, but the Brauer characters do not determine the modular representations uniquely, except in the case of irreducible modular representations.

A fundamental construction in representation theory, introduced by Frobenius, is the induced representation. First note that for a finite group G and a field F, the F-vector space $F[G]$ with basis G becomes a ring when endowed with the unique extension of the group multiplication to $F[G]$ via the distributive law. $F[G]$ may also be regarded as the algebra of F-valued functions on G with convolution product and, as such, has natural generalizations in the categories of Lie and algebraic groups. An F-vector space V with a G-action is an $F[G]$-module in a natural way.

Definition: *Let G be a finite group, H a subgroup of G, F a field and V an $F[H]$-module. The induced $F[G]$-module V^G is the tensor product $F[G] \otimes_{F[H]} V$ with the action of $F[G]$ via left multiplication.*

There is a similar construction in the categories of Lie groups and algebraic groups, which plays a fundamental role, for example, in Harish-Chandra's construction of unitary representations of semisimple Lie groups. In this context it is often best to study representations of the associated Lie algebra, in which case the universal enveloping algebra substitutes for the group algebra.

Induced modules are analogous to imprimitive sets in the theory of permutation groups. Indeed, a G-module V is called imprimitive if $V = U^G$, where U is an H-module for some proper subgroup H of G. Otherwise V is called a primitive G-module.

A new complication in representation theory relates to the size of the field F. This is the extension of the basic problem of finding eigenvalues in the field for a matrix or linear operator. Thus the theory works most smoothly over algebraically closed fields such as $\mathbf{C}$. Sometimes, however, it is necessary to work over smaller fields and due caution is necessary. For example, an $F[G]$-module V may be irreducible but not absolutely irreducible, in the sense that V becomes reducible upon suitable extension of the field of scalars. The theory of Schur indices and Brauer groups is important in this context.

There is a further important way of "analyzing" a G-module into simpler constituents. An $F[G]$-module V is said to be tensor decomposable if $V \cong U \otimes W$ with U and W $F[G]$-modules. [Here $\otimes$ denotes the ordinary tensor product over F and $g(u \otimes w) = g(u) \otimes g(w)$.] Otherwise V is tensor indecomposable. A fundamental theorem

of Steinberg, the tensor product theorem, describes all irreducible rational modules for simple algebraic groups and all irreducible modules for finite groups of Lie type in the defining characteristic (i.e., p-modular representations, where p is the defining prime for the group) as tensor products of certain basic modules and their Galois "twists."

As tensor decomposability parallels reducibility, so too there is a notion of a tensor-induced $F[G]$-module which is analogous to the notion of an imprimitive $F[G]$-module. We can call a module tensor-primitive if it is neither tensor decomposable nor tensor-induced. Thus the "prime" object in this context is an absolutely irreducible primitive and tensor-primitive $F[G]$-module.

In the context of linear representation theory, the socle is no longer the correct subgroup to consider. For example, whereas the socle of the permutation group S_n (when $n \geq 5$) is the nonabelian simple group A_n, which captures much of the structure of S_n, the socle of the general linear group $\mathrm{GL}(n, q)$, when n divides $q-1$, is a subgroup of the group Z of scalar matrices and captures very little of the structure of $\mathrm{GL}(n, q)$. Surprisingly it was not until 1970 that the correct replacement for the socle in the context of linear groups or general finite groups was defined. Before giving the definition, we must finally discuss the important class of nilpotent groups.

Definition: *For a group G, we define recursively $G^0 = G$ and $G^{i+1} = [G^i, G]$ for $i \geq 0$. [Thus $G^1 = [G, G]$ is the commutator subgroup of G.] A group G is said to be nilpotent* (*of nilpotence class n*) *if $G^n = \{e\}$ for some positive integer n* (*with n the smallest such positive integer*).

Thus an abelian group is a nilpotent group of nilpotence class 1. As G^i is a normal subgroup of G for all i and as G^i/G^{i+1} is abelian, every nilpotent group is a solvable group. However, the converse is false, as shown by the symmetric group S_3. Sylow proved that every finite p-group is nilpotent, and indeed, the following theorem characterizes finite nilpotent groups.

Theorem: *A finite group G is nilpotent if and only if G is a direct product of finite p-groups.*

In the category of linear algebraic groups, the quintessential (though certainly not the only) examples of connected nilpotent groups are the groups $U(n, F)$ of all upper triangular matrices with all diagonal entries equal to 1. We call a matrix unipotent if it is conjugate to a matrix in $U(n, F)$. We have the following theorems.

Theorem: *Let U be a subgroup of* $\mathrm{GL}(n, F)$ *all of whose elements are unipotent matrices. Then U is a nilpotent group and is conjugate to a subgroup of $U(n, F)$.*

Lie's Theorem: *Let G be a closed connected solvable subgroup of* $\mathrm{GL}(n, \mathbf{C})$. *Then G is conjugate to a subgroup of $B(n, \mathbf{C})$, the solvable group of all upper triangular matrices in* $\mathrm{GL}(n, \mathbf{C})$.

Thus every subgroup of $U(n, \mathbf{C})$ is nilpotent and every closed connected nilpotent subgroup of $\mathrm{GL}(n, \mathbf{C})$ is conjugate to a subgroup of $B(n, \mathbf{C})$. Lie's theorem does not extend to arbitrary fields. For example, SO(2) is a closed connected abelian subgroup of $\mathrm{SL}(2, \mathbf{R})$ which is not conjugate to a subgroup of $B(2, \mathbf{R})$.

Returning to abstract groups, it can easily be shown that the product of two normal nilpotent subgroups of a group G is again nilpotent. Hence if G is a finite group, then G has a unique maximal normal nilpotent subgroup, called the fitting subgroup of G, $F(G)$. Likewise the product of two normal semisimple subgroups of a group G is again semisimple and so a finite group G has a unique maximal normal semisimple subgroup denoted $E(G)$. Moreover, the subgroups $E(G)$ and $F(G)$ commute with each other elementwise.

Definition: *The generalized Fitting subgroup $F^*(G)$ of the finite group G is the central product $F^*(G) = E(G) \circ F(G)$.*

Notice that if $F(G)$ is an abelian group, then $F^*(G)$ is an almost semisimple group. In the general theory of finite groups (or more generally of groups having a composition series), the group $F^*(G)$ plays the role that the socle plays in the theory of permutation groups. Thus, returning to the example of $\mathrm{GL}(n, q)$, although the socle is typically a subgroup of the group of scalar matrices Z, $F^*(\mathrm{GL}(n, q)) = SL(n, q) \circ Z$ captures most of the structure of $\mathrm{GL}(n, q)$.

To further appreciate the fundamental significance of $F^*(G)$ we must introduce a basic concept.

Definition: *Let X be any subset of the group G. The set*

$$C_G(X) = \{g \in G : gx = xg \text{ for all } x \in X\}$$

is a subgroup of G called the centralizer in G of X.

Definition: *Let G be a group and N a normal subgroup of G. The conjugation action of G on the elements of N defines a homomorphism $\Phi : G \to \mathrm{Aut}(N)$. The kernel of this homomorphism is $C_G(N)$. Thus $G/C_G(N)$ is isomorphic* (*via Φ*) *to a subgroup of* $\mathrm{Aut}(N)$.

Theorem (Fitting–Bender): *Let G be a finite group. Then*

$$C_G(F^*(G)) = Z(F(G)).$$

Thus $G/Z(F(G))$ is isomorphic to a subgroup of $\mathrm{Aut}(F^*(G))$.

In particular, this result says that $|G|$ is bounded by a function of $|F^*(G)|$. Specifically, $|G| \leq (|F^*(G)|)!$. (This

upper bound is achieved only when $G = S_n$ for $n \leq 4$.) In fact, much more is true in most practical applications.

Returning briefly to linear groups, we recall that the fundamental case to analyze was the following: G is a subgroup of $\mathrm{GL}(V)$, where V is an absolutely irreducible primitive and tensor-primitive G-module. In this case the following structure theorem is valid. We need one further definition.

Definition: *Let p be a prime. An extraspecial p-group E is a finite p-group such that $|Z(E)| = p$ and $E/Z(E)$ is a nontrivial abelian p-group of exponent p.*

Extraspecial p-groups are the finite cousins of the Heisenberg groups, which play a prominent role in quantum mechanics.

Theorem: *Let G be a finite subgroup of* $\mathrm{GL}(V)$, *where V is an n-dimensional vector space over the field F. Suppose that for every normal subgroup N of G not contained in $Z = Z(\mathrm{GL}(V))$, V is an absolutely irreducible primitive and tensor-primitive $F[N]$-module. Then either*

1. *$F^*(G) = E \circ (Z \cap G)$ with E an extraspecial p-group for some prime p such that the field F contains primitive* pth *roots of* 1; *or*
2. *$F^*(G) = E \circ (Z \cap G)$ with E a quasi-simple finite group and $Z(E) \leq Z$.*

A version of this theorem figures prominently in Aschbacher's analysis of the maximal subgroups of the finite classical matrix groups.

The importance of finite groups G for which $F^*(G) = E$ is an extraspecial p-group (or a close relative thereof) affords an excuse for an illustration of the use of the Fitting–Bender theorem and of linear group methods in the study of abstract finite groups. First, let E be an extraspecial p-group and let $V = E/Z(E)$. Then V may be regarded as a finite-dimensional vector space over the finite field $\mathbf{F}_p$. Moreover, we may identify $Z(E)$ with the field $\mathbf{F}_p$. Then the function $b : V \times V \to \mathbf{F}_p$, defined by

$$b(u + Z(E), v + Z(E)) = [u, v] \qquad \text{for all } u, v \in E,$$

is a nondegenerate alternating form on the vector space V. Moreover, if p is odd, then there is a surjective homomorphism $\Phi : \mathrm{Aut}(E) \to \mathrm{CSp}(V)$, the conformal symplectic group of all similarities of the symplectic space (V, b). The kernel of Φ is the group of all inner automorphisms of E, i.e., the automorphisms induced by the conjugation action of E onto itself. This group, $\mathrm{Inn}(E)$ may be identified with $V = E/Z(E)$ and then we see that $\mathrm{Aut}(E) \cong V : \mathrm{CSp}(V)$. When $p = 2$, the squaring map $Q : V \to \mathbf{F}_2$, defined by

$$Q(u + Z(E)) = u^2 \qquad \text{for all } u \in E,$$

is a quadratic form on V whose associated bilinear form is b. Now there is a surjective homomorphism $\Phi : \mathrm{Aut}(E) \to O(V, Q)$ whose kernel is again $\mathrm{Inn}(E) \cong V$. Thus $\mathrm{Aut}(E)/\mathrm{Inn}(E) \cong O(V, Q)$. In this case, however, Griess proved that the group $\mathrm{Aut}(E)$ is not in general a semidirect product. In any case, we get the following theorem.

Theorem: *Let G be a finite group such that $F^*(G) = E$ is an extraspecial p-group. Set $V = E/Z(E)$. Then G/E is isomorphic to a subgroup of* $\mathrm{CSp}(V)$. *If $p = 2$, then in fact G/E is isomorphic to a subgroup of $O(V, Q)$, where Q is the quadratic squaring map. Moreover, G/E has no nontrivial normal p-subgroup.*

Thus the structure of G/E for such groups G may be analyzed by the methods of linear representation theory. In fact, a similar line of reasoning may be applied to any finite group G such that $F^*(G)$ is a p-group for some prime p. One of the earliest and deepest results in this vein is the Hall–Higman theorem, which illustrates the relevance of the final assertion of the preceding theorem.

Hall–Higman Theorem B: *Let V be a finite-dimensional vector space over a field of characteristic p, p an odd prime. Let G be a solvable subgroup of* $\mathrm{GL}(V)$ *having no nontrivial normal p-subgroup. Let x be an element of G of order p^n. Then the minimum polynomial $m_x(t)$ of x is $(t-1)^{p^n}$, except possibly if p is a Fermat prime and G contains a nonabelian normal 2-subgroup.*

Note that p^n is the largest possible size of a Jordan block for a linear transformation of order p^n acting on a vector space in characteristic p.

The general theory of p-modular representations of finite groups was developed primarily by Richard Brauer. The sharpest results are achieved when every p-subgroup of G is cyclic, for example, when $|G|$ is divisible by p but not by p^2. A related theme of great importance is the p-modular representation theory of a finite group of Lie type $G(q)$ defined over a field $\mathbf{F}_q$ of characteristic p. The methodology here is completely different from Brauer's theory and instead is analogous to the theory of (rational) representations of semisimple Lie groups or algebraic groups. Indeed, Steinberg proved that all irreducible representations of $G(q)$ come by restriction from the irreducible rational representations over $\bar{\mathbf{F}}_q$ of the algebraic group $G(\bar{\mathbf{F}}_q)$, where $\bar{\mathbf{F}}_q$ is the algebraic closure of $\mathbf{F}_q$ and $G(q)$ arises from $G(\bar{\mathbf{F}}_q)$ by taking fixed points of a Frobenius–Steinberg endomorphism. The group $G(\bar{\mathbf{F}}_q)$ is the characteristic p analog of the Lie group $G(\mathbf{C})$. Now, the irreducible continuous representations of $G(\mathbf{C})$ are parametrized by "highest weights" and the characters of these representations are given by the Weyl character formula. Curtis and Richen showed that an analogous parametrization holds for the finite groups of Lie type. An

analog of the Weyl character formula has been conjectured by Lusztig and proved generically, but not yet for all primes p.

For applications to topology and number theory, there have been efforts to study integral representations of a finite group G, i.e., homomorphisms of G into $\mathrm{GL}(n, R)$, where R is the ring of integers of some algebraic number field, e.g., $R = Z$. The situation here is quite subtle, and only small cases can be handled effectively.

VI. FINITE SIMPLE GROUPS

Around 1890, Wilhelm Killing published a series of papers classifying the finite-dimensional semisimple Lie algebras over **C**, modulo a significant error corrected by E. Cartan. In particular, via Lie's correspondence, this gave a classification of the finite-dimensional simple Lie groups over **C**, and this classification was shortly extended to the real field as well by Cartan. In addition to the Lie algebras associated with the classical linear groups over **C**, Killing discovered five exceptional simple Lie algebras over **C**, which he denoted E_2, F_4, E_6, E_7, and E_8, the subscript denoting the maximum dimension of a diagonalizable subalgebra, later known as a Cartan subalgebra. Later E_2 came to be known as G_2. In Killing's notation the classical families of Lie groups over **C** are: $A_n(\mathbf{C}) = \mathrm{PSL}(n+1, \mathbf{C})$, $B_n(\mathbf{C}) = \mathrm{PSO}(2n+1, \mathbf{C})$, $C_n(\mathbf{C}) = \mathrm{PSp}(2n, \mathbf{C})$, and $D_n(\mathbf{C}) = \mathrm{PSO}(2n, \mathbf{C})$.

The classification theorem of Killing and Cartan, which is a fundamental precursor of the classification of the finite simple groups, is the following result.

Theorem: *Let G be a finite-dimensional simple Lie group with trivial center. Then G is either* (*an adjoint version of*) *a member of one of the four infinite families of classical Lie groups $A_n(\mathbf{C})$, $B_n(\mathbf{C})$, $C_n(\mathbf{C})$, and $D_n(\mathbf{C})$; or G is isomorphic to the adjoint version of one of the five exceptional Lie groups $E_6(\mathbf{C})$, $E_7(\mathbf{C})$, $E_8(\mathbf{C})$, $F_4(\mathbf{C})$, or $G_2(\mathbf{C})$.*

In 1955 Chevalley published a paper constructing analogs of Killing's groups over all fields. In particular, when the fields are finite, these Chevalley groups are finite simple groups, except in a few cases over fields of cardinality 2 or 3. Shortly thereafter, Steinberg did the analog of Cartan's passage to real forms of Lie groups and constructed the so-called twisted Chevalley groups or Steinberg groups ${}^2A_n(q) = \mathrm{PSU}(n+1, q)$, ${}^2D_n(q)$, ${}^3D_4(q)$, and ${}^2E_6(q)$. If V is an even-dimensional vector space over a finite field $\mathbf{F}_q$, then there are exactly two nonisomorphic orthogonal groups on V: $O^+(V)$ and $O^-(V)$, where $O^+(V)$ is the isometry group of an orthogonal space of maximal Witt index (i.e., an orthogonal sum of hyperbolic planes). Then, for $n \geq 3$, $D_n(q)$, and ${}^2D_n(q)$ are the unique nonabelian simple composition factors of the groups $O^+(V)$, resp. $O^-(V)$, where V is an n-dimensional $\mathbf{F}_q$-space. The groups ${}^3D_4(q)$ and ${}^2E_6(q)$ were new families of nonabelian finite simple groups. ${}^2E_6$ had arisen already as a real form of E_6 in Cartan's classification, but the ${}^3D_4$ groups were truly new, arising as the fixed points on $D_4(F)$ of $\rho \circ \sigma$, where ρ is the special triality automorphism of the D_4 oriflamme geometry and σ is a field automorphism of F of order 3. [Note: only involutory automorphisms arise in the classification of real forms of Lie groups, since $(\mathbf{C} : \mathbf{R}) = 2$.]

As 1960 dawned, the known nonabelian finite simple groups were the alternating groups of degree at least 5, the Chevalley and Steinberg groups (including the classical linear groups), and the five Mathieu groups, which had been dubbed sporadic groups by Burnside around 1900. Each of these groups has even order, and indeed it had been conjectured as early as 1900 by Miller and Burnside that groups of odd order were necessarily solvable groups. Even more, each of these groups has order divisible by 6. In fact, they all have subgroups isomorphic to either $\mathrm{SL}(2, 3)$ or $\mathrm{PSL}(2, 3) \cong A_4$, with the exception of the 2-transitive simple permutation groups $\mathrm{PSL}(2, 2^n)$ for n odd, $n \geq 3$.

In 1960 Michio Suzuki discovered the first known nonabelian simple groups of order not divisible by 3, the infinite family of 2-transitive simple permutation groups $Sz(2^n)$, n odd, $n \geq 3$. Shortly thereafter, Ree showed that a modification of Steinberg's twist could be apply to the Chevalley groups B_2 and F_4 over fields of order 2^n, n odd, and to G_2 over fields of order 3^n, n odd, to produce the families of simple groups ${}^2B_2(2^n)$, ${}^2F_4(2^n)$, and ${}^2G_2(3^n)$, n odd. In particular, the groups ${}^2B_2(2^n)$ were precisely the Suzuki groups $\mathrm{Sz}(2^n)$. The other two families were new and were dubbed Ree groups. The finite Chevalley, Steinberg, Suzuki, and Ree groups are now often called the finite groups of Lie type, inasmuch as they can be uniformly constructed as the fixed points of Frobenius–Steinberg endomorphisms of simple algebraic groups over algebraically closed fields of prime characteristic, and these groups are analogous to the simple Lie groups over **C** classified by Killing and Cartan.

Meanwhile, in 1960–1962, Walter Feit and John G. Thompson wrote the most remarkable paper in the history of finite group theory, proving the Miller-Burnside conjecture.

The Odd-Order Theorem (Feit–Thompson): *Every finite group of odd order is solvable.*

This paper and the successor "N-Group Paper" of Thompson provided most of the fundamental ideas for the classification of the finite simple groups. The first tool in the analysis of finite simple groups was provided in 1872 by Ludvig Sylow.

Sylow's Theorem: *If G is a finite group with $|G| = p^n m$ for some prime p, with m not divisible by p, then G has subgroups of order p^k for all $k, 0 \le k \le n$, and all subgroups of G of order p^n are G-conjugate.*

The maximal p-subgroups of G are called Sylow p-subgroups of G. It is interesting to note that there are somewhat analogous results in the category of linear algebraic groups, namely, the conjugacy of Borel subgroups (maximal closed connected solvable subgroups) and of maximal tori (maximal connected semisimple abelian subgroups) of the linear algebraic group G. Note that a Borel subgroup $B = N_G(U) = UT$, where U is a maximal unipotent subgroup and T is a maximal torus. If G is defined over an algebraically closed field of characteristic p, then U is a maximal p-subgroup of G, in the sense that U is maximal with the property that every element of U has order a power of p.

Returning to finite group theory, the set of all normalizers and centralizers of nonidentity p-subgroups of the finite group G is called the set of p-local subgroups of G, and the study of G via the analysis of these subgroups is called p-local analysis. The "N-Group Paper" combined with the "Odd Order Paper" completed the classification of finite simple groups all of whose p-local subgroups are solvable groups. The strategy in brief is to choose a prime p and a Sylow p-subgroup P for which the p-rank (the dimension of an elementary abelian p-subgroup, thought of as a vector space over $\mathbf{F}_p$) is as large as possible. A theorem of Burnside, using monomial representations, guarantees that p may be chosen so that either the p-rank is at least 3 or $p = 2$ and $|G|$ is a multiple of 12. One now studies the normalizers of all nonidentity subgroups of P. If G is going to turn out to be a finite group of Lie type defined over a field of characteristic r, then almost always the chosen p will turn out to be r and the geometry defined by the coset spaces $G\backslash M_i$, where M_i is a p-local subgroup of G containing P, will be precisely the Tits building for the group G. If there are at least two maximal p-local subgroups M_i containing P, then the Tits building will have rank at least 2 and the geometry will be rich enough to characterize the group G. More accurately, finite buildings of rank at least 3 were classified in a major paper of Tits. Finite rank 2 buildings include all finite projective planes. However, the buildings of rank at least 2 which occur in the context of the simple group classification satisfy a "Moufang condition," which permits their complete identification. On the other hand, if there is a unique maximal p-local subgroup M of G containing P, then the "geometry" is simply the point set $G\backslash M$. This leads to a problem in permutation group theory.

Problem: *Classify finite transitive permutation groups G in which, for some fixed prime p, every nonidentity p-element fixes exactly one point.*

For $p = 2$, this problem was solved by a combination of independent results of Suzuki and Bender.

Theorem: *Let G be a finite transitive permutation group in which every involution (element of order 2) fixes exactly one point. Then either G has 2-rank at most 1 or $G \cong SL(2, 2^n)$, $\mathrm{Sz}(2^{2n-1})$, or $\mathrm{PSU}(3, 2^n)$ for some $n \ge 2$.*

For groups of odd order, the problem was solved by Feit and Thompson in the "Odd Order Paper." The theory of group characters plays a major and seemingly unavoidable role in this delicate analysis. The complete problem has been solved as a corollary of the classification of finite simple groups, but an independent solution for p odd remains elusive.

A somewhat different strategy for the classification of finite simple groups was pioneered by Richard Brauer starting around 1950. For groups of even order, Brauer championed an inductive approach focusing on the centralizer $C_G(t)$ of an involution t. A philosophical underpinning for this approach was provided by the following result.

Brauer–Fowler Theorem: *Let G be a finite simple group of even order containing the involution t. If $|C_G(t)| = c$, then $|G| < (c^2)!$.*

The Brauer–Fowler bound is useless in practice, but it does establish that given a finite group H with center of even order, the problem of finding all finite simple groups G containing an involution t with $C_G(t) \cong H$ is a finite problem. In practice, as Brauer, Janko, and their students demonstrated in the ensuing decades, the problem is not only finite, it is doable. Indeed, a posteriori, $C_G(t)$ usually determines G uniquely. Once Feit and Thompson proved that every nonabelian finite simple group has even order, Brauer's strategy became an inductive strategy for the remainder of the classification proof. Brauer's strategy is significantly different from the Feit–Thompson strategy in the following sense: since most primes are odd, a finite simple group of Lie type is almost always defined over a field of characteristic τ with $\tau \ne 2$. Thus, for most finite simple groups G, each involution t is a semisimple element in the sense that $F^*(C_G(t))$ is an almost semisimple group. Fortunately, the two approaches mesh and complement each other, and the current proof is a blending of both.

In the course of pursuing Brauer's strategy, Janko investigated many possible specific structures for the centralizer of an involution in a simple group. One of these structures, $C_2 \times A_5$, led him to a new simple group, J_1, the first sporadic group discovered since Mathieu. Shortly thereafter, Janko discovered two more sporadic groups, J_2 and J_3. The former was soon constructed as a rank-3 permutation group by M. Hall. The involution centralizer approach and the rank-3 permutation group approach were the main tactics leading to the discovery of 21 sporadic groups in the decade 1965–1975.

In a different vein, John Leech constructed in 1967 the Leech lattice, the densest sphere-packing lattice in $\mathbf{R}^{24}$, based on the Steiner system $S(5.8.24)$ for M_{24}. John Conway investigated the automorphism group .0 of the Leech lattice and discovered that $.0/\{\pm 1\} = \mathrm{Co}_1$ was a new finite simple group, as were two of its subgroups, Co_2 and Co_3. In 1974, pursuing the involution centralizer philosophy, starting with a centralizer C built out of the Leech lattice modulo 2, $\Lambda/2\Lambda$, and Co_1, Bernd Fischer and Robert L. Griess, Jr., independently discovered the largest of the sporadic simple groups, dubbed **M**, the Monster. The Monster was constructed by Griess as the automorphism group of a 196, 884-dimensional nonassociative commutative **C**-algebra, the Griess algebra. Twenty-one of the 26 sporadic simple groups are contained (as quotients of subgroups) in the Monster. The investigation of numerical mysteries (dubbed Monstrous Moonshine) associated with **M** led Frenkel, Lepowsky, Meurman, and Borcherds to develop the mathematical theory of vertex operator algebras, objects which were first studied by physicists.

The classification theorem for finite simple groups is the following theorem.

Classification Theorem: *Let G be a finite simple group. Then G is isomorphic to a member of one of the following families of simple groups*:

1. *The cyclic groups of prime order*;
2. *The alternating groups of degree at least* 5;
3. *The finite simple groups of Lie type*; *and*
4. *The* 26 *sporadic simple groups.*

There are a small number of unusual isomorphisms among the simple groups. For example, $A_5 \cong \mathrm{SL}(2, 4) \cong \mathrm{PSL}(2, 5)$, $A_6 \cong \mathrm{PSL}(2, 9) \cong [\mathrm{Sp}(4, 2), \mathrm{Sp}(4, 2)]$, and $A_8 \cong \mathrm{SL}(4, 2)$.

The proof is a massive inductive argument, i.e., one assumes througout that G is a minimal counterexample to the statement of the theorem, and so every composition factor of every proper subgroup of G (in particular, of every p-local subgroup of G) is one of the listed simple groups. Having chosen a prime p upon which to perform p-local analysis according to either the Feit–Thompson or Brauer strategy, one is confronted by the major problem of attempting to establish that for many of the maximal p-local subgroups H of G, either $F^*(H)$ is an almost semisimple group or $F^*(H)$ is a p-group. In the latter case we say that H is of parabolic type, since in a finite simple group G of Lie type in characteristic p, all subgroups which contain a Sylow p-normalizer (the so-called parabolic subgroups of G) are of parabolic type. Aschbacher and Timmesfeld were leaders in the analysis of such groups in the 1970s. Later, Stroth, Stellmacher, and Meierfrankenfeld also pursued this vein.

The principal obstruction to establish this structure theorem for maximal p-locals is the hypothetical existence of certain p'-subgroups (subgroups of order relatively prime to p) whose normalizers contain large p-subgroups. These were dubbed p-signalizers by Thompson, who developed the principal strategies for controlling them. These strategies were honed into a "signalizer functor theory" by Gorenstein and Walter with major contributions by Goldschmidt, Glauberman, Harada, Lyons, McBride, and others.

VII. OTHER TOPICS

Thus far the article has focused on finite groups, with some reference to Lie groups and linear algebraic groups. Certain other classes of groups have played a fundamental role in mathematics. Klein and Poincaré pioneered the study of discrete subgroups of PSL(2, **R**) and PSL(2, **C**). For instance, PSL(2, **R**) acts naturally as fractional linear transformations on the upper half-plane of $\mathbf{R}^2$, which may be identified with the hyperbolic plane with PSL(2, **R**) acting as orientation-preserving isometries. A discrete subgroup is then a subgroup Γ which does not contain arbitrarily small translations or rotations. A similar interpretation may be given to discrete subgroups of PSL(2, **C**) viewed as isometries of hyperbolic 3-space. An important class of examples of these discrete subgroups is given by PSL(2, **Z**) and its congruence subgroups, i.e., the kernels of the natural homomorphisms of PSL(2, **Z**) onto PSL(2, $\mathbf{Z}/\mathbf{n}\mathbf{Z}$), where $\mathbf{Z}/\mathbf{n}\mathbf{Z}$ is the ring of integers modulo n. These discrete groups may be regarded as the symmetry groups of tessellations (tilings) of hyperbolic space by congruent (hyperbolic) polygons. This theory has been generalized to the study of arithmetic subgroups of higher-dimensional Lie groups. Like the integers, these groups do not have a composition series and so they cannot be "built up from the bottom" like finite groups: they have no bottom from which to build. They are, however, usually generated by a finite set of elements or proper subgroups and may be viewed as a quotient of the universal or freest object so generated.

Thus, if G is generated by the set of elements S, then G is a quotient of the free group $F(S)$. A relator is a word which becomes 1 when interpreted in G rather than in $F(S)$. In general, if R is a set of relators, then there is a natural homomorphism from $F(S)/N(R)$ onto G, where $N(R)$ is the smallest normal subgroup of $F(S)$ containing all of the members of R. If that homomorphism is an isomorphism, then the generators S and relations R "present" the group G. In general, it is quite difficult to "understand" a group given by generators and relations. In fact, it is a theorem (the "Undecidability of the Word Problem") that there is no

recursive algorithm for deciding whether a given finitely presented group is the identity group.

A striking exception to the intractability of the "Word Problem" is the family of Coxeter groups $C(m_{ij})$ defined by the generators $\{s_i\}_{i\in I}$ and relators $(s_i s_j)^{m_{ij}}$, where $M=(m_{ij})$ is a symmetric matrix with $m_{ii}=1$ for all i and with $m_{ij}\in\{2,3,\ldots,\omega\}$ for $i\neq j$. Classical examples of Coxeter groups are discrete groups of isometries of spherical, Euclidean, or hyperbolic n-spaces. The spherical Coxeter groups are well understood and form the skeletons of Tits' spherical *BN* pairs. Beyond the finite dihedral groups, all but two of the spherical Coxeter groups are finite Weyl groups, whose classification is a key step in the modern proof of the Killing-Cartan classification theorem. The Euclidean Coxeter groups are also well understood and play a major role in the theory of affine buildings and p-adic groups. Closely associated to Coxeter groups are the braid groups and Artin groups, whose generators have infinite order but which satisfy relations similar to the Coxeter relations. They have featured in recent work in numerous areas, including knot theory, singularity theory, and inverse Galois theory, i.e., the problem of finding a polynomial (usually in $\boldsymbol{Q}[x]$) having a specified Galois group.

The braid groups arise as the fundamental groups of topological spaces, an important concept introduced by Poincaré. The elements of the fundamental group are equivalence classes of loops (closed paths) in the space with a distinguished base point. Multiplication is concatenation of loops and inversion is reversal of direction. Fundamental groups are naturally described via generators and relations, with the generators being certain loops and a relation being a closed path which can be contracted to the base point in the space. For example, if the space X is the union of n circles which intersect only at a common base point, then the fundamental group of X is the free group on n generators. The fundamental group acts naturally on the universal cover $\tilde{X}$ of the space X. In this example, $\tilde{X}$ is a regular tree (graph without circuits) of valency $2n$.

The study of fundamental groups of topological spaces attached along embedded subspaces motivates the group-theoretic study of so-called free products with amalgamation, HNN extensions, and group actions on trees, all of which is subsumed in the Bass–Serre theory of graphs of groups. The objective is understand the universal completion of a graph of groups, i.e., the largest possible group containing certain specified subgroups (attached to the vertices and edges of the graph) subject to certain relating homomorphisms mapping edge groups to vertex groups. The amalgamated product of two groups over a specified common subgroup is a "free" construction, which in all nontrivial cases leads to an infinite completion.

The free product $H*K$ of two groups H and K is the freest group generated by H and K with $H\cap K=\{e\}$. Underlying the Brauer–Fowler theorem on finite simple groups is the elementary fact that the free product C_2*C_2 is an infinite dihedral group generated by an element x of infinite order and an involution y such that $yxy=x^{-1}$. All finite homomorphic images of C_2*C_2 are finite dihedral groups (the symmetry groups of regular polygons) or are cyclic of order 1 or 2. By contrast, the free product C_2*C_3 is isomorphic to PSL(2, **Z**) and almost every finite simple group occurs as a homomorphic image of C_2*C_3. PSL(2, **Z**) is in turn the quotient of the 3-string braid group B_3 by an infinite cyclic central subgroup.

It follows from the theory of fundamental groups and covering spaces that the study of discrete subgroups (at least the torsion-free ones, i.e., those having no nontrivial elements of finite order) of PSL(2, **R**) and PSL(2, **C**) is essentially identical to the problem of finding Riemannian metrics of constant (sectional) curvature -1 on manifolds of dimensions 2 and 3, respectively. This suggests that one should be especially interested in studying fundamental groups of negatively curved Riemannian manifolds (or negatively curved spaces). Quite recently, Gromov has developed a theory of "word hyperbolic groups" which encompasses the group-theoretic aspects of negative curvature. For example, free groups as well as the fundamental groups of negatively curved manifolds are all word hyperbolic. In contrast to the general undecidability of the Word Problem, it can be shown that the Word Problem is solvable for word hyperbolic groups. Indeed, this has led to a study of the larger class of "automatic groups" for which the Word Problem is decidable by a finite-state automation.

Recently there have been projects to develop efficient computer algorithms for the identification of finite groups from data consisting either of a set of generating permutations or a set of generating matrices or an abstract set of generators and relators (a black-box group). Most of these algorithms use the classification of finite simple groups as well as numerous corollaries concerning simple groups with small linear or permutation representations. Computer algorithms played a relatively small role in the classification of finite simple groups. The existence of most of the sporadic simple groups can be established as a corollary of the existence of the Monster, which Griess constructed "by hand." Several of the sporadic groups were first constructed on a machine, however, and for a few this remains the only proof of their existence.

GLOSSARY

Brillouin zone Volume in k space (reciprocal lattice space) bounded by planes of energy discontinuities.
Character Trace of a matrix in a representation.
Color Physical property of the strong interactions [SU(3)] analogous to electric charge in electrodynamics.
Critical point The highest pressure and the highest temperature at which a liquid and gas can coexist in equilibrium. This is the point at which the difference between the density of the liquid phase and that of the gaseous phase becomes zero.
Group Finite or infinite set of elements which have certain properties defining a group.
Isospin Symmetry [SU(2)] which elementary particles obey if the electromagnetic interaction is neglected; this accounts for the charge multiplets which are observed in particle physics.
Lie algebra Certain commutation relations obeyed by the generators of a continuous Lie group.
Normal modes Fundamental vibrations into which any vibrational mode of molecule can be decomposed.
Particle physics Study of the fundamental constituents of matter and their interactions.
Quark model Model in which all hadrons (strongly interacting particles) are described in terms of fundamental particles called quarks.
Representation Set of matrices which represents the elements of a group.
SU(2), SU(3) Lie groups whose elements are unitary matrices in two and three dimensions with determinant $+1$.

APPLIED GROUP THEORY is the study of the theory of group representations and its applications in various areas of physics such as atomic physics, molecular physics, solid-state physics, and particle physics. Group theory is essentially a mathematical description of symmetry in nature, and it is very interesting that this symmetry plays an important role in understanding many experimental phenomena in physics.

I. BRIEF HISTORY

Ancient as well as modern works of art and architecture tell us that humans have long familiarity with symmetry. An Egyptian pyramid, a Greek temple, an Indian Taj Mahal, and a Chinese pagoda strike us as beautiful examples of symmetry. There is symmetry in works of nature as well, in living organisms, and in people. It is interesting to note, however, that while knowledge of symmetry existed for centuries, it was only toward the end of the eighteenth century that it was realized that symmetry has a scientific basis in the mathematical theory of groups. Since the mathematical structure and analysis of groups is the subject matter of another article in this *Encyclopedia*, we will discuss here only the applications of group theory in physics and engineering.

In a series of papers published toward the end of the nineteenth century and at the beginning of the twentieth century Frobenius and Schur laid the foundation of the theory of group representations for finite groups. The structure and representation of continuous groups is the work of Lie, Cartan, and Weyl. Wigner was probably the first to recognize the importance of Frobenius's work to quantum mechanics and modern physics. He applied representation theory to physical problems in many areas of physics. Subsequently several others played important roles in developing and applying group theory as a tool—Bargmann, Bethe, Casimir, Gell-Mann, Pauli, to name a few.

II. GROUP REPRESENTATION THEORY

It is necessary to discuss briefly some important theorems in representation theory, since all the applications in the physical sciences are based on these theorems. First, a Cayley multiplication table (Table I) defines a group abstractly. In the table the operation of "multiplication" is to be understood as, for instance, the correspondences $AB = D$ and $BA = F$. A word of caution is in order here. There is usually a notational difference between mathematicians and physicists. Here the operation AB is to be performed from right to left (i.e., the operation A to be made after the operation B, akin to the left multiplication of a matrix B by a matrix A). A function of an independent variable x is written $F(x)$. These notations are consistent with the customary usage in group theory books by physicists (e.g., Wigner, 1959). The set of six elements form a finite group or order $g = 6$ (G or S_3 or C_{3v}), and from the table one can see that it is closed with respect to multiplication. There exists an identity element (E) and every element has an inverse element such that the product of the element and its inverse (or vice versa) is the identity. If the multiplication is commutative (i.e., $AB = BA$) the group is known as an abelian group.

TABLE I Cayley Multiplication Table of C_{3v} or S_3

	E	A	B	C	D	F
E	E	A	B	C	D	F
A	A	E	D	F	B	C
B	B	F	E	D	C	A
C	C	D	F	E	A	B
D	D	C	A	B	F	E
F	F	B	C	A	E	D

This abstract group multiplication table can be "realized" in more than one way by different types of elements with a multiplication rule appropriately defined. For instance, the following numbers satisfy all the group properties under ordinary multiplications:

$$E = 1 = D = F, \qquad A = B = C = -1. \tag{1}$$

This, for instance, is an abelian group. Another realization of the group table is obtained by elements which are operations of permutations of three objects and this group is known as the symmetric group S_3. Explicitly, the elements are

$$E \begin{bmatrix} 1 & 2 & 3 \\ 1 & 2 & 3 \end{bmatrix}, \quad A \begin{bmatrix} 1 & 2 & 3 \\ 1 & 3 & 2 \end{bmatrix}, \quad B \begin{bmatrix} 1 & 2 & 3 \\ 3 & 2 & 1 \end{bmatrix},$$
$$C \begin{bmatrix} 1 & 2 & 3 \\ 2 & 1 & 3 \end{bmatrix}, \quad D \begin{bmatrix} 1 & 2 & 3 \\ 2 & 3 & 1 \end{bmatrix}, \quad F \begin{bmatrix} 1 & 2 & 3 \\ 3 & 1 & 2 \end{bmatrix}. \tag{2}$$

The permutation D is defined to read "1 is replaced by 2, 2 by 3, and 3 by 1." AB is defined as the result of the permutation corresponding to A performed after the operation B. Yet another way of realizing this group, which is of importance in molecular physics, is by choosing for the elements certain geometric symmetry operations. This group is known as C_{3v}. These symmetry operations are

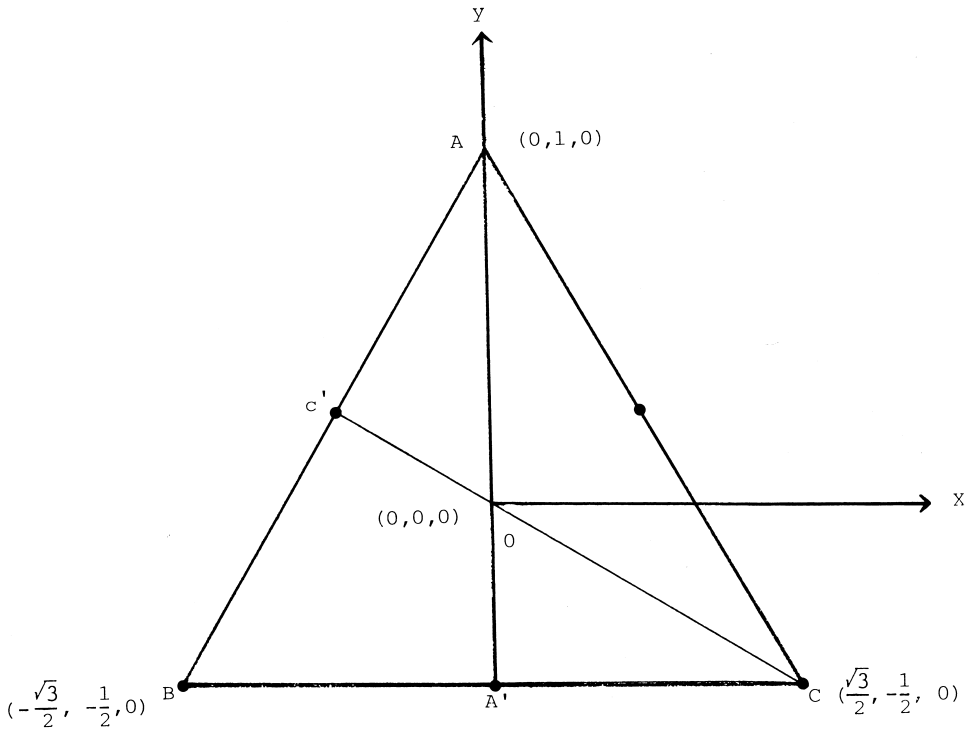

FIGURE 1 Equilateral triangle (C_{3v}) with coordinates of vertices. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979). "Group Theory Made Easy for Scientists and Engineers," Wiley-Interscience, New York. Copyright 1979 John Wiley and Sons.]

easily understood by applying them to the equilateral triangle in Fig. 1. In this A, B, C are the vertices, A', B', C' are the midpoints of the opposite sides such that AA', BB', CC' are the medians of the triangle. Let us assume the triangle to be in the XY plane of a rectangular coordinate system whose origin is at the centroid of the triangle O. Here the identity element means "leave it alone." Elements D,F correspond to rotations through 120° and 240°, respectively, about the Z axis through O perpendicular to the plane of the triangle. These are called C_3, C_3^2 operations, the subscript 3 referring to the angle of rotation $2\pi/3$ and the letter C stands for the cyclic axis. A, B, C are operations of reflections in three vertical mirror planes passing through AA', BB', CC' and containing the cyclic axis. Although we labeled the vertices to be able to understand the geometric symmetry operations of rotations and reflections, it is important to note that the operations bring the triangle into coincidence with itself, which implies that all the vertices are identical and hence indistinguishable. The ammonia molecule NH_3 has the symmetry of the C_{3v} group. The three hydrogen atoms are at the vertices of the triangle and the nitrogen atom sits somewhere on the cyclic axis and thus all the six geometric operations bring the molecule into coincidence with itself. The groups S_3 and C_{3v} are said to be isomorphic, which means that the elements E, A, B, ... of S_3 are in one-to-one correspondence with elements E, σ_v, σ_v', ... of C_{3v} uniquely such that group multiplication is preserved. $AB = D$ in the case of the group S_3 means that the product of the elements corresponding to A and B in C_{3v}, in that order, results in the element corresponding to D. Here multiplication means the group operation. Isomorphic groups have the same Cayley multiplication table. A many-to-one correspondence is known as homomorphism. In this case more than one element of one group corresponds to the same element in the other group, but products do correspond to products in either group. Thus the group of numbers in (1) is homomorphic to S_3 or C_{3v}.

We notice from the Cayley table for S_3 that subsets of elements (E), (E, A), and (E, D, F) themselves satisfy all the group properties. These are known as subgroups of the main group, of orders $h = 1$, 2, and 3, respectively. There is a theorem of Lagrange which says that the order h of a subgroup is a divisor of the order g of the group. Thus a group or order 11 can have only one subgroup, of order 1, the trivial group with only the identity element. Given an element A, one defines its conjugate of BAB^{-1}, where B is any element of the group. For instance, in Table I, $DAD^{-1} = DAF = DC = B$. Thus B is a conjugate of A, the operation of conjugation

resembling a similarity transformation in matrix theory. A set of self-conjugate elements is called a class, and a group is divided into classes. Thus, A, B, C form a class because the conjugate of A, XAX^{-1}, is again one of the elements of this set no matter which element of the group X is. For any finite group the identity element forms a class all by itself. A subgroup which has whole classes of the original group as its elements is known as an invariant subgroup. Thus for the above group the subgroup E, D, F is an invariant subgroup consisting of the classes $K_1(E)$ and $K_2(D,\ F)$. If a group does not have an invariant subgroup it is called a simple group. An isomorphism of a group with itself (i.e., a one-to-one correspondence between elements of the group preserving multiplication) is called an automorphism. If this is brought about by conjugation it is called an inner automorphism. For instance, the set E, A, B, C, D, F is an inner automorphism induced by the identity as the conjugating element. This is mapped into E, B, A, C, F, D if the conjugation is done by C. This then is an inner automorphism induced by C.

A. Representations and Characters

If a Cayley multiplication table is realized by choosing the elements as (unitary) matrices this set is known as a representation of the group. Frobenius and Schur did pioneering work in demonstrating quite a few important theorems in representation theory. For instance, the following set of 3×3 matrices is a representation Γ of S_3 or C_{3v}, of dimension 3:

$$\begin{matrix} E \\ \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \end{matrix}, \quad \begin{matrix} A \\ \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix} \end{matrix}, \quad \begin{matrix} B \\ \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{bmatrix} \end{matrix},$$
$$\begin{matrix} C \\ \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \end{matrix}, \quad \begin{matrix} D \\ \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \end{matrix}, \quad \begin{matrix} F \\ \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix} \end{matrix}. \tag{3}$$

Here obviously "multiplication" means matrix multiplication. It is easy to see, however, that another set of matrices, obtained from the one given through a similarity transformation, is also a representation of the group. Two sets of matrices which differ only through a similarity transformation are said to be equivalent representations of the group. Furthermore, this Γ is known as a reducible representation because the following one matrix S generates an equivalent representation through a similarity transformation:

$$\mathbf{S} = \begin{bmatrix} 1/\sqrt{3} & 1/\sqrt{3} & 1/\sqrt{3} \\ 0 & -1/\sqrt{2} & 1/\sqrt{2} \\ 2/\sqrt{3} & -1/\sqrt{6} & -1/\sqrt{6} \end{bmatrix},$$

$$S\mathcal{D}(A)S^{-1} \equiv A' = \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

$$= (1) \oplus \begin{matrix} B' \\ \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix} \end{matrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1/2 & \sqrt{3}/2 \\ 0 & \sqrt{3}/2 & -1/2 \end{bmatrix}$$

$$\times \begin{matrix} C' \\ \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1/2 & -\sqrt{3}/2 \\ 0 & -\sqrt{3}/2 & -1/2 \end{bmatrix} \end{matrix} \begin{matrix} D' \\ \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1/2 & -\sqrt{3}/2 \\ 0 & \sqrt{3}/2 & -1/2 \end{bmatrix} \end{matrix}$$

$$\times \begin{matrix} F' \\ \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1/2 & \sqrt{3}/2 \\ 0 & -\sqrt{3}/2 & -1/2 \end{bmatrix} \end{matrix}. \tag{4}$$

(Boldface letters represent operators; letters with arrows represent vectors.) This latter set is seen to be a direct sum of two matrices of dimensions 1 and 2. It can be shown that the two-dimensional representation cannot further be reduced and is therefore called an irreducible representation. It is the irreducible representation of a group that is of paramount importance in physics. The sums of the diagonal elements of the matrices in an irreducible representation, or the traces of the matrices, are called characters χ. The relevant irreducible representation and characters of S_3 are rewritten as

$$\begin{matrix} E \\ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \chi = 2 \end{matrix}, \quad \begin{matrix} A \\ \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix} \\ \chi = 0 \end{matrix}, \quad \begin{matrix} B \\ \begin{bmatrix} 1/2 & \sqrt{3}/2 \\ \sqrt{3}/2 & -1/2 \end{bmatrix} \\ \chi = 0 \end{matrix},$$
$$\begin{matrix} C \\ \begin{bmatrix} 1/2 & -\sqrt{3}/2 \\ -\sqrt{3}/2 & -1/2 \end{bmatrix} \\ \chi = 0 \end{matrix}, \quad \begin{matrix} D \\ \begin{bmatrix} -1/2 & -\sqrt{3}/2 \\ \sqrt{3}/2 & -1/2 \end{bmatrix} \\ \chi = -1 \end{matrix}, \tag{5}$$
$$\begin{matrix} F \\ \begin{bmatrix} -1/2 & \sqrt{3}/2 \\ -\sqrt{3}/2 & -1/2 \end{bmatrix} \\ \chi = -1 \end{matrix}$$

It is interesting to note that the representation can be a homomorphism and need not necessarily be an isomorphism. An important lemma, called Schur's lemma, says that no matrix other than a multiple of the identity matrix commutes with all the matrices in an irreducible representation. This therefore gives a red-litmus-blue type of test for checking whether a given representation is reducible or irreducible. One of the interesting representations is known as the regular representation. From the multiplication table for the S_3 group of order 6 (Table I) we know, for instance, that $DA = C$. If we consider this result as a linear combination of all the elements we get

$$DA = OE + OA + OB + 1C + OD + OF.$$

If we express the other operations in the Cayley table (i.e., DB, DC, DD, DF, and DE) we can write the result in matrix form. The transpose of this matrix is the representation matrix of the element D in the regular representation

$$\mathcal{D}(D) = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix}. \tag{6}$$

The matrices representing other elements of S_3 are obtained similarly. This is, however, a reducible representation. One matrix, by a similarity transformation, can reduce all the six matrices into block-diagonal form as a direct sum of lower-dimensional matrices. It can be shown that in the reduction every irreducible representation occurs as many times as its dimensionality. This regular representation decomposes into two one-dimensional and two two-dimensional representation matrices, because the S_3 group happens to have two one-dimensional and one two-dimensional representation.

We take the symmetric group S_4 (permutations on four objects) as an example to illustrate important theorems on representations and characters. The multiplication table for this group of order 24 is given in Table II. An interesting

TABLE II Cayley Multiplication Table for S_4

theorem in permutation groups is that the "number of q" classes of the symmetric group S_n (of order $n!$) is equal to the number of distinct partitions in n. We thus have

$$
\begin{aligned}
&K_1 = (E) \quad 1+1+1+1\,(1^4), && g_1 = 1,\\
&K_2 = (C,\ D,\ F,\ G,\ H,\ Q) \quad 1+1+2+0 \quad (1^2 2)\\
&\qquad\qquad && g_2 = 6,\\
&K_3 = (K,\ L,\ M) \quad 2+2+0+0 \quad (2^2)\\
&\qquad\qquad && g_3 = 3, \qquad (7)\\
&K_4 = (A, B, I, J, N, O, V, W) \quad 1+3+0+0 \quad (31)\\
&\qquad\qquad && g_4 = 8,\\
&K_5 = (P, R, S, T, U, X) \quad 4+0+0+0 \quad (4^1)\\
&\qquad\qquad && g_5 = 6.
\end{aligned}
$$

Here we have denoted the classes by K_i, the number of elements in each class g_i. The partitions of the number 4 associated with the different classes are shown as (1^4), etc., which can be taken as an alternative description of classes. According to representation theory:

1. The number of inequivalent irreducible representations is equal to the number of classes. S_4 thus has five representations.
2. The sum of squares of the dimensions of the irreducible representations equals the order of the group:

   $n_1^2 + n_2^2 + n_3^2 + n_4^2 + n_5^2 = g = 24$ for the S_4 group.

$D^{(2)}$: →

$$
D(A) = \underset{\chi = 0}{\begin{bmatrix} -i/2 & i/\sqrt{2} & -i/2 \\ 1/\sqrt{2} & 0 & -1/\sqrt{2} \\ i/2 & i/\sqrt{2} & i/2 \end{bmatrix}}, \qquad
D(F) = \underset{\chi = -1}{\begin{bmatrix} -1/2 & -1/\sqrt{2} & -1/2 \\ -1/\sqrt{2} & 0 & 1/\sqrt{2} \\ -1/2 & 1/\sqrt{2} & -1/2 \end{bmatrix}}, \qquad
D(J) = \underset{\chi = 0}{\begin{bmatrix} -i/2 & 1/\sqrt{2} & i/2 \\ -i/\sqrt{2} & 0 & i/\sqrt{2} \\ -i/2 & -1/\sqrt{2} & i/2 \end{bmatrix}},
$$

$$
D(B) = \underset{\chi = 0}{\begin{bmatrix} i/2 & 1/\sqrt{2} & -i/2 \\ -i/\sqrt{2} & 0 & -i/\sqrt{2} \\ i/2 & -1/\sqrt{2} & -i/2 \end{bmatrix}}, \qquad

\mathscr{D}(E) = \underset{\chi = 3}{\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}}.
$$

This equation has the solution $1^2 + 1^2 + 2^2 + 3^2 + 3^2$.

Thus S_4 has two one-dimensional, two three-dimensional, and one two-dimensional representations. All finite groups have a trivial one-dimensional representation where each element is represented by 1. One set of the three-dimensional representation matrices of S_4 is given on the previous page. Swamy and Samuel give all the representation matrices in their work. It is important to note that, while the inequivalent representations will be finite in number, there will be an infinite number of equivalent representations, each differing from the other only by a similarity transformation. We use the notation $D^{(j)}$ for the jth irreducible representation, $D^{(j)}(R)$ for the matrix representing the general group element R in the Jth representation, and $D^{(j)}_{mm'}(R)$ for the mm'th matrix element of that particular matrix, $\chi^{(j)}(R)$ is the character of the element R in the Jth irreducible representation.

All the elements of one class have the same character in a given irreducible representation. Table III gives the classwise character table for S_4. Two important theorems in representation theory are summarized in the formulas

$$\sum_R D^{(\mu)}_{il}(R) D^{(\nu)^*}_{jm}(R) = (g/n_\mu)\,\delta_{\mu\nu}\,\delta_{ij}\,\delta_{lm},$$
$$\sum_R \chi^{\mu}(R)\chi^{(\nu)^*}(R) = g\,\delta_{\mu\nu}, \tag{8}$$

or, equivalently,

$$\sum_i^k \chi_i^{(\mu)} \chi_i^{(\nu)^*} g_i = g\,\delta_{\mu\nu}.$$

Here μ and ν label the different irreducible representations, R as a general group element, n_μ the dimensionality of the μth representation, g_i the number of elements in the ith class, and g the total number of elements or the order of the group. In other words, the above theorems go to show that, treated as vectors in the space of group elements, these are orthogonal. Similarly, characters $\chi^{(j)}(R)$ of the irreducible representations form an orthogonal vector system in the same space of group elements. It is easy to verify the above numerically with the help of the representation matrices for S_4 and its character table (Table III). The third relation above shows that normalized characters $\sqrt{g_i/g}\,\chi_i^{(j)}$ form an orthonormal vector system in the k-dimensional space of classes. Various prescriptions exist for calculating the characters of a finite group, and it is much easier to determine characters in many instances than the representation matrices themselves. Frobenius developed a systematic algebraic procedure for determining the characters of any permutation group. If we know the characters of a permutation group we can infer therefrom the characters of all finite groups because of a theorem in group theory which says that any finite group is isomorphic to a subgroup of some permutation or symmetric group. Isomorphic groups have the same character table. One of the interesting prescriptions for obtaining characters is the class product relation

$$k_i k_j = \sum_t C_{ijl} k_l, \tag{9}$$

where the k_i are classes and the summation is done over all the classes. From this can be derived

$$g_i g_j \chi_i^{(\mu)} \chi_j^{(\mu)} = n_\mu \sum_l C_{ijl} g_l \chi_l^{(\mu)}, \tag{10}$$

where the C coefficients are identical to the ones in Eq. (9). To illustrate the first identity let us take classes k_2 and k_3 of S_4:

$$\begin{aligned} k_3 k_2 &= (K,\ L,\ M)(C,\ D,\ F,\ G,\ H,\ Q) \\ &= (G,\ S,\ U,\ C,\ R,\ X), (T,\ H,\ X,\ P,\ D,\ U), \\ &\quad (P,\ R,\ Q,\ T,\ S,\ F) \\ &= k_2 + 2k_5. \end{aligned}$$

This gives for the values of the C coefficients

$$\begin{aligned} &C_{321} = 0, \quad C_{322} = 1, \quad C_{323} = 0, \\ &C_{324} = 0, \quad C_{325} = 2. \end{aligned} \tag{11}$$

With these numbers determined it is a trivial exercise to check (10) from the character table for S_4. Frobenius also gave a prescription for determining the characters of a group from the known characters of its subgroups. This is discussed lucidly in the work of Littlewood.

TABLE III Character Table of S_4

	K_1 $g_1 = 1$	K_2 $g_2 = 6$	K_3 $g_3 = 3$	K_4 $g_4 = 8$	K_5 $g_5 = 6$
$D^{(1)}$	1	−1	1	1	−1
$D^{(2)}$	3	−1	−1	0	1
$D^{(3)}$	2	0	2	−1	0
$D^{(4)}$	3	1	−1	0	−1
$D^{(5)}$	1	1	1	1	1

B. Construction of Representations

The construction of the representation of a finite group depends on the choice of a suitable set of basis functions, and the dimensionality of the representation is the number of basis functions chosen. If $\psi_1,\ \psi_2, \ldots,\ \psi_n$ are a set of n

TABLE IV $O_R X, O_R Y, O_R Z$

	$E\,X_i$	$F(132)$ $C_3 X_i$	$D(123)$ $C_3 X_i$	$A(23)$ $\sigma_v X_i$	$C(12)$ $\sigma_{v'} X_i$	$B(13)$ $\sigma_{v''} X_i$
$X_1 = X$	X	$-(1/2)x - (\sqrt{3}/2)y$	$-(1/2)x + (\sqrt{3}/2)y$	$-X$	$(1/2)x - (\sqrt{3}/2)y$	$(1/2)x + (\sqrt{3}/2)y$
$X_2 = Y$	Y	$(\sqrt{3}/2)x - (1/2)y$	$-(\sqrt{3}/2)x - (1/2)y$	Y	$-(\sqrt{3}/2)x - (1/2)y$	$(\sqrt{3}/2)x - (1/2)y$
$X_3 = Z$	Z	Z	Z	Z	Z	Z

basis functions, the fundamental formula of representation theory then is expressed as

$$\mathbf{O}_R \psi_\nu = \sum_{\mu=1}^{n} D_{\mu\nu}(R)\psi_\mu. \tag{12}$$

This means that the result of a group operation $\mathbf{O}_R$ (element of the group) on one of the basis functions is a linear combination of the basis functions and the matrix of the coefficients in the linear combination essentially determines the representation. We will illustrate this for the C_{3v} group. In Fig. 1 let us choose a rectangular coordinate system with origin at the centroid O and the Y axis through the median AA' with the X axis perpendicular to it in its plane. The Z axis will be pointing up from the origin perpendicular to the plane of the figure. The vertices will then have the coordinates $A = (0,\ 1,\ 0)$, $B(\sqrt{3}/2,\ -1/2,\ 0)$, and $C(\sqrt{3}/2,\ -1/2,\ 0)$. In Table IV we gather the results of making all the six operations of the group C_{3v}, on x, y, and z. From formula (12) and the table we see that if we choose z as one basis function, we have a one-dimensional representation with the number 1 representing all the elements. In the character table (Table V) this is shown as the A_1 representation, which means that the basis function is symmetric with respect to rotation about the cyclic axis. If we choose a pair of functions $x = \psi_1$, $y = \psi_2$ in that order we obtain the two-dimensional (E representation) irreducible representation

$$\begin{aligned}
&\mathfrak{D}(R) && \mathfrak{D}(A)\\
&\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, && \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix},\\
&\chi = 2 && \chi = 0\\
&\mathfrak{D}(B) && \mathfrak{D}(C)\\
&\begin{bmatrix} 1/2 & \sqrt{3}/2 \\ \sqrt{3}/2 & -1/2 \end{bmatrix}, && \begin{bmatrix} 1/2 & -\sqrt{3}/2 \\ -\sqrt{3}/2 & -1/2 \end{bmatrix},\\
&\chi = 0\\
&\mathfrak{D}(D) && \mathfrak{D}(F)\\
&\begin{bmatrix} -1/2 & -\sqrt{3}/2 \\ \sqrt{3}/2 & -1/2 \end{bmatrix}, && \begin{bmatrix} -1/2 & \sqrt{3}/2 \\ -\sqrt{3}/2 & -1/2 \end{bmatrix}.\\
&\chi = -1 && \chi = -1
\end{aligned} \tag{13}$$

The characters are shown underneath each matrix, and Table V gives all the characters classwise. x, y are written against the E representation since these transform accordingly. x is said to belong to the first row of the representation $D^{(E)}$ and y to its second row. Since the A_2 representation is also one-dimensional, the matrix elements (numbers which are also the characters) are easily obtained by applying the orthogonality relations either to the matrix elements of different irreducible representations or to the characters. It is to be noted that the choice of x and y for the two-dimensional representation is fortuitous inasmuch as it straightaway generated the representation. However, there is a general prescription for obtaining the basis functions starting with any arbitrary function by means of projection operators. The formula for this projection operator is

$$p_i^{(\mu)} = \frac{n_\mu}{g} \sum_R D_{ii}^{(\mu)*}(R)\mathbf{O}_R, \tag{14}$$

$$p_i^2 = p_i, \qquad p_i p_j = 0, \tag{14a}$$

and for the two-dimensional representation these are explicitly

$$\begin{aligned}
p_1 &= \tfrac{1}{3}\{E - \tfrac{1}{2}D - \tfrac{1}{2}F - A + \tfrac{1}{2}B + \tfrac{1}{2}C\},\\
p_2 &= \tfrac{1}{3}\{E - \tfrac{1}{2}D - \tfrac{1}{2}F + A - \tfrac{1}{2}B - \tfrac{1}{2}C\}.
\end{aligned} \tag{15}$$

If we choose the arbitrary function $\phi(x, y, z) = x + y + z$, then it is easily seen that

$$\begin{aligned} p_1\Phi &= x\\ p_2\Phi &= y \end{aligned} \qquad \text{or} \qquad \psi_i^{(\nu)} = p_i^{(\nu)}\Phi. \tag{16}$$

We will conclude this discussion of representation theory by introducing the concept of direct product of two groups. Let a group G_1 be of order g_1 with elements A_1, $A_2, \ldots, A_{g_i}$ and another group of G_2 of order g_2 with elements $B_1, B_2, \ldots, B_{g_2}$. A direct product group $G_1 \times G_2$

TABLE V **Character Table of S_3 or C_{3v}**

	$K_1(1^3)E$ $g_1 = 1$	$K_2 21(A, B, C)$ $(g_2 = 3)$	$K_3(3)(D, F)$ $g_3 = 2$	
$D^{(A_1)}$	1	1	1	z
$D^{(A_2)}$	1	-1	1	
$D^{(E)}$	2	0	-1	(x, y)

is defined if the elements of G_1 commute with the elements of G_2. This group consists of the ordered pair of elements A_1B_1, $A_1B_2, \ldots$, and will be of the order g_1g_2. The multiplication rule for the elements of the direct product follows simply from the multiplication rules for each group. Thus if in group G_1, $A_1A_2 = A_5$ and in group G_2, $B_1B_2 = B_7$, then in the direct product group $(A_1B_1) \times (A_2B_2)$ will be equal to $(A_1A_2) \times (B_1B_2)$ the element corresponding to A_5B_7. For example, C_{3h}, is a direct product group of the cyclic group C_3 (with elements E, C_3, and C_3^2) and the group C_h consisting of the identity element and reflection in a horizontal plane. The rotation–reflection group in Lie groups is a direct product of the rotation group and the inversion group (parity operation). The direct products of some Lie groups decompose into a direct sum of irreducible components. A well-known theorem, called the Clebsch–Gordan theorem, prescribes how to construct basis functions for their irreducible representations (IRs) from the basis functions of the IRs of the factors making up the direct product. The characters of the direct product groups can be calculated easily from the characters of the two "factors" according to the formula

$$\chi^{(\nu)}(A_1)\chi^{\nu}(B_2) = \chi^{(\mu \times \nu)}(A_1B_2). \tag{17}$$

III. CONTINUOUS LIE GROUPS

The theory of continuous or topological groups is due to the Norwegian mathematician Sophus Lie and hence these are familiarly known as Lie groups. In these groups the group element is a continuous invertible transformation of a set of variables and the transformations satisfy the group postulates. For instance, the fundamental property of a group being closed with respect to multiplication here means that the transformation of a transformation is another transformation, and the identity element means a mapping of the variables into themselves. Translations and rotations of a coordinate system in three- or four-dimensional space are examples of these transformations which form a group.

A continuous transformation of a set of variables is best described in terms of parameters which can take on continuous values in a finite (compact) or infinite (noncompact) range, a certain equilibrium value of the parameters corresponding to the identity transformation. If $x_1, x_2, x_3, \ldots, x_n$ are the variables and $a_1, a_2, \ldots, a_k$ are the parameters, we can write the transformation as

$$\begin{aligned} x_i' &= f_i(x_i, a_r), \qquad i = 1, \ldots, n, \\ & \qquad\qquad\quad r = 1, \ldots, k \\ x_i' &= x_i, \qquad\quad \text{(identity)} \\ & \qquad\qquad\quad \text{for} \quad a_1 = a_1^0, \quad \text{etc.}, \end{aligned} \tag{18}$$

and further, for any arbitrary functions of the variables we have

$$\phi(x_i') = \phi(f_i). \tag{19}$$

While the precise nature of the finite transformations defines the Lie group, Lie proved that these transformations can be built up from the identity (since they are continuous) by means of infinitesimal generators X_k, there being in general as many generators as essential parameters. According to Lie,

$$\mathbf{X}_\alpha = \sum_{i=1}^{n} \left.\frac{\partial x_\iota'}{\partial a_\alpha}\right|_{a_\alpha 0} \frac{\partial}{\partial x_i}, \tag{20}$$

$$X_i' = \{e^{\varepsilon_1\mathbf{X}_1 + \varepsilon_2\mathbf{X}_2 + \cdots + \varepsilon_n\mathbf{X}_n}\}X_i, \tag{21}$$

and

$$\phi(x_i') = (e^{\Sigma_i \varepsilon_i \mathbf{X}_i})\phi(x_i). \tag{22}$$

The interesting thing about the Lie group is that it is uniquely defined in terms of certain structure relations that exist among these derived infinitesimal generators. These are

$$[\mathbf{X}_\chi, \mathbf{X}_\mu] = \sum_\lambda C_{\chi\mu}^{\lambda}\mathbf{X}_\lambda, \qquad [\mathbf{A}, \mathbf{B}] \equiv \mathbf{AB} - \mathbf{BA}, \tag{23}$$

where $C_{\chi\mu}^{\lambda}$ are called structure constants. Knowing the structure constants is synonymous with knowing the group of finite transformations f_i. The above relations are usually referred to as the Lie algebra of the generators, and often a Lie group is defined in terms of its Lie algebra. Sometimes a subset of the operators X_α itself satisfies a relation of the above type, and in this case we say these smaller number of generators constitutes a subgroup of the Lie group. In quantum mechanics and in particle physics there is a lot of interest in a certain category of Lie groups known as semisimple groups. The French mathematician E. Cartan, to whom we owe several developments of the original Lie theory, established the criterion for a Lie group to be semisimple. If we define

$$g_{\mu\rho} = \sum_{\alpha\beta} C_{\mu\alpha}^{\beta} C_{\nu\beta}^{\alpha}, \tag{24}$$

then $\|g_{\mu\rho}\|$ is the determinant of the matrix whose ordered coefficients are $g_{\mu\nu}$, and nonvanishing of this determinant is the condition for the group to be semisimple. Casimir has shown that in the case of such groups there exists a certain function of the infinitesimal generators, called the Casimir operator, that commutes with every generator

$$\begin{aligned} [\mathbf{C}, \mathbf{X}_\alpha] &= 0 \qquad \text{for all} \quad \alpha, \\ \mathbf{C} &= \sum_{\mu\nu} g^{\mu\nu}\mathbf{X}_\mu\mathbf{X}_\mu, \end{aligned} \tag{25}$$

where $g^{\mu\nu}$ is the matrix inverses to $g_{\mu\nu}$. Such an operator which commutes with all the generators is called an invariant of the Lie group, and this plays an important

role in understanding the structure of the group and also in constructing its irreducible representations.

A. Three-Dimensional Rotation Group

As an application of the preceding ideas we will discuss the three-dimensional rotation group SO(3) which describes one of the fascinating symmetries in physics. If a sphere is rotated in space about its radius it is brought into coincidence with itself and this is known as spherical symmetry. Spherical symmetry (rotational invariance) has experimentally interesting consequences in classical as well as quantum physics. Rotational invariance implies in general conservation of angular momentum. In classical physics, for instance, the latter conservation principle explains why a figure skater draws her outstretched arms closer to her body to increase her speed of gyration, or why a cat always lands on its feet when it falls! Three-dimensional rotations form a Lie group called the SO(3) group. as

$$x_i' = \left(e^{\Sigma_i \varepsilon_i \mathbf{X}_i}\right) X_i = \left(e^{t_3 X_3} e^{t_2 X_2} e^{t_1 X_1}\right) X_i. \tag{28}$$

This is a semisimple group with $g_{\mu\nu}$ being a diagonal unit matrix and the Casimir operator, the invariant of the group, is simply the sum of the squares of the generators,

$$\mathbf{C} = \mathbf{X}_1^2 + \mathbf{X}_2^2 + \mathbf{X}_3^3. \tag{29}$$

In quantum mechanics this operator is related to the square of the angular momentum, which is one of the experimentally observable quantities.

The spherical harmonics Y_l^m defined on the surface of the unit sphere and originally discovered in the context of solving the Laplace equation are eigenfunctions of this Casimir operator, that is, they satisfy the equation

$$\mathbf{C} Y_l^m(\theta,\, \phi) = -l(l+1) Y_l^m(\theta,\, \phi). \tag{30}$$

Here l is any positive integer and for a given l m can assume any integral value between $-l$ and $+l$, a total of $2l+1$ values. Thus for a given l there are $2l+1$ spherical harmonics and these are the basic functions which generate the odd $(2l+1)$-dimensional irreducible representations of the three-dimensional rotation group. If a dynamical system in quantum mechanics has a certain symmetry, or more precisely if the Hamiltonian of the dynamical system is invariant to a certain set of group operations, then its solutions generate the representations of that group. In particular, if the dynamical system has spherical symmetry, which means that the Hamiltonian has rotational invariance, the spherical harmonics must be a factor in its solution. The Laplace operator is indeed rotationally invariant, and its solutions are either

$$r^l Y_l^m \qquad \text{or} \qquad r^{-l-l} Y_l^m. \tag{31}$$

$$\begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} \cos t_2 \cos t_3 & -\cos t_2 \sin t_3 & \sin t_2 \\ \cos t_1 \sin t_3 + \sin t_1 \sin t_2 \cos t_3 & \cos t_1 \cos t_3 - \sin t_1 \sin t_2 \sin t_3 & \sin t_1 \cos t_2 \\ \sin t_1 \sin t_3 - \cos t_1 \sin t_2 \cos t_3 & \sin t_1 \cos t_3 + \cos t_1 \sin t_2 \sin t_3 & \cos t_1 \cos t_2 \end{bmatrix} \begin{bmatrix} x \\ y \\ z \end{bmatrix} \tag{26}$$

$$x'^2 + y'^2 + z'^2 = x^2 + y^2 + z^2.$$

The way to describe rotations of a coordinate system mathematically in three-dimensional space was shown by Euler, centuries ago, who introduced three real parameters called the Eulerian angles. An alternative and equivalent description is given in Eq. (26). Here t_i are the parameters of the Lie group and these are naturally functions of the Eulerian angles. Following the Lie prescription, the infinitesimal generators are seen to be

$$\begin{aligned} \mathbf{X}_{t_1} \equiv \mathbf{X}_1 &= z\frac{\partial}{\partial y} - y\frac{\partial}{\partial z}, \\ \mathbf{X}_2 &= x\frac{\partial}{\partial z} - z\frac{\partial}{\partial x}, \\ \mathbf{X}_3 &= y\frac{\partial}{\partial x} - x\frac{\partial}{\partial y}, \end{aligned} \tag{27}$$

and the associated Lie algebra is

$$[\mathbf{X}_1,\, \mathbf{X}_2] = \mathbf{X}_3 \qquad \text{and cyclically.} \tag{27a}$$

This relation is written somewhat cryptically as

$$[\mathbf{X}_i,\, \mathbf{X}_j] = \sum_k \varepsilon_{ijk} \mathbf{X}_k, \tag{27b}$$

where the Levi–Civita symbol ε_{ijk} assumes the value 0 whenever any two indices are equal, equals $+1$ when ijk is an even permutation of 123, and equals -1 for an odd permutation. The finite transformation (26) can be obtained

B. SU(2) Covering Group of the Rotation Group

The even-dimensional representations of SO(3) were first discovered by Weyl. He showed that the covering group of this rotation group is SU(2), which is the unitary unimodular group in two dimensions. This group played a crucial role in characterizing the spin properties of particles such as electrons and protons (fermions), and recently it has proved to be one of the cornerstones of a theory that led to the discovery of the $W^{\pm}$ and Z^0 bosons.

A general element of the SU(2) group can be written as a 2×2 unitary matrix of determinant $+1$.

$$U = \begin{bmatrix} \alpha & \beta \\ -\beta^* & \alpha^* \end{bmatrix}, \qquad \alpha\alpha^* + \beta\beta^* = 1. \tag{32}$$

Here the asterisk stands for the complex conjugate. This is called a covering group of SO(3) because it not only induces three-dimensional rotations, it gives the odd- as well as even-dimensional representations of the latter. For instance, a similarity transformation with U of the matrix

$$\vec{\sigma} \cdot \vec{\mathbf{r}} = \begin{bmatrix} z & x - iy \\ x + iy & -z \end{bmatrix} \tag{33}$$

gives

$$\vec{\sigma} \cdot \vec{\mathbf{r}}' = \mathbf{U}^+ \vec{\sigma} \cdot \vec{\mathrm{r}}\, \mathbf{U}. \tag{34}$$

$r'(x',\ y',\ z')$ is related to $r(x,\ y,\ z)$ through α, β and their complex conjugates. From the theory of determinants we know that $\vec{\sigma} \cdot \vec{\mathrm{r}}'$ and $\vec{\sigma} \cdot \vec{\mathrm{r}}$ have the same determinant or

$$x^2 + y^2 + z^2 = x'^2 + y'^2 + z'^2.$$

Wigner has given the explicit connection between the complex α, β and of SU(2) and the Eulerian angles α, β, γ which characterize the three-dimensional rotations. It is straightforward algebra to establish the relation between the SU(2) elements and the t_i of (26). The Lie algebra satisfied by the generators of SU(2) is isomorphic to that of the SO(3) group. The Pauli spin operators that describe the magnetic electron in atomic physics, the Cayley–Klein operators that describe rigid body spin in classical mechanics, and quoternions in vector space theory all have algebras similar to the SU(2) algebra. The basis functions which generate the irreducible representations of SU(2) are known as monomials or tensors. A typical even-dimensional representation of SU(2) is given in Eq. (35). Some of the properties of SU(2) groups will be discussed elsewhere in this article in the context of applications in particle physics.

$$D^{1/2}_{mm'}(\alpha\beta\gamma) = \begin{bmatrix} e^{-i(\alpha/2)}(\cos\beta/2)e^{-i(\gamma/2)} & -i^{-i(\alpha/2)}(\sin\beta/2)e^{i(\gamma/2)} \\ e^{i(\alpha/2)}(\sin\beta/2)e^{-i(\gamma/2)} & e^{i(\alpha/2)}(\cos\beta/2)e^{i(\gamma/2)} \end{bmatrix}. \tag{35}$$

C. Four-Dimensional Rotation Group and Homogeneous Lorentz Group

The extension of the rotation group to four dimensions is straightforward but not trivial. The SO(4) group elements are the linear transformations that ensure

$$x_1^2 + x_2^2 + x_3^2 + x_4^2 = x_1'^2 + x_2'^2 + x_3'^2 + x_4'^2, \tag{36}$$

where each element of the group transforms x_i into x_i':

$$x'_\mu = \sum_\lambda b_{\mu\lambda} x_\lambda. \tag{37}$$

The transformation matrix $b_{\mu\lambda}$, an element of the SO(4) group, can be expressed in terms of six real parameters $\alpha, \beta, \gamma, \alpha', \beta', \gamma'$. Forsyth has shown that the matrix elements $b_{\mu\lambda}$ are somewhat complicated trigonometric functions of these parameters. This matrix, as well as the element of SO(3), is an orthogonal matrix. The Lie algebra of the six infinitesimal generators is best given in terms of two sets of operators $X_1 = L_1$, $X_2 = L_2$, $X_3 = L_3$, and $X_4 = A_1$, $X_5 = A_2$, $X_6 = A_3$:

$$\begin{aligned} [\mathbf{L}_i, \mathbf{L}_j] &= \sum_k \varepsilon_{ijk}\, \mathbf{L}_k, \\ [\mathbf{A}_i, \mathbf{A}_j] &= \sum_k \varepsilon_{ijk}\, \mathbf{L}_k, \\ [\mathbf{L}_i, \mathbf{A}_j] &= \sum_k \varepsilon_{ijk}\, \mathbf{A}_k. \end{aligned} \tag{38}$$

These relations identify the SO(4) group and any six operators, which obey the same commutation relations as the X_i generate a group isomorphic to SO(4). It is interesting to note that the L_j themselves form a closed Lie algebra isomorphic to SO(3). This group is then a subgroup of SO(4). This group has two invariant operators,

$$\begin{aligned} \mathbf{F} &= \sum \mathbf{L}_i^2 + \mathbf{A}_i^2, \\ G &= \mathbf{L}_1\mathbf{A}_1 + \mathbf{L}_2\mathbf{A}_2 + \mathbf{L}_3\mathbf{A}_3. \end{aligned} \tag{39}$$

This group plays an important role in understanding the bound states of the nonrelativistic hydrogen atom as well as in particle physics.

If instead of Eq. (36) we have transformations which leave

$$X_1^2 + X_2^2 + X_3^2 - X_4^2 \tag{40}$$

invariant, then these form the elements of the homogeneous Lorentz group, of fundamental importance in the special theory of relativity and elementary particle physics. We have explicitly

$$X'_\mu = \sum_\lambda a_{\mu\lambda} x_\lambda. \tag{41}$$

The $a_{\mu\lambda}$ are once again expressed in terms of six real parameters. How algebraically complicated these functions, elements of $a_{\mu\lambda}$, are can be judged from the typical element

$$\begin{aligned} a_{12} = \sin\gamma\cos\gamma\{&\cosh\alpha'\cos^2\beta \\ &- \cos\alpha\cosh^2\beta' + \cos\alpha\sin^2\beta \\ &+ \cosh\alpha'\sinh^2\beta'\} - \sin a\sin\beta\cosh\beta' \\ &+ \sinh\alpha'\sinh\beta'\cos\beta. \end{aligned} \tag{42}$$

For instance, when $\alpha = 1$, $\beta = 0.7$, $\gamma = 0.35$, $\alpha' = 0.5$, $\beta' = 1.4$, and $\gamma' = 0.1$, the $a_{\mu\lambda}$ becomes a numerical matrix, the element of the homogenous Lorentz group, as given in Eq. (43). The

$$a_{\mu\lambda} = \begin{bmatrix} 0.5930545 & 0.3897004 & -0.9044001 & 0.5670270 \\ 1.2037232 & -1.2987247 & 1.5783052 & -2.1509726 \\ 0.5232450 & -2.2304747 & 0.7592345 & -2.1966429 \\ -1.0365561 & 2.4111345 & -1.6986536 & 3.2822924 \end{bmatrix} \tag{43}$$

infinitesimal generators of this group and the associated Lie algebra are

$$\begin{aligned} \mathbf{X}_1 &= y\frac{\partial}{\partial z} - z\frac{\partial}{\partial y} \equiv \mathbf{L}_1, \\ \mathbf{X}_2 &= z\frac{\partial}{\partial x} - x\frac{\partial}{\partial z} \equiv \mathbf{L}_2, \\ \mathbf{X}_3 &= x\frac{\partial}{\partial y} - y\frac{\partial}{\partial z} \equiv \mathbf{L}_3, \\ \mathbf{X}_4 &= t\frac{\partial}{\partial x} + x\frac{\partial}{\partial t} \equiv \mathbf{A}_1, \\ \mathbf{X}_5 &= t\frac{\partial}{\partial y} + y\frac{\partial}{\partial t} \equiv \mathbf{A}_2, \\ \mathbf{X}_6 &= t\frac{\partial}{\partial z} + z\frac{\partial}{\partial t} \equiv \mathbf{A}_3, \\ &(t \equiv x_4); \\ [\mathbf{L}_i, \mathbf{L}_j] &= -\sum_k \varepsilon_{ijk}\mathbf{L}_k, \\ [\mathbf{A}_i, \mathbf{A}_j] &= \sum_k \varepsilon_{ijk}\mathbf{L}_k, \\ [\mathbf{L}_i, \mathbf{A}_j] &= -\sum_k \varepsilon_{ijk}\mathbf{A}_k, \end{aligned} \tag{44}$$

When three of the parameters are set equal to zero we have the "Lorentz rotations" or the Lorentz transformation, where one frame of reference moves with respect to another frame with constant velocity $\vec{\mathrm{v}}$ in an arbitrary direction. In this case the general element reduces to Eq. (45a) below.

In (45a),

$$\begin{bmatrix} a\cdot \\ \cdot b \end{bmatrix} \equiv ab. \tag{45b}$$

The above matrix elements are related to the velocity components of the moving frame (with the speed of light $c = 1$) as

$$\begin{aligned} v_x &= \tanh\alpha' \cosh\beta' \cosh\gamma', \\ v_y &= i \tanh\alpha' \cosh\beta' \cosh\gamma', \\ v_z &= i \tanh\alpha' \sinh\beta', \\ v &= \sqrt{v_x^2 + v_y^2 + v_z^2} = \tanh\alpha'. \end{aligned} \tag{46}$$

This group also has two invariant operators, somewhat complicated functions of the generators. The representations of the homogeneous Lorentz group can be obtained from its covering group which was shown by Bargmann to be SL(2, C), an element of which is a 2×2 complex matrix with determinant $+1$. For example, the element of the covering group corresponding to the element of the homogeneous Lorentz group in Eq. (43) is

$$\begin{bmatrix} -1.222144 + i(0.2411005) & -0.6624081 - i(1.0352785) \\ 0.1311536 - i(0.9976158) & 1.9325431 - i(0.4832207) \end{bmatrix}. \tag{47}$$

It is important to mention that the full group of relativistic quantum mechanics is the inhomogeneous Lorentz group or the Poincaré group which has, in addition, elements corresponding to translations in space–time.

IV. APPLICATIONS IN ATOMIC PHYSICS

A. Symmetry of the Hydrogen Atom

The nonrelativistic quantum mechanical Hamiltonian describing the motion of an electron in the hydrogen atom is

$$a_{\mu\lambda} = \begin{bmatrix} \cosh\alpha' & \sinh\alpha'\sinh\beta' & \sinh\alpha'\cosh\beta'\sinh\gamma' & \sinh\alpha'\cosh\beta'\cosh\gamma' \\ -\sinh\alpha'\sinh\beta' & \begin{Bmatrix}\cosh\alpha' \\ +(1-\cosh\alpha')\cosh^2\beta'\end{Bmatrix} & \begin{Bmatrix}(1-\cosh\alpha')\sinh\beta' \\ \cdot\cosh\beta'\sinh\gamma'\end{Bmatrix} & \begin{Bmatrix}(1-\cosh\alpha') \\ \cdot\sinh\beta'\cosh\beta'\cosh\gamma'\end{Bmatrix} \\ -\sinh\alpha'\cosh\beta'\sinh\gamma' & \begin{Bmatrix}(1-\cosh\alpha') \\ \cdot\sinh\beta'\cosh\beta'\sinh\gamma'\end{Bmatrix} & \begin{Bmatrix}(1-\cosh\alpha')\cosh^2\beta' \\ \cdot\sinh^2\gamma'+1\end{Bmatrix} & \begin{Bmatrix}(1-\cosh\alpha') \\ \cdot\cosh^2\beta'\sinh\gamma'\cosh\gamma'\end{Bmatrix} \\ \sinh\alpha'\cosh\beta'\cosh\gamma' & \begin{Bmatrix}(\cosh\alpha'-1) \\ \cdot\sinh\beta'\cosh\beta'\cosh\gamma'\end{Bmatrix} & \begin{Bmatrix}(\cosh\alpha'-1) \\ \cdot\cosh^2\beta'\sinh\gamma'\cosh\gamma'\end{Bmatrix} & \begin{Bmatrix}(\cosh\alpha'-1) \\ \cdot\cosh^2\beta'\cosh^2\gamma'+1\end{Bmatrix} \end{bmatrix}. \tag{45a}$$

$$H = \frac{-1}{2m}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r},$$
$$r = \sqrt{x^2 + y^2 + z^2}, \tag{48}$$

where e and m are the charge and mass of the electron and r the distance from the nucleus. The electron is in a central field, the potential energy e^2/r being invariant to rotations in three-dimensional space. This Hamiltonian thus has SO(3) symmetry and its bound-state solutions, which generate the irreducible representations of the three-dimensional rotation groups, are expressed in terms of three quantum numbers n, l, m:

$$U_{nlm}(\vec{\mathrm{r}}) = Y_l^m(\theta, \phi)R_{nl}(r). \tag{49}$$

As can be expected from our discussion of the rotation group, the spherical harmonics Y_l^m are a factor in the solution. $D^{(l)}_{mm'}$ are the matrices of the irreducible representation of SO(3) of dimension $2l+1$. U_{nlm} is the general form of a central field wave function. L^2 and L_z are the angular momentum operators which commute with the Hamiltonian and U_{nlm} is an eigenfunction of both with eigenvalues $l(l+1)$ and m in units of $\hbar = l$. The L^2 is just the Casimir operator of the SO(3) group apart from a constant and L_z is essentially one of the infinitesimal generators of the SO(3) group.

Schrödinger, who solved the quantum mechanical equation for the hydrogen atom, pointed out that the energy (eigenvalue of H) depends on only one quantum number n, the so-called principal quantum number, and is independent of both l and m. Since there are n^2 number of different states (combinations of l and m for a given n), all these have the same energy and this is known as degeneracy. The independence of the energy on the orbital angular momentum quantum number l is known as accidental degeneracy and was difficult to understand for quite some time. As a result of the work of Pauli, Fock, and Bargmann we now know that this degeneracy exists because the hydrogen atom has a higher symmetry than SO(3). The Hamiltonian is invariant to rotations in four-dimensional space, or the group of this Hamiltonian is SO(4), the four-dimensional rotation group. Fock showed that the Schrödinger equation in momentum space can be written as a four-dimensional Laplacian equation,

$$\left(\frac{\partial^2}{\partial p_1^2} + \frac{\partial^2}{\partial p_2^2} + \frac{\partial^2}{\partial p_3^2} + \frac{\partial^2}{\partial p_4^2}\right)\Phi = 0, \tag{50}$$

and that its solutions Φ can be written in terms of spherical harmonics defined on the three-dimensional surface of a sphere in four-dimensional space. We recall that there are six generators of SO(4) which satisfy the Lie algebra appropriate to this group. Pauli demonstrated that there exists another vector operator, besides the usual angular momentum operator $\vec{\mathrm{L}}$, which commutes with this Hamiltonian. He generalized the classical Runge–Lenz vector to make it a quantum mechanical invariant. This vector operator, which commutes with the Hamiltonian, is

$$\vec{\mathbf{A}} = \frac{1}{\sqrt{-8m\mathbf{H}}}(\vec{\mathrm{p}} \times \vec{\mathrm{L}} - \vec{\mathrm{L}} \times \vec{\mathrm{p}}) - \frac{m}{-2H}\frac{\vec{\mathrm{r}}}{r}. \tag{51}$$

The three components of $\vec{\mathrm{A}}$ and the three components of $\vec{\mathrm{L}}$ make up the six generators of SO(4) and the quantum mechanical commutation relations among these operators are the same as the Lie algebra of the infinitesimal generators of SO(4). This group has two invariants and one of them, $\vec{\mathrm{L}} \cdot \vec{\mathrm{A}} = \vec{\mathrm{A}} \cdot \vec{\mathrm{L}}$, vanishes in this case. The other invariant is simply the sum of the squares of the six components of $\vec{\mathrm{A}}$ and $\vec{\mathrm{L}}$. It is interesting to note that linear combinations of $\vec{\mathrm{A}}$ and $\vec{\mathrm{L}}$, $\vec{\mathrm{j}}_1$, and $\vec{\mathrm{j}}_2$ commute with each other and each satisfies an SU(2) Lie algebra:

$$\vec{\mathrm{j}}_1 = \tfrac{1}{2}(\vec{\mathrm{L}} + \vec{\mathrm{A}}), \qquad \vec{\mathrm{j}}_2 = \tfrac{1}{2}(\vec{\mathrm{L}} - \vec{\mathrm{A}}),$$
$$[j_{1i}, j_{1j}] = \sum_k \varepsilon_{ijk} j_{1k},$$
$$[j_{2i}, j_{2j}] = \sum_k \varepsilon_{ijk} j_{2k}, \tag{52}$$
$$[j_{1i}, j_{2j}] = 0 \qquad \text{for all} \quad i,\ j.$$

This means that SO(4) is the direct product SU(2)⊗ SU(2). Bargmann showed that this is related to the solution of the Hamiltonian in parabolic coordinates (of importance in the Stark effect resulting from putting the hydrogen atom in an electric field), just as the existence of $\vec{\mathrm{L}}$ as an invariant is related to its solutions in spherical polar coordinates. Furthermore, $\vec{\mathrm{j}}_1 + \vec{\mathrm{j}}_2 = \vec{\mathrm{L}}$, which means that the two solutions are connected through a Clebsch–Gordan-type relation.

B. Isotropic Harmonic Oscillator

In atomic physics it is possible to have quantum mechanical Hamiltonians because the forces between particles are well known. The Coulomb field is an outstanding example. Another such example is the three-dimensional isotropic harmonic oscillator, and the Schrödinger equation with this potential has exact solutions which are helpful in understanding its symmetry properties. In sharp contrast, it is difficult to have a Hamiltonian in elementary particle physics because the forces between strongly interacting particles such as the neutron and proton are known only vaguely. One thus derives maximum benefit from knowledge of symmetries such as SO(4), SU(3), and SU(2) in understanding which atomic physics plays a big role.

To understand the symmetry of the isotropic harmonic oscillator it is necessary to express its Hamiltonian in terms

of coordinates and momenta (with units $\hbar = m = c = 1$)

$$H = \tfrac{1}{2}\left(p_x^2 + p_y^2 + p_z^2\right) + \tfrac{1}{2}\omega^2(x^2 + y^2 + z^2). \quad (53)$$

Here ω is the angular frequency which characterizes the oscillator. In the Schrödinger scheme of quantization the operator $\frac{1}{2}\left(p_x^2 + p_y^2 + p_z^2\right)$ is the Laplace operator $-\frac{1}{2}\nabla^2$ and the Schrödinger equation has exact solutions of the form

$$U_{nlm}(r^2) = Y_l^m(\theta,\ \phi)R_{nl}(r^2). \quad (54)$$

Since the Laplacian

$$\nabla^2 \equiv \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

and $r^2 = x^2 + y^2 + z^2$ both do not change on a rotation of the coordinate system in space, the Hamiltonian has rotational invariance and naturally the spherical harmonics Y_l^m are a factor in the eigenfunctions of H. However, the harmonic oscillator, like the hydrogen atom, has a higher symmetry than SO(3). Jauch, Hill, and Baker demonstrated that the group of the isotropic harmonic oscillator is SU(3), a three-dimensional generalization of SU(2), the unitary unimodular group in three dimensions. A typical element of this group is a 3×3 unitary matrix with determinant $+1$. To establish the group structure or symmetry of a Hamiltonian one should find, on the one hand, operators that commute with it and show, on the other, that these operators are the infinitesimal generators of that particular Lie group. In the 3×3 matrix there are nine complex elements or 18 real parameters. However, the conditions that need to be satisfied by the rows and columns of a unitary matrix, as well as the requirement that the determinant of the matrix should be $+1$, reduce the number to eight independent real parameters. These eight parameters lead to eight generators of the SU(3) group. Three of these are the familiar L_x, L_y, and L_z operators,

$$y\frac{\partial}{\partial z} - z\frac{\partial}{\partial y}, \qquad z\frac{\partial}{\partial x} - x\frac{\partial}{\partial z}, \qquad \text{and} \qquad x\frac{\partial}{\partial y} - y\frac{\partial}{\partial x},$$

respectively, which are the operators that generate the SO(3) group. The other generators are the five independent components of the symmetric tensor

$$\mathbf{A}_{ij} = (1/2\omega)\left(\mathbf{p}_i\mathbf{p}_j + \omega^2\mathbf{x}_i\mathbf{x}_j\right), \quad (55)$$

the sum of whose diagonal elements is essentially the Hamiltonian. The Lie algebra of SU(3) can be conviently expressed in terms of linear combinations of these eight operators:

$$\begin{aligned}
\mathbf{H}_1 &= (1/2\sqrt{3})\mathbf{L}_z,\\
\mathbf{H}_2 &= (1/6)(\mathbf{A}_{11} + \mathbf{A}_{22} - 2\mathbf{A}_{33}),\\
\mathbf{E}_1 &= (1/2\sqrt{6})(\mathbf{A}_{11} - \mathbf{A}_{22} + 2i\mathbf{A}_{12}),\\
E_{-1} &= (1/2\sqrt{6})(\mathbf{A}_{11} - \mathbf{A}_{22} - 2i\mathbf{A}_{12}),\\
E_2 &= (1/4\sqrt{3})(\mathbf{L}_x + i\mathbf{L}_y - 2\mathbf{A}_{13} - 2i\mathbf{A}_{23}),\\
E_{-2} &= (1/4\sqrt{3})(\mathbf{L}_x - i\mathbf{L}_y - 2\mathbf{A}_{13} + 2i\mathbf{A}_{23}),\\
E_3 &= (1/4\sqrt{3})(\mathbf{L}_x + i\mathbf{L}_y + 2\mathbf{A}_{13} + 2i\mathbf{A}_{23}),\\
E_{-3} &= (1/4\sqrt{3})(\mathbf{L}_x - i\mathbf{L}_y + 2\mathbf{A}_{13} - 2i\mathbf{A}_{23}). \quad (56)
\end{aligned}$$

The structure relations can be written explicitly as

$$\begin{aligned}
&[H_i,\ H_j] = 0, && i, j = 1, 2, \ldots, l \ (l = 2 \text{ here}),\\
&[H_i,\ E_\alpha] = r_i(\alpha)E_\alpha, && \alpha = \pm1, \pm2, \ldots, \quad (57)\\
&[E_\alpha,\ E_{-\alpha}] = r_i(\alpha)H_i,\\
&[E_\alpha,\ E_\beta] = \sum_\gamma C_{\alpha\beta}^\gamma E_r, && \alpha = \beta = \pm1, \pm2, \ldots.
\end{aligned}$$

The number of mutually commuting generators of this group, called the rank of the group l, is 2 in this case, H_1 and H_2 being these generators $r_i(\alpha)$ is considered as the ith component of an l-dimensional "root vector" $\vec{\mathrm{r}}(\alpha)$. The different root vectors and their components are $\vec{\mathrm{r}}(1) = (1/\sqrt{3},\ 0)$ or $r_1(1) = (1/\sqrt{3})r_2(1) = 0$,

$$\begin{aligned}
\vec{\mathrm{r}}(-1) &= (-1/\sqrt{3},\ 0),\\
\vec{\mathrm{r}}(2) &= \left(\tfrac{1}{2}\sqrt{3},\ \tfrac{1}{2}\right),\\
\vec{\mathrm{r}}(-2) &= \left(-\tfrac{1}{2}\sqrt{3},\ -\tfrac{1}{2}\right), \quad (58)\\
\vec{\mathrm{r}}(3) &= \left(\tfrac{1}{2}\sqrt{3},\ -\tfrac{1}{2}\right),\\
\vec{\mathrm{r}}(-3) &= \left(-\tfrac{1}{2}\sqrt{3},\ \tfrac{1}{2}\right).
\end{aligned}$$

These are represented graphically in Fig. 2 in a root diagram with r_1 and r_2 as rectangular axes. The root vectors have the "orthonormal" property

$$\sum_\alpha r_i(\alpha)r_j(\alpha) = \delta_{ij}. \quad (59)$$

In the relation $[E_\alpha,\ E_\beta] = C_{\alpha\beta}^\gamma E_\gamma$ the structure constants $C_{\alpha\beta}^\gamma$ vanish whenever $\vec{\mathrm{r}}(\alpha)$ and $\vec{\mathrm{r}}(\beta)$is not a root vector. The root diagram is a concise way of showing the structure of the Lie algebra.

The well-known solutions of the isotropic harmonic oscillator can be used as basis functions for calculating the irreducible representations of the SU(3) group and enumeration of the degenerate states give us the dimensionality of the representations. This degeneracy is easily known from the expression for the energy eigenvalue of the Hamiltonian:

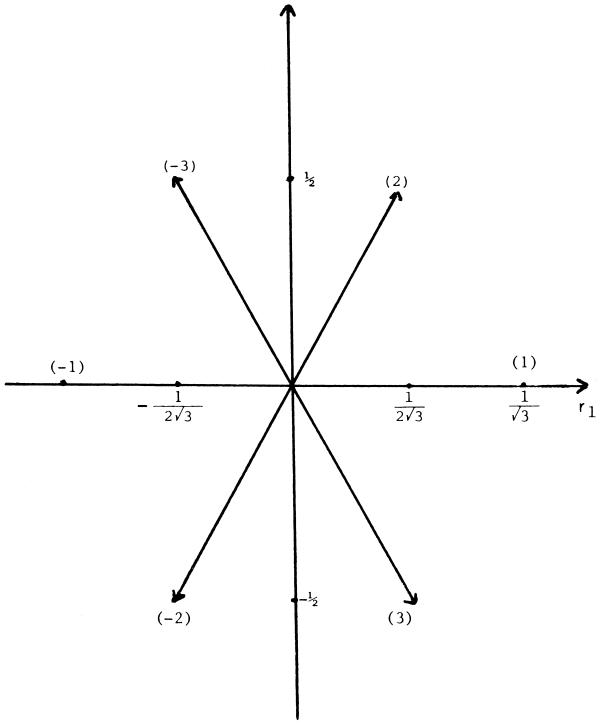

FIGURE 2 Root vector diagram. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979). "Group Theory Made Easy for Scientists and Engineers," Wiley-Interscience, New York. Copyright 1979 John Wiley and Sons.]

$$\begin{aligned}\mathbf{H}U_{nlm} &= \left(2(n-1)+l+\tfrac{3}{2}\right)\omega U_{nlm} \\ &\equiv \left(N+\tfrac{3}{2}\right)\omega U_{nlm}, \qquad N=0,\ 1,\ 2,\ 3,\ \ldots.\end{aligned} \tag{60}$$

Since n assumes an integral value from 1 onward and l likewise from 0 onward, the degeneracy arises from the different partitions of N between n and 1. We thus have, since for a given l there are $2l+1$ substates, 1, 3, 6, 10, etc., states having energies $\frac{2}{2}$, $\frac{5}{2}$, $\frac{7}{2}$, etc., in units of ω. Thus the dimensionality of the representations provided by the solutions of this Hamiltonian are 1, 3, 6, 10, etc. The three basis functions with $n=1$, $l=1$ (1p states) are simultaneous eigenfunctions of the commuting generators H_1 and H_2 with eigenvalues m_1 and m_2 and the latter are treated as components of a vector in l-dimensional space called a "weight vector." The weight vector for $l=1$ are shown in Fig. 3, the weight diagram. The explicit matrices of this representation are

$$H_1=\frac{1}{2\sqrt{3}}\begin{bmatrix}1&0&0\\0&-1&0\\0&0&0\end{bmatrix}, \quad H_2=\frac{1}{\sqrt{6}}\begin{bmatrix}0&0&0\\0&1&0\\0&0&-2\end{bmatrix},$$

$$E_{-1}=\frac{1}{\sqrt{6}}\begin{bmatrix}0&0&0\\1&0&0\\0&0&0\end{bmatrix}, \quad E_1=\frac{1}{\sqrt{6}}\begin{bmatrix}0&1&0\\0&0&0\\0&0&0\end{bmatrix},$$

$$E_2=\frac{1}{\sqrt{6}}\begin{bmatrix}0&0&1\\0&0&0\\0&0&0\end{bmatrix}, \quad E_{-2}=\frac{1}{\sqrt{6}}\begin{bmatrix}0&0&0\\0&0&0\\1&0&0\end{bmatrix},$$

$$E_3=\frac{1}{\sqrt{6}}\begin{bmatrix}0&0&0\\0&0&0\\0&1&0\end{bmatrix}, \quad E_{-3}=\frac{1}{\sqrt{6}}\begin{bmatrix}0&0&0\\0&0&1\\0&0&0\end{bmatrix}. \tag{61}$$

The SU(3) group plays an important role in nuclear as well as particle physics.

C. Splitting of Atomic Levels

The energy levels of an electron in a spherically symmetric field (central field) in an atom are degenerate, more than one state having the same energy. Quantum mechanical perturbation theory shows that very often a perturbation splits the degenerate levels. For instance, in a hydrogen-like atom such as sodium the energy levels, taking the spin of the electron into account, are $2(2l+1)$ degenerate having 2S ($l=0$) levels, 6P ($l=1$) levels, and so on. If the magnetic field due to the spin current of the electron interacts with the magnetic field due to its orbital motion

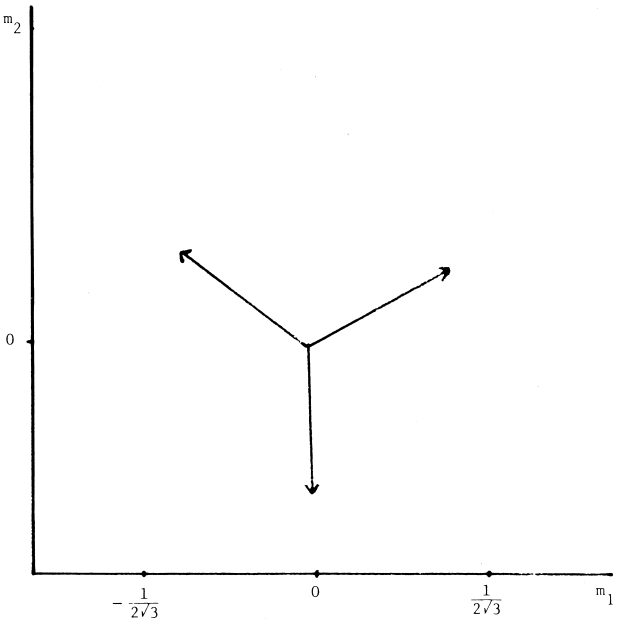

FIGURE 3 Weight diagram. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979). "Group Theory Made Easy for Scientists and Engineers," Wiley-Interscience, New York. Copyright 1979 John Wiley and Sons.]

around the nucleus, which is called spin–orbit coupling, then these degenerate levels are split into two groups, giving rise to what is known as fine structure of spectra lines. In the case of sodium a 5896-Å wavelength sodium D line is really made up of two lines of 5890 and 5896 Å wavelengths, the D_1 and D_2 lines. The unsplit line is due to an electric dipole transition between one of the six degenerate P states to an S state. The two lines appear because the six states split into two groups and there are transitions between levels in either group and the S state. This splitting can be predicted by group theory if the symmetries of the degenerate states and the symmetry of the perturbation are known, as was first pointed out by Bethe.

We will calculate and see how the levels of the atom are split when the perturbation arises, say from the atom being in a crystalline field of D_{3d} symmetry. The elements of D_{3d} form a subgroup of the full rotation–reflection group and hence the irreducible representations of the latter become reducible representations of the subgroup. The reduction theorem

$$a_\mu = \frac{1}{g}\sum_i g_i \chi_i^{(\mu)^*} \chi_i \tag{62}$$

gives a_μ the number of times the μth irreducible representation of the subgroup is contained in the reducible representation in which the elements of the ith class have the compound character χ_i (see Table VI). g_i is the number of elements in class K_i which have the character $\chi_i^{(\mu)}$ in the μth representation. The character table (Table VII) specifies g_i, K_i, and χ_i. The irreducible representations are classified as even or odd (g or μ) because of inversion (or the parity operation) as an element of the subgroup. In the rotation–reflection group $O(3)$ the rotation angles that correspond to elements in classes K_1, K_2, and K_3, are, respectively 0, $2\pi/3$, and $2\pi/2$, although the axes for the cyclic and dihedral rotations (i.e., rotations about axes perpendicular to the cyclic axis) are different. The characters are given by the formula

$$\chi_{(\alpha)}^{(l)} = \frac{\sin(1+\frac{1}{2})\alpha}{\sin(\alpha/2)} \qquad (\alpha = \text{angle of rotation}). \tag{63}$$

TABLE VI Compound Character Table of Subgroup D_{3d}

	E	$2C_3$	$3C_2$	i	$2S_6$	$3\sigma_d$
$\chi^{(l=6)}$	1	1	1	1	1	1
$\chi^{(1)}$	3	0	−1	−3	0	1
$\chi^{(2)}$	5	−1	1	5	−1	1
$\chi^{(3)}$	7	1	−1	−7	−1	1
$\chi^{(4)}$	9	0	1	9	0	1
$\chi^{(5)}$	11	−1	−1	−11	1	1

Applying this formula and remembering that the spherical harmonics Y_1^m have parity $(-)^l$, we obtain the compound characters displayed in Table VI. Since we know the compound characters of the subgroup and its characters $\chi_i^{(\mu)}$, calculation of a_μ following formula (62) is straightforward. For instance, the sevenfold-degenerate level $l = 3$ of the free atom (ignoring spin) is split into one level of symmetry A_{1u}, two levels of symmetry A_{2u}, and two twofold-degenerate levels each of symmetry E_μ. The splitting of the other levels is shown below. Thus group theory predicts the number of split levels and their symmetries, which implies that the transitions and spectral lines can be predicted without calculation. The magnitude of the splitting or the frequency of the spectral lines cannot, of course, be known from symmetry considerations alone. These types of symmetry considerations are of great importance in solid state. For instance, the presence in a crystal of an impurity atom occupying a site of cubic symmetry leads to the formation of a localized triply degenerate vibrational mode. If the crystal has C_{3v} point symmetry at that site the triply degenerate level will split into a doublet (two levels E type) and a singlet (a type). This is of experimental use in infrared studies of crystal defects:

$$\begin{aligned}
E_0 &\to A_{1g},\\
E_1 &\to A_{2u} + E_u,\\
E_2 &\to A_{1g} + 2E_g,\\
E_3 &\to A_{1u} + 2A_{2u} + 2E_u,\\
E_4 &\to 2A_{1g} + A_{2g} + 3E_g,\\
E_5 &\to A_{1u} + 2A_{2u} + 4E_u.
\end{aligned} \tag{64}$$

D. Selection Rules in Atomic Spectra

The spectrum radiated by an atom, hydrogen for example, consists in general of discrete lines, all of which do not have the same intensity of illumination. Also, in the spectra of different atoms it usually happens that some expected lines are not seen; these are called forbidden lines. It was Neils Bohr who pointed out that a spectral line is the result of a quantum mechanical transition between two states of energy E_i and E_f and that the frequency of the radiated line is given by the following Bohr frequency condition, which follows from the principle of conservation of energy:

$$\frac{hc}{\lambda} = h\nu = E_i - E_f. \tag{65}$$

Here ν and λ, respectively, are the frequency and wavelength of the spectral line, h Planck's constant, and c the speed of light. Since more than one atom in a gas makes

TABLE VII Character Table of D_{3d}

the same transition between quantized states, the intensity of a spectral line depends on the population of these atoms, which can be determined from the statistical distribution of the atoms at a given temperature and the quantum mechanical transition probability between these states. For instance, the transition probability for transition from a 2P state to a 1S state in a hydrogen atom is $6.25\times10^8\text{s}^{-1}$. The radiation is usually expressed as a sum of multipoles and the transition probability decreases, by several orders of magnitude, with increasing order of multipoles. That certain transitions are seen to happen experimentally and others not is related to selection rules which vary with the multipole order of the radiation. For a linearly polarized electric dipole radiation, the transition probability between states $|i\rangle$ and $|f\rangle$ is given by

$$A_{if}=(64\pi^4\nu^3/3hc^3)|\langle f|e\mathbf{z}|i\rangle|^2. \tag{66}$$

Here ν is the frequency of the radiation, $e\mathbf{z}$ the dipole operator, and $\langle f|e\mathbf{z}|i\rangle$ the quantum mechanical matrix element which depends on the nature of the initial state $|i\rangle$ and the final state $|f\rangle$. It is this matrix element that dictates whether the transition $|i\rangle\to|f\rangle$ is allowed or not. If the matrix element vanishes, then that transition is forbidden—at least in the electric dipole approximation. The selection rules then depend on this matrix element and it is the vanishing or nonvanishing of this matrix element that can be predicted by group theory without actual calculation.

Let us assume that the initial quantum state of the electron $|i\rangle$ in the hydrogen atom making the transition is the central field state $U_{nl_im_i}$, and that the final state it jumps into is $|1\rangle U_{nl_fm_f}$. The matrix element is explicitly

$$e\int U^*_{nl_fm_f}(e\mathbf{z})U_{nl_im_i}\,d\tau. \tag{67}$$

Now $U_{nl_im_i}$ is the basis function which belongs to the m_ith row of the $D^{(li)}$ irreducible representation of the rotation group. The operator $\mathbf{z}$ which is Y_1^0, apart from a constant, belongs to the $D^{(1)}$ representation and the product $zU_{nl_im_i}$ belongs to the direct product $D^{(1)}\times D^{(li)}$. More precisely, $zU_{nl_im_i}$ is a certain linear combination of the basis functions which generate the representations of the irreducible components of $D^{(1)}\times D^{(li)}$. $U_{nl_fm_i}$ belongs to the m_fth row of the $D^{(lf)}$ representation of SO(3). If $D^{(lf)}$ is not one of the terms in the direct sum into which $D^{(1)}\times D^{(li)}$ decomposes, the matrix element vanishes. According to the Clebsch–Gordan theorem we have

$$D^{(1)}\times D^{(l_i)}=D^{(l_i+1)}\oplus D^{(l_i)}\oplus D^{(l_i-1)}. \tag{68}$$

It is clear that unless $l_f=l_i+1$, l_i, l_i-1, the matrix element vanishes with the exception that when $l_i=0$, l_f can only be $+1$. Furthermore, the central field functions have definite parity. For a reflection operation $x\to-x$, $y\to-y$, $z\to-z$ these functions are even (do not change sign) if l is even, and vice versa. In other words, they are also basis functions of the inversion or parity group. Since z has odd parity, the matrix element vanishes unless $l_f=l_i+1$ or l_i-1. Since l_i cannot equal l_f, it is customary to say that parity should change in an electric dipole transition. Thus the electron can make a transition between a P state and an S state.

If an atom is not free but is in a crystalline field, say of C_{3v} symmetry, the matrix element can be analyzed as follows. The initial state function $\psi_\mu^{(i)}$ belongs to the μth row of the ith irreducible representation of C_{3v} and $\psi_\nu^{(f)}$ belongs to the νth row of the fth representation. From the character table of C_{3v} we see that z belongs to the one-dimensional representation $D^{(A_1)}$ of C_{3v}. Hence the matrix element will vanish unless $D^{(f)}$ occurs in the decomposition of the direct product $D^{(A_1)}\times D^{(i)}$. Without having to apply the systematic reduction formula one can easily see from the character table, for instance,

$$\begin{aligned}D^{(A_1)}\times D^{(A_1)}&=D^{(A_1)}\oplus OD^{(A_2)}\oplus OD^{(E)},\\ D^{(A_1)}\times D^{(A_2)}&=OD^{(A_1)}\oplus D^{(A_2)}\oplus OD^{(E)}.\end{aligned} \tag{69}$$

The coefficients of the sums of the right-hand side of the equation are determined by looking at the appropriate characters on both sides. Thus if $\psi_\mu^{(i)}$ refers to A_1, then $\psi_\nu^{(f)}$ also must have A_1 symmetry and likewise for A_2. Thus A_1-to-A_2 transition, or vice versa, is strictly forbidden in electric dipole radiation.

V. APPLICATIONS IN NUCLEAR PHYSICS

Nuclear physics is somewhat unique in that, because the fundamental interaction between two nucleons is only approximately known, there does not exist one model which can account for all the different phenomena observed experimentally. Thus, for instance, the shell model has successfully predicted the ground-state spins and the observed shell structure of many nuclei. The optical model has been very useful in analyzing neutron scattering. The Bohr–Mottelson model successfully explains the properties of deformed nuclei. It is therefore not surprising that more than one group has been used in understanding the different characteristics of nuclear structure and nuclear levels, and once again the pioneering work was done by Wigner in his theory of supermultiplets proposed in 1937. We will discuss here

1. The construction of the many-particle wavefunction following symmetry principles
2. A model based on the SU (3) group and then comment on recent applications.

In the L–S coupling scheme of central field wave functions the many-particle wave function is a simultaneous eigenfunction of $\vec{\mathrm{L}}^2$, L_z, $\vec{\mathrm{S}}^2$, and S_z where $\vec{\mathrm{L}}$ is a vector sum of orbital angular momenta of all the particles and $\vec{\mathrm{S}}$ the sum of spin operators:

$$\vec{\mathrm{L}} = \sum_i \vec{l}_i, \qquad \vec{\mathrm{s}} = \sum_i \vec{\mathrm{S}}_i. \tag{70}$$

The corresponding Hamiltonian is symmetrical in the interchange of particle coordinates and is free of any spin operators. The Pauli principle restricts the many-particle function to be antisymmetric in the interchange of the coordinates (space as well as spin coordinates) of any two particles because all the nucleons are fermions with spin $\frac{1}{2}$. This implies that, when written as a product of space and spin functions, the function is symmetrical in space coordinates and antisymmetric in spin coordinates and vice versa. To illustrate this let us take a three-nucleon system and consider the spin functions first. Denoting an up-spin state by α and a down-spin state by β and labeling the particles 1, 2, 3, we have both symmetric and antisymmetric functions which are built following the Clebsch–Gordan theorem. Two such functions, one symmetric and the other antisymmetric, in the interchange of 1 and 2 are given below. These are eigenfunctions of S^2 and S_z with eigenvalues $\frac{1}{2}$ and $\frac{1}{2}$:

$$\begin{aligned}\phi_3 \equiv \chi_{1/2}^{1/2} = \frac{1}{\sqrt{6}}\{&2\alpha(1)\alpha(2)\beta(3) - \alpha(2)\alpha(3)\beta(1) \\ &-\alpha(3)\alpha(1)\beta(2)\},\end{aligned} \tag{71}$$

$$\phi_4 \equiv \chi_{1/2}^{1/2} = \frac{1}{\sqrt{2}}\{\alpha(1)\beta(2)\alpha(3) - \alpha(2)\beta(1)\alpha(3)\}.$$

Since the Hamiltonian is symmetric in the coordinates of all particles, its eigenfunctions should be basis functions of the irreducible representations of permutation group, here the group S_3. Two of the representation matrices generated by the above set, together with the respective characters, are

$$\begin{array}{cc} \mathscr{D}(A) & \mathscr{D}(C) \\ \begin{bmatrix} -1/\sqrt{2} & \sqrt{3}/2 \\ \sqrt{3}/2 & 1/2 \end{bmatrix}, & \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}. \\ \chi = 0 & \chi = 0 \end{array} \tag{72}$$

We have seen that the most straightforward way of generating basis functions for irreducible representations, starting with any arbitrary function, is by means of projection operators. For the permutation group there is an elegant theory of Young tableaux for deriving these projection operators. Let us assume three boxes arranged in rows and columns as

$$\begin{array}{cc} \boxed{1} & \boxed{2} \\ \boxed{3} & \end{array} \qquad \begin{array}{cc} \boxed{1} & \boxed{3} \\ \boxed{2} & \end{array} \tag{73}$$

A standard tableau is an arrangement of the numbers 1, 2, 3 in the boxes such that they are in increasing order in rows as well as columns, as shown above. The number of such standard tableaux is the dimensionality of the representation, which in this case is two. Since each diagram is obtained from the other by interchanging rows and columns, these are said to be conjugate to each other. The projection operators corresponding to these two diagrams are

$$\begin{aligned} \mathbf{P}_1 &= \tfrac{1}{3}[E - (13)][E + (12)] \\ &= \tfrac{1}{3}(E + C - B - D), \\ \mathbf{P}_2 &= \tfrac{1}{3}[E - (12)][E + (13)] \\ &= \tfrac{1}{3}(E - C + B - F), \end{aligned} \tag{74}$$

where we used the notation of Section II. Operating with these on $\alpha(1)\alpha(2)\beta(3)$, for instance, generates the basis functions

$$\begin{aligned} &\tfrac{2}{3}\{\alpha(1)\alpha(2)\beta(3) - \alpha(2)\alpha(3)\beta(1)\}, \\ &\tfrac{1}{3}\{\alpha(2)\alpha(3)\beta(1) - \alpha(1)\alpha(3)\beta(2)\}. \end{aligned} \tag{75}$$

The elements A, C of the S_3 group are represented in this basis by the matrix

$$\begin{array}{cc} \mathscr{D}(A) & \mathscr{D}(C) \\ \begin{bmatrix} 0 & -\frac{1}{2} \\ -2 & 0 \end{bmatrix}, & \begin{bmatrix} 1 & 0 \\ 2 & -1 \end{bmatrix}. \\ \chi = 0 & \chi = 0 \end{array} \tag{76}$$

Other matrices can be calculated in a similar manner. The characters show that this representation is equivalent to the one in Eq. (72). Thus linear combinations of functions of the type $\alpha(1)\alpha(2)\beta(3)$ give rise to basis functions identical to the ones in Eq. (71). The functions of the space coordinates can be treated likewise. On the one hand, since the single-particle states are described by central field functions (product of spherical harmonics and appropriate radial function) the three-particle function must be an eigenfunction of $\vec{\mathrm{L}}^2$ and L_z. This means that the latter should be a Clebsch–Gordan-type linear combination of products of single-particle functions. On the other hand, they should be basis functions for the irreducible representations of S_3, which means that these should be obtainable by means of projection operators associated with appropriate Young tableaux. Since the wavefunction, a product of space and spin functions, has to be antisymmetric in the interchange of all the coordinates (space and spin) of any two particles, we need spatially symmetric functions multiplying spin antisymmetric functions and vice versa. The space and spin functions then correspond to conjugate Young diagrams. More details about these can be known from the work of Swamy and Samuel.

A. The Elliott Model

In 1958 Elliott introduced a model of the nucleus wherein the particles move in a common harmonic oscillator potential and in addition have a mutual interaction of the quadrupole type. Before writing this Hamiltonian which mathematically describes the model, let us recall some of the features of the nonrelativistic isotropic harmonic oscillator in three dimensions discussed earlier. The simultaneous eigenfunctions of energy and angular momentum have the central field form

$$U_{nlm}(\vec{\mathrm{r}}) = Y_l^m(\theta,\ \phi)R_{nl}(r), \tag{77}$$

which means three quantum numbers define a single state. While the energy levels are equally spaced they are degenerate. The ground state is nondegenerate, but the higher excited states have degeneracies 3, 6, 10, etc., which is the underlying basis for the shell structure. These states are labeled $1s$, $1p$ ($2s$, $1d$), ($2p$, $1f$), and so on. Because of the presence of Y_l^m as a factor, these are basis functions for the irreducible representation of the rotation group (the orbital angular momentum group), the Hamiltonian being invariant to rotations in space. However, as we saw earlier, the bigger group is SU(3) with eight infinitesimal generates H_1, H_2, E_1, E_{-1}, E_2, E_{-2}, E_3, E_{-3} satisfying the Lie algebra appropriate to this group, and commuting with the Hamiltonian of the oscillator. The Casimiar operator **C** is simply the sum of squares of these eight operators and this commutes with every generator of the group. As Lipkin has shown, the Elliott Hamiltonian can be written

$$\mathbf{H} = H_0 + \lambda_1 V\mathbf{C} + \lambda_2 V\vec{\mathrm{L}}^2, \tag{78}$$

where λ_1 and λ_2 are constants and V is related to the strength of the quadrupole interaction between two particles. H_0 describes the independent particle motion in an oscillator potential. The additional terms are intended to remove some of the degeneracies associated with H_0; in other words, the SU(3) multiplets are split. Since the added terms commute with H_0 the eigenfunction of H is also simultaneously an eigenfunction of **C** as well as the angular momentum $\vec{\mathrm{L}}^2$. The required eigenfunctions are chosen to make sure that they are SU(3) multiplet states and within these multiplets they are also eigenfunctions of the angular momentum $\vec{\mathrm{L}}^2$. Since the energy levels corresponding to the eigenvalues of $\vec{\mathrm{L}}^2$ are in the nature of rotational energy level, each SU(3) multiplet constitutes a rotational band. Thus the rotational spectrum, which is assumed to be due to collective motions of the nuclear particles, is derivable from an SU(3)-type independent-particle shell model under the assumption of a quadrupole two-body interaction. Experiments have shown, for instance, that in ^{20}Ne (whose outer nucleons can be considered to be in the $2s$–$1d$ harmonic oscillator shell) there are excited levels, corresponding to a rotational spectrum, of energies 9.48 MeV(2^+), 10.24 MeV(2^+), 10.64 MeV(6^-), 11.99 MeV(8^+), and so on.

We conclude this section by remarking that currently much research activity is related to supersymmetries such as $U(6/4)$ and $U(6/12)$ starting with the interacting boson model initiated by Iachello and Arima. In the original interacting boson model the valence neutrons and protons, which are fermions individually, are paired into "s" and "d" bosons in even–even nuclei, similar to Cooper pairs in the theory of superconductivity. The $U(6/4)$ is extended

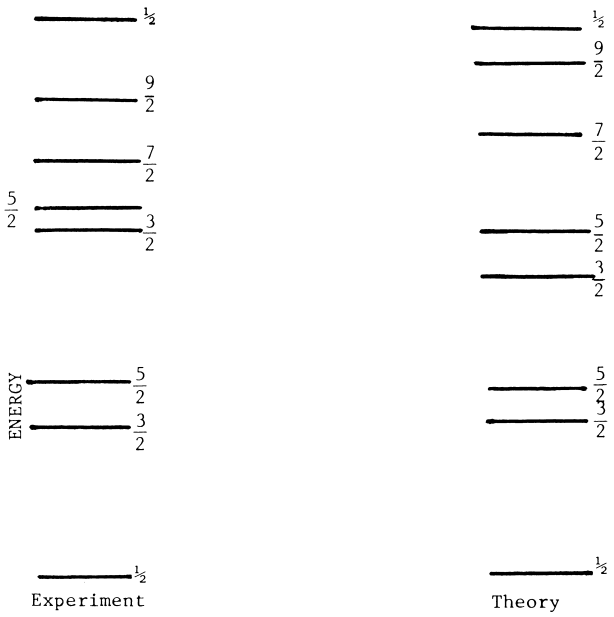

FIGURE 4 Experimental and theoretical levels of ^{195}Pt.

to $U(6/12)$ to include fermions and account for the spectra of odd–even nuclei as well. In Fig. 4 we show the success of this model in predicting the level structure of ^{195}Pt. The levels in this figure are not, however, drawn to the exact scale of numerical energies.

VI. APPLICATIONS IN MOLECULAR AND SOLID-STATE PHYSICS

A. Normal Modes of Vibration in Molecules

The application of group theory to the vibrations of symmetrical molecules was done by Wigner, who analyzed the normal modes of tetrahedral methane. We will illustrate his method by studying the vibrations of an OL_4-type molecule having a C_{4v} symmetry. Stephenson and Jones made an experimental study of the vibrational spectra of BrF_5 and concluded from its features that this molecule should have C_{4v} symmetry. The geometric arrangement of the five atoms in the OL_4 arrangement is shown in Fig. 5. In the case of BrF_5, the fifth fluorine atom is vertically above the bromine atom which is located at the pyramidal point O in the figure. The elements of this group of order $g = 8$ are the identity E (E), three cyclic rotations through angles $2\pi/4$, $4\pi/4$, and $6\pi/4$, respectively ($C_4 = M$, $C_4^2 = N$, $C_4^3 = P$), about the Z axis passing through the point O, reflections in vertical planes XZ and YZ (Q and S, respectively), and two reflections in vertical planes containing O and the diagonal L_1L_3 and L_2L_4 (T and U, respectively). Reflections, or improper rotations so-called, are treated as rotations through the angle 0° in this analysis. The group has five classes $K_1(E)$, $K_2(N_4)$, $K_3(M_4, P_4)$, $K_4(Q, S)$, and $K_5(T, U)$, and therefore has five irreducible representations. Two of these are one-dimensional A_1, A_2 symmetric with respect to the cyclic

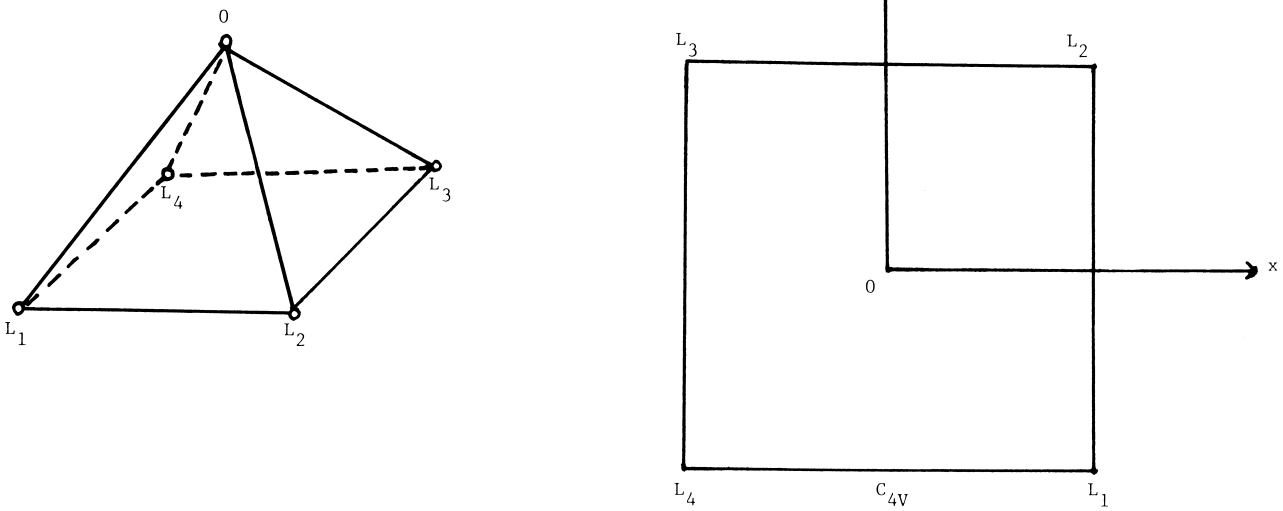

FIGURE 5 Arrangement of atoms in OL_4 molecule. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979). "Group Theory Made Easy for Scientists and Engineer," Wiley-Interscience, New York. Copyright 1979 John Wiley and Sons.]

axis, two antisymmetrical one-dimensional representations B_1 and B_2, and a degenerate two-dimensional representation. The subscripts 1 and 2 and A and B indicate whether it is symmetric or antisymmetric with respect to the vertical reflections. Wigner's fundamental demonstration has been that the allowed normal modes of any molecule with a certain symmetry (belonging to a group) should correspond to the symmetries of these irreducible representations and none else.

According to the theory of small vibrations in classical mechanics, a system of N particles connected by springs can have only $3N-6$ normal modes unless all the particles are in one line. In the case of BrF_5 this means 12 frequencies, and these modes should have the symmetries of the C_{4v} representations. We will apply the Wigner prescription to ascertain these symmetries. The first step is to calculate the compound character $\chi(R)$ of each symmetry operation following the rule

$$\begin{aligned}\chi(R) &= (\mu_R - 2)(1 + 2\cos\phi) \\ &\quad \text{for proper rotations,} \\ &= \mu_R(-1 + 2\cos\phi) \\ &\quad \text{for improper rotations.}\end{aligned} \tag{79}$$

Here μ_R indicates the number of atoms left unchanged by that particular group operation. These compound characters as well as the characters of the C_{4v} group (not classwise) are shown in Table VIII. Following the usual reduction formula relating characters to compound characters, the number of modes of each symmetry type is

$$N_i = \frac{1}{g}\sum_R \chi(R)\chi_i(R). \tag{80}$$

Calculation shows that there will be $3A_1$, $0A_2$, $1B_1$, $2B_2$, and three sets of degenerate E-type vibrations. For instance, for the A_1 type we have

$$\begin{aligned}N_{A_1} &= \tfrac{1}{8}[(12\times 1) + (1\times 0) + (1\times 0) + (1\times 0) \\ &\quad + (2\times 1) + (2\times 1) + (4\times 1) + (4\times 1)] \\ &= 3\end{aligned} \tag{81}$$

Since the E type are doubly degenerate, we notice that we have accounted for all 12 frequencies. Pictures of the modes of vibration of all important symmetry types are found in the classic work of Herzberg. The transformation properties of the components of the dipole moment vector (essentially x or y or z) and the components of the polarizability tensor (xz, yz, $x^2 - y^2$, etc.) determine whether these modes are Raman active or infrared active. From the character table we notice that both these sets of components transform as the A_1 and E representations, whereas only the components of the polarizability tensor have the B-type symmetries. Thus the A_1 and E modes are both Raman and infrared active, whereas B_1 and B_2 are only Raman active. The experimentally measured frequencies of Stephenson and Jones (expressed in units of cm^{-1}) are 365, 572, 683 (A type), 315, 481, 536 (B type), 244, 415, 626 (E type).

It is important to note that group theory predicts only the symmetries of the normal modes but not their numerical frequencies. One needs to solve the secular determinant to obtain these frequencies and even then the numerical values are dependent on assumed force constants between the atoms. In general the calculation is cumbersome, but considerable reduction in labor and time will result if "symmetry-adapted eigenfunctions (symmetry coordinates)" are used in the evaluation of the individual matrix elements. These latter set of functions are easily obtained by means of projection operators. Four of the representations are one-dimensional and we give

TABLE VIII Characters and Compound Characters of C_{4v}

	E	M	N	P	Q	S	T	U
A_1 z, x^2+y^2, z^2	1	1	1	1	1	1	1	1
A_2	1	1	1	1	−1	−1	−1	−1
B_1 x^2-y^2	1	−1	1	−1	1	1	−1	−1
B_2 xy	1	−1	1	−1	−1	−1	1	1
E $(x,\ y)(xz,\ yz)$	2	0	−2	0	0	0	0	0
ϕ	0°	90°	180°	270°	0°	0°	0°	0°
$\pm 1 + 2\cos\phi$	3	1	−1	1	1	1	1	1
μ_R	6	2	2	2	2	2	4	4
$\chi(R)$	12	0	0	0	2	2	4	4

a set of irreducible representation matrices for the two-dimensional E representation:

$$\underset{\mathscr{D}(E)}{\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}}, \quad \underset{\mathscr{D}(M)}{\begin{bmatrix}0 & -1\\ 1 & 0\end{bmatrix}}, \quad \underset{\mathscr{D}(N)}{\begin{bmatrix}-1 & 0\\ 0 & -1\end{bmatrix}}, \quad \underset{\mathscr{D}(P)}{\begin{bmatrix}0 & 1\\ -1 & 0\end{bmatrix}},$$

$$\underset{\mathscr{D}(Q)}{\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}}, \quad \underset{\mathscr{D}(S)}{\begin{bmatrix}-1 & 0\\ 0 & 1\end{bmatrix}}, \quad \underset{\mathscr{D}(T)}{\begin{bmatrix}0 & -1\\ -1 & 0\end{bmatrix}}, \quad \underset{\mathscr{D}(V)}{\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}}. \tag{82}$$

Applying formula (14), we can readily obtain the projection operators

$$\begin{aligned}
P_{A_1} &= \tfrac{1}{8}\{E + M + N + P + Q + S + T + U\},\\
P_{B_1} &= \tfrac{1}{8}\{E - M + N - P + Q + S - T - U\},\\
P_{B_2} &= \tfrac{1}{8}\{E - M + N - P - Q - S + T + U\},\\
P_{E_1} &= \tfrac{1}{4}(E - N + Q - S),\\
P_{E_2} &= \tfrac{1}{4}(E - N - Q + S).
\end{aligned} \tag{83}$$

A convenient set of symmetry coordinates is easily obtained by simply applying these projection operators to the changes in the various bond lengths and bond angles of the molecule (Table VIII).

B. Brillouin Zones and Compatibility Relations

Because of the lattice structure, an electron moves in a periodic electric potential field in the solid and the Hamiltonian describing its motion has the form

$$\mathbf{H} = -\left(\frac{h^2}{2m}\right)\nabla^2 + V(\vec{\mathrm{r}}), \tag{84}$$

where $V(\vec{\mathrm{r}})$ satisfies the periodicity condition

$$V(\vec{\mathrm{r}} + \vec{\mathrm{a}}) = V(\vec{\mathrm{r}}). \tag{85}$$

Here $\vec{\mathrm{a}}$ describes the periodicity of the lattice in three dimensions. This Hamiltonian has translational invariance and its eigenfunctions are basis functions for the irreducible representations of the group of translations in space. Bloch showed that group theory requires the stationary-state solution $\psi_{\vec{\mathrm{k}}}$ of the Schrödinger equation,

$$\mathbf{H}\psi_{\vec{\mathrm{k}}}(\vec{\mathrm{r}}) = E\vec{\mathrm{k}}\psi_{\vec{\mathrm{k}}}(\vec{\mathrm{r}}), \tag{86}$$

be of the form

$$\psi_{\vec{\mathrm{k}}}(\vec{\mathrm{r}}) = e^{i\vec{\mathrm{k}}\cdot\vec{\mathrm{r}}}U_{\vec{\mathrm{k}}}(\vec{\mathrm{r}}), \tag{87}$$

where $U_{\vec{\mathrm{k}}}$ is a periodic function with the periodicity of the lattice. This translational symmetry of the crystal is in addition to its point group symmetry of the lattice, whose elements are those rotations and reflections which always leave one point fixed. The point group is the local symmetry at the site of an atom. In an earlier section we discussed how the symmetry of the crystalline field splits the degenerate energy levels of a free atom when this is in a crystal. The complete set of symmetry operations carrying a crystal into itself, including translations and the point group operations, is known as the space group.

The eigenvalues $E(\vec{\mathrm{k}})$ are such that there are planes of energy discontinuity in $\vec{\mathrm{k}}$ space which are the boundaries of a volume, the Brillouin zone. The translational symmetry enables one to consider a single unit cell in $\vec{\mathrm{k}}$ space known as the first Brillouin zone or the reduced zone with the corresponding reduced wave vector. Bouckaert, Smoluchowski, and Wigner studied the symmetry properties of the Brillouin zone and derived "compatibility relations" between adjoining points, lines, and planes of symmetry. These relations are of fundamental importance in the analysis of solid-state experiments. For instance, energy-band calculations become considerably simplified for states along symmetry lines and at symmetry points in the Brillouin zone. Selection rules for the absorption of polarized electromagnetic radiation depend on the symmetry associated with a given point in the reduced zone. In the analysis of the vibronic spectra of doped crystals, vibronic selection rules need to be determined for phonons at various points in the Brillouin zone, and compatibility relations are indispensable for doing this. We now discuss these compatibility relations.

The Bloch function is a product of two factors, the phase function $e^{i\vec{\mathrm{k}}\cdot\vec{\mathrm{r}}}$ which determines what is known as the "star of $\vec{\mathrm{k}}$" and the periodic function $U_{\vec{\mathrm{k}}}$ which determines the "small representations" of the "group of the wave vector $\vec{\mathrm{k}}$." The "star of $\vec{\mathrm{k}}$" is the figure one obtains when a given wave vector $\vec{\mathrm{k}}$ is subjected to all the symmetry operations of the point group. If $\vec{\mathrm{k}}$ terminates on a zone boundary, two points separated by a reciprocal lattice vector are considered identical. Those elements of the point group that leave a $\vec{\mathrm{k}}$ invariant constitute a subgroup called "group of the wave vector." Suppose an irreducible representation Γ_j of the point group is decomposed in terms of the irreducible representations of its subgroup. If Γ_j, a given irreducible representation of the latter, occurs in this decomposition, it is said to be compatible with Γ_j. In band theory, compatibility relates states that can exist together in a single band.

To illustrate the star of $\vec{\mathrm{k}}$ let us assume a two-dimensional square zone, the length of whose side equals a reciprocal lattice vector. Let OE in Fig. 6 be the position of our k vector and let this correspond to the identity element of the group C_{4v} of the square. The other symmetry operations, C_4, C_4^2, C_4^3, σ_x, σ_y, σ_α, and σ_α, take the vector into the positions shown in the figure, which does resemble a

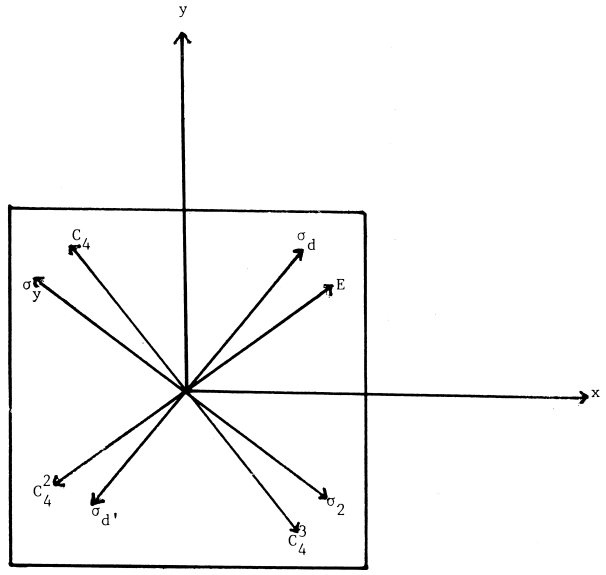

FIGURE 6 Star of $\vec{k}$. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979) "Group Theory Made Easy for Scientists and Engineers," Wiley-Interscience, New York. Copyright 1979 John Wiley and Sons.]

star. Since only the identity element leaves OE alone, the group of the wave vector in this case is just this trivial one (identity) element. Other cases of the star of $\vec{k}$, can be found in Wigner's original paper or the book of Tinkham. To understand the compatibility relations let us consider a Brillouin zone with the symmetry of the simple cubic lattice as in Fig. 7. The wave vector $\vec{k}=0$ (Γ) has a full symmetry O_h, as does the wave vector ΓR in the figure. To establish the compatibility relations between points Γ and Λ consider a k vector which lies at an intermediate position along the body diagonal (line joining Γ and Λ).

T_{1u}	3	0	1	−1	−1	−3	0	−1	1	1
C_{3v}										
A_1	1	1								1
A_2	1	1								−1
E	2	−1								0

This vector is invariant to three rotations C_3, C_3^2, C_3^3 (identity) about this line as the cyclic axis, and reflections in the diagonal planes of the cube passing through this line. These are the six symmetry operations that are elements of O_h and which also leave the wave vector $\Gamma\Lambda$ invariant. It is easy to see that these six operations are elements of the group C_{3v}. The characters of these elements in the irreducible representations of C_{3v} and the characters of the elements of O_h in some of its irreducible representations are given in Table IX. With the use of these characters of the reducible representations in the well-known reduction formula, a trivial calculation shows that

$$\begin{aligned} A_{1g} &= A_1, \qquad E_g = E, \qquad T_{1g} = A_2 + E, \\ A_{1u} &= A_2, \qquad E_u = E, \qquad T_{1u} = A_1 + E. \end{aligned} \tag{88}$$

We thus conclude that A_{1g} is compatible with A_1, E_g with E, A_{1u} with A_2, E_u with E, T_{1g} with A_2, E and T_{1u} with A_1 and E. There is then continuity between the symmetry orbitals at Λ and at Γ.

VII. APPLICATION OF LIE GROUPS IN ELECTRICAL ENGINEERING

The application of the underlying concepts of Lie groups in frequency modulation (FM) in electrical engineering is best described by means of an example. Figure 8 is a block diagram of a Wien bridge $RC(t)$ variable frequency oscillator (VFO) network, where μ is the appropriate amplifier circuit. In the mathematical analysis by Gardner of the modulation rate distortion originating in the VFO, the modulated signal output V_{FM} satisfies a somewhat complicated linear differential equation

$$V_{\mathrm{FM}} + 3\frac{\dot{c}}{c}\dot{V}_{\mathrm{FM}} + \left[\left(\frac{\dot{c}}{c} + \frac{\dot{c}^2}{c^2}\right) + \frac{1}{(Rc)^2}\right]V_{\mathrm{FM}} = 0. \tag{89}$$

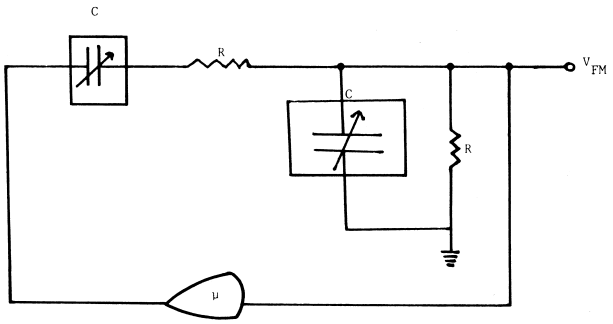

FIGURE 8 Block diagram of Wien bridge oscillator.

Here the dot above a variable means derivative with respect to time. This second-order equation can be transformed into an equivalent matrix differential equation involving coupled first-order quantities by the substitution

$$\begin{aligned} \dot{V}_1 &= -(\dot{c}/c)V_1 = (1/Rc)V_2, \\ \dot{V}_2 &= (1/Rc)V_1 - (\dot{c}/c)V_2, \qquad V_2 = V_{\mathrm{FM}}. \end{aligned} \tag{90}$$

Thus

$$\begin{bmatrix} \dot{V}_1 \\ \dot{V}_2 \end{bmatrix} = \begin{bmatrix} -\dot{c}/c & -1/Rc \\ 1/Rc & -(\dot{c}/c \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix}, \tag{91}$$

which can be written in operator form $d\mathbf{V}/dt = \mathbf{A}(t)\mathbf{V}$. Here $\mathbf{V}$ is a column vector and $\mathbf{A}$ a 2×2 matrix representing the modulator element. This is sought to be solved with the initial condition $\mathbf{V}(0) = \mathbb{I}$. This can be treated as a special case of an abstract operator equation,

$$\frac{d\mathbf{U}}{dt} = \mathbf{A}(t)\mathbf{U}, \qquad \mathbf{U}(0) = I, \tag{92}$$

I being the identity operator. Magnus, and Wei and Norman developed a technique for solving this equation in the special case where $A(t)$ is expandable in terms of the infinitesimal generators $\mathbf{X}_i$ of a certain Lie group. In particular, let $\mathbf{A}(t)$ be written as

$$\mathbf{A}(t) = \sum_{i=1}^{m} a_i(t)\mathbf{X}_i, \qquad m \text{ finite} \tag{93}$$

where the time-independent operators $\mathbf{X}_i$ are the generators of a Lie group. The Lie algebra of the $\mathbf{X}_i$ is given by

$$[\mathbf{X}_\chi, \mathbf{X}_\mu] = \sum_\lambda C^\lambda_{\chi\mu}\mathbf{X}_\lambda \tag{94}$$

$C^\lambda_{\chi\mu}$ being the structure constants defining the group. In the so-called global representation of the solution Wei and Norman show that this is a product of exponentials,

$$\mathbf{U}(t) = \prod_i \exp[g_i(t)\mathbf{X}_i] \tag{95}$$

where the g_i are related to $a_i(t)$ through a set of simple first-order differential equations, and thus the question of solving (92) reduces to solving the latter more simple set of equations. As an illustration, let us assume that $\mathbf{A}(t)$ is the matrix

$$\begin{aligned} \mathbf{A}(t) &= \begin{bmatrix} i(1-\sin t) & e^{2it}\left(\frac{1}{2} - i\cos t\right) \\ -e^{-2it}\left(\frac{1}{2} + i\cos t\right) & -i(1-\sin t) \end{bmatrix}, \\ &= \sum_k a_k(t)\mathbf{X}_k. \end{aligned} \tag{96}$$

It turns out that this particular operator $\mathbf{A}$ can be expanded in terms of the generators of a Lie group isomorphic to the SO(3) group familiar in quantum mechanics, with the defining Lie algebra

$$[\mathbf{X}_i, \mathbf{X}_j] = \varepsilon_{ijk}\mathbf{X}_k. \tag{97}$$

ε_{ijk} is the well-known Levi–Civita tensor symbol, whose components can only assume values $1, -1$, or 0, and Einstein summation convention over repeated indices is implied. In the 2×2 matrix realization the generators are explicitly

$$\begin{aligned} \mathbf{X}_1 &= \begin{bmatrix} i/2 & 0 \\ 0 & -i/2 \end{bmatrix}, \qquad \mathbf{X}_2 = \begin{bmatrix} 0 & 1/2 \\ -1/2 & 0 \end{bmatrix}, \\ \mathbf{X}_3 &= \begin{bmatrix} 0 & i/2 \\ i/2 & 0 \end{bmatrix}. \end{aligned} \tag{98}$$

If we now write

$$U(t) = e^{\alpha\mathbf{X}_1}e^{\beta\mathbf{X}_2}e^{\gamma\mathbf{X}_3} \tag{99}$$

and use the Baker–Hausdorff expansion

$$\begin{aligned} &\exp(\mathbf{X}_1)\mathbf{X}_2\exp(-\mathbf{X}_1) \\ &\quad = \mathbf{X}_2 + [\mathbf{X}_1, \mathbf{X}_2] + \left(\frac{1}{2!}\right)[\mathbf{X}_1[\mathbf{X}_1, \mathbf{X}_2]] + \cdots \end{aligned} \tag{100}$$

we arrive at the defining differential equations for α, β, γ:

$$\begin{aligned} a_1 &= 2 - s\sin(t) = \dot{\alpha} + \dot{\gamma}\sin\beta, \\ a_2 &= \cos(2t) + 2\sin(2t)\cos(t) \\ &= \dot{\beta}\cos\alpha - \dot{\gamma}\sin\alpha\cos\beta, \\ a_3 &= \sin(2t) - 2\cos(2t)\cos(t) \\ &= \dot{\beta}\sin\alpha + \dot{\gamma}\cos\alpha\cos\beta. \end{aligned} \tag{101}$$

$$U(t) = \begin{bmatrix} U_{11} & U_{12} \\ (e^{-it}[\cos t \cos(t/2) - i \sin t \sin(t/2)]) & (e^{it}[\cos t \sin(t/2) - i \sin t \sin(t/2)]) \\ U_{21} & U_{22} \\ -(e^{-it}[\cos t \sin(t/2) + i \sin t \cos(t/2)]) & (e^{-it}[\cos t \cos(t/2) + i \sin t \sin(t/2)]) \end{bmatrix} \tag{102}$$

Solving these leads to the final solution given in Eq. (102) above. If, on the other hand, the given U is treated as a column vector, then either column of the above matrix satisfies the equation with the initial values $\binom{1}{0}$ and $\binom{0}{1}$, respectively.

It is interesting to note that, unlike in quantum mechanics or elementary particle physics, the properties of the Lie group itself do not seem to be amenable to a direct physical interpretation bearing on the behavior of the VFO, although the structure constants that define the group are involved in the differential relations satisfied by the g_i's in the exponential solutions.

VIII. APPLICATIONS IN PARTICLE PHYSICS

Group theory has been important in particle physics since the early 1960s. The hadrons were first classified into charge multiplets (isospin). Then approximate SU(3) symmetry was used to classify the hadrons into larger multiplets. (This is the so-called flavor SU(3).) More recently, in quantum chromodynamics (QCD), exact SU(3) color symmetry is necessary to describe the strong interactions.

A. Unitary Irreducible Representations of SU(2)

Consider the transformation

$$\begin{aligned} U(a,\ b)\colon \begin{bmatrix} u' \\ v' \end{bmatrix} &= U(a,\ b)\begin{bmatrix} u \\ v \end{bmatrix} \\ &= \begin{bmatrix} a^* & -b \\ b^* & a \end{bmatrix}\begin{bmatrix} u \\ v \end{bmatrix}, \end{aligned} \tag{103}$$

with $|a|^2 + |b|^2 = 1$. U is thus a unitary matrix, $U^{-1} = U^+$, and is an element of the SU(2) group. To obtain the unitary irreducible representations consider the basis polynomials (functions of u and v)

$$f_j^m = \frac{u^{J+m} v^{J-m}}{\sqrt{(J+m)!(J-m)!}}, \qquad m = -J, \ldots, +J,$$

and

$$\begin{aligned} U(a,\ b) f_J^m &= f_J'^m = f_J^m\left[U^{-1}\begin{bmatrix} u \\ v \end{bmatrix}\right] \\ &= \frac{(au + bv)^{J+m}(-b^*u + av)^{J-m}}{\sqrt{(J+m)!(J-m)!}}. \end{aligned} \tag{104}$$

As shown in Hamermesh's (1959) text, a straightforward binomial expansion leads to the relation

$$U(a,\ b) f_J^m = \sum_{m'} f_J^{m'} D^J_{m'n}(a,\ b),$$

where the representation matrix $D^J_{m'm}$ is explicitly

$$\begin{aligned} &\sum_k \frac{\sqrt{(J+m)!(J-m)!(J+m')!(J-m')!}}{(J+m-k)!k!(J-m'-k)!(m'-m+k)!} \\ &\quad \times a^{J+m-k} a^{*J-m'-k} b^k (-b^*)^{m'-m+k}. \end{aligned} \tag{105}$$

We now show that the representation is unitary. The normalization of the f_J^m was chosen so that

$$\begin{aligned} &\sum_{m=-J}^{J} f_J^m \left(f_J^m\right)^* \\ &\quad = \sum_{m=-J}^{J} \frac{1}{(J+m)!(J-m)!} |u|^{2(J+m)} |v|^{2(J-m)} \\ &\quad = \sum_{k=0}^{2J} \frac{|u|^{2k}|v|^{2(2J-k)}}{k!(2J-k)!} = \frac{(|u|^2 + |v|^2)^{2J}}{(2J)!} \end{aligned} \tag{106}$$

by binomial expansion. Similarly,

$$\begin{aligned} \sum_{m=-J}^{J} f_J^m \left(f_J'^m\right)^* &= \sum_{m=-J}^{J} \left|U(a,b) f_J^m\right|^2 \\ &= \sum_{m=-J}^{J} \frac{|au + bv|^{2(J+M)} \times |-b^*u + a^*v|^{2(J-M)}}{(J+m)!(J-m)!} \\ &= \frac{(|u|^2 + |v|^2)(|a|^2 + |b|^2)}{(2J)!} \\ &= \frac{(|u|^2 + |v|^2)}{(2J)!} = \sum_{m=-J}^{J} \left|f_J^m\right|^2. \end{aligned} \tag{107}$$

Therefore,

$$\sum_{m=-J}^{J}\sum_{m'} f_J^{m'} D^J_{m'n} \sum_{m''} \left(f_J^{m''}\right)^* \left(D^J_{m''m}\right) = \sum_{m=-J}^{J} f_J^m \left(f_J^m\right)^*. \tag{108}$$

Since the $(2J+1)^2$ functions $f_{m'}(f_{m''})^*$ are linearly independent, the representation matrices must satisfy

$$\sum_{m=-J}^{J} D^J_{m'm}\left(D^J_{m''m}\right)^* = \delta_{m'm''}. \tag{109}$$

That is, $DD^+ = I$ and the representation are unitary.

One can show that a matrix A which commutes with all matrices of the representation $D^J(a,\ b)$ must be a multiple of the unit matrix. Hence, by Schur's lemma, the representation matrices $D^J(a,\ b)$ are irreducible.

B. Glebsch–Gordan Coefficients for SU(2) and Isospin

The SU(2) group has three infinitesimal generators, J_1, J_2, and J_3, and the Casimir invariant $J^2 = J_1^2 + J_2^2 + J_3^2$. The $(2j+1)$-dimensional representations $D^{(j)}$ are generated by the basis functions $|jm\rangle$, where the labels are, respectively, the eigenvalues of $J^2(j(j+1))$ and $J_3(m)$. The electron spin in quantum mechanics is an outstanding example of SU(2) symmetry. Consider two different irreducible representations $D^{(j_1)}$ and $D^{(j_2)}$ (say, e.g., two electron spins). $D^{(j_1)} \times D^{(j_2)}$, a direct product of the two representations, is, in general, reducible. The Clebsch–Gordan (C–G) theorem essentially relates to the reduction of the representation

$$D^{(j_1)} \times D^{(j_2)} = \textstyle\sum_J D^{(J)} \quad \text{where } |j_1 + j_2| \leqq J \leqq (j_1 + j_2), \tag{110}$$

$$|JM\rangle = \textstyle\sum_{m_1 m_2} \langle j_1 m_1 j_2 m_2 | JM\rangle |j_1 m_1\rangle |j_2 m_2\rangle, \tag{111}$$

where $|j_1 m_1\rangle$ are the basis functions of the irreducible representations $D^{(j_1)}$ and similarly for $|j_2 m_2\rangle$; $|JM\rangle$ are the basis functions of the irreducible representations $D^{(J)}$; $\langle j_1 j_2 m_1 m_2 | JM\rangle$ are real numbers called C–G (or Wigner) coefficients.

This corresponds to the quantum mechanical vector addition of two commuting angular momentum vectors $\vec{\mathrm{J}}_1 + \vec{\mathrm{J}}_2 = \vec{\mathrm{J}}$. The derivation of these coefficients is given in several textbooks and Wigner's well-known classic (1959). Here we give instead a brief demonstration by induction for the case $j_2 = \frac{1}{2}$.

According to the C–G theorem we have

$$\begin{aligned}\left|J = j_1 + \frac{1}{2}, M = m\right\rangle &= \sqrt{\frac{j_1 + m + \frac{1}{2}}{2j_1 + 1}}\left|j_1, m_1 = m - \frac{1}{2}\right\rangle \\ &\times \left|j_2 = \frac{1}{2}, m_2 = \frac{1}{2}\right\rangle + \sqrt{\frac{j_1 - m + \frac{1}{2}}{2j_1 + 1}} \\ &\times \left|j_1, m_1 = m + \frac{1}{2}\right\rangle\left|j_2 = \frac{1}{2}, m_2 = -\frac{1}{2}\right\rangle,\end{aligned} \tag{112}$$

$$\begin{aligned}\left|j_1 - \frac{1}{2}, m\right\rangle &= -\sqrt{\frac{j_1 - m + \frac{1}{2}}{2j_1 + 1}} \\ &\times \left|j_1, m_1 = m - \frac{1}{2}\right\rangle\left|\frac{1}{2}\frac{1}{2}\right\rangle \\ &+ \sqrt{\frac{j_1 + m + \frac{1}{2}}{2j_1 + 1}}\left|j_1, m - \frac{1}{2}\right\rangle\left|\frac{1}{2} - \frac{1}{2}\right\rangle.\end{aligned} \tag{113}$$

It is true for $m_1 + \frac{1}{2}$; $|j_1 + \frac{1}{2},\ j_1 + \frac{1}{2}\rangle = |j_1 j_1\rangle|\frac{1}{2}\frac{1}{2}\rangle$. Assume it is true for m. We now show it is true for $m-1$. Once a basis function of a representation $D^{(j)}$ is known, its partners can be generated by means of step-up and step-down operators J_+ and J_- that satisfy

$$J_\pm |j_1 j_3\rangle = \sqrt{(j \pm j_3)(j \pm j_3 + 1)}\,|j_1 j_3 \pm 1\rangle. \tag{114}$$

Similar relations are well known in quantum mechanics where, for instance, $|l\mathrm{m}\rangle$ will be a spherical harmonic when J refers to the orbital angular momentum. Incidentally, it is important to note that SU(2) is the covering group for the three-dimensional rotation group $O(3)$ to which the spherical harmonics belong. Operating with $(\boldsymbol{J}_1 + \boldsymbol{J}_2)_- = J_-$ on the state $|j_1 + \frac{1}{2},\ m\rangle$ we have

$$\begin{aligned}J_-\left|j_1 + \frac{1}{2}, m\right\rangle &= \sqrt{\frac{j_1 + m + \frac{1}{2}}{2j_1 + 1}} \\ &\times \left\{\sqrt{\left(j_1 + m - \frac{1}{2}\right)\left(j_1 - m + \frac{3}{2}\right)}\right. \\ &\times \left|j_1, m - \frac{3}{2}\right\rangle\left|\frac{1}{2}, \frac{1}{2}\right\rangle \\ &+ \left.\left|j_1, m - \frac{1}{2}\right\rangle\left|\frac{1}{2}, -\frac{1}{2}\right\rangle\right\}\end{aligned}$$

$$
\begin{aligned}
&+\sqrt{\frac{j_1-m+\frac{1}{2}}{2j_1+1}}\\
&\times\sqrt{(j_1+m+\tfrac{1}{2})(j_1-m+\tfrac{1}{2})}\\
&\times\left|j_1, m-\frac{1}{2}\right\rangle\left|\frac{1}{2}, -\frac{1}{2}\right\rangle\\
=&\sqrt{\frac{j_1-m+\frac{1}{2}}{2j_1+1}}(j_1+m-\tfrac{1}{2})\\
&\times\left(j_1-m+\frac{3}{2}\right)\left|j_1, m-\frac{3}{2}\right\rangle\\
&\times\left|\frac{1}{2}, \frac{1}{2}\right\rangle+\left(j_1-m+\frac{3}{2}\right)\\
&\times\left|j_1, m-\frac{1}{2}\right\rangle\left|\frac{1}{2}, -\frac{1}{2}\right\rangle. \qquad (115)
\end{aligned}
$$

The representations being unitary, the basis functions must be orthonormal. We normalize Eq. (115) by multiplying it with the factor

$$\frac{1}{\sqrt{(j_1+m+\frac{1}{2})(j_1-m+\frac{3}{2})}}$$

and obtain

$$
\begin{aligned}
\left|j_1+\frac{1}{2}, m-1\right\rangle=&\sqrt{\frac{j_1+m-\frac{1}{2}}{2j_1+1}}\left|j_1, m-\frac{3}{2}\right\rangle\left|\frac{1}{2}\frac{1}{2}\right\rangle\\
&+\sqrt{\frac{j_1-m+\frac{3}{2}}{2j_1+1}}\left|j_1, m-\frac{1}{2}\right\rangle, \left|\frac{1}{2}, -\frac{1}{2}\right\rangle, \qquad (116)
\end{aligned}
$$

and this means that the result is true for $m-1$, and therefore true for all m. In particular, when $m=j_1-\frac{1}{2}$ we have

$$
\begin{aligned}
\left|j_1+\frac{1}{2}, j_1-\frac{1}{2}\right\rangle=&\sqrt{\frac{2j_1}{2j_1+1}}|j_1, j_1-1\rangle\left|\frac{1}{2}, \frac{1}{2}\right\rangle\\
&+\sqrt{\frac{1}{2j_1+1}}|j_1, j_1\rangle\left|\frac{1}{2}, -\frac{1}{2}\right\rangle. \qquad (117)
\end{aligned}
$$

Now for the case $j=j_1-\frac{1}{2}$ we note that the basis function $|j_1-\frac{1}{2}, j_1-\frac{1}{2}\rangle$ must be normalized and orthogonal to the above state. Equation (114) gives, with $m=j_1-\frac{1}{2}$,

$$
\begin{aligned}
\left|j_1-\frac{1}{2}, j_1-\frac{1}{2}\right\rangle=&-\sqrt{\frac{1}{2j_1+1}}|j_1, j_1-1\rangle\left|\frac{1}{2}, \frac{1}{2}\right\rangle\\
&+\sqrt{\frac{2j_1}{2j_1+1}}|j_1, j_1\rangle\left|\frac{1}{2}, -\frac{1}{2}\right\rangle, \qquad (118)
\end{aligned}
$$

which is indeed orthogonal to $|j_1+\frac{1}{2}, j_1-\frac{1}{2}\rangle$ and is normalized. Hence the equation is correct for $m=j_1-\frac{1}{2}$. By going through a process of induction similar to the one for $j=j_1+\frac{1}{2}$, the proof is readily established.

C. Isospin Clebsch–Gordan Coefficients

Consider the reactions

$$
\begin{aligned}
&(1) \quad \pi^+ + p \to \pi^+ + p\\
&(2) \quad \pi^- + p \to \pi^- + p\\
&(3) \quad \pi^- + p \to \pi^0 + n
\end{aligned}
$$

The C–G expansion is

$$
\begin{aligned}
\left|JM\right\rangle &= \sum_{m_1+m_2=M}\left\langle lm_1\tfrac{1}{2}m_2|JM\right\rangle|lm_2\rangle\left|\tfrac{1}{2}m_2\right\rangle,\\
\left|JM\right\rangle &= \sum_{m_1+m_2=M} C^{JM}_{lm,\frac{1}{2}m_2}|l, m_1\rangle\left|\tfrac{1}{2}, m_2\right\rangle,\\
\left|\tfrac{3}{2}\tfrac{3}{2}\right\rangle &= |1,\ 1\rangle\left|\tfrac{1}{2},\ \tfrac{1}{2}\right\rangle,\\
\left|\tfrac{3}{2}\tfrac{1}{2}\right\rangle &= \sqrt{\tfrac{1}{3}}|1,\ 2\rangle\left|\tfrac{1}{2}-\tfrac{1}{2}\right\rangle+\sqrt{\tfrac{2}{3}}|1,\ 0\rangle\left|\tfrac{1}{2}\tfrac{1}{2}\right\rangle,\\
\left|\tfrac{3}{2}-\tfrac{1}{2}\right\rangle &= \sqrt{\tfrac{1}{3}}|1,\ -1\rangle\left|\tfrac{1}{2}\tfrac{1}{2}\right\rangle+\sqrt{\tfrac{2}{3}}|1,\ 0\rangle\left|\tfrac{1}{2}-\tfrac{1}{2}\right\rangle,\\
\left|\tfrac{3}{2}-\tfrac{3}{2}\right\rangle &= |1\ -1\rangle\left|\tfrac{1}{2}-\tfrac{1}{2}\right\rangle,\\
-\left|\tfrac{1}{2},\ \tfrac{1}{2}\right\rangle &= \sqrt{\tfrac{1}{3}}\left|\tfrac{1}{2},\ \tfrac{1}{2}\right\rangle|1,\ 0\rangle-\sqrt{\tfrac{2}{3}}\left|\tfrac{1}{2}-\tfrac{1}{2}\right\rangle|1,\ 1\rangle,\\
\left|\tfrac{1}{2},-\tfrac{1}{2}\right\rangle &= \sqrt{\tfrac{1}{3}}\left|\tfrac{1}{2}-\tfrac{1}{2}\right\rangle|10\rangle-\sqrt{\tfrac{2}{3}}\left|\tfrac{1}{2}\tfrac{1}{2}\right\rangle|1,\ -1\rangle. \qquad (119)
\end{aligned}
$$

Identifying,

$$
\begin{aligned}
|11\rangle &= |\pi^+\rangle,\\
|10\rangle &= |\pi^0\rangle,\\
|1-1\rangle &= |\pi^-\rangle, \qquad (120)\\
\left|\tfrac{1}{2}\tfrac{1}{2}\right\rangle &= |\mathrm{p}\rangle,\\
\left|\tfrac{1}{2}-\tfrac{1}{2}\right\rangle &= |\mathrm{n}\rangle.
\end{aligned}
$$

One obtains

$$
\begin{aligned}
\left|\tfrac{3}{2},\ \tfrac{3}{2}\right\rangle &= |p,\ \pi^+\rangle,\\
\left|\tfrac{3}{2},\ \tfrac{1}{2}\right\rangle &= \sqrt{\tfrac{1}{3}}|n,\ \pi\rangle+\sqrt{\tfrac{2}{3}}|p,\ \pi^0\rangle,
\end{aligned}
$$

$$
\begin{aligned}
\left|\tfrac{3}{2}, -\tfrac{1}{2}\right\rangle &= \sqrt{\tfrac{1}{3}}|p,\ \pi\rangle + \sqrt{\tfrac{2}{3}}|n,\ \pi^0\rangle \\
\left|\tfrac{3}{2}, -\tfrac{3}{2}\right\rangle &= |n,\ \pi^-\rangle, \\
\left|\tfrac{1}{2}, \tfrac{1}{2}\right\rangle &= \sqrt{\tfrac{2}{3}}|n,\ \pi^+\rangle - \sqrt{\tfrac{1}{3}}|p,\ \pi^0\rangle, \\
\left|\tfrac{1}{2}, -\tfrac{1}{2}\right\rangle &= \sqrt{\tfrac{1}{3}}|n,\ \pi^0\rangle - \sqrt{\tfrac{2}{3}}|p,\ \pi^-\rangle,
\end{aligned} \tag{121}
$$

$$
\begin{aligned}
|p,\ \pi^+\rangle &= \left|\tfrac{3}{2}, \tfrac{3}{2}\right\rangle, \\
|p,\ \pi^-\rangle &= \sqrt{\tfrac{1}{3}}\left|\tfrac{3}{2}, -\tfrac{1}{2}\right\rangle - \sqrt{\tfrac{2}{3}}\left|\tfrac{1}{2}, -\tfrac{1}{2}\right\rangle, \\
|n,\ \pi^0\rangle &= \sqrt{\tfrac{2}{3}}\left|\tfrac{3}{2}, -\tfrac{1}{2}\right\rangle + \sqrt{\tfrac{1}{3}}\left|\tfrac{1}{2}, -\tfrac{1}{2}\right\rangle,
\end{aligned} \tag{122}
$$

By SU(2) invariance of (isospin conservation in) strong interactions,

$$
\frac{\langle \pi^+ p|T|\pi^+ p\rangle}{\langle \pi^- p|T|\pi^- p\rangle} = \frac{T^{(3/2)}}{\frac{1}{3}T^{(3/2)} + \frac{2}{3}T^{(1/2)}}
$$

and

$$
\frac{\langle \pi^+ p|T|\pi^+ p\rangle}{\langle \pi^0 n|T|\pi^- p\rangle} = \frac{T^{(3/2)}}{\sqrt{\frac{2}{3}}T^{(3/2)} - \sqrt{\frac{2}{3}}T^{(1/2)}}.
$$

At low energy we may take

$$
T^{(1/2)} = 0,
$$

and

$$
\begin{aligned}
&\sigma(\pi^+ p \to \pi^+ p) : \sigma(\pi^- p \to \pi^- p) : \sigma(\pi^- p \to \pi^0 n) \\
&= |\langle \pi^+ p|T|\pi^+ p\rangle|^2 : |\langle \pi^- p|T|\pi^- p\rangle|^2 : |\langle \pi^0 n|T|\pi p\rangle|^2 \\
&= 1 : (1/3)^2 : (\sqrt{2}/3)^2 \\
&= 9 : 1 : 2.
\end{aligned} \tag{123}
$$

In general, for $T^{(1/2)} = 0$,

$$
\sqrt{2}\langle \pi^0 n|T|\pi^- p\rangle + \langle \pi^- p|T|\pi^- p\rangle = \langle \pi^+ p|T|\pi^+ p\rangle.
$$

D. SU(3) and Particle Physics

SU(3) is the group of transformations $\psi'_a = U_{ab}\psi_b$, where U is any unitary, unimodular 3×3 matrix with determinant $\|U\| \neq 0$. This is the group of the three-dimensional isotropic harmonic oscillator in quantum mechanics (see Schiff 1968). In terms of Lie's infinitesimal generators U is given by

$$
U = \exp\left\{ i \sum_{i=1}^{8} \varepsilon_k F_k \right\}
$$

where $F_k \equiv \frac{1}{2}\lambda_k$ are the infinitesimal generators. An explicit matrix form for the λ_k's, due to Gell-Mann, in which λ_3 and λ_8 are diagonal is

$$
\begin{aligned}
\lambda_1 &= \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, & \lambda_2 &= \begin{bmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \\
\lambda_3 &= \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{bmatrix}, & \lambda_4 &= \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix}, \\
\lambda_5 &= \begin{bmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{bmatrix}, & \lambda_6 &= \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}, \\
\lambda_7 &= \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{bmatrix}, & \lambda_8 &= \begin{bmatrix} 1/\sqrt{3} & 0 & 0 \\ 0 & 1/\sqrt{3} & 0 \\ 0 & 0 & 2/\sqrt{3} \end{bmatrix}.
\end{aligned} \tag{124}
$$

The usual structure relations satisfied by these generators are

$$
[F_\alpha,\ F_\beta] = \sum_\gamma C^\gamma_{\alpha\beta} F_\gamma = i \sum_\gamma f_{\alpha\beta\gamma} F_\gamma.
$$

It is more convenient to express the structure constants in terms of $f_{\alpha\beta\gamma}$ rather than $C^\gamma_{\alpha\beta}$. The nonvanishing $f_{\alpha\beta\gamma}$ are

$$
\begin{aligned}
&f_{123} = 1, && f_{246} = \tfrac{1}{2}, && f_{367} = -\tfrac{1}{2}, \\
&f_{147} = \tfrac{1}{2}, && f_{257} = \tfrac{1}{2}, && f_{458} = \sqrt{3}/2 \\
&f_{156} = -\tfrac{1}{2}, && f_{345} = \tfrac{1}{2}, && f_{678} = \sqrt{3}/2,
\end{aligned} \tag{125}
$$

The $f_{\alpha\beta\gamma}$ are odd under permutation of any two indices.

We now define the combinations of generators, using the standard notation $T_\pm$, T_3 for isospin instead of $J_\pm$, J_3:

$$
\begin{aligned}
T_\pm &= F_1 \pm i F_2, \qquad U_\pm = F_6 \pm i F_7, \\
V_\pm &= F_4 \pm i F_5, \\
T_3 &= F_3, \qquad \text{and} \qquad Y = (2/\sqrt{3})F_8.
\end{aligned} \tag{126}
$$

The commutation relations satisfied by these operators can easily be derived. For example,

$$
\begin{aligned}
[T_3, T_\pm] &= [F_3, F_1 \pm i F_2] \\
&= [F_3, F_1] \pm i[F_3, F_2] \\
&= i F_2 \pm F_1 = \pm T_\pm.
\end{aligned}
$$

Similarly,

$$
\begin{aligned}
&[Y, T_\pm] = 0 = [T_3, Y], [T_3, U_\pm] = \mp\tfrac{1}{2}U_\pm, \\
&[Y, U_\pm] = \pm U_\pm,
\end{aligned} \tag{127}
$$

$$[U_+, U_-] = \tfrac{3}{2}Y - T_3 = 2U_3,$$
$$[V_+, V_-] = \tfrac{3}{2}Y + T_3 = 2V_3, \quad \text{etc.}$$

The generators have been chosen so that T_3 and Y are diagonal with eigenvalues t_3 and y. The states ψ are labeled with t_3 and y. The action of the shift operators $T_\pm$, $U_\pm$, and $V_\pm$ on the state $\psi(t_3', y')$ is illustrated on the two-dimensional grid in Fig. 9. The action of $T_\pm$ is determined by the commutation relations

$$[T_3, T_\pm] = \pm T_\pm \qquad \text{and} \qquad [Y, T_\pm] = 0,$$

that of $U_\pm$ by

$$[T_3, U_\pm] = \mp\tfrac{1}{2}U_\pm \qquad \text{and} \qquad [Y, U_\pm] = \pm U_\pm,$$

and that of $V_\pm$ by

$$[T_3, V_\pm] = \pm\tfrac{1}{2}V_\pm \qquad \text{and} \qquad [Y, V_\pm] = \pm V_\pm. \quad (128)$$

One can generate all the states of an irreducible representation by repeated application of the shift operators to any one of them. The irreducible representations can be labeled by the pair of integers (p, q). If one begins at the unique state of maximum t_3, $\psi_{\max}$, the boundary of distribution of occupied sites (states), is p steps long in the -120° direction (i.e., $V_-^{p+1}\psi_{\max} = 0$) and $V_-^p\psi_{\max}$ is proportional to the state at the next corner, moving clockwise along the boundary from $\psi_{\max}$. If one now heads in the $-t_3$ direction, there are q steps until the next corner in the boundary is reached [i.e., $T_-^{q+1}(V_-^p\psi_{\max}) = 0$] and $T_-^q(V_-^p\psi_{\max})$ is proportional to the state at the second corner, clockwise along the boundary from $\psi_{\max}$ (the boundary is always convex).

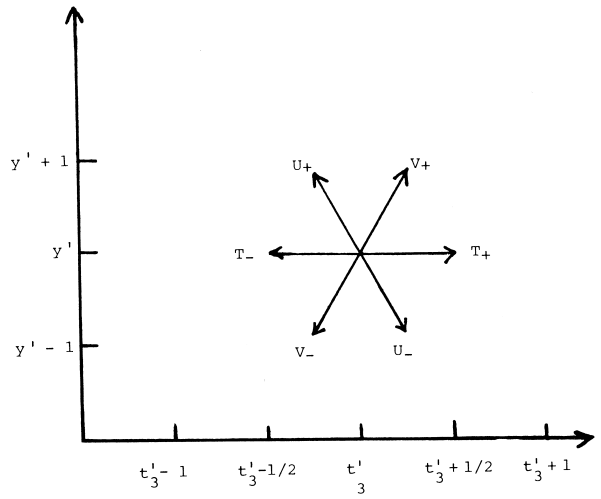

FIGURE 9 Results of shift operations on the state $\psi(t_3', y')$. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979). "Group Theory Made Easy for Scientists and Engineers," Wiley Interscience, New York. Copyright 1979 John Wiley and Sons.]

The multiplicity (dimensionality) of the representation (p, q) is $N = \frac{1}{2}(p+1)(q+1)(p+q+2)$. This can be seen as follows. Consider the case $p > q$. The boundary is, in general, a sixsided figure with sides of length p, q, p, q, p, q as one goes around clockwise from $\psi_{\max}$ and each with interior angles of 120°. There is one state at each site on the boundary. As one moves in from the boundary, each successive six-sided figure has the length of each side reduced by one, and the number of states at each site increased by one. This continues until the short sides are reduced to zero and one has an equilateral triangle with sides of length $(p-q)$ and multiplicity $(q+1)$. As one continues inward now, the multiplicity remains $(q+1)$.

The number of states on the boundary and inside the triangle is

$$(q+1)\sum_{k=1}^{p-q+1} k = \tfrac{1}{2}(q+1)(p-q+1)(p-q+2). \quad (129)$$

The number of states on the six-sided figures is given by

$$3\sum_{k=0}^{q-1}(q-k)(p-q+2k+2).$$

Therefore,

$$\begin{aligned} N &= \frac{1}{2}(q+1)(p-q+1)(p-q+2) \\ &\quad +3\sum_{k=0}^{q=1}(q-k)(p-q+2k-2), \\ &= \frac{1}{2}(p+1)(q+1)(p-q+2) \\ &\quad -\frac{1}{2}q(q+1)(p-q+2) \\ &\quad +3(p-q+2)\frac{1}{2}(q+1)+6\sum_{k=0}^{q-1}(q-k)k. \end{aligned} \quad (130)$$

and since

$$\sum_{k=0}^{q-1}(q-k)k = \tfrac{1}{6}(q+1)q(q-1),$$

we readily get

$$N = \tfrac{1}{2}(p+1)(q+1)(p+q+2).$$

This result, symmetric under interchange of p and q, is also valid for $p < q$.

If one now applies U_+ to the state of maximum t_3, $\psi_{\max}$, one moves along the boundary in the counterclockwise direction, reaching the next corner, ψ' after q steps. These $q+1$ states form a U-spin multiplet of

which $\psi_{\max} = |U = \frac{1}{2}q, u_3 = -\frac{1}{2}q\rangle$ is the lowest state and $\psi' = |U = \frac{1}{2}q, u_3 = +\frac{1}{2}q\rangle$ is the highest state. ψ' carries the maximum value of y that occurs in the representation $y_{\max}$, since continuing counterclockwise from ψ' the (convex) boundary runs parallel to the t_3 axis and then turns downward to smaller values of y, but u_3, y, and t_3 are not independent: $\frac{3}{2}y - t_3 = 2u_3$. Applying this equation to $\psi'(t_3 = \frac{1}{2}p, u_3 = \frac{1}{2}q)$ we find

$$\psi_{\max} = \tfrac{4}{3}\left(\tfrac{1}{3}q\right) + \tfrac{2}{3}\left(\tfrac{1}{2}p\right) = \tfrac{1}{3}(p + 2q). \qquad (131)$$

[The eigenvalue of Y for $\psi_{\max}$ is $\frac{1}{3}(p - q)$]. One can also find the value of t_3 carried by $\psi_{\max}$, $(t_3)_{\max}$ and hence the largest value of t, $t_{\max}$, which occurs in the representation. $t_{\max} = (t_3)_{\max} = \frac{1}{2}(p + q)$, since in moving back from ψ' to $\psi_{\max}$ the value of t_3 increases by $\frac{1}{2}$ for each of the q steps.

One makes here the usual association of the three (3) representation with the quarks and the three-star (3^*) representation with the antiquarks, y with hypercharge $y = B + S$ (B is the baryon number and S the strangeness), and t_3 with the third component of isospin. The formula $y_{\max} = \frac{1}{3}(p + 2q)$ gives $y_{\max} = \frac{1}{3}$ for the three representation, $y_{\max} = \frac{2}{3}$ for the three-star representation. Using $t_{\max} = \frac{1}{2}(p + q)$ one obtains $t_{\max} = \frac{1}{2}$ for both the three and three star. Using the Gell-Mann–Nishijima relation for the charge (in units of the proton charge) $Q = t_3 + \frac{1}{2}y$ we obtain the usual quantum numbers for the quarks and antiquarks (Table X). These representations are shown in Fig. 10. Figure 11 shows the usual association of the octet with the 0^- mesons and the $\frac{1}{2}^+$ baryons (there are other octets with $J^P = 1^-, 2^+$). The octet is easily constructed using the aforementioned rules and the values given by our formulas $y_{\max} = 1$ and $t_{\max} = 1$. The decuplets (Fig. 12) are easily constructed after determining that $t_{\max} = \frac{3}{2}$, $y_{\max} = 1$ for the 10 representation and $t_{\max} = \frac{3}{2}$, $y_{\max} = 2$ for the 10^* representation. The Gell-Mann–Nishijima relation is used to obtain the charges.

TABLE X Quantum Numbers for the Quarks and the Antiquarks

	B	t	t_3	y	S	Q
p	1/3	1/2	1/2	1/3	0	2/3
n	1/3	1/2	−1/2	1/3	0	−1/3
λ	1/3	0	0	−2/3	−1	−1/3
$\bar{p}$	−1/3	1/2	−1/2	−1/3	0	−2/3
$\bar{n}$	−1/3	1/2	1/2	−1/3	0	1/3
$\bar{\lambda}$	−1/3	0	0	2/3	1	1/3

E. Gell-Mann–Okubo Mass Formula

If one assumes that the mass operator is the sum of two terms, one which transforms like a U-spin scalar ($U = 0$) and the other which transforms like $U = 1$ (this is equivalent to the usual "octet enhancement" assumption), one

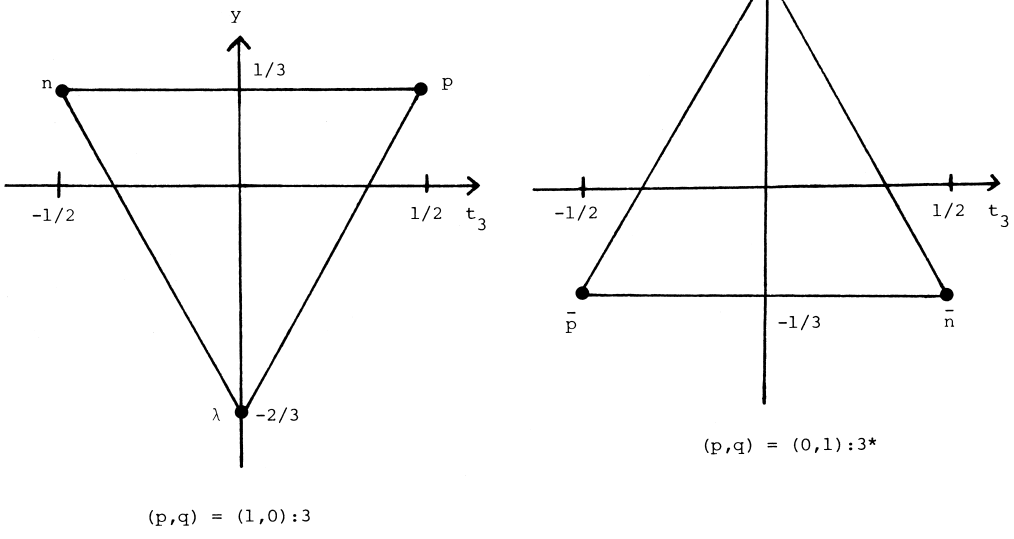

FIGURE 10 The fundamental triplet representation. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979). "Group Theory Made Easy for Scientists and Engineers," Wiley-Interscience, New York. Copyright 1979 John Wiley and Sons.]

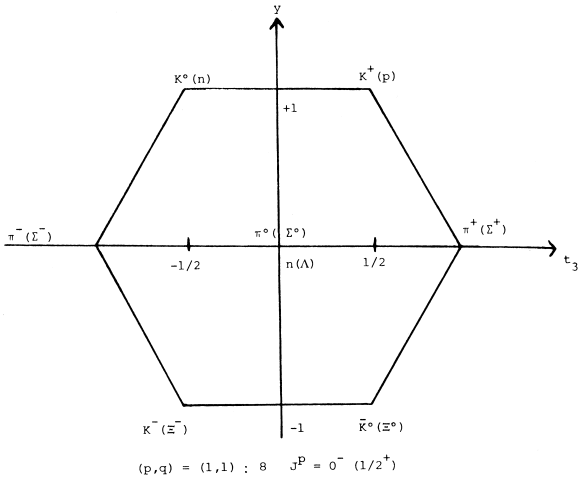

FIGURE 11 The octet. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979). "Group Theory Made Easy for Scientists and Engineers," Wiley-Interscience, New York. Copyright 1979 John Wiley and Sons.]

obtains $M = a + bU_3$ for a given U-spin multiplet. For the $\frac{1}{2}^+$ octet,

$$\begin{aligned} M(\Xi^0) &= a - b, \\ M(\Sigma') &= a = \tfrac{3}{4}M(\Lambda) + \tfrac{1}{4}M(\Sigma^0), \\ M(n) &= a + b, \end{aligned}$$

so that $M(\Xi^0) + M(n) = M(\Sigma')$, which leads to the famous mass formula

$$\tfrac{1}{2}(M(\Xi^0) + M(n)) = \tfrac{1}{4}(3M(\Lambda) + M(\Sigma^0)). \qquad (132)$$

For the 0^- octet the corresponding formula (using M^2 for mesons instead of M) is

$$\begin{aligned} \tfrac{1}{2}(M^2(\bar{k}^0) + M^2(k^0)) &= M^2(k^0) \\ &= \tfrac{1}{4}(3M^2(\eta) + M^2(\pi^0)). \end{aligned} \qquad (133)$$

For the $\frac{3}{2}^+$ decuplet,

$$\begin{aligned} M(\Omega^-) &= a - \tfrac{3}{2}b, \\ M(\Xi^*) &= a - \tfrac{3}{2}b, \\ M(\Sigma^-) &= a + \tfrac{1}{2}b, \\ M(\Delta^-) &= a + \tfrac{3}{2}b, \end{aligned} \qquad (134)$$

which leads to the "equal spacing rule,"

$$\begin{aligned} M(\Omega^-) - M(\Xi^8) &= M(\Xi^*_-) - M(\Sigma^-) \\ &= M(\Sigma^-) - M(\Delta^-). \end{aligned}$$

F. SU(6) and the Quark Model

We have seen that the hadrons fit well into the representations of SU(3). This can be understood well in terms of the quarks (antiquarks) which fit into the fundamental 3 (and 3*) representations of SU(3). We now have to take spin into account. We assume that the quarks are fermions and have spin $\frac{1}{2}$. This gives us naturally the result that the mesons (qq states) have spin 0 or 1 and the baryons (qqq states) have spin $\frac{1}{8}$ or $\frac{3}{2}$

Our six-quark states (Kokkedee) consist of $|p\uparrow\rangle$, $|p\downarrow\rangle|n\uparrow\rangle$, $|n\downarrow\rangle$, $|\lambda\uparrow\rangle$, and $|\lambda\downarrow\rangle$, where the arrows refer to spin-up and spin-down. The SU(6) generalization for qq is

$$[6] \times [6] = [1] + [35]. \qquad (135)$$

The SU(6) singlet has total spin zero. The 35-plet consists of an SU(3) octet with spin 0, another SU(3) octet with spin 1, and an SU(3) singlet with spin 1. This is represented as

$$[6] = \left[\{3\}, \tfrac{1}{2}\right], \qquad [\bar{6}] = \left[\{\bar{3}\}, \tfrac{1}{2}\right], \qquad (136)$$

where the first entry is the SU(3) representation and the second is the spin. With this notation we have

$$[1] = [\{1\}, 0]$$

and

$$[35] = [\{1\}, 1] + [\{8\}, 0] + [\{8\}, 1]. \qquad (137)$$

This accommodates very well the pseudo-scalar meson octet, the vector meson octet, and the vector meson singlet.

For the qqq states the SU(6) expansion is

$$[6] \times [6] \times [6] = [20] + [56] + [70] + [70]. \qquad (138)$$

The expansions in terms of SU(3) representations and spin are

$$\begin{aligned} [20] &= \left[\{1\}, \tfrac{3}{2}\right] + \left[\{8\}, \tfrac{1}{2}\right], \\ [56] &= \left[\{8\}, \tfrac{1}{2}\right] + \left[\{10\}, \tfrac{3}{2}\right], \end{aligned}$$

and

$$[70] = \left[\{1\}, \tfrac{1}{2}\right] + \left[\{8\}, \tfrac{1}{2}\right] + \left[\{8\}, \tfrac{3}{2}\right] + \left[\{10\}, \tfrac{1}{2}\right]. \qquad (139)$$

This describes very well the baryon singlets, octets, and decuplets.

G. Gauge Theories: Applications to Elementary Particle Physics

Group theory plays a very important role in our current understanding of the elementary particles, the basic building blocks of nature, and their fundamental interactions.

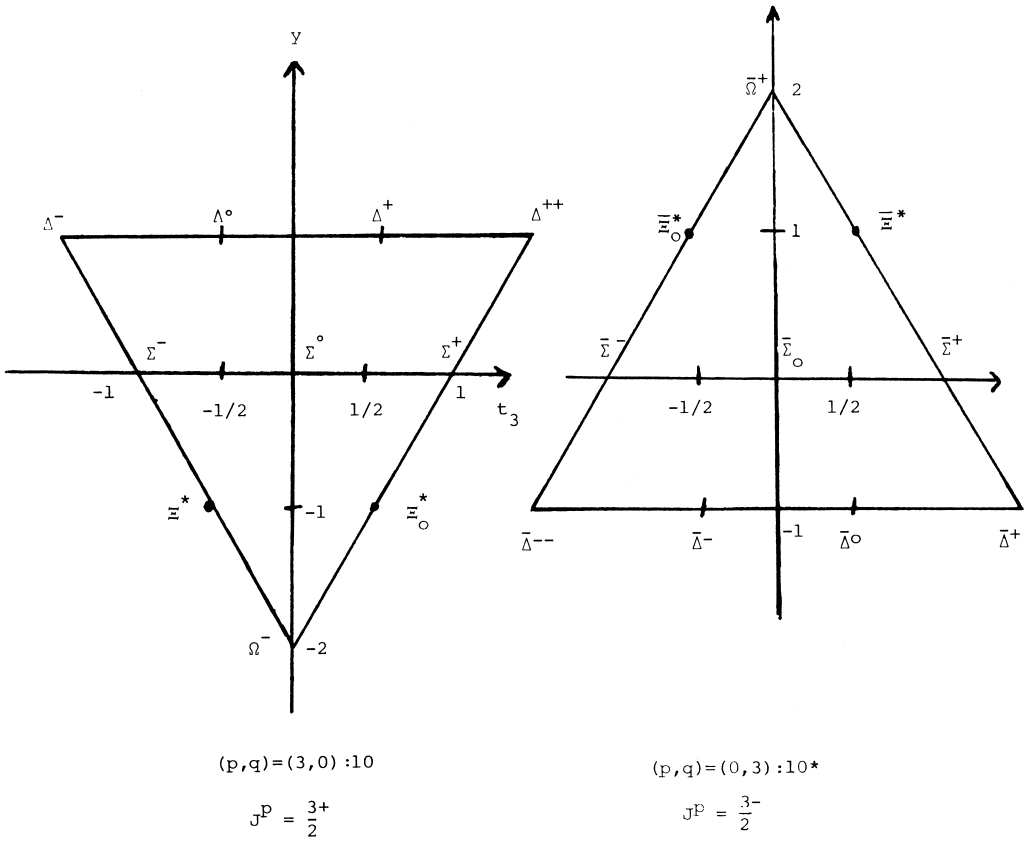

FIGURE 12 The decuplet. [Reprinted with permission from Swamy, N. V. V. J., and Samuel, M. A. (1979). "Group Theory Made Easy for Scientists and Engineers," Wiley-Interscience, New York. Copyright 1979 John Wiley and Sons.]

There are four fundamental interactions, electromagnetic, weak, strong, and gravitational. It is well established now that these are all gauge interactions based on various gauge groups which are continuous Lie groups. All the elementary particles falls neatly with the various representations of the gauge groups. The allowed interactions between the different particles are completely determined by the gauge symmetry, the mathematical requirement that the action be invariant under the transformation of the various fields under these group transformations. Historically, the pioneering step in this development was taken by H. Weyl who proposed (Weyl, Fock) that the electromagnetic interaction, currently known as quantum electrodynamics (QED), is invariant under a local $U(1)$ gauge symmetry. The experimental consequences of this symmetry had been tested to a very high degree of precision. Then, in 1954, Yang and Mills (Yang, Mills) extended this idea to include nonabelian gauge symmetry, such as SU(2), SU(3), etc. One new feature in this generalization is that the gauge bosons belonging to the adjoint representation of the gauge groups now can have interaction among themselves. [Such an interaction is not present in the $U(1)$ gauge symmetry. The photon cannot interact with itself at the tree level.] One problem in pure gauge theories is that all the gauge particles must be massless. While the photon, the gluons, and the graviton are massless, the gauge particles such as weak intermediate vector bosons, $W^{\pm}$, Z are not. Thus, part of the gauge symmetry must be broken so that some of these gauge particles can acquire masses. In 1964, P. Higgs incorporated (Higgs, Englert, Brout, Guralnik, Hagen, Kibble) the idea of spontaneous symmetry breaking with the introduction of additional scalar particles in the theory, called now the Higgs bosons. The self-interaction of these particles (the so-called Higgs potential) is such that the vacuum expectation values of some of these Higgs fields are nonzero and the gauge symmetry is broken spontaneously to a smaller gauge group. As a result, some of the gauge bosons, as well as matter fields, acquire masses. This idea of nonabelian gauge symmetry and the spontaneous symmetry braking was successfully integrated to build a unified theory of weak and electromagnetic interactions (Weinberg, Salam, Glashow). The gauge group is SU(2) $\times$ $U(1)$, which is spontaneously broken to $U_{\mathrm{EM}}(1)$. Thus the theory has one massless gauge

boson, the photon, and three massive gauge bosons, W^+, W^-, and Z. All three were discovered experimentally (Arnison *et al.*) in the CENN proton–antiproton collider at their theoretically predicted masses. All the detailed experimental predictions of this theory have been verified to better than 1% accuracy, and not a single deviation has been found. S. L. Glashow, A. Salam, and S. Weinberg were awarded the Nobel Prize in 1979 for proposing this theory, and C. Rubia and S. Van der Meer were awarded the Nobel Prize in 1984 for the experimental discovery of these theoretically predicted gauge bosons, $W^{\pm}$ and Z.

It is now well established that the protons and neutrons, which are the building blocks of the nuclei, are not elementary particles. They are made of elementary constituents called quarks, bound by interaction through a set of gauge particles called gluons. The gauge symmetry group for this interactions is SU(3), sometimes called SU(3) color. The quarks, antiquarks, and gluons have nonzero color charges under this symmetry, and the gluons can interact with themselves in addition to interacting with the quarks and antiquarks. This theory is called quantum chromodynamics (QCD). This interaction, which is responsible for the binding of three quarks, or a quarks and an antiquark, is very strong at low energy, and is responsible for the confinement of the quarks and gluons. At very high energy, the interaction becomes weaker and the theory becomes asymptotically free (Gross, Wilczek, Politzer). Many predictions of the theory at high energies have been tested experimentally to a good degree of accuracy.

Our current understanding of all three particle interactions, the electromagnetic, weak, and strong, is thus based on the gauge group SU(3) $\times$ SU(2) $\times$ $U(1)$ called the *standard model of particle physics*. All the existing elementary particles, the fermions, and gauge bosons fall neatly into various representations of this gauge group as shown in Table XI, where u_L stands for the left-handed up quark and u_R for the right-handed up quark. The index α is the SU(3) color index and takes the values 1, 2, 3. The same is true for the down quark, d. Here u_L and d_L are doublets under the weak SU(2), with u_L having $I_3 = +\frac{1}{2}$ and d_L having $I_3 = -\frac{1}{2}$. The electron-type neutrino, ν_{eL}, and the electron, e_L, have no color, and are doublets under the weak SU(2). All the right-handed fermions are singlets under SU(2). The last entries in the parentheses represent the values of all the $U(1)$ hypercharges, Y, and are related to the usual electric charge by the relation

$$Q = I_3 + \frac{Y}{2}. \tag{140}$$

Here I_3 is the third component of the weak isospin [the diagonal generator for SU(2)]. Note that all the right-handed particles are singlets under SU(2) weak, and hence they do not participate in the SU(2) weak interaction. This set of 15 chiral fermions $(u_{La}, d_{La}\nu_{eL}, e_L, u_{R\alpha}d_{R\alpha}, e_R)$ constitute what is called the first family of fermions. This is called the electron family. There are two other families, the muon family consisting of $(c_{La}, s_{La}, \nu_{\mu L}, \mu_L, c_{R\alpha}, s_{R\alpha}, \mu_R)$, and the tao family consisting of $(t_{L\alpha}, b_{L\alpha}, \nu_{\tau L}, \tau_L, t_{R\alpha}, b_{R\alpha}, \tau_R)$. The families are exact replica of each other except for the particles masses. The g_a $(a = 1\text{–}8)$ represent the eight gluons, and belong to the adjoint representation of the color SU(3). The weak gauge bosons $A_a (a = 1\text{–}3)$ belong to the adjoint representation of SU(2), and B is the gauge bosons for the $U(1)$ group. The observed gauge bosons $W^{\pm}$ are linear combination of A_1 and A_2, and are given by

$$W^{\pm} = \frac{1}{\sqrt{2}}(A_1 \mp i A_2) \tag{141}$$

while the observed photon γ and the Z boson are linear combinations of A_3 and B,

$$\begin{aligned} \gamma &= B\cos\theta_W + A_3 \sin\theta_W, \\ Z &= -B\sin\theta_W + A_3\cos\theta_W. \end{aligned} \tag{142}$$

The angle θ_W is known as the weak mixing angle. All the experimental observations, at both low and high energy scales (up to few hundred GeV) agree very well with the predictions of the standard model. However, the standard Model has several theoretically unsatisfactory features. Since it is based on the semisimple group containing the product of three group factors, it has three independent gauge couplings associated with gauge groups $U(1)$, SU(2), and SU(3), respectively. It will be theoretically much more beautiful as well as predictive if these three couplings can be unified into a simple group. Such a unification group (Georgi, Glashow, Pati, Salam), such as

TABLE XI Particle Contents of the Standard Model

Particles	SU(3)×SU(2)×U(1) representations
$u_{L\alpha}$	$(3, 2, \frac{1}{3})$
$d_{L\alpha}$	$(3, 2, \frac{1}{3})$
ν_{eL}	$(1, 2, -1)$
e_L	$(1, 2, -1)$
$u_{R\alpha}$	$(3, 1, \frac{4}{3})$
$d_{R\alpha}$	$(3, 1, -\frac{2}{3})$
e_R	$(1, 1, -2)$
g_a	$(8, 1, 0)$
A_a	$\begin{pmatrix} & & +1 \\ 1, & 3, & 0 \\ & & -1 \end{pmatrix}$
B	$(1, 1, 0)$
H	$(1, 2, 1)$

SU(5), has been proposed. This not only relates the three coupling strengths g, g', and g_3, it also predicts many interesting new phenomena such as proton decay, nonzero neutrino masses, matter–antimatter asymmetry etc.

So far, we have left out the gravitational interaction. This is also a gauge theory, the gauge group being that of a general coordinate transformation. Is it possible to unify also the gravity with the three gauge interactions of the standard model? Recent development of a new symmetry, called the supersymmetry (Wess, Zumino, Volkov, Akulov), based on graded Lie algebra, makes such unification not only possible, but a requirement. Supersymmetry is a generalization of a 10-parameter Poincaré group to a 14-parameter super-Poincaré group (Wess, Zumino). It has four additional fermionic generators. Making these fermionic parameters local requires the introduction of gravity. An exciting new development in the 1990s, known as string theory (Polchinski) (which includes local supersymmetry) allows the unification of the standard model with gravity. The most interesting prediction of the superstring theory is that space–time is 10-dimensional, with the extra six dimensions possibly being compact. Below we discuss the formalism of the standard model, grand unification, and supersymmetry in the context of the group theory point of view.

H. Standard Model

1. Quantum Chromodynamics

The standard model (SM) is based on the local gauge symmetry group $\mathrm{SU}(3) \times \mathrm{SU}(2) \times U(1)$. SU(3) corresponds to strong color interactions, while $\mathrm{SU}(2) \times U(1)$ corresponds to electroweak interactions. Let us discuss SU(3) color interactions first. The representations of the quarks and gluons under the SU(3) color are given in Table XI.

The Yang–Mills Lagrangian, for the pure gauge sector involving the gluons only, invariant under the local SU(3) gauge transformations, is given by

$$L_1 = -\tfrac{1}{4} F_{\mu\nu\alpha} F^{\mu\nu\alpha}, \tag{143}$$

where

$$F_{\mu\nu\alpha} = \partial_\mu A_{\nu\alpha} - \partial_\nu A_{\mu\alpha} + g_3 C_{\alpha\beta\gamma} A_{\mu\beta} A_{\nu\gamma}.$$

Here $A_{\mu\alpha}$ are the SU(3) gauge fields belong to the adjoint representation; μ, ν are space–time indices; α, β are the adjoint SU(3) indices ($\alpha, \beta, \gamma = 1$–$8$); g_3 is the coupling constant; and the $C_{\alpha\beta\gamma}$ are the structure constants for SU(3) given by

$$[T_\alpha, T_\beta] = i C_{\alpha\beta\gamma} T_\gamma, \tag{144}$$

where the T_α are the SU(3) generators given by Eq. (124) with $T_\alpha = \frac{1}{2}\lambda_\alpha$. The transformation law for the gauge fields $A_{\mu\alpha}$ is given by

$$A^\alpha_\mu \longrightarrow A'^\alpha_\mu = A^\alpha_\mu - \frac{1}{g_3}\partial_\mu \varepsilon^\alpha + C_{\alpha\beta\gamma}\varepsilon^\beta A^\gamma_\mu, \tag{145}$$

where ε^α are the infinitesimal parameters of SU(3).

The Lagrangian describing the interaction of the quarks (q) with the gluons is given by

$$L_2 = \bar{q}(\partial_\mu - i g_3 T_\alpha A_{\mu\alpha}) q + M \bar{q} q, \tag{146}$$

where M is the mass of the quark. The SU(3) transformation law for the triplet quark fields q_i ($i = 1$–3) is given by

$$q_i \longrightarrow (e^{i\varepsilon_\alpha T_\alpha})_{ij} q_j, \tag{147}$$

where ε_α are the local (space–time-dependent) infinitesimal parameters. The sum of the Lagrangians $L_1 + L_2$ describes the complete SU(3) color interactions involving the quarks and the gluons and is known as quantum chromodynamics (QCD). This symmetry is exact, so that the gluons are massless. One very interesting feature of this nonabelian local gauge theory is that the coupling constant decreases logerithmically with the energy scale (this will be discussed in detail later, in the renormalization group equation section). Thus, the coupling constant vanishes at infinite energy, so the theory approaches the behavior of a free field theory as the energy scale approaches infinity. This is known as asymptotic freedom. This logarithmic decrease of the coupling parameter with energy has been tested up to few hundred GeV. On the other hand, as the energy scale decreases, the coupling increases logarithmically so that it becomes very large at low energy and the theory becomes nonperturbative. This is sometimes called infrared slavery, and it has been speculated that this may be responsible for the confinement of the quarks and the gluons.

2. Electroweak Theory

The $\mathrm{SU}(2) \times U(1)$ part of the SM is known as the electroweak theory (Weinberg, Salam, Glashow), since it describes the weak and EM interactions. The multiplet structure of the quarks, leptons, and the electroweak gauge bosons as given in Table XI. The gauge boson part of the Lagrangian under this symmetry is given by

$$L_1 = -\frac{1}{4} F_{\mu\nu\alpha} F^{\mu\nu\alpha} - \frac{1}{4} B_{\mu\nu} B^{\mu\nu}, \tag{148}$$

where

$$B_{\mu\nu} = \partial_\mu B_\nu - \partial_\nu B_\mu$$
$$F_{\mu\nu\alpha} = \partial_\mu A_{\nu a} - \partial_\nu A_{\mu a} + g\varepsilon_{abc} A_{\mu b} A_{\nu c}.$$

The transformation laws for the gauge fields B_μ and $A_{\mu a}$ are given by

$$B_\mu \longrightarrow B'_\mu = B_\mu - \frac{1}{g'}\partial_\mu \varepsilon,$$

$$A_{\mu a} \longrightarrow A'_{\mu a} = A_{\mu a} - \frac{1}{g}\partial_\mu \varepsilon_a - \varepsilon_{abc}\varepsilon_b A_{\mu c}.$$

Although the photon is massless, the gauge bosons $W^\pm$ and Z are massive ($M_W = 80$ GeV, $M_Z = 91$ GeV). Thus $SU(2) \times U(1)$ symmetry must be broken to $U_{EM}(1)$ at the 100-GeV scale. In analogy with the spontaneous breaking of the rotational symmetry in the case of ferromagnetism, this symmetry is also spontaneously broken by using suitable scalar fields, the so-called Higgs fields. The Higgs fields required is an SU(2) weak doublet, as shown in Table XI. The Higgs potential is such that although the Lagrangian is invariant under the symmetry group, the ground state (the vacuum state) is not. The required Higgs Lagrangian is

$$L_2 = D^\mu H^\dagger D_\mu H - V(H), \tag{149}$$

where

$$D_\mu = \partial_\mu - igT_i A_{\mu i} - i\frac{g'}{2} Y B_\mu$$

is known as the gauge-covariant derivative, and Y is the $U(1)$ hypercharge.

$$V(H) = -\mu^2 H^\dagger H + \lambda (H^\dagger H)^2 \tag{150}$$

is called the Higgs potential.

Note that for positive values of μ^2 and λ, $V(H)$ has minimum for nonzero values of $\langle H \rangle$, where $\langle H \rangle \equiv \langle 0|H|0\rangle \equiv V$ is the vacuum expectation value of H. Thus, the $SU(2) \times U(1)$ symmetry is broken spontaneously to $U_{EM}(1)$, which is a linear combination of the diagonal part of the SU(2) and the $U(1)$. The charged ($W^\pm$) and the neutral (Z) gauge bosons acquire masses

$$M_w = \frac{1}{2} gV, \qquad M_z = \frac{1}{2}\sqrt{g^2 + g'^2}\, V, \tag{151}$$

while the photon A_μ, corresponding to the unbroken $U_{EM}(1)$ gauge symmetry, remains massless. In terms of the original gauge fields (A_1, A_2, A_3) and B, the expressions for the $W^\pm$, Z, and γ fields are given by Eqs. (141) and (142). The expression for the weak mixing angle θ_w given by

$$\tan\theta_w = \frac{g'}{g}. \tag{152}$$

The Lagrangian for the fermionic part of the gauge interactions is given by

$$L_3 = \bar{\Psi}_L D_{\mu L} \Psi_L + \bar{\Psi}_R D_{\mu R} \Psi_R, \tag{153}$$

where

$$D_{\mu L} = \partial_\mu - igT_i A_{\mu i} - i\frac{g'}{2} Y_L B_\mu,$$

$$D_{\mu R} = \partial_\mu - i\frac{g'}{2} Y_R B_\mu.$$

Here Ψ_L represent left-handed quarks or leptons doublets, while Ψ_R represent right-handed quarks or leptons singlets under the SU(2) transformations given in Table XI.

$$\Psi_L = q_L = \begin{pmatrix} u \\ d \end{pmatrix}_L, \qquad \ell_L = \begin{pmatrix} \nu_e \\ e \end{pmatrix}_L,$$

$$\Psi_R = u_R, d_R, e_R.$$

Finally, the Lagrangian for the Yukawa part of the interaction responsible for giving rise to the masses of the fermions is given by

$$L_4 = f_d \bar{q}_L d_R H + f_u \bar{q}_L U_R \tilde{H} + f_e \bar{\ell}_L e_R H,$$

where

$$\tilde{H} \equiv i\tau_2 H^* \qquad \text{and} \qquad \tau_2 = \begin{pmatrix} o & -i \\ i & o \end{pmatrix}. \tag{154}$$

When the symmetry is broken spontaneously, the fermions acquires masses.

$$m_u = f_u \frac{V}{\sqrt{2}}, \qquad m_d = f_d \frac{V}{\sqrt{2}}, \qquad m_e = f_e \frac{V}{\sqrt{2}}. \tag{155}$$

Thus, in electroweak gauge theory, the gauge boson masses are predicted by the gauge symmetry, while the fermion masses are parametrized in terms of the unknown Yukawa couplings f_u, f_d and f_e.

I. Grand Unification

We saw that the gauge theory based on the SM gauge group, $SU(3) \times SU(2) \times U(1)$, involves three independent coupling constants, g_3, g, and g' (or g_3, g_2, g_1, where $g_2 \equiv g$, $g_1 = \sqrt{5/3}g'$ in a different normalization). The question naturally arises whether the SM gauge group can be embedded into a simple group so that it will involve only one coupling constant. It turns out that there are such unification groups, the simplest being SU(5). (Since the SM gauge group has rank 4, the minimum rank of such a unifying symmetry group must be rank 4.) The unification of the three SM gauge interactions in a simple gauge group is known as the *grand unification theory* (GUT).

J. SU(5) Grand Unification

The SU(5) grand unification theory can accommodate the chiral nature of the fermion representation under $SU(2) \times U(1)$ as well as the absence of chiral anomalies

without introducing new fermions. One can also calculate the value of the weak mixing angle. The gauge bosons belong to the adjoint representation of SU(5). The 24 gauge bosons have the following decomposition under the SM, $SU(3) \times SU(2) \times U(1)$ representations:

$$24 = (8, 1, 0) + (1, 3, 0) + \left(3, 2, \tfrac{5}{3}\right) + \left(3^*, 2, -\tfrac{5}{3}\right) + (1, 1, 0),$$

where (8, 1, 0) represents the eight gluons, (1, 3, 0) represents the three SU(2) gauge bosons, and (1, 1, 0) represents the $U(1)$ gauge bosons. The particles in $(3, 2, \frac{5}{3})$ and $(3^*, 2, -\frac{5}{3})$ represent 12 new gauge bosons that are not present in the SM. These are denoted by X_α, Y_α, the (X, Y) being the doublet under the weak SU(2) and the triplet under the color SU(3) ($\alpha = 1, 2, 3$). The six gauge bosons in $(3^*, 2, -\frac{5}{3})$ are the complex conjugate fields of (X, Y). There are 24 generators, λ_A ($A =$ 1–24) of SU(5), where λ_α ($\alpha =$ 1–8) are the 5×5 matrix generalization of those given in Eq. (124). $\lambda_{20+\alpha} = 1, 2, 3$ corresponds to the generalization of three SU(2) generators, while λ_{24} corresponds to that of the hypercharge $U(1)$ generator. The generators $\lambda_A (A =$ 9–20) are the new ones that are not present in the SM gauge group. The corresponding gauge bosons X_α, Y_α can change quarks into leptons and thus violate baryon and lepton number conservation. This is a new feature of all grand unified theories.

The fermions belong to the SU(5) representations 5^* and 10, which under $SU(3) \times SU(2) \times U(1)$ representations decompose as follows:

$$5^* = \left(3^*, 1, \tfrac{2}{3}\right) + (1, 2, -1),$$
$$10 = \left(3^*, 1, -\tfrac{4}{3}\right) + \left(3, 2, \tfrac{1}{3}\right) + (1, 1, 2).$$

Expressing all fermions as left-handed Weyl fermions, $(3^*, 1, \frac{2}{3})$ contains the three color singlet SU(2) doublet-down-type antiquarks (d_1^c, d_2^c, d_3^c), $(1, 2, -1)$ contains the color singlet SU(2) doublet electron-type neutrino and the electron (ν_e, e), $(3, 2, \frac{1}{3})$ contains the color triplet SU(2) doublet-up and- down quarks, $(3^*, 1, -\frac{4}{3})$ contains the color triplet SU(2) singlet up-type antiquarks, and (1, 1, 2) contains both the SU(3) and SU(2) singlet positrons. Note that all the known fermions in one family fit neatly, and no extra fermions are needed.

K. Symmetry Breaking in SU(5)

SU(5) symmetry must be broken spontaneously at a very high energy scale ($\sim 10^{16}$GeV) because X, Y gauge bosons have baryon number-violating interactions, and will cause proton decay. The agreement with the current experimental lifetime of the proton demand $M_{x,y} \geq 10^{16}$ GeV. There are two stages of symmetry breaking:

$$\mathrm{SU}(5) \xrightarrow[\text{first stage}]{\mu \sim 10^{16}\mathrm{GeV}} \mathrm{SU}(3) \times \mathrm{SU}(2) \times U(1) \xrightarrow[\text{second stage}]{\mu \sim 10^{2}\mathrm{GeV}} \mathrm{SU}(3) \times U_{\mathrm{EM}}(1).$$

The first stage of symmetry breaking can be achieved using a 24-dimensional Higgs representation of SU(5), while the second stage of symmetry breaking can be achieved by using a 5-dimensional Higgs representation of SU(5). The gauge bosons X, Y acquire masses after the first symmetry breaking, while $W^\pm$, Z get their masses at the second symmetry breaking. Fermions also receive their masses from the second stage of symmetry breaking.

L. Renormalization Group Equations and Evolutions of Gauge Couplings

In grand unified theories (GUTs) with a simple gauge group G such as SU(5), we have only one coupling constant, g_G. Thus, at the energy scale M_{GUT} above which the symmetry is exact, the three coupling g_3, g_2, g_1 are equal. (Note that we are using a normalization for which $g_2 \equiv g$, $g_1 = \sqrt{5/3}g'$). The reason for the values of the three coupling being so different at low energy is due to the fact that they evolve in energy differently, making the effective couplings g_2, and g_1 much smaller than the strong coupling g_3. The renormalization group evolution of a coupling g_i is given by

$$\mu \frac{dg_i}{\partial \mu} = \beta_i(\{g\}), \tag{156}$$

Where $\beta_i(\{g\})$ is the beta-function for the coupling g_i. At the one-loop level, for the three SM gauge couplings, $\beta_i(\{g_i(\mu)\}) = b_i g_i^3(\mu)$ for $g_i \langle\langle 1$. The boundary condition is

$$g_1 = g_2 = g_3 = g_G \qquad \text{at} \quad \mu = M_{\mathrm{GUT}}. \tag{157}$$

For the SM,

$$b_3 = -\frac{1}{16\pi^2}\left(11 - \frac{2}{3}N_f\right),$$
$$b_2 = -\frac{1}{16\pi^2}\left(\frac{22}{3} - \frac{2}{3}N_f - \frac{1}{6}N_H\right), \tag{158}$$
$$b_1 = \frac{1}{16\pi^2}\left(\frac{2}{3}N_f + \frac{1}{10}N_H\right),$$

where N_f is the number of quark flavors ($N_f = 6$ for six quark flavors, u, d, c, s, t, b) and N_H is the number of Higgs doublets.

The experimental values of the three coupling at the low energy scale, such as at $\mu = M_Z$ is very well determined from the studies of Z-boson decay:

$$\alpha_3^{-1}(M_Z) = 8.5 \pm 0.5, \qquad \alpha_2^{-1}(M_Z) = 29.61 \pm 0.13,$$
$$\alpha_1^{-1}(M_Z) = 98.29 \pm 0.13, \tag{159}$$

where $\alpha_i(\mu) \equiv g_i^2(\mu)/4\pi$. Using these values at $\mu = M_Z$ and evolving the couplings to higher energy scale using Eqs. (156) and (157), we find that the couplings do not unify for this simple minimal SU(5) GUT. Also, the very approximate unification scale is too small, $M_X \sim 10^{13}$ GeV, so the dominant proton decay rate in this model, $P \to e^+\pi^o$ is too high compared to the experimental limit. Thus, this simple SU(5) GUT theory is ruled out experimentally. However, for supersymmetric SU(5) GUT, the unification works beautifully and the unification scale is $\sim 10^{16}$ GeV, in complete agreement with the current experimental proton lifetime limits. So, next we turn to supersymmetry, supersymmetric SM (also known as MSSM), and supersymmetric GUTS.

M. Supersymmetry

Supersymmetry is a beautiful mathematical generalization of 10-parameter Poincaré group to 14-parameter super-Poincaré or supersymmetry groups. The 10-parameter Poincaré group, with the generators $J_{\mu\nu}$ and P_μ ($\mu, \nu = 0, 1, 2, 3$), satisfy the algebra.

$$[J_{\mu\nu}, J_{p\sigma}] = g_{\mu\rho} J_{\nu\sigma} - g_{\nu\rho} J_{\mu\sigma} + g_{\mu\sigma} J_{\nu\rho} - g_{\nu\sigma} J_{\mu\rho}, \tag{160}$$
$$[P_\mu, P_\nu] = 0, \qquad [J_{\mu\nu}, P_\rho] = g_{\mu\rho} P_\nu - g_{\nu\rho} P_\mu.$$

Wess and Zumino (1974) discovered that this Poincaré algebra beautifully generalizes to a new symmetry algebra by introducing four new generators, S_α. S_α's are fermionic, the index α ($\alpha = 1, 2, 3, 4$) is a spinor index, and the corresponding parameters ε_α are anticommuting Majorana spinors. S_α's satisfy the following algebra:

$$[S_\alpha, P_\mu] = 0, \qquad [J_{\mu\nu}, S_\alpha] = \frac{1}{2}(\sigma_{\mu\nu})_{\alpha\beta} S_\beta, \tag{161}$$
$$\{S_\alpha, S_\beta\} = (\gamma^\mu c)_{\alpha\beta} P_\mu,$$

where c is the Dirac charge conjugation matrix.

In Eq. (161), the curly braces represent anticommutators. The introduction of anticommuting parameters and the associated fermonic generators, together with the bosonic ones, brought lot of excitement among the mathematicians. The usual Lie algebra has now been generalized to include both commutators and anticommutators and is known as graded Lie algebra. Graded Lie algebras have now been classified. The representation of the super Poincaré algebra, Eqs. (160) and (161), involves both bosons and fermions in the same representation and is called Fermi–Bose symmetry or supersymmetry. In a given representation, we have particles of both spin j and $j - \frac{1}{2}$. The simplest irreducible representation is called the chiral scalar superfield, in which we have a complex scalar field and a chiral fermionic field. Next is the vector representation, which has a massless vector field and a Majorana spinor field. Thus, in the SM, each representation will be associated with its superpartner. The particle content of the minimal supersymmetric extension of the SM is given in Table XII. The first column represent the usual SM particles, and the second column their supersymmetric partners. The intrinsic spins of the superpartners differ by half a unit. For example, $\tilde{e}_L$ has spin 0, a scalar particle. Note that an additional new feature is that that two Higgs doublets are needed to cancel chiral anomalies.

Since none of the superpartners has so far been observed, supersymmetry must be broken at a few hundred GeV scale or higher. Two popular supersymmetry breaking mechanisms are the gravity mediated and the gauge mediated (GMSB). The superpartners are expected to a have masses less than TEV for the supersymmetry to solve the gauge hierarchy problem, and are expected to be discovered at the Large Hadron Collider (LHC), if not at the upgraded Tevatron. Local supersymmetry, in which the fermionic parameters ε_α are arbitrary functions of space–time (x, t), necessarily needs the introduction of the gravity supermultiplet containing the spin-2 graviton and its supersymmetric partner, the gravitino.

TABLE XII Particle Contents of the Supersymmetric Standard Model

Particles	Superpartners	SU(3)× SU(2)×U(1) representations
$u_{L\alpha}$	$\tilde{u}_{L\alpha}$	$(3, 2, \frac{1}{3})$
$d_{L\alpha}$	$\tilde{d}_{L\alpha}$	$(3, 2, \frac{1}{3})$
ν_{eL}	$\tilde{\nu}_{eL}$	$(1, 2, -1)$
e_L	$\tilde{e}_L$	$(1, 2, -1)$
$u_{R\alpha}$	$\tilde{u}_{R\alpha}$	$(3, 1, \frac{4}{3})$
$d_{R\alpha}$	$\tilde{d}_{R\alpha}$	$(3, 1, -\frac{2}{3})$
e_R	$\tilde{e}_R$	$(1, 1, -2)$
g_a	$\tilde{g}_a$	$(8, 1, 0)$
A_a	$\tilde{A}_a$	$\begin{pmatrix} +1 \\ 1, 3, \ 0 \\ -1 \end{pmatrix}$
B	$\tilde{B}$	$(1, 1, 0)$
H_1	$\tilde{H}_1$	$(1, 2, 1)$
H_2	$\tilde{H}_2$	$(1, 2, -1)$

In supersymmetric SM, there will be additional contributions to the evolution of the gauge coupling above the supersymmetric thresholds. Thus, above threshold, the coefficients to the beta-factors b_1, b_2, and b_3 are modified to

$$\begin{aligned}\tilde{b}_3 &= -\frac{1}{16\pi^2}(9-N_f),\\ \tilde{b}_2 &= -\frac{1}{16\pi^2}\left(6-N_f-\frac{1}{2}N_H\right),\\ \tilde{b}_1 &= \frac{1}{16\pi^2}\left(N_f+\frac{3}{10}N_H\right).\end{aligned} \tag{162}$$

Starting with the experimental values of $\alpha_1(M_Z)$, $\alpha_2(M_Z)$, and $\alpha_3(M_Z)$ given in Eq. (162), and evolving these to higher energy scales, these coupling unify at an energy scales, $\mu = M_{\rm GUT} \simeq 2\times 10^{16}$ GeV. Thus, although in non-SUSY SU(5) the unification does not take place, unification does occur very accurately in SUSY SU(5). Also, because of the very high scale of the unifications, the proton decay limits are easily satisfied.

IX. APPLICATIONS IN GEOMETRICAL OPTICS

A nondegenerate, skew-symmetric bilinear form in $2n$ ($n=2$, for example) dimensions is usually written as

$$\sum_{i=1}^{4}\sum_{k=1}^{4} a_{ik}, x_i y_k, \qquad a_{ik} = -a_{ki}. \tag{163}$$

In matrix form this can be expressed as $\mathbf{X}^T\mathbf{A}\mathbf{Y}$, where x_i and y_k are treated as components of the Vectors $\vec{\rm X}$ and $\vec{\rm Y}$, respectively, and the matrix $\mathbf{A}$ satisfies the relation

$$\mathbf{A}^T = -\mathbf{A}, \tag{164}$$

the superscript T meaning the transposition operation. We assume that the variables as well as the coefficients are real. By suitable transformations the above bilinear form can be reduced to "canonical form,"

$$\sum_{i=1}^{\nu=2}\left(\xi_i\eta_{i+\nu}-\xi_{i+\nu}\eta_i\right) = \vec{\xi}^{\,T}\mathbf{K}\vec{\eta} \tag{165}$$

Here $\vec{\xi}$ is the vector $(\xi_1,\xi_2,\xi_3,\xi_4)$, $\vec{\eta}$ the vector $(\eta_1,\eta_2,\eta_3,\eta_4)$, and $\mathbf{K}$ the matrix

$$\mathbf{K} = \begin{pmatrix} 0 & 0 & 1 & 0\\ 0 & 0 & 0 & 1\\ -1 & 0 & 0 & 0\\ 0 & -1 & 0 & 0\end{pmatrix} \equiv \begin{pmatrix} 0 & 1\\ -1 & 0\end{pmatrix}. \tag{166}$$

The set of all matrices $\mathbf{S}$ that leave this skew-symmetric form invariant constitute a Lie group called the *symplectic group* Sp($2n$) (here $2n$ is 4), and this is a subgroup of the general linear group GL($2n$). The requirement of skew symmetry implies that the general element of this group of transformations $\mathbf{S}$ should satisfy

$$\mathbf{S}^T\mathbf{K}\,\mathbf{S} = \mathbf{K}. \tag{167}$$

In geometric optics a single ray incident on a refracting surface is usually defined by one of its points in object space, given by a vector $\vec{\rm a}$ and a vector $\vec{\rm s}$ which gives the direction of the ray. The length of $\vec{\rm s}$ is n, the refractive index of the medium in that space.

In image space the corresponding vectors describing the refracted ray are $\vec{\rm a}'$ and $\vec{\rm s}'$, n' being the appropriate refractive index there. A two-dimensional manifold of such rays is adequately described by the components of the vector expressed as continuous functions of two variable parameters u and v. It has been proven by Herzberger that a fundamental invariant governing image formation is $(\vec{a}_u\cdot\vec{s}_v)-(\vec{a}_v\cdot\vec{s}_u)$. In other words,

$$(\vec{a}_u'\cdot\vec{s}_v')-(\vec{a}_v'\cdot\vec{s}_u') = (\vec{a}_u\cdot\vec{s}_v)-(\vec{a}_v\cdot\vec{s}_u), \tag{168}$$

equivalent to the Lagrange bracket in analytical mechanics. Here $\vec{a}_u$ is a notation for the partial derivative $\partial\vec{a}/\partial u$. It turns out that the invariant is valid for any point on the ray, and as such it is convenient to refer to the intersection of the ray with a plane $Z=0$, so that the components of $\vec{a}$ are (x,y). Let the components of $\vec{s}$ be $(\xi,\eta,\sqrt{n^2-\xi^2-\eta^2})$. Taking the pair of parameters u, v to be (x,y), (x,ξ), (x,η), (y,ξ), (y,η), and (ξ,η) [every pair of the four variables (x,y)], in turn, the above invariant relation yields the following six equations for the components of the vectors:

$$\begin{aligned}
x_x'\xi_y' + y_x'\eta_y' - x_y'\xi_x' - y_y'\eta_x' &= 0\\
x_x'\xi_\xi' + y_x'\eta_\xi' - x_\xi'\xi_x' - y_\xi'\eta_x' &= 1\\
x_x'\xi_\eta' + y_x'\eta_\eta' - x_\eta'\xi_x' - y_\eta'\eta_x' &= 0\\
x_y'\xi_\xi' + y_y'\eta_\xi' - x_\xi'\xi_y' - y_\xi'\eta_y' &= 0\\
x_y'\xi_\eta' + y_y'\eta_\eta' - x_\eta'\xi_y' - y_\eta'\eta_y' &= 1\\
x_\xi'\xi_\eta' + y_\xi'\eta_\eta' - x_\eta'\xi_\xi' - y_\eta'\eta_\xi' &= 0
\end{aligned} \tag{169}$$

This set of equations can be expressed in matrix form as

$$\mathbf{M}^T\mathbf{K}\,\mathbf{M} = \mathbf{K} \tag{170}$$

where $\mathbf{K}$ is given in Eq. (166). The matrix $\mathbf{M}$ now becomes

$$\mathbf{M} = \begin{pmatrix} x_x' & x_y' & x_\xi' & x_\eta'\\ y_x' & y_y' & y_\xi' & y_\eta'\\ \xi_x' & \xi_y' & \xi_\xi' & \xi_\eta'\\ \eta_x' & \eta_y' & \eta_\xi' & \eta_\eta'\end{pmatrix}$$

recalling that $y_\xi' \equiv \partial y'/\partial\xi$, etc. Thus we see that Eq. (170), sometimes called the "lens equation," is identical to

Eq. (167), and the latter describes the symplectic group Sp(4). Thus, the symplectic group is of fundamental importance in geometric optics.

An interesting application of the techniques based on the symplectic Lie group has been made to charged-particle beam optics, which is of importance in particle accelerator physics. The article in *Annual Review of Nuclear and Particle Science* cited in the Bibliography (Dragt *et al.*, 1988) gives an illuminating discussion of this application.

X. THE RENORMALIZATION GROUP

The *renormalization group* (RG) theory has applications in several areas of physics but we shall confine our treatment here to "critical phenomena". The importance of RG theory in elementary particle physics is discussed elsewhere in this article.

The concept of renormalization has its origins in quantum electrodynamics, which is the theory that explains the properties and behavior of electrons and photons or light quanta. According to quantum field theory, particles are the outcome of quantizing appropriate wave fields. For instance, photons are quanta resulting from quantizing the classical electromagnetic field of Maxwell. A disturbing feature of quantum electrodynamics has been the existence of infinities or divergent integrals. For instance, if we assume the charge of an electron e to be uniformly distributed in a sphere of radius a, the electrostatic self-energy of this sphere is $\frac{3}{5}(e^2/a)$ according to Maxwell's theory, and this becomes infinite in the limit of a going to zero. In other words, a point electron has infinite self-energy. Many such divergences exist, of which two important cases are the self-energy of the photon and the polarizability of the vacuum induced by an external electric field. This vacuum happens to be an infinite sea of occupied electron states of negative energy which are the inevitable consequences of Dirac's relativistic electron theory. According to Oppenheimer, the roots of charge renormalization lie in the efforts to overcome these infinities by asserting that the experimentally measured charge of the electron is the sum of the "true" and "induced" charges, and it is this prescription that is the genesis of renormalization of charge. The existence of a similar distinction between "bare electron mass" and "dressed electron mass" has been pointed out by Kramers in his study of the interaction between charged particles and the radiation field.

These concepts took concrete shape ten years later in the epoch-making contributions of Schwinger, Tomonoga, and Feynman, and the term *renormalization* has been in vogue ever since. According to Yukawa, the forces between particles are mediated by quanta and, in particular, the forces between electrons are mediated by light quanta or photons. A popular picture of this electron can thus be that of a bare particle modestly apparelled in photons. It is important to note that underlying all these ideas is the mass–energy equivalence of Einstein's special relativity theory.

As a preliminary to the introduction of the renormalization group, it is helpful to discuss certain ideas of "critical phenomena", to which it has its important application. We shall single out phase transitions in liquids for this purpose. It is common knowledge that under appropriate conditions of temperature and pressure, water exists in the three phases of solid (ice), liquid (water), and gas (steam). In a three-dimensional plot of pressure, density, and temperature, the domains of these phases and their boundaries are clearly demarcated. Across the boundary separating gas from a liquid, for instance, there is a discontinuity in density. In his experiments on the liquefaction of carbon dioxide gas by isothermal compression, Andrews noticed in 1869 the existence of a critical temperature T_c, above which there is a continuity of the gas and liquid phases. In other words, it is only below the critical temperature that condensation of a gas can take place. The pressure at this point is called the critical pressure P_c, and likewise the density ρ_c. As the temperature is increased to T_c, the density of the gas phase, ρ_g, tends to equal the density of the liquid phase, ρ_l, and the two become one ρ_c at the critical temperature T_c. For water, for instance, T_c is 648, P_c is 218, and ρ_c is 0.25 in appropriate units.

A classical theoretical foundation for the behavior of a gas at equilibrium temperature T is the equation of state relating the thermodynamic variables pressure p, volume (or density ρ) V, and temperature T. Taking into account possible intermolecular forces and the finite size of molecules, van der Waals derived in 1873 the equation of state

$$\left(p + \frac{a}{V^2}\right)(V - b) = NkT, \tag{171}$$

where a and b are constants pertaining to the gas, k is the universal Boltzmann constant, and N is the Avogadro number. This equation does predict the existence of critical constants according to the following relations:

$$\begin{aligned} &\frac{\partial p}{\partial V} = 0, \qquad \frac{\partial^2 p}{\partial V^2} = 0, \\ &p_c = \frac{a}{27b^2}, \qquad V_c = 3b, \qquad T_c = \frac{8a}{27bNk}. \end{aligned} \tag{172}$$

In terms of reduced variables $\rho = p/p_c$, $\nu = V/V_c$, $t = T/T_c$, the van der Waals equation can be written in the so-called universal form applicable to any gas:

$$\left(p + \frac{3}{\nu^2}\right)\left(\nu - \frac{1}{3}\right) = \frac{8}{3}t. \tag{173}$$

This is known as the *law of corresponding states*. The existence of such a universal relation, through not the exact quadratic equation, has been demonstrated by Guggenheim, who plotted the reduced density (ρ/ρ_c) as a function of the reduced temperature (T/T_c) for eight different fluids on which experimental measurements have been made. This has given rise to the suggestion that the *order parameter* $\rho_l - \rho_g$ satisfies a power law in the reduced temperature,

$$\rho_l - \rho_g \sim |\tau|^\beta, \qquad \tau = \frac{T}{T_c} - 1 = t - 1, \tag{174}$$

and β has since come to be known as a critical exponent. The other critical exponents are γ, related to the isothermal compressibility,

$$\kappa_T = -\frac{1}{V}\left(\frac{\partial V}{\partial p}\right)_T = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial p}\right)_T = |\tau|^{-\gamma}, \tag{175}$$

and α, related to specific heat at constant volume,

$$C_v = \left(\frac{\partial V}{\partial T}\right)_V = |\tau|^{-\alpha}. \tag{176}$$

From thermodynamic reasoning it has been shown that the exponents are not all independent but are coupled by a relation

$$\alpha + 2\beta + \gamma = 2. \tag{177}$$

One of the achievements of the RG theory has been the derivation of these critical exponents.

The concept of a renormalization group, like the concept of renormalization itself, originated in quantum electrodynamics. Stueckelberg and Petermann introduced this is quantum field theoretic language and worked out its details including infinitesimal transformations and their Lie algebra. However, this found little application and was almost ignored. The foundation for the currently used RG is the work of Gell-Mann and Low, also in the context of quantum electrodynamics. Recognizing this and making a systematic development of RG theory and its adaptability to critical phenomena analysis has been the indefatigable effort of Wilson.

The RG is a Lie group of transformations which are functions of certain variables and parameters that vary continuously over a given domain. The fundamental group postulate of multiplication here means that a transformation followed by a transformation is still another transformation with different values of the parameters. To illustrate this in one dimension let us assume x_i variable point on the X axis and s_j a parameter. The transformation with parameter s_i takes x_j to x_k on the line

$$f(-s_i, x_j)x_j = x_k. \tag{178}$$

A second transformation involving a parameter s_j takes x_k to x_l. A succession of these two transformations then moves x_j to x_l.

$$\{f(-s_j, x_k)x_k\}\{(-s_i, x_j)x_j\} = x_e. \tag{179}$$

However, there must also exist a transformation, say with parameter s_k, which takes x_j directly to x_l.

$$f(-s_k, x_j)x_j = x_e. \tag{180}$$

In other words, we have the group multiplication

$$\{f(-s_j, x_k)x_k\}\{f(-s_i, x_j)x_j\} = f(-s_k, x_j)x_j = x_e. \tag{181}$$

We assume this can happen provided the parameters satisfy the relation

$$s_j s_i = s_k. \tag{182}$$

For a certain value of the parameters, say $s = 1$, the transformation must be an identity and this means that

$$f(-1, x) = 1 \tag{183}$$

for any point x. It is generally agreed that the RG is really a semigroup, because the inverse transformation cannot always be uniquely defined. To be applicable to actual physical situations these transformation must be such that the transformed system describes the same physics as the original one. In statistical mechanics, for instance, the partition function will be the same in different systems. In quantum mechanics the original and transformed Hamiltonians relate to the same dynamical system.

The importance of the RG transformation is that it is iterative:

$$f(\mathbf{H}) = \mathbf{H}^1, \qquad f(\mathbf{H}^1) = \mathbf{H}^{11}, \text{ etc.} \tag{184}$$

In one dimension the functional equation is like a recursion relation,

$$f(x) = x^1, \qquad f(x^1) = x^{11}, \ldots, \tag{185}$$

and this implies that after very many iterations one can hope to approach a fixed point x^*,

$$f(x^*) = x^*. \tag{186}$$

As in the case of the roots of an algebraic equation, there can be several fixed points. Let us assume we have at a fixed point x^*,

$$\begin{aligned} x &= x^* + \delta x, \\ x^1 &= x^* + \delta x^1. \end{aligned} \tag{187}$$

In the vicinity of the fixed point a Taylor expansion gives

$$f(x^* + \delta x) = f(x^*) + \frac{\partial f}{\partial x^*}\delta x + \cdots = x^* + \delta x^1,$$

or

$$\delta x^1 = \frac{\partial f}{\partial x^*}\delta x + \text{higher powers of } \delta x, \tag{188}$$

We thus have, to a linear approximation in δx,

$$\delta x^1 = \frac{\partial f}{\partial x^*}\,\delta x \tag{189}$$

In higher dimensions the variables can be regarded as components of a vector and Eq. (154) now generalizes to

$$f(\vec{r}) = \vec{r}^{\,\mathrm{I}}, \qquad f(\vec{r}^{\,\mathrm{I}}) = \vec{r}^{\,\mathrm{II}}, \ldots, \qquad f(\vec{r}^{\,*}) = \vec{r}^{\,*}. \tag{190}$$

The linear approximation above now becomes

$$\delta\vec{r}^{\,l} = \mathbf{M}(\vec{r}^{\,*})\delta\vec{r}, \tag{191}$$

where the matrix elements of $\mathbf{M}$ are evaluated at the fixed point r^*. We presume $\mathbf{M}$ satisfies the eigenvalue equation

$$\mathbf{M}\,\vec{\xi}_i = \lambda_i\vec{\xi}_i. \tag{192}$$

The behavior of $\vec{r}$ after several iterations is governed by the magnitude of the eigenvalue λ. If $|\lambda|\langle 1$, under iterations the higher powers of λ will then be progressively smaller and Eq. (155) shows that x will converge to (attracted to) the fixed point x^*, and for this reason this is said to be an "irrelevant" eigenvalue. On the other hand, when $|\lambda|\rangle 1$ the point x will drift farther and farther away from the fixed point. This is then a "relevant" eigenvalue. We will now illustrate this by a hypothetical example in two dimensions.

In component form let us assume the recursion equations

$$x^1 = \frac{2x}{1+x^3}, \qquad y^1 = \frac{y^3}{1+x^3}. \tag{193}$$

The fixed points (x^*, y^*), obtained by solving for $x^1 = x$, $y^1 = y$, are (0, 0), (0, 1), $(1,\sqrt{2})$, $(1, -\sqrt{2})$. We will now set

$$x + \delta x^1 = \frac{2(x+\delta x)}{1+(x+\delta x)^3}, \quad y + \delta y^1 = \frac{(y+\delta y)^3}{1+(x+\delta x)^3}. \tag{194}$$

In the linear approximation the matrix $\mathbf{M}$ of Eq. (192) is

$$\begin{pmatrix}\delta x^1\\ \delta y^1\end{pmatrix} = \begin{pmatrix}\dfrac{2-4x^3}{(1+x^3)^2} & 0\\ \dfrac{-3x^2y^3}{(1+x^3)^2} & \dfrac{3y^2}{(1+x^3)}\end{pmatrix}\begin{pmatrix}\delta x\\ \delta y\end{pmatrix}. \tag{195}$$

It is easy to see that the eigenvalues of this matrix are

$$\lambda_1 = \frac{2-4x^3}{(1+x^3)^2}, \qquad \lambda_2 = \frac{3y^2}{1+x^3}. \tag{196}$$

At the fixed point (0, 0), $\lambda_1 = 2, \lambda_2 = 0$, and we have one relevant eigenvalue and one marginal. At the fixed point (0, 1), $\lambda_1 = 2, \lambda_2 = 3$ and both are relevant. At $(1, \sqrt{2})$, $\lambda_1 = -\frac{1}{2}$, $\lambda_2 = 3$, and so one is irrelevant and one relevant. At $(1, -\sqrt{2})$, $\lambda_1 = -\frac{1}{2}$, $\lambda_2 = 3$ and this is the same case as the fixed point $(1, \sqrt{2})$. The marginal case can be decided only when one calculates beyond the linear approximation. As mentioned earlier, relevant parameters are those that tend to make the system unstable to small disturbances.

The RG transformations in practice are designed to reduce the degrees of freedom of the system from, say, N to N', and this involves a scale change of the vectors $\vec{r}$ in coordinate space by the factor b,

$$b^d = (N/N'), \qquad \vec{r}' = \left(\frac{\vec{r}}{b}\right), \tag{197}$$

where d relates to its dimensionality. This makes the eigenvalues λ_i functions of the scale factor b and the iterative nature of the transformation makes

$$\lambda_i = b^{\eta_i}, \tag{198}$$

where η_i are independent of the scale factor. The use of this in thermodynamic functions like free energy eventually yields the critical exponents. A remarkable similarity in the values of these exponents in seemingly different phase transitions led to the hypothesis of "universality," which states that all phase-transition problems belong to a few classes determined by certain parameters such as dimensionality and the order. This is confirmed by RG theory, according to which these universality classes are determined by the different ranges of attraction of the fixed point.

ACKNOWLEDGMENT

We would like to dedicate this to the late Prof. Mark A. Samuel, who was a co-author on the first two editions of this article.

Integral Equations

Ram P. Kanwal
Pennsylvania State University

GLOSSARY

Cauchy representation Representation of a function $f(z)$:

$$F(z) = \frac{1}{2\pi i}\int_C \frac{f(\zeta)}{\zeta - z}\,d\zeta$$

where z and ζ are points in the complex plane $\mathbb{C}$ while C is a contour in $\mathbb{C}$.

Compact operator Operator that transforms any bounded set in a Hilbert space onto a precompact set.

Eigenvalue Complex numbers λ_n of the integral equation $g(x) = \lambda \int_a^b K(x, y)g(y)\,dy$.

Eigenfunctions Nonzero solutions $g_n(x)$ of the integral equation $g(x) = \lambda \int_a^b K(x, y)g(y)\,dy$.

Fredholm alternative Alternative that specifies the conditions under which a linear integral equation can have a unique solution.

Green's function Kernel obtained when a differential operator is inverted into an integral operator.

Hermitian kernel Kernel $K(x, y)$ if $K(x, y) = \overline{K(y, x)}$, where bar indicates complex conjugate.

Hilbert–Schmidt theory Theory pertaining to the series expansion of a function $f(x)$ which can be represented in the form $\int_a^b K(x, y)h(y)\,dy$.

Kernel Function $K(x, y)$ occurring under the integral sign of the integral equation $\phi(x)g(x) = f(x) + \lambda \int_a^b K(x, y)F\{y, g(y)\}\,dy$.

Neumann series Series obtained by solving the integral equation by successive approximations.

Riemann–Hilbert problem Conversion of a singular integral equation with Cauchy kernel into an algebraic

equation in terms of the boundary values of the function.

Separable kernel Kernel $K(x, y) = \sum_{i=1}^{n} a_i(x)b_i(y)$; also called degenerate.

Singular integral equation Equation in which either the kernel in the integral equation is singular or one or both of the limits of integration are infinite.

INTEGRAL EQUATIONS are equations in which the unknown function appears under the integral sign. They arise in the quest for the integral representation formulas for the solution of a differential operator so as to include the boundary and initial conditions. They also arise naturally in describing phenomena by models which require summation over space and time. Among the integral equations which have received the most attention are the Fredholm- and Volterra-type equations. In the study of singular integral equations, the prominent ones are the Abel, Cauchy, and Carleman type.

I. DEFINITIONS, CLASSIFICATION, AND NOTATION

An integral equation is a functional equation in which the unknown variable $g(x)$ appears under the integral sign. A general example of an integral equation is

$$\phi(x)g(x) = f(x) + \lambda \int_a^b F\{x, y; g(y)\}\, dy \qquad a \le x \le b, \quad (1)$$

where $\phi(x)$, $f(x)$, and $F\{x, y, g(y)\}$ are known functions and $g(x)$ is to be evaluated. The quantity λ is a complex parameter. When $F\{x, y, g(y)\} = K(x, y)g(y)$, Eq. (1) becomes a *linear* integral equation:

$$\phi(x)g(x) = f(x) + \lambda \int_a^b K(x, y)g(y)\, dy \qquad a \le x \le b, \quad (2)$$

where $K(x, y)$ is called a kernel. Four special cases of Eq. (2) are extensively studied. In the *Fredholm* integral equation of *the first kind* $\phi(x) = 0$, and in his equation of the *second kind* $\phi(x) = 1$; in both cases a and b are constants. The *Volterra integral equations* of the first and second kinds are like the corresponding Fredholm integral equations except that now $b = x$. If $f(x) = 0$ in either case, the equation is called homogeneous.

A nonlinear integral equation may occur in the form (1) or the function $f\{x, y, g(y)\}$ may have the form $K(x, y)F(y, g(y))$ where $F(y, g(y))$ is nonlinear in $g(y)$.

When one or both limits of integration become infinite or when the kernel becomes infinite at one or more points within the range of integration, the integral equation is called *singular*.

We shall mainly deal with functions which are either continuous or integrable or square integrable. A function $g(x)$ is square integrable if $\int_a^b |g(x)|^2\, dx < \infty$, and is called an $\mathcal{L}_2$ function. The kernel $K(x, y)$ is an $\mathcal{L}_2$ function if

$$\int_a^b |K(x, y)|^2\, dx < \infty$$

$$\int_a^b |K(x, y)|^2\, dy < \infty \quad (3)$$

$$\int_a^b \int_a^b |K(x, y)|^2\, dx\, dy < \infty.$$

We shall use the inner product (or scalar product) notation

$$\langle \phi, \psi \rangle = \int_a^b \phi(x)\bar{\psi}(x)\, dx, \quad (4)$$

where the bar indicates complex conjugate. The functions ϕ and ψ are orthogonal if $\langle \phi, \psi \rangle = 0$. The norm of the function ϕ is $||\phi|| = (\langle \phi, \phi \rangle)^{1/2}$. If $\|\phi\| = 1$, then ϕ is called *normalized*. In terms of this norm the famous Cauchy–Schwarz inequality can be written as

$$|\langle \phi, \psi \rangle| \le \|\phi\| \|\psi\| \quad (5)$$

while the Minkowski inequality is

$$\|\phi + \psi\| \le \|\phi\| + \|\psi\|. \quad (6)$$

NOTATION. We shall sometimes write the right-hand side of Eq. (2) as $f + \lambda K g$ and call K the *Fredholm operator*. Furthermore, for Fredholm integral equations it will be assumed that the range of integration is a to b unless the contrary is stated. The limits a and b will be omitted.

II. THE METHOD OF SUCCESSIVE APPROXIMATIONS

Our aim is to solve the inhomogeneous Fredholm integral equation

$$g(x) = f(x) + \lambda \int K(x, y)g(y)\, dy, \quad (7)$$

where we assume that $f(x)$ and $K(x, y)$ are in the space $\mathcal{L}_2[a, b]$, by Picard's method of successive approximations. The method is based on choosing the first approximation as $g_0(x) = f(x)$. This is substituted into Eq. (7) under the integral sign to obtain the second approximation and the process is then repeated. This results in the sequence

$$\begin{aligned} g_0(x) &= f(x) \\ g_1(x) &= f(x) + \lambda \int K(x,y) g_0(y)\, dy \\ &\vdots \\ g_m(x) &= f(x) + \lambda \int K(x,y) g_{m-1}(y)\, dy. \end{aligned} \tag{8}$$

The analysis is facilitated when we utilize the iterated kernels defined as

$$\begin{aligned} K_1(x,y) &= K(x,y) \\ K_2(x,y) &= \int K(x,s) K_1(s,y)\, ds \\ &\vdots \\ K_m(x,y) &= \int K(x,s) K_{m-1}(s,y)\, ds. \end{aligned} \tag{9}$$

It can be proved that $K_{m+n}(x,y) = \int K_m(x,s) K_n(s,y)\, ds$. Thereby, we can express the mth approximation in (8) as

$$g_m(x) = f(x) + \lambda \int \left[\sum_{n=1}^{m} \lambda^{n-1} K_n(x,y) \right] f(y)\, dy \tag{10}$$

When we let $m \to \infty$, we obtain formally the so-called *Neumann series*

$$\begin{aligned} g(m) &= \lim_{m\to\infty} g_m(x) \\ &= f(x) + \sum_{m=1}^{\infty} \lambda^m \int K_m(x,y) f(y)\, dy. \end{aligned} \tag{11}$$

In order to examine the convergence of this series, we apply the Cauchy–Schwarz inequality (5) to the general term $\int K_m(x,y) f(y)\, dy$ and get

$$\begin{aligned} &\left| \int K_m(x,y) f(y)\, dy \right|^2 \\ &\quad \le \left(\int |K_m(x,y)|^2\, dy \right) \int |f(y)|^2\, dy. \end{aligned} \tag{12}$$

Let us denote the norm $\|f\|$ as D and the upper bound of the integral $\int |K_m(x,y)|^2\, dy$ as C_m^2, so that relation (12) becomes

$$\left| \int K_m(x,y) f(y)\, dy \right|^2 \le C_m^2 D^2 \tag{13}$$

We can connect the estimate C_m^2 with C_{m-1}^2 by applying the Cauchy–Schwarz inequality to relation (9) and then integrating with respect to y so that $\int |K_m(x,y)|^2\, dy \le B^2 C_{m-1}^2$ where $B^2 = \int\int |K(x,y)|^2\, dx\, dy$. Continuing this process we get the relation $C_m^2 \le B^{2m-2} C_1^2$. Substituting it in (13) we arrive at the inequality

$$\left| \int K_m(x,y) f(y)\, dy \right|^2 < C_1^2 D^2 B^{2m-2}. \tag{14}$$

This means that the infinite series (11) converges faster than the geometric series with common ratio $|\lambda| B$. Thus, if $|\lambda| B < 1$, the Neumann series converges uniformly and absolutely. Fortunately, the condition $|\lambda| B < 1$ also assures us that solution (11) is unique as can be easily proved. In view of the uniform convergence of series (11) we can change the order of integration and summation in it and write it as

$$g(x) = f(x) + \lambda \int \Gamma(x,y;\lambda) f(y)\, dy, \tag{15}$$

where $\Gamma(x,y;\lambda) = \sum_{m=1}^{\infty} \lambda^{m-1} K_m(x,y)$ is called the *resolvent kernel*. This series is also convergent at least for $|\lambda| B < 1$. Indeed, the resolvent kernel is an analytic function of λ, regular at least inside the circle $|\lambda| B < 1$. From the uniqueness of the solution it can be proved that the resolvent kernel is unique.

A few remarks are in order:

1. We can start with any other suitable function for the first approximation $g_0(s)$.
2. The Neumann series, in general, cannot be summed in closed form.
3. The solution of Eq. (7) may exist even if $|\lambda| B > 1$.

The same iterative scheme is applicable to the Volterra integral equation of the second kind:

$$g(x) = f(x) + \lambda \int_a^x K(x,y) g(y)\, dy. \tag{16}$$

In this case the formulas corresponding to (11) and (15) are

$$g(x) = f(x) + \sum_{m=1}^{\infty} \lambda^m \int_a^x K_m(x,y) f(y)\, dy \tag{17}$$

and

$$g(x) = f(x) + \lambda \int_a^x \Gamma(x,y;\lambda) f(y)\, dy, \tag{18}$$

where the iterated kernel $K_m(x,y)$ satisfies the recurrence formula $K_m(x,y) = \int_y^x K(x,s) K_{m-1}(s,y)\, ds$, with $K_1(x,y) = K(x,y)$ as before. The resolvent kernel is given by the same formula as given previously and is an entire function of λ for any given (x,y).

III. THE FREDHOLM ALTERNATIVE

Let us consider the inhomogeneous Fredholm integral equation of the second kind

$$g(x) = f(x) + \lambda \int K(x, y) g(y)\, dy, \tag{19}$$

when the kernel is *degenerate* (*separable*) (i.e., $K(x, y) = \sum_{k=1}^{n} a_k(x) b_k(y)$, where $a_k(x)$ and $b_k(y)$, $k = 1, \ldots, n$, are linearly independent functions). Thus, Eq. (19) becomes

$$g(x) = f(x) + \lambda \sum_{k=1}^{n} a_k(x) \int b_k(y) g(y)\, dy, \tag{20}$$

where we have exchanged summation with integration. It emerges that the technique of solving Eq. (20) depends on the choice of the complex parameter λ and on the constants c_k defined as

$$c_k = \int b_k(y) g(y)\, dy, \tag{21}$$

which are unknown because $g(y)$ is so. Thereby, Eq. (20) takes the algebraic form

$$g(x) = f(x) + \lambda \sum_{k=1}^{n} c_k a_k(x) \tag{22}$$

Next, we multiply both sides of (22) by $b_i(x)$ and integrate from a to b so that we have a set of linear algebraic equations

$$c_i = f_i + \lambda \sum_{k=1}^{n} a_{ik} c_k, \qquad i = 1, 2, \ldots, n, \tag{23}$$

where

$$\begin{aligned} f_i &= \int b_i(x) f(x)\, dx \\ a_{ik} &= \int b_i(x) a_k(x)\, dx. \end{aligned} \tag{24}$$

Let us write the algebraic system (23) in the matrix form

$$(\mathbf{I} - \lambda \mathbf{A})\mathbf{c} = \mathbf{f}, \tag{25}$$

where $\mathbf{I}$ is the identity matrix of order n, $\mathbf{A}$ is the matrix a_{ik}, while $\mathbf{c}$ and $\mathbf{f}$ are column matrices.

The determinant $D(\lambda)$ of the algebraic system (23) is

$$D(\lambda) = \begin{vmatrix} 1 - \lambda a_{11} & -\lambda a_{12} & \cdots & -\lambda a_{1n} \\ -\lambda a_{21} & 1 - \lambda a_{22} & \cdots & -\lambda a_{2n} \\ \vdots & & & \\ -\lambda a_{n1} & -\lambda a_{n2} & \cdots & 1 - \lambda a_{nn} \end{vmatrix}, \tag{26}$$

which is a polynomial of degree at most n in λ. Note that $D(\lambda)$ is not identically zero because when $\lambda = 0$, it reduces to unity. Accordingly, for all values of λ for which $D(\lambda) \neq 0$, the algebraic system (25) and thereby integral equation (19) has a unique solution. On the other hand, for all values of λ for which $D(\lambda) = 0$, algebraic system (25), and with it integral equation (19), is either insoluble or has an infinite number of solutions. We discuss both these cases.

The Case $D(\lambda) \neq 0$. In this case the algebraic system (25) has only one solution given by Cramer's rule

$$\begin{aligned} c_k &= \left(\frac{D_{1k} f_1 + \cdots + D_{hk} f_h + \cdots + D_{nk} f_n}{D(\lambda)} \right) \\ & k = 1, 2, \ldots, n, \end{aligned} \tag{27}$$

where D_{hk} denotes the cofactor of the (h, k)th element of the determinant (26). When we substitute (27) in (22) we obtain the unique solution

$$\begin{aligned} g(x) &= f(x) + \lambda \frac{\sum_{j=1}^{n} \sum_{k=1}^{n} D_{jk} f_i a_k(x)}{D(\lambda)} \\ &= f(x) + \frac{\lambda}{D(\lambda)} \\ &\quad \times \int \left\{ \sum_{j=1}^{n} \sum_{k=1}^{n} D_{jk} b_j(y) a_k(x) \right\} f(y)\, dy, \end{aligned} \tag{28}$$

where we have used relation (24). This expression can be put in an elegant form if we introduce the determinant

$$\begin{aligned} & D(x, y; \lambda) \\ &= \begin{vmatrix} 0 & -a_1(x) & -a_2(x) & \cdots & -a_n(x) \\ b_1(y) & 1 - \lambda a_{11} & -\lambda a_{12} & \cdots & -\lambda a_{1n} \\ b_2(y) & -\lambda a_{21} & 1 - \lambda a_{22} & \cdots & -\lambda a_{2n} \\ \vdots & & & & \\ b_n(y) & -\lambda a_{n1} & -\lambda a_{n2} & \cdots & 1 - \lambda a_{nn} \end{vmatrix} \end{aligned} \tag{29}$$

which is called the *Fredholm minor*. Then Eq. (28) takes the form

$$g(x) = f(x) + \lambda \int \Gamma(x, y; \lambda) f(y)\, dy \tag{30a}$$

where the resolvent kernel Γ is the ratio of two determinants, that is,

$$\begin{aligned} \Gamma(x, y; \lambda) &= D(x, y; \lambda)/D(\lambda) \\ &= \frac{1}{D(\lambda)} \sum_{j=1}^{n} \sum_{k=1}^{n} D_{jk} b_j(y) a_k(x). \end{aligned} \tag{30b}$$

It is clear from the above analysis that if we start with the homogeneous integral equation,

$$g(x) = \lambda \int K(x, y) g(y)\, dy, \tag{31}$$

we shall obtain the homogeneous algebraic system

$$(\mathbf{I} - \lambda\mathbf{A})\mathbf{c} = 0. \tag{32}$$

When $D(\lambda) \neq 0$, this algebraic system and the homogeneous integral equation (31) have only the trivial solutions.

The Case $D(\lambda) = 0$. In this case the algebraic system (32) and hence the homogeneous integral equation (31) may have either no solution or infinitely many solutions. To examine these possibilities it is necessary to discuss the subject of eigenvalues and eigenfunctions of the homogeneous problem (31). Strictly speaking we should write it as $\int K(x, y)g(y)\,dy = \omega g(x)$ for ω to be an eigenvalue, but in the theory of integral equations it has become customary to call the parameter $\lambda \neq 0$, for which the homogeneous equation (31) has a nontrivial solution, its eigenvalue. The corresponding solution $g(x)$ is called the eigenfunction of the operator K. From the above analysis it follows that the eigenvalues of (31) are the solutions of the polynomial $|\mathbf{I} - \lambda\mathbf{A}| = 0$. There may exist more than one eigenfunction corresponding to a specific eigenvalue. Let us denote the number r of such eigenfunctions as $g_{i1}, g_{i2}, \ldots, g_{ir}$ corresponding to the eigenvalue λ_i. The number r is called the *index* of the eigenvalue λ_i (it is also called the *geometric* multiplicity of λ_i while the *algebraic* multiplicity m means that $D(\lambda) = 0$ has m equal roots). We know from linear algebra that if p is the rank of the determinant $D(\lambda_i) = |\mathbf{I} - \lambda_i\mathbf{A}|$, then $r = n - p$. If $r = 1$, λ_i is called a simple eigenvalue. Let us assume that the eigenfunctions $g_{i1}, \ldots, g_{ir}$ have been normalized (i.e., $\|g_{ij}\| = 1$ for $j = 1, \ldots, r$). Then to each eigenvalue λ_i of index $r = n - p$, there corresponds a solution $g_i(x)$ of the homogeneous integral equation (31) of the form $g_i(x) = \sum_{k=1}^{r} \alpha_k g_{ik}(x)$, where α_k are arbitrary constants.

For studying the case when the inhomogeneous integral equation (19) has a solution even when $D(\lambda) = 0$, we need the integral equation

$$\psi(x) = f(x) + \lambda \int \overline{K(y, x)}\psi(y)\,dy, \tag{33}$$

which is called the *transpose* (or *adjoint*) of Eq. (19) which is then the transpose of Eq. (33). For the separable kernel $K(x, y)$ as considered in this section, the transpose kernel is $\overline{K(y, x)} = \sum_{k=1}^{n} \overline{a_k(y)b_k(x)}$. When we follow the same steps that we followed for integral equation (19) we find that the transposed integral equation (33) leads to the algebraic system $(\mathbf{I} - \lambda\bar{\mathbf{A}}^{\mathrm{T}})\mathbf{c} = \mathbf{f}$, where $\mathbf{A}^{\mathrm{T}}$ stands for the transpose of $\mathbf{A}$ while c_k and f_k are now defined as
